The spectra of the naphthionic acid ion (No. 2) are illustrated in Fig. 2. In this case, the spectral change was not observed above pH 4.4, and the spectra were in accord with curve I, while for pH values below 4.4 the spectra changed, while, however, keeping the isosbestic points. The absorption curve (V) for the smallest pH value closely resembles that of α-naphthalene sulfonic acid, which is shown in Fig. 1.

The absorption spectra of NW-acid (No. 3) are shown in Fig. 3. The isosbestic points appeared in the 6.3—10.8 pH range, and the curve did not change in shape below pH 6.3.

According to the above data, naphthionic acid and NW-acid show the two isosbestic

points in different pH regions, namely the acid and alkali regions respectively. Because this is apparently due to the different properties of the amino and the hydroxyl groups, samples with two such kinds of groups are expected to show the isosbestic points in the two corresponding pH ranges. In truth γ-acid (No. 5), J-acid (No. 6) and H-acid (No. 9) behaved as expected. The case of γ-acid is shown as an example in Figs. 4a and 4b; there are well defined isosbestic points in the respective pH regions of 2.55—6.5 and of 9.2—10.6. In the pH range of about 5—8, of course, the absorption spectra did not change.

The pH regions in which the isosbestic points appear are illustrated schematically in Fig. 5 for all samples. In the figure, the shadings indicate the pH range with the isosbestic points, and the blank spaces, that with no spectral change. According to Fig. 5, the shading of naphthionic acid (with only one amino group) and that of NW-acid (one hydroxyl group) exist in quite separated pH regions. The two shaded regions of J-acid (with amino and hydroxyl group) nearly correspond in situation to those of naphthionic acid and NW-acid, whereas, in the case of γ-acid or H-acid, the two shaded regions do not coincide with those of naphthionic acid and NW-acid, and shift together toward the higher pH side. Further, the following facts are noticed: SS-acid indicates no spectral change in the acid region

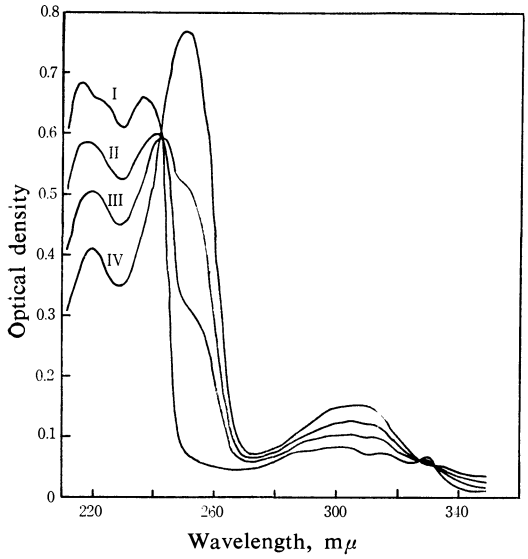

Fig. 4a. Spectral change of γ-acid with pH in acidic solution.

despite the presence of an amino group, the shading region of chromotropic acid corresponding to that of NW-acid shifts to a much lower pH side, and so on. In the following section these problems will be discussed.

## Discussion

The existence of the isosbestic points implies that there are two kinds of molecular species with different characters in absorption, with an equilibrium kept between them. The equilibrium depends on the change in pH. There will be, therefore, an equilibrium in the addition and dissociation of the hydrogen ion. Since the naphthalene sulfonic acid ion did not show any spectral change in the pH range measured here, the amino and hydroxyl groups must be responsible for the spectral change in connection with the hydrogen ion.*

For that reason, the following equilibrium can be considered for the case of naphthionic acid;

If we use the notation, for instance, of $(-NH_2)_N$, etc. standing for naphthionic acid, etc., the above equilibrium can be written as follows;

$$(-NH_2)_N + H^+ \rightleftarrows (-NH_3^+)_N \qquad (1)$$

The lone pair electrons on the nitrogen atom ($2p\pi$ type) can not conjugate with the naphthalene link when a proton is attached to the amino group. Thus, the above-mentioned fact that the absorption spectrum of naphthionic acid in the solution of pH 1.45 (Fig. 2) is almost identical with that of α-naphthalene sulfonic acid (Fig. 1) can be explained as the result of the complete shift of the equilibrium 1 to the right side.

For NW-acid, similarly, the following equation may be considered as the dissociation equilibrium of the hydroxyl groups;

$$(-OH)_{NW} \rightleftarrows (-O^-)_{NW} + H^+ \qquad (2)$$

This equilibrium should move toward the right side with a lowering of the concentration of the hydrogen ion. Therefore, it can be said that curves I and IV in Fig. 3 indicate the electronic spectra of $(-O^-)_{NW}$ and $(-OH)_{NW}$ respectively.

Similarly, all the spectral changes of the other samples should be explained by a proton addition or dissociation process like that of Eq. 1 or 2. According to Fig. 5, however, the

* From a different standpoint from that of the present discussion, an equilibrium may be plausibly considered between the monomer and the dimer (e.g., an ion pair). This would, however, be unreasonable for the following reason: the spectrum of naphthionic acid in the acid solution, for instance, did not reveal the Davydov splitting, even in the most concentrated hydrogen ion employed here, but, on the contrary, approached the simple spectrum of α-naphthalene sulfonic acid.

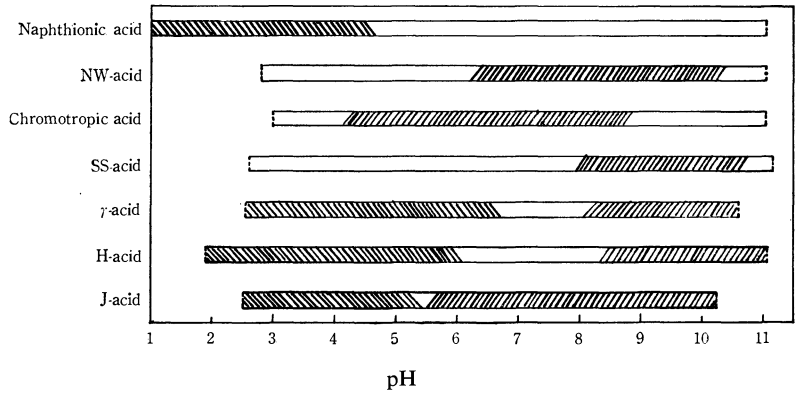

Fig. 5. Schematical diagram of the pH ranges with the spectral change; The shading indicates the pH ranges with the isosbestic points and the blank space that with no spectral change.

TABLE II. THE ORDER OF THE STARTING pH VALUES OF THE ADDITION AND THE DISSOCIATION PROCESS

| Sample[1] | Effects by[2] (A) sulfonic group and (B) hydrogen bond | The order of the starting pH values of the process of addition or dissociation | | |
|---|---|---|---|---|
| | | To be estimated by factor A and B[2] | Taking account of factor C | Observed |
| N-acid | $\sigma_p$ ($-NH_2$) | | | |
| NW-acid | $\sigma_p$ ($-OH$) | Addition | Addition | Addition |
| Ch-acid | $\sigma_m-\delta$ ($-OH$), $\sigma_m+\delta$ ($-OH$) | $N<\binom{\gamma}{J}<H$ | $\begin{cases} N<J<H \\ J<\gamma \end{cases}$ | $N<J<H<\gamma$ |
| SS-acid | $\sigma_{o,p}+\delta$ ($-NH_2$), $-\delta$ ($-OH$) | | | |
| γ-acid | $\sigma_m$ ($-NH_2$), $\sigma_m$ ($-OH$) | Dissociation | Dissociation | Dissociation |
| H-acid | $\sigma_m-\delta$ ($-NH_2$), $\sigma_m+\delta$ ($-OH$) | | | |
| J-acid | $\sigma_m$ ($-NH_2$), $\sigma_m$ ($-OH$) | $\binom{Ch}{H}<\binom{\gamma}{J}<NW<SS$ | $\begin{cases} Ch<J<NW<SS \\ Ch<H \\ J<\gamma \end{cases}$ | $Ch<J<NW<\binom{SS}{\gamma}{H}$ |

Note. 1) N-acid and Ch-acid mean naphthionic acid and chromotropic acid, respectively.
2) The electric charge induced by the sulfonic group or by the hydrogen bond formation is indicated by $\sigma$ or $\delta$, respectively, and is assumed that $\delta>\sigma$.

starting values of the pH of the corresponding processes do not always coincide with one another; the orders of the pH value are $N<J<H<\gamma$ for the addition process and $Ch<J<NW<SS\leq\gamma\leq H$ for the dissociation (see Table II). The possible reasons for this may be a change in the electron density of the functional group as a result of (A) the displacement of the $\sigma$ electron by the sulfonic group as the electron-accepting group, (B) the formation of an intramolecular hydrogen bond between the functional groups, and (C) the resonance effect of the functional group.

First let us consider the A factor. The electron density on a substituent will be reduced by the inductive effect of the sulfonic group. If the effect from the sulfonic group in the other link is disregarded, the positive charge on each functional group will be represented by the notation $\sigma$, as is shown in the second column of Table II, where the suffix of $\sigma$ used with, for example, *o*, *m* or *p* indicates the position of the sulfonic group with respect to the functional group. Since the magnitude of $\sigma$ will be in the order $\sigma_o>\sigma_m>\sigma_p$, the amino and the hydroxyl groups of H-acid, for instance, become more positive than the corresponding groups of naphthionic acid and NW-acid. Therefore, the following processes, 3 and 4, for H-acid

$$(-NH_2, -OH)_H + H^+ \rightleftarrows (-NH_3^+, -OH)_H \quad (3)$$

$$(-NH_2, -OH)_H \rightleftarrows -(NH_2, -O^-)_H + H^+ \quad (4)$$

will take place at a lower pH than Eqs. 1 and 2 respectively. Thus the orders of the pH values starting the processes of addition and dissociation because of only the A factor will become SS<H<N<$\gamma$=J and Ch=$\gamma$=H=J<NW<SS respectively.

Next let us consider the B factor. The formation of the intramolecular hydrogen bond between the two functional groups will occur in chromotropic acid, SS-acid and H-acid. The relative displacement of charge due to this effect will be described by the notation $-\delta$ or $+\delta$, as is shown in Table II. Here, as for H-acid, the hydrogen atom of the amino group is employed in the hydrogen bond in order to make both of the groups conjugate to the naphthalene link.* On the other hand, in the case of SS-acid, hydrogen of the hydroxyl group may be used, because the N–C bond is largely twisted from the plane of the link due to the steric hindrance of the sulfonic group adjacent to the amino group[1] (see Table I). Therefore, the spectral change corresponding to the proton addition to the amino group of SS-acid should not appear. This is indeed true, as is indicated in Fig. 5. For only the B factor, therefore, the starting points in the pH value of the addition or the dissociation process to be estimated will become the order N=$\gamma$=J<H or Ch=H<NW=$\gamma$=J<SS respectively.

As for the A and B factors in connection with the $\sigma$-electron, if we assume that the effect of A is smaller than that of B, the correlations of the starting pH values of the proton addition and the dissociation process will be obtained as shown in the third column of Table II.

Finally, let us take into consideration the effect of the C factor; the resonance effect of the functional groups in connection with the $\pi$-electron system. In only $\gamma$-acid is the direct conjugation through the link between the functional groups allowed. In such a particular case, the positive charge on the groups to be produced by the migration of $\pi$-electron to the link should be much decreased compared to the case without such direct conjugation or lacking in either functional groups. For that reason, the negative net charge on the two groups of $\gamma$-acid may be the largest. According to the experimental results (the last column of Table II), $\gamma$-acid is ranked in the highest orders of the pH values of the addition and the dissociation process. This indicates that the resonance effect by the direct conjugation is quite large.

For the other samples, the two functional groups will indirectly affect each other by means of repulsive interaction between the negative charges on the link induced by the resonance effect of the individual group. As will be seen later, the order of the magnitude of the resonance effect of the groups on the naphthalene link is $-NH_3^+ < -OH < -NH_2 < -O^-$. From this relation, it may be accepted that $-OH^{-\delta} < -NH_2^{-\delta}$. The $-OH^{+\delta}$ group of H-acid to be dissociated, therefore, should become more negative than that of chromotropic acid as a result of the resonance effect of $-NH_2^{-\delta}$ being larger than that of $-OH^{-\delta}$. For that reason, the dissociation process of H-acid becomes more difficult than that of chromotropic acid, namely, Ch<H. Unfortunately, at present the relative position of H-acid in the order can not be decided.

At any rate, most of the experimental results have been explained, as is shown in the fourth column of Table II, though the order in each case does not always coincide in detail with that observed; for example, the expected and the observed order of NW-acid and J-acid are just the converse of one another.

**The Direction of the Transition Moment of the Absorption Bands.**—With the introduction of the amino and/or the hydroxyl group, the absorption spectra of the original naphthalene sulfonic acid ion are changed markedly by the resonance effect of the group. According to the clarified findings concerning such a substitution effect,[2,3] in $\alpha$-substitution the band with the transition vector in the a direction (short axis) is subjected to a larger effect than when the vector is in the b direction (long axis). Here, in order to obtain some information about the transition direction of each band, the spectral change will be discussed from this standpoint.

Figure 6 illustrates the substitution effect on the absorption spectra of $\alpha$-naphthalene sulfonic acid. The intense band in the higher wave number region (to be called the second band) of $\alpha$-naphthalene sulfonic acid is shifted

* Though it is generally accepted that the proton-donating power is stronger in the hydroxyl group than in the amino group, in the case of H-acid the hydrogen bond of the N-H···O type must be considered, because H-acid shows the typical spectral change for the proton addition process. This indicates that the lone-pair electrons on the amino group can migrate to the naphthalene link in the neutral state.

— - — Naphthionic acid; [$-NH_2$]

merely 350 $cm^{-1}$ lower when the hydroxyl group is introduced to the α-position (NW-acid), while the weak band in the lower region (the first band) is shifted lower by as much as 2190 $cm^{-1}$. Moreover, the $\varepsilon_{max}$ of the first band increases from 5340 to 7050, whereas that of the second band decreased nearly one half, from 61600 to 35100. In the case of naphthionic acid, nearly the same relation as that above may be seen. Figure 7 also indicates that a similar tendency appears for the cases of chromotropic acid and H-acid with two substituents at α-positions. This time, however, in the first band there appeared a fine structure which was not obvious for 2, 7-naphthalene disulfonic acid, the parent molecule of the samples (cf. Fig. 1). Such a fine structure appears at about 285 mμ of the naphthalene spectrum; according to Platt,[4] this can be assigned to the $^1L_a$ transition. Therefore, it seems plausible that the transition

— - — H-acid; [$-NH_2$, −OH]

4) J. R. Platt, *J. Chem. Phys.*, **17**, 487 (1949).

vector of the first band of the naphthalene sulfonic acid derivatives is in the a direction on the naphthalene skeleton as a result of the shifting of the $^1L_a$ transition. On the other hand, the second band is in the b direction. It is not possible, however, to assign the intense second band to the $^1L_b$ transition, because the $^1L_b$ of naphthalene appears at about 310 mμ and is very weak. The second band under consideration, therefore, must be the $^1B_b$ transition, which is the next b direction. In this case, the bands shift to the longer wavelength side without changing the order.

As γ-acid has the hydroxyl group at the α-position and the amino group at the β, it is interesting to compare the band position in the acidic, the neutral and the basic solutions (Fig. 8). When we compare the spectra in the neutral solution of γ-acid with that of β-naphthalene sulfonic acid, which is the parent molecule, it is found that both the first and the second band shift to the lower wave number in the same order (about 4000 $cm^{-1}$). Since the hydroxyl group at the α-position shifts the band with the transition moment of the a direction (the first band), the displacement of the second band must be brought about mainly by the amino group at the β-position. However, it may be noticed that the first band of γ-acid shifts by 4080 $cm^{-1}$ in contrast with the shift of 2190 $cm^{-1}$ of NW-acid. This means that the effect of the amino group at the β-position is largely responsible for the first band, too. On the other hand, in the acidic solution, only the hydroxyl group at the α-position is left as a group able to resonate with the link, since the substitution effect of the amino group is very much reduced. In such a situation, the first band is

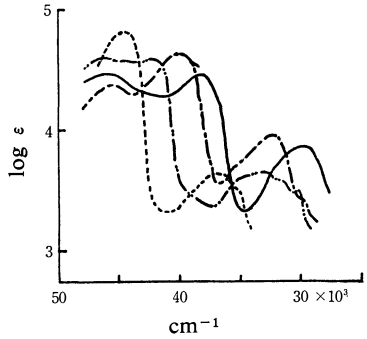

Fig. 8. Substitution effect on the absorption spectra of β-naphthalene sulfonic acid.
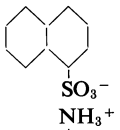
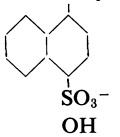
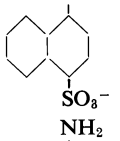
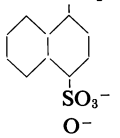
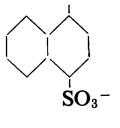
- - - - β-Naphthalene sulfonic acid
——— γ-Acid in alkaline solution; [$-NH_2$, $-O^-$]
— - — γ-Acid in neutral solution; [$-NH_2$, −OH]
— - - — γ-Acid in acidic solution; [$-NH_3^+$, −OH]











expected to be affected more largely than the second band; this expectation is in agreement with the results of NW-acid and others described above. In the basic solution, the shifts of both bands become the same order again, because the $-O^-$ group is at the $\alpha$- and the $-NH_2$ group at the $\beta$-position. As may be seen from Fig. 8, the shifts are, even though very slight, relatively large for the second band in the neutral solution and for the first band in the basic solution. This must be due to the magnitude of the resonance effect of the substituent groups; judging from the present deta, it seems that $-NH_2 < -O^-$.

Taking into account the band shifts of $\gamma$-acid in the neutral and the acid solutions, the order of the effect of the amino group at the $\beta$-position on the a and b directions can be estimated approximately.* Because the amino group of $\gamma$-acid loses its resonance effect in the acid solution, the contribution by the amino group must be estimated by subtracting the change of the wave number in the acid solution from that in the neutral one. The results indicate that the contribution is 420 $cm^{-1}$ for the first band (a direction) and 2350 $cm^{-1}$ for the second (b direction). Consequently, it is established that the substituent at the $\beta$-position is more effective in the b direction (five to sixfold) not in the same order in both the directions, a and b.

In order to decide the order of magnitude of the substitution effect, the positions of the first bands for the $\alpha$-substituent were compared. The results are shown in Table III. It is apparent from the table that the order of the substitution effect is as follows;

$$-NH_3^+ < -OH < -NH_2 < -O^-$$

TABLE III. SUBSTITUTION EFFECT ON THE FIRST BAND

| Sample (nature of solution) | Structure | First band mμ |
|---|---|---|
| α-Naphthalene sulfonic acid |  | 280 |
| Naphthionic acid (acidic) |  | 285 |
| NW-acid (acidic) |  | 295 |
| Naphthionic acid (alkaline) |  | 318 |
| NW-acid (alkaline) |  | 330 |

* When the amino and the hydroxyl group coexist, the respective resonance effects will have an influence upon each other. However, the order of the magnitude will roughly be obtained.

## Summary

1) The absorption spectra of some naphthalene sulfonic acid derivatives have been determined in various pH solutions.

2) The remarkable spectral change revealed by the variation in pH value can be interpreted in terms of the process of the proton association and dissociation of the functional groups.

3) The pH region in which the process takes place is characteristic of the kinds, $-NH_2$, $-OH$, and the number of the functional groups and their locations on the naphthalene skeleton.

4) The relative pH regions have been explained in outline by taking into account the effects of the sulfonic group, the intramolecular hydrogen bond formed between the functional groups, and the resonance of the functional group to the link.

5) The band assignment concerning the transition direction of the derivatives has been decided; the first and the second band correspond, respectively, to the $^1L_a$ and $^1B_b$ of naphthalene.

6) The order of the magnitude of the substitution effect has been clarified as $-NH_3^+ < -OH < -NH_2 < -O^-$.

# Studies of the Stability of Cobalt Ferrocyanide Sol in Ultrasonic Field. The Ultrasonic Dispersion of Cobalt Ferrocyanide

By Satya PRAKASH, Om PRAKASH and Sheo PRAKASH

(Received August 8, 1964)

High frequency, inaudible sound waves can bring about various dispersion effects, such as the mutual emulsification of the liquid phase, the disintegration of certain solids, the peptization and liquefaction of gels, and the depolymerization of high molecular substances. Polotoskii[1] prepared hydrosol of camphor and iodine in water, and Sata and his co-workers[2] dispersed metallic hydroxide in water by means of ultrasonic waves. Prakash and Pandey[3] successfully utilized ultrasonic energy in the preparation of a colloidal cobalt hydroxide solution. The present authors have been able to obtain a very stable sol of cobalt ferrocyanide by using the ultrasonic dispersion method. The sol obtained was then stabilized by further irradiation. Our findings on the influence of ultrasonic waves on this sol in presence as well as in absence of oxygen and in presence of non-electrolytes, such as methanol, ethanol and acetone, will be reported in this paper.

## Experimental

**Materials.**—B. D. H. (Analar) samples of potassium ferrocyanide, cobalt chloride, barium chloride, potassium chloride and hydrochloric acid and distilled methanol, ethanol and acetone (B. D. H., L. R.) were used.

**Instruments, Procedures and Calculation.**—*Electrical Conductance Measurements.*—The measurements of electrical conductance were carried out with a Leeds and Northrup Kohlrausch slidewire, with an audio-frequency oscillator. A dip-type cell was used. The temperature was kept constant (30±0.2°C).

*pH Measurements.*—The hydrogen ion concentration of the solution was measured with a Leeds and Northrup direct-reading pH indicator with a glass calomel electrode system. The instrument was standardised from time to time with a standard buffer of pH 6.8.

*Transmission Measurements.*—The transmission in percentage was determined with a Unicam SP 1400 prism absorptiometer, and the optical density was calculated by the equation:

$$\text{Optical density} = \log (1/T)$$

where $T$ is the transmission.

*Ultrasonic Generator.*—The source of ultrasonic power was a Mullard high frequency ultrasonic generator, type E-7562, with a barium titanate transducer. The principal diagram of the electrical circuit is shown in Fig. 1. The frequency of the transducer was 1 Mc./sec.

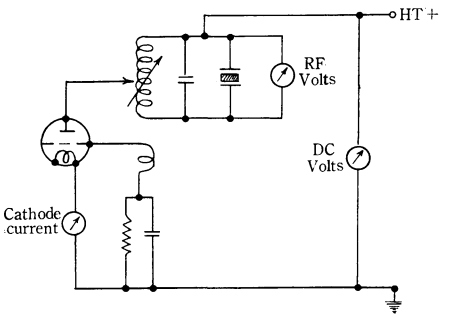

Fig. 1

Decinormal solutions of cobalt chloride and potassium ferrocyanide were mixed together, with more of the latter. The precipitate of cobalt ferrocyanide was filtered and washed. The precipitate was put into distilled water in a Jena glass bottle and exposed to ultrasonic waves. A cobalt ferrocyanide sol of a dirty brown colour was obtained within thirty minutes. In this way a sufficient amount of the sol was prepared and stored in a Jena bottle for detailed study. The sol was then purified by dialysis for three days. The concentration of the sol was determined by evaporating a known volume of the sol to dryness on a water bath. The sol concentration was found to be 19.3526 g./l.

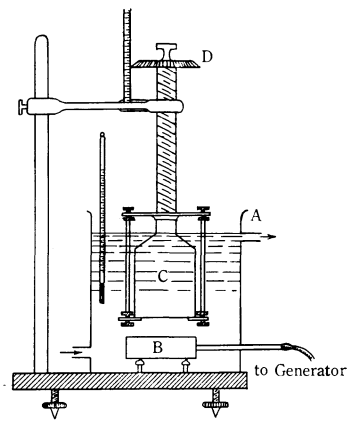

Fig. 2

1) G. G. Polotoskii, *Colloid. J. (U. S. S. R.)*, **6**, 779 (1940).
2) N. Sata and S. Watanabe, *Kolloid-Z.*, **73**, 50 (1935).
3) S. Prakash and A. D. Pandey, ibid., **181**, 46 (1962).

The above sol, 30 ml., was then placed in a 250 ml. flat-bottomed Jena glass vessel with a ground glass stopper and exposed to the action of ultrasonic waves for various intervals of time. The ultrasonic bath (Fig. 2) was kept at a constant temperature (30±0.2°C) by circulating water into it. The Jena vessel was held vertically above the transducer, and the distance between the vessel and the crystal was so adjusted as to produce a maximum fountain inside the vessel. The distance was kept unchanged as much as possible during the course of the experiments.

The stability of the sol was determined after each exposure by noting the amount of potassium chloride and barium chloride required to coagulate the negatively-charged sol of cobalt ferrocyanide in a fixed time (30 min.). The variation in specific conductivity and hydrogen-ion concentration of the sol was also recorded every time. The change in optical density was thus observed.

The experiments were carried out in the absence of oxygen. The air was replaced with nitrogen by bubbling for thirty minutes. Nitrogen from a cylinder had previously been passed through solutions of vanadous sulphate and alkaline pyrogallol in order to remove the oxygen.

The influence of ultrasonic waves on this sol in the presence of methanol, ethanol and acetone was also studied. Measurements similar to those mentioned above were carried out after each exposure, and the results were compared with those when no non-electrolyte was present.

## Results and Discussion

Figure 3 shows the amount of the dispersion of cobalt ferrocyanide when it is subjected to ultrasonic waves. As may be seen in the figure, the amount increases rapidly in the beginning. When the exposure time is further increased, the increment is slowed down and attains a maximum value.

The coagulation values of the sols under various conditions are shown in Tables I and II.

A perusal of these tables will show that, with the increase in the time of exposure to

the ultrasonic waves, the stability of the sol increases in the presence as well as in the absence of oxygen. The small difference in the extent of stabilization under the two conditions shows that the presence or absence of oxygen in no way affects the ultrasonic action on this sol, as had previously been observed by the present authors in the case of the manganese dioxide sol.[4] As the sol is negatively charged, the enhanced stability may be attributed to the decrease in hydrogen ion concentration. The hydroxyl ions are increased in the system; they are adsorbed on the double layer, with the result that the sol attains more stability.

4) S. Prakash and O. Prakash, *Kolloid-Z.*, **188**, 136 (1963).

Dhar and his collaborator[5] have shown that ferrocyanide sols are appreciably hydrolysed in aqueous solutions and that this hydrolysis makes the sol more stable towards electrolytes. It is possible that, under the influence of ultrasonic waves, the sol of cobalt ferrocyanide becomes more hydrolysed and hence more stable to electrolytes. As Figs. 4 and 5 show, the specific conductivity of the sol also increases as the time of exposure is increased. A number of investigators[6-9] have found $H_2O_2$, $HNO_2$ and $HNO_3$ present in the sonolysis of water exposed to ultrasonic waves. The acid nature of these substances would increase the specific conductivity.

In spectroscopic studies (Figs. 8 and 9) of the unexposed and exposed sol, it is observed that an absorption maximum occurs at the same wavelength in both cases suggesting that no change in the basic characters of the substance has taken place. It seems that the ultrasonic waves have brought about a change in the physical character of the particles by their own cavitating action on larger aggregates, thus making them smaller. This theory is confirmed by the observation that, as the time of exposure increases, the turbidity in the unexposed sol continues to vanish and the sol becomes transparent.

The stability, specific conductivity and hydrogen ion concentration of the sol are very little affected by ultrasonic waves in the presence of methanol, ethanol and acetone, as Tables III and IV, and Figs. 10, 11 and 12 show. The great majority of the disruptive actions and the chemical reactions caused by ultrasonic

waves have been attributed to the phenomenon of cavitation. Because of a high dielectric constant, high surface tension and low vapour pressure values of water, the aqueous medium greatly favours the formation of cavitation bubbles, with the result that the ultrasonic activity observed in such a medium will be at a maximum. Thus, the inhibitive effect of non-electrolytes, e. g., methanol, ethanol and acetone, may be due to the suppression of this cavitation, because the presence of substances of a high vapour pressure[10] suppresses the breakdown of cavitation bubbles. Consequently, ultrasonic activity is very much lessened. Secondly, the energy released upon the collapse of the cavitation bubble is comparatively much less if the surface tension[11] and the internal

pressure[12] of the medium are low, resulting in a decrease in the rate of ultrasonic action.

## Summary

A negatively-charged cobalt ferrocyanide sol has been prepared ultrasonically subjecting the washed precipitate of cobalt ferrocyanide and distilled water to ultrasonic waves. The amount of dispersion increases with the time of exposure. The sol is rendered more stable in an ultrasonic field in the presence as well as in the absence of oxygen. The enhanced stability has been attributed to the increase in hydroxyl ions in the medium as a result of the hydrolysis of cobalt ferrocyanide sol. The stability, pH and specific conductivity values are very little affected in the presence of methanol, ethanol and acetone. The inhibition is due to the suppression of cavitation and to a lesser energy release on the collapse of cavitational bubbles.

# The Hydrogen Bond in the Diols. I

By Teijiro YONEZAWA, Hazime SAITÔ,* Shinichi MATSUOKA and Kenichi FUKUI

(Received August 18, 1964)

The diols form intramolecular as well as intermolecular hydrogen bonds with two hydroxyl groups in a molecule. Though the intramolecular hydrogen bonds of the diols were investigated by Kuhn[1] using infrared spectra, intermolecular hydrogen bonds have never, so far as we know, been elucidated.

In the NMR spectra, the term "hydrogen bond shift" is defined[2] as the extreme shift of the proton signal between the non-associated state and the completely-associated state. In the associated state of the diols, both the intra- and the intermolecular hydrogen bonds are involved.

In the present paper, the hydrogen bond of the diols will be investigated by a nuclear magnetic resonance technique, and a procedure for estimating the hydrogen bond shifts of the diols will be proposed. For this purpose, the non-associated (free) OH proton shift, which is necessary to evaluate the hydrogen bond shift, will be calculated theoretically, since it seems very difficult to measure free OH proton shifts. Not only is there the technical difficulties arising from the slight solubility of the diols in an inert solvent as well as from their higher boiling points, but also the intramolecular hydrogen bond may occur even in the gaseous state or in an infinitely dilute solution. Therefore, the free OH proton shift will be obtained by a theoretical treatment, wherein the local diamagnetic shielding constants of OH protons in the diols and the shielding constant due to the paramagnetic anisotropy of the oxygen attached to the proton will be calculated by a molecular orbital method.

The measurement of the OH proton shift will be made at a temperature just above the freezing point in a pure liquid state, since a completely hydrogen-bonded state is realized at this temperature. Hence, the hydrogen bond shift of the diols can be derived from the difference between the chemical shift in the completely associated state and the theoretical shift stated above.

The hydrogen bond shifts thus obtained will then be compared with that of ethanol and found to be smaller. From these results, we can point out that the proportion of intramolecular hydrogen bonds can not be ingnored in the hydrogen bonds of the diols.

## The Measurement of Proton Shifts

All materials used were of guaranteed grade. The vacuum distillation was made before use after drying over anhydrous sodium sulfate. The measurements of the NMR spectra were performed by a Varian DP-60 60 MC spectrometer equipped with a V-4340 variable temperature accessory at a temperature just above the freezing point. Samples were measured in a pure liquid state. The plots of the OH proton shift vs. the temperature are shown in Fig. 1. The bulk susceptibility correction was made in the observed chemical shifts, which are referred to methylene

chloride as an external standard. The volume susceptibility for correction is calculated from Pascal's rule. These shifs are listed, together with the temperature of measurement, in Table I.

### The Calculation of the Hydrogen Bond Shift

In order to obtain the hydrogen bond shift, free OH proton shifts were calculated theoretically by the following procedure. According to Pople,[3] the shielding constant of the free OH proton consits of the diamagnetic shielding constant, $\sigma_{dia}(OH)$, which depends on electrons around the proton in question, and the shielding constant, $\sigma_{para}(O)$, due to the paramagnetic anisotropy of the oxygen atom attached to the proton:[4]

$$\sigma(OH) = \sigma_{dia}(OH) + \sigma_{para}(O) \quad (1)$$

The free OH proton shift, $\delta(OH)$, referred to gaseous methane, is then given as:

$$\delta(OH) = \sigma_{dia}(OH) - \sigma_{dia}(CH_4) + \sigma_{para}(O) \quad (2)$$

since there is no contribution of the neighbor anisotropy in methane. The shielding constants, $\sigma_{dia}(OH)$, $\sigma_{dia}(CH_4)$ and $\sigma_{para}(O)$, are calculated by a simple LCAO MO method for $\sigma$-electron systems.

**The Diamagnetic Shielding Constant.**—It has been shown that the local diamagnetic shielding constant of a proton is given by:[3]

$$\sigma_{dia} = \lambda q_H \quad (3)$$

where $q_H$ is the total $\sigma$-electron density at the hydrogen atom and $\lambda$ is a constant. In the present paper, $\lambda$ is put as equal to 25 p. p. m.[5]

The total $\sigma$-electron density, $q_H$, is calculated by a simple LCAO MO method for sigma systems, where the $j$-th molecular orbital is expressed as a linear combination

* Resonance integral between the different atomic orbitals of the same atom.

of the atomic orbitals constructing bonds in a molecule:

$$\varphi_j = \sum_r c_r^j \chi_r \quad (4)$$

The parameters adopted for the coulomb and resonanance integrals are nearly the same as in our previous paper;[6] they are listed in Table II. For the $H_2O$ molecule, we have adopted two different values for the coulomb integral of the oxygen atom with $sp^2$ and $sp^3$ hybrid orbitals and for the resonance integral between the two different hybrid orbitals of the oxygen atom. For the diols and alcohols, however, we have adopted the integrals for the oxygen of $sp^3$ hybridization.

The total $\sigma$-electron densities in the diols and some related compounds are given in Fig. 2. No remarkable variation in the electron density in the C-O-H bond is observed for the diols and alcohols.

**The Shielding Constant due to the Paramagnetic Anisotropy of the Oxygen Atom.**—The shielding constant arising from the magnetic anisotropy of the adjacent atom is written:

$$\sigma_{para}(O) = \frac{1}{3R^3H}\{\mu_x(1-3\cos^2\theta_x) + \mu_y(1-3\cos^2\theta_y) + \mu_z(1-3\cos^2\theta_z)\} \quad (5)$$

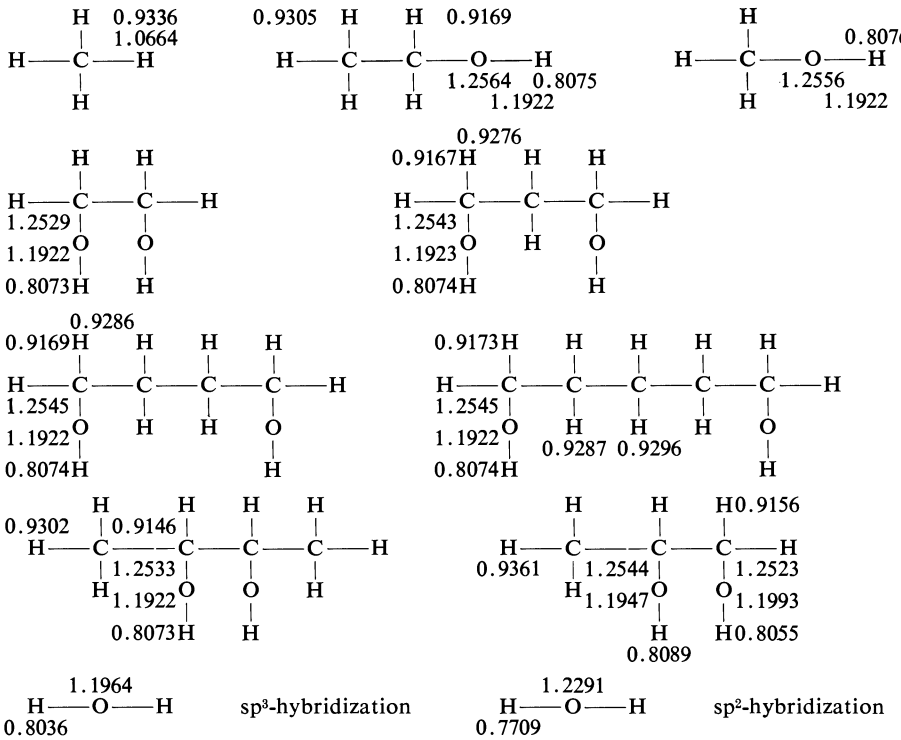
where $\mu_x$, $\mu_y$ and $\mu_z$ denote the components of the magnetic dipole moment induced at the oxygen atom by the paramagnetic current

3) J. A. Pople, *Proc. Roy. Soc.*, A239, 549, 557 (1954).

4) Evidently, the terms due to the neighbor anisotropy of other atoms do exist. These terms may be small since they are located rather far from the proton in question.

5) This value corresponds to the effective nuclear charge, $z=1.40$, in the Slater-type 1s orbital.

6) K. Fukui, H. Kato and T. Yonezawa, This Bulletin, 33, 1201 (1960); 34, 442 (1961); 35, 38 (1962).



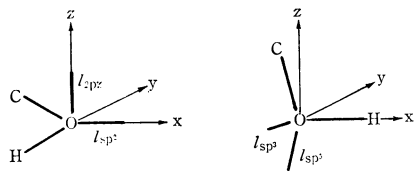


Fig. 2. Total $\sigma$-electon density in the diols and related compounds.

around the oxygen atom; $H$ is the external magnetic field; $\cos\theta_x$, $\cos\theta_y$ and $\cos\theta_z$ are the direction cosines of the vector, $\boldsymbol{R}$, connecting the oxygen atom to the hydrogen atom in question, and $R$ is the distance between them.

sp² hybridization sp³ hybridization

Fig. 3. Coordinate system used.

In the calculation of the magnetic dipole moment, as we do not have sufficient knowledge to determine whether the hybridization of the oxygen atom in the X-O-Y bond is of the $sp^3$ or the $sp^2$ type, the calculation has been performed for both cases. The coordinate system chosen in this treatment is shown in Fig. 3. The notations, $l_{2pz}$, $l_{sp^2}$ and $l_{sp^3}$ in Fig. 3 imply the lone pair electrons occupying 2pz, $sp^2$ and $sp^3$ hybrid orbitals respectively.

When we substitute the values of the direction cosines for two different cases, Eq. 5 becomes:

$$\left.\begin{aligned}\sigma_{para}(O)&=\frac{1}{12R^3H}(\mu_x+4\mu_z-5\mu_y)\\ &\qquad\text{for } sp^2 \text{ hybridization}\\ \sigma_{para}(O)&=\frac{1}{3R^3H}(\mu_y+\mu_z-2\mu_x)\\ &\qquad\text{for } sp^3 \text{ hybridization}\end{aligned}\right\}\quad(6)$$

The formulas for $\mu_x$, $\mu_y$ and $\mu_z$ of the oxygen atom in C-O-H and H-O-H bonds, which are derived in order to check the validity of the present treatment, are written as:

(1) COH

Case 1. oxygen of $sp^2$ hybridization

$$\left.\begin{aligned}\mu_x&=\frac{1}{2}\left(\frac{e\hbar}{mc}\right)^2H\left\{\frac{(a^*)^2}{\varepsilon^*_{OH}-\varepsilon_{l2pz}}+\frac{(c^*)^2}{\varepsilon^*_{CO}-\varepsilon_{l2pz}}\right\}\\ \mu_y&=\frac{1}{6}\left(\frac{e\hbar}{mc}\right)^2H\left\{\frac{(a^*)^2}{\varepsilon^*_{OH}-\varepsilon_{l2pz}}+\frac{(c^*)^2}{\varepsilon^*_{CO}-\varepsilon_{l2pz}}\right\}\\ \mu_z&=\frac{1}{3}\left(\frac{e\hbar}{mc}\right)^2H\left\{\frac{(a^*)^2}{\varepsilon^*_{OH}-\varepsilon_{lsp^2}}+\frac{(c^*)^2}{\varepsilon^*_{CO}-\varepsilon_{lsp^2}}+\frac{(ac^*)^2}{\varepsilon^*_{CO}-\varepsilon_{OH}}+\frac{(ca^*)^2}{\varepsilon^*_{OH}-\varepsilon_{CO}}\right\}\end{aligned}\right\}\quad(7)$$

Case 2. Oxygen of $sp^3$ hybridization

$$\left.\begin{aligned}
\mu_x &= \frac{2}{3}\left(\frac{e\hbar}{mc}\right)^2 H\left\{\frac{(c^*)^2}{\varepsilon^*_{CO}-\varepsilon_{lsp^3}}\right\}\\
\mu_y &= \frac{1}{4}\left(\frac{e\hbar}{mc}\right)^2 H\left\{\frac{3(a^*)^2}{\varepsilon^*_{OH}-\varepsilon_{lsp^2}}\right.\\
&\quad \left.+\frac{1}{3}\frac{(c^*)^2}{\varepsilon^*_{CO}-\varepsilon_{lsp^3}}\right\}\\
\mu_z &= \frac{1}{4}\left(\frac{e\hbar}{mc}\right)^2 H\left\{\frac{2(ac^*)^2}{\varepsilon^*_{CO}-\varepsilon_{OH}}\right.\\
&\quad +\frac{2(ac^*)^2}{\varepsilon^*_{OH}-\varepsilon_{CO}}+\frac{(a^*)^2}{\varepsilon^*_{OH}-\varepsilon_{lsp^3}}\\
&\quad \left.+\frac{(c^*)^2}{\varepsilon^*_{CO}-\varepsilon_{lsp^3}}\right\}
\end{aligned}\right\} \quad (8)$$

(2) HOH

Case 1. Oxygen of $sp^2$ hybridization

$$\left.\begin{aligned}
\mu_x &= \left(\frac{e\hbar}{mc}\right)^2 H\left\{\frac{(a^*)^2}{\varepsilon^*_{OH}-\varepsilon_{l2pz}}\right\}\\
\mu_y &= \frac{1}{3}\left(\frac{e\hbar}{mc}\right)^2 H\left\{\frac{(a^*)^2}{\varepsilon^*_{OH}-\varepsilon_{l2pz}}\right\}\\
\mu_z &= \frac{2}{3}\left(\frac{e\hbar}{mc}\right)^2 H\left\{\frac{(a^*)^2}{\varepsilon^*_{OH}-\varepsilon_{lsp^2}}\right.\\
&\quad \left.+\frac{(aa^*)^2}{\varepsilon^*_{OH}-\varepsilon_{OH}}\right\}
\end{aligned}\right\} \quad (9)$$

Case 2. Oxygen of $sp^3$ hybridization

$$\left.\begin{aligned}
\mu_x &= \frac{2}{3}\left(\frac{e\hbar}{mc}\right)^2 H\left\{\frac{(a^*)^2}{\varepsilon^*_{OH}-\varepsilon_{lsp^3}}\right\}\\
\mu_y &= \frac{5}{6}\left(\frac{e\hbar}{mc}\right)^2 H\left\{\frac{(a^*)^2}{\varepsilon^*_{OH}-\varepsilon_{lsp^3}}\right\}\\
\mu_z &= \frac{1}{2}\left(\frac{e\hbar}{mc}\right)^2 H\left\{\frac{2(aa^*)^2}{\varepsilon^*_{OH}-\varepsilon_{OH}}\right.\\
&\quad \left.+\frac{(a^*)^2}{\varepsilon^*_{OH}-\varepsilon_{lsp^3}}\right\}
\end{aligned}\right\} \quad (10)$$

These equations are derived according to the procedure of Pople.[3] In Eqs. 7, 8, 9 and 10, $\varepsilon_{XY}$ and $\varepsilon^*_{XY}$ denote the energies of the bonding and antibonding X-Y orbitals, and $\varepsilon_{l2pz}$, $\varepsilon_{lsp^2}$ and $\varepsilon_{lsp^3}$ are those of one electron of the lone pair in 2pz, $sp^2$ and $sp^3$ hybridized orbitals. The wave functions of the bonding and antibonding C-O and O-H obtitals are expressed, for the sake of simplicity, by the linear combination of two atomic orbitals with the coefficients which appear in Eqs. 7, 8, 9 and 10:

$$\left.\begin{aligned}
\varphi_{OH} &= a\chi_O + b\chi_H\\
\varphi^*_{OH} &= a^*\chi_O + b^*\chi_H\\
\varphi_{CO} &= c\chi_O + d\chi_C\\
\varphi^*_{CO} &= c^*\chi_O + d^*\chi_C
\end{aligned}\right\} \quad (11)$$

To carry out the numerical calculation, these energies and coefficients were determined by a similar procedure, one which appeared in one of our previous papers,[7] using empirical data such as the ionization potentials, bond moments and absorption spectra of related compounds, $R$ was taken as 0.958 Å, corresponding to a standard bond distance of the O-H bond. These values are summarized in Tables III and IV. All the energy levels in Table IV are given relative to the value of $\varepsilon_{OH}$ for the two cases stated above. Here we made a crude assumption that the variation in the molecular orbital coefficients and energies representing the characteristics of the O-H and C-O bonds for the diols and related compounds may be ignored.

TABLE III. MOLECULAR ORBITAL COEFFICIENTS

| MO Coefficients of MO's for | O-H | | C-O | |
|---|---|---|---|---|
| | $a^2$ | $(a^*)^2$ | $c^2$ | $(c^*)^2$ |
| $sp^2$ system | 0.600 | 0.400 | 0.500 | 0.500 |
| $sp^3$ system | 0.539 | 0.461 | 0.500 | 0.500 |

TABLE IV. MOLECULAR ORBITAL ENERGIES $\varepsilon_{X-Y}$'s

| Energy of $\varepsilon_{X-Y}$ in $sp^2$ system | Energy of $\varepsilon_{X-Y}$ in $sp^3$ system |
|---|---|
| $\varepsilon_{O-H}=0$ | $\varepsilon_{O-H}=0$ |
| $\varepsilon_{C-O}=-2.0$ eV. | $\varepsilon_{C-O}=-2.0$ eV. |
| $\varepsilon_{lsp^2}=+1.0$ eV. | $\varepsilon_{lsp^3}=+2.5$ eV. |
| $\varepsilon_{l2pz}=+2.0$ eV. | $\varepsilon^*_{O-H}=+10.0$ eV. |
| $\varepsilon^*_{C-O}=+12.0$ eV. | $\varepsilon^*_{C-O}=+12.0$ eV. |
| $\varepsilon^*_{O-H}=+10.0$ eV. | |

The shielding constants, $\sigma_{para}(O)$, thus calculated with the aid of Eq. 6 become:

| | $H_2O$ | COH |
|---|---|---|
| $sp^2$ system | +3.42 p.p.m. | +2.89 p.p.m. |
| $sp^3$ system | +2.02 p.p.m. | +2.18 p.p.m. |

On the shielding constant, $\sigma_{para}(O)$, for the proton in $H_2O$, Pople[3] obtained +2.75 p. p. m. by using the results of the LCAO MO SCF calculation performed by Ellison and Shull.[8] Using the same results, Matsuoka and Hattori[9] obtained an alternative value of +3.47 p. p. m. It may be concluded that the present result for $H_2O$ is reasonable.

With the shielding constants calculated by Eqs. 3 and 6, the free OH shift of the proton in $H_2O$ becomes −0.65 p. p. m. for the $sp^2$ hybrid system and −1.03 p. p. m. for the $sp^3$ system, whereas the chemical shift of gaseous $H_2O$ is −0.60 p. p. m.[10] Hence, the agreement between theoretical and experiment is

c) Measured by present authors using Perkin-Elmer 125 spectrometer.

better when $sp^2$ hybridization is assumed for the oxygen atom. For ethanol, the OH shift calculated relative to gaseous methane becomes −0.97 p. p. m. if the hybridization of the oxygen atom is assumed to be $sp^3$ and if the experimental value is −0.48 p. p. m.[10] In the following calculation, the value of +2.60 p. p. m. is adopted for the shielding constant, $\sigma_{para}(O)$, in the diols, since better agreement is obtained if we adopt +2.60 p. p. m. for the shielding constant, $\sigma_{para}(O)$, which ranges from +2.89 p. p. m. to +2.18 p. p. m. with the change in the hybridization of the oxygen atom, as has been shown above.

## Results and Discussion

The hydrogen bond shift, $\Delta$, is defined as the difference between the free OH proton shift, $\delta_2$, and the maximum OH proton shift as measured in a pure liquid state referred to gaseous methane, $\delta_1$, as follows:

$$\Delta = \delta_2 - \delta_1 \qquad (12)$$

The free OH proton shift is obtained theoretically as has been described above, while the OH maximum shift is measured at a temperature just above the freezing point. The hydrogen bond shifts thus calculated are listed in Table V. The second column of the table shows free OH shifts; the third column, OH proton shifts referred to gaseous methane, and the final column, frequency shifts of the OH stretching vibrations due to intramolecular hydrogen bonds in the infrared spectra.

The hydrogen bond shifts listed in Table V show that the values for the diols are 5.37 −5.87 p. p. m. and are smaller than that of ethanol, 6.15 p. p. m.[11] This seems reasonable, since in the diols there exists a considerable number of intramolecular hydrogen bonds and probably some free OH groups, which cause a small hydrogen bond shift, while there is no free OH proton in the linear structure of the alcohols at a low temperature. The infrared spectra show the intramolecular hydrogen bond to be weaker than the intermolecular bond. This correlation in NMR spectra will be discussed in a following paper.

# The Fractionation of Halogen Compounds through the Process of the Volatilization and the Sublimation from Volcanic Rocks on Heating*

By Minoru YOSHIDA, Ichiro MAKINO, Norinobu YONEHARA and Iwaji IWASAKI

(Received September 16, 1964)

The fractionation of elements through the deposition of the solid phases from magmatic gas is one of the most important processes in the differentiation of the magmatic emanation;[1] the solid phases thus formed appear in nature as volcanic sublimates. The "volcanic sublimates" observed at craters or fumaroles are not, however, always the true sublimates deposited from the magmatic emanation; they also include products of reactions among volcanic gases, surface waters and wall rocks. We can not yet clearly distinguish the true sublimates from others, such as the alteration products of the surrounding rocks.

Brun[2] reported in 1911 that ammonium chloride and some other chlorides sublimed from igneous rocks on heating. One of the present authors (M. Y.) reported in a previous paper[3] that small amounts of fluorine and chlorine were deposited on the surface of a silica-glass tube (or on the surface of a hard glass cap) on out-gassing the igneous rocks by heating them above 800°C, and that sodium and ammonium ions were found as the corresponding cations by qualitative tests. These results suggest that a detailed study of the sublimates formed in the laboratory experiments will give exact information about the sublimates directly derived from the magmatic emanation. The results of the previous study[3] and of the preliminary experiments indicate that the main parts of the sublimates are water-soluble and are composed mainly of chlorine, fluorine, sodium, potassium and ammonium.

To study the fractionation of these chemical species during sublimation, the sublimates deposited on the surface of the silica-glass tube were collected into several fractions, at 100°C intervals, by using a thermal-gradient furnace and silica-glass tubes designed for this purpose. The amounts of the chemical species mentioned above were determined separately in each fraction. Further, the amounts of bromine and iodine volatilized and sublimed from volcanic rocks were determined. Qualitative tests were also run in order to examine if there were some other compounds sublimed from the volcanic rock.

## Experimental

**Materials.**—The rock samples used in the study are listed in Table I, together with their chlorine, fluorine, sodium and potassium contents. The bromine and iodine in these rocks have not yet been determined. The bromine content of basalt from Ō-sima was reported by Sugiura et al.[4] as 0.00003%. The methods used in the determination of fluorine and chlorine in the rocks were the same as those used in the previous study.[3] The main chemical compositions of these rocks are also known.[5,6]

Reagent-grade chemicals and redistilled water were used in the preparation of all reagents and in the procedure described in the following section.

**Apparatus and Procedures.**—The apparatus used in this study is shown in Fig. 1. A platinum

TABLE I. HALOGEN AND ALKALI CONTENTS OF THE ROCK SPECIMENS USED IN THE PRESENT STUDY

| No. | Sample | F% | Cl% | Na% | K% |

resistance furnace (A) is so made as to obtain an almost linear thermal gradient of 20°C/cm. from 200°C to 1000°C. The temperature distribution is controlled by two transformers; one is connected to a main heater, and the other to an auxiliary heater. The temperature in the furnace is measured by a pyrometer with a movable platinum-platinum, 10% rhodium thermocouple (D); the thermocouple position is read by a stainless steel measure (E) attached to the furnace.

The temperature distribution curves in the furnace measured at the inside and at the outside of the silica-glass tube are also shown in Fig. 1. In the main experiments, the temperature was first measured at the outside and was then corrected to the inside value by means of these curves. The constancy of the distribution of the temperature during an experiment was enough for the present purpose.

The shape of the silica-glass tube used is also shown in Fig. 1 (B). The big end of the tube is 36 mm. in inside diameter and 10 cm. long, while the narrower part is 6 mm. in inside diameter and 65 cm. long. The narrower end of the tube is connected by a taper joint to the absorption vessel (C), which is made of borosilicate glass. To minimize the contamination, the tube was heated and washed twice before use.

Fifty grams of a finely-powdered sample were packed into the big end of the silica-glass tube by using a thistle tube like that used in Penfield's method for the determination of water in rocks. The tube was then connected to the absorption vessel and carefully evacuated to $10^{-1}$—$10^{-2}$ mmHg. The cock 1 was closed and about 10 ml. of redistilled water was introduced into the vessel. After

the vessel had been sufficiently evacuated again, cock 1 was opened and cock 2 was closed. Then the silica-glass tube was inserted into the furnace, which had been heated beforehand to obtain the programed temperature distribution, at the sample site temperature of 1000°C. The absorption vessel was cooled by ice water.

About 15 min. were necessary for the stable temperature distribution to be attained. The temperature distribution in the furnace was charefully checked throughout the experiment and was controlled by the transformers if necessary. After 3 hours' heating, cock 1 was closed and the furnace was cooled. Small amounts of liquid water were condensed on the cold part of the tube.

After the furnace had been cooled, a part of the

silica-glass tube where water was condensed was cut off and washed with water. The washing and the solution in the absorption vessel were combined and made up to 100 ml. in a volumetric flask. The other part of the tube was carefully observed by the naked eyes and by using a magnifying lens. The tube was cut into several pieces of lengths corresponding to the temperature intervals of 100°C. Each piece was washed with water, and the washings were analyzed for halogens and for sodium, potassium and ammonium ions.

The methods for the determination of these chemical species are listed in Table II, together with their precision and the concentration limits of the determination.

The solution in the absorption vessel was made

turbid by colloidal sulfur in some experiments. In these cases, an aliquot of the solution was heated by the addition of sodium peroxide to oxidize the sulfur compounds. The halogen content was determined from this solution. Another portion was treated with basic zinc carbonate to remove sulfides, and the ammonium ion content was determined from this. The sodium and potassium contents were determined from the original solution.

## Results

Two white spots were observed in the silica-glass tube in all the experiments; one was seen in the 100—200°C range and the other in the 500—700°C range. These two spots were soluble in water. A red or reddish-yellow spot was often found in the 500—700°C range; it was only partly soluble in water, but wholly soluble in 6 N hydrochloric acid. The washings of the pieces of the tube corresponding to the 500—700°C range showed reactions of ferric iron. It has not yet been confirmed what kinds of iron compounds were deposited and how iron was transported. A yellowish-white spot which was insoluble in water was observed in the 100—200°C range in some experiments; this was confirmed to be sulfur by qualitative tests.

The results of the determination of water-soluble halogens and alkalies are shown in Table III, together with the F/Cl, Br/Cl and I/Cl atomic ratios. In this table, "Abs." indicates the amounts of the chemical species found from the solution in the absorption vessel plus the liquid water condensed at the cold part of the silica-glass tube. "Sub." means the amounts of the chemical species found in the washings of each fraction of the tube cut out at 100°C intervals. In the columns of atomic ratios, ( ) means that the amounts of the halogens are fairly small and that the atomic ratio might, therefore, contain a comparatively larger error, while > means that the exact value of the atomic ratio can not be calculated, but only a lower limit of the value given, because the amount of chlorine evolved is smaller than the limit of exact determination.

The amounts of the chemical species contaminated in the experimental procedures were found to be smaller than the lower limit of the determination by means of blank tests.

## Discussion

First, comparison between the total amounts of the chemical species evolved from the rocks at 1000°C and those originally contained in the rocks are made. The $(X_{\text{total evolved}}/X_{\text{rock}}) \times 100$ values are calculated in Table IV for the elements the contents of which in the rocks are known.

The amounts of sodium and potassium volatilized from the rocks at 1000°C are very small compared with the amounts in the rocks. Fairly large amounts of chlorine and bromine are evolved from the rock at 1000°C, and the $(Br/Cl)_{\text{total evolved}}$ value is almost equal to the $(Br/Cl)_{\text{rock}}$ value, although there is only one datum on the bromine content in the rock. The $(Cl_{\text{total evolved}}/Cl_{\text{rock}}) \times 100$ value decreases with an increase in the amounts of the sample; this should be compared with the results of the previous report,[3] in which only 1 g. of the samples was used. The effect is more remarkable in the case of fluorine. The mean value of $(F_{\text{total evolved}}/F_{\text{rock}}) \times 100$ was about 50% in the previous study, but only about 5% in this study. The "$(F/Cl)_{\text{evolved}} < (F/Cl_{\text{rock}})$" relation is more clearly recognized in this study than in the previous study.

The second problem to be discussed is the distribution of the chemical species between "Abs." and "Sub." The $(X_{\text{total sub.}}/X_{\text{total evolved}}) \times 100$ values are calculated in Table V.

TABLE V

| Sample No. | $(X_{\text{total sub.}}/X_{\text{total evolved}}) \times 100$ | | | | | | |
|---|---|---|---|---|---|---|---|
| | F | Cl | Br | I | $NH_4$ | Na | K |
| 1 | 13 | 15 | 78 | 66 | 74 | 74 | 63 |
| 2 | 13 | 8.6 | 71 | 22 | 72 | 100 | 91 |
| 3 | 29 | 15 | 77 | 54 | 84 | 67 | 83 |
| 4 | 1.7 | 7.5 | 75 | 66 | 70 | 77 | 90 |
| 5 | 6.4 | 5.5 | 86 | 93 | 72 | 94 | 85 |
| 6 | 6.7 | 4.5 | 49 | 42 | 84 | 89 | 93 |

Large percentages of sodium, potassium, ammonium and bromine are deposited on the silica-glass tube. The amounts of chlorine and fluorine deposited are small as compared to those absorbed in water while the amounts of iodine deposited are comparable to those absorbed. The "$(F/Cl)_{\text{abs.}} \fallingdotseq (F/Cl)_{\text{total sub.}}$," "$(Br/Cl)_{\text{abs.}} < (Br/Cl)_{\text{total sub.}}$" and "$(I/Cl)_{\text{abs.}} < (I/Cl)_{\text{total sub.}}$" relations may, therefore, be recognized. On the other hand, Yoshida reported in a previous paper[3] that the $(F/Cl)_{\text{sub.}}$ ratio is always larger than the $(F/Cl)_{\text{abs.}}$ ratio. The discrepancy between the two reports may be ascribed to the difference between the materials

on which the halogens were deposited. In the present study, "sublimates" are deposited on the silica-glass surface only. On the other hand, in the previous study "sublimates" might be deposited not only on the silica-glass surface, but also on the hard-glass surface used as a cap for the connection to the absorption vessels. This difference indicates that the main portion of the fluorine determined as "Sub." in the previous study was not a true sublimate, but was deposited by the reaction with the silicate surface.

The third point to be discussed is the problem of how the chemical species are distributed among the sublimates deposited in various temperature regions. To see the general tendency of the distribution, $[X_{(t-t+100°C)\,sub.}/X_{total\,sub.}]\times 100$ values were calculated; their mean values are shown in Table VI.

TABLE VI

Mean values of the $[X_{(t-t+100°C)sub.}/X_{total\,sub.}]\times 100$ for 6 experiments

| Temp., °C | F | Cl | Br | I | $NH_4$ | Na | K |
|---|---|---|---|---|---|---|---|
| <200 | 76 | 80 | 94 | 73 | 97 | 11 | 11 |
| 200—300 | 6 | 3 | 2 | 12 | 0 | 2 | 4.5 |
| 300—400 | 4.5 | 1 | 0.5 | 5 | 0 | 2 | 1.5 |
| 400—500 | 5 | 3 | 0 | 1 | 0 | 17 | 18 |
| 500—600 | 5 | 5 | 1 | 1 | 1 | 23 | 32 |
| 600—700 | 1 | 7 | 1 | 1 | 0.5 | 44 | 32 |
| 700—800 | 1 | 0 | 0 | 1 | 0.5 | 0 | 0 |
| 800—900 | 1 | 0 | 1 | 5 | 0.5 | 0 | 0 |

The following facts may be seen in Table VI:

1) Chlorine and fluorine resemble each other in their distributions. About eighty per cent of each is deposited below 200°C and they show a second maximum in the region between 400°C and 700°C.

2) Almost all ammonium compounds are deposited below 200°C.

3) Large percentages of sodium and potassium are deposited between 400°C and 700°C.

4) Almost all bromine is deposited below 200°C, as in the case of the ammonium compound.

5) Iodine is also largely deposited below 200°C, but it is distributed in higher temperature regions, unlike bromine.

The equivalent relations between the total amounts of cations determined and those of anions are examined for every fraction in Table III. Cations are very deficient in the "Abs." fractions because of the existence of free halogen acids in the solutions. In most "Sub." fractions, the amounts of cations determined are equivalent to those of anions within the range of analytical error. The cations determined are fairly deficient in some fractions, that is, in the 200—300°C fraction and the 500—600°C fraction in the experiment on the obsidian from Imari; in the 200—300°C fraction and the 400—600°C fraction in the experiment on the liparite from Kōzu-sima, and in the 200—300°C fraction in the experiment on the glassy andesite from Syōwa-iwō-zima. Iron is found in the 400—700°C region qualitatively; it may be responsible for the definciency of cations in this temperature region. In the 200—300°C region, some other cations, such as calcium or magnesium must be present, but we have not been able to confirm their existence.

The distribution and equivalent relation of the chemical species determined show that water soluble sublimate deposited below 200°C is mainly composed of ammonium chloride and that that deposited in the 400—700°C region is mainly composed of sodium and potassium chloride.

The F/Cl value has no definite maximum point in any fraction from 100°C to 900°C. The Br/Cl value, in general, reaches its maximum in the 100—300°C region and the I/Cl value, in the 200—400°C region.

**A Comparison with Natural Volcanic Emanation.**—The Br/Cl (atomic ratio) value of the volcanic gases in Japan has been reported to be $(1—10)\times 10^{-4}$, and the I/Cl value, to be $(1—20)\times 10^{-5}$.[4,11,12] These value agree with the $(Br/Cl)_{abs.}$ and $(I/Cl)_{abs.}$ values obtained in the laboratory experiments. Bromine and iodine in the volcanic gases are, therefore, thought to be supplied from the magma; it is, in general, unnecessary to postulate any other sources.

The water-soluble component of volcanic ash was chosen as a representative of the natural volcanic sublimates in a previous paper,[3] and the "$(F/Cl)_{sublimate} > (F/Cl)_{gas}$" relation was obtained by comparison with natural volcanic gases. As has already been stated, fluorine is not enriched relative to chlorine in the "true sublimate" as compared with the gas phase, but it is enriched in the "so-called sublimate," probably by the reaction with silicates. The enrichment of fluorine in the natural "volcanic sublimates" may be caused by the reaction with silicates or other substances.

| | (two analyses) | $0.7\times10^{-3}$ | $2.8\times10^{-3}$ | $1\times10^{-6}$ | 0.12 |

the iodine content in the water-soluble component of volcanic ash. Their study shows that the I/Cl value of the water-soluble component of volcanic ash was $(6—430)\times10^{-5}$, larger than that of volcanic gases. This relation coincides with that obtained in the laboratory experiment.

Ammonium chloride is widely distributed in active volcanoes. In Japan, it has been found in Syōwa-sinzan,[14] Tokati-dake,[15] Mt. Iwate,[12] Miyake-zima,[15,16] etc.[17] It has not, however, been clearly decided whether ammonia was derived from the magma as an essential component or was the result of contamination from other sources. The results of this study show that ammonia is a common constituent of volatiles from volcanic rocks when they are heated at 1000°C, and that it is deposited below 200°C as ammonium chloride. Mizutani[14] and Noguchi et al.[12,16] analyzed natural ammonium chloride. The atomic ratios among halogens calculated from their data and from our new data[15] are shown in Table VII.

Bromine is strongly enriched and fluorine is not enriched in natural ammonium chloride as compared with the gas phase, in good accordance with the results of the laboratory experiments. Iodine is not enriched in natural ammonium chloride. Mizutani[14] explained the enrichment of bromine in terms of the difference in volatility between ammonium chloride and ammonium bromide. According to this explanation, iodine must also be enriched; he stated that the unstable nature of iodide under fomarolic conditions might be the primary cause of the paucity.

From the results of the present study, the problem may be explained as follows: There is a tendency for iodine to be deposited in higher temperature regions than the region where ammonium chloride is deposited. The temperature gradient may be not so steep at orifice of the natural fumarole as in the furnace used in this study, and so iodine will be more effectively separated from chlorine and bromine.

Sodium chloride has been found as volcanic sublimates in Mt. Mihara, Ō-sima volcano,[18] Miyake-zima volcano[19] and Iwō-zima volcano[15],*; these volcanoes are the most active volcanoes in Japan. Potassium chloride is less common than ammonium and sodium chlorides. It was recently found with sodium chloride at the Kuromoe fumarole (where the orifice temperature is about 600°C) *at Iwō-zima volcano.

Chemical analysis shows that a small amount of potassium is also present in the sodium chloride found in Miyake-zima. The atomic ratios among halogens and alkalies are shown in Table VIII.

Bromine is not so highly enriched in sodium and potassium chloride as in ammonium chloride. Fluorine and iodine are also not enriched.

* The specimen was collected by Minoru Yoshida as sodium chloride (March 1964). The existence of the sylvine phase was found by Jōyo Ossaka by X-ray analysis. The formula percentage of potassium chloride was found to be 12—16% by chemical analysis. A detailed description of alkali halides found as volcanic sublimates will be given in another paper.

## Conclusion

Ammonium chloride, sodium chloride, potassium chloride, iron compounds and sulfur, which have often been found in active volcanoes, have been proved to be capable of forming directly from the magmatic emanation.

By comparing the ratio among halogens in natural volcanic products and in products from the laboratory experiments, the following conclusions have been obtained. Bromine is more enriched in the ammonium chloride fraction as compared with the gas phase. Fluorine and iodine behave fairly differently from chlorine in volcanic phenomena. The mechanisms of the fractionation of fluorine and iodine from chlorine are essentially different from one another. The behavior of fluorine in volcanic phenomena is strongly affected by its reaction with silicates.

The authors are much obliged to Dr. Jōyo Ossaka and Mr. Takejirō Ozawa, Tokyo Institute of Technology, for kindly supplying the specimens of alkali halides they have found as volcanic sublimates and for their fruitful discussions.

# Studies on Antibiotics and Related Substances. XX. The Synthesis of Adenine Nucleosides of 3-Amino-3-deoxyglucose and 6-Amino-6-deoxyglucose

By Shunzo FUKATSU and Sumio UMEZAWA

(Received October 30, 1964)

Several compounds obtained from streptomyces or fungi which contain purine or pyrimidine rings have shown an antibiotic or an antitumor property. The simplest examples are angustmycins,[1] nucleocidin,[2] cordycepin,[3] and nebularine.[4] Puromycin, an antibiotic purine derivative, belongs to the so-called aminonucleosides and exhibits carcinostatic and trypanocidal activities; its derivatives have been extensively synthesized by Baker and his coworkers.[5] Recently, 3'-amino-3'-deoxyadenosine[6] has been added to the group of aminonucleoside-antibiotics and shown to exhibit antitumor activity. We have also been interested in the aminonucleosides and have instituted a program aiming at the synthesis of nucleosides of rare aminosugars found in antibiotics. In this paper the syntheses of adenine nucleosides from chloromercuri-6-benzamidopurine and acetohalogeno derivatives of 3-amino-3-deoxy-D-glucose and 6-amino-6-deoxy-D-glucose, uncommon amino-sugars found as moieties of kanamycin, will be reported.

The required halogenoses, $\alpha$-1-bromo- and $\beta$-1-chloro-derivatives of 2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-1, 3-dideoxy-D-glucopyranose and 2, 3, 4-tri-*O*-acetyl-6-carbobenzoxyamino-1, 6-dideoxy-D-glucopyranose, were synthesized by the methods previously reported.[7]

Chart A

The condensation of 2, 3, 4-tri-*O*-acetyl-6-carbobenzoxyamino-β-1-chloro-1, 6-dideoxyglucopyranose (Ia) with chloromercuri-6-benzamidopurine gave 6-benzamido-9-(2′, 3′, 4′-tri-*O*-acetyl-6′-carbobenzoxyamino-6′-deoxy-β-D-glucopyranosyl)-purine (III in Chart A). The hydrolysis of III with methanolic ammonia gave 9-(6′-carbobenzoxyamino-6′-deoxy-β-D-glucopyranosyl)-adenine (IV). Finally, the hydrogenolysis of the carbobenzoxy derivative with a palladium catalyst gave 9-(6′-amino-6′-deoxy-β-D-glucopyranosyl)-adenine (V). The structure of V was indicated by its elemental analyses, its ultraviolet spectrum, which was similary to that of a 9-substituted adenine, and its slightly negative rotation. The β-configuration of the aminonucleoside was deduced from Tipson's "trans rule"[8] as extended by Baker and his coworkers.[9] The values of the specific rotation of the aminonucleoside was consistent with the theoretical presumption and the reported values[10] for 9-β-D-glucopyranosyladenine. Hydrolysis with weak acid gave only adenine, 6-amino-6-deoxy-D-glucose and the unchanged nucleoside.

When 2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-β-1-chloro-1, 3-dideoxy-D-glucose (VIa) was used instead of the blocked acetohalogeno 6-aminoglucose (Ia), 6-benzamido-9-(2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-β-D-glucopyranosyl)-purine (VII) was obtained. This was converted to the desired nucleoside (IX) by deacetylation and hydrogenolysis.

Applications of exactly identical series of reactions to α-bromo-anomers of 2, 3, 4-tri-*O*-acetyl-6-carbobenzoxyamino-1, 6-dideoxy-D-glucopyranose and 2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-1, 3-dideoxy-D-glucopyranose furnished 9-(6-amino-6-deoxy-β-D-glucopyranosyl)-adenine and 9-(3-amino-3-deoxy-D-glucopyranosyl)-adenine respectively; they were identical

determined because this derivative showed exceptionary low solubility in ordinary solvents tested.

with the above-mentioned $\beta$-anomers of aminonucleosides V and IX. Thus, it has been shown that the $\alpha$- and $\beta$-anomers of blocked acetohalogeno aminosugars (I, VI) both yield the same $\beta$-nucleosides (V, IX), a fact which can be interpreted adequately in terms of the extension of the "trans rule" made by Baker and his co-workers.[8]

The biological test of these compounds may be summarized as follows: compound IX possessed a weak anti-HeLa cell activity, but compound V was inactive in the antitumor tests. Both the compounds had a low toxicity.

## Experimental

The data of yields, of ultraviolet absorption, and of specific rotation and the analyses of title compounds are summarized in Table I.

**6-Benzamido-9-(2, 3, 4-tri-*O*-acetyl-6-carbobenzoxyamino-6-deoxy-$\beta$-D-glucopyranosyl)-purine (III).**—The method used here was virtually analogous to that described by Baker and his co-workers.[11] A mixture of Hyflo Super Cel (diatomaceous earth) (2.56 g.), the chloromercuric salt (II) (2.16 g.) of 6-benzamidopurine,[12] and toluene (265 ml.) was stirred and heated, while about 20 ml. of toluene was distilled off to remove azeotropically any moisture present. After the mixture had then been refluxed for 30 min. and cooled to approximately 60°C, 2,3,4-tri-*O*-acetyl-6-carbobenzoxyamino-$\beta$-1-chloro-1,6-dideoxy-D-glucopyranose (Ia) (2.26 g.) was added. The mixture was stirred and refluxed for 10 hr. and then filtered hot. The filter-cake was thoroughly washed with hot ethanol. The filtrate and washings were combined and evaporated to dryness in vacuo. The residue was dissolved in chloroform, and the solution was shaken with a 30% aqueous potassium iodide solution. The chloroform layer was separated, dried over anhydrous sodium sulfate, and evaporated to dryness in vacuo, leaving a dark gum (2.8 g.).

The crude product was purified by chromatography on alumina. To a solution of the crude product (2.8 g.) in methanol, alumina (5 g., aluminum oxide, Merck) was added, and then the mixture was evaporated to dryness. The residue was placed on a column (1.0×30 cm.) of alumina (34 g.) and developed with cyclohexane-ethyl acetate (1 : 1) ; eighty-seven fractions were cut, containing 7 ml. each. The ultraviolet absorption spectra of the residue obtained from tube Nos. 5—50 showed a characteristic absorption at 280 m$\mu$. The combined residues (2.49 g.) from the fractions were dissolved in a small quantity of methanol and filtered, and water was added to turbidity. After it had stood overnight, the solution deposited colorless crystals of the title compound (1.81 g.). The crystals had no definite melting point; a sample sintered from 96°C and became an opaque liquid. This compound was a 9-glucosyl derivative of adenine, as is shown by its ultraviolet absorption spectrum (Table I). In the infrared region, this compound in KBr showed absorptions at 3325 (NH), 1759 (C=O in OAc), 1718 ($\nu$C=C in Cbzo), 1608, 1589 (C=C), (C=N), 1219 ($\nu$C-O in OAc), 895 (shoulder, type 2b of pyranose ring), and 775, 739, 699 (phenyl) $cm^{-1}$.

The product was soluble in methanol, ethanol, benzene, dioxane or ethyl acetate, but practically insoluble in ether, ligroin, hexane, cyclohexane or water.

The same compound, III, was obtained by the condensation of the $\alpha$-bromo-anomer (Ib) of 2,3,4-tri-*O*-acetyl-6-carbobenzoxy-amino-1,6-dideoxy-D-glucopyranose with 6-benzamidopurine (II). The product showed an infrared spectrum identical with that of the specimen prepared from Ia and 6-benzamidopurine. The yield, the ultraviolet absorption, and the specific rotation are shown in Table I

11) B. R. Baker, J. P. Joseph and R. E. Schaub, *J. Org. Chem.*, **19**, 1780 (1954).
12) J. Davoll and B. A. Lowy, *J. Am. Chem. Soc.*, **73**, 1650 (1951).

comparison with those of a sample of III obtained from Ia.

**9-(6-Carbobenzoxyamino-6-deoxy-β-D-glucopyranosyl)-adenine (IV).** — A solution of III (3.1 g.) in absolute methanol (190 ml.) was saturated with ammonia at 0°C, and then the solution was allowed to stand in a refrigerator overnight. The solution was evaporated to dryness in vacuo, and the residue was washed with water in portions to give a slightly brown solid (1.5 g.). Recrystallization from *n*-propanol gave colorless crystals (0.79 g.) of the title compound. The product sintered at about 127—128°C and decomposed at 180°C with the evolution of gas. The ultraviolet spectrum of the product in methanol showed characteristic absorptions (Table I.).

The compound was soluble in methanol or ethanol but almost insoluble in benzene, petroleum ether or water.

**9-(6-Amino-6-deoxy-β-D-glucopyranosyl)-adenine (V).**—A solution of IV (1.5 g.) in 25% aqueous methanol (40 ml.) was shaken with 5% Pd-C (1.0 g.) and hydrogen at room temperature for 14 hr. After filtration, the filtrate was evaporated up to dryness under reduced pressure to give a colorless powder (0.825 g.). To a solution of the crude product (0.2 g.) in water, a solution of picric acid (1.45 g.) in methanol (14.5 ml.) was added; this mixture was then allowed to stand in a refrigerator to give a picrate (0.447 g.). Recrystallization from water gave yellow needles (0.226 g.). The picrate sintered at 168°C, gradually darkened, and decomposed at 215°C.

Found: C, 36.90; H, 3.27; N, 21.57. Calcd. for $C_{23}H_{22}N_{12}O_{18}$ (754.4): C, 36.59; H, 2.94; N, 22.29%.

The picrate (0.226 g.) was dissolved in water (8.2 ml.) and stirred with Dowex 1X2 ion exchange resin (OH form) (200—400 mesh, 10 ml.); the filtrate was passed through a column (1.5×30 cm.) of Dowex 1X2 (OH form). The column was then developed with water, and those fractions which showed characteristic ultraviolet absorptions at 259 mμ were collected. The product obtained by evaporation to dryness under reduced pressure was a colorless powder (84 mg.); the product sintered at about 205°C, darkened, and decomposed at 211°C, with the evolution of gas. The ultraviolet spectrum of the product in water showed absorptions characteristic of 9-substituted adenine.

The product showed a single ninhydrin-positive spot of $R_{fad}$ 0.36* upon the use of the descending method using an *n*-butanol - ethanol - water (10 : 5 : 7) solvent system and Toyo filter paper No. 52. The product was soluble in water, but nearly insoluble in methanol or ethanol.

A sample V was hydrolyzed with 1% acetic acid at room temperature for 5 days.

Chromatography on Toyo filter paper No. 50 by the ascending method using an *n*-butanol - acetic acid - water (4 : 2 : 1) solvent system showed two ninhydrin-positive spots ($R_f$ 0.12, 0.25) of 6-amino-6-deoxy-D-glucose and unchanged nucleoside, and another spot of adenine ($R_f$ 0.57), located by its slight opacity to the ultraviolet light of 2536 Å.

* $R_f$-Value relative to that of adenine taken as a unit.

**6-Benzamido-9-(2,4,6-tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-β-D-glucopyranosyl)-purine (VII)** was prepared from 2,4,6-tri-*O*-acetyl-3-carbobenzoxyamino-1-β-chloro-1,3-dideoxy-D-glucopyranose (VIa) and 6-benzamidopurine (II) by a procedure analogous to that described in III; a sample purified by alumina chromatography and then by recrystallization from ethanol-water sintered at about 80°C.

The same compound, VII, was obtained in a similar condensation of the α-bromo anomer (VIb) of 2,4,6-tri-*O*-acetyl-3-carbobenzoxyamino-1,3-dideoxy-D-glucopyranose with 6-benzamidopurine (II). The product showed an infrared spectrum identical with that of the specimen prepared from VIa and 6-benzamidopurine. The yield, the ultraviolet absorption and the specific rotation are shown in Table I in comparison with those of a sample of VII obtained from VIa.

**9-(3-Carbobenzoxyamino-3-deoxy-β-D-glucopyrnosyl)-adenine (VIII)** was prepared from VII by a procedure analogous to that described in IV; a sample recrystallized from methanolic ammonia gradually darkened and decomposed at 233°C with the evolution of gas.

**9-(3-Amino-3-deoxy-β-D-glucosyl)-adenine (IX)** was prepared from VIII by a procedure analogous to that described in V. Picrate of IX: yield from a crude product, 84%; it gradually darkened and decomposed at 216—220°C.

Found: N, 21.55. Calcd. for $C_{23}H_{22}N_{12}O_{18}$ (754.4): N, 22.28%.

The yield of IX from its picrate was 92%. A sample purified with ion exchange resin Dowex 1X2 was recrystallized from water-ethanol; the product sintered a 170°C and decomposed at 191°C with the evolution of gas; the ultraviolet spectrum of the product in water showed the absorption characteristic of 9-substituted adenine. In the infrared region, this compound in KBr showed absorptions at 3320, 3180 (OH, NH), 1642, 1602 (C=N, C=C), 1058, 1043 (C-O), 890 $cm^{-1}$. (type 2b of the pyranose ring)

The product showed a single ninhydrin-positive spot of $R_{fad}$ 0.63 by a method similar to that used for V. The paper chromatographic analysis of the acid-hydrolyzate of a sample of IX by the same procedure as that used for V showed two ninhydrin-positive spots of 3-amino-3-deoxy-D-glucose ($R_f$ 0.16) and unchanged nucleoside ($R_f$ 0.41) and a spot of adenine ($R_f$ 0.57).

**Bioassays.**—It is interesting that IX shows antitumor activity. The minimum necessary concentration of IX for the anti-HeLa cell effect was 1 mg./ml. Preliminary tests indicated that IX possessed a weak antibacterial activity; IX completely inhibited the growth of Bacillus subtilis in the dilution of 1 : 1000. V showed almost no antitumor and antibacterial activity. V and IX had a low toxicity; V: $LD_0$ 500 mg./kg. (mice, i. v.), IX: $LD_0 > 500$ mg./mg./kg. (mice, i. v.).

## Summary

1) The subject amino-nucleoside have been synthesized from blocked acetohalogeno aminosugars and 6-benzamidopurine.

2) It has been shown that the $\alpha$- and $\beta$-anomers of blocked acetohalogeno aminosugars (Ia, Ib and VIa, VIb) both yield the same $\beta$-nucleosides (V, IX).

3) 9-(3-Amino-3-deoxy-$\beta$-D-glucopyranosyl)-adenine was found to possess a weak antitumor activity.

The authors are indebted to Professor Hamao Umezawa, of the National Institute of Health, Tokyo, for his antitumor assays. This work has been supported in part by a cancer research grant from the Ministry of Education, to which the authors' thanks are due. The authors are also grateful to Mr. Saburo Nakada for his microanalysis.

# Studies on Antibiotics and Related Substances. XXII. Syntheses of Di(3-amino-3-deoxy-D-glucosyl)- and Di(6-amino-6-deoxy-D-glucosyl)-deoxystreptamine[1]

By Shinkiti KOTO, Yukio ITO and Sumio UMEZAWA

(Received January 28, 1965)

In a previous paper[2] we described the synthesis of di-*O*-(D-glucopyranosyl)-deoxystreptamine, in which two sugars are linked to C-4 and C-6 of deoxystreptamine in a manner analogous to that two amino sugars are linked in kanamycin. In an effort to determine the effect of amino groups on the antibiotic activity of glucosides of this kind, the amino glucosides of the title have been synthesized. The basis of the work of this series[3] arose with the recent discovery of a number of antibiotics which are the glucosides of deoxystreptamine but which differ primarily in the structures of their sugar moieties.

The condensation of *N*, *N'*-dicarbobenzoxydeoxystreptamine (II)[2] with an excess of 2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-$\alpha$-D-glucopyranosyl bromide (I)[4] in nitromethane in the presence of mercuric cyanide gave 4, 6-di-*O*-(2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-$\beta$-D-glucopyranosyl)-*N*, *N'*-dicarbobenzoxy-deoxystreptamine (III) in a 25% yield.

The deacetylation of III with methanolic ammonia gave 4, 6-di-*O*-(3-carbobenzoxyamino-3-deoxy-$\beta$-D-glucopyranosyl)-*N*, *N'*-dicarbobenzoxy-deoxystreptamine (IV) in a 68% yield.

The catalytic hydrogenolysis of IV with palladium black gave 4, 6-di-*O*-(3-amino-3-deoxy-$\beta$-D-glucopyranosyl)-deoxystreptamine (V) in an 80% yield.

The reaction sequence used in the synthesis of 4, 6-di-*O*-(6-amino-6-deoxy-$\beta$-D-glucopyranosyl)-deoxystreptamine (V') was analogous to that of V.

Since the structure of 4, 6-(tetra-*O*-acetyl-$\beta$-D-glucopyranosyl)-deoxystreptamine, which corresponds to the hydrogenolysis product of III had been previously[2] confirmed by means of periodate oxidation, the two amino sugar moieties in V and V' were assigned to the 4- and 6-positions in deoxystreptamine.

Futhermore, V' rapidly consumed about four moles of periodate, and the paper chromatography of the hydrolyzate of the oxidation mixture showed the presence of deoxystreptamine and the complete absence of 6-amino-6-deoxy-D-glucose. The survival of deoxystreptamine is indicative of glucosidation at the 4- and 6-positions of deoxystreptamine.

The designation of V and V' as $\beta$-anomers was based on their optical rotations and infrared spectra. The optical rotations of V and V' are $[\alpha]_D^{27}$ $-5.5°$ (*c* 1.2, water) and $[\alpha]_D^{15}$ $-0.1°$ (*c* 0.5, water) respectively. Compared with the optical rotation of the kanamycin free

base $[\alpha]_D^{13}$ +140° (*c* 1.35, water)[5] with an α-configuration, that of V and V′ are levorotatory, and since the amino sugar moieties in V and V′ have a D-configuration, the assignment of β-configurations to V and V′ appears to be reasonable. The infrared spectra of V showed absorption band at 895 $cm^{-1}$, indicating a characteristic absorption band for β-glucoside, while the kanamycin free base showed absorption bands at 838 and 823 $cm^{-1}$ corresponding to two α-anomeric configurations.[6]

A similar condensation of *N*, *N*′-dicarbobenzoxy-deoxystreptamine with 3, 4, 6-tri-*O*-acetyl-2-carbobenzoxyamino-2-deoxy-α-D-glucopyranosyl bromide[7] was unsuccessful; only 4, 5-(3, 4, 6-tri-*O*-acetyl-D-glucopyrano)-2-oxazolone[8] was obtained.

## Experimental

**4, 6-Di-*O*-(2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-β-D-glucopyranosyl)-*N*, *N*′-dicarbobenzoxy-deoxystreptamine (III).**—To a suspension of *N*, *N*′-dicarbobenzoxy-deoxystreptamine (0.38 g., 0.9 mmol.) and 2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-α-D-glucopyranosyl bromide[4] (1.11 g., 2.2 mmol.) in nitromethane* (20 ml.), powdery mercuric cyanide (0.57 g., 2.3 mmol.) was addded, the suspension was then stirred at 27°C for 24 hr. The resulting mixture was filtered and the filtrate evaporated to dryness at about 40°C under reduced pressure. Extraction with chloroform was followed by repeated washings with water in order to remove mercuric salts. After drying over sodium sulfate, the chloroform solutions was evaporated to dryness under reduced pressure to give a residue (1.05 g.), which was washed with ether to give a crude product (250 mg.) (25%). Recrystallized from absolute ethanol; m. p. 277°C (decomp., sintered at about 277°C), $[\alpha]_D^{15}$ −13.0° (*c* 1.75, dioxane).

Found: C, 58.11; H, 5.75; N, 4.41; Mw, 1150. Calcd. for $C_{62}H_{72}O_{25}N_4$: C, 58.48; H, 5.70; N, 4.40%; Mw, 1273.

**4, 6-Di-*O*-(3-carbobenzoxyamino-3-deoxy-β-D-glucopyranosyl)-*N*, *N*′-dicarbobenzoxy-deoxystreptamine (IV).** — Three hundred and ten milligrams of III was suspended in 75 ml. of absolute methanol, and to this was added 50 g. of absolute methanol saturated with ammonia. Since, after this mixture had been left overnight, there was a considerable quantity of solid left in the mixture, absolute methanol saturated with ammonia was again added to the mixture. After again having been left overnight at room temperature, a clear solution was obtained; this was filtered, and the filtrate was concentrated under reduced pressure to yield colorless crystals, which were collected and washed with absolute methanol and chloroform in turn; 0.17 g., m. p. 264—265°C (decomp., sintered at about 200°C), $[\alpha]_D^{15}$ +5.0° (*c* 1.22, dimethyl formamide).

Found: C, 58.67; H, 5.60. Calcd. for $C_{50}H_{60}O_{19}N_4$: C, 58.81; H, 5.92%.

**4, 6-Di-*O*-(3-amino-3-deoxy-β-D-glucopyranosyl)-deoxystreptamine (V).** — One hundred and sixty milligrams of IV was suspended in 12 ml. of a dioxane-water mixture (7:5), and then this mixture was added to a prehydrogenated palladium black (50 mg.) in 1.5 ml. of a dioxane-water mixture (1:1). The mixture was hydrogenated under mechanical shaking at 23—25°C for 1.5 hr. and further at 30—31°C for 4 hr. A further suspension of 20 mg. of prehydrogenated palladium black in dioxane-water was added to the resulting mixture, and hydrogenolysis was continued at 38—42°C for about 7 hr. The resulting mixture was strongly alkaline. After the removal of the catalyst by filtration, the solution was evaporated under reduced pressure to give 60 mg. of an amorphous solid. The product was dissolved in hot methanol, and ethanol was added to yield a crystalline powder of the title compound, $[\alpha]_D^{27}$ −5.5° (*c* 1.2, water).

Found: C, 44.58; H, 7.30; N, 10.95. Calcd. for $C_{18}H_{36}O_{11}N_4$: C, 44.61; H, 7.49; N, 11.57%.

The infrared absorption spectrum of the product in Nujol contained absorptions at 3260 (NH, OH), 1665, 1595 (NH), 1040 (C-O) and 895 $cm^{-1}$ (type 2b of the pyranose ring).

**4, 6-Di-*O*-(6-amino-6-deoxy-β-D-glucopyranosyl)-deoxystreptamine (V′).** — To a suspension of *N*, *N*′-dicarbobenzoxy-deoxystreptamine (0.42 g., 1.0 mmol.) and 2, 3, 4-tri-*O*-acetyl-6-carbobenzoxyamino-6-deoxy-β-D-glucopyranosyl chloride[9] (1.00 g., 2.2 mmol.) in dry nitromethane (30 ml.), powdery mercuric cyanide (0.56 g., 2.2 mmol.) was added; then the suspension was shaken at about 27°C for 4 days in a dark room. The resulting mixture was filtered, and the filtrate was evaporated under reduced pressure. The residue was extracted with chloroform, and the chloroform extract was washed with water to remove mercuric salts. After it had been dried over sodium sulfate, the chloroform solution was evaporated under reduced pressure. The pale yellow syrup (1.1 g.) obtained was suspended in absolute methanol saturated with ammonia (62 g.). After having been left overnight at room temperature, the mixture was filtered, and the filtrate was evaporated under reduced pressure. The resulting syrup was treated several times with 2-ml. portions of water, and the residue was dried up under reduced pressure to give a colorless syrup (0.480 g.). The residue was dissolved in 10 ml. of 25% aqueous methanol, and to this solution was added a prehydrogenated palladium black (100 mg.). The mixture was hydrogenated under mechanical shaking at room temperatuer for 50 hr. During the hydrogenation, dilute hydrochloric acid was

* Dry nitromethane obtained by distillation with phosphorus pentoxide.
9) S. Umezawa, S. Koto and Y. Ito, This Bulletin, **36**, 183 (1963).

added several times in order to acidify the reaction mixture.* After the catalyst had been removed, the solution was evaporated under reduced pressure to yield a syrup (324 mg.). Descending-paper chromatography of the product by ninhydrin coloration, using an *n*-butanol - pyridine - water - acetic acid (6 : 4 : 3 : 1) solvent system at room temperature for 19 hr., showed five spots of $R_{f6AG}$ 1.00, 0.65 (deoxystreptamine), 0.31, 0.10 and 0.04.** The spot of $R_{f6AG}$, 0.10, corresponded to the main product.

The product was mixed with cellulose powder (100—200 mesh) (1.0 g.) and water (3.0 ml.) and dried over phosphorus pentoxide in a desiccator under reduced pressure. It was then placed on a column (11×2.5 cm.) of cellulose powder (15 g.) and developed with the above-metioned solvent system at a rate of 10 ml./hr. The product of $R_{f6AG}$, 0.10, emerged from 340 to 800 ml. of the eluate. The fractions were then combined and evaporated under reduced pressure at 30—35°C. A solution of the residue (116 mg.) in water (1.0 ml.) free from carbon dioxide was placed on a column (0.5×5 cm.) of Dowex 1X2 (OH form) and developed with water free from carbon dioxide. The ninhydrin-positive fractions were then collected and evaporated under reduced pressure at about 20°C to give a colorless powder of the title compound (65 mg.) (13.5%). Purification for analysis was accomplished by dissolving the product in hot methanol, with the subsequent addition of ethanol; colorless amorphous powder, $[\alpha]_D^{15}$ −0.1° (*c* 0.5, water).

Found: C, 43.90; H, 7.25; N, 11.04. Mw, 480. Calcd. for $C_{18}H_{36}O_{11}N_4$: C, 44.61; H, 7.49; N, 11.57%. Mw, 484.

**The Periodate Oxidation of V′.**—An accurately-weighed sample (2.42 mg.) of V′ was dissolved in 5.0 ml. of a 0.03 M sodium periodate solution (acetate buffer, pH 4.4). The oxidation was carried out at 2—3°C. in the dark. To each one-ml. aliquot was added a measured excess of 0.05 M sodium arsenite at eight-hour intervals, beginning three hours after the dissolving of the sample, and then these solutions were titrated with a 0.01 M iodine solution. The product consumed 2.1 mol. of periodate at 3 hr. and 3.9 mol. at 24 hr. A parallel experiment using a sample (2.52 mg.) of kanamycin base gave a titration curve similar to that obtained from the product (V′); kanamycin consumed 2.6 mol. of periodate at 3 hr. and 4.0 mol. at 24 hr.

Another weighed sample (2.6 mg.) of V′ was oxidized similarly for 120 hr. After the addition of ethylene glycol (1.0 ml.), the mixture was again allowed to stand over night. To the mixture concentrated hydrochloric acid (5.0 ml.) was then added, and the mixture was heated at 90—95°C for 3 hr. The hydrolyzate was chromatographed on Toyo filter paper No. 51 by the descending method, using *n*-butanol - pyridine - water - acetic acid (6 : 4 : 3 : 1) for 16 hr. Detection by ninhydrin-coloration gave the spot corresponding to deoxystreptamine.

**The Paper Chromatography of the Acid Hydrolyzate of V′.**—Two 0.5 mg. samples of V′ were dissolved in 1.75 ml. of 2 N and 6 N hydrochloric acid respectively, and then allowed to stand at about 95°C for 6 hr. The hydrolyzates were chromatographed on Toyo filter paper No. 51 by the ascending method, using the above-mentioned solvent system, for 19 hr. Detection by ninhydrin-coloration gave only three spots, corresponding to 6-amino-6-deoxy-D-glucose, deoxystreptamine and unchanged V′.

**Bioassay.**—Compounds V and V′ did not show any antibacterial activity against *M. Pyogenes var. aureus* 209-p, *E. coli* and *Mycobacterium tuberculosis* 607 in a dilution of 1 : 1000.

The authors are indebted to Mr. Saburo Nakada for the microanalysis and to Mr. Yasushi Suzuki for his technical assistance. This research was supported in part by a grant from the Ministry of Education.

* When the hydrogenation was effected without the addition of hydrochloric acid, the crude product (syrup) showed a remarkable inhibition against *B. subtilis* PCI 219. The antibacterial activity seems to be due to the presence of the complex diorthoester reported by R. U. Lemieux, C. I. C. Medal Lecture, "The Chemical Synthesis of Glucosides," Chemical Institute of Canada (1964).

** $R_{f6AG}$: $R_f$ values relative to the $R_f$ value of 6-amino-6-deoxy-D-glucopyranose taken as 1.0.

# Studies of the Chlorination of the Carboxylic Acids with *t*-Butyl Hypochlorite

By Yasuo SHIGEMITSU, Yoshinobu ODAIRA and Shigeru TSUTSUMI

(Received November 19, 1964)

Investigations of chlorination with *t*-butyl hypochlorite have been carried out for many years; recently Walling and his co-workers have indicated that the above hypochlorite is an efficient free-radical chlorinating agent for various hydrocarbons.[1-3]

We have been making studies of the extensive utilization of *t*-butyl hypochlorite, which can readily seprepared from *t*-butyl alcohol, in synthetic organic chemistry. As a part of these studies, our attention has been drawn to the telomerization using *t*-butyl hypochlorite.

In general, it is well-known that, with the exception of a few cases of using some such reagents as carbon tetrachloride or cyanogen chloride as a telogen, the telomerization affords a telomer with only one functional group, as is shown in the reactions of olefins with *N*-alkyl substituted formamides, acetic acid or alkyl acetates in the presence of di-*t*-butyl peroxide as the initiator.[4,5] However, when this hypochlorite is used in the telomerization, one would expect that the telomer with two functional groups at the both end sites, would be obtained, as is shown in the following scheme:

$$t\text{-BuOCl} \xrightarrow{h\nu} t\text{-BuO}\cdot + \text{Cl}\cdot \quad (1)$$

$$t\text{-BuO}\cdot + \text{RH} \rightarrow t\text{-BuOH} + \text{R}\cdot \quad (2)$$

$$\text{R}\cdot + n\text{R}'\text{-CH=CH}_2 \rightarrow \cdot(\text{CH}(\text{R}')\text{-CH}_2)_n\text{-R} \quad (3)$$

$$\cdot(\text{CH}(\text{R}')\text{-CH}_2)_n\text{-R} + t\text{-BuOCl} \rightarrow \text{Cl-}(\text{CH}(\text{R}')\text{-CH}_2)_n\text{-R} + t\text{-BuO}\cdot \quad (4)$$

We have already demonstrated that we have succeeded in the synthesis of 5-chloro-2-pentanone by means of this new telomerization using acetone and ethylene.[6] Since the carboxylic acids as well as acetone seem to be available for the telogen, we have first investigated the reactions of *t*-butyl hypochlorite with the carboxylic acids as an experiment preliminary to the telomerization using the carboxylic acids as the telogen. Now, in this paper, we wish to describe the reactions of *t*-butyl hypochlorite with a number of carboxylic acids in the presence of a solvent such as benzene or carbon tetrachloride and, especially, to demonstrate the effects of the acidity of the carboxylic acids and those of the solvents on the reactions, as well as to demonstrate the reactivities of the *t*-butoxy radical.

## Experimental

**Materials.** — *t*-Butyl hypochlorite was prepared according to the procedure of Teeter and Bell.[7] The hypochlorite was distilled before use; its b. p. was 79.5—80°C, and it was stored in the dark at 0°C. The purity was 95—99% as determined by iodometric analysis. The other materials were commercial-grade chemicals and were purified by the usual method and distilled or recrystallized before use.

**Reaction Procedures.** — All the reactions were carried out in a 200-ml. (or 300-ml.) four-necked flask equipped with a thermometer, a mechanical stirrer, a gas inlet and a condenser, to which a trap at −78°C and a gas holder were attached. *t*-Butyl hypochlorite and the carboxylic acid (and the solvent) were placed in the flask wrapped in aluminum foil designed to intercept the light. After completely replacing the system by nitrogen for 15 min. prior to irradiation, the aluminum foil was removed and the system was irradiated by a 60-watt incandescent light bulb at a distance of 5 cm. The conditions of the reaction are shown in Table I.

**Analytical Procedures.** — The gaseous products and the trapped fraction were analyzed by gas chromatography using a 2.5 m. silica gel and a 2.5 m. $\beta,\beta'$-oxydipropionitrile column. The low-boiling products and the solvent were distilled and determined quantitatively by gas chromatography using a 2.5 m. dinonyl phthalate column. Unreacted liquid carboxylic acids (acetic, propionic and *n*-butyric acids) were also distilled and titrated with 0.1 N sodium hydroxide, using phenolphthalein as

an indicator. The high-boiling products were fractionally distilled under reduced pressure and determined quantitatively by gas chromatography, using a 2.5 m. dinonyl phthalate, a 2 m. polyethylene glycol-6000 or a 2.5 m. silicon DC-550 column; they were also determined qualitatively by means of their infrared spectra, by various spot tests, or by introduction to their derivatives. In the case of monochloroacetic acid, the high-boiling fractions, containing the unreacted acid, were treated with diazomethane and analyzed by gas chromatography, using a 3 m. tricresyl phosphate column. In the case of trichloroacetic acid in the presence of benzene, the low-boiling products and benzene were treated as has been described above. The residue was dissolved in water and extracted with benzene. The benzene extract was washed with 10% aqueous sodium carbonate and water successively. The residue obtained by the removal of benzene was a polymeric product; further investigation was not undertaken.

## Results

**Reactions with Acetic Acid.** — When *t*-butyl hypochlorite was illuminated by an incandescent light bulb in the presence of acetic acid, the acid was scarcely chlorinated, whereas the self-decomposition of *t*-butyl hypochlorite proceeded predominantly. As a consequence, acetone and methyl chloride were obtained as the main products, accompanied by small amounts of *t*-butyl alcohol, monochloroacetic acid, chloroacetone and chloro-*t*-butyl alcohol. The results on acetic acid are listed in Table II.

As Table II shows, the reactions in the presence of benzene or carbon tetrachloride gave the same results as the above, except that the formation of *t*-butyl alcohol increased somewhat. Interestingly, the formation of carbon dioxide suggests that the *t*-butoxy radical generated by the decomposition of *t*-butyl hypochlorite may abstract the hydrogen of the carboxyl group.

* Basis on *t*-butyl hypochlorite used.

yields of chlorinated carboxylic acids were considerably higher than those in the chlorination of acetic acid. On the other hand, in the presence of benzene as the solvent, the amounts of chlorinated carboxylic acids and *t*-butyl alcohol decreased, in contrast to an increase in those of acetone. From the formation of ethyl chloride along with carbon dioxide, we would conclude that the decarboxylation of the carboxylic acid might well occur. In Table III it can also be observed that *n*-butyric acid is more efficiently chlorinated than propionic acid by *t*-butyl hypochlorite. The isomer distributions of chlorinated carboxylic acids of propionic and *n*-butyric acids are summarized in Table IV.

TABLE IV. ISOMER DISTRIBUTIONS OF CHLORINATED CARBOXYLIC ACIDS

| Exp. No. | Carboxylic acid | $\alpha$-Isomer % | $\beta$-Isomer % | $\gamma$-Isomer % |
|---|---|---|---|---|
| 5 | $C_2H_5COOH$ | 61.2 | 38.8 | — |
| 6 | $C_2H_5COOH$ | 63.2 | 36.8 | — |
| 7 | $n$-$C_3H_7COOH$ | 20.6 | 46.4 | 33.0 |

The $\alpha$-isomer was rich in the case of propionic acid, but the ratio of $\alpha$- and $\beta$-isomers was constant, regardless of the presence or absence of the solvent. On the other hand, in the case of *n*-butyric acid, the $\beta$-isomer was predominantly formed and the $\gamma$-isomer was preferentially formed over the $\alpha$-isomer.

**Reactions with Other Acids.** — All the reactions with other acids were carried out in the presence of the solvent. The major products are listed in Table V.

TABLE V. MAJOR PRODUCTS OF REACTIONS WITH OTHER ACIDS

| Exp. No. | 8 | 9 | 10 | 11 |
|---|---|---|---|---|
| Product, mol. %* | | | | |
| *t*-Butyl alcohol | 32.4 | 41.9 | 12.6 | 41.8 |

| Gaseous products | $CO_2$ $CH_3Cl$ | Iso-butene | $CH_3Cl$ | $CH_3Cl$ |

* Basis on *t*-butyl hypochlorite used.

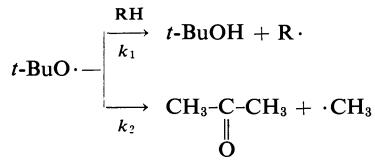
The reaction of *t*-butyl hypochlorite with monochloroacetic acid gave the same results as in the case of acetic acid in the presence of benzene with the exception of the increase in the formation of chlorobenzene. The reactions of *t*-butyl hypochlorite with trichloroacetic acid provided very interesting results. When benzene was used as the solvent, the decomposition of *t*-butyl hypochlorite began immediately, without any illumination, as soon as the hypochlorite was dropped into the flask containing benzene and trichloroacetic acid. The products were *t*-butyl alcohol, chlorobenzene and isobutene, accompanied by trace amounts of acetone. Isobutene may be formed from *t*-butyl alcohol during distillation by the acid-catalytic action of trichloroacetic acid. On the other hand, using carbon tetrachloride as the solvent, the major products were acetone, methyl chloride, *t*-butyl alcohol, chloroacetone and chloro-*t*-butyl alcohol.

## Discussion

**The Effects of the Acidity of Carboxylic Acids.**—*t*-Butyl hypochlorite is often used as an electrophilic-chlorinating reagent in the presence of an acid-catalyst. For example, benzene has been efficiently chlorinated by *t*-butyl hypochlorite in the presence of sulfuric acid.[8] In our study, benzene was also chlorinated easily by *t*-butyl hypochlorite in the presence of trichloroacetic acid, which is a strong acid as well as a sulfuric acid, whereas scarcely any acetone was formed. From these results, it may be concluded that, in this reaction, the chlorination of benzene proceeds predominantly by the electrophilic attack of the chloro cation on the aromatic nucleus. The acidity of carboxylic acids in benzene and the yield of chlorobenzene are summarized in Table VI.

TABLE VI. THE YIELD OF CHLOROBENZENE IN THE PRESENCE OF THE CARBOXYLIC ACID

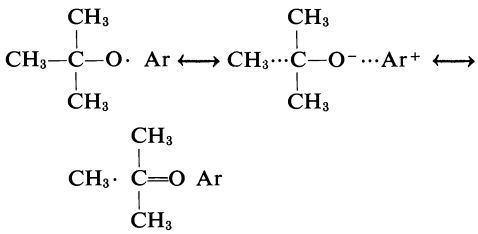
| Exp. No. | Carboxylic acid | p$K$ in $C_6H_6$*1 | Yield of chlorobenzene*2 % |
|---|---|---|---|
| 3 | $CH_3COOH$ | 5.18 | 3.5 |
| 6 | $C_2H_5COOH$ | | 4.9 |
| 8 | $CH_2ClCOOH$ | 1.75 | 6.2 |
| 10 | $CCl_3COOH$ | 0.70 | 41.8 |
| 11 | None | — | 2.2 |



*1 V. K. LaMer and H. C. Dowens, *J. Am. Chem. Soc.*, **55**, 1860 (1933).
*2 Mol. % of *t*-butyl hypochlorite used.

In Table VI it can be observed that, although chlorobenzene was formed in a 2.2% yield by the homolytic decomposition of *t*-butyl hypochlorite in benzene, the yield of chlorobenzene was higher than 2.2% in the presence of the carboxylic acid, and that the yield of chlorobenzene increased with the increase in the

8) M. Anbar, Ph. D. Thesis, Hebrew University, Jerusalem (1953).



acidity of the carboxylic acids. Consequently, it may be presumed that the ionic process in the reaction becomes more important with the increase in the acidity of the carboxylic acids. However, in such weak acids as acetic and propionic acids, this ionic process may be almost ignored; we therefore studied in more detail the radical reactions of *t*-butyl hypochlorite with such weak acids.

**The Solvent Effects.**—As is well known, the *t*-butoxy radical formed by the photo-induced chain decomposition of *t*-butyl hypochlorite abstracts hydrogen or proceeds competitively via fragmentation, as is shown hereunder;

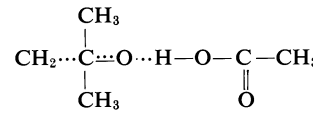
From the mole ratio of the *t*-butyl alcohol and acetone obtained from the above reactions, it is possible to calculate the $k_1/k_2$ ratio. Although, in our experiments, the $k_1/k_2$ rate ratio cannot be given precisely because of the further reactions of *t*-butyl alcohol or acetone with *t*-butyl hypochlorite, for convenience it is permissible to adopt the mole ratio of *t*-butyl alcohol and acetone as a measure of the reactivity of the *t*-butoxy radical.

Recently, Russel has investigated particularly the solvent effects in the decomposition of di-*t*-butyl peroxide in the presence of cyclohexane at 130°C,[9] he has shown that such aromatic solvents as benzene caused a decrease in the $k_1/k_2$ rate ratio due to the high dissociation of the aromatic hydrocarbon-*t*-butoxy radical $\pi$-complex. Moreover, Walling has also pointed out that the aromatic solvents stabilize the transition state for $\beta$-scission through the contribution of the charge-transfer type structure, as is shown below:[10]

Concerning the solvent effects, however, the dilution effect with a solvent must also be taken into consideration, because the hydrogen abstraction reaction by the *t*-butoxy radical is proportional to the concentration of the *t*-butoxy radical and RH. The $\beta$-scission becomes preferential in the presence of a solvent as a result of this dilution effect. This effect is summarized in Table VII.

Table VII. Dilution effect

| Exp. No. | $C_6H_6$/*t*-BuOCl Mole ratio | $R$*1,*2 Mole ratio |
|---|---|---|
| 11 | 10 | 0.83 |
| a*3 | 5 | 1.14 |
| b*3 | 14 | 0.7 |



*1 $R = \dfrac{(t\text{-BuOH} + \text{chloro-}t\text{-BuOH})}{(\text{acetone} + \text{monochloroacetone})}$

*2 The value of $R$ may be influenced by reaction temperature, but we considered that there was no great difference of $R$ values within the range of 30°C to 40°C.

*3 C. Walling and B. B. Jacknow, *J. Am. Chem. Soc.*, **82**, 6111 (1960).

The mole ratio ($R$) of *t*-butyl alcohol and acetone decreases in proportion as the mole ratio of benzene and *t*-butyl hypochlorite increases. The $R$ ratio in this experiment is summarized in Table VIII.

In the case of propionic acid, the $R$ ratio is smaller than unity in the presence of benzene. In the reactions with monochloro- and trichloroacetic acids, $R$ is always smaller than unity. In the case of acetic acid, however, $R$ is, contrariwise, larger when the solvent is present than when there is no solvent. These results suggest that, as Walling has also described,[10] hydrogen bonding between the *t*-butoxy radical and acetic acid stabilizes the transition state of the $\beta$-scission.

In the case of propionic acid, however, this hydrogen bonding may be fairly unstable, the *t*-butoxy radical preferentially abstracts a hydrogen from the acid, and in the presence of the solvent, the $\beta$-scission of the radical proceeds predominantly as a results of the dilution effect.

**The Reactivities of the *t*-Butoxy Radical.**—Russell investigated the solvent effects in the photochlorination of hydrocarbons by molecular chlorine and found that, in the presence of some aromatic solvents, the chloro radical attacked hydrocarbons with a high selectivity.[11] Consequently, he considered that the selectivity may be ascribed to the formation of a $\pi$-complex between the chloro radical and the aromatic nucleus, and that this complex was less reactive and, therefore, more selective

than the free chloro radical. On the other hand, Walling and his co-workers studied the similar chlorination by $t$-butyl hypochlorite.[1-3] They indicated that, even in the presence of an aromatic solvent, there was no change in the selectivitity of the $t$-butoxy radical as to the hydrogen abstraction. In our study of the chlorination of propionic acid as is shown in Table IV, the ratio of the $\alpha$- and, $\beta$-isomers was constant, regardless of the presence or absence of benzene. These facts suggest that the $t$-butoxy radical does not form a $\pi$-complex with the aromatic solvent because of the small electron affinity and the bulkiness of the $t$-butoxy radical.

Now we will discuss in more detail the selectivity of the $t$-butoxy radical in the hydrogen abstraction from the carboxylic acids. For this purpose, our data are compared with other data and the results summarized in Table IX.

Propionic acid was chlorinated somewhat predominantly in the $\alpha$-position in our study, but, on the contrary, in the $\beta$-position in Kharasch's experiment. On the other hand, chlorinations of $n$-butyric acid by all the methods listed in Table IX show a similar trend for the $\beta$-isomer to be formed most preferentially, followed by the $\gamma$-isomer. In our method, however, the formation of the $\alpha$-isomer increased to some extent as compared with the other methods. From these results, we would conclude that the direction of the hydrogen abstraction by a radical with a large electron affinity, such as the chloro radical, is greatly influenced by the electron density on the carbon atoms of the alkyl group (the values of 88 kcal./mol. was determined for the electron affinity of the chloro radical). Thus, the $\alpha$-position of propionic or $n$-butyric acid becomes inactive as a result of the electron-withdrawing effect of the carboxyl group. In $n$-butyric acid, the $\beta$-position is most reactive for the following two reasons. First, the inductive effect of the carboxyl group may be not so effective in the $\beta$-position as in the $\alpha$-position. Second, the hyperconjugation of the methyl group makes a contribution to the $\beta$-position. For these two reasons, the electron density on the carbon atoms of the alkyl group becomes greatest in the $\beta$-position; therefore, this position may be easily attacked by a highly-electrophilic chloro radical. On the other

hand, the electron affinity of the *t*-butoxy radical is not so high as the chloro radical (it is known that the electron affinity of the alkoxy radical is about 50 kcal./mol.) and, therefore, the electron density is not so effective in controlling the direction of the hydrogen abstraction from the alkyl group of the carboxylic acid by the *t*-butoxy radical. Consequently, *t*-butyl hypochlorite chlorinates *n*-butyric acid without selectivity, and the $\alpha$-isomers increase in number in the chlorination of propionic acid by *t*-butyl hypochlorite.

Although Walling has recently reported that the formation of carbon dioxide was not detected in the reaction of *t*-butyl hypochlorite in acetic acid,[12] the formation of carbon dioxide was observed in our study. The decarboxylation of the carboxylic acids may proceed through the formation of acyl hypochlorite, followed by decomposition to give carbon dioxide and the corresponding alkyl chloride, as is shown below:

# Magnetic Properties of Bi- and Uni-Nuclear Chromium(III) Complex Compounds at Low Temperatures

By Hanako KOBAYASHI,* Taiichiro HASEDA and Masayasu MORI

(Received November 30, 1964)

There are various theories on the mechanism of the superexchange interaction between magnetic ions in crystals. Kanamori,[1] for instance, studied the superexchange interaction, taking into consideration the symmetry of the electron orbitals of magnetic ions. It was shown that the sign** of the superexchange interaction is closely connected with the symmetry of the orbitals of the magnetic ions and non-magnetic ions which are in the path of the superexchange interaction. The cases in which each cation is subject to an octahedral cubic field and in which the lines connecting cations to the intervening anion make an angle of either 180° or 90° were discussed as simple and typical examples. His study suggested that the 180° superexchange interaction is antiferromagnetic and the 90° one, ferromagnetic in the case of $Cr^{3+}\cdots Cr^{3+}$ interaction. In the real crystals, there are usually both paths, 180° and 90°, of the superexchange interaction. The sign of the superexchange interaction in a magnetic substance depends on all the contributions from relevant paths. There is, in general, no simple and direct way to examine the above-cited theory by experimentation. Moreover, there have been few papers[2] which make clear any mechanism of the superexchange interaction actually occurring in the observed crystal.

It seems that the investigation of some sort of bi-nuclear complex salts, in which the superexchange interaction between two magnetic ions passes through only one path, either 180° or 90° would make possible a direct examination of the relation between the bond angle and the sign of the superexchange interaction.

The first part of the present paper will concern the study of the magnetic properties of bi-nuclear complex compounds. The experimental results of magnetic and optical measurements of the following four bi-nuclear complex salts will be discussed; $\mu$-hydroxo-bis-{pentamminechromium(III)} 3/2-chloride 7/2-perchlorate 1/2-hydrate,[3] $\mu$-hydroxo-{hydroxotetramminechromium(III)-pentamminechromium(III)}tetrachloride 1-hydrate, $\mu$-oxo-bis{pentamminechromium(III)}perchlorate, and

* Present address: Department of Chemistry, Faculty of Science, Kyoto University, Kyoto.

** Through this paper, a negative sign is used for the antiferromagnetic exchange interaction.

μ-dihydroxo-bis{tetramminechromium(III)}dithionate 4-hydrate.

In the cases of μ-hydroxo-bis{pentamminechromium(III)}3/2-chloride 7/2-perchlorate 1/2-hydrate, μ-hydroxo{hydroxotetramminechromium(III)-pentamminechromium(III)}tetrachloride 1-hydrate and μ-oxo-bis{pentamminechromium(III)}perchlorate, the linkage of the superexchange interaction is considered to pass through a path of about 180°, connecting two chromic ions via one oxygen atom. In the case of μ-dihydroxo-bis{tetramminechromium-(III)}dithionate 4-hydrate, the linkage of the superexchange interaction is considered to turn at oxygen atoms, making angles of about 90°. We have already measured[3] the susceptibilities of some of these salts and have suggested some interpretations. We now add the salt which has a nearly 90° angle linkage. We shall discuss all of these experimental data from the above-mentioned point of view.

The second problem of the present paper is the comparison of the superexchange interaction among $Cr^{3+}$ ions which are octahedrally co-ordinated by various ligands. The interaction between two magnetic ions depends on the distance between the two ions and on the linkage from one magnetic ion to the other magnetic ion. If some ligands in a complex ion are replaced by other atoms or by atomic groups, leaving the distances almost the same as before substitution, the experimental results of the substituted compounds will contribute to an understanding of the interactions among magnetic ions through various linkages.

The following co-ordination compounds of $Cr^{3+}$ ions with various kinds of ligands were investigated: hexamminechromium(III) chloride, chloropentamminechromium(III) chloride, dibromo-diaquo-diamminechromium(III) bromide, and dihydroxo-diaquo-diamminechromium(III) bromide.

## Preparation

**μ-Hydroxo-bis{pentamminechromium(III)}3/2-chloride 7/2-perchlorate 1/2-Hydrate**[4] was prepared by Mori, Ueshiba and Yamatera's procedure (Ref. 5).

**μ-Hydroxo-{hydroxotetramminechromium(III)-pentamminechromium(III)}tetrachloride 1-Hydrate** was prepared by Jörgensen's procedure (Ref. 4).

**μ-Oxo-bis{pentamminechromium(III)}perchlorate.**—Two hundred milliliters of 30% perchloric acid (guaranteed grade) were carefully neutralized with sodium carbonate (guaranteed grade) until the mixture was only slightly acidic to methyl red. Twenty milliliters of concentrated aqueous ammonia was then added, and the mixture was filtered. To the filtrate was added 5 g. of μ-hydroxo-bis{pentamminechromium(III)}3/2-chloride 7/2-perchlorate 1/2-hydrate, and the mixture was cooled in an ice bath for 30 min. with occasional stirring. The deep blue precipitate was collected on a glass filter and washed with alcohol and ether. After it had been dried for several minutes under strong suction, the compound was kept in a desiccator with soda lime and dry ammonia gas under protection from light.

**μ-Dihydroxo-bis{tetramminechromium(III)}-dithionate 4-Hydrate.**—The procedure of preparation was that given by Dubsky in Ref. 6.

**Hexamminechromium(III) Chloride.**[7]—A green solution containing chromium(III) salt was prepared in a 1000 ml. beaker by mixing 30 g. of potassium dichromate, 40 ml. of ethanol and 80 ml. of concentrated hydrochloric acid. This solution was then transferred into a smaller beaker and covered with a 3-cm. layer of liquid paraffine. Sixty grams of pure zinc grains were added, and the mixture was heated to 80—90°C on a steam bath. When the solution had become perfectly blue, the container was cooled in running water, then the solution was removed, together with the mineral oil, into an Erlenmeyer flask containing a mixture of 200 ml. of concentrated aqueous ammonia, 50 g. of ammonia chloride and 50 g. of ammonium sulfate. The whole mixture was gently stirred and cooled in an ice bath for several minutes. To this was added 10 g. of powdered iron(II) ammonium sulfate. Finally the vessel was loosely stoppered and allowed to stand in an ice bath over night or longer. The yellow crystals thus formed were washed on a Buchner funnel with 50% ethanol, and dissolved in 400 ml. of water. After the addition of 2 ml. of concentrated aqueous ammonia and 2 ml. of 30% hydrogen peroxide, the solution was filtered, treated with 400 ml. of 12 N hydrochloric acid and 800 ml. of ethanol, and cooled in an ice bath. The yellow precipitate of hexamminechromium(III) chloride 1-hydrate thus obtained was dissolved in water, recrystallized by the addition of hydrochloric acid and ethanol, and dehydrated at 80°C until a constancy in weight was attained. The anhydrous salt was preserved in a desiccator under protection from light.

**Chloro-pentamminechromium(III) Chloride** was prepared by the procedure described in Ref. 8.

**Dibromo-diaquo-diamminechromium(III) Bromide:** Ref. 9.

**Dihydroxo-diaquo-diamminechromium(III) Bromide:** Ref. 9.

## Experimental Results

were measured by an a.c. bridge method in the temperature range between 1.5°K and room temperature. The a.c. bridge was constructed so as to enable to measure magnetic susceptibilities of the order of $10\times10^{-6}$ c.g.s.e.m.u. with an accuracy of $\pm1\%$, when the amount of the sample was about 1 g. The cryostat and the procedure for measurment have been described in the literature.[10] The susceptibility is given in molar units for each compound. The calibration for diamagnetism was made by using the values listed in Table I.

TABLE I. CALIBRATION FOR DIAMAGNETISM

| Atomic or atomic group | $\chi$, c.g.s.e.m.u. |

susceptibilities which follow the Curie-Weiss law.

The molar magnetic susceptibility of dibromo-diaquo-diamminechromium(III) bromide is shown in Fig. 6 as a function of the temperature, while that of dihydroxo-diaquo-diamminechromium(III) bromide is shown in Fig. 7. The susceptibilities of both salts follow the Curie-Weiss law down to the temperature region of liquid hydrogen and have maxima at about 3°K and about 3.5°K respectively. The shape of the maximum is broad in the former and steep in the latter.

## Discussion

**Bi-nuclear Complex Salts.**—The magnetic susceptibilities of $\mu$-hydroxo-bis{pentamminechromium(III)}3/2-chloride 7/2-perchlorate 1/2-hydrate and $\mu$-hydroxo{hydroxo-tetramminechromium(III) - pentamminechromium(III)}-tetrachloride 1-hydrate are similar, as is shown in Fig. 1. They have broad maxima near 50°K and become very small in the temperature region of liquid helium. The magnetic behavior of these salts indicates that their electronic structures and the mechanisms of their magnetic interaction are similar. The resemblance of the absorption spectra of these complex cations, as may be seen in Fig. 3, also seems to support this.[11] In this case, the difference in anions is probably of little importance since it is complex cations that are mainly responsible for both the absorption spectra and the magnetic susceptibilities of these compounds.

The energy levels of $Cr^{3+}$ spins ($S=3/2$) in the bi-nuclear salts can easily be calculated under the following simplified conditions. If the orbital angular momentum of the $Cr^{3+}$ ion in the bi-nuclear complex salts is assumed to be completely quenched, the spins of $Cr^{3+}$ ions in the same cation are expressed as $S_1$ and $S_2$, with the expectation value of $S=3/2$. In this case, the Hamiltonian of the two spins under a magnetic field, $H$, can then be written as:

$$\mathscr{H} = JS_1S_2 + g\mu_B (S_1+S_2)H$$

where $J$ is a coefficient of the exchange interaction between the two $Cr^{3+}$ ions and is negative in the case of these two salts. The magnetic susceptibility can be calculated by a standard method. The calculated curves of $\chi_{2M}$ with a parameter of $J$ are shown in Fig. 1 as a function of the temperature, where $g$ is assumed to be 2.00. The experimental values of $\mu$-hydroxo-bis{pentamminechromium(III)}-3/2-chloride 7/2-perchlorate 1/2-hydrate fit well the calculated curve with $J=k\times(-28°K)$, and the values of $\mu$-hydroxo-{hydroxotetramminechromium(III)-pentamminechromium(III)}tetrachloride 1-hydrate agree with the calculated curve with $J=k\times(-36°K)$. Judging from the chemical or photo-chemical inspections,[12] angle made by the lines connecting the two $Cr^{3+}$ ions to the intervening oxygen atom of the hydroxide group seems to be nearly 180°. The agreement of the experimental results with the above-mentioned calculations indicates that the superexchange interaction between two $Cr^{3+}$ ions through the oxygen of the hydroxide in these bi-nuclear complex cations has a constant of the superexchange interaction of about $k\times(-28°K)-k\times(-36°K)$.

11) Y. Inamura and Y. Kondo, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **74**, 627 (1953).
12) W. K. Wilmarth, H. Graff and S. T. Gustin, *J. Am. Chem. Soc.*, **78**, 2683 (1956).

The magnetic property of $\mu$-oxo-bis{pentamminechromium(III)}perchlorate was expected to show the typical character of the 180° superexchange interaction of $3d^3$ electrons through a linear linkage. The minute details of the temperature dependence of the susceptibility could not be determined because of its change is too small. If the same calculation is applied as with the former two salts, $J$ is negative and is quite large ($>|k\times 200°K|$), as was expected. This means the antiferromagnetic interaction between $Cr^{3+}$ ions by the hydroxide group in the former two complex salts is much weaker than that of the perfect 180° bridge because of their deviation from linear linkage. $\mu$-Dihydroxo-bis{tetramminechromium(III)}dithionate 4-hydrate is a sample which is considered to have two nearly-90° bridges between two $Cr^{3+}$ ions. In the case of the 90° path between two $Cr^{3+}$ ions, the sign of the superexchange interaction may be expected to be plus.[1] The results of the measurements of magnetic susceptibility are shown in Figs. 1 and 2. In the region of the liquid hydrogen temperature, the experimental curve roughly agrees with the calculated curve, with negative $J\simeq k\times(-20°K)$.

From these results, we may conclude that $\mu$-oxo-bis{pentamminechromium(III)}perchlorate has 180° superexchange interaction and that the paths of the superexchange interaction of $\mu$-hydroxo-bis{pentamminechromium(III)}-3/2-chloride 7/2-perchlorate 1/2-hydrate and $\mu$-hydroxo-{hydroxotetramminechromium(III)-pentamminechromium(III)}tetrachloride 1-hydrate deviate from linear linkage. The path of $\mu$-dihydroxo-bis{tetramminechromium(III)}-dithionate 4-hydrate shows the smallest value of J, but it does not yet show a positive sign.

**Uni-nuclear Complex Salts.**—The crystalline structure of hexamminechromium(III) chloride is of the bismuth fluoride type. Each $Cr^{3+}$ ion is octahedrally co-ordinated by six ammonia molecules in the salt. The exchange interaction among the magnetic ions in this salt is through the following path:

$$Cr^{3+}\cdots\cdots NH_3\cdots\cdots Cl^-\cdots\cdots H_3N\cdots\cdots Cr^{3+}$$

ligand anion ligand

The experimental magnetic susceptibility curve as a function of the temperature follows the Curie-Weiss law quite well, with the absolute value of the Curie-Weiss constant, $\Theta$, smaller than 0.01°K, as is shown in Fig. 4. The sign of the $\Theta$ could not be determined from the experiment with the above-mentioned accuracy. The spectroscopic splitting factor, $g$, can be calculated from the next equation when the absolute value of $\Theta$ is smaller than 0.01°K:

$$\chi_M=\frac{N\mu_B^2\ g^2S(S+1)}{3k\ (T-\Theta)}$$

The mean $g$-value at the temperatures of liquid helium and liquid hydrogen is 2.00± 0.02. The very small absolute value of the Curie-Weiss constant implies quite a weak interaction among $Cr^{3+}$ ions in this salt.

The co-ordination of the ligands of chloropentamminechromium(III) chloride is not of the pentamminerhodium(I) chloride type, but of the chloropentamminerhodium(III) chloride type: that is, a ligand ammonia of the hexamminechromium(III) ion is replaced by a chlorine ion. The crystalline structure of this salt is of the calcium fluoride type,[13] so the paths of the interactions among $Cr^{3+}$ ions may be considered to pass through any of the following:

$$Cr^{3+}\cdots\cdots Cl^-\cdots\cdots Cl^-\cdots\cdots H_3N\cdots\cdots Cr^{3+}$$

ligand anion ligand

$$Cr^{3+}\cdots\cdots Cl^-\cdots\cdots Cl^-\cdots\cdots Cl^-\cdots\cdots Cr^{3-}$$

ligand anion ligand

$$Cr^{3+}\cdots\cdots NH_3\cdots\cdots Cl^-\cdots\cdots H_3N\cdots\cdots Cr^{3+}$$

ligand anion ligand

$$Cr^{3+}\cdots\cdots Cl^-\cdots\cdots H_3N\cdots\cdots Cr^{3+}$$

ligand ligand

$$Cr^{3+}\cdots\cdots Cl^-\cdots\cdots Cl^-\cdots\cdots Cr^{3+}$$

ligand ligand

$$Cr^{3+}\cdots\cdots NH_3\cdots\cdots H_3N\cdots\cdots Cr^{3+}$$

ligand ligand

From the magnetic susceptibility curve as a function of the temperature, a Curie-Weiss constant, $\Theta$, of about −0.8°K was obtained, as is shown in Fig. 5. This shows that the superexchange interaction between $Cr^{3+}$ ions

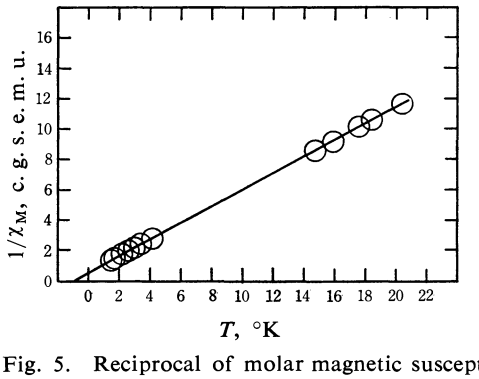

Fig. 5. Reciprocal of molar magnetic susceptibility of chloropentamminechromium(III) chloride as a function of temperature

13) Y. Nakao, S. Oi, Y. Komiyama and H. Kuroya, The 13th Symposium on Co-ordination Chemistry, Nagoya, 1963.

is considerably large than that of hexamminechromium(III) chloride, which may reasonably be attributed to the presence of the paths of the latter three types. The latter three paths, which do not pass through anions, are shorter than the former, and the presence of a large ion in the path strengthens the superexchange interaction. The mean value of $g$ is $1.95\pm0.09$ in the temperature region of liquid helium and liquid hydrogen, when 3/2 is given as the spin quantum number, $S$.

The crystal structure of dibromo-diaquo-diamminechromium(III) bromide has not yet been analyzed. However, some paths of the superexchange interaction can be considered to be the shortest, as in the case of chloropentamminechromium(III) chloride. The Curie-Weiss constant, $\Theta$, is estimated to have a larger absolute value than that of chloropentamminechromium(III) chloride, because the number of large $Br^-$ ligands is two in this salt, one more than in the case of chloropentamminechromium(III) salt. The $\Theta$ obtained was about $-3$°K. The curve of the molar magnetic susceptibility as a function of the temperature has a broad maximum at 2.5°K, showing a transition to an antiferromagnetic state (Fig. 6).

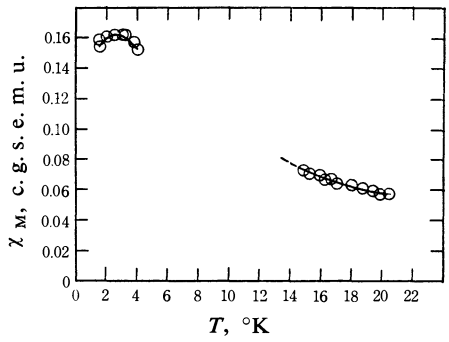

Fig. 6. Molar magnetic susceptibility of dibromo-diaquo-diamminechromium(III) bromide as a function of temperature

Dihydroxo - diaquo - diamminechromium(III) bromide has two hydroxyl groups in place of two bromine ligands of dibromo-diaquo-diamminechromium(III) bromide. The crystalline structure is not yet known. The experiment of the magnetic susceptibility gave a Curie-Weiss constant of about $-9$°K and a mean $g$-value of about $2.00\pm0.01$, when $S$ was taken as 3/2. This Curie-Weiss consant is larger than that of dibromo-diaquo-diamminechromium(III) bromide. The magnetic susceptibility-versus-temperature curve shows a steep peak at about $3.5\text{°K}\pm0.2\text{°K}$, as is shown in Fig. 7. Perhaps this is a transition to an antiferromagnetic state, though its shape is different from the typical antiferromagnetic transition.

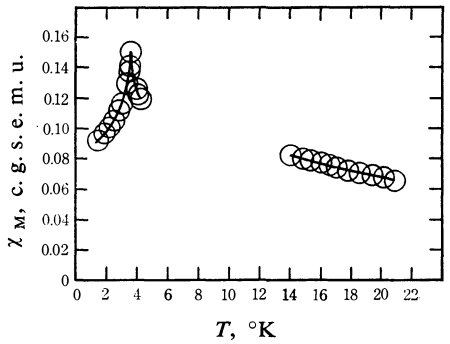

Fig. 7. Molar magnetic susceptibility of dihydroxo-diaquo-diamminechromium(III) bromide as a function of temperature

It may be noted that dihydroxo-diaquo-diamminechromium(III) salts are almost insoluble in water, although all chromammines with similar chemical formulae are known to be freely soluble. This peculiar insolubility and the comparatively large superexchange interaction of dihydroxo-diaquo-diamminechromium(III) bromide may be an indication that this compound is a co-ordination polymer, with each hydroxyl group ligated to different chromium ions. If this is the case, the above nomenclature must be revised somewhat, although names correctly expressing their true status will be hard to devise.

## Summary

The experimental study of the magnetic properties of bi- and uni-nuclear chromium(III) complex compounds in the low temperature

TABLE III.

| Multi-nuclear Cr(III) complex ion | Estimated angle of Cr-O-Cr linkages | Coefficient of the superexchange interactions |
|---|---|---|
| $(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5$ | 180° | $k\times(-200\text{°K})$ |
| $(NH_3)_5Cr\text{-}OH\text{-}Cr(NH_3)_5$ | ~180° | $k\times(-28\text{°K})$ |
| $(NH_3)_5Cr\text{-}OH\text{-}Cr(OH)\text{-}(NH_3)_4$ | ~180° | $k\times(-36\text{°K})$ |
| $(NH_3)_4Cr\langle^{OH}_{OH}\rangle Cr(NH_3)_5$ | 90° | $k\times(-20\text{°K})$ |

TABLE IV.

| Uni-nuclear Cr(III) complex salt | Transition point | Curie-Weiss constants | $g$-Values |
|---|---|---|---|
| $[Cr(NH_3)_6]Cl_3$ | | $\lvert\Theta\rvert<0.01$°K | $2.00\pm0.02$ |
| $[CrCl(NH_3)_5]Cl_2$ | | $-0.8$°K | $1.95\pm0.09$ |
| $[CrBr_2(OH_2)_2(NH_3)_2]\text{-}Br$ | ca. 2.5°K | $-3$°K | $1.69\pm0.04$ |
| $[Cr(OH)_2(OH_2)_2\text{-}(NH_3)_2]Br$ | ca. 3.5°K | $-9$°K | $2.00\pm0.01$ |

region has given the results summarized in Tables III and IV. As has been mentioned above, the results listed in Table III show the tendency expected from the superexchange interaction theories.

The authors would like to thank Professor Eizo Kanda for his continuous interest in this problem.

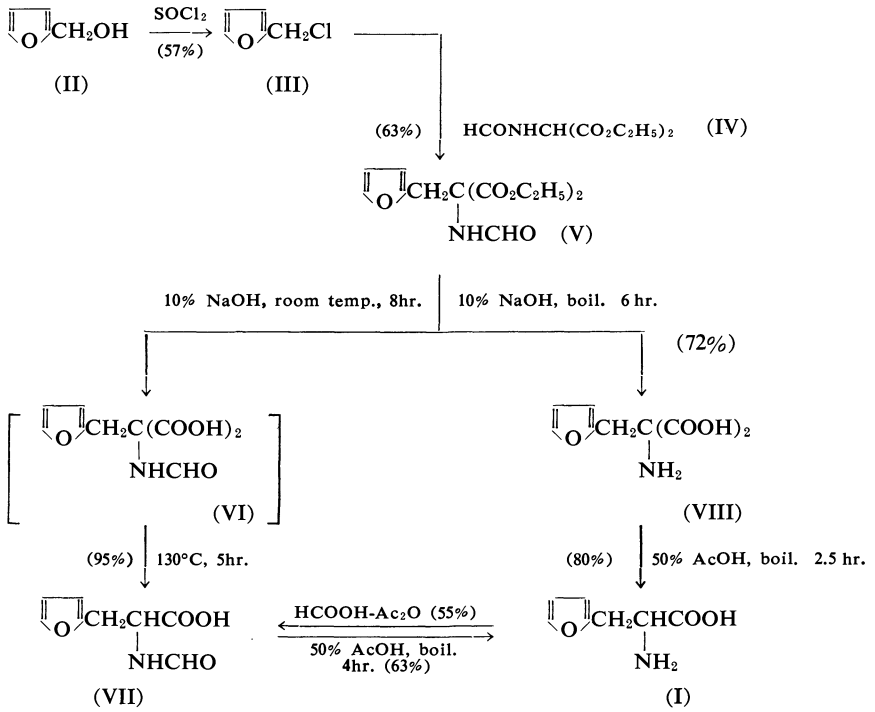
# A Study of Unnatural Amino Acids and Their Peptides. I. The Synthesis of DL-β-(2-Furyl)-α-alanine*1

By Hiroshi WATANABE, Shigeru KUWATA, Shigeru NAKAJIMA*2
Kazuo KOSHIDA*3 and Motoshige HAYASHI*4

(Received December 7, 1964)

With the development of the chemistry of antibiotics and other microbial products, or of the constituents of microbes themselves, e. g., the cell wall of bacteria, it has been clarified that there are many sorts of amino acids which have not hitherto been encountered in common proteins. One of them is the D-amino acid, e. g., D-phenylalanine in gramicidin S[1] or tyrocidine,[2] D-serine in cycloserine,[3] and D-glutamic acid in the capsular substance of *Bact. anthracis*.[4] Another group is the amino acid with a hetero-ring, e. g., β-(2-thiazole)-β-alanine in bottromycin[5] or 3-oxy-2-picolic acid and 4-oxopipecolic acid in staphylomycin[6] and ostreogrycin.[7]



We are interested in these "unnatural amino acids" and in their peptides, especially those of the latter group, in connection with their biological properties. Therefore, we intend to begin to study in this field. In this paper the synthesis of DL-β-(2-furyl)-α-alanine (I), an amino acid with a furyl residue in place of the phenyl residue in phenylalanine, will be reported.

This amino acid has not yet been found in nature, but it has been synthesized in many ways, such as through the condensation of furfural with hydantoin,[8] rhodanine,[9] diketopiperazine,[10] or hippuric acid.[11] The condensation of furfurylchloride with acetamidomalonate[12] or acetamidocyanoacetate[12] has also been utilized for this purpose. Of these, the rhodanine method was tested first, but this was found not suitable for large-scale preparations. The acetamidomalonate method was then tried. The condensation of furfurylchloride (III) with ethyl acetamidomalonate proceeded smoothly, but no promising results were obtained in the hydrolysis of the condensation product. Although this difficulty can be avoided, according to Herz,[12] by using acetamidocyanoacetate instead of acetamidomalonate, the total yield is still too low. Thus ethyl formamidomalonate (IV) was chosen because the removal of formyl group is, in general, far easier than that of the acetyl group, and because, moreover, the formylfurylalanine itself may be useful as an intermediate for the further peptide synthesis.

Diethyl formamido-(2-furfuryl)-malonate (V) was obtained as a well-crystallizable compound in a 63% yield by the reaction of III and IV in ethanol using sodium as a condensing agent.

Acylamidomalonates can be hydrolyzed smoothly with mineral acid in one step, but in our case such an acid hydrolysis is inapplicable because of the sensitivity of the furan ring. In fact, when furylalanine was boiled with 6 N hydrochloric acid, it was decomposed very rapidly and the ninhydrin reaction became completely negative.

The alkaline hydrolysis of acylamidomalonate needs a step-by-step treatment, as has been shown in the synthesis of tryptophan[13]; hence, the hydrolysis conditions were investigated. First, V was refluxed with a 10% sodium hydroxide solution for one hour. The extraction of the acidified hydrolysate with ethyl acetate gave a crystalline product, a part of which decomposed at about 120°C under effervescence, though it all melted clearly at 145°C. Comparing these figures with the melting point of formylfurylalanine (VII), 144—146°C, we suspected that the product obtained here might be formylfurylalanine contaminated with a compound decomposing at about 120°C, probably VI, a precursor of formylfurylalanine. In order to verify this assumption, the product was heated at 130°C for 5 hr. Then it was observed that it melted at 146°C without preliminary effervescence and showed a good agreement with an authentic sample of formylfurylalanine prepared by the formylation of furylalanine (as ascertained by a mixed melting point determination and by a comparison of the infrared spectra).

When the refluxing period was elongated to 6 hr., the hydrolysate gave plenty of white precipitates at pH ca. 5.6 (72% yield), which showed a positive ninhydrin reaction and which could be formylated with formic acid and acetic anhydride, the product of which, in turn, afforded formylfurylalanine when heated at 120°C for about 3 hr. From these results we assumed this compound to be amino-(2-furfuryl)-malonic acid (VIII), though, unfortunately, we did not succeed in ascertaining this by analysis. Schlossberger and Kuch[14] have also obtained an intermediate analogous to ours during the synthesis of tryptophan derivatives.

The decarboxylation of the substituted malonic acid (VIII) was attempted by heating it in water. The reaction was found to be very slow, even under prolonged refluxing, but it proceeded smoothly at 190°C in an autoclave. The paper chromatogram of the reaction product showed its almost complete conversion into furylalanine, though a faint spot was still

13) N. F. Albertson, S. Archer and C. M. Suter, *J. Am. Chem. Soc.*, **66**, 500 (1944); H. R. Snyder and C. W. Smith, ibid., **60**, 350 (1944).

14) H. G. Schlossberger and H. Kuch, *Ann.*, **662**, 132 (1963).

observed near the position corresponding to the starting material even after 6 hrs' heating. By the elongation of the reaction time, this spot became more distinct, and refluxing it with hydrochloric acid could not extinguish it. Those facts indicate that this spot does not respond to the original malonic acid derivative (VIII), but to some further degradated product. The comparison of its $R_f$-value with that of DL-aspartic acid proved the identity of the two compounds. It is probable, as will be seen later, that part of the furylalanine produced by the decarboxylation is oxidized further at the furan ring during the reaction into aspartic acid.

In the investigation of the tryptophan synthesis, Schlossberger[14] has used 50% acetic acid and obtained good results in the decarboxylation of aminomalonic acid derivatives with an acid labile indole nucleus. Thus, the decarboxylation was carried out according to his method, that is, by heating it in 50% acetic acid, because furylalanine itself was found, in a preliminary test, to be stable under such conditions. The reaction proceeded very rapidly without any formation of aspartic acid; thus we could obtain furylalanine in an excellent yield (80%).

In order to obtain formylfurylalanine, an intermediate for the peptide synthesis, it will be enough to hydrolyze the ester V into VI, reserving the formyl group, and to decarboxylate the reaction product. Thus V was stirred with a 10% sodium hydroxide solution for 8 hr. at room temperature, and then the product was heated at 130°C for 5 hr.; we thus succeeded in obtaining formylfurylalanine almost quantitatively.

The method of deformylating formylfurylalanine was also investigated. In general, the formyl-protecting group is removed by either oxidative cleavage or acid solvolysis. The former method was found, however, not to be applicable to furylalanine, for furylalanine, when treated with hydrogen peroxide even under mild conditions, is oxidized into DL-aspartic acid very rapidly; this was confirmed by a mixed melting point determination, by a comparison of the infrared spectra, and by paper electrophoresis with an authentic sample. The acid hydrolysis with hydrochloric acid in dioxane at room temperature was attempted, but it was also found to be impractical because of its low yield. With hydrochloric acid in methanol, deformylation and esterification occurred simultaneously and the methyl ester of furylalanine, also an important intermediate in the peptide synthesis, was obtained in one step, but the yield was not as satisfactory. On the other hand, the hydrolysis with alkali or 50% acetic acid gave good results; the yields were 59% and 63% respectively.

An attempt to obtain furylalanine in one step from V by treating it with 50% acetic acid proved unpromising. The reaction was too slow and not complete even after 20 hr.

These results described above are summarized in the scheme.

## Experimental

**DL-β-(2-Furyl)-α-alanine (I) by the Rhodanine Method.**—According to Gränacher,[9] rhodanine[15] was condensed with furfural to 5-furfulidene-rhodanine (m. p. 2282—28.5°C) in a 89% yield, and was then hydrolyzed with 3 N sodium hydroxide to β-(2-furyl)-α-thioketopropionic acid (m. p. 113—116°C) in a 99% yield. The thioketoacid was then converted by the action of hydroxylamine into β-(2-furyl)-α-oximino-propionic acid (m. p. 138—140°C) in a 56% yield. The reduction of the oximino acid with lactic acid and the sodium-amalgam afforded I in a 64% yield; m. p. 251—252°C (from 80% ethanol); lit.[9] m. p. 252°C (decomp.). $R_f$=0.60—0.64 (circular paper chromatography, *n*-butanol - acetic acid - water (4 : 2 : 1) system). Furylalanine showed a characteristic color reaction by ninhydrin on paper (greenish or reddish gray at first, but gradually changing to gray).

**DL-β-(2-Furyl)-α-alanine (I) by the Formamidomalonate Method.**—*α-Furfurylchloride (III).*—The chloride was prepared from furfuryl alcohol and thionyl chloride in a 57% yield; b. p. 49—50°C/27 mmHg; lit.[16] b. p. 49.6—50°C/27 mmHg. The chloride was so unstable that it was used at once after distillation.

*Diethyl Formamidomalonate (IV).*—According to Shaw and Nolan,[17] diethyl malonate was converted by the action of sodium nitrite and acetic acid to diethyl oximinomalonate in a 89% yield, then isolated as an addition compound with sodium acetate, and finally reduced with zinc and formic acid to diethyl formamidomalonate in a 79% yield; m. p. 51—53°C; lit.[17] m. p. 53—54°C.

*Diethyl Formamido-(2-furfuryl)-malonate (V).*—IV (20.5 g.) was dissolved in a sodium ethoxide solution (absolute ethanol 100 ml., sodium 2.3 g.), into which III (12 g.) was then added at once. After the mixture had been refluxed for 2 hr., sodium chloride was filtered out and washed with hot ethanol. The combined ethanolic solution was concentrated in vacuo. Water (100 ml.) was added to the residue, and the mixture was left to stand overnight in a refrigerator. Brown needle crystals (22.8 g.) were filtered off and recrystallized from hot ethanol; yield 18 g. (63%). Slightly brown needles; m. p. 98—99.5°C (from aqueous ethanol).

Found: C, 55.20; H, 5.97; N, 4.98. Calcd. for $C_{13}H_{17}O_6N$; C, 55.12; H, 6.05; N, 4.95%.

***N*-Formyl-DL-β-(2-furyl)-α-alanine (VII).**—*a) From Furylalanine (I).*—Acetic anhydride (16.6 ml.)

15) C. E. Redmann, R. N. Icke and G. A. Alles, "Org. Synth.," Coll. Vol. II, 763 (1955).
16) W. R. Kirner, *J. Am. Chem. Soc.*, **50**, 1955 (1928).
17) K. N. F. Shaw and C. Nolan, *J. Org. Chem.*, **22**, 1668 (1957).

was added drop-by-drop into a solution of I (3.1 g.) in 88% formic acid (5 ml.) at 50—60°C. After it had been stirred at room temperature for 2 hr., the mixture was diluted with ice water (16 ml.) and concentrated in vacuo. The crystalline residue was then dissolved again in water, decolorized and, after a small amount of hydrochloric acid had been added, extracted with ethyl acetate. White crystals were obtained on evaporating the solvent; yield 2 g. (55%); m. p. 143—145°C. Recrystallized from ethyl acetate - petroleum ether; m. p. 144—145°C.

Found; C, 52.29; H, 4.88; N, 7.63. Calcd. for $C_8H_9O_4N$: C, 52.46; H, 4.95; N, 7.65%.

*(b) From Diethyl Formamido-(2-furfuryl)-malonate (V).*—V (52 g.) was suspended in 10% sodium hydroxide (270 ml.) and stirred at room temperature. After 5 hr. all the crystals were dissolved. Stirring was continued for another period of 3 hr., and then the solution was left to stand overnight. After the unreacted material had been extracted with ethyl acetate, the solution was made strongly acidic with concentrated hydrochloric acid and extracted with ethyl acetate. After the solvent had been evaporated, the residue was heated at 120—130°C for 5 hr. and the resultant product was dissolved in ethanol and decolorized. White crystals were obtained on evaporating off the solvent; yield 32 g. (95%); m. p. 143.5—145.5°C. Recrystallized from ethyl acetate, m. p. 144.5—146°C. The identity of this compound with that obtained by a) was confirmed by a mixed melting point determination and by a comparison of the infrared spectra.

When hydrolysis was carried out by refluxing with 10% sodium hydroxide, the yield was decreased with the elongation of the reaction time as follows; 0.5 hr., 65%; 1 hr., 50%; 2 hr., 39%; 3 hr., 16%.

*Amino-(2-furfuryl)-malonic Acid (VIII).*—V (358 g.) was refluxed with a 10% sodium hydroxide solution (1900 ml.) for 6 hr. After the unreacted V had been removed by extraction with ethyl acetate, the solution was acidified with hydrochloric acid. A white precipitate was obtained at pH ca. 5.6; yield 180 g. (72%); m. p. 285—288°C (from aqueous ethanol). $R_f$=0.48.

When this compound (10 g.) was formylated by the usual method with 85% formic acid and acetic anhydride, crystals (4 g.) melting at ca. 120—135°C with effervescence were obtained. After they had been heated at 120°C for several hours, the crystals melted at 143—145°C; they showed no depression of melting point when mixed with authentic formylfurylalanine.

**DL-β-(2-Furyl)-α-alanine (I).**—*a) From Amino-(2-furfuryl)-malonic Acid (VIII).*—i) VIII (3 g.) was dissolved in water and heated at 190°C for 6 hr. in an autoclave. After being decolorized and concentrated to dryness, the product was recrystallized from aqueous ethanol; yield 1.5 g. (64%); m. p. 244—247°C.

ii) VIII (20 g.) was refluxed with 50% acetic acid for 2.5 hr. and then concentrated to dryness after decolorization. The residue was dissolved in water, and a small amount of ethanol was added. On cooling, colorless crystals were separated; yield 12.5 g. (80%).

*b) From N-Formyl-DL-β-(2-furyl)-α-alanine (VII).*—i) VII (1 g.) was boiled with 25% sodium hydroxide (2 ml.) for 10 hr. After being decolorized and neutralized with hydrochloric acid, the mixture was filtered and the filtrate was made to have a pH value of 5 with hydrochloric acid. When the solution was cooled and a small amount of ethanol added, white crystals were obtained; yield 0.5 g. (59%).

ii) VII (1 g.) was boiled with 50% acetic acid (3 ml.) for 4 hr. and treated as above; yield 0.53 g. (63%); m. p. 248—250°C.

The identity of both the compounds with authentic furylalanine was confirmed by the mixed melting point determination of the purified samples and by a comparison of the $R_f$ values in paper chromatography.

# Vibrational Spectra of Triethylfluorosilane

By Toshio TANAKA and Shigezo MURAKAMI

(Received December 11, 1964)

One of the present authors has previously reported on the normal vibrations of methyltrimethoxysilane, $CH_3Si(OCH_3)_3$,[1] in which the methyl groups were treated as one particle. The vibrational spectra of this molecule can be explained by assuming the point group $C_{3v}$ for the molecular symmetry. Triethylhalogenosilanes, $(C_2H_5)_3SiX$ (X=halogen atoms), can be treated as $YM(XZ)_3$-type molecules with regard to their skeletal vibrations in the same way as methyltrimethoxysilne.

Among triethylhalogenosilanes, the Raman spectrum has been obtained previously only for triethylchlorosilane. Tentative assignments have been made for this compound.[2] The present paper will report on the infrared and the Raman spectra of triethylfluorosilane and a normal coordinate treatment for the skeletal modes by Wilson's ***FG*** matrix method[3] using a simple Urey-Bradley potential function.

## Experimental

**Material.**—Triethylfluorosilane was prepared by the reaction of triethylchlorosilane with hydrofluoric acid (a 46% aqueous solution) in a copper flask.[4] A sample for measuring the infrared and Raman spectra was purified by two fractional distillations through a Stedman column (about 25 plates); b. p. 110°C/760 mmHg, $n_D^{25}$ 1.3895; (lit. b. p. 109°C/730 mmHg, $n_D^{25}$ 1.3900[4]).

**Spectra.**—The infrared spectrum of the neat liquid sample was recorded using a Reitz infrared spectrophotometer equipped with an NaCl or KBr prism. The Raman spectrum was measured by the photographic method using a Japan Yūki-gōsei Raman Spectrograph. The observed and calculated frequencies are shown together in Table III.

## Normal Coordinate Treatment

It has been assumed that the molecule belongs to the point group $C_{3v}$ and has the structure shown in Fig. 1, in which an F–Si–C–C plane and a C–Si–C plane, including the same Si–C bond, has an interplanar angle of 120°. This molecule has twelve skeletal vibrations; five of $A_1$ species, one of $A_2$ species, and six of E species. One of the six skeletal vibrations of the E species is the torsional oscillation of the $Si–CH_2–CH_3$ group. All vibrations except the $A_2$ torsional mode are active in both the infrared and the Raman spectra. The $Si–CH_2–CH_3$ torsional vibration of the E species could not, however, be observed in the present experiment. This may be due to the weak intensity of this band, which may appear in the region lower than 100 $cm^{-1}$, where any weak band is difficult to measure with the spectrograph used here. For this reason, the $Si–CH_2–CH_3$ torsional oscillation of the E species has not been considered in the normal coordinate treatment.

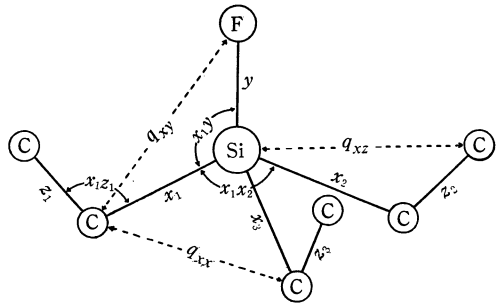

Fig. 1. Internal coordinates of the skeletal modes of triethylfluorosilane.

The orthonormal symmetry coordinates are shown in Table I. The numbering of these symmetry coordinates corresponds to that of the fundamentals in Table III.

The types of ***F*** matrix elements in the simple Urey-Bradley force field are the same as those reported earlier for methyltrimethoxysilane,[1] in which ∠Si–O–C was represented by a general angle of $\theta$. In the present molecule, the corresponding angle of Si–C–C is tetrahedral. The ***G*** matrix elements used previously for methyltrimethoxysilane[1] were also used, changing the masses of the atoms or groups concerned and replacing $\theta$ with a tetrahedral angle.

At first we adopted the force constants transferred or estimated from those obtained

in many related compounds which had previously been studied on the basis of a simple Urey-Bradley force field;[6] the values of $F'$ in the $\boldsymbol{F}$ matrix elements were assumed to be equal to $-F/10$. These trial force constants were then modified so as to give a good agreement between the observed and the calculated frequencies. The molecular parameters and final potential constants used in the calculation are shown in Table II.

The value of $K_x$(Si–F) used in the present calculations is considerably smaller than that of tetrafluorosilane.[6] This may reflect the tendency for the bond distance of Si–F bond to increase as the number of fluorine atoms attached to silicon decreases; 1.54, 1.565, 1.577 and 1.595 Å for $SiF_4$, $HSiF_3$, $H_2SiF_2$ and $H_3SiF$ respectively.[7] The tendency of a bond-stretching force constant is quite similar to that for Si–O bond, whose stretching force constant in methylmethoxysilanes, $(CH_3)_nSi(OCH_3)_{4-n}$, ($n=0-3$), decreases with the number of oxygen atoms attached to silicon, as has been described previously by one of the present authors.[8] The other potential constants in Table II seem reasonable considering those in related compounds.

## Results and Assignment

The calculated frequencies are shown in Table III, together with the observed wave numbers of the infrared and Raman spectra. The calculated wave numbers of $\nu_{10}$ and $\nu_{11}$ are considerably lower than the observed values. This seems to be due to the neglect of the Si–$CH_2$–$CH_3$ torsional oscillation of E species in the normal coordinate treatment. The $\boldsymbol{L}$ matrices and the distribution of potential energy in symmetry coordinates have been calculated for the skeletal normal modes; the results are shown in Tables IV and V respectively. The skeletal vibrations have been assigned on the basis of the potential energy distribution in the symmetry coordinates; also, the hydrogen vibrations have been tentatively assigned.

The most characteristic line in the Raman spectrum of triethylfluorosilane is the strong doublet observed at 571 and 587 $cm^{-1}$. The corresponding bands in the infrared spectrum are very weak. This doublet can be assigned to the symmetric-stretching vibration of Si–C bonds on the basis of the intensities of the infrared and Raman spectra, although the observed wave numbers are somewhat lower than the calculated values. There are no corresponding doublets in the vibrational spectra of triethylchlorosilane,[2] methyltrimethoxysilane,[1] and triethyltinchloride,[9] which are considered to have a symmetry similar to that of the present molecule. It is not clear from the present work why the doublet appears for the symmetric-stretching vibration of the Si–C bond in this molecule.

As is shown in Table V, the Si–C–C symmetric deformation and $FSiC_3$ symmetric deformation modes of the $A_1$ species, and the Si–C–C degenerate deformation and Si–F deformation modes of the E species, are coupled with each other considerably. This coupling behavior is similar to that found for methyltrimethoxysilane.[1] However, the symmetric-stretching mode of the Si–C bonds is not so coupled with the Si–F stretching mode as with the vibrational coupling between Si–C and

Si–O stretching modes in methyltrimethoxysilane.[1] This is because the vibrational frequency of the stretching vibration of the Si–F bond is not so close to that of Si–C bonds in triethylfluorosilane.

## Summary

The infrared and the Raman spectra of triethylfluorosilane have been measured, and the normal vibrations for the skeletal modes have been calculated by Wilson's ***FG*** matrix method, using a simple Urey-Bradley force field and assuming point group $C_{3v}$ for the molecular symmetry. The skeletal vibrations have been assigned quantitatively on the basis of the normal coordinate treatment, and the hydrogen vibrations have been tentatively assigned. The vibrational spectra of this molecule have also been discussed in comparison with those of triethylchlorosilane and methyltrimethoxysilane.

# The Reaction of the Copper(II) Chelate of Ethyl Acetoacetate with Bromine* and the Reactions of the Copper(II) Chelates of Acetylacetone and Ethyl Acetoacetate with Dry Hydrogen Bromide**

By Tetsuya OGURA, Yoshitane KOJIMA, Yukio NAKAMURA and Shinichi KAWAGUCHI

(Received December 17, 1964; in revised form January 12, 1965)

In a previous paper[1] we have reported on the reaction of bis(acetylacetonato)copper(II) with bromine in dichloromethane. When 2 mol. of bromine was added to 1 mol. of the chelate at room temperature, copper(II) bromide and 3-bromoacetylacetone were formed, but if 1.5 mol. or less of bromine was employed against 1 mol. of the chelate, copper(I) bromide resulted instead of copper(II) bromide. The pathway of the reaction is not yet clear. Therefore, similar reactions of the copper(II) chelate of ethyl acetoacetate with bromine and dry hydrogen bromide have been studied, as has been the reaction of bis(acetylacetonato)-copper(II) with the latter reagent, in hopes of determining some reaction intermediates.

## Experimental

**Materials.**—The copper(II) chelate of ethyl acetoacetate was prepared according to the method of Wislicenus[2] by adding an ether solution of ethyl acetoacetate to an ammoniacal solution of copper sulfate. The complex thus obtained was then recrystallized from a hot chloroform solution. M. p. 193°C (lit., 192—193°C). (Found: Cu, 19.65; C, 44.79; H, 5.96%). Bis(acetylacetonato)copper(II) was also synthesized by a standard method reported previously.[1]

Commercial bromine was washed with pure water repeatedly (more than five times) and then distilled from an aqueous solution containing potassium bromide. The distillation of bromine was further repeated over calcium oxide in order to exclude all water.

Dry hydrogen bromide was prepared by dropping purified bromine into tetralin which had previously been dried and fractionally distilled. The evolved gas was passed through a column of calcium bromide and condensed in a trap immersed in a dry ice-methanol bath. Hydrogen bromide was then evaporated and absorbed in dry dichloromethane.

Dichloromethane from a commercial source was washed with a 5% solution of sodium hydrogen carbonate and then with pure water. After having been dried with calcium chloride, it was fractionally distilled through a Widmer column.[3]

**Reaction Procedure.**—In the reaction of the copper(II) chelate of ethyl acetoacetate with bromine, dry or wet dichloromethane was adopted as the reaction medium. The "dry" solvent was found by the Karl Fischer method to contain water in the concentration of $4.9\times10^{-3}$ mol./l. (8.8 mg. water in 100 ml. dichloromethane). In the experiment to clarify the role of water, dichloromethane saturated with water was employed; the water content was estimated to be 0.14 mol./l. (0.189 g. water in 100 g. dichloromethane) at 25°C.[4] The

reaction was caused to proceed by dropping the bromine solution of a particular concentration (around 0.1 mol./l.) into a chelate solution of a similar concentration under vigorous agitation. Mole ratios of the metal chelate to bromine of 1 : 1, 1 : 1.5 and 1 : 2 were examined. In the latter two cases, the precipitate formed in the reaction mixture was filtered, washed with the solvent, dried, weighed and then analyzed for copper and bromine. The filtrate was also applied to the analysis of organic bromine. In the first case (1 : 1), when the desired amount of the bromine solution was added, a gray colloidal precipitate was formed; this was difficult to filter and so was separated from the solution by centrifugation after it had stored one day in a dessicator.

In the reaction of the copper(II) chelate of acetylacetone or ethyl acetoacetate with hydrogen bromide, dry dichloromethane was employed exclusively as a solvent. A desired amount of a hydrogen bromide solution was added from a burette to a chelate solution drop by drop or at full speed under vigorous agitation. Alternatively, a chelate solution was added gradually to a hydrogen bromide solution in experiments to investigate the effect of an excess of hydrogen bromide.

**Analysis.** — The concentration of hydrogen bromide in the dichloromethane solution was determined by titration, after the addition of dilute acetic acid, with a silver nitrate solution employing Eosin as the indicator.

The precipitate formed in the dry reaction medium was generally a mixture of copper(I) and copper(II) bromide. It was dissolved in aqueous ammonia and was kept standing in air overnight. A small amount of sodium hydroxide was then added to the solution, and it was heated in order to expel any ammonia. A black precipitate of copper(II) oxide was filtered off to be submitted to the electrolytic analysis of copper, and the bromide ion in the filtrate was determined gravimetrically to be silver bromide.

The precipitate formed in the reaction of the copper(II) chelate of ethyl acetoacetate with bromine in a wet solvent was a mixture of copper(I) bromide, copper(II) bromide and copper(II) hydroxide. When the precipitate was treated with acetic acid, copper(II) compounds were dissolved, but copper(I) bromide remained insoluble. The solution was then submitted to iodometry in order to determine the copper(II) content. On the other hand, the whole copper and bromine contents in the precipitate were determined as above.

The brominated $\beta$-dicarbonyl compound contained in the organic filtrate of each experiment was concentrated under reduced pressure and added to an acetic acid solution of potassium iodide. Iodine liberated in the solution was titrated with a solution of sodium thiosulfate.

## Results

**The Reaction of the Copper(II) Chelate of Ethyl Acetoacetate with Bromine in Dry Dichloromethane.**—The results of the analysis of reaction products under the dry conditions are listed in Table I. When the copper(II) chelate reacted with bromine in the mole ratio of 1 : 2, the precipitate formed was found to be practically copper(II) bromide. The filtrate contained ethyl $\alpha$-bromoacetoacetate; this was determined by iodometry as has been described in the Experimental section. Copper could not be detected in the filtrate. Thus, the net reaction may be represented by the following equation:

$$Cu(HA)_2 + 2\,Br_2 = CuBr_2 + 2HABr \qquad (1)$$

where $H_2A$ stands for the ethyl acetoacetate molecule, HA, for the enolate anion, and HABr, for ethyl $\alpha$-bromoacetoacetate. The yield of the bromoester listed in the last column of Table I was calculated on the basis of Eq. 1.

In the reaction of the 1 : 1.5 mole ratio, the precipitate formed was essentially copper(I)

bromide, and no copper remained in the solution. The stoichiometry of the reaction may satisfactorily be represented by the equation:

$$Cu(HA)_2 + 3/2\ Br_2 = CuBr + 2HABr \quad (2)$$

When an equimolar amount of bromine was added to the chelate solution, copper(I) bromide precipitated. In this case the solution still contained unchanged copper(II) chelate, which was determined to amount to about one-third of the original quantity. The material balance may be represented by the equation:

$$Cu(HA)_2 + Br_2 = 1/3\ Cu(HA)_2 + 2/3\ CuBr + 4/3\ HABr \quad (3)$$

The net change in this case should also be shown by Eq. 2.

Besides dichloromethane, chloroform and benzene (in the dark) were also used as solvents. The pattern of the reactions was the same as in dichloromethane.

**The Reaction of the Copper(II) Chelate of Ethyl Acetoacetate with Bromine in Wet Dichloromethane.**—When dichloromethane saturated with water was employed as the solvent, the precipitate formed in the reaction of the 1:1 mole ratio consisted essentially of copper(II) compounds, as is shown in Table II. This is in marked contrast to the case in a dry solvent, where copper(I) bromide was exclusively obtained in the 1:1 reaction (Table I). These results may be well reconciled with the following equation:

$$Cu(HA)_2 + Br_2 + H_2O = 1/2\ CuBr_2 + 1/2\ Cu(OH)_2 + HABr + H_2A \quad (4)$$

No trace of copper could be detected in the filtrate. The difference between the total copper content and that of copper(II) corresponds to that of copper(I), and ethyl α-bromoacetoacetate is obtained beyond the theoretical yield calculated on the basis of Eq. 4. These are considered to be formed in the following slow reaction:

$$2CuBr_2 + H_2A = 2CuBr + HABr + HBr \quad (5)$$

Copper(II) halide is known to react easily with acetone[5] and other compounds containing active hydrogen.[6] Reaction 5 really proceeds gradually at room temperature.

**The Reaction of the Copper(II) Chelate of Ethyl Acetoacetate with Bromine under Other Conditions.**—When dichloromethane containing ethyl alcohol or diethyl ether instead of water is employed as the reaction medium, the color of the reaction mixture changes from deep green to light blue on the addition of bromine, and the appearance of a precipitate is remarkably retarded. However, the precipitate is formed immediately on the addition of water.

When a 1:1 reaction is conducted in dry dichloromethane at −78°C, a grayish black muddy precipitate is formed; this changes to white copper(I) bromide when it is warmed to room temperature, reproducing thereby some quantity of the original copper(II) chelate. The dark precipitate is soluble in alcohol or ether, giving a light blue solution which is stable even at room temperature.

**The Reactions of Copper(II) Chelates of Acetylacetone and Ethyl Acetoacetate with Dry Hydrogen Bromide.**—In the reaction of these chelates with bromine in a mole ratio of 1:2, copper(II) bromide is formed exclusively, as has been reported above. However, it is not certain whether copper(II) bromide is directly produced through some intermediate or is formed secondarily by the reaction between copper(I) bromide and an excess of bromine. This problem is expected to be solved by an investigation of the reaction of the copper(II) chelates with hydrogen bromide, since even an excess of hydrogen bromide has no ability to oxidize copper(I) bromide once produced.

The analytical results of reaction products when the hydrogen bromide solution was added gradually to the chelate solution in various mole ratios, are summarized in Tables III and IV. In either case the sum of copper and

* The bromination product in the solution could not be determined accurately because of the disturbance by the remaining chelate.

bromine found in the precipitate coincides quite well with the weight of the precipitate, indicating that the latter contains nothing but copper and bromine. The atomic ratio of bromine to copper in the precipitate is slightly larger than 1, showing that the reaction product is a mixture of copper(I) bromide and a small amount of copper(II) bromide. The number of millimoles of copper(I) bromide and that of copper(II) bromide were calculated from these equations:

$$CuBr = 2\ \text{Total Cu} - \text{Total Br}$$

$$CuBr_2 = \text{Total Br} - \text{Total Cu}$$

They are listed in Tables III and IV.

The results obtained in reactions at mole ratios of 1 : 1 and 1 : 1.5 are essentially simillar to those obtained in analogous reactions with bromine; they can be represented by the following equation:

$$Cu(HA)_2 + 3/2\ HBr = CuBr + 3/2\ H_2A + 1/2HABr \qquad (6)$$

where $H_2A$ stands for acetylacetone or ethyl acetoacetate, and HABr, for 3-bromoacetylacetone or ethyl α-bromoacetoacetate. The presence of free acetylacetone or ethyl acetoacetate in the solution was confirmed, after solvent evaporation in vacuo, by the nuclear magnetic resonance absorptions. The theoretical yield of brominated β-dicarbonyl compounds listed in the last column of Tables III and IV was calculated on the ground that 2 mol. of the original chelate produced 1 mol. of the

brominated compound, according to Eq. 6. A necessary correction for the occurrence of reaction 7 was made on the basis of the yield of copper(II) bromide.

As Tables III and IV show, a very small amount of copper(II) bromide is formed in the reaction at a mole ratio of 1 : 1.5 or 1 : 1; this is considered to result from the following reaction, which is analogous to Eq. 1:

$$Cu(HA)_2 + 2HBr = CuBr_2 + 2H_2A \qquad (7)$$

The relative amount of copper(II) bromide produced in comparison with copper(I) bromide indicates the relative probability of the occurrence of reaction 7 compared with reaction 6. Even in the reaction at a mole ratio of 1 : 2, the quantity of copper(II) bromide formed is far less than that of copper(I) bromide, suggesting that the reaction according to Eq. 6 proceeds far more rapidly than the reaction represented by Eq. 7 under such reaction conditions. The yield of copper(II) bromide might depend upon the speed of feeding hydrogen bromide to the intermediate.

Table V shows the results obtained when the hydrogen bromide solution was caused to flow at full speed from a burette into the chelate solution. The amount of copper(II) bromide produced in each experiment is much larger than that shown in Tables III and IV. In other experiments, the chelate solution was dropped gradually from a burette into a solution containing twice as many moles of hydrogen bromide. In these cases copper(II) bromide was produced predominantly, as was expected (Table VI). It must be noticed, however, that a small amount of copper(I) bromide was also produced, even when such a circumstance as an excess of hydrogen bromide should favor the reaction path of Eq. 7.

## Discussion

The stoichiometry of the reaction between the copper(II) chelate of ethyl acetoacetate and bromine in dry dichloromethane has been established for the two cases of the reactants mole ratio represented by Eqs. 1 and 2. In either case, the copper(II) chelate is decomposed by the attack of bromine, and the product is copper(II) or copper(I) bromide, depending upon whether 2 or 1.5 mol. of bromine is added to 1 mol. of the chelate. There are two possible reaction pathways to be considered: (i) copper(I) bromide is produced first, and then it is oxidized to copper(II) bromide by an excess of bromine. (ii) Copper(II) bromide is formed at first, and then it is reduced to copper(I) bromide by an excess of the chelate or the free ester produced. Copper(I) bromide is oxidized by bromine very rapidly, but copper(II) bromide is reduced by these compounds rather slowly; thus, the second pathway could not be responsible for the rapid formation of

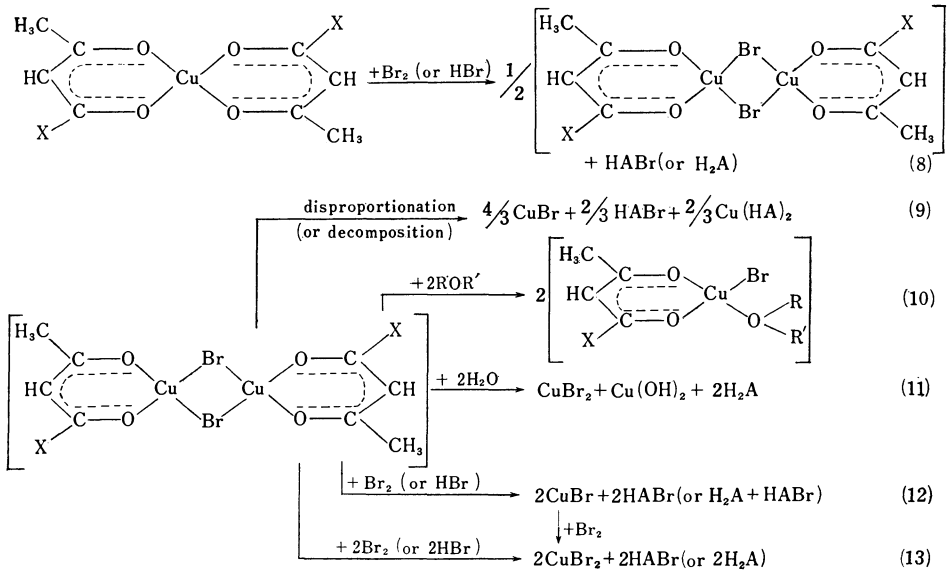

Fig. 1. Suggested pattern of the reaction between the copper(II) chelate of acetylacetone (X=$CH_3$) or ethyl acetoacetate (X=$C_2H_5O$) and bromine or hydrogen bromide. Bracketed species are still unidentified; their structures are only postulated here. ROR' represents alcohol or ether.

copper(I) bromide in the present case. Furthermore, the results obtained in the reaction of copper(II) chelates with hydrogen bromide strongly support the former reaction course under such reaction conditions.

The dark precipitate which is produced in the 1 : 1 reaction mixture of copper(II) chelate of ethyl acetoacetate and bromine at −78°C looks like a precursor of copper(I) bromide in the reaction pathway; it changes, in fact, to copper(I) bromide whenever warmed to room temperature. The precipitate is, however, soluble in alcohol or ether and does not produce copper(I) bromide in these solutions, even when warmed. Furthermore, in dichloromethane containing alcohol or ether, the formation of copper(I) bromide is greatly suppressed in the 1 : 1 reaction at room temperature. The water contained in dichloromethane also prohibits the formation of copper(I) bromide, so copper(II) bromide and hydroxide are produced instead. Thus, we may presume an intermediate with some stability, which decomposes (or disproportionates), spontaneously to copper(I) bromide and the original chelate, reacts with alcohol or ether to form some more stable species, or reacts with water to produce copper(II) bromide and hydroxide. It must be emphasized that, though one-third of the chelate employed is recovered in a 1 : 1 reaction (Eq. 3), it is not really unchanged, but is reproduced through an intermediate. We may now assume the following structure for this intermediate, and can picture the entire reaction pattern by virtue of it, as Fig. 1 shows. The experimental results obtained in the reactions of the copper(II) chelates with hydrogen bromide can also be explained by means of the same pattern.

An intermediate containing a double bridge of bromine is assumed to be formed in process 8. In the reactions at a mole ratio of 1 : 1, the intermediate disproportionates (or decomposes) according to Eq. 9, reproducing one-third of the original chelate. In the reaction at a mole ratio of 1 ; 1.5, copper(I) bromide is formed by process 12. In reactions with hydrogen bromide, copper(II) bromide can be produced only when two molecules of hydrogen bromide attack an intermediate molecule cooperatively, as is shown by Eq. 13.

The reactions represented by Eqs. 9, 12 and 13 are all very fast, and the competition between them is influenced by the chance of an encounter between the intermediate and the bromine or hydrogen bromide molecule. These reactions may not be elementary processes, and even their relative rates are not yet certain. Further extensive investigations are needed to elucidate the mechanisms of these reactions.

The preparation of the copper chelate of ethyl α-bromoacetoacetate was attempted but was unsuccessful, in contrast with that of 3-bromoacetylacetone.[1] This was due to the

lower stability of the copper(II) chelate of the $\alpha$-bromoester, and is related to Pedersen's finding[7] that copper(II) ions can not catalyze the second step of the bromination of ethyl acetoacetate by bromine in an aqueous solution, although it can accelerate the first step remarkably.

## Summary

When the copper(II) chelate of ethyl acetoacetate reacts with bromine in dry dichloromethane, the chelate is broken, forming the $\alpha$-bromoester and copper(I) or copper(II) bromide depending on the reactants' mole ratio. However, in the reaction between bromine and the chelate at a mole ratio of 1 : 1 in dichloromethane saturated with water, copper(I) bromide is not produced primarily; instead copper(II) hydroxide is formed, as is copper(II) bromide.

In the reactions of the copper(II) chelate of acetylacetone or ethyl acetoacetate with dry hydrogen bromide at the mole ratio of 1 : 1 or 1 : 1.5, more than 98% of the total copper precipitated as copper(I) bromide. Even when 2 mol. of hydrogen bromide was employed against 1 mol. of the chelate, more than 90% of the original copper changed to copper(I) bromide, in contrast with the results obtained in a similar reaction with bromine.

The entire reaction pattern has been suggested employing a presumed intermediate binuclear complex containing a bromine double brigde.

# The Anomalous Behavior of Some 2, 6-Disubstituted Iodobenzenes in the Jacobsen Reaction[1]

By Hitomi SUZUKI, Kazuhiro MARUYAMA and Ryozo GOTO

(Received December 19, 1964)

Aromatic iodo compounds containing electron-releasing groups in the nucleus readily undergo disproportionation in the presence of sulfuric acid to give polyiodo compounds.[2] This is the Jacobsen reaction. The reaction proceeds like a progressive iodination of the starting material, an entering iodine atom always taking the position of higher electron density and smaller steric hindrance, in accordance with the orientation rule of the usual electrophilic substitution. An example is the conversion of iodotoluenes to polyiodotoluenes:

As has been reported in previous papers of this series,[2] however, some 2, 6-disubstituted iodobenzenes, such as 2-iodo-*m*-xylene, 2, 3-diiodotoluene, and 1, 2, 3-triiodobenzene, exhibit anomalous behavior in the reaction, affording none of the expected vicinal (or asymmetrical) compounds, but only symmetrically-substituted products; that is, the

PPA = Polyphosphoric acid

iodine atom located in the position 2 in the original compound migrates to the position 4 in the final product, as is shown in the following scheme:

In the present paper, the authors wish to report the results of their mechanistic study of this novel reaction. We used only 2-iodo-*m*-xylene as the reagent because of its ease of synthesis. To get more precise knowledge about the reaction, we also prepared four isomeric diiodo-*m*-xylenes and subjected them to the several conditions of the Jacobsen reaction; the results of these experiments will, however, be described in a succeeding paper. The reaction products were identified by an inspection of their infrared spectra and gas chromatogram.

## Experimental

**Procedure.** — Weighed 2-iodo-*m*-xylene and sulfuric acid (or PPA) were placed in a small, stoppered flask and then stirred magnetically at a given temperature for a definite time. Then the mixture was diluted with water, and the precipitated solid or oily matter was separated by extraction and purified through an alumina column, using petroleum ether as the eluant. The solid or oily matter which remained after the evaporation of the solvent was then subjected to infrared spectroscopic or gas chromatographic inspection. The reaction conditions and the products are summarized in Table I.

**Materials.** — 2-Iodo- and 4-iodo-*m*-xylene were prepared from the corresponding *m*-xylidines (Tokyo Kasei products, G. R. grade) by the ordinary procedure: 2-iodo-*m*-xylene[3] (b. p. 100—101°C/12 mmHg), 4-iodo-*m*-xylene[4] (b. p. 108—109°C/12 mmHg). The synthesis of four isomeric diiodo-*m*-xylenes will be reported in the succeeding paper.

## Results and Discussion

In the presence of an excess of sulfuric acid, the disproportionation of 2-iodo-*m*-xylene was completed so fast that in order to find out any possible intermediates it was necessary to carry out the reactions in the system containing an insufficient amount of sulfuric acid. As one molecule of *m*-xylene-4-sulfonic acid was inevitably formed for every intermolecular migration of an iodine atom, the disproportionation was considerably suppressed and the isomerization became prominent.[5] As may be seen from Fig. 2a and Fig. 3a, at an early stage of the reaction only a slight formation of diiodo-*m*-xylenes was found on the gas chromatogram, while on the infrared spectrogram the absorption bands characteristic of 2-iodo-*m*-xylene (698 and 767 $cm^{-1}$) were already much weakened and the absorption bands due to 4-iodo-*m*-xylene (805 and 872 $cm^{-1}$) were considerably strengthened. Even in the presence of a slight amount of sulfuric acid, 2-iodo-*m*-xylene gradually isomerized to the 4-iodo isomer during a prolonged reaction time. These facts clearly establish the prior isomerization of 2-iodo-*m*-xylene to the 4-iodo isomer.

Figure 3b indicates that two diiodo-*m*-xylenes were formed at an early stage of the reaction,

but one of them was gradually diminished during the usual Jacobsen reaction, which was carried out with a large excess of sulfuric acid. This minor precursor was identified as 2,4-diiodo-*m*-xylene. As will be described in the succeeding paper, however, 2,4-diiodo-*m*-xylene is comparatively stable towards the action of sulfuric acid and does not isomerize so readily to 4,6-diiodo-*m*-xylene under these conditions. Therefore, this compound cannot be considered to be a major intermediate.

In the crossed Jacobsen reaction of *m*-xylene-4-sulfonic acid with *p*-iodocumene (this compound readily liberates the iodinium cation in sulfuric acid), a considerable amount of elementary iodine was liberated, and the iodinated *m*-xylenesulfonic acid could not be isolated from the reaction mixture. Thus, it is reasonable not to postulate the complete detachment of the migrating iodine atom during the isomerization, because the iodinium cation formed under those conditions cannot be so active as to iodinate the *m*-xylene-4-sulfonic acid successfully. Little liberation of elementary iodine or sulfur dioxide during the reaction also supports this view.

An effort to isolate 2-iodo-*m*-xylene sulfonic acid from the reaction mixture was fruitless; *m*-xylene-4-sulfonic acid was always obtained, together with small amounts of 4-iodo-*m*-xylene-6-sulfonic acid. This may be interpreted as indicating that the migration of the iodine atom from the hindered (=2) to the less hindered position (=4) occurs prior to the completion of the sulfonation. If the reaction was carried out with an excess of mesitylene, the iodine atom was readily transferred to give iodomesitylene. This fact indicates that the iodine atom migrates to the position of higher electron density, because mesitylene is supposed to be much more basic than either 2- or 4-iodo-*m*-xylene. Characteristic color changes which always accompany the halogen migration were also observed during the reaction, and the color disappeared upon the addition of water.

In this connection, another interesting phenomenon was observed in the similar isomerization of 2-iodo-*m*-xylene caused by polyphosphoric acid (PPA) of a high temperature (Fig. 2b). Here, however, only an intramolecular migration of the iodine atom was observed, and the reaction needed more severe conditions and a much longer time in order to be completed.

From the results described above, we may conclude that the reaction proceeds mainly through the prior isomerization of 2-iodo-*m*-xylene to the 4-isomer, followed by the usual disproportionation; this process may be formulated as follows:

2-Iodo-*m*-xylene reacts reversibly with sulfuric acid to form a $\sigma$-complex, a benzenonium intermediate (I), in which the iodine atom, blocked on both sides by two ortho methyl groups, is jammed so hard by the entry of a bulky sulfo group that it is crowded out and migrates through $\pi$ and $\sigma$-complex transition states to the position of the next

highest electron density. If it settles down at the position 4 of the same molecule or replaces the sulfo group at the position 6, the isomerization occurs; if another molecule attacks the intermediate I or II nucleophilically and if the iodine is transferred, a disproportionation results. The easy transfer of the iodine atom generally found in the crossed Jacobsen reaction of some aromatic iodo compounds with highly alkylated benzenes[6] may also be explained consistently by this mechanistic scheme, assuming that the benzenonium intermediate formed by the entry of the sulfo group is attacked by the highly basic polyalkylbenzenes. The differences in the ease of migration between the reaction caused by sulfuric acid and that brought about with PPA is best interpreted as follows: in PPA 2-iodo-*m*-xylene is first protonated to form a benzenonium intermediate in which the iodine atom is less hindered than in a corresponding sulfonic acid intermediate (I) and thus migrates at a slower rate intramolecularly to the position 4.

This anomalous Jacobsen reaction draws our attention for the very interesting reason that the migrating group is not that one which is replaced directly by the attacking group (this type of replacement is the most general one encountered in the anomalous electrophilc substitution of aromatic compounds), but is one which is present at a position (meta) distant from the place where the actual reaction occurs. Further evidence to support the above mechanism will be reported in the succeeding paper.

6) H. Suzuki, T. Sugiyama and R. Goto, This Bulletin, 37, 1858 (1964).

**Summary**

Some 2, 6-disubstituted iodobenzenes undergo an anomalous Jacobsen reaction and so afford none of the expected vicinal, but only symmetrical diiodo products. This anomaly has been investigated using 2-iodo-*m*-xylene as the reagent. The reaction has been found to proceed mainly through the rapid isomerization of 2-iodo-*m*-xylene to the 4-iodo isomer, followed by the normal disproportionation to 4, 6-diiodo-*m*-xylene. A possible mechanism has also been proposed on the basis of the results obtained.

# Solvent Extraction Studies of Tellurium(IV) with Dithizone

By Hisao MABUCHI and Isao OKADA

(Received January 6, 1965)

Dithizone (diphenylthiocarbazone, designated in this paper as $H_2Dz$) has previously been widely used for the extraction or the colorimetric determination of various metals. In a previous paper, one of the present authors reported that tellurium(IV), when shaken with a dithizone solution, was extracted into an organic layer, thus forming a complex compound with dithizone.[1] Generally, however, relatively little is known about the species and about the nature of the tellurium complex which is extracted by organic solvents. Therefore, we investigated the behavior of tellurium(IV) in the solvent extraction process by using dithizone.

1) H. Mabuchi, This Bulletin, **29**, 842 (1956).

## Experimental

**Dithizone Solution.** — The Merck product dithizone was purified by the ammonia water extraction method given by Sandell.[2] The purity of dithizone in carbon tetrachloride was checked spectrophotometrically by the use of the ratio of $E_{620}/E_{450}$, where $E_{620}$ and $E_{450}$ stand for the extinction of dithizone at 620 and 450 m$\mu$ respectively.[3] When this ratio is higher than 1.67, the solution may be considered sufficiently pure. The concentration of dithizone was determined spectrophotometrically each time it was used.

**Carbon Tetrachloride.**—Reagent-grade chemicals

2) E. B. Sandell, "Colorimetric Determination of Traces of Metals," Interscience Publishers, New York, London (1959), p. 170.

3) S. S. Cooper and M. L. Sullivan, *Anal. Chem.*, **23**, 613 (1951).

were distilled once, and the middle fraction of the distillate was used.

**Ammonium Hydroxide.**—A Concentrated C. P. reagent was distilled and absorbed in redistilled water. The ammonia solution used for the purification of dithizone was prepared by diluting this purified solution.

**Hydrochloric Acid.**—A concentrated C. P. reagent was distilled, and the middlle fraction of the distillate was used.

**Water.**—Water was distilled twice in an all-glass distilling apparatus.

All other chemicals were of the reagent grade and were used without further purification.

**The Preparation of a Tellurium Carrier Solution.**—Tellurium dioxide was prepared from a tellurium crystal by the method described in "Inorganic Syntheses"[4]; then it was dissolved in acid solutions. The concentrations were determined gravimetrically.

**The Preparation of Radioactive Tellurium.**—Radioactive tellurium was produced by Sb (p, $x$n) reactions ($x$=1—4) by bombarding an antimony metal target with the 56 MeV. proton at the Institute for Nuclear Study, the University of Tokyo. After several weeks of cooling, carrier-free tellurium(IV) was separated from the antimony target by the dithizone-extraction method.[5] Since short-lived tellurium nuclides must already have decayed, the radioactive tellurium solution may be supposed to have been mainly composed of a mixture of Te-121m ($T_{1/2}$=154 d.) and Te-123 m ($T_{1/2}$=104 d.).

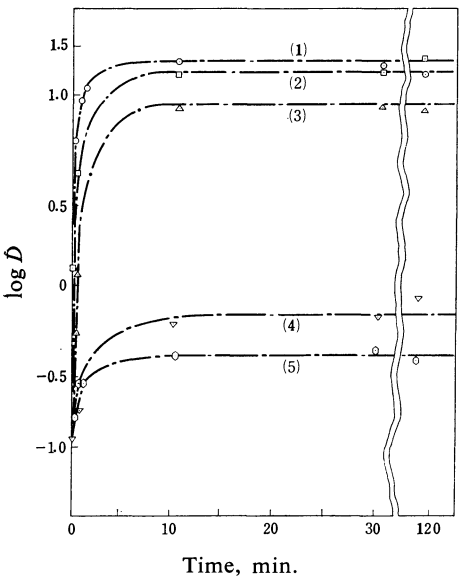

Fig. 1. Effect of shaking time on the extraction.

$H_2Dz$ in $CCl_4$: —⊙— (1) $9.60\times10^{-4}$ M, —⊡— (2) $2.00\times10^{-3}$ M, —△— (3) $1.00\times10^{-3}$ M, —▽— (4) $2.82\times10^{-4}$ M, —⬡— (5) $1.20\times10^{-4}$ M

$HClO_4$: (1) and (5) 2.43 M, (2), (3) and (4) 0.179 M

Shaking temp.: 20°C

Te(IV): $\sim10^{-11}$ M

**The Measurement of the Distribution Ratio.**—Two milliliters of a carbon tetrachloride solution of dithizone was equilibrated by shaking it with 2 ml. of an aqueous solution containing tracer amounts of tellurium(IV) ($\sim10^{-11}$ M) for 30 min. in a 15-ml. flask with a glass-stopper at 25°C. One milliliter of each layer was then put into a test tube and its radioactivity measured with a well-type NaI scintillation counter. The distribution ratio, $D$, for tellurium(IV) is given by the radioactivity of the organic layer divided by that of the aqueous layer.

Similarly, with macro amounts of tellurium the distribution ratio was measured radiometrically by using radioactive tellurium as a tracer.

**Spectrophotometric Measurements.**—All absorptiometric works were carried out with a Cary recording spectrophotometer, model 14.

**The Attainment of Equilibrium.**—This was investigated by shaking a number of tubes, each containing 2 ml. of an organic layer and 2 ml. of an aqueous layer, for various lengths of time (Fig. 1). The equilibrium between the two layers was attained within about 10 min.

## Results and Discussion

**The Chemical Composition of the Tellurium Dithizonate in the Organic Layer.**—The dependence of the distribution ratio, $D$, on the dithizone concentration in carbon tetrachloride, $(H_2Dz)_{org}$, was studied in the perchloric acid - sodium perchlorate media, using tracer amounts of radioactive tellurium. The results are shown in Fig. 2. It may be seen from Fig. 2 that the plot of $\log D$ vs. $\log (H_2Dz)_{org}$ at the constant $(H^+)_{aq}$ has a straight line whose slope is 2. This suggests, as is established below, that each tellurium(IV) cation in the organic layer is combined with two dithizonate anions.

In general, if one expresses the chemical species of tellurium in the acidic aqueous layer after the attainment of equilibrium as $(Te(OH)_n(HDz)_m)^{(4-m-n)+}$, and those in the organic layer as $Te(OH)_{4-p}(HDz)_p$, the slope of $\log D$ vs. $\log (H_2Dz)_{org}$, $\partial \log D/\partial \log (H_2Dz)_{org}=\bar{p}-\bar{m}$, where $\bar{m}$ and $\bar{p}$ are the average number of $HDz^-$ per tellurium(IV) cation in the aqueous and organic layers respectively. Here polymerized species of tellurium are neglected. This assumption may be valid as far as tracer experiments of tellurium are concerned.

As $HDz^-$ is a bidentate ligand, the coordination number, $N=4-p+2p$. From these considerations, one finds the two equations, (1) and (2):

$$\bar{p}-\bar{m}=2 \quad (1)$$

$$p+4=N \quad (2)$$

4) "Inorganic Syntheses," Vol. III, 143 (1950).

5) Y. Yokoyama, H. Mabuchi, H. Shoji and N. Saito, This Bulletin, 36, 352 (1963).

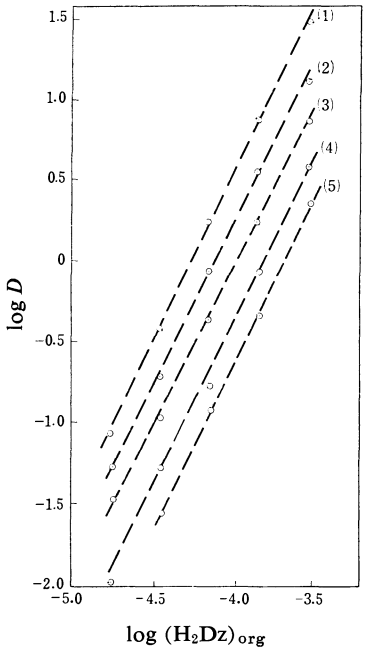

Fig. 2. Dependence of distribution ratio on the dithizone concentration.

$HClO_4$: (1) 0.10 M, (2) 0.23 M, (3) 0.55 M, (4) 1.31 M, (5) 3.12 M
Ionic strength: 3.12
Shaking temp.: 25°C
Shaking time: 30 min.
Slope of broken lines is 2.

The coordination number of the quadrivalent tellurium that appears in the solid compounds is 4 or 6. Although no data have been reported concerning its coordination number in solution, one may consider it not to exceed 6. If $N=4$, the extraction of tellurium with dithizone would not be possible, for in that case $p=0$. The only solution that satisfies Eqs. 1 and 2 is $N=6$, $\bar{p}=p=2$ and $\bar{m}=0$.

Therefore, the chemical species of tellurium extracted is supposed to be $Te(OH)_2(HDz)_2$* and the process of the extraction may be written as follows:

$$Te(OH)_n^{(4-n)+}\ (aq.) + 2H_2Dz\ (org.) = Te(OH)_2(HDz)_2\ (org.) + (4-n)H^+\ (aq.) + (n-2)H_2O\ (aq.) \quad (3)$$

The distribution ratios of macro amounts of tellurium whose initial concentration in the aqueous layer is $4.25\times10^{-5}$ M are shown in Fig. 3. Since, in the case of macro amounts, the concentration of dithizone at the extraction equilibrium differs from the initial concentration, the concentrations of dithizone were corrected on the assumption that the complex of dithizone contained two dithizonate anions to one tellurium cation. Plotting the logarithm of the distribution ratios against that of the concentrations of dithizone at equilibria, one could also obtain a straight line whose slope was 2 (Fig. 3).

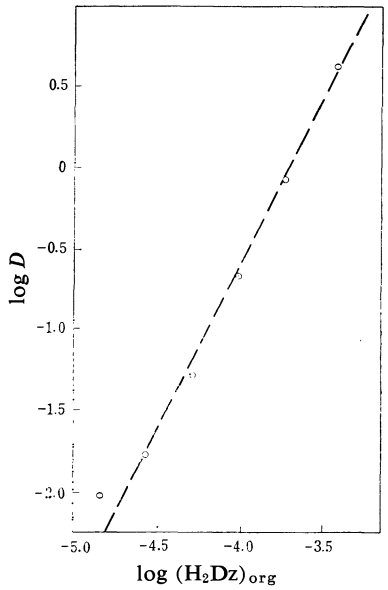

Fig. 3. Dependence of distribution ratio on the dithizone concentration.
Te(IV) before shaking: $4.25\times10^{-5}$ M
$HClO_4$: 1.17 M
Shaking temp.: 20°C
Shaking time: 30 min.
Slope of broken line is 2.

**The Tellurium Species in the Aqueous Layer.** —In order to determine the species of tellurium in an acidic aqueous solution, the distribution ratio was measured as a function of the hydrogen ion concentration. The results are shown in Fig. 4, where $\log D$ is plotted against $\log (H^+)$.

The equilibrium quotients for Eq. 3 are represented as:

$$K_n = \frac{(Te(OH)_2(HDz)_2)_{org}(H^+)_{aq}^{(4-n)}(H_2O)_{aq}^{(n-2)}}{((Te(OH)_n)^{(4-n)+})_{aq}(H_2Dz)_{org}^2} \quad (4)$$

The distribution ratio is given by:

$$D = \frac{(Te(OH)_2(HDz)_2)_{org}}{\sum_n (Te(OH)_n^{(4-n)+})_{aq}} \quad (5)$$

* $TeO(HDz)_2$ or $TeDz_2$ is also expected as the species of tellurium(IV) dithizonate. However, since $TeDz_2$ should be in the so-called "enol form,"[6] $TeDz_2$ may be excluded; because the "enol form" does not appear in other metal dithizonates extracted from a strongly acidic aqueous solution. At any rate, from this experiment, it is impossible to distinguish between $Te(OH)_2(HDz)_2$ and $TeO(HDz)_2$.

6) E. B. Sandell, "Colorimetric Determination of Traces of Metals," Interscience Publishers, New York, London (1959), p. 140.

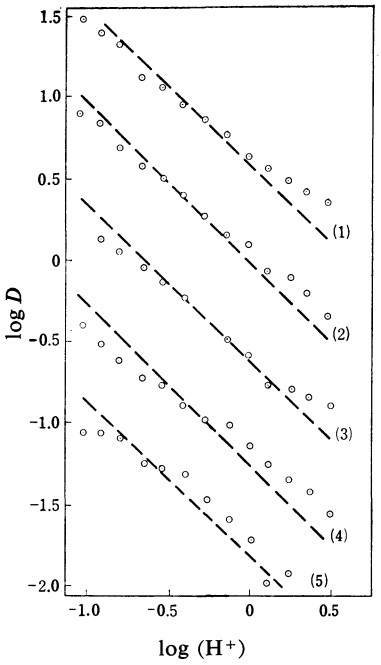

Fig. 4. Dependence of distribution ratio on the acid concentration.

$H_2Dz$ in $CCl_4$: (1) $2.76\times10^{-4}$ M, (2) $1.38\times10^{-4}$ M, (3) $6.90\times10^{-5}$ M, (4) $3.45\times10^{-5}$ M, (5) $1.73\times10^{-5}$ M
Ionic strength: 3.12
Shaking temp.: 25°C
Shaking time: 30 min.
Slope of broken lines is −1.

In this formulation the tellurium species containing dithizonate anions in the aqueous layer are neglected. This assumption may be valid under the present experimental conditions. Taking the partial derivative of log $D$ with respect to log $(H^+)$,

$$\partial \log D/\partial \log (H^+) = -4+f_1+2f_2+3f_3+4f_4+5f_5+6f_6 \qquad (6)$$

where;

$$f_n=\frac{(Te(OH)_n^{(4-n)+})}{(Te^{4+})+(Te(OH)^{3+})+\cdots+(Te(OH)_6^{2-})}$$

and

$$0 \leqq f_n \leqq 1$$

By using Eq. 6 and the value of $\partial \log D/\partial \log (H^+)$ experimentally obtained, one can calculate the average number of hydroxyl groups attached to one tellurium atom. As can be seen from Fig. 4, $\partial \log D/\partial \log (H^+)$ is nearly −1, so $f_3$ is the predominant factor, corresponding to $Te(OH)_3^+$.

That tellurium(IV) exists as $Te(OH)_3^+$ in acid solutions (0.10—3.0 M) agrees with the results obtained from solubility[7,8] and ion-exchange studies[9]. Thus, the overall reaction of tellurium(IV) with dithizone in the extraction process may be written as follows:

$$Te(OH)_3^+(aq.)+2H_2Dz(org.) = Te(OH)_2(HDz)_2(org.)+H^+(aq.)+H_2O(aq.) \qquad (7)$$

**The Effect of the Temperature on the Distribution Ratio.**—In order to determine the effect of the temperature on the extraction, measurements of the distribution ratio of tellurium were made at 3, 10, 20, 30 and 40°C. The results are shown in Fig. 5.

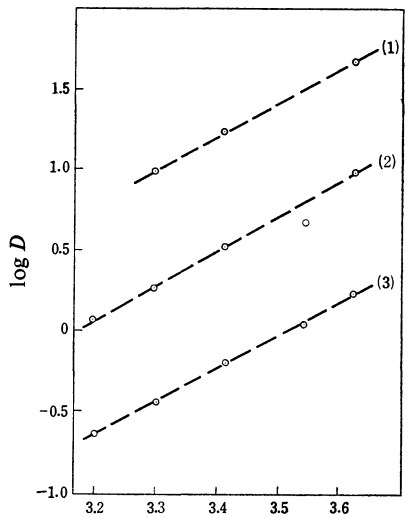

Fig. 5. Effect of temperature on the distribution ratio.

$H_2Dz$ in $CCl_4$: (1) $5.80\times10^{-4}$ M, (2) $2.54\times10^{-4}$ M, (3) $1.27\times10^{-4}$ M
Aqueous medium: $HClO_4$ 2.00 M
Shaking time: 30 min.

In general, for the equilibrium constant, $K$, of a reaction and the absolute temperature, $T$, the following thermodynamical relation holds:

$$(\partial \ln K/\partial(1/T))_p = -\Delta H^\circ/\boldsymbol{R} \qquad (8)$$

where $-\Delta H^\circ$ is the standard enthalpy change, $\boldsymbol{R}$ is the gas constant, and the subscript, $p$, implies that the pressure is constant.

The equilibrium constant, $K$, for Eq. 7 is written as follows:

$$K=\frac{[Te(OH)_2(HDz)_2][H^+]}{[Te(OH)_3^+][H_2Dz]^2} \qquad (9)$$

Shaking temp.: 20°C
Shaking time: 50 min.
Ionic strength: 2.00
* After shaking dithizone was partially oxidized by nitric acid.

$$K=D\times\gamma_2\times\gamma_H\times(H^+)/\gamma_1\times\gamma_D{}^2\times(H_2Dz)^2 \quad (10)$$

where $\gamma_1$, $\gamma_2$, $\gamma_H$ and $\gamma_D$ are the activity coefficients of the tellurium(IV) ion, tellurium dithizonate, the hydrogen ion and dithizone respectively. Since the concentration of the solutes in the organic layer is very low, both $\gamma_2$ and $\gamma_D$ could be regarded as unity. When one assumes that the temperature dependence of the ratio, $\gamma_H/\gamma_1$, is very small, one can take the following formulation:

$$(\partial \ln K/\partial(1/T))_p \cong (\partial \ln D/\partial(1/T))_p \quad (11)$$

Thus, by plotting $\log D$ vs. $1/T$, one can obtain straight lines. From the slope of the lines in Fig. 5, the enthalpy change, $\Delta H°$, may be roughly estimated to be $-10.4$ kcal./mol.

**The Effect of Various Anions on the Distribution Ratio.** — Figures 6, 7 and 8 show the effects of fluoride, chloride, bromide, iodide, bisulfate and nitrate on the distribution ratios of tellurium(IV). In each case, the ionic strength was kept constant with perchloric acid. In the experiments involving fluoride, the extraction was carried out in glass tubes

the insides of which were coated with "Silicone."*

Another series of experiments extracting tellurium by dithizone were carried out in the presence of various acids, including phosphoric acid, boric acid, silicic acid and several organic acids. The results are shown in Table I.

**The Absorption Spectrum and the Molar Extinction Coefficient of Tellurium Dithizonate in Carbon Tetrachloride.**—Four milliliters of perchloric, sulfuric, hydrochloric or nitric acid solutions of tellurium(IV) were shaken with 4 ml. of a freshly-purified dithizone carbon tetrachloride solution. An aliquot of the organic layer was then diluted with carbon tetrachloride and subjected to the spectrophotometric measurement.

In all these cases, one could not obtain a pure tellurium dithizonate solution, only a mixture of dithizone and tellurium dithizonate. For example, the absorption spectrum for the extract from sulfuric acid is shown in Fig. 9. Assuming that the absorption peak at 620 mμ is wholly due to dithizone, one can analyze the curve into two components and assign the maximum absorption of tellurium dithizonate at 427 mμ, as Fig. 9 shows.

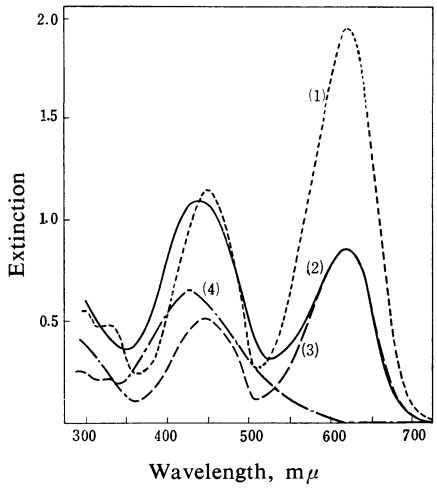

Fig. 9. Absorption spectra of dithizone and tellurium dithizonate in carbon tetrachloride.
----- (1): Absorption spectrum of dithizone ($5.66\times10^{-5}$ M)
——— (2): Absorption spectrum of a mixture of tellurium dithizonate ($1.58\times10^{-5}$ M) and dithizone ($2.50\times10^{-5}$ M)
——— (3): Assumed absorption spectrum of dithizone in (2)
— — — (4): Resulting absorption spectrum of tellurium dithizonate in (2), that is: (2) − (3).

Table II. Molar extinction coefficient of tellurium dithizonate in carbon tetrachloride

| Aqueous medium | Concn. M | Initial concn. of Te(IV) M | $\varepsilon_{427\,m\mu}$ $M^{-1}cm^{-1}$ |
|---|---|---|---|
| $HClO_4$ | 1.90 | $9.77\times10^{-5}$ | $4.13\times10^4$ |
| $H_2SO_4$ | 0.692 | $4.88\times10^{-3}$ | $4.12\times10^4$ |
| | 0.433 | $1.63\times10^{-3}$ | $4.17\times10^4$ |
| HCl | 1.07 | $8.02\times10^{-3}$ | $4.03\times10^4$ |
| | 0.230 | $3.76\times10^{-4}$ | $4.07\times10^4$ |
| $HNO_3$ | 0.814 | $8.34\times10^{-4}$ | $3.90\times10^4$ |

The molar extinction coefficients at 427 mμ were calculated for several extracts; they are tabulated in Table II. Since the wavelengths of the maximum absorption and the molar extinction coefficients are equal for all these extracts within the range of experimental error, they are supposed to be identical entities.

* Polone T, made by Shin-etsu Kagaku Co., Ltd., Japan.

**Summary**

Tellurium(IV) can be extracted into organic layers with dithizone. The analysis of the experimental results suggests, as the main process of extraction:

$$Te(OH)_3^+ \text{ (or } TeOOH^+) \text{ (aq.)} + 2H_2Dz \text{ (org.)} = Te(OH)_2(HDz)_2 \text{ (or } TeO(HDz)_2) \text{ (org.)} + H^+ \text{(aq.)} + xH_2O \text{ (aq.)}$$

The spectrophotometric measurements show that tellurium dithizonate in carbon tetrachloride has an absorption maximum at 427 mμ, where the molar extinction coefficient is $4.10 \times 10^4$ M$^{-1}$ cm$^{-1}$.

The authors wish to thank Professor Nobufusa Saito, Dr. Yukiyoshi Sasaki, Dr. Akira Yamasaki and Mr. Hitoshi Shoji for their helpful advice and discussions.

# The Reaction of Tropoids with Quinone Derivatives. VIII. The Reaction of Several Tropolones with *p*-Benzoquinonemonobenzenesulfonimide

By Yukio NISHIYAMA

(Received January 11, 1965)

The reactions of tropolones with quinone derivatives have been investigated in our laboratory several times. For example, in one earlier paper of this series[1], it was reported that the reactions of *p*-benzoquinonedibenzenesulfonimide with tropolone and its bromo derivatives in the presence of a catalytic amount of triethylamine gave *N*-(tropolon-5-yl)-*N*,*N*'-dibenzenesulfonyl-*p*-phenylenediamine and its bromo derivatives in comparatively good yields.[2,3]

The present paper will describe the determination of the structure of the products of the reaction of *p*-benzoquinonemonobenzenesulfonimide (I)[4] with tropolone and its bromo derivatives without a catalyst.

The addition of tropolone to *p*-benzoquinonemonobenzenesulfonimide (I) dissolved in a mixture of methanol and benzene resulted in an orange solution. When this mixture had been allowed to stand overnight at room temperature, colorless crystals (II) were precipitated out. The analytical values of II corresponded to the molecular formula $C_{19}H_{15}O_{55}$·NS, and its ultraviolet and infrared absorption spectra revealed that the tropolone ring was retained. Furthermore, from an analogy to the reaction of quinonediimide derivatives,[5-8] it was assumed that the *N*-benzenesulfonyl-*p*-aminophenol moiety entered into the 5-position of the tropolone ring. The experimental results described below support this assumption.

In order to ascertain the position where the tropolone ring links, a similar reaction was carried out with 3-bromotropolone and 3,7-dibromotropolone in place of tropolone itself; pale yellow crystals III and yellow crystals IV were obtained respectively. The analytical values of III and IV agreed with the formulae for the monobromo and dibromo derivatives of II respectively.

The hydrogenolysis of III and IV in the presence of palladium-carbon afforded II. Since the electrophilic substitution of tropolone is

2) See also Y. Nishiyama, Y. Ikegami and S. Seto, ibid., 38, 72 (1965).

3) It was reported in an earlier paper of this series[1] that the structures of the reaction products of *p*-benzoquinonedibenzenesulfonimide with tropolone and its bromo derivatives were 5-(2',5'-dibenzenesulfonamidophenyl)tropolone and its bromo derivatives. However, further examination of these reaction products has revealed that they were *N*-(tropolon-5-yl)-*N*,*N*'-dibenzenesulfonyl-*p*-phenylenediamine and its bromo derivatives.[2]

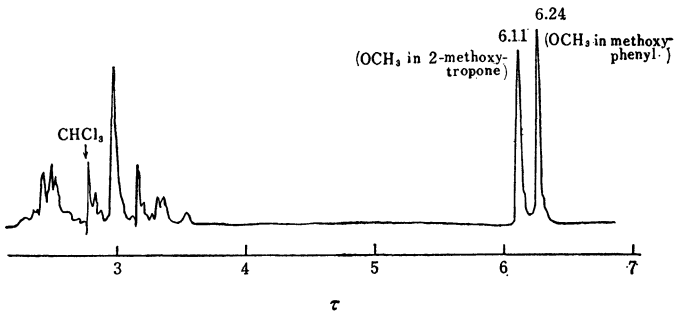

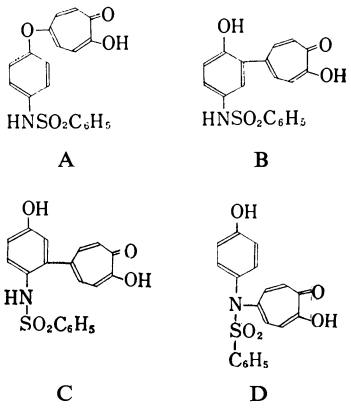

Fig. 1. The NMR spectrum of X.

known to occur at the 3, 5, and 7-position, these facts clearly indicate that the *N*-benzenesulfonyl-*p*-aminophenol moiety in II, III and IV is situated in the 5-position of the tropolone ring. Accordingly, formulae A, B, C and D have been taken into consideration in determining the structure of II.

The heating of II in a sealed tube with concentrated hydrochloric acid afforded the *p*-aminophenol derivative V.

The acetylation of II and V afforded diacetyl derivative VI and triacetyl derivative VII respectively, these acetyl derivative did not exhibit any absorption band due to the NH and OH groups in their infrared spectra.

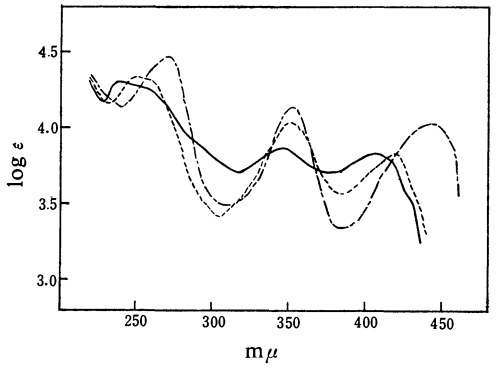

Fig. 2. Ultraviolet absorption spectra of II (——), III(----) and IV(-·--) in methanol.

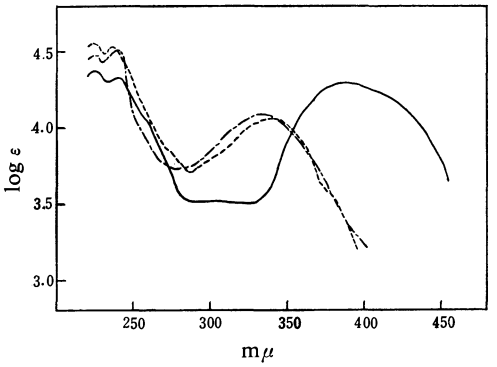

Fig. 3. Ultraviolet absorption spectra of V (——), VI(----) and VII(-·--) in methanol.

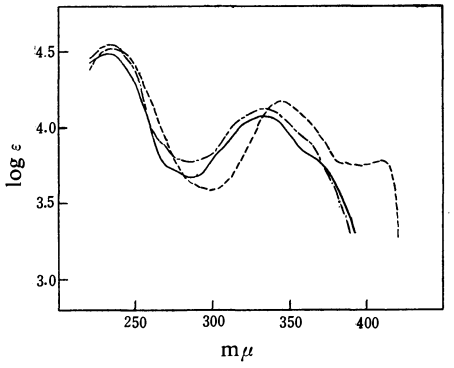

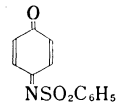

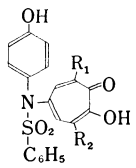

Fig. 4. Ultraviolet absorption spectra of VIII (——), IX(----) and X(-·--) in methanol.

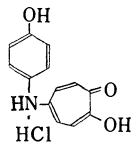
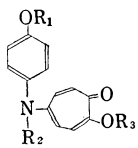
The reaction of II with diazomethane afforded a methyl ether, the analytical values of which corresponded to those of the monomethyl compound VIII. Its ultraviolet absorption spectrum and the absence of coloration with ferric chloride revealed that VIII was a 2-methoxytropone derivative. The methylation of II with dimethyl sulfate in the presence of potassium hydroxide gave another monomethyl ether derivative, IX, which showed coloration with ferric chloride. The further methylation



of IX with diazomethane afforded a dimethyl compound, X, that showed no coloration with ferric chloride. The infrared spectrum of X does not show any absorption band due to the NH and OH groups, and in the NMR spectrum[9] the signals for the protons of the $OCH_3$ groups in methoxyphenyl and 2-methoxytropone appear at 6.24 and 6.11 $\tau$[2] respectively, with almost equal intensities. If X had the $NCH_3$ group, the signal for the $NCH_3$ group would appear near 6.8—6.9 $\tau$.[2] Therefore, X, was identified as *N*-benzenesulfonyl-*N*-(2-methoxytropon-5-yl)-*p*-anisidine.



I

II: $R_1=R_2=H$
III: $R_1=Br$, $R_2=H$
IV: $R_1=R_2=Br$

V

VI: $R_1=R_3=COCH_3$, $R_2=SO_2C_6H_5$
VII: $R_1=R_2=R_3=COCH_3$
VIII: $R_1=H$, $R_2=SO_2C_6H_5$, $R_3=CH_3$
IX: $R_1=CH_3$, $R_2=SO_2C_6H_5$, $R_3=H$
X: $R_1=R_3=CH_3$, $R_2=SO_2C_6H_5$

From these facts, formulae A, B and C must be excluded for structure of II; thus it may be concluded that the reaction product of *p*-benzoquinone-monosulfonimide (I) with tropolone is *N*-benzenesulfonyl-*N*-(tropolon-5-yl)-*p*-aminophenol (II), and that III and IV are monobromo and dibromo derivatives of II respectively.

## Experimental[10]

***N*-Benzenesulfonyl-*N*-(tropolon-5-yl)-*p*-aminophenol (II).**—A solution of *p*-benzoquinonemonobenzenesulfonimide (I) (200 mg.) and tropolone (180 mg.) in 9 ml. of a mixture (3 : 1 by volume) of benzene and methanol was allowed to stand at room temperature. After 24 hr., the colorless crystals (120 mg.) which precipitated were collected by filtration. Recrystallization from ethanol afforded 110 mg. of II; m. p. 228°C.

Found: C, 61.90; H, 4.27; N, 3.74. Calcd. for $C_{19}H_{15}O_5NS$: C, 61.81; H, 4.06; N, 3.79%.

UV $\lambda_{max}^{MeOH}$ m$\mu$ (log $\varepsilon$): 235 (4.28), 345 (3.84), 403 (3.82).

***N*-Benzenesulfonyl-*N*-(3-bromotropolon-5-yl)-*p*-aminophenol (III).**—To a solution of I (300 mg.) in 7 ml. of benzene-methanol (3 : 1 by volume) was added a solution of 3-bromotropolone (490 mg.) in 2 ml. of the same solvent; the mixture was then allowed to stand at room temperature. After 2 days, the solvent was evaporated under reduced pressure. To this residue, a small amount of ethanol was added, whereupon pale yellow crystals (270 mg.), m. p. 240°C (decomp.) were obtained.

Found: C, 51.22; H, 3.96. Calcd. for $C_{19}H_{14}O_5NSBr$: C, 50.89; H, 3.13%.

UV $\lambda_{max}^{MeOH}$ m$\mu$ (log $\varepsilon$): 250 (4.32), 350 (4.04), 420 (3.83).

The filtrate left after the separation of III was evaporated under reduced pressure. When the residue was sublimed at 2 mmHg in a bath of 130°C, 130 mg. of 3-bromotropolone was recovered.

***N*-Benzenesulfonyl-*N*-(3,7-dibromotropolon-5-yl)-*p*-aminophenol (IV).**—When treated in the same way as above, I (400 mg.) and 3,7-dibromotropolone (480 mg.) afforded 670 mg. of yellow crystals, m. p. 197°C (decomp.).

Found: C, 43.47; H, 2.79; N, 2.39. Calcd. for $C_{19}H_{13}O_5NSBr_2$: C, 43.26; H, 2.47; N, 2.66%.

UV $\lambda_{max}^{MeOH}$ m$\mu$ (log $\varepsilon$): 270 (4.47), 353 (4.13), 445 (4.02).

**The Hydrogenolysis of III.**—A solution of the monobromo derivative III (50 mg.) in water (6 ml.) and ethanol (2 ml.) containing potassium hydroxide (100 mg.) was shaken in a hydrogen atmosphere over palladium-carbon (50 mg.) at room temperature. When the absorption of hydrogen had ceased, the catalyst was filtered off, the filtrate was acidified with diluted sufuric acid, and the precipitate thereby formed was collected by filtration. Recrystallization from ethanol afforded 30 mg. of colorless crystals, m. p. 227—228°C, undepressed on admixture with II. The ultraviolet and infrared absorption spectra of these two substances were also in complete agreement.

**The Hydrogenolysis of IV.**—A solution of the dibromo derivative IV (150 mg.) in water (6 ml.) and ethanol (4 ml.) containing potassium hydroxide (200 mg.) was added to palladium-carbon (50 mg.). The mixture was then treated as in the foregoing example. The recrystallization of the precipitate gave 70 mg. of crystals with a m. p. of 227—228°C, undepressed on admixture with II. The

9) The NMR spectrum was measured in deuteriochloroform, using a Varian 4301 high-resolution NMR spectrometer (60 Mc.); the measurements were performed by Assistant Professor Tsuneo Ikenoue of this Institute, to whom the author is indebted.

10) All melting points are uncorrected. The microanalyses were carried out by Misses Yoko Endo and Yukiko Endo in this Institute. The measurements of the ultraviolet and infrared spectra were made, respectively, with a Hitachi EPI-2A-type spectrophotometer in methanol and with a Hitachi EPI-S2-type infrared spectrophotometer using a potassium bromide disk.

ultraviolet and infrared absorption spectra of this product were also in agreement with those of II.

**The Reaction of II with Concentrated Hydrochloric Acid.** — A mixture of II (100 mg.) and concentrated hydrochloric acid (2 ml.) was heated in a sealed tube at 130°C for 5 hr. When it had cooled, the tube was opened and the orange red crystals that separated out were collected by filtration. Recrystallization from dilute hydrochloric acid gave 20 mg. of the hydrochloride of *N*-(tropolon-5-yl)-*p*-aminophenol (V) as orange red crystals, m. p. 265—266°C (decomp.).

Found: C, 58.04; H, 4.34; N, 5.44. Calcd. for $C_{13}H_{10}O_3NCl$: C, 59.20; H, 4.55; N, 5.31%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 225 (4.37), 240 (4.32), 390 (4.26).

***N*-Benzenesulfonyl-*N*-(2-acetoxytropon-5-yl)-*p*-acetoxyaniline (VI).**—A mixture of II (200 mg.) and acetic anhydride (4 ml.) was heated at 130°C for 1 hr. The mixture was then evaporated under reduced pressure, and the residue was crystallized from ethanol to give 60 mg. of colorless crystals, melting at 139—140°C.

Found: C, 60.57; H, 4.33; N, 3.15. Calcd. for $C_{23}H_{19}O_7NS$: C, 60.95; H, 4.19; N, 3.09%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 225 (4.54), 235 (4.48), 340 (4.05).

***N*-Acetyl-*N*-(2-acetoxytropon-5-yl)-*p*-acetoxyaniline (VII).**—A mixture of the hydrochloride V (150 mg.), anhydrous sodium acetate (50 mg.) and acetic anhydride (2 ml.) was heated at 130°C for 2 hr. The mixture was then evaporated under reduced pressure, and the residue was washed with water. The crystalline residue was recrystallized from ethyl acetate to give 80 mg. of colorless crystals, m. p. 173—174°C.

Found: C, 65.08; H, 5.04; N, 4.38. Calcd. for $C_{19}H_{17}O_6N$: C, 64.26; H, 4.79; N, 3.94%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 225 (4.48), 240 (4.50), 335 (4.09).

***N*-Benzenesulfonyl-*N*-(2-methoxytropon-5-yl)-*p*-aminophenol (VIII).**—An ether solution of diazomethane was added to a suspension of II (150 mg.) in methanol (10 ml.). The mixture was then allowed to stand overnight, and the crystals that separated out were collected by filtration. Recrystallization from a methanol and chloroform mixture afforded 400 mg. of colorless needles, m. p. 160—162°C.

Found: C, 62.97; H, 5.04; N, 3.32. Calcd. for $C_{20}H_{17}O_5NS$: C, 62.68; H, 4.44; N, 3.65%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 232.5 (4.48), 332 (4.07).

This product does not show any coloration with ferric chloride.

**The Methylation of II with Dimethyl Sulfate.**—A solution of II (300 mg.) in 2 N sodium hydroxide (16 ml.) was stirred at room temperature. To this solution, dimethyl sulfate (1 ml.) was added. A colorless solid began to separate after a few minutes. After 30 min., the solid was collected by filtration and suspended in a small amount of water. The mixture was then acidified with dilute sulfuric acid, and the solid that remained was collected and recrystallized from ethanol to give 130 mg. of *N*-benzenesulfonyl-*N*-(tropolon-5-yl)-*p*-methoxyaniline (IX) as colorless needles, m. p. 169—170°C.

Found: C, 63.62; H, 4.63; N, 3.89. Calcd. for $C_{20}H_{17}O_5NS$: C, 62.68; H, 4.44; N, 3.65%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 235 (4.51), 345 (4.17), 407 (3.76).

This compound showed a positive color reaction with ferric chloride.

The filtrate left after the separation of IX was acidified with dilute sulfuric acid, and the solid that precipitated was collected. Recrystallization from ethanol gave 120 mg. of colorless crystals m. p. 228°C, undepressed on admixture with II.

**The Reaction of IX with Diazomethane.**—An ether solution of diazomethane was added to a suspension of IX (100 mg.) in methanol (4 ml.). After the mixture had been allowed to stand overnight, the crystals that separated were collected. Recrystallization from ethanol afforded 40 mg. of *N*-benzenesulfonyl-*N*-(2-methoxytropon-5-yl)-*p*-methoxyaniline as colorless crystals, m. p. 175—176°C.

Found: C, 63.91; H, 4.89; N, 3.64. Calcd. for $C_{21}H_{19}O_5NS$: C, 63.49; H, 4.78; N, 3.52%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 235 (4.54), 332 (4.15).

Compound X did not show any coloration with ferric chloride.

The author wishes to express his gratitude to Professor Shuichi Seto for his kind guidance and encouragement throughout this work. A part of the expenses was defrayed by the Sankyo Co., Ltd., to which the author is deeply indebted.

# The Crystal Growth of Synthetic Fluor-phlogopite by the Moving Crucible Technique

By Tokiti NODA, Nobutoshi DAIMON, Michio INAGAKI, Mitsuru TANAKA
Takashi AMANO and Minoru HIRAO

(Received January 18, 1965)

Fluor-phlogopite crystallizes from a melt with a composition corresponding approximately to the composition of mica, [$KMg_3AlSi_3O_{10}F_2$]. In the earlier stage of our experiments, the crystal growth of mica in the melt of a large mass was carried out and thus large mica crystals were obtained.[1] A carbon granular resistance furnace was used for the melting and crystallization of mica. A batch of 30 kg. of a raw material mixture was heated in an aluminous clay or graphite crucible until a clear melt was obtained. The melt was then cooled at a cooling rate of 2 to 5°C per hour and left to cool to room temperature. The solidified mass was composed of interlocking mica crystals of various sizes. The maximum size of single crystals was about 5 cm. by 5 cm., but the yield of crystals of this size was small.

In order to increase the yield of large crystals in a given batch, it is necessary to prevent the formation of excess crystal nuclei at the beginning of crystallization and to give a preferred orientation to the growing crystals. Van Valkenburg and Pike[2] used an elliptical crucible with a wedge-shaped bottom for the melting and crystallization of fluor-phlogopite. With a steep temperature gradient within the melt (larger than 50°C between the top and the bottom of the melt) and a slow rate of cooling (less than 1°C/hr.), a good development of the vertical and lateral orientation of mica crystals was obtained.

The Electrotechnical Experimental Station, Bureau of Mines,[3] has developed an internal-electrical-resistance melting process for the manufacture of fluor-mica. This process can be used for the melting of a large quantity of a mica batch, but it usually results in the formation of a large number of interlocking crystals. Noda and Sumiyoshi[4] used two sets of graphite electrodes placed vertically one over the other and thus obtained a development of the vertical orientation of growing crystals by changing the ratio of the electrical current passing through the upper and the lower parts of the mica melt with the internal-electrical-resistance melting process.

Daimon et al.[5] applied the Kyropoulos (or Czockralski) technique of single-crystal growing to the crystal-growing of fluor-phlogopite, but they could not continue to grow crystals because of the change in the chemical composition of the surface layer of the melt caused by the evaporation of fluorine compounds.

Noda and Tsujimura[6] used a stationary crucible technique of single crystal growing for fluor-mica single-crystal growing. The furnace used for the experiments had three platinum ribbon heaters placed at the bottom, the top, and the side of the furnace chamber, the electrical current of each heater being regulated separately. A platinum crucible containing the fluor-phlogopite batch mixture was placed in the chamber and heated to a temperature above the melting point of the mica. The average temperature gradients obtained by changing the electrical current of heaters ranged vertically from 10 to 80°C/cm., with the extreme temperature at the top. The fluctuation of temperature around the crucible could be kept within ±0.1°C by using fine alumina powder as a thermal insulator between the heaters and the crucible. A charge of 20 to 40 g. was melted and crystallized at a cooling rate ranging from 0.5 to 90°C/min. Mica crystals grew with their basal planes vertically parallel to the temperature gradient when the temperature gradient was larger than 40°C/cm. However, no lateral orientation was developed, and the breadth of the crystals was limited by the intersection of the neighbor crystals. Good crystals of a length equal to the depth of the melt were grown with an estimated rate of growth (the rate of the descent of the crystal-melt boundary) of less than 1 mm./hr. Sometimes a few crystals were observed to have grown to project above the surface of the melt.

6) T. Noda and S. Tsujimura, ibid., **61**, 477 (1958).

With a given temperature gradient, the maximum depth of the melt is limited by the highest temperature, which is in turn limited by the furnace used. Also, too high a temperature should be avoided because of the increase in the evaporation of the fluorine compound from the melt. Therefore, the size of the grown crystals can not be made large when a large temperature gradient is required for the growing of single crystals with the stationary crucible technique.

### Crystal Growth Without Seed Crystals
(Noda, Inagaki, Tanaka)

It is well known that the thermal history of melt affects the nucleation in the melt. In order to reduce the number of nuclei available for new crystal formation, the melt should be heated at a high enough temperature or for a long enough time for it to become a clear melt without any residual particles of raw material which may induce the nucleus formation.[7] On the other hand, when the melt is heated for an excessively long time or at too high a temperature, the melt cools, with a large undercooling which causes the sudden formation of a very large number of nuclei, once the nucleation begins.[8] Therefore, the control of the amount of nucleus formation needs a very delicate operation of the heating procedure.

**Apparatus and Experimental Procedure.**—The apparatus used for the moving crucible technique was a furnace the chamber of which was divided into two sections by a baffle plate.[9] The sections were heated by separate platinum-rhodium ribbon heaters in order to control the temperature of each room separately and in order to get a desired temperature gradient in the chamber. A charge of the fluor-phlogopite batch mixture was contained in a thin-walled platinum crucible 9 to 20 mm. in diameter, 20 to 30 mm. high, and with a conical bottom. The angle of the cone was 60°, and the apex of the cone was held on a platinum rod 5 mm. in diameter and 150 mm. long, the opposite end of which was in contact with the upper end of a stainless steel rod of the descending device. The crucible and the platinum rod were covered with refractory cases. The space between the crucible and the refractory case was filled with alumina powder so that no possible leakage of the batch melt might damage the wall of the furnace chamber.

The contact of the crucible apex with the platinum rod was designed to cool the apex preferentially by thermal conduction through the rod and to get so sharp a temperature gradient in the melt of the conical part of the crucible that the nucleation would take place only in the apex.

The rate of descent could be changed within the range of 0.1 to 1.0 mm./hr., because it was found from preliminary experiments that a rate of descent of 0.1 to 1.0 mm./hr. was good enough to grow single crystals of a good quality.

As raw materials, powdered fluor-phlogopite crystals or pre-melted blocks of fluor-phlogopite crystals were used. A crucible containing a charge of 20 to 300 g. of raw material was sealed by welding in order to prevent any change in the chemical composition of the charge by decomposition.

First, the crucible was placed in the upper section of the furnace; then the temperature of the furnace was raised. After the highest temperature of the furnace had reached about 1400°C, the temperature distribution in the furnace was measured and the crucible was moved to the position indicated as A in Fig. 1. In the figure the temperature distribution in the furnace is schematically described. The crucible was left there for a fixed time in order to complete the melting of the charge, and then it was manually moved to the position B, where the temperature of the crucible apex reached a definite temperature almost equal to or a little below the crystallization point of fluor-phlogopite (1375°C[8]). The crucible was

* The rate of cooling was calculated from the rate of descent and the temperature gradient in the furnace by the following relation:

Rate of cooling $(\Delta\theta/\Delta t)$ = Temperature gradient $(\Delta\theta/\Delta l) \times$ Rate of Descent $(\Delta l/\Delta t)$

where $t$ is time, $\theta$ temperature and $l$ distance.

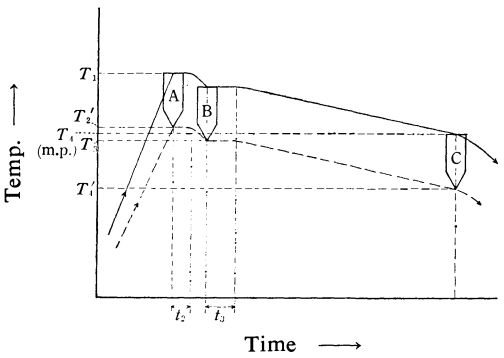

Fig. 2. Schematical heating program in the growth of fluor-phlogopite crystal with the moving crucible technique.

left there for a fixed time in order to form nuclei in the apex; then it was moved downward automatically at the rate of 0.75 mm./hr. The whole heating program is shown schematically in Fig. 2. When the top of the charge had passed the level of the crystallization temperature (the position C) and all of the melt was supposed to have crystallized, the furnace was cooled to room temperature. The temperature of the apex was measured by a thermocouple inserted between the crucible apex and the top of the platinum rod.

**Results.** — Some of experimental data are shown in Table I. When the apex of the crucible was placed directly on the platinum rod, the cooling effect of the rod was so large that the temperature of the apex was about 50—70°C lower than the furnace temperature of the same level. The temperature difference was reduced to about half (25—45°C) when a sintered alumina disk 1 mm. thick was inserted between the apex and the rod. The experiments with this inserted alumina disk are marked (A) in Table I.

In series I of the experiments, powdered crystals of fluor-phlogopite were used as raw material, while in series II of the experiments premelted blocks of fluor-phlogopite crystals were used. The premelted blocks were opaque white and were composed of minute, entangled crystals of mica.

In Exp. No. 50, in which the apex was held for 30 min. at the crystallization point of the mica, a very small number of unmelted crystals remained in the apex and a few single crystals of a good quality grew vertically from the apex to the top of the charge, orienting their basal planes parallel to the direction of growth, but without any lateral orientation (Plate I-1). Similar results were obtained with Exp. No. 55 (A) and 57, in which the apex temperature was held a little below the melting point of the mica (Plate I-2, -3). In Exp. No. 54, in which the apex was held for 90 min. at the crystallization point of mica, the resultant mass was composed of many randomly-oriented crystals (Plate I-4).

In Exp. No. 44, in which the apex was kept at 1390—1380°C for 90 min., the resultant mass was white, porcelain-like, and opaque, and was composed of a large number of minute

mica crystals and a small amount of needle crystals, probably chondrodite, all oriented vertically along the direction of growth (Plate II-1). In Exp. No. 47, in which the apex was kept a little below the crystallization point for a short time, small crystals remained at the apex; the size of the crystals deposited was small, but it became larger in the upper part of crucible, even though the apex was kept for 90 min. at 1300°C before the descent (Plate II-2). In Exp. No. 58, the thermal history of which was very similar to that of No. 57, single crystals of a good quality grew from the apex to the top of the charge (Plate II-3). This result was very similar to that obtained in Exp. No. 57. It can be seen from the similar results obtained in Exps. Nos. 57 and 58 that either powdered crystals or premelted crystalline aggregates can be used as raw material for the successful growing of fluor-phlogopite crystals.

As can be seen from the above experiments, the excessive heat treatment of the melt resulted in a large undercooling, which in turn resulted in the sudden formation of a large number of nuclei once the crystallization began. On the other hand, a number of seed crystals remained unmelted when the melting was insufficient. Experiments No. 54 and No. 44 are cases of excessive heat treatment, and Exp. No. 47 seems to be a case of insufficient melting, even though the apex was kept for a long time at a temperature a little below the crystallization point. Just to melt crystals down to the apex part may be the optimum

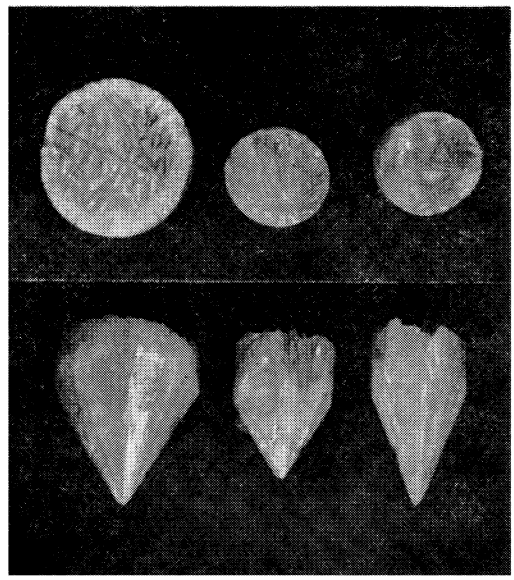

Plate III. Crystals grown by the moving crucible technique without seed crystals showing vertical and lateral orientation.

heat treatment for the growing of a few single crystals from the apex to the top of charge. This heat treatment can, however, be carried out only by a very careful control of the apex temperature. Experiments Nos. 50, 55 and 58 have heat treatments very close to the optimum.

With the moving crucible technique, the height of the charge is not necessarily as limited as it is with the stationary crucible technique, but the situation, in which the lateral orientation of grown crystals is random, is the same as with the latter technique. Some of the crystals grown by the moving crucible technique are shown in Plate III; they show a very good vertical orientation but a poor lateral orientation of crystal growth.

### Crystal Growth Using Seed Crystals
(Daimon, Hirao, Amano)

One of the authors (Daimon) invented a technique of using parallel-packed sheets of fluor-phlogopite as seeds with the moving crucible technique for growing single crystals of fluor-phlogopite.[10]

As seed crystals, transparent, apparently flawless sheets were cut from fluor-phlogopite crystals which had been hand-splitted from crystal aggregates produced by the internal-electrical-resistance melting method. Platinum crucibles with square sections were made by welding platinum sheets 0.03 mm. thick by an oxygen-city gas torch. Several sheets of seed crystals were put together parallel to each other in order to make a book-like packet; they were then placed on the bottom in the crucible with their basal planes parallel to the vertical axis of the crucible, as is shown in Fig. 3. The raw material of fluor-phlogopite

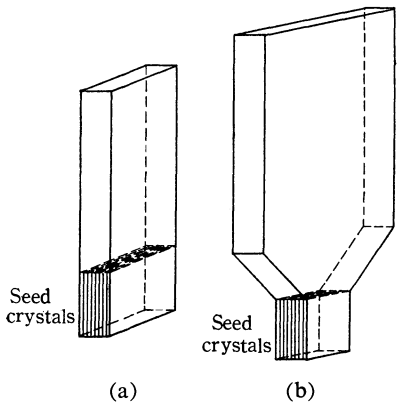

Fig. 3. Shaped crucible for the moving crucible technique with seed crystals.

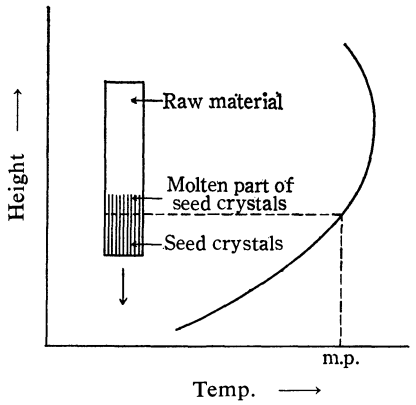

Fig. 4. Temperature gradient across the crucible in the moving crucible technique with seed crystals.

composition was put in the space over the seed crystals in the crucible, and the crucible was sealed by welding it in order to prevent the decomposition of the content. The crucible encased in a refractory sagger was placed in such a position in the furnace that when the highest-temperature part in the furnace was raised to 1400°C, the total charge of the raw material and the uppermost part of the seed crystals were to be melted. The temperature gradient across the crucible at the beginning of the descent is shown schematically in Fig. 4.

The sagger was connected with a descending device, the rate of descent being varied from 0.4 to 35 mm./hr. The temperature of the highest-temperature part in the furnace was kept at 1400°C during the descent. The temperature gradient around the crystal-melt boundary was estimated from the temperature difference between 1400°C and 1375°C, the crystallization point of fluor-phlogopite, divided by the distance between the seed crystal-grown crystal boundary and the highest temperature (1400°C) level in the furnace. The temperature gradient varied from 60 to 10°C/cm.

Powdered crystals of fluor-phlogopite, pre-melted blocks of fluor-phlogopite crystals, and a batch mixture of chemicals the composition of which corresponded to that of fluor-phlogopite or its pre-melted blocks were used as raw materials. When a batch mixture of an off composition was used, the concentration of fluor-phlogopite in the melt gradually decreased and, consequently, the crystallization temperature of fluor-phlogopite gradually decreased,[11] as the crystallization proceeded. This situation is in general not favorable for the growth of single crystals in the melt.

11) T. Noda, *J. Am. Ceram. Soc.*, **38**, 147 (1955).

As the result of a number of growing experiments,[12,13] the optimum temperature gradient in the growing zone was found to be about 40°C/cm. and a good, clear "booklet" of mica crystals was obtained with the rate of descent of 1.0 to 0.4 mm./hr. (Plate IV). It seems that better crystals may be grown with a smaller rate of descent. A booklet as large as 10 cm.×5 cm.×1 cm. was grown in the authors' laboratory.[14] (Plate V)

Synthetic fluor-phlogopite has been reported to have a monoclinic monolayer (1 M) structure. The optical angles (2V) of the mica reported range from 0 to 14°.[15-18] The results of the measurement of a large number of both seeds and grown crystals of fluor-phlogopite showed that the optical angles were distributed in the range from 0 to 16°, with a maximum distribution at angles less than 9 and around 15°. The optical angles of the grown crystals were mostly the same as those of their seed crystals; only a few had smaller or larger angles than those of their seeds.[13]

crystal of fluor-phlogopite with an optical angle around 14° showed the 1 M symmetry, while that of the crystal with an optical angle of less than 9° gave reflection spots which could be interpreted by the polysynthetic-twin model.[19]

By etching fluor-phlogopite crystals with gaseous hydrogen fluoride or its concentrated aqueous solution, isosceles trianglar etch pits were observed on the surface of crystals with optical angles around 15° (Plate VI-a) and apparent equilateral trigons (Plate V-b) on the surface of crystals with optical angles of less than 9°, corresponding to the 1 M and polysynthetic twin-type structure respectively.[20]

The etch pit concentration of crystals grown at a smaller rate was smaller than those grown at a larger rate; for example, the etch pit concentration of crystals grown at the rate of 1.5 mm./hr. was $0.3—0.5\times10^4/cm^2$, about half that of crystals grown at the rate of 13 mm./hr. The etch pit concentration of seed crystals, which were produced by the internal-electrical-resistance melting method, was about the same as those grown at the rate of 13 mm./hr.[21]

# The Spectrophotometric Determination of Anions by Solvent Extraction with Metal Chelate Cations. XIII. A New Method for the Determination of Picric Acid

By Shigehiko HAYASHI, Keiya KOTSUJI, Toshiyuki SAKURAI, Kenji KIMURA and Yuroku YAMAMOTO

(Received January 18, 1965)

Several procedures for the determination of picric acid have been published in the literature. In the well-known alkalimetric assay procedure, however, it is evident that a fictiously high value of the picric acid content is given because of the presence of lower-nitrated phenols as contaminates. Similarly, Bolliger's titration method,[1] based upon the principle that methylene blue picrate is extracted into chloroform, while methylene blue is not extractable, has been found by Baker[2] not to be universally applicable. Moreover, a titration method described by Johnson et al.,[3] in which the Koppeschaar method is applied to the procedure, is not desirable because of its experimental complexities.

Gravimetric methods using nitron[2,4,5] or 4-*n*-octyloxyphenylguanidine chloride[6] as a precipitant are too time-consuming and lack sensitivity.

Mites et al.[7] have studied the reduction of picric acid at a mercury cathode under a constant potential. Tur'yan et al.[8] have also investigated the polarographic behavior of picric acid, but their method requires the preliminary separation of some nitrophenols.

In an earlier work, Ruchhoft et al.[9] have described a spectrophotometric method of measuring the absorbance of ammonium picrate. Stöhr et al.[10] have reported that color is produced by heating picric acid with glucose in a weakly-alkaline medium.

Although it has been generally known that

picric acid can be quite well extracted into organic solvents with cationic dyes, such as methylene blue[1] and crystal violet[11], little attention has been paid to employing such solvent extraction techniques for the spectrophotometric determination of picric acid.

On the other hand, it has been found by the present authors that the 2, 2'-dipyridyl iron(II) chelate is extracted into nitrobenzene from an aqueous solution in the presence of picric acid as well as of pentachlorophenol[12] and that the color intensity of the nitrobenzene extract is proportional to the amount of picric acid.

On the basis of these facts, this work was undertaken in order to establish a method for the determination of picric acid by solvent extraction, followed by the measurement of the absorbance of the extracted picrate of the 2, 2'-dipyridyl iron(II) chelate. The proposed method has the advantage of being simpler, and the extraction is adequate to remove the interference of moderate amounts of mono- and dinitrophenols.

## Experimental

**Apparatus and Reagents.**—Unless otherwise stated, the apparatus and reagents were the same as those described in a preceding paper.[13]

**Standard Picric Acid Solution.**—A standard solution containing 1 mg. of picric acid per milliliter was prepared by dissolving purified picric acid (m. p. 120—121°C) in distilled water, as has been described by Meites et al.[7] This standard solution was then diluted to the concentration required for the experiments.

**Other Nitrophenols.**—All were purified until they had the proper constant melting points, *o*-nitrophenol by steam distillation and the others by recrystallization.

All other reagents of the analytical grade were used without further purification.

*Procedure.*—Mix a 2, 2'-dipyridyl solution ($6\times10^{-3}$ M), a ferrous ammonium sulfate solution ($1.5\times10^{-3}$ M), a sodium acetate solution (3 M) and a standard picric acid solution in the proper concentration. Adjust the pH of the solution to the required value and dilute it to 25 ml. with distilled water. To this, add 10.0 ml. of nitrobenzene and shake the solution for 5 min. After the solution has stood for 30 min., transfer the organic layer into a flask containing 1 g. of anhydrous sodium sulfate and shake it vigorously in order to make the solution transparent. Then transfer it through a folded filter paper into a 10 mm. cell. Measure the absorbance of the solution at 528 m$\mu$, using a reagent blank solution or nitrobenzene as a reference. Measure the pH of the aqueous layer after the separation.

## Results and Discussion

**The Absorption Spectrum.**—The spectral absorbance curves using nitrobenzene as a reference are shown in Fig. 1. Curve 1 is a spectrum of the extract when picric acid is absent, while curve 2 is that of the extract with picric acid. Curve 2 corresponds essentially to a spectrum of the 2, 2'-dipyridyl iron(II) chelate in an aqueous solution. The maximum absorbance is shifted from 522 m$\mu$ in an aqueous solution, and to 528 m$\mu$ in nitrobenzene. As Joshi and Bhargava[14] have shown that picric acid forms a 2:1 complex with $Cu(NH_3)_4^{2+}$, the extracted species is assumed to be a complex of 1 part 2, 2'-dipyridyl iron(II) chelate and 2 parts picric acid.

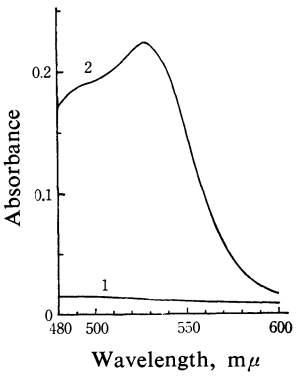

Fig 1. Absorption spectra.
Reference: Nitrobenzene, pH: 2.5
Curve 1: Spectrum of organic phase extracted from the aqueous solution (25 ml.) contained Dip. $2.4\times10^{-4}$ M, Fe(II) $6\times10^{-5}$ M, NaAc 0.24 M but picric acid is absent.
Cueve 2: Spectrum of organic phase extracted from the aqueous solution (25 ml.) containing 4 p. p. m. of picric acid in addition to the same component as that of curve 1.

**The Effect of Reagents.**—*The Effect of the 2, 2'-Dipyridyl Iron(II) Chelate Concentration.*—The formation of extractable species may be governed mainly by the concentration of the 2, 2'-dipyridyl iron(II) chelate cation.

Various amounts of ferrous ammonium sulfate and 2, 2'-dipyridyl were added to a solution containing a definite amount of picric acid, the mole ratio of dipyridyl to ferrous iron being kept at 4 to 1. In this case, because of the high stability of the chelate,[15]

11) M. Rebek and M. K. Semlitsch, *Monatsh. Chem.*, **92**, 254 (1961).

the molar concentration of the 2, 2'-dipyridyl iron(II) chelate was assumed to be equivalent to that of the ferrous iron added. The pH of the solutions was kept at 2.5, and the extraction was then carried out. As is shown in Fig. 2, an excess of the 2, 2'-dipyridyl iron(II)

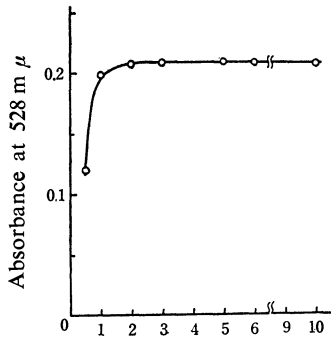

Fig. 2. Effect of 2, 2'-dipyridyl iron(II) chelate concentration.

Shaking time, 5 min.
Reference, Reagent blank

chelate is necessary to obtain a quantitative recovery; therefore, the concentration of ferrous ammonium sulfate was usually kept at 6 $\times 10^{-5}$ M in this work.

*The Effect of the 2, 2'-Dipyridyl Concentration.*—While the concentrations of ferrous iron, sodium acetate and picric acid in the final solutions were kept at $6\times 10^{-5}$ M, 0.24 M and 4 p. p. m. respectively, various amounts of 2, 2'-dipyridyl were added in which the mole ratio of dipyridyl to ferrous iron was varied from 3 to 5. The experiments were then carried out in a manner similar to that described above. The variation in the mole ratio did not effect any measurable change in the absorbance of the extracts. This mole ratio was always kept at 4 to 1 in this work.

*The Effect of the Sodium Acetate Concentration.*—When the concentration of sodium acetate was low in the solution, it took much time to separate the two layers because of the formation of an emulsion. When, however, the acetate concentration was kept between 0.2 to 0.3 M, the formation of an emulsion could be prevented. Thus, the concentration of the acetate was kept at 0.24 M in this work.

**The Effect of the Shaking Time.**—Although a good recovery could be obtaind with a one-minute shaking, the shaking time was fixed at 5 min. in this work.

**The Effect of pH.**—The effect of changes in the pH on the extraction is shown in Fig. 3 (curve 1). The absorbances of the extracts are at a maximum and are uniform over the pH range of the aqueous solution from 2.2 to 11.5. In addition, it was found that the extraction behavior of dinitrophenols was similar to that of picric acid in this system, while dinitrophenols were scarcely extracted into nitrobenzene from an aqueous solution at low

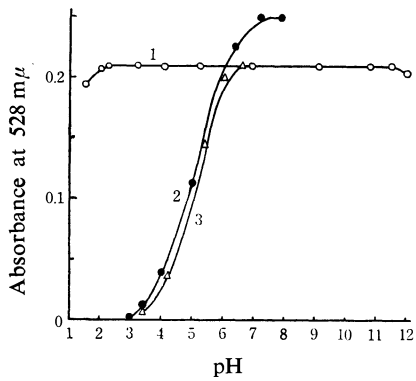

Fig. 3. Effect of pH.
The concentrations of dipyridyl, iron(II) and acetate in the final solutions were $2.4\times 10^{-4}$ M, $6\times 10^{-5}$ M and 0.24 M respectively.
Curve 1: Picric acid, 4 p. p. m.

Reference, Reagent Blank

pH values (pH 2—3). Thus, the pH of the solution to be extracted was adjusted to 2.5, because it appeared feasible that the interference of moderate amounts of dinitrophenols were avoided by the extraction procedure described above.

**The Stability of the Color.**—The color intensity of the extract in the transmission cell with a stopper was stable, even after 24 hr.

**The Choice of an Organic Solvent.**—The extracting solvents, such as nitrobenzene, benzene, cyclohexanone, 1, 2-dichloroethane, chloroform, carbon tetrachloride, isoamylalcohol and methylisobutylketone, were tested; of these, nitrobenzene proved to give the highest net absorbance.

The effect of the times of extraction was examined in the following manner. An aqueous solution containing a definite amount of picric acid and an optimum amount of the reagents was prepared; the extraction was then carried out with successive portions of nitrobenzene. The absorbance at 528 mμ was measured for the nitrobenzene solution obtained by each extraction. As Fig. 4 shows, the second extract has an appreciable absorbance, but the absorbance of the third extract is

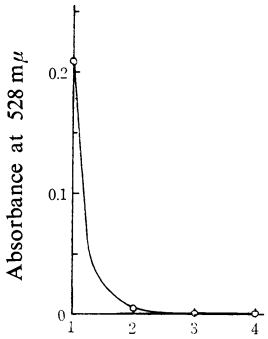

Fig. 4. Effect of times of extraction.
The concentrations of ferrous iron, dipyridyl, sodium acetate and picric acid in the aqueous solution before the first extraction were $6\times10^{-5}$ M, $2.4\times10^{-4}$ M, 0.24 M and 4 p. p. m. respectively, and the absorbance was measured for the nitrobenzene solution obtained by each extraction.
Reference, Reagent blank

almost negligible. Thus, a single extraction was used in this work.

**Calibration Curve.**—One milliliter of the 2, 2'-dipyridyl solution, 1 ml. of the ferrous ammonium sulfate solution, 2 ml. of the sodium acetate solution, and varying amounts (1—10 ml.) of the standard picric acid solution (20 p. p. m.) were mixed; the pH of this solution was then adjusted to 2.5 with a dilute sulfuric acid. The resulting solution was diluted to 25 ml. with distilled water. Then 10.0 ml. of nitrobenzene was added, and the mixture was treated by the preceding procedure. As can be seen from Fig. 5, up to 8 p. p. m. of picric acid obeys Beer's law.

**Interferences.**—A study was made of the effects of the appropriate substances which commonly occur in picric acid. Absorbance measurements were made for the nitrobenzene extracts from solutions containing various amounts of each substance with 4 p. p. m. of picric acid. The results are given in Table I. No interference was found in concentrations as high as 40 p. p. m. for nitrophenols, except with 2, 4-dinitrophenol. Although satisfactory results were obtained in the presence of large amounts of sulfate and phosphate, a small amount of nitrate produced a positive error.

**Summary**

The solvent extraction method has been applied to the spectrophotometric determination of minute amounts of picric acid with the 2, 2'-dipyridyl iron(II) chelate. The selectivity of the procedure is largely dependent on the pH of the solution. At pH 2.5 the extraction is selective for picric acid in the presence of nitrophenols.

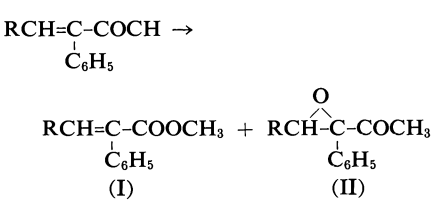
# The Peracid Oxidation of Ketones. III. The Reaction of $\alpha, \beta$-Unsaturated Ketones with Peroxybenzoic Acid*[1]



By Tai YOKOYAMA and Fujio NOHARA

(Received January 22, 1965)

In preceding papers[1] it was reported that the rate sequence of the peracid oxidation of ketones was the reverse to that of their oximation, and that the ketone peroxide was rearranged in the presence of both acid and peracid. It was concluded that the rate-determining step was the rearrangement of the addition intermediate which is formed by the nucleophilic attack of the peracid on the ketone. From the migratory aptitude in cycloalkylphenylketones,[2] it was considered that the most bulky group which is conformationally trans to the leaving carboxyl group migrates preferentially. Recently, Howthorne and his co-workers[3] reported that the rate-determining step was the acid-catalyzed decomposition of the peracid-ketone adduct and suggested that, in migration, although both electronic and steric effects were important, the electronic interpretation appeared to be the most promising.

In the present paper, the peracid oxidation of $\alpha, \beta$-unsaturated ketones will be undertaken in an attempt to provide additional information. Böeseken and his co-workers[4] studied the peroxyacetic acid oxidation of 4-phenyl-3-buten-2-one and 3-methyl-4-phenyl-3-buten-2-one; they were found to give mainly the enol acetates of phenylacetaldehyde and of phenylacetone respectively. The authors also carried out the peroxybenzoic acid oxidation of the same ketones and obtained the same products exclusively. These results show that mainly the unsaturated group rearranges. It is interesting to compare the migratory aptitude of the unsaturated group with that of the phenyl group, which has a superior migratory ability. When the peroxybenzoic acid oxidation of 1, 3-diphenyl-2-propen-1-one and 2-methyl-1, 3-diphenyl-2-propen-1-one was carried out, the analysis of the product showed phenyl migrations of 20 and 14% respectively. It is considered that the reaction proceeds through the process described in Scheme 1, that the migratory aptitude of the 1-methyl-2-phenylethenyl group is somewhat larger than that of the 2-phenylethenyl group, and that the migratory ability of the 2-phenylethenyl group is about three times that of the phenyl group.

Meanwhile, it has been reported by Wenkert and Rubin[5] that $\alpha$-phenyl-$\alpha, \beta$-unsaturated

Scheme 1

Scheme 2

ketone reacted with peroxyacetic acid to give a mixture consisting mainly of compounds I and II.

This indicates that the methyl group migrates exclusively. To confirm this point, the proxybenzoic acid oxidation of 3,4-diphenyl-3-buten-2-one was carried out. The hydrolysis of the peracid oxidation products gave desoxybenzoin as a main product, plus small amounts of bezoin, benzaldehyde and benzoic acid. On the other hand, the peroxybenzoic acid oxidation of methyl $\alpha$-phenyl cinnamate gave neither benzoin nor desoxybenzoin. These results show that the reaction proceeds through the process described in Scheme 2 and that the unsaturated group migrates exclusively.

These results indicate that the unsaturated group migrates exclusively as compared to the methyl group, that the migratory aptitude of the 2-phenylethenyl group is about three times that of the phenyl group, and that the more bulky groups migrate favorably. These results and the kinetic results*2 (the rate of the peroxybenzoic acid oxidation of 4-phenyl-3-buten-2-one was $2\times10^2$ faster than that of acetophenone) suggest that the favored transition state involves the participation of the carbon-carbon double bond.

*2 The kinetic studies are now in progress.

## Experimental*3

**Materials.**—*1, 3-Diphenyl-2-propen-1-one* was prepared from benzaldehyde and acetophenone according to the procedure of Kohler and Chadwell[6]; m. p. 56—57°C.

*2-Methyl-1, 3-diphenyl-2-propen-1-one* was prepared from benzaldehyde and propiophenone according to a procedure similar to the above one. B. p. 173—174°C/3 mmHg.

*3, 4-Diphenyl-3-buten-2-one* was prepared from benzaldehyde, phenylacetone, benzene and piperidine with a Dean and Stark distillation apparatus according to the procedure of Zimmerman, Singer and Thyagarajan.[7] B. p. 162—163°C/3 mmHg, m. p. 55—56°C.

**The Peroxybenzoic Acid Oxidation of 1, 3-Diphenyl-2-propen-1-one.**—10.69 g. (0.0514 mol.) of the ketone was added to a chloroform solution

*3 All melting points are uncorrected.

containing 0.0624 mol. of peroxybenzoic acid. The reaction mixture was swirled at intervals and then kept for 45 hr. in a thermostat maintained at 25°C. The reaction mixture was then extracted with an aqueous sodium bicarbonate solution in order to remove acids; then it was extracted with water. The aqueous phase was combined and extracted with ether. The ethereal layer was combined with the chloroform solution and dried over anhydrous sodium sulfate. After the solvent had been removed under reduced pressure, the residue was hydrolyzed by refluxing it for 10 hr. with 15% sulfuric acid and the hydrolysate was extracted with ether in a continuous extraction apparatus for 10 hr. The ethereal solution was shaken with a 15% sodium hydroxide solution and distilled under reduced pressure. The following fractions were obtained:

Fraction I: 1.64 g., b. p. 41—48°C/3 mmHg
Fraction II: 5.99 g., b. p. 159—187°C/3 mmHg
Residue: 1.62 g.

Fraction I was benzaldehyde (0.0155 mol.), identified as its 2,4-dinitrophenylhydrazone, m. p. 236 237°C; when it was mixed with an authentic sample, its melting point was not depressed.

Fraction II was the recovered ketone (0.0288 mol.); melting point and mixed melting point with an authentic sample, 54—55°C after recrystallization from ethyl acetate and petroleum ether.

To the alkaline solution dilute hydrochloric acid was added until a small amount of precipitate appeared, and then sodium bicarbonate was added. The mixture was then shaken violently and extracted with ether 10 hr. in a continuous extraction apparatus. The removal of the solvent gave 0.43 g. (0.0047 mol.) of phenol, which was then converted to tribromophenol (m. p. 87—89°C, melting point and mixed melting point with an authentic sample, 94—95°C after recrystallization from ethanol). To the aqueous solution, concentrated hydrochloric acid was added and then extracted with ether. The ethereal extracts were dried over anhydrous sodium sulfate. After the removal of the solvent, 1.89 g. (0.0155 mol.) of benzoic acid was obtained. The ratio of phenol to the reacted ketone, which corresponds to the extent of phenyl migration, was 20.8%. The repetition of the experiment showed a 21.3% phenyl migration.

The ester content in the products was analyzed by a saponification test. Thus, 0.576 g. of the peracid oxidation product mixture was stirred with 50 ml. of a 0.096 N sodium hydroxide solution for 20 hr. at room temperature, and then the excess alkali was back-titrated with 0.102 N hydrochloric acid. 11.9 ml. of the alkaline solution was consumed. It was ascertained that the starting ketone and 2,3-epoxy-1,3-diphenyl-2-propen-1-one consumed only 0.3 ml. and 0.5 ml. of the alkaline solution, respectively, under the same conditions. These results indicate that the product mixture was exclusively made up of the epoxy ester (0.0012 mol.) and the starting ketone (0.0013 mol.).

**The Peroxybenzoic Acid Oxidation of 1,3-Diphenyl-2-methyl-2-propen-1-one.**—15.81 g. (0.071 mol.) of the ketone was treated with peroxybenzoic acid (0.0763 mol.) at 25°C for 118 hr. When the reaction product was then treated as above, 1.98 g. (0.0187 mol.) of benzaldehyde and 8.66 g. (0.0389 mol.) of the recovered ketone were obtained from the neutral fraction. From the acidic fraction, 3.08 g. (0.0253 mol.) of benzoic acid and 0.49 g. (0.00477 mol.) of phenol were obtained. The yield of phenol based on the reacted ketone was 14.3%; the extent of phenyl migration was estimated to be 14.3%. The repetition of the experiment showed 13.6%.

**The Peroxybenzoic Acid Oxidation of 3,4-Diphenyl-3-buten-2-one.** — 13.380 g. (0.060 mol.) of the ketone was treated with peroxybenzoic acid (0.0712 mol.) at 27°C. From the acidic fraction of the hydrolysate, 0.854 g. (0.007 mol.) of benzoic acid was obtained. From the neutral fraction, the following fractions were obtained.

Fraction I: 1.353 g., b. p. ~110°C
Fraction II: 0.216 g., b. p. 52—57°C/6 mmHg
Fraction III: 10.110 g., b.p. 162—182°C/6 mmHg
Residue: 0.844 g.

Fraction II was benzaldehyde (0.002 mol.) identified as its 2,4-dinitrophenylhydrazone; a mixed melting point determination with an authentic sample showed no depression. From fraction III, crystals of benzoin (1.74 g.) were separated; melting point and mixed melting point with an authentic sample, 131—132°C after recrystallization from ethanol. The 2,4-Dinitrophenylhydrazone of the liquid part was fractionally crystallized from ethyl acetate and an orange yellow crystal (m. p. 198—199°C) was obtained. This was identified with the 2,4-dinitrophenylhydrazone of desoxybenzoin on the basis of a mixed melting point determination. From the mother liquor, small amounts of red crystals (m. p. 200—201°C) were obtained. A mixed melting point determination with the 2,4-dinitrophenylhydrazone of the starting ketone gave no depression. It was shown that the neutral fraction was made up of 1.74 g. (0.0082 mol.) of benzoin, 8.37 g. (0.043 mol.) of desoxybenzoin, 0.22 g. (0.002 mol.) of benzaldehyde, 0.85 g. (0.007 mol.) of benzoic acid, and a small amount of the recovered ketone.

The authors wish to express their thanks to Professor Yasuhide Yukawa of Osaka University for his helpful advice and kind encouragement. We are also grateful to Miss Shizuko Kuriyama for her helpful assistance.

# The Peracid Oxidation of Ketones. IV. The Peroxybonzoic Acid Oxidation of Cyclopentenone Derivatives*

By Tai YOKOYAMA and Noriaki IZUI

(Received January 22, 1965)

In the preceding paper,[1] the peracid oxidations of 4-phenyl-3-buten-2-one and its 3-substituted derivatives, and of 1, 3-diphenyl-2-propen-1-one and its 2-methyl derivative, were carried out. It was found that the unsaturated group migrated exclusively as compared to the methyl group, that the migratory aptitude of the 2-phenylethenyl group was about three times that of the phenyl group, and that the more bulky group migrated favorably.

In the present paper, the peroxybonzoic acid oxidation of the cyclic $\alpha$, $\beta$-unsaturated ketone was studied. The peracid oxidation of cyclic $\alpha$, $\beta$-unsaturated ketone has not been studied except for one example[2] of the trifluoroperoxyacetic acid oxidation of 2-cyclopentenone, which gave 2-hydroxyadipic acid. In this paper, the peroxybenzoic acid oxidation of 3-phenyl- and 2, 3-diphenyl-2-cyclopentenone was carried out. The acid obtained from the alkaline extract of the oxidation product was polymeric, and its crystalline derivatives could not be obtained. After the oxidation product had been esterified, the ester was hydrolyzed with dilute alkali at room temperature; the crystalline acid could thus be obtained in a 50% yield. This acid showed a m. p. of 115—116°C after recrystallization from petroleum ether and ethyl acetate. This acid and its *S*-benzylisothiouronium salt (m. p. 130—130.5°C) have the compositions of $C_{10}H_{10}O_3$ and $C_{18}H_{20}O_3N_2S$ respectively; the acid was found in a mixed meltlng point determination to be identical with $\beta$-benzoylpropionic acid.

From the alkaline extract of the peracid oxidation product of 2, 3-diphenyl-2-cyclopentenone, the acid A (m. p. 121.5—122°C) was obtained in a nearly quantitative yield, as based on the reacted ketone. The oxidation of A with potassium permanganate gave $\beta$-benzoylpropionic acid. The reduction of A with hydroiodic acid gave an acid with a m. p. of 134—135°C. Its methyl ester was identical in melting point and in mixed melting point with methyl $\gamma$-benzoyl-$\gamma$-phenylbutyrate prepared from desoxybenzoin, methyl acrylate and sodium ethoxide according to the procedure of Bertocchio and Dreux.[5]

It is considered that the peracid oxidation of 3-phenyl- and 2, 3-diphenyl-2-cyclopentenone proceeds through the process described in Fig. 1.

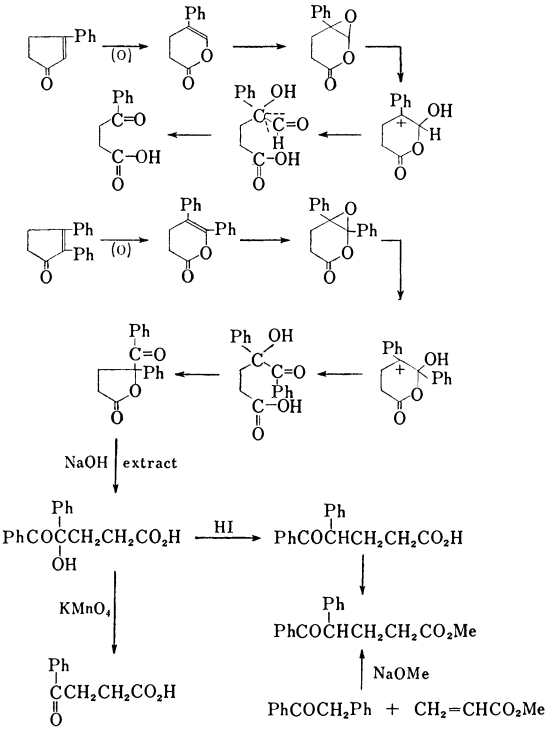

Fig. 1

These results can be explained as follows. In the favored transition state of the peracid rearrangement of cyclic $\alpha$, $\beta$-unsaturated ketone, the ring has a stable half-chair conformation, and the carbon-carbon double bond participate in the oxygen-oxygen fission (Fig. 2).

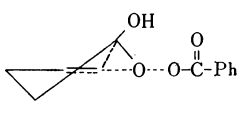

Fig. 2

* Presented at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

2) E. E. Smissman and F. B. Block, *J. Am. Pharm. Assoc. Sci. Ed.*, Vol. XLVIII, No. 9, 526 (1959).

## Experimental**

**Materials.**—*3-Phenyl-2-cyclopentenone* was prepared from 2% sodium hydroxide and ethyl α-phenacyl acetoacetate, which in turn had been prepared from phenacyl bromide and ethyl acetoacetate according to the procedure of Borsche and Fels;[3] m. p. 82.5—83°C (recrystallized from ethyl acetate and petroleum ether).

*2,3-Diphenyl-2-cyclopentenone* was obtained from 2% sodium hydroxide and ethyl α-phenyl-α-phenacylacetoacetate, which had been prepared from ethyl α-phenacylacetoacetate, phenacyl bromide and sodium in ether according to the procedure of Borsche and Klein.[4] M. p. 94—95°C.

**The Peroxybenzoic Acid Oxidation of 3-Phenyl-2-cyclopentenone.**—a) Ten grams of the ketone was added to a chloroform solution of peroxybenzoic acid and kept for 45 hr. at 25°C. The reaction mixture was then extracted with sodium bicarbonate solution in order to remove acids, and then it was extracted with water. The aqueous layer was combined and extracted with ether. The ethereal layer was combined with the chloroform solution and extracted with a 5% sodium hydroxide solution. When the neutral solution remaining after the sodium hydroxide extraction was evaporated, 4.8 g. of a crystalline solid was obtained. This was recovered ketone (0.03 mol.); melting point and mixed melting point with an authentic sample, 82—83°C after recrystallization from ethyl acetate and petroleum ether. The basic extracts were acidified with concentrated hydrochloric acid and extracted with ether. After the removal of the ether, 3.8 g. of an acid was obtained. This was again dissolved in ether and extracted with a sodium bicarbonate solution. From the basic extracts, 2.1 g. of an acid was obtained. This acid was a brown, viscous oil; no crystalline derivatives could be obtained.

b) 25.01 g. (0.158 mol.) of the ketone was treated with peroxybenzoic acid (0.233 mol.) at 28°C. The reaction mixture was extracted with a sodium bicarbonate solution, and then with water. The aqueous phase was combined and extracted with ether. The ethereal layer was combined with the chloroform solution and dried over anhydrous sodium sulfate. After the solvent had been removed the residual oil was refluxed 8 hr. with 240 ml. of ethanol and 12 ml. of concentrated sulfuric acid. The reaction mixture was then extracted with ether. The ethereal solution was extracted with a sodium bicarbonate solution, and the ethereal layer was dried over anhydrous sodium sulfate. The solvent was then removed, and the residue was distilled under reduced pressure. The following fractions were obtained:

Fraction I: 36.689 g., b. p. 90—100°C/20 mmHg
Fraction II: 17.411 g., b. p. 132—197°C/4 mmHg
Residue: 6.90 g.

Fraction I was ethyl benzoate. Fraction II was stirred for 2.5 hr. with 100 ml. of a 10% sodium hydroxide solution at room temperature and then the hydrolysate was extracted with ether. From the ethereal layer, the recovered ketone was obtained, (2.592 g. 0.0164 mol.). The aqueous layer was acidified with concentrated hydrochloric acid and extracted with ether. After the removal of the ether, 11.003 g. of an acid was obtained, m. p. 115—116°C. The infrared spectrum of this acid showed no band in the 3000—4000 $cm^{-1}$ region originating in the hydroxyl group.

Found for this acid: C, 66.88; H, 5.53. Calcd. for $C_{10}H_{10}O_3$: C, 67.40; H, 5.66%.

*S*-Benzylisothiouronium salt of this acid, m. p. 130—130.5°C.

Found: C, 63.28; H, 5.64. Calcd. for $C_{18}H_{20}O_3N_2S$: C, 62.80; H, 5.81%.

From these results, this acid was confirmed to be β-benzoylpropionic acid; identification was established by a mixed melting point determination with an authentic sample. The yield of β-benzoylpropionic acid was 50% on the basis of the reacted ketone.

**The Peroxybenzoic Acid Oxidation of 2,3-Diphenyl-2-cyclopentenone.**—24.59 g. (0.105 mol.) of the ketone was added to 0.14 mol. of peroxybenzoic acid at 28°C for 24 hr. After the acids had been removed with sodium bicarbonate, 30.76 g. of a crude reaction product was obtained. This was dissolved in ether and extracted with a 10% sodium hydroxide solution. From the ethereal solution after the sodium hydroxide extraction, 13.016 g. (0.0556 mol.) of the recovered ketone was obtained. To the basic extracts, concentrated hydrochloric acid was added and then extracted with ether. The ethereal solution was extracted with the sodium bicarbonate solution. From the ethereal solution after the sodium bicarbonate extraction, 1.73 g. of an oil was obtained. The morpholide of this oil showed a m. p. of 188—188.5°C and showed no depression on a mixed melting point determination with the morpholide of the crude oxidation product. It was confirmed that this oil was the lactone of the acid A and that the peracid oxidation product contained this lactone.

To the sodium bicarbonate extracts, concentrated hydrochloric acid was added and then extracted with ether. After the removal of the ether, 12.088 g. of an acid A was obtained (m. p. 121.5—122°C, recrystallized from ethyl acetate and petroleum ether). This acid showed an infrared absorption band at 3450 $cm^{-1}$ (OH) and gave a benzoyl derivative, m. p. 40—41.5°C. The oxidation of A with potassium permanganate in an acidic media gave an acid, m. p. 115—116°C, a mixed melting point determination with β-benzoylpropionic acid showed no depression. To the acid A, was added an excess of 57% hydroiodic acid; this mixture was then refluxed for one hour under a constant stream of dry nitrogen. The mixture was then dissolved in ether and dried. The removal of the solvent gave an acid, m. p. 134—134.5°C; its methyl ester had a m. p. of 60—61.5°C. This methyl ester was methyl γ-benzoyl-γ-phenylbutyrate; identification was made by means of a mixed melting point determination with an authentic sample which had been prepared from methyl acrylate, desoxybenzoin and sodium ethoxide according to the procedure of

** All melting points are uncorrected.

Bertocchio and Dreux.[5] The acid A also showed no depression on admixture with an authentic specimen. The yield of A was 86% and that of the lactone of A was 12% on the basis of the reacted ketone.

The authors wish to express their deep thanks to Professor Yasuhide Yukawa of Osaka University for his helpful suggestions and kind encouragement throughout this work. The authors also wish to thank Dr. Toshikazu Ibata and Miss Kayo Kabazawa of the Institute of Science and Industrial Research of Osaka University for their measurements of infrared spectra, and Dr. Noboru Takabayashi of Toyama University for his elementary analysis. # Oxidation of Alcohols with *t*-Butyl Chromate. III. The Oxidation of Alicyclic Alcohols*1

By Takayuki SUGA and Tamon MATSUURA

(Received January 26, 1965)

The previous papers[2,3] of this series have shown that the *t*-butyl chromate oxidation of the primary alcohol with an olefinic double bond or a phenyl group adjacent to a carbinol carbon gave the corresponding aldehyde, but did not produce the ester, and that the oxidation of the alcohol without these functional groups produced a mixture of the corresponding ester, aldehyde and acid. We have now attempted the *t*-butyl chromate oxidation of primary alicyclic alcohols, a secondary alicyclic alcohol and cyclic $\alpha$-glycols as an extension of our study of the oxidation of alcohols.[2,3]

**The Oxidation of Primary Alicyclic Alcohol.**—The oxidation of cyclohexylcarbinol (Exp. 1) at 1—2°C for 6 hr. with a benzene solution of *t*-butyl chromate prepared in the 1 : 1 mole ratio of the alcohol to this chromate gave the corresponding aldehyde (40% yield based on the alcohol), acid (28%) and ester, i. e., cyclohexylcarbinyl cyclohexanecarboxylate (19%). This oxidation is in contrast to that of benzyl alcohol,[3] which gave no ester but did give the corresponding aldehyde. The reason for the difference between these oxidations will be discussed in Part IV. The oxidation of myrtenol (Exp. 2) under the same conditions as in Exp. 1 produced no ester but did give the corresponding aldehyde (66%) and acid (5%). This finding agrees with those obtained in the oxidation of geraniol,[2] benzyl alcohol,[3] and *trans*-cinnamyl alcohol.[3]

**The Oxidation of Secondary Alicyclic Alcohol and Cyclic $\alpha$-Glycol.**—The oxidation of cyclohexanol at 35°C for 6 hr. with the oxidant solution prepared in the 1 : 3 mole ratio of the alcohol to the oxidant gave only the corresponding ketone (85%) (Exp. 3), but the oxidation for 48 hr. produced the cleavage product, adipic acid (7%), together with the ketone (68%) (Exp. 4). The oxidation of cyclohexane-*trans*-1, 2-diol*2 at 35°C for 3.5 hr. (Exp. 5) afforded no corresponding diketone, but it did afford adipic acid (57%) and a cyclic ester, *trans*-1, 2-adipoxycyclohexane (I) (7%).

(I)

*1 The oxidation of cyclohexanol and cyclohexane-*trans*-1, 2-diol, which composes a part of the present work, has been reported in Ref. 1 by one of the present authors. The other part was presented at the 4th Symposium on Perfume, Terpene and Essential Oil Chemistry of the Chemical Society of Japan, Sapporo, July, 1960.

1) T. Suga, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **80**, 918 (1959).

2) T. Suga, K. Kihara and T. Matsuura, This Bulletin, **38**, 893 (1959).

3) T. Suga, K. Kihara and T. Matsuura, ibid., **38**, 1141 (1965).

*2 L. P. Kuhn (Ref. 4) showed the two hydroxyl groups to be in the equatorial orientation.

4) L. P. Kuhn, *J. Am. Chem. Soc.*, **74**, 2492 (1952).

That the corresponding diketone was not obtained may be explained as being because this diketone, produced transiently, was immediately subjected to an oxidative fission to yield adipic acid. The formation of the ester (I) has not yet been reported in the oxidation of this diol; the mechanism will be discussed in Part IV. The oxidation of *p*-menthane-*trans*-3, 4-diol*[3] at 30°C for three different reaction times and with the oxidant prepared in the 1 : 1 mole ratio, as in Exps. 1 and 2, gave only the corresponding hydroxyketone (47, 60 and 63% in Exps. 6, 7 and 8 respectively). As regards the cyclic $\alpha$-glycol with a secondary and a tertiary hydroxyl group, a secondary hydroxyl group was oxidized to a ketone group, and only the corresponding hydroxyketone was formed, in contrast to the oxidation of cyclohexane-*trans*-1, 2-diol.

## Experimental

**Samples.** — Cyclohexylcarbinol was synthesized from cyclohexyl bromide and formaldehyde according to the known method[6]: b. p. 91.8°C/23.5 mmHg. Myrtenol was prepared by the oxidation of $\alpha$-pinene with selenium dioxide in a solvent of *t*-butyl alcohol according to the work[7] performed by one of the present authors: b. p. 96°C/9 mmHg. Cyclohexanol was obtained from a commercial source: b. p. 160—161°C. Cyclohexane-*trans*-1, 2-diol[8] (m. p. 103—104°C) and (+)-*p*-menthane-*trans*-3, 4-diol[5,9] (m. p. 76.5—77°C; $[\alpha]_D^{25}$ +27.5°, *c*, 1 in methanol) were prepared by the hydroxylation of cyclohexene and (+)-*p*-menth-3-ene respectively with performic acid. All the samples were purified by distillation or recrystallization just before use.

**The Oxidation, and the Treatment of a Reaction Mixture.**—A benzene solution of *t*-butyl chromate was prepared in the same manner as used in a preceding paper.[2] In Table I, the quantity of each component and the concentration of *t*-butyl chromate in this benzene solution are shown, together with the quantity of the sample alcohol and its solvent. After the oxidation was carried out under the conditions described above in a manner similar to that described in Ref. 2, the reaction mixture was treated with oxalic acid and water, as has also been shown in Ref. 2. The separated benzene solution containing a reaction product was subjected to the described examinations in each experiment. Each of the constituents of the reaction product was identified by a comparison of its infrared spectrum with that of an authentic sample and by a mixed melting point determination of a constituent or its crystalline derivatives; the yield of the constituents is shown above. Liquid-column chromatographic separation was made on a silica gel with a mixture of ethyl acetate and *n*-hexane.

**The Oxidation of Cyclohexylcarbinol (Exp. 1).** —The removal of the solvent from the separated benzene solution gave a reaction product (30.1 g.). The distillation of the reaction product gave cyclohexylaldehyde (b. p. 60—62°C/26.5 mmHg; $\nu_{aldehyde}^{liq.}$

Table I. The weights of the alcohol used and each component in the oxidant, and conditions of the oxidation

9) Y.-R. Naves, *Helv. Chim. Acta*, 42, 1174 (1959).

2857, 2810, 2707, 1725, 955 $cm^{-1}$; 2,4-dinitrophenylhydrazone, m. p. 173—174°C), cyclohexanecarboxylic acid (b. p. 103—108°C/7 mmHg, m. p. 30.5—31.5°C, acid number, 436) and cyclohexylcarbinyl cyclohexanecarboxylate (b. p. 136—137°C/7 mmHg, $n_D^{25}$ 1.4727, $d_4^{25}$ 0.9763; $\nu_{ester}^{liq.}$ 1736, 1173 $cm^{-1}$); no original alcohol remained. The hydrolysis of the ester afforded cyclohexylcarbinol (its phenylurethane, m. p. 81.8—82.2°C) and cyclohexanecarboxylic acid (m. p. 30—31°C).

**The Oxidation of Myrtenol (Exp. 2).** — The separated benzene solution was extracted with a sufficient volume of a 3% sodium bicarbonate solution, which then gave myrtenic acid ($\nu^{liq.}$ a broad band of 2700—3500, 1686, 1424, 1270, 949 (COOH), 1623, 841 (trisubstd. C=C) $cm^{-1}$) on acidification. The removal of the solvent from the neutral benzene solution gave a neutral product (6.3 g.). The liquid-column chromatography of the neutral product gave myrtenal (b. p. 84—87°C/9 mmHg; $\nu_{aldehyde}^{liq.}$ 2816, 2733, 1682 $cm^{-1}$; 2,4-dinitrophenylhydrazone, m. p. 217—218°C), unchanged alcohol ($\nu_{OH}^{liq.}$ 3374, 1014 $cm^{-1}$; 3% yield), and a resinous substance (9%), probably a polymer.

**The Oxidation of Cyclohexanol (Exps. 3 and 4).** —The separated benzene solution was treated as in Exp. 2. The product (b. p. 153—155°C) obtained from the neutral benzene solution was then examined by infrared spectroscopy and chromatostrip chromatography,[10] while cyclohexanone was estimated by the 2,4-dinitrophenylhydrazine method.[11] The sodium bicarbonate extracts were combined with the aqueous solution used for hydrolyzing the residual oxidant. Adipic acid (m. p. 151—152°C) was obtained by extracting the combined solution with ether after acidification. No original alcohol remained in either experiment.

**The Oxidation of Cyclohexane-*trans*-1,2-diol (Exp. 5).**—The removal of the solvent from the separated benzene solution gave a viscous, neutral product (6.1 g.) and adipic acid (m. p. 151—152°C), which was also obtained from the aqueous solution used for hydrolyzing the residual oxidant (cf. Exps. 3 and 4). The neutral product deposited a crystalline mass (2.2 g.; m. p. 125—125.5°C; $\nu_{ester}^{KBr}$ 1733, 1271, 1155 $cm^{-1}$).

Found: C, 63.44; H, 8.29; ester number, 247.8. Calcd. for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%; ester number, 248.0.

The hydrolysis of the crystalline ester gave, quantitatively, cyclohexane-*trans*-1,2-diol (m. p. 103—104°C) and adipic acid (m. p. 151—152°C). Therefore, the ester was confirmed to be *trans*-1,2-adipoxycyclohexane (I).

No cyclohexane-1,2-dione was detected, and the other, resinous part of the neutral product looked like a polymer.

**The Oxidation of (+)-*p*-Menthane-*trans*-3,4-diol (Exps. 6—8).**—The separated benzene solution was treated in the same manner as in Exp. 2. The sodium bicarbonate extracts did not give any reaction product. The liquid-column chromatography of the reaction product obtained from the neutral benzene solution gave (−)-4-hydroxymenthone (b. p. 104—105°C/13 mmHg; $[\alpha]_D^{25}$ −96.7° (neat); $\nu^{liq.}$ 3493, 1154 (OH), 1709 (C=O), 1430 ($-CH_2-CO-$) $cm^{-1}$; 2,4-dinitrophenylhydrazone, m. p. 102.5—103°C; Found: N, 15.73. $C_{16}H_{22}O_5N_4$ requires N, 15.99%). (−)-4-Hydroxymenthone 2,4-dinitrophenylhydrazone was produced on treating the keto alcohol with a 2 N hydrochloric acid solution of 2,4-dinitrophenylhydrazine. On the other hand, the treatment of the keto alcohol with an ethanol-sulfuric acid solution of 2,4-dinitrophenylhydrazine gave (±)-*p*-menth-3-en-5-one 2,4-dinitrophenylhydrazone (m. p. 147.5—148.5°C).

## Summary

1) The *t*-butyl chromate oxidation of myrtenol gave no ester, but it did give the corresponding aldehyde as the main product, while the oxidation of cyclohexylcarbinol gave a mixture of the corresponding aldehyde, acid and ester in comparable yields.

2) A similar oxidation of cyclohexanol afforded the corresponding ketone in a high yield, while the oxidation of cyclohexane-*trans*-1,2-diol produced no corresponding diketone, but it did produce the glycol fission product and a cyclic ester such as *trans*-1,2-adipoxycyclohexane (a new compound). On the other hand, *p*-menthane-*trans*-3,4-diol yielded only the corresponding hydroxyketone in a good yield.

# Cobalt(II) Complexes of Schiff Bases Derived from Salicylaldehyde and Aromatic Amines[1]

By Hiroaki NISHIKAWA and Shoichiro YAMADA

(Received January 26, 1965)

The preparation and the configuration of cobalt complexes of Schiff bases derived from salicylaldehyde and alkyl amines have been described in previous papers.[2] On the other hand, there have also been a comparatively large number of papers available about cobalt complexes of *N*-aryl-salicylideneimines.[3] As a conclusion of the previous studies, it has generally been postulated that quadri-co-ordinate cobalt(II) complexes do not exist with Schiff bases which have substituents on the ortho-carbon atom in Fig. 1. In fact, bis-(*N*-*o*-methoxyphenyl-salicylideneiminato)-cobalt(II) was synthesized, but its formation

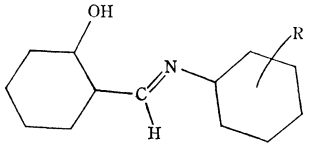

Fig. 1. *N*-Aryl-salicylideneimine.

was regarded as due to stabilization through the sexa-co-ordination attained by the additional linkage of the oxygen atoms of the methoxy groups with the cobalt(II) ion.[3] The present authors have recently succeeded in preparing several cobalt(II) complexes with Schiff bases which have substituents on the *o*-carbon atom. In the present paper the syntheses of bis(*N*-aryl-salicylideneiminato)cobalt-(II) complexes will be described, and the configurations of these complexes will be examined on the basis of the results of the preceding papers.

## Experimental

**Meterials.** — Salicylideneiminato-cobalt(II) complexes with *N*-*o*-substituted aryl groups were generally prepared in the following way. A yellow powder of $Co(sal)_2 \cdot 2H_2O$ was mixed with an excess (1.5 to 4.5 times the theoretical amount) of one of the amines to yield orange-colored paste; the notation "*sal*" denotes an anion which is formed when a molecule of salicylaldehyde loses a proton. A suitable organic solvent was boiled in another flask until the flask was filled with its vapor above the liquid phase. The paste of the mixture was then placed into the flask, and immediately the flask was closed tightly. The reaction was continued at a temperature just below the boiling point of the solvent. The period required for the reaction varied depending upon the amine used. After the reaction was over, the solution was cooled very slowly. The solution underwent oxidation when the temperature was appreciably higher than room temperature.

For the preparation of bis(*N*-*o*-tolylsalicylideneiminato)cobalt(II), $Co(sal)_2 \cdot 2H_2O$ (1.0 g.) and *o*-toluidine (3.0 g.) were used as the starting materials and ethanol (30 ml.) as a solvent. The general method described above was followed. After the flask had been closed tightly, the reaction was continued for about fifteen minutes at 70°C to 75°C; then the solution was allowed to stand until its temperature went down to room temperature. After it had been kept for a day or two at −15°C, the compound was obtained in deep-red, hexagonal plates.

Found: C, 69.9; H, 5.08; N, 5.92. Calcd. for $C_{28}H_{24}N_2O_2Co$: C, 70.2; H, 5.05; N, 5.84%.

For the preparation of bis(*N*-*o*, *m*-xylidyl-salicylideneiminato)cobalt(II), $Co(sal)_2 \cdot 2H_2O$ (1.0 g.) and *o*, *m*-xylidine (1.2 ml.) were used as the starting materials and methanol (22 ml.) as a solvent. After the flask had been closed tightly, the reaction was continued for about four hours at 60°C. Then the solution was allowed to cool slowly to −15°C. After the solution had been kept at −15°C for three days, the deep-red needles which separated out were collected.

Found: C, 70.7; H, 5.53; N, 5.86. Calcd. for $C_{30}H_{28}N_2O_2Co$: C, 71.0; H, 5.56; N, 5.52%.

For the preparation of bis(*N*-*o*, *o'*-xylidyl-salicylideneiminato)cobalt(II), $Co(sal)_2 \cdot 2H_2O$ (1.0 g.) and *o*, *o'*-xylidine (1.4 g.) were used as the starting materials and methanol (40 ml.) as a solvent. The reaction was continued for several hours at 60°C. Then the orange powder of $Co(sal)_2 \cdot 2H_2O$ was completely dissolved, giving a bright red solution. The reaction was then continued for several more hours until the red crystals started to separate out. Then the solution was cooled to 15°C, and the red crystals of the product were collected. The compound was also synthesized by the reaction of

theoretical amounts of cobalt(II) acetate tetrahydrate, *o*, *o'*-xylidine, salicylaldehyde and sodium hydrogencarbonate in ethanol, stirring the solution for about four hours at room temperature. Recrystallization from methanol yielded pure crystals of the product.

Found: C, 71.1; H, 5.52; N, 5.22. Calcd. for $C_{30}H_{28}N_2O_2Co$: C, 71.0; H, 5.56; N, 5.52%.

For the preparation of bis(*N*-*α*-naphthyl-salicylideneiminato)cobalt(II), $Co(sal)_2 \cdot 2H_2O$ (1.0 g.) and *α*-naphthyl amine were used as the starting materials and methanol as a solvent. After the flask had been closed tightly, the reaction was continued. As the orange powder of $Co(sal)_2 \cdot 2H_2O$ was dissolved, red crystals started to separate out. The flask was cooled very slowly to room temperature.

Found: C, 73.6; H, 4.36; N, 4.96. Calcd. for $C_{34}H_{24}N_2O_2Co$; C, 74.0; H, 4.39; N, 5.08%.

For the preparation of bis(*N*-*o*-chlorophenyl-salicylideneiminato)cobalt(II), $Co(sal)_2 \cdot 2H_2O$ (1.0 g.) and *o*-chloroaniline (3.3 g.) were used as the starting materials and ethanol (45 ml.) as a solvent. After the flask had been closed, the reaction was continued for four hours at 70°C to 75°C. The flask was cooled to room temperature, and the solution was kept at −15°C for one day, A brownish black mass was obtained. By extracting the mass with pyridine, orange-yellow crystals of $Co(O \cdot C_6H_4 \cdot CH : N \cdot o\text{-}Cl \cdot C_6H_4)_2 \cdot 2py$ were obtained.

Found: C, 63.5; H, 4.31; N, 8.51; Cl, 10.21. Calcd. for $C_{36}H_{28}N_4O_2Cl_2Co$: C, 63.7; H, 4.16; N, 8.26; Cl, 10.5%.

After the pyridine adduct had been left at 70°C in vacuo for several hours, an orange-yellow powder of bis(*N*-*o*-chlorophenyl-salicylideneiminato)cobalt-(II) was obtained.

Found: C, 60.3; H, 3.61; N, 5.22. Calcd. for $C_{26}H_{18}N_2O_2Cl_2Co$: C, 60.0; H, 3.49; N, 5.38%.

For the preparation of bis(*o*, *p*, *o'*-trichlorophenyl-salicylideneiminato)cobalt(II), a theoretical amount of potassium metal (0.8 g.) dissolved in ethanol (10 ml.) was stirred into a solution of cobalt acetate tetrahydrate (2.5 g.) and *N*-*o*, *p*, *o'*-trichlorophenyl-salicylideneimine (6.2 g.) in lukewarm ethanol (25 ml.). The vessel was then tightly closed and left to stand for a day at −15°C. The orange powder which sparated out was collected by filtration and washed with ether. The compound was soluble in chloroform and benzene.

Found: C, 47.5; H, 2.45; N, 4.15. Calcd. for $C_{26}H_{14}N_2O_2Cl_6Co$: C, 47.5; H, 2.14; N, 4.26%.

For the preparation of bis(*o*, *p*, *o'*-tribromophenyl-salicylideneiminato)cobalt(II), salicylaldehyde (4.9 g.) and tribromoaniline (13.2 g.) were refluxed for two hours in 150 ml. of amyl alcohol. Then piperidine (4.0 g.) and cobalt acetate tetrahydrate (4.9 g.) were added to the solution, and it was refluxed for about two hours. About 100 ml. of toluene was then added to the solution, and it was refluxed for about ten minutes. After the solution had been gradually evaporated at about 100°C to a volume of about 70 to 80 ml., it was cooled and allowed to stand at −15°C for a few days. The compound was obtained as an orange-red crystalline powder, which was then washed with benzene and chloroform.

Found: C, 33.8; H, 1.66; N, 3.13. Calcd. for $C_{26}H_{14}N_2O_2Br_6Co$: C, 33.6; H, 1.52; N, 3.01%.

Bis(*N*-phenyl-salicylideneiminato)cobalt(II), bis-(*N*-*m*-substituted aryl-salicylideneiminato)cobalt(II) and bis(*N*-*p*-substituted aryl-salicylideneiminato)-cobalt(II) were prepared by the method of West.[3]

All these compounds in the solid state are stable to the atmosphere.

**Measurements.**—The electronic absorption spectra of the compounds in soltuion were determined with a Beckman DU spectrophotometer in the near-infrared, visible and ultraviolet regions. Beer's law was generally obeyed in the concentration range between $10^{-3}$ and $10^{-5}$ mol./l., except for the trichlorophenyl derivative of cobalt(II). Pyridine for a solvent is purified by distillation after having been dried with potassium carbonate.

## Results and Discussion

**Bis(*N*-aryl-salicylideneiminato)cobalt(II).**—It seems to be significant that bis(*N*-*o*-substituted aryl-salicylideneiminato)cobalt(II) complexes were prepared as crystals in this work. It has generally been believed that, because of the serious strain to the tetrahedral co-ordination around the cobalt(II) ion, quadri-co-ordinate cobalt(II) complexes can not be formed with the Schiff bases which are shown as having a substituent on the ortho-carbon atom in Fig. 1. One success in preparing these compounds, however, shows that this is definitely not the case. The preparation of bis(*N*-*o*-tolyl-salicyli-

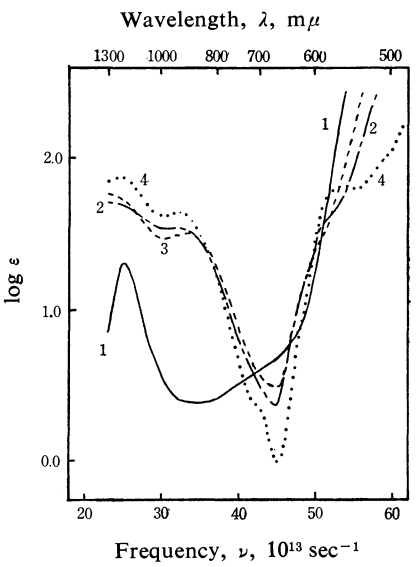

Fig. 2. Electronic absorption spectra of: 1, $Co(O \cdot C_6H_4 \cdot CH : N \cdot CH_2CH_2N : CH \cdot C_6H_4 \cdot O)$ in chloroform (——); 2, $Co(O \cdot C_6H_4 \cdot CH : N \cdot o\text{-}CH_3 \cdot C_6H_4)_2$ in benzene (—·—); 3, $Co(O \cdot C_6H_4 \cdot CH : N \cdot p\text{-}CH_3 \cdot C_6H_4)_2$ in benzene (----); 4, $Co(O \cdot C_6H_4 \cdot CH : N \cdot t\text{-}C_4H_9)_2$ in benzene (·····).

deneiminato)cobalt(II) has also been announced quite recently by West.

As has been shown previously,[2] the electronic absorption spectrum of the cobalt(II) complex depends upon the configuration of the complex, and it may be used diagnostically in the discussion of the configuration of the cobalt(II) complexes. For substituents such as methyl and chloro groups, bis(*N*-*o*-substituted aryl-salicylideneiminato)cobalt(II) complexes in non-co-ordinating solvents (Figs. 2 and 3) all show similar absorption spectra which are different from the spectra characteristic of the planar cobalt(II) complexes,[4] but which bear a close resemblance to the spectra regarded as being characteristic of quadri-co-ordinate, tetrahedral cobalt(II) complexes.[2] It may, therefore, be concluded that all these cobalt(II) complexes take a tetrahedral co-ordination around the cobalt(II) ion. The same configuration may be concluded for the trichlorophenyl- and the tribromophenyl- complexes in non-co-ordinating solvents (Fig. 3), although these complexes were not stable enough for us to determine the exact absorption spectra in solution. When a group attached to N is $\alpha$-naphthyl, the situation is similar to that with the corresponding complex with *o*-substituted phenyl for R; the comparison of the spectra, which are shown in Fig. 2, indicates that bis(*N*-$\alpha$-naphthyl-salicylideneiminato)-cobalt(II) also has a tetrahedral co-ordination.

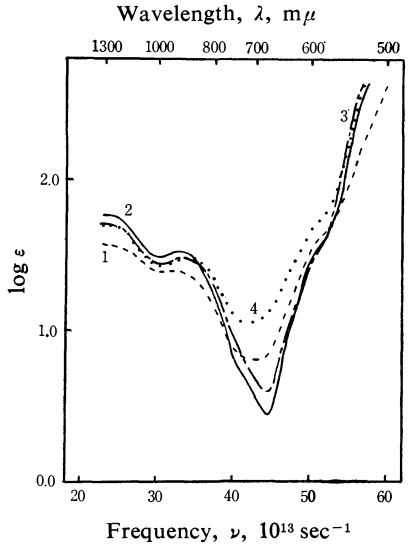

Fig. 3. Electronic absorption spectra of Co(O·$C_6H_4$·CH : N·R)$_2$ in benzene: 1, R=*o*-Cl·$C_6H_4$ (----); 2, R=*m*-$CH_3$·$C_6H_4$ (——); 3, R=*p*-Cl·$C_6H_4$ (—·—); 4, R=*m*-Cl·$C_6H_4$ (……).

4) H. Nishikawa and S. Yamada, This Bulletin, 37, 8 (1964).

Bis(*N*-*m*- and bis(*N*-*p*-substituted aryl-salicylideneiminato)cobalt(II) complexes were concluded previously from magnetic measurements to have a tetrahedral configuration.[3] The electronic absorption spectra examined in this work (Fig. 3) also support this conclusion. The absorption bands at about $24\times10^{13}$ sec$^{-1}$ may be tentatively assigned as a $^4A_2\rightarrow{}^4T_1(F)$ transition in the notation of the $T_d$ field symmetry.

It may be concluded that the co-ordination around the cobalt(II) ion in these compounds is tetrahedral, whether the substituent is on the *o*-, *m*- or *p*-position. It should be noted that the cobalt(II) complexes of the *o*,*o*'-disubstituted and of the mono-substituted ligands have a tetrahedral configuration, while the corresponding compounds of copper(II) and nickel(II) are known to take a planar co-ordination. Thus, it is again found that, in general, a tetrahedral configuration is more favorable for the cobalt(II) complex than for the copper(II) and the nickel(II) complexes, in agreement with the conclusion reached by the simple crystal field theory.

Bis(*N*-*o*-methoxyphenyl-salicylideneiminato)-cobalt(II) shows the ligand field bands at about 33 and $20\times10^{13}$ sec$^{-1}$, as may be seen in Fig. 4. These bands bear a resemblance to those of the other cobalt(II) compounds of the Schiff bases prepared in the present work. A slight difference between the *o*- and the *p*-derivatives, however, is seen in the ligand field bands of the complexes, the bands of the *o*-methoxy-derivative, for instance, being broader

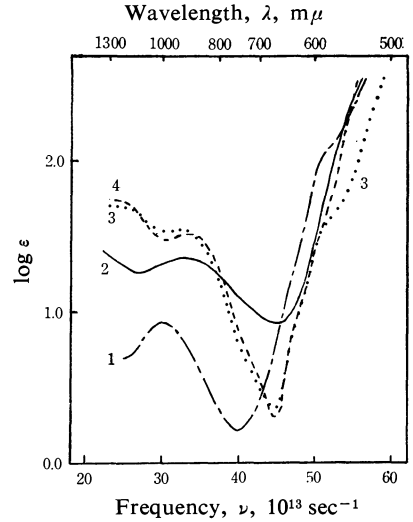

Fig. 4. Electronic absorption spectra of Co(O·$C_6H_4$·CH : N·R)$_2$: 1, R=*o*-$OCH_3$·$C_6H_4$, in pyridine (—·—); 2, R=*o*-$OCH_3$·$C_6H_4$, in chloroform (——); 3, R=*o*-$CH_3$·$C_6H_4$, in benzene (……); 4, R=*p*-$OCH_3$·$C_6H_4$, in benzene (----).

than those of bis(*N*-*p*-methoxyphenyl- as well as those of bis(*N*-*o*-tolyl-salicylideneiminato)-cobalt(II). This fact suggests that the configuration of the cobalt(II) complex with the *o*-methoxyphenyl group is somewhat anomalous compared with those of the other compounds of a similar type, in agreement with the view of West,[3] who postulated a weak interaction between the oxygen atom of the methoxy group and the central cobalt(II) ion. Since the absorption spectrum of the compound, however, is quite different from that of a typical sexa-co-ordinate cobalt(II) compound, the interaction between the oxygen atom and the cobalt(II) ion may not be very strong.

**The Configuration of Bis(*N*-aryl-salicylideneiminato)cobalt(II) Complexes in Pyridine.** — When R represents *m*- and *p*-methyl radicals, the steric condition does not greatly differ from that of the corresponding phenyl compound. The absorption spectra of these complexes (Fig. 5) clearly show that their configurations, which are all tetrahedral in non-donor solvents, are sexa-co-ordinate, octahedral in pyridine.[5] The absorption bands at about 30 and $51.5\times10^{13}$ sec$^{-1}$ may be tentatively identified as $^4T_1\rightarrow{}^4T_2$ and $^4T_1\rightarrow{}^4T_1(P)$ transitions respectively. Judging from the steric condition, it is quite difficult for the two molecules of pyridine to be co-ordinated to the central cobalt(II) ion in the bis(*N*-*o*, *o*'-xylidyl-salicylideneiminato) complex to complete a sexa-co-ordination around the cobalt(II) ion. The absorption spectra of these cobalt(II) complexes in pyridine (Fig. 6) differ definitely, though not greatly, from the spectra of the tetrahedral cobalt(II) complexes. The presence of the sexa-co-ordinate pyridine adduct of this complex may be excluded since (1) the steric factor is quite unfavorable for the octahedral configuration around the cobalt(II) ion, and (2) the absorption curve shows no clear peak in the frequency region, where the octahedral pyridine adduct is expected to absorb. It is, therefore, most likely that the quinque-co-ordinate complex with one molecule of pyridine is present in the pyridine solution. Thus, the inspection of the absorption curve seems to indicate that in the pyridine solution there is an equilibrium consisting of the quadri-co-ordinate, the tetrahedral and the quinque-co-ordinate complexes.[6] Evidence for the existence of the quinque-co-ordinate complex may be afforded by the isolation of the possibly

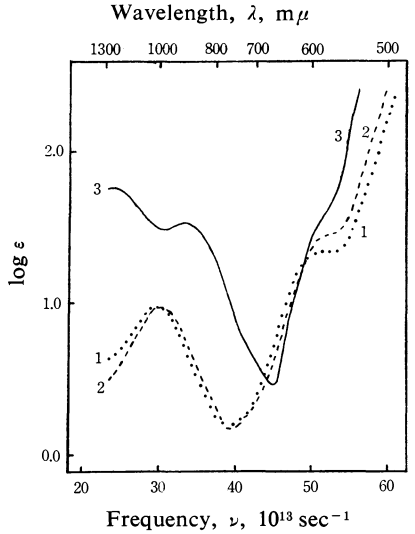

Fig. 5. Electronic absorption spectra of Co(O·$C_6H_4$·CH : N·R)$_2$: 1, R=*o*-$CH_3$·$C_6H_4$, in pyridine (·····); 2, R=*m*-$CH_3$·$C_6H_4$, in pyridine (----); 3, R=*m*-$CH_3$·$C_6H_4$, in benzene (——).

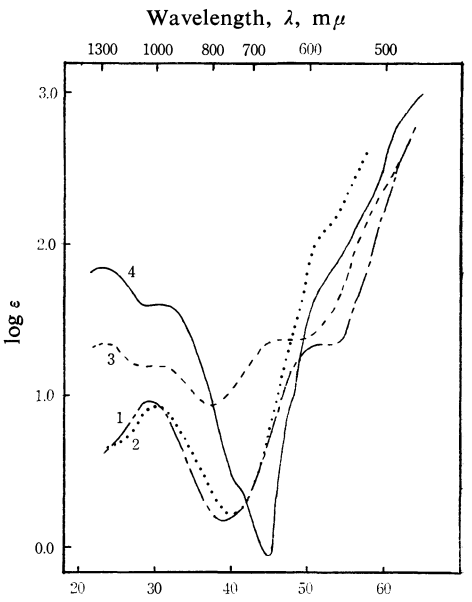

Fig. 6. Electronic absorption spectra of Co(O·$C_6H_4$·CH : N·R)$_2$: 1, R=*o*-$CH_3$·$C_6H_4$, in pyridine (——); 2, R=*o*-$OCH_3$·$C_6H_4$, in pyridine (·····); 3, R=*o*, *o*'-$(CH_3)_2$·$C_6H_3$, in pyridine (----); 4, R=*o*, *o*'-$(CH_3)_2$·$C_6H_3$, in benzene (——).

5) About the *N*-phenyl-complex of cobalt(II), the same result was reported previously; L. Sacconi, M. Ciampolini, F. Maggio and F. P. Cavasino, *J. Am. Chem. Soc.*, **84**, 3246 (1962).

6) Quite recently, Sacconi and Ciampolini (private communication) studied the equilibrium between bis-(salicylaldehyde)-*N*, *N*-disubstituted polymethylenediiminato cobalt(II) complexes and their pyridine adducts in solution, and found that, in some cases, the first step of the equilibrium was that between the original tetrahedral complex and the quinque-co-ordinate cobalt(II) adduct with one pyridine molecule.

quinque-co-ordinate adduct of the *o,o'*-dimethyl complexes with one pyridine molecule, which is quite a different color from that of the parent compound.[7] The reflection spectrum of the compound is obviously different from any of the known spectra of the tetrahedral, square-planar and octahedral complexes of cobalt(II).[7]

The adducts with two pyridine molecules were generally isolated for the corresponding cobalt(II) complexes of most *N*-aryl-substituted Schiff bases and show absorption bands which are considered to be characteristic of the octahedral complexes.

When a group attached to N is an *o*-methoxyphenyl radical, the absorption spectrum of the cobalt(II) complex in pyridine (Fig. 4) is quite different from that in chloroform; it shows the band at $30\times10^{13}\,\mathrm{sec}^{-1}$ ($\log\varepsilon$ about 0.9) which is considered to be the ligand field band of the sexa-co-ordinated cobalt(II) complex formed by the co-ordination of two molecules of pyridine.[8] It is most likely, therefore, that the weak bond originally present between the oxygen atom of the methoxy group and the cobalt(II) ion is broken in pyridine, so that the molecules of pyridine are combined with the cobalt(II) ion to yield another sexa-co-ordinate cobalt(II) complex.

7) S. Yamada and H. Nishikawa, This Bulletin, **38**, 683 (1965).

8) The electronic spectrum of the *o*-methoxyphenyl complex in chloroform in Fig. 4 is essentially the same as the spectrum of the same complex in benzene.

## Summary

Bis(*N*-aryl-salicylideneiminato)cobalt(II) complexes, including several new compounds, have been prepared and their configurations examined. These cobalt(II) compounds have been concluded, from their electronic spectra, to have a tetrahedral configuration around the cobalt(II) ion. All these compounds in pyridine have been concluded to take an octahedral configuration with the exception of the *N-o,o'*-disubstituted cobalt(II) compounds.

# The Determination of Micro Amounts of Polythionates. I.* A Photometric Method for the Determination of Pentathionate by Means of Its Cyanolysis

By Tomozo KOH

(Received January 26, 1965)

Although it is important and desirable, from the viewpoints of geochemistry and medical science, to determine the amounts of polythionates in hot springs, there have been no suitable procedures for determining the polythionates in such micro amounts as are present in hot springs. Many investigations[1-15] have been made regarding the analysis of the polythionates. None of these methods, however, is suitable for micro quantities of polythionates.

Nietzel and DeSesa[16] have proposed a method for the estimation of a small amount of tetrathionate which is based on the reaction:

$$S_4O_6^{2-} + 3CN^- + H_2O = S_2O_3^{2-} + SO_4^{2-} + 2HCN + SCN^-$$

followed by the photometric determination of the thiocyanate with ferric iron. They have pointed out that their method might also be suitable for pentathionate and hexathionate, because the higher polythionates react more easily with cyanide to form thiocyanate. Recently, Urban[17] has improved the Nietzel and DeSesa's method and applied it to the evaluation of *n*, the mean number of sulfur atoms in the formula, $S_nO_6^{2-}$, for polythionate above trithionate, in order to indicate the polythionate composition of the solution.

In the present investigation, it is confirmed that pentathionate is not quantitatively converted into thiocyanate under the conditions of the Nietzel-DeSesa's and the Urban's methods,[16,17] because of the partial alkaline decomposition arising from the higher pH value caused by the addition of a sodium cyanide solution. Consequently, their methods are not suitable for the higher polythionate, pentathionate. The present author has, therefore, investigated, in greater detail, a photometric method for the determination of a small amount of pentathionate which is dependent on the reaction:

$$S_5O_6^{2-} + 4CN^- + H_2O = S_2O_3^{2-} + SO_4^{2-} + 2HCN + 2SCN^-$$

and he has established an excellent method, finding the most suitable conditions for the reaction of pentathionate with cyanide to go well to completion and to be stoichiometric.

This paper will be concerned with the results of this investigation and with the determination of pentathionate by means of its cyanolysis.

## Experimental

**Apparatus.**—The photometric measurements were made with a Hirama photometer with a 460 mμ filter (maximum transmission at 460 mμ) and with 10.0 mm. cells.

All pH measurements were made with a Toa Denpa Model HM-5A pH meter.

The desired temperatures were controlled by a Taiyo Model K-II thermostat.

The standard pentathionate solution was kept in a Hitachi Model R-104K refrigerator, the temperature of which was maintained at 5±2°C.

Potassium pentathionate was kept in a Sanyo Model HF-33 freezer in which the temperature was maintained at −8±2°C.

Volumetric flasks of 25 ml. were coated with black paint, except for small vertical areas on opposite sides near the top graduation.

17) P. J. Urban, *Z. anal. Chem.*, **180**, 110 (1961).

**Materials.**—Potassium pentathionate was prepared according to the procedure of Goehring and Feldmann.[18] The pentathionate obtained was recrystallized twice with 0.5 N hydrochloric acid and dried at room temperature for 4 days. The total water content in the pentathionate, including the water of crystallization, was estimated to be 8.2% by the Karl Fischer method. This result indicates that some moisture is adsorbed on the pentathionate besides the water of crystallization of one and a half molecules which corresponds to 7.5%.

*The Purity of the Potassium Pentathionate.*—The purity of this salt was estimated by determining the total sulfur and potassium as follows. The pentathionate was oxidized[19,20] by bromine in an alkaline medium on heating; the sulfate ion formed was determined by the usual gravimetric method.

The potassium pentathionate is decomposed into potassium sulfate by heating;

$$K_2S_5O_6 \rightarrow K_2SO_4$$

The potassium was determined by weighing[19] the potassium sulfate thus formed.

Table I. Determination of S for the potassium pentathionate* used in the present study

| Sample taken | As $K_2S_5O_6$ | Found as $BaSO_4$ | K found for $K_2S_5O_6$ | K calcd. for $K_2S_5O_6$ |
|---|---|---|---|---|
| mg. | mg. | mg. | % | % |
| 133.1 | 122.1 | 423.7 | 47.65 | 47.92 |
| 101.5 | 93.1 | 322.3 | 47.54 | |

* Total water content including the water of crystallization was 8.2%.

Table II. Determination of K for the potassium pentathionate* used in the present study

| Sample taken | As $K_2S_5O_6$ | Found as $K_2SO_4$ | S found for $K_2S_5O_6$ | S calcd. for $K_2S_5O_6$ |
|---|---|---|---|---|
| mg. | mg. | mg. | % | % |
| 310.2 | 284.8 | 148.8 | 23.44 | 23.38 |
| 215.4 | 197.7 | 103.2 | 23.43 | |

* Total water content including the water of crystallization was 8.2%.

The results listed in Tables I and II show that this potassium pentathionate is pure enough for the purpose of this study.

*The Standard Pentathionate Solution.*—182.2 mg. of the potassium pentathionate was dissolved in redistilled water and diluted to 500 ml. to give a $1.0\times10^{-3}$ M solution. This standard solution proved to be stable; even after four months, no measurable change was found by the present method when it was kept in a refrigerator at the temperature of

18) M. Goehring and U. Feldmann, *Z. anorg. Chem.*, **257**, 223 (1948).

19) F. Martin and L. Metz, *Z. anorg. u. allgem. Chem.*, **127**, 83 (1923).

20) C. Mishima, *Bull. Tokyo Inst. Tech.*, No. 1, 27 (1951).

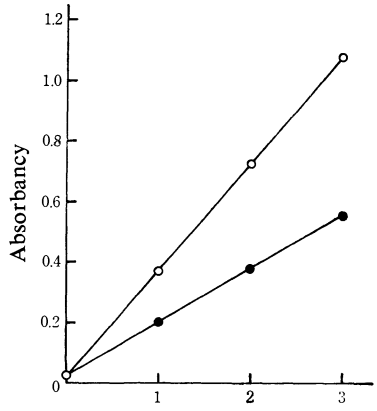
5±2°C. This was diluted to the concentration required for the experiments.

*The Standard Thiocyanate Solution.* — The stock solution of thiocyanate was prepared by dissolving guaranteed potassium thiocyanate in redistilled water; it was then standardized acording to Volhard's method. The working thiocyanate solutions were prepared by diluting the stock solution properly; they were used as standards to ascertain whether or not the reaction of pentathionate with cyanide went to completion and was stoichiometric.

*Buffer Solutions.*—A 0.2 M sodium dihydrogenphosphate solution was mixed with a 0.2 N sodium hydroxide solution, at various ratios, in order to obtain the buffer solutions from pH 6.0 to 8.0.

*The Sodium Cyanide Solution.*—The working cyanide solutions were prepared by diluting a 1 M solution properly.

*The Ferric Nitrate - Perchloric Acid Solution.* — 303.0 g. of guaranteed ferric nitrate, $Fe(NO_3)_3 \cdot 9H_2O$, was dissolved in a small volume of redistilled water containing 217.4 ml. of concentrated perchloric acid; then the mixture was diluted to 500 ml. to give a 1.5 M ferric nitrate - 4 N perchloric acid solution.

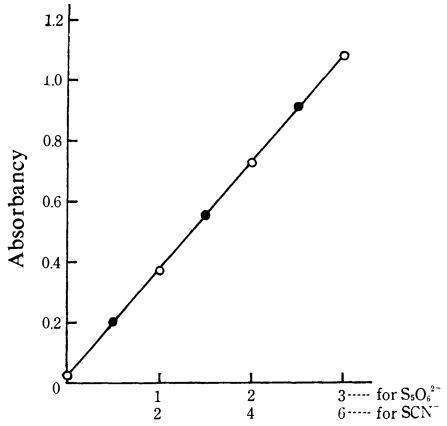


**Procedure.** — 10.0 ml. of the standard pentathionate solution is placed in a 25 ml. volumetric flask. To this solution are added first 4.0 ml. of the buffer solution of pH 7.4, and then 2.6 ml. of 0.05 M sodium cyanide; the pH of the solution is thereby brought to 8.6.

The volumetric flask is kept in the thermostat at 40°C for 30 min.; pentathionate is thereby converted into thiocyanate quantitatively. Then, 3.0 ml. of 1.5 M ferric nitrate - perchloric acid solution is added. After the flask has been filled with redistilled water to the mark, the contents are mixed well. The absorbancy of the solution of the ferric-thiocyanate complex thus formed is measured at the wavelength of 460 mμ, using distilled water as a reference.

## Results and Discussion

**Calibration Curves.** — The calibration curves shown in Figs. 1 and 2 were obtained by a procedure using standard pentathionate and thiocyanate solutions of known concentrations.



As can be seen in Figs. 1 and 2, the absorbancy and the concentration were in a good linear relationship. When one ion of pentathionate undergoes cyanolysis, two ions of thiocyanate are formed. Consequently, if the pentathionate is pure enough and if it is, moreover, converted into thiocyanate quantitatively, the sensitivity of the pentathionate should be just twice as much as that of thiocyanate. In fact, Fig. 1 shows that the calibration curve for pentathionate is twice as sensitive as that for thiocyanate. As can also be seen in Fig. 2, the calibration curve of pentathionate exactly coincides with that of thiocyanate when the scale of thiocyanate concentration is made to a half of the pentathionate

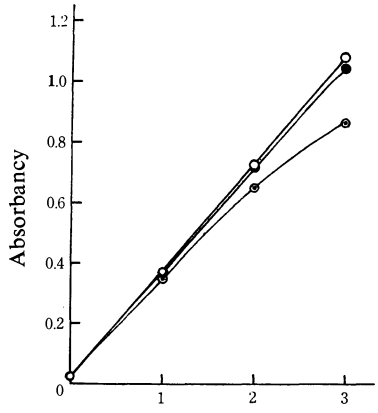
concentration, demonstrating that a stoichiometric reaction has occurred.

**The Effect of the Amount of Sodium Cyanide.** — In measuring the effect of the amount of sodium cyanide on the cyanolysis, from 0.5 to 6.0 ml. of a 0.05 M sodium cyanide solution was added to a standard pentathionate solution containing 4.0 ml. of the buffer solution of pH 7.4. Then, the mixiture was kept in the thermostat at 40°C for 30 min. and then treated as in the procedure described above. The experimental results are shown in Fig. 3.

When up to 2.6 ml. of a sodium cyanide solution, the more of it was added, the more the calibration curves approach the theoretical curve (see I, II and III). On the contrary, when more than 3.0 ml. was added, the more the absorbancies deviated from the theoretical value (see IV and V), except for the absorbancy of



Concn. of pentathionate, $\times 10^{-4}$ M

Fig. 3. Effect of sodium cyanide amount.

Use is made of 4.0 ml. of the buffer solution of pH 7.4 in all cases.

○ 2.6 ml. (III) ● 4.0 ml. (IV)
◑ 6.0 ml. (V)

the reagent blank, which remains constant (see I—V). These facts led the author to the conclusion that the pH has a great effect on the cyanolysis and that pentathionate undergoes a partial alkaline decomposition as a result of the higher pH caused by the addition of the cyanide. As will be disclosed below, it was confirmed that the optimum pH for the reaction of pentathionate with cyanide is within a range from 8.0 to 8.8 under the conditions of the above procedure. A solution of from 0.5 to 4.0 ml. of 0.05 M sodium cyanide was employed; in all cases the solution is buffered over the optimum pH. The effect of the amount of sodium cyanide on the cyanolysis is shown in Fig. 4. The calibration curves with 0.5 and 1.0 ml. do not form straight lines (see I and II), indicating that the conversion of pentathionate is not quantitative because of the insufficient amounts of cyanide. Figure 4 shows that 2.0 ml. of a 0.05 M sodium cyanide solution is sufficient for the quantitative cyanolysis and that the amount of sodium cyanide does not have any effect on the method as long as it is sufficient and the pH is adjusted to an optimum value.

Concn. of pentathionate, $\times 10^{-4}$ M

The pH was adjusted over a range from 8.0 to 8.8 in all cases.
Cyanolysis time: 30 min. at 40°C
⊙ 0.5 ml. (I) ● 1.0 ml. (II)
○ 2.0, 2.6 and 4.0 ml. (III)

**The Effect of the pH.**—At higher pH levels, pentathionate also undergoes the alkaline decomposition, so the procedure should be carried out below a pH value of 8.8. Figure 5 shows the dependence of the rate of cyanolysis on the pH of the solutions at 20°C.

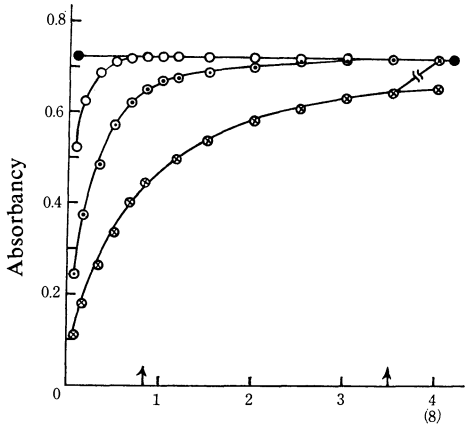

Fig. 5. Effect of pH on the rate of cyanolysis at 20°C.

● $4.0\times10^{-4}$ M $SCN^-$
○ pH 8.7 (I)
⊙ pH 8.0 (II)
⊗ pH 7.5 (III)
} $2.0\times10^{-4}$ M $S_5O_6^{2-}$

The maximum absorbancy, which means the quantitative cyanolysis, is reached in 50 min. at pH 8.7; then it remains constant (see I). The reaction at pH 7.5 does not go to completion in 4 hr.; however, it goes stoichiometrically to completion after 8 hr. (see III).

In order to accelerate the rate of cyanolysis, the reaction temperature was raised from 20°C to 40°C and 70°C. At 40°C, the reaction goes well to completion and is stoichiometric in 15 min. at pH 8.7 (see I in Fig. 6); the reactions at pH 8.0 and 7.5 go well to completion in 30 min. and 1 hr. 20 min. respectively (see II and III in Fig. 6). At 70°C, thermodecomposition occurs in addition to cyanolysis, so

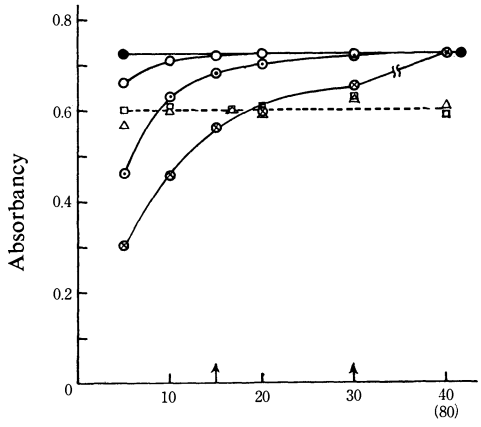

Fig. 6. Effect of pH on the rate of cyanolysis.

—●— $4.0\times10^{-4}$ M $SCN^-$
—○— pH 8.7 (I) } at 40°C
—⊙— pH 8.0 (II) } at 40°C
—⊗— pH 7.5 (III) } at 40°C
--△-- pH 8.7 (IV) } at 70°C
--□-- pH 8.0 (IV) } at 70°C
} $2.0\times10^{-4}$ M $S_5O_6^{2-}$

the reaction is not stoichiometric (see IV in Fig. 6).

In order to study the effect of the pH on the cyanolysis, the reaction of pentathionate with cyanide was carried out both at 20°C for 70 min. and at 40°C for 30 min. The results are shown in Fig. 7, where the reaction at 20°C for 70 min. gives maximum absorbancies over the pH range from 8.8 to 8.4 (see I) and that at 40°C for 30 min., over the pH range from 8.8 to 8.0 (see II). The decrease in absorbancy above the pH value of 9.0 may be attributed to the alkaline decomposition of pentathionate. The optimum pH range for the reaction with cyanide can be extended from both 8.0 and 8.4 to a lower pH value by making the cyanolysis time longer, because the rate of cyanolysis decreases with the lowering of the pH.

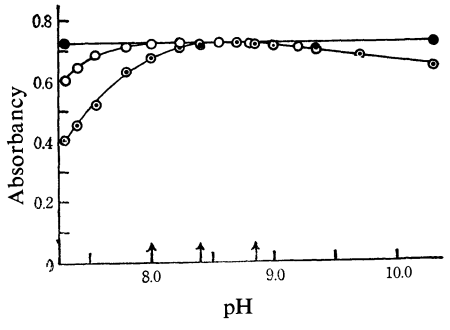

Fig. 7. Effect of pH.

● $4.0\times10^{-4}$ M $SCN^-$
○ 30 min. at 40°C (II) } $2.0\times10^{-4}$ M $S_5O_6^{2-}$
⊙ 70 min. at 70°C (I) } $2.0\times10^{-4}$ M $S_5O_6^{2-}$

**The Amount of Ferric Ntirate.** — It is well known that the phosphate interferes with the color development of ferric-thiocyanate because of the formation of a ferric-phosphate complex.

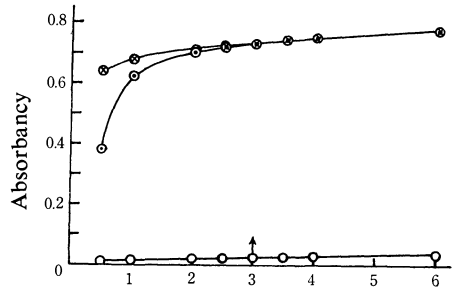

Fig. 8. Effect of ferric nitrate amount.
Use is made of 1.5 M ferric nitrate - 4 N perchloric acid solution

⊗ $4.0\times10^{-4}$ M thiocyanate without buffer solution.
⊙ $4.0\times10^{-4}$ M thiocyanate with 4.0 ml. of 0.2 M phosphate buffer solution of pH 7.4.
○ Reagent blank with 4.0 ml. of 0.2 M phosphate buffer solution of pH 7.4

Figure 8 shows how the phosphate buffer solution interferes; it also shows that 3.0 ml. of a 1.5 M ferric nitrate - perchloric acid solution is sufficient in the recommended procedure.

A similar method for the determination of micro amounts of hexathionate will be reported on in another paper. Moreover, the effect of diverse ions on the method and a detailed study regarding the stability of polythionate solutions will also be reported on.

## Summary

The photometric method for the determination of a small amount of pentathionate has been developed; it is based on the formation of thiocyanate equivalent to the pentathionate, and on the determination of thiocyanate with an excess of ferric iron.

The buffer solution is first added to the standard pentathionate solution so that the pH values of the mixture solution after the addition of the cyanide solution may be over an optimum range; othewise the pentathionate undergoes alkaline decomposition because of the higher pH value which results from the addition of the cyanide.

The conditions under which the reaction of pentathionate with cyanide is rapid and goes well to completion have been established by varying the cyanide amount, the pH, the reaction time, and the temperature.

The author wishes to express his gratitude to Professor Iwaji Iwasaki of the Tokyo Institute of Technology for his kind guidance throughout this study. He is also much indebted to Dr. Satori Utsumi and Mr. Takejiro Ozawa for their valuable advice. In addition, he wishes to express his hearty appreciation to the members of the Laboratory of Analytical Chemistry and Geochemistry, Tokyo Institute of Technology, for their helpful discussion, and to Dr. Kaname Muroi, the Central Research Laboratory of Mitsubishi Chemical Industries, Ltd., for the determination of the water content in the pentathionate by the Karl Fischer method.

# The Oxidation-Reduction Potential of the System of Mn(II)EDTA-Mn(III)EDTA Complexes and the Stability Constant of Mn(III)EDTA Complex

By Nobuyuki TANAKA, Takashi SHIRAKASHI and Hiroshi OGINO

(Received January 26, 1965)

Recently Yoshino and his co-workers[1] have succeeded in preparation of a manganese(III) complex with ethylenediaminetetraacetate (EDTA), and its decomposition has been studied by several authors.[1-3] The thermodynamic properties of this complex, however, have not been reported yet. Meanwhile, the stability constant of the corresponding chromium(III) complex has been determined by Pecsok et al.[4] This urged us to undertake the determination of the stability constant of the manganese(III)-EDTA complex.

A preliminary investigation of the complex revealed that the change with time in the concentration of the Mn(III)EDTA complex can be followed by measuring the limiting current at the dropping mercury electrode, and the change with time in the equilibrium potential of the Mn(III)EDTA-Mn(II)EDTA system can be followed by measuring the zero-current potential at the rotated platinum electrode. In this paper, the standard oxidation-reduction potential of the Mn(III)EDTA-Mn(II)EDTA system and the stability constant of Mn(III)EDTA complex are presented.

## Theoretical

The following reactions are considered:

$$Mn^{3+} + e \rightleftharpoons Mn^{2+}, \quad E^{\circ}_{Mn} \qquad (1)$$

$$MnY^{-} + e \rightleftharpoons MnY^{2-}, \quad E^{\circ}_{MnY} \qquad (2)$$

$$Mn^{2+} + Y^{4-} \rightleftharpoons MnY^{2-}, \quad K_{Mn(II)Y} \qquad (3)$$

$$Mn^{3+} + Y^{4-} \rightleftharpoons MnY^{-}, \quad K_{Mn(III)Y} \qquad (4)$$

where $Y^{4-}$ is a quadrivalent anion of EDTA, $E^{\circ}_{Mn}$ and $E^{\circ}_{MnY}$ are the standard oxidation-reduction potentials for Eqs. 1 and 2 and $K_{Mn(II)Y}$ and $K_{Mn(III)Y}$ are the stability constants of $MnY^{2-}$ and $MnY^{-}$, respectively.

From Eqs. 1 and 2, one obtains,

$$Mn^{3+} + MnY^{2-} \rightleftharpoons Mn^{2+} + MnY^{-} \qquad (5)$$

and

$$E^{\circ}_{Mn} - E^{\circ}_{MnY} = 0.0591 \log K^{Mn(III)}_{Mn(II)}, \text{ at } 25°C \qquad (6)$$

where $K^{Mn(III)}_{Mn(II)}$ is the equilibrium constant of Eq. 5 given as,

$$K^{Mn(III)}_{Mn(II)} = \frac{[Mn^{2+}][MnY^{-}]}{[Mn^{3+}][MnY^{2-}]} = \frac{K_{Mn(III)Y}}{K_{Mn(II)Y}} \qquad (7)$$

All the activity coefficients are assumed to be unity.

From Eqs. 6 and 7,

$$\log K_{Mn(III)Y} = \frac{E^{\circ}_{Mn} - E^{\circ}_{MnY}}{0.0591} + \log K_{Mn(II)Y}, \quad \text{at } 25°C \qquad (8)$$

is obtained. In Eq. 8, the values of $E^{\circ}_{Mn}$ and $\log K_{Mn(II)Y}$ are referred from the literature. The value of $E^{\circ}_{MnY}$ is obtained in the present experiment.

The equilibrium potential $E_{t=0}$ is expressed as,

1) Y. Yoshino, A. Ouchi, Y. Tsunoda and M. Kojima, *Can. J. Chem.*, 40, 775 (1962).
2) Y. Yoshino, A. Ouchi and Y. Tsunoda, *Sci. Papers. Coll. Gen. Educ. Univ. Tokyo*, 13, 27 (1963).
3) K. A. Schroeder and R. E. Hamm. *Inorg. Chem.*, 3, 391 (1964).
4) R. L. Pecsok, L. D. Shields and W. P. Schaefer, ibid., 3, 114 (1964).

$$E_{t=0}=E^{\circ}_{MnY}-0.0591\log\frac{[Mn(II)Y]_0}{[Mn(III)Y]_0},\ \text{at } 25^{\circ}C \quad (9)$$

where $t$ means the time after the dissolution of the Mn(III)EDTA complex, and the subscript 0 represents $t=0$. The value of $E^{\circ}_{MnY}$ in Eq. 9 can be determined from the plot of $E_{t=0}$ vs. $\log([Mn(II)Y]_0/[Mn(III)Y]_0)$.

## Experimental

Mn(III)EDTA complex, $KMn(C_{10}H_{12}O_8N_2)2\cdot 5H_2O$, was prepared according to the method of Yoshino.[1] In an aqueous solution, it decreases in concentration gradually due to the thermal decomposition. Therefore, it was weighed at each measurement and dissolved into the solution. The time when the complex was dissolved was considered to be the initial time of decomposition; the dissolution was readily completed by bubbling nitrogen gas through the solution. To avoid the effect of light, the measurements were made with a brown-colored cell under the safety lamp in a dark room. A DME and a rotated platinum electrode were inserted into an electrolysis cell; the former was connected to a Yanagimoto Galvarecorder Model GR-103 and the latter to a potentiometer to follow the change in the limiting current and the equilibrium potential as a function of time, respectively. The limiting current was measured at −0.5 V. vs. SCE. The pH of the solution was adjusted to be 4.63±0.03 with sodium acetate-acetic acid buffer and the ionic strength, to be 0.2 with potassium chloride.

## Results and Discussion

The measurements were made with the solutions given in Table I at 25.0±0.1°C. In Fig. 1, the equilibrium potentials at time $t$, $E_{t=t}$, measured with the rotated platinum electrode were plotted against time $t$. Since the equilibrium potentials at $t=0$, $E_{t=0}$, are not accurately determined from Fig. 1, they were obtained by the following procedure.

Table I. Concentrations of Mn(II)EDTA and Mn(III)EDTA complexes in the solutions*

| Expt. No. | Concn. of Mn(II)Y mM | Concn. of Mn(III)Y** mM | pH |
|---|---|---|---|
| 1 | $0.101_0$ | $1.02_8$ | $4.6_4$ |
| 2 | $0.252_5$ | $1.00_2$ | $4.6_3$ |
| 3 | $0.505_0$ | $1.00_6$ | $4.6_5$ |
| 4 | $1.01_0$ | $1.00_3$ | $4.6_1$ |
| 5 | $1.76_8$ | $0.992_5$ | $4.6_6$ |
| 6 | $5.05_0$ | $0.988_8$ | $4.6_0$ |
| 7 | $10.1_0$ | $0.984_1$ | $4.6_0$ |

* Containing 0.05 M sodium acetate-acetic acid buffer and about 1 mM uncomplexed ethylenediaminetetraacetate, $\mu=0.2$ (KCl).
** Approximately 21 mg. of the complex were dissolved in 50 ml. of solution.

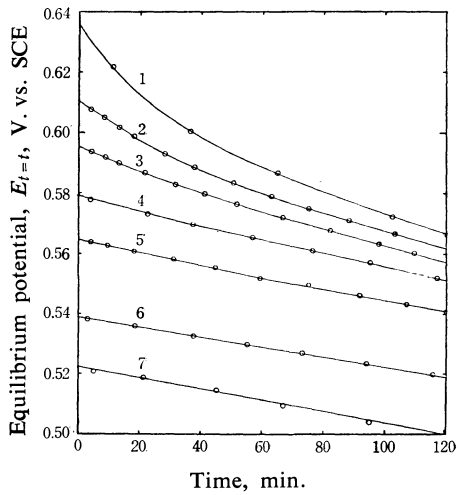

Fig. 1. $E_{t=t}$ as a function of time. Figures on the curves indicate experimental numbers given in Table I.

It was assumed that the decomposition product would have the same oxidation potential as the Mn(II)EDTA complex, and consequently, Eq. 9′ was derived from Eq. 9.

$$E_{t=t}=E^{\circ}_{MnY}-0.0591\times\log\frac{[Mn(II)Y]_0+[Mn(III)Y]_0-[Mn(III)Y]_t}{[Mn(III)Y]_t} \quad (9')$$

where the subscript $t$ means $t=t$. In Eq. 9′ the value of $[Mn(III)Y]_t$ was determined from the limiting current obtained with the DME at −0.5 V. vs. SCE; the limiting current of the Mn(III)EDTA complex was proved to be diffusion-controlled.* The values of $E_{t=t}$ were plotted against $\log\{([Mn(II)Y]_0+[Mn(III)Y]_0-[Mn(III)Y]_t)/[Mn(III)Y]_t\}$. Linear plots were obtained, and the more accurate values were determined for the equilibrium potential $E_{t=0}$ by the extrapolation of those plots to the points where the logarithmic terms equal to the values of $\log([Mn(II)Y]_0/[Mn(III)Y]_0)$.

According to Eq. 9, the values of $E_{t=0}$ determined by the above procedure were plotted against $\log([Mn(II)Y]_0/[Mn(III)Y]_0)$ which was calculated from Table I. Since this plot was very linear and its slope was found to be 57.2 mV., which was close to 59 mV. of the theoretical value, the above assumption and the determination of $E_{t=0}$ by the above procedure were considered to be valid and correct. From Fig. 2, the value of $E^{\circ}_{MnY}$ was determined to be $0.57_9$ V. vs. SCE at the point of

* The datails will be published elsewhere.

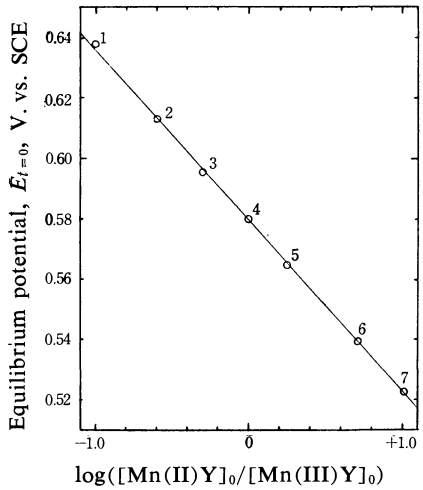

Fig. 2. Relation between equilibrium potential $E_{t=0}$ and log([Mn(II)Y]$_0$/[Mn(III)Y]$_0$) in Eq. 9. Figures on the plot indicate experimental numbers given in Table I.

log([Mn(II)Y]$_0$/[Mn(III)Y]$_0$)=0. Introducing into Eq. 8 the values of $E^\circ_{Mn}=1.49$ V. vs. NHE,[5] log $K_{Mn(II)Y}=13.64$[6] and $E^\circ_{MnY}=0.57_9$ V. vs. SCE (i. e. $0.82_3$ V. vs. NHE), the value of log $K_{Mn(III)Y}$ was calculated to be 24.9. As $E^\circ_{Mn}$ and $E^\circ_{MnY}$ are not determined under the identical condition, however, the value of the log $K_{Mn(III)Y}$ may involve a somewhat minor error. The logarithmic stability constants of EDTA complexes of some transition metals are given in Table II. The value of log $K_{Mn(III)Y}$ seems to be appropriate in comparison with those of other metals.

Table II. Logarithmic stability constants of EDTA complexes of some transition metals

| Metal | Cr | Mn | Fe | Co |
|---|---|---|---|---|
| log $K_{M(II)Y}$ | 13.6[4] | 13.64[6] | 14.33[7] | 15.71[6] |
| log $K_{M(III)Y}$ | 23.40[4] | 24.9 | 25.1[7] | 40.6[8] |

## Summary

The standard oxidation-reduction potential of the system of Mn(II)EDTA-Mn(III)EDTA complexes has been determined to be $E^\circ_{MnY}=0.57_9$ V. vs. SCE from the potentiometric measurement with the rotated platinum electrode. From this value the logarithmic stability constant of the Mn(III)EDTA complex (log $K_{Mn(III)Y}$) has been calculated to be 24.9 at 25.0°C and $\mu=0.2$.

# Vinyl Polymerization. CXVI.[1] The Effects of Several Sulfides and Oxides on Radical Polymerization

By Kazuichi TSUDA, Shigeru KOBAYASHI and Takayuki OTSU

(Received January 29, 1965)

It is known that some aliphatic disulfides can act as the initiator in radical polymerization.[2,3] Many studies have been made of the reaction and of the mechanism of the radical decomposition of these sulfides. Tobolsky[3] and Otsu et al.,[4] for example, investigated the polymerization of styrene or methyl methacrylate initiated by tetraalkylthiuramdisulfides. On the other hand, little progress has been made in the field of aromatic disulfide, although Pierson[5] and Otsu[6] used some aromatic disulfides, including diphenyl disulfide, as

initiators and chain transfer agents of radical polymerization.

The present paper will deal with the polymerization of styrene and methyl methacrylate in the presence of aromatic sulfide or oxide. Some sulfides and oxides of a similar structure were employed in order to see (1) how these compounds act as initiators or chain transfer agents in radical polymerization, and (2) how the differences in structure affect on the radical polymerization.

The compounds used here are:

1) Sulfides: diphenyl sulfide (DPS), diphenyl disulfide (DPDS), dibenzyl sulfide (DBS), and dibenzyl disulfide (DBDS).

2) Oxides: diphenyl ether (DPE), and dibenzyl ether (DBE).

## Experimental

**Preparation and Purification of Materials.**—*Diphenyl Sulfide (DPS).*—Hartman's method[7] was adopted in preparing DPS, and the product obtained was purified by distillation. B. p. 160—161°C/23 mmHg (Found: C, 77.37; H, 5.47; S, 17.39. Calcd. for $C_{12}H_{10}S$: C, 77.37; H, 5.41; S, 17.22%).

*Diphenyl Disulfide (DPDS).*—This sulfide was obtained by the oxidation of thiophenol with iodine in ethanol. The crude product was recrystallized from dichloroethane. M. p. 58.8—59.0°C (Found: C, 66.33; H, 4.59; S, 29.21. Calcd. for $C_{12}H_{10}S_2$: C, 66.01; H, 4.62; S, 29.37%).

*Dibenzyl Sulfide (DBS).*—This was prepared by Seriner's process,[8] and the resulting DBS was purified by recrystallization. M. p. 47.5—48.0°C (lit.[8] 49.0°C) (Found: C, 78.43; H, 6.60; S, 14.85. Calcd. for $C_{14}H_{14}S$: C, 78.45; H, 6.59; S, 14.96%).

*Dibenzyl Disulfide (DBDS).*—Frank's process[9] was adopted for the preparation of this sulfide, and the product was recrystallized from dichloroethane. M. p. 69.0—69.5°C (lit.[9] 69—70°C) (Found: C, 67.96; H, 5.72; S, 25.99. Calcd. for $C_{14}H_{14}S_2$: C, 68.25; H, 5.73; S, 26.03%).

*Oxides.*—Commercial diphenyl ether was purified by distillation and recrystallization, while dibenzyl ether was purified by distillation alone.

*The Purification of the Other Reagents.*—Monomers were purified by the standard methods. Azobisisobutyronitrile (AIBN) was recrystallized from alcohol. M. p. 102.0—102.5°C.

**Polymerization.** — Bulk polymerization by the glass-tube method was employed. Given amounts of the monomer and of sulfide or oxide were charged into a tube and evacuated by the usual method. Thermal polymerizations were carried out at 60°C under shaking. During the polymerization, the outside light was completely excluded. Photo-polymerizations were made at room temperature by applying the ultraviolet rays from a mercury lamp. The conversion of both cases was controlled below 10%. The rate of polymerization was decided by the weight of the polymer obtained after it had been put into a quantity of methanol, let pass through glass filters, and dry.

**The Determination of Degree of Polymerization and the Chain Transfer Constants.**—The polymer obtained was precipitated again from a benzene solution by pouring it into methanol. The intrinsic viscosity $[\eta]$ was determined in benzene at 30°C by using Ubbelohde's viscometer. The number-average degree of polymerization ($\bar{P}_n$) was calculated by formulas 1 and 2:

For polystyrene[10] $\log \bar{P}_n = 3.205 + 1.37 \log[\eta]$ (1)

For polyMMA[11] $\log \bar{P}_n = 3.420 + 1.13 \log[\eta]$ (2)

The chain transfer constants ($C$) to sulfides or oxides were determined by Mayo's formula 3:

$$\frac{1}{\bar{P}_n} = \frac{1}{\bar{P}_0} + C\frac{[S]}{[M]} \qquad (3)$$

where [S] and [M] are the initial concentrations of the chain transfer agent and the monomer respectively.

## Results

**The Results of Thermal Polymerization.**—The results of thermal polymerization conducted at 60°C in the presence of sulfides or oxides are shown in Table I.

| | 0 | 390 | 0.59 | 0 | 240 | 0.50 |

As may be easily seen from Table I, the concentration of the sulfides or oxides used does not have much effect on the rate of polymerization. As compared with the result in the absence of these compounds, they may safely be said to show little ability either to initiate or to retard.

Figures 1 and 2 show the effect of sulfides or oxides on the polymerizations of styrene and MMA, when AIBN was empolyed as the initiator in the presence and absence of sulfides or oxides.

It may be noted from Figs. 1 and 2 that sulfides or oxides have little effect on the reterdation or acceleration of the polymerization. Thus, the results shown here are much the same as those obtained when sulfides or oxides were employed in thermal polymerization. In order to determine the chain transfer constants to the sulfides or oxides, $1/\overline{P_n}$ was plotted against [S]/[M] according to Mayo's formula 3 as Figs. 3 and 4 show. The linear relationships were observed, but their intercepts did not converge at one point in all cases. The reason for this is not clear at the present time.

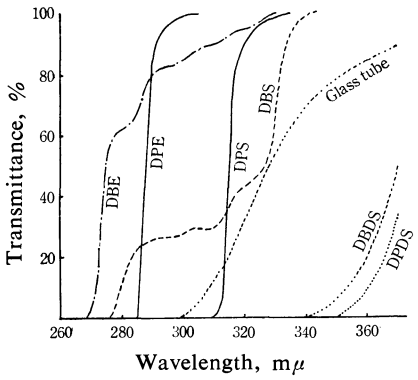

Fig. 11. Absorption spectra of sulfides and oxides.

## Discussion

As may be readily seen from Table I, it was found that the sulfides or oxides show little activity as initiators or retarders in the thermal polymerizations of styrene and MMA at 60°C. Accordingly, it may be concluded that the S-S or C-S bonds do not decompose spontaneously at 60°C.

The behavior of the sulfides and oxides as photo-sensitizers, as is shown in Figs. 5 and 6, may be taken to mean that the sulfides are subjected to radical decomposition in contact with light, though they showed no activity in thermal polymerizations. Similar phenomena may be observed from Figs. 7 and 8, which show the results of the experiment in which AIBN was employed as a photo-sensitizer in the presence of sulfides or oxides. Figures 5 and 6 show that DPDS is an excellent photo-sensitizer. It may be of some interest to note, however, that an increase in the concentration of the sulfides used here does not serve to increase the rate of polymerization very much. It is to be inferred that the sulfide radical produced by the application of the light of a mercury lamp starts the initiation, and that at the same time termination occurs; hence, the apparent rate of polymerization begins to decrease. This is why the rate of polymerization here is not in proportion to the square root of the amount of the sulfides or oxides used as the initiators, as Figs. 5 and 6 show.

As may be seen in Table II, when the chain transfer constants to sulfides and oxides as indicated in Table II are compared with the chain transfer constants to benzene ($0.28 \cdot 10^{-5}$, as determined by Misra et al.[12] in the polymerization of styrene and with the constant to benzene of $0.40 \cdot 10^{-5}$ in the polymerization[13] of MMA, the chain transfer constants to the sulfides or oxides are quite large. It may be said, therefore, that the transfer constants of these compounds result from the attack of the polymer radical on the S-S bond or C-S bond. The chain transfer constants to the oxides are much smaller than those to the sulfides of a similar structure.

As is shown in Figs. 5—8, DPDS alone could serve as an effective photo-sensitizer in the sulfides and oxides used. This result may be explained in terms of the transmittance of light under the conditions of polymerization referred to in this work. Figure 11 shows the absorption spectra of the sulfides or oxides at the concentration used and the transparency of the glass tube used. A comparison of the transparency of the glass tube with the light absorption of sulfides has shown that DPDS and DBDS could absorb effective sufficient light under the present conditions, while other sulfides or oxides did not. It may, therefore, be said that the activities of the compounds employed as photo-sensitizers depend more on the transmittance of the glass tubes than on the structure and the absorbancy of the compounds. The characteristic absorptions of these sulfides exist at nearly 243, 249, 255, and 261 mμ. It is to be expected that interesting results may be obtained by applying the lights of these wavelengths.

## Summary

A study has been made to see how some sulfides, such as diphenyl disulfide, diphenyl sulfide, dibenzyl disulfide, and dibenzyl sulfide, and such oxides as diphenyl ether and dibenzyl ether affect the radical polymerization of styrene or methyl methacrylate. None of these compounds acted effectively either as an initiator or as a retarder in the thermal

polymerization at 60°C. When employed as photo-sensitizers, the disulfides have been proven to have a remarkable activity of initiation, the monosulfides acting less effectively as initiators. Moreover, the oxides showed no such activity at all. When sulfides were used as photo-sensitizers, the rate of polymerization did not obey the equation of the square root of the concentrations of the sulfides. This may be attributable to the participation of the sulfide radicals in the initiation and termination. The chain transfer constants of these compounds at 60°C were in the order of disulfides>monosulfides>oxides.

# *t*-Amyloxycarbonyl as a New Protecting Group in Peptide Synthesis. I. The Synthesis and Properties of *N*-*t*-Amyloxycarbonylamino Acids and Related Compounds

By Shumpei SAKAKIBARA, Masaru SHIN, Masahiko FUJINO,* Yasutsugu SHIMONISHI, Sumiko INOUE and Noriyoshi INUKAI**

(Received February 1, 1965)

The *t*-butoxycarbonyl group (BOC group) is well known as a useful *N*-protecting group in the preparation of complicated peptides. Although *t*-butyl azidoformate,[1] *t*-butyl *p*-nitrophenyl carbonate[2] and *t*-butyl cyanoformate[3] have been recommended as *t*-butoxycarbonylating reagents, these can not be synthesized as easily as carbobenzoxy chloride. Thus, there is as yet no good practical method for synthesizing BOC-amino acids on a large scale. If *t*-butyl chloroformate, which corresponds to carbobenzoxy chloride, were stable against water or amines under normal conditions, it would be a most useful reagent for the purpose.[2,4]

In the present investigation, the *t*-amyloxycarbonyl group (AOC group) was found to be a much more convenient *N*-protecting group than BOC in many cases. The AOC group could be introduced quite readily into amino acid esters by using *t*-amyl chloroformate (I) as a reagent. Reagent I was originally prepared by Merck's group in 1912 as a material for hypnotics.[5] According to the description of the patent, it was synthesized by adding quinoline to a cold mixture of *t*-amyl alcohol and phosgene. When this procedure was tested, however, it was found that the product was colored and decomposed spontaneously within few days, even in a deep freezer at −20°C. Therefore, the procedure was improved in the present study. It was found that pyridine was a better condensing reagent than quinoline, and that excess phosgene was necessary to obtain a good yield of reagent I. The reagent thus obtained was a colorless liquid, which did not decompose when stored for over ten days in a deep freezer. The *N*-acylation reaction with amino acid esters was carried out readily in chloroform in the presence of triethylamine, with an almost quantitative yield. The AOC-esters were then converted to their respective free acids or hydrazides by the normal procedure. Generally, the hydrogenation of benzyl esters gave better yields of free acids than the saponification of ethyl or methyl esters. The yields, physical constants and analytical data of the AOC-amino acids are listed in Table I.

Since reagent I was unstable in the presence of water, it was not possible to get AOC-amino

acids directly by the Schotten-Baumann procedure; this was a disadvantage of the method. Some AOC-amino acids were prepared as oils, but usually good crystalline derivatives could be derived from them, as with BOC-derivatives. These crystalline derivatives are listed in Table II. When the cleavage of the AOC group from various derivatives was tested, it was found that trifluoroacetic acid or anhydrous hydrogen chloride in an organic solvent decomposed AOC readily at room temperature. This property was quite similar to that of the corresponding BOC-derivatives in all cases. Since it is possible to prepare several moles of reagent I within 24 hr., this procedure should be of great use in the practical synthesis of complicated peptides.

Incidentally, 3-methyl-3-pentyl chloroformate (II) was synthesized, and several kinds of 3-methyl-3-pentoxycarbonylamino acids (MPC-acids) were prepared by following the same procedure as was used in the case of AOC-amino acids. These data are listed in Table III. Although the MPC group could be removed, as in the case of the AOC group, the difficulty of obtaining 3-methyl-3-pentanol would limit the application of the procedure.

## Experimental

***t*-Amyl Chloroformate (I).**—Dried phosgene (105 g., 1.06 mol.) was introduced into a solution of *t*-amyl alcohol (46 g., 0.52 mol.) in dry ether (500 ml.), and then the mixture was cooled to −60°C in an acetone - dry ice bath. A solution of pyridine (41 g., 0.52 mol.) in dry ether (500 ml.) was added dropwise into the cooled mixture with vigorous stirring. Then the reaction mixture was stored overnight in a deep freezer at −20°C. The pyridine hydrochloride which formed was removed by filtration, and the mother liquor was concentrated to a small volume (about 120 ml.) in an ice water bath under reduced pressure. The product thus obtained was used without further purification in the following reactions. Its purity was determined by acylating a known amount of phenylalanine methyl ester as described below; it was found that about 4 ml. of the product corresponded to 0.01 mol. The yield was about 60%.

**3-Methyl-3-pentyl Chloroformate (II).**—When 3-methyl-3-pentanol (b. p. 119—122°C; 31 g., 0.3 mol.) was allowed to react with phosgene (99 g., 1 mol.) as in the case of I using pyridine (24 g., 0.3 mol.), crude II was obtained as a colorless liquid (about 135 ml.). About 15 ml. of the product corresponded to 0.01 mol. The yield was about 30%.

a) 22°C. b) 20°C. c) 24°C. d) Calcd.: S, 7.21. Found: S, 7.04%.

**AOC- and MPC-amino Acids.**—Into a solution of an amino acid-ester hydrochloride or tosylate (0.1 mol.) in chloroform (200 ml.), portions of I or II and triethylamine (0.1 mol.) were added alternately at −5 to −10°C. The addition of I or II was continued untill the ninhydrin-positive material had disappeared from the reaction mixture; this was checked by thin-layer chromatography. Then, the reaction mixture was washed successively with water, 0.5 N hydrochloric acid and a 5% sodium bicarbonate solution. The solution was dried over anhydrous magnesium sulfate and then concentrated to an oil. The yied of the oil (AOC-ester) was generally quantitative. Then the esters were subjected to saponification in acetone or, if benzyl esters, to hydrogenation in a suitable organic solvent (such as methanol); the AOC- or MPC-amino acids were obtained after following the usual purification procedures (Tables I and III).

**AOC-L-serine Hydrazide.**—AOC-L-serine methyl ester, which was obtained from L-serine methyl ester hydrochloride (3.9 g., 0.025 mol.), was dissolved in ethanol (18 ml.), and then hydrazine hydrate (4 ml.) was added to the solution. After the solution had stood for about 20 hr. at room temperature, it was concentrated to dryness, and the residue was recrystallized from ethyl acetate (Table II).

**Dicyclohexylamine Salts of AOC- and MPC-amino Acids.**—Each AOC- or MPC-amino acid was mixed with an equimolar amount of dicyclohexylamine in dry ether. The crystals which appeared were filtered off and recrystallized from a suitable solvent system. When the product was soluble in ether, it was precipitated by the addition of petroleum ether to the solution. The data are listed in Tables II and III.

**AOC-amino Acid *p*-Nitrophenyl Ester.**—A solution of each AOC-amino acid and an equimolar amount of *p*-nitrophenol in ethyl acetate was treated with an equimolar amount of dicyclohexylcarbodiimide at −10°C for one hour, and then the mixture was allowed to react for an additional 2 hr. at room temperature. The dicyclohexylurea which formed was removed by filtration, and the mother liquor was concentrated to dryness. The residual product was recrystallized from a suitable solvent system. The data are listed in Table II.

TABLE III. 3-METHYL-3-PENTOXYCARBONYLAMINO ACIDS AND THEIR DICYCLOHEXYLAMINE SALTS

| Compound | Recryst. solvent | M. p., °C | Yield % | $[\alpha]_D^{24}$ (*c* in Ethanol) | Empirical formula | Anal. Calcd. / Found | | |
|---|---|---|---|---|---|---|---|---|
| | | | | | | C % | H % | N % |
| A) MPC-deriv. of | | | | | | | | |
| Glycine | AcOEt-Pet. ether | 71.5—73 | 84 | | $C_9H_7O_4N$ | 53.19<br>53.02 | 8.43<br>8.42 | 6.89<br>7.00 |
| L-Leucine | | Oil | 84 | | | | | |
| L-Proline | | Oil | 90 | | | | | |
| B) Dicyclohexylamine salt of MPC-deriv. of | | | | | | | | |
| L-Leucine | Pet. ether | 114—116.5 | 63 | −4°(2) | $C_{25}H_{48}O_4N_2$ | 68.14<br>68.17 | 10.98<br>10.91 | 6.36<br>6.55 |

**The Cleavage of the AOC Group from AOC-glycine.**—a) AOC-glycine (1.14 g., 0.006 mol.) was dissolved in trifluoroacetic acid (3 ml.). After the solution had been kept at room temperature for 40 min., it was concentrated to dryness. The residue was dissolved in ethanol (10 ml.), and the solution was neutralized with triethylamine. The crystals which appeared were collected by filtration and washed well with ethanol. The recrystallization of the product from water-ethanol afforded glycine (0.42 g., 93% yield), which was identified with an authentic sample by infrared spectral analysis.

b) AOC-glycine (1.90 g., 0.01 mol.) was dissolved in 10% anhydrous hydrogen chloride in acetic acid (4 ml.). After about 30 min. ether (20 ml.) was added to the reaction mixture in order to precipitate the product completely, and the latter was collected by filtration. Then the crystals were dissolved in ethanol (25 ml.), and the solution was neutralized with pyridine (about 1.2 ml.) to precipitate free glycine. The product (glycine) was collected by filtration, washed well with ethanol, and then recrystallized from water-ethanol; the yield of glycine was 97% (0.730 g.).

**Summary**

It has been shown that the *t*-amyloxycarbonyl group (AOC group) can be introduced quite readily into amino acid esters by using *t*-amyl chloroformate as a reagent, and that the AOC group can be cleaved as smoothly as the *t*-butoxycarbonyl group (BOC group) under acidic conditions. Since this reagent is much easier to prepare than any other reagents used for the introduction of the BOC group, the new procedure is considered to be of great use in the practical synthesis of complicated peptides. 3-Methyl-3-pentoxycarbonylamino acids were also prepared by following the same procedure as was used in the case of AOC-amino acids.

# Kinetic Studies of the Formation and Decomposition of the Meisenheimer Complex of 2, 4, 6-Trinitroanisole with Sodium Methoxide in Methanol

By Takehiro ABE, Toshihiko KUMAI and Hiroko ARAI

(Received February 5, 1965)

It has been widely accepted that aromatic polynitro-compounds react with alkalis to form colored intermediates of Meisenheimer's type. However, no investigation of the kinetics of both the coloration and the decoloration reactions has hitherto been reported on the color reaction of a polynitrobenzene in an alkaline solvent, although there have been several papers reporting the activation energy for either the coloration or the decoloration. In the present work, therefore, an attempt has been made to obtain the activation energies for the formation and decomposition of the Meisenheimer complex of 2, 4, 6-trinitroanisole with sodium methoxide in methanol.

It has been reported that 2, 4, 6-trinitroanisole reacts with the methoxide ion as follows:[1-9]

The Meisenheimer complex

The Meisenheimer complex in methanol has two absorption maxima, at about 485 and 415 mμ.[8,9]

## Experimental

**Materials.** — Commercial-grade 2,4,6-trinitroanisole was purified by several recrystallizations from methanol to a constant melting point. The Meisenheimer complex used was prepared by the same method as in the previous paper.[8] A solution of sodium methoxide in methanol was prepared by mixing freshly-cut pieces of sodium in methanol. The concentration was determined by the titration of samples diluted with water against a standard aqueous solution of hydrochloric acid. Methanol of a commercial grade was used without further purification.

**Measurements.**—Each run of the decomposition of the Meisenheimer complex prepared was started by the dissolution of very small pieces of the complex in methanol at the temperature of the thermostat. The rate of decomposition was followed by measuring the absorbancy at 480 mμ.

Each run of the formation of the Meisenheimer complex was started by pipetting 1 ml. of the methanolic sodium methoxide solution ($2.025\times10^{-3}$ M) into 2 ml. of the methanolic solution of 2,4,6-trinitroanisole ($3.980\times10^{-5}$ M) in a cell at the temperature of the thermostat. The resulting solution was then stirred by bubbles of nitrogen gas. The change in the absorbancy at 410 mμ was followed.

In the wavelength region above 400 mμ, 2,4,6-trinitroanisole scarcely absorbs at the low concentration of $2.65\times10^{-5}$ M, but it does at higher concentrations. The Meisenheimer complex absorbs more intensely at 410 mμ than at 480 mu. Moreover, it is likely that, at high concentrations of the methoxide ion, 2,4,6-trinitroanisole further reacts with the methoxide ion to form a second complex,[9] possibly absorbing in the visible region. (Details of this will be published later.) Accordingly, the absorbances at 410 mμ were measured for the runs of the formation of the Meisenheimer complex. The methoxide ion does not absorb in this wavelength range. On the other hand, the Meisenheimer complex slowly dissolves and rapidly decomposes in methanol. For convenience, therefore, the colored solutions for the runs of the decomposition were prepared by dissolving the Meisenheimer complex in methanol at arbitrary concentrations. The solutions contained considerable amounts of 2,4,6-trinitroanisole which results from the decomposition of the Meisenheimer complex. Consequently, the runs for the decomposition were followed by measuring the absorbancy at the longer wavelength of 480 mμ, at which scarcely any 2,4,6-trinitroanisole absorbs at high concentrations.

The absorbancies were measured with a Hitachi EPU-2A quartz spectrophotometer, a pair of 1 cm. cells with ground glass-stoppers being used in a thermostatted cell housing at constant temperatures. The temperature control in all cases was better than ±0.1°C. Methanol was used as a blank.

## Results

**The Decomposition of the Meisenheimer Complex.**—The decomposition of the Meisenheimer complex in methanol obeyed the first-order equation:

$$-\log A=(t-t_0)k_{-1}/2.303-\log A_0 \qquad (2)$$

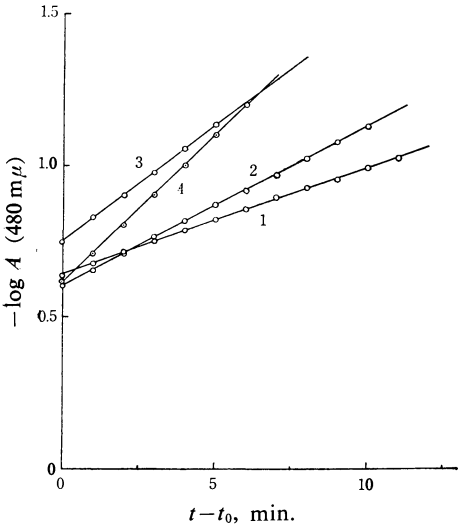

Fig. 1. Rates of decoloration reaction of the Meisenheimer complex in methanol.
1: 20.0°C 2: 25.0°C
3: 30.0°C 4: 34.0°C

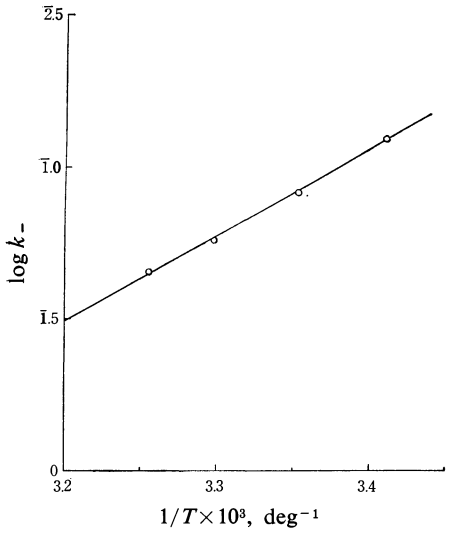

Fig. 2. Plots of $\log k_{-1}$ against reciprocal absolute temperature $1/T$°K.

Here $A$ is the absorbancy of the solution measured at time $t$, and the subscript zero indicates the starting time. By the least-squares calculations for the observed values in Fig. 1, we obtained the rate constants, $k_{-1}$'s, from whose temperature dependency in Fig. 2 the activation energy, $E_{-1}$, was found to be 12.9 kcal./mol.

**The Formation of the Meisenheimer Complex.**—The result of the runs for the reaction between 2, 4, 6-trinitroanisole and sodium methoxide are shown in Fig. 3. It is obvious from the figure that the reaction is exothermic,

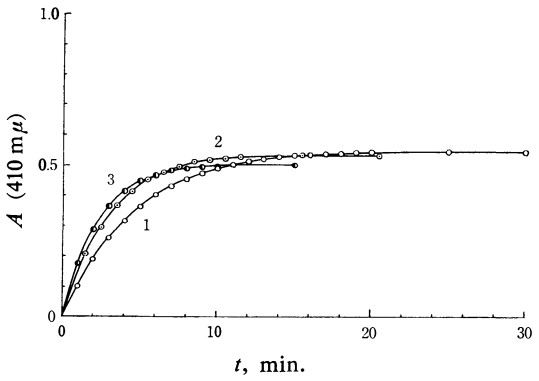

Fig. 3. Rates of reaction of 2,4,6-trinitroanisole ($2.653\times10^{-5}$ M) with sodium methoxide ($6.75\times10^{-4}$ M) in methanol.
1: 20.0°C 2: 25.0°C 3: 30.0°C

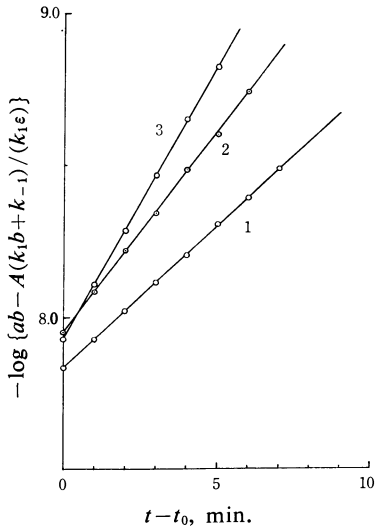

Fig. 4. Plots of $-\log\{ab-A(k_1b+k_{-1})/(k_1\varepsilon)\}$ against $(t-t_0)$.
1: 20.0°C, $(k_1b+k_{-1})/(k_1\varepsilon)=3.23\times10^{-8}$ mol./l.
2: 25.0°C, $(k_1b+k_{-1})/(k_1\varepsilon)=3.24\times10^{-8}$ mol./l.
3: 30.0°C, $(k_1b+k_{-1})/(k_1\varepsilon)=3.50\times10^{-8}$ mol./l.

because the absorbancy at the equilibrium point becomes lower as the temperature increases. If the initial concentration of 2, 4, 6-trinitroanisole ($a$) is considerably smaller than that of sodium methoxide ion ($b$), reaction mechanism 1 gives the kinetic equation of the second order as:

$$t-t_0=2.303\,[\log\{ab-A_0(k_1b+k_{-1})/(k_1\varepsilon)\}-\log\{ab-A(k_1b+k_{-1})/(k_1\varepsilon)\}]/(k_1b+k_{-1}) \quad (3)$$

where $k_1$ is the rate constant of the forward reaction, and $\varepsilon$ is the molar extinction coefficient of the Meisenheimer complex. By the trial-and-error method we found the values of

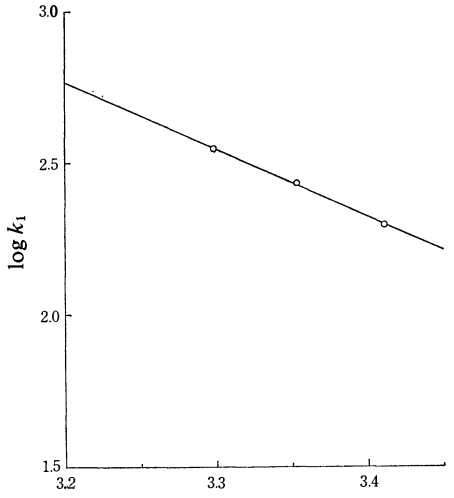

Fig. 5. Plots of $k_1$ against reciprocal absolute temperature $1/T$°K.

$(k_1b+k_{-1})/(k_1\varepsilon)$ that gave the best straight lines for the plots of $-\log\{ab-A(k_1b+k_{-1})/(k_1\varepsilon)\}$ against $(t-t_0)$ to be those shown in Fig. 4. From the slopes of the plots the values of $k_1$ were determined to be those listed in Table I, where the values of $k_{-1}$ determined above were used. The activation energy, $E_1$, obtained from Fig. 5 is 10.1 kcal./mol. The equilibrium constants $k_1$'s, for equilibrium 1 were estimated from the values of $k_1/k_{-1}$. The values of $\varepsilon$ in Table I were estimated from $(k_1b+k_{-1})/(k_1\varepsilon)$.

| 34.0 | — | 2.23 | — | — |

## Discussion

It is evident from Fig. 6 that the Meisenheimer complex of 2,4,6-trinitroanisole is quite stable. This leads to the interpretation of why the complex is easily prepared.

Assuming that 2,4,6-trinitroanisole at $3.43\times10^{-5}$ M was completely converted into the Meisenheimer complex at the methoxide concentration of $1.28\times10^{-1}$ M, Gold and Rochester[9] obtained the value of $7.7\times10^3$ l./mol. for $k_1$ at 25°C and the value of $2.42\times10^4$ for $\varepsilon$ at 410 m$\mu$. This $K_1$ value is much higher than the present one of $2.26\times10^3$ l./mol. They estimated the rough values of 240 l./mol. min. and $3\times10^{-2}$/min. for $k_1$ and $k_{-1}$ respectively at 25°C.

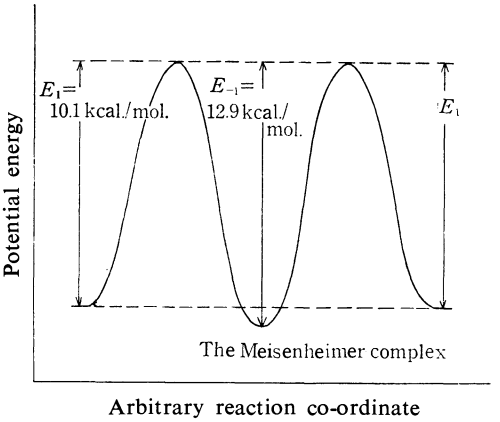

Fig. 6. The energy profile for the reaction of 2,4,6-trinitroanisole with sodium methoxide in methanol.

Our activation energy of 10.1 kcal./mol. for the forward reaction corresponds to Ainscough and Caldin's value of 13.1 kcal./mol. for the "slow" reaction of 2,4,6-trinitroanisole with ethanolic sodium ethoxide at temperatures from −20° to 10°C.[2]

Miller[7] calculated the activation energies for the same reaction, utilizing bond energies, electron affinities and solvation energies. According to his calculation, the values of $E_1$ and $E_{-1}$ are 14 and 16 kcal./mol., respectively; these values accord fairly well with our experimental values. By means of the simple LCAO MO method, Abe[8] also made the same calculation, although he did not consider the important solvation energy. His value of 15.7 kcal./mol., for $E_{-1}$ is, however, fairly good. This seems to be due to the cancellation of the solvation energies for a $\sigma$- and a $\pi$-part in his calculation.

# The Chemistry of Polyazanes. I. The Decomposition of 1, 3, 5-Tri-*p*-tolyl-1, 4-pentazdiene

By Hiroshi MINATO and Masayoshi OKU*

(Received February 19, 1965)

Although the organic compounds containing a chain of more than three nitrogen atoms appear to be very interesting, they have not been fully investigated. Our laboratories have, therefore, been investigating the chemistry of various polyazanes; in this paper the chemistry of 1, 3, 5-tri-*p*-tolyl-1, 4-pentazdiene (TTP) will be described.

Pechmann and Frobenius[1] studied the syntheses of TTP and other pentazdienes and found that these compounds underwent the following decomposition:

$$C_6H_5\text{-}N{=}N\text{-}\underset{\underset{Me}{|}}{N}\text{-}N{=}N\text{-}C_6H_5 \xrightarrow[\text{organic solvents}]{HCl} C_6H_5N_2Cl + MeNHN{=}NC_6H_5$$

$$\xrightarrow[H_2O]{HCl} C_6H_5OH + C_6H_5NH_2 + MeOH + N_2$$

Wicklatz[2] prepared TTP and other pentazdienes, and used these compounds as the initiators of the emulsion polymerization of butadiene and styrene at 0—50°C. Hall and Seed[3] used 1, 5-diaryl-3-alkyl-1, 4-pentazdienes as the initiators of the polymerization of ethylene at 120—150°C and of methyl methacrylate at 40°C. Rondestvedt and Davis[4] reported on the syntheses of 1, 5-diaryl-3-methyl-1, 4-pentazdienes as the by-products of the syntheses of triazenes. However, the spontaneous decomposition of 1, 3, 5-trisubstituted 1, 4-pentazdienes has never been investigated.

## Results and Discussion

1, 3, 5-Tri-*p*-tolyl-1, 4-pentazdiene (TTP) was obtained as a yellow solid when two moles of *p*-toluenediazonium chloride and one mole of *p*-toluidine were coupled in the presence of sodium methoxide, according to the method of Pechmann and Frobenius.[1] TTP is sparingly soluble in diethyl ether, alcohols or ligroin. It dissolves in acetone, benzene or chloroform, with a rapid evolution of nitrogen, at room temperature. The recrystallization of TTP is possible when it is handled quickly in ether, benzene or acetone-water at 0°C.

The spontaneous decomposition of TTP was investigated by dissolving one gram of TTP in one hundred milliliters of cumene at lower temperatures and by keeping the solution at 0°C, 15.0°C or 25.8°C. The decomposition followed good first-order kinetics, as may be seen in Fig. 1. The first-order rate constants at those three temperatures are shown in Table I, together with the half-lives. When $\ln(k/T)$ was plotted against $1/T$, a straight line was obtained, as may be seen in Fig. 2. The values of activation parameters obtained from the slope of Fig. 2 were $\Delta H^{\ddagger} = 22.6$ kcal./mol. and $\Delta S^{\ddagger} = 3.8$ e. u. Table II lists the products obtained from the decomposition of TTP at 25.8°C.

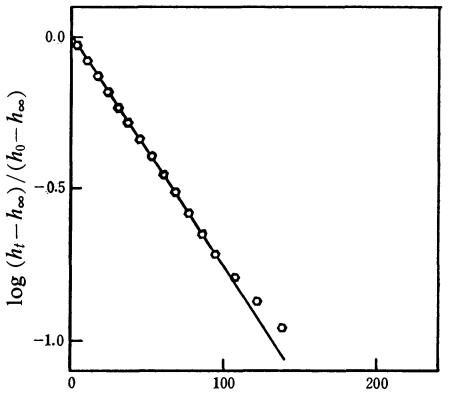

Fig. 1. Rate of decomposion of TTP in cumene at 15.0°.
$h_0$, $h_t$ and $h_\infty$ are the difference of the mercury heights at $t=0$, $t=t$ and $t=\infty$, respectively.

TABLE I. RATES OF DECOMPOSITION OF TTP IN CUMENE

| Temp. °C | $k_1$ sec$^{-1}$ | Half life min. |
|---|---|---|
| 25.8 | $12.9\times10^{-4}$ | 8.95 |
| 15.0 | $2.93\times10^{-4}$ | 39.2 |
| 0.0 | $0.325\times10^{-4}$ | 354 |

| $MeC_6H_5$ | 2.58 | 0.884 |
| $(C_6H_5CMe_2)_2$ | 1.18 | 0.405 |

* 1.000 g. of TTP (2.91 mmol.) was dissolved in 100.0 ml. of cumene, and decomposed at 25.8°C for 20 hr. in the absence of air.

The three most plausible mechanisms of the decomposition of TTP in inert solvents are the following:

$$MeC_6H_4\text{-}N{=}N\text{-}\underset{\displaystyle C_6H_4Me}{\underset{|}{N}}\text{-}N{=}N\text{-}C_6H_4Me \rightarrow MeC_6H_4\text{-}N{=}N\text{-}\underset{\displaystyle C_6H_4Me}{\underset{|}{N^{\ominus}}} + N_2 + {}^{\oplus}C_6H_4Me \quad (1)$$

$$MeC_6H_4\text{-}N{=}N\text{-}\underset{\displaystyle C_6H_4Me}{\underset{|}{N}}\text{-}N{=}N\text{-}C_6H_4Me \rightarrow MeC_6H_4\cdot + N_2 + \cdot\ddot{N}\text{-}C_6H_4Me + N_2 + \cdot C_6H_4Me \quad (2)$$

$$MeC_6H_4\text{-}N{=}N\text{-}\underset{\displaystyle C_6H_4Me}{\underset{|}{N}}\text{-}N{=}N\text{-}C_6H_4Me \rightarrow MeC_6H_4\text{-}N{=}N\text{-}\underset{\displaystyle C_6H_4Me}{\underset{|}{N}}\cdot + N_2 + \cdot C_6H_4Me \quad (3)$$

Mechanism 1 cannot, however, account for the production of toluene and 2, 3-dimethyl-2, 3-diphenylbutane. Mechanism 2 can account for the production of these two hydrocarbons, but it cannot account for the production of 1, 3-di-*p*-tolyl-triazene. Only mechanism 3 is consistent with the experimental results. Thus the mode of the decomposition of TTP resembles that of azohydrocarbons, which decompose to yield a nitrogen molecule and two free radicals.

In Table III the rate of the decomposition of TTP is compared with the rates of the decomposition of several azohydrocarbons. The fact that TTP decomposes about 300 times as fast as 1′, 1′, 1′-triphenylbenzeneazomethane is rather surprising. The order of the increasing ease of decomposition in the series of azomethane, azobisisobutyronitrile, 1′, 1′-diphenylbenzeneazomethane and 1′, 1′, 1′-triphenylbenzeneazomethane may be ascribed to the production of free radicals with an increasing stability. However, it is difficult to suppose that the resonance energy of $MeC_6H_4\dot{N}\text{-}N{=}N\text{-}C_6H_4Me$ is greater than that of the triphenylmethyl radical. Therefore, some factors in addition to the resonance energy must be responsible for the rapid decomposition of TTP.

It has been found that peroxyoxalates decompose relatively fast among various peroxyesters.[10-15] The similarity of the rate of decomposition of ethyl *t*-butylperoxyoxalate to

$$EtO\text{-}\overset{\displaystyle O}{\overset{\|}{C}}\text{-}\overset{\displaystyle O}{\overset{\|}{C}}\text{-}O\text{-}O\text{-}CMe_3 \quad \text{Half life at 60°C, 35.6 min.}$$

$$Ph_2CH\text{-}\overset{\displaystyle O}{\overset{\|}{C}}\text{-}O\text{-}O\text{-}CMe_3 \quad \text{Half life at 60°C, 26 min.}$$

that of *t*-butyl diphenylperoxyacetate suggests that the ethoxycarbonyl radical is about as stable as the diphenylmethyl radical. However, since the ethoxycarbonyl radical has no special structural characteristic which might account for this apparent stabilization, it is likely that the rate difference is due to the ease of the cleavage of the carbon-carbon bond of oxalates rather than to any special stabilization of the carbon radical formed. This reasoning may also be applicable to the rapid decomposition of TTP. Just as the decomposition of peroxyoxalates is aided by the repulsion

| | Benzene | 25 | 0.042 | 9) |
| $C_7H_7-N=N-N(C_7H_7)-N=N-C_7H_7$ | Cumene | 25.8 | 12.9 | |

of the two central positively-polarized carbon atoms, the decomposition of TTP is aided by the repulsion of the electronegative nitrogen atoms, which weakens the bond between $N_b$ and $N_c$ in the structure $MeC_6H_4-N_a=N_b-N_c-(C_6H_4Me)-N_b=N_a-C_6H_4Me$.

In a number of cases, polar substituent effects have been discerned in the reactions of homolytic cleavage. For instance, Bartlett and Rüchardt[16] found that the thermal decomposition of substituted phenylperoxyacetates fits the Hammett equation when $\sigma^+$ is used rather than $\sigma$, and the observed $\rho$ value was $-1.04$ at 100°C. The transition state has been pictured as a resonance hybrid of ionic and radical structures:

$$XC_6H_4CH_2\bullet\cdots C(=O)\cdots\bullet OCMe_3 \longleftrightarrow XC_6H_4CH_2^{\oplus}\cdots C(=O)\cdots{}^{\ominus}OCMe_3$$

In a similar fashion, the transition state of the decomposition of TTP can be presented as a resonance hybrid of ionic and radical structures:

$$MeC_6H_4\bullet\cdots N\equiv N\cdots\bullet N(C_6H_4Me)-N=N-C_6H_4Me \longleftrightarrow MeC_6H_4^{\oplus}\cdots N\equiv N\cdots{}^{\ominus}N(C_6H_4Me)-N=N-C_6H_4Me$$

The ionic form had a negative charge on the electronegative nitrogen atom, and this is a favorable form. The contribution of the ionic form to the transition state will reduce the activation energy required for the decomposition of TTP. Hence, this may be one of the factors responsible for the rapid decomposition of TTP.

One of the remarkable features of TTP is that it is very stable as a solid, whereas it is unstable in a solution. As has been described above, the half life of TTP is 9.0 min. at 25.8°C, but no apparent decomposition was observed for the solid TTP when it was allowed to stand at room temperature for several weeks. Such unusual behavior was never observed in other free radical initiators, such as peroxides and azohydrocarbons. The reason for the abnormal behavior of TTP is not clear, but the following speculation is attractive.

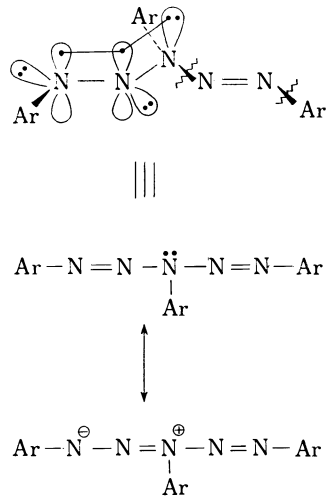

Fig. 3(a)

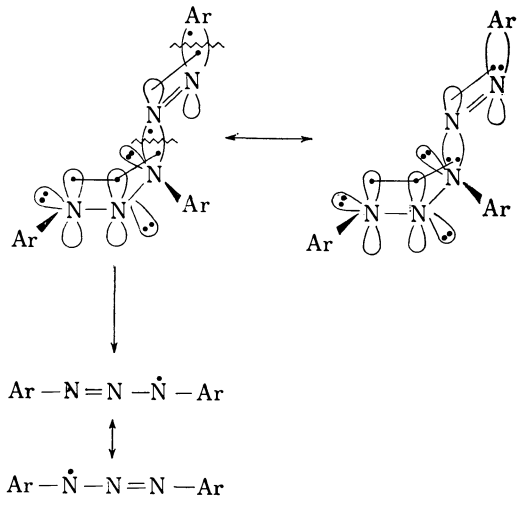

Fig. 3(b)

The lone pair electrons of the central nitrogen atom of TTP are in resonance with the *p*-orbitals of azo linkages, and hence these orbitals are parallel with one another, as is shown in Fig. 3(a). The structure of solid TTP is

16) P. D. Bartlett and C. Rüchardt, ibid., 82, 1756 (1960).

fixed as such. However, when the molecule of TTP with the structure shown in Fig. 3(a) is to decompose, the radical $MeC_6H_4N=\dot{N}NC_6H_4Me$ to be formed at the transition state does not have the resonance energy which is available for the molecules with the structure 3(b). The rotation of the groups in 3(a) to obtain 3(b) is possible in solution, but it is not possible in solids. This might be the reason why TTP is very unstable in solutions, though it is very stable as a solid.

Wicklatz[2] reported that a mixture of 72 parts of butadiene and 28 parts of styrene slowly polymerized and that the conversion of 90.6% was attained in 11 hr. when the monomers were mixed with 180 parts of water, 5 parts of soap flakes and 3.43 parts of TTP at 50°C. The slow rate of the decomposition of TTP in this system is surprising compared with the half life of 9.0 min. in cumene at 25.8°C. Although TTP dissolves in styrene, it does not dissolve in ligroin, diethyl ether or alcohols, and hence it would probably not dissolve in butadiene. The solubility of TTP in the mixture of butadiene and styrene may be very small, especially when they are scattered as oil droplets covered with soap molecules in the aqueous phase. Therefore, the slow prolonged polymerization may be ascribed to the fact that TTP is sparingly soluble in this emulsified system. As soon as molecules of TTP dissolve at 50°C, they will quickly decompose to yield free radicals, which in turn initiate the polymerization of butadiene and styrene.

## Experimental

**Materials.**—Tokyo Kasei Co. G. R. cumene was shaken wih portions of concentrated sulfuric acid until the acid layer no longer became colored upon long shaking. After it had been washed with water, a sodium bicarbonate solution, and water again, the cumene was dried with calcium chloride and distilled from sodium through a 90-cm. column packed with glass helices. The center fraction boiling at 152—152.3°C was stored under a nitrogen atmosphere and used.

All the other chemicals were of the best grade commercially available and were used without further purification.

**The Synthesis of 1, 3, 5-Tri-*p*-tolyl-1, 4-pentazdiene (TTP).** — The method of Pechmann and Frobenius[1] was modified a little and used for the synthesis of TTP. 10.7 g. of *p*-toluidine (0.1 mol.) in 15 ml. of water was diazotized by the addition of 6.9 g. of sodium nitrite (0.1 mol.) in 20 ml. of water and 25.1 g. of 35% hydrochloric acid (0.1 mol.) at 0°C. 5.1 g. of sodium (0.22 mol.) was dissolved in 150 ml. of methanol, and to this sodium methoxide solution 5.35 g. of *p*-toluidine (0.05 mol.) in 110 ml. of methanol was added. Then this methanolic solution was stirred, drop by drop, within half an hour to the aqueous soluion of *p*-toluenediazonium chloride. The yellow TTP precipitated was filtered and washed with cold ether. When the crude TTP was quickly recrystallized from cold ether, 5.5 g. of yellow crystals was obtained (16%). M. p. 84.5 — 85.0°C (decomp.) (literature:[1] 85.0°C).

When the ethereal solution of TTP was kept at −3°C for 36 hr., all the TTP were found to have decomposed. When TTP was added to acetone, benzene, ether or chloroform at room temperature, it quickly dissolved, with a rapid evolution of nitrogen. When TTP was added to chloroform, the decomposition was accompanied with a strong smell which resembled that of phenyl isocyanide. When the chloroform solution was viewed against pure chloroform in the infrared region, an absorption at 2220 $cm^{-1}$ was observed; this may be ascribed to *p*-tolyl isocyanide.

**Kinetic Procedure.**—One gram of TTP was placed in a container attached to one end of a U-shaped tube, while 100 ml. of cumene was placed in a container attached to the other end of the U-shaped tube, as is shown in Fig. 4. These two were degassed and then mixed at −78°. This U-tube was attached to an evacuated system of a known volume

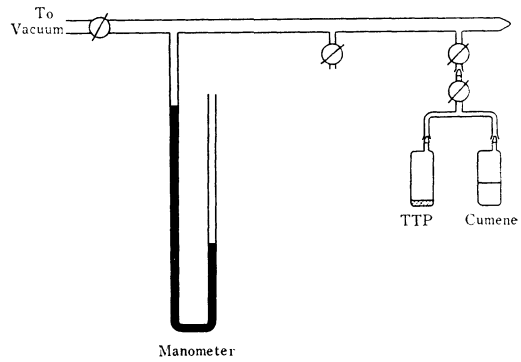

Fig. 4. Vacuum system used for kinetic and product studies.

with a mercury manometer. Then a water bath of a constant temperature (0.00, 15.00 or 25.80± 0.05°C) was raised so that the U-tube was immersed in the bath. By turning a cock, the U-tube was opened to the evacuated system, and the increase in the pressure of the system was measured versus the time. After the U-tube had been warmed to the temperature of the bath, the plots of the increase in the pressure showed good first order behavior. The infinity point was taken after about ten half lives.

**Procedure for Product Studies.**—The TTP solution used for kinetic studies was analyzed for the products of decomposition. The amount of nitrogen was determined from the data on the pressure, the volume and the temperature of the system. The cumene solution was distilled to yield brownish solids and a distillate. When the distillate was investigated by a Shimadzu Gas Chromatograph GC-2B, the only peaks observed were those of toluene and cumene. The amount of toluene was determined by using benzene as the internal standard.

When the brown residue was recrystallized from cold petroleum ether, brownish yellow crystals of 1,3-di-*p*-tolyltriazene were obtained, while upon the evaporation of the filtrate crystals of 2,3-dimethyl-2,3-diphenylbutane (bicumyl) were obtained. The melting points and the infrared spectra of these two products were the same as those of authentic samples.

# The Preparation of Heteropoly Salts of Selenium and Molybdenum

By Sarju PRASAD and Virendra Nath GARG

(Received November 30, 1964)

Gibbs[1] and Péchard[2] seem to have been the first to observe the formation of heteropoly acids and their salts of selenium and molybdenum with different ratios of selenium dioxide and molybdenum trioxide. Rosenheim and Krause[3] prepared ammonium salt, $3(NH_4)_2O \cdot 2SeO_2 \cdot 8MoO_3 \cdot 6H_2O$, by treating one mole of selenium dioxide with one mole of molybdenum trioxide; they also prepared another type of ammonium salt, $2(NH_4)_2O \cdot 5SeO_2 \cdot 5\,MoO_3 \cdot 8H_2O$. Prandtl and Blochin[4] isolated ammonium salt ($2(NH_4)_2O \cdot 2SeO_2 \cdot 5MoO_3 \cdot 3H_2O$), rubidium salt ($2Rb_2O \cdot 2SeO_2 \cdot 5MoO_3 \cdot 5H_2O$), and also barium salt ($2BaO \cdot 2SeO_2 \cdot 5MoO_3 \cdot 7H_2O$). By acidifying a boiling ammoniacal solution of selenium dioxide and molybdenum trioxide in a molar ratio of 1 : 6 with nitric acid, Prandtl, Blochin and Obpacher[5] obtained a compound with the composition of $(NH_4)_2O \cdot SeO_2 \cdot 6MoO_3 \cdot 4H_2O$.

The present communication will deal with the preparation of and the properties of two new ammonium molybdoselenites and their heavy metal salts, which have been confirmed by conductometric titrations.

## Experimental and Results

All the chemicals used were of Merck's or B.D.H. quality of purity.

**Ammonium Salt of Molybdoselenite, Type, I.**—*Preparation.*—Seleneous acid and molybdic acid in the molar ratio of 1 : 4 were dissolved in aqueous ammonia and refluxed for 6 hr. at about 110°C. The clear solution thus obtained was evaporated to a small volume and then acidified with acetic acid to pH 3. On cooling, a white crystalline powder appeared; this was then recrystallized from water. It was analyzed after dried by successive washings with alcohol and finally by keeping it in a vacuum desiccator.

*Analytical Results and Properties.* — Found: $(NH_4)_2O$, 9.39; $SeO_2$, 13.82; $MoO_3$, 42.90; $H_2O$, 33.89. Calcd. for $3(NH_4)_2O \cdot 2SeO_2 \cdot 5MoO_3 \cdot 30H_2O$: $(NH_4)_2O$, 9.62; $SeO_2$, 13.52; $MoO_3$, 44.10; $H_2O$, 32.76%.

It is a white crystalline powder stable at room temperature, but it decomposes when heated, giving a residue containing molybdenum trioxide and a small amount of selenium dioxide. It is soluble in water, and insoluble in alcohol, ether, benzene and nitrobenzene. Dilute nitric acid or dilute hydrochloric acid produces a slight change in color when boiled with this compound.

**Silver Salt of Molybdoselenite, Type I.** — A yellowish white compound was produced when silver nitrate was added to the ammonium salt solution.

Found: $Ag_2O$, 37.15; $SeO_2$, 11.09; $MoO_3$, 36.46; $H_2O$, 15.42. Calcd. for $3Ag_2O \cdot 2SeO_2 \cdot 5MoO_3 \cdot 17H_2O$: $Ag_2O$, 36.6; $SeO_2$, 11.4; $MoO_3$, 37.14; $H_2O$, 15.83%.

**Lead Salt of Molybdoselenite, Type I.**—This salt was prepared by adding an aqueous solution of lead nitrate to the ammonium salt solution. It is dirty white in color.

Found: PbO, 42.1; $SeO_2$, 13.3; $MoO_3$, 40.2; $H_2O$, 3.4. Calcd. for $3PbO \cdot 2SeO_2 \cdot 5MoO_3 \cdot 3H_2O$: PbO, 41.01; $SeO_2$, 13.09; $MoO_3$, 42.1; $H_2O$, 3.2%.

**Ferric Salt of Molybdoselenite, Type I.**—This is a powdery, yellow precipitate, insoluble in water and alcohol, formed when a dilute solution of ferric chloride is added in excess to the solution of the ammonium salt.

Found: $Fe_2O_3$, 10.09; $SeO_2$, 14.26; $MoO_3$, 45.6; $H_2O$, 27.5. Calcd. for $Fe_2O_3 \cdot 2SeO_2 \cdot 5MoO_3 \cdot 24H_2O$: $Fe_2O_3$, 10.4; $SeO_2$, 14.48; $MoO_3$, 46.9; $H_2O$, 28.4%.

**Cerous Salt of Molybdoselenite, Type I.**—A light yellow salt is obtained by adding a cerous nitrate solution to a dilute solution of the ammonium salt.

| $10.107\times10^{-5}$ | $10.15\times10^{-3}$ | 0.65 | 1 : 2.95 |
| $13.476\times10^{-5}$ | $10.15\times10^{-3}$ | 0.86 | 1 : 2.93 |
| $16.845\times10^{-5}$ | $10.15\times10^{-3}$ | 1.08 | 1 : 2.94 |
| $20.214\times10^{-5}$ | $10.15\times10^{-3}$ | 1.31 | 1 : 2.96 |
| | Titration with cerous nitrate | | |
| $10.107\times10^{-5}$ | $10.28\times10^{-3}$ | 0.63 | 1 : 2.91 |
| $13.476\times10^{-5}$ | $10.28\times10^{-3}$ | 0.84 | 1 : 2.94 |
| $16.845\times10^{-5}$ | $10.28\times10^{-3}$ | 1.05 | 1 : 2.93 |

Found: $Ce_2O_3$, 23.31; $SeO_2$, 15.1; $MoO_3$, 48.94; $H_2O$, 10.7. Calcd. for $Ce_2O_3\cdot2SeO_2\cdot5MoO_3\cdot9H_2O$: $Ce_2O_3$, 22.9; $SeO_2$, 15.5; $MoO_3$, 50.27; $H_2O$, 11.3%.

**Ammonium Salt of Molybdoselenite, Type II.**—This compound was prepared by dissolving seleneous acid and molybdic acid in a molar ratio of 1:4 in aqueous ammonia and by then acidifying the boiling solution with nitric acid. A yellow compound was precipitated. The compound is insoluble in water, alcohol, and ether, but soluble in dilute hydrochloric acid.

Found: $(NH_4)_2O$, 10.56; $SeO_2$, 10.18; $MoO_3$, 67.4; $H_2O$, 11.86. Calcd. for $4(NH_4)_2O\cdot2SeO_2\cdot9MoO_3\cdot12H_2O$: $(NH_4)_2O$, 10.71; $SeO_2$, 11.43; $MoO_3$, 66.8; $H_2O$, 11.1%.

**Conductometric Titrations.**—0.01 M solutions of ammonium molybdoselenite, type I, and the titrants (i.e., silver nitrate, lead nitrate, ferric chloride and cerous nitrate), were prepared in conductivity water. The titrants were added from a micro buret in small amounts to different volumes of the ammonium salt solution (0.001 M) diluted to 65 ml., the mixture was stirred well, and the readings were recorded after allowing the precipitate to settle down. The end point was obtained graphically by plotting the volume of the titrant added against the conductance. The results are given in Table I.

## Discussion

The compounds present great difficulty in determining their structure because of the large size of the molecule. However, the compositions of the salts have been determined on the basis of our analytical results, which have been proved further by conductometric titrations.

Conductometric titrations of the ammonium salt, type I, with the titrants with univalent, bivalent or trivalent cations have been carried out. In all the cases except silver nitrate, sharp breaks at the molar ratios of the ammonium salt to the titrant of 1:3 (divalent) and 1:2 (trivalent) cations lend support to the formation of the salts reported.

In the case of silver nitrate, apparently there is no formation of the salt at that particular dilution; this results in a regular increase in the conductance giving a straight line.

The authors are thankful to the authorities of the Banaras Hindu University for providing facilities. One of the authors (V. N. G.) is also grateful to the C. S. I. R., New Delhi, for its financial assistance.

# The Polymerization of Butene Isomers*

By Akihiko SHIMIZU, Takayuki OTSU and Minoru IMOTO

(Received January 11, 1965)

In a previous paper,[1] the effect of the substituents on the radical polymerization of three propenyl chloride isomers, isopropenyl, *trans*-propenyl and *cis*-propenyl chlorides, has been reported. The results obtained may be summarized as follows: 1) All of these isomers homopolymerize with a radical or an ionic initiator only with difficulty, 2) the reactivity of these isomers toward an attack by a polymer radical decreases in the order of isopropenyl$\gg$*trans*-propenyl$\geq$*cis*-propenyl chloride, and 3) isopropenyl chloride copolymerizes with maleic anhydride easier than other isomers to yield a high-molecular-weight alternate copolymer. These results can be interpreted in terms both of the steric effect and the allylic termination of the substituents in these isomers.

In order to further clarify the effect of the substituents on vinyl polymerization, a study of the polymerization of four butene isomers, *n*-butene-1 (NB), isobutene (IB), *trans*-butene-2 (TB) and *cis*-butene-2 (CB), was taken up and will be reported on the present work. Several studies of the polymerization of butenes have been reported,[2-7] but no detailed study as to the polymerization of the respective butene monomers under similar conditions has been found. The present paper will deal with the effect of the methyl substituents on the polymerization and copolymerization of pure butene monomers in the presence of a radical or an ionic initiator.

## Experimental

**Materials.** — Butene monomers (Matheson Co.) were dried over calcium hydride and then purified by distillation. The physical properties of the butene monomers used in this work are shown in Table I, in which their purities as determined by gas chromatography are also indicated. The gas chromatography of the respective butene isomers was carried out by using an acetonyl-aceton column in a stream of hydrogen (30 ml./min.) at 0°C.

The vinyl acetate (VAC), acrylonitrile (AN), methyl methacrylate (MMA) and maleic anhydride (MAH) used as comonomers were purified by conventional methods.[8] Azobisisobutyronitrile (AIBN) was recrystallized from ethanol. Boron trifluoride-diethyl etherate was used after distillation. Butyllithium (Hans Heinrich Hütte), triethylaluminum (Ethyl Corp.), and titanium trichloride (Staufer Chem. Co.) were used without further purification.

**Polymerization Procedure.**—In a hard glass tube with a 20-ml. content, the required amount of initiator, solvent and comonomers were placed; this tube was then connected to a vacuum system. After degassing its contents by a repeated freezing and thawing technique, the required amount of butene monomer (which had been weighed beforehand in the vacuum system) was charged into the tube by distillation, and then the tube was sealed off.

In the case of ionic polymerization, a hard glass tube provided with a rubber stopper and from which catalytst had been charged through a syringe, besides a connecting part to vacuum system was used. The polymerization and copolymerization were carried out under shaking in a thermostat maintained at a constant temperature for a given time. After polymerization, the contents of the tube were poured into a large amount of methanol (ether was used in the case of MAH) to precipitate the polymer. The resulting polymer was washed thoroughly, filtered, dried under a vacuum at 40°C, and then weighed. In the case of the polymerization with the Ziegler catalyst, the contents of the tube were poured into a large amount of a hydrochloric acid - isopropyl alcohol mixture to precipitate the polymer, and then the polymer was purified by reprecipitation with isopropyl alcohol from a hot *n*-heptane solution. The rate of conversion was calculated from the weight of the dry polymer obtained.

The composition of the unreacted monomers after cationic or coordinated anionic polymerization was determined by gas chromatography in order to confirm the isomerization of butenes during the polymerization.

**The Analysis of the Polymer.**—The composition of the resulting polymer was determined by elemental analyses on carbon and hydrogen. The

TABLE I. PURITIES AND PROPERTIES OF THE BUTENE ISOMERS

| Monomer | Purity[a] % | B. p. °C | $d$ | Relative retention volume[b] | Composition of butenes[c] | | | |
|---|---|---|---|---|---|---|---|---|
| | | | | | IB | NB | TB | CB |
| IB | 99.27 | −6.7 | 0.674(−49°C) | 435 | 99.7 | 0.3 | 0.0 | 0.0 |
| NB | 97.90 | −6.3 | 0.669(−46°C) | 405 | 0.0 | 100.0 | trace | trace |
| TB | 99.35 | 0.9 | 0.635(−42°C) | 531 | trace | 0.0 | 99.7 | 0.3 |
| CB | 99.16 | 3.6 | | 633 | trace | 0.0 | 0.4 | 99.6 |

a) Determined by gas chromatography.
b) Relative retention volume of the butenes was calculated taking the retention time of air as unity.
c) Corrected wt. % in the butenes determined by gas chromatography.

structure of the resulting polymers was also checked by means of the infrared spectra of their films, which were made from an ethyl ether or a hot *n*-heptane solution.

The monomer reactivity ratios ($r_1$ and $r_2$) were calculated by the Fineman-Ross method.[9]

**The Determination of the Chain Transfer Constants of Butene Monomers.** — The apparent chain transfer constants ($C_m$) of butene monomers toward an attack by the polymethyl methacrylate radical were determined at 40, 50 and 60°C. The intrinsic viscosity of the resulting polymer was determined by the viscosity measurement of its dilute chloroform solution at 30°C. The number-average degree of polymerization ($\bar{P}_n$) was then calculated from the intrinsic viscosity, [$\eta$], according to the following equation:[10]

$$\log \bar{P}_n = 3.261 + 1.256 \log [\eta]$$

## Results

**The Homopolymerization of Butene Monomers.** —The results of the homopolymerization of butene monomers with various initiators are summarized in Table II. These monomers were found not to be polymerized in the presence of AIBN or of *n*-butyllithium.

In the cationic polymerization of the $BF_3 \cdot O(C_2H_5)_2$ catalyst, the reactivities of these monomers were quite low and decreased in the order of IB≫NB>TB—CB. In all cases the resulting polymers were colorless, oily and viscous. The isomerization of the respective butene monomers to the other isomers during the cationic polymerization was not observed, as Table II indicates.

Figure 1 shows the infrared spectra of the resulting polymers, in which the absorption bands characteristic of the sequences of the respective monomer units are observed in their polymers: the absorption bands due to the sequence of the butene-2 unit (1125 $cm^{-1}$),[11] the ethyl group (766 $cm^{-1}$),[12] and

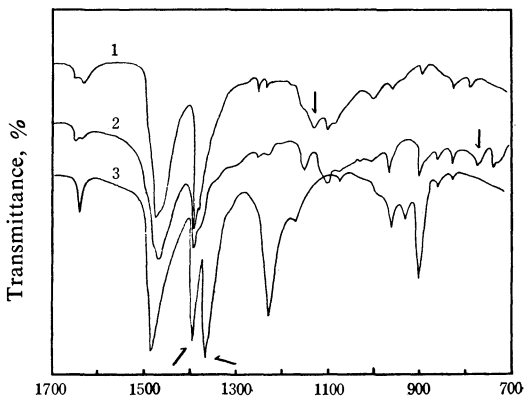

Fig. 1. Infrared spectra of polybutenes obtained with $BF_3 \cdot O(C_2H_5)_2$ (liquid film): (1) poly-*cis*-butene-2, (2) poly-*n*-butene-1, (3) polyisobutene.

*gem.*-dimethyl groups (1370, 1389 $cm^{-1}$)[13] were observed in the resulting polymers obtained from butene-2 (TB and CB), NB and IB, respectively.

In the coordinated anionic polymerization of these butene monomers by the $(C_2H_5)_3$-Al-$TiCl_3$ catalyst, as is also shown in Table II, their reactivities were in the order of NB≫CB—TB≫IB. From the results of the composition analyses (Table II) of unreacted butene monomers after the polymerization of IB and NB, the isomerization was not observed in the presence of any catalysts. However, the isomerizations from butene-2 (TB and CB) to NB and from CB to TB (or TB to CB) during the polymerization in the presence of the $(C_2H_5)_3Al$-$TiCl_3$ catalyst were observed.

Figure 2 shows the infrared spectra of these resulting polymers. It was clear that the polymers obtained from IB and NB showed absorption bands due to IB and NB units, respectively, in their infrared spectra. On the other hand, the infrared spectra of the

the monomer feed ratio and to be a 1 : 1 molar composition of MAH and the butene monomer.

IB copolymerized quite readily with MAH to give a colorless polymer which had a relatively high specific viscosity. However, the other butene monomers copolymerized at a rather slow rate, and light yellow-colored copolymers of a lower specific viscosity were obtained. Accordingly, it was clear that the tendency of these butene monomers to alternate copolymerization with MAH decreased in the order of IB≫NB≥CB≥TB.

The rate of the copolymerization of butene monomers with MAH increased with an increase in the initial concentration of the butene monomer and showed the maximum shown in Fig. 6.

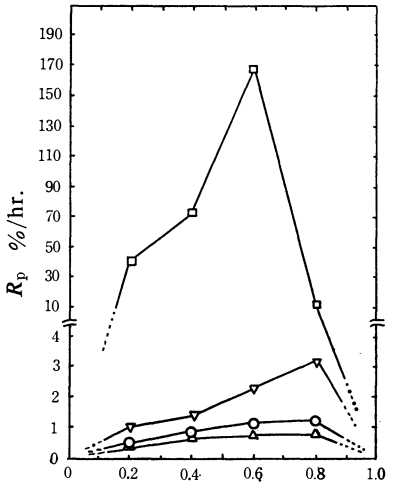

Fig. 6. Relationship between $R_p$ and monomer feed ratio for copolymerization of butenes ($M_1$) with MAH ($M_2$) initiated by AIBN at 60°C.

▽ *n*-Butene
△ *trans*-Butene
○ *cis*-Butene

**The Monomer Reactivity Ratio and the *Q* and *e* Values for Butene Monomers.**—The monomer reactivity ratios ($r_1$ and $r_2$) were calculated for these copolymerizations according to the Fineman-Ross method.[9] The results are summarized in Table V. From the values of $r_1$ and $r_2$ for the copolymerization with VAC, the $Q$ and $e$ values for butene monomers were calculated by assuming that $Q=0.026$ and $e=-0.22$ for VAC.[14]

As may be understood from this table, the values of $Q_1$ for butene monomers and the values of $1/r_2$ which might indicate the reactivity of butene monomers to polymer radicals were found to have the same tendency in their reactivities to cationic polymerization.

**The Chain Transfer Constants of Butene Monomers.**—Since it was confirmed from the elemental analyses and the infrared spectra of the resulting polymers that these butene monomers scarcely copolymerized with MMA at all, the apparent chain transfer constant of

these butene monomers toward an attack by a polymethyl methacrylate radical were determined. The results are shown in Figs. 7—10 and Table VI.

Table VI also shows the relative reactivities of a methyl radical to butene isomers determined by Szwarc and his co-workers.[15] In this table, $k_1$, $k_2$ and $k_3$ are the rate constants, respectively, for hydrogen abstraction from isooctane, for addition to butenes, and for hydrogen abstraction from butenes toward the attack of a methyl radical.

## Discussion

In Tables II and III it was observed that these butene monomers did not homopolymerize in the presence of a radical initiator and that their copolymerization reactivities with VAC were in the order of IB≫NB>TB—CB. The

15) R. P. Buckley, F. Leavitt and M. Szwarc, *J. Am. Chem. Soc.*, **78**, 5557 (1956); R. P. Buckley and M. Szwarc, *Proc. Royal Soc.*, **A240**, 396 (1957).

results for butene isomers were almost the same as those for propenyl chloride isomers.[1)]

The low reactivitities of butene-2 monomers which are 1,2-disubstituted ethylene may be understood as the result of an increased steric effect of the substituents. It is also supported by the smaller $Q$ values of TB and CB than those of IB and NB, as Table V shows.

In the copolymerizations of propenyl chloride isomers, it was found that the trans-isomers were about two or three times more reactive than the cis-isomer toward attacks by polymer radicals. However, TB and CB were found to have almost the same reactivity. This result may be interpreted as indicating that CB takes a coplanar structure just like that of TB in the transition state.

From Table IV it is obvious that the tendency of the butene monomers to alternate copolymerization with MAH decreases in the order of IB$\gg$NB$>$CB$\geq$TB, which is similar to the findings concerning propenyl chloride isomers.[1)] This order in the reactivity of butene isomers was also similar to that of their hydrogen abstractions by the methyl radical and the polymethyl methacrylate radical, as is shown in Table VI. Accordingly, it may be concluded that the degradative chain transfer reactivity of butene isomers, which might be determined by their steric effects, is an important factor in their polymerizations and copolymerizations in the presence of a radical initiator.

The rate of the copolymerization of butene or propenyl chloride isomers with MAH markedly decreases with an increase in the concentration of butene or propenyl chloride in the monomer mixture. However, it is interesting that the rates of the copolymerizations of butenes with MAH gave a maximum as a function of the monomer concentration, as is shown in Fig. 6. This result might indicate that the specific stabilization of the transition state in alternating propagation which would lead to an energy-lowering is significant, as has been pointed out by Price[16)] and Walling[17)].

As can be seen from Table II, no butene monomers could be homopolymerize in the presence of *n*-butyl lithium, and only IB could be homopolymerized by $BF_3 \cdot O(C_2H_5)_2$. Their reactivities for cationic polymerization decreased in the order of IB$\gg$NB$>$TB—CB, and no isomerization was observed during the polymerization.

As is clearly shown in Table II, however, NB, TB and CB could be easily homopolymerized in the presence of the $(C_2H_5)_3Al$-$TiCl_3$ catalyst to give high-molecular-weight polymers. It was noted that TB and CB, which were known[18)] not to homopolymerize because of the steric effect, could homopolymerize at rather high temperatures. It was confirmed by infrared spectra and X-ray diffraction analyses that all of the polymers resulting from TB and CB consisted of the NB sequence.

The isomerization from TB to CB or NB and that from CB to TB or NB during the polymerization were observed in the presence of this coordinated catalyst. Accordingly, it was deemed that TB and CB isomerized into NB in the presence of $(C_2H_5)_3Al$-$TiCl_3$ catalyst and then polymerized to give a high-molecular-weight polymer of NB. The mechanism of the polymerization of butene-2 by the Ziegler-Natta catalyst will be described in detail in the next paper.

## Summary

The effect of the methyl substituents of four butene isomers (IB, NB, TB and CB) on their polymerizations and copolymerizations has been investigated. None of these monomers homopolymerized in the presence of an ordinary radical or in that of anionic catalysts, but they were homopolymerized by cationic catalysts. The reactivity of these monomers toward their cationic polymerizations and radical copolymerizations has been found to decrease in the order of IB$\gg$NB$>$TB—CB. These results have been interpreted on the basis of the steric effect and the chain transfer reactivity of the methyl substituents in these monomers.

These monomers, except for IB, can easily be homopolymerized by the Natta catalyst in the reactivity order of NB$\gg$TB—CB. The resulting polymers from TB and CB have been confirmed to be the same as the polymer from NB, which consisted of the recurring unit of *n*-butene-1.

The authors wish to thank Dr. Riichiro Imoto of the Toyo Soda Co. for his helpful suggestions and encouragement.

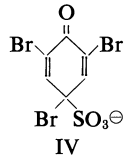
# The Reaction of 3, 5-Dibromo-4-hydroxybenzenesulfonyl Chloride with Weak Bases (The Question of the "Quinoid Sulfene" Intermediate*)

By Shigeru OAE and Reiko KIRITANI

(Received February 22, 1965)

Many decades ago, Zincke[1] and his coworkers suggested the formation of the "sulfene" intermediate (II) in the reaction of 3, 5-dibromo-4-hydroxybenzenesulfonyl chloride (I) with either sodium acetate or carbonate in an aqueous acetone solution; they made this suggestion on the basis of their observations that a bright yellow color is formed and then gradually disappears during the reaction, finally giving a colorless precipitate which was presumed to have structure (III).



I II III

The possibility of this "quinoid sulfene" intermediate is rather fascinating in view of the recent interest in aliphatic "sulfene."[2] However, there has been no legitimate evidence to substantiate the formation of the intermediate during the reaction, nor has the product ever been proved to have structure III.

We have investigated this reaction, first by following the change in the ultraviolet absorption and then by determining the structure of the product. When an acetone solution of 3, 5-dibromo-4-hydroxybenzenesulfonyl chloride was mixed with a 20% aqueous solution containing an equimolar amount of potassium acetate, a bright yellow color developed immediately. Meanwhile, colorless precipitates started to form gradually and the yellow color faded away. Then the ultraviolet absorption was swept at several time intervals. The results are shown in Fig. 1. At an early stage of the reaction, when the yellow color was still strong, one saw a clear maximum at 310 m$\mu$, but this maximum gradually faded away as time passed. The strong absorption around 310 m$\mu$ might be due to the quinoid structure of the intermediate "sulfene."

However, Cannell[3] has recently shown that the quinoid intermediate (IV) formed during the bromination of sodium 3, 5-dibromo-4-hydroxybenzenesulfonate has a strong absorption around 280 m$\mu$ ($\varepsilon = 11400$).

IV

The process was also followed by the sweeping of the infrared spectrum around 1500—2000 $cm^{-1}$, in order to detect the presence of a conjugated carbonyl group. However, as Fig. 2 shows, there was no detectable absorption of any carbonyl function in the spectrum.

Since quinoid compounds are known to undergo electron transfer with phenolic compounds, thus forming fairly stable radicals, usually detectable by means of ESR spectroscopy,[4] the color which appeared in this reaction was suspected of being associated with the formation of an radical. The ESR spectrum was taken during the process of color formation. However, no detectable signal was observed.

Therefore, we have at present no concrete evidence to support the formation of the "quinoid sulfene" intermediate, nor can we offer any alternative suggestion as to the nature of the yellow color or of the incipient ultraviolet absorption perk at 310 m$\mu$.

When triethylamine was used in place of sodium acetate, it was found to effect the same reaction. In fact, with the tertiary amine one

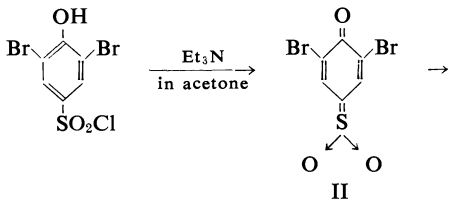
can use anhydrous conditions and usually get better results. However, in this case the product appeared to be slightly more soluble in benzene, nitrobenzene or dioxane, possibly because of the lower molecular weight. Several attempts were made to freeze the intermediate for physical measurement by running the reaction in a dry-ice acetone bath. However, as soon as the solvent was evaporated, only a colorless precipitate remained.

The colorless precipitate, which was presumed to have structure III, is insoluble in most common solvents but only sparingly soluble in benzene and a little more soluble in nitrobenzene. It has no melting or decomposition points below 350°C. Since the amorphous precipitate is sparingly soluble in benzene and nitrobenzene, the molecular weight determination in these solvents was not successful, despite repeated careful attempts.

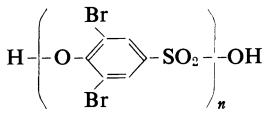
When this material was refluxed in a 6 N sodium hydroxide solution for an hour, the precipitate dissolved completely to give a clear solution. From the clear solution 3, 5-dibromo-4-hydroxybenzenesulfonic acid was recovered almost quantitatively as its *S*-benzylthiuronium salt. The mode of the facile hydrolysis was very similar to that with phenyl benzenesulfonate.[5] The acid hydrolysis was very sluggish and was found to take place only above 160°C in a sealed tube using 10 N hydrochloric acid, similar to the case of phenyl benzenesulfonate.[6] When it was hydrolyzed at 180°C for 24 hr., 3, 5-dibromo-4-hydroxybenzenesulfonic acid was recovered in an almost quantitative yield as its *S*-benzylthiuronium salt. These observations on the hydrolyses, together with the analytical data, seem to suggest that the precipitate has a structure similar to phenyl benzenesulfonate, possibly a linear oligomer such as V.

V



Both the infrared and the ultraviolet spectra of the material is almost identical with those of 3, 5-dibromo-4-hydroxybenzenesulfonic acid. Zincke's cyclic structure will not give similar ultraviolet and infrared spectra, because the molecule of the structure would be terribly strained and might be expected to change the nature of the electronic behavior considerably.

A rough determination of the terminal hydroxy group was carried out by reacting with phenyl isocyanate the precipitate obtained in the reaction with triethylamine. The product, presumably the urethan of the oligomer V, obtained in this reaction did not melt below 350°C, but its analytical composition is that of the phenyl urethan of either tetramer or pentamer of V, or a mixture of both.



It is interesting to note that the oligomer can be crystallized from benzene, but that the crystals become amorphous powder when benzene is completely evaporated. A preliminary X-ray analysis[7] revealed the same phenomena.

Since the crystals were rather short-lived outside of the benzene solution, no further attempt was made to determine the structure. However, they are most likely a kind of clathrate complex, the oligomer and benzene being the host and the guest molecules respectively.

In conclusion, the reaction of 3, 5-dibromo-4-hydroxybenzenesulfonyl chloride (I) with a base such as triethylamine produces an quasi-stable intermediate, possibly the "quinoid sulfene" intermediate (II), which is sufficiently long-lived to find a few similar partner with which to oligomerize to the oligomer V, as is shown below:

II

## Experimental

**3, 5-Dibromo-4-hydroxybenzenesulfonyl Chloride.** — Sodium 3, 5-dibromo-4-hydroxybenzenesulfonate was obtained by the methods reported by Huston and Neeley,[8] and by Oshima[9] (yield 88%). The product was recrystallized from water and identified as 3, 5-dibromo-4-hydroxybenzenesulfonic acid *S*-benzylthiuronium salt; m. p. 192—193°C.

Found: C, 33.23; H, 2.81. Calcd. for $[C_6H_3Br_2O_4S]^-[C_6H_5CH_2SC(NH_2)_2]^+$: C, 33.05; H, 2.60%.

When the product was then allowed to react with a mixture of phosphorus oxychloride and

phosphorous pentachloride,[1a] 3,5-dibromo-4-hydroxybenzenesulfonyl chloride was obtained (66% yield from sodium salt). The sulfonyl chloride thus obtained was recrystallized from benzene; m. p. 128—129°C (Found: C, 20.2; H, 0.82%).

**The Reaction of 3,5-Dibromo-4-hydroxybenzenesulfonyl Chloride with Sodium Acetate.**[1b]—A solution of 3,5-dibromo-4-hydroxybenzenesulfonyl chloride (2 g., 0.0058 mol.) and 5 ml. of acetone was cooled in an ice-water bath. As soon as an equimolar amount of a 20% aqueous sodium acetate solution (3.5 ml.) was slowly added to the solution, the mixture turned a bright yellow; this color gradually disappeared during the reaction, and white precipitates were formed. The mixture was heated to reflux gently for a few minutes and then allowed to stand. The colorless solid product was obtained in a 30—35% yield based on the starting sulfonyl chloride. It could be recrystallized from nitrobenzene (no m. p. below 350°C). Together with the water-insoluble solid, the hydrolysis product, 3,5-dibromo-4-hydroxybenzenesulfonic acid, was also obtained from the filtrate; it was identified as a *S*-benzylthiuronium salt. The unchanged reactant was also recovered.

**The Reaction of 3,5-Dibromo-4-hydroxybenzenesulfonyl Chloride with Triethylamine.**—An acetone solution of 3,5-dibromo-4-hydroxybenzenesulfonyl chloride (2 g. in 5 ml. of acetone) was cooled and added to an equimolar amount of triethylamine. The reaction was nearly identical with that in an aqueous acetone solution with sodium acetate. The water-insoluble colorless product (yield 30—35%) was slightly soluble in hot benzene (no m. p. below 350°C). Recrystallization from benzene gave colorless shiny prismatic crystals in the bottom of the benzene layer; however, when the crystals were collected on filter paper, they gradually pulverized to an amorphous white powder. The analytical values of the colorless precipitate are as follows:

| | C% | H% | Br% | S% |
|---|---|---|---|---|
| Calcd. for III | 22.92 | 0.64 | 50.93 | 10.21 |
| Calcd. for $V_{n=5}$ | 22.69 | 0.76 | 50.33 | 10.10 |
| Found (by Zincke et al.) | 23.36 | 0.40 | 50.75 | 10.07 |
| Present investigation | 22.59 | 0.77 | 50.83 | 9.99 |

**The Alkaline Hydrolysis of the Colorless Precipitate.**—The colorless precipitate (1 g.) was added to a 20% aqueous sodium hydroxide solution (25 ml.); the mixture was refluxed for 1.5 hr., neutralized with hydrochloric acid, and finally evaporated down to 2 ml. When a few drops of hydrochloric acid and *S*-benzylthiuronium chloride (0.7 g.) were added to this solution, the *S*-benzylthiuronium salt of 3,5-dibromo-4-hydroxybenzenesulfonic acid (1.5 g.) was obtained (in a nearly quantitative yield).

**The Acid Hydrolysis of the Colorless Precipitate.**—The colorless precipitate (1 g.) and 10 N hydrochloric acid (20 ml.) were sealed in a tube and heated at 180°C for 24 hr. The resultant mixture was filtered, and the filtrate was treated with *S*-benzylthiuronium chloride as described above; the *S*-benzylthiuronium salt of 3,5-dibromo-4-hydroxybenzenesulfonic acid (1.3 g.) was obtained. The precipitate was found to be the unchanged polymer (0.1 g., 10%).

**The Reaction of the Colorless Precipitate with Phenyl Isocyanate.**[10]—Phenyl isocyanate (0.3 g., 0.0025 mol.) was added to a solution of the colorless precipitate (1.6 g., 0.0025 mol. as the linear dimer) in 20 ml. of dioxane, and then a few drops of anhydrous pyridine were added to the mixture. After the mixture has been refluxed for one hour, the solvent was removed. The residual precipitate was washed thoroughly with a large quantity of ice-water. Thus, a light brown precipitate partially soluble in benzene was obtained (1.6 g.) (no m. p. below 350°C). The analytical values of the product recrystallized from benzene, shown below, indicate that the urethan derivative of the oligomer was a mixture of the tetramer and the pentamer.

Found: C, 26.43; H, 1.15; Br, 46.46; S. 9.31; N, 0.88. Calcd. for $C_{37}H_{17}O_{17}Br_{10}S_5N$ (pentamer): C, 26.03; H, 1.00; Br, 46.82; S, 9.39; N, 0.82, for $C_{31}H_{15}O_{14}Br_8S_4N$ (tetramer): C, 26.73; H, 1.09; Br, 45.90; S, 9.21; N, 1.01%.

**Ultraviolet Spectra.**—The ultraviolt spectra of the "quinoid sulfene" intermediate, the colorless precipitate and 3,5-dibromo-4-hydroxybenzenesulfonyl chloride are shown in Fig. 1.

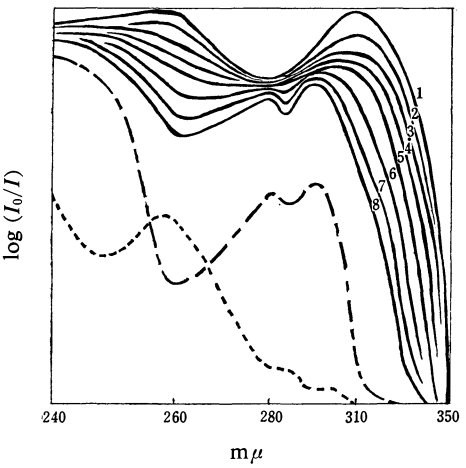

Fig. 1

—— UV spectra of quinoid sulfene intermediate: 1, 2, 3, ···, 8, after mixing the 3,5-dibromo-4-hydroxybenzenesulfonyl chloride in dioxane with an aqueous equimolar amount solution of potassium acetate, 30 sec., 5, 10, 20, 30, 40, 50, and 60 min.

—·— The oligomer V

---- 3, 5-Dibromo-4-hydroxybenzenesulfonyl chloride ($4\times10^{-7}$ mol./ml.) in *n*-hexane

A known amount of 3,5-dibromo-hydroxybenzenesulfonyl chloride was dissolved in pure dioxane ($1\times10^{-5}$ mol./10 ml.), and also an aqueous solution in which has been dissolved an equimolar amount of potassium acetate solution ($1\times10^{-5}$

10) See "Urethans" in "The Systematic Identification of Organic Compounds," by R. L. Shriner and R. C. Fuson, John Wiley & Sons, New York, N. Y. (1956), p. 211.

mol./10 ml.) was prepared. The two solutions were separately cooled in an ice-salt bath before mixing. As soon as the cooled dioxane solution was mixed with the aqueous solution, the ultaviolet spectra of the mixed solution were followed from time to time by a ultraviolet photospectrometer, with special attention paid to the absorption band at 310 mμ.

**Infrared.**—The infrared spectrum of the "quinoid sulfene" intermediate, sweeping at around 1500—2000 $cm^{-1}$, is shown in Fig. 2.

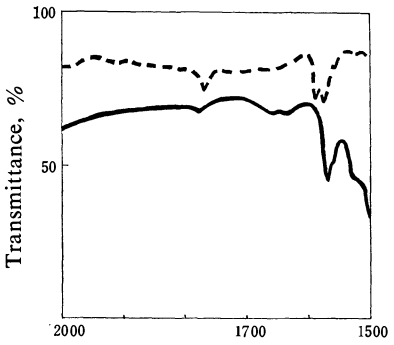

Fig. 2

—— Infrared spectra of quinoid sulfene intermediate: after mixing the 3,5-dibromo-4-hydroxybenzenesulfonyl chloride in dioxane with triethylamine, 1 min.

---- 3,5-Dibromo-4-hydroxybenzenesulfonyl chloride in dioxane

A triethylamine-dioxane solution (1 mol. soln.) was put into a liquid cell (0.5 mm. thick) containing the same amount of a solution of 3,5-dibromo-4-hydroxybenzenesulfonyl chloride in dioxane (1 mol. soln.). After the mixture has been sufficiently shaken, the absorption of the carbonyl group was followed as soon as possible. The infrared spectrum of the solid precipitate, the oligomer V, is shown in Fig. 3.

At 3450 $cm^{-1}$, the absorption of the hydroxy group is clearly observed, while at 1210—1150, 1060—1030 and near 650 $cm^{-1}$ the absorption of the $-SO_3H$ and $-SO_3-$ groups are observed in contrast with that of the reactant. The figure is simple and resembles the combined infrared absorption spectra of 3,5-dibromo-4-hydroxybenzenesulfonic acid phenyl benzenesulfonate.

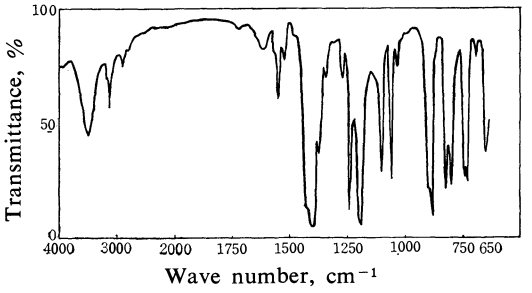

Fig. 3. Infrared spectrum of polymer in KBr disk.

**Electron Spin Resonance.**—All the ESR measurements were performed at X band frequencies, using a spectrometer equipped with a 100 Kc. modulation unit. A solution of 3,5-dibromo-4-hydroxybenzenesulfonyl chloride in dioxane (1.43 mol. soln.) was put into a quartz cell, and then a few drops of a triethylamine or potassium acetate-dioxane solution were added. Before the yellow color had disappeared, the samples were measured at room temperature and −180°C (the *g*-factor was 2.05—1.95). As no electron spin resonance signals were detected, the radical concentration was presumed to be below $10^{-6}$ mol.

## Summary

The formation of the "quinoid sulfene" intermediate, II, during the reaction between 3,5-dibromo-4-hydroxybenzenesulfonyl chloride and a weak base has been investigated by following the ultraviolet spectra of the reaction mixture. It has been suggested that the colorless precipitate formed as the final product of the reaction is an oligomer and has structure V.

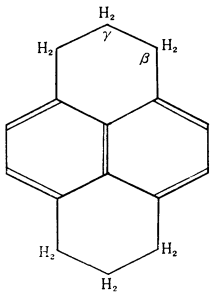
# Line-Width Alternation in the Electron Spin Resonance Spectra of the Anion Radicals of Hydropyrenes[1)]

By Masamoto IWAIZUMI and Taro ISOBE



(Received February 23, 1965)

Recently, a number of ESR spectra have been reported in which the line width alternate in magnitude from one hyperfine component to another. This althernating line-width has been observed in the spectra of the durosemiquinone cation,[2)] the naphthazarine semiquinone cation,[3)] the dinitrodurene anion,[4)] the *m*-dinitrobenzene anion,[5)] the pyracene anion,[6)] and several other radicals.[7)] In the former two cases, the phenomenon has been attributed to the hindered rotation or rotational isomerization of the hydroxy groups, and in the dinitrodurene radical, to the hindered rotation of the nitro groups. On the other hand, in the case of the *m*-dinitrobenzene anion, the phenomenon has been ascribed to the effect of the collisions with solvent molecules or to the effect of formation of short-lived solvent complexes, and in the case of the pyracene anion, to the effect of the movement of the associated counter ions.

In this paper, we will report on the ESR of the anion radicals of 4, 5, 9, 10-tetrahydropyrene (I) and 1, 2, 3, 6, 7, 8-hexahydropyrene

(I)

(II)

(II). The ESR spectra of these radicals vary with the temperature remarkably and exhibit a marked line-width alternation effect, which may be attributed to the conformational interconversion: the inversion in the tetrahydropyrene anion radical, and the isomerization between the chair-like conformation and the boat-like one in the hexahydropyrene anion radical. Recently, de Boer et al.[8)] found the same phenomenon in the hexahydropyrene anion radical. We will indicate, furthermore, that the ESR spectrum of the hexahydropyrene anion radical, when the radical is prepared with sodium or with potassium in THF, shows one more additional line-width alternation effect, which may be attributed to the effect of the associated counter ions, as in the case of the alkali-pyracene radical ion.

## Experimental

Commercial tetrahydropyrene and hexahydropyrene were purified by chromatography. The radicals were prepared by an alkali metal reduction method. The alkali metals used were lithium, sodium, and potassium, and the solvents used were 1,2-dimethoxyethane (DME) and tetrahydrofuran (THF). The ESR spectra were measured with a Hitachi X-band ESR spectrometer, model MPU-3B, using field modulation at 100 kc./s. The temperature was controlled by letting dry and cooled nitrogen gas flow through a Dewar jacket passing through the sample cavity, and the temperature was varied by changing the flow rate of the gas. The temperature was measured with a copper-constantan thermocouple.

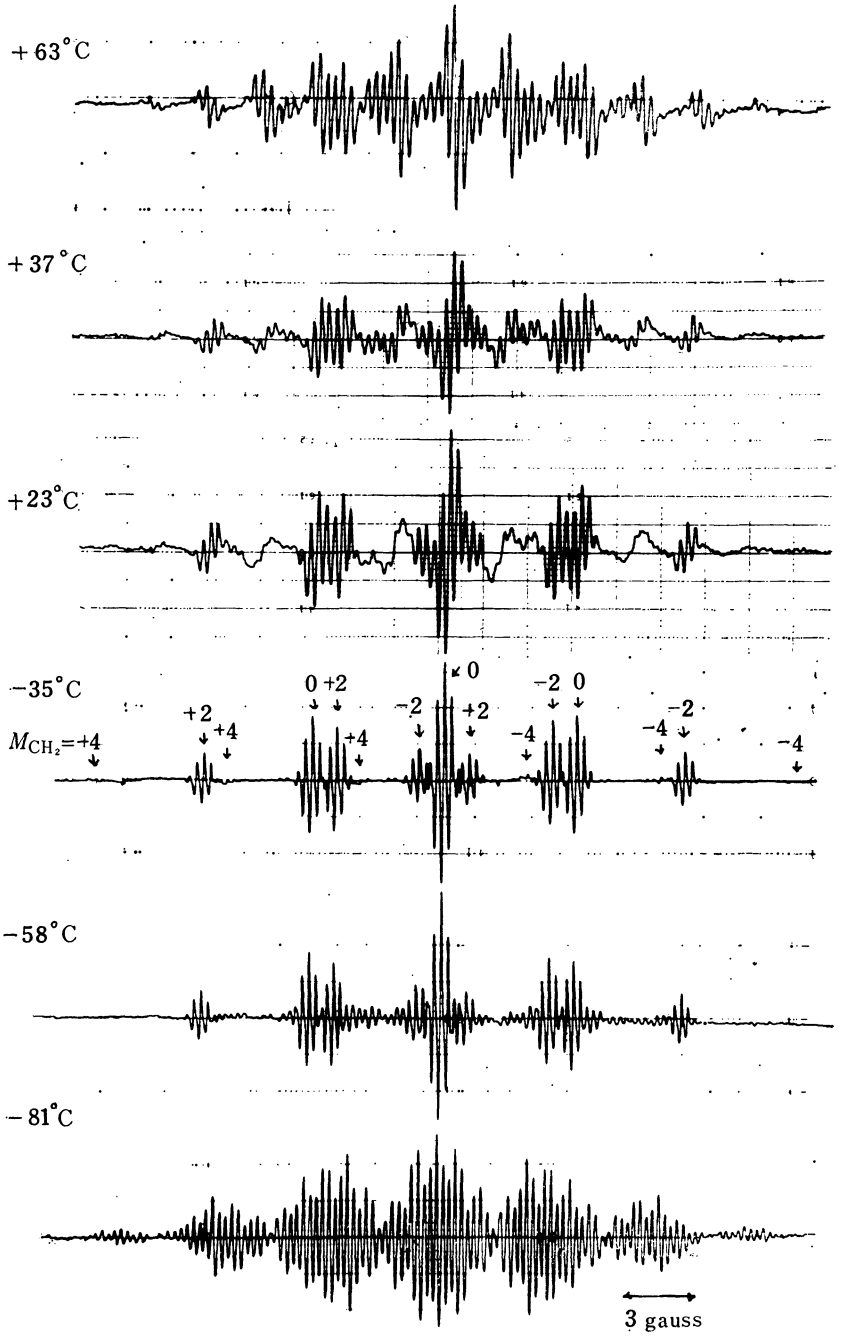
## Results and Discussion

**The ESR Spectra of the Tetrahydropyrene Anion Radical.**—All the anion radicals of the tetrahydropyrene prepared under the respective conditions mentioned above exhibit similar spectra, though the spectra are not strictly identical in respect to the broadening, probably because of the coupling with metal ions. Representative spectra are shown in Fig. 1. At elevated temperatures, +63°C, the spectrum is well resolved and can be interpreted as arising from a triplet splitting due to the two equivalent protons, a fairly small nonet splitting from eight equivalent protons, and a still smaller quintet splitting from four equivalent



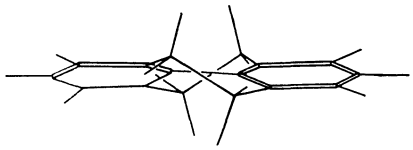


Fig. 1. ESR spectra of 4,5,9,10-tetrahydropyrene anion radical in DME at various temperatures with $K^+$ as counter ion.

protons. Based on the symmetry of the molecule, one can unambiguously attribute the triplet splitting to the coupling at position 2, the nonet splitting, to the coupling with aliphatic protons, and the quintet splitting, to the coupling at position 1. On the other hand, at room temperature or below, the spectrum exhibits a marked line-width alternation effect: let $M_{CH_2}$ be the total $z$ component of the nuclear spin angular momenta of the methylene protons; the hyperfine components with $M_{CH_2} = \pm 1$ and $\pm 3$ are then broadened considerably, and at $-35°C$, they are not observed in a spectrum recorded at a low amplitude of the field modulation. At still lower temperatures, this alternation effect again disappears, and the splittings due to the methylene protons are divided into two quintet splittings, the hyperfine splitting constants being 3.78 and 0.79 gauss. The variation in the spectra with the temperature was completely reversible except that, about 50°C, a diminution in the signal intensity due to the decomposition of the radicals was observed. The observed hyperfine splitting constants are listed in Table I.

Here, one would like to consider the structure of the tetrahydropyrene anion radical. In view of the results obtained by Braude et al.,[9] it is likely that the tetrahydropyrene anion radical is in a non-planar conformation (III)

(III)

and that the two methylene protons are not in the same situation: one of them is placed in the axial conformation, while the other is in the equatorial. When the inversion of the molecular conformation occurs, the situations of the two methylene protons will be reversed. If the life time of the individual configuration, $\tau$, is sufficiently short compared with $|\gamma(a_{equ.} - a_{ax.})|^{-1}$, where $\gamma$ is the gyromagnetic ratio of the electron and where $a_{equ.}$ and $a_{ax.}$ are the respective hyperfine splitting constants for the equatorial and the axial protons, the hyperfine splitting due to the methylene protons will be an average of the axial and the equatorial proton splittings. If the life time of the individual configuration is sufficiently long, the respective splittings due to the equatorial and the axial protons will be observed. However, when the life time of the individual configuration is comparable with $|\gamma(a_{equ.} - a_{ax.})|^{-1}$, the line-width alternation effect will be observed. Experiments at various temperatures yield spectra corresponding to each of these situations. The spectrum observed at 63°C corresponds to $|\gamma(a_{equ.} - a_{ax.})|^{-1} \ll \tau$, that observed at $-81°C$, to $|\gamma(a_{equ.} - a_{ax.})|^{-1} \gg \tau$, and that observed at intermediate temperatures, to $|\gamma(a_{equ.} - a_{ax.})|^{-1} \approx \tau$. Therefore, it seems reasonable to conclude that the variation in the spectra with the temperature and the line-width alternation effect may be attributed to the dynamical motion of the inversion of the molecular conformation. The two hyperfine coupling constants for the methylene protons, observed at $-81°C$, are assigned to the couplings with the axial and the equatorial protons, the larger to the axial protons and the smaller to the equatorial, on the basis of theoretical considerations.[10] Recently, Ōki et al.[11] examined the rate of the inversion of $o,o'$-bridged biphenyls by the NMR technique. In their technique, the rate of the inversion of the tetrahydropyrene was found to be too fast for the two kinds of methylene protons to be observed separately.

Using the hyperfine coupling constants for the equatorial and the axial protons, the life time of the individual configuration can be calculated to be in the range of $10^{-7}$—$10^{-9}$ sec. From the temperatures of their upper and lower limits, the inversion barrier may be estimated to be 4—5 kcal./mol.

Table I. Hyperfine splitting constants for the tetrahydropyrene anion radical
(in gauss)

| | +23°C | −81°C |
|---|---|---|
| $a_1$ | 0.32 | 0.28 |

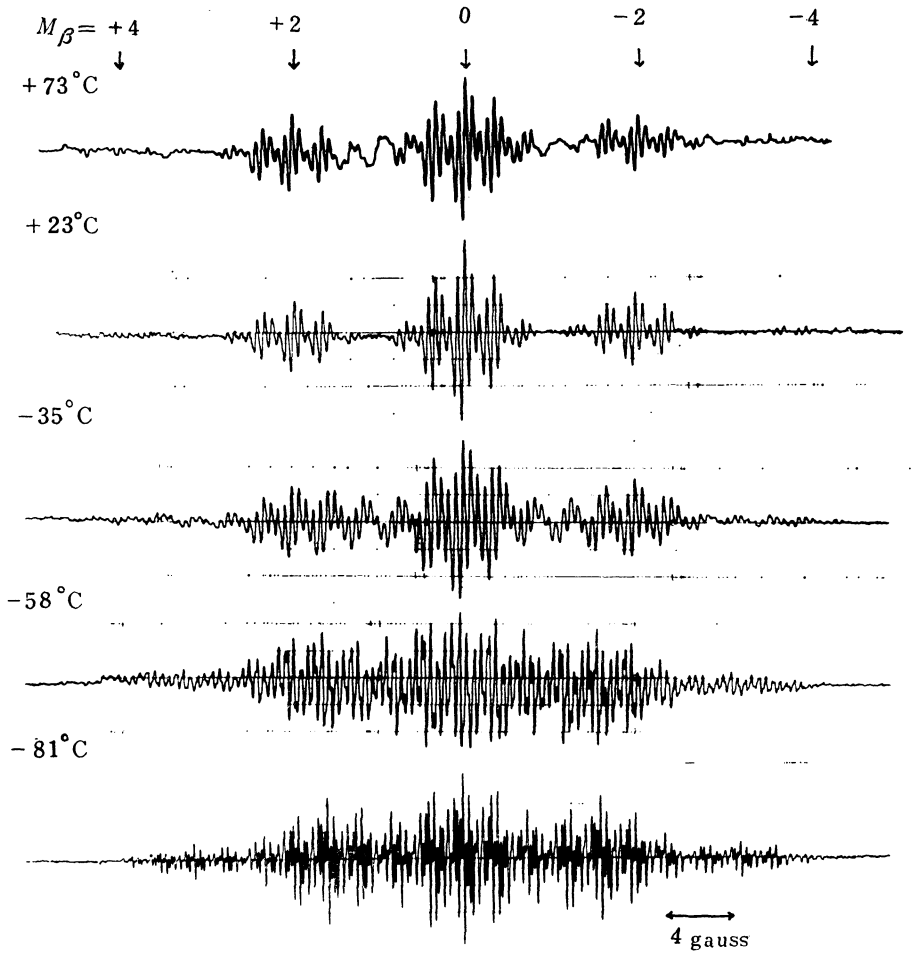

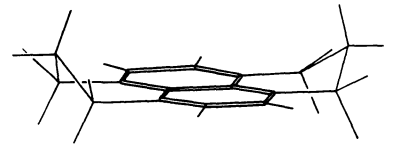

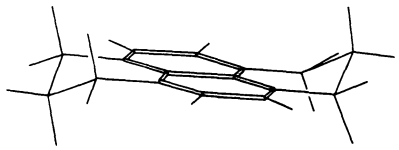

Fig. 2. ESR spectra of 1,2,3,6,7,8-hexahydropyrene anion radical in DME at various temperatures with $K^+$ as counter ion.

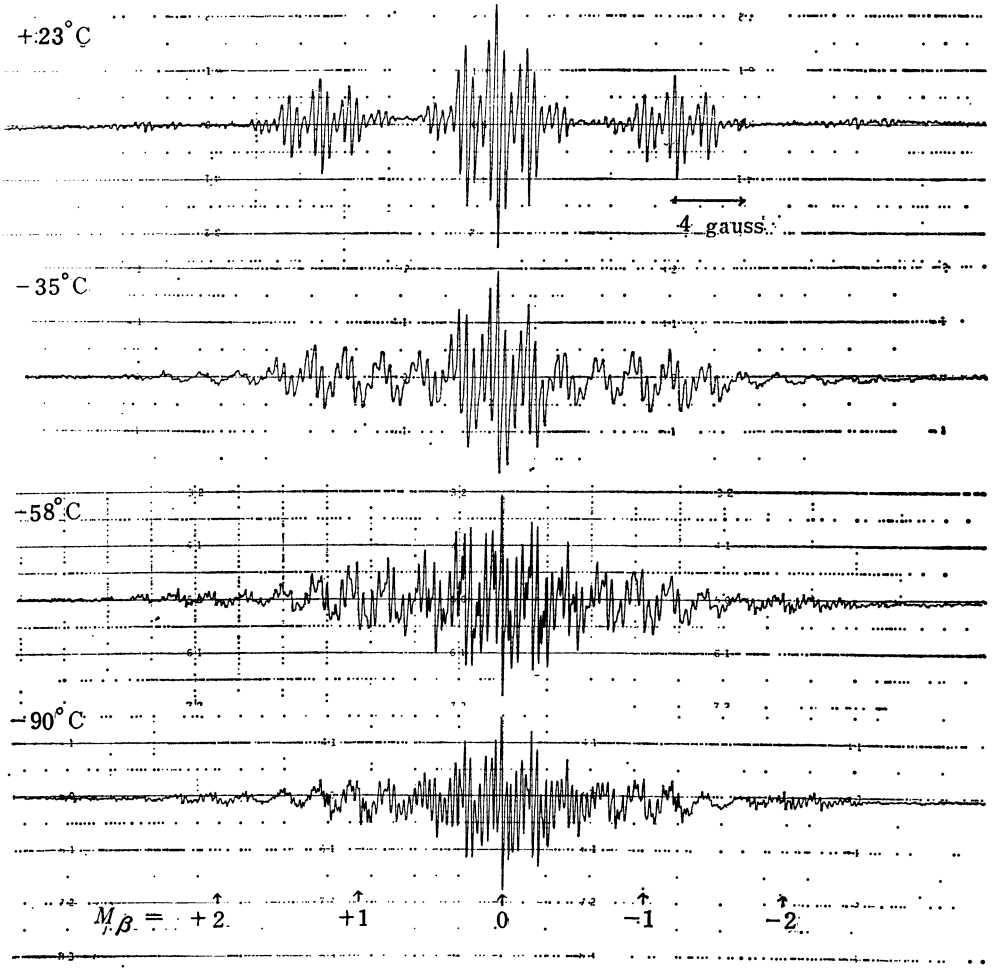
These changes in the spectrum with the temperature can be explained, as has recently been reported by de Boer et al.,[8] in terms of the dynamical equilibrium between the boat-like (IV) and the chair-like (V) conformations of the radical ions. This causes modulations in the isotropic hyperfine splittings, giving rise to a pronounced line-width alternation effect. The spectrum at a lower temperature is well explained by the hyperfine splittings coming from the fixed conformations of the radical. The hyperfin splitting constants are listed in Table II. However, when the temperature of the solution is raised, a marked alternation in the widths of the hyperfine components of the $\beta$ proton multiplet is observed. At room temperature, only the five components with $M_\beta$= 0, $\pm 2$ and $\pm 4$ and with statistical weights of 18 : 8 : 1 are observed, where $M_\beta$ is the total $z$ component of the nuclear spin angular momenta of the methylene protons at the $\beta$ position. The other components are broadened and unobservable at a low field amplitude of the field modulation, and the mean life time of the individual configuration may be comparable with the hyperfine separation between two $\beta$ protons, $\sim 10^{-8}$ sec.

(IV)

(V)

As compared with the spectra in Fig. 2,



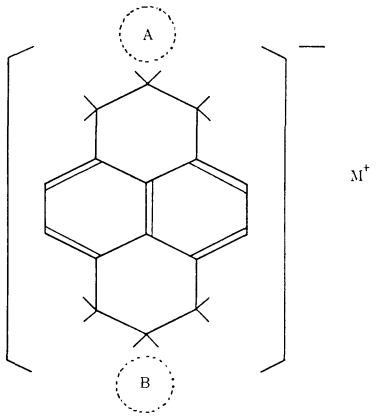


Fig. 3. ESR spectra of 1,2,3,6,7,8-hexahydropyrene anion radical in THF at various temperatures with $K^+$ as counter ion.

however, the spectra coming from the radicals prepared by the reduction with potassium or sodium in THF show somewhat different features, at lower temperatures, from those in Fig. 2, as is shown in Fig. 3. In these spectra, a marked alternation in the widths of the hyperfine components of the axial protons at the $\beta$ position is observed; the hyperfine components with $M_{\beta.ax.}=\pm1$ are broader than those with $M_{\beta.ax.}=0$ and $\pm2$, where $M_{\beta.ax.}$ is the total $z$ component of the nuclear spin angular momenta of the axial protons at the $\beta$ position.

Recently, de Boer et al.[6] observed a line width alternation effect in the ESR spectrum of the alkali-pyracene radical ion. In this case the phenomenon was ascribed to the effect of the motion of the associated alkali metal ion between two equivalent positions in the anion radical. In the present case the situation seems similar to that of the pyracene anion radical. Therefore, the following may be considered. In DME the alkali metal-hexahydropyrene radical is completely dissociated into ions, whereas in THF an ion pair (VI)

(VI)

occurs, and a dynamic equilibrium exists between the two possible conformations of the ion pair. Considering it analogously to the alkali-pyracene radical ion, the alkali metal may be placed on two symmetrical positions, A and B.

**The Hyperfine Splitting Constants of the Aliphatic Protons.** — The isotropic hyperfine splitting constants of aliphatic protons in a variety of hydrocarbon-free radicals have been determined by ESR studies. Heller and McConnell[10] have suggested that the hyperfine splitting constants for protons at the $\beta$ position* can be described by the relation:

$$a_{\beta}^{H} = (A + B\cos^2\theta)\,\rho_C^{\pi}$$

where $\rho_C^{\pi}$ is the spin density in the p orbital of the contiguous carbon atom, $\theta$ is the angle between the axis of the p orbital and the C-H bond, both projected on a plane perpendicular to the C-Ar bond, and $A$ and $B$ are constants. This equation has been justified by the studies of a variety of irradiated single crystals of alkyl carboxylic acids and others.[12] In these crystals the protons are frequently considered to be in fixed orientations.

In our experiments, at a sufficiently low temperature, the radicals reveal the hyperfine splitting constants in a fixed orientation, although the radicals are in solutions. If it is assumed that $A=0$, $B=46$ gauss and $\theta_{ax.}=\theta_{equ.}-120°$, where $\theta_{ax.}$ and $\theta_{equ.}$ are the $\theta$ values for the axial and the equatorial protons, from the above relation one may calculate that $\theta_{ax.}=3°$ and $\rho_C^{\pi}=0.08$ for the tetrahydropyrene anion radical, and $\theta_{ax.}=0°$ and $\rho_C^{\pi}=0.17$ for the hexahydropyrene anion radical. These angles are approximately that found in models of these molecules. The values of $\rho_C^{\pi}$ are comparable to the spin densities, 0.11 and 0.20, at the corresponding positions in the naphthalene and the biphenyl anion radicals,[13] which have conjugation systems similar to those of the tetrahydropyrene and the hexahydropyrene anion radicals respectively. For the $\gamma$ protons of the hexahydropyrene anion radical, one would expect two different splitting constants. However, only a single $\gamma$ splitting constant was observed. Theoretical calculations of the spin distribution in these radicals are in progress.

The authors wish to express their thanks to Miss Akie Sakai for her help in the purification of the samples.

# The Optical Resolution of DL-Aspartic Acid, DL-Glutamic Acid, DL-Asparagine and DL-Glutamine by Preferential Crystallization*

By Kaoru HARADA

(Received December 28, 1964)

Several studies of optical resolutions of organic compounds by mechanical sorting[1,2] and by preferential crystallization[3-11] have been reported.

DL-Asparagine was first resolved by Piutti[2] using Pasteur's mechanical sorting method.[1] Ostromisslensky[3] also resolved DL-asparagine by seeding its supersaturated aqueous solution

with crystals of glycine, which has no asymmetric carbon. Although the optical activity of the resolved asparagine was not recorded, one seeding experiment resulted in the crystallization of the L-form, while the other induced crystallization of the D-from. The investigator could not predict which from of asparagine would crystallize in any given experiment. L-Histidine hydrochloride and some D-histidine hydrochloride were isolated by the successive crystallizations of the mixture of DL-histidine hydrochloride and L-histidine hydrochloride. DL-Threonine was resolved by seeding with L-threonine.[8] DL-Aspartic acid was partially resolved by preferential crystallization with optically active glutamic acid.[10] DL-Aspartic acid was totally resolved from its supersaturated copper complex solution by seeding it with an L- or D-aspartic acid copper complex.[11] DL-Glutamic acid was resolved completely from its supersaturated aqueous solution by seeding.[9] This type of simple optical resolution by the preferential crystallization procedure is the most advantageous method providing we can obtain an optically pure isomer. However, in the resolution of the DL-amino acids, most of the methods used are impractical or result in a partial resolution, with the exception of DL-glutamic acid[9] and the copper complex of DL-aspartic acid.[11]

In this report, the total optical resolution of DL-$\alpha$-amino acid from its supersaturated solution by an inoculation procedure will be described. The method will be applied to the optical resolution of DL-aspartic acid, DL-glutamic acid, DL-asparagine, and DL-glutamine.

One important condition in the optical resolution by the crystallization procedure is that the attraction between L- and D-isomers be weak; preferably, the compound should be a racemic mixture (conglomerate). However, most $\alpha$-amino acids form racemic compound crystals upon crystallization from an aqueous solution.[12,13] For this reason the seeding procedure did not give any optically active aspartic acid when a pure aqueous DL-aspartic acid solution was seeded by an optically active isomer.[11] The ammonium formate which was added to the aqueous aspartic acid solution may act as an agent (I) to stabilize the supersaturated solution, (II) to slow down the crystallization rate, and (III) to weaken the attraction between the D- and L-molecules, thus forming a racemic compound.

Formate ($HCOO^-$) and ammonium ($NH_4^+$) ions might not be essential for this type of resolution of amino acid. An aqueous solution of glycine was also used for this purpose. However, the results of the resolution using glycine were not as good as those obtained using ammonium formate.

## Experimental

**The Resolution of DL-Aspartic Acid.**—DL-Aspartic acid (14.0 g.) was dissolved in a mixture of ammonium formate (25.0 g.) and 30 ml. of water at 80°C in a water bath. The hot solution was then filtered and cooled slowly to 43°C. Into this supersaturated solution 0.50 g. of finely-pulverized L-aspartic acid ($[\alpha]_D^{25}$ +24.6°, 6 N HCl) was seeded and mixed. The mixing is important, and the procedure should be standardized in order to obtain the best results. This is also true in the resolution of other amino acids. The seeded solution was allowed to stand undisturbed at room temperature (23°C) for 15 min. The crystals which were precipitated were filtered and washed with cold water. 1.57 g. of L-aspartic acid (including seed) was obtained (1st L-asp). When this was recrystallized from 39 ml. of water, 1.28 g. of purified L-aspartic acid crystals were obtained; $[\alpha]_D^{25}$ +24.6°, (*c* 2.13, 6 N HCl).

Found: C, 36.09; H, 5.34; N, 10.57. Calcd. for $C_4H_7O_4N$: C, 36.09; H, 5.30; N, 10.52%.

Into the filtrate, 0.50 g. of pulverized D-aspartic acid ($[\alpha]_D^{25}$ −24.3°, 6 N HCl) was added. The mixture was then kept undisturbed at room temperature (23°C) for 45 min. 1.69 g. of crystals (including seed) was thus obtained (1st D-asp). When this was recrystallized from water, 1.39 g. of purified D-aspartic acid was obtained; $[\alpha]_D^{25}$ −23.6° (*c* 2.03, 6 N HCl). (Found: C, 36.11; H, 5.30; N, 10.24%.) In the mother liquor, 2.50 g. of DL-aspartic acid was dissolved at 80°C. The solution was then filtered and cooled to 43°C at room temperature. Into the supersaturated solution, 0.50 g. of L-aspartic acid was seeded. After 15 min., 1.79 g. of 2nd L-asp was obtained. By seeding the filtrate with D-aspartic acid, 1.70 g. of 2nd D-asp was obtained after the solution had stood for 45 min. The same procedures were used to obtain 3rd L-asp, 1.79 g. and 3rd D-asp, 1.78 g. after dissolving 2.50 g. of DL-aspartic acid in the mother liquor. The nitro-

TABLE I. THE RESOLUTION OF DL-ASPARTIC ACID

| 3rd L | 1.79 | +24.8 | 100 |
| 3rd D | 1.78 | −23.0 | 93 |

*1 DL-Aspartic acid, 14.0 g., was resolved by seeding of 0.50 g. of L- and D-aspartic acids.
*2 Specific rotations were measured in 6 N hydrochloric acid.
*3 Specific rotation of pure L-aspartic acid: $[\alpha]_D^{25}$ +24.8°, 6 N hydrochloric acid.

gen analyses of 2nd L-, 2nd D-, 3rd L-, and 3rd D-aspartic acids agreed with the theoretical values. The specific rotations are listed in Table I.

**The Resolution of DL-Glutamic Acid.**—DL-Glutamic acid monohydrate (5.0 g.) was dissolved in a mixture of 20 ml. of water and 5.0 g. of ammonium formate at 80°C. The solution was then filtered, and the filtrate was cooled slowly. 0.25 g. of L-glutamic acid ($[\alpha]_D^{25}$ +31.5°, 6 N HCl) was seeded in the supersaturated solution at 43°C. The L-glutamic acid which was crystallyized was filtered after it had stood 20 min. at room temperature (23°C). L-Glutamic acid (0.97 g.) (1st L-glu) was obtained. This was recrystallized from 12 ml. of water. $[\alpha]_D^{25}$ +28.5° (*c* 2.05, 6 N HCl).

Found: C, 40.96; H, 6.18; N, 9.62. Calcd. for $C_5H_9O_4N$: C, 40.81; H, 6.17; N, 9.52%.

To the filtrate, 0.25 g. of D-glutamic acid ($[\alpha]_D^{25}$ −30.1°, 6 N HCl) was seeded. After it had stood 20 min. at room temperature (23°C), 1.04 g. of crystals were obtained (1st D-glu). The D-glutamic acid was recrystallized from water. $[\alpha]_D^{25}$ −27.5° (*c* 2.10, 6 N HCl). (Found: C, 40.83; H, 6.21; N, 9.65%.) 1.50 g. of DL-glutamic acid monohydrate was dissolved in the mother liquor, and the resolution procedures were repeated to isolate 2nd L- (0.87 g.), 2nd D- (0.90 g.), 3rd L- (1.13 g.), and 3rd D- (1.03 g.) glutamic acids. The specific rotations of these isolated glutamic acids are listed in Table II. The results of the nitrogen analyses

Table II. The resolution of DL-glutamic acid

| | Yield, g.*1 | $[\alpha]_D^{25}$*2 | Optical purity, %*3 |
|---|---|---|---|
| 1st L | 0.97 | +28.5 | 91 |
| 1st D | 1.04 | −27.5 | 88 |
| 2nd L | 0.87 | +30.8 | 99 |
| 2nd D | 0.90 | −26.3 | 84 |
| 3rd L | 1.13 | +27.2 | 87 |
| 3rd D | 1.03 | −27.5 | 88 |

*1 DL-Glutamic acid, 5.0 g., was resolved by seeding of 0.25 g. of L- and D-glutamic acids.
*2 Specific rotations were measured in 6 N hydrochloric acid.
*3 Specific rotation of pure L-glutamic acid: $[\alpha]_D^{25}$ +31.2°, 6 N hydrochloric acid.

of 2nd L-, 2nd D-, 3rd L- and 3rd D-glutamic acids agreed with the theoretical values.

**The Resolution of DL-Asparagine.**—DL-Asparagine monohydrate (10.0 g.) was dissolved at 60°C in 40 ml. of water containing 10.0 g. of ammonium formate. After the solution had been filtered and cooled slowly to about 40°C, it was seeded with 0.50 g. of L-asparagine monohydrate ($[\alpha]_D^{25}$ +30.6°, 3.4 N HCl). The solution was then kept undisturbed at room temperature for 30 min. The crystals which were precipitated were filtered and washed with cold water and ethanol. A total of 2.43 g. of L-asparagine monohydrate (1st L-asp $NH_2$) was obtained. When this was recrystallized from 12 ml. of water and 24 ml. of ethanol, 1.98 g. of purified L-asparagine was obtained; $[\alpha]_D^{25}$ +28.6° (*c* 3.10, 3.6 N HCl).

Found: C, 31.92; H, 6.44; N, 18.52. Calcd. for $C_4H_{10}O_4N_2$: C, 32.00; H, 6.11; N, 18.66%.

0.50 g. of D-asparagine ($[\alpha]_D^{25}$ −30.3°, 3.4 N HCl) was seeded in the filtrate. After 30 min. of undisturbed standing at room temperature, the crystals which were precipitated were isolated (1st D-asp $NH_2$). Yield, 3.05 g. This was recrystallized from water and alcohol; 2.54 g., $[\alpha]_D^{25}$ −29.7° (*c* 2.93, 3.6 N HCl). (Found: C, 32.32; H, 6.79; N, 18.76%.) In the mother liquor 4.50 g. of DL-asparagine monohydrate was then dissolved. The resolution procedures were repeated in a manner similar to that described above. Second L- (2.68 g.) and 2nd D- (2.48 g.) asparagines were thus obtained. The specific rotations are listed in Table III. The elemental analyses of 2nd L- and D-asparagines agreed with the theoretical values.

Table III. The resolution of DL-asparagine

| | Yield, g.*1 | $[\alpha]_D^{25}$*2 | Optical purity, %*3 |
|---|---|---|---|
| 1st L | 2.43 | +28.6 | 93 |
| 1st D | 3.05 | −29.7 | 97 |
| 2nd L | 2.68 | +30.0 | 98 |
| 2nd D | 2.48 | −28.9 | 94 |

*1 DL-Asparagine monohydrate, 10.0 g., was resolved by seeding of 0.50 g. of L- and D-asparagine monohydrate.
*2 Specific rotations were measured in 3.6 N hydrochloric acid.
*3 Specific rotation of pure L-asparagine: $[\alpha]_D^{25}$ +30.6°, 3.6 N hydrochloric acid.

**The Resolution of DL-Glutamine.**—DL-Glutamine was resolved under the same conditions as were used with DL-asparagine (DL-glutamine 10.0 g.; ammonium formate, 10.0 g., and 40 ml. of water). 0.5 g. of L-glutamine ($[\alpha]_D^{25}$ +32.8°, 1 N HCl) was seeded in a supersaturated glutamine solution. After 20 min., 2.05 g. of L-glutamine (1st L-glu $NH_2$) was obtained. This was recrystallized from 16 ml. of water and 30 ml. of ethanol; 1.65 g., $[\alpha]_D^{25}$ +32.8° (*c* 2.22, 1 N HCl).

Found: C, 41.06; H, 7.00; N, 18.67. Calcd. for $C_5H_{10}O_3N_2$: C, 41.09; H, 6.90; N, 19.19%.

From the filtrate, 2.32 g. of D-glutamine (1st D-glu $NH_2$) was obtained by the seeding of D-glutamine

Table IV. The resolution of DL-glutamine

| | Yield, g.*1 | $[\alpha]_D^{25}$*2 | Optical purity, %*3 |
|---|---|---|---|
| 1st L | 2.05 | +32.8 | 100 |
| 1st D | 2.32 | −31.4 | 96 |
| 2nd L | 2.45 | +32.5 | 99 |
| 2nd D | 2.38 | −31.1 | 95 |
| 3rd L | 2.04 | +32.9 | 100 |
| 3rd D | 2.15 | −30.5 | 93 |

*1 DL-Glutamine, 10.0 g., was resolved by seeding of 0.5 g. of each L-glutamine and D-glutamine.
*2 Specific rotations were measured in 1 N hydrochloric acid.
*3 Specific rotation of pure L-glutamine: $[\alpha]_D^{25}$ +32.8°, 1 N hydrochloric acid.

after 30 min.'s standing. This was recrystallized from water and alcohol; 1.86 g., $[\alpha]_D^{25}$ −31.4° (*c* 2.31, 1 N HCl). (Found: C, 41.48; H, 6.99; N, 19.21%.)

To the mother liquor 4.40 g. of DL-glutamine was then added and the resolution procedures repeated. Second L- (2.45 g.), 2nd D- (2.38 g.), 3 rd L- (2.04 g.) and 3rd D-glutamines (2.15 g.) were obtained. The results are shown in Table IV. The results of the nitrogen analysis of 2nd L-, 2nd D-, 3rd L- and 3rd D-glutamines agreed with the theoretical values.

This work was supported by Grant NsG-173-62 and NsG-689 from the National Aeronautics and Space Administration. Thanks are extended to Dr. Sidney W. Fox for his encouragement and to Mr. Arthur I. Holden for his measurement of optical rotation.

# NOTES

## Thermodynamic Functions of the Ionisation of Aminobenzoic Acids

By H. C. SARASWAT and Uma Dutta TRIPATHI

(Received August 1, 1964)

Studies of the ionisation of substituted benzoic acids have received the attention of numerous workers in recent years.[1-5] Besides the value of the knowledge of p$K$ and related functions in chelate chemistry,[6] these data have been found to be extremely significant in elucidating a number of structural features, such as hydrogen bonding and the dipolar ion.[7] It is for the latter purposes that not only the change in the free energy of ionisation but also such other thermodynamic quantities as the changes in entropy or in heat content, have been found to be of importance. It was, therefore, considered worthwhile to undertake a systematic study of the thermodynamic functions of the ionisation of a few substituted benzoic acids; the results of the investigation of *o*-, *m*- and *p*-aminobenzoic acids will be reported in the present communication.

### Experimental

Oxalic acid and *m*-aminobenzoic acid were analar samples of B. D. H. *o*-Aminobenzoic acid was crystallised from alcohol while *p*-aminobenzoic acid was recrystallised from water.[8] Sodium hydroxide was a Mercks guaranteed reagent.

**Procedure.**—pH metric titrations were carried out with a Beckman pH meter model H2. The temperature was maintained with an accuracy of $\pm 0.1$°C. Nitrogen was bubbled in the solution before and during the titrations.

### Results and Discussion

p$K$ values were calculated by plotting the values of pH against $(HA)/(A^-)$, where the terms in parantheses refer to the activity of undissociated acid and the anions. The concentration of anions present at any stage of titration was calculated by the method of Britton,[9] while the activity coefficients were calculated in the usual manner, using the values of the Debye and Hückel constant given by Bales and his coworkers;[10] the activity coefficient of undissociated acid was taken as unity.

Figure 1 gives a typical set of titration curves of *o*-aminobenzoic acid at different temperatures. It may be seen that these curves show a marked inflexion, as is the case with most of the benzoic acids. Similar titration curves were obtained for other acids also. The values of p$K$ at different temperatures were obtained by the graphical procedure given in Fig. 2. These data are given in Table I.

The variation in p$K$ with the temperature has been studied theoretically by Harned and Robinson.[11] When the data in Table I are examined on the basis of the equation of Harned and Robinson, the following equations were derived:

*o*-Aminobenzoic acid

$$T\text{p}K = 13.589\times10^3 - 83.07T + 1.427\times10^{-1}T^2$$

*m*-Aminobenzoic acid

$$T\text{p}K = 12.929\times10^3 - 76.12T + 1.261\times10^{-1}T^2$$

*p*-Aminobenzoic acid

$$T\text{p}K = 13.73\times10^3 - 85.9T + 1.5\times10^{-1}T^2$$

The validity of these equations was established by the close agreement between observed and calculated values of p$K$. From the parameters of these equations, the values of the thermodynamic functions of ionisation were calculated in the usual way.[11] These are given in Table II.

TABLE IIA. THERMODYNAMIC FUNCTIONS OF IONISATION OF *o*-AMINOBENZOIC ACID

As was expected on the basis of the resonance effect and in accordance with deductions from physico-chemical measurements[12] the data obtained in the present work also suggest that there is a greater tendency for meta acid than for ortho and para acids to exist in the form of the dipolar ion.

# Extraction of the Bismuth-Thiourea Complex with Tributyl Phosphate from a Perchloric Acid Medium

By Fumio Aoki and Hideo Tomioka

(Received February 23, 1965)

Though the colorimetric method for bismuth based on the formation of a bismuth-thiourea complex has been widely known, the literature does not seem to contain any report on the solvent extraction of the complex compound.

The present writers have found, however, that the complex can be quantitatively extracted with tributyl phosphate from a perchloric acid solution with an acidity ranging from 0.1 to 0.6 M.

The absorption curve of the extract, exactly like that of the aqueous solution, has two absorption peaks due to the complex. They are located at 322 nm and 470 nm, their molar absorptivities being $2.45\times10^4$ and $6.97\times10^3$ respectively. The 470 nm peak is thought to be better for analytical purposes, in spite of its lower sensitivity, since the 322 nm peak suffers more from the interference of diverse ions and has a poorer reproducibility. Beer's low is obeyed up to 45 $\mu$g./ml. of bismuth when the absorbance is measured at 470 nm. The colored system is stable for at least 3 hr.

Chloroform, carbon tetrachloride, benzene, methyl isobutyl ketone, ethyl ether, *n*-butyl alcohol and butyl acetate do not extract the complex.

On the basis of these observations we propose the following procedure:

A sample solution containing up to 400 $\mu$g. of bismuth is taken in a separatory funnel; 2.5 ml. of 60% perchloric acid and 25 ml. of 12% thiourea solution are added, and the solution is diluted to 50 ml. with water. Then exactly 10 ml. of tributyl phosphate is added, and the funnel is vigorously shaken for 2 min. Twenty minutes after the extraction the absorbance of the organic phase is measured at 470 nm. in a 1 cm. cell.

Osmium, ruthenium, and palladium interfere seriously with the determination of bismuth. Molybdenum and antimony also interfere to some extent.

A full paper will be published soon in Japanese.

# Evidence for the Activity Difference between Pure and Supported Nickel Catalysts

By Yoshie HIRONAKA and Kozo HIROTA

(Received February 3, 1965)

In a previous paper,[1] we reported on the difference in catalytic activity between nickel alone and nickel supported on $\gamma$-alumina (Ni : $Al_2O_3$ = 1 : 1 in weight) in the isotopic hydrogen exchange of propene with deuterium oxide. From the infrared and NMR spectroscopic data then obtained, we suggested that vinyl hydrogens are more exchangeable than methyl hydrogens on nickel and that the ratio of the exchangeability of the vinyl group to that of the methyl group was about 3.4, while supported nickel shows the opposite exchangeability (i. e., methyl hydrogens are more exchangeable). By the microwave spectroscopic method,[2-4] this suggestion was not only confirmed quantitatively, but also detailed knowledge could be obtained, as has been reported already.[2,3]

Table I shows the experimental conditions, while Table II shows the subspecies distribution of $d_1$ determined by the microwave spectroscopic method, as well as the $d_y$-distribution determined by a mass spectrometer.

TABLE I. EXPERIMENTAL CONDITIONS

| No. | Catalyst | | Reaction | | Sample | |
|---|---|---|---|---|---|---|
| | | | Temp. | Time | $C_3H_6$ | $D_2O$ |
| | | g. | °C | hr. | mol. $\times 10^3$ | |
| 3513 | Ni | 1.65 | 17 | 25 | 2.18 | 10 |
| A9 | $Ni\text{-}Al_2O_3$ | 5.0 | 18.6 | 354 | 6.00 | 18.1 |

The $\phi$ values of the two samples are nearly equal, both being ca. eight, so that their $d_y$-distribution shows the initial stage of the reaction in these cases. By comparing the amount of catalyst (only the weight of nickel) and the reaction time, it may be seen that the exchange rate is markedly decreased, by 7—8 times, if nickel is supported on $\gamma$-alumina. Besides, important information was obtained from the difference between the infrared spectra of No. 3513 (Ni) and No. A9 ($Ni\text{-}Al_2O_3$). However, the spectrum of No. 3513 (Ni) is not shown because it is almost identical with that of No. A4, which has already been shown in a previous report.[1] A completely different feature can be seen in the region of the C-D stretching band, suggesting that the catalytic activities of the two catalysts are different.

According to a comparison of the subspecies distribution of the $d_1$ of No. 3513 with that of No. A9, methine hydrogen is the most exchangeable on nickel (No. 3513), while methyl hydrogens are the most exchangeable on supported nickel (No. A9). The subspecies distribution of $d_1$ in the product of the catalytic exchange reaction shows some similarity between supported nickel (No. A9) and palladium in that methyl hydrogens became exchangeable to some extent, though methine hydrogen was still more exchanged on supported nickel than on palladium.[2] Such a tendency has been recognized in the exchange reaction of para-xylene with deuterium oxide,[5] though in this system only methyl hydrogens were exchanged on nickel, while both methyl and aromatic hydrogens became exchangeable on palladium and on supported nickel. Such a tendency in the exchangeability with respect to the double bond showed a tendency opposite to that of the present system.

From Table II, it may be seen that the exchangeability of methine hydrogen was larger than that of methylene hydrogen on both catalysts. The result of No. A9 may be interpreted in terms of the existence of two different active sites on supported nickel for this reaction. One of the sites (A), ascribable to nickel, has an activity similar to that of unsupported nickel, and the subspecies distribution of $d_1$ may, consequently, be similar to that of No. 3513, as is shown in Table II. The other site (B) has an activity similar to that of palladium, and the subspecies distribution of $d_1$ may become similar to that of palladium.[2] It may, therefore, be concluded that the activity of the A site has no interaction with the $\gamma$-alumina and that the activity of the B site may result from the interaction with $\gamma$-alumina. The subspecies distribution of $d_1$ of No. A9 may, therefore, be regarded as a mean value of two different distributions.

TABLE II. DEUTERIUM DISTRIBUTION (%) AND SUBSPECIES DISTRIBUTION OF $d_1$ (%)

| Subspecies | No. A9(Ni-$Al_2O_3$) | No. 3513(Ni)** | No. 3315(Pd)** |
|---|---|---|---|
| $CH_2DCH=CH_2$ | 45.3±2.5(15.1)* | 22.5±2.7(7.5)* | 59.2±2.2(19.7) |
| *t*-$CH_3$ CH=CHD | 12.5±1.5 | 9.5±2.1 | 16.4±1.5 |
| *c*-$CH_3$ CH=CHD | 11.3±1.7 | 9.9±2.2 | 13.4±2.1 |
| $CH_3$ CD=$CH_2$ | 30.9±2.8 | 58.1±5.1 | 16.1±2.4 |
| $d_0$ | 63.6 | 58.4 | 51.3 |
| $d_1$ | 29.8 | 33.3 | 36.8 |
| $d_2$ | 5.9 | 7.3 | 10.7 |
| $d_3$ | — | 1.0 | 1.6 |
| $\phi=\frac{1}{6}\sum_{y=1}^{6} yd_y$ | 7.4 | 8.5 | 10.4 |

* Numerals in parenthesis are the ones alloted per one hydrogen atom.
** These data, already published,[2] were shown for the sake of comparison.

Morikawa and Nozaki[6] reported that both free metallic nickel and nickel atoms forming chemical bonds with $\gamma$-alumina existed in supported nickel. These states seem to correspond to the two states mentioned above.

The catalytic activity of supported nickel decreased as compared with that of nickel, as has been mentioned already. This decrease in activity may be attributed to the formation of nickel oxide with the oxygen absorbed on $\gamma$-alumina, because neither nickel oxide nor $\gamma$-alumina could catalyze this reaction. However, since the answers to these problems are not evident, further investigation is necessary on this point.

The authors wish to express their thanks to Professor Yonezo Morino and Dr. Eizi Hirota, the University of Tokyo, who kindly measured the samples with the microwave-spectroscopic method and discussed the results.

# The Effect of Pressure on the Fluorescence Spectra of Anthracene, Chrysene and Pyrene

By Jiro TANAKA,* Takao KODA, Shigeo SHIONOYA and Shigeru MINOMURA

(Received February 17, 1965)

Recently the fluorescence spectra of aromatic molecular crystals have been found to be intimately connected with the crystal structure; the anomalous, long wavelength emission has been explained in terms of the formation of the excited dimer state.[1-3] In this note we will present a study of the effect of static high pressure on the fluorescence spectra of anthracene, chrysene and pyrene.

A Drickamer-type optical cell[4] available for measurement under high pressure up to 52 kb. was used. A small amount of pure crystal was put in the optical cell and excited by a 365 m$\mu$ mercury light. The measurement of the fluorescence spectra was made with a Bausch and Lomb 250 mm. monochromator and by a sensitive-photomultiplier detecting system.

The emission peaks of these crystals were found to shift remarkably to lower frequencies almost linearly with an increase in the pressure, the shift being 80 $cm^{-1}$/kb. for anthracene and 40 $cm^{-1}$/kb. for chrysene and pyrene (cf. Fig. 1). The vibrational structures in the fluorescence spectra were blurred under high pressure. The red shifts could be reversed for pyrene and chrysene by applying and releasing the pressure, but the shift was irreversible for anthracene. The fluorescence

The values for anthracene were determined from the reduced zero pressure value (475 mμ).

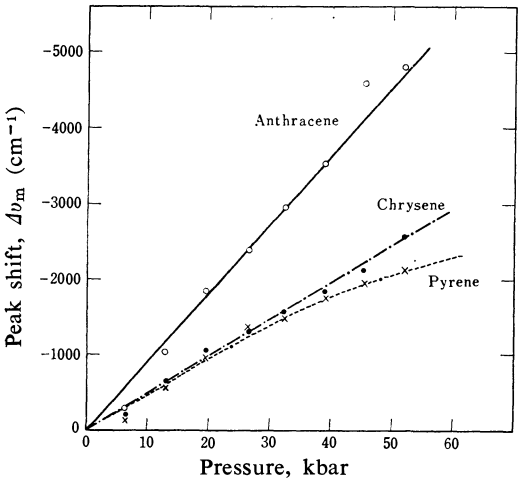

Fig. 2. Change in the fluorescence spectrum of anthracene with an increase in the pressure at room temperature.

of anthracene did not recover completely to the original spectrum once it had been pressed under high pressure, and it showed a strong broad emission in the 475 mμ region (cf. Fig. 2). The red shift of the crystal might be explained by assuming a potential energy diagram in which the curve for the ground state is steeper than that of the excited state and in which the minimum of the excited state is located at a smaller configurational coordinate than the ground state.[5]

The larger red shift of the anthracene crystal needs some comment. According to Wiederhorn and Drickamer,[6] the absorption spectrum of the anthracene crystal shifts to frequencies lower by 45 cm$^{-1}$/kb. with an increase in the pressure. The red shift of 80 cm$^{-1}$/kb. of the fluorescence will be partly due to the shift of the $^1L_a$ excited level. The second point to be considered is that the 475 mμ emission occurs even after the pressure is released. This might be explained by assuming the formation of an emission center of the dimer type produced under the high pressure. As a result of the hysteresis effect of the pressure, the emission center will remain in the crystal and the 475 mμ band will occur from this emission site, even if the pressure is released. This idea is supported by the observation that the 475 mμ band disappears when the pressed crystal is warmed up in vacuo.

# The Copolymerization of β-Substituted Styrenes with Maleic Anhydride*

By Shunsuke MURAHASHI, Shun'ichi NOZAKURA, Kazuo EMURA and Katsutoshi YASUFUKU

(Received February 19, 1965)

It has been reported that 1, 2-disubstituted ethylenes, such as *p*-dioxene,[1] dihydropyrane,[2] butene-2,[3] and stilbene,[4] do not homopolymerize by a radical mechanism, but do copolymerize with maleic anhydride (MAn) to yield copolymers with a 1 : 1 alternating composition. The present paper will describe copolymerizations of some β-substituted styrenes with MAn by a radical mechanism and will compare their reactivities.

The copolymerizations were carried out in

a sealed glass tube at 60°C, using 2, 2'-azobisisobutyronitrile as the initiator and benzene as the solvent. β-Substituted styrenes of a known isomeric purity were used. The results are shown in Tables I, II and III.

All the β-substituted styrenes were found to be markedly less reactive than styrene. The general low reactivity may be attributed to the steric factor of the β-substituent,[5] and the magnitude of the steric factor may be considered to differ from one substituent to another. In Table I, however, a tendency is observed for the rate of the copolymerization of the β-substituted styrenes with MAn to decrease approximately with the increase in the electron-attracting character of β-substituents, except for the case of stilbenes. Thus, the effect of β-substituents is rather complicated; they exert a predominant steric effect and a

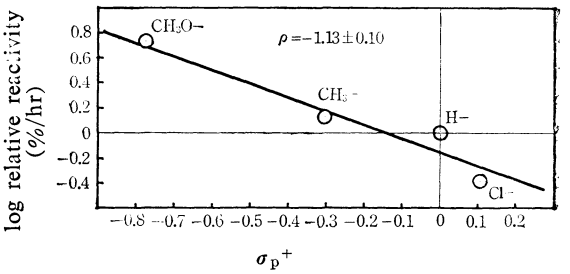

Fig. 1. Correlation of log relative reactivity and $\sigma_p^+$ for the copolymerization of *p*-substituted-β-methyl-Sts with MAn.

5) T. Alfrey, Jr., J. Bohrer and H. Mark, "Copolymerization," Interscience Pub. Inc., N. Y. (1952), p. 51.

polar effect as well as, presumably, a resonance effect.

On the other hand, the effect of *p*-substituents of β-methylstyrenes is a little more clean-cut, as is shown in Table II. Since these systems gave 1 : 1 copolymers as Table III shows, the logarithms of the relative reactivities (%/hr. in Table II) of *p*-substituted β-methylstyrenes to that of β-methylstyrene are plotted against Brown-Okamoto $\sigma_p^+$ values for the substituents (in Fig. 1). When the Hammett $\sigma_p$ was used instead of $\sigma_p^+$, the correlation was worse, the standard deviation of $\rho$ being $\pm 0.9$. A better linearity was observed for $\sigma_p^+$ with the $\rho$ value of $-1.13 \pm 0.10$, showing that the polar effect operates in this case. This result seems reasonable, since the steric factor around the double bond may not be altered by the *p*-substituent.

Table III demonstrates that these β-methylstyrenes formed 1 : 1 alternating copolymers with MAn independent of the monomer feed ratios, and that the rate of copolymerization increased with the increase in the fraction of MAn, sometimes showing maxima.

It should be noted that β-substituted styrenes of a comparatively high reactivity show thermal copolymerization with MAn, and that these copolymerization mixtures exhibit a deep yellow color. The phenomena of discoloring may be due to the formation of charge transfer complexes between the donor molecules (β-substituted-St-derivatives) and the accepter molecule (MAn), as reported by Walling[6] and Barb.[7] We are now studying whether the complex makes any contribution to the copolymerization reaction.

## SHORT COMMUNICATIONS

# Stain Film Formed Photochemically on Silicon

By Yasuo NAKAI

(Received May 21, 1965)

It is known that stain film can contribute to the stabilization of transistors.[1] The stain film has been obtained hitherto by reaction with hydrogen fluoride-nitric acid[2] or by anodic oxidation in hydrogen fluoride solution.[3]

In this experiment, it was found that the formation of stain film can be effected by the photochemical reaction of HF-$O_3$ with silicon crystal. For example, oxygen gas (1200 cc./min.) containing 5% ozone (in weight) and HF-$N_2$ gas (500 cc./min.) was brought into contact with the (111) surface of 2- to 80-chm-cm. n-type silicon crystals for 0.5 to 2 hr. at room temperature and under irradiation from a high-pressure mercury lamp (1 kW.) through filters transmitting at 5800, 5460, 4358, 4047 and 3650 Å. Ozone was obtained by a silent discharge. The mixture of HF-$N_2$ gas was obtained by bubbling nitrogen gas through a 24 N hydrogen fluoride solution at 25°C.

It was found to be necessary, for the formation of stain film, to irradiate the silicon surface with photons of energy higher than approximately 2.7 eV.

Infrared, optical absorption, electron spin resonance and solid mass spectra were investigated in studying the physicochemical properties of stain film.

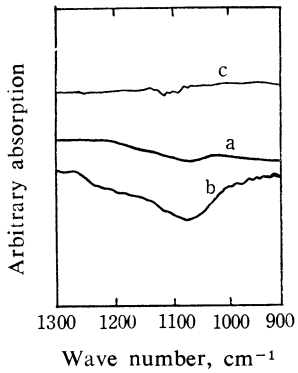

Fig. 1. The infrared spectra of stain film (a) before and (b) after thermal treatment at 250°C for 10 hr., and (c) of silicon crystal.

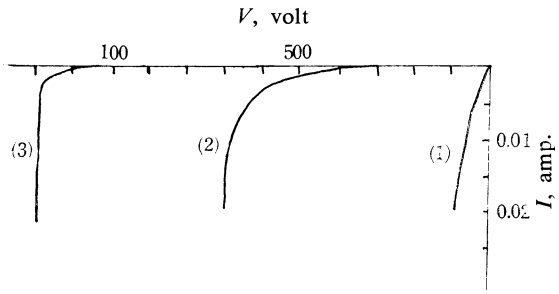

Fig. 2. Reverse characteristic (*I-V* curve) of a $p^+-n$ diode on which stain film was photochemically formed.
(1) Before heat treatment (2) after being kept at 250°C for 2 hr. in air, and (3) after being kept at 250°C for 10 hr. in air.

Figure 1 shows the infrared spectrum of stain film. The band at 1080 $cm^{-1}$, whose intensity is weak before heat treatment (as is shown by curve 1a), appears strongly after being kept at 250°C for approximately 10 hr. in air (curve 1b). The band at 1080 $cm^{-1}$ is assigned to the Si-O stretching mode; its shape is similar to that of amorphous silica.

The electron-spin resonance-absorption curve of stain film at an operation microwave frequency in the vicinity of 9.2 kMc./sec. exhibits three peaks ($g_1=2.0068$, $g_2=2.0048$ and $g_3=2.0000$) at 77°K. Two optical absorption bands were observed, at 7500Å and 5000Å. Silicon, oxygen and fluorine atoms were detected in stain film by solid mass spectroscopy, but its molecular formula is not clear at present.

Stain film was photochemically formed upon the junction of mesa $p^+-n$ diodes. A typical variation of the reverse *I-V* curve with aging is shown in Fig. 2. Diodes had a very inferior reverse characteristic just after forming stain film, but the breakdown voltage became stable and the drift decreased after they had been kept at 250°C for 10 hr. in air.[4]

# The Synthesis of a Heptadecapeptide Amide Corresponding to a Modified Sequence in the Corticotropin Structure

By Hideo OTSUKA, Ken INOUYE, Makoto KANAYAMA and Fusako SHINOZAKI

(Received June 9, 1965)

In order to examine whether or not the level of hormonal potency depends simply on the degree of basicity at positions 15—18 of the corticotropin (ACTH) molecule, we have synthesized a heptadecapeptide amide, H-Gly-Tyr-Ser-Met-Glu-His-Phe-Arg-Try-Gly-Lys-Pro-Val-Gly-Lys-Arg - Arg - $NH_2$ ($\alpha^{1-14,16-18}$ - Gly$^1$-ACTH-18-$NH_2$) (I);*1 The peptide I has bene found to possess 1.26 and 2.72 USP units per mg. of steroidogenic activity, as estimated in vitro[1] and in vivo[2] respectively.*2 On the other hand, the peptide I has been found to elicit a high lipolytic activity at minimal effective doses of 0.0037 $\mu$g. in rat adipose tissue and of 0.00042 $\mu$g. in rabbit.[3],*2

Cbz-Arg($NO_2$)-OH (II) was converted, via

* All amino acid residues are of the L-configuration with the exception of glycine. In this communication, the following abbreviations will be used: Cbz, carbobenzoxy; BOC, *t*-butyloxycarbonyl; Ac, acetyl; But, *t*-butyl; CMC, carboxymethyl cellulose.

a mixed anhydride, into Cbz-Arg($NO_2$)-$NH_2$ (m. p. 220—221°C, $[\alpha]_D^{24}$ +4.9° (*c* 1.95, dimethylformamide); lit.[4] m. p. 219—220°C); this was then treated with HBr/AcOH to obtain H-Arg($NO_2$)-$NH_2$·HBr (III) (m. p. 237—239°C, $[\alpha]_D^{26}$ +13.7° (*c* 2.6, water)). The coupling of II with III by the mixed anhydride procedure gave Cbz-Arg($NO_2$)-Arg($NO_2$)-$NH_2$ (IV), (m. p. 115—115.5°C, $[\alpha]_D^{25}$ −6.2° (*c* 2.1, 50% AcOH)). Cbz-Lys(BOC)-Pro-Val-Gly-Lys(BOC)-$N_3$, which was derived from the hydrazide,[5] was allowed to react with H-Arg($NO_2$)-Arg($NO_2$)-$NH_2$·HBr (m. p. 153—156°C decomp., $[\alpha]_D^{23.5}$ +14.1° (*c* 2.0, water)), which had been obtained from IV by the HBr/AcOH treatment, to give Cbz-Lys(BOC)-Pro-Val-Gly-Lys(BOC)-Arg($NO_2$)-Arg($NO_2$)-$NH_2$ (V) ($[\alpha]_D^{25.5}$ −40.4° (*c* 1.8, methanol)). Compound V was then hydrogenolyzed to obtain H-Lys(BOC)-Pro-Val-Gly-Lys(BOC)-Arg-Arg-$NH_2$ (VI) ($[\alpha]_D^{24}$ −44.8° (*c* 1.5, 50% AcOH).

The activated decapeptide ester, BOC-Gly-Tyr-Ser-Met-Glu($\gamma$-Bu$^t$)-His-Phe-Arg-Try-Gly-ON(CO-$CH_2$)$_2$[6], was allowed to react with VI to afford BOC-Gly-Tyr-Ser-Met-Glu($\gamma$-Bu$^t$)-His-Phe-Arg-Try-Gly-Lys(BOC)-Pro-Val-Gly-Lys(BOC)-Arg-Arg-$NH_2$ (VII). A crude sample of VII was, after having been treated with thioglycollic acid, purified by CMC column chromatography ($[\alpha]_D^{23.5}$ −35.8° (*c* 0.44, 50% AcOH). The purified VII was treated with 90% trifluoroacetic acid in order to liberate the heptadecapeptide I. $\lambda_{max}^{0.1N\ NaOH}$ = 281.5 mμ (ε 7070), 288.5 mμ (ε 6850). $[\alpha]_D^{23.5}$ −57.4° (*c* 0.5, 0.1 N AcOH). # The Mechanism of the Copolymerization of Some Olefins with Maleic Anhydride*

By Chuji Aso and Toyoki KUNITAKE

(Received June 11, 1965)

Alternating free-radical copolymerization have been explained as resulting from the polar interaction of a growing radical and a monomer,[1] from the stabilization of the transition state of propagation due to electron transfer,[2] and from the charge-transfer complex between monomers.[3]

Although $\omega$-phenylalkenes copolymerize with maleic anhydride easily,[4] it has been found in this laboratory that 4-cyclohexyl-1-butene (CHBu) does not give a copolymer with maleic anhydride under the conditions under which 4-phenyl-1-butene copolymerizes. For example, the phenylbutene (1.0 mol./l.) and maleic anhydride (1.0 mol./l.) in methyl ethyl ketone, with azobisisobutyronitrile ($0.25\times10^{-2}$ mol./l.) as an initiator, gave 21% of a copolymer (M. W.> 2000) with an approximately 60 : 40 composition at 70°C in 5 hr. On the other hand, 4-cyclohexyl-1-butene and 1-octene gave trace amounts of solid products under the same conditions. This difference in reactivity cannot be considered to be due wholly to the different inductive effects of the benzene and cyclohexane rings, since these rings are separated from the double bond by two methylene groups.

Assuming similar initiation and termination

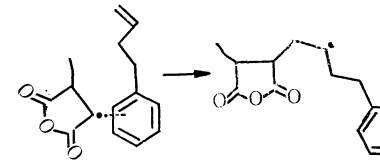
reactions, the higher copolymerizability of 4-phenyl-1-butene may be attributable to the following propagation mechanisms, which are specific to this monomer:



(1)

(2)

In Eq. 1, the benzene ring of the propagating radical and maleic anhydride form a charge-transfer complex, while in Eq. 2 the propagating maleic anhydride radical forms a similar complex with the phenylbutene monomer.[5]

A third possibility to be considered is the intramolecular complex-formation of the phenylbutene radical, as may be assumed in the polymerization of vinyl benzoate.[6] The radical would then become a kind of ocnjugated free radical, and would show a very different reactivity from that of the cyclohexylbutene radical.

Which of these three schemes contributes most to the higher copolymerizability of the phenylbutene remains to be clarified. However, the process depicted by Eq. 2 seems important in the copolymerization of styrene and maleic anhydride; evidence which supports this mechanism has been presented elsewhere.[7]

# A Mössbauer Study of the Hot-atom Effect of EC Decay in Cobalt(II) Oxalate

By Hirotoshi SANO and Fukiko HASHIMOTO

(Received June 22, 1965)

Mössbauer spectroscopy provides unambiguous information about the chemical consequences of nuclear transformations. It is especially useful as a method for studying such effects on a rapid time scale which is inaccessible to classical chemical experimentation. The first excited state in the $^{57}$Fe nuclide is populated by the EC decay of $^{57}$Co, followed by the emission of a 123 keV. gamma ray from the second excited state. It has been found that the electron shake-off Auger cascade resulting from these precursor events gives rise to iron atoms in both $3d^5$ and $3d^6$ configurations, in cobalt(II) oxide,[1] cobalt(III) acetylacetonate[2] and biscyclopentadienyl cobalt(III) salts[3].

The Mössbauer study of the radiolysis of iron(III) oxalate has shown that iron(II) oxalate is formed as an irradiation product.[4] It has been also reported that the $G(Co^{2+})$ value in the $\gamma$-ray irradiated oxalatocobalt(III) complexes increases with an increase in the

oxalate ion content of the complexes,[5] and that ninety percent or more of the radiocobalt atoms are found as cobalt(II) species after the dissolution of the neutron-irradiated oxalatocobalt(III) complexes.[6] In the present study, the Mössbauer spectrum of $^{57}Fe$ produced from $^{57}Co$ in the $CoC_2O_4 2H_2O$ host crystal will be determined.

Pale pink-colored crystal of cobalt(II) oxalate was made by adding oxalic acid to cobalt(II) nitrate solution (containing 2 millicurie of $^{57}Co$). The cobalt content was determined radiochemically. The Mössbauer spectrum was measured with a stainless steel absorber moving at various constant velocities at room temperature. The spectra were also measured with iron(II) oxalate and iron(III) oxalate absorbers, using a $^{57}Co$ diffused copper foil source.

Typical spectra are shown in Fig. 1. With respect to a stainless steel source, iron(II) oxalate and iron(III) oxalate give isomer shifts of 1.28 and 0.49 mm./sec., and quadrupole splitting of 1.73 and 0.43 mm./sec., respectively. In the case of $^{57}Co$-labeled cobalt(II) oxalate, it may be expected that the EC precursor event leaves the daughter $^{57}Fe$ atom not only in the same oxidation state as that of parent cobalt atom, but also in a different oxidation state from those observed in cobalt(II) oxide, cobalt(III) acetylacetonate and biscyclopentadienyl cobalt(III) salts. However, no evidence for ionic charge states other than 2+ is observed. As may be seen in Fig. 1, the electron configuration around the $^{57}Fe$ atom produced in the cobalt(II) oxalate crystal is essentially identical to that in ferrous oxalate. This may be explained by assuming that higher charge species—even if formed as a consequence of the prior nuclear event—have been reduced by the oxalate ions in times brief compared to $10^{-7}$ sec. at room temperature; this is in accordance with the remarkable reducing power of oxalate ions observed in the radiolyses of iron(III) oxalate,[4] potassium trisoxalatoferrate(III)[7] and oxalatocobalt(III) complexes,[5] and with hot-atom effect of the latter.[6]

# The Infrared Spectra of Alkylaluminum-Ether Complexes*1

By Saburo TAKEDA and Ryokichi TARAO

(Received July 30, 1964)

Because of experimental difficulties, the infrared spectra of alkylaluminum-ether complexes have never been reported except for Hoffmann's report dealing with the triethylaluminum - diethyl ether complex along with nine alkylaluminum compounds.[1] As the importance of compounds of this type is increasing from both theoretical and practical points of view, however, fifteen kinds of such complexes have now been prepared and a systematic study of their infrared spectra has been carried out.

Their spectra have been assigned in the 2000 —350 $cm^{-1}$ region, although some of them are tentative. Hoffmann's assignment of the infrared spectrum of the triethylaluminum - diethyl ether complex has been partly corrected. Special attention has been paid to two absorption bands corresponding to the C-O antisymmetric and the C-O symmetric stretching vibration of ether. These C-O bands shift to lower frequencies when ether forms an alkylaluminum complex; the magnitudes of the shifts caused by trimethylaluminum and triethylaluminum complex formation have been compared with each other. The magnitudes of the shifts caused by $AlR_3$-, $AlR_2X$- or $AlRX_2$- (R=methyl, or ethyl, X=halogen) diethyl ether complex formation have also been compared. The infrared spectra of five kinds of ethylaluminum ethoxide have also been measured.

## Experimental

**Preparation of Alkylaluminum-Ether Complexes.** —Trialkylaluminums, dialkylaluminum halides and alkylaluminum dihalides, which were distilled just before use, were mixed with dimethyl ether, tetrahydrofuran, ethyl methyl ether and diethyl ether which had been dried and distilled just before use, in a molar ratio of 1 : 1, and distilled in vacuo. All manipulations were carried out under an atmosphere of purified nitrogen. Trimethylaluminum, dimethylaluminum chloride, and methylaluminum dichloride

were purchased from Texas Alkyls, Inc., and triethylaluminum, diethylaluminum chloride and ethylaluminum dichloride, from the Ethyl Co. Diethylaluminum bromide and ethylaluminum dibromide were prepared by the method of Grosse and Mavity.[2] Table I shows the boiling points, aluminum contents, and molecular weights of alkylaluminum-ether complexes prepared as above.*2

**Preparation of Ethylaluminum Ethoxides.** — Diethylaluminum ethoxide, and ethylaluminum diethoxide were prepared by the method of Grosse and Mavity.[2] Ethylethoxyaluminum chloride and ethylethoxyaluminum bromide were prepared by the reaction of ethylaluminum sesquihalide and aluminum triethoxide.[3] Ethylethoxyaluminum iodide was prepared by the reaction of diethyl aluminum iodide and anhydrous ethanol.[4] Table VI shows the boiling points, aluminum contents, and molecular weights of the ethylaluminum ethoxides thus obtained.

**Measurements of the Infrared Spectra.**—A Japan Spectroscopic Co. model DS-402G infrared spectrophotometer was used for the infrared absorption measurements. Thin liquid films of the samples were used in all cases. Freshly-distilled samples were injected in KRS-5 airtight cells in a glove box filled with purified nitrogen; this operation had to be performed as rapidly as possible, because even

in an atmosphere of carefully-purified nitrogen long exposure of samples brings about contamination with oxidation as a result of the trace amount of oxygen present. Absorption bands due to oxidized contaminants were discriminated by comparing the spectrum obtained with the spectrum obtained with the intentionally airoxidized samples. To make sure that samples did not react with window materials, the observed spectrum was compared with that taken by the polyethylene-sandwich method. No absorption band disappeared even if the polyethylene-sandwich method was applied, showing that no absorption bands due to reaction products with window materials could be detected at all.

## Results and Discussion

**Methylaluminum-Ether Complexes.**—The observed frequencies of the infrared spectra of seven kinds of methylaluminum-ether complexes in the 2000—350 $cm^{-1}$ region are shown in Table II. Figure 1 shows three typical spectra charts. As the spectrum of trimethylaluminum has no absorption band in the 1150—800 $cm^{-1}$ region,[1] and that of dimethyl ether has two bands, 1094 and 920 $cm^{-1}$ (C-O antisymmetric and symmetric stretching vibrations),[5] the absorption bands of the trimethylaluminum-dimethyl ether complex at 1046 and 891 $cm^{-1}$ are assigned to the C-O antisymmetric and symmetric stretching vibrations

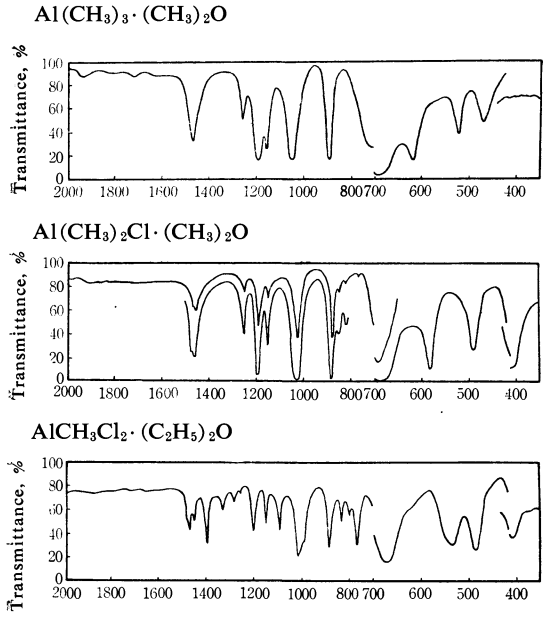

Fig. 1. Spectra of methylaluminum-ether complexes.

5) Y. Mashiko, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **79**, 470 (1958); Y. Mashiko, ibid., **80**, 593 (1959).

respectively. These two C-O stretching bands are also easily found for the six other complexes. Table III shows the shifts of the C-O bands of dimethyl ether, tetrahydrofuran, ethyl methyl ether and diethyl ether upon trimethylaluminum-complex formation. The assignments of the other bands have been made by comparing the spectra of these seven complexes with one another.

Table III. Shifts of the C-O vibration bands of ethers on $AlMe_3$ complex formation

| | $\nu_{as}$(CO) ($cm^{-1}$) | | $\nu_s$(CO) ($cm^{-1}$) | |
|---|---|---|---|---|
| | Ether* | Complex | Ether* | Complex |
| $AlMe_3 \cdot Me_2O$ | 1094 | 1046 | 920 | 891 |
| $AlMe_3 \cdot THF$ | 1073 | 1017 | 913 | 869 |
| $AlMe_3 \cdot MeOEt$ | 1120 | 1042 | 925 | 833 |
| $AlMe_3 \cdot Et_2O$ | 1120 | 1036 | 926 | 898 |

* The values listed are taken from Mashiko's data in $CCl_4$ solution for $Me_2O$, MeOEt, and $Et_2O$.[5] For THF, the frequencies obtained by us in the pure liquid state are used.

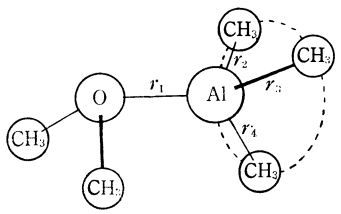

Fig. 2. Molecular model and internal coordinates of $Al(CH_3)_3 \cdot (CH_3)_2O$.

The assignment in the KBr prism region is guided by a consideration of the molecular model $Al(CH_3)_3 \cdot (CH_3)_2O$, as is illustrated in Fig. 2.*3 On the assumption that the trimethylaluminum-dimethyl ether complex has the $C_s$ symmetry only, the symmetry coordinates for each type of vibration in the model are as given in Table IV. Table IV also summarizes the symmetry coordinates for the dimethylaluminum chloride-dimethyl ether complex (in which $r_4$ represents the Al-Cl distance) and the methylaluminum dichloride-diethyl ether complex (in which $r_3$ and $r_4$ represent the two Al-Cl distances).

The assignments for the trimethylaluminum-dimethyl ether, -tetrahydrofuran, -ethyl

*3 Bauer and his co-workers measured the bond lengths and the angles of the boron trifluoride-dimethyl ether complex. They found that all angles of $BF_3 \cdot (CH_3)_2O$ are 109.5° and that the carbon atoms are staggered relative to the fluorine atoms. [S. H. Bauer, G. R. Finlay and A. W. Laubengayer, *J. Am. Chem. Soc.*, **67**, 339 (1945).]

Although the bond lengths and angles of $Al(CH_3)_3 \cdot (CH_3)_2O$ have not been measured, it seems most probable in this case that we may assume a staggered conformation as in the case of $BF_3 \cdot (CH_3)_2O$.

TABLE IV. SYMMETRY COORDINATES

| Complex | Coordinate | Description |
|---|---|---|
| $AlMe_3 \cdot Me_2O$ | $\Delta r_1$ | Al-O stretching |
| | $(\Delta r_2+\Delta r_3+\Delta r_4)/\sqrt{3}$ | Al-C symmetric stretching |
| | $(2\Delta r_2-\Delta r_3-\Delta r_4)/\sqrt{6}$ | Al-C degenerate stretching* |
| | $(\Delta r_3-\Delta r_4)/\sqrt{2}$ | |
| $AlMe_2Cl \cdot Me_2O$ | $\Delta r_1$ | Al-O stretching |
| | $(\Delta r_2+\Delta r_3)/\sqrt{2}$ | Al-C symmetric stretching |
| | $(\Delta r_2-\Delta r_3)/\sqrt{2}$ | Al-C antisymmetric stretching |
| | $\Delta r_4$ | Al-Cl stretching |
| $AlMeCl_2 \cdot Et_2O$ | $\Delta r_1$ | Al-O stretching |
| | $\Delta r_2$ | Al-C stretching |
| | $(\Delta r_3+\Delta r_4)/\sqrt{2}$ | Al-Cl symmetric stretching |
| | $(\Delta r_3-\Delta r_4)/\sqrt{2}$ | Al-Cl antisymmetric stretching |

* If only $AlMe_3 \cdot O$ part of the skeleton is taken into consideration, the symmetry is $C_{3v}$ and these two coordinates must be doubly degenerate. When the two methyl groups are attached to the oxygen atom, the over all symmetry of the complex becomes $C_s$ and these degenerate frequencies split into two. See also Ref. 6.

methyl ether and - diethyl ether complexes are given straightforwardly in Table II, the band appearing at 473—455 $cm^{-1}$ being assigned to the Al-O stretching mode.

The assignments for the methylaluminum dichloride -, the ethylaluminum dichloride - and the diethylaluminum bromide - diethyl ether complexes can also be given straightforwardly, as in Tables II and V (see also Fig. 3). The two Al-Cl vibrations appear at 489 and 408 $cm^{-1}$ for the methylaluminum dichloride complex and at 502 and 405 $cm^{-1}$ for the ethylaluminum dichloride complex. The Al-Br vibration appears at 356 $cm^{-1}$ for the diethylaluminum bromide complex.*4 The Al-O stretching vibrations are assigned for these molecules in Tables II and V. These assignments for the Al-O stretching vibrations are reasonable when we compare them with the B-O stretching vibration assigned by Begun, Fletcher and Palko.[6],*5

The spectra in the KBr region of the dimethylaluminum chloride - dimethyl ether, the dimethylaluminum chloride - diethyl ether and

*4 We also measured the spectrum of the ethylaluminum dibromide - diethyl ether complex. It has 425 and 362 $cm^{-1}$ bands, which are assigned to two Al-Br stretching bands.

6) G. M. Begun, W. H. Fletcher and A. A. Palko, *Spectrochim. Acta*, **18**, 655 (1962).

*5 The difference between 670 $cm^{-1}$ (the B-O stretching vibration) and 530—460 $cm^{-1}$ (the Al-O stretching vibration) can be explained in terms of the difference between the masses of boron and aluminum atoms.

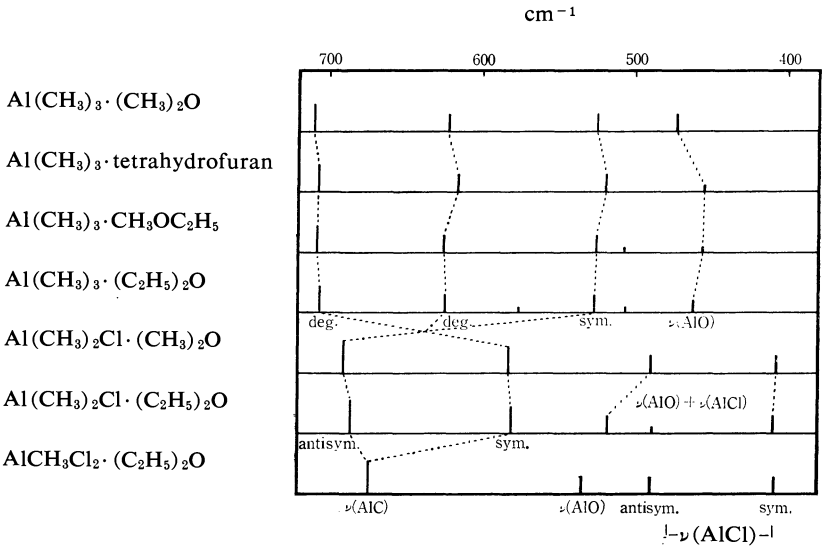

Fig. 3. The KBr region spectra of methylaluminum-ether complexes.

TABLE VI. ETHYLALUMINUM ETHOXIDES

| Ethoxide | B. p., °C (mmHg) | Al, % | | Mol. wt. | |
|---|---|---|---|---|---|
| | | Calcd. | Found*1 | Calcd.*2 | Found*3 |
| $AlEt_2OEt$ | 59.0 (1.5) | 20.7 | 20.4 | 260.3 (2) | 278.7 |
| $AlEt(OEt)_2$ | 155.0—165.0 (3) | 18.5 | 19.0 | 438.5 (3) | 450.4 |
| AlEt(OEt)Cl | 96.0—97.0 (4.5) | 19.8 | 19.7 | 409.7 (3) | 395.9 |
| AlEt(OEt)Br | 130.0 (7) | 14.9 | 15.0 | 362.0 (2) | 374.5 |
| AlEt(OEt)I | 120.0—122.0 (4) | 11.8 | 11.8 | 456.0 (2) | 471.8 |

*1 Method of analysis is the same as in Table I.
*2 Molecular weights were calculated by assuming degree of polymerization as shown in parentheses.
*3 Experimental method is the same as in Table I. AlEt(OEt)Cl isomerized from dimeric to trimeric form in a few days and AlEt(OEt)Br in a few months (see footnote in Appendix). The data listed for these two compounds come from measurements at the time one week after they had been synthesized.

the diethylaluminum chloride - diethyl ether complexes, given in Tables II and V, are somewhat complex. They have two bands in this region, 489 and 407 $cm^{-1}$ for the dimethylaluminum chloride - dimethyl ether, 517 and 409 $cm^{-1}$ for the dimethylaluminum chloride - diethyl ether, and 515 and 406 $cm^{-1}$ for the diethylaluminum chloride - diethyl ether complex. These bands can only be understood in terms of the strong coupling between the Al-O stretching and the Al-Cl stretching vibrations. As has been mentioned above, the Al-O stretching vibration of the trimethylaluminum complex appears near 460 $cm^{-1}$, while that of the methylaluminum dichloride complex appears near 534 $cm^{-1}$. These two facts suggest that the A-O stretching bands of the dimethylaluminum chloride complex appear in the region between 470 and 500 $cm^{-1}$. In this region the Al-Cl stretching vibration is also expected to appear. Therefore, it is very probable that these two bands are coupled with each other and appear as two bands, as has been postulated above.

**Ethylaluminum-Ether Complexes.**—The observed frequencies of the infrared spectra of eight kinds of ethylaluminum-ether complexes in the 2000—350 $cm^{-1}$ region are shown in Table V. Figure 4 shows three typical spectra charts. The assignments are almost self-evident if one uses the results of the assignments of methylaluminum-ether complexes.

Hoffmann assigned the absorption band near 770 $cm^{-1}$ of the triethylaluminum - diethyl ether complex to the C-O symmetric stretching vibration.[1] The above assignment for the C-O symmetric stretching band of the trimethylaluminum - dimethyl ether complex, however, suggests that the band at 894 $cm^{-1}$ originates from the C-O symmetric stretching. Since only the diethyl ether complexes of

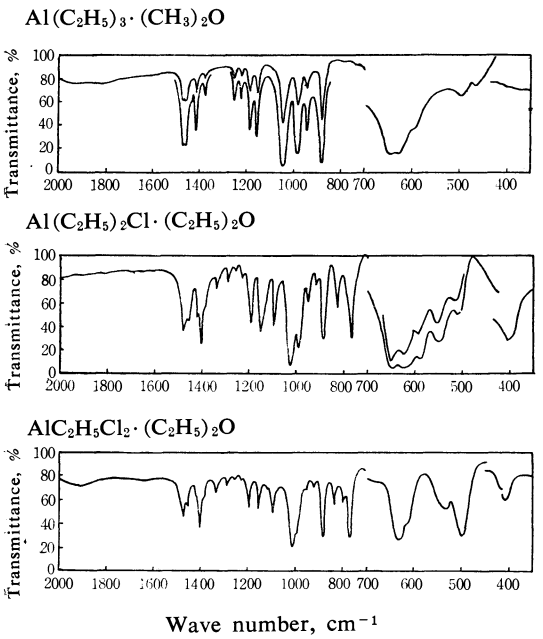

Fig. 4. Spectra of ethylaluminum-ether complexes.

alkylaluminums show an absorption band near 770 $cm^{-1}$, while the dimethyl ether, tetrahydrofuran and ethyl methyl ether complexes do not, this band is assigned to the $CH_2$ rocking vibration of diethyl ether, as is shown in Tables II and V.

In the KBr prism region, the $CH_2$ rocking band of the $CH_2$ group adjacent to the aluminum atom appears near 630 $cm^{-1}$ and the spectra of ethylaluminum-ether complexes become more complicated than those of methylaluminum-ether complexes.[1] The spectrum of the ethylaluminum dibromide-diethyl ether complex in the 710—350 $cm^{-1}$ region is not simple and no adequate assignment has been made.

**Shifts of the C-O Antisymmetric and Symmetric Stretching Bands of Ether on Forming Complex.**—Both the C-O antisymmetric stretching (near 1100 $cm^{-1}$) and the symmetric stretching vibration bands (near 920 $cm^{-1}$) of ether shift to lower frequencies when a complex is formed either with trimethylaluminum (Tables II and III) or with triethylaluminum (Table V). For trimethylaluminum and triethylaluminum, the magnitudes of the shifts are almost the same. These facts suggest that, in the alkylaluminum-ether complex, the C-O bonds of ether are somewhat weaker than those in the free ether molecule because an unshared pair of electrons of the oxygen atom coordinates to the aluminum atom.

If we compare the magnitudes of the shifts of the C-O antisymmetric and symmetric stretching bands of diethyl ether caused by the complex formation with trimethylaluminum, dimethylaluminum chloride and methylaluminum dichloride, the shifts become larger in this order. As regards the magnitudes of the shifts of these two bands of diethyl ether caused by the complex formation with triethylaluminum, diethylaluminum halide and ethylaluminum dihalide, the shifts become larger in this order. Figure 5 shows the shifts of the C-O stretching bands in eight kinds of diethyl ether complexes. From this figure, the following two conclusions can be drawn.

i) The electron-accepting tendency of alkylaluminum becomes larger in the order of $AlR_3 < AlR_2X < AlRX_2$ (R=methyl or ethyl, X=halogen).

ii) The electron-accepting tendencies of $Al(CH_3)_nX_{3-n}$ and $Al(C_2H_5)_nX_{3-n}$ ($n$=1, 2, 3) are almost the same.

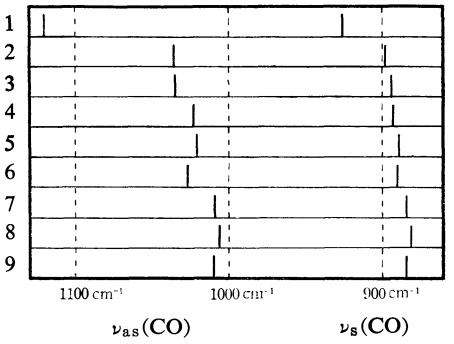

Fig. 5. Shifts of the absorption bands of CO antisymmetric and symmetric stretching vibration of ether on complex formation.

1 $(C_2H_5)_2O$
2 $Al(CH_3)_3 \cdot (C_2H_5)_2O$
3 $Al(C_2H_5)_3 \cdot (C_2H_5)_2O$
4 $Al(CH_3)_2Cl \cdot (C_2H_5)_2O$
5 $Al(C_2H_5)_2Br \cdot (C_2H_5)_2O$
6 $Al(C_2H_5)_2Cl \cdot (C_2H_5)_2O$
7 $AlCH_3Cl_2 \cdot (C_2H_5)_2O$
8 $AlC_2H_5Br_2 \cdot (C_2H_5)_2O$
9 $AlC_2H_5Cl_2 \cdot (C_2H_5)_2O$

As has been mentioned previously, the Al-O stretching vibration bands of trialkylaluminum-diethyl ether and alkylaluminum dihalide-diethyl ether complexes appear near 460 and 534 $cm^{-1}$ respectively. This fact suggests that the Al-O co-ordination bond in alkylaluminum dihalide-diethyl ether complexes is stronger than that in trialkylaluminum-diethyl ether complexes. This interpretation corresponds closely with the above two conclusions, i) and ii).

Lehmkuhl has reported, in comparing the thermal stabilities of complex salts, that the tendency of ethylaluminum compounds to form

a $K^+[Al(C_2H_5)_3Cl]^-$-type complex salt with alkali halides increases in the order of triethylaluminum < diethylaluminum chloride < ethylaluminum dichloride.[7] It is of interest that the electron-accepting tendencies of alkylaluminum compounds obtained by the thermal and the infrared spectroscopic methods give the same order: trialkylaluminum < dialkylaluminum halide < alkylaluminum dihalide.

## Summary

Fifteen samples of alkylaluminum-ether complexes (alkyl=methyl or ethyl) have been prepared, and their infrared spectra have been measured in the 2000—350 $cm^{-1}$ region. Most of the absorption bands in this region have been assigned. In the KBr prism region, the assignments of the absorption bands of the trimethylaluminum - dimethyl ether complex have been made on the assumption that this complex has the $C_s$ symmetry only. The absorption bands of these complexes have been found to shift to lower frequencies in the C-O antisymmetric and symmetric streching vibrations in the order of trialkylaluminum-ether < dialkylaluminum halide - ether < alkylaluminum dihalide - ether complexes. The infrared spectra of five samples of ethylaluminum ethoxides have also been measured in the 2000—350 $cm^{-1}$ region.

The authors are indebted to Professor Takehiko Shimanouchi of the University of Tokyo for his valuable discussions throughout this work.

## Appendix

**Ethylaluminum Ethoxides.** — These compounds were studied as model substances of partly-oxidized ethylaluminum derivatives. The infrared spectra of five kinds of ethylaluminum ethoxides in the 2000—350 $cm^{-1}$ region are shown in Table VII. Figure 6 shows three typical spectra charts. The infrared spectrum of ethylaluminum diethoxide is reported to have been studied by Schomburg, but his result is not easily accesible.[8] The spectrum of ethylethoxyaluminum chloride has been reported by

8) G. Schomburg, Dissertation, Technische Hochschule Aachen (1956).

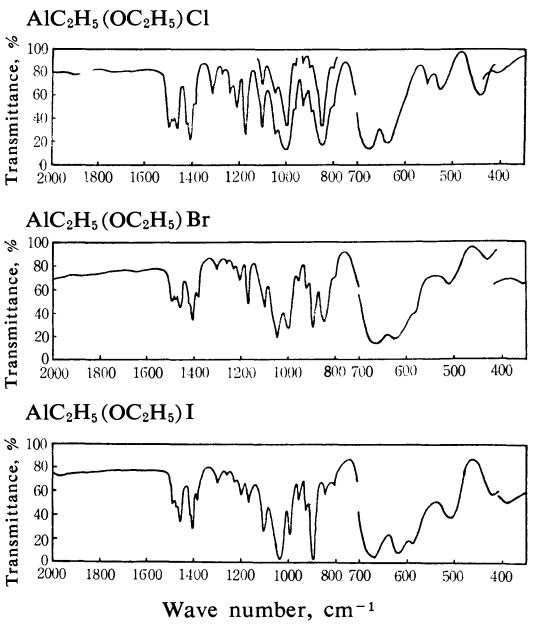

Fig. 6. Spectra of ethylaluminum ethoxides.

Scherer and Seydel ;[9] a comparison of our spectrum with theirs shows a good qualitative agreement.* The spectra of diethylaluminum ethoxide, ethylethoxyaluminum bromide and ethylethoxyaluminum iodide have not been published as yet. All five spectra show very strong bands near 1050 $cm^{-1}$; these bands may be due to the C-O stretching vibration band. The assignments of other bands are also still uncertain.

9) H. Scherer and G. Seydel, *Angew. Chem.*, **75**, 846 (1963).

* Scherer and Seydel found that ethylethoxyaluminum chloride was dimeric just after it was synthesized, but that it isomerized to the trimeric form in a few days; they also reported a corresponding change in the infrared spectrum (intensity changes of four bands at 9.6, 10.0, 11.14 and 11.7 $\mu$). The present authors recognized the same phenomenon. Our spectrum in this paper corresponds to that obtained by the measurement of an aged sample. In our laboratory it was found that ethylethoxyaluminum bromide and ethylethoxyaluminum iodide behaved analogously (isomerization from the dimeric to the trimeric form with a corresponding change in the infrared spectrum - intensity changes of four bands at 9.6, 10.05, 11.2 and 11.8 $\mu$ for ethylethoxyaluminum bromide - though the isomerization was much slower and the change of spectrum was less striking than in the case of ethylethoxyaluminum chloride).

# Transition Metal Complex Catalysts for the Oligomerization of Butadiene. II. The Reaction of Catalyst Components

By Katsumi TAMAI, Taro SAITO, Yasuzo UCHIDA and Akira MISONO

(Received August 11, 1964)

There have been several reports on the remarkable activities of catalysts composed of transition metal complexes and organometallic compounds on the oligomerization of butadiene.[1] The present authors have reported in previous papers[2),3)] that butadiene dimerizes into 3-methyl-hepta-1, 4, 6-triene with the catalyst system consisting of cabalt(III) acetylacetonate and triethylaluminum, and that it trimerizes into *n*-dodeca-1, 3, 6, 10-tetraene with iron(III) acetylacetonate and triethylaluminum. In these reactions, it has been found that the order of the mixing of the catalyst components and butadiene has a great effect on the rate of the formation of oligomers; this has been explained[4)] as being true because in the presence of butadiene, triethylaluminum reduces cobalt(III) or iron (III) acetylacetonate and makes butadiene coordinate to the low valent metal, while without butadiene, cobalt(III) or iron(III) acetylacetonate and triethylaluminum react to form a complex to which butadiene coordinates only with difficulty. The present investigation was undertaken in order to acquire knowledge about the behavior of catalyst components in these reactions. The structure of the catalysts, the oxidation states of the transition metals, the role of triethylaluminum, and the mechanism of the reactions will be discussed on the basis of the results of the magnetic

susceptibility, infrared spectra, gasometry, and electron spin resonance spectra of the reaction solutions.

## Experimental

**Reagents.**—The reagents used in these experiments were prepared and purified in the way which has been described in previous reports.

**Magnetic Susceptibility Measurements.**—Most of the reactions were carried out in a specially-made Erlenmeyer flask (100 ml.) with a small cell on its side. Known amounts of cobalt(III) acetylacetonate or iron(III) acetylacetonate (benzene solution) and triethylaluminum (benzene solution), one introduced in the main body of the flask and the other in the side cell separately under an atmosphere of nitrogen, were mixed by inclining the flask. The reaction solution was then transfused into a Gouy tube with a hypodermic syringe.

The magnetic susceptibility was measured using a Gouy balance. The Gouy tube was 250 mm. long and 10 mm. in diameter and was calibrated with distilled water. The sample transfused into the Gouy tube was placed in the field of 10000 gauss, and the measurements ware carried out at room temperature. The calculations of the magnetic susceptibility and the magnetic moment were performed with the following equations:

$$\chi_M = (\chi_g - \sum_i w_i \chi_{gi}) M/w$$

$$\mu_{eff} = 2.84\sqrt{\chi_M T}$$

where $\chi_M$: the moalr susceptibility based on the cobalt or the iron atom
$\chi_g$: the gram susceptibility of the sample solution
$\sum_i w_i \chi_{gi}$: the diamagnetic correction
$M$: the molecular weight of $Co(acac)_3$ or $Fe(acac)_3$
$w$: the weight fraction of $Co(acac)_3$ or $Fe(acac)_3$
$\mu_{eff}$: the effective magnetic moment (B.M.)
$T$: the absolute temperature

**Gasometry.**—The reaction was carried out in a 300 ml. four-necked flask equipped with a gas burette and a dropping funnel. With a magnetical stirring of the benzene solution of cobalt(III) acetylacetonate or iron(III) acetylacetonate, a certain quantity of a benzene solution of triethylaluminum in the funnel was dropped intermittently, with an allowed interval long enough to complete the gas evolution after each addition. During the measurement, the temperature was kept at 25°C. A change in the order of mixing the components was achieved by interchanging the contents of the flask and the funnel. The gas volume was converted into that at 0°C.

**Infrared Spectra.**—The infrared spectra of the samples were measured by a Hitachi EPI-S2 spectrometer for the sodium chloride region and by a Nihon-bunko Model 201 for the potassium bromide region. A certain amount of cobalt(III) acetylacetonate or iron(III) acetylacetonate was weighed in the same reaction apparatus as was used in the gasometry, and then dissolved in benzene. After the air in the flask has been displaced with nitrogen triethylaluminum in benzene was introduced into the solution, which was kept at room temperature and stirred magnetically. Then a part of the miexed solution was transfused into a KRS-5 cell (0.1 mm. path length) with a glass syringe.

**Electron Spin Resonance Spectra.**—The spectra were recorded in the X-band (9400 Mc.), with 100 kc. modulation, by a Nihon-denshi Model JES-3B ESR spectrometer. The method of sample preparation was similar to that described as having been used for the magnetic susceptibility measurements.

## Results and Discussion

**Infrared Spectra Analysis.**—When triethylaluminum was added to cobalt(III) acetylacetonate, the green color of $Co^{3+}$ faded and the reaction solution changed to purple and then black, with heat and gas generation. Changes in the infrared spectra of the reaction solution were observed with the variation in the amount of triethylaluminum added. A significant change in the absorption band was recognized between 1260 and 1300 $cm^{-1}$. In this region the following bands were assigned[5]: 1261 $cm^{-1}$ for the C-C stretching + C-$CH_3$ stretching of cobalt(II) acetylacetonate, 1284 $cm^{-1}$ for that of cobalt(III) acetylacetonate, and 1288 $cm^{-1}$ for that of aluminum(III) acetylacetonate. The changes in these bands of the solution due to the increase in triethylaluminum added are shown in Fig. 1. As triethylaluminum was added to cobalt(III) acetylacetonate, the band at 1284 $cm^{-1}$ gradually decreased, and a new band at 1261 $cm^{-1}$ began to grow; then a new band at 1288 $cm^{-1}$ was also observed. These results indicate the reduction of cobalt(III) acetylacetonate with triethylaluminum and the resultant formation of cobalt(II) acetylacetonate and aluminum(III) acetylacetonate. At a molar ratio of triethylaluminum to cobalt(III) acetylacetonate of

5) K. Nakamoto, P. J. McCarthy, A. Ruby and A. E. Martell, *J. Am. Chem. Soc.*, **83**, 1066, 1272 (1961).

about 0.5, the amount of cobalt(II) acetylactonate formed suddenly increased; then the amount of cobalt(II) acetylacetonate reached a maximum and gradually decreased with the increase in the amounts of triethylaluminum added. The band at 1288 $cm^{-1}$ of aluminum-(III) acetylacetonate increased until the amounts of triethylaluminum added reached a level about 1.5 times that of cobalt(III) acetylacetonate. In the presence of butadiene, the addition of triethylaluminum changes the benzene solution of cobalt(III) acetylacetonate from green to purple, and then to wine red. In this case, the formation of cobalt(II) acetylacetonate was less than in the former case, as is shown in Fig. 1, which suggests that the presence of butadiene made the further reduction of cobalt(II) faster by means of complex formation.

When iron(III) acetylacetonate was employed instead of cobalt(III) acetylacetonate, almost the same tendency was observed, as is shown in Fig. 2. In this case the band at 1276 $cm^{-1}$ decreased; new bands were observed at 1288 $cm^{-1}$ and 1265 $cm^{-1}$ with the adddition of triethylaluminum. The band at 1265 $cm^{-1}$ reached a maximum at an Al/Fe ratio of about 0.5 and then gradually decreased in just the same way as the band at 1261 $cm^{-1}$ of cobalt-(II) acetylacetonate. The behavior of the band at 1288 $cm^{-1}$ was also similar to the case of the cobalt(III) acetylacetonate and triethylaluminum system. The bands at 1276 $cm^{-1}$ and 1288 $cm^{-1}$ were assigned to the C-C stretching + $C-CH_3$ stretching of iron(III) acetylacetonate and aluminum(III) acetylacetonate respectively[5]. The band of 1265 $cm^{-1}$ was assigned to the C-C stretching + $C-CH_3$ stretching of iron(II) acetylacetonate from the infrared observation of iron(II) acetylacetonate prepared by the method described by Buckingham.[6] Thus, in either the presence or absence of butadiene, iron(III) acetylacetonate, as well as cobalt(III) acetylacetonate, may be supposed to be reduced via the bivalent state to the zero valent state by the addition of triethylaluminum, with the resultant formation of aluminum(III) acetylacetonate.

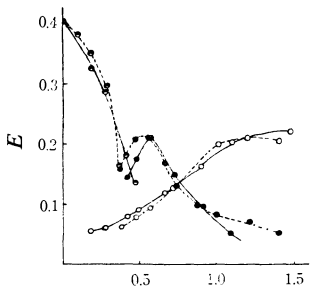

Fig. 2. Variation of the absorbance of IR spectra in 1260—1290 $cm^{-1}$ region upon addition of $AlEt_3$ to $Fe(acac)_3$ in benzene (6.76 $\times 10^{-2}$ M) in the presence (—) or in the absence (···) of butadiene.

○ for 1288 $cm^{-1}$

In order to acquire knowledge about the variation in metal-oxygen band through the reaction, the infrared spectra of several reaction, mixture were recorded in the potassium bromide region from 18 $\mu$ to 27 $\mu$. When more than 0.5 mol. of triethylaluminum to 1.0 mol. of cobalt(III) acetylacetonate was added, the band at 21.4 $\mu$, assigned to the $Co^{3+}$-O stretching of cobalt(III) acetylacetonate almost disappered, new bands appeared at 20.5 $\mu$ and about 23.6—23.7 $\mu$. The former band was assigned to the Al-O stretching of aluminum(III) acetylacetonate, while the band at 23.6—23.7 $\mu$ was assigned to the overlap of the $Co^{2+}$-O stretching of cobalt(II) acetylacetonate and the out-of-plane bending of aluminum(III) acetylacetonate. Although the exchange of the ligand from cobalt to aluminum was confirmed, a quantitative treatment was unsuccessful because of the overlapping bands.

**Gasometry.**—When triethylaluminum was added drop-by-drop into the cobalt(III) acetylacetonate - benzene solution, gas evolved. This gas evolution was gradual until the amount of triethylaluminum added reached about a half of the cobalt(III) acetylacetonate in the solution, whereupon a sudden violent gas evolution was observed. The amount of gas evolved by the violent reaction was nearly 1.5—2 times the total amount of that which had been evolved before. The further addition of triethylaluminum made more gas evolve; the gradients of the plots of the evolved gas and the triethylaluminum added before and after the violent gas evolution are nearly equal as shown in Fig. 3. When nearly the same amount of triethylaluminum as cobalt(III) acetylacetonate in the solution was added, the gas evolution ceased. These observations suggest that, in the first step of the reaction, triethylaluminum reacts with cobalt(III) acetylacetonate in the following way to from cobalt(II) acetyl acetonate:

$$AlEt_3 + Co(acac)_3 =$$
$$AlEt_2(acac) + Co(acac)_2 + \cdot Et$$

It is considered that the diethylaluminum monoacetylacetonate and cobalt(II) acetylacetonate thus formed exist in a meta-stable state with residual cobalt(III) acetylacetonate

6) D. A. Buckingham, J. L. E. Cheong, J. E. Fergusson and C. J. Wilkins, *J. Chem. Soc.*, **1963**, 3461.

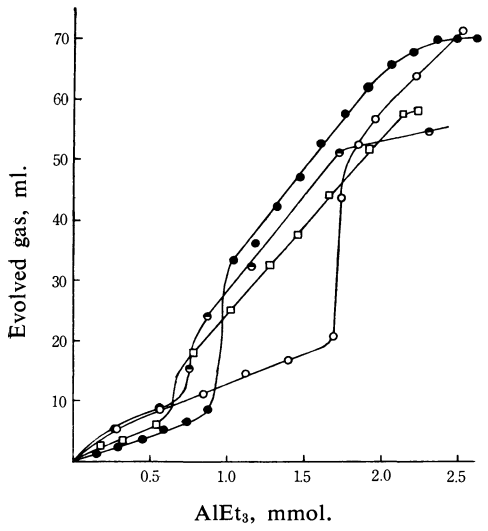

Fig. 3. Plots of amounts of evolved gas upon addition of $AlEt_3$ to $Co(acac)_3$ or $Fe(acac)_3$ in benzene.
- ○ 0.278 M of $AlEt_3$ in benzene was added to 3.66 mmol. of $Co(acac)_3$ in 20 ml. of benzene.
- ◓ 0.571 M of $AlEt_3$ in benzene was added to 1.41 mmol. of $Co(acac)_3$ in 20 ml. of benzene.
- ● 0.292 M of $AlEt_3$ in benzene was added to 2.31 mmol. of $Co(acac)_3$ in 20 ml. of benzene.
- □ 0.336 M of $AlEt_3$ in benzene was added to 1.46 mmol. of $Fe(acac)_3$ in 20 ml. of benzene.

by solvation or complex formation. The violent reaction, induced by the further addition of only one drop of triethylaluminum to the solution when about a half of the triethylaluminum was added to the cobalt(III) acetylacetonate, can be understood by considering that the meta-stable state is destroyed by the decrease in the amount of cobalt(III) acetylacetonate to less than that of cobalt(II) acetylacetonate. It is considered that the following reactions occurred in this case:

$$AlEt_2(acac) + 2Co(acac)_3 = Al(acac)_3 + 2Co(acac)_2 + 2\cdot Et$$

$$AlEt_2(acac) + Co(acac)_2 = Al(acac)_3 + Co^0 + 2\cdot Et$$

This mechanism was supported by the infrared observations. Thus, cobalt(III) is supposed to be reduced to cobalt(II), and then to the zero valent state:

$$Co(acac)_3 \rightarrow Co(acac)_2 \rightarrow Co^0$$

Cobalt(I) acetylacetonate is probably too unstable to exist as an intermediate state. The same results were found in the case of the iron(III) acetylacetonate and triethylaluminum system (Fig. 3).

When cobalt(III) acetylacetonate was added to an excess of triethylaluminum, cobalt(III) seemed to be reduced immediately to the zero valent state (Fig. 4).

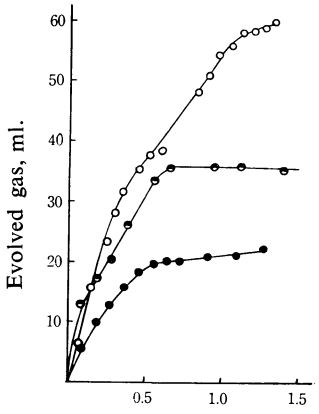

Fig. 4. Plots of amounts of evolved gas upon addition of $Co(acac)_3$ in benzene to $AlEt_3$.
- ○ 0.0734 M of $Co(acac)_3$ in benzene was added to 2.22 mmol. of $AlEt_3$ in 20 ml. of benzene.
- ◓ 0.0914 M of $Co(acac)_3$ in benzene was added to 1.11 mmol. of $AlEt_3$ in 10 ml. of benzene.
- ● 0.0894 M of $Co(acac)_3$ in benzene was added to 1.11 mmol. of $AlEt_3$ in 20 ml. of benzene.

The amount of gas observed in the gasometry was 50—60% of the theoretical value. When the composition of the evolved gas was determined by gas chromatography, it was found that the gas was about 85% ethane and 15% ethylene. The deficiency in gas evolution compared with the theoretical value could be explained by the dissolution of gas in benzene and by the chemisorption of ethylene to the complex formed with the reduced cobalt or iron.

**Magnetic Susceptibility Measurements.**—The composition and the gram magnetic susceptibility for the sample solution are shown in Table I.

a) When cobalt(III) acetylacetonate in benzene was added to an excess of triethylaluminum, the magnetic moment of the solution was 0.6 B. M. (at Al/Co=7.3). This shows that the cobalt complex in the solution is probably diamagnetic. With the addition of cobalt(III) acetylacetonate, the magnetic moment of the solution increased and reached a maximum at an Al/Co ratio equal to 1. At the same time, the solution turned from brown

to black, and a precipitate formed. Here an extraordinarily large $\mu_{eff}$ value of 12.1 was observed, which could not be attributed to the paramagnetism arising from first transition metals. If the magnetic moment is considered to be attributed only to the electron spin of the first transition metal, the value can not be expected to be higher than 6. The contribution of orbital motion will probably not be large enough to explain the extraordinarily large magnetic moment. These phenomena can only be explained in terms of the ferromagnetism due to the coagulation of the reduced zero valent cobalt to the unstable metallic state. The above observation suggest that the excess triethylaluminum has the ability to stabilize the cobalt of the zero valent by the formation of a complex like that suggested by Sartori and Costa in such a way as that shown below[9]:

$$Co(acac)_3 + 3AlEt_3 \rightarrow Co^0 \cdots [AlEt_2(acac)]_3 + \frac{3}{2}(C_2H_4 + C_2H_6)$$

As $Co^0$ has a $d^7s^2$ ground state, the diamagnetism can be explained by the assumption of a dimer structure or of cobalt hydride, for example. As cobalt(III) acetylacetonate was then added to the reaction mixture which included the above complex, the remaining ethyl groups of $AlEt_2(acac)$ were also used for the reduction of the cobalt atom. The resultant $AlEt(acac)_2$ or $Al(acac)_3$ perhaps has no ability to stabilize $Co^0$ or to prevent its coagulation.

b) When cobalt(III) acetylacetonate and triethylaluminum were mixed at the same time, it was observed that the magnetic moment was somewhat larger than in the case of a) in the region of an Al/Co ratio greater than four. These results are understood to indicate that small coagulations of cobalt occurred during the mixing.

c) In the case of the addition of triethylaluminum to cobalt(III) acetylacetonate, the magnetic moment also reached a maximum ($\mu_{eff}=12$) at an Al/Co ratio around unity, but the further addition of triethylaluminum to this solution made the $\mu_{eff}$ decrease to some degree. This phenomenon can be explained in terms of the fact that the added triethylaluminum dissolved the coagulated cobalt by the complex formation, as has been mentioned above. It may be supposed that the bonds formed by the coagulation of cobalt are either so weak or so active that they have a tendency to enter into the reaction. This was elucidated by the decrease in $\mu_{eff}$ caused by the addition of some organic compounds. The addition of butadiene in the solution prepared by adding triethylaluminum to cobalt(III) acetylacetonate in a Al/Co ratio of unity decreased the $\mu_{eff}$ value to 7.8. This shows some coordination of butadiene to reduced cobalt, but the amount is not so large that the dependency of the rate of the formation of methylheptatriene on the mixing order ($Co(acac)_3 + AlEt_3$ + butadiene) is small.[2,4] When methanol was added to the solution of cobalt(III) acetylacetonate and triethylaluminum (Al/Co=1) and the mixture was brought into contact with air, the coagulated cobalt dissolved and the solution changed red. From the infrared spectra it was considered that cobalt was oxidized to cobalt(II) acetylacetonate. The magnetic moment ($\mu_{eff}=5.1$) also supported this supposition.

d) When iron(III) acetylacetonate instead of cobalt(III) acetylacetonate was added to triethylaluminum, the curve of the relation between the Al/Fe ratio and the magnetic

moment showed almost the same tendency as in the system of cobalt(III) acetylacetonate and triethylaluminum. In this case, however, the $\mu_{eff}$ value of the solution was much larger than in the case of cobalt throughout the Al/Fe ratio range. The extraordinarily large $\mu_{eff}$ value of the iron system, even when there is excessive triethylaluminum, may be due to the unstability of the complex between reduced iron and aluminum derivatives of this sort.

**ESR Spectra.**—With the view of deciding whether the extraordinarily large magnetic moments are aroused by paramagnetism or by ferromagnetism, the electron spin resonance spectra of a benzene solution of cobalt(III) acetylacetonate and triethylaluminum were recorded. A single line signal was observed at a *g*-value of 2.128. The signal was hardly observed at all in the Al/Co ratio region about 0.5—1, where an extraordinarily large magnetic moment was shown. However, the intensity of the signal increased as the Al/Co ratio became as large as 3—5, which is a tendency opposite to that of the magnetic moment. At an Al/Co ratio of 3—5, the presence of an unpaired electron was supposed, but the spin concentration was quite small. Thus, it is obvious that the large susceptibility is not due to paramagnetism, but to ferromagnetism.

## Summary

In order to obtain some knowledge on the behavior of catalysts in the oligomerization of butadiene, the reaction between cobalt(III) acetylacetonate or iron(III) acetylacetonate and trietylaluminum has been investigated by means of magnetic susceptibility measurements, infrared spectra, gasometry, and electron spin resonance spectra.

When triethylaluminum was added to an excess of cobalt(III) acetylacetonate, the infrared spectra and gasometry suggested that the latter was reduced via stable cobalt(II) acetylacetonate to zero valent cobalt and that, at the same time, the former was transformed into aluminum(III) acetylacetonate. The extraordinarily large magnetic moment ($\mu_{eff}$= 12) and the absence of the signal of the electron spin resonance specra suggested the formation of metallic cobalt. The metallic cobalt was active enough to be readily oxidized by the addition of methanol. The addition of butadiene to this solution decreased the magnetic moment to 7.8. This shows some coordination of butadiene to reduced cobalt.

When cobalt(III) acetylacetonate was reduced in the presence of an excess of triethylaluminum (Al/Co>4), the zero valent cobalt was stablilized as a result of the formation of a certain diamagnetic complex with triethylaluminum. However, the addition of cobalt (III) acetylacetonate to this reaction mixture decomposed the above complex, and the very large magnetic moment indicated the formation of metallic cobalt.

Iron(III) acetylacetonate was, like cobalt(III) acetylacetonate, reduced to zero valent iron via stable iron(II) acetylacetonate. In the presence of an excess of triethylaluminum, however, zero valent iron did not form a stable complex with triethylaluminum, and from the ferromagnetism metallic iron was observed toresult.

# Basic Bile Acids. V. On the Syntheses and Properties of Basic Bile Acids and Their Derivatives

By Yasuo SATOH

(Received December 7, 1964)

In the previous papers of the series,[1] the syntheses and properties of the several basic bile acids and their derivatives have been reported. The present paper will summarize the syntheses and properties of the basic bile acids, including new derivatives.

## 3-Amino Derivatives

In the catalytic reduction of the oxime of 3-keto bile acid, it was found that the configurations of the amino groups formed are identical with those of the hydroxyl groups formed in the case of 3-keto steroids.[2] That is, in the catalytic reduction of the oxime in an acidic medium, a 3$\beta$-amino derivative is formed, with a speedy absorption of hydrogen, as in the case of 3-keto bile acids. The configuration of this product has been determined by a comparison of its properties with those of the 3$\beta$-amino derivative prepared by Walden's inversion of 3$\alpha$-tosylate with liquid ammonia. Moreover, in the catalytic reduction of the oxime in a neutral medium, a 3$\alpha$-amino derivative is formed, with a slow absorption of hydrogen, contrary to that formed in the case of an acidic medium.

On the other hand, in the metallic reduction of the oxime, a 3$\alpha$-amino derivative is obtained which has the same configuration as the hydroxyl group formed in the case of the reduction of 3-keto steroids.[2]

These results agree well with the facts obtained previously from the reduction of the oxime of 5$\beta$-cholestan-3-one by Shoppee et al.[3,4]

The reaction of the 3-amino derivatives with nitrous acid was also examined. It has generally been confirmed that the course of the deamination of cyclohexylamines and decalylamines is conformationally specific[5,6]: if the amino group is equatorial in the most stable conformation of the molecule, deamination gives an alcohol of the same configuration; if it is axial, elimination and inversion occur.

In basic steroids, the same result has been reported by several workers.[4,7] When the reaction is examined with respect to the synthesized 3-aminocholanic acids, the following results are obtained:

3$\alpha$-Amino derivative ($C_3$–$NH_2$: e) $\rightarrow$
3$\alpha$-Hydroxy derivative ($C_3$–OH: e)

3$\beta$-Amino derivative ($C_3$–$NH_2$: a) $\rightarrow$
3$\beta$-Hydroxy derivative ($C_3$–OH: a)
+ 3-Cholenic acid

These results coincide with the experiential rule described above for the deamination of alicyclic and steroidal amines.

The additive charactor of the molecular rotation has generally been proposed to exist in the steroid field.[8] When the molecular rotations of methyl 3-acetamidocholanates are calculated from that of the 3-acetamido-5$\beta$-cholestane prepared by Shoppee et al.,[3] the results are as follows:

$M_D$ of 3$\alpha$-acetamido-5$\beta$-cholestane $= +206$ (a)

$M_D$ of 3$\beta$-acetamido-5$\beta$-cholestane $= +112$ (b)

$M_D$ of 5$\beta$-cholestane $= +97$ (c)

(a) $-$ (c) $= (+206) - (+97) = +109$

$\Delta M_D$ of 3$\alpha$-$NHCOCH_3$ in the 5$\beta$ series

(b) $-$ (c) $= (+112) - (+97) = +15$

$\Delta M_D$ of 3$\beta$-$NHCOCH_3$ in the 5$\beta$ series

$M_D$ of methyl cholanate $= +80$ (d)

(d) + ($\Delta M_D$ of 3$\alpha$-$NHCOCH_3$ in 5$\beta$ series)
$= (+80) + (+109) = +189$

calculated value of $M_D$ for methyl 3$\alpha$-acetamidocholanate

(d) + ($\Delta M_D$ of 3$\beta$-NHCOCH$_3$ in 5$\beta$ series)
= (+80) + (+15) = +95

Calculated value of $M_D$ for methyl 3$\beta$-acetamidocholanate

Observed values:

Methyl 3$\alpha$-acetamidocholanate = +177

Methyl 3$\beta$-acetamidocholanate = +95

From the good agreement between the calculated values and the observed values, the configurations previously deduced from each methyl ester acetate seem indeed to be correct; almost no effect of the side chain in $C_{17}$ is present, and, in these substances, the additive character of the molecular rotation holds.

### 7-Amino Derivatives

The 7-position of cholanic acid suffers a larger steric hindrance than that in the 3-position, considered not only from the molecular model but from the following facts. In the catalytic reduction of 7-keto bile acid, it is well known that the 7$\alpha$-hydroxyl group ($C_7$–OH: a) is mainly formed either in an acidic or in a neutral medium, in contrast to the behavior of the 3-keto bile acids. That is, in the catalytic reduction of 3$\alpha$-hydroxy-7-ketocholanic acid, the main product is chenodeoxycholic acid ($C_7$–OH: a) rather than ursodeoxycholic acid ($C_7$–OH: e), which has a stable equatorial hydroxyl group in the 7-position.[9,10] Moreover, in the reduction of that acid with sodium ethoxide, the results are similar to those in the case of catalytic reduction.[9] On the basis of these data and the results of catalytic reduction in an acidic medium for decalones, their oximes[11,12] and the oxime of 3-keto 5$\beta$-steroid,[3] it seems reasonable to assume that the product obtained from the oxime of 7-ketocholanic acid by catalytic reduction in an acidic medium is 7$\alpha$-aminocholanic acid.

In order to determine more precisely the configuration of this product, a reaction with nitrous acid was attempted with the methyl ester of 7-amino acid similar to that described above for the 3-amino derivatives. As has been described in the previous paper,[1] an unsaturated compound is obtained from the methyl 7-aminocholanate in this reaction. The 7-amino group formed by the catalytic reduction of the oxime, therefore, may be assigned the $\alpha$-configuration (axial).

Furthermore, the unsaturated compound formed by the reaction of methyl 7$\alpha$-aminocholanate with nitrous acid is assumed to be 7-cholenate. This assumption is based on the consideration that, although two axial hydrogens at the $C_6$- and $C_8$-positions, are present in this compound, elimination between $C_8$–H and $C_7$–NH$_2$ may be expected according to the Saytzeff rule. A similar situation has also been reported in the case of deamination for 6$\beta$-amino-5$\alpha$-cholestane.[4]

In order to confirm the structure of the unsaturated product in this reaction, it was desirable to examine the propriety of the structure presumed above by the application of the additive character in molecular rotation:

$\Delta M_D$ of $C_7$-double bond = +119[2] (a)

$M_D$ of methyl cholanate = +80[13] (b)

(a) + (b) = (+119) + (+80) = +199 Calculated value of $M_D$ for methyl 7-cholenate

Observed value: +195

This good agreement between calculated and observed values gives further confirmation that the product from the reaction with nitrous acid and the 7-amino derivative is methyl 7-cholenate, and that the reduction product of the oxime in an acidic medium is 7$\alpha$-aminocholanic acid.

A number of years ago attempts by several workers to prepare the 7$\beta$-hydroxy derivative from 7-keto bile acid were unsuccessful.[9,10,14] It was reported by Hoshino et al.[15] in 1954, however, that ursodeoxycholic acid could be obtained in a good yield by reduction with sodium and *n*-propanol. In order to prepare the 7$\beta$-amino derivative from the oxime of 7-ketocholanic acid, therefore, this procedure was used. The results showed that the methyl ester acetate of the product is different from the 7$\alpha$-amino epimer (obtained from the oxime by catalytic reduction) in melting point, infrared spectrogram, thin-layer chromatogram and specific rotation, while their elementary analyses are the same. It might, therefore, be concluded that the product is 7$\beta$-aminocholanic acid.

### 12-Amino Derivative

The 12-position of cholanic acid suffers a larger steric hindrance than the 3- or 7-position. This can easily be understood from the fact that the acetylation and oxidation of the 7$\alpha$-hydroxyl group are more easily accomplished

than in the case of the 12$\alpha$-hydroxyl group ($C_{12}$–OH : a).[16] Moreover, in the reductions of 12-ketocholanic acid[17] and 12-hydroxyiminocholan,[18] 12$\alpha$-epimers with a thermodynamically-unstable bond are predominantly formed as a result of the steric hindrances, while under the same conditions, unhindered ketone gives an equatorial hydroxyl group. Also, in the reduction of the respective oxime it has been found in the present work that the reaction rates have the same relationship.

When the hydroxyimino group at such a highly-hindered position was reduced with sodium and *n*-propanol, as has been described in the case of the 7-position, the product obtained was the same as that of the catalytic reduction in an acidic medium. Since this position has such a large steric hindrance compared with the 7-position, it seems reasonable to assume, from the results, that the factor in determining the direction of the reaction is concerned rather with the steric approach control than with the product development control.

The configuration of the amino group in the basic bile acid prepared from the 12-hydroxyimino derivative by catalytic reduction is presumed to the axial by deduction from the cases of the 3- and 7-derivatives. When this substance is allowed to react with nitrous acid, a product which gives a positive tetranitromethane test and which has an absorption band at 1635 $cm^{-1}$ in its infrared spectrum is obtained. From these results, it may be inferred that elimination has occurred in this reaction. On the basis of these data, it was concluded that the basic derivative obtained from the oxime is 12$\alpha$-aminocholanic acid ($C_{12}$–$NH_2$ : a).

### Methyl 3$\alpha$-Acetoxy-12$\alpha$-acetamidocholanate

The molecular rotation of this substance is as follows:

$M_D$ of methyl 12$\alpha$-acetamidocholanate $= +397$ (a)

(a) $-$ ($M_D$ of methyl cholanate)
$= (+397) - (+80) = +317$

$\Delta M_D$ of 12$\alpha$-$NHCOCH_3$ in 5$\beta$ series (b)

$\Delta M_D$ of 3$\alpha$-$OCOCH_3$ in 5$\beta$ series $= +114$ (c)

Calculated value of $M_D$ for methyl 3$\alpha$-acetoxy-12$\alpha$-acetamidocholanate
$= (M_D$ of methyl cholanate$) + (b) + (c)$
$= (+80) + (+317) + (+114) = +511$

Observed value : $+547$

The observed value is in fairly good agreement with the calculated value. The small difference may come from the molecule's being subject to a little strain due to the $\alpha$-orientated two groups.

### On the Leuckart-Wallach Reaction of Methyl Ketocholanate

This reaction had already been attempted by Hadáček et al. for methyl 7-keto-3$\alpha$, 12$\alpha$-dihydroxycholanate and methyl 3, 7, 12-triketocholanate,[19] but, as their results seemed to be inadequate for a determination of the structure, it was reinvestigated. They reported that the configuration of the formamido groups in the products is equatorial. In view of the following points, however, the determination of this configuration seems to contain an error.

1) The configuration of the formamido group formed was determined by Hadáček et al. by means of the formation of a free amino group by hydrolysis. That is, the configuration was determined only on the basis that the melting point of this amino derivative was virtually identical with that of the 7-amino-3$\alpha$, 12$\alpha$-dihydroxycholanic acid prepared from the 7-hydroxyimino derivative with sodium and isoamyl alcohol by Webb et al.[20] According to Barton, the reduction of a ketoxime with sodium and alcohol gives an equatorial amino group predominantly.[12] Then, on the basis of the Barton report, Hadáček et al. determined that the configuration of the amino group in the product formed by Webb et al. has a 7$\beta$-orientation ($C_7$–$NH_2$ : e), and, since the melting points of both this 7$\beta$-amino derivative and their product derived from formamido derivative by hydrolysis were almost the same, they concluded that the product of the Leuckart-Wallach reaction of methyl 7-keto-3$\alpha$, 12$\alpha$-dihydroxycholanate might be methyl 7$\beta$-amino-3$\alpha$, 12$\alpha$-dihydroxycholanate. However, Barton's theory seems inadequate to determine the configuration of the 7-position in bile acids, because the reaction of this position gives a result different from that of the 3-position, as has been mentioned above for the catalytic reduction of the 7-ketone.

18) M. Alauddin and M. Martin-Smith, ibid., **28**, 886 (1963).
19) J. Hadáček, and B. Čajánek, *Publs. Fac. Sci. Univ. Masaryk*, **395**, 259 (1958).
20) S. P. James, F. Smith and M. Webb, *J. Chem. Soc.*, **1946**, 665; A. S. Jones, M. Webb and F. Smith, ibid., **1946**, 2164.

2) They carried out an elementary analysis and measured the melting point of this substance, but they did not report its optical rotatory power.

Hadáček et al. determined, as has been described above, that the product of the Leuckart-Wallach reaction of methyl 7-keto-3$\alpha$, 12$\alpha$-dihydroxycholanate is the 7$\beta$-amino derivative, with an equatorial amino group, they did this on the agreement of the basis of the melting point with the literature.[20] They then deduced that the reaction gave an equatorial amino group in all other positions, also. They concluded, therefore, that the product of this reaction of 3, 7, 12-triketocholanic acid is 3$\alpha$, 7$\beta$, 12$\beta$-triaminocholanic acid ($C_3$–, $C_7$– and $C_{12}$–$NH_2$: e). For the reasons pointed out above, however, the present author cannot accept this conclusion. From the experimental results[1] and the consideration of them in the present work, it may be firmly concluded that the configuration of the amino group formed from the ketone of bile acid in this reaction is axial, and, at the same time, that the presumed configuration proposed by Hadáček et al.[19] should be corrected.

## Thin-layer Chromatography of Methyl Acetamidocholanates

This chromatography was carried out using the technique of Hara[21] for the methyl esters of bile acids; results are listed in Table I.

On the relationship between the configuration of substituted groups and adsorbability, it has been reported that axial epimers are generally adsorbed more weakly than equatorial epimers.[22]

It would be interesting to compare this general rule with the reults obtained in the present work for acetamido derivatives. In the 3-substituted compounds, the adsorbability of axial-bonded derivatives ($\beta$) is larger than that of the equatorial-bonded derivative ($\alpha$), while in the 7-substituted compounds that relation is reversed (e>a). Although this relation seems to be inconsistent with the general rule, this inconsistency may be accounted for by considering the overall shape of the molecule. The 3$\alpha$(e)- and 7$\alpha$(a)-bonds are oriented almost parallel to the axis of the steroidal nucleus; in other words, these bonds correspond to the axial bonds in the cyclohexane ring. Therefore, the adsorbability of 3$\alpha$- and 7$\alpha$-derivatives is smaller than that of 3$\beta$- and 7$\beta$-derivatives, and, consequently, the former moves more quickly than the later in thin-layer chromatography. In the case of the thin-layer chromatography of both epimer of methyl 3-acetoxycholanate, the same relations are also observed (Solvent, benzene/pet.-ether: 3$\alpha$-OAc (e), $R_f$ 0.74; 3$\beta$-OAc (a), $R_f$ 0.65).

TABLE I. $R_f$ VALUES OF METHYL ACETAMIDOCHOLANATES IN THIN-LAYER CHROMATOGRAPHY

## On the Infrared Spectrography of Mathyl Acetamidocholanates

Some of the characteristic bands of individual methyl acetamidocholanates are listed, with their wave numbers, in Table II.

In an associated acyl amide derivative, the stretching vibration of C=O has been observed to shift to a lower wave number, the bending vibration of N–H has been observed to shift to a higher wave number, and the stretching vibration of N–H and unknown vibration appear above 3000 $cm^{-1}$.[23]

Each absorption band in a chloroform solution of these methyl acetamidocholanates, as is shown in Table II-I, is almost identical with the standard value for the non-associated second-amide type, while the values in the cases of the KBr disk method are observed to shift to longer wavelengths than those values for $\nu_{N-H}$ and $\nu_{C=O}$ and to shorter wavelength than those values for $\delta_{N-H}$. In view of the above facts, the conclusion may be drawn that these compounds may exist in the non-associated state in such a solution and in the associated state in the KBr disk.

Moreover, with reference to Table II-Ia, in the 7$\alpha$-acetamido derivative only one absorption band above 3000 $cm^{-1}$ was observed, while

*1 The sample was prepared by drying at 25°C/760 mmHg/24 hr.
*2 The sample was prepared by drying at 105—110°C/1 mmHg/6 hr.
*3 The sample was prepared by drying at 160—165°C/1 mmHg/8 hr.

the other derivatives show two bands. However, one of the two bands of the 3β-acetamido derivative above 3000 $cm^{-1}$ disappeared for the sample in Table II-Ib. In a chloroform solution the absorption bands above 3000 $cm^{-1}$ of all derivatives are shifted to about 3400 $cm^{-1}$, where the values are identical with those of the stretching vibration of N-H for the non-associated secondary amide type, as has been described above. A band at 3070 $cm^{-1}$, for which the assignment has not yet been distinctly made, was not observed for the 3β-derivative when it was dried at 105—110°C under 1 mmHg; on the other hand, in the 3α- and 12α-acetamido derivatives, the band does not disappear even at 160—165°C under 1 mmHg. Moreover, these compounds with an absorption band at about 3070 $cm^{-1}$ (e. g., methyl esters of 3α-, 7β- and 12α-acetamidocholanic acids) also possess an absorption band near 720 $cm^{-1}$ with a broad shape. (This band is called an amide V band and has been reported to possess only a secondary associated-amide type.[24]) Though the absorption bands of these derivatives are considered to shift as a result of their crystalline structure, the shift may be smaller than that arising from association. On the basis of the facts that, in Table II-Ib, considerable shifts of the absorption bands of $\nu_{N-H}$, $\nu_{C=O}$ and $\delta_{N-H}$ are observed and that the absorption band near 720 $cm^{-1}$ is presented, it seems reasonable to assume that the 3α-, 7β- and 12α-acetamido derivatives exist in the associated states in the KBr disk.

The author wishes to express his gratitude to Professor Akira Hagitani for his discussions and encouragement throughout the course of this work. He is also indebted to Professor Yuzo Kakiuchi for his valuable discussions of the infrared spectra.

# The Isocyanurates. I. A Novel Method of Synthesizing Trialkyl Isocyanurates

By Kenichi FUKUI, Fumio TANIMOTO and Hisao KITANO

(Received December 18, 1964)

Some esters of isocyanuric acid are interesting as heat resistant resins[1,2] because of their symmetrical triazine ring structure. Only a few of the isocyanurates have, however, been used as practical chemical intermediates. This is because of the methods of synthesizing them are not sufficiently economical for general use.

Hofmann first indicated that trimethyl isocyanurate had been prepared by the thermal isomerization of trimethyl cyanurate both without[3] or with[4] methyl iodide. The trimethyl cyanurate was synthesized from cyanuric chloride and methyl alcohol in the presence of alkali hydroxide. However, his method was applied only to the preparation of lower alkyl esters. Other classical preparative methods of isocyanurates were by the reaction of alkyl iodides with silver cyanurate[5] and by that of potassium alkyl sulfate with potassium cyanate or potassium cyanurate.[6] The trimerization of alkyl isocyanates to isocyanurates catalyzed by phosphines or tertiary amines[7-9] has been used in laboratory techniques. Since, however, this method involves the treatment of poisonous and expensive isocyanates, it is not preferable to synthesizing many isocyanurates.

Although Kaiser and his co-workers reported[10] that the reaction of alkali cyanates with alkyl halides in acetonitrile as a solvent under pressure afforded alkyl isocyanurates, the yield was generally very low and it was difficult to purify the products to an extent similar to that of the other known methods. Kaiser also reported that the syntheses of unsaturated carbamates from potassium cyanate and alkenyl halides in alcohols were accompanied by the formation of alkenyl isocyanurates as a by-product.[11] De Pree reported that, in the syntheses of isocyanates from the reaction of alkyl halides with alkali cyanates catalyzed by tertiary amines, considerable amounts of isocyanurates were formed, along with isocyanates.[12]

In the previous works of our laboratory,[13-22] several aprotic solvents, such as dimethylformamide, dimethyl sulfoxide, dimethylacetamide, tetramethylene sulfoxide, tetramethyl urea, *N*-formyl morpholine, and *N*-formyl piperidine, were found to be powerful solvents for the nucleophilic displacement reaction of organic halides with metal cyanates and for the subsequent trimerization of isocyanates to isocyanurates.

Recently Frazier[23] reported an improvement of the isocyanurates synthesis by means of the reaction of alkenyl halides with cyanuric acid in aqueous alkali in the presence of cuprous chloride. Tazuma and his co-worker patented[24] a method of synthesizing isocyanurates from potassium cyanate and alkyl halides with tertiary amines in inert solvents. As an improvement of Frazier's method, Francis showed that the reaction of alkyl halides with alkali cyanurates proceeded smoothly in dimethylformamide as a reaction medium.[25]

In the present paper, the reactions between alkyl halides and potassium cyanate in aprotic solvents, such as dimethylformamide and dimethyl sulfoxide, have been studied. The

yield of the isocyanurates was generally good enough to be applied to the synthetic purpose, and the techniques of synthesis and the purification of the products were also easy. The reactions may be written as follows:

$$RX + KCNO \xrightarrow[\text{or DMSO}]{\text{in DMF}} RNCO + KX \quad (1)$$

$$3\ RNCO \xrightarrow[\text{or DMSO}]{\text{in DMF}} \quad (2)$$

As a side reaction, the formation of 1,3-dialkyl ureas from moisture and alkyl isocyanates were observed as follows:

$$2\ RNCO + H_2O \xrightarrow[\text{or DMSO}]{\text{in DMF}} (RNH)_2CO + CO_2 \quad (3)$$

Although the rate of the reaction 3 of isocyanates with miosture was faster than that of the reaction 2, the formation of ureas was effectively avoided by drying the solvents and reactants before use. The condition of reactions 1 and 2 were moderate. The preferable conditions were a reaction temperature of 110—150°C and a molar ratio of the solvent to the halide of at least 2.5. The yields and the

properties of isocyanurates are listed in Table I.

The trialkyl isocyanurates and tris-(2-alkoxyethyl) isocyanurates shown in Table I were relatively thermostable compounds, could be distilled under atmospheric pressure without decomposition, and were resistant to chemicals at ordinary temperatures. Tris-(2-vinyloxyethyl) isocyanurate was easily polymerized with a cationic catalyst such as boron trifluoride etherate in a hydrocarbon solvent, leading to a heat-stable polymer.

The urea formation was affected by the amount of water involved in the reaction mixture. The influence of water was observed in the reaction of *n*-butyl bromide with potassium cyanate. The results are listed in Table II.

To increase the yield of isocyanurate, it is extremely necessary to remove the water in the reaction mixture carefully. The total yield of tri-*n*-butyl isocyanurate and 1, 3-di-*n*-butyl urea was 80—87%.

## Experimental[26]

**1) Materials.**—Alkyl halides were prepared from the corresponding alcohols by the usual method and were purified by fractional distillation. 2-Alkoxyethyl bromides were prepared by the reaction of alkyl cellosolves with phosphorus tribromide, and crude products were fractionally distilled to give pure samples. 2-Vinyloxyethyl chloride was obtained by the elimination distillation of bis-(2-chloroethyl)ether with sodium hydroxide. The raw product was dried over potassium carbonate and then fractionally distilled. A distillate which boiled at 109—110°C was collected.[27]

Potassium cyanate was prepared by a method of fusing analytical-grade anhydrous potassium carbonate and pure urea,[28] while the hard blocks of potassium cyanate were pulverized by a closed-type ball-mill in order to get them through a 40 mesh sieve. The fine potassium cyanate was then dried over phosphorus pentoxide in vacuo. The purity was determined by the use of a silver nitrate solution. There was a min. of 98% of potassium cyanate. If the blocks of potassium cyanate formed by the fusion method had dull surfaces, the potassium cyanate content was 70% (max.), indicating the presence of unreacted potassium carbonate.

Commercial dimethylformamide (DMF) or dimethyl sulfoxide (DMSO) was mixed with about 10% benzene and distilled to remove water as by the benzene-water azeotrope process. After most of the water had been removed, the aprotic solvent was dried over porous barium oxide overnight and then fractionally distilled under reduced pressure.[29-31] The pure DMF had a boiling point of 72—73°C/41 mmHg, while the pure DMSO boiled at 73—74°C/10 mmHg.

**2) Trimethyl Isocyanurate.**—In a 1 l. four-necked flask fitted with a reflux condenser, a thermometer, a stirrer and a dropping funnel, 105 g. (1.3 mol.) of potassium cyanate and 300 g. (4.0 mol.) of DMF were placed. The mixture was then heated to 130—134°C in an oil bath, and 142 g. (1 mol.) of methyl iodide was added from the dropping funnel over a period of about 1 hr. with stirring. The temperature was kept at 100—110°C for about 2 hr. From the reaction mixture, a precipitate of potassium iodide was then filtered off and washed with 50 ml. of acetone. After the solvents had been removed from the combined filtrate, the residue was recrystallized from aqueous ethanol to give trimethyl isocyanurate, m. p. 176—177°C.[32] (Yield, 51 g. (90%)).

**3) Triethyl Isocyanurate.**—A mixture of 47 g. (0.3 mol.) of ethyl iodide, 110 g. (1.3 mol.) of DMSO and 30 g. (0.37 mol.) of potassium cyanate was kept, with stirring, at 70—80°C for about 3 hr. (until no refluxing of ethyl iodide was observed in the condenser). The temperature was then raised to 135°C and maintained at that point for about 1 hr. After the reaction mixture had then been cooled, 50 ml. of ethanol was added for filtration. The filtrate yielded, on the evaporation of the solvents under reduced pressure and recrystallization from aqueous ethanol, triethyl isocyanurate, m. p. 94—95°C (Ref. 32 : 95°C).

**4) Tri-*n*-propyl Isocyanurate.**—*n*-Propyl bromide (124 g.) (1 mol.) was dropped into a mixture of 105 g. (1.3 mol.) of potassium cyanate and 250 ml. (3.6 mol.) of DMSO at 110°C with stirring. After all of the bromide had been added over a 1.5-hr. period, the reaction mixture was gradually heated to 130°C and the stirring was continued for an additional 2 hr. The reaction mixture was then poured into cold water, and the product was extracted with ether. The extract was washed, dried over anhydrous magnesium sulfate, and distilled.

**5) Tributyl Isocyanurates.**—To a mixture of 105 g. of potassium cyanate (1.3 mol.) and 200 g. (2.7 mol.) of DMF, 137 g. (1 mol.) of butyl bromide was added drop-by-drop at 135—140°C. The reaction time depended on the reactivity of the bromide, generally it took 1—3 hr. after addition of the bromide. The reaction mixture was then cooled, and a white precipitate of potassium bromide was filtered off and washed with small portions of ethyl methyl ketone. From the combined filtrated, tributyl isocyanurate was yielded by the evaporation of the solvents and by the fractional distillation of the residue.

**6) Tri-*s*-heptyl Isocyanurate.**—A mixture of 108 g. (1.35 mol.) of potassium cyanate, 179 g. (1 mol.) of 3-bromo-heptane and 250 g. (3.4 mol.) of DMF was heated to 140—145°C while being stirred in

26) The boiling points and melting points are uncorrected.

an oil bath. As the reaction proceeded, the reaction temperature was seen to become lower as a result of the formation of heptenes as by-products. When most of the bromide had been added, the reaction temperature was lowered to about 100°C, the reaction was then continued for 3 hr. more. The reaction mixture was then cooled, poured into ice-cold water, and filtered after which the filtrate was extracted with ether. The ethereal solution was separated and dried over calcium chloride. After the ether had been removed, heptenes (13.5 g.) (20%), 3-bromo-heptane (3.5 g.) (2%) and crude tri-*s*-heptyl isocyanurate (73 g.) (57%) were obtained. Tri-*s*-heptyl isocyanurate was redistilled to give a pure sample. The above-mentioned precipitate, which had been separated from the water extract, was recrystallized from boiling water to give mono-potassium isocyanurate (about 1 g.).

**7) Tribenzyl Isocyanurate.**—To a suspension of 105 g. (1.3 mol.) of potassium cyanate in 250 ml. (3.2 mol.) of DMF, 126.6 g. (1 mol.) of benzyl cholride was added through a dropping funnel, the reaction mixture was then stirred at 140—145°C for 3 hr. The reaction mixture was then cooled and poured into cold water. The flocculated product was collected by filtration, crushed into small particles, and recrystallized from ethanol to give colorless needles. (The m.p. in Ref. 33 is 157°C, while that in Ref. 32 is 165°C.)

**8) Tri-higher Alkyl Isocyanurate.**—Two moles of potassium cyanate and 1 mol. of higher alkyl bromide were reacted in 300 g. (4 mol.) of DMF in a manner which has been described in Experiments 5). The temperature of the reaction mixture should be kept at 140—150°C for at least 3 hr. The mixture was then poured into cold water and extracted with benzene. After the extract had been dried with anhydrous magnesium sulfate and the solvents had been removed, the residue was distilled to yield pure tri-higher alkyl isocyanurate.

**9) Tris-(2-alkoxyethyl) Isocyanurates.**—A mixture of 200 g. (2.7 mol.) of DMF, 88 g. (1.1 mol.) of potassium cyanate and 153 g. (1 mol.) of 2-ethoxyethyl bromide was heated to 135—140°C while being stirred for 2 hr. After it had then been cooled, the reaction mixture was poured into cold water and extracted with benzene. The extract was washed with water, dried with anhydrous potassium carbonate, and distilled. Other tris-(2-alkoxyethyl) isocyanurates were prepared by a similar method from corresponding bromides.

**10) Tris-(2-vinyloxyethyl) Isocyanurate.**—Into a suspension of 249 g. (3 mol.) of potassium cyanate in 500 ml. (6.5 mol.) of DMF, 213 g. (2 mol.) of 2-vinyloxyethyl chloride (freshly distilled) was gradually stirred through a dropping funnel for about 2 hr. After half of the solvent had been removed under reduced nitrogen pressure, the reaction mixture was poured into brine and extracted with benzene. Under a nitrogen current, the solvent was carefully removed; the residue was then distilled to collect a 130—180°C/4 mmHg fraction. The distillate was recrystallized from ethanol to give pure tris-(2-vinyloxyethyl) isocyanurate as colorless needles. (Precaution should be taken against polymerization during the distillation.)

One gram of the tris-(2-vinyloxyethyl) isocyanurate was dissolved in 250 ml. of pure *n*-heptane by slightly warming it, yielding a clear solution. To this solution 0.1 g. of boron trifluoride etherate was added, and the mixture was stirred for about an hour. The resulting white precipitate was then filtered, washed with ether, and dried under reduced pressure to give poly-tris-(2-vinyloxyethyl) isocyanurate. The polymer did not show a weight loss on 1 hr.'s exposure to 200°C in a nitrogen stream and did not dissolve in ethanol, acetone or DMF.

**11) The Influence of Water in the Reaction System.**—In a 300-ml. flask, 41 g. (0.3 mol.) of *n*-butyl bromide, 40.5 g. (0.5 mol.) of potassium cyanate and 110 g. (1.5 mol.) of DMF were mixed; then a calculated quantity of water was added. After the temperature of the mixture had been raised to 130°C, the reaction mixture was stirred at 128—130°C for 3 hr. The solvent was then removed after the filtration of the potassium bromide. The residue was mixed with a 1/2 vol. of petroleum ether and cooled to −3°C. 1,3-Di-*n*-butyl urea was then separated as white crystals. Tri-*n*-butyl isocyanurate was obtained after the evaporation of the petroleum ether and weighed. The results are shown in Table II. The crude 1,3-*n*-butyl urea was recrystallized from a ligroin-methyl ethyl ketone mixture to form a pure sample melting at 74°C; this was identified by means of comparison with an authentic specimen.

## Summary

Reactions of alkyl halides with potassium cyanate have been carried out in several aprotic solvents. Dimethylformamide and dimethyl sulfoxide have been proved to play a superior role as aprotic solvents in the displacement reaction and also in the subsequent trimerization of the isocyanates. Several trialkyl isocyanurates have been obtained in yields better than those of the other known methods.

From 2-alkoxyethyl halides and 2-vinyloxyethyl chloride respectively, tris-(2-alkoxyethyl) isocyanurates and tris-(2-vinyloxyethyl) isocyanurate have been synthesized.

The presence of water in the reaction mixture results in the formation of 1,3-dialkyl ureas, consequently decreasing the yield of isocyanurates.

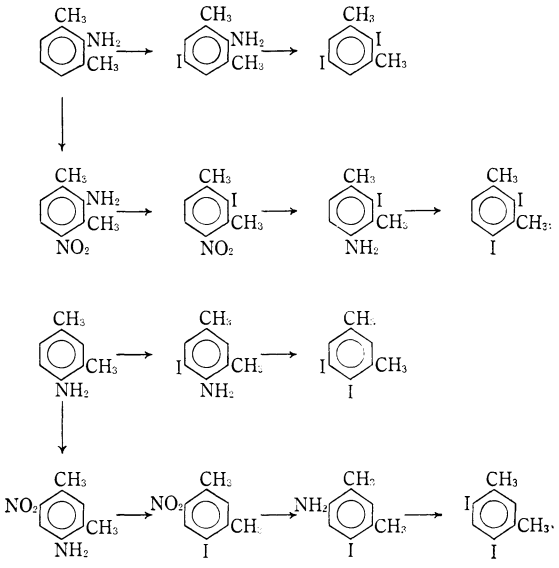
# The Synthesis of Four Isomeric Diiodo-*m*-xylenes. Their Isomerization in Sulfuric and Polyphosphoric Acids[1)]

By Hitomi SUZUKI, Kazuhiro MARUYAMA and Ryozo GOTO



(Received December 21, 1964)

Since the general pattern of the Jacobsen reaction of aromatic iodo compounds is the progressive iodination of the starting materials, vicinally-substituted 2, 4-diiodo-*m*-xylene may be expected to be a main product in the reaction of 2-iodo-*m*-xylene. As has been shown in a previous paper,[1)] however, the latter compound readily undergoes disproportionation to give 4, 6-diiodo-*m*-xylene and *m*-xylene-4-sulfonic acid. The mechanism proposed for this unexpected result involves the migration of the iodine atom of 2-iodo-*m*-xylene from the hindered position (=2) to a less hindered one (=4), facilitated by the increased steric stress caused by the entry of a bulky sulfo group in the position meta to the iodine atom. The 4-iodo-*m*-xylene thus formed, undergoing the normal Jacobsen reaction, affords 4, 6-diiodo-*m*-xylene as a final product. This is shown by the following scheme:

(1)

The present work aims to provide definite evidence for the interpretation that the sulfo group in the position meta to the iodine atom plays an important role in such an easy intramolecular migration of an iodine atom. In the pursuit of this problem, it was necessary to ascertain whether any other isomers might be formed during the reaction, and if so, how they would behave under those conditions. Because of the difficulties encountered in the separation of each isomer, we inspected the product spectroscopically and gas chromatographically. Therefore, four isomeric diiodo-*m*-xylenes were prepared as authentic specimens. As little was known about diiodo-*m*-xylenes, we synthesized them from *m*-xylidines by the procedure shown below:

The direct iodination of 2-*m*-xylidine in a weakly alkaline medium proceeded smoothly and afforded a fairly high yield of the product, whereas that of 4-*m*-xylidine afforded a poorer yield under the same conditions, with much tarry matter formed. The diazotizations of the iodo-xylidines were carried out in concentrated sulfuric acid, while in an aqueous acid solution the diazotization was incomplete and the yields were often very poor. The replacement of the diazo group by an iodine atom was always accompanied by a remarkable formation of black resinous substances, which lowered the yields of the products considerably. The infrared spectra of four isomers are shown in Fig. 1. Absorption bands due to the aromatic C–I bond (990—1050 $cm^{-1}$) show remarkable changes according to the differences in relative positions of the iodine atoms in

1) The Reaction of Polysubstituted Aromatics, Part VII. Part VI: This Bulletin, 38, 1474 (1965).

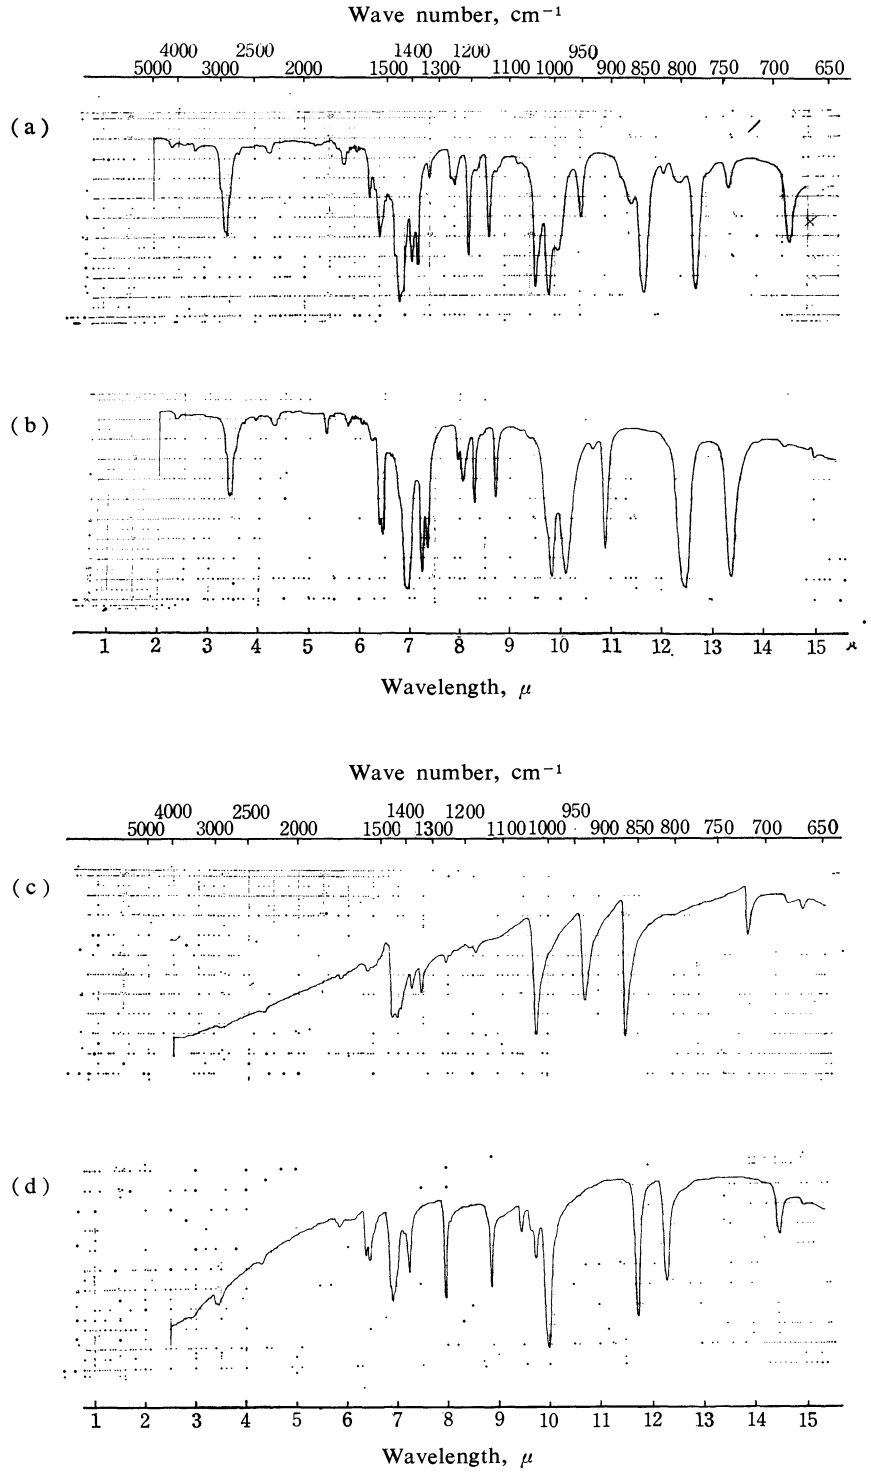


Fig. 1. Infrared spectra of diiodo-*m*-xylenes.

(b) 2,4-Diiodo-*m*-xylene (liquid film)
(c) 4,6-Diiodo-*m*-xylene (KBr disk)
(d) 2,5-Diiodo-*m*-xylene (KBr disk)

the nucleus. The appearance of the doubling of the band in the 990—1040 $cm^{-1}$ region may be correlated with the presence of the iodine atoms at hindered positions. Both 4, 5- and 2, 4-diiodo-*m*-xylenes show a strong doubling in this region, whereas the 2, 5-diiodo isomer shows an incomplete doubling and the 4, 6-diiodo isomer no doubling. Similar doublings are also observed in the infrared spectrogram of some other aromatic polyiodo compounds carrying hindered iodine atoms. However, these findings are not conclusive.

**The Isomerization of Diiodo-*m*-xylenes in Concentrated Acids.**—Two of the four diiodo-*m*-xylenes, 2, 4- and 4, 5-diiodo-*m*-xylenes underwent the isomerization easily in concentrated sulfuric acid and fairly readily in polyphosphoric acid (PPA) at a high temperature, but not at all in concentrated hydrochloric acid or perchloric acid. All four isomers underwent disproportionation with hot sulfuric acid to give mixtures of tri- and tetraiodo-*m*-xylenes.

*In Sulfuric Acid.*—The instability of diiodo-*m*-xylenes in sulfuric acid was found to be in the increasing order of 4, 5->2, 4->2, 5->4, 6-. The iodine atom located in the position of highest crowding migrated to the position which was less hindered and of the next highest electron density. Figure 2a shows the isomerization of 2, 4-diiodo-*m*-xylene to 4, 6-diiodo-*m*-xylene; after 5 hr. there still remained strong absorption bands due to the vicinal compound (803 $cm^{-1}$), while those due to the symmetrical compound (865 $cm^{-1}$) were comparatively weak. This indicates that 2, 4-diiodo-*m*-xylene cannot be a possible major intermediate of reaction 1, because 2-iodo-*m*-xylene is rapidly converted to 4, 6-diiodo-*m*-xylene under the same conditions. The increase in temperature (up to 50—60°C), however, brought about an immediate disproportionation to give mixtures of tri- and tetraiodo-*m*-xylenes, with little liberation of elementary iodine. 2, 5-Diiodo-*m*-xylene was more stable towards sulfuric acid than was 2-iodo-*m*-xylene and underwent disproportionation only at an elevated temperature. 1, 3-Dimethyl-5-*t*-butyl-2-iodobenzene was also comparatively stable in reaction to cold sulfuric acid, whereas iodomesitylene readily underwent disproportionation. These facts clearly indicate the importance of the buttressing effect of the sulfo groups taking the meta position to the iodine atom; that, is, the bulky substituent group (the iodine atom or the *t*-butyl group) at position 5 inhibits the entry of a sulfo group

* PPA=polyphosphoric acid

into the unoccupied position so greatly that the iodine atom at the 2-position, in spite of the similar structural conditions, resists both intra- and intermolecular migration. We could not detect any diiodo-*m*-xylenes other than 4,6-isomer in the final reaction products from 2- and 4-iodo-*m*-xylenes.

*In Polyphosphoric Acid (PPA).* — The isomerization of aromatic iodo compounds in PPA seems never to have been described. Diiodo-*m*-xylenes were stable in cold PPA, but they gradually decomposed in resinous substances and in elementary iodine in acid at high temperature; in PPA only 2,4- and 4,5-diiodo-*m*-xylenes, which have an iodine atom at the highly-hindered position, underwent a slow isomerization to 4,6- and 2,5-diiodo-*m*-xylenes respectively (Figs. 2a and 2b).

Under the same conditions, 4,5-diiodo-*m*-xylene isomerized much more readily than the 2,4-isomer. The migration caused by PPA differs from those caused by sulfuric acid in the following two points: first, the migration of the iodine atom needs much more severe conditions and a longer reaction time, and second, the reaction is limited to the isomerization — no disproportionation is observed. The possibility of a thermal isomerization was excluded, because no change was observed in the absence of the acid at those temperatures. These facts may be taken to indicate that the migration of an iodine atom proceeds through a benzenonium intermediate, as is shown in Eq. 1, where the iodine atom expelled by a proton migrates, seeking the position of the next highest electron density, intramolecularly (isomerization). The substantial steric stress developed in the benzenonium intermediate is relieved during the migration of the iodine atom from the 2- to the 4-position, thus contributing to the ease of migration.

From these and related previous studies,[2] it may be concluded that this new type of rearrangement observed in the Jacobsen reaction of some 2,6-disubstituted iodobenzenes, especially 2-iodo-*m*-xylene, is essentially caused by the entry of a bulky and powerfully electron-attracting sulfo group in the position meta to the iodine atom blocked on both sides by substituent groups. This conclusion follows from these observations: (1) 2,4-diiodo-*m*-xylene did not isomerize so readily as 2-iodo-*m*-xylene under the same conditions; (2) 2,5-diiodo-*m*-xylene and 5-*t*-butyl-1,3-dimethyl-2-iodobenzene were rather more stable in relation to sulfuric acid than was 2-iodo-*m*-xylene; (3) isomerization occurred more readily in sulfuric acid than in PPA, and diluted sulfuric acid could not bring about any isomerization; (4) some color changes were observed during the reaction, and the color disappeared upon the addition of water; (5) the iodinium cation, when completely detached from the nucleus, could not attack *m*-xylene-4-sulfonic acid to any great extent, and (6) in the presence of an excess of mesitylene, the iodine atom of 2-iodo-*m*-xylene was readily transferred to the hydrocarbon, resulting in the formation of iodomesitylene and *m*-xylene-4-sulfonic acid. The reaction mechanism described at the beginning of this paper is consistent with these experimental observations.

## Experimental

**General Procedure for Isomerization.**—The reactions were carried out with magnetic stirring in small stoppered vessels which were heated externally. The mixtures were diluted with water;

2) H. Suzuki and R. Goto, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **84**, 284 (1963); H. Suzuki, This Bulletin, **36**, 1642 (1963).

the precipitated substances were separated and then chromatographed on an alumina column to remove higher iodinated products. The solid or oily substances which remained after the evaporation of the solvent were inspected by means of infrared spectroscopy and gas chromatography as has been described in the preceding paper.[1]

**Synthesis of Four Isomeric Diiodo-*m*-xylenes.**—All the procedures employed in these preparations were well-known to exclude the possibility of the migration of the iodine atom under ordinary conditions, so the definite location of the substituent groups attached to the ring could readily be ascertained by the annexed scheme. The structure proof of each isomer was also achieved by means of infrared spectroscopy (Fig. 1).

**2-Amino-4-nitro-*m*-xylene (I).**—A solution of 22 g. of 2-*m*-xyledine in 220 g. of concentrated sulfuric acid was cooled to 5°C; then 18 g. of concentrated nitric acid ($d$=1.38) was slowly but vigorously stirred in. During this operation, the temperature of the reaction mixture was held below 15°C. After 30 minutes' agitation, the mixture was poured onto crushed ice; the resulting aqueous solution was neutralized with a sodium hydroxide solution with cooling. The precipitated amine was collected by filtration and recrystallized from a petroleum ether - tetrahydrofuran mixture. The yield was 26 g. (86%); the product, golden yellow needles, melted at 81—82°C (reported,[3] 81—82°C).

**2-Iodo-4-nitro-*m*-xylene (II).**—To a solution of 21 g. of I in 300 ml. of sulfuric acid was added, with stirring and cooling to hold the temperature below 5°C, 10 g. of finely powdered sodium nitrite. The mixture was stirred for an additional 30 min. and then poured onto crushed ice. The resulting solution of the diazonium salt was filtered, and the filtrate was added slowly to a solution of 33 g. of potassium iodide in a little water. After the mixture had stood overnight, the precipitated tan solid was collected by filtration and chromatographed through a short alumina column with benzene. The evaporation of the benzene afforded 28 g. of pale yellow crystals of a pure iodo compound; m. p. 51—52°C. Yield, 80%.

Found: C, 34.60; H, 2.66; N, 4.93. Calcd. for $C_8H_9INO_2$: C, 34.68; H, 2.90; N, 5.06%.

**2-Iodo-4-amino-*m*-xylene (III).**—One hundred grams of stannous chloride dihydrate was dissolved in 200 ml. of hydrochloric acid diluted with 200 ml. of ethanol. To this solution was slowly but vigorously stirred in 25 g. of finely powdered II. The reaction preceeded with a moderate evolution of heat, the white crystalline solid which was gradually precipitated was collected by filtration. This material was then suspended in water, and an excess of a sodium hydroxide solution was added until the precipitated stannic hydroxide redissolved. The resulting solution was steam-distilled until the distillate became clear. The product was then separated from the distillate by ether extraction. The evaporation of the ether gave 17.0 g. of a pale yellow oil, which solidified to white needles in an ice box and which melted at 17—18°C. Yield, 76%.

Acetanilide; white needles from aqueous ethanol, m. p. 171—172°C.

Found: C, 41.82; H, 4.38; N, 4.58. Calcd. for $C_{10}H_{12}NIO$: C, 41.55; H, 4.19; N, 4.84%.

**2,4-Diiodo-*m*-xylene (IV).**—A solution of 17 g. of 2-iodo-4-amino-*m*-xylene in 150 ml. of concentrated sulfuric acid was cooled to 5°C and diazotized by the addition of 8.5 g. of sodium nitrite at 5—10°C. After 30 minutes' agitation, the mixture was poured onto crushed ice and the resulting solution was filtered. The filtrate was added slowly to a solution of potassium iodide dissolved in a small amount of water. The mixture was then allowed to stand overnight, and the black oil which precipitated was separated by decantation and chromatographed through an alumina column with petroleum ether. The evaporation of the solvent, followed by distillation, gave 11.5 g. of a colorless oil, boiling at 176—177°C/18 mmHg, which solidified in an ice box and which melted at 6—7°C. The yield was 47%.

Found: C, 26.93; H, 2.23. Calcd. for $C_8H_8I_2$: C, 26.84; H, 2.25%.

The infrared spectrum showed a band at 803 $cm^{-1}$ for two adjacent hydrogen atoms. The pattern in the 1650—2000 $cm^{-1}$ region also confirms the vicinal structure. Aromatic carbon-iodine bands were observed at 990 and 1017 $cm^{-1}$.

**2-Amino-5-iodo-*m*-xylene (V).**—To a suspension of 17 g. of sodium hydrogen carbonate in 150 ml. of water, 10 g. of 2-*m*-xylidine and 80 ml. of ether were added; the mixture was then stirred rapidly while 20 g. of iodine was added at such a rate that the color of the free iodine disappeared within a few minutes. Stirring was then continued for an additional hour, after which the reaction mixture was steam-distilled until 4 l. of the distillate had been collected. The amine separated as white needles in the distillate, which was filtered and recrystallized from boiling petroleum ether. The resulting large needles weighed 11.0 g. and melted at 52—53°C. Yield, 49%.

Found: C, 39.20; H, 4.14; N, 5.70. Calcd. for $C_8H_9IN$: C, 38.88; H, 4.08; N, 5.67%.

**2, 5-Diiodo-*m*-xylene (VI).**—Ten grams of V was diazotized in 80 ml. of sulfuric acid with 5.0 g. of sodium nitrite in the same manner as has been described above. The mixture was then poured onto crushed ice, and the resulting solution was, after filtration, added to a concentrated solution of 16.0 g. of potassium iodide in water. The mixture was allowed to stand overnight, and the brown solid which precipitated was removed by filtration and chromatographed through a short alumina column, using light-boiling ligroin as an eluant. The evaporation of the solvent gave 3.6 g. of the product, white needles with a m. p. of 64—65°C. The yield was low (25%) because of the formation of a large amount of resinous matter.

Found: C, 27.05; H, 2.30. Calcd. for $C_8H_8I_2$: C, 26.84; H, 2.25%.

The infrared spectrum showed a band at 850 $cm^{-1}$ which may be attributed to one isolated ring-hydrogen. The absence of ring CH absorption in the

3) E. Noelting, A. Braun and G. Thesmar, *Ber.*, **34**, 2242 (1901).

910—950 $cm^{-1}$ region was associated with the presence of a center of symmetry ($A_2$ vibration). The pattern in the 1650—2000 $cm^{-1}$ region also supports the 1,2,3,5-tetra substitution. Aromatic carbon-iodine band was observed at 1000 and 1023 $cm^{-1}$.

**4-Amino-5-iodo-*m*-xylene (VII).** — 4-*m*-Xylidine was directly iodinated with free iodine by the same method as has been used above. In this case, however, the reaction proceeded with some difficulty and resinous matter was formed in an appreciable amount. The product separated out as white needles from the steam-distillate. Recrystallization from boiling petroleum ether gave white needles, m. p. 65°C. Reported,[4] 65°C. The yield was 16% on the basis of the *m*-xylidine used.

**4,5-Diiodo-*m*-xylene (VIII).** — The diazonium salt solution prepared from VII was slowly added to a solution of potassium iodide in water. The mixture was then allowed to stand overnight, and the black oil which precipitated was chromatographed as usual. The evaporation of the solvent, followed by the distillation of the residual oil, afforded a pale pink-colored oil, boiling at 176—177°C/18 mmHg, which did not solidify upon standing in an ice box. The yield was very poor.

Found: C, 27.00; H, 2.31. Calcd. for $C_8H_8I_2$: C, 26.84; H, 2.25%.

The infrared spectrum showed a peak at 849 $cm^{-1}$ which may be attributed to one isolated ring-hydrogen. A band at 950 $cm^{-1}$ was attributed to the B vibration of the ring CH bond which distinguished 4,5-diiodo-*m*-xylene from the 2,5-diiodo isomer. Aromatic carbon-iodine bands were observed at 1012 and 1040 $cm^{-1}$.

**4-Amino-6-nitro-*m*-xylene (IX).** — 4-*m*-Xylidine was dissolved in concentrated sulfuric acid and nitrated as in the preparation of I. The crude amine obtained was then triturated and extracted several times with small amounts of cold tetrahydrofuran in order to remove the accompanying isomer, 2-nitro-4-amino-*m*-xylene. Then the product was recrystallized from an aqueous ethanol solution. The yield was 50%, and the product, orange yellow needles, melted at 122—124°C. Reported,[5] 124°C.

**4-Iodo-6-nitro-*m*-xylene (X).**—The amine IX was converted into this compound by the same method as that used in the preparation of II. The product was purified through an alumina column using light-boiling ligroin as an eluant. Recrystallization from boiling petroleum ether afforded large pale yellow crystals which melted at 87—88°C. The yield was 60%.

Found: C, 34.96; H, 2.27; N, 4.87. Calcd. for $C_8H_9INO_2$: C, 34.68; H, 2.90; N, 5.05%.

**4-Iodo-6-amino-*m*-xylene (XI).**—Fifty grams of stannous chloride dihydrate was dissolved in a mixture of 200 ml. of concentrated hydrochloric acid and 200 ml. of ethanol; to the resultant solution 12.5 g. of X was added and it was gradually heated to a gentle refluxing. After the complete dissolution of the crystal, refluxing was continued for an additional 2 hr., and then the mixture was cooled. An excess of sodium hydroxide was added to redissolve the precipitated tin hydroxide, after which the mixture was steam-distilled. The amine was readily steam-distilled and solidified in a condenser as white crystals, which were collected and recrystallized from boiling petroleum ether. The product was obtained as a cluster of white leaflets which weighed 9.4 g. (84%); m. p. 68—69°C.

Found: C, 39.03; H, 4.27; N, 5.45. Calcd. for $C_8H_9NI$: C, 38.88; H, 4.08; N, 5.67%.

**4,6-Diiodo-*m*-xylene (XII).**—The amine XI was diazotized and converted into this compound by the same procedure as that used in the preparation of IV. The crude product was purified through an alumina column using petroleum ether, from which 4,6-diiodo-*m*-xylene separated as large plates, m. p. 72—74°C. Reported,[6] 72°C. The yield was 72%.

Found: C, 27.17; H, 2.53. Calcd. for $C_8H_8I_2$: C, 26.84; H, 2.25%.

Peaks (865 and 931 $cm^{-1}$) and a pattern (1650—2000 $cm^{-1}$) indicating the appropriate aromatic substitution were present in the infrared spectrum. Aromatic carbon-iodine band was observed at 1023 $cm^{-1}$.

## Summary

Four isomeric diiodo-*m*-xylenes have been synthesized and their isomerization in concentrated acids investigated in order to elucidate the mechanism of the new rearrangement observed in the Jacobsen reaction of 2-iodo-*m*-xylene. 2,4- and 4,5-Diiodo-*m*-xylene, in the presence of cold sulfuric or hot polyphosphoric acid, isomerize to 4,6- and 2,5-diiodo-*m*-xylene respectively. All four isomers readily undergo disproportionation with hot sulfuric acid to give mixures of tri- and tetraiodo-*m*-xylenes. No disproportionation has been observed in the reaction with polyphosphoric acid. The important role played by a sulfo group in this reaction has been discussed.

# The Chemical Behavior of Low Valence Sulfur Compounds. I. Oxidation of Elemental Sulfur with Compressed Oxygen in Aqueous Ammonia Solution

By Mu-Chang SHIEH, Hiroshi OTSUBO and Taijiro OKABE

(Received December 28, 1964)

Recently, the chemistry of sulfane (hydrogen sulfide), sulfane monosulfonic acid (the family of the derivatives of thiosulfuric acid formulated as $H_2S_{x+1}O_3$ or $H_2S_x \cdot SO_3$) and sulfane disulfonic acid (polythionic acids formulated as $H_2S_{x+2}O_6$ or $H_2S_x \cdot 2SO_3$) has been splendidly systematized, as a series of sulfane derivatives, by the excellent work of Feh'er[1] and Schmidt[2]. Nevertheless, the details of the mechanisms by which these compounds react are still obscure, because of the lack of reliable methods of chemical analysis and because of the complexity of the reactions. Knowledge of these mechanisms has, in fact, so far been based mainly on speculation.

In the well-known work of Forward[3] on the hydrometallurgy of nonferrous metals, which involves the leaching of complex sulfide ores containing nickel, cobalt and copper with ammonia solution and compressed air, it has yet been reported that the metal sulfides can be easily converted into sulfate through thiosulfate trithionate and sulfamate as intermediates, but no concrete evidence for their mechanism has been provided. The formation of sulfate by the oxidation of thiosulfate has been observed by Glund[4] in the high pressure oxidation of sodium thiosulfate, but the reaction mechanism has not yet been reported.

The intention of this paper is to clarify the reaction mechanism of the oxidation of sulfide to sulfate, when elemental sulfur suspended in aqueous ammonia is used as the starting material. This study will show that, under optimum conditions, 50% or more of the sulfur can be converted into ammonium sulfamate, a compound which is expected to become an important raw material for various products, as weed killers, fire-proofing agents, and sweetening agents. This oxidation can, therefore, profitably be applied to the manufacture of sulfamate-form sulfur-bearing materials.

## Experimental

**Apparatus.**—A Sakashita Seisakusho Model SR-50 autoclave with a 500-ml. capacity and made of SUS 32 stainless steel, which is the same as alloy AISI 316 or V4A, was used for the reaction. The apparatus is depicted schematically in Fig. 1.

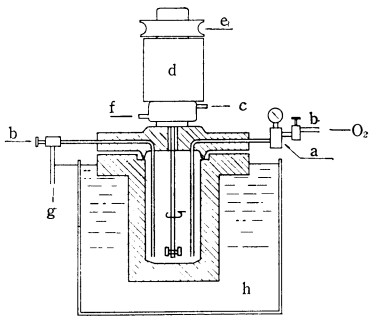

Fig. 1. Experimental apparatus.

| | | | |
|---|---|---|---|
| (a) | Oil trap | (e) | Pulley |
| (b) | Needle valve | (f) | Cooling water |
| (c) | Ammonia gage | (g) | Sampling pipe |
| (d) | Magnetic stirrer | (h) | Glycerine bath |

**Procedure.**—After the addition of the sulfur and aqueous ammonia, the autoclave was kept in a heated glycerine bath regulated within 1°C. After one hour the disproportionation reaction had been completed; oxygen was then introduced through a control valve and carefully kept at a constant pressure. Every few hours, 10 ml. aliquots of the solution were withdrawn for analysis.

**Analysis.**—The sample solution did not contain any sulfite or dithionate. Although the presence of polythionates, such as 3-, 4-, and 5-thionate, was proved by the the paper chromatography proposed by Pollard,[5] their concentrations were too low to permit their determination by chemical analysis. Therefore, after it had been diluted to a suitable concentration, the sample solution was analyzed for sulfides, thiosulfate, sulfate, and sulfamate as follows:

$S_x^{2-}$: a 1N cadmium acetate solution was added to the diluted solution; the cadmium sulfide precipitated, after being separated by filtration, was oxidized to sulfate with nitric acid and potassium chlorate and weighed as barium sulfate.

5) F. H. Pollard, *Brti. Med. Bull.*, **10**, 187 (1954).

$S_2O_3^{2-}$ : One portion of the sample solution was directly titrated with a 0.02 N iodine solution.

$SO_3NH_2^-$ : After the addition of a 1 N silver nitrate solution, the sample solution was heated on a water bath in order to convert $S_2O_3^{2-}$ into $SO_4^{2-}$ by the following reaction:

$$S_2O_3^{2-} + 2Ag^+ + 2OH^- = Ag_2S + SO_4^{2-} + H_2O$$

The silver sulfide was then removed by filtration, and the sulfate ions and excess silver nitrate in the filtrate were precipitated, as barium sulfate and silver chloride respectively, by the addition of a barium chloride solution. Then the filtered solution was acidified with dilute hydrochloric acid and heated to boiling, after a sufficient amount of sodium nitrite had been added to decompose the $SO_3NH_2^-$ as follows:

$$SO_3NH_2^- + NO_2^- = SO_4^{2-} + N_2 + H_2O$$

The sulfate ion formed was determined by the ordinary method as barium sulfate, and the amount of sulfamate was estimated.

## Results

**General View of the Entire Reaction.**—When elemental sulfur is heated in aqueous ammonia at about 100°C, the solution gradually becomes reddish brown and is found to contain polysulfide and thiosulfate, as is shown in Table I and II. Although these results are not completely accurate, as the result of a poor sampling, the molar ratio, $S_x^{2-}/S_2O_3^{2-}$, seems to indicate that the value of $x$ has a tendency to decrease from about 8 to 5 during the course of the reaction. This fact can be explained by assuming the successive formation of $S_8^{2-}$ and $S_5^{2-}$. When oxygen is introduced into a solution in which the sulfur has been entirely disproportionated, the red color of the solution rapidly fades away and the temperature of the solution rises; at the same time a large amount of thiosulfate is formed. The oxidation of polysulfide which proceeds faster than that of thiosulfate, appears to be the rate-determining step for the over-all reaction; thus thiosulfate temporarily reaches a maximum concentration and then gradually changes into sulfate and sulfamate, the final products. If oxygen is introduced at the beginning of the reaction, both the disproportionation and the oxidation will occur in the early stages. These aspects are shown schematically in Fig. 2. The kinetics of these reactions could not be determined, because free ammonia is continuously consumed in the course of the reaction and, consequently, the partial pressure of oxygen increases under a constant pressure. These relations become even more complicated when the changes in temperature are taken into account.

**The Effect of the Ammonia Concentration.**—The ammonia concentration varied from 4 N to 16 N. An increase in the concentration of ammonia caused a remarkable increase in the reaction rate and improved the yield of sulfamate.

**The Effect of the Oxygen Pressure.**—The effect of the oxygen pressure was examined in the 20—100 kg./cm² range. This pressure includes the vapor pressure of the solution. As is shown in Fig. 3, the increase in the reaction rate is proportional to the oxygen pressure, but only at pressures below 50 kg./cm². On the other hand, while high oxygen pressures cause a small improvement in the yield of sulfamate, this enhancement of the yield of sulfamate is not as great as that due to a decrease in the temperature or that due to an increase in the ammonia concentration.

**The Effect of the Reaction Temperature.**—The reaction rate is increased by raising the reaction temperature, but the yield of sulfamate is thus decreased, probably because of the decomposition of trithionate into sulfate by the hydrolysis. The results are shown in Fig. 4.

**The Catalytic Effect of Metal Ions.**—The transition metals, such as cobalt, nickel, and

copper, are known to accelerate remarkably the oxidation of sulfite with oxygen. The expected catalytic effects of these metals on the above oxidation of sulfur are shown in Figs. 5 and 6. The reaction rate is significantly affected by the presence of these metals, but the effect is not as large as that in the sulfite oxidation. However, the yield of sulfamate can be remarkably increased by the addition of copper sulfide ores. Since most of the dissolved copper is precipitated as sulfide in the course of the reaction, there are very few copper ions to serve as catalysts.

**The Decomposition of Trithionate.**—Related experiments were made on trithionate; the results, shown in Fig. 7, indicate that the yield of sulfamate ions increases with the concentration of ammonium hydroxide, while that of sulfate ions shows a reverse tendency.

## Discussion

Although the reaction mechanism has not yet been fully established, the main course of the reaction is roughly disclosed by this study. The oxidation of sulfur does not occur as a series of simultaneous reactions; Rather, it proceeds through the following series of consecutive steps:

**The Disproportionation of Sulfur.**—According to Pryor's review,[6] the most widely-accepted mechanisms of the disproportionation of sulfur in an alkaline solution are as follows;

$$\frac{1}{2}S_8 + 4NaOH = Na_2S_2O_3 + 2NaHS + H_2O \qquad (100-200°C)$$

$$\frac{1}{2}S_8 + 5NH_4OH = (NH_4)_2SO_4 + 3NH_4SH + H_2O \qquad (250-350°C)$$

However, the present study, at 100°C, revealed that unstable ammonium octasulfide forms at the beginning and that this polysulfide gradually degrades to pentasulfide. This behavior can be understood easily by assuming that the eight-membered ring of the sulfur molecule is broken open to form an octasulfide by the attack of the ammonia, and that the octasulfide is then converted into the stable pentasulfide by the step-by-step elimination of three sulfur atoms. Consequently, the disproportionation can be represented as follows:

$$\frac{3}{2}S_8 + 6NH_4OH = 2(NH_4)_2S_5 + 2(NH_4)_2S_2O_3$$

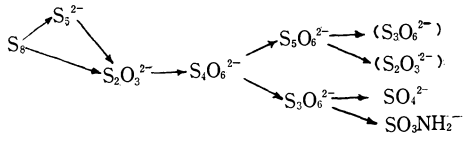
**The Oxidation of Sulfide.**—Bloxam[7] reported

6) W. A. Payor, "Mechanisms of Sulfur Reaction," McGraw-Hill Inc., New York (1962), p. 12.
7) W. P. Bloxam, *J. Chem. Soc.*, **67**, 277 (1895), see also E. Schulek and E. Koros, *Acta Chim. Acad. Sci. Hung.*, **3**, 125 (1953); *Chem. Abstr.*, **47**, 10390 (1953).

the formation of thiosulfate in the oxidation of ammonium sulfide under atmospheric pressure at room temperature, but the reaction velocity must be very small under such conditions. It has been found that, if compressed oxygen is employed, the oxidation of sulfide to thiosulfate is almost instantaneous. The rise in the temperature of the reaction mixture must be due to a strongly exothermic reaction, such as the following:

$$2(NH_4)_2S_5 + 6NH_4OH + 6O_2 = 5(NH_4)_2S_2O_3 + 3H_2O + 640\ \text{kcal.}$$ [8]

**The Oxidation of Thiosulfate.**—Most thiosulfates can hardly be oxidized at all with oxygen under ordinary pressures. The oxidation of thiosulfate by air was first studied by Gluud,[4] who employed a pressure of 10 atm. at 100°C for the sodium salt. The thiosulfate was found to afford only sulfate in alkaline solutions, but in neutral solutions it was converted into free sulfur and sulfate. Moreover, Forward[3] reported that ammonium thiosulfate is first oxidized to trithionate with compressed air at 175—300°C. From the fact that thiosulfate is usually oxidized to tetrathionate with iodine and other mild oxidants, it is most reasonable to regard tetrathionate as the product first formed from thiosulfate. The decomposition of the tetrathionate produces trithionate, pentathionate and thiosulfate; the pentathionate then further decomposes, thus forming both trithionate and thiosulfate. Therefore, it now remains to clarify the behavior of trithionate in an aqueous ammonia solution. Its yield is improved by an increase in the ammonia concentration, as Fig. 7 shows. The decomposition of trithionate must, therefore, proceed mainly as:



$$S_3O_6^{2-} + NH_3 + OH^- = SO_3NH_2^- + S_2O_3^{2-} + H_2O$$

but partly as:

$$S_3O_6^{2-} + 2OH^- = SO_4^{2-} + S_2O_3^{2-} + H_2O$$

When these reactions are considered, the reason for the increase in the yield of the sulfamate with the increase in the ammonia concentration becomes obvious.

Consequently, although further studies are required, the oxidation of sulfur in an aqueous ammonia solution may be considered to proceed via the following course:

## Summary

1) The oxidation of sulfur with compressed oxygen proceeds through the following sequence of steps: (a) The disproportionation of sulfur to both pentasulfide and thiosulfate. (b) The oxidation of pentasulfide to thiosulfate. (c) The oxidation of thiosulfate to sulfate and sulfamate through a series of complicated intermediates.

2) Sulfamate forms only in the decomposition of trithionate.

3) The over-all reaction of the oxidation is prompted by a rise in the temperature, an increase in the ammonia concentration, and the addition of transition metal ions, especially copper ions.

# An Attempt to Determine Fluorescein's S*–T Transition Probability and a Preliminary Investigation of the Behavior of Its Semiquinone in an Alkaline Solution

By Yoshihiro MOMOSE, Kengo UCHIDA and Masao KOIZUMI

(Received January 6, 1965)

Having previously reported on the determination of $\varphi_{S-T}$* for eosine,[1] we will report here on a similar attempt with fluorescein. Although a value of $2.01\times10^{-2}$ for $\phi_{S-T}$ at pH 7.0 has been reported by Oster et al.,[2] it seems desirable to repeat this experiment and to examine more critically the conditions necessary for this method to be applicable. For example, a more detailed investigation of the rate formula and of the steps in the reaction following the formation of semiquinone seems to be required. Moreover, the pH value at which their experiment was made may have been the cause of some ambiguity, because in this pH region divalent and monovalent anions exist simultaneously.[3,4] We have, therefore, chosen a pH >10.9 and used disodium ethylenediaminetetraacetate (EDTA) and allylthiourea (ATU) as the reducing agents. In addition, it must be recalled that leuco-fluorescein can be oxidized photochemically by using fluorescein as a sensitizer in the evacuated state.[5,6] If the product of the photoreduction with EDTA or ATU is really a leuco compound, a similar phenomenon may be expected; therefore, this fact must be taken into consideration in order to obtain an exact kinetic treatment. Hence, the behavior of the reaction product was investigated; the effect of the addition of the reducing agents on the sensitized oxidation of leucofluorescein was also examined to some extent.

It was established that semiquinone is formed as a rather stable intermediate product and that the behavior of the final product differs from that of the product obtained by the photoreduction in an alcoholic solution. It was further found that most of the semiquinone is gradually converted to the oxidized form in the dark and, quite astonishingly, in the ratio of 1 : 1.

A simple rate formula could not always be given, and even a rather tentative value of $\varphi_{S-T}$ was determined only under special conditions.

## Experiment

**Materials.**—*Allylthiourea.*—Tokyo Kasei G. R. 1-allyl-2-thiourea was recrystallized three times from the aqueous solution.

*Disodium Ethylenediaminetetraacetate, Dihydrate (DOTITE 2 Na).*—The special grade reagent of the Dojindo Pharm. Ltd., was used.

*Fluorescein.*—Commercial material was repeatedly recrystallized from ethanol.

*Leuco-fluorescein.*—Fluorescein was reduced with sodium amalgam and, after repeated recrystallizations from ethanol solution, desiccated in a high vacuum.[5]

*Sodium Hydroxide.*—A saturated solution was prepared from the G.R. reagent of the Wako Junyaku Co. The supernatant liquid was diluted to the desired concentration.

*Disodium Hydrogen Phosphate.*—A G. R. reagent of Wako Junyaku Co. was recrystallized three times from the aqueous solution.

**Apparatus.**—The apparatus is shown in Fig. 1.

**Procedure.**—The light source, L, was a tungsten lamp (Kondo Projection Lamp 100 V.-500 W.); this was always operated at 50.0 V. All the experiments were carried out at 25°C in a thermostat. The fluorescein solution was ordinarily made up in a $1\times10^{-5}$ M aqueous solution. The concentration of reducing agents (ATU or EDTA) was $3\times10^{-2}$—$3\times10^{-3}$ M. The sample solutions were made up in a sodium hydroxide-disodium hydrogen phosphate buffer at pH 10.95 or in a $1.0\times10^{-1}$ N, $5.0\times10^{-2}$ N, or $1.0\times10^{-3}$ N sodium hydroxide solution. The solution was usually degassed five times by using a mercury diffusion pump, melting and freezing being repeated each time. After degassing, the solution was poured into a reaction cell 1 cm. thick. The fading and coloring of the solution was followed with a photoelectric tube (Toshiba 7211). The absorption spectra of the solutions were measured with a Hitachi EPU-2A spectrophotometer or a Hitachi EPS-2 recording spectrophotometer. The absolute intensity of the light falling on the reaction cell was determined with a calibrated thermopile (Kipp & Zonen, type E 5) with a sensitivity of $1.02\times10^{-5}$ V./W. of radiant energy.

## Results and Discussion

**Preliminary Observation.**—A check was made to ensure that the addition of EDTA or ATU did not essentially affect the absorption spectra of the dye, and that no dark reaction occurred. When the sample was illuminated with visible light, the absorption spectra in the visible region always declined monotonously, without any even slight shift. When EDTA was used as a reducing agent, the absorption due to semiquinone was readily apparent near 394 m$\mu$, and at the same time, the decrease in the absorbance near 300 m$\mu$ was somewhat less. The last phenomenon[7] is considered to be due to the formation of leuco-uranine. Figure 2 shows a typical example. In the case of ATU, the absorption spectrum of the product could not be obtained in detail, because ATU absorbs up to $\lambda=310$ m$\mu$. The increase in the absorbance near 394 m$\mu$, however, could be clearly detected, although the intensity of the absorbance near 394 m$\mu$ was much less than in the case of EDTA.

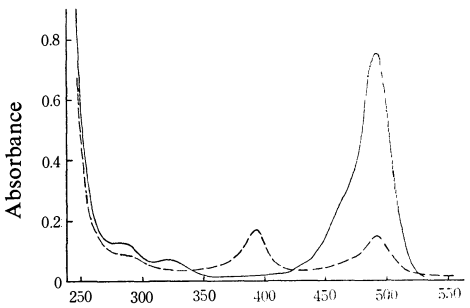

Fig. 2. Change of the absorption spectra of fluorescein by irradiation.
$[U]_0=1\times10^{-5}$ M, $[EDTA]_0=4.0\times10^{-3}$ M, $[NaOH]=0.1$ N
—— before irradiation
---- immediately after 28.3 min. irradiation

**Studies of the Reaction Products.**—*The Formation of Semiquinone and Its Kinetic Behavior.*—Since semiquinone was found to be formed as a rather stable product both when EDTA and when ATU were used, its behavior was investigated in some detail. Figure 3 shows a typical example of the change in the absorption spectra when the irradiated solution involving EDTA was kept in the dark. It shows that the gradual dercrease in the height of the peak at 394 m$\mu$ is accompanied by an increase in the main absorption of the dye. An isosbestic point is seen at 430 m$\mu$. The behavior agrees quite well with that, in ethanol-water or in isopropanol-water, observed by Imamura.[7] The molar absorbance of semiquinone at $\lambda=394$ m$\mu$ was determined in the following way.

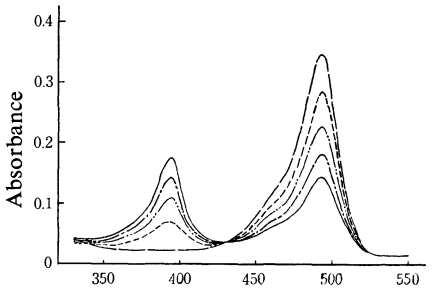

Fig. 3. Change of the absorption spectra when the solution having the spectra --- in Fig. 2, is kept in the dark.
—— after 2 min. 35 sec.
—— after 20 min. 25 sec.
—— after 45 min. 15 sec.
---- after 129 min.
—— after 1000 min.

After the absorbances at 394 and 490 m$\mu$ of the partially-bleached solution had been measured, air was introduced into the solution and changes in the absorbances were examined immediately. Since it was confirmed that only semiquinone is converted to the original dye by this procedure, $\varepsilon_{394}$ can easily be obtained by using the $\varepsilon_{490}$ value of uranine ($7.80\times10^4$ at pH 9). Table I gives some of the results.

The value, $5.0\times10^4$, obtained from the mixture of uranine and leuco-uranine is a little

* $[L]_0$ and $[U]_0$ are the initial concentrations of leuco-uranine and uranine.
** [NaOH]=$5.0\times10^{-2}$ N.

larger than that ($4.7\times10^{4}$) found for the solution containing EDTA. Since, however, the former agrees quite well with the published date ($\varepsilon_{394}=5\times10^{4}$ (Lindqvist[4]; 0.01 N NaOH), $\varepsilon_{395}=4.9\times10^{4}$* (Imamura; water-ethanol or water-isopropanol alkaline solution)), it may be accepted as reliable.

Using $\varepsilon_{394}=5.0\times10^{4}$, the quantities of semiquinone produced under various conditions were evaluated. It was found that when the alkaline solution, 0.1 N sodium hydroxide, containing $1\times10^{-5}$ M fluorescein and various amounts of EDTA was illuminated for twenty minutes, about one-half of the bleached dye was present as a semiquinone. Some of the results are shown in Table II.

TABLE II. THE CHANGE IN THE ABSORBANCE AT 490 mμ ($-D_{ox}$) AND AT 394 mμ ($+D_{sem}$) DURING THE PHOTOREDUCTION BY EDTA

| Concn. of EDTA, M | $-D_{ox}$ | $+D_{sem}$ | $R(-\frac{D_{sem}}{D_{ox}})$ | $f_{sem}$ |
|---|---|---|---|---|
| $1\times10^{-2}$ | 0.506 | 0.142 | 0.28 | |
| $1\times10^{-2}$ | 0.462 | 0.148 | 0.32 | |
| $6\times10^{-3}$ | 0.562 | 0.146 | 0.26 | |
| $6\times10^{-3}$ | 0.563 | 0.128 | (0.22) | |
| $4\times10^{-3}$ | 0.544 | 0.180 | 0.33 | |
| $4\times10^{-3}$ | 0.546 | 0.144 | 0.32 | |
| $3\times10^{-3}$ | 0.544 | 0.151 | 0.27 | |
| $3\times10^{-3}$ | 0.433 | 0.145 | 0.33 | |
| | | Av. | 0.29±0.03 | 0.45±0.05 |

* Imamura's value was recalculated since the method of evaluation was found to involve some misunderstanding.

The ratio of the quantity of the produced semiquinone to that of the consumed dye, $f_{sem}$, is 0.45±0.05.

In the case of ATU, the quantity of produced semiquinone is much smaller and appears to change according to the experimental conditions. Table III gives the values of $f_{sem}$ obtained, when 0.1 N aqueous sodium hydroxide solutions of fluorescein, $1\times10^{-5}$ M, containing various amounts of ATU were irradiated for twenty minutes.

TABLE III. $f_{sem}$ FOR ATU

| Concn. of ATU, M | $-D_{ox}$ | $f_{sem}$ |
|---|---|---|
| $3.0\times10^{-2}$ | 0.534 | 0.04 |
| $1.6\times10^{-2}$ | 0.532 | 0.03 |
| $1.0\times10^{-2}$ | 0.532 | 0.07 |
| $6.0\times10^{-3}$ | 0.530 | 0.06 |
| $(4.0\times10^{-3}$ | 0.631 | 0.02) |

Thus, $f_{sem}$ value for ATU is only few hundredths for EDTA. Furthermore, in the mixed solvent of ethanol and water containing $3\times10^{-2}$—$4\times10^{-3}$ M ATU and $5\times10^{-2}$ N sodium hydroxide, $f_{sem}$ reaches 0.34 (the average of four determinations). From these results, one may characterize the reaction as follows. The reducing agent, $RH_2$, attacks the triplet dye, $D^t$, and forms a transient intermediate consisting of semiquinone and a half-oxidized reducing agent. If the intermediate simply dissociates into its two components, then the semiquinone would remain as a stable product,

while if the cleavage involves a hydrogen transfer, then leuco-uranine or a leuco-type compound would be produced. Schematically, this may be written as follows:

$$D^t + RH_2 \rightarrow DH\cdots RH$$

$$DH\cdots RH \rightarrow DH + RH \quad (a)$$

$$DH\cdots RH \rightarrow DH_2 + R \quad (b)$$

Thus, the behavior of the D-R redox-intermediate is quite different in EDTA and ATU; the reaction in the former case proceeds along both paths, a and b, with equal probabilities, while in the latter case the principal path is b.

When a solution which had been illuminated and which contained some semiquinone was kept in the dark, semiquinone gradually returned to the oxidized form. For example, when the solution containing about $3\times10^{-6}$ M of semiquinone, obtained by illuminating the 0.1 N sodium hydroxide solution containing $1\times10^{-5}$ M uranine and $3.0\times10^{-2}$ M EDTA, was kept in the dark, $2.58\times10^{-6}$ M of semiquinone disappeared and $3.07\times10^{-6}$M of dye was recovered in about 220 min. The ratio is close to one, indicating that 1 M semiquinone is converted into the 1 M oxidized form. This is quite unexpected, because the disproportionation of the semiquinone is generally considered to be the normal process.

Analogous results were obtained for the irradiated solution containing $5.0\times10^{-2}$ N sodium hydroxide, $9.0\times10^{-6}$ M leuco-uranine and a small quantity of uranine. The illumination of this solution for about 20 min. produced $5.04\times10^{-6}$ M of semiquinone. When the solution thus obtained was kept in the dark for five hours, the decrease in semiquinone and the increase in the oxidized form were, respectively, $3.46\times10^{-6}$M and $3.15\times10^{-6}$M; after an additional twelve hours, the two quantities increased, respectively, to $5.04\times10^{-6}$ M and $4.87\times10^{-6}$M. The ratios of the two quanties in the two cases are, respectively, 1.10 and 1.03, again indicating that the main reaction is $2DH \rightarrow 2D + H_2$. Even in the presence of ATU or EDTA, illumination converts leuco-uranine into semiquinone (see below) and the ratio of the decrease in semiquinone to the increase in uranine is also about one. All these results suggest that semiquinone, once produced, is not affected very much by EDTA, ATU, leuco or oxidized dye.

This view was further supported by the fact that semiquinone in all cases disappears according to the second order rate formula, although the rate constant itself is affected moderately by the presence of the reducing agent. Some of the rate constants in various conditions are given in Table IV. Figure 4 gives some examples of the second order plots.

Although the data are still preliminary, it can be said that the rate constant is very sensitive to the pH value. Further, it appears that the addition of EDTA or ATU increases the rate costant to some extent.

*The Behavior of the Leuco Dye.*—As has already been reported (in 1962),[5] leuco-uranine is oxidized to uranine by a photosensitized reaction using uranine as a photosensitizer.

TABLE IV. SECOND ORDER RATE CONSTANTS FOR THE DISAPPEARANCE OF SEMIQUINONE

△ for the solution $[U]_0=1\times10^{-5}$ M $[EDTA]_0=4.0\times10^{-3}$ M, [NaOH]=0.1 N, irradiated for 28.3 min. $k=83.4\ M^{-1}\ sec^{-1}$

In order to compare the behavior of the photoproduct (other than semiquinone) obtained in the present experiments with that of leuco dye, the above photooxidation of leuco-uranine was reinvestigated. The results obtained in the present investigation were somewhat different from those that had been obtained before.

For instance, in the previous experiments, leuco-uranine was photooxidized to the dye, with the peak at 490 m$\mu$ rising monotonously, whereas in the present experiments the absorbance at 490 m$\mu$ showed a distinct maximum in the course of irradiation. For example, when a $5.0\times10^{-2}$ N aqueous sodium hydroxide solution of $9.0\times10^{-6}$ M leuco-uranine containing $1.0\times10^{-6}$ M uranine was irradiated, the peak at 490 m$\mu$ rose at first, but soon, within a few minutes, it reached a maximum, equivalent to $3.38\times10^{-6}$ M, and then fell to a constant value. After about twenty minutes' illumination, the concentrations of the oxidized dye and of the semiquinone reached, respectively, $2.11\times10^{-6}$ M and $5.04\times10^{-6}$ M. In another example using a similar solution, illumination caused the peak at 490 m$\mu$ to increase until, after 1.75 min., it reached a maximum value, equivalent to $2.64\times10^{-6}$ M; after 50 minutes' illumination, the concentration of the oxidized form decreased to $0.90\times10^{-6}$ M, while the concentration of semiquinone rose to $5.82\times10^{-6}$ M.

These results imply that the oxidized form is produced in the initial stage, perhaps by the reaction c, $D^t+DH_2\rightarrow 2D+H_2$, that at the same time, semiquinone is also produced, perhaps according to the reaction d, $D^t+DH_2\rightarrow 2DH$, and, furthermore, that the latter reaction gradually supersedes the former, causing a decrease in the oxidized form. It is evident from the above results that the entire quantity of D produced by the reaction $D^t+DH_2\rightarrow 2D+H_2$ is actually much larger than the increment of D at the maximum point, as long as one can consider that the formation of semiquinone is due to the reaction $D^t+DH_2\rightarrow 2DH$. When the solution was kept in the dark, semiquinone was gradually converted to the oxidized form, as has been mentioned already. When this solution was illuminated again, a steady decrease in the peak at 490 m$\mu$ was observed. A typical series of experiments is shown in Fig. 5.

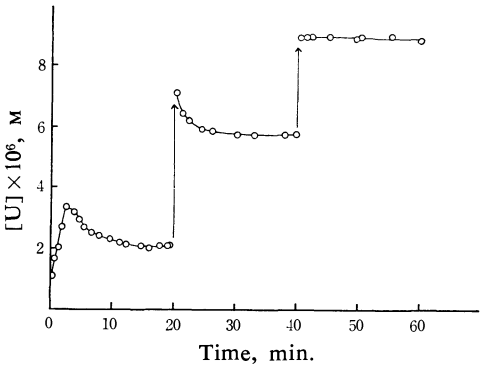

Fig. 5. Change of the dye concentration when the solution, $[L]_0=9.0\times10^{-6}$ M, $[U]_0=1.0\times10^{-6}$ M, [NaOH]=0.05 N, is irradiated.
↑ Change when the solution is kept in the dark for several days.

It appears that when the concentration of the oxidized dye exceeds a certain value, the peak at 490 m$\mu$ falls from the starting point instead of undergoing an initial increase; apparently a large excess of the oxidized form favors the reaction d. Although the present results are very curious and apparently differ from the previous results, the overall reaction is the same in both cases, i.e., $D^t+DH_2\rightarrow 2D+H_2$.

The oxidation of leuco-uranine is observed even in the presence of a moderate quantity of ATU or EDTA. The quantum yields for the production of the oxidized form at the initial stage are $3.3\times10^{-2}$, $1.6\times10^{-2}$, and $8.4\times10^{-3}$ when the concentrations of added ATU are zero, $4.0\times10^{-3}$ and $1.0\times10^{-2}$ M respectively. In the case of $4.0\times10^{-3}$ M EDTA, the quantum yield is $2.0\times10^{-2}$ under otherwise similar conditions. The behavior during the course of illumination is at least qualitatively similar to that in the absence of any reducing agent. Thus the quantity of the oxidized form usually reaches a maximum after a few minutes and then decreases. The quantity of semiquinone produced during irradiation varies,

however, according to the experimental conditions. When the solution is kept in the dark for a long time, about the same quantity of the oxidized form as that of semiquinone is produced.

The cause of the discrepancy between these results and those obtained previously is at present unknown.

*The Final Products when the Reducing Agent is EDTA.*—It was established that when EDTA is used as a reducing agent in an alkaline solution, the reaction product consists mainly of semiquinone and leuco-uranine. The evidence will be given below.

Firstly, the absorbances for uranine, leuco-uranine and semiquinone were determined at two wavelengths in order to make the analysis spectroscopically. The extinction coefficients given in Table V were obtained by the following procedures.

TABLE V. THE EXTINCTION COEFFICIENTS OF URANINE, LEUCO-URANINE AND SEMIQUINONE AT 285 AND 300 mμ

| | 285 mμ | 300 mμ |
|---|---|---|
| Uranine: $\varepsilon_U$ | $1.3\times10^4$ | $7.2\times10^3$ |
| Leuco-uranine: $\varepsilon_L$ | $6.1\times10^3$ | $6.1\times10^3$ |
| Semiquinone: $\varepsilon_S$ | $5.8\times10^3$ | $4.9\times10^3$ |

$\varepsilon_U$: from the alkaline solution of uranine at a known concentration.
$\varepsilon_L$: from the solution of leuco-uranine at a known concentration.
$\varepsilon_S$: from the irradiated solution of (leuco+uranine) at a known concentration ($[L]+[U])_0$.

The concentration of semiquinone produced by the reaction $D^t+DH_2\rightarrow 2DH$ was evaluated from $\varepsilon_S$ at 394 mμ, where $\varepsilon_U$ and $\varepsilon_L$ are practically nil. The concentration of uranine was obtained from the absorbance at 490 mμ. The concentration of leuco-uranine was calculated from $[L]+[S]+[U]=([L]+[U])_0$. Two examples of analysis by the use of the above data are given in Table VI.

Thus, the sum of [L] and [S] agrees with the total concentration of bleached dye within the range of experimental error. The above data confirm the afore-mentioned result that semiquinone forms about one-half of the total dye that has disappeared.

A remarkable fact that was found is that the leuco dye produced in this case goes back to the oxidized form, although very slowly. When the solution is kept in the dark, the reaction proceeds as a second order reaction in regard to [L]. This may be due to the reaction between leuco dye and the oxidized product of EDTA. A few examples of the second order plot are given in Fig. 6.

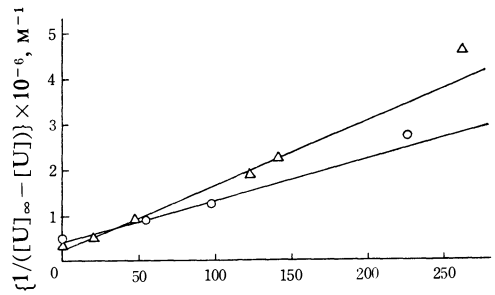

Fig. 6. Second order plot for the recovery of dye from the final product obtained by illuminating the solution containing uranine and EDTA.
○ for the solution, $[U]_0=1\times10^{-5}$ M, $[EDTA]_0=3.0\times10^{-2}$M, $[NaOH]=0.1$N, $k=2.7$ sec$^{-1}$ M$^{-1}$
△ for the solution, $[U]_0=1\times10^{-5}$ M, $[EDTA]_0=1.0\times10^{-2}$M, $[NaOH]=0.05$N, $k=4.0$ sec$^{-1}$ M$^{-1}$

Some of the rate constants obtained are:

i) $[NaOH]=1.0\times10^{-1}$ N; $[U]_0=1\times10^{-5}$ M; $[EDTA]_0=3.0\times10^{-2}$ M; $k=2.7$ sec$^{-1}$ M$^{-1}$ (181 sec$^{-1}$ M$^{-1}$)

ii) $[NaOH]=5.0\times10^{-2}$ N; $[U]_0=1\times10^{-5}$ M; $[EDTA]_0=1.0\times10^{-2}$ M; $k=4.0$ sec$^{-1}$ M$^{-1}$ (49.5 sec$^{-1}$ M$^{-1}$)

The values in parentheses refer to the second order rate constant for the decay of semiquinone. The order of magnitude for the two rate constants being different, one can treat the two processes separately. The total dye recovered from the solution usually reached about 90% of the original quantity.

*The Product when ATU was Used.* — The absorption spectra of the reaction product could not be investigated, because ATU absorbs

TABLE VI. ANALYSIS OF THE PRODUCTS

| Irradiated solution | | | [L], M | [S], M | Total of the bleached dye, M |
|---|---|---|---|---|---|

| $1.0\times10^{-1}$ N [NaOH], | $1\times10^{-5}$ M $[U]_0$, | $6.0\times10^{-3}$ M $[EDTA]_0$, | $5.4\times10^{-6}$* $4.9\times10^{-6}$** | $3.4\times10^{-6}$ | $8.7\times10^{-6}$ |

* From $\varepsilon_{285}$ ** From $\varepsilon_{300}$

up to 310 mμ. Hence, the reaction product, other than semiquinone, was examined by means of a paper chromatograph. As a developer, a mixture of water (75 vol.%), ethanol (15 vol.%) and a 28% ammonia solution (10 vol.%) was used. The spots after development were detected by the emitted fluorescence.[5] Table VII gives the results obtained in one experiment.

Table VII. The results for a paper chromatograph

| | Sample | $R_f$ Uranine | $R_f$ Leuco |
|---|---|---|---|
| 1) | Aq. soln. of uranine | 0.79 (yellow) | |
| 2) | Aq. soln. of (ATU+ Leuco) | 0.79 (faint yellow) | 0.85 (dark yellow) |
| | | 0.78 (faint yellow) | 0.85 (dark yellow) |
| 3) | Leuco -uranine | 0,78 (faint yellow) | 0.84 (dark yellow) |
| 4) | The irradiation product of uranine (buffer soln.) | 0.77 (weak) | 0.95 (?) |

The product does not seem to be leuco-uranine. ATU and leuco dye might form some kind of intermolecular complex. The solution, after being kept in the dark for a day, showed no change in the absorption spectra.

In connection with the nature of the photoproduct in the case of ATU, it is important to note that if the main product were leuco-uranine (the quantity of semiquinone forms only a small percentage, as has already been stated), the photoreduction should cease at a certain point, since the rate of the reverse reaction is quite large. However, this is not the case, as is evident from Fig. 7. This is additional evidence that the photoproduct is not leuco-uranine in the case of ATU.

*Concluding Remarks.*—When EDTA is used as a reducing agent, the photoproduct consists of semiquinone and leuco dye in the ratio of about 1. Semiquinone is rather indifferent to EDTA and very slowly returns to the oxidized form, mainly by the $2DH \rightarrow 2D + H_2$ reaction but this does not affect the rate of the photoreduction under ordinary conditions. Leuco-uranine, on the other hand, reacts according to $D^t + DH_2 \rightarrow 2D + H_2$ or $D^t + DH_2 \rightarrow 2DH$; either process would affect the overall reduction rate in the opposite direction. It may, therefore, be inferred that the effect of the product on the rate would not be very large.

When ATU is used as a reducing agent, the quantity of semiquinone forms only a small percentage of the total product and the main product is some substance other than leuco-uranine. The effect of this substance on the rate is quite unknown at present.

**Kinetic Studies and the Determination of $\varphi_{S-T}$.***—Most of the experiments concerning the effect of various factors upon the rate were made using ATU as a reducing agent in a sodium hydroxide - disodium hydrogen phosphate buffer solution (pH=10.94). However, the simple rate formula did not generally hold for this solution, while it did hold when a strong alkaline solution of sodium hydroxide was used. Hence, the later experiments for determining $\varphi_{S-T}$ were performed in such a solution.

*Rate Formula.*—The following two rate formulas were tested:

a) First order rate formula with respect to the quantity of absorbed light:

$$-\frac{dc}{dt} = \Phi\frac{I_0}{d}(1-e^{-\alpha c d}) \times 1000$$

By integration:

$$\ln(e^{\alpha c d}-1) = \ln(e^{\alpha c_0 d}-1) - 1000\Phi\alpha I_0 t$$

where $\Phi$, $\alpha$, $d$, $c$ and $I_0$ are, respectively, the quantum yield, the mean absorption coeffecient, the length of the light path, the concentration of dye, and the number of input photons (in mole) per $cm^2$. The above relation corresponds to the situation where bleaching is simply proportional to the absorption of light.

b) Second order rate formula;

$$\frac{1}{C} - \frac{1}{C_0} = kt$$

Although neither a) nor b) can reproduce the general bleaching curve when ATU is present in the buffer solution, it seems that when the concentration of ATU is large enough, the relation a holds approximately; it seems further that the relation holds better at lower dye concentrations. On the other hand, at lower concentrations of ATU and higher concentrations of dye the relation b seems to hold better. Some examples are shown in Fig. 7.

These results suggest that the D-R mechanism[1] predominates in the higher concentration region of ATU, whereas the D-D mechanism[1] begins to play a part in its lower concentration region. This suggestion is consistent with

* Details of the method were described in a previous paper. See Ref. 1.

○ $3.0\times10^{-2}$ M; △ $1.5\times10^{-2}$ M;
● $7.0\times10^{-3}$ M; □ $3.5\times10^{-3}$ M

the following rate constants reported by Lindqvist[4]:

$$D^t+D \rightarrow 2D \qquad 5\times10^7\ M^{-1}\,sec^{-1}$$

$$D^t+D \rightarrow D^-+D^+ \qquad 5\times10^7\ M^{-1}\,sec^{-1}$$

$$D^t+ATU \begin{cases} \nearrow D^-+(ATU)^+ \\ \searrow D+ATU \quad 2\times10^5\ M^{-1}\,sec^{-1} \end{cases}$$

(all in the alkaline region)

*Intensity Effect.*—Using a buffer* solution of $1\times10^{-5}$ M uranine containing $6.0\times10^{-3}$ M ATU, the effect of the intensity of the exciting light was examined. When the metallic net with a transmission coefficient of 39.3% was inserted into the light path, the rate decreased to 36% of the original value. The rate is thus proportional to the intensity of light.

*The Effect of the Dye Concentration on the Rate.*—Using a solution containing $4.0\times10^{-3}$ M ATU, and $5.0\times10^{-2}$ N sodium hydroxide the concentration of the dye was varied from 4.6 to $23\times10^{-6}$ M. The $1/\Phi$** vs. $[U]_0$ plot given in Fig. 8 clearly demonstrates that, in contrast to the case of eosine, the concentration of fluorescein has little effect on the quantum yield.

This different behavior may be accounted for by the value of the rate constant for:

$$D^t+D \begin{cases} \nearrow 2D \\ \searrow D^-+D^+ \end{cases}$$

and for:

$$D^t+ATU \begin{cases} \nearrow D^-+(ATU)^+ \\ \searrow D+ATU \end{cases}$$

* A sample solution with a pH value of 10.9 was usually prepared from a 1/5 M $Na_2HPO_4$ - 1/10 N NaOH solution.

** is evaluated from the initial slope of the ln $(e^{acd}-1)$ vs. $t$ plot.

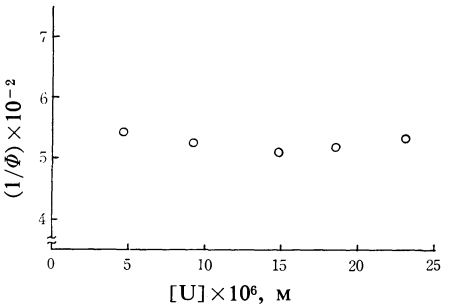

Fig. 8. $1/\Phi$ vs. $[U]_0$ plot for the solution containing $[ATU]_0=4.0\times10^{-3}$ M, [NaOH]= 0.05 N.

(The values for fluorescein are given above; the values for eosine are, respectively, $8.8\times10^8\ M^{-1}\,sec^{-1}$ and $3.4\times10^5\ M^{-1}\,sec^{-1}$)

*The Effect of the Reaction Product.*—Using a buffer solution containing $5.0\times10^{-3}$ M ATU and $1\times10^{-5}$ M uranine, the effect of the reaction product on the rate was examined. The solution was irradiated and the initial rate was measured. After about 70% of dye had been bleached, the concentration of uranine was again increased to $1.2\times10^{-5}$ M and the experiment was repeated. The rate in the second run was found to be about one-half of that in the first run.

*The Determination of $\varphi_{S-T}$ under Various Conditions.*—The rate formula a holds practically in $5.0\times10^{-2}$ N and $1.0\times10^{-1}$ N sodium hydroxide alkaline solution when the concentration of ATU is in the $4\times10^{-3}$—$3\times10^{-2}$ M range. The plot of $1/\Phi$ against $1/[ATU]_0$ as shown in Fig. 9, gives a satisfactorily straight line.

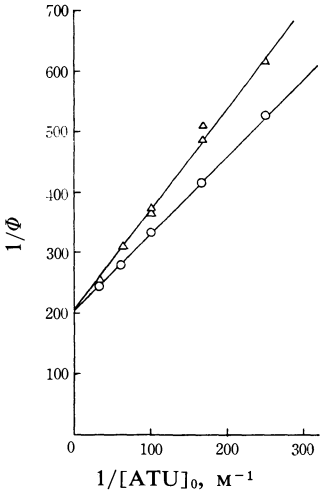

Fig. 9. $1/\Phi$ vs. $1/[ATU]_0$ plot ($1\times10^{-6}$ M $[U]_0$).
△ 0.1 N [NaOH]; ○ 0.05 N [NaOH]

TABLE VIII. QUANTUM YIELDS UNDER VARIOUS CONDITIONS

a) ATU

| $[ATU]_0$ M | $1.0\times10^{-3}$ N [NaOH] | $5.0\times10^{-2}$ N [NaOH] | $1.0\times10^{-1}$ N [NaOH] |
|---|---|---|---|
| $3.0\times10^{-2}$ | $2.8\times10^{-3}$ | $4.1\times10^{-3}$ | $3.9\times10^{-3}$ |
| $1.6\times10^{-2}$ | | $3.6\times10^{-3}$ | $3.2\times10^{-3}$ |
| $1.0\times10^{-2}$ | $1.5\times10^{-3}$ | $3.0\times10^{-3}$ | $2.7\times10^{-3}$ |
| $6.0\times10^{-3}$ | $0.99\times10^{-3}$ | $2.4\times10^{-3}$ | $2.1\times10^{-3}$ |
| $4.0\times10^{-3}$ | | $1.9\times10^{-3}$ | $1.6\times10^{-3}$ |

b) EDTA

| $[EDTA]_0$ M | $5.0\times10^{-2}$ N [NaOH] | $1.0\times10^{-1}$ N [NaOH] |
|---|---|---|
| $3.0\times10^{-2}$ | $7.2\times10^{-3}$ | $11\times10^{-3}$ |
| $1.0\times10^{-2}$ | $4.6\times10^{-3}$ | $7.2\times10^{-3}$ |
| $6.0\times10^{-2}$ | $3.8\times10^{-3}$ | $5.7\times10^{-3}$ |
| $4.0\times10^{-3}$ | $3.4\times10^{-3}$ | $4.2\times10^{-3}$ |
| $3.0\times10^{-3}$ | $2.5\times10^{-3}$ | $3.2\times10^{-3}$ |

TABLE IX. A SUMMARY OF THE $\varphi_{S-T}$ VALUES

| Reducing agent | $[U]_0$, M | [NaOH], N | $\varphi_{S-T}$ | $k_7/k_6$ |
|---|---|---|---|---|
| ATU | $1.0\times10^{-5}$ | $5.0\times10^{-2}$ | $4.9\times10^{-3}$ | $6.2\times10^{-3}$ |
| ATU | $1.0\times10^{-5}$ | $1.0\times10^{-1}$ | $4.9\times10^{-3}$ | $8.2\times10^{-3}$ |
| EDTA | $1.0\times10^{-5}$ | $5.0\times10^{-2}$ | $8.7\times10^{-3}$ | $7.2\times10^{-3}$ |
| EDTA | $1.0\times10^{-5}$ | $1.0\times10^{-1}$ | $1.5\times10^{-2}$ | $10.8\times10^{-3}$ |

As for EDTA, the rate formula a also holds for $5.0\times10^{-2}$ N and $1.0\times10^{-1}$ N sodium hydroxide solutions. However, we could not get a satisfactory plot of $1/\Phi$—$1/[EDTA]_0$, as Fig. 10 shows. The $\varphi_{S-T}$ value obtained from these plots is, therefore, not very accurate.

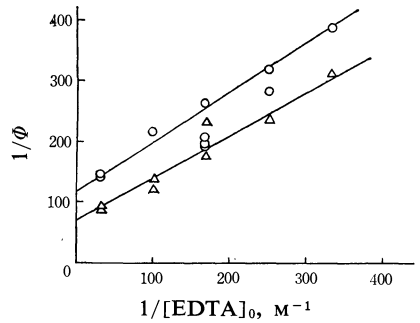

Fig. 10. $1/\Phi$ v. s. $1/[EDTA]_0$ plot ($1\times10^{-5}$ M $[U]_0$).
△ 0.1 N [NaOH]; ○ 0.05 N [NaOH]

Table VIII gives a summary of the quantum yields under various conditions.

Table IX gives the value of $\varphi_{S-T}$ obtained in this paper. The value of $k_7/k_6$ was evaluated from the inclination and the intercept.

Since the validity of the present method for obtaining $\varphi_{S-T}$ values has by no means been established beyond doubt, only a brief additional comment will be made on them. As is evident from the present studies, the main reaction product in the case of ATU is believed to be some leuco-like compound which is produced directly by the interaction of $D^t$ and ATU and which is believed to have little effect on the reduction rate at the initial stage. In view of the fact that the rate is simply proportional to the absorption of light until about 50% of dye is bleached, the value of $\varphi_{S-T}$ for ATU is considered to be more reliable.

On the other hand, the product in the case of EDTA consists mainly of semiquinone and leuco-dye. The former will not affect the reduction rate very much, but the latter will do so to some extent, probably by increasing it. In any case, these facts must be taken into consideration if we try to obtain a reliable $\varphi_{S-T}$ value. Moreover, it is not unlikely that the two reducing agents cause simple deactivation of $D^t$. The value of $\varphi_{S-T}$ obtained for ATU is, therefore, still tentative.

## Summary

An attempt to obtain a reliable value of $\varphi_{S-T}$ for fluorescein in an alkaline solution has been unsuccessful since the values for EDTA and ATU were quite different. It has been found that a large quantity of semiquinone is produced when EDTA is used as a reducing agent. In the case of ATU, the quantity of semiquinone produced is very small. Semiquinone in an alkaline solution reverts to the oxidized dye by the second-order thermal reaction and, quite astonishingly, mostly by the reaction $2DH \rightarrow 2D+H_2$. The photochemical behavior of leuco-fluorescein has been invesigated to some extent in the presence of and in the absence of a reducing agent.

# A Study of Concentrated Solutions of Mixed Electrolytes. Ultrasonic Velocities and Viscosities of Mixtures of Aqueous Solutions of Potassium and Sodium Chlorides at High Concentrations

By J. KUPPUSAMI, A. S. LAKSHMANAN, R. LAKSHMINARAYANAN, N. RAJARAM and C. V. SURYANARAYANA

(Received January 11, 1965)

Stearn,[1] Ruby and Kawai,[2] and Smith and Gortner[3] determined the conductivity of concentrated aqueous mixtures of alkali halides. The conductivity of mixed salt solutions is not strictly additive. In these mixtures, the ion of a higher mobility is slowed down while that of a lower mobility is speeded up. Onsager and Fuoss[4] and Van Rysselberghe and Nutting[5] gave quantitative theories for the mobility changes occuring in mixed electrolyte solutions. However, the rather anomalous behaviour of mixtures of electrolyte solutions has not been properly explained; often such behaviour may be attributed to the ion pairing on complex formation and ionic hydration. O'Connor[6] examined mixtures of calcium and strontium dithionates in different proportions and found the same equivalent conductivity throughout the concentration range examined. It has been felt by previous workers that the effect of the hydration of the ions on the electrical conductivity is a factor of major importance. Against this background, we have undertaken a very systematic study of mixtures of potassium and sodium chlorides from the points of view of ionic hydration and viscosity.

## Experimental Procedure

**The Preparation of Solutions.**—All solutions were made by weighing the constituents. At a chosen constant molality of one salt, mixtures were made in such a way that the molality of the other salt was increased in steps. This was repeated systematically by choosing different increasing molalities of the first salt. For instance, 0.1, 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0 and 4.5 m of sodium chloride could be obtained at each of the potassium chloride molalities of 0.1, 0.5, 1.0, 1.5, 2.0 and 2.5, subject to both the constituents being soluble. The potassium and sodium chlorides used were of the B. D. H. Analar variety. Solutions were prepared in distilled water.

**Ultrasonic Velocities.**—The measurements of ultrasonic velocities were made by the Debye and Sears[7] diffraction method. The frequency of the piezo-electric quartz oscillator used in our experiments was 5 Mc./s. The third-order diffraction fringes were taken in all the cases for measurement. Hilger's X-ray microphotometer L 486 was used with a Multiflex galvanometer with a sensitivity of $8\times10^{-9}$ amp./mm. to measure the distance between the fringes.

The hydration numbers were calculated by Passynsky's method:[8]

$$\text{Hydration number}=\frac{n_1}{n_2}\left\{1-\frac{\beta}{\beta_0}\right\} \qquad (1)$$

where $n_1$ and $n_2$ are the numbers of the moles of the solvent and of the solute respectively, and $\beta$ and $\beta_0$ are the adiabatic compressibilities of the solution and solvent respectively. The adiabatic compressibility is given by:

$$\beta_s=\frac{1}{u^2\rho} \qquad (2)$$

where $u$ is the ultrasonic velocity and $\rho$, the density of the medium.

For measuring the ultrasonic velocity of the solutions at 34.9±0.05°C, a special water-jacketted stainless-steel cubical cell with a chromium-plated inside was fabricated with two optical-plane glass windows cemented on opposite faces to give a perfect transmission of the sodium light. The cell was thermostated at 34.9±0.05°C.

**The Measurement of Viscosities.**—A Cannon-Fenske type viscometer was used, immersed in a glass-walled thermostat at 34.9±0.05°C. The viscosity values reported herein are subject to an error of ±0.5%. The flow time of the solutions ranged from 62.0 sec. to 93.0 sec. measured to an accuracy of ±0.2 sec.

**Density.**—A 10 ml. picnometer was used. Care was taken that the picnometer and its contents attained the thermostat temperature before they were weighed. A Sartorius semi-micro single-pan balance accurate to the fifth place was used for weighing.

## Results and Discussion

Figures 1A and 1B show that the viscosity varies exponentially with the ionic strength of the electrolyte mixture:

$$\eta = A\exp[B\mu] \quad (3)$$

where A and B are constants, and $\mu$ and $\eta$ are the ionic strength and viscosity of the solution respectively. In Fig. 1A, a few points at a higher ionic strength in a solution of lower potassium chloride concentrations are off the straight line. In Fig. 1B, the exponential relationship is valid in most cases, except at low ionic strengths containing lower sodium chloride concentrations. Up to a 1.0 m sodium chloride concentration, the viscosity falls or remains almost constant initially, and

then there is a linear rise. The initial effect may be ascribed to the well-known negative viscosity effects due to potassium chloride.

Table IIA gives the intercepts and slopes of the linear plots of Figs. 1A and 1B. In all the cases, the intercepts, ideally speaking should have corresponded to $\log_{10}\eta_{H_2O}$, which is 0.858. In Fig. 1A all intercept values are less than 0.858, whereas the reverse is the case with the intercepts in Fig. 1B, excepting that which corresponds to 0.1 m sodium chloride. One interesting observation is that, for purposes of viscosity, the solution of a constant molality chosen as the base of reference, in which varying concentrations of the other salts are investigated, acts as the

solvent. For example, mixtures of varying concentrations of sodium chloride in a solution of 2.5 m potassium chloride of a constant molality, give, on extrapolation, an intercept of 0.881 at an ionic strength of 2.5; the $\log_{10}$ of the viscosity of a 2.5 m potassium chloride solution alone is 0.879. In the case of almost all the plots of Figs. 1A and 1B the above observation is fully verified when compared with the respective viscosities of individual solutions of sodium and potassium chloride reported earlier.[9]

The intercept corresponding to zero ionic strength is always lower than for pure water in the case of the plots in Fig. 1A. In general, this may be ascribed to the lowering of the viscosity by potassium chloride. From Table IIA the ratio of the corresponding slopes of the plots in Figs. IA and IB may be seen to be a constant around 3.68.

Table III gives the ultrasonic velocities measured by us in different mixtures. Table IV gives the compressibility values calculated using Eq. 2.

Table V gives hydration numbers calculated from Eq. 1.

Figures 2A and 2B give plots of the hydration numbers vs. the total concentrations the mixtures. The plots in Fig. 2A are from the point of view of potassium chloride solutions to which varying amounts of sodium chloride have been added, whereas Fig. 2B gives the plots from the point of view of sodium chloride as the base of reference. For one thing, these

hydration number plots do not satisfactorily explain the conductance data obtained by previous workers. No single plot in any graph gives a uniform variation. Peaks and troughs occur too often, and both the sets of graphs are rather difficult to explain. A very broad trend seems, however, to be that, with an increasing total molality, the hydration declines.

With an increasing salt mixture concentration, either the water molecules required for the hydration of ions are not enough to go around all the ions, or ion pairing occurs preferentially. The viscosity behaviour and the hydration data of these mixed electrolyte solutions do not throw any light on the conductivity behaviour they exhibit and they at last leave us in the same position we were in previously.

A quantity called "Relative Association" was defined by some previous workers[10,11] as:

$$\text{R. A.} = \frac{\rho_c}{\rho_0} \cdot \left(\frac{u_0}{u_c}\right)^{1/3} \qquad (4)$$

where $\rho_0$ and $\rho_c$ are the densities of water at 0°C and of a solution at room temperature,

and $u_0$ and $u_c$ are the velocities of ultrasonic waves in water at 0°C and in a solution at room temperature. Figures 3A, 3B, 3C, 3D and 3E show the plots of the "Relative Association" vs. the total molality. The general trend is for relative association to increase steadily, almost linearly, in most of the cases examined. All the plots have approximately the same slope. One must, therefore, doubt whether "Relative Association" is a measure of the hydration at all.

## Summary

The electrical conductance of mixtures of aqueous solutions of potassium and sodium chlorides has been studied by previous workers. However, no valid explanation has been given for the conductance behaviour of the mixtures.

We have reported herein the results of our ultrasonic and viscometric studies of the same mixtures. Even now the hydration numbers and the viscosity variation are inadequate to explain the conductance behaviour of the mixtures. We have observed that all the mixtures follow the exponential relation, $\eta = A_e^{B\mu}$, where $A$ and $B$ are constants; $\eta$ the viscosity of the mixture, and $\mu$, the ionic strength.

Our thanks are due to Professor K. S. G. Doss, Director of the Central Electrochemical Research Institute, for his kind encouragement.

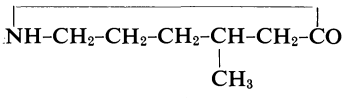
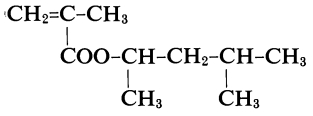
# Optically Active Polymers. III.* Polymers of 1, 3-Dimethylbutyl Methacrylate



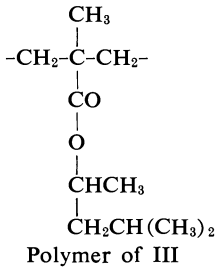
By Minoru IMOTO and Yoshiyuki KUMATA

(Received January 16, 1965)

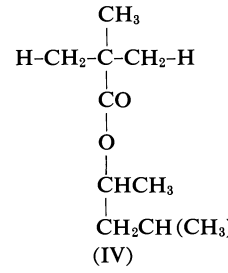


In an earlier study, Imoto and Sakurai[1] synthesized a polymer of (−)-*l*-4-methyl-7-isopropyl-2-oxohexamethyleneimine (I) and found that its optical rotation increased with the molecular weight. Recently Overberger and Jabloner[2] obtained a polymer of D-(−)-β-methyl-ε-caprolactam (II), measured its rotatory dispersion, and concluded that the polymer showed no definite proof for the assignment of a helical structure. However, if we can assume that the longer the molecule, the greater is the portion of molecular-structural (helical) asymmetry, an increase in molecular rotation with molecular weight is understandable.

(I)



(II)



(III)

Arcus and West[3] synthesized (+)-1, 3-dimethylbutyl methacrylate (III) and carried out its polymerization in the presence of benzoyl peroxide or azobisisobutyronitrile. The molecular rotation [M] of the polymer and (+)-1, 3-dimethylbutyl pivalate (IV) was determined for five wavelengths at 25°C in tetrachloroethane. Compound IV could be recognized as the unit of the polymer of compound III.

Polymer of III

(IV)

Moreover, the difference between the values of [M] of IV and the polymer of III was considered to be that part of the [M] which was due to structural features other than the individual ester units. For example, at 4358 Å, the values of [M] were determined as follows: IV, +82°; Polymer of III, +60°, and the difference, −22°. It was concluded that the contribution of the difference was due to disymmetric coiling of the main chain.

This paper will deal with the preparation of three kinds of polymers of (+)-1, 3-dimethylbutyl methacrylate (III), polymers which were assumed to be isotactic, syndiotactic and atactic, as well as with the determination of the optical rotatory dispersion of the polymers. Moreover, the polymerization of optically impure (−)-1, 3-dimethylbutyl methacrylate and the optical rotatory dispersion of the polymers will be investigated.

* Part II: M. Imoto and S. Kimura, *Makromol. Chem.*, 53, 210 (1962).

1) M. Imoto, H. Sakurai and T. Kono, *J. Polymer Sci.*, 50, 467 (1961).

2) C. G. Overberger and J. Jabloner, *J. Am. Chem. Soc.*, 85, 3431 (1963).

3) C. L. Arcus and D. West, *J. Chem. Soc.*, 1959, 2699.

It is known that methyl methacrylate can be polymerized with *n*-BuLi at −78°C to give an isotactic polymer, while with azobisisobutyronitril (AIBN) at a higher temperature it gives an atactic polymer, and at about −40°C, a syndiotactic polymer. Granting that these specific polymerizations of methyl methacrylate could also be applied to 1,3-dimethylbutyl methacrylate, isotactic, syndiotactic and atactic polymers of optically active 1,3-dimethylbutyl methacrylate may be obtained.[4] It seemed an interesting problem to investigate the relationship between the change in the optical rotatory power of a polymer, with its molecular weight, and the stereospecific configuration of the polymer molecule. However, no definite result could be obtained.

## Experimental

**Syntheses of Optically Active Monomers.** — 1) The resolution of *dl*-1,3-dimethylbutanol was carried out through the salt of 1,3-dimethylbutyl hydrogen phthalate with brucine, according to the method of Kenyon et al.[5] In recrystallization from acetone, the salt of *d*-ester crystallized out first. accordingly, optically pure *d*-1,3-dimethylbutanol could be obtained. However, the *l*-isomer was recovered in a less optically pure state. The specific rotations observed were as follows:

*d*-1,3-dimethyl butanol $[\alpha]_D^{14}$ +20.41°

*l*-1,3-dimethyl butanol $[\alpha]_D^{17}$ −7.53°

2) 1,3-Dimethylbutyl methacrylate was prepared by the reaction of the alcohol with methacrylic chloride, according to the method of Arcus et al.[3] *d*-, *l*- and *dl*-1,3-Dimethylbutyl methacrylate (DBMA) were purified by repeated distillation in the stream of nitrogen and in the presence of picric acid (an inhibitor for polymerization). Their boiling points were 75—78°C/20 mmHg and 65°C/15 mmHg.

| | | |
|---|---|---|
| *d*-DBMA | $[\alpha]_D^{20}$ +58.1° | $n_D^{24}$ 1.4232[a] |
| *l*-DBMA | $[\alpha]_D^{20}$ −21.8° | $n_D^{24}$ 1.4229 |
| *dl*-DBMA | $d_4^{25}$ 0.8698[b] | $n_D^{24}$ 1.4237 |

a) $n_D^{24}$ 1.4224 (Arcus, West[3]).
b) $d_4^{20}$ 0.8714 (Crawford[6]).

**Hydrogenation of the *d*-Monomer to *d*-1,3-Dimethylbutyl Pivalate.** — Three milliliters of the *d*-monomer in *n*-hexane was hydrogenated in the presence of 0.3 g. of the palladium charcoal catalyst with shaking. After the absorption of hydrogen had stopped, the content was filtered and fractionated. The yield was 1.8 g. B. p. 75°C/21.5 mmHg; $n_D^{23}$ 1.4053; $[\alpha]_D^{23}$ ±1 (lit.[3]: b. p. 78°C/22 mmHg, $n_D^{23}$ 1.4070). The structure was identified from its infrared spectrum.

**Polymerization.**—*Isotactic Polymerization.*—To a solution of 5 ml. of DBMA in 10 ml. of purified toluene, 0.2 ml. of a 4 N *n*-butyl lithium solution in heptane was added at −78°C. After it had stood for 2 hr., the mixtue was poured into mixture of a large amount of methanonl and a small quantity of hydrogen chloride. What was assumed to be isotactic polymer was precipitated out.

*Atactic Polymerization.*—To 0.005 g. of azobisisobutyronitrile in a hard glass tube, 5 ml. of DBMA was added. The tube was then deaerated, sealed and heated at 60°C for 5.5 hr. while being shaken. The contents were dissolved in benzene and then poured into methanol to isolate the atactic poly-DBMA.

*Syndiotactic Polymerization.*—A solution of 0.02 g. of azobisisobutyronitrile in 5 ml. of DBMA was placed in a tube. The tube was deaerated, sealed, cooled at −35°C—−50°C, and irradiated for 30—36 hr. The light was obtained from a high-voltage mercury lamp of the Mazda SHL-100 type and filtered through $UVD_1$-filter. The contents were dissolved in a mixture of benzene and a small quantity of hydroquinone, and then poured into methanol. What was assumed to be syndiotactic poly-DBMA was isolated. These poly-DBMA's were then purified by the reprecipitation method using benzene and methanol.

**Fraction of the Polymer of DBMA.**—One gram of the polymer was dissolved in 50 ml. of benzene. When, to this solution, methanol was added portion-by-portion, 4—7 fractions were obtained.

**Measurement of the Softening Temperature (Ts).** — The Ts was measured by the deck-glass method, using an electroheating melting point apparatus and raising the temperature by one degree per minute.

**Optical Rotation and Dispersion.**—The apparatuses used were a Lippich-type polarimeter, a dispersion polarimeter (the Rudolf 260/655/850/810 type) and a spectrophotometer equipped with a polarimetric attachment (the Shimadzu QR-50 type). The two types of dispersion polarimeters gave the same results.

## Results and Discussion

**Polymerization of DBMA.**—The results obtained are shown in Table I. All the polymers were colorless and soluble in petroleum ether, acetone, benzene, toluene, dioxane, chloroform and dichloroethane, while they were insoluble in methanol and swelled in ethanol. The tacticities of the polymers could be observed from their softening temperatures (Ts) and from their infrared spectra. Ts's of the isotactic, atactic and syndiotactic polymers fell in the ranges of the Ts's of the isotactic, atactic and syndiotactic polymethyl methacrylates which have previously been described by Fox, Stroupe et al.[7]

4) T. Tsuruta and H. Kanai (XII Annual Meeting of the Polymer Society of Japan, Preliminary Issue, [A17], p. 26 (1963)) stated that ethyl-, isopropyl- and *t*-butylesters of methacrylic acid could be polymerized to polymers having the same tacticity as methyl methacrylate, by the methods applied to methyl methacrylate.

*3 Soluble part in dioxane.

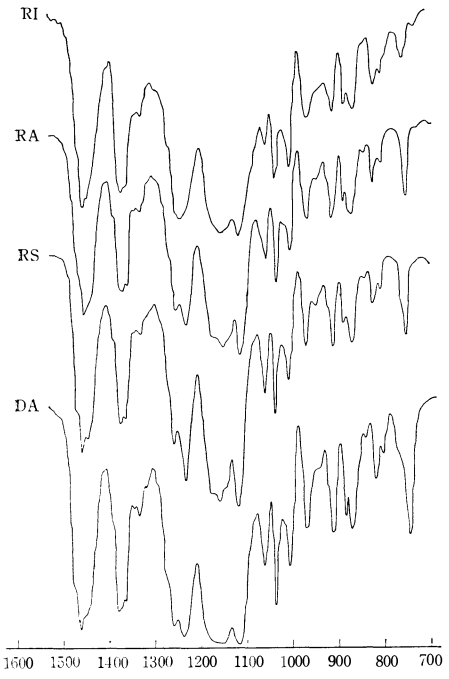

Fig. 1. IR-spectra of poly-DBMA.
RI: racemic-isotactic RA: racemic-atactic
RS: racemic-syndiotactic DA: dextro-atactic

The infrared spectra of the polymers are shown in Fig. 1. From the figure, the relative intensities of the absorption bands for the three kinds of poly-DBMA's (RS, RA and RI) were tabulated as in Table II.

The orders of the intensities in this table coincide with those for polymethylmethacrylates which were described Baumann et al.[8] From

8) U. Baumann, H. Schreiber and K. Tessmar, *Makromol. Chem.*, **36**, 81 (1959).

Table II. The relative intensities of the infrared absorption bands of poly-DBMA

| $cm^{-1}$ | 752 | 806 | 825 | 915 | 1060 | 1238 |
|---|---|---|---|---|---|---|
| $\mu$ | 13.38 | 12.40 | 12.12 | 11.00 | 9.45 | 8.08 |
| RS | 4+ | + | 2+ | 4+ | 4+ | 3+ |
| RA | 4+ | + | 2+ | 4+ | 3+ | 2+ |
| RI | 2+ | + | + | 2+ | 1+ | 0 |

the order of the Ts's and from the comparison of the intensities of the absorptions with the data obtained by Baumann et al., it was concluded that the polymers obtained in the present work consisted principally of isotactic, atactic and syndiotactic poly-DBMA's) respectively. Furthermore, Fig. 1 shows that the spectra of DA (atactic (+)-polymer) and RA (atactic (±) polymer) were almost exactly the same. This means that the presence of asymmetric carbon in the side chain had no effect on the stereospecific polymerization.

**Optical Rotation of Poly-DBMA.**—The values of specific rotation ($[\alpha]_D$ (20°C, in chloroform)) given in Table III were measured at the concentrations of 1.0—1.5 g./dl. In other measurement, it was confirmed that $[\alpha]_D$ was constant over such a range of concentrations.

From the data in Table III, the relationships between specific rotations and molecular weights may be illustrated as in Fig. 2. It seems that, in the cases of DI(isotactic (+)-polymer) and DA, the specific rotation increases with the molecular weight, while in the cases of DS (syndiotactic (+)-polymer), LS (syndiotactic (−)-polymer) and LA (atactic (−)-polymer), the specific rotation remains constant during the change in molecular weight. It may be assumed that the difference between isotactic (DI) and syndiotactic polymers (DS) suggests a difference in the molecular conformation.

TABLE III. RESULTS OF FRACTIONATIONS OF POLYMERS AND SPECIFIC ROTATIONS OF EACH FRACTIONATES

**Optical Rotatory Dispersion of the Polymer.** —The optical rotatory dispersions of the polymers are illustrated in Fig. 3. The dispersion curves of the polymers from the *d*-monomer could not be compared with those of the polymers from the *l*-monomer because of the optical impurity of the *l*-monomer. If $[\alpha]$ comes only from asymmetric carbon, the relation between $[\alpha]$ and the wavelength, $\lambda$, may be given by the simple Drude equation (1):

$$[\alpha]=\frac{k\lambda_c^2}{\lambda^2-\lambda_c^2} \qquad (1)$$

where $\lambda_c$ is the dispersion constant and $k$ is the rotatory constant. The results are illustrated in Figs. 4 and 5. As the figures shows, the results of poly-DBMA did not fit the equation, while the *d*-monomer and its hydrogenated compound obeyed the equation.

Recently, Klabunovskii et al.[9] obtained poly-(+)-2-methylbutyl methacrylate and investigated its structure spectro-polarimetrically. Their polymerization was carried out with radical and ionic catalysts (benzoyl peroxide and phenyl magnesium bromide). The optical dispersion curves in the 302—589 m$\mu$ range

—··— Atactic polymer
——— Syndiotactic polymer

were determined and could be described by Drude's single term equation. The value of $\lambda_c$ for the monomer was close to that of both polymers (173 m$\mu\pm$14).

As is known from the studies of polypeptides, if the optical activity comes from assymmetric carbon and the molecular helical structure, $[\alpha]$ may obey Moffitt's equation (2):

$$\frac{3}{n^2+2}\cdot\frac{M}{100}[\alpha]=\frac{a\lambda_0^2}{\lambda^2-\lambda_0^2}+\frac{b\lambda^4}{(\lambda^2-\lambda_0^2)^2} \quad (2)$$

where $n$ is the refractive index of the solvent; $M$ is the molecular weight of the structural unit of the polymer; $a$ is a term for the helix and the residue, and $b$ is a constant for the helical structure. As Fig. 6 shows, if a value of 212 was adopted for $\lambda_0$, a straight line was obtained in the case of the atactic *d*-polymer (DA). (In the case of polypeptides, a value of 212 is also suitable.) From the inclination of the straight line, it was deduced that $b$ was −64.3. This value of $b$ would correspond to about 10% of the right-hand helical structure if we were dealing with polypeptide. However, the polymer which we have dealt with is not a polypeptide. Therefore, no definite

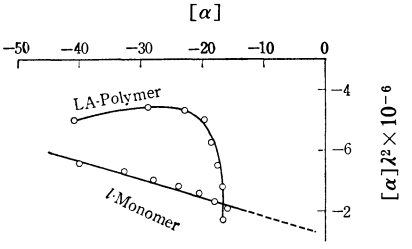

Fig. 5. Adaptability of the Drude equation for *l*-monomer and *l*-polymer.

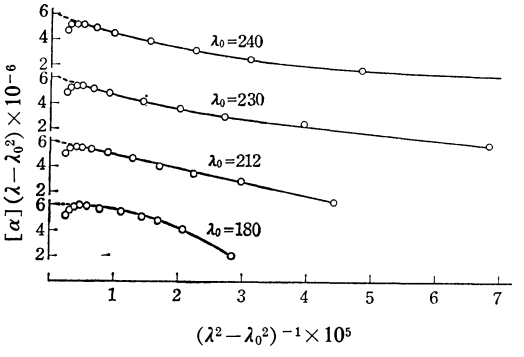

Fig. 6. Adaptability of the Moffit equation for DA.

conclusion as to its molecular asymmetry can be made. In the cases of isotactic and syndiotactic *d*-polymers (Dl and Sl), a straight line could not be obtained by using a value of 212 for $\lambda_0$. However, it could be concluded qualitatively that the $b$ constant for Dl was negative, and for those for LA, LI and LS, positive.

## Summary

The polymerization of (+)-1, 3-dimethylbutyl methacrylate and its optically impure

(−)-isomer have been carried out through different three initiations:

(1) *n*-BuLi in toluene at −78°C gave isotactic polymers (DI and LI). (2) Azobisisobutyronitrile at 60°C gave atactic polymers (DA and LA). (3) Photopolymerization in the presence of azobisisobutyronitrile at −35—−50°C gave syndiotactic polymers (DS and LS). The tacticities of the resulting polymers have been deduced from their softening temperatures and their infrared spectra. Optically active polymers have been fractionated from a benzene solution by adding methanol. In the cases of DI and DA, the specific rotation $[\alpha]_D$ increased with the molecular weight, while in the cases of DS, LS and LA, $[\alpha]_D$ remained constant during the change in molecular weight. The optical rotatory dispersion of the polymers has been measured. Drude's equation does not hold. In the case of DA, however, a straight line was obtained by Moffitt's equation, giving −64.3 as the *b*-values.

The authors wish to thank Professor Naokazu Sakota of Ehime University, Professor Takayuki Otsu of Osaka City University and Assistant Professor Hideki Sakurai of Kyoto Univesity for their helpful discussions. Besides, they wish to express their deep thanks to Professor Sakota for his permission to use dispersion polarimeter. The authors are also much indebted to the Shionogi Research Laboratory, Shionogi and Co., Ltd., for measuring the rotatory dispersion.

# Studies of Thermosetting Resin. I. The Infrared Analysis of Cured Epoxy Resins

By Tadao SUGITA and Mitsuko ITO

(Received January 18, 1965)

Recently many investigations of epoxy resins has been made. However, as analyses of thermosetting resins are generally difficult, a method of identifying the curing agents used has not yet been established for cured epoxy resins.

We have learned that the infrared analysis of pyrolyzates, which Harms[1] has successfully applied with various resins and elastomers and McGarvey[2] and Tanaka[3,4] with elastomers only, is very useful for thermosetting resins. Therefore, we have applied this method, along with a more standard procedure, in the analyses of cured epoxy resins. Some studies[5-10] of amine-cured resins performed by means of the infrared spectroscopic technique have been published, but only a single study[11] has been reported on acid anhydride cured resins.

In the present paper, only cured epoxy resins which contain no other materials (e.g., fillers and plasticizers) will be studied. Infrared spectra are recorded for the powders of cured epoxy resins and their pyrolyzates as a means to establish a method of identifying the curing agents.

Although Harms identified the types of resins, he did not identify the types of curing agents in the case of epoxy resins. From the infrared spectra of the powders of cured epoxy resins, we can determine only whether the cured resin is an acid anhydride or an amine-cured type. However, from the spectra of the pyrolyzates of cured epoxy resins, we can readily identify the types of acid anhydrides which were used in the curing process.

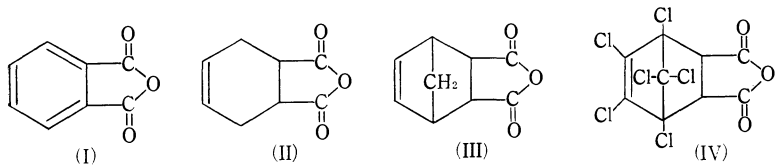
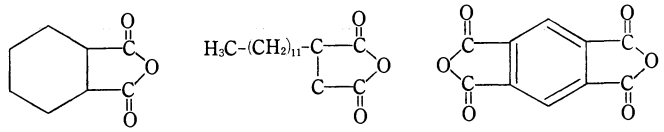
Here the infrared spectra of the pyrolyzates of seven acid anhydride-cured epoxy resins will be studied in detail.



## Experimental

**Measurements.**—Spectra were scanned using a Perkin-Elmer Model 21 infrared spectrophotometer, with a sodium chloride prism in the 600 $cm^{-1}$- to -4000 $cm^{-1}$ region.



**The Preparation of Cured Epoxy Resins.**—As the epoxy resin, Epon 828 (Shell Chemical Corp.) was used. Figure 1 shows the structures of Epon 828 and the curing agents. Table I shows the mixing composition and the curing conditions accepted as standard. The solid curing agent was stirred

* K KBr pellet technique, S Sandwich technique, ◎ Indicates the fractions utilized for identification of the curing agents used.

into warmed Epon 828, stirring was continued and the mixture was heated until the curing agent had been dissolved uniformly into the resin. The liquid curing agent was thoroughly mixed with the resin at room temperature. Then the sample was cured in an oven.

**The KBr Pellet Technique of Cured Resins.**—A file was used to reduce a block of cured resin to small particles. This method was found to be very simple and convenient for preparing a powdered sample for infrared analysis. The powdered sample thus obtained was passed through a 200 mesh screen. About 1 mg. of the sieved sample was thoroughly mixed with about 200 mg. of KBr powder, and a KBr pellet about 1 mm. thick was then prepared.

**The Method of Pyrolysis.**—Figure 2 shows the equipment of pyrolysis. About 2 g. of a sieved sample was placed into a horizontal borosilicate glass tube in an electric furnace. In the case of Epon 828, the sample was inserted into the furnace in a platinum boat. Then the temperature was raised at the rate of 2°C/min.; pyrolysis was continued until the temperature reached 500°C under a stream of high-purity nitrogen at a flow rate of 32 cc./min. Pyrolysis products were trapped in five temperature sections: (I) room temperature to 300°C; (II) 300—350°C; (III) 350—400°C; (IV) 400—450°C, and (V) 450—500°C (Table II). As can be seen from Fig. 2, three traps, the air-, water- and dry ice-cooled traps, were connected in series. Liquid and crystalline pyrolyzates caught in the traps were washed out with acetone. After the acetone had evaporated, the infrared spectra were recorded using the KBr-pellet technique or the sandwich technique.

## Results and Discussion

The infrared spectra of Epon 828 (the top of Fig. 5) and acid anhydrides (the top of Figs. 6 through 12) used as curing agents were recorded for reference. All anhydrides show two characteristic carbonyl absorption bands near 1780 and 1850 $cm^{-1}$.

**The Infrared Spectra of Cured Epoxy Resins.**—In the case of the amine-cured resins, a hydroxyl group is formed by the reaction of the amine with the epoxy group. Accordingly, the absorption band of the epoxy group at 907 $cm^{-1}$ disappears and the absorption intensity of the hydroxyl group in the 3400 $cm^{-1}$ region increases. Examples of two spectra (DETA- and MPDA- cured resins) are shown in Fig. 3. The spectra of three other types (DEAPA-, TTA- and DDM-cured resins) give patterns very similar to the first two (DETA and MPDA). Therefore, while the spectra of these cured resins can not be used to identify the specific type of amine utilized as the curing agent, the characteristic pattern can be used to determine that an amine and not an anhydride was used in the curing process.

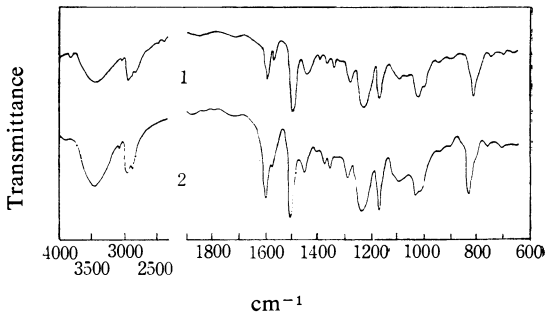

Fig. 3. Spectra of amine cured epoxy resins.
1 DETA-cured resin
2 MPDA-cured resin

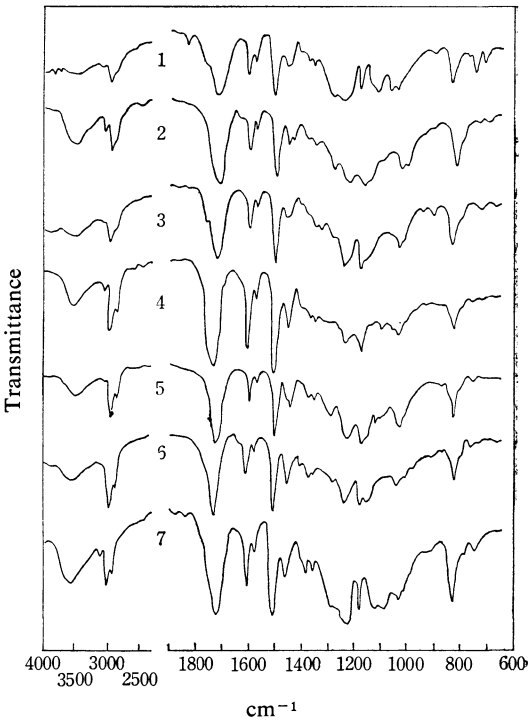

Fig. 4. Spectra of acid anhydride cured epoxy resins.
1 PA-cured resin
2 THPA-cured resin
3 EMTHPA-cured resin
4 HET-cured resin
5 HHPA-cured resin
6 DDSA-cured resin
7 PMDA-cured resin

In the case of acid anhydride-cured resins (Fig. 4), an ester-linkage is formed by the reaction of the anhydride with the hydroxyl group and an acid with the epoxy group, while a further ether linkage is formed by the reaction of the epoxy group with the hydroxyl group. Therefore, the absorption band of the epoxy group at 907 $cm^{-1}$ disappears and a strong ester carbonyl band appears at 1730 $cm^{-1}$.

Furthermore, small differences in the spectra are observed for each acid anhydride in the 1300—1000 $cm^{-1}$ region. The spectra of these anhydride-cured resins can not be utilized to identify the types of anhydrides used as curing agents, but they are useful in determining whether or not the resin is an anhydride-cured epoxy resin by the form of the curve, especially through the presence of a strong carbonyl band.

**The Infrared Spectra of Pyrolyzates of Cured Epoxy Resins.**—As the amounts of pyrolyzates caught in the water- and dry ice - cooled traps were very small, their infrared spectra were not studied. Most of the pyrolyzates caught in the air-cooled trap were studied by means of their infrared spectra. As can be seen from the properties of the pyrolyzates (Table II) and their infrared spectra (Figs. 6 through 12), pyrolyzates of PA-, THPA-, EMTHPA-, and HET-cured epoxy resin obtained at room temperature through 300°C were crystalline, and their infrared spectra gave nearly the same patterns as those of the individual acid anhydride-curing agents. Meanwhile, the pyrolyzates of HHPA- and DDSA-cured epoxy resins obtained at room temperature through 350°C were liquid, and each of the acid anhydride-curing agents used could be identified by the finger-print region of their infrared spectra.

In the spectra of the pyrolyzates of HHPA-cured resin, the formation of aliphatic compounds was observed. In the case of PMDA-cured resin, the infrared spectra of pyrolyzates did not give the pattern of PMDA utilized for curing at a low pyrolysis temperature, but did give the specific pattern at a high pyrolysis temperature; this pattern was different from those shown in the cases of other acid anhydride-cured resins. The ordinary acid anhydride used as a curing agent can be identified by the characteristic curve shown by the infrared spectra of pyrolyzates, while the presence of PMDA as a curing agent may be presumed from the fact that the spectra of the pyrolyzates do not have the absorption bands of PMDA, in contrast with the other acid anhydride-cured resins.

The experimental results with Epon 828 and each acid anhydride cured-epoxy resin will be discussed in detail below.

**Epon 828 (Fig. 5).**—Epoxy resin itself was also investigated as a related study. The infrared spectrum of the pyrolyzate obtained at room temperature through 350°C is almost the same as that of the original sample. At temperatures above 350°C, the intensities of the absorptions at about 3400 $cm^{-1}$ ($\nu$OH) and 1700 $cm^{-1}$ ($\nu$C=O) increase. At temperatures above 400°C the intensities of the absorptions at about 1025 $cm^{-1}$ (ether linkage $\nu$ C–O–C) and 907 $cm^{-1}$ (stretching vibration of epoxy ring) decrease; the characteristic spectrum is obtained from the sample at temperatures between 400—450°C.

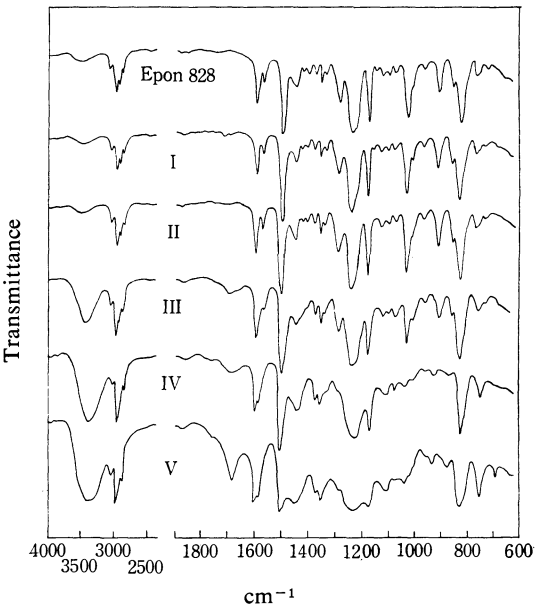

Fig. 5. Spectra of Epon 828 and its pyrolyzates.

This typical spectrum appears in every spectrum of the pyrolyzates above 350°C of cured epoxy resins subsequently mentioned, and so it is referred to as the *characteristic spectrum* hereafter. From these spectra, the opening of epoxy rings, the scission of ether linkages and the formation of hydroxyl groups may be assumed.

The main absorption bands of this *characteristic spectrum* are assigned as follows: 755 $cm^{-1}$: CH out-of-plane vibration of the mono-substituted benzene ring; 830 $cm^{-1}$: CH out-of-plane vibration of the para-substituted benzene ring; 1240, 1514 and 1610 $cm^{-1}$: vibrations related to the benzene ring; 1695 $cm^{-1}$: C=O stretching vibration.

Further, when an ethyl alcohol solution of 2, 4-dinitrophenylhydrazine acidified with hydrochloric acid was added to an ethyl alcohol solution of fractions IV and V, brown oily products separated out. From this fact and from the absorption near 1695 $cm^{-1}$ in spectra IV and V, the formation of carbonyl compound may be assumed.

**PA-Cured Resin (Fig. 6).**—Spectrum I is the same as that of PA. Pyrolyzate II is a mixture of a crystalline and a yellow liquid material, but except for the absorption of PA, only the absorption of the hydroxyl group (near 3400

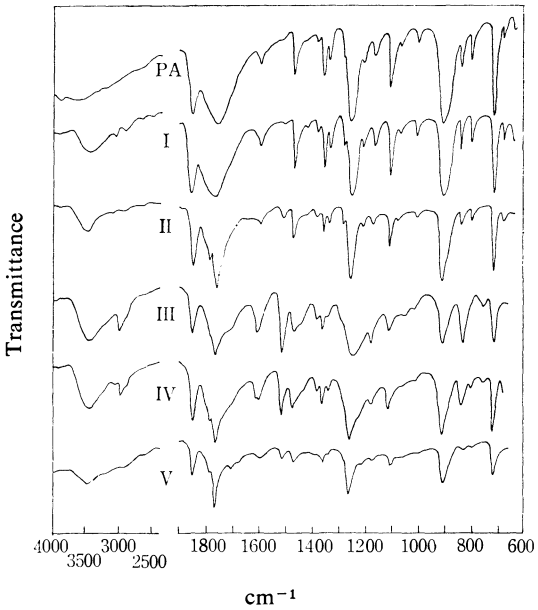

Fig. 6. Spectra of PA and pyrolyzates of PA-cured resin.

$cm^{-1}$) appears. Pyrolyzate III and IV show the absorptions of PA (at 1845, 1763, 1107, 905, and 715 $cm^{-1}$) overlapped with the *characteristic spectrum*. From the absorption as a shoulder at 1700 $cm^{-1}$ the formation of a carboxyl group may be assumed. Even in spectrum V the absorptions of PA (at 1845, 1763, 1260, 905, and 715 $cm^{-1}$) are clearly observed.

**THPA-Cured Resin (Fig. 7).**—Spectrum I is nearly the same as that of THPA. In spectrum II the absorptions of THPA are also observed at 1831, 1770, 1179, 1090, 995, 964, 933, 772, and 730 $cm^{-1}$. In spectrum III the *characteristic spectrum* strongly appears, while the absorptions of THPA are not clearly observed. The absorption curve becomes broad in spectrum IV.

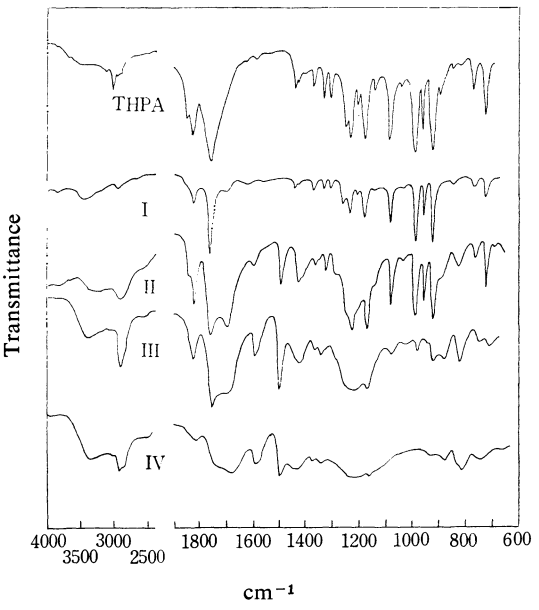

Fig. 7. Spectra of THPA and pyrolyzates of THPA-cured resin.

**EMTHPA-Cured Resin (Fig. 8).**—In spectrum I the absorption bands at 1860, 1770, 1335, 1293, 1117, 1078, 910, 791, and 732 $cm^{-1}$ are identical with those of EMTHPA. In spectra II, III, and IV the *characteristic spectrum* appears strongly, but the absorptions of EMTHPA could not be clearly observed. However, unlike the case of PA and THPA, the higher the pyrolysis temperature, the lower the carbonyl band shifts in the wave numbers of the spectrum (for example, 1725, 1717, 1695 and 1680 $cm^{-1}$ in II, III, IV and V respectively).

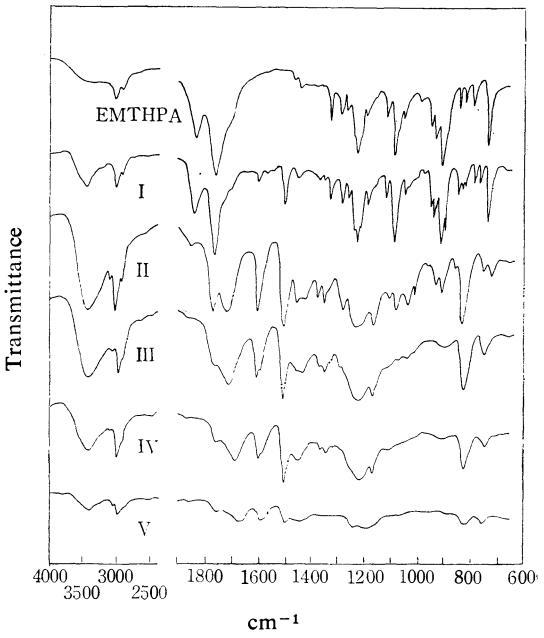

Fig. 8. Spectra of EMTHPA and pyrolyzates of EMTHPA-cured resin.

When an ethylalcohol solution of 2, 4-dinitrophenylhydrazine acidified with hydrochloric acid was added to the fractions from I to V, yellow oily products separated out, except for fraction I.

The amount of the products is highest in fractions III and IV. From this fact and from the above-mentioned carbonyl band shifts, the formation of a carbonyl compound may be assumed.

**HET-Cured Resin (Fig. 9).**—Pyrolyzate I is crystalline, and HET is identified by the absorptions at 1883, 1782, 1598, 1243, 1216, 1067,

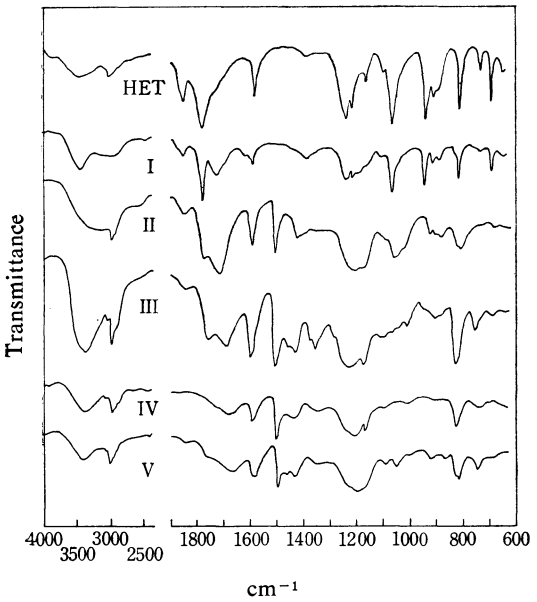

Fig. 9. Spectra of HET and pyrolyzates of HET-cured resin.

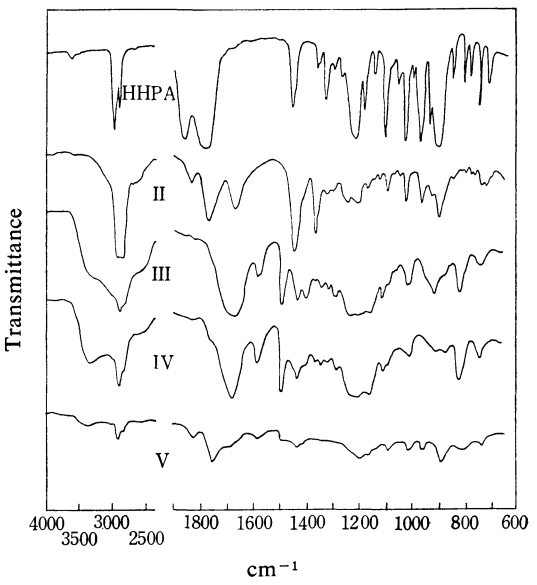

Fig. 10. Spectra of HHPA and pyrolyzates of HHPA-cured resin.

942, 817, and 695 $cm^{-1}$. The *characteristic spectrum* becomes strong in the spectra of the sample obtained above 300°C; the absorption bands of HET could not be identified. Similarly, in the case of EMTHPA, at the higher pyrolysis temperatures, the carbonyl band shifts to a lower wave number (for example, 1725, 1722, 1692, 1680, and 1675 $cm^{-1}$ in I, II, III, IV and V respectively).

In this case 2, 4-dinitrophenylhydrazine test was omitted, but the formation of a carbonyl compound may be assumed.

**HHPA-Cured Resin (Fig. 10).**—The amount of pyrolyzate I was too small to get a satisfactory spectrum. From spectrum II HHPA is identified by the absorptions at 1841, 1780, 1100, 1027, 971, and 900 $cm^{-1}$. Furthermore, strong absorption bands appear near 2800, 1450, and 1380 $cm^{-1}$. From this fact, the formation of aliphatic chain compounds by the opening of the cyclohexane ring of HHPA may be assumed. The *characteristic spectrum* becomes strong in the spectra of the samples obtained above 350°C. Furthermore, in contrast with other acid anhydrides, the carbonyl bands of this acid anhydride could not be observed, while the carbonyl band appears strongly near 1675 $cm^{-1}$. After several experiments, it was recognized that the two carbonyl bands of HHPA appeared when the spectra were measured immediately after the pyrolysis. Therefore, a high reactivity of HHPA was assumed.

**DDSA-Cured Resin (Fig. 11).**—As DDSA is a liquid with an aliphatic chain, its pyrolyzate is also a liquid, as would be expected. DDSA

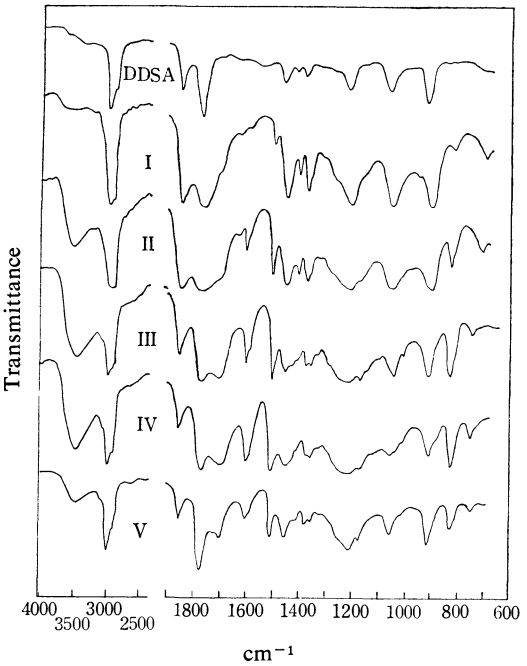

Fig. 11. Spectra of DDSA and pyrolyzates of DDSA-cured resin.

is identified from spectra I and II. With a rise in the temperature of the pyrolysis, spectra III, IV, and V give a pattern similar to the *characteristic spectrum.*

**PMDA-Cured Resin (Fig. 12).**—The spectra of pyrolyzates I and II are almost identical with the *characteristic spectrum.* Pyrolyzate III is a mixture of liquid and a small amount of

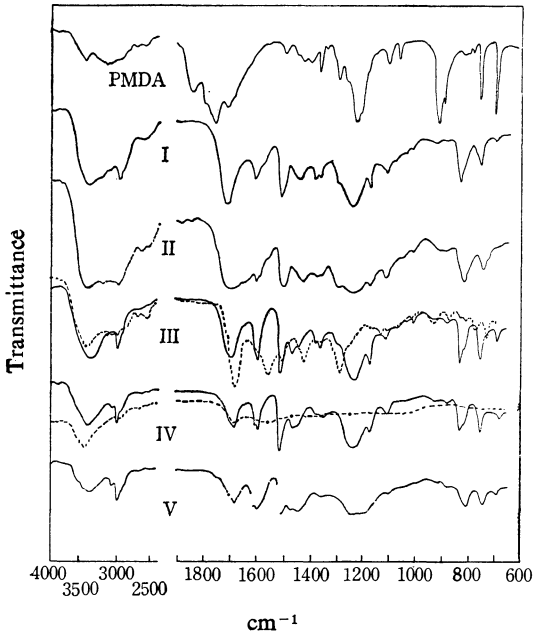

Fig. 12. Spectra of PMDA and pyrolyzates of PMDA-cured resin.
III, IV: — liquid, --- solid

solid. The liquid portion gives almost the same spectra as the pyrolyzates I and II. Meanwhile, the spectrum of the solid portion is very specific, but it has not been identifide as yet. Only in the case of PMDA-cured resin is the original acid anhydride used as a curing agent (PMDA) not formed by pyrolysis. However, PMDA can be assumed by a comparison of the pyrolyzate spectra of PMDA-cured resin with those of another acid anhydride resins.

**Summary**

To pulverize the cured hard resins for the infrared KBr technique, the method using a file is very simple and convenient.

From the infrared spectra of the powder of cured epoxy resins using the KBr-pellet technique, the curing agent used can be readily identified by type whether it is an amine or an acid-anhydride type by the absence or presence of the carbonyl absorption band.

Furthermore, in the case of the acid anhydride-cured epoxy resins, the acid anhydride used as the curing agent can be identified by type from the spectra of the resin pyrolyzate. Namely, PA, THPA, EMTHPA, HET, and DDSA may be identified immediately from the spectra of pyrolyzates between room temperature and 300°C, and HHPA, from the spectrum of the pyrolyzate between 300 and 350°C. The results of these experiments are summarized in Table II.

PMDA used as a curing agent can not be so straightforwardly identified as in the other cases, but even this may be identified by a comparison of the spectra of the pyrolyzates of PMDA-cured resin with those of the pyrolyzates of each resin.

The authors are indebted to Dr. Shigeyuki Tanaka, Associate Professor of the University of Tokyo, for his helpful advice and comments.

By Nobuo MORI, Satoshi ŌMURA,* Hiroyuki YAMAKAWA and Yojiro TSUZUKI

(Received January 25, 1965)

The intramolecular hydrogen bonding in some cyanoalkanols in dilute carbon tetrachloride solutions was previously investigated by means of infrared measurements in the OH-stretching region near 3 $\mu$.[2,3] Acetaldehyde- and cyclohexanone-cyanohydrins show only one absorption band, at 3604 and 3594 $cm^{-1}$ respectively, the latters are lower by ca. 20 $cm^{-1}$ than those of the corresponding unsubstituted secondary and tertiary alcohols. Flett[2] suggested that the lowering in frequency is to be attributed to the electron-attracting effect of the cyano group and that the OH bands are, then, due to the free OH group. On the other hand, Allerhand and Schleyer[3] attributed the lowering in frequency to the formation of an internal

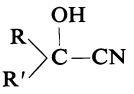
hydrogen bond of the OH group with the $\pi$-electrons of the cyano group; they based their suggestion on a comparison with the OH frequency (3620 $cm^{-1}$) of propargyl alcohol, which had been assigned to the OH group internally banded to the $\pi$-electrons of the triple bond.[4] However, the re-investigation of propargyl alcohol, which has recently been reported,[5] shows the frequency to be that of the free OH group. Thus, the basis for the assignment given for the cyanoalkanols by Allerhand and Schleyer has been lost. Accordingly, we must re-investigate to determine whether or not such $\alpha$-cyanoalkanols form intramolecular hydrogen bonding. This problem has now been solved through the infrared measurements of a series of $\alpha$-cyanoalkanols. Further, this paper will report on the limitation of intramolecular hydrogen bonding* through the length of an alkylene chain in the series of $\omega$-cyanoalkanols, $NC(CH_2)_nOH$.

## Experimental



$\alpha$-Cyanoalkanols were prepared from the corresponding aldehydes and ketones in the usual manner, while 4- and 10-cyanoalkanols were synthesized from the corresponding haloalkanols by reaction with potassium cyanide[6]; b. p. 130°C/14 mmHg ($n_D^{25}$ = 1.4371) and 178—179°C/8 mmHg. $\beta$-Cyanoethanol was commercially obtained and was fractionally distilled; b. p. 110°C/15 mmHg.

Infrared measurements in the OH-stretching region were carried out at 25°C with solutions of 0.004 mol./l. in carbon tetrachloride on a Perkin Elmer 21 spectrophotometer equipped with a lithium fluoride prism. The cell used was 3 cm. long, and the slit width was always 0.029 mm. The observed frequencies were calibrated on the standard of atmospheric vapor and within a range of error of $\pm 1$ $cm^{-1}$. At that concentration, there was observed, in addition to a strong absorption band near 3600 $cm^{-1}$, a very weak and broad bond at 3470—3490 $cm^{-1}$ which varied with the concentration; the latter is indicative of some intermolecular hydrogen bonding. The infrared data are summarized in Table I.

## Results and Discussion

The spectrum of cyclohexanone cyanohydrin (V) includes only one symmetric sharp band, at 3591 $cm^{-1}$, while the other $\alpha$-cyanoalkanols (I—IV) each show a band rather broadened on the higher frequency side. 4- and 10-cyanoalkanols (VIII and IX) each show a band somewhat broadened on the lower frequency side. The lack of symmetry of the bands may be produced by the overlap of symmetric bands of the Lorentz type, which should be assigned to the OH groups in the conformational isomers possible by rotation around the $C_\alpha$-O bond, as will be presented below. The symmetric bands can graphically be separated from the original unsymmetric band, e.g., as is shown in Fig. 1. $\beta$-Cyanoethanol (VI) apparently

Table I. Summary of infrared data

| Compound | R | R′ | $\nu_{OH}$ ($cm^{-1}$)* | log $I_0/I$ | $\Delta\nu_{1/2}$ |

shows partially-resolved doublet, with maxima at 3626 and 3612 cm$^{-1}$, whose frequencies agree with those previously reported by Flett,[2] but this doublet can not be separated into two symmetric bands which have maxima at the above frequencies and which by overlapping with each other can reproduce the doublet. However, it can be synthesized from the two symmetric bands whose maxima are at 3631 and 3610 cm$^{-1}$, as Fig. 2 shows. This separation seems to be rather reasonable as will be discussed below. The frequencies of the separated bands are summarized in Table I, but they are somewhat rough because of the graphical separation and the relatively poor resolving power of the spectrophotometer employed.

According to the infrared study by Ōki and Iwamura[7] of the rotational isomerism around the C-O bond in alcohols, a methyl group skew to the OH group has a steric effect serving to make the OH frequency lower by ca. 13 cm$^{-1}$, as is shown in Table II.

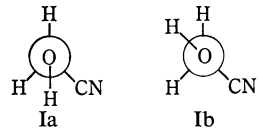

TABLE II. THE ROTATIONAL ISOMERS OF ALCOHOLS AND THEIR OH FREQUENCIES

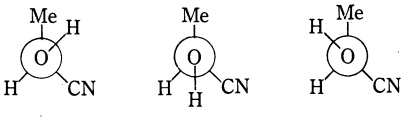
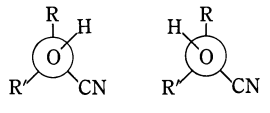
| | (A) | (B) | (C) |
|---|---|---|---|
| $\nu_{OH}$ cm$^{-1}$ | 3617 | 3627 | 3640 |

R : H or alkyl.



In consideration of the above assignments, the lower and the higher frequency band of cyanomethanol (I) should be assigned to the OH groups of Ia and Ib respectively.



3610 cm$^{-1}$ 3623 cm$^{-1}$ $\Delta\nu$ : 13 cm$^{-1}$

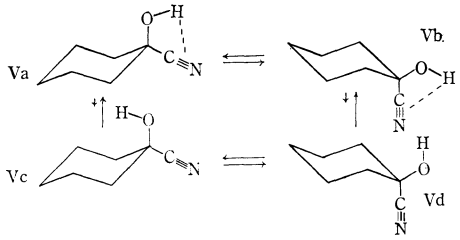
The shift of the higher frequency band by 17 cm$^{-1}$ from that of the corresponding rotational isomer (C) of ethanol, may be attributed to the electron-attracting effect of the cyano group; this is also true with the other α-cyanoalkanols, but the shifts is drastically decreased by the intervention of a methylene group, as may be seen in β-cyanoethanol (VI), whose free OH frequency is 3631 cm$^{-1}$. Although the separation between the two bands, $\Delta\nu$, is only 13 cm$^{-1}$, equal to that in the case of ethanol, the OH grop in Ia interacts with the π-electrons of the cyano group, because its absorption intensity is very high with respect to that of the OH in Ib.

Similarly, the follwing assignment may be given for the other α-cyanoalkanols (II—V):

For II 3604 cm$^{-1}$ ca. 3615 cm$^{-1}$ $\Delta\nu$ : 11 cm$^{-1}$

For III and IV 3599 cm$^{-1}$ ca. 3607 cm$^{-1}$ $\Delta\nu$ : 8 cm$^{-1}$

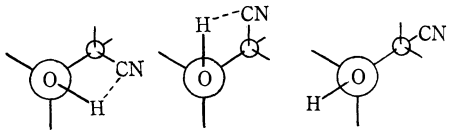
For V 3591 —



The difference in frequency between Ib and IIc, 8 cm$^{-1}$, may result from the steric effect of the methyl group.

In the case of compound II, the 3604 cm$^{-1}$ of the symmetric, interacted OH band lies just between the OH frequencies of forms Ia and IIIa. This compound can take two interacted forms, IIa and IIb, which correspond to forms IIIa and Ia respectively. Accordingly, one may say that the OH frequencies of forms IIa and IIb are close to 3604 cm$^{-1}$, that the major component of the band is due to the OH group

7) M. Ōki and H. Iwamura, This Bulletin, 32, 950 (1959). The same assignments were also reported by F. Dalton, G. D. Meakins, J. H. Robinson and W. Zaharia, *J. Chem. Soc.*, **1962**, 1566.



in form IIb, and that its minor component is due to the OH in form IIa, since form IIb should be thermodynamically more stable than form IIa.

The OH band of cyclohexanone cyanohydrin (V) is symmetric, as has been mentioned above; this indicates that all the molecules substantially exist in at least one of the interacted forms, Va or Vb:

Form Vc may be negligible because the axial hydrogens on $C_3$ and $C_5$ sterically repel the hydroxyl-hydrogen atom, thus directing it towards the cyano group, and form Vd is less stable than Vb because, similarly, the latter is possibly more stabilized through the interaction between the OH group and the $\pi$-electrons of the cyano group. Let us now consider which of the forms, Va or Vb, is more stable. The difference in free energy between the equatorial and the axial OH group is 0.4—0.9 kcal./mol.,[8] which is higher than the value of 0.15—0.25 kcal./mol. for the cyano group.[9] The difference between the respective, averaged values, 0.45 kcal./mol., corresponds to a $K$ value of 2.1 in the van't Hoff isotherm: $\Delta G^\circ = -RT \ln K$. This means that the number of molecules taking form Vb is larger by a factor of roughly 2.1 than that taking form Va. Further, the symmetric shape of the band can be confirmed from this population of molecules and by the fact that the difference in frequency between axial and equatorial tertiary OH groups is generally 6 $cm^{-1}$ at most.[10] That the frequency of this compound is lower by 8 $cm^{-1}$ than those of compound III and IV may be explained in terms of the *gem*-dialkyl effect,[11] by which the O-$C_\alpha$-CN bond angle is decreased, thus bringing the OH and the cyano group closer together.

For $\beta$-cyanoethanol (VI), one may consider nine rotational isomers to be possible by rotation around the single bonds: three (the number of rotational isomers around the $C_\alpha$-O bond) times three (the number of rotational isomers around the $C_\alpha$-$C_\beta$ bond). Eight of these form four pairs of mirror images, and only one pair of VIa and VIb are those favorable for intramolecular interaction. Since forms VIa and VIb contain, in addition to the methyl effect, interaction between the OH and the $\beta$-cyano group, the interacted OH frequency will be lower than the 3627 $cm^{-1}$ of the above-mentioned ethanol B. On the other hand, form VIc may be the least strained conformation of those free from interaction. Thus the OH frequency will be near the 3640 $cm^{-1}$ of ethanol C. The observed frequencies of 3610 and 3631 $cm^{-1}$ are in accordance with those expected and are rather more reasonable values than those of the apparent peaks (3612 and 6326 $cm^{-1}$). The interacted OH frequency of 3617 $cm^{-1}$ reported by Allerhand and Schleyer might be incorrect because the frequency was that of the shoulder of band.

Compounds VIII and IX are free from intramolecular interaction. The bands at 3622 and 3637 $cm^{-1}$ may be due to the free OH groups in the rotational isomers formed by rotation around the $C_\alpha$-O bond, such as forms B and C of ethanol respectively. The absence of interaction may be due to the formation of a larger ring through interaction being thermodynamically more difficult.

From the above findings, it may be concluded that the OH group in the $\alpha$-cyanoalkanols interacts with the $\pi$-electrons of the cyano group, and that the interaction in the series of $NC(CH_2)_n$-OH occur when $n$ is 1 or 2, as has previously been reported[3].

The authors wish to express their gratitude to Professor Dr. Michinori Ōki of the University of Tokyo for his kind advice and suggestions concerning the OH-$\pi$ interaction, and to Mr. Teruo Kajiura and Mr. Tadao Tamura of the Government Chemical Industrial Research Institute of Tokyo for their infrared measurements.

# Intramolecular Hydrogen Bonds. IV.[1] Phenylalkane-diols

By Nobuo Mori, Satoshi Ōmura* and Yojiro Tsuzuki

(Received January 25, 1965)

The present investigation is concerned with intramolecular hydrogen bonding in the systems of poly-functional compounds in which one or more proton-donating groups can form a hydrogen bond with a few proton-accepting groups. Such systems are complicated because various types of intramolecular hydrogen bonding may simultaneously appear, depending on the thermodynamical stability of the geometries to be formed through the intramolecular hydrogen bonding between the groups. Of such compounds, some phenylalkane-diols, such as diaryl pinacols[2] and phenylcycloalkane-diols,[3] have recently been investigated by means of infrared spectroscopy in the OH-stretching region.

This paper will deal with intramolecular hydrogen bonding in phenyl-$\alpha,\omega$-alkane-diols and with its limitation through the length of an alkylene chain intervening between the hydroxyl groups.

Intramolecular hydrogen bonding occurs in $\alpha,\omega$-alkane-diols HO-$(CH_2)_n$-OH and in $\omega$-phenylalkanols Ph-$(CH_2)_n$-OH when $n$ is an integer of from 2 to 4* in the former[5,6] and from 1 to 2 in the latter.[7,8] As $n$ increases, the separation between the free and the bonded OH band ($\Delta\nu$) increases from 32 through 78 to 156 $cm^{-1}$ in the former[5] and from 17 to 30 $cm^{-1}$ in the latter.[8] Moreover, the intensity ratio of the free OH band to the bonded OH generally grows with the increasing $n$.

In consideration of these facts, it is to be expected, in the present series of Ph-CHOH-$(CH_2)_n$-OH, that the primary alcoholic hydroxyl group will predominantly form a hydrogen bond with both the secondary hydroxyl group and the $\pi$-electrons of the phenyl group when $n$ is equal to 1, and with only the former when $n$ is 2 or 3. However, it forms a hydrogen bond with neither of them when $n$ is 4. At the same time, the secondary hydroxyl group may be expected to form a hydrogen bond with both the proton-accepting groups when $n$ is an interger of from 1 to 3, but with the $\pi$-electrons only when $n$ is 4.

In this paper, the free OH group is that OH which contains an unbonded H atom, i.e., which includes an OH group not participating in any hydrogen bond and an OH group whose oxygen atom hydrogen-bonds to the hydrogen of another OH. The bonding of the oxygen atom of a free OH group to the hydrogen of another OH group has, in general, little effect upon the frequency of the free OH group.[5,10] Accordingly, the following discussion and assignments will be made mainly on the basis of the frequencies and the intensities of the bonded OH bands, with some

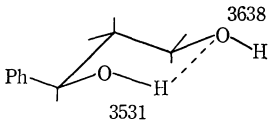
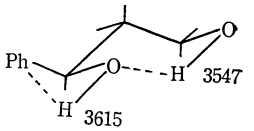
consideration also of those of the free OH bands.



The spectrum of phenylethane-1,2-diol (I) contains a partially resolved doublet with maxma at 3624 and 3600 $cm^{-1}$; this doublet can graphically be separated into two symmetric components, as is shown in Fig. 1, which can reproduce almost the same doublet as the original one by overlapping with each other. The former frequency accords with the free $\nu_{OH}$ of 3627 $cm^{-1}$ of $\alpha$-phenylethanol,[8] and the latter, with the bonded $\nu_{OH}$ of ca. 3605 $cm^{-1}$ of $\beta$-phenylethanol.[7,8,11] Consequently, diol I may predominantly take form Ia rather than form Ib:



Ia Ib

The secondary OH group in Ia is completely free, but in Ib it is hydrogen-bonded with the primary one. Form Ib may be absent because this diol shows no OH band near 3550 $cm^{-1}$, at which point *cis*-1-phenylcyclohexane-1,2-diol containing a hydrogen-bonded conformation similar to form Ib shows a strong band due to the tertiary OH group bonded to the secondary OH.[3a] Also, the diol may be free from hydrogen bonding between the secondary OH group and the $\pi$-electrons because there is no absorption band near 3616 $cm^{-1}$, at which point $\alpha$-phenylethanol shows a bonded OH band.[8]

1-Phenylpropane-1,3-diol (II) shows two unsymmetric bands at 3615 and 3547 $cm^{-1}$, the former having a shoulder on the higher frequency side and the latter, a shoulder on the lower frequency side. Therefore, the bands can be resolved into four substantially symmetric components by graphical separation, as is shown in Fig. 2. The bands at 3638 and 3531 $cm^{-1}$ may be assigned to the free and the bonded OH group, as in IIa, and similarly, the other pair of 3615 and 3547 $cm^{-1}$, to the bonded OH groups, as in IIb.

IIa

IIb

The separation between the primary OH bands is 91 $cm^{-1}$, but for the secondary OH bands it is 84 $cm^{-1}$. In the latter case, however, it is increased to a reasonable value of 93 $cm^{-1}$ by replacing the bonded secondary OH frequency in IIb by the free one of 3624 $cm^{-1}$ of compound I.

1-Phenylbutane-1,4-diol (III) similarly shows two unsymmetric bands, with peaks at 3614 and 3452 $cm^{-1}$, which have shoulders at about 3636 and 3473 $cm^{-1}$ respectively, as Fig. 3 shows. The former band could graphically be separated into two components, whose maxima are at 3636 and 3614 $cm^{-1}$, but the latter band was difficult to divide into components and the apparent shoulder was taken to be the peak of the additional unresolved components. As is shown in forms IIIa and IIIb, these bands may, respectively, be assigned to the free

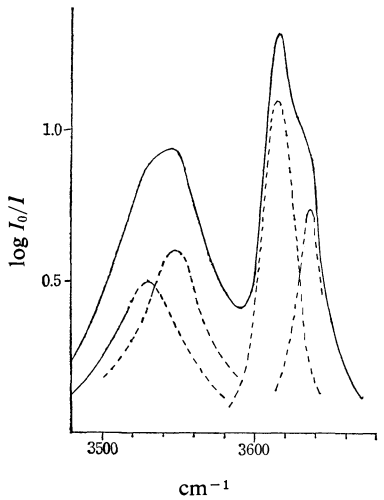


Fig. 2. IR spectrum of 1-phenylpropane-1,3-diol (II).

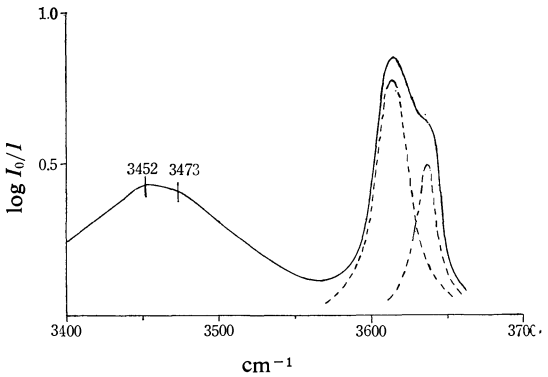

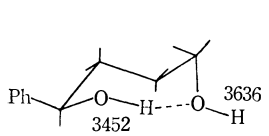

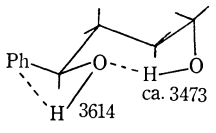

Fig. 3. IR spectrum of 1-phenylbutane-1,4-diol (III).

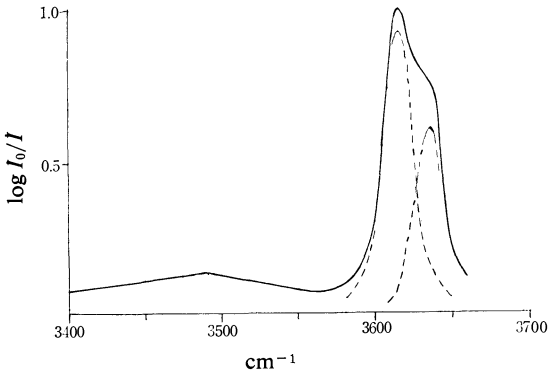
11) F. Dalton, *J. Chem. Soc.*, **1962**, 1566.

primary OH group, the secondary OH bonded to the $\pi$-electrons, the primary OH bonded to the secondary OH, and the secondary OH bonded to the primary OH.

IIIa

IIIb

1-Phenylpentane-1, 5-diol (IV) shows a strong band at 3615 $cm^{-1}$ and a very weak, broad band at about 3491 $cm^{-1}$. The former has a shoulder on the higher frequency side and can be separated into two symmetric bands, at 3636 and 3615 $cm^{-1}$, which may be due to the free primary OH group and the secondary OH bonded to the $\pi$-electrons respectively. Since the absorbance of the free primary OH band is lower than that of the secondary OH band, the weak band is probably due to the primary OH group whose H atom hydrogen-bonds with the oxygen of the bonded secondary OH group, in spite of the fact that the phenyl group makes the secondary OH group more acidic than the primary OH.[3a] 5-Methoxypentanol shows a weak, broad band due to the internally bonded OH group at 3501 $cm^{-1}$.[6]



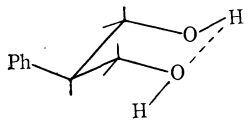


Fig. 4. IR spectrum of 1-phenylpentane-1, 5-diol (IV).

2-Phenylpropane-1, 3-diol (V) shows two almost symmetric bands at 3634 and 3553 $cm^{-1}$, which accord with those of 2-alkylpropane-1, 3-diols.[12] The following internally-bonded form Va may be the most favorable for this compound:

Va

12) P. von R. Schleyer, *J. Am. Chem. Soc.*, **83**, 1368 (1961).

The phenylalkane-diols will also contain a certain proportion of molecules in which both the OH groups are free and/or one of them is free and the other forms a hydrogen bond with the phenyl group; this proportion may not be significantly high in the case of diols other than I and IV.

TABLE I. SUMMARY OF INFRARED DATA FOR Ph-CHOH-$(CH_2)_n$-OH

| Compound | $n$ | $\nu_{OH}$, $cm^{-1}$ | log $I_0/I$ | $\Delta\nu_{1/2}$ |
|---|---|---|---|---|
| I | 1 | 3624 | 0.60 | 35 |
| | | 3600 | 0.52 | 46 |
| II | 2 | 3638 | 0.74 | 25 |

| | | 3553 | 0.12 | 24 |

## Experimental

Compound I was prepared from styrene by the method described in the literature.[13] Compounds II and V were synthesized in the usual way by the hydrogenolysis of ethyl $\beta$-phenyl-$\beta$-hydroxypropionate[14] and diethyl phenylmalonate[15] with lithium aluminum hydride, while compounds III and IV were similarly prepared from the ethyl esters of $\omega$-benzoyl-propionic and -butyric acid[16] and recrystallized from ether. Their properties and data of analysis are shown in Table II.

TABLE II

| Compound | M. p., °C (B. p., °C/mmHg) | Calcd. C | Calcd. H | Found C | Found H |
|---|---|---|---|---|---|
| I | 65—66[13] | | | | |
| II | (152/5[17]) $n_D^{25}=1.4528$ | | | | |
| III | 75 (155/2) | For $C_{10}H_{14}O_2$ 72.26 | 8.49 | 72.53 | 8.78 |

# A Study of the Growth of Particles in Silica Sol and Hydrogel as a Factor Determining the Final Structure of Silica Gel

By Hiroshi OTOUMA and Hiroshi UKIHASHI

(Received February 2, 1965)

Many investigations have been made of the polymerization of silicic acid. However, few studies have been undertaken of the systems with relatively high concentrations and of the changes in the turbidity of the silicic acid sol in relation to the growth of the ultimate particles comprising the sol after its gelation.

The purpose of the present work is to gain new information, by the light scattering method, about the growth of particles at a relatively high concentration of silicic acid before and after the gelation of its sol, which is prepared by adding sodium silicate solutions to sulfuric acid; we also eventually hope to find some relationship with the final structure of dried silica gel.

In the sol state the changes in particle size with time was indirectly determined by the weight-average molecular weights obtained by the dilution method. After gelation, the dissymmetry, which is especially related to the size of the large particles, and the turbidity were measured at frequent intervals in pursuit of the growth of primary particles and the state of their aggregation. The surface area of dried gel was measured in seeking its relationship with the size of the primary particles as determined by light scattering. The light scattering behavior of the sol and hydrogel will be consistently discussed in connection with the growth of the primary and secondary produced particles by aggregation.

## Experimental

**The Preparation of the Silica Sol and the Gel.**—Samples with various pH values were prepared by controlling the addition of sodium silicate solutions ($SiO_2 : Na_2O = 3.22$) to sulfuric acid. The concentrations and other experimental conditions are listed in Table I. The sodium silicate solutions, sulfuric acid and sols prepared were purified by the use of glass filters (No. 4 and No. 5) and a solvent filtration apparatus. The sols which were used for determination of the particle size were filtered with great care. The turbidity of the distilled water used in the dilution was below $5 \times 10^{-5}$ $cm^{-1}$. Silica hydrosol changed into hydrogel after a definite time. Both the sols and the hydrogels were always kept at 30°C in a thermostat except when measurements were being made.

**Light Scattering Measurement and Equipment.**—Light scattering measurements were made on a Shimadzu Photoelectric Light-Scattering Photometer Model-21 type, with a green light (546 m$\mu$). The turbidity was evaluated against the incident beam from the scattering intensity at a direction of 90 degrees. The calibration of the turbidity was made by using a glass block. In the sol state small portions of samples, immediately after being taken up at definite intervals after their formation, were diluted to a concentration of $10^{-3}$ g./ml. in distilled water maintained at 30°C, then they were measured.

By using Eq. 1,[1] the weight-averge molecular weight, $\overline{M}_w$, was determined from the reciprocal of the intercept on the $Hc/\tau$ axis. Particle sizes were obtained by assuming the spheres to have the uniform density 2.2 g./cm$^3$.[2]

$$\frac{Hc}{\tau} = \frac{1}{\overline{M}_w} + Ac \qquad (1)$$

$\lambda$: the wavelength of the light in vacuum
$n_0$: the refractive index of the solvent
$\frac{dn}{dc}$: the refractive index increment

$\frac{dn}{dc}=0.151$ (determined by the differential refractometery)

After gelation, the change in the dissymmetry Z, the ratio of the intensity of the scattered light at 45° to that at 135°, was sought together with the intensity of the scattered light at 90°. For the measurement of the surface area, parts of the hydrogel were taken out at appropriate intervals after gelation and then repeatedly washed and dried at 200°C for 2 hr. Surface area was determined after calcination at 540°C for 4 hr. by the BET method.

## Results and Discussion

Figure 1 shows the variation, with time, of the particle diameters in the sol state as calculated from the weight-average molecular weights.

The variation in the intensity of scattered light, and that in the dissymmetry, with the time elapsed after gelation are shown in Fig. 2 and Fig. 3 respectively. The curves of the scattering intensity are of the sigmoid type, with a maximum slope immediately after gelation. An almost constant value (not shown in Fig. 2) was reached in every case after a long period. In the curves in Fig. 3, on the other hand, the dissymmetry increases rapidly near the gelation point and finally reaches a constant value after only about two hours. The relations between the increase in the scattering intensity and the decrease in the surface area are shown in Fig. 4.

The experimental data on the changes in particle diameters in the sol state indicate

that it is likely that the following changes are likely when sodium silicate solutions are added to sulfuric acid.

First of all, particles with diameters of about 10—20Å rapidly appear in the mixture, as is estimated from Fig. 1, where three curves extrapolated to time zero intercept the coordinate at about 10—20Å, though their exact values in the initial stage could not be obtained because of the undue light scattering caused by impurities. The rapid growth of particles at the start, as seen in the results of sample IV (Fig. 5a), has also been predicted by Greenberg's[3] and Debye's[4] experiments. As Fig. 5a shows the large dissymmetry at $t=0$ is possibly due to impurities included rapidly decreased during the initial one hundred minutes, and then slowly increased with the growth of the particles, until gelation is completed ten days after. The interpretation of the rapid decrease in the dissymmetry in the initial stage would be: the light scattering arising from rapidly-growing particles after mixing surpassed that of impurities. Therefore, the decreased dissymmetry observed after one hundred minutes or so was due largely to the particles thus grown; these, however, were not so large as to make the dissymmetry deviate greatly from unity, so a value of around unity was obtained. Thus, the rapid decrease in the dissymmetry gives evidence of the rapid growth of particles at the start.

Greenberg obtained the particle diameter, at $t=0$, of approximately 200Å from his dissymmetry measurements. A similar observation has been reported elsewhere.[4]

In view of these facts, it may be concluded that the rapid growth occurred soon after mixing.

In the initial stage, as has been mentioned in the literature,[4] the association of particles seems to occur to a minor extent. According to Greenberg's experiment, the diameter of the particles at zero time is approximately 200Å. We, however, obtained the corresponding value of 10—20Å. This marked discrepancy can only be ascribed to the association-dissociation process, in which particles of 10—20Å are very weakly bounded together to form associated particles in a "highly solvated state"[3] and in which, upon progressive dilution, the aggregates dissociate into smaller particles 10—20Å in diameter.

This is also suggested by the negative value of $A$ (a constant in Eq. 1) being obtained only in the initial stage.

In the final stage, in turn, bonds between primary particles became stronger to such an extent that aggregates no longer dissociated into components upon dilution. This would be the reason why the particle size obtained in the final stage (Fig. 1) was substantially larger than that (only 40—45Å) which could be presumed from the BET surface area of dried gel[2] (Fig. 4). In this connection the data on sample IV are very interesting, in this

3) S. A. Greenberg and D. Sinclair, *J. Phys. Chem.*, **59**, 435 (1955).
4) P. Debye and R. V. Nauman, ibid., **65**, 10 (1961).

case the change in particles size was followed by the measurements of the dissymmetry. A particle size of approximately 1200Å before gelation is shown in Fig. 6. Dried gel after gelation, however, shows a surface area of 274 $m^2/g.$, which may indicate a primary particle only 110Å in diameter.[2)]

These observations suggest that, in the final stage of the sol, not only the continued growth of ultimate particles but also association and partial gelation occur.

So far discussions have been made on primary and secondary particles and their growth in the sol state. Our further remarks will be centered upon the continued polymerization, resulting in the growth of primary particles, and upon the continued aggregation in the gel state.

Although the value of the dissymmetry and the scattering intensity are measures of the growth of particles, their behaviors with time in the same sample are markedly different from each other (Figs. 2 and 3). A possible explanation may be based on the fact that the increase in dissymmetry shows an increase in the size of secondary particles and that gel is built up as a result of three-dimensional linkages of such secondary particles. Though hydrogel is seemingly of a solid state at the gelation point, the networks are not completed. It takes still more time for the gel to form a complete network. Therefore, the time would be shown by the point of constant dissymmetry, when the net works are finished, since the aggregation accompanies gelation. The final diameter of the secondary particles in this experiment may be of the order of 800Å as calculated from the final dissymmetry uncorrected for concentrations.

A slight fall in the dissymmetry observed after a long time would be the result of a decrease in the size of secondary particles by dehydration condensation.

The change in scattering intensity is, on the other hand, due not only to the growth of primary particles but also to that of secondary particles. The increase in the earlier parts of the curves is probably due to the light scattering from secondary particles. While the dissymmetry reached a constant about two hours after gelation, the intensity of the scattered light continuously increased. Accordingly, the growth in the size of secondary particles would stop at the time given above. The fact that the intensity of scattered light exhibits a continuous increase furnishes evidence of the continued growth of primary particles as a result of the reaction of primary particles with the silicate ions remaining unreacted in gel. This reaction or polymerization certainly accompanies the change in the weight of secondary particle, but it does not accompany the change in size.

A series of surface area measurements of samples after gelation elucidated the light scattering behavior in connection with the internal change in the gel. The increase in the scattering intensity was clearly shown to be accompanied by an increase in the size of primary particles as determined from the surface area measurement. Accordingly, a decrease in the surface area will be related to an increase in the intensity of light scattering.

Although it seemed difficult to obtain a priori the relationship from the light scattering data because of the effects of secondary particles in gel and of the relatively high concentrations, resulting in interference between particles, nevertheless the following equation was derived from the straight line shown in Fig. 4 within a limited pH range:

$$S=690-21.5\cdot(I_{90}/I_0\times10^{-2})$$

where $S$ is the surface area in $m^2/g.$

## Summary

The growth of particles in the polymerization of silicic acid has been investigated by means of light scattering. The following results were obtained:

1) Polymerization does occur for a long period, even after gelation.

2) While the aggregation is predominant near the gelation point, it seems to occur to a lesser extent even in the initial stage. The aggregate finally grows to as much as 800Å in diameter. It is of a porous and sponge-like structure, including the solvent in it.

3) Hydrogel must be understood as an entity built up of secondary particles which also consist of primary ones. Consequently, hydrogel has prime structure and a substructure, by the former three-dimensional linkages among secondary particles are meant, while by the latter are meant those among primary particles.

4) There is a linear relationship between the scattering intensity of the hydrogel and the surface area of dried gel.

# Semi-empirical Self-consistent Field Molecular Orbital Calculation of the Electronic Structure of the Base Components of Nucleic Acids

By Chikayoshi NAGATA, Akira IMAMURA, Yusaku TAGASHIRA and Masahiko KODAMA

(Received February 2, 1965)

Investigations of the $\pi$-electronic structure of such base components as adenine, guanine, cytosine, thymine and uracil are of importance in connection with the biological activities of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). Pullman[1] and Ladik[2] have calculated the $\pi$-electronic structures of base components by means of the Hückel MO method, and have compared them with experimental results; various kinds of physicochemical properties of bases and nucleic acids, such as the relative stability of the base paring or the base tautomers, the positions of attack in the hydration of pyrimidine bases, etc., have been well explained. However, in the Hückel MO method an ambiguity in choosing the parameters cannot be avoided, and, furthermore, the method has failed to explain such optical properties of the bases as the absorption wavelength and the oscillator strength. That is, as was pointed out by Ladik,[2] the calculated wavelengths are larger than the experimental results by 150 m$\mu$ or more (cf. Table II).

In view of this disagreement between the theories and experiments with absorption spectra, calculation by means of the SCF MO method may be valuable since the iterative procedure in this method is known to eliminate the parameter dependence. Veillard and Pullman[3] have carried out semi-empirical SCF MO calculations on the bases and the base analogs, but they have not attempted to explain such optical properties of bases as their absorption wavelengths and their oscillator strengths. Recently Nesbet[4] has calculated the wavelengths and oscillator strengths for adenine, guanine, cytosine and thymine and also for the base-pair, but no attempt to explain the direction of polarization has been made. Furthermore, in Veillard's treatment, no SCF MO calculations on the thymine molecule were carried out, and Nesbet has calculated the electronic structure of thymine by neglecting the methyl group. They did this bacause of the difficulty of estimating the energy of the valence state and the repulsion integral for the methyl group. The present authors have attempted in this paper to compare the calculated wavelengths, oscillator strengths and directions of polarization with the experimental results for adenine, guanine, cytosine, thymine, uracil, 9-methyladenine and 1-methylthymine. In the estimation of two-center repulsion integral, two alternative methods have been used, the Pariser-Parr[5] and Mataga-Nishimoto approximations.[6] Veillard and Pullman[3] used the former method, and Nesbet,[4] the latter. In our calculation, both these methods of approximation have been used and have been compared.

## Calculation Procedure

In the calculation, only $\pi$-electrons have been taken into account explicitly. The Hamiltonian of the system is written in this form:

$$H=\sum_{\mu}\left\{-\frac{\hbar^2}{2m}\Delta_{\mu}+V(\mu)\right\}+\sum_{\mu>\nu}\frac{e^2}{r_{\mu\nu}} \tag{1}$$

and the molecular orbitals have been formed by a linear combination of atomic orbitals:

$$\varphi_j=\sum_{r} C_{jr}\chi_r \tag{2}$$

Then, the energies and coefficients have been determined by solving the secular equation;

$$\begin{vmatrix} F_{11}-E & F_{12}\cdots\cdots & F_{1m} \\ F_{21} & F_{22}-E\cdots\cdots & F_{2m} \\ \cdots\cdots & \cdots\cdots & \\ \cdots\cdots & \cdots\cdots & \\ F_{m1} & F_{m2}\cdots\cdots & F_{mm}-E \end{vmatrix}=0 \tag{3}$$

where

$$F_{rr}=\alpha_r+\sum_{t}^{m}P_{tt}(rr\,|\,tt)-\frac{1}{2}P_{rr}(rr\,|\,rr) \tag{4}$$

$$F_{rs}=\beta_{rs}-\frac{1}{2}P_{rs}(rr\,|\,ss) \tag{5}$$

with

$$\alpha_r=\int\chi_r(1)\Big(-\frac{\hbar^2}{2m}\Delta_1+V(1)\Big)\chi_r(1)\mathrm{d}\tau_1$$
$$=\int\chi_r(1)\Big(-\frac{\hbar^2}{2m}\Delta_1+U_r(1)\Big)\chi_r(1)\mathrm{d}\tau_1$$
$$+\sum_{s\neq r}\int\left[\chi_r(1)\left\{U_s^0(1)-\int\frac{\chi_s^2(2)e^2}{r_{12}}\mathrm{d}\tau_2\right\}\right]\times$$
$$\chi_r(1)\mathrm{d}\tau_1\fallingdotseq W_{2p}-\sum_{s\neq r}\{(s:rr)+(rr\,|\,ss)\} \tag{6}$$

$$\beta_{rs}=\int\chi_r(1)\Big(-\frac{\hbar^2}{2m}\Delta_1+V(1)\Big)\chi_s(1)\mathrm{d}\tau_1 \tag{7}$$

and

$$(rr\,|\,ss)=\iint\chi_r(1)\chi_r(1)\frac{e^2}{r_{12}}\chi_s(2)\chi_s(2)\mathrm{d}\tau_1\mathrm{d}\tau_2 \tag{8}$$

In Eq. 6, the Coulomb penetration integral $(s:rr)$ is neglected, as usual. $W_{2p}$ is taken as equal to $-I$; $I$ is the ionization potential of the atomic valence state. One-center repulsion integral $(rr\,|\,rr)$ is usually estimated as $I$-$A$, where $A$ is the electron affinity. In our calculation the values of $I$ and $A$ have been taken from the paper of Hinze and Jaffé.[7] As was stated above, two alternative ways of estimating the two center repulsion integral have been used; the Pariser-Parr and Mataga-Nishimoto approximations. In the former method, the following equations are used: at the $R\leqq 2.8$ Å distances;

$$(rr\,|\,ss)=1/2\{(rr\,|\,rr)+(ss\,|\,ss)\}+aR+bR^2 \tag{9}$$

and at $R>2.8$ Å:

$$(rr\,|\,ss)=7.1975(1/\sqrt{R^2+1/4(R_r+R_s)^2}$$
$$+1/\sqrt{R^2+1/4(R_r-R_s)^2}) \tag{10}$$
$$R_r=(4.597/Z^*)\times10^{-8}\,\mathrm{cm}.$$

where $R$ is the internuclear distance, and $a$ and $b$ are parameters determined from Eq. 10 when $R$ is equal to 2.8 Å and 3.7 Å respectively. $Z^*$ is the effective nuclear charge.

In the case of the Mataga-Nishimoto approximation, the following relation is used:

$$(rr\,|\,ss)=e^2/(R_{rs}+a_{rs}) \tag{11}$$

The constant, $a_{rs}$ is determined by using the relation:

$$(rr\,|\,rr)=14.39/a=I_r-A_r \tag{12}$$

For the case of two-heteronuclear centers, i.e. carbon and nitrogen, the value of $a$ is taken as the harmonic mean of $a_C$ and $a_N$.

The above two methods of approximation have been used in our calculations, and their results have been compared with each other and also with the experimental results.

Several ways of evaluating the values of $\beta_{rs}$ have been proposed[4,5,8]; Pariser-Parr's method, which determins $\beta_{rs}$ from the spectroscopic data for only the nearest neighbor atomic orbitals, has especially been used. However, we used the following relation:

$$\beta_{rs}=lS_{rs} \tag{13}$$

where $S_{rs}$ is the overlap integral between the $r$th $\pi$-atomic orbital and $s$th one, and $l$ is a parameter, which was determined as $-12.65$ from the mean of the following values:

$\beta_{CO}=-2.70$ eV. $S_{CO}=0.2063$

$\beta_{CN}=-2.39$ eV. $S_{CN}=0.1957$

Moreover, in our calculation, $\beta_{rs}$ was taken into account not only for the nearest neighbors but also for all pairs of $r$ and $s$.

The oscillator strengths of the transitions from the ground state to the excited states have been calculated by using the following equation;

$$f=1.085\times10^{-5}\,\sigma_{ob}\,\boldsymbol{m}_{ob}^2 \tag{14}$$

where $\sigma_{ob}$ is the wave number of the transition from the ground state to the excited state $b$. $\boldsymbol{m}_{ob}$ in Eq. 14 is given by:

$$\boldsymbol{m}_{ob}=\int\Psi_{ob}\sum_i\boldsymbol{r}_i\,\Psi_b\,\mathrm{d}\tau \tag{15}$$

in which $\Psi_o$ and $\Psi_b$ are the wave functions of the ground and excited states respectively, and $\boldsymbol{r}_i$ is the position coordinate of the $i$th electron.

## Choice of Parameters

Values of $W_{2p}$ and $(rr\,|\,rr)$ semi-empirically evaluated are tabulated in Table I.

Table I. Semi-empirically evaluated values of $W_{2p}$ and $(rr|rr)$

| $r$ | $W_{2p}$ | $(rr\|rr)$ |
|---|---|---|
| C | −11.16 | 11.13 |
| O | −17.28 | 15.27 |
| N(azo) | −14.12 | 12.34 |
| N(amino) | −28.53 | 16.57 |
| OH | −34.75 | 21.18 |
| $H_3$* | −10.256 | 9.326 |

* Hyperconjugation in the methyl group is taken into account, and the group orbital of $H_3$ is assumed to overlap with $\pi$-orbitals.

The values of $W_{2p}$ and $(rr\,|\,rr)$ for the carbon, oxygen and azo-nitrogen are taken from the paper of Hinze and Jaffé.[7] It is difficult to

7) J. Hinze and H. H. Jaffé, *J. Am. Chem. Soc.*, **84**, 540 (1962).
8) G. Leroy, *J. chim. phys.*, **60**, 1270 (1963).

choose the values of $W_{2p}$ for such atoms as amino-nitrogen, which contribute two electrons to the $\pi$-system; many different values for this atom have been adopted by different authors.[3,9-11] In the present paper, we have adopted the value of $-28.526$ eV. for the $W_{2p}$ of amino-nitrogen (that is, $N^+(t_r t_r t_r, \pi) \rightarrow N^{++}(t_r t_r t_r)$) from the following relations:

$$N^+(s^2p^2) \rightarrow N^+(t_r t_r t_r, \pi) \quad 9.814 \text{ eV.}$$

$$N^+(s^2p^2) \rightarrow N^{++}(s^2p) \quad 29.41 \text{ eV.}$$

$$N^{++}(s^2p) \rightarrow N^{++}(t_r t_r t_r) \quad 8.930 \text{ eV.}$$

Similarly, the values of $W_{2p}$ and $(rr|rr)$ for the quasi-$\pi$ orbital of $H_3$ in the methyl group are difficult to evaluate semi-empirically, therefore, no calculation has ever been carried out for thymine and its analogs. The values adopted in our calculation are presented in Table I; the values have been determined by Morita for the SCF MO calculation of the benzenium ion by taking hyperconjugation into account.[12] By using these values, he has successfully explained the experimental results of the absorption spectra of the benzenium ion.

The values of the interatomic distances for adenine, guanine, cytosine and thymine are taken from the paper of Spencer,[13] while the values for uracil are taken from Wyckoff's table.[14] For such methylderivatives as 1-methylthymine and 9-methyladenine, the data for their parent molecules, i. e., thymine and adenine are used except for the distance of the N-$CH_3$ bond. The value for this N-C distance is tentatively taken as 1.46 Å, which is the distance between the carbon and the nitrogen in $CH_3NH_2$ molecules.

All the calculations in this paper have been carried out on the NEAC 2101 electronic computer in this Institute.

## Results and Discussion

**Wavelength and Oscillator Strength.** — The results of the calculation of the transition energies and oscillator strengths for adenine, guanine, thymine, cytosine and uracil are presented in Table II in comparison with the experimental values. The experimental data of the absorption spectra have been given by Beaven et al.[15] For the sake of comparison, the values obtained in the Hückel MO method, taken from the paper of Ladik,[2] are also indicated. It may clearly be seen that the SCF MO treatment improves the results strikingly and that the agreement between the theoretical results and experiments is satisfactory, especially for adenine and cytosine. That is, if the 6→7 transition of adenine and 5→6 transition of cytosine are assigned to the first bands of these molecules respectively, the calculated wavelengths coincide with experimental values within the limits of 15—20 Å. Agreements between the theory and experiment for these transitions are very good also for the values of the oscillator strengths.

The calculated wavelength for thymine is shorter than the experimental value by about 60 m$\mu$ in the case of the Pariser-Parr approximation. This is the largest discrepancy between theory and experiment among the bases calculated in this paper. First of all, an inappropriate choice of the semi-empirical parameter for the methyl group was deemed the cause of this large discrepancy. Therefore, calculation has been carried out for demethylated thymine, and the wavelength of 198 m$\mu$ has been obtained. This result shows that the cause of the disagreement for thymine is not in the unsuitable choice of the parameter of methyl group. In general, it is known that the agreement between the calculated and experimental wavelengths for the compounds which contain two oxygens is not very good for other compounds. Thus, the calculated wavelength for parabenzoquinone gave a value 50 m$\mu$ shorter than the experimental value.[16] Many attempts have been made to improve the theoretical results by changing the values of the semi-empirical parameters, but no remarkable improvement has been achieved.[16,17] It may be expected that the theoretical wavelength for thymine can be improved in connection with these compounds.

The wavelengths and oscillator strengths for the transitions other than the maximum wavelength have been calculated; they are indicated in Table II, together with the observed values. From a comparison of these values, the following assignments may be made: the bands at 210 m$\mu$ in cytosine, 246 m$\mu$ in guanine and 207 m$\mu$ in thymine might be assigned to the transitions of 4→6 or 5→7 in cytosine, 7→9 in guanine and 5→8 in thymine respectively. The transitions of 6→8 and 5→7 in thymine may be neglected, because the calculated

** Numerals in parenthesis are $\varepsilon \times 10^{-3}$, where $\varepsilon$ is the absorption coefficient.

oscillator strengths of these transitions are very small, i. e., 0.005 and 0.038 respectively.

It is difficult to determine the relative merits of the Pariser-Parr and Mataga-Nishimoto approximations.

**The Direction of Polarization.**—It may be of interest to compare the polarized absorption spectra of bases with the theoretically-determined directions of polarization. As far as we are aware, the experimental data for the polarized absorption spectra of bases or their analogs have been obtained only for 9-methyladenine and 1-methylthymine. That is, Stewart and Davidson[18] have obtained the polarized absorption spectra of the single crystal of 9-methyladenine, 1-methylthymine and the A-T dimer.[18] As a result, for 1-methylthymine the first absorption band has been shown to polarize close to the $N_1$–$C_4$ axis, and the second band, approximately perpendicular to the first, and for 9-methyladenine the direction of polarization has been determined along the shorter axis, $D_4$–$C_5$. From the results for 9-methyladenine, Stewart and Davidson also assumed that the main band of adenine ($\lambda_{max}=261$ mμ) should be assigned to a short-axis polarized band and the weak shoulder ($\lambda_{max}=267$ mμ), to a long-axis band

The theoretical treatment of Tinoco and DeVoe[19] has led to the same assignment; that is, by using the Hückel MO method they have assigned the 6→8 transition to the main band of adenine and the 6→7 transition to the shoulder band. On the other hand, Mason has attributed the intense absorption (261 mμ) in adenine to a long-axis polarized band.[20] Thus, the assignments of the transitions in adenine and 9-methyladenine contradict to one another; in view of this contradiction, it may be worth while to determine the directions of polarization for adenine and 9-methyladenine by means of the SCF MO calculation and to compare them with the experimental values.

As may be seen in Fig. 1, the theoretically-predicted direction of polarization of the 7→9 transition for 9-methyladenine is close to the $C_4$–$C_5$ axis (short-axis polarized), whereas the 7→8 transition is nearly perpendicular to the direction of the 7→9 transition. This is true in both methods of approximations, the Pariser-Parr and Mataga-Nishimoto methods. When these results are compared with those of the experiment of Stewart and Davidson,[18] it may

| | | 190(6→8) | 199(6→8) | | 0.042 | 0.049 |
| | | 172(6→9) | 175(6→9) | | 0.396 | 0.428 |
| | | 129(6→10) | 138(6→10) | | 0.203 | 0.087 |

* These are spectra in solution. Spectra in crystal state are 275 and 230 mμ for 1-methylthymine and 275, 255 and 230 mμ for 9-methyladenine (Ref. 18).

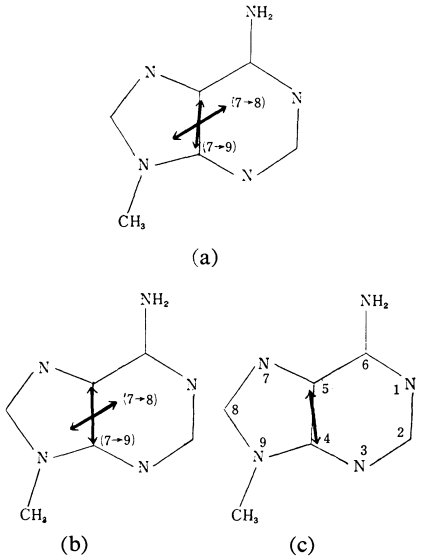

Fig. 1. Comparison of the predicted direction of polarization of 9-methyladenine with the experiment: (a) Calculation according to Mataga-Nishimoto and (b) Pariser-Parr approximations. (c) Experiment of Stewart and Davidson (Ref. 18).

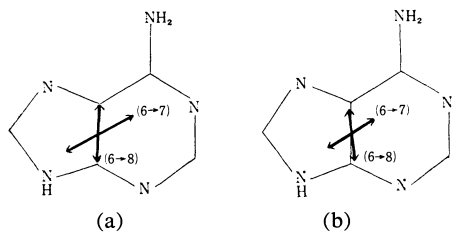

Fig. 2. Predicted directions of polarization of adenine: (a) Mataga-Nishimoto approximation and (b) Pariser-Parr approximation.

be seen that the intense band which is polarized to the $C_4$-$C_5$ axis may be assigned to the second transition, 7→9. Similarly, the first (6→7) transition of adenine is predicted to polarize to the long-axis, and the second (6→8) transition, to be short-axis polarized (Fig. 2). If Stewart's assignment for adenine were true, 6→7 and 6→8 transitions in adenine should be assigned to the weak shoulder (267 mμ) and to the main band (261 mμ) respectively. However, as has been stated above, Mason[20] attributed the long-axis polarized band to the main band of adenine. From this point of view, the 6→7 transition may reasonably be assigned to the main band. In these controversial circumstances, it is difficult to determine which assignment is true for adenine and 9-methyladenine. From a comparison of the calculated transition energy and the experimental results, the main band of adenine was assigned to the 6→7 transition; in this point Mason's assignment is supported. Thus, the first and the second bands of 9-methyladenine (261 mμ and 206 mμ respectively) may be assigned to the 7→8 and 7→9 or 7→10 transitions (Table III). As may be seen in Table III, the 7→9, 7→10, 6→8, 6→9 and 6→10 transitions in 9-methyladenine have nearly the same energies of absorption; therefore, the absorption of 206 mμ may consist of these transitions. The magnitude of the oscillator strength of this absorption may well be understood if it is assigned as above.

The calculated optical indexes for 1-methylthymine are also shown in Table III, in comparison with the experimental results. The

calculated oscillator strength of the first band, i.e., the 7→8 transition, is the largest, and that of the 6→9 transition is next largest. The strengths of the other transitions are relatively weak compared with these two transitions, and, as may be seen in Fig. 3, the directions of these transitions agree well with the experimentally-determined values. With regard to the transition energy, agreement between theory and experiment is very poor,

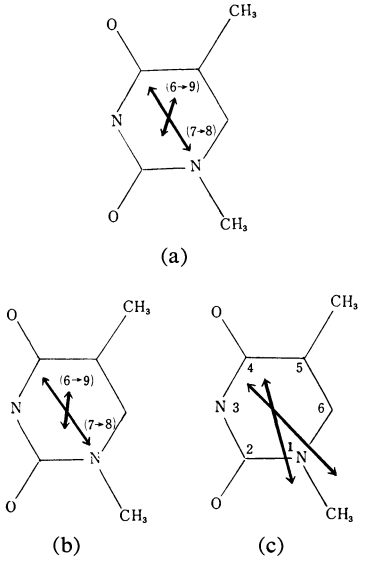

Fig. 3. Comparison of the predicted direction of polarization of 1-methylthymine with the experiment: (a) Calculation according to the Mataga-Nishimoto and (b) Pariser-Parr approximations. (c) Experiment of Stewart and Davidson (Ref. 18).

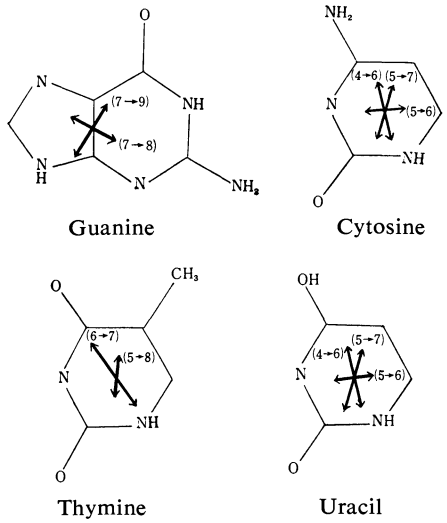

Fig. 4. Predicted directions of polarization of guanine, cytosine, thymine and uracil (Pariser-Parr approximation).

as in the case of thymine itself; in this case, the results of the Mataga-Nishimoto approximation are better than those of the Pariser-Parr method.

Similarly, the theoretically-determined direction of the polarization for guanine, thymine, cytosine and uracil are indicated in Fig. 4. Although the experiments have not yet been carried out for these compounds, the theoretical results may give an insight into the direction of the polarization and the assignment of the optical transition. In determining the direction of polarization, calculations were carried out by means of the Pariser-Parr approximation. The results using the Mataga-Nishimoto approximation are nearly the same in all these molecules. DeVoe and Tinoco,[19] from their Hückel MO calculation, have predicted the directions of polarization of these molecules and of adenine. It is worth noticing that their results are very similar to those of our SCF MO treatment. Therefore, it may be said that the direction of the transition moments is not sensitive to the degree of approximation.

**The Orbital Energy and the π-Electron Distribution.** — The energies of the highest-occupied and lowest-vacant orbitals are indicated in Table IV. The meanings of the orbital energy in the Hückel and SCF MO methods are not necessarily the same, but it may be of interest to compare the relative magnitudes of the orbital energies obtained by the two methods. The order of the energies

TABLE IV. THE ENERGIES OF THE HIGHEST OCCUPIED AND LOWEST VACANT ORBITALS OF BASES (in eV.)

| Compound | Energies of the highest occupied levels | | Energies of the lowest vacant levels | |
|---|---|---|---|---|
| | Pariser-Parr | Mataga-Nishimoto | Pariser-Parr | Mataga-Nishimoto |
| Thymine | −12.045 | −10.131 | −1.450 | −1.861 |
| Uracil | −10.472 | −9.419 | −1.332 | −2.109 |
| Cytosine | −10.460 | −9.401 | −1.145 | −1.914 |
| Adenine | −9.513 | −9.029 | +0.132 | −0.980 |
| Guanine | −9.236 | −8.289 | −0.314 | −1.305 |

9-Methyladenine 1-Methylthymine

Fig. 6. $\pi$-Electron distributions of 9-methyladenine and 1-methylthymine (Pariser-Parr approximation).

of the highest-occupied level of bases is written, in the order of decreasing energy, as follows; guanine>adenine>cytosine>uracil. This order is in accordance with that obtained by Veillard and Pullman,[3] and also with the results of the Hückel MO method.[1,2] For thymine, however, the results by the SCF MO and Hückel MO methods are not in accord; in the former method, the energy of the highest-occupied level of this molecule is the lowest among the bases, but the latter method gives a value between those of cytosine and adenine.

The $\pi$-electron distributions of adenine, thymine, guanine, cytosine, uracil, 9-methyladenine and 1-methylthymine are shown in Figs. 5 and 6. The relative magnitude of the $\pi$-electron density for guanine and cytosine is the same as that of the SCF MO calculation of Veillard and Pullman[3] and also that of the Hückel MO calculation by Pullman,[1] but for adenine the relative magnitude is in disagreement; that is, the order is $N_1>N_3>N_7$ in our calculation, whereas it is $N_7>N_1>N_3$ in Veillard and Pullman.[3] The protonation has been known to occur at the $N_1$ position of adenine,[21,22] and this fact is in accord with the results of the present authors.

21) J. M. Broomhead, *Acta Cryst.*, **1**, 324 (1948); **4**, 92 (1951).
22) W. Cochram, ibid., **4**, 81 (1951).

As may be seen in Figs. 5 and 6, the electron densities for 9-methyladenine and 1-methylthymine are nearly the same as those of its parent molecules, adenine and thymine. Thus, the changes in the $\pi$-electron distributions due to the methyl substitution are known to be small. The changes in the transition wavelengths due to the methyl substitution are zero and 10 m$\mu$ for 9-methyladenine and 1-methylthymine respectively (cf. Tables II and III). The fact that there is no shift due to the methyl substitution in adenine seems very curious; the spectra of adenine and 9-methyladenine should be measured under the same conditions.

## Summary

SCF MO calculations have been carried out for adenine, guanine, thymine, cytosine, uracil, 9-methyladenine and 1-methylthymine. In evaluating the two-center repulsion integral, the Pariser-Parr and Mataga-Nishimoto approximations have both been used, and the results compared with each other and with the experimental data on the optical properties. In the calculation of thymine, 9-methyladenine, and 1-methylthymine, the hyperconjugation of the methyl group has been taken into account. The calculated wavelength and the oscillator strength of the singlet-singlet transition for the above-mentioned molecules explain the experimental values well except for thymine and 1-methylthymine. The theoretically-determined directions of the polarization of the transition moments have been compared with the experimental results for adenine, 9-methyladenine and 1-methylthymine. With regard to the direction of the polarization of the transition moments of the first and the second absorptions of adenine and 9-methyladenine, the results are questionable. From the theoretical point of view, it is difficult to determine which assignment is correct, however, in view of the wavelength and the oscillator strength, the first absorption may

reasonably be assigned to the long-axis polarized band. The calculated and the experimentally-determined direction of polarization for 1-methylthymine agree well with each other. The energies of the highest and lowest vacant orbitals and the $\pi$-electron densities for the molecules treated in the present paper have been calculated and compared with the results obtaied by the Hückel MO method.

# The Benzene-Photosensitized cis-trans Isomerization of Butene-2

By Masahiro TANAKA, Terumi TERAO and Shin SATO

(Received February 4, 1965)

Recently there have been a number of reports on the photochemical cis-trans isomerization of olefins by organic sensitizers.[1-3] Hammond et al.[1,2] have examined the photosensitized isomerization in the liquid phase, using mainly carbonyl compounds as sensitizers. Cundall and his co-workers[3] studied the gas-phase-photosensitized isomerization of butene-2, using several organic sensitizers. They showed that the photostationary trans-to-cis ratio was 1.37 when benzene and pyridine were used as sensitizers.

The photosensitization by organic substances seems to be of great importance not only in elucidating intermolecular energy transfer phenomena in general, but also in solving the problem of assimilation in plants.

This paper will describe the benzene-photosensitized cis-trans isomerization of butene-2 in the gas phase.[4]

## Experimental

The benzene used was a special-grade reagent which had been fractionally distilled; the middle third was used. The *cis*- and *trans*-butene-2 were commercially available substances whose vapor-phase chromatography showed to be 99.9% pure. They were thus used without further purification.

Special care was taken to keep the vacuum line free of mercury. The light source used was a low-pressure mercury arc lamp. Between the lamp and the quartz reaction vessel, a UV25 filter (supplied by the Toshiba Denki Co.) which eliminated the light shorter than 2300 Å was placed.

The analysis was carried out gas chromatographically, using dimethylsulfolane on celite as a separation column.

In the course of the experiment, it was shown that the light absorbed by benzene did not obey Lambert-Beer's law. When necessary, the ratio of absorbed light and incident light, $I_a/I_0$, was obtained as follows: the light transmitted was measured by the mercury-photosensitized decomposition of ethylene[5,6] in a cell just behind the reaction cell, which contained various pressures of benzene. This procedure gave the relation $\log_{10}(I_0/I_t) = 0.0205p - 0.0000883p^2$, where $I_0$ and $I_t$ are the intensities of transmitted light when the reaction cell contains no benzene and $p$ mmHg benzene respectively. From this relation, $I_a/I_0$ ratio could be calculated at any benzene pressure.

All experiments were carried out at room temperature.

## Results

The reaction was very clean, no products other than the isomerized butene-2 being detected.

Figure 1 shows the time dependence of the cis-to-trans ratio, both *cis*- and *trans*-butene-2 being used as starting materials. The photostationary cis-to-trans ratio may be seen from the figure to be about unity.

The effect of the benzene pressure on the cis-to-trans isomerization rate is summarized in Table I. It can be seen from the Table that the isomerization rate increases with the pressure of benzene. The rate tends to decrease, however, after the benzene pressure reaches a certain value. The ratio of the absorbed light to the isomerization rate is also seen to increase with the pressure of benzene.

The dependence of the isomerization rate on

the butene-2 pressure was also examined. The results are summarized in Table II, which shows that the rate increases monotonously as the pressure increases, while at high pressures it tends to saturate.

## Discussion

Table I clearly shows that scarcely any cis-trans isomerization of butene-2 occurs in the absence of benzene, but that the rate increases

TABLE II. BUTENE-2 PRESSURE DEPENDENCE OF PHOTOSENSITIZED ISOMERIZATION

Benzene pressure, 69 mmHg
Irradiation period, 2 min.

| 14.9 | 0.0565 |
| 28.5 | 0.0596 |

markedly as the pressure of benzene increased. It is evident from this fact that the energy transfer from excited benzene to butene-2 induces the ovserved isomerization. Among the excited states of benzene, the lowest-excited singlet ($^1B_{2u}$, 4.7 eV.)[7,8] and the lowest triplet ($^3B_{1u}$, 3.6 eV.)[8] are conceivably involved in the reaction when, as is the case in the present study, the 2537 Å mercury resonance line is employed. A possible reaction mechanism involving these excited states is

$$B + h\nu \longrightarrow {}^1B_n \quad (1)$$

$${}^1B_n + M \longrightarrow {}^1B_0 + M \quad (2)$$

$${}^1B_0 \longrightarrow B + h\nu' \quad (3)$$

$$\longrightarrow {}^3B_n \quad (4)$$

$${}^1B_0 + B \longrightarrow B + B \quad (5)$$

$${}^3B_n + M \longrightarrow {}^3B_0 + M \quad (6)$$

$${}^3B_0 \longrightarrow B(+ h\nu'') \quad (7)$$

$${}^3B_0 + B \longrightarrow B + B \quad (8)$$

$${}^1B_0 + C \longrightarrow B + {}^1C \quad (9)$$

$${}^3B_0 + C \longrightarrow B + {}^3C \quad (10)$$

$$\left.\begin{array}{l} {}^1C \xrightarrow{1-\alpha} C \\ \quad\xrightarrow{\alpha} T \end{array}\right\} \quad (11)$$

$$\left.\begin{array}{l} {}^3C \xrightarrow{1-\beta} C \\ \quad\xrightarrow{\beta} T \end{array}\right\} \quad (12)$$

where B, C and T refer to benzene, *cis*- and *trans*-butene-2 respectively, where the superscripts and subscripts denote the electronic multiplicities and the vibrational quantum numbers respectively and where M indicates any third body carrying away the vibrational energy of excited benzene. The steady-state treatment gives the following equation:

7) M. Goeppert-Meiyer and A. L. Sklar, *J. Chem. Phys.*, 6, 645 (1938).
8) R. Pariser, ibid., 24, 250 (1956).

$$R_T \equiv \frac{[dT]}{dt} = \frac{\alpha k_9[C] I_a}{k_3+k_4+k_5[B]+k_9[C]} + \frac{\beta k_{10}[C]}{k_7+k_8[B]+k_{10}[C]} \cdot \frac{k_4 I_a}{k_3+k_4+k_5[B]+k_9[C]} \quad (1)$$

The photochemical cis-trans isomerization of olefins by organic sensitizers has been extensively studied in the liquid phase by Hammond et al.,[1,2] the results being best understood in terms of a triplet energy transfer from sensitizer to olefin. Since butene-2 has little absorption in the neighborhood of 2500 Å, and since the life-time of a singlet excited state is much shorter than that of a triplet, the excitation of butene-2 by an energy transfer from a singlet-excited benzene to butene-2 is unlikely; the intersystem crossing from an excited-singlet benzene to its lowest triplet would be much faster than the energy transfer to butene-2. Therefore, it may be safe to say that the isomerization we observed resulted from a triplet state of butene-2 formed by the energy transfer from the triplet benzene to butene-2. By applying $k_4 \gg k_9[C]$ to Eq. 1, we obtain:

$$\frac{\beta I_a}{R_T} = \frac{k_3+k_4+k_5[B]}{k_4}\left(1+\frac{k_7+k_8[B]}{k_{10}[C]}\right) \quad (2)$$

Equation 2 requires that, under a constant pressure of benzene, a linear relationship should hold between the reciprocal of the isomerization rate and that of the butene-2 pressure. As may be seen from Fig. 2, this is indeed the case. The ratio of the slope to the intercept gives $(k_7+k_8[B])/k_{10}$. We may assume $k_7$ to be negligibly small compared with $k_8[B]$, since the triplet benzene seems to have a rather long life-time, of the order of magnitude $10^{-4}$ to $10^{-5}$ sec., as has been found for other aromatic molecules,[9] and we obtain 11.2 as the value of $k_{10}/k_8$. That is, butene-2 quenches triplet benzene more efficiently than does benzene.

The relation between the reciplocal of the isomerization rate and the pressure of benzene is shown in Fig. 3. Although the plots show a considerable scatter a straight line may be drawn. This linear relationship[10] may be expected from Eq. 2 in two cases: (1) $k_3+k_4 \gg k_5[B]$, or (2) $1 \gg (k_7+k_8[B])/k_{10}[C]$. In case 1, the ratio of the slope to the intercept gives $k_8/(k_7+k_{10}[C])$. Neglecting $k_7$ compared with $k_{10}[C]$, one obtains the value of $k_{10}/k_8$ as 12.8, which is comparable to the value (11.2) ob-

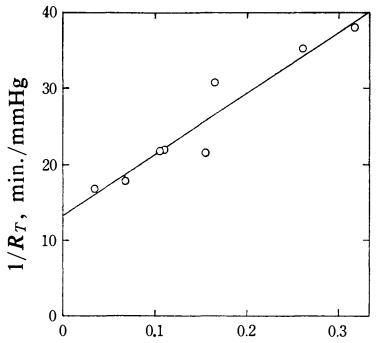

Fig. 2. The relation between the reciprocal of isomerization rate and that of butene-2 pressure.
Benzene, 69 mmHg; irradiation time, 2 min.

*cis*-Butene-2, 20.7 mmHg; irradiation time, 15 min.

tained from the relation between $1/R_T$ and the butene-2 pressure. Because our experiment was carried out below 100 mmHg of benzene, the condition $k_3+k_4 \gg k_5[B]$ will be satisfied if we take 10 as the value of the ratio $(k_3+k_4)/k_5[B]$ at 100 mmHg of benzene, which gives $(k_3+k_4)/k_5 = 1\times10^3$ mmHg. In case 2, the slope to intercept ratio gives $k_5/(k_3+k_4)$. The value of $(k_3+k_4)/k_5$ thus obtained is $3.05\times10^2$ mmHg. If we take the ratio $(k_7+k_8[B])/k_{10}[C]$ to be 1/10 at 100 mmHg of benzene, the highest pressure employed in our experiment, the condition $(k_7+k_8[B])/k_{10}[C] \ll 1$ will be satisfied. Neglecting $k_7$, we obtain from this relation 48.3 as the value of $k_{10}/k_8$.

Ishikawa and Noyes[11] have obtained the value of $k_5$ of $4.6\times10^{-3}$ ml./molec./sec. $= 1.5\times10^4$/mmHg/sec., taking $k_3+k_4 = 1.7\times10^6$ sec$^{-1}$. The value of $(k_3+k_4)/k_5$ calculated from these values is $1.2\times10^2$ mmHg, which is smaller than the values estimated above in both cases. The true value of $(k_3+k_4)/k_5$ might somewhat larger than the value given by Ishikawa and Noyes,

although the considerable scatter of our data makes questionable the accuracy of our value. It cannot be decided at this stage whether case 1 or case 2 is actually operative under our experimental conditions; more precise experiments must be carried out before further discussions can be made.

A crude estimation of the quantum yield can be made. Behind the reaction cell another quartz cell was placed; in this cell the mercury-photosensitized decomposition of ethylene was carried out. Using 0.502 as the quantum yield of hydrogen production in the mercury-photosensitized decomposition of ethylene,[6] the light quanta transmitted through a cell containing various pressures of benzene were obtained. On the basis of these measurements the quantum yield of the formation of *trans*-butene-2 in the benzene-photosensitized isomerization was calculated to be 1.5. Since the incident light beam was not a parallel one and since the light was reflected on the surfaces of the reaction vessels, the light absorbed by benzene must have been estimated too low by a factor of about 3. The true quantum yield seems to be nearly 0.5, the value which is to be expected from a full utilization of the light absorbed by benzene in the isomerization and from $\beta=0.5$. The isomerization observed in the present experiment, therefore, can be said to have proceeded very efficiently.

The observed photostationary cis-to-trans ratio was about 1.0 in our experiment. The value obtained by Cundall and his co-workers[3] was 0.73 in the benzene and pyridine sensitizations. The reason for this discrepancy is not clear, but the difference in the light sources employed by them (possibly a medium-pressure mercury arc lamp) and by us (a low-pressure mercury arc lamp) might be responsible for it.

The energy curve of the ground singlet state as a function of the relative angle of the rotation of two methyl groups around the axis passing through the two central carbon atoms of butene-2 would have its maximum at 90°. On the other hand, the energy of the lowest-triplet butene-2 would go down from 4.2 eV.[12] at 0° to a minimum at 90°. Thereby the two energy curves are very likely to intersect each other. That the triplet benzene sensitizes the isomerization implies that the energy of the crossing point is smaller than 3.6 eV., the energy of triplet benzene. The cis-to-trans ratio at the photostationary state may depend, according to Landau and Zener,[16] on the angle of the crossing of singlet and triplet energy curves and on the speed at the crossing point. Accordingly, the cis-to-trans ratio may depend on the energy of the sensitizers and on the pressure of the system. A detailed study along these lines is now in progress in this laboratory.

## Summary

The benzene-photosensitized cis-trans isomerization of butene-2 has been investigated in the gas phase. The results have been discussed on the basis of a mechanism involving triplet-energy transfer from benzene to butene-2.

The quantum yield measurements indicate that the reaction occurs at a very high efficiency. The triplet-benzene quenching efficiency of butene-2 has been shown to be considerably greater than that of the ground-state benzene.

The photostationary cis-to-trans ratio has been about unity, unlike the value obtained by Cundall et al. A mechanism which may explain the dependence of the ratio on the pressure and on the energy of the sensitizer has been suggested.

12) Although the energy of the triplet butene-2 has not been measured, this value was estimated as follows: The energy of triplet ethylene has been measured by Kupperman and Raff[13] by electron diffraction method and by Evans[14] spectroscopically. Kupperman and Raff gave the value of 4.8 eV., possibly a vertical one. Comparing the excitation energies of ethylene and butene-2 calculated by Sato and Cvetanović,[15] together with the above measured value of the triplet energy of ethylene, we obtain 4.2e V. as the value of the triplet energy of butene-2.

# Studies of the Organic Reaction of Metal Carbonyl. VII.* The Acceleration Effect of the Addition of Inorganic Compounds on the Reaction of Olefin Oxide with Cobalt Hydrocarbonyl

By Yoshinobu TAKEGAMI, Chikao YOKOKAWA, Yoshihisa WATANABE and Hiromitsu MASADA

(Received February 5, 1965)

Previous work[1] in this laboratory has shown that the reaction of olefin oxide with cobalt hydrocarbonyl is accelerated by the addition of even a relatively small amount of such organic compounds as alcohol, ketone, ether and esters.

In the present paper, the effects of the addition of various inorganic compounds will be examined for this type of reaction. The results obtained in this investigation indicate that some inorganic compounds, such as cuprous oxide and halide, silver oxide and aluminum chloride, also have an acceleration effect on this reaction.

## Experimental

**Reaction Procedures.** — The reactions of olefin oxide with cobalt hydrocarbonyl were carried out in the way which has been described in a previous paper.[2] Into a 100 ml. four-necked flask, fitted with a 50 ml. dropping funnel, a stirrer and a rubber stopple and connected with a 500 ml. gas buret, various amounts of inorganic compounds were introduced, and the air in the system was replaced with carbon monoxide. By the use of a syringe, 50 ml. of a 0.09 M cobalt hydrocarbonyl solution in toluene or in *n*-hexane and various amounts of organic compounds were put into the flask. To this system, 0.5 ml. of propylene oxide (1.6 mol./mol. cobalt hydrocarbonyl) was then introduced, after which the reaction mixture was agitated at 0°C for several hours.

**Analytical Procedures.** — The reaction products (ethyl $\beta$-hydroxybutyrate and ethyl $\gamma$-chloro-$\beta$-hydroxybutyrate) were analyzed by gas chromatography and by means of infrared spectra which were taken on a Shimadzu model IR-27 infracord spectrophotometer. The details were given in the previous paper.[2]

**Materials.** — All of the materials used in this study were commercial products.

## Results and Discussion

**The Reaction of Propylene Oxide with Cobalt Hydrocarbonyl in the Presence of Various Inorganic Compounds.** — All reactions were carried out at 0°C and under one atmosphere of carbon monoxide, and with the mole ratio*

of propylene oxide fixed at 1.6. Under these conditions, the reaction without additives proceeds very slowly (Exp. 1 in Table I).[2] The results of the reactions which were carried out in the presence of inorganic additives are summarized in Figs. 1 and 2 and in Tables I—III. The values of the gas absorption rate at the early stage of the reactions relative to the absorption rate of Exp. 1 are shown as a measure of the acceleration effect.

As the gas absorption curves in Fig. 1 show, the gas absorption rate was highly promoted by the addition of a relatively small amount of cupric and cuprous chloride; the gas absorption rate at the early stage of the reaction was about twenty times as large as that of Exp. 1, which was carried out without additives. The amount of cupric chloride necessary for this acceleration effect seemed to be about 0.05 mol. or less, since the gas absorption rates of Exps. 3—5 (0.1, 0.2 and 0.8 mol. of cupric chloride were added respectively) were comparable to that of Exp. 2. Cuprous chloride also had an effect similar to that of cupric chloride, as Exps. 6—9 and curve 6 show. In all of these reactions, an induction period of

*1 Other condition: 1.6 mol. of propylene oxide and under one atmosphere of carbon monoxide.
*2 The relative value of the gas absorption rate to Exp. 1.
*3 β-Hydroxy-*n*-butyrate.
*4 25 ml. of toluene refluxed with cuprous oxide and chloride was added respectively.
*5 6.2 mol. of propylene oxide. The rate of the gas absorption in *n*-hexane is about one-fourth that in toluene.[1]

about 5 min. was observed. As the main product in these reactions, ethyl β-hydroxy-*n*-butyrate* was obtained.

Accordingly, it may be concluded that the carbonylation of propylene oxide, i.e. the formation of β-hydroxy-*n*-butyrylcobalt carbonyl, is promoted by the addition of cupric or cuprous chloride.

Gas absorption was observed in the reaction system of cobalt hydrocarbonyl and cuprous chloride (Exp. 13). The gas chromatography, however, gave no indication of the presence of an organic product, and the amount of the gas evolved by treatment with iodine was comparable to the sum of the amount of the gas absorbed and that to be expected from the cobalt hydrocarbonyl used, indicating that the gas absorption is due to the formation of cuprous carbonyl chloride. This interpretation is supported by the facts that a 0.1 N hydrogen chloride - cuprous chloride aqueous solution readily absorbs carbon monoxide and that the gas absorbed was evolved by the treatment with iodine. However, the formation of cuprous carbonyl chloride seemed to be independent of its acceleration effect, since no gas absorption was observed in the reaction system of cobalt hydrocarbonyl and cupric chloride.

Cuprous iodide and cyanide and cupric chloride dihydrate had an acceleration effect almost equal to that of cuprous and cupric chloride (Exps. 10—12).

Silver chloride also had an effect which was smaller than that of cuprous chloride, and it had a longer induction period (about 15 min.) (Exp. 14 and curve 14). Aluminum trichloride had a larger acceleration effect than cuprous chloride and had no induction period (Exp. 15 and curve 15).

The reaction system of cobalt hydrocarbonyl and aluminum trichloride gradually caused gas to evolve, with a color change from yellow to pale green, suggesting that the aluminum chloride decomposed the cobalt hydrocarbonyl.

Tin tetrachloride seemed to have a relatively small acceleration effect (Exp. 16). However, zinc chloride, nickel chloride, ferric chloride, potassium chloride and magnesium chloride-dihydrate had no effect at all on this reaction (Exps. 17—21). The addition of palladium chloride and titanium chloride caused the color of the reaction system to change rapidly from yellow to brown black and green brown

* Obtained from the corresponding acylcobalt carbonyl by cleavage with iodine and ethyl alcohol.

respectively, without gas absorption or evolution, and it gave no ethyl β-hydroxy-*n*-butyrate as a product, suggesting that some reaction other than the carbonylation reaction of propylene oxide occurred (Exps. 22 and 23).

Cuprous and cupric oxide had an acceleration effect similar to that of their chlorides, but the effects of these oxides are several times larger than that of the chlorides (Table III). When more than 0.005 mol. of cuprous oxide or more than 0.02 mol. of cupric oxide was added, the rates of the gas absorption were, respectively, about seventy and sixty times as large as that of the standard run (curves 25 and 29 in Fig. 2). However, the acceleration effect decreased with the decrease in the amount of cuprous and cupric oxide, as Exps. 24 and 28 show. This indicates the following relation: 0.001 mol.<enough cuprous oxide for this reaction<0.005 mol. and 0.005 mol.<enough cupric oxide<0.02 mol.

Copper powder also had a promoting effect, one which seems to be about one-fifth that of cuprous chloride (Exp. 32 and curve 32). Silver oxide had a promoting effect about three times as large as that of silver chloride (Exp. 33). On the other hand, aluminum oxide had no effect on this reaction (Exp. 34).

These inorganic additives are insoluble in toluene. Even 0.005 mol. of cuprous oxide (3.5 mg. in 50 ml. of toluene) seemed not to dissolve in the reaction solution. From the standpoint of solubility, the inorganic additives differ from the organic additives, which are very soluble in toluene. It may reasonably be considered that the inorganic additives are effective for the reaction as the solid state. This consideration is supported by the following fact: when 25 ml. of toluene,* refluxed with cuprous oxide or chloride for one hour, was used in the reaction after the separation of the solid phase, only a relatively small acceleration effect was observed (Exps. 35 and 36).

As has been mentioned above, various compounds of copper and silver, but not aluminum chloride, significantly promote the carbonylation reaction of propylene oxide, suggesting that compounds of metals which belong to Periodic Group Ib have an acceleration effect on this type of reaction. This acceleration effect may be attributed to the formation of some active complex from propylene oxide and the inorganic additives. This theory is supported by the fact that the inorganic additives have no effect on the reaction of styrene or ethyl acrylate with cobalt hydrocarbonyl.

* 25 ml. of a 0.18 M cobalt hydrocarbonyl solution in toluene was diluted with 25 ml. of this refluxed toluene in the experiment.

Cuprous oxide and chloride have also an effect in *n*-hexane (Exps, 37 and 38), but the effect in this solvent seems to be one-fourth that of the reaction in toluene (cf. Exps. 6 and 26). Without additives, however, the reaction in *n*-hexane seems to proceed about one-fourth as fast as in toluene (Exp. 39), suggesting that this reaction is highly influenced by the solvent. However, the additives seem to be effective in the reaction independently of the solvent.

**The Reactions of Propylene Oxide and Epichlorohydrin in the Presence of Inorganic and Organic Additives.** — As has previously been reported,[1] the reaction of olefin oxide with cobalt hydrocarbonyl is remarkably promoted by the addition of various organic compounds, such as ethyl alcohol and tetrahydrofuran. The effect of the combination of the inorganic additives described above with organic additives has, therefore, been examined, the results are summarized in Tables IV and V and in Fig. 3.

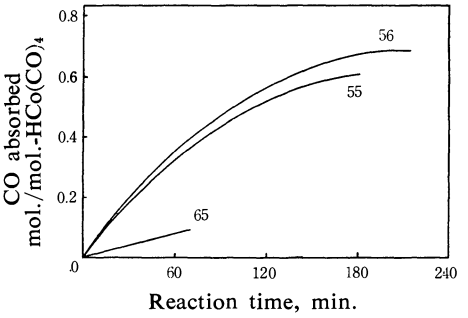

Fig. 3. CO absorption vs. time plots for the reaction of epichlorohydrin in the presence of cuprous oxide or ethyl alcohol.
Number: Exp. No.

As Exps. 41 and 42 clearly show, the reaction of propylene oxide is further promoted by the combination of cuprous chloride with ethyl alcohol, suggesting that such a combination has a synergistic effect.

The combination of cuprous chloride with various organic additives, such as tetrahydrofuran (30*[1]), acetone (25*[1]), ethyl acetate (12*[1]) and ethyl ether (6*[1]), also has a synergistic effect (Exps. 45 and 48). Cupric chloride and cuprous oxide in combination with ethyl alcohol have also a synergistic effect (Exps. 50 and 52). However, the combination of cuprous chloride with cupric chloride has no synergistic effect (Exp. 51). Ethylene chlorohydrin (10) has no synergistic effect, even when combined with cuprous oxide (75) (Exp. 53).

mol. of ethyl alcohol and 0.10 mol. of cuprous chloride (Exp. 43) are comparable. This may be interpreted as follows: under the reaction conditions (the apparatus, the speed of stirring, etc.) used, the maximum rate of gas absorption seems to be about 120 of the relative value.

The results with epichlorohydrin are summarized in Table V and Fig. 3, in which the values of the gas absorption rates relative to that of Exp. 55, carried out in the presence of 1.0 mol. of ethyl alcohol at a 14.5 mol. ratio*2 of epichlorohydrin, are shown as a measure of the acceleration effect.

As the results in Fig. 3 show, cuprous oxide also had an acceleration effect on this reaction (Exp. 56). The effect of cuprous oxide is almost comparable to that of 1.0 mol. of ethyl alcohol. The main product of these reactions

*2 Mole of epichlorohydrin per mole of cobalt hydrocarbonyl used.

has been proved to be $\gamma$-chloro-$\beta$-hydroxy-*n*-butyrate.[2] Thus, the carbonylation reaction is similarly promoted by the addition of cuprous oxide as ethyl alcohol.

However, the combination of cuprous oxide with ethyl alcohol has a retardation effect on this reaction. As Exps. 58—64 show, the relative values of the gas absorption rate in the presence of both cuprous oxide and ethyl alcohol decreased to about two thirds of those in the presence of ethyl alcohol alone. Thus, the equation*3 of the gas absorption rate at the early stage of the reaction, obtained in the presence of ethyl alcohol alone, may be corrected by the combination of ethyl alcohol with cuprous oxide as follows:

$$\text{Rate} = 0.6 - 0.7\,k \times [\text{epichlorohydrin}]\,[\text{ethyl alcohol}]$$

In the light of the above equation, cuprous oxide seems to lose its own acceleration effect and to retard some of the active complex formation of ethyl alcohol with epichlorohydrin.

## Summary

The reaction of olefin oxide with cobalt hydrocarbonyl in the presence of inorganic (and organic) additives has been investigated.

1) The addition of relatively small amounts of various compounds of copper and silver promote the carbonylation of propylene oxide. The order of the promoting effect of these compounds is $Cu_2O$, 70>CuO, 60>($AlCl_3$, 30)>$Ag_2O$, 27>$CuCl_2$, CuCl and CuI, 20>CuCN, 15>AgCl, 9>Cu powder, 4>None, 1 (the numbers indicating the relative rates of the gas absorption at the early stage of the reaction). Among these, cuprous oxide has the largest effect. The amount of cuprous oxide necessary for this effect is only about 0.005 mol./mol. $HCo(CO)_4$. $\beta$-Hydroxy-*n*-butyrate has been the main reaction product obtained. On the other hand, chlorides of zinc, nickel, ferric, potassium, magnesium, palladium and titanium have no promoting effect on the reaction.

2) The combination of cuprous halide (and oxide) with various organic additives, which also have a promoting effect,[1] has a synergistic effect on the reaction of propylene oxide.

3) The reaction of epichlorohydrin is also promoted by the addition of cuprous oxide. However, in this case cuprous oxide combined with ethyl alcohol has a retardation effect.

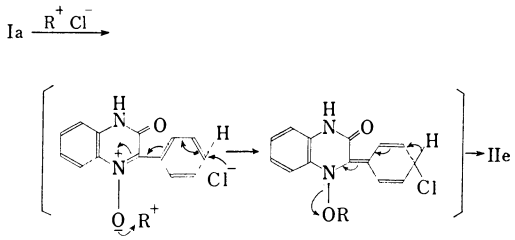
*Sakyo-ku, Kyoto*

*3 When only ethyl alcohol is present, the gas absorption rate at the early stage of the reaction is represented as follows:[1] Rate=$k$[epichlorohydrin] [ethylalcohol].

# Quinoxaline Derivatives. VI.[1] An Unusual Chlorine Substitution during the Reaction of 3-Hydroxy-2-phenylquinoxaline 1-Oxide with Acetyl Chloride

By Yusuf AHMAD, M. S. HABIB,*[1] ZIAUDDIN and Naz BASHIR

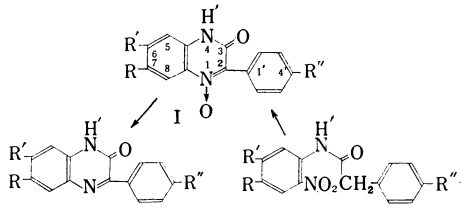
(Received February 8, 1965)



During an attempted acetylation of 3-hydroxy-2-phenylquinoxaline 1-oxide[2] (Ia) with acetyl chloride, it was observed that, instead of the normal acetyl derivative, a compound X was obtained; it was analysed as $C_{14}H_9ClN_2O$. The parent compound ($C_{14}H_{10}N_2O_2$) had gained a chlorine atom at the expense of one hydrogen and one oxygen atom, and the chlorine in the molecule was in the non-ionic form. The same compound X was obtained if the *N*-oxide (Ia) was heated with a mixture of concentrated hydrochloric acid and acetic acid (1 : 1 by volume). The reactions seemed to be general ones, as 7-chloro-, 7-ethoxy-, 7-methoxy- derivatives (Ib—d) of 3-hydroxy-2-phenylquinoxaline 1-oxide behaved similarly and gave the corresponding chlorine-substituted compounds. Although the *N*-oxide function was lost during the transformation, electrophilic chlorination by the chlorine generated at the expense of the *N*-oxide function was ruled out, as in each case a uniform single-chlorinated compound was obtained in almost a quantitative yield.

1) Part V: Y. Ahmad, M. S. Habib, M. Iqbal and Ziauddin, This Bulletin, **38**, 562 (1965).

*1 Burroughs Wellcome & Co. (Pakistan), Ltd., D/43 S. I. T. E., Karachi, Pakistan.



2) Y. Ahmad, M. S. Habib, Ziauddin and N. Bashir, *Tetrahedron*, **21**, 861 (1965).

The evidence presented in earlier papers[1,3,4] strongly indicated that the presence of an oxide function at $N_{(1)}$, coupled with an electron-withdrawing group on $C_{(2)}$ in the quinoxaline molecule, made $C_{(2)}$ strongly electrophilic. The acetylation (or protonation) of the *N*-oxide would further enhance this effect, making the nucleophilic chlorination of the molecule quite feasible. However, in the case of 3-hydroxy-2-phenylquinoxaline 1-oxide, this effect was not expected to remain localised at $C_{(2)}$; it could have been relayed further, through the mesomeric effect, making the 4'-position of the phenyl ring at $C_{(2)}$ liable to the attack by a nucleophile (in the present case a chloride anion). The reaction was expected to take the course indicated below:

(R=Ac or H)

To test the feasibility of this hypothesis, an authentic sample of 2-(*p*-chlorophenyl)-3-hydroxyquinoxaline (IIe) was synthesised in order to compare it with compound X, by the condensation of *o*-nitroaniline with *p*-chlorophenylacetyl chloride, and the resulting α-(*p*-chlorophenyl)-*o*-nitroacetanilide (IIIe) was cyclised with hot aqueous alkali to 2-(*p*-chlorophenyl)-3-hydroxyquinoxaline 1-oxide (Ie), which, on deoxygenation with sodium dithionite in aqueous ethanol, gave IIe. However, the infrared spectrum, melting point and other properties of compound X indicated it to be different from 2-(*p*-chlorophenyl)-3-hydroxyquinoxaline (IIe).

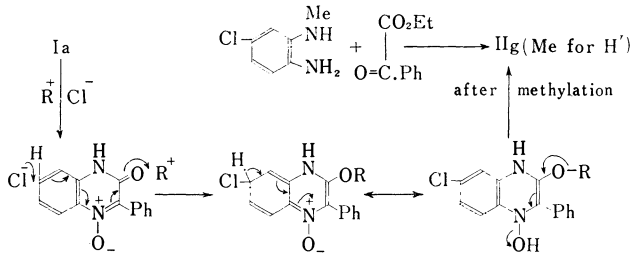
| (f) | Cl | H | Cl | (l) | Cl | Cl | Cl |

7-Chloro-2-(*p*-chlorophenyl)-3-hydroxyquinoxaline 1-oxide (If) was obtained by a similar sequence of reactions: [*p*-chlorophenylacetyl chloride + 4-chloro-2-nitroaniline → 4-chloro-α-(*p*-chlorophenyl)-2-nitroacetanilide (IIIf) → If]. Ie and If, derivatives of 3-hydroxyquinoxaline 1-oxide, had, at position 2, a phenyl ring, in which the *p*-position was already blocked. Even these compounds, on being heated with acetyl chloride, lost the *N*-oxide and gained an extra chlorine atom in the molecule. These observations indicated that probably the point of the attack of the chloride anion was not in the phenyl ring at position 2 of these quinoxaline derivatives, but at position 5, 6 or 8 of the molecule. Position 7 was excluded, as 2-phenyl-7-chloro-3-hydroxyquinoxaline (IIb), the synthesis of which has already been reported in Part IV,[2] was different (infrared spectra and melting point) from the compound X.

A survey of the literature brought to our notice a similar case. Nowbold and Spring,[5] on heating 3-ethoxy-2-methylquinoxaline 1-oxide (IV) with ethanolic hydrochloric acid, obtained a chlorine substituted quinoxaline, to which they assigned the 2-chloromethyl-3-hydroxyquinoxaline (V) structure, obviously on considerations similar to those above and on some spectroscopic evidence. Later,[6] when they synthesised 2-chloromethyl-3-hydroxyquinoxaline by an unambiguous route, it turned out



IV V VI

to be different from their earlier chloro-derivative, which they then proved to be 6-chloro-3-hydroxy-2-methyl quinoxaline (VI) through another synthesis. Spring et al.[5,6] had proposed no mechanism for this unusual chlorination, which they had earlier considered to have taken place on the methyl at position 2 and had later found to replace $C_{(6)}$ of the quinoxaline molecule.

In view of the above observation, 6-chloro-3,4-dihydro-4-methyl-3-oxo-2-phenylquinoxaline (IIg, Me for H′) was synthesised by two different routes: (a) 5-chloro-2-nitro-*N*-methylaniline with phenylacetyl chloride gave 5-chloro-*N*-methyl-2-nitro-α-phenylacetanilide

(R=Ac or H)

(IIIg, Me for H′), which, with hot aqueous alkali, cyclised to 6-chloro-3,4-dihydro-4-methyl-3-oxo-2-phenylquinoxaline 1-oxide (Ig, Me for H′), and its deoxygenation with sodium dithionite in boiling aqueous ethanol gave IIg (Me for H′). (b) 2-Amino-5-chloro-*N*-methylaniline, on condensation with ethyl phenylglyoxalate, gave IIg (Me for H′). The chloro-base (IIg, Me for H′) as prepared by either of the methods was identical (infrared spectra and mixed melting point) with the product of the methylation of the compound X.

The dichloro-compound obtained by heating 7-chloro-3-hydroxy-2-phenylquinoxaline 1-oxide (Ib) with acetyl chloride in a sealed tube was identical (infrared spectra and mixed melting point) with 6, 7-dichloro-3-hydroxy-2-phenylquinoxaline (IIh), which was synthesised by the condensation of 4, 5-dichloro-*o*-phenylenediamine with ethyl phenylglyoxalate. The trichloro-compound, which resulted when 7-chloro-2-(*p*-chlorophenyl)-3-hydroxyquinoxaline 1-oxide (If) and acetyl chloride were heated together in a sealed tube, was identical (infrared spectra and mixed melting point) with 6, 7-dichloro-2-(*p*-chlorophenyl)-3-hydroxyquinoxaline (III), an authentic sample of which, for the sake of comparison, was prepared by following sequence of reactions: [4, 5-dichloro-2-nitroaniline + *p*-chlorophenylacetyl chloride → 4, 5-dichloro-$\alpha$-(*p*-chlorophenyl)-2-nitroacetanilide (IIII), which cyclised with alkali → 6, 7-dichloro-2-(*p*-chlorophenyl-3-hydroxyquinoxaline 1-oxide (II), which on deoxygenation gave → III].

The above reactions clearly establish that 3-hydroxy-2-phenylquinoxaline 1-oxide and its derivatives, when heated with acetyl chloride or a mixture (1 : 1) of concentrated hydrochloric acid and acetic acid, undergoes chlorination at position 6 with simultaneous deoxygenation. By analogy, the chloro compounds similarly obtained from 2-(*p*-chlorophenyl)-3-hydroxyquinoxaline 1-oxide (Ie) and 7-ethoxy- and 7-methoxy- derivatives (Ic and Id) of Ia should be formulated as IIk, IIi and IIj respectively. In this reaction, powerful electron-withdrawing properties of the *N*-oxide function at $N_{(1)}$, augmented by the interaction of an $Ac^+$ (or $H^+$)*2 with the oxygen function at $C_{(3)}$ of quinoxaline molecule, made position 6 prone to nucleophilic attack by the chloride anion (as shown below), particularly so if position 2 was already occupied. The presence of an oxygen function at position 3 of the quinoxaline 1-oxides seemed to be essential for directing this nucleophilic chlorination to position 6. Otherwise[8] either the chlorination did not take place at all under the conditions of this reaction, or, if it did take place, it was directed to the substituent at position 2.

This mechanism† satisfactorily accounted for the cases of chlorination with the simultaneous deoxygenation of quinoxaline *N*-oxide derivatives reported above, and also for all such cases reported earlier by other workers.[5,6,9]

On the other hand, when 3-hydroxy-2-phenylquinoxaline 1-oxide (Ia) was heated with fuming hydrobromic acid, the product isolated, instead of being 6-bromo-3-hydroxy-2-phenylquinoxaline (IIg, Br for Cl), was the halogen-free deoxygenated base, i. e., 3-hydroxy-2-phenylquinoxaline (IIa). This was not entirely unexpected, as Loudon et al.[10,11] had obtained chlorinated quinoline derivatives when they

*2 Acetyl chloride, when used as a reaction medium, has been shown[7] to ionise as $CH_3COCl \rightleftarrows CH_3CO^+ + Cl^-$. Therefore, hydrochloric acid and acetyl chloride can be considered to follow the same course of reaction, to effect the nucleophilic chlorination reaction in the present investigation.

† We do not wish to imply that the initial attack of the reagent on the *N*-oxide is to be excluded here. This probably takes place and helps in further enhancing the electron-withdrawing properties of the *N*-oxide. However, this alone does not seem to direct the attack of the nucleophile ($Cl^-$) to position 6 of the quinoxaline molecule. It is the attack (or simultaneous attack) of the reagent at the oxygen function at $C_{(3)}$ which seems to control it. For the sake of brevity, the attack of the reagent on the *N*-oxide is, therefore, not shown in the mechanism.

reacted *o*-nitrobenzaldehyde with compounds containing an active methylene group in the presence of hydrogen chloride. However, when they replaced hydrogen chloride by hydrogen bromide, the compounds isolated, although similar in structure, were free from halogen.

Further work is in progress.

## Experimental*3

**α-(*p*-Chlorophenyl)-2-nitroacetanilide (IIIe).** — *o*-Nitroaniline (0.1 mol.) and *p*-chlorophenylacetyl chloride[12] (0.12 mol.) dissolved in minimum quantity of dry benzene were heated together under reflux for 25—30 min. More benzene was then added and, the solution was washed with 5% aqueous hydroxide and with water and then dried (sodium sulphate). The residue obtained after the removal of the solvent under reduced pressure was crystallised from light petroleum as yellow plates of the anilide (IIIe) in 80% yield, m. p. 91—92°C.

Found: N, 9.4. Calcd. for $C_{14}H_{11}ClN_2O_3$: N, 9.6%. The same procedure was followed for the preparation of the anilides described below.

**4-Chloro-α-(*p*-chlorophenyl)-2-nitroacetanilide (IIIf).**—4-Chloro-2-nitroaniline,[13] when treated by the above method, gave, in a 86% yield, yellow plates (from benzene-light petroleum) of the dichloroanilide (IIIf), m. p. 127—128°C.

Found: C, 51.9; H, 3.3; Cl, 21.2; N, 7.9. Calcd. for $C_{14}H_{10}Cl_2N_2O_3$: C, 51.7; H, 3.1; Cl, 21.8; N, 7.7%.

**4,5-Dichloro-α-(*p*-chlorophenyl)-2-nitroacetanilide (IIII).**—4,5-Dichloro-2-nitroaniline[14] gave, in 78% yield, yellow needles (from benzene) of the trichloroanilide (IIII), m. p. 150—151°C.

Found: Cl, 30.2; N, 7.6. Calcd. for $C_{14}H_9Cl_3N_2O_3$: Cl, 29.6; N, 7.8%.

**5-Chloro-*N*-methyl-2-nitro-α-phenylacetanilide (IIIg; H′=Me).** — 5-Chloro-2-nitro-*N*-methylaniline,[15] on being allowed to react with phenylacetyl chloride[16] as described above, gave, in 83% yield, yellow microneedles (from benzene-light petroleum) of the 5-chloro-*N*-methylanilide (IIIg; H′=Me), m. p. 140—141°C.

Found: N, 8.9. Calcd for $C_{15}H_{14}ClN_2O_3$: N, 9.2%.

**2-(*p*-Chlorophenyl)-3-hydroxyquinoxaline 1-Oxide (Ie).**—A solution of the anilide (IIIe) (4.0 g.) in pyridine (20 ml.) was heated with 20% aqueous potassium hydroxide (20 ml.) on a water bath for 1 hr. The reaction mixture, after dilution with water and acidification with dilute hydrochloric acid, gave a solid which crystallised from ethanol as yellow needles of the *N*-oxide (Ie) in 65% yield, m. p. 316—318°C (decomp.).

Found: N, 10.1. Calcd. for $C_{14}H_9ClN_2O_2$: N, 10.3%.

These needles, on being heating with an excess of sodium dithionite in 50% aqueous ethanol, was deoxygenated, and, on removal of the excess solvent, gave a solid which crystallised from benzene as yellow needles of *2-(p-chlorophenyl)-3-hydroxyquinoxaline (IIe)* in 82% yield, m. p. 291—292°C.

Found: N, 10.5. Calcd. for $C_{14}H_9ClN_2O$: N, 10.9%.

The *N*-oxides described below were obtained and deoxygenated by the procedures outlined above.

**7-Chloro-2-(*p*-chlorophenyl)-3-hydroxyquinoxaline 1-Oxide (If).**—The compound IIIf when treated by the above method, gave yellow microneedles (from dimethylformamide-ethanol) of the dichloro-*N*-oxide (If) in 62% yield, m. p. 333°C (decomp.).

Found: C, 54.4; H, 2.9; N, 8.9. Calcd. for $C_{14}H_8Cl_2N_2O_2$: C, 54.7; H, 2.6; N, 9.1%; these microneedles, on reduction with sodium dithionite in 50% aqueous acetic acid, gave pale yellow microneedles (from benzene) of *7-chloro-2-(p-chlorophenyl)-3-hydroxyquinoxaline (IIf)* in quantitative yield, m. p. 220—222°C.

Found: C, 57.0; H, 2.8; N, 9.8. Calcd. for $C_{14}H_8Cl_2N_2O$: C, 57.7; H, 2.7; N, 9.6%.

**6,7-Dichloro-2-(*p*-chlorophenyl)-3-hydroxyquinoxaline 1-Oxide (II).** — The anilide (IIII) gave, in 64% yield, yellow needles (from ethanol) of the trichloro *N*-oxide (II), m. p. 310°C (decomp.).

Found: Cl, 30.5; N, 8.2. Calcd. for $C_{14}H_7Cl_3N_2O_2$: Cl, 31.2; N, 8.2%.

**6,7-Dichloro-2-(*p*-chlorophenyl)-3-hydroxyquinoxaline (III).**—a) The *N*-oxide (II), on reduction with sodium dithionite in 50% aqueous ethanol, gave, in good yield, pale yellow microneedles (from ethanol) of the trichloroquinoxaline (III), m. p. 320—323°C.

Found: C, 51.3; H, 2.2; N, 8.5. Calcd. for $C_{14}H_7Cl_3N_2O$: C, 51.6; H, 2.15; N, 8.6%.

b) The *N*-oxide (If) (0.5 g.) and acetyl chloride (30 ml.) were heated together in a sealed tube at 100°C for 72 hr. The excess solvent was then removed, and the residue was washed with water and the crystallised from ethanol as pale yellow microneedles of the trichloroquinoxaline (III) in 75% yield, m. p. 322—323°C. This was identical (infrared spectra and mixed melting point) with the sample described under a).

**6-Chloro-3,4-dihydro-4-methyl-3-oxo-2-phenylquinoxaline 1-Oxide (Ig; H′=Me).** — The anilide (IIIg; H′=Me) cyclised in 58% yield as pale yellow plates (from methanol) of the 6-chloro-dihydro *N*-oxide (Ig; H′=Me), m. p. 191—192°C.

Found: Cl, 12.0; N, 9.9. Calcd. for $C_{15}H_{11}ClN_2O_2$: Cl, 12.3; N, 9.75%.

**6-Chloro-3,4-dihydro-4-methyl-3-oxo-2-phenylquinoxaline (IIg; H′=Me).** — a) The above *N*-oxide, on reduction with sodium dithionite in 50% aqueous ethanol, gave, in a good yield, pale yellow microneedles (from ethanol) of the 6-chloro-dihydroquinoxaline (IIg; H′=Me), m. p. 123°C.

Found: Cl, 13.3; N, 10.2. Calcd. for $C_{15}H_{11}ClN_2O$: Cl, 13.1; N, 10.35%.

*3 All melting points are uncorrected. Infrared spectra were measured in Nujol mull. Light petroleum used was of 60—80°C boiling range.

b) 5-Chloro-2-nitro-*N*-methylaniline[15] (1.0 g.) in benzene (40 ml.) was reduced with hydrogen over Pd-C. The catalyst was then filtered off, and the solvent from the dried (sodium sulphate) solution was completely removed under reduced pressure. The residue in a minimum of ethanol was heated with ethyl phenylglyoxalate[17] (1.2 g.) under reflux for 3 hr. The solid obtained on cooling was crystallised from ethanol as colourless microneedles of IIg (H′=Me), m. p. 122—123°C. It was identical (infrared spectrum and mixed melting point) with the product obtained under a).

**6-Chloro-3-hydroxy-2-phenylquinoxaline (IIg).**—3-Hydroxy-2-phenylquinoxaline 1-oxide[2] (Ia) (1.0 g.) and acetyl chloride (40 ml.) or a mixture of hydrochloric acid and acetic acide (1 : 1) were heated under reflux for 6—8 hr. The excess solvent was then removed under reduced pressure, and the residue was washed with water and then crystallised from ethanol as pale yellow microneedles of the 6-chloroquinoxaline (IIg) in 88% yield, m. p. 274—275°C.

Found: C, 65.55; H, 3.9; Cl, 13.5; N, 10.7. Calcd. for $C_{14}H_9ClN_2O$: C, 65.5; H, 3.5; Cl, 13.8; N, 10.9%.

This, on being methylated with methyl sulphate in the presence of anhydrous sodium carbonate in acetone, gave, in a good yield, colourless microneedles (from ethanol) of the 6-chloro-3,4-dihydro-4-methyl-3-oxo-2-phenylquinoxaline (IIg; H′=Me), m. p. 123—124°C; these microneedles were identical (infrared spectra and mixed melting point) with the sample prepared under a) and b) above.

**6, 7-Dichloro-3-hydroxy-2-phenylquinoxaline (IIh).** — a) A mixture of 7-chloro-3-hydroxy-2-phenylquinoxaline 1-oxide[2] (Ib) (1.0 g.) and acetyl chloride (40 ml.) was heated in a sealed tube at 100°C for 72 hr. After the acetyl chloride had then been removed, the residue was washed with water. The solid thus obtained (in a quantitative yield) was crystallised from ethanol as yellow needles of the dichloroquinoxaline (IIh), m. p. 305—306°C.

Found: Cl, 24.3; N, 9.75. Calcd. for $C_{14}H_8Cl_2N_2O$: Cl, 24.4; N, 9.6%.

It was identical (infrared spectra and mixed melting point) with an authentic sample synthesised as described below.

b) A solution of 4,5-dichloro-*o*-phenylenediamine (obtained in situ by reduction with hydrogen of 4,5-dichloro-2-nitroaniline[14] (1.0 g.) in ethanol over Pd-C) and ethyl phenylglyoxalate[17] (1.2 g.) in ethanol (about 10 ml.) was heated under reflux for 3 hr. The solid obtained on cooling was crystallised from ethanol (in a quantitative yield) as yellow needles of 6,7-dichloro-3-hydroxy-3-phenylquinoxaline (IIh), m. p. 305—306°C.

**6-Chloro-7-ethoxy-3-hydroxy-2-phenylquinoxaline (IIi).** — 7-Ethoxy-3-hydroxy-2-phenylquinoxaline 1-oxide[2] (Ic) (1.0 g.) and a mixture of concentrated hydrochloric acid and acetic acid (1 : 1) (40 ml.) were heated under reflux for 6 hr. The mixture, after the excess acetic acid had been removed, was diluted with water and chilled overnight; a solid was thereby obtained (yield 70%) which crystallised from ethanol as yellow needles of the chloroethoxyquinoxaline (IIi), m. p. 283—284°C.

Found: Cl, 11.5; N, 9.4. Calcd. for $C_{16}H_{13}ClN_2O_2$: Cl, 11.8; N, 9.3%.

**6-Chloro-7-methoxy-3-hydroxy-2-phenylquinoxaline (IIj).** — 7-Methoxy-3-hydroxy-2-phenylquinoxaline 1-oxide[2] (Id), on being heated with acetyl chloride under reflux for 15 hr. (and being worked up as usual) gave, in a quantitative yield, yellow needles (from ethanol) of the chloromethoxyquinoxaline (IIj), m. p. 260—261°C.

Found: Cl, 12.3; N, 10.2. Calcd. for $C_{15}H_{11}ClN_2O_2$: Cl, 12.4; N, 9.8%.

**6-Chloro-2-(*p*-chlorophenyl)-3-hydroxyquinoxaline (IIk).**—2-(*p*-Chlorophenyl)-3-hydroxyquinoxaline 1-oxide (Ie) (1.0 g.), on being heated under reflux for 12 hr. with a mixture of concentrated hydrochloric acid and acetic acid (1 : 1) (40 ml.) (an additional 5 ml. of concentrated hydrochloric acid was added every hour) and on being worked up as usual, gave a solid which crystallised from ethanol as pale yellow microneedles (yield 95%) of the dichlorophenylquinoxaline (IIk), m. p.>325°C.

Found: Cl, 22.9; N, 9.1. Calcd. for $C_{14}H_8Cl_2N_2O \cdot H_2O$: Cl, 23.0; N, 9.1%.

**The Action of Hydrobromic Acid on 3-Hydroxy-2-phenylquinoxaline 1-Oxide (Ia).** — The *N*-oxide[2] (Ia) (1.0 g.), on being heated with a mixture of fuming hydrobromic acid and acetic acid (1 : 1) (40ml.) at 100°C for 12 hr., gave after the excess acids had been removed and it had been washed with water, a product which crystallised from ethanol as pale yellow microneedles (yield 60%) of the 3-hydroxy-2-phenylquinoxaline (IIa), m. p. 243—245°C. It was identical (infrared spectrum) with an authentic sample prepared[2] by the condensation of *o*-phenylenediamine with ethyl phenylglyoxalate.

## Summary

3-Hydroxy-2-phenylquinoxaline 1-oxide (Ia), on being heated with acetyl chloride, instead of giving the acetyl derivative, gives a chloro compound (IIg), with a simultaneous loss of its *N*-oxide function. Ia, on being refluxed with a mixture of concentrated hydrochloric acid and acetic acid, undergoes the same transformation. Other derivatives (Ib—f) of Ia behave similarly and give the corresponding chlorine-substituted bases (IIh—l), the structure of which has been established by authentic syntheses.

A nucleophilic mechanism of this chlorination has been proposed, in which the presence of an oxygen function a position 3 of the 2-substituted quinoxaline 1-oxides seems to direct the chlorine substitution to position 6.

The authors wish to thank Dr. S. Siddiqui F. R. S. Chairman, Pakistan Council of Scientific and Industrial Research, for his interest and encouragement. Analyses were carried out by M/S. Pascher & Pascher, Bonn (W. Germany);

# Quinoxaline Derivatives. VII.[1] The Mechanism of the Formation of 6-Chloro-1, 2, 3, 4, 2′, 3′-hexahydro-4, 1′-dimethyl-3, 2′-dioxoquinoxaline-2-spiro-3′-indole from a Quinoxaline *N*-Oxide Derivative by Nucleophilic Chlorination

By Yusuf Ahmad, M. S. Habib,* M. Iqbal, M. I. Qureshi and Ziauddin

(Received February 8, 1965)

Usherwood and Whiteley[2] found that 3, 4-dihydro-4-methyl-2-(*N*-methyl-*N*-phenylcarbamoyl)-3-oxoquinoxaline 1-oxide (Ia), on reaction with ethanolic hydrogen chloride, was converted to the compound $C_{17}H_{16}ClN_3O_2$, whereas with acetyl chloride it gave the compound $C_{19}H_{18}ClN_3O_3$. The latter compound apparently was the acetyl derivative of the former, and in both the compounds chlorine was inactive. However, no structures were proposed for these products. Clark-Lewis and Katekar[3] in 1959 re-examined the problem and revised the molecular formula of these compounds to $C_{17}H_{14}ClN_3O_2$ and $C_{19}H_{16}ClN_3O_3$ respectively; on the basis of spectroscopic data, the study of the degradation products and the synthesis of 6-chloro-3, 4-dihydro-4-methyl-2-(*o*-methylaminophenyl)-3-oxoquinoxaline (IIb, the major product of the degradation of $C_{19}H_{16}ClN_3O_3$), they deduced the structure of the compound $C_{17}H_{14}ClN_3O_2$ to be 6-chloro-1, 2, 3, 4, 2′, 3′-hexahydro-4, 1′-dimethyl-3, 2′-dioxoquinoxaline-2-spiro-3′-indole (IVb), the acetylation of which with acetyl chloride gave a product which was identical with the other compound, $C_{19}H_{16}ClN_3O_3$. However, no synthesis of the compound, which would have confirmed the proposed structure of the spiro-indole (IVb) had previously been reported. It has now been accomplished and is reported below.

Clark-Lewis and Katekar[3] discounted the electrophilic chlorination of the molcule in this interaction of the *N*-oxide (Ia) with acetyl chloride (or ethanolic hydrogen chloride) on the grounds that the "formation of such chlorinating species would consume the *N*-oxide function, and subsequent cyclisation would then be difficult to understand." According to them, for this chlorination, the protonation of the *N*-oxide (Ia) to the conjugate acid (V) is the first step; the powerful inductive effect of the hydroxylammonium ion then promotes the intramolecular electrophilic substitution at the ortho-position of the methylanilide moiety by the quinoxaline 2-C-atom, giving the *N*-hydoxy-compound (VI). The known nucleophilic substitution by chloride ions (i.e., *N*-phenylhydroxylamine with hydrochloric acid → *p*-chloro-aniline[4]) with the intermediate (VI) then leads to the formation of the 6-chloro-spiro-indole (IVb). If this order

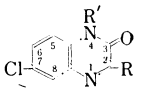
VII

the same authors between this substitution by chlorine in the 6-position of this quinoxaline spiro-indole (IVb) and the reported[5] conversion of 3-ethoxy-2-methyl-quinoxaline 1-oxide (VII) into 6-chloro-3-hydroxy-2-methylquinoxaline (VIIIa; R=Me) cannot be explained, as the cyclisation step to convert VII into an *N*-hydroxy intermediate analogous to VI is not possible in the latter case. The mechanism proposed in Part VI[1] for this type of nucleophilic chlorination of quinoxaline *N*-oxides satisfactorily accounts for both the cases, as, according to it, this nucleophilic chlorination takes place as a result of the combined action of the protonation of oxygen functions at $C_{(3)}$ and $N_{(1)}$ of the quinoxaline molecule, whereby $C_{(6)}$ becomes prone to the attack of the nucleophile (chloride anion), irrespective of the substituent at position 2.



Accordingly, the *N*-oxide (Ia) first gives the chloroquinoxalineanilide (IIIb), which then immediately undergoes the known[6,12] acid-catalysed rearrangement to the isomeric 6-chloro-spiro-indole (IVb).

It is now well established, on the basis of the studies made in earlier papers,[6,12] that 3, 4-dihydro-4-methyl-2-(*N*-methyl-*N*-phenylcarbamoyl)-3-oxoquinoxaline (IIIa), when treated with concentrated sulphuric acid or ethanolic hydrogen chloride, isomerises to 1, 2, 3, 4, 2′, 3′-hexahydro-4, 1′-dimethyl-3, 2′-dioxoquinoxaline-2-spiro-3′-indole (IVa). Substituted derivatives of IIIa behave similarly and give the corresponding spiro-indoles.[12] On the other hand, the *N*-oxides of IIIa and its substituted derivatives, with concentrated sulphuric acid, undergo rearrangement,[13] accompanied by dehydration and decarboxylation, to give the corresponding amines (IIa and its substituted derivatives).

For the synthesis of spiro-indole IVb, 6-chloro-3, 4-dihydro-4-methyl-3-oxoquinoxaline-2-carboxylic acid (VIIIe, see below) was converted to its methylanilide (IIIb) by the usual methods.[12,13] IIIb, when heated with ethanolic hydrogen chloride, rearranged intramolecularly to the isomeric spiro-indole (IVb), which was identical (infrared spectrum and mixed melting point) with the product obtained by the action of ethanolic hydrogen chloride on the chlorine free *N*-oxide (Ia), as described by Clark-Lewis and Katekar.[3] The position of the entering chlorine atom in the molecule in the latter reaction is thereby fully established.

7-Chloro-3-hydroxyquinoxaline-2-carboxylic acid (IXd) was converted to its methylanilide (IXi), and then this was further methylated to IIIc. IXi and IIIc, on being heated with ethanolic hydrogen chloride, rearranged, as expected,[6,12] to their corresponding 7-chloro-spiro-indoles IVc (H for Me′) and IVc. IIIb and IIIc both were smoothly converted to their *N*-oxides (Ib and Ic) with hydrogen peroxide and acetic acid. Both of these *N*-oxides (Ib and Ic) underwent intramolecular rearrangement, accompanied by dehydration and decarboxylation, in concentrated sulphuric acid, yielding 6-chloro-3, 4-dihydro-4-methyl-2-(*o*-methylaminophenyl)-3-oxoquinoxaline (IIb) and the 7-chloro-isomer (IIc) respectively, which were identical (infrared spectrum and mixed melting point) with the synthetic samples provided by Professor J. W. Clark-Lewis.

As expected,[14] the methylanilide IXi, on reaction with hydrogen peroxide in hot acetic acid, yielded 6-chloro-2, 3-dihydroxyquinoxaline (IXa; R=OH) instead of giving its *N*-oxide.

During the preparation of the intermediates needed for this investigation, it was observed

that if a large excess of ethyl mesoxalate was not used in its condensation with 4-chloro-*o*-phenylenediamine or 4-chloro-2-methylaminoaniline, instead of the expected quinoxaline-2-carboxylic esters, products of a very high melting point were formed; these probably resulted from the further condensation of the ethoxycarbonyl moiety of the esters formed with another molecule of the *o*-phenylenediamines, as these products[7] were sparingly soluble in, and stable to, acids and alkalies. 4-Chloro-2-methylaminoaniline, on being heated with an excess of ethyl mesoxalate in ethanol (or dry benzene), gave, in a good yield, the ester VIIIc, which, on being shaken with aqueous potassium hydroxide, hydrolysed to the acid VIIIe. The ester which was separated in a good yield by the reaction of 4-chloro-*o*-phenylenediamine with ethyl mesoxalate under similar conditions was the 7-chloro isomer (IXb); its hydrolysis with aqueous alkali gave the corresponding acid (IXd), which, on decarboxylation, gave 6-chloro-2-hydroxyquinoxaline (IXa), identical with a sample[8] which had previously been obtained by an unambiguous route. The 6-chloro isomeric ester (VIIIb), which was the second expected product of the reaction, was formed to a much lesser extent and remained in the mother liquor; on hydrolysis in situ with aqueous alkali it gave 6-chloro-3-hydroxyquinoxaline-2-carboxylic acid (VIIId), which, on decarboxylation, in turn gave the known 6-chloro-3-hydroxyquinoxaline (VIIIa). The structure of this acid (VIIId) was further confirmed by methylation, with methyl sulphate in acetone in the presence of anhydrous potassium carbonate, to lead to a product identical (infrared spectrum and mixed melting point) with the 6-chloro-3,4-dihydro-4-methyl-3-oxoquinoxaline-2-carboxylic acid (VIIIe) described above.

## Experimental

The infrared spectra were measured in Nujol mulls with a Perkin-Elmer spectrophotometer model 137. The light petroleum used had a boiling range of 60—80°C.

**The Condensation of 4-Chloro-*o*-phenylenediamine with Ethyl Mesoxalate.**—4-Chloro-*o*-phenylenediamine (8.4 g.), obtained by the reduction of 4-chloro-2-nitroaniline[9] (10 g.) with stannous chloride and hydrogen chloride (by adopting the procedure of Dawson et al.[5]), was taken up in dry benzene (150 ml.), and then the solution was added portion-by-portion to ethyl mesoxalate (35 ml.). After the mixture had been heated under reflux for 1 hr., about half of the solvent of the mixture was removed under reduced pressure. On cooling, a yellow solid separated (10.5 g.); this was collected and crystallised from ethanol as yellow needles of ethyl 7-chloro-3-hydroxyquinoxaline-2-carboxylate (IXb), m. p. 206—207°C.

Found: Cl, 13.9; N, 11.3. Calcd. for $C_{10}H_9ClN_2O_3$: Cl, 14.05; N, 11.1%.

This compound, which separated as the major product of the condensation, gave, on hydrolysis, an acid the decarboxylation of which afforded the known 6-chloro-2-hydroxyquinoxaline (IXa, see below); this established its structure as a 7-chloro-ester (IXb).

The 6-chloro-ester (VIIIb), the other expected product of the condensation, remained in the mother liquor and was hydrolysed in situ by heating it with 3 N aqueous potassium hydroxide (50 ml.) on a steam bath for 2 hr. The dark red mixture was filtered, and the filtrate, on acidification with concentrated hydrochloric acid, gave a precipitate (purified by dissolution in aqueous potassium hydrogen carbonate and reprecipitation with acid) of 6-chloro-3-hydroxyquinoxaline-2-carboxylic acid (VIIId), m. p. 194—196°C (decomp.).

Found: Cl, 15.2; N, 11.6. Calcd. for $C_9H_5ClN_2O_3 \cdot H_2O$: Cl, 14.7; N, 11.55%.

This acid (VIIId), on being heated to its melting point, gave 6-chloro-3-hydroxyquinoxaline (VIIIa), m. p. 251—252°C, for which Crowther et al.[10] have recorded a m. p. of 270°C (decomp.). VIIId, on methylation, gave the methylated acid (VIIIe), which was identical with the product of the hydrolysis of the authentic ester (VIIIc, see below).

**Ethyl 6-Chloro-3,4-dihydro-4-methyl-3-oxoquinoxaline-2-carboxylate (VIIIc).** — 4-Chloro-2-methylaminoaniline (6.2 g.), obtained from 5-chloro-*N*-methyl-2-nitroaniline (7.5 g.) according to the method of Dawson et al.[5]; was taken up in dry benzene (125 ml.) and then the solution was added to ethyl mesoxalate (28 ml.). After the mixture had been heated under reflux on a water bath for 1.5 hr., the excess solvent was removed under reduced pressure. The solid which separated (in a 60% yield) on cooling was crystallised from ethanol as light yellow needles of the 6-chloro-*N*-methyl ester (VIIIc), m. p. 134—135°C.

Found: Cl, 12.8; N, 9.9. Calcd. for $C_{12}H_{11}ClN_2O_3$: Cl, 13.3; N, 10.5%.

The mother liquor contained more of the ester, as the residue obtained on its evaporation to dryness, on hydrolysis with aqueous alkali, gave an additional amount of the 6-chloro-4-methyl acid (VIIIe, see below).

In the preparation of the esters VIIIc and IXb above, if a large excess of ethyl methoxalate was not used, products with very high melting points were formed; these probably resulted from the further condensation of the ethoxycarbonyl moiety of these esters with another molecule of the *o*-phenylenediamines. These products[7] were stable and sparingly soluble in, acids and alkalies.

**6-Chloro-3, 4-dihydro-4-methyl-3-oxoquinoxaline-2-carboxylic Acid (VIIIe).**—a) 6-Chloro-*N*-methyl ester (VIIIc; 5 g.) was shaken with 20% aqueous potassium hydroxide (100 ml.) at room temperature for 2 hr., during which period it dissolved. On acidification with 25% sulphuric acid with cooling, a light brown precipitate was obtained; this crystallised from ethanol as cream-coloured needles of the 6-chloro-4-methyl acid (VIIIe), m. p. 186—187°C (decomp.). Yield 3.9 g.

Found: Cl, 14.3; N, 11.4. Calcd. for $C_{10}H_7ClN_2O_3$: Cl, 14.8; N, 11.7%.

b) The acid VIIId (1 g.), methyl sulphate (0.5 ml.) and anhydrous potassium carbonate (2 g.) were heated together under reflux in an acetone suspension (100 ml.) for 3 hr. The mixture was then evaported to dryness and acidified with dilute hydrochloric acid. The solid which separated was collected and crystallised from ethanol as cream-coloured needles, m. p. 188—189°C (decomp.), identical (infrared spectrum and mixed melting point) with the 6-chloro-4-methyl acid (VIIIe) described under a).

**7-Chloro-3-hydroxyquinoxaline-2-carboxylic Acid (IXd).**—The ester (IXb) and 3 N aqueous potassium hydroxide were heated on a steam bath for 1 hr. The reaction mixture was then filtered, and the filtrate, on acidification with concentrated hydrochloric acid, gave the 7-chloro acid (IXd) in quantitative yield, m. p. 308—310°C (decomp.).

Found: Cl, 15.5; N, 12.8. Calcd. for $C_9H_5ClN_2O_3$: Cl, 15.8; H, 12.5%.

This could, when heated at 310°C, be decarboxylated to 6-chloro-2-hydroxyquinoxaline (IXa), m. p. 320—321°C, identical with that of a sample[8] (m. p. 320—321°C) obtained by the reduction of 7-chloro-2-cyano-3-hydroxyquinoxaline 1-oxide (IXj) with sodium dithionite in boiling 50% aqueous ethanol.

**7-Chloro-3, 4-dihydro-4-methyl-3-oxoquinoxaline-2-carboxylic Acid (IXe).**—The ester (IXb) in acetone was methylated with methyl sulphate in the presence of anhydrous potassium carbonate to give the 7-chloro-4-methyl ester (IXc) (crystallised from ethanol as yellow needles) in a good yield, m. p. 125—126°C.

Found: Cl, 10.4; N, 12.8. Calcd. for $C_{12}H_{11}ClN_2O_3$: Cl, 10.5; N, 13.3%.

This ester, on hydrolysis with 3 N aqueous potassium hydroxide, gave yellow cubes (from ethanol) of the 7-chloro-4-methyl acid (IXe) (yield 80%), m. p. 198—199°C (decomp.).

Found: Cl, 13.9; N, 11.9. Calcd. for $C_{10}H_7ClN_2O_3$: Cl, 14.8; N, 11.7%.

**7-Chloro-3-hydroxyquinoxaline-2-carboxyamide (IXf).**—The ester (IXb), on being heated with concentrated ammonia on a steam bath for 2 hr., afforded a solid which crystallised from ethanol as yellow micro-crystals of the amide (IXf) in a quantitative yield, m. p. 310—311°C.

Found: Cl, 15.2; N, 18.4. Calcd. for $C_9H_6ClN_3O_2$: Cl, 15.8; N, 18.8%.

**7-Chloro-3,4-dihydro-4-methyl-3-oxoquinoxaline-2-carboxyamide (IXg).**—Similarly, the ester (IXc) with concentrated ammonia gave yellow needles (from ethanol) of the 4-methyl amide (IXg) in a good yield, m. p. 325—326°C (decomp.).

Found: Cl, 13.7; N, 16.6. Calcd. for $C_{10}H_8ClN_3O_2 \cdot H_2O$: Cl, 13.9; N, 16.4%.

**6-Chloro-3, 4-dihydro-4-methyl-2-(*N*-methyl-*N*-phenylcarbamoyl)-3-oxoquinoxaline (IIIb).**—The acid (VIIIe) (1 g.) and thionyl chloride (20 ml.) were heated under reflux for 1 hr. The solid obtained after the removal of thionyl chloride was taken up in a small amount of dry benzene and added portion-by-portion to a solution of *N*-methylaniline (8 ml.) in dry benzene (10 ml.). The reaction mixture was then heated on a steam bath for 10 min. and washed with 2 N hydrochloric acid. The solid which separated was crystallised from ethanol as light yellow cubes of the 4-methyl-*N*-methylanilide (IIIb); yield 80%; m. p. 192—193°C.

Found: C, 62.7; H, 4.6; Cl, 10.6. Calcd. for $C_{17}H_{14}ClN_3O_2$: C, 62.3; H, 4.3; Cl, 10.8%.

This general procedure was also used for the preparation of the other anilides described below.

**7-Chloro-3-hydroxy-2-(*N*-phenylcarbamoyl)-quinoxaline (IXh).**—The acid chloride from the acid (IXd), on reaction as above, gave with aniline yellow needles (from glacial acetic acid) of the anilide (IXh); yield 90%, m. p. >340°C.

Found: Cl, 11.45. Calcd. for $C_{15}H_{10}ClN_3O_2$: Cl, 11.85%.

**7-Chloro-3, 4-dihydro-4-methyl-2-(*N*-methyl-*N*-phenylcarbamoyl)-3-oxoquinoxaline (IIIc).**—Similarly, the acid chloride from the acid (IXd) with methylaniline gave yellow needles (from ethanol) of 7-chloro-3-hydroxy-2-(*N*-methyl-*N*-phenylcarbamoyl)-quinoxaline (IXi); yield 70%; m. p. 285°C.

Found: Cl, 10.9; N, 13.7. Calcd. for $C_{16}H_{12}ClN_3O_2$: Cl, 11.3; N, 13.4%.

The methylation of this anilide with methyl sulphate and anhydrous potassium carbonate in acetone gave cream-coloured cubes (from benzene-light petroleum) of 4-methyl-*N*-methylanilide (IIIc) in a good yield, m. p. 164—166°C.

Found: Cl, 10.7. Calcd. for $C_{17}H_{14}ClN_3O_2$: Cl, 10.8%.

**6-Chloro-1, 2, 3, 4, 2', 3'-hexahydro-4, 1'-dimethyl-3, 2'-dioxoquinoxaline-2-spiro-3'-indole (IVb).**—The anilide (IIIb) (0.5 g.) was boiled under reflux for 2 hr. with saturated ethanolic hydrogen chloride (25 ml.), and then the mixture was evaporated under reduced pressure to dryness. The residue crystallised from ethanol as colourless needles of the spiro-indole (IVb), m. p. 239—240°C, in a good yield. The spiro-indole was identical (infrared spectrum and mixed melting point) with a sample[2] obtained by the action of ethanolic hydrogen chloride on 3, 4-dihydro-4-methyl-2-(*N*-methyl-*N*-phenylcarbamoyl)-3-oxoquinoxaline 1-oxide (Ia). The above procedure was used for the preparation of the following spiro-indoles.

**7-Chloro-1, 2, 3, 4, 2', 3'-hexahydro-1'-methyl-3, 2'-dioxoquinoxaline-2-spiro-3'-indole (IVc; H for Me').**—The anilide (IXi), on being treated with ethanolic hydrogen chloride as above, gave white needles (from acetic acid) of the spiro-indole (IVc; H for Me'); yield 70%; m. p. 320°C (decomp.).

Found: C, 61.6; H, 4.5; Cl, 11.7. Calcd. for $C_{16}H_{12}ClN_3O_2$: C, 61.2; H, 3.8; Cl, 11.3%.

**7-Chloro-1, 2, 3, 4, 2', 3'-hexahydro-4, 1'-dimethyl-3,2'-dioxoquinoxaline-2-spiro-3'-indole (IVc).**—Similarly, the anilide (IIIc) gave light yellow needles (from ethanol) of the 4-methyl spiro-indole (IVc); yield 80%; m. p. 260—262°C (decomp.).

Found: Cl, 61.8; H, 4.1. Calcd. for $C_{17}H_{14}ClN_3O_2$: C, 62.3; H, 4.3%.

**6-Chloro-3, 4-dihydro-4-methyl-2-(*N*-methyl-*N*-phenylcarbamoyl)-3-oxoquinoxaline 1-Oxide (Ib).**—The anilide (IIIb) (1.0 g.), acetic acid (10 ml.), and 30% hydrogen peroxide (1 ml.) were heated at 55—60°C for 72 hr.; the acetic acid was removed under reduced pressure, and the residue was crystallised from benzene-light petroleum as yellow crystals of the 1-oxide (Ib); yield 25%; m. p. 160—162°C.

Found: C, 57.9; H, 3.8; N, 12.0. Calcd. for $C_{17}H_{14}ClN_3O_3 \cdot 1/2H_2O$: C, 57.9; H, 4.0; N, 11.9%.

**7-Chloro-3, 4-dihydro-4-methyl-2-(*N*-methyl-*N*-phenylcarbamoyl)-3-oxoquinoxaline 1-Oxide (Ic).**—Similarly, the anilide (IIIc) gave yellow crystals (from benzene-light petroleum) of the 1-oxide (Ic); yield 40%; m. p. 180—182°C.

Found: N, 12.5. Calcd. for $C_{17}H_{14}ClN_3O_3$: N, 12.2%.

**6-Chloro-2, 3-dihydroxyquinoxaline (IXa; R=OH).**—The anilide (IXi), on being treated with a mixture of hydrogen peroxide and glacial acetic acid at 60°C, gave colourless flakes (from glacial acetic acid) of the dihydroxyquinoxaline (IXa; R=OH); yield 50%; m. p. >350°C, identical (infrared spectrum) with an authentic sample.[10]

**6-Chloro-3, 4-dihydro-4-methyl-2-(*o*-methylaminophenyl)-3-oxoquinoxaline (IIb).**—The *N*-oxide (Ib) (0.5 g.) was stirred gradually into concentrated sulphuric acid (2 ml.) at room temperature. After the evolution of carbon dioxide had ceased, the solution was poured on ice and filtered. The basification of the filtrate gave a precipitate which crystallised from ethanol as orange needles of the 6-chloro-amine (IIb) (yield 40%); m. p. 186—188°C; identical (infrared spectrum and mixed melting point) with the synthetic sample[3] supplied by Professor J. W. Clarke-Lewis.

**7-Chloro-3, 4-dihydro-4-methyl-2-(*o*-methylaminophenyl)-3-oxoquinoxaline (IIc).**—The *N*-oxide (Ic) (0.5 g.) obtained by the above method yielded the 7-chloroamine (IIc); yield 50%; m. p. 163—164°C; indentical (infrared spectra and mixed melting point) with a synthetic sample[3] supplied by Professor J. W. Clark-Lewis.

## Summary

The compound IVb named in the title has been obtained by an unambiguous route. It has been shown to be identical with the product of the reaction of the *N*-oxide (Ia) with ethanolic hydrogen chloride. Clark-Lewis and Katekar's mechanism[3] for the nucleophilic chlorination in the latter case has been discussed, and a modified mechanism proposed.

Isomeric 7-chloro-spiro-indole (IVc) has also been obtained by the rearrangement of the anilide IIIc. Similarly, the anilide IXi gives spiro-indole (IVc; H for Me').

The anilides IIIb and IIIc give normal *N*-oxides Ib and Ic, which, with concentrated sulphuric acid, decompose and afford the amines IIb and IIc. IXi, instead of giving its *N*-oxide, yields 6-chloro-2, 3-dihydroxyquinoxaline.

The authors wish to thank Dr. S. Siddiqui, F. R. S., Chairman, Pakistan Council of Scientific and Industrial Research, for his interest and encourgement. Analyses were carried out by M/S. Pascher and Pascher, Germany; Wellcome Research Laboratories (through the courtesy of Dr. H. T. Openshaw), England; and Microanalytical Section, Central Laboratories, Pakistan Council of Scientific and Industrial Research, Karachi. We are also indebted to Professor J. W. Clark-Lewis for the samples of 6-chloro- and 7-chloro-3, 4-dihydro-4-methyl-2-(*o*-methylaminophenyl)-3-oxoquinoxalines (IIb and IIc).

# Equilibria in the System $FeO$–$Fe_2O_3$–$MgO$ at 1160°C

By Takashi KATSURA and Shigeyuki KIMURA

(Received February 15, 1965)

The system $FeO$–$Fe_2O_3$–$MgO$ is one of the most important systems not only for ceramics, but also for metallurgy and geochemistry. The subsolidus study of this system may establish the fundamental thermodynamic properties of both magnesioferrite and magnesiowüstite solid solutions. This knowledge will in turn furnish chemical data for the investigation of the system $FeO$–$Fe_2O_3$–$MgO$–$SiO_2$, which is very important since it includes the stability relationship between the pyroxene solid solution, $FeSiO_3$–$MgSiO_3$, and the olivine solid solution, $Fe_2SiO_4$–$Mg_2SiO_4$, which usually coexist in igneous rocks. However, no investigation of a complete isothermal phase diagram of the system Fe–Mg–O at a subsolidus temperature under various oxygen partial pressures has yet been published.

Darken and Gurry[1] studied the system Fe–O and precisely re-determined the thermodynamic properties of metallic iron, wüstite, and magnetite in their equilibrated states. Richards and White[2] and Woodhouse and White[3] studied the system Fe–Mg–O at high temperatures, up to 1650°C, in air and constructed a modified phase diagram showing the extensive solid solubility of iron(II) oxide and iron(III) oxide in periclase. Phillips, Sōmiya, and Muan[4] also studied the system and determined the phase relations in air at temperatures up to 1800°C by means of the quenching technique. Moreover, Brynestad and Flood[5] studied this system at 1400°C and at various oxygen partial pressures in order to clarify the equilibrium between ferrous and ferric iron in wüstite containing various amounts of magnesium oxide; these data were then used for a discussion of the applicability of the mass-action law on the redox equilibrium. Roberts and Merwin[6] investigated the system $FeO$–$Fe_2O_3$–$MgO$ at temperatures above 1000°C in an isobar 1/5 atmosphere of $O_2$. As for the binary system $MgO$–$Fe_2O_3$, they found no compound other than $MgO \cdot Fe_2O_3$ which dissociates slightly on heating, and established that the solid solution extends from this compound for a short distance toward MgO. On the basis of studies by Schenck and Dingmann[7] and of those by Roberts and Merwin[6] and Bowen and Schairer[8] on the system $FeO$–$MgO$, White[9] constructed approximate phase relations for the system Fe–Mg–O.

The purpose of the present study is to determine the detailed phase equilibria in the system $FeO$–$Fe_2O_3$–$MgO$ at 1160°C by varying partial oxygen pressures from 0.21 atm. to $10^{-13.5}$ atm. The temperature of 1160°C was adopted for convenience in studying the subsolidus equilibria in the system $FeO$–$Fe_2O_3$–$MgO$–$SiO_2$.

## Experimental Methods

**General Procedures.**—The different experimental methods were used in the present investigation—quenching and thermogravimetric methods as previously described by Katsura and Muan.[10]

In the thermogravimetric method, pellete of oxide mixtures of iron(III) oxide and magnesium oxide were suspended by a thin platinum wire from one beam of an analytical balance, and the weight changes were recorded as a function of the oxygen pressure at 1160°C. The data thus obtained were used to locate oxygen isobars. According to Richards and White,[2] no change was observed in the weight of mixtures of iron(III) oxide and magnesium oxide in any ratio when the mixtures (starting materials) were heated at 700°C and in air. In the present study, we checked the fact mentioned above. The weight in air at 700°C was taken as the reference state for calculation of the amount of $Fe^{2+}$ produced in drawing the isobaric line, and subsequently in determining the phase boundary.

In the quenching method, oxide samples were heated at 1160°C and at a chosen oxygen pressure until equilibrium was attained among gas and condensed phases. The samples were then quenched rapidly to the temperature of ice by burning away the thin platinum wire with an electric current. The sample thus obtained were used for determining

the phases present by X-ray and the microscopic examinations and for the determination of the compositions by chemical analysis. The amounts of ferrous iron determined by thermogravimetric and by chemical analysis were in good agreement.

**Materials.**—Guaranteed reagents of iron(III) oxide and magnesium oxide were used as the starting materials. Each oxide was heated separately in air at 1000°C for several hours. Mixtures of the desired ratios of the two oxides were then prepared. Each mixture was finely ground by an agate mortar, mixed, and heated at 1250 to 1300°C in air for 3 to 12 hr., depending on the composition. The sintered mixture was again finely ground and repeatedly heated in air at 1300°C. A suitable starting material for thermogravimetry was obtained by this treatment. Some of the mixed samples thus prepared were heated for several hours at 1160°C and at the low oxygen pressures necessary to produce the magnesiowüstite. Reduced samples with the same iron/magnesium ratios were obtained by this treatment, and equilibrium could be approached in opposite directions by using these reduced samples in subsequent equilibration runs, as will be described later.

**The Control of the Atmosphere.**—Atmospheres of the desired oxygen pressures were obtained by using pure oxygen, air, carbon dioxide, and $CO_2$-$H_2$ mixtures. The $CO_2$-$H_2$ mixtures were prepared by proportioning the two gas components in the desired ratios in a gas mixer principally similar to that described by Darken and Gurry.[1] Oxygen pressures in the $CO_2$-$H_2$ mixtures were calculated from the thermodynamic data summarized by Elliot and Gleiser.[11] The fluctuation of the $CO_2/H_2$ ratio was within ± 1% throughout the present study, the fluctuation of the value of $\log P_{O_2}$ due to the maximum variation in the $CO_2/H_2$ ratio is thus about 0.01. The oxygen partial pressures at 1160°C were checked by means of the relationship between the chemical composition of wüstite and the oxygen pressure at which the composition is equilibrated as has previously been established by Darken and Gurry,[1] Katsura and Muan,[10] and Taylor.[12] The purities of the carbon dioxide and hydrogen used in the present study were sufficient for the present purposes.

**Furnaces and Temperature Control.**—A vertical tube quench furnace with an 80%Pt20%Rh winding was used for the equilibration runs. A brass-made attachment for quenching was connected with the lower end of a mullite furnace tube with a 30 mm. diameter. The gases used for controlling the oxygen partial pressure were passed through the furnace from bottom to top.

The furnace temperatures were kept constant to approximately ±2° by means of electric controllers activated by a Pt-87%Pt13%Rh thermocouple inserted close to the hot spot of the furnace. The actual temperatures within the furnace were measured with another Pt-90%Pt10%Rh thermocouple which was calibrated against the melting points of diopside ($CaMgSi_2O_6$), 1391.5°C, and Gold (Au), 1063°C. (This thermocouple was provided by the courtesy of Dr. E. F. Osborn and Dr. A. Muan, of the Pennsylvania State University).

**The Identification of Phases and the Determination of the Lattice Parameter.**—The phases present in the quenched samples were identified by an X-ray diffractometer. Silicon powder was used as the standard in determining the lattice parameters of the phase present.

An indirect and useful check on the phases present is afforded by the location and shape of the oxygen isobars, as determined in the thermogravimetric study. These relations have been explained in detail in recent papers by Taylor[12] and Katsura and Muan.[10]

The presence of metallic iron in the phase assemblages was evidenced by the liberation of hydrogen gas when samples were dipped in hydrochloric acid. This test is sensitive enough to detect iron in amounts as small as 0.2%.

**Chemical Analysis.**—The ferrous iron content of the quenched samples was determined volumetrically by the method described in detail by Iwasaki et al.,[13] while the total iron content was determined by the zinc-amalgam method described by Katsura.[14] In cases of small amounts of iron, the colorimetric method was adopted to determine the total iron by using $\alpha, \alpha'$-dipyridyl.

**Checking Equilibration and Quenching Procedures.**—First, the most suitable linear rate of flow of a homogeneous mixture of gases through the mixing apparatus to the furnace was checked for the equilibration within the gas phase at 1160°C. When the linear rates of flow was kept at 5 mm/sec., and 4 mm./sec. respectively, the equilibrium state in the condensed phases was never attained. That is to say, the chemical composition was not constant in each run of the same starting material under identical conditions; even in a quenched pellet with about a 1 cm. cube, an appreciable difference was observed in appearance. When we adopt 2.5 mm./sec., the equilibrium was approached within a reasonable period of time and the relationships between the oxygen partial pressures and the chemical compositions of both magnetite and wüstite were just the same as those obtained by Darken and Gurry[1] although they used a mixture of $CO_2$-CO instead of $CO_2$-$H_2$ to obtain constant oxygen partial pressure. In the present study, the linear rate of flow, therefore, was kept close to 2.5 mm./sec.

The rate of approach to equilibrium was studied thermogravimetrically. Mixtures with identical iron/magnesium ratios but of different initial degrees of oxidation were used in these experiments to ensure that the equilibrium measured was independent of the time and could be established from both sides. The procedures were as follows: A pellet with a fixed ratio of iron/magnesium which has been heated preliminarily at 700°C was heated at 1160°C in air for 3 hr. After ensuring no

change in the weight by the thermobalance, the degree of weight-loss was followed by the thermobalance at a desired oxygen partial pressure. When there was no recognizable change in weight over, at least, one hour, the weight thus obtained was regarded as the nearest point to the equilibrated state during the course from the oxidized state to the reduced state. Then the oxygen pressure was very greatly decreased to form magnesiowüstite with a large amount of ferrous iron. After fixing the desired oxygen partial pressure as the same as that in the course from the oxidized state to the reduced state, the degree of weight-gain was measured. The results obtained from both sides were identical within the limits of experimental error.

The thermogravimetric determination of ferrous iron was also ascertained by chemical analysis after rapid quenching. In addition, the composition of both the inside and the outside of a pellet equilibrated after a reasonable period of time was determined to check whether or not there was an uniform compositional distribution, as has been pointed out by Katsura[15] in the case of magnetite solid solution. These careful checks showed that the equilibrium point with regard to composition was experimentally determined by the thermogravimetric method.

Whereas the total compositions of condensed phases remained constant during the quenching, the phase assemblages present after the quenching were not always the same as they were at the end of the equilibration. For instance, the magnesiowüstite of the composition in the vicinity of the magnesiowüstite-spinel boundary curve could not be quenched. In such cases, the phase evidence given by the thermogravimetric data (the shape and location of oxygen isobars) is more reliable than that obtained by the quenching technique.

## Results and Discussion

The equilibrium data obtained at 1160°C are summarized in Table I, while they are illustrated graphically in Fig. 1.

Three oxide phases are stable under the present experimental conditions : hematite, $Fe_2O_3$, with a rhombohedral structure ; an oxide solid solution with a spinel structure (it is simply called spinel in this paper), and an oxide solid solution with sodium chloride structure (simply called magnesiowüstite). The detailed phase relations were studied mainly in those areas with both spinel and magnesiowüstite phases.

Figure 2 shows the relationship between the oxygen partial pressure (as $-\log P_{O_2}$) and the mole fraction of iron(II) oxide produced in a starting material of iron(III) oxide. We can see the discontinuous points in Fig. 2 as marked by letters from a to e. These may reasonably be responsible for the points where the starting material is in characteristic states at specified,

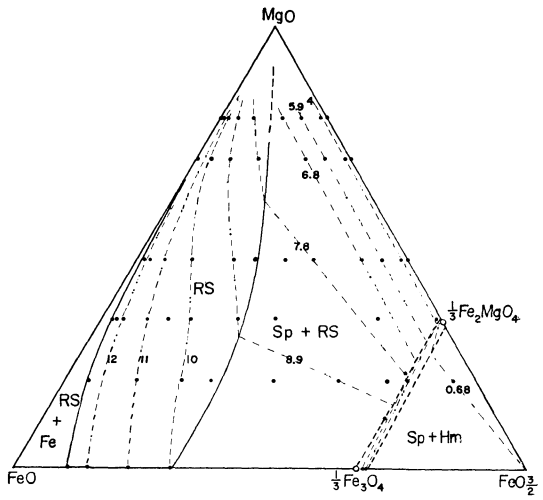

Fig. 1. Diagram illustrating phase relationship in the system $FeO$-$Fe_2O_3$-$MgO$. For convenience, the three components are taken as FeO, $FeO_{3/2}$, and MgO. Heavy lines are boundary curves. Heavy dashed lines are for the approximate spinel phase, and light dashed lines are isobaric lines with numbers meaning $-\log P_{O_2}$. Solid circles represent compositions, as shown in Table I. Abbreviations used have the following meaning : Hm= hematite, Sp=oxide with spinel structure, RS=oxide with NaCl structure, and Fe= metallic iron.

*** The phases at 1160°C could not be quenched.

stable coexistence of wüstite and metallic iron. These assignments are generally consistent with the Gibbs' Phase Rule. Figure 3 (a—e) was constructed on the basis of the treatment described above, but with different ratios of iron/magnesium in the starting materials. Figure 1 shows the phase boundaries over the whole system of $FeO-Fe_2O_3-MgO$ based on the results obtained from Fig. 2 and Fig. 3. The isobaric lines are also given by the broken lines Fig. 1. Each isobaric line is uniquely bent on the phase boundary curve.

The compositions of the spinel solid solution are generally represented by the formula $(Fe, Mg)_3O_4$. However, the solid solubility of the iron(III) oxide component into spinel extends pretty widely, as is approximately shown by the heavy broken line in Fig. 1. In addition, this solid solution seems to be stable, with a small deviation in the oxygen-to-cation ratio below the stoichiometric 4 : 3 value and with, at least, a 1 mole per cent of excess FeO. Table II shows the chemical composition of spinel with excess FeO at various oxygen partial pressures and at 1160°C. The lattice parameters of these metal-rich spinels were almost identical; $a_0=8.398\pm0.003$ Å. The lattice parameter of the stoichiometric spinel solid solution was also measured, but the difference was very small, ranging from 8.396 Å

of $Fe_3O_4$ to 8.399 Å of $MgFe_2O_4$.

The wüstite phase is characterized by wide variations in the iron/oxygen ratios; a continuous areal solid solution (magnesiowüstite) with sodium chloride structure is seen in Fig. 1. The present results sustain the observations of Brynestad and Flood[5] that the magnesiowüstite field in the $FeO$-$Fe_2O_3$-$MgO$ ternary system has an extensive range of stable existence at 1400°C and at various oxygen pressures ranging from $10^{-3.1}$ atm. to $10^{-7.46}$ atm. Figure 4 shows the relationship between the mole fraction of MgO and the ratio of $Fe^{3+}/(Fe^{2+}+Fe^{3+})$ within the field of magne siowüstite. It may be seen

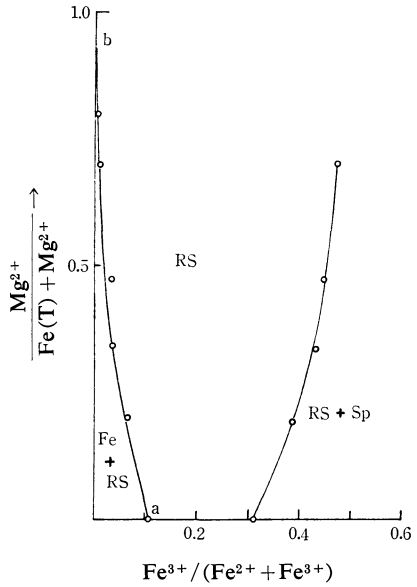

Fig. 4. The relationship between mole fraction of $Mg^{2+}$ and the ratio of $Fe^{3+}/(Fe^{2+}+Fe^{3+})$ within the field of magnesiowüstite. The curve a—b is the equilibrium boundary between magnesiowüstite and metallic iron + magnesiowüstite.

from Fig. 4 that the amount of $Fe^{2+}$ increases with an increse in the amount of magnesium on the equilibrium boundary between magnesiowüstite and metallic iron + magnesiowüstite (a—b in Fig. 4); the ratio of $Fe^{3+}/(Fe^{2+}+Fe^{3+})$ becomes nearly zero when the $Mg^{2+}/(Fe_{total}+Mg^{2+})$ ratio exceeds 0.7, while, as has been established by Darken and Gurry,[1] wüstite is unstable when the $Fe^{3+}/(Fe^{2+}+Fe^{3+})$ ratio becomes smaller than 0.10 (0.106 in the present study) at 1160°C.

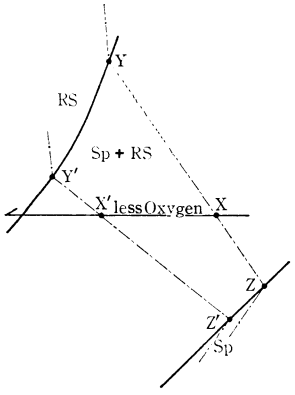

Fig. 5. A distorted diagram illustrating the equilibrated compositions within the field of spinel + magnesiowüstite.
Heavy lines are the boundary curves.
Light dash-hot lines are isobaric lines.

The area between the field of the magnesiowüstite solid solution and that of the magnetite-magnesioferrite solid solution is for the two phases. A mixed oxide witha composition within this area, say X, consists of an extremely reduced spinel, lettered Z and an extremely oxidized magnesiowüstite, letteredY as in Fig. 5.

The left side of the area of magnesiowüstite is for the two phases comprising metallic iron and magnesiowüstite. The metallic iron in equilibrium with magnesiowüstite within the range of oxygen pressures used in the present investigation is assumed to be pure because of the great stability of MgO. Therefore, consider the reaction:

$$Fe_{metal}+1/2\,O_2=(FeO)_{ss}$$

where $(FeO)_{ss}$ means the molality in the solid solution considered. The equilibrium constant $K$ is, therefore, expressed by:

$$K=a_{FeO}/a_{Fe}\cdot(P_{O_2})^{1/2}=a_{FeO}/(P_{O_2})^{1/2}$$

where $a$ means activity. When we assume that Raoult's law is applicable in the vicinity of $N_{FeO}\cong 1$, we have

$$K=N_{FeO}/P_{O_2}{}^{1/2}$$

where $N$ indicates the mole fraction.

According to the present study the maximum value of $N_{FeO}$ in pure wüstite was 0.894 at 1160°C (see Fig. 2) and log $P_{O_2}$ was $-12.40$, while the interpolated values based on the results of Darken and Gurry[1] were 0.903 and $-12.48$ respectively. From the present values, we get:

$$\log K=6.15$$

and

$$\log N_{FeO}=1/2\log P_{O_2}+6.15$$

The calculated values of $N_{FeO}$ in magnesiowüstite in equilibrium with matallic iron are plotted against $-\log P_{O_2}$ in Fig. 6 on the basis of the present study. The dotted line shows the experimental values in order to facilitate comparison with the calculated values. It is clear from Fig. 6 that a solid solution with more than 30 mole per cent of magnesium oxide deviates significantly from ideality. On the other hand, the calculated values agree rather well with the experimental values in the oxide solid solution with less than 30 mole per cent of magnesium oxide. This means that the assumption of Raoult's law may be correct near the composition $N_{FeO}\cong 1$. On the basis of this assumption, we can calculate the standard free energy of the formation of the stoichiometric ferrous iron oxide, $FeO_{1.000}$, which has never been synthesized in the standard state:

$$\Delta F^\circ{}_{1160^\circ C}=-RT\ln K=-40.3\ \text{kcal./mol.}$$

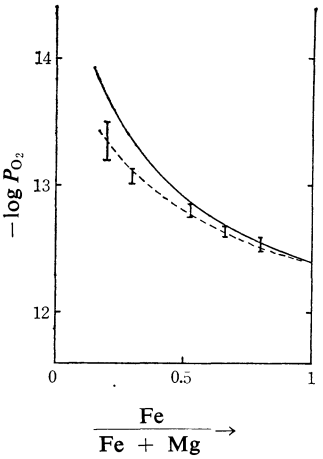

Fig. 6. The deviation from the Raoult's law in magnesiowüstite solid solution in equilibrium with metallic iron. Solid line is for calculated values, and dashed line is for observed with the width of experimental error.

When we compare this with the standard free energy of the formation of the most reduced and the actual wüstite, $FeO_{1.053}$ ($N_{FeO}=0.894$), we recognize that the stoichiometric compound, $FeO_{1.000}$, is unstable by $+0.4$ kcal. based on the following calculations: we calculate the free energy change on the reaction,

$$1.053\,FeO_{1.000}=0.053Fe+FeO_{1.053}$$

to be

$$\Delta F^\circ=1.053\times(-40.7)-1.053\times(-40.3),\ \text{(cal.)}$$

Here, the standard free energy of the formation of $FeO_{1.053}$ is equal to $1.053\,RT\ln P_{O_2}$ where $P_{O_2}$ is $10^{-12.40}$ atm.

Hahn and Muan[16] studied the activity of wüstite "FeO" in "FeO"-MgO solid solution in the temperature interval from 1100 to 1300°C by equilibrating oxide samples with pure metallic iron in atmospheres of known oxygen partial pressures. In their study, the component iron(III) oxide in the solid solution was neglected; they pointed out that the system shows a considerable positive deviation from Raoult's low. However, when we discuss the deviation from ideality, we must not neglect the actual component iron(III)oxide in magnesiowüstite; that is to say, we have to plot the values of $a_{FeO}$ against the actual values of $N_{FeO}$ instead of $(1-N_{MgO})$, which is equal to the marked "FeO." The results derived from the Gibbs-Duhem equation will, therefore, inform us only about the approximate thermodynamic properties of systems involving an iron(II) oxide component.

# Kinetic Studies of Ammonia Oxidation in Shock Waves. I. The Reaction Mechanism for the Induction Period

By Tetsu TAKEYAMA and Hajime MIYAMA

(Received February 16, 1965)

The catalytic oxidation of ammonia has been studied extensively. On the contrary, however, because of the relatively lower reactivity of ammonia, only a few works can be found on non-catalytic oxidation. Stephens and Pease obtained only qualitative results from their flow[1] and static[2] experiments. Volders and Van Tiggelen[3] proposed a mechanism involving $NH_2$, OH and NOH for the slow thermal reaction. Recently, Husain and Norrish[4] investigated the photolytic oxidation of ammonia by the flash photolysis method and by kinetic spectroscopy. They postulated a mechanism in which a relatively stable intermediate, HNO, plays the role as a degenerate branching reagent, although they themselves could not actually detect it.

However, no information can be found with respect to the mechanism responsible for the high-temperature oxidation of ammonia. In order to clarify this, we have made experiments at temperatures between 1550 and 2300°K by using the shock-tube technique combined with the spectroscopic method. In this paper, we will report on the results obtained from the measurements of the induction periods for the appearance of OH and of the time relations among the concentration changes of NH, $NH_2$, NO and OH.

## Experimental

The experimental arrangements were much the same as have been reported previously:[5] by means of a Shimadzu QR-50 monochromator and an R106 photomultiplier, the ultraviolet absorptions of OH and NH and the intensity distributions of light emitted at various wavelengths were measured.

The reaction mixtures were prepared in an all-glass apparatus with a 10 l. reservoir and were stirred magnetically for an hour before being used. Commercial ammonia (99.98%), oxygen (99.5%) and argon (99.999%) were used without further purification.

## Results

**Induction Period.**—The induction period for the appearance of OH absorption was measured in reflected shock waves for two mixtures at initial pressures from 50 to 110 mmHg. The experimental conditions covered are presented in Table I.

The induction period was found to be dependent neither on the ammonia concentration nor on the product of the ammonia and oxygen concentration, but on the oxygen concentration alone over the 1.5—0.67 range of the ammonia to oxygen ratio, as is shown in Fig.

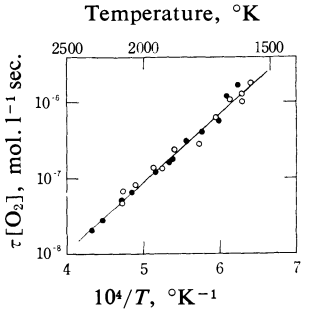

Fig. 1. Induction period for appearance of OH-absorption vs. reciprocal temperature. Open and solid circles are obtained from mixtures I and II (see Table I), respectively.

Table I. Experimental conditions

| Mixture | $\%O_2$ | $\%NH_3$ | %Ar | Temp. range °K | Press. range atm. | $[O_2]$ range $10^{-3}$ mol./l. |
|---|---|---|---|---|---|---|
| I | 6 | 4 | 90 | 1550—2110 | 3.5—5.5 | 1.23—2.47 |
| II | 4 | 6 | 90 | 1600—2300 | 3.5—4.5 | 0.741—1.37 |

1. The least-squares line in the figure is expressed by:

$$\log \tau [O_2]\,(\text{mol.}\,l^{-1}\text{sec.}) = -11.71 + (9300 \pm 270)/T$$

where the temperature dependence corresponds to an activation energy of 42.5±1.2 kcal./mol.

The pressure of the reaction system was measured simultaneously at the same location in the tube by a quartz transducer. However, the pressure increase due to the reaction was far less than that found by us in the oxidation of hydrogen,[6] acetylene[5] and methane[7]; it was not appreciable in most runs.

**The Spectroscopic Identification of Reaction Intermediates.**—The reaction intermediates, the NH radical, nitric oxide and the $NH_2$ radical, were identified by measuring the intensity distribution of light emitted in the ultraviolet and visible region:

*The NH Radical.*—Since NH has a strong band emission at 3360 Å due to its $^3\Pi \rightarrow {}^3\Sigma$ transition,[8] the intensities of light emitted at 1960±10°K were measured over the 3270—3430 Å wavelength range. The width of the exit slit of the monochromator was set at 0.20 mm., allowing a band pass of about 12Å. The results are shown in Fig. 2, where the intensities given in the ordinate are corrected with the spectral response of the R106 photomultiplier and divided by the intensities, which were measured simultaneously by means of an interference filter (Baird-Atomic, Inc., $\lambda_{max}$: 3070Å, transmission at $\lambda_{max}$: 13%, half width: 120Å) and an RCA 1P28 photomultiplier. There is a sharp peak at 3360 Å; hence, the existence of the NH radical is definite.

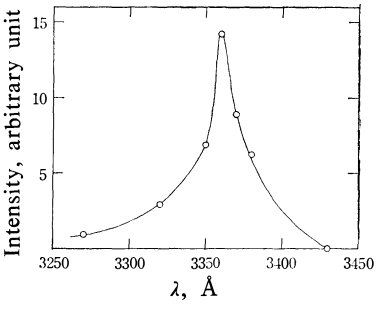

Fig. 2. Intensity distribution of light emitted between 3250 and 3450Å.
Mixture II, initial pressure 55.0 mmHg, shock temperature 1960±10°K

*Nitric Oxide.*—The β-band of nitric oxide has weak emissions at 4303 and 4310Å because of its $B^2\Pi \rightarrow X^2\Pi$ transition.[9] Therefore, the intensity distribution was measured over the 4215—4360Å wavelength range, with the slit width of the monochromator being set at 0.25 mm. and the band pass at 30Å. The results obtained at 2120±30°K are shown in Fig. 3, where the intensities are treated as has been described above. Although the peak near 4300Å is less definite than that found at 3360 Å, it may be attributed to nitric oxide, for there is no other possible emitter at this wavelength.

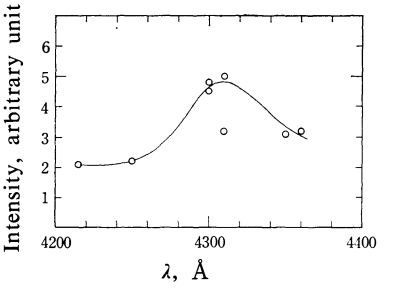

Fig. 3. Intensity distribution of light emitted between 4200 and 4400Å.
Mixture I, initial pressure 50.0 mmHg, shock temperature 2120±30°K

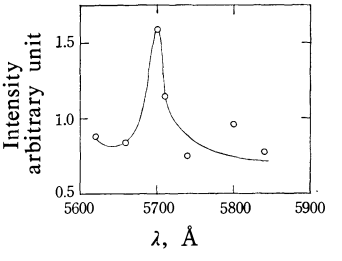

Fig. 4. Intensity distribution of light emitted between 5600 and 5900Å.
Mixture II, initial pressure 55.0 mmHg, shock temperature 1970±20°K

*The $NH_2$ Radical.*—The visible emission of $NH_2$, which is found in oxy-ammonia flames

6) H. Miyama and T. Takeyama, *J. Chem. Phys.*, **41**, 2287 (1964).

9) R. W. B. Pearse and A. G. Gaydon, "The Identification of Molecular Spectra," Chapman & Hall Ltd., London (1950), p. 180.

and is called the ammonia $\alpha$-band, is composed of a very large number of fine lines as a result of its rotational structure.[10] We have tried to find the bright band at about 5705 Å,[10] measuring the intensities of light emitted at 1970±20°K over the 5620—5840Å wavelength range; the slit width of the monochromator was set at 0.1 mm., which allows a band pass of 30Å. As is shown in Fig. 4, a peak is observed at 5700Å, thus confirming the existence of $NH_2$ radicals.

**Concentration Changes of Intermediate Species with Time.**—In order to observe the concentration changes of the above-described intermediates in the course of the reaction, the changes in the absorption and/or the emission of these species were followed by means of a monochromator with a photomultiplier. Since, however, the experimental arrangement does not allow the simultaneous measurements of absorptions or emissions of all these species, the ultraviolet emission, which was measured simultaneously at the auxiliary observation station by a Baird-Atomic interference filter and an RCA 1P28 photomultiplier, has been used as a reference standard for the time scale. A typical example of the changes observed in this way can be seen in Fig. 5, which was obtained by shock-heating the reaction mixture II at an initial pressure of 65.0 mmHg to 1840 ±10°K.

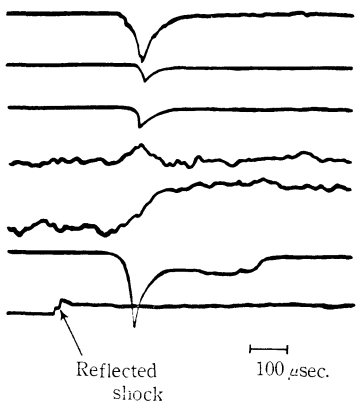

Fig. 5. Changes in absorption and/or emission of various intermediates with time.
Traces represent, from top to bottom, $NH_2$-, NO- and NH-emission, NH- and OH-absorption, the ultraviolet emission measured by an interference filter, and pressure.
Mixture II, initial pressure 65.0 mmHg, shock temperature 1840±10°K

The general features observed under various conditions are as follows: (a) the absorptions of OH and NH appear at the same time, after the arrival of the reflected shock; (b) the emissions of NH and nitric oxide appear and reach their maxima at almost the same time, while the emission of $NH_2$ seems to reach its maximum a little earlier than do those of NH and nitric oxide; and (c) the absorption of NH reaches its maximum earlier than that of OH and decays within a few tens of micro seconds.

## Discussion

The experimental observations a and b, concerning the time relations of various intermediates, lead us to postulate the following reaction scheme as the main steps governing the induction period of the high-temperature, homogeneous oxidation of ammonia:

$$NH_2+O_2 \rightarrow NH+HO_2 \quad (I)$$

$$NH+O_2 \rightarrow NO+OH \quad (II)$$

$$OH+NH_3 \rightarrow NH_2+H_2O \quad (III)$$

The $HO_2$ radical produced in Reaction I is unstable at these high temperatures[6] and so may soon decompose into OH and O by Reaction IV rather than reacting with ammonia.

$$HO_2 \rightarrow OH+O \quad (IV)$$

The oxygen atom will then abstract hydrogen from ammonia by Reaction V; the reactions between such intermediates as $NH_2$, NH, OH and O should be excluded from the reaction scheme for the induction period.[6,7]

$$O+NH_3 \rightarrow OH+NH_2^{\cdot} \quad (V)$$

An application of the treatment given by Schott and Kinsey for the hydrogen-oxygen reaction[11] to Reactions I—V will explain the dependence of the induction period on the oxygen concentration and the activation energy obtained from the temperature coefficient. By assuming that the principal chain carrier is the $NH_2$ radical, and that the OH, O, NH and $HO_2$ radicals are steady-state intermediates, [OH] and the rate of formation of the $NH_2$ radical are expressed by Eqs. 1 and 2 respectively:

$$[OH]=3k_1[O_2][NH_2]/k_3[NH_3] \quad (1)$$

$$d[NH_2]/dt=3k_1[O_2][NH_2] \quad (2)$$

Here, $k_1$ and $k_3$ are the rate constants of Reactions I and III respectively.

The integrated form of Eq. 2, assuming that the concentrations of ammonia and oxygen are not decreased during the induction period, is:

$$[NH_2]=[NH_2]_0 \exp\{3k_1[O_2](t-t_0)\} \quad (3)$$

10) Ref. 9, p. 178.

11) G. L. Schott and J. L. Kinsey, *J. Chem. Phys.*, **29**, 1177 (1958).

where $t_0$ is any reference time following which Eqs. 2 and 3 are valid, and the concentration with the subscript zero represents the concentration at $t=t_0$. It is assumed that at $t_0=0$ the rate of the chain branching becomes equal to the rate of initiation, although the initiation step can not be identified in the present study. [OH] can then be expressed by Eq. 4 and builds up exponentially, as has been found experimentally:

$$[OH] = [OH]_0 \exp(3k_1 [O_2] t) \quad (4)$$

$[OH]_0$ is given by Eq. 1.

Therefore,

$$\log\{[OH]_\tau / [OH]_0\} = 1.303\, k_1 [O_2] \tau \quad (5)$$

$[OH]_\tau$ being the concentration at the end of the induction period.

If it can be assumed, as in the hydrogen-oxygen reaction,[11] that the $[OH]_\tau / [OH]_0$ ratio remains approximately constant over the temperature range studied, the following relation is obtained from Eq. 5:

$$\tau [O_2] \propto 1/k_1 \quad (6)$$

Therefore, a plot of $\log(\tau [O_2])$ against $1/T$ would give a straight line, the slope of which corresponds to the activation energy of Reaction I. This has been found to be true, as has been described in the preceding section; the straight line shown in Fig. 1 gives an experimental activaion energy of 42.5±1.2 kcal./mol. for Reaction I, which is endothermic by 41 kcal./mol., if the bond energies of NH–H and H–$O_2$ are taken to be, respectively, 88[12,16] and 47[16] kcal./mol. The relatively small difference between the activation energy and the endothermicity may be due to the low activation barrier which is usually found in free radical reactions.[17] The results from the induction period measurements, therefore, suggest strongly that Reaction I is rate-controlling.

In the photolytic oxidation of ammonia, Husain and Norrish[4] have found NH, OH and nitric oxide to be absent in the initial stages of the reaction and have, therefore, postulated the following scheme:

$$NH_2 + O_2 \rightarrow HNO + OH \quad (VI)$$

$$OH + NH_3 \rightarrow NH_2 + H_2O \quad (VII)$$

$$HNO \rightarrow H + NO \quad (VIII)$$

$$2HNO \rightarrow H_2O + N_2O \quad (IX)$$

where they regarded the HNO intermediate as a degenerate branching reagent, although they could not detect it. At high temperatures such as those studied by us, the HNO molecule cannot be stable enough to play such a role. Furthermore, it is impossible for their scheme VI—IX to account for the experimental activation energy of 42.5 kcal./mol. and for Findings a and b.

Volders and Van Tiggelen[3] studied, by the static method, the slow oxidation of ammonia around 800°K and proposed the following mechanism:

$$NH_3 \overset{\text{wall}}{\rightarrow} NH \quad (X)$$

$$NH + O_2 \rightarrow NO + OH \quad (XI)$$

$$OH + NH_3 \rightarrow NH_2 + H_2O \quad (XII)$$

$$NH_2 + O_2 \rightarrow NOH + OH \quad (XIII)$$

$$OH + NO \rightarrow HNO_2 \quad (XIV)$$

Since NOH was not detected, Reaction XIII is rather speculative and open to question. In addition, the heterogeneous Reaction X yielding NH should be ruled out for the reaction in shock waves.

Therefore, our mechanism accounts most reasonably for the experimental findings concerning the induction period, i.e., for those except Finding c. In order to explain this, it is necessary to obtain the reaction profile after the induction period by using the values of rate constants, the concentrations of intermediates, and their thermochemical properties. Unfortunately, the available data at present are inadequate for carrying out such a numerical calculation.

## Summary

The oxidation of ammonia has been studied at temperatures between 1550 and 2300°K by using the shock-tube technique combined with ultraviolet absorption spectroscopy.

The measurements of the induction periods for the appearance of OH have shown that they are strongly dependent on the concentration of oxygen and that the activation energy required is 42.5±1.2 kcal./mol.

The intermediates of the reaction, NH, NO and $NH_2$, have been detected spectroscopically, and the time relations between their appearance and their accumulation have been determined.

As a result, the following mechanism has been postulated as the main steps governing the induction period of the high-temperature oxidation of ammonia:

12) E. D. Coon, *Proc. N. Dakota Acad. Sci.*, 7, 46 (1953); This value is also calculated from the values of the bond energies of $NH_2$–H and N–H and of the average N–H bond energy in ammonia, if they are taken to be 106,[13] 85[14] and 93[15] kcal./mol., respectively.

13) S. N. Foner and R. L. Hudson, *J. Chem. Phys.*, 29, 442 (1958).

14) A. G. Gaydon "Dissociation Energies and Spectra of Diatomic Molecules," Chapman and Hall Ltd., London (1953), p. 228.

15) Ref. 14, p. 170.

16) A. P. Altshuler, *J. Chem. Phys.*, 22, 1947 (1954).

17) N. N. Semenov, "Some Problems in Chemical Kinetics and Reactivity," Vol. I, Princeton University Press (1958), p. 4.

$$NH_2+O_2 \rightarrow NH+HO_2 \quad (I)$$

$$NH+O_2 \rightarrow NO+OH \quad (II)$$

$$OH+NH_3 \rightarrow NH_2+H_2O \quad (III)$$

$$HO_2 \rightarrow OH+O \quad (IV)$$

$$O+NH_3 \rightarrow OH+NH_2 \quad (V)$$

where Reaction I is considered to be rate-controlling.

We are grateful to Mr. Kazutoshi Sugiyama for his help in performing the experiments.

# A Study of the Charge-Transfer Complexes. I. The Interaction of Pyromellitic Dianhydride with Polymethylbenzenes*

By Yusuke NAKAYAMA, Yukihiko ICHIKAWA and Taku MATSUO

(Received February 20, 1965)

The formation of molecular complexes between pyromellitic dianhydride and aromatic compounds, such as anisole, tetralin etc., was first reported by Seka and Sedlatschek as early as 1926.[1] In spite of the remarkable advances made thereafter in the investigation of charge-transfer complexes, however, no further paper had been published on the phenomena until Heaton and others recognized pyromellitic dianhydride as a strong electron acceptor.[2] Heaton and his co-workers studied the complexes by the spectroscopic method and concluded that pyromellitic dianhydride was one of the strongest electron acceptors which had yet been found. Recently, Briegleb reported on the electron affinity of pyromellitic dianhydride, among other compounds, as estimated from the charge-transfer band.[3] Nothing else is known about the charge-transfer complexes of pyromellitic dianhydride, which is in contrast with the abundance of information about the behavior of such other acceptors as halogens, quinones, and nitro compounds. A little further investigation is reported, in this paper, into the complex formation of pyromellitic dianhydride (abbreviated as PMDA hereafter) with polymethylbenzenes, both in a solution and in the solid phase. Polymethylbenzenes were chosen as the donor to be studied for the following reasons.

1) The basicity or the ionization potential of each molecule is well known.[4]

2) The frame work of the $\pi$-electron system can be taken as a simple hexagon throughout the system.

3) The introduction of the methyl group into the benzene nucleus results in only a small perturbation in the $\pi$-electron system to be treated theoretically.

4) The charge-transfer complexes between polymethylbenzenes and iodine or chloranil have been studied fairly well in the past.[4b),5,6)]

Consequently, the discussion of the experimental results becomes much easier than in the case of other aromatic donors, which have many complicated unknown factors. This experiment was designed with some emphasis on the investigation of the nature of the solid molecular complexes.

## Experimental

*o*- and *p*-Xylenes were purified by repeated distillations and recrystallizations from commercial products until the purity in the gas chromatograph exceeded 98%. Tetralin was purchased from the Wako Pure Chemical Company, Ltd.; it was purified and proved to be free from naphthalene. Indan was synthesized by the reduction of indanone which had been prepared from cinnamic acid through 3-phenylpropionic acid.[7] Mesitylene was synthesized from acetone[8] and was determined to be pure by

CH analysis, infrared spectra and gas chromatography. Durene, penta- and hexamethylbenzenes were prepared by succesive Friedel-Crafts reactions and were purified by several fractional distillations and recrystallizations from either methanol or a methanol-benzene mixture. Infrared spectra and CH analysis were used to identify the prepared methylbenzenes, whose melting points are as follows: durene (80.8—81.0°C), pentamethylbenzene (52.7—53.2°C), and hexamethylbenzene (168.0—168.3°C).

Pyromellitic dianhydride was prepared by the dehydration of pyromellitic acid, a reagent-grade product of Tokyo Kasei Kogyo Co., Ltd., through refluxing in acetic anhydride for several hours. The product was then recrystallized from purified ethylacetate and proved to be free from any trace of the original acid. (Found: C, 55.05: H, 0.93%: m. p. 299.8—300.0°C). The melting points are the values as observed on a Kofler micro hot-stage and are uncorrected.

Solid molecular complexes were prepared by adding pyromellitic dianhydride either to a donor or to an ethyl acetate solution of the donor at an elevated temperature and then cooling the solution to room temperature. The formation of charge-transfer molecular complex could easily be noticed by the precipitation of crystals with a characteristic shape and color. Extra care was taken here to avoid the coprecipitation of the uncomplexed pyromellitic dianhydride. The degree of heating and the relative ratio of the donor to the pyromellitic dianhydride in the best conditions varied from case to case.

The ultraviolet and visible spectra were measured by a conventional method using an EPS-2U model Hitachi recording spectrophotometer.

The solid complexes were ground on an agate mortar and were dispersed evenly in approximately ten times as much talcum powder (as determined by weight). The sample was packed in a cylindrical cell and was mounted on the wall of the integrating sphere of the reflectance attachment of an EPU-2A model Hitachi photoelectric spectrophotometer. The reflectance of the sample was determined against a standard sample of talcum powder under the same geometrical conditions.

The X-ray diffraction data of the powdered solid samples were obtained by the use of a Norelco X-ray spectrophotometer.

## Results and Discussion

**Complexes in Solution.**—After many attempts, ethyl acetate was found to be the best solvent for the complexes of PMDA with a wide variety of aromatic compounds. The newly-appeared absorption bands due to the complex formation of mesitylene, durene, penta- and hexamethylbenzenes with PMDA in ethylacetate are shown in Fig. 1. There is no appreciable absorption due to the donor in the longer-wavelength region beyond 330 mμ (Fig. 2). The absorption of PMDA is practically negligible in the visible range under

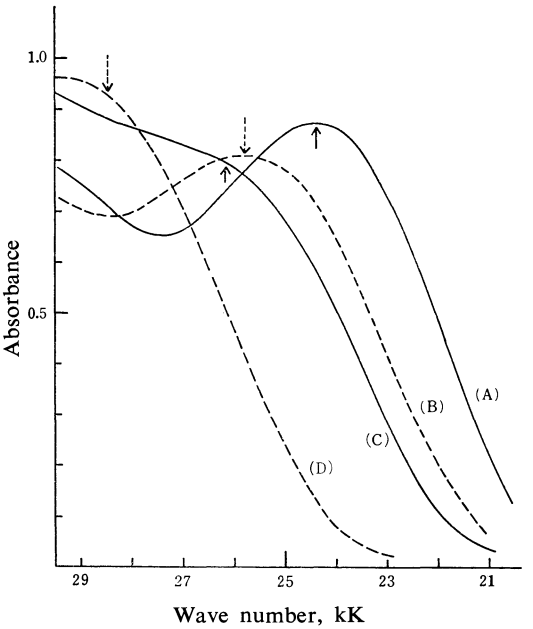

Fig. 1. The charge-transfer absorption bands of PMDA-polymethylbenzene complexes in ethyl acetate (18±1°C).
(A) Hexamethylbenzene ($4.0\times10^{-2}$ mol./l.)-PMDA
(B) Pentamethylbezene ($7.3\times10^{-2}$ mol./l.)-PMDA
(C) Durene ($1.5\times10^{-1}$ mol./l.)-PMDA
(D) Mesitylene ($2.4\times10^{-1}$ mol./l.)-PMDA
The concentration of PMDA is $1.0\times10^{-2}$ mol./l.

these experimental conditions (Fig. 2). An unmistakable charge-transfer absorption band is observed for each complex of hexa- and pentamethylbenzenes with PMDA. The peak still appears as a shoulder in the case of durene, but it is not at all obvious in the case of the mesitylene complex.

Since the charge-transfer absorptions in general are expected to be sensitive to the solvent polarity, the charge transfer bands of the well-known chloranil complexes with polxmethylbenzenes or pyrene were studied in several solvents; the results are summarized in Table I. It may be seen from this table that the charge-transfer band shows a hypsochromic shift as the solvent polarity increases. In addition, the apparent peak height decreases considerably if the donor-acceptor pair is present in a polar medium. The frequency of the charge-transfer band $\nu$ is correlated with the electron affinity ($E_A$) of the acceptor and the ionization potential ($I_D$) of the donor by Eq. 1:

$$h\nu = I_D - E_A + \Delta \quad (1)$$

where $\Delta$ is a correction term mainly due to

*1 The values are expressed in kilo-kaysers (kK).
*2 Quoted from the Ref. 6.

the Coulombic interaction of $D^+$ and $A^-$.[9] Thus, the hypsochromic shifts observed above may be interpreted mainly as due to the decrease in the electron affinity of the acceptor level as a consequence of the solvation by the polar molecules. If the last term in Eq. 1 is approximately constant among the complexes with donors of a similar type, the band separation among the polymethylbenzene-chloranil complexes in ethyl acetate can be used to estimate the difference in the ionization potentials of the donors in the same solvent. Using these values and taking hexamethylbenzene as the standard, the location of the charge-transfer band of each polymethylbenzene-PMDA complex is calculated. The values are indicated by the arrows in Fig. 1. Then the newly-appeared absorptions of the polymethylbenzene-PMDA complex are resolved into two bands of a different nature. The first band is found at the frequency indicated by the arrow in Fig. 1; it is, of cause, believed to originate from the transfer of an electron from the highest-occupied donor orbital to the lowest unoccupied acceptor orbital. The band moves to the longer-wavelength region as the number of methyl groups increases. The second band, with a rather diffuse shape, is noticed clearly on the higher frequency side in the case of the hexamethylbenzene complex in Fig. 1. The first band becomes less distinct in comparison with the second band as the number of methyl groups decreases. In the case of the mesitylene complex, finally, the first band appears to be merged in the second band. The origin of this second band is not certain. Obviously, however, it is not the so-called "second charge-transfer band," which is defined as due to the electron transfer from the second highest occupied orbital of the donor to the lowest unoccupied orbital of the acceptor. It is more likely that the second band comes from the combination of many complexes with different geometries and electronic states, including the contact charge transfer.[10]

No matter where they come from, these newly-appeared absorption bands can be used to estimate the equilibrium constants of the charge-transfer complexes in the solution. It must be remembered, however, that the equilibrium constants thus obtained are contributed by charge-transfer complexes of various types.[11] The original Benesi-Hildebrand equation[12] for a one-to-one complex was modified into the follwing form:

$$\frac{1}{(\mathrm{ArH})} = \frac{[\mathrm{PMDA}] \times l}{\mathrm{ABS}} \times K\varepsilon - K \qquad (2)$$

where (ArH) is the concentration of methylbenzenes in mole fractions; [PMDA] is the concentration of PMDA in mol./l.; $l$ stands

(B) Pentamethylbenzene: $0.4\times10^{-1}$—$1.6\times10^{-1}$ mol./l.
(C) Durene: $0.5\times10^{-1}$—$3.0\times10^{-1}$ mol./l.
(D) Mesitylene: $1.2\times10^{-1}$—$4.6\times10^{-1}$ mol./l.
and PMDA: $0.1\times10^{-1}$ mol./l. or less
The plots are made after converting the donor concentrations into mole fractions.

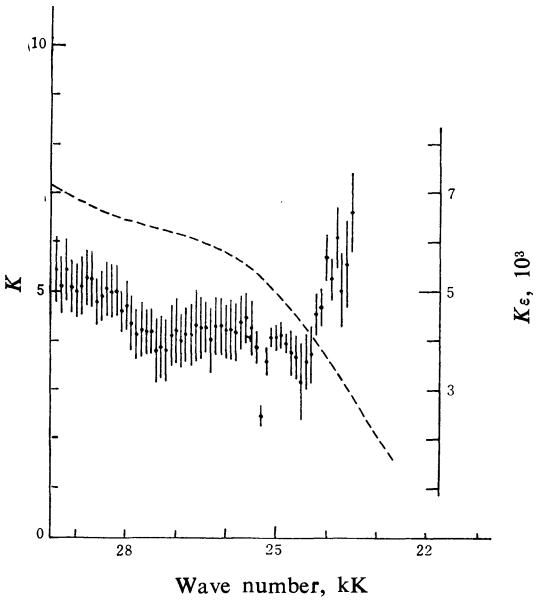

Fig. 4. The stability constant $K$ as calculated by the modified Benesi-Hildebrand equation at various positions of the charge-transfer band of durene-PMDA complex in ethylacetate (18°C).
Molar fractions were used in the calculation as the units of donor concentration. The dotted line represents $K\varepsilon$ which is obtained from the slope of the modified Benesi-Hildebrand equation.

for the length of the absorption cell in cm.; $K$ is the equilibrium constant (dimensionless quantity), and ABS and $\varepsilon$ are the absorbance and the extinction coefficient (l./mol.) for the complex at a particular wavelength respectively.

Plotting 1/(ArH) vs. [PMDA]$\times l$/ABS at a fixed wavelength yields the equilibrium constant and $K\varepsilon$ as the intercept and the slope of the straight line respectively. Examples are shown in Fig. 3, where the plots are made by using the data of four polymethylbenzene complexes at their absorption maxima. Rather low donor concentrations were used in these experiments because of the limited solubilities. The equilibrium constants of the complexes, however, hardly ever exceed ten, as may be found below. Therefore, a simple calculation shows that the concentrations of the complexed species are negligibly small in comparison with that of the added donor in the experiments. Thus the basic condition for the applicability of the Benesi-Hildebrand equation is fulfilled. The plotting of the experimental data as in Fig. 3 gives a straight line and verifies the correctness of the treatment. The equilibrium constants and $K\varepsilon$'s were evaluated by applying the method of least squares to the data at various frequencies of the absorption bands; an example is shown in Fig. 4. The arithmetic means of the values obtained over the absorption band of each complex are summarized in Table II. The equilibrium constants of the methylbenzene-chloranil complexes are also quoted from Smith's data[6] in the third column of Table II. The trends in both

*3 In butylether.[6]

series are in good agreement and indicate that the methyl groups have similar stabilizing effects on the charge-transfer complexes of both types, as was expected. No direct comparison was made of the present results with those reported by Heaton et al.,[2] since the donors and the solvents used in the two experiments are quite different. It appears, however, that the equilibrium constants obtained in ethyl acetate are less than those measured in carbon tetrachloride. An attempt is now being made to investigate the solvent effect by employing donors whose equilibrium constants in complex formation can be determined in either solvent with a satisfactory accuracy.

**Solid Complexes.**—The relative diffuse reflectance, $R$, of a solid material is correlated with the absorption coefficient, $k$, by the following Kubelka-Munk remission function, $f(R)$ :

$$f(R)=\frac{k}{S}=(R-1)^2/2R \qquad (3)$$

where $S$ denotes a scattering coefficient.[13]

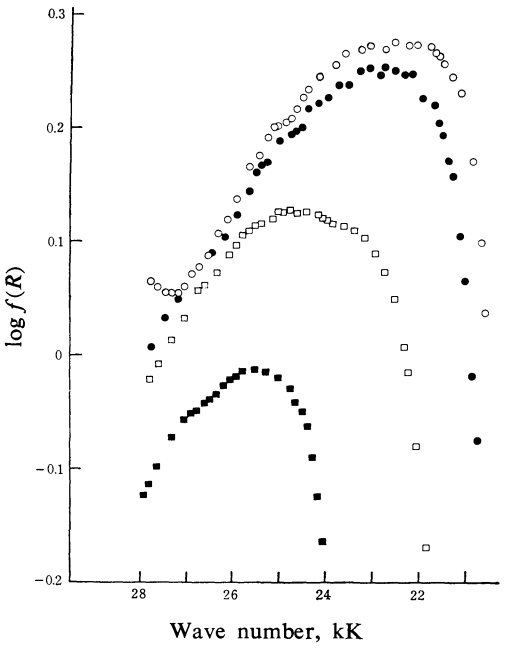

Fig. 5. The diffuse reflectance spectra of PMDA-polymethylbenzene complexes.

Kortum and Braun successfully applied Eq. 3 in their studies of the pyrene- and anthracene-trinitrobenzene complexes.[14]

The diffuse reflectances of PMDA-polymethylbenzene complexes obtained above were then used to calculate the $f(R)$ function; the results are shown in Fig. 5. When Fig. 5 is compared with Fig. 1, it may be noticed that the spectra of PMDA-polymethylbenzene complexes in the solid state show a regular red-shift from those in solution. The red-shift of the absorption of the durene-PMDA complex, however, is extraordinarily large, showing that the band is situated between those of penta- and hexamethylbenzene complexes. Apparently, the durene molecule takes a more favorable position with regard to the PMDA molecule in the charge-transfer complex than do other polymethylbenzenes. This odd behavior of durene in the solid state will be discussed, together with that of *o*-xylene, in the following section.

Heaton et al. noticed that the equilibrium constant of the *o*-xylene-PMDA complex exceeded those of meta and para isomers, and explained this as being due to the dipole moment of *o*-xylene.[2] In solid states, the

absorptions of PMDA-xylene complexes are fairly sharp, as is indicated by $f(R)$ functions in Fig. 6, and simple, well defined structures may be expected for the molecular complexes. A comparison of the peak positions does not give any fruitful results in this case, since the solution spectra of the corresponding complexes are too broad to make a fine argument. The anomalous behavior of *o*-xylene becomes clear when the molar ratios of the donor to the acceptor in xylene-PMDA complexes are compared. The molar ratio was determined by heating the solid samples up to 80°C under reduced pressure and by then measuring the weight decrease due to the loss of the donor molecule. The results are summarized in Table III.

Included in the same table are complexes of tetralin and indan, which are taken as the analogues of *o*-xylene. These *o*-xylene analogues are seen to make definite two-to-one complexes with PMDA. All of the other polymethylbenzenes, dimethoxybenzene isomers, and polycyclic aromatic hydrocarbons, without exception, make one-to-one complexes. Therefore, the formation of two-to-one complexes with PMDA is a special characteristic of the *o*-xylene analogues which have two alkyl groups at adjacent positions on a benzene nucleus.

X-Ray diffraction from the powdered sample affords another method to differentiate between two-to-one and one-to-one complexes. As may be seen from Figs. 7 and 8, the two-to-one complexes show characteristic diffraction in the neighborhood of 13Å. Analogously strong peaks are observed around 7Å in the case of the one-to-one complexes. Not only the X-ray diffraction patterns but also the crystalline form of the complex changes vividly from monoclinic needles to leaflets as the molar ratio increases. Obviously, the arrangement of the molecules differs considerably for these two types of solid complexes. As is generally agreed, the smallest unit of a charge-transfer complex with $\pi, \pi$-interaction is a donor and acceptor pair, their molecular planes facing each other. Thus the structure of the one-to-one complex is considered to consist of the layers of the PMDA-donor pair in succession.

The presence and position of the second donor molecule in the two-to-one complex is more difficult to explain. In order to understand this problem more fully, the $\pi$-electron systems of PMDA and donor molecules were studied by the simple LCAO MO method. The coefficients of the atomic orbitals contributing to the lowest unoccupied molecular orbital of PMDA are shown in Fig. 9. On the basis of these figures, it is reasonable to consider PMDA as a bifunctional electron acceptor consisting of two molecules of maleic anhydride. The same LCAO MO calculation was made on polymethylbenzenes, assuming an inductive model for the methyl group. The energies and the coefficients of AO's for the

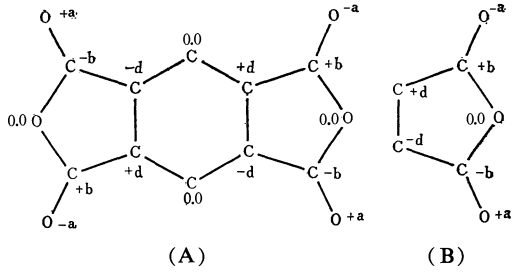

Fig. 9. The coefficients of AO's in the lowest unoccupied molecular orbital of anhydride.
(A) PMDA: $a=0.317$, $b=0.283$, $d=0.263$
$E=\alpha+0.11\beta$
(B) Maleic anhydride: $a=0.449$, $b=0.401$, $d=0.372$
$E=\alpha+0.11\beta$

The parameters used in the calculation are as the following, $h_{\dot{O}}=1.0$, $h_{\ddot{O}}=2.0$, $k_{C=O}=1.0$, $k_{C-O}=0.8$ and an auxiliary inductive parameter as suggested by Streitwieser (A. Streitwieser, Jr., "Molecular Orbital Theory," John Wiley & Sons, Inc., New York (1961), p. 135).

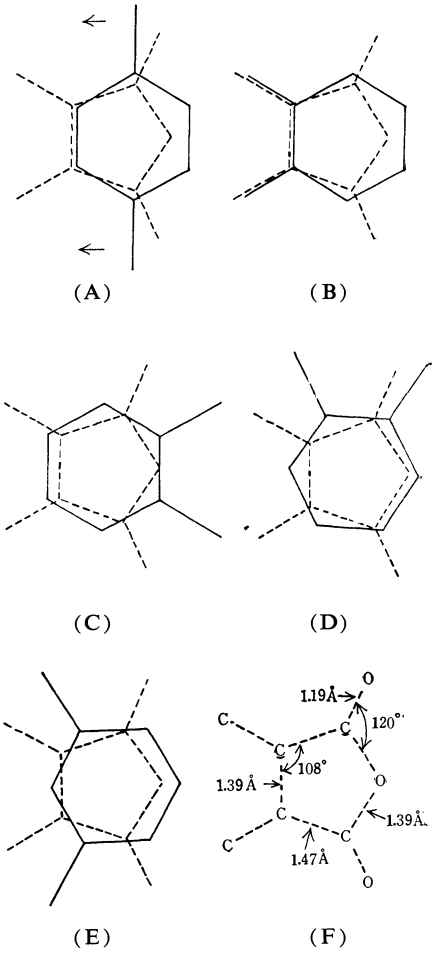

Fig. 11. Possible orientations of xylene isomers with respect to PMDA.
(A) *p*-Xylene (B), (C), (D) *o*-Xylene
(E) *m*-Xylene

The dotted lines indicate the right hand half of PMDA molecule. The dimensions as shown in (F) are assumed for PMDA on the basis of the reported X-ray data about maleic anhydride (R. E. Marsh, E. Ubell and H. E. Wilcox, *Acta Cryst.*, **15**, 35 (1962)).

occupied orbitals are listed in Table IV. The highest occupied MO's of xylene isomers are also shown in Fig. 10.

One of the most important conditions for a stable charge-transfer complex is a good overlapping between the acceptor orbital (the MO, as illustrated in Fig. 9(A) in this case) and the donor orbital (the highest occupied orbital of the donor in general). From this point of view, the symmetry properties of the above MO's may be seen to indicate that the anhydride group of PMDA would work as a better electron-accepting site to the donors under consideration than the central benzene ring in the same molecule. In addition to this electronic factor, the van der Waals repulsion should affect, to some extent, the relative orientation of the donor-acceptor pair. The highest occupied molecular orbital of *p*-xylene, for example, is ideal for "lock and

key" fitting[2] to the accepting orbital of the anhydride group, as is shown, in Fig. 11(A). The distance between the molecular planes is assumed to be 3.3Å, which is the value commonly found in the cases of chloranil- and trinitrobenzene complexes with aromatic hydrocarbons. Some van der Waals repulsion results from the methyl and carbonyl groups being in an exact superposition. This repulsion is relieved by shifting the donor molecule horizontally in the direction indicated by the arrows. The *o*-xylene analogues represent a case where the van der Waals repulsion between the substituents and PMDA strongly depends on their mutual orientation if the inter-planar distance is held at 3.3Å. In the orientation as is illustrated in Fig. 11(B), a considerable change in the van der Waals repulsion may be expected if the comparison is made between the complexes of *o*-xylene and tetralin or indan. Since all of these *o*-xylene analogues show similar complexing behavior, it is unlikely that a coordination of this type really exists. Furthermore, both models, B and C, may be eliminated by considering the symmetry properties of the MO's concerned. The model D is the only one left as a possible structure. Certainly it is not the best one as judged on the maximum overlap principle. The van der Waals repulsion mentioned above, however, is at a minimum in this configuration. Similar arguments predict model E as the most probable structure for the *m*-xylene - PMDA complex. This situation is rather satisfactory in view of both the electronic interaction and the intermolecular repulsion.

Coming back to the case of the two-to-one complex, the above theoretical considerations do not give any explanation of why it is found only in the *o*-xylene analogue. In any case, however, a donor molecule is taken to be located directly above one of the anhydride groups of PMDA. Therefore, there is not enough room left for another donor on the same side of PMDA. The second donor may come in freely from the back of PMDA, as is shown in Fig. 12. The formation of such a donor-acceptor-donor sandwich, if one exists, should be favored by a strong electron donor such as hexamethylbenzene or anthracene. Since this is not the actual case, however, such a system has very poor prospects to be the unit of the *o*-xylene analogue-PMDA complex in the solid state. As has been pointed out by Heaton et al.,[2] the existence of large dipolement is an important characteristic of the *o*-xylene and its analogue, differentiating them the isomers. The donor-acceptor pair in the charge-transfer complex

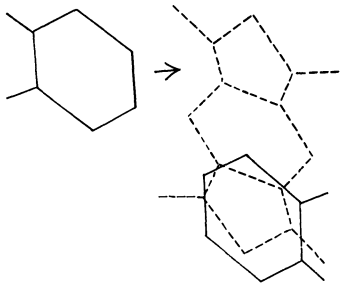

Fig. 12. One of the possible routes for the second donor to approach PMDA.

is also polar by its own nature. Therefore, the truth may be that the second *o*-xylene (or its analogue) is paired off to the first donor-PMDA couple in such a way as to stabilize the whole system in the solid state. The role may be close to that played by the water of crystallization in ionic crystals. Of course, some charge-transfer-type interaction is to be expected between the second donor and the unoccupied anhydride group. Therefore, it may be predicted that the second donor will be found somewhere close to the vacant electron-accepting site of PMDA. The final answer must, however, await the results of the X-ray diffraction and spectroscopic studies of a single crystal of the complex.

In the above discussion of the xylene complexes, the second-highest-occupied MO (abbreviated as SHO MO) of the donor is not taken into consideration. This treatment may be justified on the basis of the following facts:

(1) The SHO level of xylene is located between the highest occupied levels of toluene and benzene, as may be seen in Table IV.

(2) No solid complex is formed between benzene and PMDA, while the complex yielded from toluene is rather unstable.

The treatment, however, can not be applied to the highly methylated benzenes any more. In some of these donors, the energy of the SHO MO is too close to that of the highest occupied orbital to be neglected in the discussion. The difference between the highest-occupied and the SHO MO's is seen in their symmetry properties. The highest occupied MO's of mesitylene, durene, penta- and hexamethylbenzenes are shown schematically in Fig. 13(A). It should be noticed here that the coefficients are antisymmetric and symmetric with respect to the x and the y axes respectively. Exactly reverse situations are found for the coefficients in the corresponding SHO MO's (or the counterparts of the degenerate pairs in the cases of mesitylene and hexamethylbenzene), as Fig. 13(B) shows.

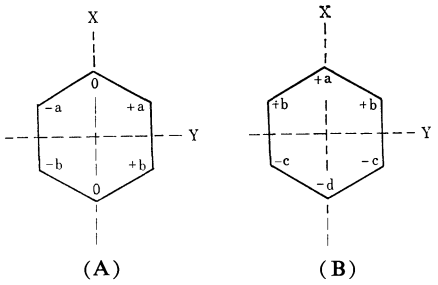

Fig. 13. The symmetry properties of the highest and the second highest occupied molecular orbitals of the highly methylated benzenes.

The lowest unoccupied MO of PMDA, on the other hand, is antisymmetric with respect to the longitudinal axis of symmetry, as is shown in Fig. 9.

As far as the symmetry properties are concerned, therefore, the predicted orientation of the donor molecule with relation to PMDA is approximately ninety degrees apart, depending on the particular orbital used in the interaction. In other words, the electronic interaction between PMDA and the highest occupied MO is counteracted by that due to the SHO MO. The higher the energy level of the SHO MO, the stronger the interaction. If a strong counteraction is exerted, the actual orientation of the donor molecule becomes less favorable to the overlapping between the highest occupied MO and the acceptor orbital. Furthermore, the best orientation of the SHO MO's results in the worst situation for the van der Waals repulsion due to the methyl groups. As may clearly be seen in Table IV, the SHO MO of durene is located considerably lower than those of mesitylene, penta- and hexamethylbenzenes. Therefore, the anomalous peak position observed in the solid spectra of durene-PMDA complex may be explained as being due to the more effective overlapping between the highest occupied MO of the donor and the acceptor orbital than in the cases of other polymethylbenzenes.

The above theoretical prediction seems to explain the behavior of polymethylbenzene-PMDA complexes very well. The findings regarding simple LCAO MO method, however, should be applied to actual cases with great care. It is well known that the quantitative results obtained by the method differ considerably from the true values. Even a qualitative prediction is sometimes in error, as in the case of the iodine-benzene complex.[15] The situation is expected to be a little better for the $\pi-\pi^*$ charge-transfer complexes, where no other arrangement of the donor acceptor pair is conceivable except a sandwich type with their molecular planes facing each other. Many atomic orbitals in both the donor and the acceptor molecules are involved in the overlapping of the MO's. Consequently, a minor change in the relative orientation of the molecules causes an appreciable difference in the overlap integral between the donor and the acceptor orbitals. Therefore, the symmetry consideration of the problem would be more fruitful than it is in the cases of the other type of complexes. Nevertheless, it is advisable to evaluate the results of the simple LCAO MO method with some reservations. Further studies are required to solve the problem.

In summary, the study of PMDA-polymethylbenzene solid complexes reveals many characteristics which are not found in the complexes in solution. These phenomena may be explained as representing the finer differences in the donor properties, such as the polarity of the molecule, the symmetry of the orbitals concerned, and the van der Waals repulsion due to the substituents. The compact and well-defined arrangement of the donor-acceptor pair in the solid state is considered to be responsible for the appearance of these phenomena.

The authors are grateful to Miss Katsumi Mera for measuring the ultraviolet and visible spectra reported in this paper. They are also indebted to Miss Tsuneko Ito and Miss Mizue Moritomo for their help in preparing the manuscript.

# The Mössbauer Spectra of Several Inorganic Iron Salts

By Yoshimasa TAKASHIMA* and Shigeru OHASHI*

(Received February 25, 1965)

Since the discovery of the Mössbauer effect, a number of papers have appeared concerning this phenomenon, which consists of the recoilless emission and resonant recoilless absorption of nuclear gamma radiation. However, the great majority of previous investigations of the Mössbauer effect have been concerned almost exclusively with nuclear physics, solid state physics and theoretical physics.

Takashima et al.[1] and Fluck et al.[2] have, in earlier reviews pointed out the applicability and significance of the Mössbauer effect in chemical research. In recent years, chemical Mössbauer studies of iron cyanide complexes,[3] iron carbonyl complexes,[4,5] ferrocene derivatives[6] and iron phenanthroline complexes[7] have, therefore, been carried out by several groups of workers. However, a large number of other compounds are still unexplored. Meanwhile, increasing interest is being shown in chemical applications of the Mössbauer effect.

The purpose of the present work is to measure the isomer shift and the quadrupole splitting for the 14.4 keV. $\gamma$-transition of $^{57}Fe$ in various iron compounds, in the hope that the wealth of the resultant data will make clear any correlation between these values and the chemical binding of iron atoms.

## Theoretical Considerations

The very low gamma ray level used in Mössbauer study tells us that the vibrational and rotational states in the molecule will have little effect on the Mössbauer spectrum. The shape of the spectrum is mainly affected by the electronic charge distribution around the iron atom. As has been shown in previous papers,[4-7] the Mössbauer measurements can give extremely valuable information about the electronic charge distribution in the molecule as a function of the structure.

Two quantities, the isomer shift and the quadrupole splitting, are readily derived from Mössbauer spectra. The magnitude of these values is considered to be closely related to the molecular structure with which $^{57}Fe$ is concerned.

The isomer shift, $\delta$, is given in first approximation by the formula:

$$\delta = C(R_e^2 - R_g^2)[|\psi_a(0)|^2 - |\psi_s(0)|^2]$$

where $C$ is a constants; $R_e$ and $R_g$ are the effective charge radii in the excited and ground states respectively, and $|\psi_a(0)|^2$ and $|\psi_s(0)|^2$ are, respectively, the $s$-electron densities at the iron nucleus in the absorber and in the source. This density is greatest for the inner $s$-electrons, but it is nonzero for even the outermost $s$-electrons.

If we consider two atoms of the same element that differ only in respect to the molecule in which they are bound, the difference in the electron density at the nucleus will reflect the difference in the chemical nature. Thus the extent of the isomer shift will give semiquantitative information as to the chemical binding.

The quadrupole slitting, $\varepsilon$, is characterized by the $1/4\, e^2qQ$, quantity where $e$ is the electronic charge, $q$ is the electronic field gradient at the nucleus, and $Q$ is the quadrupole moment of the nucleus. Splitting occurs if the electronic charge distribution at the atom is not spherically symmetrical.

Therefore, the quadrupole splitting provides a measure of the crystal field parameters in various compounds. However, there is, at present, no general method for predicting the relative isomer shift (or the quadrupole splitting) of various compounds with different types of bindings.

## Experimental

**Materials.**—The following chemicals were used, all were commercial reagent grade products, and all were used without further purification.

Iron(III) chromate $\{Fe_2(CrO_4)_3\}$, Basic iron(III) chromate $(Fe_2O_3 \cdot 4CrO_3 \cdot H_2O)$, Iron(III) arsenate $(FeAsO_4)$, Iron(III) phosphate $(FePO_4 \cdot 4H_2O)$, Iron(III) pyrophosphate $Fe_4(P_2O_7) \cdot 9H_2O$, Iron(II)

7) L. M. Epstein, ibid., **40**, 435 (1964).

phosphate $Fe_3(PO_4)_2 \cdot 8H_2O$, Graham's salt $\{(NaPO_3)_n\}$, Iron oxides ($Fe_2O_3$ and $Fe_3O_4$), Potassium ferricyanide $K_3[Fe(CN)_6]$.

Most of the samples studied were especially prepared for the measurements.

*Metal Ferricyanide Complexes $M_3[Fe(CN)_6]_2$ (M= Zn, Cd, Ni and Co).*—Solutions (approximately 0.1 M) of metal sulfate and potassium ferricyanide were prepared. Equivalent quantities of the former were then added to the latter, so that four different precipitates were obtained. After that, the precipitate was centrifuged off, washed with water, and dried on filter paper.

*Alkali-Iron(III) Double Sulfates $M'Fe(SO_4)_2 \cdot 12H_2O$, (M'=K, Rb and Cs).*—A saturated solution of metal sulfate was mixed with an equivalent amount of an iron(III) sulfate solution. The mixture was then placed in a desiccator for several days until crystals formed. The precipitate was filtered off and dried on filter paper.

*Glassy Substances Consisting of $(NaPO_3)_n$-$Fe_2O_3$ and $(NaPO_3)_n$-$Fe_3O_4$.*—Graham's salts (10 g.), prepared by the thermal dehydration of dihydrogen phosphate, was mixed with varying amounts of $Fe_2O_3$ (or $Fe_3O_4$) in a platinum crucible so that the P/Fe ratios became 5, 7, 10 and 50. The mixtures were then fused by heating them at 900°C for one hour and then rapidly cooling them. The products were all brownish, glassy substances.

*Cement.*—A vinyl cemedine*-chloroform solution was used to cement the sample on a sample holder disk.

**Apparatus.** — Our experimental arrangements, shown in Fig. 1, were essentially the same as those described by De Pasquali et al.[8] (1960) and by Shirley et al.[9] (1961).

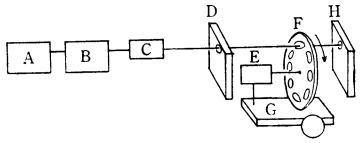

Fig. 1. Experimental arrangement.

A Scaler
B Single channel pulse height analyser
C NaI detecter
D Slit
E Synchronous motor
F Absorber disk
G Angle changer
H Source

About 5 mc. of $^{57}Co$ electroplated on metallic copper was used as a source. The main advantage of such a large amount of source material is the feasibility of time-saving measurements.

The constant velocity drive consists of a constant speed synchronous motor (4 r.p.m.) with a round absorber disk (7.4 cm. in diameter). The absorber disk has eight open windows in which a sample is mounted. The gamma ray passing through the disk sees, in its direction of motion, a velocity component, $r\omega \sin\theta$, where $r$ is the distance from the axis of rotation to the point where the gamma ray passes through the absorber, and where $\theta$ is the angle between the gamma ray and the axis of motion.

The gamma ray (14.4 keV.) was measured by means of a single-channel pulse-height analyzer equipped with a thin NaI scintillation detector (1 cm.×2 cm., 1 mm. thick). The detector face was located 40 cm. from the source. The absorber was placed between the source and detector face, at a distance 9 cm. from the source. The instrumental conditions were unchanged for many months.

A multichannel pulse-height analyzer,[10] coupled with an instantaneous velocity measurement of the gamma ray source, was also used for the measurement of several samples, but only when enough sample for the previous technique was not available.

**Procedure.** — A known amount of a powdered sample was mounted on an absorber disk by using a vinyl cemedine-chloroform solution. The total amount of sample taken varied within the range from 0.8 to 2.4 g. (10—20 mg. Fe/cm²), depending on its iron content. The sample sheet was made as uniform as possible.

The gamma ray transmissions were measured at room temperature for each Doppler velocity, these velocity were arbitrarily selected by changing the angle of the absorber disk. The relationship between the intensity of the transmitted radiation and the relative velocity of the absorber was plotted in graphical form, and then both the isomer shift and the quadrupole splitting were read out from the curve. All the values of the isomer shift were represented by the shifts (mm./sec.) relative to the stainless steel. The activity was measured by counting the $\sim 10^5$ total for each point. Statistical error ($\pm\sqrt{n}\cdots n$=counts) was taken into account in drawing the spectral lines. The reading errors of $\delta$ and $\varepsilon$ depend on the sharpness of the absorption peak. The estimated error for metal ferricyanides was about $\pm 0.01$ mm./sec. On the other hand, the error increased to $\pm 0.02$ mm./sec. in the case of the $(NaPO_3)_n$-$Fe_2O_3$ system.

## Results and Discussion

The results obtained for the isomer shift and the quadrupole splitting are summarized in Table I, together with some of the data obtained by other workers.[2] The data cited from other papers were normalized to our data, which were obtained by using a $^{57}Co$-Cu source and a stainless steel reference. In all our measurement the source absorber were held at room temperature (20—25°C).

In a closely-related series of compounds, such as metal ferricyanides $\{M_x[Fe(CN)_y]\}$, small differences in the Mössbauer spectra are to be expected because of the similar $s$-electron

density around the Mössbauer nucleus. This rule appeared to be only roughly valid for the group of compounds. Our results on metal ferricyanides and metal-iron double sulfates seem to indicate that small differences in the isomer shifts and the quadrupole splittings exist.

In a series of metal ferricyanide complexes, the absorption peak appeared close to zero velocity in every case, showing the strong covalent character of the bond between Fe and CN. The "outside" metal, separated from the iron atom by more than about 4 Å, was considered to have very little effect on the peak position. However, our results seemed to show a systematic change in the isomer shifts depending on the electronegativity of the "outside" metal. The positive shifts of the isomer shift were observed with a decrease in the electronegativities of the metals. This rule was also observed in the case of a series of metal-iron double sulfates. Lithium and sodium containing double sulfate were not measured because of the difficulty in preparing such compounds.

All the Mössbauer spectra of the metal-iron double sulfates studies displayed a single peak. On the contrary, all the metal ferricyanide salts, except zinc and cadmium salts, gave small quadrupole splittings. As examples, three spectra are illustrated in Fig. 2.

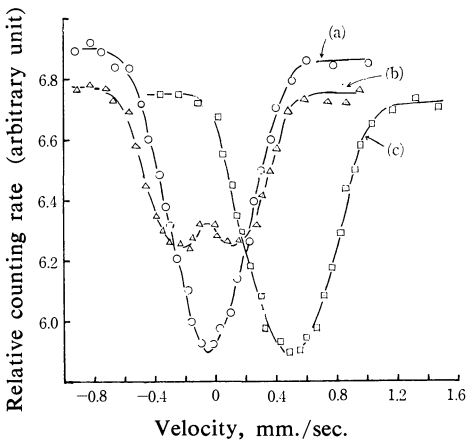

Fig. 2. Mössbauer spectra of $Cd_3[Fe(CN)_6]_2$ (a), $Co_3[Fe(CN)_6]_2$ (b) and $KFe(SO_4)_2\cdot 12H_2O$ (c).

Since these ferricyanide complexes have no water molecule in them, a direct comparison of the data is possible; i. e., one can neglect the influence of water molecules on the spectral shape. The sharp single absorption peak in the spectra for zinc and cadmium ferricyanide complexes indicates that the iron atoms in these complexes have spherically symmetric electron distribution.

As has been discussed earlier, the quadrupole splitting is caused by a nonzero electric field gradient at the iron nucleus. Moreover, the electric field gradient depends on various collective factors, i. e., the bonding character and the crystallographic character of the compound, the electronegativity of the neighboring atoms, etc. In this case, however, it appears that the sizable quadrupole splitting of these metal ferricyanides is to be attributed to their crystallographic distortion from a cubic structure caused by the "outside" metals. A noticeable broadening of the spectral lines in some ferricyanide complexes (nickel and cobalt) has been observed. This might be due to a small unresolved quadrupole splitting.

The purpose of the present investigation of the glassy substances of iron-phosphate was to elucidate the bonding character between the iron and the phosphate group in the materials. Originally, it was thought that one of the fundamental requirements for the Mössbauer effect to arise was that Mössbauer atoms should be bound in a crystal lattice. It was, however, shown in an earlier paper[11] that there is a high possibility of observing the effect even in amorphous substances (or in solid solutions).

In view of the above fact, we chose a series of fused products or iron-phosphate as samples. The spectral shapes of two series of the substances, the $(NaPO_3)_n$-$Fe_2O_3$ system and the $(NaPO_3)_n$-$Fe_3O_4$ system, were essentially identlcal, and both exhibited characteristic peaks at about 0.50 mm./sec. This fact means that iron(II) in $Fe_3O_4$ was oxidized into iron-(III) in the course of the sample preparation.

It is very difficult to conclude from the present data whether the isomer shifts obtained are due to the original iron(III) oxide or to new bonding between iron and the phosphate group. At any rate, the iron atoms are supposed to be surrounded predominantly by oxygen atoms. Therefore, relatively close values of isomer shift were observed for $Fe_2O_3$, $Fe_4(P_2O_7)_3 \cdot 9H_2O$ and $FePO_4 \cdot 4H_2O$, as is shown in Table I. However, there is one thing to be noted: the spectral characteristics of $(NaPO_3)_n$-$Fe_2O_3$ (P/Fe=5) differ from those of iron(III) oxide itself. The former displayed no quadrupole splitting, and the isomer shift value agreed well with that of $Fe_4(P_2O_7)_3 \cdot 9H_2O$. In view of this fact, all one can conclude at present is that the iron(III) pyrophosphate type of bonding grew, at least in $(NaPO_3)_n$-$Fe_2O_3$ (P/Fe=5).

The samples chosen for the remaining studies were iron(III) arsenate and iron(III) chromates. The results obtained suggest that the bonding between Fe and $AsO_4$ is typically ionic, while the bonding between Fe and $CrO_4$ (or $CrO_3$) is more or less covalent.

The Mössbauer spectrum of iron(III) chromate is shown in Fig. 3a. It can be resolved into two components (dotted curves), showing that iron(III) chromate has two different isomer shifts. This fact obviously indicates that there are two sites for iron atoms in the iron-(III) chromate crystal. Consequently, it is recommended that the chemical formula of iron(III) chromate be written as $Fe[Fe(CrO_4)_3]$ instead of $Fe_2(CrO_4)_3$. We interpreted the single peak as being due to ionic Fe ($\delta$=0.38 mm./sec.), while we attributed the doublet to

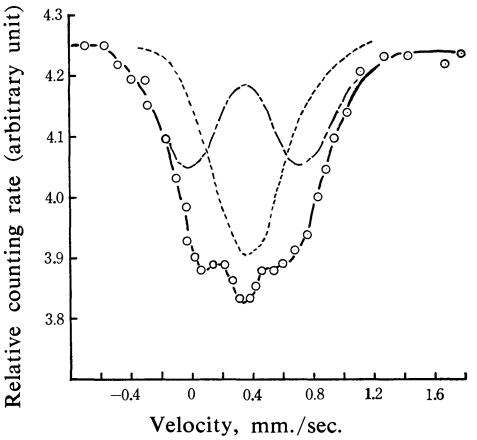

Fig. 3a. Mössbauer spectrum of iron(III) chromate.

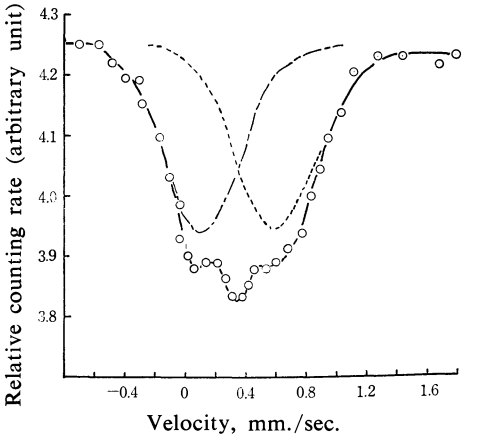

Fig. 3c. Mössbauer spectrum of iron(III) chromate.

covalent iron atoms ($\delta$=0.34 mm./sec., $\delta$=0.38 mm./sec.). It should be noted that the spectrum may also be resolved in the two ways

11) V. A. Bryukhanov, V. I. Col'danskii, N. N. Delyagin, L. A. Korytko, E. F. Makarov, I. P. Suzdalev and V. S. Shpinel, *Soviet Phys., JETP*, **16**, 321 (1963).

shown in Fig. 3b ($\delta_1 = +0.58$, $\delta_2 = +0.10$ mm./sec.) and in Fig. 3c. ($\delta_1 = +0.21$, $\delta_2 = +0.52$ mm./sec.).

As has been described elsewhere, however, the magnitude of one of the isomer shifts (+0.10 mm./sec.) in Fig. 3b is not in the region of iron(III) salts. Though the isomer shifts obtained from Fig. 3c are reasonable, any possible analysis of the spectrum can be made only in a rough manner. The assumption of the presence of two different types of iron atoms should be confirmed chemically in future study.

We have as yet comparatively little knowledge as to what chemical information can be obtained from the Mössbauer spectrum. More extensive studies and discussion by many workers are desired.

## Summary

The Mössbauer spectra of a variety of as-yet-unexplored iron compounds have been investigated by using 14.4 keV. gamma rays from $^{57}Fe$. The isomer shifts and the quadrupole splitting extracted from the spectra have been discussed in terms of the electronegativity of the atoms connected to the iron atom. The correlation of these values with the bond character and the chemical structure has also been discussed qualitatively. The results obtained for a series of glassy substances of iron-phosphate suggest that the Mössbauer spectra may permit us to study the chemical structure of iron compounds in an amorphous substance.

The authors are indebted to Drs. Kazuo Ôno, Atsuko Ito, Masatake Honda, Hideo Yamatera, Masako Shima, Hirotoshi Sano and Kunihiko Mizumachi for their helpful discussions. Grateful aknowledgement is also made to Messrs. Terumasa Nakamura and Fumitoshi Inenaga for their technical assistance in the preparation of several samples.

# Mössbauer Spectra of Various Organic Iron Chelates

By Yoshimasa TAKASHIMA and Yasuyuki TATEISHI

(Received February 25, 1965)

In a previous paper,[1] the Mössbauer spectra of various inorganic iron compounds were studied and some significant aspects of the spectra were discussed. The results showed that such an investigation can give valuable information concerning the change in the charge distribution in the molecule as a function of the chemical structure or bindings.

In the studies reported on in this paper, the work on the Mössbauer spectra was extended to a variety of organic iron chelates. The choice of organic iron chelates as an absorber was made because a series of structurally-related compounds are readily available and because various kinds of bindings are included in the organic iron chelates.

The two parameters of major interest, the isomer shift and the quadrupole splitting, will be discussed, as will the correlation between the above values and the molecular structure.

Special attention will be paid to the effect on the isomer shift of varying ligands bonded to the iron atom.

## Experimental

**Apparatus and Procedure.** — The apparatus and procedure employed were essentially the same as those described in the previous paper.[1] All measurements were made at room temperature and with respect to a $^{57}Co$ source diffused into metallic copper. The isomer shifts were referred to the stainless steel absorber.

Minor variations in technique were matters of convenience in the cases of hygroscopic and light-sensitive substances. Such samples were stored under a vacuum in the dark until they were mounted to the absorber disk. The mounted samples were then covered with a piece of black paper and adhesive tape to avoid light and moisture respectively.

**Materials.** — Most of the chemicals used were commercial reagent-grade products which were used without any further purification. (The Mössbauer effect is not very sensitive to a small impurity.) Several samples were prepared in the laboratory because of the lack of commercial ones. Two

1) Y. Takashima and S. Ohashi, This Bulletin, **38**, 1684 (1965).

samples, bis(salicylaldehyde)ethylenediimine iron(III) chloride and oxide, were provided by Professor Tamotsu Yoshino of Kyushu University.

The commercially-obtained samples were the following:

Monosodium-ethylenediaminetetraacetato-iron(III), (Na·Fe-EDTA), iron(III)-nitrilotriacetate, (Fe(III)-NTA), iron(III)-acetylacetonate, {Fe(III)-$(AA)_3$}, iron(III)-trifluoroacetylacetonate, {Fe(III)-$(TAA)_3$}, iron(III)-thenoyltrifluoroacetonate, {Fe(III)-$(TTA)_3$}.

The above chemicals were obtained from Dojin Pharmaceutical Laboratories, Kumamoto. All the other chemicals, shown below, were purchased from Wako Pure Chemical Industries, Ltd., Osaka:

Iron(III) formate $\{Fe(HCO_2)_3 \cdot H_2O\}$, iron(III) succinate $\{Fe_2(C_3H_4O_4)_3\}$, iron(III) tartrate $\{Fe_2(C_4H_4O_6)_3 \cdot H_2O\}$, iron(III) malate $\{Fe_2(C_4H_4O_5)_3\}$, iron(III) citrate $\{FeC_6H_5O_7 \cdot 5H_2O\}$ ammonium iron(III) citrate $\{(NH_4)_3[Fe(C_6H_5O_7)_2]\}$, basic iron(III) benzoate $\{[Fe_3(C_6H_5COO)_6 \cdot (OH)_2](OH)\}$, iron(II) oxalate $(FeC_2O_4 \cdot 2H_2O)$, iron(II) lactate $\{Fe(C_3H_5O_3)_2 \cdot 3H_2O\}$, iron(II) gluconate $\{Fe(C_3H_6O_4)\}$, iron(II) tartrate $(FeC_4H_4O_6 \cdot H_2O)$.

The following samples were prepared in the laboratory. The preparation techniques were based on "Gmelins Handbuch der anorganishen Chemie" in most cases. Trisalicylaldehyde-diimine iron(III), phenylnitrosohydroxylamine-iron(III) oxide and phenylnitrosohydroxylamine iron(III) were made by Tsumaki's method.[2]

*Iron(III) Acetate A.* — Wet iron(III) hydroxide containing 10% iron was dissolved in 95% acetic acid. The solution was then allowed to stand over concentrated sulfuric acid in a vacuum desiccator for several days until the precipitate appeared.

*Iron (III) Acetate B.* — Wet iron(III) hydroxide containing 20% iron was dissolved in pure acetic acid. The following procedures were the same as those described above.

*Iron(III)+Cr(III) Acetate (Cr : Fe=1 : 2 and 2 : 1).* —These compounds were prepared in a way similar to that described in the case of iron(III) acetate A. However, the initial hydroxides used were mixed hydroxides of iron(III) and chromium(III) having ratios (atom) of 1 : 2 and 2 : 1.

*Iron(III) Salicylate.* — To 50 ml. of an aqueous solution of 4.8 g. of sodium salicylate, 40 ml. of ether and 50 ml. of an aqueous solution of 2.7 g. iron(III) chloride were added. After the mixture had stood for several hours, the red precipitate formed was filtered. The precipitate was dried over calcium chloride.

*1,10-Phenanthroline Iron(II) Chloride,* $\{(Phen)_3Fe\}Cl_2 \cdot 7H_2O$.—Ethanolic solutions of both 1,10-phenanthroline and iron(II) chloride were mixed. The precipitate was obtained by the addition of acetone. The resultant red precipitate was recrystallized from a small amount of water.

*1,10-Phenanthroline Iron(III) Chloride,* $[(Phen)_2Fe(OH)_2Fe(Phen)_2]Cl_4$. — The method of preparation was essentially the same as that described above. The only exception was the use of iron(III) chloride instead of iron(II) chloride.

*Hexaureo-iron(III) Chloride,* $\{[Fe(CON_2H_4)_6]Cl_3 \cdot 3H_2O\}$.[3]—Concentrated iron(III) chloride and urea solutions were mixed. The mixture was then evaporated in a vacuum desiccator containing sulfuric acid until the precipitate was produced.

*Potassium Iron(III) Diglycolate,* $\{K[Fe(CH_2O \cdot COO)_2] \cdot H_2O\}$.[4]—To 2 ml. of a 1 M iron(III) chloride solution was added 40 ml. of a 2 M potassium glycolate solution. The addition of alcohol to the mixture yielded a pale green precipitate.

*Iron(III) Oxalate,* $Fe_2(C_2O_4)_3$. — Iron(III) nitrate and oxalic acid were dissolved in 65% nitric acid to saturation. The yellow solution thus obtained was then let stand over sulfuric acid in a vacuum desiccator until the precipitate was formed.

*Bis(quinaldinato) Iron(II),* $\{Fe(C_{10}H_6O_2N)_2\}$. — Iron(II) chloride (5 g.) was added to 50 ml. of an aqueous solution made up with 10 g. of quinaldic acid. A red precipitate was formed almost immediately. After the mixture had stood for several hours, the color of the precipitate changed from red to purple. This purple precipitate (cis form) was used for the Mössbauer measurement.

## Results and Discussion

The isomer shifts and the quadrupole splittings obtained for a variety of organic iron compounds are summarized in Table I.

The magnitudes of the isomer shift can, in principle, be related to the details of the bonding between iron and the ligands; i.e., the isomer shifts decrease regularly with the increasing covalency. In this connection, we indicated in the previous paper[1] that even atoms well separated from the iron affect the isomer shift.

The general tendency to be noticed from Table I is that the compound of more complicated chemical structures show the larger values of the isomer shift and of the quadrupole splitting within the series of chemically-related compounds.

Comparing the results for the isomer shifts and the quadrupole splittings for a series of iron-carboxylic acid compounds, it can be interpreted that the simpler compounds have a more covalent tendency in their bonds between the iron atom and carboxylic acid groups.

It was noted that[5] there was negligible quadrupole splitting in the case of the ionic ferric compound because of its $3d^5$ electron configuration. However, in almost all the organic iron chelates investigated, splitting did occur. This probably was caused by the field gradient from the neighboring atoms rather than by the iron atom itself. Presumably, the magnitude of the quadrupole splitting can be a measure of the crystallographic asymmetry.

| $[(Phen)_3Fe^{II}]Cl\cdot 7H_2O$ | 1,10-Phenanthroline iron(II) chloride | +0.29 | 0 |
| $[(Phen)_2Fe(OH)_2Fe(Phen)_2]Cl_4$ | 1,10-Phenanthroline iron(III) chloride | +0.64 | 0.41 |
| Fe(III)-$(AA)_3$ | Iron(III) acetylacetonate | Absorption not observed | |
| Fe(III)-$(TAA)_3$ | Iron(III) trifluoroacetylacetonate | Absorption not observed | |
| Fe(III)-$(TTA)_3$ | Iron(III) thenoyltrifluoroacetonate | Absorption not observed | |
| $[Fe(CON_2H_4)_6]Cl_3\cdot 3H_2O$ | Hexaureo-iron(III) chloride | Absorption not observed | |
| $(C_{12}H_{10}O_4Fe)_2O$ | Phenylnitrosohydroxylamine-iron(III) oxide | Absorption not observed | |
| $(C_6H_5O_2N_2)_3Fe$ | Phenylnitrosohydroxylamine-iron(III) | Absorption not observed | |

Considering all of the above concepts, we are now in a position to discuss some characteristics in each particular spectrum.

**Iron(III) Oxalate.**—The iron atoms in $Fe_2(C_2O_4)_3\cdot 5H_2O$, $K_3[Fe(C_2O_4)_3]$ and $(NH_4)_3[Fe(C_2O_4)_3]$ have been considered to be located in similar chemical environments. Nevertheless, the latter two compounds showed no absorption, while the former displayed a single absorption peak at room temperature. Unfortunately, it is hardly possible at present to make a detailed discussion. However, one

possible interpretation is that there may be different types of iron atoms in these compounds; i.e., the one shows absorption, but the other does not for some unidentified reason. Suppose we write the molecular formula as $Fe^*[Fe(C_2O_4)_3]\cdot 5H_2O$ instead of $Fe_2(C_2O_4)_3\cdot 5H_2O$, the asterisked iron atom differing in its binding mode from the other iron atom. This situation may be favorably compared with that of iron(III) chromate discussed in the previous paper.[1] Experiments to elucidate this assumption need to be conducted at a lower temperature. The chemical ascertainment of the structure of iron oxalate is also needed.

**Iron(III) Acetates and Iron(III) Benzoate.**—The spectra of these compounds have triple absorption peaks. They may be resolved either into two single lines or into one doublet and one single line. We tried out both analyses and felt that the latter is more reasonable. Thus, the spectrum was interpreted as the superposition of a quadrupole split and a single line. This may naturally be explained by the presence of different types of iron atoms in these compounds as a result of their polynuclear structure. For example, the spectrum and a generally-adopted structural formula of iron(III) acetate A are given in Figs. 1a and 1b:

The components of the composite spectra are shown by the broken line. The first analysis, shown in Fig. 1a, does not support the structure described above, because the split peak should be assigned to the central iron atom in view of its intensity. This fact is inconsistent with the general rule that a central atom is in a more symmetrical environment than are outside atoms. This difficulty was overcome by using the other analysis, shown in Fig. 1b, where two outer lines correspond to

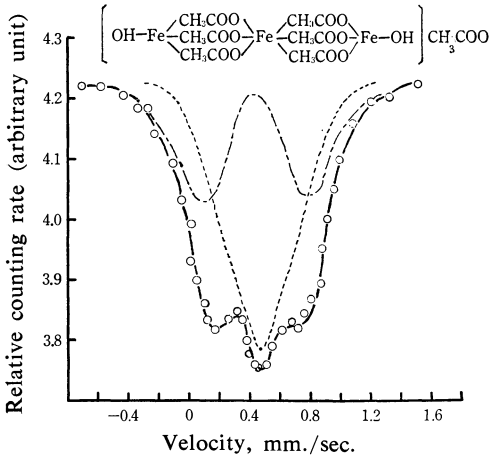

Fig. 1a. Mössbauer spectrum of iron(III) acetate A.

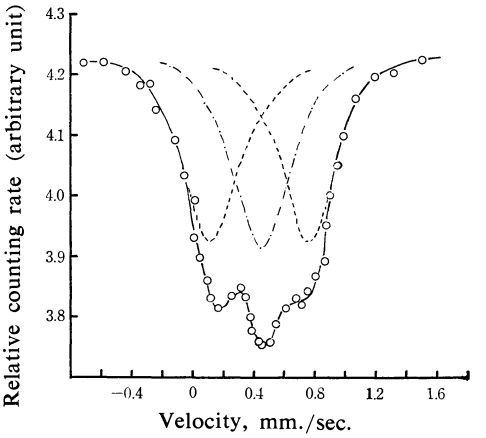

Fig. 1b. Mössbauer spectrum of iron(III) acetate A.

the quadrupole splitting due to two "outside" iron atoms and the central single line assigned to a central iron atom.

The spectra for iron(III) acetate A and B were almost identical. The minor difference observed must have arisen from the slightly different molecular structures of these acetates.

A particularly instructive case was the comparison of the spectra obtained for iron(III)+chromium(III) acetates with that obtained previously for iron(III) acetate A. The middle single peak was slightly decreased in intensity in the case of the mixed acetate (Fe : Cr = 2 : 1), and it disappeared almost completely in the case of the other mixed acetate (Fe : Cr = 1 : 2), while the outer double peaks remained essentially unchanged in shape. This fact could be interpreted qualitatively as meaning that chromium atoms can occupy any iron sites in the molecule, while the resultant distribution of chromium is not uniform but one-sided.

**Iron(III) Salicylates.**—The Mössbauer spectrum of this compound showed four resonance

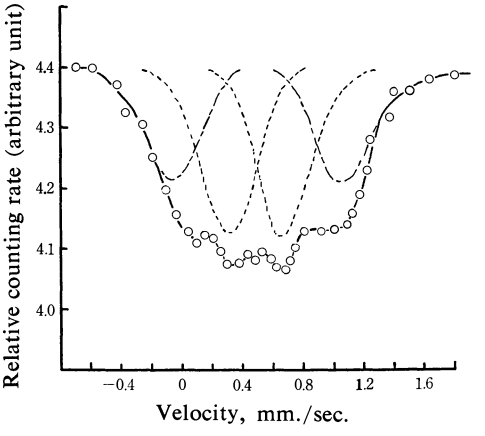

Fig. 2. Mössbauer spectrum of iron(III) salicylate.

absorption maxima (Fig. 2). The spectrum was analyzed by assuming that the quadrupole pair were of equal intensity. Thus, it was concluded that this spectrum is resolved into two doublets (dotted curves), the middle one showing an isomer shift of 0.49 mm./sec., while that for the outer one is 0.51 mm./sec. The measured values of the quadrupole splitting of the middle and outer doublets are 0.17 and 0.55 mm./sec. respectively. By assuming a trinuclear structure for the compounds, both the outside and central iron atoms can be considered to be situated at a point where the electric field gradient is nonzero.

**Na·Fe(III)-EDTA, Fe(III)-NTA.**—The spectra of these compounds showed main single peaks at +0.60 and +0.41 mm./sec. respectively. This fact indicates that the bondings are primarily ionic and that the iron atoms are in an octahedral symmetry. This conclusion is not in agreement with that of a previous infrared spectroscopic study,[6] in which the bonding between iron and EDTA has been reported to be covalent. It seems possible that this disagreement may be ascribed to an ambiguous definition of terms, ionic and covalent.

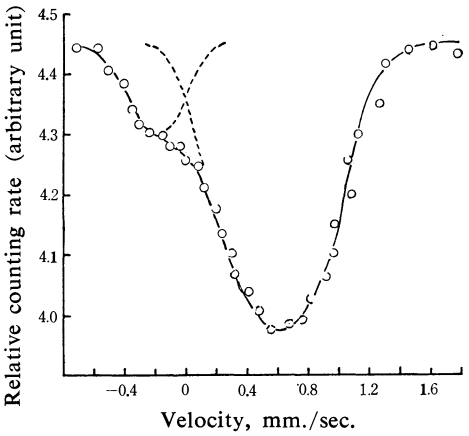

Fig. 3. Mössbauer spectrum of Na·Fe(III)-EDTA.

One peculiar anomaly of the spectrum was observed in the case of the Fe(III)-EDTA sample. As is shown in Fig. 3, the spectrum exhibited considerably more line broadening than other typical spectra. In addition, a shoulder appeared at −0.16 mm./sec. This shoulder can not be readily explained, but it could possibly be attributed to some impurity which has a strong covalent character. The investigation of this possibility must be the subject of future research.

6) D. T. Sawyer and J. M. McKinnie, *J. Am. Chem. Soc.*, **82**, 4191 (1960).

**Bis(salicylaldehyde)ethylenediimine Iron(III) Chloride and Oxide.** — As may be seen from Fig. 4, these two compounds are closely related

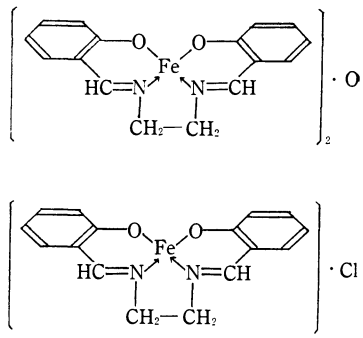

Fig. 4. Structural formulas of bis(salicylaldehyde)ethylenediimine iron(III) chloride and the oxide.

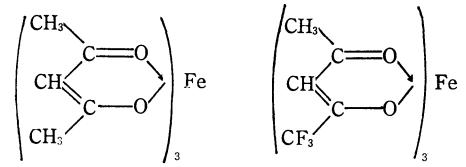
in chemical structure. Accordingly, no large differences in the isomer shift and quadrupole splitting were expected between them. Nevertheless, the experimental observations showed relatively large differences in their magnitude. This fact must be attributed to the molecular architecture of these compounds. In this connection we should note that, in a book by Martell and Calvin[7] on the chemistry of the metal chelate compound, they mentioned that the cobalt chelate of salicylaldehyde ethylenediimine crystallizes in layers, with holes running through the layers. The results of our Mössbauer study of the iron chelates also support the view of such a planar structure of the compounds. The oxygen or chlorine atoms may be interposed between two closely adjacent pairs of the unit cell, so that they behave as an atom covalently bonded to two adjacent iron atoms. The electronic charge distribution around the iron atoms which determine the isomer shift and quadrupole splitting can be considerably affected by the oxygen or chlorine in the molecule because of their high electronegativity.

**1, 10-Phenanthroline Iron(II) Chloride.**—This compound, which is regarded as a very stable covalent compound, showed a small isomer shift, suggesting greater covalency, whereas the relatively unstable iron(III) compound of 1, 10-phenanthroline shows a large isomer shift, suggesting a small covalent contribution. Since the bonding arrangement of the former compound resembles that of the ferrocyanide complex, the spectrum showed a single peak.

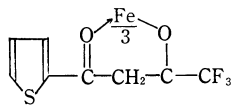


7) A. E. Martell and M. Calvin, "Chemistry of the Metal Chelate Compounds," Prentice-Hall, Inc. Englewood Cliffs, N. J. (1956), pp. 270, 342.

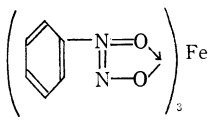
On the contrary, the latter displayed a double-peaked spectrum which may have arisen from the binuclear structure of the molecule.

**Divalent Iron Organic Compounds.**—Table I includes the values of the isomer shift and quadrupole splitting for several divalent iron compounds. The magnitude of these values were, of course, far larger than those of trivalent iron compounds. However, the present data may not be very accurate because of instrumental limitations; i.e., our instrument is not designed for a wide-range Doppler velocity, but is, rather, most useful in the neighborhood of zero velocity covering the $\pm 1.0$ mm./sec. range. For this reason, these data will not be further discussed here.

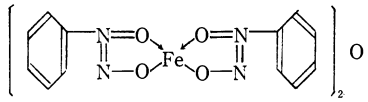
**Compounds Whose Resonance Absorption was not Observed at Room Temperature.** — In our observation, there are several iron-bearing organic compounds that did not show any resonance absorption. The chemical structures of the compounds studied are shown in Fig. 5.



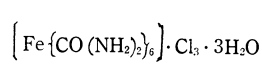
All these compounds are characteristic in their binding nature; i.e., in all cases an iron atom is coordinated with oxygen atoms. There is no a priori reason why the resonance absorption does not occur in these compounds.



(I)



(II)



(III)

(IV)

(V)

(III) Iron(III) thenoyltrifluoroacetonate
(IV) Phenylnitrosohydroxylamine-iron(III)
(V) Phenylnitrosohydroxylamine-iron(III) oxide
(VI) Hexaureo-iron(III) chloride

In any event, however, the absence of the Mössbauer effect should be attributed to either the low Debye temperature or the high recoil probability of the compound. Nevertheless, although such data for these organic compounds are not available at present, our speculation would prefer the interpretation that the disappearence of the absorption is caused by the latter.

It should be noted that the Mössbauer effect was not observed in the case of a dry cation exchanger (Dowex 50) saturated with iron(III) ions (thickness $=\sim 10$ mg. Fe/cm$^2$). The further measurement of these compounds at a low temperature would be an interesting subject for future research.

## Summary

Continuing our previous studies of the Mössbauer spectra of inorganic iron compounds,[1] we have found some characteristic features of the spectra of some organic iron compounds. There is a general tendency, in a series of related compounds, for the isomer shift and the quadrupole splitting to increase regularly with increase in the structural complexity of the compounds.

The data for iron(III) acetate, benzoate and salicylate suggest the polynuclear structure of these compounds. The observed isomer shifts for other organic iron compounds may also be interpreted in terms of the chemical binding in the molecule.

No resonance absorption was observed for a few groups of organic iron chelates (1, 3 diketone derivatives, etc.). Though our interpretation is still conjectual, the reason for this is believed to rest in the high recoil probability of these compounds.

# The Far-infrared Spectra of Some Phenols

By Kunio FUKUSHIMA

(Received March 5, 1965)

Many greatly-successful infrared investigations of substances with the X-H···Y hydrogen bond have been made using the X-H stretching absorption band. However, it seems that these have not given any information on the minute differences in the conformation of the X-H···Y group.

The infrared absorption band due to a vibration of the X-H···Y group, which is expected to give more information about the conformation of the X-H···Y group, appears in the far-infrared spectral region. Green et al. have found a band in the far-infrared spectra of phenol in the crystalline state; they have tentatively assigned it to the stretching vibration of the O-H···O group.[1] Stanevich has measured the far-infrared spectra of crystalline phenol, *m*- and *p*-nitrophenols, hydroquinone, resorcinol, *o*-nitrophenol, and 2,6-dinitrophenol. He has found that only in the case of phenol does a frequency shift when it is dissolved into a non-polar solvent.[2]

In the present investigation, the far-infrared spectra of *o*- and *p*-hydroxybenzaldehydes and *o*- and *p*-methoxyphenols will be measured and compared with those of carbon tetrachloride solutions.

## Experimental

**Material Employed.**—*o*- and *p*-Hydroxybenzaldehydes and *o*- and *p*-methoxyphenols were of the reagent grade. Phenol was recrystallized from its carbon tetrachloride solution.

**Infrared Spectra.**—The infrared spectra were recorded with a Perkin-Elmer model 201C far-infrared spectrometer in the region from 80 to 350 $cm^{-1}$, and with a Perkin-Elmer model 221 spectrophotometer equipped with a LiF prism in the region from 2800 to 3800 $cm^{-1}$.

The spectra of crystals were measured in Nujol mull sandwiched between two polyethylene plate 1 mm. thick while those of solutions were measured using liquid cells with polyethylene windows 3 mm. thick. The concentrations of the solutions and the cell thicknesses are listed in Table I. The sample solution of phenol in carbon tetrachloride was prepared by the dilution of its saturated solution with carbon tetrachloride in a volume ratio of 1 to 12.5. The spectra obtained are shown in Figs. 1—8.

TABLE I. CONCENTRATION OF SOLUTIONS AND CELL THICKNESS

| Substance | Concn. | Cell thickness | |
|---|---|---|---|
| $C_6H_5(OH)$ | | 2 | |
| *o*-$(CHO)C_6H_4(OH)$ | 0.38 | 2 | (Fig. 5) |
| | 0.15 | 5 | (Fig. 6) |
| *o*-$(CH_3O)C_6H_4(OH)$ | 0.46 | 2 | (Fig. 8(A)) |
| | 0.18 | 5 | (Fig. 8(B)) |

* Concentration in mol./l.; Cell thickness in mm.

## Results and Discussion

As Figs. 1—3 show, it is clear from the frequency values of O-H stretching bands in the 3$\mu$ region (phenol, 3279 $cm^{-1}$; *p*-hydroxybenzaldehyde, 3175 $cm^{-1}$) that strong hydrogen bonds are formed in phenol and *p*-hydroxybenzaldehyde in the crystalline state. Both these compounds have a band in the region from 170 to 180 $cm^{-1}$ (phenol, 172 $cm^{-1}$; *p*-hydroxybenzaldehyde, 180 $cm^{-1}$). The band at 170 $cm^{-1}$ of phenol has been assigned to the stretching vibration of the O-H···O group by Stanevich, on the basis of its frequency change observed through the change in the state from crystal to solution.[1] This frequency

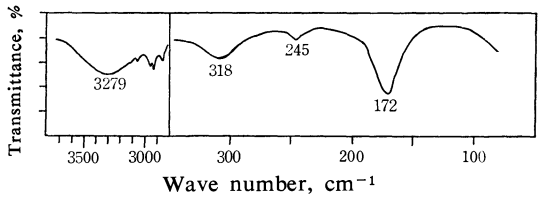

Fig. 1. Far-infrared spectra of phenol in crystalline state.

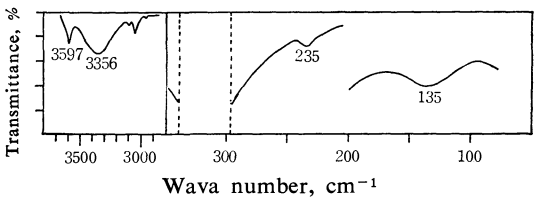

Fig. 2. Far-infrared spectra of phenol in carbon tetrachloride solution.

2) A. E. Stanevich, *Optics and Spectroscopy*, **16**, 539 (1964).

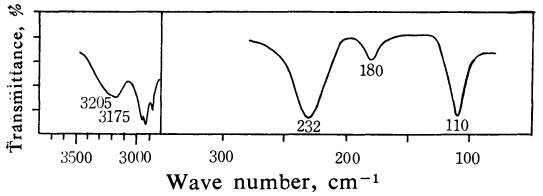

Fig. 3. Far-infrared spectra of *p*-hydroxybenzaldehyde in crystalline state.

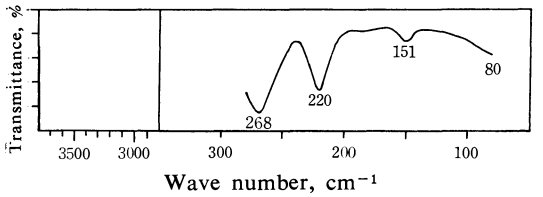

Fig. 4. Far-infrared spectra of *o*-hydroxybenzaldehyde in liquid state.

change was confirmed by the present investigation, as Figs. 1 and 2 show. Among the three bands in the spectra of *p*-hydroxybenzaldehyde (Fig. 3, 80—300 $cm^{-1}$ region), two bands, at 110 $cm^{-1}$ and 232 $cm^{-1}$, can be assigned to the vibrations of the CHO-C group by a comparison of the spectra with those of benzaldehyde,* no other bands are expected to appear in the region from 100 to 300 $cm^{-1}$ except for the stretching vibration of the O-H···O group. Therefore, the band at 180 $cm^{-1}$ of *p*-hydroxybenzaldehyde is considered to correspond to the stretching vibration of the intermolecular hydrogen bond.

The band at 179 $cm^{-1}$ in the far-infrared spectra of *p*-methoxyphenol in the crystalline state may correspond to the stretching vibration of the intermolecular hydrogen bond.

It may be suggested, from the fact that the frequency values of the stretching vibration of the intermolecular hydrogen bond are nearly the same in phenol, in *p*-hydroxybenzaldehyde and in *p*-methoxyphenol, that the types of the intermolecular hydrogen bond of *p*-hydroxybenzaldehyde and *p*-methoxyphenol are similar to that of the phenol crystal.[3]

In the case of *o*-hydroxybenzaldehyde in the liquid state, which is considered to have an intramolecular hydrogen bond on the basis of the frequency value of the O-H stretching band in its 3$\mu$ region and the geometry of its molecule, no band was observed in the region from 100 to 200 $cm^{-1}$, except for a band at 151 $cm^{-1}$. This band can be assigned to a vibration of the CHO-C group by a comparison of the spectra with those of benzaldehyde. When *o*-hydroxybenzaldehyde is diluted with carbon tetrachloride, no change takes place in the spectra, as Figs. 5 and 6 show. Therefore, the bands at 268, 220, 151 and about 80 $cm^{-1}$ in Fig. 4 may reasonably be interpreted as being due to the vibrations of non-associated molecules. As the three bands, 268, 220 and 151 $cm^{-1}$, can be assigned to the vibrations of the CHO-C group, we might assign the band at about 80 $cm^{-1}$ to the stretching vibration of an intramolecular hydrogen bond. In the spectra of a solution of *o*-methoxyphenol in carbon tetrachloride, the O-H stretching bands were observed at 3565 and 3470 $cm^{-1}$. The former is due to the O-H stretching vibration of free molecules, while the latter is due to

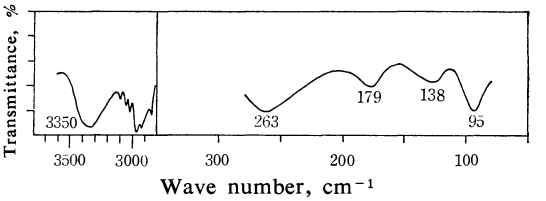

Fig. 7. Far-infrared spectra of *p*-methoxyphenol in crystalline state.

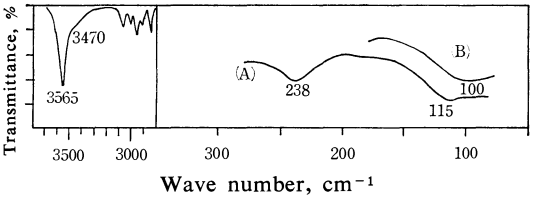

Fig. 8. Far-infrared spectra of *o*-methoxyphenol in carbon tetrachloride solution.

* Benzaldehyde has three bands, 130, 224 and 235 $cm^{-1}$, in the region from 80 to 250 $cm^{-1}$, these are assigned to the vibrations of the CHO-C group[1].

3) C. Scheringer, O. J. Wehrhahn und M. v. Stackelberg, *Z. Elektrochem.*, **64**, 381 (1960).

that of the hydrogen-bonded O-H group. As the intensity of the latter band is very weak, it is expected that the amount of molecules forming a hydrogen bond is not great. Corresponding to this fact, no band that is considered to be due to the stretching vibration of the O-H···O group was observed in the far infrared region, as is shown in Fig. 8.

On the basis of the experimental results in the present investigation, it may be suggested that the frequency value of the stretching vibration of the O-H···O group in the far-infrared region is very sensitive to the structural difference of the O-H···O group and can be useful in the study of molecular structure.

# The Rapid Solvent Extraction and Simultaneous Spectrophotometric Determination of Palladium with TTA - Methyl Propyl Ketone

By Asha V. RANGNEKAR and S. M. KHOPKAR

(Received March 8, 1965)

The chelating agent 2-thenoyltrifluoroacetone (TTA) has been extensively utilised for the extraction, separation and spectrophotometric determination of numerous metals.[1] From a slightly acidic solution palladium(II) gives an orange yellow chelate with TTA which is extractable into methyl propyl ketone (MPK), giving a brilliant orange yellow solution. It appears that MPK exerts a synergestic effect on the extraction of palladium with TTA.

Dimethylglyoxime[2] is commonly used for the solvent extraction separation of palladium in chloroform. 2-Nitroso-1-naphthol in toluene[3] was used for the extraction and colorimetric determination at 370 m$\mu$. In a highly alkaline medium it was extracted with diethyldithiocarbamate.[4] Its complex with dibenzyldithiooxamide[5] was extracted and measured at 450 m$\mu$ in order to determine palladium in the presence of platinum. The iodide complex[6] was extracted with tri-*n*-butyl phosphate, whereas the pyridine thiocyanate complex[7] aminoquinoline complexes[8] or chloroiodopyridine complexes[9] were extracted in chloroform and were determined colorimetrically.

In this paper, systematic investigations of the liquid-liquid extraction behaviour of the palladium(II) TTA chelate at different pH's and spectrophotometric studies of it will be described. It will also offer a simple and rapid procedure for the rapid solvent extraction and simultaneous spectrophotometric determination of palladium(II) at the microgram level. (A preliminary note on this work has been published.[10])

## Experimental

**Apparatus.**—Absorbance measurements were carried out with a quartz CØ4 spectrophotometer, using matched 10-mm. quartz cells, while pH measurements were made with a Cambridge pH meter (Marshal model). Reagents grade chemicals were used. TTA (B. D. H.) solutions in MPK (about 0.15 M) were used. A stock solution of palladium chloride was prepared by dissolving about 0.6334 g. of palladous chloride in one litre of distilled water containing 1 per cent hydrochloric acid. The diluted solution was then prepared by ten-fold dilution and was standardized gravimetrically with dimethyl glyoxime (II). The diluted solution contained 6.334 $\gamma$ of palladium per millilitre.

**General procedure.**—An aliquot of the palladous chloride solution (3 ml.), containing 6.334 $\gamma$ of palladium(II) per millilitre, was adjusted to the desired pH with 0.01 N hydrochloric acid and 0.01 N sodium hydroxide, using a pH meter. For the study of diverse ions, a solution containing the ion under investigation was added prior to the pH

control. The aqueous solution, unless otherwise mentioned, was adjusted to pH ~4.0. Final volume was maintained with water at 25 ml. in each case. It was introduced into a separatory funnel (250 ml.) and shaken for 10 min. with 10 ml. of 0.15 M TTA-MPK. The lower aqueous layer was transferred to a beaker, and the upper MPK layer, to a 10 ml. volumetric flask. The MPK extract was made up exactly to 10 ml. with MPK, and the absorbance was read at 430 mμ against a reagent blank. The amount of palladium extracted was directly obtained from the calibration curve. The aqueous layers at the end of extraction were saved for the pH measurement.

## Results and Discussion

**Absorption Curve.**—The absorption spectrum of a solution of the palladium(II) - TTA complex ($Pd=1.78\times10^{-5}$ M), extracted at pH 4.0, is illustrated in Fig. 1, the reagent blank being used as the reference solution. The spectrum of the reagent blank against MPK was also taken. The orange-yellow palladium(II) chelate solution shows a maximum absorbtion at 415 mμ. Then the curve steadily falls untill the absorbance becomes negligible beyond 500 mμ. The reagent blank itself has a strong absorption up to 400 mμ; this becomes insignificant, compared to the chelate solution, from 420 mμ onward. All the absorbance measurements were performed at 430 mμ. The absorptivity at 430 mμ is $4.2\times10^5\pm51.4$ (calculated on the basis of the palladium content).

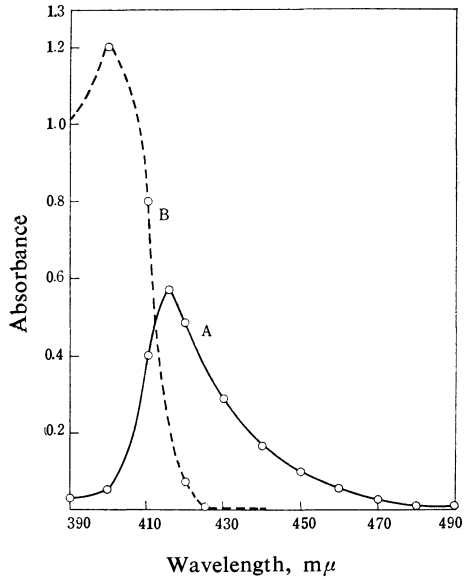

Fig. 1. Absorption spectrum.
A Palladium(II)-TTA chelate in MPK against reagent blank.
Pd(II) $1.78\times10^{-5}$ M at pH 4.0
B Reagent blank against MPK.
TTA $15\times10^{-2}$ M at pH 4.0

**The Effect of the pH Value.**—The pH range from 0.8 to 6.2 was studied in order to investigate the liquid-liquid extraction behaviour of the palladium(II)-TTA system. At higher pH values the precipitation of palladium hydroxide causes trouble. The distribution ratios, $D$, were calculated from the extraction curve in a manner described earlier[12] (Fig. 2 and Table I). The extraction starts after pH 1.6 and becomes 100% at pH 4.0. In the pH range from 3.4 to 4.9 extraction occurs to the extent of 80% or more. The extraction curve drops sharply beyond pH 5.0 and terminates at pH 6.0, corresponding to

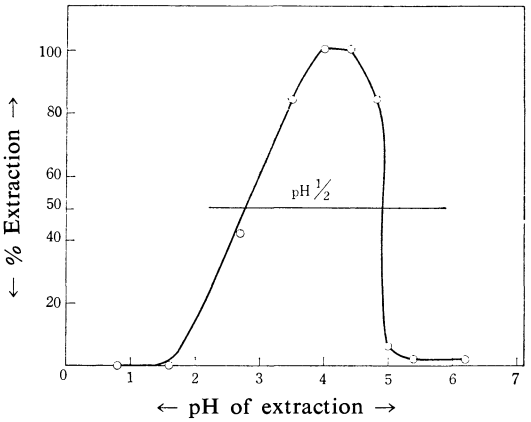

Fig. 2. Extraction of Pd-TTA chelate with MPK as the function pH.

Table I. Distribution ratios of palladium(II)-thenoyl trifluoroacetone between MPK and aqueous solution as a function of pH

| pH | % Palladium extraction in MPK | $D$ |
|---|---|---|
| 0.8 | 0.0 | 0.0 |
| 1.6 | 0.0 | 0.0 |
| 2.1 | 18.4 | 0.56 |
| 2.7 | 42.1 | 1.8 |
| 3.0 | 65.7 | 4.7 |
| 3.5 | 84.2 | 13.3 |
| 3.6 | 84.2 | 13.3 |
| 4.0 | 100.0 | 2500 |
| 4.4 | 100.0 | 2500 |
| 4.6 | 18.4 | 0.56 |
| 4.8 | 84.2 | 13.3 |
| 5.0 | 7.8 | 0.21 |
| 5.4 | 2.6 | 0.06 |
| 5.8 | 5.2 | 0.13 |
| 6.2 | 2.6 | 0.06 |

11) A. I. Vogel, "The Text Book of Quantitative Inorganic Analysis," ELBS Series (1960), p. 511.

zero extraction. The pH for the 50% extraction is 2.8 and 4.9.

Beyond pH 6.2, hydroxide precipitation commences and inhibits the extraction procedure.

**Calibration Curve.**—Different amounts of palladium(II) were taken and extracted as above at pH 4.0, and the corresponding absorbances were measured against the reagent blank at various wavelengths (420, 430 and 440 mμ) in order to observe the adherence of the coloured system to Beer's law. In each case the solution of palladium(II) was exhaustively extracted for 10 min.; the aqueous phase was always clear and colourless. Table II indicates that the palladium(II)-TTA system closely obeys Beer's law at 430 mμ over the concentration range from 0.60 to 6 γ of palladium per millilitre.

TABLE II. ADHERENCE TO BEER'S LAW

| Palladium(II) taken, γ | Absorbance | | |
|---|---|---|---|
| | 420 mμ | 430 mμ | 440 mμ |
| 3.16 | 0.065 | 0.040 | 0.025 |
| 6.33 | 0.140 | 0.095 | 0.055 |
| 9.49 | 0.210 | 0.140 | 0.080 |
| 12.66 | 0.265 | 0.195 | 0.105 |
| 15.82 | 0.340 | 0.240 | 0.140 |
| 18.99 | 0.410 | 0.300 | 0.170 |
| 22.15 | 0.470 | 0.350 | 0.190 |
| 25.32 | 0.540 | 0.400 | 0.220 |
| 28.48 | 0.610 | 0.460 | 0.255 |

**The Stability of the Colour.**—The absorbance of the MPK solution of the palladium(II)-TTA complex, prepared according to the general procedure at pH 4.0, was measured at elapsed times of 30 min., 1, 24, 48, 72, 96, 144 and 190 hr. The corresponding absorbances were 0.300, 0.300, 0.300, 0.300, 0.300, 0.310, 0.320 and 0.320 respectively. It is evident that the colour is stable up to 72 hr., at the end of 94 hr. the absorbance increases by about 3%, and after 144 hr. by about 8%. Hence, it is suggested that the colour be measured within 72 hr.

TABLE III. EFFECT OF REAGENT CONCENTRATION

19 γ of palladium(II) after extraction by TTA-MPK at pH 4.0 gives an absorbance of 0.300 ±0.005 in 10 ml. of MPK.

| TTA Concn., M | TTA added, ml. | Absorbance at 430 mμ |
|---|---|---|
| 0.50 | 10 | 0.310 |
| 0.25 | 10 | 0.300 |
| 0.15 | 10 | 0.300 |
| 0.10 | 10 | 0.210 |
| 0.075 | 10 | 0.210 |
| 0.050 | 10 | 0.200 |
| 0.025 | 10 | 0.195 |
| 0.015 | 10 | 0.120 |
| 0.15 | 1 | 0.150 |
| 0.15 | 2 | 0.170 |
| 0.15 | 4 | 0.210 |
| 0.15 | 6 | 0.220 |
| 0.15 | 8 | 0.280 |

**Reagent Concentration.**—With other factors constant, the concentration of TTA was varied from 0.015 M to 0.5 M. The results in Table III prove that the optimum reagent concentration is 0.15 M. The absorbance is constant, even at such a higher reagent concentration as 0.50 M. With a dilute solution of the reagent, e.g., 0.025 or 0.015 M, the extraction is incomplete.

TABLE IV. DIVERSE IONS

Palladium(II) = 19 γ pH = 4.0

| Foreign ion | Added as | Ion concen. mg./ml. | Absorbance at 430 mμ 0.300±0.010 |

| $AsO_3^{3-}$ | $Na_3AsO_3$ | 2.0 | 0.275 |

**Diverse Ions.**—The following ions (~2.0—10 mg.) were carried through the procedure, the pH being maintained at about 4.0:
$Pb^{2+}$, $Hg^{2+}$, $Tl^{+}$, $Cu^{2+}$, $Cd^{2+}$, $Sb^{3+}$, $Bi^{3+}$, $Sn^{4+}$, $Pt^{4+}$, $Fe^{3+}$, $Al^{3+}$, $Zn^{2+}$, $Mn^{2+}$, $Co^{2+}$, $Ni^{2+}$, $U^{6+}$, $Th^{4+}$, $Zr^{4+}$, $Ce^{4+}$, $Ca^{2+}$, $Sr^{2+}$, $Ba^{2+}$, $Mg^{2+}$ $Li^{+}$, $SO_4^{2-}$, $PO_4^{3-}$, $WO_4^{2-}$, $CN^{-}$, $CH_3COO^{-}$, $C_2O_4^{2-}$, $CrO_4^{2-}$, $VO_4^{3-}$, $AsO_3^{3-}$, citrate$^{3-}$, tartrate$^{3-}$, ascorbate$^{2-}$.

The results in Table IV show that about 5—10 mg. of lead(II), thallium(I), cadmium(II), antimony(III), bismuth(III), platinum(IV), aluminum(III), zinc(II), nickel(II), zirconium-(IV), chromate, phosphate, acetate and sulphate do not interfere, whereas copper(II), iron(III), uranium(VI), and cerium(IV) give colour reactions. Palladium can tolerate less than 5 mg. each of mercury(II), thorium(IV), calcium(II), strontium(II), barium(II), magnesium(II), lithium, vanadate, tungstate and arsenite. The ions showing strong interferences are tin(IV), manganese(II), cobalt(II), ascorbate, oxalate, citrate, tartarate and cyanide.

Because palladium(II) is extracted from weakly acidic solutions, metals that yield chelates with TTA under these conditions may be expected to interfere if present in large amounts.

The interferences due to ascorbate, oxalate, citrate, tartarate and cyanide can be easily eliminated by passing them on an anion exchange resin like Dowex 21 K (chloride form). These anions are retained in the resin bed, while palladium(II) passes through. Palladium-(II) may then be extracted as usual with 0.15 M TTA in MPK at pH 4.0.

## Recommended Procedure

Take an aqueous solution containing 19 $\gamma$ of palladium(II) and adjust the pH ~4.0 with a pH meter by using 0.01 N hydrochloric acid and 0.01 N sodium hydroxide. Introduce the solution into a 250 ml. separatory funnel. Shake for 10 min. with 10 ml. of a 0.15 M TTA-MPK solution. Allow the layers to settle; transfer the aqueous layer into a beaker and the MPK layer into a 10 ml. volumetric flask, and measure the absorbance as 430 m$\mu$ against the reagent blank. In nine runs with 19 $\gamma$ of palladium(II), the absorbance found was 0.296 ±0.005. The standard deviation was ±1.2%. Different amounts of palladium(II) were taken and determined by the recommended procedure. The results (Table V) are accurate to within ±1.5%.

TABLE V. ACCURACY OF METHOD

| Palladium(II) taken, $\gamma$ | Absorbance at 430 m$\mu$ | Palladium(II) found, $\gamma$ | % Error |
|---|---|---|---|
| 9.5 | 0.145 | 9.25 | +2.7 |
| 12.66 | 0.195 | 12.66 | 0.0 |
| 19.00 | 0.300 | 19.00 | 0.0 |
| 25.33 | 0.380 | 24.0 | +5.2 |
| 28.50 | 0.450 | 28.5 | 0.0 |
| | | | Av. ±1.5% |

Thus the proposed method is fairly precise, being accurate to within ±1.5%. The total operation for each run requires only 20—25 minutes. As little as 1 $\gamma$ of palladium(II) can be detected.

## Summary

A spectrophotometric method has been developed for the determination of palladium-(II) at microgram levels; the method is based on the colour reaction with 2-thenoyltrifluoro-acetone (TTA) in methyl propyl ketone (MPK). The bright orange-yellow-coloured palladium(II) - TTA chelate solution follows Beer's law at 430 m$\mu$ over the 0.6—6.0 $\gamma$ range of palladium(II) per millilitre. At pH values from 3.4 to 4.9, about 80% or more of palladium(II) is removed from an aqueous solution of TTA-MPK in a single extraction. The coloured system is stable for 72 hr. It can tolerate lead(II), thallium(I), cadmium(II), antimony(III), bismuth(III), platinum(IV), aluminium(III), zinc(II), nickel(II), zirconium-(IV), phosphate, chromate, acetate and sulphate, whereas tin(IV), manganese(II), cobalt(II), ascorbate, oxalate, citrate, tartarate and cyanide seriously interfere. Mercury(II), thorium(IV), calcium(II), strontium(II), barium(II), magnesium(II), vanadate and tungstate are moderately tolerated. The method is accurate and reproducible to within ±1.5%, and it offers a simple procedure for the simultaneous extraction and spectrophotometric determination of palladium(II).

# Studies of the Aqueous Solution of a Surface Active Substance by Means of an Ultrasonic Interferometer. I. Determinations of the Critical Concentration and Compressibility of Micelles of Several Alkyl Sulfates

By Koji SHIGEHARA*

(Received March 9, 1965)

The dissolved state and the properties, especially the micelle formation and the solubilization, of surface active substances in an aqueous solution have been studied by various methods of measurements, such as light scattering, X-ray diffraction, diffusion, electrolytic conductance, osmometry and dialysis.[1] The hydration of the surface active substance in a solution has been studied by many authors, it also is important for the study of the properties of an aqueous solution of a surface active substance. Among such studies, Stigter, Williams and Mysels[2] have estimated the hydration of micelles to be monomolecular, a theory which is in accordance with the light scattering and micelle diffusion data. However, little is known about the hydration of the solute in the state of a single molecule, which is rather important in relation to the amphipathic nature of the substance in question and also in relation to the builder action of the inorganic salt usually added to enhance the surface activity. In this connection, ultrasonic interferometry offers another useful method, since the compressibility of a solution of a surface active substance, as calculated from the sound velocity, is closely related to the hydration of the solute in a solution, which is often difficult to measure by other methods. Thus, a number of studies have been reported on the hydration of inorganic and organic substances using an ultrasonic interferometer.[3,4] However, similar studies have not yet been reported of solutions of surface active substances. This is mainly due to the fact that the accuracy of the sound velocity of $\pm 0.5$ m./sec. attainable by an ordinary ultrasonic interferometer is still insufficient for a study which requires the measurement of such a small difference in sound velocity as that between pure water and dilute solution of the most surface active substance near CMC. The present investigation, therefore, used a differential ultrasonic interferometer with an accuracy of $\pm 3$ cm./sec. which had already been devised by Sasaki and Yasunaga.[5]

The present paper will describe the results of measurements of the sound velocity and compressibility of aqueous solutions of homologues of alkyl sulfates and sodium hydrogen sulfate. Further, the CMC's will be determined and the compressibility of micelles calculated from sound velocity data.

## Experimental

**Materials.**—The alkyl sulfates used were sodium *n*-tetradecyl (STS), *n*-dodecyl (SDS), *n*-octyl (SOS) and methyl (SMS) sulfates. They were prepared from their corresponding alcohols and then purified, except for SMS, which was prepared from a commercial product by drying it over silica gel. Sodium hydrogen sulfate (SHS) was also used for the sake of comparison. Its aqueous solution was prepared by dissolving an equimolar amount of pure sulfuric acid and recrystallized sodium sulfate in water.

**Apparatus and Procedure.**—The apparatus used for the measurement of the sound velocity was the usual ultrasonic interferometer, somewhat modified so as to determine the change in the sound wavelength in the solution resulting from the change in the concentration of the solute by measuring the change in the length of a series of several hundred stationary sound waves. The main part of the cell (Fig. 1) consisted of a glass tube 34 cm. long and 1.8 cm. in diameter, to one end of which a quartz ultrasonic generator plate 2.5 cm. in diameter and with a frequency of $f=1.432$ Mc./sec. was attached, while to the opposite end there was connected a vertical glass tube so that a vertical glass reflector

plate could move in the solution contained in the cell by means of a comparator with a $\pm 0.002$ mm. accuracy. The sample liquid in the cell was circulated during the measurement by means of an all-glass circulation pump. The cell was immersed in a thermostat of $30.00 \pm 0.003$°C.

The principle of measurement is based on the fact that if we fix the reflector plate of the interferometer to the $n$'th node (counting from the quartz ultrasonic generator plate) of the stationary wave produced in the sample solution, as in the case of ordinary ultrasonic interferometry, and trace the change in the position ($\Delta L$) of the same node due to the increase in the wavelength ($\Delta\lambda$) produced by the change in the concentration ($C$) of the solution, we can calculate $\Delta\lambda$ and the change in the sound velocity ($\Delta U$) by:

$$\Delta\lambda = \Delta L/n \qquad (1)$$

and

$$\Delta U = f \times \Delta\lambda \qquad (2)$$

The actual position we follow shifts from the node by a constant amount equal to the phase difference of the sound wave at the reflector plate, but this dose not alter the above relation, since it is considered to be constant and does not affect $\Delta L$.

To carry out the experiment, it is necessary to increase the concentration gradually, starting from pure water, and following carefully the shift of the specified node of the stationary sound wave produced in it. For this purpose, 250 cc. of distilled and degassed water was first introduced in the cell, and then the reflector plate was fixed to an appropriate node corresponding to the minimum of the interference current. Then a certain volume (10—50 cc.) of water in the cell was replaced by an equal volume of the sample solution of a known concentration, and the concentration of the solution in the cell was slightly changed. The reflector plate was then shifted in order to follow the resulting change in the position of the node to which the plate was initially fixed. The distance ($\Delta L$) traveled by the plate was recorded. $\Delta\lambda$ was then calculated by means of Eq. 1. Here the $n$ value was calculated from the distance between the quartz oscillator and the reflector divided by the exactly-measured wavelength of the stationary sound wave.* The value of $n$ was a definite integer near 300. From the value of $\Delta\lambda$, we calculated change in the sound velocity by means of Eq. 2. From the measurements of a series of such successive increments $\Delta U$ corresponding to the successive values of concentration $C$, we obtain the relation:

$$\Delta U = F(C) \quad \text{or} \quad U_c = U_w + \Delta U = U_w + F(C)$$

where $U_w$ and $U_c$ denote the sound velocity in pure water and in the solution with the concentration $C$ respectively, and $F(C)$, the measured concentration function of the sound velocity. The value of $U_w = 1509.44$ m./sec. was used in the present experiment.[6] The error introduced in the measurement of $\Delta U$ was $\pm 3$ cm./sec. for $n = 300$.

The density of the solution at 30°C was calculated from the measurement of its change from the value of pure water, which was taken as a standard,[7] by using an ordinary float balance[8] in a thermostat controlled to $\pm 0.001$°C (measurement being possible down to $\pm 10^{-6}$ g./cc.), except for the measurement of concentrated solutions of SOS and SHS where a pycnometer was used at 30 $\pm 0.01$°C.

The compressibility ($\beta$) of the solution was further calculated from the sound velocity and the density ($\rho$) by the Laplace equation:

$$\beta = 1/U^2\rho$$

and was also expressed as a function of the solute concentration.

## Results and Discussion

Figures 2 and 3 show the sound velocity vs. concentration diagrams, and Figs. 4 and 5, the compressibility vs. concentration diagrams for aqueous solutions of SHS, SMS, SOS, SDS and STS. It can be seen in these figures that the diagrams for SMS and SHS solutions consist of a single straight line, while in the cases of

STS, SDS and SOS solutions each of the diagrams, especially that for compressibility, consists of two linear portions with a break point between them. This break point coincided with the CMC of the respective solute, as is shown in Table I. This proves the differential ultrasonic interferometry to be a useful method for the measurement of the CMC.

Figure 6 further shows that the inclination of the $\beta$ vs. concentration diagram ($d\beta/dC$) above and below CMC is in a linear relation with the number of carbon atoms ($N$) in the solute molecule, and that when extrapolated the two straight lines to $N=0$ coincide with each other and with the $d\beta/dC$ value for sodium hydrogen sulfate of a moderate concentration of about 0.1 mol./l., where it is considered to behave as a uni-univalent electrolyte composed of $HSO_4^-$ and $Na^+$.[9] These relations are expressed by the following equations:

$$d\beta/dC = -5.94\times10^{-12} + 0.445\times10^{-12}\times N \quad (3)$$

for solutions above CMC, and:

$$d\beta/dC = -5.94\times10^{-12} - 0.776\times10^{-12}\times N \quad (4)$$

9) I. M. Klotz and C. F. Eckert, *J. Am. Chem. Soc.*, **64**, 1878 (1942); P. L. Khare, *Trans. Faraday Soc.*, **58**, 359 (1962).

for solutions below CMC, where $d\beta/dC$ is expressed as $(cm^2/dyn.)/(mol./1.)$. This suggests that the dissolved state of the $SO_4Na$ radical of alkyl sulfates in an aqueous solution is the same as that of $HSO_4Na$, whether they are in the state single ions or micelles, and that the contribution to $d\beta/dC$ of each $CH_2$-chain in the solute molecule is constant, which is different in signs according to their dissolved states. Since the value of $-5.94\times10^{-12}$ in Eq. 4 expresses the compressibility decrease due to the introduction of one mole of $Na^+$ and $HSO_4^-$ in water, the portion of the ordinate of the lower line below the dotted horizontal line in Fig. 6 expresses the additional decrease

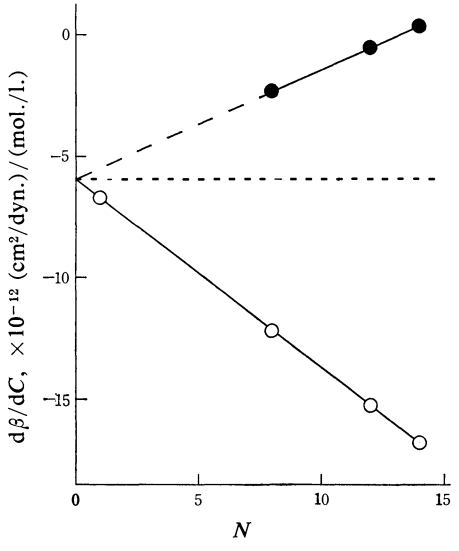

Fig. 6. $d\beta/dC$ vs. $N$.
○ $d\beta/dC$ below CMC
● $d\beta/dC$ above CMC
Dotted line: $d\beta/dC$ for SHS

in compressibility due to the dissolution of one mole of alkyl chains of the respective carbon numbers in a molecule in the state of molecular dispersion in water, and the portion of the ordinate between the dotted horizontal line and the upper straight line expresses a similar increase in compressibility due to the introduction of one mole of alkyl chains in a micellar state in water. Both of these values may, therefore, be considered to be proportional to the carbon number in the solute molecule, and Eqs. 3 and 4 may be expected to intersect at the zero point of the carbon number in the solute molecule.

Similar results are obtained for the partial molar volume ($\bar{V}$) of alkyl sulfate by the measurement of the density for the solution. Figure 7 shows the results. Here the diagram of $\bar{V}$ vs. the carbon number ($N$) in the solute molecule consists of two straight lines, above

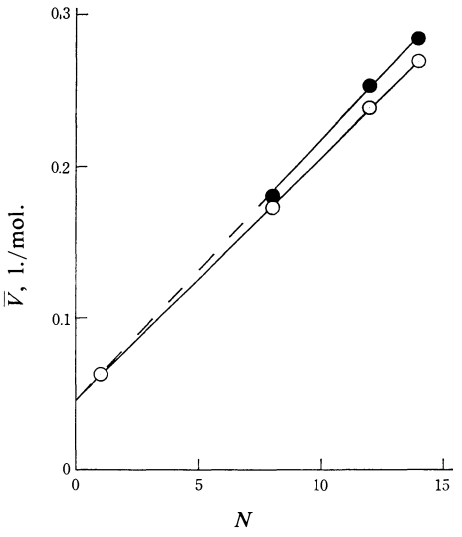

Fig. 7. $\bar{V}$ vs. $N$.
○ $\bar{V}$ below CMC
● $\bar{V}$ above CMC

and below CMC, which coincide with each other at $N=0$. These ralations are expressed by the following equations:

$$\bar{V}=0.0171\,N+0.046 \tag{5}$$

for solutions above CMC, and:

$$\bar{V}=0.0159\,N+0.046 \tag{6}$$

for solutions below CMC, where $\bar{V}$ is expressed in l./mol.

To derive theoretically the equations corresponding to those of Eqs. 3 and 4, the solution of the volume ($V$) and compressibility ($\beta$) as a whole is assumed to consist of several volume elements ($V_1$, $V_2$, $\cdots$) of different compressibilities ($\beta_1$, $\beta_2$, $\cdots$). Therefore, we have:

$$V=V_1+V_2+\cdots \tag{7}$$

$$V\beta=V_1\beta_1+V_2\beta_2\cdots \tag{8}$$

From these equations and with an additional assumption, usually accepted,[3] that such an ionic radical as $HSO_4^-$ or $-SO_4^-$ of alkyl sulfate, together with its water of hydration, is incompressible and is independent of the micellization of the solute, as may reasonably be understood from Fig. 6, the following equations are derived for solutions above CMC:

$$d\beta/dC=V_mN\ (\beta_m-\beta_1)-V_s\beta_1 \tag{9}$$

$$\bar{V}=V_mN+V_s-n_xV_1 \tag{10}$$

where $\bar{V}$ denotes the partial molar volume of alkyl sulfate; $V_1$ and $V_m$, the molar volume of free water and of $CH_2$ in micelle respectively; $\beta_1$ and $\beta_m$, the compressibility of free water and the hydrocarbon part of the micelle

respectively; $n_x$, the mole number of hydration water per mole of $SO_4Na$, and $V_s$, the molar volume of the $SO_4Na$ radical, together with the volume of $n_x$ moles of hydration water.

By comparing Eq. 9 with Eq. 3, and Eq. 10 with Eq. 5, the $V_s$, $V_m$, $n_x$ and $\beta_m$ values are calculated to be as shown in Table II.

It may be seen in this table that the compressibility of the micelle and the mole volume of the $CH_2$ radical in the micellar state are constant, independent of the number of the carbon atoms of the alkyl sulfate molecule, and that they are nearer to the value for liquid rather than solid hydrocarbon. These facts are additional evidence for the view that the hydrocarbon interior of the ionic micelle is liquid-like rather than solid-like.[10] The amount of hydration, $n_x=4.9$, for the $SO_4Na$ radical is comparable with the corresponding value of 5.7 for $NaHSO_4$ near a 0.1 molar solution, where the solution as a whole is considered to contain $HSO_4^-$ and $Na^+$ ions,[9] although we can cite other data which is somewhat different.[11]

## Summary

The sound velocity and the density of aqueous solutions of sodium hydrogen (SHS), methyl (SMS), octyl (SOS), dodecyl (SDS) and tetradecyl (STS) sulfates have been measured by using, respectively, a differential ultrasonic interferometer and a float balance, and the compressibility ($\beta$) has then been calculated from these results. Each of these three quantities, when plotted against the concentration ($C$), has shown a nearly straight line for SHS and SMS, while it consists of two nearly straight lines, with a break point between them at CMC, in the cases of SOS, SDS and STS. The values of $d\beta/dC$ below and above CMC, when plotted against the number of carbon atoms in the alkyl chain of the solute molecule, again showed two straight lines which intersected with each other at the zero number of carbon atoms. This value of $d\beta/dC$ is equal to that of SHS at a moderate concentration. These results have been explained by taking account of the dissolved state of these solutes. The compressibility of the micelle ($\beta_m$), the molar volume of the $CH_2$ radical in the micellar state ($V_m$), and the ionic hydration number of solute have been calculated; the values of $\beta_m$ and $V_m$ show evidence for the view that the hydrocarbon interior of the ionic micelle is liquid-like rather than solid-like.

The author wishes to express his deep gratitude to Professor Tsunetaka Sasaki of our University for his kind direction and valuable criticism. The cost of this research has been defrayed by a grant of the Ministry of Education given to Professor Sasaki.

# The Calculation of the Adsorptive Separation Factors of Hydrogen Isomers

By Shozo FURUYAMA and Nozomu EBARA

(Received March 11, 1965)

Static and gas chromatographic studies of hydrogen mass isomers and spin isomers have been carried out by many authors.[1-8] Recently the gas chromatographic separation of radioactive isomers has been carried out at the temperature of liquid nitrogen in separate experiments by Carter and Smith,[9] King,[10] and West and Marston[11]; an apparent separation factor between each pair among the nine isomers has thus been determined. On the other hand, a quantum mechanical explanation of the separation between para- and ortho-hydrogen has been given by several other investigators, and a qualitative agreement with experiments has been obtained.[12-16]

There are still, however, several problems left to be resolved. (i) Why is the elution of tritium hydride, which is composed of two atoms of different weights (a hetero-isomer) faster than that of deuterium, which is composed of two like atoms (a homo-isomer), although they have the same mass? (ii) Ortho-hydrogen and hydrogen deuteride can hardly be separated at all by gas chromatography, except for a single experiment of one of the present authors using an interconverting double-column method. Why does the mass effect play an insignificant role in this case? (iii) Para- and ortho-tritium have not yet been separated. Is it not possible to separate them experimentally?

This paper will deal with a quantum mechanical treatment of the separation factors of hydrogen isomers at the temperature of liquid nitrogen using Evett's model,[12a] with particular emphasis on the explanation of the trend for hetero-isomers to be adsorbed strongly on an adsorbent surface than homo-isomers.

## Theory

It is assumed that each atom of a molecule to be adsorbed on an adsorbent surface is subjected to a potential of the Lennard-Jones type along an axis perpendicular to the adsorbent surface. The potential is expanded in powers of the distance in the vicinity of the equilibrium position, and the higher terms are disregarded.

$$V=-U+\frac{1}{2}K(Z_a-Z_0)^2-U+\frac{1}{2}K(Z_b-Z_0)^2 \qquad (1)$$

Here $Z_a$ and $Z_b$ are, respectively, the distances from the adsorbent surface to the atoms a and b; $Z_0$ is the equilibrium distance and $K$ and $U$ are constants. $Z_a$ and $Z_b$ can be replaced by $Z+m_b d\cos\theta/(m_a+m_b)$ and $Z-m_a d\cos\theta/(m_a+m_b)$ respectively, where $Z$ is the distance from the center of the gravity of the molecule to the adsorbent surface; $m_a$ and $m_b$ are the atomic weights and $\theta$ is the angle between the molecular axis and the axis normal to the adsorbent surface. We then have:

$$\begin{aligned}V=&-2U+K(Z-Z_0)^2\\&+|m_a-m_b|\,Kd(Z-Z_0)\cos\theta/(m_a+m_b)\\&+(m_a^2+m_b^2)Kd^2\cos^2\theta/2(m_a+m_b)^2\end{aligned} \qquad (2)$$

where $d$ is the distance between the centers of the atoms in the molecule. The second term leads to vibrational wave functions for a harmonic oscilator:

$$G_n(\xi)=(2MK/\pi^2\hbar^2)^{1/8}(2^n n!)^{-1/2}H_n(\xi)e^{-\xi^2/2}$$
$$\xi=(2MK/\hbar^2)^{1/4}(Z-Z_0)$$

where $M$ is the total mass. The third term has matrix elements only between vibrational states of different quantum numbers and is regarded as a perturbation. The last term leads to hindered rotational wave functions. Following Wilson, the rotational wave functions are expanded in powers of $\cos\theta(=x)$ and the recursive method is used to calculate the coefficients $a_{l,m,2k}$ and $a_{l,m,2k+1}$ in wave functions[17]:

$$F^{e}{}_{l,m}(x) = (2\pi)^{-1/2}(1-x^2)^{m/2}e^{im\varphi}\sum_{k=0} a_{l,m,2k}x^{2k}$$

$$F^{o}{}_{l,m}(x) = (2\pi)^{-1/2}(1-x^2)^{m/2}e^{im\varphi}\sum_{k=0} a_{l,m,2k+1}x^{2k+1}$$

In carrying out the calculation, the term

$$(2I_{ab}/\hbar^2)(Kd^2/2)(m_a^2+m_b^2)/(m_a+m_b)^2=\lambda^2$$

is regarded as a parameter.

If $m_a$ and $m_b$ are equal, the third term of 2 vanishes identically and 2 reduces to Evett's equation.[12a] The unperturbed hindered rotational energies $\mu$ of hetero-isomers, as well as those of homo-isomers, are obtained in units of $\hbar^2/2I_{ab}$, where $I_{ab}$ is the moment of inertia of the molecule. For a partition function of a hydrogen molecule at a low temperature (the temperature of liquid nitrogen), only a few low-lying energy levels are important. For para-hydrogen, ortho-deuterium and para-tritium, the exclusion principle requires that their rotational states should be associated only with even $l$ values. For ortho-hydrogen, para-deuterium and ortho-tritium, on the other hand, states are associated with odd $l$ values. The symmetry consideration violates the exclusion principle for hetero-molecules. Hence, for the calculation of the partition function, the energy levels to be taken into account are $F^{e}{}_{0,0}(x)$ for para-hydrogen, ortho-deuterium and para-tritium; $F^{e}{}_{1,1}(x)$ for ortho-hydrogen, para-deuterium and ortho-tritium, and both states for hetero-isomers. These two energy levels are both even states with respect to $\cos\theta$.

The term $K|m_a-m_b|d\cos\theta(Z-Z_0)/(m_a+m_b)$ is treated as a perturbation. As this term is an odd function with respect to both $(Z-Z_0)$ and $\cos\theta$, the first-order perturbation energy and the second-order contribution from even states vanish identically, and it is enough to consider only the first excited state of the vibration combined with odd states of rotation. The second-order perturbation energy is:

$$E''=\hbar^2/2K(m_a+m_b)\times 4K^2d^2(m_a-m_b)^2/(m_a+m_b)^2\times\langle 0|\xi|1\rangle^2\sum_{l'}\langle l,m|x|l',m\rangle^2/(\Delta E_{vib}+\Delta E_{rot}) \quad (3)$$

TABLE I. SECOND ORDER PERTURBATION ENERGIES OF HYDROGEN DEUTERIDE, TRITIUM HYDRIDE AND TRITIUM DEUTERIDE AT SEVERAL POTENTIAL BARRIERS B

| Species | States $m$ | Perturbation energy $E''$, cal./mol. $B/\Lambda$ 4 | 8 | 12 |
|---|---|---|---|---|
| HD | 0 | 16.87 | 24.45 | 29.23 |
| | 1 | 10.98 | 19.14 | 25.16 |
| HT | 0 | 32.59 | 44.91 | 54.97 |
| | 1 | 22.10 | 37.68 | 50.00 |
| DT | 0 | 5.00 | 6.74 | |
| | 1 | 3.74 | 6.11 | |

It is evaluated for hydrogen deuteride, tritium hydride and tritium deuteride at several potential barriers, $B$, in Table I, where

$$B=\lambda^2\Lambda I_{H_2}(m_a+m_b)^2/2I_{ab}(m_a^2+m_b^2)=Kd^2/4$$

and

$$\Lambda=\hbar^2/2I_{H_2}$$

The energies:

$$E=\mu\Lambda I_{H_2}/I_{ab}+E''$$

are plotted against the potential barrier, $B$, in Figs. 1 and 2.

So far as the separation factor between isomers of the same molecular weight is concerned, only rotational energies need be considered. However, for hydrogen isomers of different molecular weights, A and B, translational and vibrational factors should also be taken into account. The separation factor is defined as:

$$S=([A]/[B])_{gas}/([A]/[B])_{ads} \quad (4)$$

Here the following arrangement is to be understood:

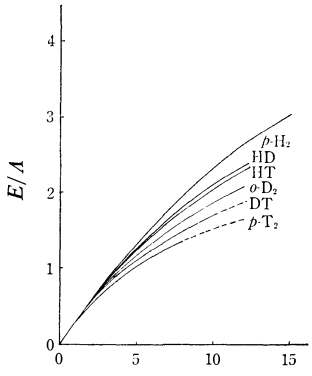

Fig. 1. The rotational energies combined with the second-order perturbation energies against the potential barrier $B$. State: $l=0$, $m=0$

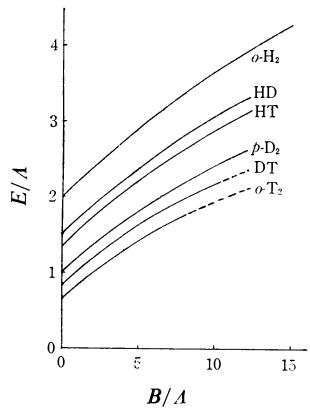

Fig. 2. The rotational energies combined with the second-order perturbation energies against the potential barrier $B$. State; $l=1$, $m=1$

(i) Between spin isomers, A should be the molecule in a state associated with an even $l$.

(ii) Between molecules of different weights, A should be the lighter molecule.

(iii) Between isobaric molecules, i.e., between tritium hydride and deuterium, A should be the tritium hydride.

Assuming that Langmuir's adsorption equation is obeyed and that the relation $[A]_{ads} \propto b_A[A]_{gas}$ holds approximately (because the extent of adsorption is small), 4 can be written in terms of Langmuir's adsorption coefficient, $b$, as $S=b_B/b_A$. When A and/or B is a mixture of spin isomers, $b_A$ is expressed approximately as $b_{A_1} \times b_{A_2}/(x_{A_1}b_{A_2}+x_{A_2}b_{A_1})$, where the suffix on A refers to the kind of spin isomer and where $x$ is the mole fraction in the adsorbed phase. As the translational and vibrational parts of $b_{A_1}$ and $b_{A_2}$ are equal, 4 is rewritten as:

$$S=(b_B/b_A)_{trans,vib} \times \left(\frac{x_{A_1}/b_{A_1}+x_{A_2}/b_{A_2}}{x_{B_1}/b_{B_1}+x_{B_2}/b_{B_2}}\right)_{rot} \quad (5)$$

In order to simplify the calculation of the separation factor, we assume that, in the adsorbed phase, a translational degree of freedom along the Z axis is replaced by a vibrational degree of freedom along the same axis and that the other modes of translation and vibration are almost the same as in the gas phase. The separation factor, $S$, is then expressed as:

$$S=\sqrt{\frac{M_A}{M_B}} \exp\left(\frac{(1/2)\hbar(\nu_A-\nu_B)}{kT}\right) \times \frac{x_{A1}(Q/q)_{A_1}+x_{A_2}(Q/q)_{A_2}}{x_{B_1}(Q/q)_{B_1}+x_{B_2}(Q/q)_{B_2}} \quad (6)$$

where $M$ is the molecular weight; $\nu$ the frequencies of vibration along the Z axis ($\sqrt{2K/4\pi^2M}$) and $Q$ and $q$ the partition functions of rotation in the gas phase and in the adsorbed phase respectively.

The calculated values of the separation factor at the temperature of liquid nitrogen are summarized in Table II for potential barriers of $4A$, $8A$ and $12A$.

## Discussion

The adsorptive separation factor of a pair of isomers can be separated into three parts:

$S_{trans}$, $S_{vib}$ and $S_{rot}$. $S_{trans}$ depends solely on the total mass ratio of molecules and decreases with an increase in the mass ratio, running from 1 to 0.577. It is, however, always less than unity. $S_{vib}$ depends on both $B$ and the mass ratio, and it increases either with an increase in the mass or in the mass ratio. It runs from 1 to 3.78 when $B=8\Lambda$, and from 1 to 5.11 when $B=12\Lambda$. $S_{rot}$ is a complicated function. In general, it increases as $B$ and the total mass ratio increase, but the reverse may be the case at particular values of $B$ and the mass ratio.

White and Lassettre have assumed that the molecule is not completely free to move along directions parallel to the adsorbent surface and that it is confined within a definite range of the surface.[13] In this case, $S_{trans}$ may exceed unity, depending on the area of the cage. However, this situation may conveniently be disregarded, as the contribution of $S_{trans}$ is not very large. The most important contribution comes from $S_{vib}$, which increases exponentially as $B$ increases. Therefore, the value of $B$ should be carefully estimated when a separation factor between isomers of different molecular weights is going to be considered.

Comparing the calculated values with the experimental results (Table II), it can be seen that the values at $B=8\Lambda$ conform well to the experiment I of Carter and Smith using a highly active alumina column, and the values at $B=4\Lambda$, to the experiment II of Carter and Smith and to that of King, using ferric oxide on alumina column. At $B=12\Lambda$, the calculated values deviate greatly from the experimental results. Therefore, for an alumina column or its modifications, the value of $B$ is most likely to fall within the range from $4\Lambda$ to $8\Lambda$. The agreement is plausible, except for several cases which we shall discuss later.

In spite of having the same mass, the elution of tritium hydride become faster than deuterium. The calculated values, 1.10 ($B=4\Lambda$) and 1.13 ($B=8\Lambda$), can be compared with the experimental values, 1.12 (alumina), and 1.05 and 1.13 (ferric oxide on alumina). This surprising agreement may in part be accidental, for the introduction of another potential, $V_\phi$, which is to be discussed later, somewhat reduces the values. To anticipate the later discussion, the decrement is small, however. Moreover, we can see from Table II that the elution of lighter molecules tends to be faster than that of heavier molecules.

There are still several disagreements. For the separation factor between para- and ortho-hydrogen, $B$ should take a value as large as $10\Lambda$ in order to obtain the best fit with the experimental value (1.37). Evett, in his first paper,[12a] estimated $B$ to be $14\Lambda$ in order to account for both the experiment of Sandler at 90°K (1.67)[1] and that of Cunningham and Johnston at 20°K (16).[2] In his later work, however, Evett found that the value of $B$ could be reduced to about $6\Lambda$, which was thought to account for the heat of adsorption (2000 cal./mol.), if another potential in the direction of $\phi$ was introduced:[12b]

$$V_\phi = D\cos 2\phi$$

This assumption is acceptable, for we may consider the substrate surface to be an array of attractive centers. In the present case, also, the potential favors the separation of para- and ortho-hydrogen and may bring about the agreement of the calculated value with the experimental value at an appropriate $B$ value.

It may also be the case for the separation of ortho-hydrogen and hydrogen deuteride, where the agreement is somewhat poor. We have good reason to assume that the potential $V_\phi$ may reduce the separation factor considerably, as the level associated with $m=1$ is affected greater than with $m=0$.

The potential $V_\phi$ may not be very important for separation factors between heavy molecules or between molecules in states of the same $m$ values. Hence, the correction should be small for values which are already in good agreement.

The separation factors between para-tritium and ortho-tritium are very close to unity. Here, the partition among various energy levels is taken into account, as they are closer together for heavier molecules. The result is practically the same as that which is obtained disregarding higher levels. The separation factor is a very insensitive function in this case, running from 1 ($B=0$) to 0.98 ($B=\infty$). Therefore, it is very probable that the experimental separation of para- and ortho-tritium is very difficult, if not impossible.

# π-Electronic Energy Levels of *o*-Benzoquinone

By Akira KUBOYAMA and Kōichi WADA*

(Received March 12, 1965)

Previously, π-electronic energy levels of quinones have been studied by one[1] of the present authors using the simple MO calculation. In that study, an attempt to explain the electronic spectra of quinones on the basis of calculated results was made. However, in order to clarify the whole aspect of the electronic spectra of quinones, it is desirable that the electronic energy levels of quinones be studied by the MO calculation using a Hamiltonian which includes electronic interaction terms. Among quinones, *p*-benzoquinone alone has been studied by many authors[2] with such a calculation. However, *o*-benzoquinone and anthraquinone are also important compounds among the quinones. We have, therefore, carried out such a calculation concerning *o*-benzoquinone and anthraquinone. In this paper the results obtained for *o*-benzoquinone will be shown.

## The Method of Calculation

In the MO calculation of a π-electronic system which contains hetero atoms such as quinones, it is desirable to use the self-consistent field (SCF) technique. In Sidman's work[2d] on carbonyl compounds and *p*-benzoquinone, Pople's SCF MO method[3] was used, but the values of the electron repulsion integrals were obtained according to Pariser-Parr's uniformly-charged sphere approximation[4] instead of Pople's point-charge approximation. The configuration interaction among low-energy excited states were also calculated. This Sidman calculation gives, on the whole, reasonable results. Therefore, our calculation was carried out according to Sidman's method.

The integrals used are shown in Table I. O and C denote oxygen and carbon atoms respectively and, for example, (OO|OO) and (OO|CC) denote the one-center electron repulsion integral of the oxygen atom and the two-center Coulomb repulsion integral over the oxygen and carbon atoms respectively. The values in Table I are those in Sidman's Table except for the formula for (OO|OO) and the values of the core-exchange integrals for the C-C bonds ($\beta_{CC'}$) ($R$=1.46, 1.49Å). The formula for (OO|OO) was obtained from the value of (OO|OO) and the formula for (OO|O'O') (for $R>2.8$Å) in Sidman's Table.[2d] Sidman regarded the $U$-term in Pople's SCF MO method as the valence-state orbital energy corrected for the fact that the atom is no longer isolated, but is now a part of a molecule. The value of $U_{CC}$ is the same as that used in Hush and Pople's paper.[5] The value of $U_{OO}$ was determined from a comparison of the valence-state ionization potentials of the oxygn and carbon atoms. As will be shown later, the energy levels are not sensitive to the value of $U_{OO}$. The values of $\beta_{CC'}$ were obtained according to the Pariser-Parr method. The value of $\beta_{CO}$ is that presented by Parks and Parr.[6]

Table I. Integral values (eV., $R$ (interatomic distance) in Å)

| | | | | |
|---|---|---|---|---|
| (OO\|OO) | 14.671 | $U_{OO}$ | | −13.00 |
| (CC\|CC) | 10.842 | $U_{CC}$ | | − 9.50 |
| (OO\|CC) | $12.757-3.966R_{CO}$ | $\beta_{CO}$ | | − 3.00 |
| | $+0.4169R^2_{CO}$ | | | |
| | | $\beta_{CC'}$ | | |
| (CC\|CC) | $10.842-2.821R_{CC'}$ | $R_{CC'}$=1.35 | | − 2.92 |
| | $+0.2454R^2_{CC'}$ | 1.46 | | − 1.76 |
| (OO\|OO) | $14.671-4.748R_{OO'}$ | 1.47 | | − 1.68 |
| | $+0.5012R^2_{OO'}$ | 1.49 | | − 1.52 |

In this work an electronic computer (NEAC 2101) was used.[7] SCF calculations were repeated until the coefficients of the symmetry orbitals[8] in the SCF MO's become consistent to three decimal places.

It is assumed that *o*-benzoquinone is planar

and that its symmetry group is $C_{2v}$. Since the molecular dimension of *o*-benzoquinone has never been reported, it was determined as follows. At first, the SCF calculation was carried out with the molecular dimension which has been obtained according to the bond order - bond distance relation[9] from the bond orders previously obtained by the simple MO calculation.[10] From the bond orders obtained by this SCF MO calculation, the molecular dimension which is shown in Fig. 1 was obtained and used in the final SCF MO calculation. The numerals in parentheses in Fig. 1 denote the numbering for the atoms.

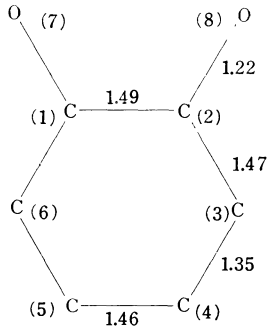

Fig. 1. The assumed molecular dimension (Å).

## Results

The molecular orbital ($\phi_i$)[11] and their orbital energies ($\varepsilon_i$) are shown in Table II. Among the excitation energies of the excited singlet and triplet configurations,[12] the lower ones are shown in Table III, along with the corresponding Coulomb and exchange integrals and transition dipole strengths ($\mu^2$) from the ground state (for singlet configurations). Configuration interactions among five low energy-excited singlet and triplet configurations in Table III were calculated. The obtained excited state wave functions ($^{1,3}\Phi_i$), their excitation energies ($^{1,3}E_i - E_0$), the transition dipole strengths from the ground state and the interconfigurational matrix elements ($\Phi_{i\to j}|H|\Phi_{k\to l}$) are shown in Table IV.

The calculated and observed energy levels[13]

11) $\chi_i$ denotes the $2p\pi$ atomic orbital of *i*-atom.

12) $\Phi_0$ and $E_0$ denote the wave function and the energy of the ground state respectively. $^1\Phi_{i\to j}$, $^1E_{i\to j}$ and $^3\Phi_{i\to j}$, $^3E_{i\to j}$ denote the wave functions and the energies of the singlet and triplet configurations, respectively, in which one electron is excited from an occupied orbital $\chi_i$ to an unoccupied orbital $\chi_j$. The excitation energy of each excited configuration is given by the following formula.

$$\left.\begin{matrix}{}^1E_{i\to j}\\ {}^3E_{i\to j}\end{matrix}\right\} - E_0 = (\varepsilon_j - \varepsilon_i) - (J_{ij} - K_{ij}) \begin{cases} +K_{ij} \\ -K_{ij} \end{cases}$$

$J_{ij}$ and $K_{ij}$ denote Coulomb and exchange integrals over $\Phi_i$ and $\Phi_j$ respectively.

13) S. Goldschmidt and F. Graef, *Ber.*, **61**, 1858 (1928). The $n\to{}^1\pi^*$ band of *o*-benzoquinone is at ca. 600 m$\mu$.

TABLE IV. WAVE FUNCTIONS, EXCITATION ENERGIES AND TRANSITION DIPOLE STRENGTHS OF EXCITED STATES AND INTERCONFIGURATIONAL MATRIX ELEMENTS

(1) Singlet states

| Symmetry | $^{1,3}\Phi_i$ | $^{1,3}E_i - E_0$, eV. | $\mu^2$, Å$^2$ |
|---|---|---|---|
| $^1B_2$ | $^1\Phi_1 = 0.9880\,^1\Phi_{4\to5} - 0.1337\,^1\Phi_{2\to5} - 0.0780\,^1\Phi_{4\to7}$ | 5.171 | 0.711 |
| $^1B_2$ | $^1\Phi_2 = 0.1494\,^1\Phi_{4\to5} + 0.6928\,^1\Phi_{2\to5} + 0.7055\,^1\Phi_{4\to7}$ | 6.615 | 0.007 |
| $^1A_1$ | $^1\Phi_3 = 0.7522\,^1\Phi_{3\to5} - 0.6589\,^1\Phi_{4\to6}$ | 6.949 | 0.014 |
| $^1B_2$ | $^1\Phi_4 = 0.0403\,^1\Phi_{4\to5} + 0.7086\,^1\Phi_{2\to5} - 0.7044\,^1\Phi_{4\to7}$ | 7.294 | 0.068 |
| $^1A_1$ | $^1\Phi_5 = 0.6589\,^1\Phi_{3\to5} + 0.7522\,^1\Phi_{4\to6}$ | 7.504 | 2.290 |

| $(\Phi_{4\to5}\|H\|\Phi_{4\to7})$ | 0.092 | 0.332 |
| $(\Phi_{2\to5}\|H\|\Phi_{4\to7})$ | −0.354 | −1.222 |
| $(\Phi_{3\to5}\|H\|\Phi_{4\to6})$ | 0.275 | −1.155 |

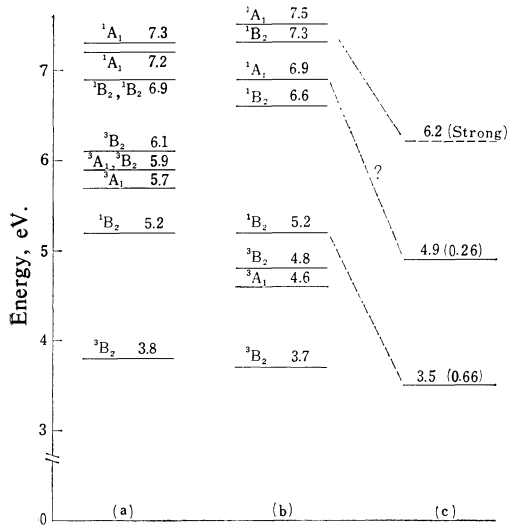

Fig. 2. Energy levels.

(a) Without configuration interaction
(b) With configuration interaction (high triplet levels not described)
(c) Observed

are shown in Fig. 2. In Fig. 2, numerical values on or below the energy levels are the excitation energies rounded to the first decimal in eV., while those in parentheses on the observed levels are the dipole strengths calculated from the observed oscillator strengths. The dipole strength of the 4.9 eV. band is not so accurate because of the overlapping of neighboring bands. As for the observed highest level at 6.2 eV., the corresponding absorption peak has never been observed, but it is certain that an absorption band whose intensity is far greater than the other two observed bands exists near 200 m$\mu$ (which corresponds to ca. 6.2 eV.).

## Discussion

In *o*-benzoquinone, all singlet $\pi$-electronic transitions are allowed and the transitions $^1A_1 \to {}^1A_1$ and $^1A_1 \to {}^1B_2$ are polarized parallel to and perpendicular to the symmetry axis respectively. In Fig. 2, considering the values of dipole strengths, the two observed levels at 3.5 and 6.2 eV. may reasonably be assigned to the $^1B_2$ level at 5.2 eV. and to the $^1A_1$ level at 7.5 eV. respectively. The calculated and observed dipole strengths for the 3.5 eV. band are in good agreement. It is noticeable that the excited-state wave function of this band ($^1\Phi_1$) consists for the most part of $^1\Phi_{4\to5}$, as may be seen in Table IV. The assignment of the observed level at 4.9 eV. is uncertain. The dipole strengths for the two $^1A_1$ configurations whose energy levels are at 7.2 and 7.3 eV. are large and nearly equal to each other. Therefore, if the mixing of these two configurations differs slightly from that given in Table IV, the dipole strength for the $^1A_1$ level at 6.9 eV. will increase to some extent. Therefore, the observed level at 4.9 eV. may be assigned to the $^1A_1$ level at 6.9 eV.

In the results described above, it is noticeable that the calcluated singlet excited levels are much higher than the observed ones. In the case of *o*-benzoquinone studied by Sidman,

TABLE V. EXCITATION ENERGIES OF THE CONFIGURATION ($^1\Phi_{4\to5}$) IN VARIOUS CASES

| | a | b | c | d | e | f | g | h | obs. |
|---|---|---|---|---|---|---|---|---|---|
| $^1E_{4\to5}-E_0$, eV. | 5.21 | 4.98 | 5.12 | 5.13 | 4.94 | 4.57 | 4.14 | 4.60 | 3.5 |

a) The value in Table III.
b) The two center Coulomb repulsion integrals obtained by the Mataga-Nishimoto's method[14] were used.
c) The value (−14.00 eV.) for $U_{OO}$ was used.
d) The value (−10.00 eV.)for $U_{CC}$ of the carbonyl carbon atoms was used.
e) $\beta$'s obtained by Kon's method[2a] were used.
f) For $\beta$'s of the conventional double and single bonds, the values (−2.7 and −1.9 eV. respectively) were used.
g) For $\beta$'s of the conventional double and single bonds, the values (−2.5 and −2.0 eV. respectively) were used.
h) For $\beta$'s the values smaller than those in the case a by the factor (0.8) were used.

TABLE VI. SIMPLE MO'S AND THEIR ENERGIES

| Symmetry | Simple MO's | Orbital energies |
|---|---|---|
| $b_1$ | $\phi_1=0.4655(\chi_1+\chi_2)+0.2820(\chi_6+\chi_3)+0.2419(\chi_5+\chi_4)+0.3811(\chi_7+\chi_8)$ | $(\alpha+)$ 1.7657$\beta$ |
| $a_2$ | $\phi_2=0.4114(\chi_1-\chi_2)+0.2801(\chi_6-\chi_3)+0.1454(\chi_5-\chi_4)+0.4808(\chi_7-\chi_8)$ | 1.3268$\beta$ |
| $b_1$ | $\phi_3=0.2231(\chi_1+\chi_2)-0.3197(\chi_6+\chi_3)-0.5136(\chi_5+\chi_4)+0.2902(\chi_7+\chi_8)$ | 1.2226$\beta$ |
| $a_2$ | $\phi_4=0.0990(\chi_1-\chi_2)-0.4908(\chi_6-\chi_3)-0.3852(\chi_5-\chi_4)+0.3177(\chi_7-\chi_8)$ | 0.6740$\beta$ |
| $b_1$ | $\phi_5=0.2682(\chi_1+\chi_2)+0.3889(\chi_6+\chi_3)-0.3484(\chi_5+\chi_4)-0.3943(\chi_7+\chi_8)$ | −0.5164$\beta$ |
| $a_2$ | $\phi_6=0.3640(\chi_1-\chi_2)+0.2374(\chi_6-\chi_3)-0.4641(\chi_5-\chi_4)-0.3095(\chi_7-\chi_8)$ | −1.1115$\beta$ |
| $b_1$ | $\phi_7=0.4020(\chi_1+\chi_2)-0.4086(\chi_6+\chi_3)+0.2373(\chi_5+\chi_4)-0.3393(\chi_7+\chi_3)$ | −1.1218$\beta$ |
| $a_2$ | $\phi_8=0.4341(\chi_1-\chi_2)-0.3526(\chi_6-\chi_3)+0.3393(\chi_5-\chi_4)-0.2686(\chi_7-\chi_8)$ | −1.1693$\beta$ |

a similar trend was observed. We examined the lowering of the calculated singlet excited levels by using modified values of various kinds of integrals. Since the $^1B_2$ level at 5.2 eV. is much lower than the other singlet excited levels, and since its state almost entirely consists of the configuration ($^1\Phi_{4\to5}$), as is mentioned above, the energy level of this configuration is thought to be reasonably usable as a measure of the lowering of the calculated singlet excited levels. The calculated energy levels of that configuration in various cases where the values of one of the three kinds of integrals (two-center Coulomb repulsion integrals, $U$ and $\beta$) are modified are shown in Table V. As may be seen in Table V, the lowering of that level is small except for the cases (f, g, h) where modified values of $\beta$ are used. From the results in Table V, it may be concluded that a satisfactory lowering of the calculated singlet excited levels cannot be expected unless values of $\beta$ are used which are much modified from those generally used. This disagreement between the calculated singlet energy levels and the observed ones may be attributed to a peculiar electronic structure of quinones, one different from those of usual aromatic compounds.

The Coulomb and exchange integrals in the simple MO method appropriate to simulate the simple MO's to the SCF MO's obtained here for *o*-benzoquinone were searched for with the trial-and-error method. The integral values obtained are shown in Fig. 3. The Coulomb integral of the oxygen atoms and the exchange integrals of the conventional single bonds are far smaller (in $\beta$ units) than those generally used. Similar results have been reported by other authors.[14,15] The MO's of *o*-benzoquinone obtained using these integral values are shown in Table VI. The molecular diagrams of the SCF and simple MO's are shown in Fig. 4. The charge densities of the oxygen atoms and the carbonyl carbon atoms in Fig. 4a are similar to those (−0.149e and +0.131e) of *p*-benzoquinone calculated with Sidman's SCF MO's.[2d] The dipole moment

(a) SCF MO

(b) Simple MO

Fig. 4. Molecular diagrams (charge densities and bond orders).

calculated from the charge densities in Fig. 4a is 1.56 D. The observed dipole moment of *o*-benzoquinone in benzene is 5.1 D.[10] In *o*-benzoquinone, the lone-pair moment of two oxygen atoms and the $\sigma$-moment cannot be estimated with certainty, but the former[16] may be quite large. Even considering this, the $\pi$-moment obtained here seems too small.

## Summary

The $\pi$-electronic energy levels of *o*-benzoquinone have been obtained by using Pople's SCF MO method, while the electron repulsion integrals have been obtained by the Pariser-Parr method. The absorption band near 360 m$\mu$ and the strong band which is thought to exist near 200 m$\mu$ have unambiguously been assigned to the first $^1A_1 \rightarrow {}^1B_2$ and the second $^1A_1 \rightarrow {}^1A_1$ transitions respectively. The calculated singlet excited energy levels are much higher than the observed levels. The reason for this has been examined by SCF MO calculations using modified values of various kinds of electron repulsion integrals and core integrals. It has been concluded that a satisfactory lowering of the calculated singlet excited energy levels cannot be expected unless values of the core resonance integrals ($\beta$) are used which are much modified from those generally used. Simple MO parameters for *o*-benzoquinone adequate to simulate the simple MO's to the SCF MO's have been obtained.

16) The lone-pair moments of sp- and $sp^2$-hybridized oxygen atoms are 1.6 D and 1.5 D respectively.

# Studies on the Liquid-Liquid Partition Systems. II. The Determination of Water Activity by the Solvent Extraction Technique

By Yuko HASEGAWA and Tatsuya SEKINE

(Received March 12, 1965)

In the course of our study on the liquid-liquid partition systems, we desired to find a way to ascertain the water activity of various electrolyte solutions easily.

As Robinson and Stokes[1] have stated, the vapour pressure method is very accurate; the limit of the error is usually less than 0.01%. However, the method is not always easy to carry out because special apparatus must be prepared and a careful control of the experimental conditions is indispensable.

It seems that the water activity in an aqueous solution can be determined by the solvent extraction technique without any special difficulty, because the water content in an organic solvent in equilibrium with the solution can be measured by Karl Fischer titration, and it will be proportional to the water activity in the solution.

1) R. A. Robinson and R. H. Stokes, "Electrolyte Solutions," Butterworths, London (1959).

Högfeldt and his co-workers[2] have studied the extraction of water and acids from various acid solutions into organic solvents by Karl Fischer titration. In these systems, the water in the organic phase consists of two fractions, the free water and the hydrated water. They calculated the hydrated water content from the difference between the total water content as determined by Karl Fischer titration and the free water content as calculated from the water activity cited in the literature.

The present work was carried out to ascertain the accuracy of the value of the water activity determined by the solvent extraction method. For this purpose, benzene was equilibrated with various electrolyte solutions, and the concentration of water in the benzene phase was determined by Karl Fischer titration. Then the water activity of the solution was calculated.

The results were compared with the data in the literature, which had been determined by the vapor-pressure method.

## Statistical Treatment

*Symbols.*

| | |
|---|---|
| $\{H_2O\}$ | water activity |
| $[H_2O]$ | water concentration |
| $\gamma$ | activity coefficient |

The following subscripts denote the activity, concentration or activity coefficient of water in:

"*aq*" an aqueous phase
"*org*" an organic phase
"0" pure water, or an organic phase in equilibrium with pure water
"*n*" an electrolyte solution, or an organic phase in equilibrium with the aqueous phase

When an aqueous solution is in equilibrium with an immiscible organic solvent, the distribution constant of water is defined as:

$$H_2O_{(aq)} \rightleftharpoons H_2O_{(org)} \quad (1)$$

$$K=\{H_2O\}_{org}/\{H_2O\}_{aq} \quad (2)$$

Moreover, an equation can be introduced for the ratio of the water activity in the organic phase in equilibrium with an electrolyte solution and pure water as:

$$\{H_2O\}_{aq,n}/\{H_2O\}_{aq,0}=\{H_2O\}_{org,n}/\{H_2O\}_{org,0} \quad (3)$$

When the water activity in pure water is defined as unity, Eq. 3 can be described, using the activity coefficient as:

$$\{H_2O\}_{aq,n}=\gamma_{org,n}[H_2O]_{org,n}/\gamma_{org,0}[H_2O]_{org,0} \quad (4)$$

Here the following will be assumed.

(i) The activity coefficient of water in the organic phase is constant when the water concentration in it is low.

(ii) The distribution of a small amount of the organic solvent in the aqueous phase does not change the character of the solution.

(iii) No extraction of species which carries water as hydrated water occurs.

On the basis of the first assumption $\gamma_{org,n}$ is equal to $\gamma_{org,0}$ and the water activity in the aqueous solution can be calculated as:

$$\{H_2O\}_{aq,n}=[H_2O]_{org,n}/[H_2O]_{org,0} \quad (5)$$

Thus the water activity of a certain solution can be determined from the ratio of the water concentration in two organic phases if these three assumptions can be made.

## Experimental

**Materials.**—The following chemicals (of a specially-purified grade) were employed without further purification: benzene, potassium bichromate, potassium nitrate, potassium chloride, sodium chloride, strontium chloride, magnesium nitrate, and magnesium chloride. Solutions for Karl Fischer titration were obtained from the Mitsubishi Kasei Co. The sodium chloride was dried in an air-bath at 120°C for several hours and then stored in a desiccator. Sodium chloride solutions of various concentrations were prepared by weighing the dried sodium chloride. Saturated-salt stock solutions were prepared from the metal salts.

**Procedures.**—All of the procedures were carried out in a thermostated room at 25±0.3°C. Twelve milliliters of benzene and 5 ml. of the sample solution were placed in glass-stoppered tubes (volume, 20 ml.). For the experiments with saturated solutions, 0.3—0.5 g. of the salt crystals was added to the sample solution in order to ensure saturation. A mechanical rotator (20 r. p. m.) was used for the agitation of the two phases in the tube; this rotation was continued overnight. It was confirmed by preliminary experiments that the distribution equilibrium was reached within one hour by this rotation. Then the two phases were centrifuged about 5 min. at 2000 r. p. m. This seems to be enough for the separation, because a centrifugation for over 15 min. at 3500 r. p. m. gave the same results.

Ten milliliters of the benzene were then pipetted out and the water content was titrated with a Karl Fischer apparatus (Kyoto Denshi Kogyo Co.).

Blank titration was carried out, and a small correction was made for the water coming from the air.

## Results

The results are given in the following tables.

2) E. Högfeldt and B. Bolander, "Arkiv for Kemie," Band 21, nr 16, Almqvist & Wiksell, Stockholm (1963).

| 5.0 | 0.812 | 0.815 | 0.814 | $0.81_3$ | 0.807 |

## Discussion

In these systems, the water concentration in benzene is very low (maximum: 0.034 M water per liter of benzene), and the benzene concentration in the aqueous phase is also very low (maximum: 0.01 M benzene per liter of water). Thus, the first and second assumptions seem to be established in the present systems.

From the results in the tables, we may also conclude that the present method is accurate to less than 1% when the procedures are carried out properly. The error of Karl Fischer titration may be 0.1—0.5% at most.

By the use of this method, the water activity of several electrolyte solutions can be determined.

## Recommended Procedures

On the basis of the present results, the following procedures can be recommended:

**Organic Solvents.**—Benzene seems to be a suitable solvent for this purpose. If the solvent is not very pure, it should be washed several times with distilled water in order to back-extract hydrophilic impurities.

**Procedures.**—Twelve to fifteen milliliters of benzene and a few milliliters of the sample solutions are placed in glass-stoppered tubes. They are agitated until the distribution equilibrium is reached, and then centrifuged. Ten milliliters of benzene is pipetted out, and the water content is titrated with a Karl Fishcer solution 1 ml. of which is equivalent to about 1 mg. of water.

The following would be useful suggestions for the experiments:

i) The phase separation should be made completely. The present experiment showed that a centrifugation at 2000 r. p. m. for 5 min. is enough for the phase separation if the viscosity of the solution is not high.

ii) The solubility of water in an organic phase is sometimes very sensitive to impurities; the blank test to determine the $[H_2O]_{org,0}$ in Eq. 5 should be made.

iii) The extraction of chemical species which co-extract water as the hydrated water should be checked. The extraction of such species increases the apparent water activity determined by this method. The extraction of chemical species which may react with the Karl Fischer reagent should also be checked.

iv) Chemical species which will change the mutual solubility should be avoided. The change in the mutual solubility may influence the distribution of water (cf. assumptions i and ii).

v) The mutual solubility between an organic solvent and an aqueous solution should not be very high, for the high solubulity changes the properties of each solution.

## Summary

An attempt has been made to apply the solvent extraction technique to the determination of the water activity in various electrolyte solutions.

3) C. W. Clifford. *Ind. Eng. Chem.*, **13**, 631 (1921).
4) E. Z. Groschuff, *Elektrochemie*, **17**, 348 (1911).
5) A. E. Hill, *J. Am. Chem. Soc.*, **45**, 1143 (1923).
6) G. G. Joris and H. S. Taylor, *J. Chem. Phys.*, **16**, 45 (1948).
7) C. K. Rosenbaum and J. H. Walton, *J. Am. Chem. Soc.*, **52**, 3568 (1930).
8) L. A. K. Staverly and J. A. E. Moy, *Trans. Faraday Soc.*, **39**, 5 (1943).

Benzene was agitated with a sample solution until the distribution equilibrium was attained, the water content in the benzene was then measured by Karl Fischer titration. The water activity was calculated on the basis of the water content.

The results agree with the data obtained by the vapor pressure method. On the basis of these, a solvent extraction procedure has been recommended as an easy and rapid method to determine the water activity in various electrolyte solutions.

# A Kinetic Study of the Catalytic Isotopic Hydrogen Exchange of Propene with Deuterium Oxide on Palladium Black

By Yoshie HIRONAKA and Kozo HIROTA

(Received May 16, 1965)

It has already been reported[1,2] that methyl hydrogen is, of all the hydrogen atoms in propene, the most exchangeable on palladium black, while methine hydrogen is the most exchangeable on nickel judging from the subspecies-distribution of propene-$d_1$ in the product.

On the other hand, when the kinetic study of this reaction was carried out on nickel, it was concluded that the exchange of vinyl hydrogen attained equilibrium faster than that of methyl hydrogen.[3]

Since the mechanism of the reaction has been discussed in the case of palladium black only in terms of the subspecies-distribution of $d_1$,[1,2] information concerning the mechanism has been insufficiently detailed for us to reach a final conclusion. The present work was therefore undertaken in order to confirm kinetically the mechanism of the isotopic hydrogen exchange of propene with deuterium black.

## Experimental

**Materials.**—Propene obtained from the Takachiho Industrial Co. (purity: 99.7%) was used without any further purification. Deuterium oxide obtained from the Showa Denko K. K. (the deuterium content, 99.7%) was used also without any further purification. The palladium black used as a catalyst, obtained from the Mitsuwa Kagaku Yakuhin K. K., was reduced at 180°C with hydrogen which had been purified by diffusion through a palladium tube, until no water was produced, followed by degassing for at least four hours at the same temperature.

**Procedure.**—Propene and deuterium oxide were throughly outgassed and were charged in vacuo at the temperature of liquid nitrogen in an ampoule (200 cc.) in which the catalyst had already been prepared. The ampoule was kept at reaction temperature. In order to carry out a kinetic run, about one milliliter (corresponding to 0.5% in a reactor) of gas was sampled from the ampoule at each reaction time. The gas was subjected to mass spectrometric analysis in order to determine the $d_y$-distribution (Hitachi RMU-5B). The infrared method was also applied to the qualitative analysis of the product in order to study the activation energy of exchange for each hydrogen atom in propene.

## Results

**The Kinetics of the Reaction.**—Table I shows the $d_y$-distribution obtained at various times at 50°C, $d_y$ representing the percentage of the isotopic species containing $y$ deuterium atoms at time $t$, while $\phi$ is defined by Eq. 1:

$$\phi = \sum_{y=1}^{6} y d_y \qquad (1)$$

The exchange rate constants measured at 50°C were calculated by assuming the reaction to be first order with respect to the concentration of propene ($d_0$). They are shown in Table I. The triangles in Fig. 1 show the plots of the log $(d_{0t} - d_{0\infty})$ vs. the time (curve a), while the circles show the plots of the log $(\phi_\infty - \phi)$ vs. the time (curve b), with the equilibrium value of $\phi$ denoted by $\phi_\infty$. Both plots show approximately straight lines. Such a tendency was not found in nickel.[3]

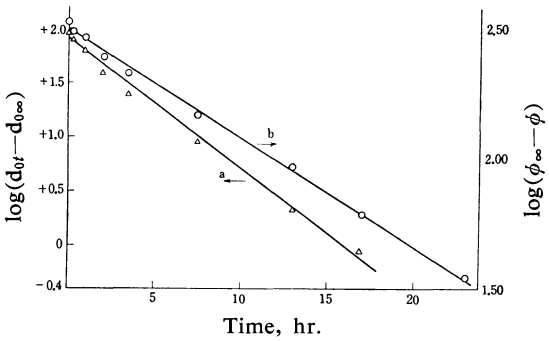

Fig. 1. The plots of $\log(d_{0t}-d_{0\infty})$ vs. time (△) and $\log(\phi_\infty-\phi)$ vs. time (○).

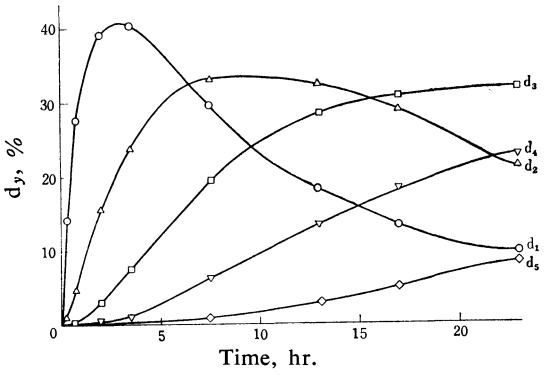

Fig. 2. Time dependency of $d_y$-species.

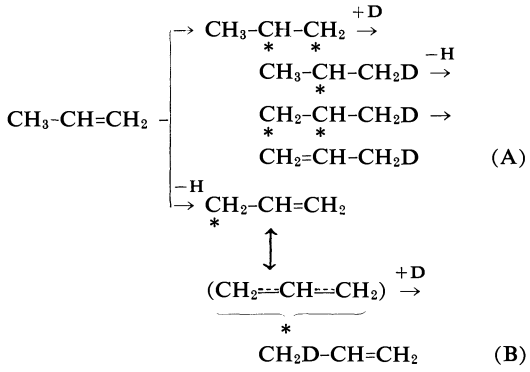
The time-dependency of the $d_1$—$d_5$ species produced (%) is shown in Fig. 2, with $\sum d_y = 100\%$. Both $d_1$ and $d_2$ rose to a maximum and then decreased, while the others increased for 23 hr.

**Activation Energy.**—The exchange was carried out at 55 and 60°C, as well as at 50°C, on the same palladium black, which was reduced with purified hydrogen gas prior to each run. When the activity was checked in the final run under the same conditions as in the initial run, the two examinations agreed well.

The $d_y$ and $\phi$ values, as well as the $k$ values, are summarized in Table II.

The apparent activation energy obtained from the first order rate constant, $k$, was 9 kcal./mol. The infrared spectra of three runs are practically identical over the range of the C-D stretching region (2100—2300 $cm^{-1}$).

## Discussion



From the data obtained by microwave analysis,[1] methyl hydrogen of propene was the most exchangeable of the three kinds of hydrogens atoms at the initial stage of the reaction (3-$d_1$=59.1%, 2-$d_1$=14.1%, t-1-$d_1$=13.1%, c-1-$d_1$=13.7%[1]*)

Nevertheless, there still remains a question whether or not the exchange occurred according to the mechanism concluded from the analysis of the subspecies-distribution of $d_1$ in the reaction process. This question can be solved by measuring the rate of this reaction. Crawford and Kemball[4] suggested that the $\log(\phi_\infty-\phi)$ curve was composed of two or more straight lines if the molecule has two or more kinds of hydrogen atoms different in their exchangeabilities. In the present case, since the $\log(\phi_\infty-\phi)$ vs. time plot shows a straight line in Fig. 1, the exchange rate of

* This data is shown in Ref. 1.

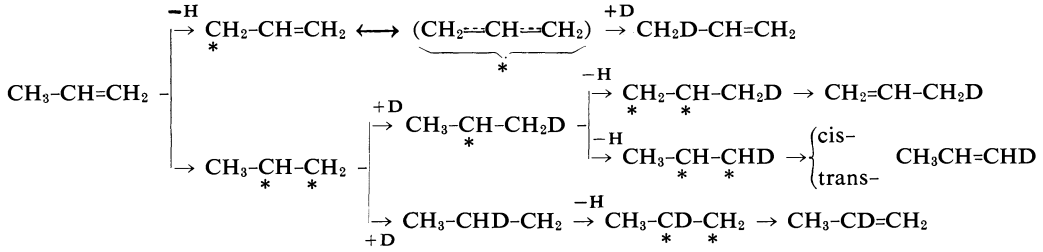
4) E. Crawford and C. Kemball, *Trans. Faraday Soc.*, **58**, 2452 (1962).

all the hydrogen atoms in propene may be equal, regardless of the groups to which they belong. However, for the purposes of explaining the finding that 3-$d_1$ is most abundant in the subspecies-distribution of $d_1$, it seems convenient to say that there are two different paths of methyl hydrogen exchange;

(A)

(B)

i. e., double-bond migration (A) and the dissociative adsorption of methyl hydrogen (B), the former isomeric mechanism having already been proposed.[3]



If the rate-determining step of the exchange is the adsorption of propene, the activation energies would be different between the A and B mechanisms, while the activation energy for methyl and methylene hydrogen exchange would be equal as they passed through the A reaction process. Secondly, if some other step is the rate-determining step, the activation energies of A and B would not be very different in general. The activation energy as determined by means of the rate constant, about 9 kcal./mol., would be the same with respect to the six hydrogen atoms in propene, because the infrared spectra of all three runs are practically identical, as has been mentioned above, as are their $d_y$-distributions (Table II).

The activation energy observed on palladium black is smaller than the value (13.7 kcal./mol.) obtained by Twigg,[5] who studied the exchange between deuterium gas and propene on nickel catalyst. The above value, however, is reasonable, because palladium is generally known to be more active than nickel in the catalytic hydrogenation of ethylene. On the other hand, the activation energies were 21.4 kcal./mol. and 23.7 kcal./mol. in the isotopic hydrogen exchanges of ethane[6] and propane[7] respectively with deuterium gas on evaporated palladium film.

Considering these facts, a higher activation energy seems to be required for the exchange of the hydrogen atom of saturated hydrocarbon. Nevertheless, for the exchange of methyl hydrogen in propene the activation energy is given as only 9 kcal./mol. If we assume the mechanism of methyl hydrogen exchange in propene is likely to be similar to that of ethane or propane, the activation energy would be higher. Considering that the existence of the dissociated propene on palladium black as an allyl-type intermediate ($CH_2{=}CH{=}CH_2$) is highly probable, as has been mentioned already,[2] the activation energy for the methyl exchange of propene would become smaller than that of propane or ethane, because the allyl-type intermediate is more stable than a propyl or ethyl intermediate. Though the rate-determining step could not be determined in this study, it may be considered that methyl exchange occurs according to both mechanisms, A and B, the exchange rates of which are given as nearly equal on the basis of the subspecies-distribution of $d_1$ and of kinetic studies.

Accordingly, the reaction scheme would be shown in Scheme 1.

On the other hand, it is possible that the exchange occurs according to either a multiple or a step-by-step mechanism[8] when the $d_2$-species are produced. Morino and Hirota[9] calculated the subspecies-distribution of $d_2$ using a statistical method. Their calculated values

Scheme 1

5) G. H. Twigg, ibid., 35, 934 (1939).
6) J. R. Anderson and C. Kemball, *Proc. Roy. Soc.*, A233, 361 (1954).
7) F. G. Gault and C. Kemball, *Trans. Faraday Soc.*, 57, 1771 (1961).
8) Cf. G. C. Bond, "Catalysis by Metals," Academic Press, London and New York (1962), p. 191.
9) Y. Morino and E. Hirota, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), 85, 535 (1964).

agreed well with the observed values. However, it was still impossible to determine which of the two mechanisms is the more probable.

If the exchange occurred according to the multiple process, highly-deuterated species would appear, even at the initial stage of reaction. If, on the other hand, the exchange occurred step-by-step, highly deuterated species would not exist at the initial stage of reaction. Therefore, the step-by-step mechanism may be more suitable in this reaction, because highly-deuterated species do not appear at the initial stage of reaction, as is shown in Table I; moreover, the amounts of $d_1$ and $d_2$ species rose to maxima and then decreased as Fig. 2 shows.

It was found to be obviously unreasonable to rely only on the $d_y$-distribution in determining the mechanism of reaction, because even if the $d_y$-distribution is the same between two different samples, subspecies-distributions of $d_y$ are not always the same as has been pointed out in a previous paper.[1] For instance, $d_y$-distributions of propene at the initial stage of exchange reaction were nearly the same on palladium and on nickel, even though the subspecies-distributions of $d_1$ were clearly different.

**Summary**

A reaction mechanism for the catalytic isotopic hydrogen exchange of propene with deuterium oxide on palladium has been offered on the basis of the observed reaction rate and activation energy.

It has been concluded from the observed similarity in the $d_y$-distribution and infrared spectra of the products at different temperatures that the exchange rates of the six hydrogen atoms in propene are nearly equal, while their activation energies are all 9 kcal./mol.

The exchange of methyl hydrogen atoms has been estimated to occur according to the double-bond migration mechanism as well as the dissociation mechanism.

A difference in catalytic activity has been found between palladium and nickel, even when their $d_y$-distributions are nearly the same.

# The Formation of Crystal Violet by the Reaction of *N, N*-Dimethylaniline with Aluminum Chloride

By Hiroyasu SATO*

(Received March 18, 1965)

As has been reported in a previous paper,[1] aniline and *N*-methylaniline adsorbed on aluminum chloride show electronic absorption spectra which are different from those of gaseous molecules; in these spectra the bands are brought nearer to those of toluene and ethylbenzene. This finding was interpreted from the LCMO point of view, and it was concluded that there was a rise in the ionization potential of the amino- or *N*-methylamino-group on adsorption.[2] It was also assumed that the lone-pair electrons of the nitrogen atom in these molecules interact with an electron-accepting center on aluminum chloride to form a Lewis acid-base type, i. e., a sigma-type complex.[1,2] In this paper, the reaction of *N, N*-dimethylaniline with aluminum chloride will be studied. No molecular complex such as is found in the cases of aniline and *N*-methylaniline is formed. The formation of crystal violet is observed in its stead.

## Experimental

Aluminum chloride was prepared from silver chloride and aluminum foils in vacuo according to Wallace and Willard's procedure.[3] *N, N*-Dimethylaniline of the Tokyo Kasei, G. P. grade, was dried with sodium hydroxide and distilled in vacuo before use. The middle fraction was used for the

experiment. Since the system studied here is very sensitive to moisture, the adsorption and spectrometry procedures were carried out in vacuo. The vacuum system apparatus used in this experiment was the same as that already reported,[1] except for one point — a glass tube for the ESR measurement was attached directly to the quartz cell. Aluminum chloride was sublimed by heating it over a free flame via a break-off seal into the cell-system composed of the quartz cell and the ESR tube. Then the vapor of *N*, *N*-dimethylaniline was introduced by opening the stopcock. The electronic spectrum recorded after the evacuation of this cell system did not show the presence of any adsorbed species, contrary to the cases of aniline and *N*-methylaniline.[1] Therefore, a larger amount of *N*, *N*-dimethylaniline was distilled in vacuo into the cell system. The distilled liquid, initially colorless, gradually became blue. This blue color deepened with time, until finally a deep blue solution was obtained. The electronic and ESR spectra of this solution were then recorded. The electronic spectra were recorded by a Hitachi recording spectrophotometer, model EPS-2.

The electronic spectra of commercial crystal violet $C_{25}H_{30}N_3Cl \cdot 9H_2O$ in *N*, *N*-dimethylaniline and in methanol were also measured for the purpose of comparison.

## Results and Discussion

The electronic spectrum of the blue solution is shown in Fig. 1a. It was stable, even for several months, when kept in vacuo. When the cell system was opened to air, however, a muddy greenish color developed (with another absorption band around 400—430 m$\mu$) and a gel-like precipitate (presumably a hydrolyzed product of aluminum chloride) appeared, and finally the liquid phase turned violet. This violet liquid was also obtained when methanol was added to the greenish mixture. The electronic spectrum of this methanol solution is shown in Fig. 1b. No ESR signal was detected for these solutions. In Fig. 2 the electronic spectra of crystal violet in *N*, *N*-dimethylaniline and in methanol are presented. The spectrum of an aqueous solution (Merrill and Spencer[4]) is reproduced in the figure for the sake of convenience. The spectra shown in Fig. 1a and Fig. 1b seem to be identical to those of crystal violet.

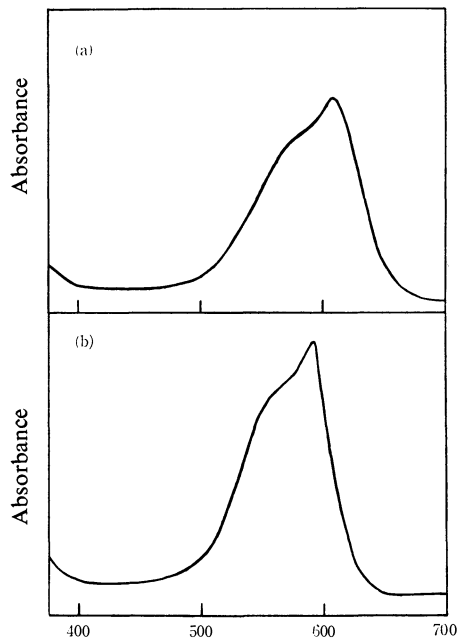

Fig. 1. The electronic spectra of the blue solution obtained by the reaction of *N*, *N*-dimethylaniline and aluminum chloride (a), and of the violet solution obtained when methanol was added to the reaction mixture (b).

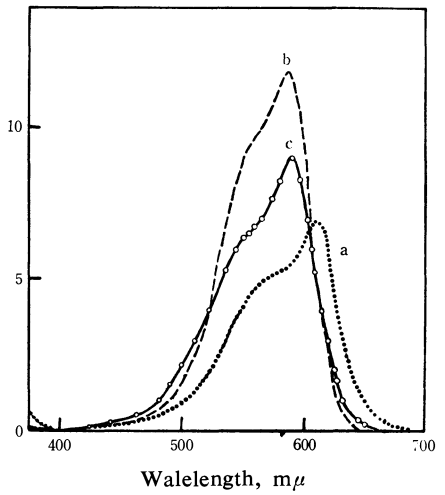

Fig. 2. The electronic spectra of crystal violet.
(a) in *N*, *N*-dimethylaniline ($1.1\times10^{-4}$ mol./l.)
(b) in methanol ($1.1\times10^{-5}$ mol./l.)
(c) in water[4] ($1.0\times10^{-5}$ mol./l.)
The ordinate shows $10^{-3}\varepsilon$ ($\varepsilon$=molar extinction coefficient) for a and $10^{-4}\varepsilon$ for b and c.

Adams and Rosenstein[5] have already shown that a green or a yellow solution is obtained when crystal violet is dissolved in hydrochloric acid (the color depending on the concentration of the acid), and that the color fades in sunlight. According to these authors, such a

4) R. C. Merrill and R. W. Spencer, ibid., **70**, 3683 (1948).

5) E. Q. Adams and L. Rosenstein, ibid., **36**, 1452 (1914). Analyzing the spectra of crystal violet in hydrochloric acid, these authors proved the presence of three colored species in equilibrium (violet with $\lambda_{max}$=590 m$\mu$, green with $\lambda_{max}$=630 m$\mu$ and yellow with $\lambda_{max}$ not located). In the present study these findings were reinvestigated and confirmed. The $\lambda_{max}$ for the yellow species was found to be 430 m$\mu$.

characteristic is common in the chromogens derived from triphenylmethane, and is especially pronounced in the cases of methyl violet and crystal violet. These facts seem to explain what happened when the cell system was opened to air. The moisture reacted with aluminum chloride to give hydrochloric acid and aluminum hydroxide on the surface of the reaction mixture, the acid reacting with crystal violet to give green species. With time this green color was faded by sunlight and/or by the reaction of hydrochloric acid with the remaining *N,N*-dimethylaniline. Finally, by the complete reaction with moisture, there developed the violet color which is like the color of crystal violet dissolved in water. These experimental findings seem to prove the presence of crystal violet in the reaction system. though chemical analysis was impossible.

The formation of crystal violet results from the oxidation of *N,N*-dimethylaniline by aluminum chloride, though the detailed mechanism of the reaction is not clear. The low ionization potential of *N,N*-dimethylaniline will facilitate this reaction. The central carbon atom in the crystal violet may come from the methyl group in the *N,N*-dimethylaniline molecule. The formation of crystal violet ions, $C_{25}H_{30}N_3^+$, will require one electron per ion to be caught in the gegen-anion or elsewhere. In the present case this electron may rest in the vacant orbital of aluminum chloride. Therefore, the finding that the blue solution gave no ESR signal could be interpreted, among other ways, in terms of the possibility that the electron may be paired in the vacant orbital.

Eastman et al.[6] have observed that *N,N*-dimethylaniline and chloranil react to give crystal violet as the final product via the formation of a charge-transfer (CT) complex. Their CT complex has an absorption maximum at 650 m$\mu$. This CT complex has also been found by Briegleb et al.[7] and Mukherjee et al.[8] In the present case also, such a CT complex might be formed during the course of the reaction, though it was not found in the present study.

## Summary

The reaction of *N,N*-dimethylaniline with aluminum chloride in vacuo has given a deep blue solution. This blue solution turns violet because of moisture or the added methanol. The electronic spectra of these solutions seem to be identical with that of crystal violet. The finding that transient green species appear when the vacuum cell system is opened to air can be interpreted in terms of the color of crystal violet dissolved in hydrochloric acid. From these findings the formation of crystal violet has been concluded.

The present author wishes to express his deep gratitude to Professor Kozo Hirota, Faculty of Science, Osaka University, for his continued interest and generous encouragement throughout the work. The author is also indebted to Mr. Toshinobu Imanaka of the same department for his useful suggestions concerning experimental techniques for preparing the evaporated film of aluminum chloride. Thanks are also due to Mr. Koichi Nishikida of the same department for the ESR measurement.

# The Radiolysis of Ethylene Glycol Diacetate

By Toshiro ISOYA, Kozo HIROTA and Motoyoshi HATADA

(Received March 19, 1965)

There have been a number of reports on the radiolysis, in the liquid phase, of various monoacetates[1-7] which have an ester group in the molecule, but the radiolysis of diacetate or polyacetate, each of which has two or more groups in the molecule, has not yet been reported. The present paper, which will describe the radiolysis of ethylene glycol diacetate (EGDA), the lowest member of diacetate, which was attempted in order to investigate the effect on radiolysis of the number of ester groups in the molecule; the paper will, it is hoped, make possible a better understanding of the radiolysis of such polymers as polyacetates, because diacetate may, in a way, be ragarded as the lowest member of these polymers.

## Experimental

**Material.** — Commercially-available EGDA was refluxed with acetic acid and then purified by distillation in vacuo. By gas chromatographic analysis, two small peaks were found in the sample, before and after the peak of EGDA; the impurities, which could not be identified, were ca. 0.8%.

**Irradiations.**—In each run, a liquid sample of 2 ml. of EGDA was by the conventional vacuum technique, degassed in a glass ampoule fitted with a break seal; the ampoule was sealed off and was then subjected to irradiation at room temperature with cobalt-60 gamma rays. The dose rate, which was determined by the use of a Fricke ferrous sulfate dosimeter, was $1.2\times10^{16}$ eV. $sec^{-1}$ $ml^{-1}$, the correction in the electron density difference between the sample and the dosimeter solution being taken into account.

**The Analysis of the Liquid Products.**—The liquid products were identified by gas chromatographic and mass spectrometric analyses. The gas chromatograph used was a Shimadzu GCIB apparatus, its operating conditions for identification being as follows: adsorbent=polyethyleneglycol (PEG) 6000; column temperature=65°C and 130°C, and adsorbent=dioctyl phthalate, column temperature=110°C, column length=3.75 m., and flow rate of the carrier gas (nitrogen)=30 cc./min. The fractions separated by the gas chromatograph were collected by fraction collectors and subjected to mass spectrometry in order to identify them. To obtain the data for kinetics, the following operating conditions were adopted: column length=3.75 m., adsorbent=PEG 6000, the flow rate of the carrier gas (nitrogen) =30 cc./min., column temperatures=65°C (and 135°C for only methyl cellosolve acetate).

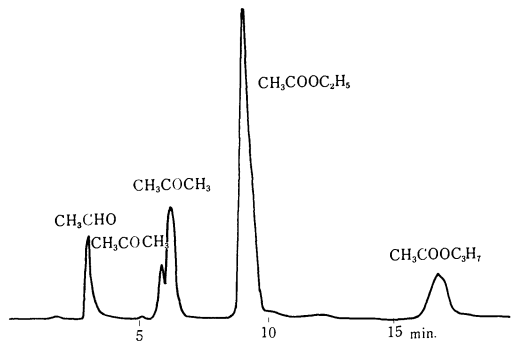

Fig. 1. Gas chromatogram of irradiated ethylene glycol diacetate.
PEG 6000 3.75 m.
$N_2$ gas 30 cc./min.
Column temp. 65°C

Figure 1 shows a typical gas chromatogram of the irradiated EGDA.

**The Analysis of the Gaseous Products.** — The gaseous products were separated into two fractions with a Toepler pump at −78°C and −196°C and were subjected to mass spectrometry.

**The Measurement of the Mass Spectra.**—The mass spectra were obtained by the use of a Hitachi RMU-5-type mass spectrometer, which was a 90°-sector-type instrument of magnetic scanning; the following conditions were adopted: accelerating potential=1500 V., bombarding electron voltage=90 V., and total electron current=100 $\mu$amp.

**The Measurement of the ESR Spectrum.**—The ESR spectrum was measured at −196°C on EGDA, which was degassed in a "Spectrosil" silica tube and irradiated with 1.5 MeV. electron beams (dose rate=$9.3\times10^{18}$ eV. $g^{-1}$ $sec^{-1}$, and total dose=$3.1\times10^{21}$ eV. $g^{-1}$) from a Van de Graaff accelerator at −196°C. The apparatus was of the X-band type, equipped with a Varian V-4500 ESR spectrometer.

## Results and Discussion

7) P. Ausloos, *J. Am. Chem. Soc.*, **83**, 1056 (1961).

The yields increased linearly with the dose in most cases; acetaldehyde and ethyl acetate were the exceptions. The $G$ values of the eleven products are listed in Table I. These values were obtained from the best-fitting lines through the experimental points in Fig. 2 and Fig. 3.

The effect of DPPH addition is shown in Table II. The yields of hydrogen, carbon dioxide, acetaldehyde and ethyl acetate decreased at the concentration of $5.5\times10^{-3}$ mol./l., but the yields of the other products were scarcely affected at all by DPPH addition at this concentration. The yields of all the products, however, decreased as the concentration became higher. Some products were affected even at the lowest concentration ($5.5\times10^{-3}$ mol./l.), while other products were not, but all the products were affected at the highest concentration ($9.2\times10^{-2}$ mol./l.). DPPH may play not only the role of a scavenger of the radicals escaping from "cage," but also that of energy-acceptor.[4]

| Methyl cellosolve acetate | 0.10 |

Figure 4 shows the mass spectrum of EGDA. The ions of $m/e=29$ and 61 are assigned to $HCO^+$ and $CH_3COOH_2^+$, which are formed by some rearrangement processes. These rearrangement peaks have often been reported in the mass spectra of various acetates.[9-13] The ion of $m/e=86$ is assigned to $CH_3COOC_2H_3^+$, which may come from the C–O bond scission of the parent molecule after a rearrangement process including an H atom transfer, and the ion of $m/e=116$ may be formed by $CH_2O$ elimination from the parent molecule.

Figure 5 shows the ESR spectrum of the irradiated EGDA.

This spectrum may be ascribed to $CH_3COOCH_2$ and/or $\dot{C}H_2COOCH_2CH_2OOCCH_3$.

The ratio of the number of carbon, hydrogen and oxygen atoms found in the products is calculated to be C : H : O = 5.0 : 10 : 2.7, clearly indicating that an excess of H is incorporated

in the products in comparison with the empirical formula for EGDA, C : H : O = 6.0 : 10 : 4.0. In addition, a brown substance remained after the unreacted EGDA had been distilled away from the irradiated sample. The elemental analysis of this residue gave C : H : O = 6.2 : 10 : 4.1, the C and O contents being slightly larger than those of EGDA. These findings suggest the formation of such undetectable products as dimers, which may come from the radicals, $\dot{C}H_2COOCH_2CH_2OOCCH_3$ and $CH_3COO\dot{C}HCH_2OOCCH_3$, formed by the primary processes 1 and 2, as well as from unsaturated compounds of a higher molecular weight.

The dimers may be formed by the recombination reaction of radicals, $\dot{C}H_2COOCH_2CH_2OOCCH_3$ and/or $CH_3COO\dot{C}HCH_2OOCCH_3$. They may be produced by abstracting a hydrogen atom from EGDA with the radicals produced primarily, such as H, $\dot{C}H_3$, $CH_3\dot{C}O$, $CH_3COO\dot{C}H_2$ and $CH_3COOCH_2\dot{C}H_2$. On the above assumption, the yields of dimers may be given by the following equation:

$$G_{\text{dimers}} = G_{H_2} + 1/2(G_{CH_4} + G_{CH_3CHO} + G_{CH_3COOCH_3} + G_{CH_3COOC_2H_5})$$

The $G_{\text{dimers}}$ value calculated by this equation is 2.1, which gives a calculated C : H : O ratio of the system of 6.0 : 10 : 3.7, a ratio close to that of EGDA, 6.0 : 10 : 4.0.

2) The following reaction scheme is possible judging from the radiolytic products and the mass spectrum of EGDA. A part of the products can be explained by recombination reactions of these radicals.

$$CH_3\overset{\overset{O}{\|}}{C}OCH_2CH_2O\overset{\overset{O}{\|}}{C}CH_3$$

$$\xrightarrow{(1)} H + \dot{C}H_2\overset{\overset{O}{\|}}{C}OCH_2CH_2O\overset{\overset{O}{\|}}{C}CH_3$$

$$\xrightarrow{(2)} H + CH_3\overset{\overset{O}{\|}}{C}O\dot{C}HCH_2O\overset{\overset{O}{\|}}{C}CH_3$$

$$\xrightarrow{(3)} CH_3\overset{\overset{O}{\|}}{C}O + \dot{C}H_2CH_2O\overset{\overset{O}{\|}}{C}CH_3$$

$$\searrow^{(4)}$$

$$\dot{C}H_3 + CO_2 + \dot{C}H_2CH_2O\overset{\overset{O}{\|}}{C}CH_3$$

$$\nearrow_{(6)}$$

$$\xrightarrow{(5)} \dot{C}H_3 + \dot{C}OCH_2CH_2O\overset{\overset{O}{\|}}{C}CH_3$$

$$\searrow^{(7)}$$

$$\dot{C}H_3 + CO + \dot{O}CH_2CH_2O\overset{\overset{O}{\|}}{C}CH_3$$

$$\nearrow_{(9)}$$

$$\xrightarrow{(8)} CH_3\overset{\overset{O}{\|}}{\dot{C}} + \dot{O}CH_2CH_2O\overset{\overset{O}{\|}}{C}CH_3$$

$$\xrightarrow{(10)} CH_3\overset{\overset{O}{\|}}{C}O\dot{C}H_2 + \dot{C}H_2O\overset{\overset{O}{\|}}{C}CH_3$$

Some other products can be explained by the following rearrangement and recombination reactions:

$$CH_3COOCH_2CH_2OOCCH_3$$

$$\xrightarrow{(11)} CH_3COOCH_2CH_2OCH_3 + CO$$

$$\xrightarrow{(12)} CH_3COOCH_2CH_2CH_3 + CO_2$$

$$CH_3COOCH_2CH_2\dot{O} + \dot{C}H_3$$

$$\xrightarrow{(13)} CH_3COOCH_2CH_2OCH_3$$

$$CH_3COOCH_2\dot{C}H_2 + \dot{C}H_3$$

$$\xrightarrow{(14)} CH_3COOCH_2CH_2CH_3$$

Table II. Yields in the presence of DPPH
(dose rate $1.2\times10^{16}$ eV. ml$^{-1}$ sec$^{-1}$)
(dose $6.3\times10^{20}$ eV. ml$^{-1}$)

| ($10^{-6}$ mol./ml.) | Concentration of DPPH ($10^{-2}$ mol./l.) | | | | | Decrease* in the presence of DPPH |
|---|---|---|---|---|---|---|
| | 9.2 | 6.5 | 1.3 | 0.55 | 0 | % |
| $H_2$ | 1.7 | 1.5 | 1.8 | 1.9 | 3.3 | 48 |
| $CH_4$ | 4.2 | 4.0 | 6.2 | 7.6 | 7.9 | 47 |
| $C_2H_6$ | 0.9 | 0.9 | 1.0 | 1.2 | 1.1 | 18 |
| CO | 7.9 | 7.5 | 9.0 | 9.0 | 8.9 | 11 |
| $CO_2$ | 2.4 | 2.4 | 2.4 | 2.8 | 3.9 | 38 |
| Acetaldehyde | 6.4 | 8.5 | 8.9 | 11.7 | 15.0 | 57 |
| Acetone | 1.2 | 1.3 | 2.0 | 2.6 | 2.7 | 56 |
| Methyl acetate | 1.4 | 1.4 | 1.4 | 2.1 | 2.0 | 80 |
| Ethyl acetate | 5.5 | 5.5 | 6.9 | 5.7 | 11.0 | 50 |
| *n*-Propyl acetate | 1.2 | 1.7 | 2.1 | 2.5 | 2.3 | 48 |
| Methyl cellosolve acetate | 0.90 | 0.75 | 1.0 | 1.1 | 1.1 | 18 |

* $(G_{DPPH(0)}-G_{DPPH(9.2)})/G_{DPPH(0)}\times100$

Carbon monoxide is produced by the molecular rearrangement or the reaction in the cage 11, as well as by the radical decomposition processes 7 and 9. Similarly, carbon dioxide is produced by the reactions 12, 4 and 6. The effect of DPPH shows that a larger part of CO and $CO_2$ is produced through reactions 11 and 12, implying that a part of the methyl cellosolve acetate is formed by reaction 11, and the remaining part, by 13. Reactions 11 and 12 are supported by the ions of $m/e=28$ and $m/e=44$, ascribable to $CO^+$ and $CO_2^+$ respectively, in the mass spectrum of EGDA. *n*-Propyl acetate is formed by reactions 12 and 14. Reaction 12 proceeds almost as that reaction 14, judging from the effect of DPPH addition.

Ethyl acetate is formed by the reaction of such radicals as $CH_3COO\dot{C}H_2$ and $\dot{C}H_3$, $CH_3COOCH_2\dot{C}H_2$ and H, while hydrogen, methane, acetaldehyde, and methyl acetate are formed by the reaction of the hydrogen radical with the corresponding radical and by hydrogen abstraction by the three radicals from the parent molecule. Since the $CH_3COO$ radical is unstable,[14,15] the reaction of $CH_3COO$ and $\dot{C}H_3$ is disregarded; in fact, acetic acid was not actually found. 80% of the methyl acetate and 50% of the ethyl acetate were formed by some processes unaffected by DPPH.

Acetone and ethane are formed by the radical reactions 15 and 16 respectively, and to some extent by molecular processes in the cage:

$$CH_3\dot{C}O+\dot{C}H_3 \xrightarrow{(15)} CH_3COCH_3$$

$$\dot{C}H_3+\dot{C}H_3 \xrightarrow{(16)} C_2H_6$$

3) Most data on the monoacetates' radiolysis so far published have been obtained by electron-beam irradiation. In order to compare our results with those for monoacetates, the total gaseous yields of deaerated EGDA was determined by the use of electron irradiation from a Van de Graaff accelerator (dose rate: $1.0\times10^{19}$ eV. ml$^{-1}$ sec$^{-1}$, and dose: $6.7\times10^{20}$ eV. ml$^{-1}$ rads) at room temperature. The results are shown in Table III, as well as those for monoacetates.

Table III. Total gaseous yields of various acetates

| | $G_{gas}$ |
|---|---|
| Methyl acetate[1,8] | 3.40 |
| *n*-Propyl acetate[1,5,8] | 2.4 |
| Isopropyl acetate[1,5,8] | 3.62 |
| Benzyl acetate[1,5,8] | 2.66 |
| EGDA | 1.45 |

The stability of EGDA against the radiation is about twice as much as that of the monoacetates. Similarly, as in the case of monoacetates, the most labile bond of EGDA is the acyl-oxygen bond, a finding from the product yields and from the mass spectrum of EGDA. The above conclusion implies that the yields of the products (acetaldehyde, acetone, carbon monoxide and methyl cellosolve acetate) formed by this bond scission are more than those of others formed by other bond scissions, the sum of the height of the peaks, $m/e=43$ ($CH_3CO^+$) and $m/e=103$ ($CH_3COOCH_2CH_2O^+$), which result from this bond scission occupies

14) L. Jaffe, E. J. Prosen and M. Szwarc, *J. Chem. Phys.*, 27, 416 (1957).
15) P. Ausloos, *Can. J. Chem.*, 36, 383 (1958).

the largest part of the total ion intensity in the mass spectrum of EGDA.

In comparison with the yield of gaseous products from methyl acetate (MA) and EGDA (Table IV), the $G_{MA}/G_{EGDA}$ ratio ranges between ca. 2 and 3. The molecular weights of MA and EGDA are 74.08 and 146.14, and the absorption energy per molecule of EGDA is about two times as much as that of MA. The ratio of the decomposition of MA to that of EGDA is 1.6, smaller than the others.

Table IV. *G* Values of gaseous products of methyl acetate and EGDA

| | Methyl acetate | EGDA | $G_{MA}/G_{EGDA}$ |
|---|---|---|---|
| $G_{-M}$ | 4.1[6] | 2.5 | 1.6* |
| $G_{H_2}$ | 0.87(0.76)[4] | 0.34 | 2.6(2.2) |
| $G_{CO}$ | 1.57(1.64) | 0.76 | 2.1(2.2) |
| $G_{CO_2}$ | 0.78(0.95) | 0.28 | 2.8(3.4) |
| $G_{CH_4}$ | 2.07(2.03) | 0.70 | 3.0(2.9) |
| $G_{C_2H_6}$ | 0.27(0.34) | 0.10 | 2.7(3.4) |

* Only this numeral denotes the ratio of decomposition of MA to that of EGDA.

The yield of each gas per molecule of MA is 1—1.5 times as much as that of EGDA. This means that the formation mechanisms of these gaseous products from EGDA are very similar to those from MA.

**Summary**

The radiolysis of air-free ethylene glycol diacetate by $^{60}Co$ $\gamma$-rays has been studied at room temperature. The following results have been obtained: a) irradiation gives five gaseous products and six liquid products; b) the *G* value of the total of all the gaseous products is 2.18; c) the *G* value of the EGDA decomposition is 2.5. The effect of DPPH addition on the radiolytic products, the relation between radiolytic products and the mass spectrum of unirradiated EGDA, and the ESR spectrum of irradiated EGDA have also been studied. No remarkable difference in the products has been found between EGDA and various monoacetates except in the gaseous products, the yields from EGDA being 1/2—1/3 of those from methyl acetate.

# Adsorption Measurements during the Synthesis of Methanol at Lower Pressures*

By Susumu TSUCHIYA and Tadao SHIBA

(Received March 20, 1965)

Various mechanisms of the methanol synthesis reaction have been proposed by many workers.[1-6] In deducing these mechanisms, however, the adsorption during the reaction has indirectly been estimated on the basis of either a Langmuir-Hinshelwood or a Temkin-Pyzhev-type mechanism. The importance of the adsorption measurements during surface catalysis has recently been emphasized by Tamaru.[7] In his method, the adsorption on the catalyst surface, as well as its reaction rate, can be directly measured; such reactions as the decomposition of formic acid on metal catalysts[8] and the synthesis and decomposition of ammonia[9,10] have already been studied by means of this new approach.

In order to obtain further information on the mechanism of the methanol synthesis reaction, the present authors used the new

method to measure the adsorption during the reaction.

## Experimental

The apparatus employed in these experiments was a closed circulating system, as Fig. 1 shows. A is a cylindrical reaction vessel 85 mm. long and 25 mm. in internal diameter. Passing through the central tube of the vessel, the circulating gas was pre-heated before reaching the catalyst bed, which was 45 mm. thick. B is an electric heater, regulated within ±2°C, and D is a thermocouple. K is a circulating pump; a piece of iron sealed in a glass piston, M, was driven reciprocally by means of an electromagnet, L. During the course of the reaction, the stop-cocks, I, J, P, Q, R, S, Y, were closed. The synthesis reaction usually proceeded in such a way that the methanol produced was

D Thermocouple
F Trap cooled with liquid nitrogen
K Circulation pump

collected in a trap, F, maintained at the temperature of liquid nitrogen. The volume of the circulating system corresponded to about 433 ml. at a reaction temperature of 250°C.

Known amounts of the reactants, pure hydrogen and carbon monoxide, in a synthesis reaction, and methanol in a decomposition reaction, were introduced into the system; the reaction followed, the pressure and composition of the circulating gas being measured at suitable time intervals. The amounts of products condensed in the trap, F, were determined at the end of each run. Gas chromatography as described by Murakami[11] was used for the analyses of gases and condensed products. In this method, the amounts of hydrogen, carbon monoxide, methane, and carbon dioxide were simultaneously determined, using two columns, one (80 cm. long) packed with silica gel as an adsorbent, and the other (2 m. long) packed with 13x Molecular Sieves, successively at room temperature, where herium was employed as a carrier gas. In the analyses of methanol and water, on the other hand, the amounts of carbon monoxide co-existing in the trap, F, were first estimated, and then the ratios of the amounts of the methanol and water to that of carbon monoxide were determined, using successively two columns (1 m. long), packed with polyethylene glycol on celite 545 and with 5A Molecular Sieves, at 60°C, where the carrier gas was hydrogen.

The amounts of the gases adsorbed on the catalyst were obtained as either hydrogen or carbon monoxide from the amounts of reactants introduced into the system, the pressure and the composition of the circulating gas, and the amounts of products trapped. Due allowance was made for the analytical samples removed from the apparatus.

Carbon monoxide was prepared by decomposing sodium formate with sulfuric acid, and it was purified by repeated fractional distillation at the temperature of liquid nitrogen after having passed through a soda-lime column. Hydrogen was obtained from a commercial cylinder, and purified over palladium asbestos at 350°C. Methanol was purified by repeated distillation after having been dried over calcium oxide.

The catalyst employed had the composition Zn : Cr : Cu = 1.0 : 0.49 : 0.16, and it was reduced at 280°C under atmospheric pressure, initially in a hydrogen stream for 60 hr. and then in a hydrogen stream saturated with methanol vapor at room temperature for 50 hr. Before each run, the catalyst was evacuated for 3 hr. at 400°C. Thus the experimental results were satisfactorily reproducible.

## Results and Discussion

The measurements of the adsorption and of the reaction rate were carried out at 250°C. A typical result during the methanol synthesis reaction is shown in Fig. 2. The amounts of the adsorption of hydrogen and carbon monoxide during the reaction were greater than those separately adsorbed, which are represented by solid symbols, when the corresponding amounts of gases were introduced. This fact can be explained as indicating a marked mutual influence on the adsorption of hydrogen and carbon monoxide in the presence of the other gas. It was thus suggested that the adsorption behavior during the reaction can not be estimated from the results observed in the absence of the other gas. A similar effect was reported during the ammonia synthesis reaction.[10] The amounts of methanol formed were far less than those calculated from the equilibrium constant and from the circulating rate. The circulating rate was occasionally measured by means of a soap film meter, connected with the system through the stop-cocks I and J, precautions being taken to prevent the

water vapor from contaminating the catalyst. The observed products of the reaction were usually identified as methanol and carbon dioxide and, depending on the reaction conditions, small amounts of water and a trace of methane.

The surface area of the catalyst was estimated to be $1.0\times10^7$ cm$^2$ by using the B. E. T. method for nitrogen adsorption at −196°C after the catalyst had been reduced.

The ratios of adsorbed hydrogen to carbon monoxide during the synthesis and the decomposition reaction of methanol are plotted against the ratios of their ambient pressures in Fig. 3. The compositions of the adsorbed phase did not depend on those of the gas phase, in spite of the wide change (about eight thousand-fold) of the partial pressure ratio. The composition of the adsorbed phase would reasonably depend on their partial pressure ratios if the two gases were separately adsorbed. The marked constancy of the composition of the adsorbed species suggests, accordingly, that most of the adsorbed hydrogen and carbon monoxide (more than 80% of the hydrogen and 75% of the carbon monoxide) form a complex, and the average value, 1.5, suggests that the stoichiometric formula of the complex is $CH_3O$.

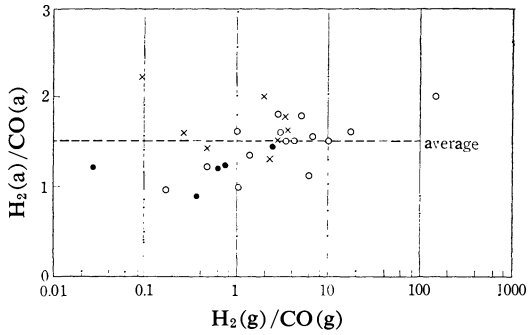

Fig. 3. Relationship between $H_2(g)/CO(g)$ and $H_2(a)/CO(a)$.
○ Synthesis with liquid nitrogen trap
● Synthesis without liquid nitrogen trap
× Decomposition

Figures 4 and 5 give two examples of the plots of the average synthesis rate against the ambient pressure, as well as the amounts of adsorption of hydrogen and carbon monoxide. The rates of methanol synthesis reaction were represented by the cumulative amounts of methanol synthesized over a four-hour period, the rates being too slow to determine with time. The ambient pressure and the amounts of the adsorption of hydrogen and carbon monoxide were represented by their average value over the four-hour period. As is shown

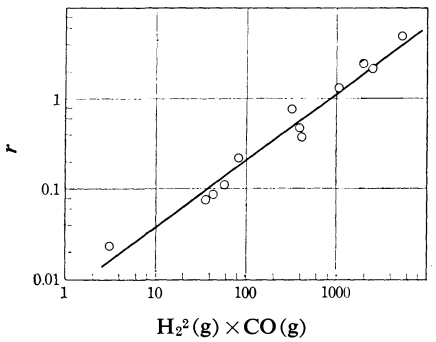

Fig. 4. Synthesis rate vs. $H_2^2(g)\times CO(g)$.

in Fig. 4, the synthesis rate of methanol can be expressed by Eq. 1:

$$r=k(P_{H_2}{}^2P_{CO})^n \qquad (1)$$

where $P_{H_2}$ and $P_{CO}$ are the ambient pressures of hydrogen and carbon monoxide respectively; $k$, the rate constant, and $n$, a constant, which is 0.75. Uchida and Ogino[5] previously reported Eq. 2:

$$r=k(P_{H_2}{}^2P_{CO})^{1-\alpha} \qquad (2)$$

where $\alpha$ is a constant equal to 0.3. These equations are in good agreement in spite of the different conditions of the experiments (at 300—360°C, under 90—150 kg./cm$^2$ by Uchida and Ogino, but at 250°C, under 100—760

TABLE I. ADSORPTION OF HYDROGEN AND CARBON MONOXIDE DURING THE METHANOL SYNTHESIS AT VARIOUS CONDITIONS (250°C)

mmHg by the present authors). These equations can be interpreted as implying that the catalyst surface is partially covered with adsorbate, assuming that a Langmuir-type adsorption is valid. It is, however, found that considerable amounts of adsorption on the surface are involved, as is shown in Table I.

It thus seems inappropriate to apply the Langmuir-type adsorption. Moreover, the results reported by Uchida and Ogino[12] indicate that the rate of the reaction of methanol synthesis can not be expressed by any equation based on the Langmuir-type adsorption.

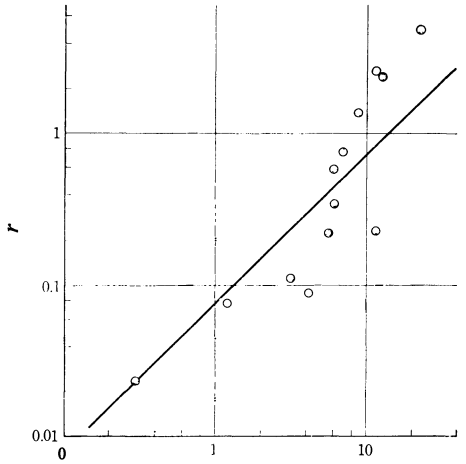

Fig. 5. Synthesis rate vs. $H_2(g)\times CO(a)$.

As Fig. 5 shows, the synthesis rate may also be expressed by Eq. 3:

$$r=kP_{H_2}A_{CO} \qquad (3)$$

where $A_{CO}$ is the amount of carbon monoxide adsorbed in any form combined or not combined with hydrogen on the surface. The adsorbed carbon monoxide mostly forms a complex, so:

$$A_{CO}\fallingdotseq A_X$$

where $A_X$ is the amount of the surface complex. Taking the surface complex to have the $CH_3O$ composition, the Eley-Rideal-type hydrogenation of the adsorbed complex would be the rate-determining step of the over-all reaction:

$$CH_3O(a)+H_2(g) \xrightarrow{-A-} CH_3OH(a)+H(a)$$

The synthesis rate is thus expressed by Eq. 4:

$$r=kP_{H_2}A_{CH_3O} \qquad (4)$$

It may, accordingly, be concluded that the Eley-Rideal-type hydrogenation of the surface complex is the rate-determining step of the methanol synthesis reaction.

## Summary

Adsorption has been studied on a three-component methanol synthesis catalyst during the synthesis of methanol in a closed circulating system. It has been shown that the adsorption of hydrogen and carbon monoxide are both enhanced by the presence of the other. The composition of the adsorbed phase has scarcely been affected at all by the ratio of the partial pressure of hydrogen to carbon monoxide, and the formation of surface complex has been suggested. The rate-determining step of the synthesis of methanol has been suggested to be the process of the Eley-Rideal type hydrogenation of the surface complex.

The authors are grateful to Professor Yoshisada Ogino of Tohoku University for providing the catalyst sample.

# The Electronic Spectra of Aniline and *N*-Methylaniline Adsorbed on Aluminum Chloride. II. The Theoretical Treatment

By Hiroyasu SATO,* Saburo NAGAKURA and Kozo HIROTA

(Received March 23, 1965)

In the preceding paper,[1] the electronic spectra of aniline and *N*-methylaniline adsorbed on aluminum chloride were measured and compared with those of gaseous aniline, *N*-methylaniline, toluene and ethylbenzene. In the case of adsorbed *N*-methylaniline, the spectrum was almost the same as that of gaseous ethylbenzene, while in the case of adsorbed aniline, a spectrum with a strong band at 192 m$\mu$ and a weak hidden band at about 218 m$\mu$ was obtained. The spectra of the adsorbed species were there discussed qualitatively by considering the location of the intramolecular charge-transfer (CT) configurations relative to those of the locally-excited (LE) configurations. In the adsorbed molecules, the former has a higher energy than in gaseous molecules, as a result of the rise of the ionization potential of the electron-donating group. This rise in the ionization potential was attributed to the interaction of the lone-pair electrons in the adsorbed molecule with some electron-accepting center on aluminum chloride, presumably with the vacant $sp^3$-orbital of the aluminum atom.

In the present paper, the electronic spectra of adsorbed molecules will be studied, by the LCMO treatment, in comparison with those of gaseous molecules. The results can explain satisfactorily the experimental findings mentioned in the preceding paper.[1]

## Calculation Procedure

The calculation was carried out according to the intramolecular charge-transfer model, which is based on the idea that the molecules to be treated consist of an electron-accepting group (the benzene ring in this case) and an electron-donating group (X=$NH_2$, $NHCH_3$, $CH_3$ and $C_2H_5$ groups). Only $\pi$-electrons were taken into account. In the case of aniline or *N*-methylaniline, the lone pair electrons on the nitrogen atom were assumed to belong to the pure 2p$\pi$ atomic orbital. For toluene and ethylbenzene, the hyperconjugation was taken into account, and two $\pi$-electrons were counted for the methyl- or ethyl-group respectively. For adsorbed aniline and adsorbed *N*-methylaniline, an intermediate situation between gaseous aniline and toluene, and between gaseous *N*-methylaniline and ethylbenzene, respectively, is to be expected, as was discussed in the preceding paper. Hence, in these cases also, two $\pi$-electrons may be taken into account for the adsorbed amino-group or the adsorbed *N*-methylamino-group respectively.

After the procedure of Longuet-Higgins and Murrell,[2] configuration interaction was considered among seven electron configurations constructed from the $\pi$-electron orbitals of the benzene ring ($\phi_1, \phi_2, \cdots, \phi_6$) and the 2p$\pi$ (or the pseudo-2p$\pi$) orbital on the electron-donating group, X. They include two CT configurations and four LE configurations, besides the ground configuration. Assuming the molecule $C_6H_5X$ to belong to the point group $C_{2v}$, these configurations can be divided into two symmetry species, $A_1$ and $B_2$. The wave functions which are obtained by the linear combination of the orbital wave functions associated with those configurations are:

$$
\begin{aligned}
A_1:\ & \psi_G = 1/\sqrt{8!}\,|\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\phi_3\bar{\phi}_3\chi\bar{\chi}| \\
& \psi_P = 1/\sqrt{2}\,\{1/\sqrt{2}\,(\phi_3^{-1}\phi_4+\bar{\phi}_3^{-1}\bar{\phi}_4) \\
& \qquad -1/\sqrt{2}\,(\phi_2^{-1}\phi_5+\bar{\phi}_2^{-1}\bar{\phi}_5)\} \\
& \psi_{\beta'} = 1/\sqrt{2}\,\{1/\sqrt{2}\,(\phi_3^{-1}\phi_4+\bar{\phi}_3^{-1}\bar{\phi}_4) \\
& \qquad +1/\sqrt{2}\,(\phi_2^{-1}\phi_5+\bar{\phi}_2^{-1}\bar{\phi}_5)\} \\
& \psi_{CT} = 1/\sqrt{2}\,(\chi^{-1}\phi_5+\bar{\chi}^{-1}\bar{\phi}_5) \\
B_2:\ & \psi_\alpha = 1/\sqrt{2}\,\{1/\sqrt{2}\,(\phi_2^{-1}\phi_4+\bar{\phi}_2^{-1}\bar{\phi}_4) \\
& \qquad -1/\sqrt{2}\,(\phi_3^{-1}\phi_5+\bar{\phi}_3^{-1}\bar{\phi}_5)\} \\
& \psi_\beta = 1/\sqrt{2}\,\{1/\sqrt{2}\,(\phi_2^{-1}\phi_4+\bar{\phi}_2^{-1}\bar{\phi}_4) \\
& \qquad +1/\sqrt{2}\,(\phi_3^{-1}\phi_5+\bar{\phi}_3^{-1}\bar{\phi}_5)\} \\
& \psi_{CT'} = 1/\sqrt{2}\,(\chi^{-1}\phi_4+\bar{\chi}^{-1}\bar{\phi}_4)
\end{aligned}
\qquad (1)
$$

Here the suffix G denotes the ground configuration; $\alpha$, P, $\beta$ and $\beta'$, the locally-excited configurations, CT and CT', the two charge-transfer configurations respectively. Considering the configuration interaction among these configurations, the energy levels of the molecule

2) H. C. Longuet-Higgins and J. N. Murrell, *Proc. Roy. Soc.*, **A68**, 601 (1955); J. N. Murrell, ibid., **A68**, 969 (1955).

can be obtained by taking the energy of the ground configuration to be zero. The energies of the LE configurations were taken to be equal to the observed excitation energies of benzene (Kimura and Nagakura[3]), while those of the CT configurations can be evaluated by the following equations:

$$\left.\begin{aligned} H_{CT} &= I_X - A_\phi - C \\ H_{CT'} &= I_X - A_\phi - C' \end{aligned}\right\} \qquad (2)$$

where $I_X$ and $A_\phi$ are the ionization potential of the electron donating group, X, and the electron affinity of the benzene molecule respectively.

The Coulombic attraction energies, $-C$ or $-C'$, can be calculated by the uniformly-charged sphere model of Pariser and Parr.[4] In order to carry out the calculation, one must know the bond length, C-X. For toluene this length has already been determined to be 1.52 Å.[5] For aniline, however, there is no data available so far. The available data on $r_{CN}$ are as follows: 1.35 Å (aniline hydrochloride), 1.39 Å (*o*-methylaniline hydrochloride), 1.45 Å (*p*-tolidine hydrochloride), 1.37 Å (*p*-nitroaniline)[6] and 1.407 Å (2, 5-dichloroaniline)[7]. In the present calculations, the $r_{CN}$ value of aniline was taken to be 1.37 Å. The C-N distance for the adsorbed aniline molecule was assumed, however, to be equal to the C-N single bond length, 1.47 Å, because the conjugation between the amino-group and the benzene ring is weakened in this case and, hence, a considerable loss of the double-bond character can be expected. The experimental analysis of molecular structure of *N*-methylaniline and ethylbenzene still has not been made. For these two substances and adsorbed *N*-methylaniline, the C-X distances were assumed to be the same as those of aniline, toluene and adsorbed aniline respectively.

The off-diagonal matrix elements can be determined as follows:

$$\left.\begin{aligned} H_{G\cdot CT} &= \sqrt{2}\int \phi_5 H\chi d\tau \\ H_{\beta'\cdot CT} &= -H_{p\cdot CT} = 1/\sqrt{2}\int \phi_2 H\chi d\tau \\ H_{G\cdot\beta'} &= H_{G\cdot p} = H_{\beta'\cdot p} = 0 \\ H_{\alpha\cdot CT} &= H_{\beta\cdot CT} = 1/\sqrt{2}\int \phi_2 H\chi d\tau \\ H_{\alpha\cdot\beta} &= 0 \end{aligned}\right\} \qquad (3)$$

In evaluating $\int \phi_5 H\chi d\tau$ and $\int \phi_2 H\chi d\tau$, Kimura's procedure[8] was adopted; i. e., besides the core resonance integral between X and the adjacent carbon atom ($\beta$), the corresponding integral between X and the ortho-carbon atom ($\beta'$) was taken into account. In estimating the values of $\beta$ and $\beta'$ for aniline and *N*-methylaniline, their proportionality to the overlap integral was assumed. The obtained values for $\beta$ (and $\beta'$) are $-1.9$ eV. (and $-0.3$ eV.) for aniline and *N*-methylaniline, and $-1.6$ eV. (and $-0.2$ eV.) for adsorbed aniline and adsorbed *N*-methylaniline[9] respectively. For toluene and ethylbenzene, $\beta$ was equated to 0.7 $\beta_0$[10] ($\beta_0$ being $\beta_{CC}$ in benzene), while $\beta'$ was estimated from this $\beta$ by assuming its proportionality to the overlap integral. The values of $-1.6$ eV. and $-0.3$ eV. were thus obtained for $\beta$ and $\beta'$.

The *I-A* values were determined by the following procedure, regarding them as parameters. Calculations were carried out for a certain range of *I-A* values, and the "best" *I-A* value was determined by observing the best fit with the observed transition energy of each substance.

Numerical calculations were carried out with a NEAC 2101 computer set up in the Protein Research Institute of Osaka University.

## Results and Discussion

The calculated results are shown in Fig. 1 and Table I. The experimental results are plotted in the figure at the position which shows the best fit with the calculated values.

As is shown in Fig. 1, a satisfactory agreement can be obtained between calculated and experimental energy values if we assign 11.0, 11.3, 11.5, 11.8, 11.8 and about 12.5 eV. to the *I-A* values of *N*-methylamino-, amino-, adsorbed amino-, adsorbed *N*-methylamino-, ethyl and methyl groups respectively. In the case of both aniline and *N*-methylaniline, the rise in the ionization potential of the electron-donating group (0.2 eV. and 0.8 eV.) is found to be a result of adsorption on aluminum

chloride, if the change in the electron affinity of benzene ring can be disregarded.

In the calculated results one can find a general tendency for bands to shift and intensities to change with an increase in the *I-A* values. The band corresponding to the $2A_1$ state (hereafter abbreviated to "$2A_1$") shifts to a shorter wavelength with a decrease in the intensity. The "$2B_2$" and "$3A_1$" bands approach each other with an increase in the intensity. For adsorbed *N*-methylaniline, ethylbenzene and toluene, these bands nearly overlap, forming a band corresponding to the degenerate $\beta$ and $\beta'$ bands of benzene. The "$4A_1$" and "$3B_2$" bands show a tendency to separate from each other with a decrease in the intensity. These general trends are just the same as those observed in the spectra of *N*-methylaniline, aniline, adsorbed aniline, adsorbed *N*-methylaniline, ethylbenzene and toluene, according to this order. Such being the case, adsorbed aniline and *N*-methylaniline clearly show intermediate spectra between aniline and toluene, and between *N*-methylaniline and ethylbenzene, respectively.

In the spectra of toluene and ethylbenzene reported by Hammond et al.,[11] more than two bands are found near 150—160 m$\mu$. They assigned them as Rydberg bands. In the light of the present calculations, however, it may be, rather, possible to assign two of these bands as CT bands. In the spectrum of adsorbed aniline,[1] two peaks are found near 160 m$\mu$, though they are weak and less-resolved than other peaks. These bands may also have much of a CT character.

Why the spectra of adsorbed aniline and adsorbed *N*-methylaniline become nearer to those of toluene and ethylbenzene is a difficult question to answer. It may result from the interaction of the lone pair electrons on the nitrogen atom of the adsorbate molecule and a vacant $sp^3$ orbital of the aluminum atom.

## Summary

The electronic spectra of aniline and *N*-methylaniline adsorbed on aluminum chloride have been examined by the LCMO method and have been compared with those of gaseous aniline, *N*-methylaniline, toluene and ethylbenzene. All of these molecules can be treated by the intramolecular charge-transfer model. In order for us to be able to interpret the spectra from the LCMO point of view, the ionization potential of the electron donating group in aniline and *N*-methylaniline molecules should rise upon adsorption on aluminum chloride.

The authors would like to express their gratitude to Dr. Katsumi Kimura, Faculty of Engineering Science, Osaka University, for his helpful discussions. The authors are also indebted to Professor Tatsuo Miyazawa, The Protein Research Institute of Osaka University, for numerical calculations with a NEAC 2101 computer.

# The Vibrational Assignment, Rotational Isomerism and Force Constants of 1, 2-Ethanedithiol

By Michiro HAYASHI, Yuji SHIRO, Toshiyuki OSHIMA and Hiromu MURATA

(Received April 1, 1965)

Many experimental data have been accumulated concerning the rotational isomerism of 1, 2-disubstituted ethanes.[1] Still, a number of molecules have not yet been studied in detail. The present work is the first of a series of papers which will deal with a group of molecules containing sulfur atoms. In this paper, we will first consider the rotational isomerism of 1, 2-ethanedithiol, and then we will determine a set of force constants in a modified Urey-Bradley force field. These force constants will then, in the subsequent paper,[2] be transferred to the other members of the series with similar structures. Finally, they will be transferred to the calculations attempted for polyethylene disulfide, which will be reported in the near future.

## Experimental

The sample used for the measurements was prepared in the following way.[3]

1, 2-Dichloroethane was refluxed over thiourea in ethanol, and the product was treated by a concentrated potassium hydroxide solution and subsequently neutralized by concentrated sulfuric acid. b. p. 70°C/48 mmHg, $n_D^{20}$ 1.5591.

A deuterated species, $DSCH_2CH_2SD$, was prepared from 1, 2-ethanedithiol by a direct exchange of hydrogen with $D_2O$ in the presence of a small amount of potassium carbonate. However, only 30% of the hydrogen was replaced by deuterium.

The infrared spectra in the crystalline state were recorded for the sample cooled with liquid nitrogen at about −120°C. In the gaseous state the infrared spectra were recorded at ten different temperatures in the range from 60 to 220°C.

## The Assignment of the Spectra

If this substance had a unique molecular form, it would show twenty-four fundamental frequencies. However, as we observed too many spectra for one molecular form and since, especially, we found that some of the spectra vanish in the crystalline state we may conclude that rotational isomers exist. Since the mass of a SH group is nearly equal to the mass of a chlorine atom, the spectra of this substance might be close to those of 1, 2-dichloroethane, which were examined in detail.[4]

Actually, this substance gives spectra very similar to those of 1, 2-dichloroethane in the region between 1000 and 1450 $cm^{-1}$. For 1, 2-dichloroethane we have the trans and gauche isomers, and only the trans isomer persists in the crystalline state. For 1, 2-ethanedithiol, the similarity of the spectra and the similar behavior of the spectra upon solidification suggest that the trans and gauche isomers around the C-C bond also exist.

From the well-known assignments for 1, 2-dichloroethane, the assignments of the observed frequencies are easy in this region, where we may have two $CH_2$ bending vibrations, two $CH_2$ wagging vibrations, two $CH_2$ twisting vibrations and one C-C stretching vibration for one molecular form. These frequencies are easily identified at nearly the same frequencies as those for 1, 2-dichloroethane. The spectra relating to the gauche isomer vanish in the crystalline state.

The spectral pattern in the region from 1000 to 650 $cm^{-1}$ looks very different from that of 1, 2-dichloroethane. In this region, we may have two $CH_2$ rocking, two CSH deformation and two C-S stretching vibrations for one molecular form. A deuterated species, $DSCH_2CH_2SD$, was measured for the purpose of the use of its spectra as an aid in the assignment of the observed spectra in this region. For this deuterated species we would expect the CSH deformation vibrations alone to be shifted strongly to the lower frequency region, where no other spectra are expected. Actually, we observed that two new bands are present at 600 and 619 $cm^{-1}$. If the deuteration were perfect, we could expect that the frequencies of two CSH deformation vibrations would vanish or become weaker. Since, however, the deuteration was, unfortunately, not perfect, we could not identify the CSH deformation frequencies directly.

However, a simple application of the product

1) S. Mizushima, "Structure of Molecules and Internal Rotation," Academic Press, New York (1954).
2) M. Hayashi, Y. Shiro and Murata, to be published.
3) J. Spaziale, "Organic Syntheses," Vol. XXX, 35 (1950).
4) For example, I. Nakagawa and S. Mizushima, *J. Chem. Phys.*, **21**, 2195 (1953).

rules reveals that 800 and 890 $cm^{-1}$ should be the CSH deformation vibrations corresponding to the CSD deformation vibrations at 600 and 619 $cm^{-1}$; as 800 $cm^{-1}$ disappears in the crystalline state, it is assigned to the gauche isomer.

We assigned the bands at 718 and 699 $cm^{-1}$ for the trans and those at 664 and 639 $cm^{-1}$ for the gauche to the C-S stretching vibrations on the basis of the assignments given to such similar molecules as methyl mercaptan, dimethyl sulfide and ethyl methyl sulfide.[5]

There remain three unassigned observed frequencies (972, 942 and 769 $cm^{-1}$) in this region; all three disappear in the crystalline state, and 974 $cm^{-1}$ is observed only in the Raman spectra. Some of these frequencies are regarded as the $CH_2$ rocking vibrations on the basis of the assignments given to ethyl methyl sulfide,[6] diethyl sulfide,[7] and $\beta$-chloroethyl methyl sulfide.[8]

Since the bands at 972, 942 and 796 $cm^{-1}$ vanish in the crystalline state, they are not for the trans isomer. There are no unassigned spectra persisting in the crystalline state, and we regarded the band at 718 $cm^{-1}$ as two overlapping frequencies, one for a C-S stretching vibration and the other for a $CH_2$ rocking vibration for the trans isomer. This is a reasonable choice from the selection rule of the trans isomer, as we will discuss in the following section. The other $CH_2$ rocking vibration is assigned to 1030 $cm^{-1}$. For the gauche isomer we have three possibilities: (A) 972 and 769 $cm^{-1}$; (B) 972 and 942 $cm^{-1}$ and (C) 942 and 769 $cm^{-1}$. The band at 942 $cm^{-1}$ is much weaker than that at 972 $cm^{-1}$ and appears as a shoulder of 972 $cm^{-1}$; if we take the pair C as the $CH_2$ rocking vibrations, the strong band at 972 $cm^{-1}$ remains unassigned. We compared the spectra with those of $\beta$-thiamethyl ethyl mercaptan[2]

8) M. Hayashi, ibid., **80**, 1084 (1959).

and found that a band corresponding to 940 $cm^{-1}$ does not exist, while bands corresponding to 972 and 769 $cm^{-1}$ are found at 959 and 776 $cm^{-1}$. Therefore, we took the pair A as the $CH_2$ rocking vibrations.

For 1, 2-dichloroethane and also for many molecules with a $-CH_2CH_2-$ structure, it is well-known that the frequency difference of two $CH_2$ rocking vibrations strongly depends on the azimuthal angle around the C-C bond.

For 1, 2-dichloroethane the frequency differences are 221 $cm^{-1}$ for the trans and 62 $cm^{-1}$ for the gauche; their ratio is 0.28. For 1, 2-ethanedithiol, according to the above assignments, the frequency differences are 312 $cm^{-1}$ for the trans and 203 $cm^{-1}$ for the gauche, while their ratio is 0.65. This ratio seems too large compared with that for 1, 2-dichloroethane. However, 0.64 is also obtained for both $\beta$-thiamethyl ethyl mercaptan and $\beta$-chloroethyl mercaptan.

Furthermore, a refined calculation of nomal vibrations, which will be described afterwards, gave a reasonable set of force costants from this assignment, while the solved force constants obtained from the other possibilities are not acceptable.

From the observed frequencies we have:

$$\sum\nu_i^2(T) = 6.334 \times 10^7$$
$$\sum\nu_i^2(G) = 6.321 \times 10^7 \quad (0.21\% \text{ difference})$$

Therefore, the assignments of the observed frequencies are quite satisfactory. Recently, Fujiyama et al.[9] published a discussion of the vibrational spectra of succinonitrile. According to their assignment, the $CH_2$ rocking frequencies of this substance also have a large ratio of frequency differences (0.62). For the $CH_2$ rocking vibrations, then, the difference of the ratio from that of 1, 2-dichloroethane might arise from the influence of some special character of sulfur atoms attached to the $-CH_2CH_2-$ group. The assignments are given in Table I.

## The Molecular Form of Isomers

In the preceding section, we have assumed that the isomers are the trans and gauche forms around the C-C bond.

The assignment of the spectra discussed above leads to the conclusion that the spectra in the crystalline state show the mutual exclusion rule between the infrared and the Raman spectra. Therefore, the isomer in this state should have the center of symmetry. This requires that the isomer have the trans form around the C-C bond.

9) T. Fujiyama, K. Tokumaru and T. Shimanouchi, *Spectrochim. Acta*, 20, 415 (1964).

We made the calculation of normal vibrations for skeletal frequencies in order to find the molecular form of the isomer disappearing in the crystalline state.

In this treatment, SH and $CH_2$ group were regarded as dynamic units, and, accordingly, only the internal rotation around the C-C bond was taken into consideration. About the force constants used in the Urey-Bradley potential function adopted for this treatment, one of the present authors reported that reasonable values were obtained from the observed vibrational frequencies of molecules with similar structures, such as dimethyl sulfide, methyl mercaptan and ethyl mercaptan.[5] These are $K(CH_2\text{-}SH) = 2.60$, $K(CH_2\text{-}CH_2) = 3.7$, $H(CH_2\text{-}CH_2\text{-}SH) = 0.15$ and $F(CH_2\cdots SH) = 0.50$ md./Å. The calculation was carried out for seven different molecular forms around the C-C bond. Skeletal deformation frequencies produce large frequency changes, as Fig. 1 shows,

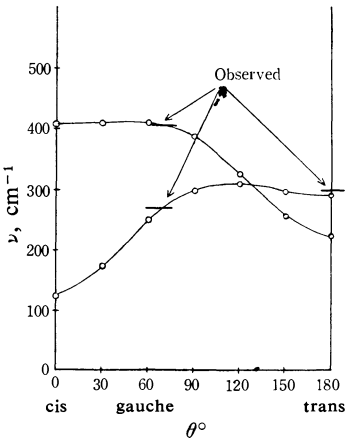

Fig. 1. Observed and calculated frequencies of skeletal deformation modes.

where arrows indicate the observed Raman lines below 450 $cm^{-1}$. The Raman line observed at 299 $cm^{-1}$ is understood to be one of the skeletal deformation vibrations for the trans form, and the other frequency is considered to be Raman-inactive from the symmetry of the trans isomer, while the lines at 267 and 407 $cm^{-1}$ are regarded as the frequencies for the gauche form around the C-C bond. Therefore, we concluded that the isomer disappearing in the crystalline state is the gauche form around the C-C bond.

When we take the rotational isomerism around two C-S bonds into consideration, we would have ten different isomers altogether. Four of them have the trans form, and six have the gauche form, around the C-C bond. The form with the center of symmetry arises twice among the four trans isomers.

We will use symbols T, G and G′ for each rotational axis to designate their molecular forms. For example, GTG′ means an isomer with the gauche, the trans and the gauche form for the first C–S, C–C and the second C–S bond respectively, where the gauche form for the second C–S bond is obtained by a 120° rotation of the hydrogen in the second SH group from its trans position to the opposite direction against the hydrogen in the first SH group. In these notations, two trans forms with a center of symmetry can be expressed as TTT and GTG′ respectively.

Since a Raman line at 255 $cm^{-1}$ is found from the refined normal vibration calculation described in the following section, as a C–S torsion, we have no unassigned spectra persisting in the crystalline state.

Since it is hard to consider that two sets of the spectra arising from TTT and GTG′ would overlap perfectly, and since the results of the normal vibration treatment also indicate that perfect overlapping never happens between two sets of the spectra of TTT and GTG′, we have concluded that only one molecular form exists in the crystalline state. About the molecular form disappearing in the crystalline state, we have not enough information to determine how many molecular forms there are and what the molecular forms are. We have only an unassigned band at 942 $cm^{-1}$ which disappears in the crystalline state; this fact suggests that two or more molecular forms probably exist. From the above discussion about skeletal deformation vibrations, it may be said that the main molecular form is the gauche form around the C–C bond. However, the complete determination of the molecular forms around the C–S bonds is a difficult problem on the basis only of the experimental data available at present.

However, it is worthwhile to note that, as we will discuss in detail, the force constants as determined by the least-squares treatment on the assumption of such molecular forms as TTT and TGT, are considered to be reasonable and can be successfully transferred to other substances with similar structures, while the force constats obtained on the assumption of such molecular forms as GTG′ and GGG are not only unreasonable but also less transferable. We believe that this is a good reason to conclude that the isomer in the crystalline state is TTT with $C_{2h}$ symmetry and that the main isomer vanishing in the crystalline state is TGT with $C_2$ symmetry.

## Energy Difference between Isomers

In the gaseous state at ten different temperatures, we made measurements of the relative absorption intensity of the bands at 1289 and 1272 $cm^{-1}$, which were assigned to the $CH_2$ wagging frequencies for the trans and gauche isomers respectively.

From the observed optical densities, we found that the energy difference of the isomer is $0.6_3$ kcal./mol. where the trans is more stable than the gauche. In order to check the accuracy of this, the measurement was made for 1,2-dichloroethane, which was reported to have an energy difference of $1.1_4$ kcal./mol.,[1] we obtained a very satisfactory agreement.

An attempt was made to measure the intensities in the liquid state at room temperature, at the temperature of ice water, and at the temperature of an ice-alcohol mixture. However, no change could be seen in the absorption intensities. This shows that the isomer have almost the same energy in the liquid state.

## Normal Vibration Calculation

We have attempted to make the normal vibration calculation, including all the vibrational freedoms, in order to get a reliable set of force constants which can then be transferred to molecules with similar structures.

For 1,2-dichloroethane we have established that the usual simple Urey-Bradley force field is not enough to reproduce the observed frequencies. Modifications of the force field have, therefore, been proposed:[10]

1) Torsional freedom is added, with the torsional force constant $Y$.

2) C–H bond interaction constants, $p$, are introduced.

3) Angle-interaction constants, $l$, are considered.

4) Trans and gauche interaction constants, $t$ and $g$, are added between the angles of different $CH_2$ groups.

For 1,2-ethanedithiol we did not know to what extent the force field should be modified. Therefore, we made a trial calculation in a simple Urey-Bradley force field with torsional freedoms for TTT and TGT isomers.

Since we have no observed C–C torsional bands and since the 255 $cm^{-1}$ Raman line is still uncertain as a C–S torsional vibration at this stage, the torsional force constant $Y$(C–S) for the C–S torsional frequencies was computed from the barrier height reported for methyl mercaptan,[11] while the $Y$(C–C) for the C–C torsional frequencies was assumed to be the same value as that for 1,2-dichloroethane.

10) T. Shimanouchi, "Proc. Intern. Sym. Mol. Str. and Spectroscopy," Tokyo, C 216 (1962).
11) T. Kojima and T. Nishikawa, *J. Phys. Soc. Japan*, **12**, 680 (1957).

Since the results have indicated that the 255 $cm^{-1}$ Raman line can be regarded as one of the C–S tortional bands for TTT isomers (species $B_g$), we made a slight change in $Y$(C–S) in order to predict the frequency better. 0.05 md. Å was obtained as a $Y$(C–S) force constant, which made the barrier height 1.7 kcal./mol. This is a little higher than that for methyl mercaptan (1.27 kcal./mol.). The assumed $Y$(C–C) is 0.15 md. Å, which corresponds to the barrier height of 4.8 kcal./mol. We have fixed these two values throughout the following treatments. The first column of Table II presents the set of force constants which best predicts the observed frequencies in the simple Urey-Bradley force field. This set has been obtained by adjusting the force constants little by little in order best to predict the observed frequencies for TTT and TGT isomers. From a comparison of the observed and the calculated frequencies for 1,2-ethanedithiol, it has been found that the force field should also be modified. Especially, as is shown in the second column of Table III, the $CH_2$ wagging, twisting and rocking frequencies strongly suggest the necessity of some modifications of the force field. For example, the observed frequency differences of two $CH_2$ wagging, two $CH_2$ twisting and two rocking vibrations are 68, 140, and 317 $cm^{-1}$ for TTT, and 19, 58, and 203 $cm^{-1}$ for TGT, respectively. The calculated values, 12, 9, and 106 $cm^{-1}$ for TTT and 69, 20, and 160 $cm^{-1}$ for TGT, are much smaller than the observed.

As the first trial of the modification, we have added $p$ and $l$, that is, the C–H bond interaction and the angle interaction terms. The set of force constants obtained is listed in the second column of Table II. As the third column of Table III shows, the above-mentioned frequency differences are improved very much. However, a large difference still remains in the $CH_2$ twisting frequencies for TTT.

As the second trial of the modification, we have added the trans and gauche interaction

a) Using a simple Urey-Bradley force field corresponding to a set of force constants No. 1 in Table II.
b) Using a modified Urey-Bradley force field corresponding to a set of force constants No. 3 in Table II.

terms between the angles of different $CH_2$ groups. As the fourth column of Table III shows, a very satisfactory agreement has thus been obtained. The set of force constants in this modified Urey-Bradley force field was obtained by the application of the least-squares method. We have twenty-two force constants, of which two for torsinal freedoms are fixed at the values mentioned before.

Forty-two observed frequencies could be predicted with an average error of 0.4%; the maximum error was 1.5%.

By the use of the set of force constants so obtained, the frequencies for $DSCH_2CH_2SD$ species were calculated; the observed frequencies have been reproduced with an average error of 0.8%. The calculated and the observed frequencies are tabulated in Table IV.

As we mentioned before, we tried to check the molecular forms. At first, as may be seen in Table V, we calculated the frequencies for GTG′ and GGG isomers as well as for TTT and TGT isomers. We concluded that the C–C stretching, $CH_2$ rocking, CSH deformation and C–S stretching frequencies for GTG′ and GGG isomers can be observed separately from those for TTT and TGT isomers if they exist. As we have no unassigned spectra in the expected region, however, GTG′ and GGG isomer may not exist.

Secondly, we tried, by the least-squares method, to get a set of force constants on the assumption that the molecular forms were GTG′ and GGG isomers. In this attempt, we found that the force constants did not converge well in a reasonable range of values. Therefore, we might say that GTG′ and GGG isomers are not actual molecular forms. We have concluded that TTT and TGT are the actual molecular forms, as we mentioned in the preceding section.

Another modification of the force field has also been attempted. As the last modification, we introduced the trans and gauche interaction terms between the angles of different $CH_2$ groups. Similar interaction terms, $t'$ and $g'$,

are possible between the angles of a $CH_2$ group and a CSH angle. The last column of Table V shows a set of force constants adjusted in this modified force field by the least-squares method. However, as we see in the last column of Table III, this modification has no appreciable influence on the $CH_2$ wagging, twisting and rocking vibrations or on the CSH deformation vibrations, and no appreciable improvement of the average errors could be obtained. Therefore, we have concluded at present that this kind of modification is not necessary for 1, 2-ethanedithiol.

The transferability of the force constants has been checked by the use of the set of the force constants of the second modification of the Urey-Bradley force field. For *n*-propyl mercaptan, β-thiamethyl ethyl mercaptan, β-halogenoethyl mercaptan and 1, 2-dithiamethyl ethane, the set can predict the observed frequencies with a very satisfactory agreement,[2] as will be reported on in the subsequent papers of this series.

# The Vibrational Assignment and Rotational Isomerism of β-Halogenoethyl Mercaptan

By Michiro HAYASHI, Yuji SHIRO, Masahiro MURAKAMI and Hiromu MURATA

(Received April 1, 1965)

In a previous paper,[1] we dealt with the vibrational spectra of 1, 2-ethanedithiol in relation to the rotational isomerism. The present work, the second of a series of papers, will deal with the vibrational spectra of β-chloroethyl mercaptan and β-bromoethyl mercaptan. We have two objects in studying the spectra of these substances. First, these molecules are suitable for checking the transferability of the force constants obtained from the observed spectra of 1, 2-ethanedithiol. Second, they can be obtained by the exchange of an oxygen in ethylene chlorohydrin with a sulfur atom. For ethylene chlorohydrin, extensive studies were reported by Mizushima and his coworkers[2] about the rotational isomerism. They reported that two rotational isomers exist in the gaseous and the liquid states, where the gauche isomer is more stable than the trans. In the crystalline state, the gauche isomer alone was found to persist. For other 1, 2-disubstituted ethanes, the trans isomer was usually found to be more stable than the gauche, and in

2) S. Mizushima, T. Shimanouchi, T. Miyazawa, K. Abe and M. Yasumi, *J. Chem. Phys.*, 19, 1477 (1951); S. Mizushima, T. Shimanouchi, K. Kuratani and T. Miyazawa, *J. Am. Chem. Soc.*, 74, 1378 (1952).

the crystalline state, the trans isomer alone was found to persist. It was understood that this irregularity in the case of ethylene chlorohydrin appears because of the presence of an intramolecular hydrogen bond between a chlorine and a OH group in the gauche form.

Since a SH group is expected to have a very weak power to make a hydrogen bond with a halogen atom, in contrast to the fact that a OH group has a strong power, the findings concerning β-halogenoethyl mercaptan are expected to be interesting.

## Experimental

β-Chloroethyl and β-bromoethyl mercaptans were prepared by adding dry hydrochloric acid and hydrobromic acid respectively to ethylene sulfide.

β-Chloroethyl mercaptan: b. p. 113°C/760 mmHg

β-Bromoethyl mercaptan: b. p. 52°C/ 28 mmHg

The purity of the samples was checked by gas chlomatography.

The Raman spectra were measured with a Cary 81 spectrometer, while the infrared spectra were recorded with EPI-S2 (Hitachi Co. Ltd.) with NaCl optics in the region from 4000 to 650 $cm^{-1}$.

The infrared spectra in the crystalline state were recorded for the samples cooled with liquid nitrogen at about −120°C.

## Rotational Isomerism

A comparison of the observed spectra in the gaseous and the liquid states with those in the crystalline state immediately reveals the existence of rotational isomers for these substances, since many infrared bands vanish in the crystalline state.

As we reported in the previous paper, in the case of 1, 2-ethanedithiol, large shifts of frequencies may be expected, depending on the molecular forms around the C-C bond, while the molecular forms around the C-S bond will cause rather smaller shifts in frequency. As we have very similar spectra to those of 1, 2-ethanedithiol, the above conclusion might also be true for β-halogenoethyl mercaptan. Therefore, we will disregard for a moment the molecular forms around the C-S bond. If the isomers are the trans and the gauche forms around the C-C bond, the trans form might be a less polar form than the gauche form. We may expect then that the spectra for the trans form will get their relative absorption intensities when a mixture is made with a non-polar substance as a solvent, while the spectra for the gauche form will get their relative intensities in a mixture with a polar solvent. Measurements were made with cyclohexane, carbon disulfide, acetone and nitromethane as a solvents for β-chloroethyl mercaptan. Around 750 $cm^{-1}$, five infrared bands (778, 753, 724, 699 and 675 $cm^{-1}$) are seen, of which two (675 and 778 $cm^{-1}$) vanish in the crystalline state. It has been found that the bands at 675 and 778 $cm^{-1}$ become stronger as the solvent becomes polar. Therefore, for β-chloroethyl mercaptan the molecular form in the crystalline state is probably the less polar form or the trans form around the C-C bond, and the other which exists only in the gaseous and liquid states, is probably the more polar form or the gauche form. Similar results have been obtained for β-bromoethyl mercaptan.

The skeletal normal vibration calculation has also given the same conclusion for both substances. We have calculated the skeletal frequencies as a four-body problem in an Urey-Bradley force field with the force constants reported in the literature.[3] They are $K(CH_2\text{-}CH_2)=3.7$, $K(CH_2\text{-}SH)=2.43$, $K(CH_2\text{-}Cl)=2.9$, $K(CH_2\text{-}Br)=2.4$, $H(CH_2\text{-}CH_2\text{-}SH)=0.15$, $H(CH_2\text{-}CH_2\text{-}Cl)=0.17$, $H(CH_2\text{-}CH_2\text{-}Br)=0.15$, $F(CH_2\cdots SH)=0.466$, $F(CH_2\cdots Cl)=0.49$ and $F(CH_2\cdots Br)=0.40$ md./Å. Seven different isomers around the C-C bond were considered as molecular forms.

For these substances there are two skeletal deformation frequencies for an unique molecular form, which would be expected below 500 $cm^{-1}$. For β-chloroethyl mercaptan, four Raman lines are seen, at 406, 300, 255 and 220 $cm^{-1}$. It has been concluded from the calculation that 406 and 255 $cm^{-1}$ correspond to the calculated frequencies (406 and 248 $cm^{-1}$) for the gauche form and that 300 $cm^{-1}$ corresponds to that (282 $cm^{-1}$) for the trans form. The line at 220 $cm^{-1}$ might not be another skeletal deformation frequency for the trans form even though the calculated frequency is 221 $cm^{-1}$, since this has been calculated as 186 $cm^{-1}$ from the refined treatment of normal vibrations to be described afterwards, and since the calculation has shown that 220 $cm^{-1}$ might be the C-S torsional frequencies for the gauche form.

For β-bromoethyl mercaptan we have three observed Raman lines, at 210, 245 and 375 $cm^{-1}$; the calculated frequencies are 375 and 225 $cm^{-1}$ for the gauche form and 235 and 169 $cm^{-1}$ for the trans form. Therefore, 245 $cm^{-1}$ corresponds to that for the trans form, while 210 and 375 $cm^{-1}$ correspond to those for the gauche form. In the gaseous and the liquid states, both the trans and the gauche isomers exist. Measurements of the relative absorption

a) Molecular forms around the C-C bond are shown in parentheses. For CSH deformations, molecular forms around both the C-C bond and the C-S bond are shown.

intensities of $CH_2$ wagging frequencies around 1250 $cm^{-1}$ were attempted in order to ascertain the energy differences in the isomers in both the gaseous and the liquid states.

In the gaseous state measurements were made at ten different temperatures in the range from 50 to 160°C. In the liquid state they were made at five different temperatures in the range from −30 to 70°C. The measurements indicated that for these substances the trans isomer is more stable than the gauche isomer in both the gaseous and the liquid state. In the gaseous state the energy differences are computed from the observed optical densities as $0.5_2$ and $0.9_5$ kcal./mol. for β-chloroethyl and β-bromoethyl mercaptan respectively. In the liquid state they are computed as $0.1_6$ and $0.6_2$ kcal./mol. respectively.

However, the spectra used for the trans and the gauche isomers are situated so close together that the errors might be expected to be relatively large (±300 cal./mol.).

## Normal Coordinate Treatment

The normal vibration calculation has been attempted for two purposes:

1) In order to use the results as an aid in the assignment of the spectra and for the consideration of the detailed molecular forms of the isomers, and

2) In order to test the set of force constants which we obtained from the observed spectra of 1, 2-ethanedithiol and to ascertain whether or not the set is applicable to these substances.

There are five possible molecular forms for these substances. In the notation described in the previous paper, these are TT, TG, GT, GG and GG' (where the first letter refers to the molecular form around the C-C bond, and the second, to those around the C-S bond). In this treatment all the vibrational freedoms were taken into account, including two torsional freedoms, and a modified Urey-Bradley force field was used which included the following modifications:[4]

(1) Torsional force constants, $Y$; (2) C-H bond interaction constants, $p$; (3) angle interaction constants, $l$, for $CH_2$ groups, and (4) trans and gauche interaction constants, $t$ and $g$, between angles of different $CH_2$ groups.

a) Molecular forms around the C-C bond are shown in parentheses. For CSH deformations, molecular forms around both the C-C bond and the C-S bond are shown.

There was no modification made between the CSH angle and those of $CH_2$ groups. Therefore, the force field remained unchanged even when the molecular form around the C–S bond changed. All of five molecular forms were considered for β-chloroethyl mercaptan, while for β-bromoethyl mercaptan only two isomers (TT and GT) were considered. Twenty-six force constants were used in the calculation; among them twenty force constants were transferred from those obtained for 1, 2-ethanedithiol. Six other force constants, which were related to halogen atoms, were determined in order to predict the observed spectra in the best possible way. They are listed in Table III; the calculated frequencies are listed in Tables IV and V with the observed frequencies, which we will discuss afterwards. The agreement between the observed and the calculated frequencies has been found to be very satisfactory; we have concluded that the set of force constants obtained in the previous paper is also applicable to these substances.

## Vibrational Assignment and Molecular Form

The assignments of these spectra can easily be found by comparing them with the spectra of 1, 2-ethanedithiol. They are given in Tables I and II. We found differences from the results of 1, 2-ethanedithiol in the region from 950 to 800 $cm^{-1}$, where we would expect CSH deformation frequencies. In this region, we have four infrared bands for both β-chloroethyl and β-bromoethyl mercaptan. As we have only one CSH deformation frequency for a unique molecular form, these are too many for two isomers.

In the previous paper on 1, 2-ethanedithiol, we noted, from the refined treatment of normal vibration calculations, that C–C stretching, C–S stretching, one of two $CH_2$ rockings and one of two CSH deformation frequencies are shifted slightly if the molecular form around the C–S bond is different. Since we had no unassigned spectra for 1, 2-ethanedithiol and since the results of normal vibration calculation gave reasonable force constants for the trans form around the C–S bonds, while the gauche form did not, we determined tentatively that the molecular form is the trans around the C–S bond.

The situation is different for β-halogenoethyl mercaptan. For β-chloroethyl mercaptan, the molecular form in the crystalline state is regarded as TT, since, from the absorption

* The values are the observed frequencies for trans form around C-S bond. Observed frequencies for other forms should be referred to Table I.

intensity measurements in mixtures, the bands persisting in the crystalline state are found to be the less polar form and since one of two $CH_2$ rocking modes in the higher frequency was calculated to be 1015 $cm^{-1}$ for TT, and 985 $cm^{-1}$ for TG, while we have only 1021 $cm^{-1}$ in the crystalline state and no corresponding band can be seen around 985 $cm^{-1}$. In the region from 950 to 800 $cm^{-1}$, there is only one infrared band, at 860 $cm^{-1}$, in the crystalline state. Therefore, this is assigned to the CSH deformation mode for the TT isomer. We have two other bands in this region where no other vibrational modes is to be expected, except for CSH deformation modes. Therefore, we may conclude that more polar form is not a unique molecular form but a group of isomers.

From the normal vibration calculation described in the preceding section, we have

Table V. Observed and calculated frequencies of β-bromoethyl mercaptan ($cm^{-1}$)

| | 112 | | 86 | torsion |

also relatively large shifts in frequency for the CSH deformation, and one of two rocking modes for β-chloroethyl mercaptan, for different isomers around the C-S bond. For $CH_2$ rocking modes we have so many spectra in the expected region that the overlapping of the spectra might hide the differences. However, for CSH deformation modes we have found infrared bands corresponding to the calculated frequencies for different isomers. That is, 928 $cm^{-1}$ corresponds to the calculated frequency, 907 $cm^{-1}$, for TG and to that, 919 $cm^{-1}$, for GG', 888 $cm^{-1}$, to the calculated frequency, 989 $cm^{-1}$, for GG, and 860 $cm^{-1}$, to the calculated frequency, 857 $cm^{-1}$, for TT and to that, 850 $cm^{-1}$, for GT. We could not determine whether all five isomers exist or not. However, at least three rotational isomers definitely exist, TT, GG and either TG or GG'. For β-bromoethyl mercaptan, we have also found results similar to those in the case of β-chloroethyl mercaptan, since we have similar spectra for CSH deformation modes. This substance, though the band at 903 $cm^{-1}$ is assigned to either TG or GG', might have a component arising from impurity; it persists in the crystalline state, the absorption intensity rapidly increases as the temperature increases in the gaseous state, and the band never loses its intensity again, even when it was cooled to room temperature.

For GG', there is a possibility of finding an intramolecular hydrogen bond between a SH group and a halogen atom. However, we could not find any evidence, though careful measurements were made with different solvents for SH stretching modes around 2570 $cm^{-1}$.

It should be noted that, even when the trans isomer consists of two molecular forms (TT and TG) and the gauche isomer consists of three molecular forms (GG, GT and GG'), the influences can not be seen for frequencies other than for CSH deformation frequencies; that is, the spectra for all the components coincide with each other except for CSH deformation modes. Therefore, we can find only two sets of the spectra for the trans and the gauche forms around the C-C bond. The assignments are shown in Tables I and II.

### Comparison with Ethylene Chlorohydrine

The following are the differences between the results for β-halogenoethyl mercaptan and those for ethylene chlorohydrin:

| | β-Halogenoethyl mercaptan | Ethylene chlorohydrin |
|---|---|---|
| 1) Molecular form around the C-C bond in the crystalline state | trans | gauche |
| 2) More stable molecular form around the C-C bond in the gaseous state | trans | gauche |
| 3) More stable molecular form around the C-C bond in the liquid state | trans | gauche |
| 4) Intramolecular hydrogen bond between XH and a halogen (X=O and S) | not be found | exists |
| 5) Molecular form around the C-S bond | several isomers | not proved |

It is very clear from the above comparison that the irregularity of the molecular form in the crystalline state and the stabilities in the gaseous and the liquid states for ethylene chlorohydrin come from the influences of the intramolecular hydrogen bonding between OH and Cl, as Mizushima and his co-workers pointed out. The results for β-halogenoethyl mercaptan strongly confirm this conclusion. For β-halogenoethyl mercaptan, the lack of the intramolecular hydrogen bonding probably makes it easy to find the different isomers around the C-S bond, since this makes the CSH deformation bands of these substances sharper than the COH deformation bands of ethylene chlorohydrin.

The author wish to express their gratitude to Mrs. Michiko Fukuyama of the Tokyo Industrial Research Institute for her measurements of the Raman spectra.

# Metal Complexs of Amino Acids. I. The Circular Dichroism of Copper(II) Complexes with Optically Active Amino Acids

By Takaji YASUI

(Received April 5, 1965)

It is well known that copper(II) complexes show a broad absorption band, which is due to the d→d transition, in the visible region. There have been many reports[1,2] concerning the assignments of the absorption components of this band, but most of these studies have been made on the basis of the absorption spectrum.

Pfeiffer and Christeleit[3] have studied the optical rotatory dispersion (ORD) of copper(II) complexes with optically active amino acids; their ORD data suggest that the Cotton effect in the visible absorption region is only one. It may be expected from the recent circular dichroism (CD) studies by other workers[4] that the split components of the d→d transition of the copper(II) complexes with optically active amino acids may also be separated by the CD method.

In the present paper, the CD curves of [Cu(am)$_2$]-type complexes (am=L- and D-alanine, L-serine, L-valine, L-threonine, L-allothreonine, L-proline and L-hydroxyproline) have been reported in the region from 1000 to 400 m$\mu$ in aqueous solutions. A preliminary letter on this subject was published recently.[5]

## Experimental

**Measurements.**—The CD curves were obtained by a Shimadzu QR-50 spectrophotometer with a CD attachment. All measurements were made at 10—12°C in the region from 1000 to 400 m$\mu$. Saturated, 1/40 or 1/20 mol./l. solutions in water, pyridine or ethylene glycol were used. The cell length employed was 1 cm. The aqueous solutions of bis(DL-threoninato)copper(II) or bis(sarcosinato)copper(II) monohydrate were used as the reference solutions instead of water.

The absorption measurements were made by a Beckman DU spectrophotometer at room temperature.

**Materials.**—All of the copper(II) amino acid complexes were prepared from copper(II) hydroxide by a modification of the method of Abderhalden and Schnitzler.[6]

1) *Bis(L-alaninato)copper(II), [Cu(L-ala)$_2$].*—To a solution containing 4.5 g. of L-alanine in 30 ml. of warm water, 2.2 g. of copper(II) hydroxide was added; the mixture was then heated for a few minutes on a water bath. After the solution had been filtered, a small amount of alcohol was added drop-by-drop to the filtrate and the solution was cooled in an ice bath. The crystals which separated were collected and washed with alcohol and then ether. Recrystallization was carried out from an aqueous alcohol solution.

Found: C, 30.31; H, 4.91; N, 11.64. Calcd. for Cu($C_3H_6NO_2$)$_2$: C, 30.06; H, 5.05; N, 11.69%.

2) *Bis(D-alaninato)copper(II), [Cu(D-ala)$_2$].*—This compound was prepared by the same procedure as was used in 1).

3) *Bis(L-serinato)copper(II), [Cu(L-ser)$_2$].*—One gram of copper(II) hydroxide was added to a solution containing 2.1 g. of L-serine in 30 ml. of warm water. The mixture was then filtered and left to stand at room temperature. When a proper amount of alcohol was added to the filtrate, blue crystals were deposited. They were washed with alcohol and then with ether. The complex was recrystallized from an aqueous alcohol solution.

Found: C, 26.75; H, 4.42; N, 10.19. Calcd. for Cu($C_3H_6NO_3$)$_2$: C, 26.52; H, 4.46; N, 10.31%.

4) *Bis(L-valinato)copper(II) Monohydrate, [Cu(L-val)$_2$]·$H_2O$.*—The compound was obtained by a method similar to that used in 1). It forms bluish-violet crystals.

Found: C, 40.63; H, 6.95; N, 9.45; $H_2O$, 6.08. Calcd. for Cu($C_5H_{10}NO_2$)$_2$·$H_2O$: C, 40.60; H, 6.81; N, 9.47; $H_2O$, 5.74%.

5) *Bis(L-threoninato)copper(II) Monohydrate, [Cu(L-thr)$_2$]·$H_2O$.*—Bluish-violet crystals were separated by the method that was used in 3).

Found: C, 32.04; H, 5.39; N, 9.39; $H_2O$, 5.91. Calcd. for Cu($C_4H_8NO_3$)$_2$·$H_2O$: C, 32.05; H, 5.38; N, 9.35; $H_2O$, 5.67%.

6) *Bis(L-allothreoninato)copper(II) Monohydrate, [Cu(L-allothr)$_2$]·$H_2O$.*—The needle crystals of a bluish-violet color were separated by a method similar to that used in 3).

Found: C, 32.01; H, 5.48; N, 9.14; $H_2O$, 5.85. Calcd. for Cu($C_4H_8NO_3$)$_2$·$H_2O$: C, 32.05; H, 5.38; N, 9.35; $H_2O$, 5.67%.

7) *Bis(L-prolinato)copper(II) Dihydrate, [Cu(L-prol)$_2$]·$2H_2O$.*—To a solution containing 3 g. of L-proline in 20 ml. of water, 1.2 g. of copper(II) hydroxide was added; then a sufficient amount of

acetone was added to the solution until crystals deposited. These crystals were collected and washed with acetone. The needle crystals were obtained in blue by recrystallizing them from an aqueous acetone solution. The complex prepared by the method of Pfeiffer and Christeleit[3] was hygroscopic, but the crystals separated by the present method were not so.

Found: C, 41.57; H, 5.53; N, 9.53; $H_2O$, 11.06. Calcd. for $Cu(C_5H_8NO_2)_2 \cdot 2H_2O$: C, 41.16; H, 5.53; N, 9.60; $H_2O$, 10.99%.

The anhydrous compound was prepared by the dehydration of bis(L-prolinato)copper(II) dihydrate in a vacuum oven at 75°C.

*8) Bis(L-hydroxyprolinato)copper(II) Trihydrate, $[Cu(L\text{-}hydprol)_2] \cdot 3H_2O$.*—The compound, obtained by the same method as was used in 7) was trihydrate and blue plates.

Found: C, 37.02; H, 5.04; N, 8.58; $H_2O$, 14.95. Calcd. for $Cu(C_5H_8NO_3)_2 \cdot 3H_2O$: C, 37.08; H, 4.99; N, 8.65; $H_2O$, 14.31%.

## Results and Discussion

The CD and absorption data in an aqueous solution are shown in Figs. 1—3 and in Table I. As is shown in Fig. 1, the absorption curve of $[Cu(L\text{-}ala)_2]$ shows a simple broad band, while the CD curve shows three bands in the region (namely, a positive band at about 730 mμ and two negative band, at 630 and 565 mμ). The CD curve of the copper complex with D-alanine is also plotted for the comparison. The CD curve of $[Cu(L\text{-}ser)_2]$ is similar to that of $[Cu(L\text{-}ala)_2]$ on the whole; namely, it has a small positive peak at about 730 mμ, a negative band at 595 mμ, and a negative shoulder at about 640 mμ. However, another small positive shoulder (about 820 mμ) is observed on the longer wavelength side of the positive peak at about 730 mμ. Similar trends are also observed in the curves of $[Cu(L\text{-}thr)_2]$, $[Cu(L\text{-}val)_2]$, and $[Cu(L\text{-}allothr)_2]$ (Figs. 1 and 2). These facts suggest that the broad positive bands in the 900—700 mμ region are composed of two weak positive CD components. As may be seen in Fig. 1, it also seems likely that the observed broad negative bands of $[Cu(L\text{-}thr)_2]$ and $[Cu(L\text{-}val)_2]$ are

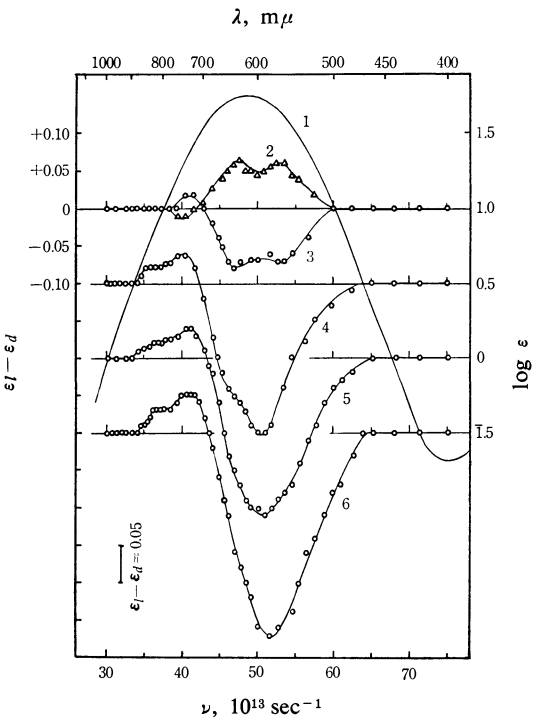

Fig. 1. Absorption curve of (1) $[Cu(L\text{-}ala)_2]$ and CD curves of (2) $[Cu(D\text{-}ala)_2]$, (3) $[Cu(L\text{-}ala)_2]$, (4) $[Cu(L\text{-}ser)_2]$, (5) $[Cu(L\text{-}thr)_2] \cdot H_2O$ and (6) $[Cu(L\text{-}val)_2] \cdot H_2O$ in aqueous solutions.

caused by the superposition of two negative CD bands.

From these results, it is concluded that the $[Cu(L\text{-}am)_2]$ complex shows *four* CD components of the d→d transitions, which are related to the magnetic dipole-allowed transitions under the symmetry of $C_2$. The signs of these CD components of the L-amino acid complexes are (+), (+), (−) and (−), listing from longer to shorter wavelengths. The single ORD inversion observed by Pfeiffer and Christeleit[3] may be thought to be a superposition of four Cotton effects.

The CD and absorption curves of the $[Cu(L\text{-}thr)_2]$ and $[Cu(L\text{-}allothr)_2]$ complexes are shown in Fig. 2. The L-threonine or L-allothreonine

molecule has two asymmetric carbon atoms, located in $\alpha$- and $\beta$-positions. The CD behavior of $[Cu(L\text{-thr})_2]$ is, on the whole, almost the same as that of $[Cu(L\text{-allothr})_2]$ except for a small difference in their intensities. These facts suggest that the vicinal effect caused by the $\alpha$-asymmetric carbon atom, which is located in the five-membered chelate ring containing a central copper atom, is more effective than that of the $\beta$-asymmetric atom, which is located in the side chain of the chelate ring. Similar work concerning the $\alpha$- and $\beta$-asymmetry of optically active amino acids has been reported on the basis of ORD study in another wavelength region,[7] but it resulted in no definite conclusion.

As may be seen in Fig. 3, the CD curve of $[Cu(L\text{-prol})_2]$ is considerably different from those of the other amino acid complexes. This may be attributed to the stereospecific activation of the nitrogen atom in the coordinated ligand, because the construction of the molecular models of the complexes shows that the nitrogen atom of the coordinated L-proline takes a forced asymmetric configuration, and that of the coordinated D-proline, the enantiomorphous configuration. This was also supported by the X-ray analysis of the $[Cu(L\text{-prol})(D\text{-prol})]\cdot 2H_2O$ crystal.[8] The $[Cu(L\text{-hydprol})_2]$ may be said to have the same conditions as $[Cu(L\text{-prol})_2]$ in view of the similarity of their CD behavior. These CD behavior will suggest that the vicinal effect from the activated nitrogen atom will be more effective than that from the $\alpha$-asymmetric carbon atom, since the nitrogen atom is directly

attached to the copper atom, while the carbon atom is attached indirectly.

The CD and absorption data of [Cu(L-prol)$_2$] in pyridine or ethylene glycol are shown in Fig. 4. This complex can be kept in these solvents without decreasing its optical activity. The absorption maxima of this complex in these solvents are almost the same as that in an aqueous solution, though the absorption intensity is slightly higher in pyridine than in the other two solvents. On the other hand, the intensity of the CD band in pyridine is less than that in ethylene glycol or in water. It may be considered, however, that these differences in behavior in these different solvents do not suggest any essential differences in the CD components.

## Summary

On the basis of the CD measurements of the complexes of the [Cu(L-am)$_2$] type, four CD components have been observed in the region of the d→d absorption band, namely, (+), (+), (−) and (−), listing from longer to shorter wavelengths. The L-configuration of the amino acids determines the signs of these CD components.

Judging from the CD curves of the copper-(II) complexes with L-threonine and with L-allothreonine, it has been suggested that the vicinal effect caused by the $\alpha$-asymmetric carbon atom is stronger than that caused by the $\beta$-asymmetric one.

It has also been suggested that, when L-proline or L-hydroxyproline is coordinated to copper, the nitrogen atoms of these ligands are activated by the configurational stereospecificity.

The author is grateful to Assistant Professor Yoichi Shimura and Dr. Jinsai Hidaka for their advice and discussions relating to this work.

# A Molecular Orbitals Study of the Nucleophilic Substitution in Methyl Chloride

By Hiroshi KATO, Keiji MOROKUMA, Teijiro YONEZAWA and Kenichi FUKUI

(Received April 9, 1965)

The mechanism of the $S_N2$-type nucleophilic substitution of aliphatic compounds has been discussed in many experimental studies.[1] Some quantitative and semi-quantitative interpretations of this type of reaction have been carried out by using semi-empirical theory[2,3] or by means of a simple LCAO-MO method.[4] No attempt, however, has yet been made to throw light on the mechanism of the electronic process of this type of reaction. Recently Hoffmann has proposed an extended Hückel method in which an MO (molecular orbital) is represented by linear combination of valence AO's (atomic orbitals) in the molecule.[5] As will be shown in the next section, this procedure, along with the Born-Oppenheimer adiabatic approximation, is particularly convenient and effective for treating the electronic structure of unstable intermediates or such molecules as contain atoms with an unusual valency, as well as ordinary stable molecules.

Accordingly, in the present paper we intend to apply this method to a discussion of the electronic structure of the molecular system which would appear near the transition state of the typical $S_N2$-type reaction, $CH_3Cl+Cl^- \rightarrow Cl^-+CH_3Cl$. This species may be written schematically as $(Cl\cdots CH_3\cdots Cl)^-$.

The calculated results will help us to ascertain the characteristic role which might be

played by each atomic orbital during the electronic interaction of this process.

### The Parameters Used and the Coordinates

The MO's to describe these systems are represented by a linear combination of valence AO's; that is, the 1s orbital of the hydrogen atom, the 2s, 2px, 2py and 2pz orbitals of the carbon atom, and the 3s, 3px, 3py and 3pz orbitals of the chlorine atom.

The Coulomb integrals of these AO's, $H_{ii}$, are given as follows:

$$H_{ii}(1s, H) = -13.60 \text{ eV.}$$
$$H_{ii}(2s, C) = -21.43 \text{ eV.}$$
$$H_{ii}(2p, C) = -11.42 \text{ eV.}$$
$$H_{ii}(3s, Cl) = -25.26 \text{ eV.}$$
$$H_{ii}(3p, Cl) = -15.09 \text{ eV.}$$

These values are cited from Pritchard and Skinner's paper[6] while that of the 3s orbital of the chlorine atom is estimated by means of the observed atomic spectra.[7] For the negative chlorine ion, the values of $H_{ii}$ is tentatively assumed to be same as that of the neutral atom.

The resonance intergral between $i$th and $j$th AO's, $H_{ij}$, is calculated by the equation:

$$H_{ij} = 0.5K(H_{ii} + H_{jj})S_{ij}$$

where $S_{ij}$ is the overlap integral and where the value of $K$ is taken to be 1.75 as in Hoffmann's paper.[5]

The effective nuclear charges for these atoms are $Z_H = 1.00$, $Z_C = 3.25$ and $Z_{Cl} = 6.10$ (for both the ionic and neutral chlorine atoms).

The coordinates of this system are presented in Fig. 1, where the carbon atom is situated at the origin of the coordinate system and where the line of $Cl_2$-C-$Cl_1$ is taken as the Y axis. (The symbol $Cl_2$ refers to the attacking chlorine atom, while $Cl_1$ refers to the one in the isolated methyl chloride at the initial stage of reaction.) The $Cl_1$-C-$H_1$ plane lies in the Y-Z plane, and the angle of $Cl_1$-C-H is named $\theta$. The C-$H_2$ bond inclines in the +X direction, and the C-$H_3$ bond, in the −X direction. The px, py, and pz orbitals of the carbon and chlorine atoms direct their positive parts in the X, Y and Z directions respectively.

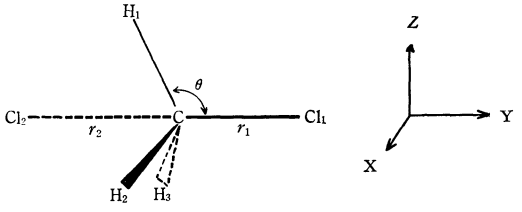

Fig. 1. The coordinate.

### The Electronic Structure of the $CH_3Cl$ Molecule

The calculated MO energies (in units of eV.), together with their irreducible representation and the values of the coefficients of the AO's of $CH_3Cl$, are summarized in Table I, where the geometry of this molecule is given as follows:[8] The C-H distance is 1.1 Å, the C-Cl distance is 1.784 Å and the angle of Cl-C-H, $\theta$, is 110°, and the molecule belongs to the $C_{3v}$ point group.

Frost and McDowell,[9] in their electron impact experiment, studied the electronic structure of methyl chloride; they give the electronic configuration of this molecule as $(a_1)^2(a_1)^2(e)^4(a_1)^2(e)^4$, where the MO energies, except for the lowest $a_1$ MO, are −18.71, −13.02, −12.07 and −11.42 eV. respectively, and where the bracket (A) refers to a molecular orbital belonging to the irreducible representation, A. This order of MO energy agrees with our results, as may be seen in Table I. However, our calculated values are uniformly ca. 3 eV. lower than the above-cited experimental values.

As is shown in Table I, the highest occupied orbital of this molecule is a $\pi$-type orbital consisting of the chlorine atom and the methyl group, which is the C-H bonding in the methyl group and which is C-Cl antibonding, and the electrons in this orbital are largely localized on the chlorine atom. Thus, this orbital may be characterized as a lone-pair orbital, as in Ref. 9. The lowest vacant orbital is now a $\sigma$-type orbital and is strongly antibonding on the C-Cl bond. This result agrees with our previous result.[10] This orbital energy, that is, +1.08 eV., seems to be too high, however, and the energy difference between the highest occupied and the lowest vacant orbitals becomes about 15 eV., while the experimental value, obtained by means of the spectroscopic data, is about 8 eV.[11]

*1 The highest occupied orbitals (degenerated).
*2 The lowest vacant orbital.
*3 The symbols $S_C$, $X_C$, $Y_C$ and $Z_C$ denote the 2s, 2px, 2py and 2pz orbitals of the carbon atom and $H_i$ denotes the 1s orbital of the $i$th hydrogen atom. The $S_{Cl}$, $X_{Cl}$, $Y_{Cl}$ and $Z_{Cl}$ refer to the 3s, 3px, 3py and 3pz orbital of the chlorine atom.

The calculated results for the charge distributions[12] are as follows: The atomic orbital populations, $N$(r), are:

$$N(S_H)=0.875$$

$$N(S_C)=1.140 \quad N(X_C)=N(Z_C)=1.111 \quad N(Y_C)=0.683$$

$$N(S_{Cl})=1.819 \quad N(X_{Cl})=N(Z_{Cl})=1.998 \quad N(Y_{Cl})=1.513$$

where the notations, $S_H$, $S_C$ and $X_C$ etc., denote the hydrogen 1s orbital, the carbon 2s and 2px orbitals, and so on. The atomic populations, $M$(A), are calculated as 4.045 on the carbon atom and as 7.329 on the chlorine atom.

The atomic bond populations, $M$(A-B), are $M$(C-H) = 0.802, $M$(C-Cl) = 0.564, $M$(H···H) = −0.074 and $M$(H···Cl) = −0.067. The calculated values of the atomic orbital bond population, $N$(r-s), between the r and s atomic orbitals are listed in Table II. For the C-Cl bond, the value of $N(Y_C-Y_{Cl})$ is 0.338 and is the largest, and the magnitude of $N(Y_C-S_{Cl})$ and $N(S_C-Y_{Cl})$ is of the same order, while $N(X_C-X_{Cl})$ and $N(Z_C-Z_{Cl})$ are both negative and very small.

TABLE II. THE $N$(r-s) VALUES BETWEEN AO'S OF THE C-Cl AND C-H BONDS IN $CH_3Cl$

| | $S_C$ | $X_C$ | $Y_C$ | $Z_C$ |
|---|---|---|---|---|
| $S_{Cl}$ | 0.022 | 0 | 0.142 | 0 |
| $X_{Cl}$ | 0 | −0.034 | 0 | 0 |
| $Y_{Cl}$ | 0.128 | 0 | 0.338 | 0 |
| $Z_{Cl}$ | 0 | 0 | 0 | −0.034 |
| $H_1$ | 0.238 | 0 | 0.048 | 0.517 |
| $H_2$ | 0.238 | 0.388 | 0.048 | 0.129 |
| $H_3$ | 0.238 | 0.388 | 0.048 | 0.129 |

Accordingly, the C-Cl bond is a $\sigma$-type bond and is mainly dependent upon the interaction between the carbon 2py orbital and the chlorine 3py orbital, whereas the 3px and 3pz orbitals of the chlorine atom do not participate in the bond formation and stand for lone-pair orbitals. On the other hand, the $N$(r-s) values of the pairs between AO's of C-H bond indicate that the carbon 2px and 2pz orbitals do participate in the C-H bonding and not in the C-Cl bonding.

## The Electronic Structure of the "Transient Species" $(Cl\cdots CH_3\cdots Cl)^-$

In this section, we will treat, on the assumption of adiabaticity, the electronic structure of the systems in which the attacking chlorine ion ($Cl_2$) interacts with the isolated methyl chloride with various assumed configurations. It is well established, in normal $S_N2$-type halogen substitutions of alkyl halides, that the replacement proceeds most often in such a way that the attacking reagent, the central carbon atom and the substitution atom lie co-linear and the hybridization of the central carbon atom shifts from $sp^3$ to $sp^2$, which is finally reached in the transition state. However, the reaction path of this reaction has not yet been strictly established. Accordingly, we have tentatively selected two hypothetical processes, a and b, and have investigated the electronic structure of the species $(Cl\cdots CH_3\cdots Cl)^-$. This is neither a stable molecule nor an unstable intermediate,

12) K. Morokuma, H. Kato, T. Yonezawa and K. Fukui, This Bulletin, 33, 1263 (1965).

but rather corresponds to a certain configuration near the transition state. The electronic structure is calculated with respect to several different configurations in each process. These calculated configurations are shown in Table III, together with the calculated total electronic energy values (in eV.), where the C–$Cl_1$ bond distance is denoted as $r_1$ and the C–$Cl_2$ distance as $r_2$, and where the $Cl_1$–C–H angle is $\theta$. The C–H distances are kept constant, as equal to 1.10Å throughout both the a and b processes. In both processes a chlorine ion approaches the isolated methyl chloride along the Y axis from the −Y direction, as may be seen in Fig. 1, and these two processes start at $r_2=3.0$Å, $r_1=1.784$Å and $\theta=110°$; the process a ends with $r_2=r_1=2.20$Å and $\theta=90°$, and the process b with $r_2=r_1=2.05$Å and $\theta=90°$ (Ingold et al.[2] adopted the value $r_2=r_1=2.05$Å, and Spinner,[13] 2.17Å, as the C–Cl bond distances at the transition state of the chlorine substitution reaction of methyl chloride.).

Table III. The various configurations and the calculated total electronic energy values (eV.) in the $(Cl\cdots CH_3\cdots Cl)^-$ systems

When we refer to the calculated values of the total electronic energies in Table III, we can see that those values have a minimum, with a variation of $\theta$ at fixed $r_1$ and $r_2$ distances. This may tentatively be referred to as a "local" minimum. The value of $\theta$ at local minima gradually decrease from 110° at the initial state to 90° at the symmetrical configuration ($r_1=r_2$, $\theta=90°$).

For the sake of simplicity, several sets of $r_1$ and $r_2$ values were selected for each process, a and b. The electronic structure was calculated with respect to the configurations in which the value of $\theta$ corresponds to a local minimum at this fixed $r_1$ and $r_2$. These configurations are summarized in Table IV, where they are named a-I, a-II,···, a-VI and b-I, b-II, ···, b-VI respectively (a-I and b-I have the same configuration.).

Now let us investigate the process of the nucleophilic reaction of aliphatic compounds. The configurations which we adopted allow

us to derive a certain semi-quantitative conclusion concerning the electronic distribution in the process of the reaction.*

**The Electronic Energy and the Atomic Population.**—The calculated values of the total electronic energy (in eV.) and the atomic population, $M(A)$, of each atom in these configurations in both processes are given in Table IV. The calculated results show that, in both processes, the total energies become higher and higher as the C–$Cl_2$ distance decreases.

On the other hand, the calculated values of $M(A)$ lead to the following results: The $M(Cl_2)$ values decrease from 7.995 at the initial state to 7.784 at the a-VI state, while the $M(C)$ values decrease from 4.056 to 3.820 and the $M(Cl_1)$ values increase from 7.333 to 7.784 through the process a. This tendency is similar to that in the process b. That is, the negative charge located on the chlorine ion at the initial configuration gradually migrates to the $Cl_1$ atom, and at the symmetrical configuration the $M(A)$ values of $Cl_2$ and $Cl_1$ atoms become equal.

In order to discuss this further, the calculated values of the atomic orbital populations, $N(r)$, of various AO's are collected in Table V, while the relation between the magnitude of $N(r)$ and the configuration at various stages is plotted in Fig. 2. In the process a, $N(S_C)$ increases gradually from 1.149 to 1.236 and $N(Y_C)$ remarkably decreases from 0.680 to 0.414, while the values of the $X_C$ and $Z_C$ orbitals are almost invariable. As for the $Cl_1$ atom, the change of $N(Y_{Cl_1})$ is the largest, i. e. from 1.516 to 1.818; that of $N(S_{Cl_1})$ is the next, and the $N(r)$ values of $X_{Cl_1}$ and $Z_{Cl_1}$ orbitals are almost constant, i. e., ca. 2.000 through the process a. The $N(r)$ values of the $Cl_1$ atom show a tendency to be the inverse of that of the $Cl_2$ atom. Thus, it is noticed that the changes in the $M(A)$ values are mainly governed by that of the 2py orbital at the carbon atom and the 3py orbitals at the chlorine atoms, whereas the $N(r)$ values of the 3px and 3pz orbitals of the chlorine atoms remain constant and these orbitals have a lone-pair orbital, as in nature. These results will be accepted more easily in the light of the discussion in the following section.

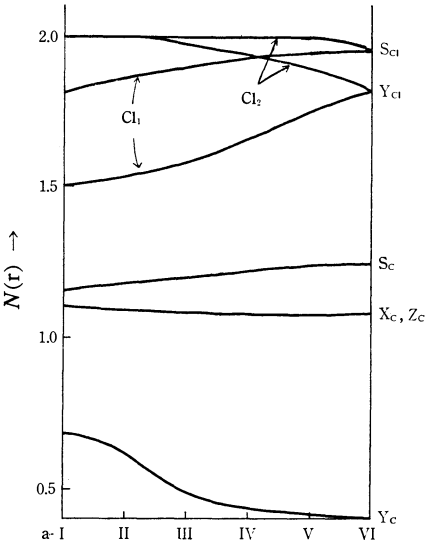

Fig. 2. The change of the $N(r)$ values of the carbon and chlorine atoms through the process a.

**The Bond Population in the C–Cl Bond.**—Tables VI and VII list, respectively, the calculated values of the atomic bond populations, $M(A–B)$, between various atoms, and also those of the atomic orbital bond populations,

* If we adopt the $M(A)$ or $M(A–B)$ values with a little different $\theta$ values from those in Tables IV and VI, our conclusions will be not seriously affected, since the variations in these magnitudes are limited within 0.02.

$N$(r-s), between various AO's. The values of $M$(C-$Cl_1$) and $M$(C-$Cl_2$) vary inversely proportionally to their bond distance; both are positive and equal at the symmetrical configuration. The value of $M$(H-C) shows only a slight change during the course of both processes, a and b, in its overall magnitude, but it varies remarkably in its terms. This point will be discussed again in a later section.

The $M$(C-$Cl_1$) values decrease rapidly in both processes, that is, from 0.558 to 0.102 in the process a and from 0.558 to 0.098 in the process b. The magnitudes of the contributions of several factors to the rapid decrease in $M$(C-$Cl_1$) may be roughly estimated as follows: a) The contribution from the change in the $\theta$ value. This magnitude may be estimated by the difference between the values of $M$(C-$Cl_1$) at $r_1=r_2=r_0$, $\theta=90°$, and the value at $r_1=r_2=r_0$, $\theta=110°$. The value of $r_0$ is taken as 2.20Å in the process a and as 2.05Å in the process b. That is, it is calculated as $-0.038$ at the process a and at $-0.018$ at the process b. b) The contribution from the interaction with the $Cl_2$ atom. This magnitude may be estimated by means of the difference between $M$(C-$Cl_1$) at $r_1=r_2=r_0$, $\theta=90°$, and the value at $r_1=r_0$, $r_2=\infty$ and $\theta=90°$, it is $-0.158$ in the process a and $-0.242$ in the process b. c) The contribution from the streching of the C-$Cl_1$ bond. This is estimated by means of the difference between $M$(C-$Cl_1$) at $r_1=r_0$, $r_2=\infty$, $\theta=110°$, and that at $r_1=1.784$Å, $r_2=\infty$, $\theta=110°$. This is $-0.246$ in the process a and $-0.160$ in the process b. On the basis of these estimations, it may be concluded that the decrease in the $M$(C-$Cl_1$) value is mainly brought about by the interaction with the $Cl_2$ atom and the streching of the C-$Cl_1$ bond, while the effect of the change in $\theta$ is very small.

On investigating the values of $N$(r-s) in the C-Cl bond given in Table VI and Fig. 3, it may be seen that a remarkable change during the processes is observed in the values of $N(Y_C-Y_{Cl_1})$ and $N(Y_C-Y_{Cl_2})$; i. e., the former decreases and the latter increases in both processes, while there is a less remarkable

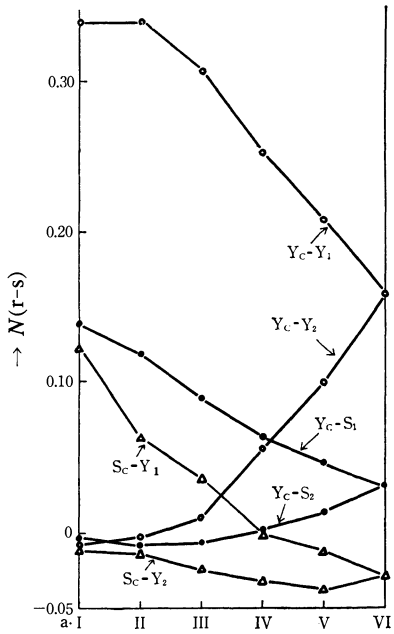

Fig. 3. The change of the $N$(r-s) values between some AO's of the carbon and chlorine atoms in the process a, where $S_1$ and $S_2$, etc. refer to the 3s orbitals of the chlorine 1 and 2 atom and so on.

change in the $N(Y_C-S_{Cl_1})$ and $N(S_C-Y_{Cl_1})$ values. In the symmetrical configuration, the magnitude $N$(r-s) decreases in the order of $N(Y_C-Y_{Cl})>N(Y_C-S_{Cl})>N(S_C-Y_{Cl})$, where the $N(S_C-Y_{Cl})$ value is negative. Accordingly, the C-Cl bond is considered to be formed mainly through the interaction between the 3py orbitals of the two chlorine atoms and the 2py orbital of the carbon atom. The interaction between the chlorine 3py and the carbon 2s orbitals is not concerned with this bond formation, especially near the symmetrical configuration. The values of $N(X_C-X_{Cl})$ and $N(Z_C-Z_{Cl})$ are almost unchangeable and are negligibly small throughout the process.

**The Change of $N$(r-s) in the C-H Bond.**— The $N$(r-s) values between AO's of the hydrogen and carbon atoms in both processes are

* The notation $H_1$-$S_C$ denotes the $N$(r-s) value between the 1s orbital of the hydrogen 1 and the 2s orbital of the carbon atom.

listed in Table VIII, where the $H_1$ 1s orbital does not overlap with the carbon 2px orbital, as is shown in Fig. 1, hence, the $N(H_1\text{-}X_C)$ values are omitted in Table VIII. By referring to the calculated results, it may clearly be seen that $N(H_1\text{-}S_C)$ values increase and $N(H_1\text{-}Z_C)$'s are almost invariable in both processes. Thus, the carbon 2s orbital is concluded to play an important role in the C–H bond-formation near the symmetrical configuration. In other words, in this state the s-nature of the C–H bond increases. This result may correspond to the change in the hybridization of the central carbon atom from $sp^3$ in the direction of $sp^2$ at the transition state of the $S_N2$-type reaction.

The discussions above concerned with the roles of various AO's in the interactions of these systems may be summarized as follows: At the carbon atom, the 2s orbital takes part in the C–H and C–Cl bondings at the initial state, whereas at the symmetrical state it participates only in the C–H bonding. The 2px and 2pz orbitals take part in the C–H bonding only, and the 2py orbital alone contributes always to the C–Cl bonding throughout the process. At the chlorine atoms, the 3s orbitals take part partially in the C–Cl bonding, while the 3py orbitals play a dominant part in the C–Cl bonding. The 3px and 3pz orbitals remain as lone-pair orbitals.

**The Energy Levels in the Symmetrical Configuration.**—The calculated values of MO energy, their irreducible representation, and those of the coefficients of AO's in the symmetrical configuration (a-VI and b-VI) are listed in Tables IX(i) and (ii), where these systems belong to the $D_{3h}$ point group. The characteristic features of these MO's may be pointed out briefly as follows: The $a_1'$ and $a_2''$ orbitals are $p\sigma$-type orbitals, the e′ orbitals are $p\pi$-type orbitals, and the e″ orbitals are lone-pair orbitals of the chlorine atoms.

Judging from the population analysis in Tables VII and VIII, the $a_2''$ occupied orbitals may be said to make an important contribution to the C–Cl bonding, while the other MO's make a minor contribution. On the other hand, the highest-occupied orbital belonging to $a_1'$ has a C–Cl antibonding and a C–H bonding character and its energy is very sensitive to the C–Cl distance, which is, in our approximation, interpreted in terms of the magnitude of the overlap between the carbon

*1 The highest occupied orbital.

*2 The lowest vacant orbital.

*3 The notation, $S_{Cl}$ and $Y_{Cl}$ denote $(S_{Cl_1}+S_{Cl_2})$ and $(Y_{Cl_1}+Y_{Cl_2})$ in the $a_1'$ orbitals and $(S_{Cl_1}-S_{Cl_2})$ and $(Y_{Cl_1}-Y_{Cl_2})$ in the $a_2''$ orbitals, for $X_{Cl}$ and $Z_{Cl}$, they represent $(X_{Cl_1}+X_{Cl_2})$ and $(Z_{Cl_1}+Z_{Cl_2})$ in the e' orbitals and $(X_{Cl_1}-X_{Cl_2})$ and $(Z_{Cl_1}-Z_{Cl_2})$ in the e'' orbitals respectively.

and chlorine atoms. Thus, this orbital originates from the splitting of the $a_1$ lowest vacant orbital of the isolated methyl chloride. The mode may be represented by the scheme:

$$a_1(C_{3v}) \rightarrow a_1' \text{ and } a_2'' \ (D_{3h})$$

Accordingly, it may be said that the unstable character and the C–Cl lengthened bond result mainly from this kind of orbital, $a_1'$.

From the above-mentioned results, it may be concluded that the $a_2''$ orbitals play an important role in the stabilization of these systems,[4] but that the $a_1'$ orbitals should be taken into account in the more rigorous treatment.

## Summary

The electronic structures of $CH_3Cl$ and a "transient" species $(Cl\cdots CH_3\cdots Cl)^-$ have been calculated by an extended Hückel method. The calculated results of $CH_3Cl$ correlate well with the experimental facts. The main features of the electronic structure of $(Cl\cdots CH_3\cdots Cl)^-$ may be summarized as follows:

1) The 3py orbitals of the chlorine atoms and the 2py orbital of the central carbon atom ($p\sigma$-orbitals) play an important role in the interaction between the C–Cl bonds.

2) The 2s orbital of the central carbon atom at the symmetrical configuration makes no contribution to the C–Cl bonding; rather, this orbital, together with the 2px and 2pz orbitals, participates in the C–H bonding.

3) The 3px and 3pz orbitals of the chlorine atoms form the lone-pair orbitals.

The natures of the MO's of the symmetrical configuration have also been briefly discussed.

It should be noticed, however, that the present treatment is not yet sufficiently qualified as a method to allow an interpretation of the stable configuration of a molecular system, since it does not explicitly take into account the nuclear repulsion and the electronic interaction. Accordingly, there remains room for criticism with respect to the theoretical significance which the configuration of such a local minimum will have in the true electronic process on the reaction path. This point will be examined further in the future.

The calculations have been carried out on an IBM 7090 computer at the Japan IBM Co., with the permission of the UNICON committee, which the authors wish to thank.

# Small-angle Scattering from Methane, Ammonia and Water by Fast Electrons†,*

By Takao IIJIMA, Russell A. BONHAM, Claude TAVARD, Monique ROUX and Marguerite CORNILLE

(Received April 17, 1965)

With the advent of improved methods for the calculation of the wave functions for a many-electron system, it has become of interest to obtain experimental measurements of quantities with direct relationships to the computed wave functions. Scattering experiments with fast electrons are of interest in this connection, since they provide direct information concerning the shape of electron-charge distributions in atoms and molecules.[1-8]

Some one-center wave functions, which are now available for the molecular systems methane, ammonia and water[9,10] have been

used to calculate the total scattering intensity for fast electrons in the first Born approximation.[4,6] When these results are compared with those of the independent-atom model, a contribution from the binding electrons is seen to appear on the first ring of scattered intensities. This last calculation may be performed using the best available wave functions for each atom in these molecules. It is therefore, the purpose of this work to compare recently-obtained experimental results with these theoretical predictions.

Sector electron-diffraction photographs of methane, ammonia, water and helium were obtained over the $s$ ($s=(4\pi/\lambda)\sin\theta/2$) range $1<s<8$ using a newly-constructed electron-fraction unit, in the Electron Diffraction Laboratory of Indiana University; this unit, to be described elsewhere,[11] has a nozzle-to-photographic plate distance of 65 cm. and an accelerating voltage of 40 kV. The diffraction patterns were recorded on Kodak process plates with an exposure time ranging from 1 to 3 min. and with a beam current of about 0.1 $\mu$ amp. The sample pressure was nearly 80 mmHg (except in the case of water, for which the pressure was $\sim$20 mmHg); the gas was expanded into the vacuum chamber through an orifice 0.15 mm. in diameter. The chamber pressure was maintained at better than $2\times10^{-4}$ mmHg during the entire exposure time by the use of a fast pumping system. The optical density of the plates as a function of the scattering angle was measured using a newly-constructed automatic recording densitometer.[12]

The optical density measurements were made with a precision of better than $\pm0.5\%$; the $s$ scale was also determined with a precision better than $\pm0.5\%$ at a maximum $s$ value ($s=8.0$). The maximum optical density on any given plate was on the order of 0.35, and the intensity of electrons striking the plate was assumed to be proportional to the optical density. The intensity of electrons on Kodak process plates characteristically exhibits a quadratic dependence on the optical density that is usually less than 10% of the linear term. The recognition of this fact, coupled with the use of a sector correction based on helium to correct the experimental intensities, further compensates for the lack of an emulsion correction. Calculations showed that, for a nonlinear term of 10% in the optical density, an error of less than 2% was introduced into the experimentally-corrected intensities due to the neglect of the emulsion calibration.

The observed intensity curves were corrected for extraneous scattering by the use of a blank photograph taken under conditions identical with those encountered in the experiments. The helium experimental results were then matched, at $s=6$, with the best available theoretical results, using a single multiplicative scale factor. A wave function of the form:

$$\psi(\vec{r}_1,\vec{r}_2)=\{\exp[-Z_1r_1-Z_2r_2]+\exp[-Z_1r_2-Z_2r_1]\}\times(1+b\exp[-\alpha r_{12}])$$

was used to calculate the first Born-approximation elastic and inelastic scattering factors[13] employed in the calculation of the theoretical helium intensity. The parameters used in the above wave function were $Z_1=1.4079$, $Z_2=2.2085$, $b=-0.5780$ and $\alpha=0.2925$ (in atomic units). The total energy given by this wave function is 2.90188 Hartrees. The necessary expressions for the scattered intensity can all be obtained in terms of closed-form analytical functions. The ratio of the calculated to the observed helium intensities was then employed to correct the methane, ammonia and water intensities for uncertainties in the shape of the rotating sector, for magnetic disturbances from the sector-bearing, and for the lack of an emulsion calibration.

For the final analysis, the three best helium plates were selected in constructing the sector correction. The helium results are shown in Fig. 1. The best two plates each for methane, ammonia and water were selected; these results,

after having been sector-corrected, are compared with the theoretical results in Figs. 2, 3 and 4. The agreement with theory in the case of methane is quite gratifying. Unfortunately, the reproducibility of the ammonia and water results indicates only a general qualitative agreement with the theory.

The uncertainty in the present results possibly occurs because of extraneous scattering or intermolecular multiple scattering. Further improvement of the experimental conditions in order to reduce such effects is currently in progress. A further possible source of confusion is the neglect of polarization effects in the theoretical scattering calculations. There

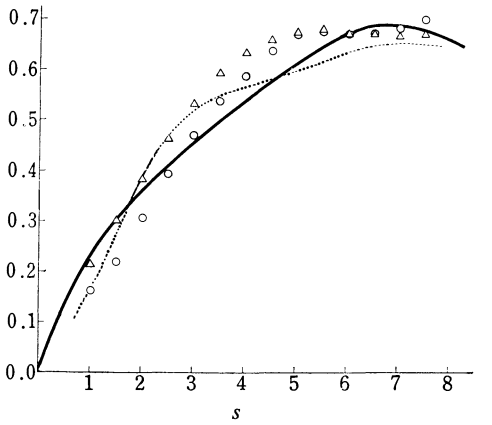

Fig. 4. Experimental and theoretical intensities for water on an arbitrary intensity scale with results matched at $s=6$.
1. Experimental points: △, ○
2. Theory including binding effects ——
3. Independent-atom model ----

are also uncertainties involved in the comparison of theoretical and experimental results because of the approximate nature of the molecular wave functions used. This error should be at a maximum for water, while it should have its smallest value for methane.

In principle there are two effects associated with chemical-bond formation on the scattered intensity from polyatomic molecules. The first is the size effect, which is the main effect in the case of molecular hydrogen; this has been discussed previously.[3,8] The size effect is essentially a change in the effective volume occupied by a fixed percentage of the electrons in the molecule when the independent-atom model goes over to the case where chemical bonds are formed. A comparison between the theoretical results for the independent-atom model and the experimental results or the theoretical calculation including chemical-binding effects shows that the formation of a stable molecular system is accompanied by a decrease in the volume occupied by a fixed percentage of the electrons.

The results of experiments on molecular hydrogen, reported elsewhere,[3,8] are essentially a measure of the effective volume occupied by a fixed percentage of the electrons in the molecule. This decrease indicates an increase in the kinetic energy over that of the independent-atom system; hence, by the use of the virial theorem, it also indicates a lowering of the total energy. Because the independent-atom model represents the size and, thus, the total energy of the system without bond formation, the difference between this curve and the experimental curve is directly related to the binding energy of the system. Unfortunately,

however, the total intensity is also related to the total number of electrons in the system, so the magnitude of the change between the independent-atom model and the experimental results will be proportional to the ratio of the number of electrons involved in the binding to the total number of electrons in the system. Thus the binding effects in systems containing large numbers of electrons, only a few of which are involved in chemical binding, will be quite small. This effect can also be observed in the differences, shown in Figs. 2, 3 and 4, between the independent-atom results (dotted curve) and the results including binding effects (solid curve). According to the simple ideas of valence theory; the magnitude of the binding effects for covalent bonds should be 8/10 for methane, 6/10 for ammonia and 4/10 for water, as compared with the effect in molecular hydrogen.[3,8] (A more detailed examination, appealing to electronegativity concepts, gives ratios slightly different from these.)

The second effect due to bonding arises because of the dipolar character of hetero-atom pairs. In the case of hetero-atoms, the scattering is sensitive to the shifts of charge from one atom to another which occur due to differences in the electronegativity of the atoms involved. This is especially significant in molecules possessing permanent dipole moments; it has been discussed previously by Altshuler.[14] The scattered intensity is proportional to $\mu^2/3s^2$, where $\mu$ is the permanent dipole moment, in the limit as $s$ goes to zero. Unfortunately, this effect may tend to be obscured by polarization effects.

Since size effects and dipole effects occur together, it is of some interest to attempt to isolate one effect from the other. One possibility which suggests itself is to analyze the molecular wave function into "ionic" and "atomic" parts according to the scheme suggested by Shull.[15] In this fashion, the scattered intensity using the "atomic"-like wave function with and without ionic contributions could be calculated. The difference between these cases could then possibly be interpreted in terms of charge drifts due to electronegativity differences in the hetero-polar chemical bonds. Unfortunately, it is felt that both the experimental and theoretical results presented in the present analysis are too crude to allow any conclusions to be drawn regarding the dipole character of the scattering. At any rate, however, the foregoing remarks point out the desireability of obtaining quantitative theoretical relationships between size and dipole effects, on the one hand, and experimental measurements of a limited part of the differential scattering cross section, on the other.

Work is presently under way to obtain more precise measurements, both experimental and theoretical, of the type of scattering presented here so that more detailed comparisons may be made. While this type of experiment is somewhat limited in the kind of information that can be obtained about charge distributions, there are many other possibilities of the use of scattering techniques to obtain such information. Indeed, many of these possibilities have already been previously discussed in the literature.[16-19]

## Summary

The total differential scattering cross sections for the 40 kV. electron from the methane, ammonia and water molecules obtained experimentally over the $1 \leqslant s \leqslant 8$ $s$ range have been compared with the theoretical results. Good agreement with the theoretical results have been obtained in the case of methane. In the cases of ammonia and water the results are in qualitative agreement with the theoretical predictions, but uncertainties in both the theory and experiment prevent a detailed comparison from being made in these cases.

The authors wish to thank Mr. Lao-Sao Su, Mr. Hollace Cox, Mr. Denis A. Kohl and Mr. Howard Brown for their help in obtaining the experimental data. Thanks are also due to Drs. Savo Bratož, M. Allavena and Roberto Moccia for the use of their wave functions prior to publication.

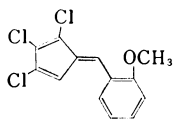
# The Crystal Structure of 1, 2, 3-Tribromo-6-(*o*-methoxyphenyl)fulvene

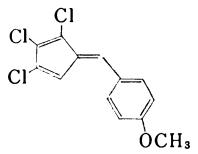
By Yukio KATO,* Yoshio SASADA and Masao KAKUDO

(Received May 4, 1965)

Sesquifulvalene (cycloheptatrienylidenecyclopentadiene), recently synthesized by Prinzbach and Rosswog,[1] is an interesting substance of non-alternant hydrocarbons. Kitahara, Murata, Funamizu and Asano[2] have attempted to obtain the tetrachloro derivative of this compound by the reaction of 1, 2, 3, 4-tetrachlorocyclopentadiene (I) and tropone (II) in a large volume of methanol.



(I)



(II)

Contrary to their expectation, however, they got two kinds of products: red prisms (m. p. 117—118°C) and reddish-orange needles (m. p. 77—78°C). Elementary analysis indicated that both of these products had the molecular formula $C_{13}H_9OCl_3$. By some chemical consideration, and with the help of infrared, ultraviolet and NMR spectra, in was concluded that these isomers were trichloro-6-(*o*-methoxyphenyl)fulvene (III) and trichloro-6-(*p*-methoxyphenyl)fulvene (IV).

(III)

(IV)

Thus they have shown that the reaction of I and II in methanol results in an entirely new type of rearrangement reaction, in which the methoxy group enters the seven-membered ring (a six-membered ring after the rearrangement) and in which a chlorine atom in the five-membered ring is librated. The conformations of these molecules were also discussed on the basis of the NMR spectra.

The reaction between tropone and 1, 2, 3, 4-tetrabromocyclopentadiene followed an entirely analogous course; red plates (m. p. 128—129°C) and red prisms (m. p. 90—91°C) were obtained.[2] These compounds were supplied to us so that we could undertake an independent verification of the structures by means of X-ray.

The present paper will describe the structure determination of 1, 2, 3-tribromo-6-(*o*-methoxyphenyl)fulvene.

## Experimental

Crystals of 1,2,3-tribromo-6-(*o*-methoxyphenyl)-fulvene (hereafter termed the "bromo derivative") and 1,2,3-trichloro-6-(*o*-methoxyphenyl)fulvene (hereafter the "chloro derivative") were supplied by Professor Kitahara of Tohoku University. Both of them are stable red laths elongated along the c axis.

From oscillation, Weissenberg and precession photographs of these crystals, the unit cell dimensions and space groups were determined. The crystal and physical data are summarized in Table I.

TABLE I. CRYSTAL AND PHYSICAL DATA

| | Bromo derivative | Chloro derivative |
|---|---|---|
| M. p. | 128—129°C | 117—118°C |
| $a$ | 11.46 Å | 11.65 |
| $b$ | 14.53 | 14.61 |
| $c$ | 7.85 | 7.64 |
| $\beta$ | 96°35′ | 98°58′ |
| Space group | $P2_1/c$ | $P2_1/c$ |
| $Z$ | 4 | 4 |
| $\rho_{obs.}$ | 2.17 g.cm$^{-3}$ | 1.50 |
| $\rho_{calcd.}$ | 2.15 | 1.49 |

Intensity data were collected only for the bromo derivative. Equi-inclination Weissenberg photographs around the c axis were taken with Cu$K\alpha$ radiation for $l$ values from 0 to 6. The crystal used had a cross section of 0.1×0.2 mm. In order to determine the scale factors among the $l$ layers, photographs for zero and first layers around the b axis were taken, also. Reflections from 2060 planes were observed out of 2900 possible ($hkl$)'s. In order to correlate the strong and the weak reflections, a multiple-film technique was applied, the relative intensities being ranged between 1 to 7000. The intensities were measured by a visual comparison with a standard intensity scale prepared with the same crystal. Lorentz and polarization corrections were made in the usual way. Since the main interest of this work was in determining the molecular conformation, the correction for absorption was omitted in spite of its large effect as a

result of the high bromine content. Tentative scale and temperature factors were estimated by Wilson statistics, the latter being $B=3.1$ Å$^2$.

## Structure Determination

The three-dimensional Patterson function was synthesized on an electronic computer (IBM 7040) with a programme written by the authors. Figure 1 shows the Patterson section

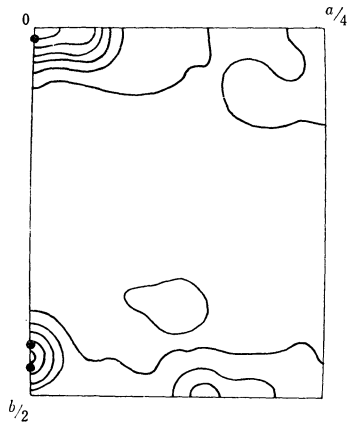

Fig. 1. Harker section $P(u,v,1/2)$. Contours are at equal intervals on an arbitrary scale. Black circles show Br-Br vectors from the final result.

$P(u,v,1/2)$. There should appear on the $u=0$ line peaks due to vectors between atoms related to each other by the c glide operation. Only two significant peaks were observed on this line, however, at $v=0$ and at $v=0.45$. Since there should be three heavy atoms in an asymmetric unit, the peak at $v=0.45$ may be supposed to be a superimposed one due to two independent bromine atoms. Therefore, the $y$ coordinate of one bromine atom was

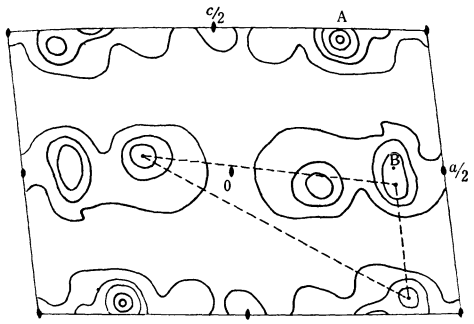

Fig. 2. Harker section $P(u,1/2,w)$. Contours are at equal intervals on an arbitrary scale. Three peaks linked by dashed lines correspond to vectors between the bromine atoms related by two-fold screw axis.

$\pm 0.250$, while those of the remaining two were $\pm 0.025$.

The interpretation of the Harker section at $v=1/2$ was very ambiguous, because there appeared not only peaks between atoms related by a two-fold screw axis, but also peaks between independent atoms, the difference between whose $y$ coordinates are, by accident, a half of the b axis. Figure 2 shows the Harker section $P(u,1/2,w)$.

The first clue to the structure was obtained by examining the intramolecular heavy atom vectors in the three-dimensional Patterson function. Chemical information tells us that three bromine atoms attached to the fulvene ring form a two-lateral triangle whose sides are 3.6, 3.6 and 5.8 Å long. Figure 3 gives a

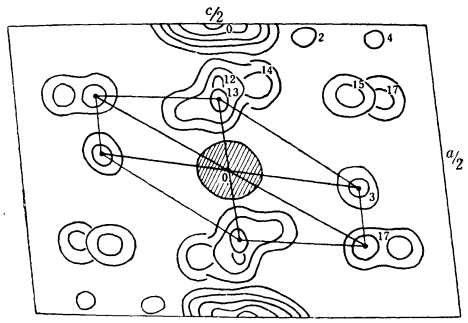

Fig. 3. Three-dimensional Patterson function. Composite diagram of sections parallel to (0 1 0). Height of section is added to each peak in unit of 1/60. Contours are at equal intervals on an arbitrary scale. Black circles show intramolecular Br-Br vector peaks.

composite three-dimensional Patterson function, showing peaks which lie within, say, 7 Å from the point of origin. Although some intermolecular vectors between the bromine atoms were observed at distances of about 4 Å from the point of origin, a constellation of Patterson peaks corresponding to the vector set of such a bromine triangle was clearly recognized, as is illustrated by the solid lines in Fig. 3. With the help of the orientation of the bromine triangle so found, the Harker section at $v=1/2$ was again examined and true Harker peaks were assigned, as is shown by the dash-line triangle in Fig. 2. The atomic coordinates of the three bromine atoms obtained were (0.605, $-0.027$, 0.225) for $Br_1$, (0.310, 0.027, 0.272) for $Br_2$ and (0.301, 0.250, 0.470) for $Br_3$. The non-Harker peak A in Fig. 2 was explained as a vector between the $Br_1$ of one molecule and the $Br_2$ of the molecule related by the c glide, and the B peak, as that between $Br_3$ atoms related to each other by the center of symmetry in different molecules.

Structure factors were computed with these

three bromine atoms with $B=3.1$ Å$^2$, the discrepancy factor, $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$, being 0.45. The first Fourier synthesis of the three-dimensional electron density distribution was carried out with signs based on the three bromine atoms. Significant peaks appearing in the Fourier map gave a reasonable molecular shape. Although some ghost peaks were observed in the map, it seemed quite certain that the molecular structure has been established by this stage. To be more precise, however, only three bromine atoms and five carbon atoms in the fulvene ring were introduced into the second calculation of the structure factors, and the *R* factor dropped to 0.36. The second Fourier synthesis looked very refined, and the coordinates of all the atoms could be read off from it. These coordinates of atoms gave reasonable bond lengths and angles. The third calculation of the structure factors resulted in an *R* factor of 0.30. At this stage, the scaling factors among the layers were corrected by the use of these calculated structure factors. All of these computations were executed on an IBM 7040 with programmes devised by the authors.

The atomic coordinates and temperature factors (anisotropic for the bromine atoms only) were refined by the successive block-diagonal matrix (9×9) least-squares method, the programmes for which were written by Tamaichi Ashida of this laboratory. Each cycle of the refinement on the IBM 7040 using all reflections took about 15 min. After four cycles, the *R* factor decreased to 0.126 (if non-observed reflections were omitted, the *R* factor was 0.113).

The final atomic coordinates and temperature factors of each atom are listed in Tables II and III respectively. The observed and calculated structure factors are shown in Table IV. Figure 4 gives the superimposed (0 0 1) sections of the final electron density distribution as taken through the atomic centers in the molecule.

TABLE II. THE FINAL ATOMIC COORDINATES

| Atom | *x/a* | *y/b* | *z/c* |
|---|---|---|---|
| $Br_1$ | 0.6048 | −0.0195 | 0.2265 |

and the low value of the discrepancy factor obtained by the block-diagonal matrix least-squares refinement guarantee that the three-dimensional molecular structure determined here is quite reliable. Thus the molecular structure of this compound, derived by chemical reasoning, has been verified by independent X-ray analysis.

As was mentioned in the previous paragraph, we used only one chemical fact to interpret the Patterson function, the fact that three bromine atoms combine with the fulvene ring. The first Fourier synthesis, computed with signs based on the three bromine atoms, gave the whole molecular shape definitely. Two low and broad peaks were observed near the position of $C_8$ in the first Fourier synthesis. They were quite a bit lower than those of O and $C_{13}$. Although another molecular model, in which the methoxybenzene rotates by 180° about the $C_6$–$C_7$ bond, seemed to be least probable, we made a least-squares refinement for it. After three least-squares, cycles the ***R*** factor dropped to 0.16 without non-observed reflections ($R=0.18$ including them). A Fourier map corresponding to the last cycle of the least-squares procedure gave peaks whose heights were only 10% of those of the other carbon atoms near these assumed atomic positions (the temperature factors for these atoms became 8.1 and 7.5 Å$^2$ in the least-squares procedure) and rather high peaks at the positions of O and $C_{13}$ where, in this calculation, we did not put any atom. Therefore, the reliability of the present analysis is further confirmed.

This molecular structure explains the NMR spectra well. For example, the $H_6$ signal of this compound (7.63 p. p. m.) shifts into a field lower by 0.41 p. p. m. than that of the *p*-methoxy compound (7.22 p. p. m.). The shift may be due to the magnetic anisotropy of the oxygen atom which is disposed near the hyrogen, $H_6$, in this configuration.

The bond lengths and angles are illustrated in Fig. 5. The average estimated standard deviations of the coordinates are 0.003, 0.022 and 0.015 Å for bromine, carbon and oxygen atoms respectively. Therefore, the estimated standard deviations of the bonds are 0.022 Å for C–Br, 0.027 Å for C–O, and 0.031 Å for C–C. In the fulvene ring, $C_1$–$C_2$ and $C_3$–$C_4$ may be double bonds, the mean bond length being 1.31 Å. The bonds $C_2$–$C_3$, $C_4$–$C_5$ and $C_5$–$C_1$ are thought to be single bonds, their mean length being 1.48 Å. The bond $C_5$–$C_6$ seems to be double, and the C–C distances in the benzene ring are within the range from 1.36 to 1.44 Å. The lengths of $C_{12}$–O (1.39 Å) and O–$C_{13}$ (1.46 Å) are reasonable if the standard deviations in the bond lengths are allowed for. The mean C–Br distance is 1.86 Å, in good agreement with the normal value of this pair (1.85 Å).[3]

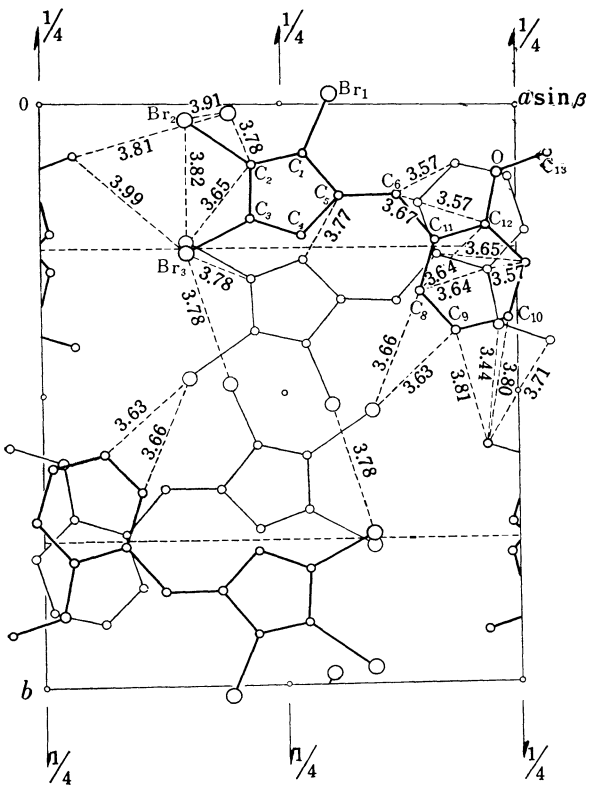

Fig. 6. Arrangement of molecules in the unit cell viewed along the c axis, with short intermolecular distances (Å).

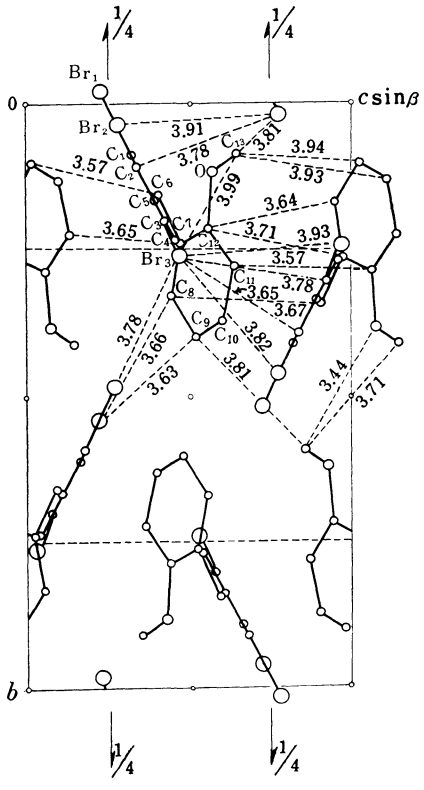

Fig. 7. Arrangement of molecules viewed along the a axis.

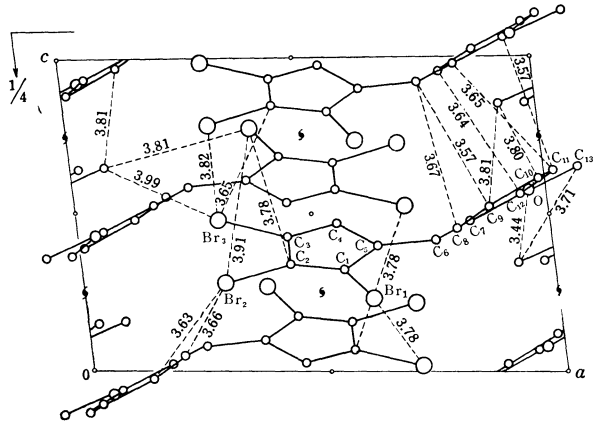

Fig. 8. Arrangement of molecules viewed along the b axis.

The benzene ring is approximately planar, the best plane being represented by the equation;

$$Y=-12.76X+27.80Z+51.01$$

where $X=x\sin\beta$, $Y=y$, and $Z=z+x\cos\beta$. The coefficients were determined by the least-squares method. The fulvene ring is also nearly planar, the best plane being described by the equation:

$$Y=0.1836X+1.859Z-3.159$$

The perpendicular displacements of the atoms from these mean planes are listed in Table V. The plane of the benzene ring makes an angle of 38°54′ with the plane of the fulvene ring. This angle between two planes mainly occurs as a result of the twisting about the bond $C_6$–$C_7$. The distance between the non-bonded atoms $C_4$ and $C_8$ is 3.21 Å; contact between

TABLE V. DEVIATIONS FROM THE LEAST-SQUARES PLANES (Å)

| Atom | From the benzene plane | Atom | From the fulvene plane |
|---|---|---|---|
| $C_7$ | 0.03 | $C_1$ | 0.00 |
| $C_8$ | −0.02 | $C_2$ | −0.01 |
| $C_9$ | −0.00 | $C_3$ | 0.01 |
| $C_{10}$ | −0.03 | $C_4$ | −0.00 |
| $C_{11}$ | 0.02 | $C_5$ | 0.00 |
| $C_{12}$ | 0.00 | $Br_1$ | 0.10 |
| $C_1$ | 0.61 | $Br_2$ | 0.12 |
| $C_2$ | 1.36 | $Br_3$ | −0.07 |
| $C_3$ | 1.98 | $C_6$ | 0.07 |
| $C_4$ | 1.56 | $C_7$ | 0.04 |
| $C_5$ | 0.67 | $C_8$ | −0.77 |
| $Br_1$ | −0.30 | $C_9$ | −0.75 |
| $Br_2$ | 1.79 | $C_{10}$ | 0.01 |
| $Br_3$ | 3.09 | $C_{11}$ | 0.83 |
| $C_6$ | 0.03 | $C_{12}$ | 0.77 |
| O | 0.04 | O | 1.53 |
| $C_{13}$ | −0.15 | $C_{13}$ | 2.20 |

them might cause this twisting. If the positions of the hydrogen atoms bonding to $C_4$ and $C_8$ are estimated with conventional C–H length and angles, the distance between them is approximately 1.9 Å; this value might be reasonable for the contact of such hydrogens.

The methyl group in the methoxy group deviates from the plane of the benzene ring, the $C_{11}$–$C_{13}$ distance being 2.82 Å. Three bromine atoms and $C_6$ are out of the plane of the fulvene ring, probably because of the mutual repulsion among these substituted atoms and this group. The $Br_1$–$Br_2$, $Br_2$–$Br_3$ and $Br_1$–$C_6$ distances are 3.56, 3.56 and 3.29 Å respectively.

Figures 6, 7 and 8 show the crystal structures projected along the c, a and b axes respectively. If the van der Waals radii of the bromine, oxygen and methyl groups are taken to be 1.95, 1.40 and 2.0 Å respectively, and if the half thickness of the aromatic ring is 1.70 Å, as is usually accepted, all the intermolecular approaches observed are equal to or longer than the sums of the radii of the corresponding atoms within the range of errors. It might be concluded from Figs. 6, 7 and 8 that the molecules are well packed by the van der Waals interactions. The benzene rings which are related to each other by the c glide plane are nearly parallel, because the plane of any benzene ring makes a very small angle with the b axis. Therefore, these nearly parallel benzene rings are piled up at a distance of about 3.5 Å in the direction of the c axis, as may be seen from Fig. 8.

Although the dipole moment of the present compound has not been measured, it is, expected to show a considerable value, judging from the value of the related chloro derivative (4.72D). If the crystal structure of the present compound is discussed in view of the arrangement of such dipolar molecules, it may be compared to that of 3-bromo-2-methoxytropone,[4] although there is a slight difference in the direction of the glide planes, the c glide in the former and the a glide in the latter.

From the similarity of the unit cell dimensions between the present crystal and that of the chloro derivative, it may be deduced that the molecular packing of the latter is essentially the same as that of the former, which has been described here.

We wish to express our deep thanks to Professor Yoshio Kitahara and Dr. Ichiro Murata of Tohoku University for supplying the materials and for their helpful discussions. We are also grateful to Dr. Tamaichi Ashida and all our collaborators for their kind suggestions on the structure analysis and computing programmes, while we are indebted to the staff of the computing center of Teijin Co., Ltd., for the numerical calculations.

# The Heat Capacity and the Entropy of Transition of Würster's Blue Perchlorate

By Hideaki CHIHARA, Minoru NAKAMURA and Syûzô SEKI

(Received May 4, 1965)

Würster's Blue perchlorate

$$[(CH_3)_2N\text{-}C_6H_4\text{-}N\text{-}(CH_3)_2]^+ ClO_4^-$$

is one of the free radical crystals that are stable at room temperatures. Other similar crystals include those of diphenylpicryl hydrazyl (DPPH) and 1, 3-bisdiphenylene-2-phenyl allyl (BDPA), which are believed to become antiferromagnetic below 1.73 and 0.2°K respectively.[1] The heat capacity measurements of BDPA indicated the occurrence of linear antiferromagnetic chains below its Néel point; the heat capacity shows a sharp spike at 1.73°K and a broad maximum at higher temperatures, centering at about 3°K.[2] The magnetic properties of BDPA and DPPH are also consistent with the idea of spin ordering into an antiferromagnetic array at low temperatures.

Würster's Blue perchlorate, on the other hand, has a transition at a relatively high temperature (190°K), as is revealed by the magnetic susceptibility measurements.[3] This transition has sometimes been referred to as antiferromagnetic transition. McConnell's electron spin resonance studies[4] showed the existence of a triplet exciton state below the transition temperature and give support to Hausser's idea that the cation radicals are dimerized to give a singlet ground state and a triplet excited state.[5] Chesnut[6] presented a simple theory, based on these experimental facts, to account for the transition in terms of cooperative interaction between triplet excitons.

The present paper will describe some results of the measurements of the heat capacities of powdered Würster's Blue perchlorate, measurements conducted in an attempt to discriminate among various possible mechanisms of the transition.

## Experimental

The calorimeter, the cryostat, and their operations were the same as have been described previously.[7]

Fine flakes of Würster's Blue perchlorate (WB) were a donation from Dr. K. Suzuki of Kwansei Gakuin University, who will describe their preparation elsewhere. The molar magnetic susceptibility of the specimen as received was $1.28\times10^{-3}$ e.m.u./mol. at room temperature (12°C), which corresponded to that of about 100% free radical; it did not show any change after having been stored in dark, dry air for a year. As the amount of the specimen available was small, only 0.7079 g. or 0.002684 mol., of powdered WB was used in the measurement of the heat capacity; as a result, the error in the heat capacity values amounted to about 2% under the most unfavorable conditions, when the empty calorimeter contributed about 3/4 to the total heat capacity. The results of the measurements to be reported in the following section are for the fresh WB of a 100 ±3% free radical. After these measurements in the copper calorimeter with a few mmHg of helium exchange gas in it, the specimen was stored in situ for about half a year, during which time the apparata were moved to the North Campus of the University. The second series of runs which were then taken did not give consistent results in the phase transition region; however, the normal portion of the heat capacity agreed with that obtained in the first series of runs within the range of experimental error. The molar magnetic susceptibility after the second run was about 73% of the intial value for the fresh WB.

## Results and Discussion

The primary experimental results are plotted in Fig. 1. There is a sharp rise in the heat capacity at 189.9°K, with a tail extending down to about 160°K. Although the temperature did not exactly stop at the transition point, it is highly probable that the transition is of the first order. Two independent runs were performed for the determination of the enthalpy change of the transition; it was 408.6±4.5 cal./mol. The entropy of the transition was 2.19±0.02 cal./deg.mol. It should be noted that this entropy change is very close to $R \ln 3$, which is 2.18 cal./deg.mol.

The temperature of the transition has been reported differently by different investigators: Duffy's susceptibility curve[3] shows a sudden decrease at 186°K, Okumura's one[3] at 189°K, Edelstein[1] gave 175±5°K, and Suzuki's differential thermal analysis[8] showed a peak at about 190°K. The present study agrees with Suzuki's probably because specimens from the same batch were used in both experiments. As has been mentioned in experimental section, the lowering of the transition temperature may be due to the partial dying of the free radicals.

We shall now compare our experimental results with several models hitherto presented to account for this transition.

**a) The Paramagnetic-antiferromagnetic Scheme.**—The shape of the curve showing the temperature dependence of the susceptibility near 190°K is similar to that in an antiferromagnetic, as has been pointed out by Elliot and Wolfsberg[9] and by Duffy[3]. Edelstein[1] developed a theory for a linear Ising chain of half spins and applied it successfully to the cases of BDPA and PAC. Here inter-chain coupling was approximated by the molecular field treatment. However, although he estimated the intra-chain exchange intergral for WB as $J/k = -27 \pm 10$, he did not explicitly mention that WB was an antiferromagnetic. Also, Duffy and Okumura pointed out that the Curie temperature, $|\theta| =$ 23°K, derived from the high temperature susceptibilities is too small, compared to the transition temperature, for an antiferromagnetic transition. The entropy of the transition to be predicted for such a scheme is $R \ln 2$; the experimental results can rule out such possibility if the transition arises solely from an order-disorder problem of the spin system. If an attempt is made to divide the total entropy of the transition into contributions from the latent heat portion and those from the low temperature tail of Fig. 1, the latter amounts to 1.36 cal./deg.mol. and is close to what one would expect for an antiferromagnetic transition. The rest of the entropy would then come from some structural changes. In fact, X-ray diffraction studies, cited by McConnell,[4b] show that the transition is accompanied with a small structural change from the room-temperature orthorhombic phase to the low temperature monoclinic phase. The X-ray density does not appear to change substantially, and the angular tilt is only 2.7°. A single crystal does not shatter in going through the transition. It is difficult to assess the entropy of a structural change, but it should come from a variation in the lattice frequency spectrum, which must also be seen in the normal part of the heat capacity below and above the transition point. As the smooth dash-line curve in Fig. 1 suggests, such a variation would appear to be small.

**b) The Dimerization Scheme.**—Hausser's study[5,10] of the electronic absorption spectra of WB in solution and in solid is believed to indicate the presence of dimerized species in solid WB at low temperatures. Suzuki's spectroscopic study also supports this view.[11] The idea of dimerization has, moreover, been indirectly substantiated by McConnell's electron spin resonance studies, in which the triplet exciton resonance, free from a nuclear hyperfine structure, was observed at low temperatures. The X-ray diffraction findings that the unit cell lengths become doubled in the directions of the a and b axes can also be regarded as showing that dimerization occurs at the transition temperature. From the temperature dependence of the ESR signal intensity, McConnell was able to derive the energy of exitation from the ground singlet state to the triplet exciton state of a dimer as 246 $cm^{-1}$. The heat capacity should see the consequence of this energy gap that a Schottky-type anomaly occurs, with the maximum of 1.02 cal./deg.mol. at 123°K. Unfortunately, no anomaly of this magnitude is discernible in Fig. 1 because of the lack of precision in the measurements. A simple calculation shows, however, that the total gain in entropy due to the Schottky anomaly is $(1/2)\ R \ln 4$ and that about 69% of this would have been acquired when the crystal reaches the transition point. Therefore, the transition would be concerned only with the dissociation of the dimerized species and the rest of the spin disordering. The dissociation does not itself contribute to the entropy, except, of course,

for the structural change which accompanies it.

The entropy of spin disordering at the transition is, thus, no larger than 31% of $(1/2)\boldsymbol{R}\ln 4$, or 0.42 cal./deg.mol., even if it is assumed that the rest of the Schottky anomaly is replaced by the cooperative disordering of spins.

c) **Exciton Interaction.**—Since the formation of cation dimers in WB at low temperatures and the excitation transfer of the triplet level of the dimers have been well established, another possible approach to the mechanism of the transition would be to incorporate the cooperative interaction between the excitons. Chesnut[6] showed that a type of order-disorder transition does occur if one includes in the interaction a term which is quadratic in the excitation density, $\rho$, and writes the Helmholtz energy for the $N$ cations as:

$$F=\frac{1}{2}N[\varepsilon_0\rho+\frac{1}{2}\varepsilon_1\rho^2-\boldsymbol{k}T\{\rho\ln g-\rho\ln\rho-(1-\rho)\ln(1-\rho)\}]$$

where $g$ is the multiplicity ($g=3$), $\varepsilon_0$ is the singlet-triplet excitation energy, and $\varepsilon_1$ is the inter-exciton energy. The justification for the quadratic energy term has already been discussed.[12,13] A diffuse first-order transition stems from the Helmholtz energy expression, and the entropy change will be:

$$\Delta S=\frac{1}{2}\boldsymbol{R}\Delta\rho\ln g$$

where $\Delta\rho$ is the change in the excitation density at the transition. The total entropy of the transition will now be:

$$\Delta S=\frac{1}{2}\times\frac{3}{4}\boldsymbol{R}\ln 3=0.82\ \text{cal./deg.mol.}$$

at the maximum since, in the limit of high temperature, the population in the triplet state would be $(3/4)N$.

We have now evaluated three possible interpretations of the transition and have found that no single mechanism can satisfactorily account for the observed change in entropy by the transition, 2.19 cal./deg.mol. Actually, if one considers only the spin system as the source of entropy creation at the transition, it is almost hopeless to get a larger value than $\boldsymbol{R}\ln 2$ out of it. One of the recourses in such a situation is to assume some disordering in the orientation of perchlorate ions; this, however, has not been substantiated in WB experimentally. If this tetrahedral ion can assume one of two equally probable orientations in the high temperature phase and can then become frozen in either one of them at low temperatures, an entropy of $\boldsymbol{R}\ln 2$ would appear at the transition point. In fact, the combination of this type of disorder with the mechanism c, or the exciton cooperation, gives the total entropy of 2.20 cal./deg.mol., a value which is very close to what has been found by experiment. A refined X-ray diffraction study will give us some direct clue to the answer of this problem.

## Summary

The heat capacity of Würster's Blue perchlorate (*N, N, N', N'*-tetramethyl-*p*-phenylenediamine perchlorate) has been measured between 66 and 200°K. A phase transition occurs at 189.9°K with its tail extending down to about 160°K. The transition is probably of the first order. The heat and the entropy of the transition are 408.6±4.5 cal./mol. and 2.19±0.02 cal./deg.mol. respectively. The magnetic susceptibility of the specimen at room temperature indicates that the paramagnetic spin density is 100±3%. The experimental results have been compared with current theories, and it has been inferred that some unknown structural changes are involved in the phase transition.

The authors would like to thank Professor Keisuke Suzuki of Kwansei Gakuin University, who gave us a sample of Würster's Blue perchlorate; the discussions with him have been helpful. The measurements of the magnetic susceptibility made, at our request, by Dr. Shuichi Tazawa of Osaka University helped to solve inconsistencies in the primary heat capacity results; to him the authors' deep gratitude is extended. Thanks are also due to Dr. Takako Shinoda, who helped us in part of the measurements.

# Phase Transitions in Crystalline Divalent Metal Dicalcium Propionates. I. Calorimetric and Dielectric Investigations of Strontium- and Lead Dicalcium Propionates

By Nobuo NAKAMURA, Hiroshi SUGA, Hideaki CHIHARA and Syûzô SEKI

(Received May 6, 1965)

There are three substances known as the double propionates of divalent metals: barium-, strontium- and lead-dicalcium propionates. The room temperature modification of the barium salt is known to be cubic.[1] The X-ray crystal structure analysis of this phase was made in 1935 by Nitta and Watanabé,[2] and also, independently, by Harris and Biefeld,[3] and its space group was found to be $O^4$–$F4_13$. In 1951, it was found in our laboratory by the use of the calorimetric method, that this material undergoes a phase transition at −8.5°C.[4] Taking account of the crystal symmetry and molecular shape, this phase transition was supposed to be a kind of order-disorder type with regard to the motion of the propionate anions in the crystal lattice.

In the case of strontium salt, the spontaneous polarization was measured by Matthias and Remeika in 1957; it was thus revealed that this salt becomes ferroelectric below 8.5°C.[5] The crystal symmetry of this compound at room temperature is tetragonal,[1] and the ferroelectric axis is the c-axis. Orioli and Pieroni applied the X-ray method to this salt in 1959 and proposed a probable space group, $D_4^4$–$P4_12_12$ or $D_4^8$–$P4_32_12$; they also determined the positions of the heavy atoms.[6] The crystal symmetry and the space group of the lower temperature phase was determined by Kobayashi and Yamada in 1962, the modification being found to be tetragonal, while the space group is either $C_4^4$–$P4_3$ or $C_4^3$–$P4_2$.[7]

The lead salt at room temperature is of tetragonal symmetry and is isomorphous to the strontium salt.[1] Using the differential thermal analysis method, the authors have found a new phase transition at about −80°C. The crystal structure analysis of its room temperature phase was made by Ferroni and Orioli in 1959; they obtained a structure similar to that for the room temperature phase of the strontium.[8] Yamada analyzed the lower temperature phase of the compound and found that it to be of tetragonal symmetry, the space group being either $C_4^4$ or $C_4^3$.[9]

It seems highly desirable to obtain further information about the mechanism of the phase transitions of these three compounds. For this purpose, the present authors have studied the thermal properties of the strontium- and the lead salts and the dielectric properties of the lead salt. In the present paper, such experimental data will be presented, and the mechanisms of the phase transitions in these two salts will be discussed.

## Experimental Procedures

**Materials.** — *a)* $SrCa_2(CH_3CH_2CO_2)_6$.—An aqueous solution of sodium carbonate (extra pure grade, manufd. by Wako Chem. Ind., Ltd.) was added to an aqueous solution of strontium chloride (Merck). The strontium carbonate precipitates were then washed with water and dried at 40°C. Powdered strontium carbonate and calcium carbonate were mixed together in the molar ratio of 1 : 2, and the mixture was dissolved in an aqueous solution of propionic acid, which, by evaporation at 40°C, yielded colorless crystals. The crystals obtained were, then, recrystallized from an aqueous solution, fed into the calorimeter vessel, and then dried in a vacuum of $10^{-4}$ mmHg at room temperature for about 30 hr.

*b)* $PbCa_2(CH_3CH_2CO_2)_6$. — The sample for the calorimetric study was prepared by a method similar to that used for strontium salt. Lead carbonate was prepared from lead dichloride (extra pure grade, manufd. by Wako Chem. Ind., Ltd.) and sodium carbonate (see in a)). For the measurement of the dielectric constant, the sample for calorimetry was dissolved again in water and kept at 25°C in a thermostated bath for about 20 days, in order to grow a single crystal about 15 mm. across. Disk specimens were then cut out with the

parallel planes corresponding to the crystallographic (110) and (001) planes. The directions of the axes were identified by taking Laue photographs. For the dielectric measurements, the specimen was sandwiched between the electrodes and dried in situ under $10^{-5}$ mmHg pressure for 5 hr. at room temperature.

**Calorimetry.** — The calorimetric measurements were made on single loadings of 25.97 g. (0.04287 mol.) and 29.53 g. (0.04071 mol.) for the strontium and the lead salts respectively. The measurements were carried out with an adiabatic calorimeter in the temperature region from 15 to 300°K. The details of the apparatus and the methods of operation have already been described.[10]

**Dielectric Measurements.** — The dielectric constants of the lead salt were measured for the planes (100) and (001) with a Cole-type mutual-inductance bridge (Ando Elec. Co., Ltd.) in the frequency range between 100 c.p.s. and 1 Mc.p.s., covering the temperature region from the liquid nitrogen temperature to 90°C. Temperatures were measured with two copper-constantan thermocouples attached to the electrodes; the errors are estimated to be within 0.5°. The details of the apparatus and the method. of operation have been described elsewhere.[11]

**Dilatometry.**—By using a simple glass-tube dilatometer, with mercury as the confining liquid, a preliminary dilatometric study was carried out with a powdered specimen of the lead salt in the temperature region from room temperature to 70°C.

## Experimental Results

**The Thermodynamic Properties of $SrCa_2(CH_3CH_2CO_2)_6$ and $PbCa_2(CH_3CH_2CO_2)_6$.**— The heat capacity curves for the strontium and the lead salts obtained are shown in Figs. 1 and 2 respectively. The smoothed values of the heat capacities, enthalpies, entropies and Gibbs energy functions are tabulated in Tables I and II for the strontium and lead salts respectively. These values are expressed in terms of the defined thermochemical calorie, equal to 4.1840 absolute joules. The ice point is taken to be 273.15°K. The experimental errors in the heat capacity were estimated to be within 1% and 0.3% in the liquid hydrogen and the liquid nitrogen temperature regions respectively. The thermodynamic functions at the standard state are shown in Table III.

As a result of this experiment on the strontium salt, we found a new phase transition at 104°K. At an ordinary cooling rate, the temperature of the calorimeter went down to the liquid hydrogen temperature with no indication of any transition. When the calorimeter was then heated, an exothermic effect appeared at around 83°K, and the crystal was

transformed into the stable lower temperature phase, as is shown in Fig. 1. The heat capacities of the stable and the metastable phases below the transition point are nearly equal within the range of experimental error and, therefore, the exothermic effect does not modify the interpretation of the results given in the following section.

For the lead salt, we also found two phase transition phenomena, as will be mentioned later. The upper transition, however, was not studied by the calorimetric method because of the limited capability of the apparatus. Table IV lists the transition temperatures and the heats and the entropies of transition obtained for the strontium and lead salt, together with those previously obtained for the barium salt for the sake of comparison.

**The Dielectric Properties of $PbCa_2(CH_3CH_2CO_2)_6$.**—As is shown in Fig. 3, the dielectric constants in each crystallographic plane, measured only in the cooling direction, jump abruptly at about 183°K; this temperature corresponds to the transition temperature observed by the

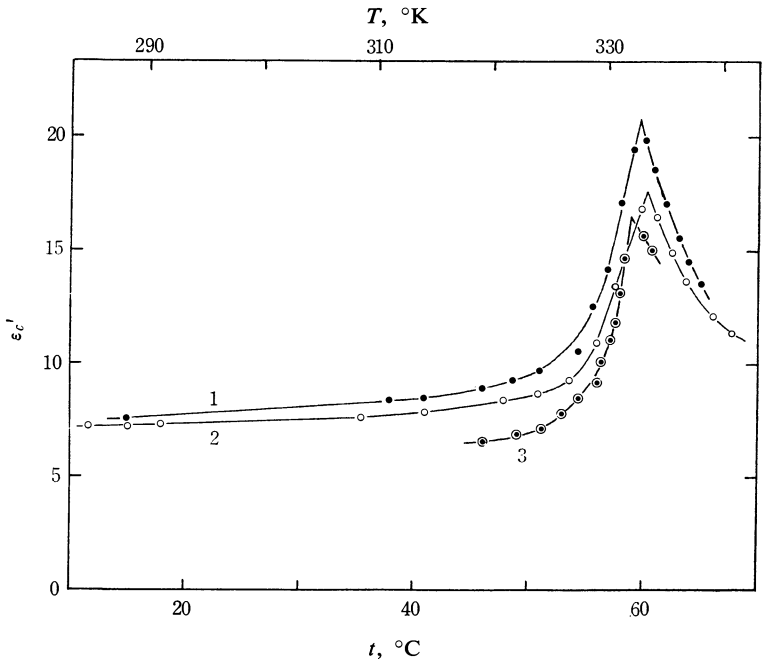

Fig. 4. Frequency dependence of dielectric constant of $PbCa_2(CH_3CH_2CO_2)_6$ (parallel to c-axis).
Curve 1: 300 c.p.s. Curve 2: 1 kc.p.s. Curve 3: 10 kc.p.s.

calorimetry, as has been mentioned above. The discrepancy in the transition temperatures found by these two methods may be due to thermal hysteresis, accompanied by a phase transition. The crystals were shattered below this temperature, and measurements in the heating direction were not possible.

No anomalous dispersion was observed in the temperature region from that of liquid nitrogen to room temperature. On further heating, we found another anomaly, around 60°C, in both directions; it is more prominent when the electric field is perpendicular to the (001) plane. The maximum temperature of the $\varepsilon'$ seems to be independent of the frequency, as is shown in Fig. 4.

With regard to this dielectric anomaly, further study was made by use of a dielectric hysteresis bridge,[12] but no hysteresis phenomenon characteristic of ferroelectricity and/or antiferroelectricity was detected either above or below this transition point. For the lower transition (183°K), no such experiment was attempted, because it has already been shown by Remeika that the crystal is not ferroelectic below room temperature.[13]

**The Thermal Expansion of $PbCa_2(CH_3CH_2CO_2)_6$.**—The results of the dilatometry of the lead salt are shown in Fig. 5. A conspicuous change in the expansion coefficient was detected at about 58°C, a change which corresponds to the anomaly found by the dielectric method. The shape of the change is indicative of what is called a higher-order transition.

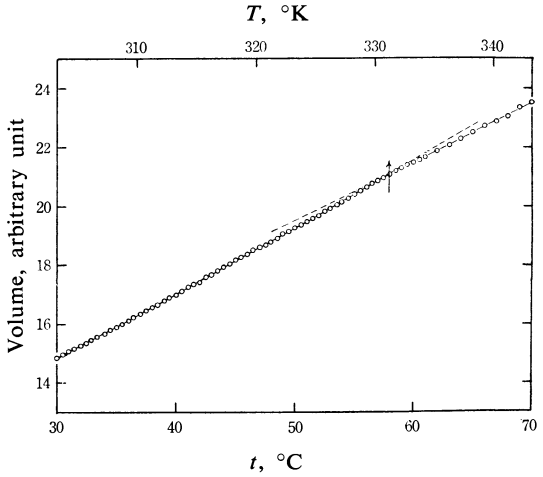

Fig. 5. Volume expansion of $PbCa_2(CH_3CH_2CO_2)_6$.

## Discussion

**$SrCa_2(CH_3CH_2CO_2)_6$.**—As the crystal structure is not precisely known, it seems difficult to propose a detailed molecular mechanism of

the ferroelectric phase transition. However, by a comparison of the crystalline data given in Table V with those for the barium salt, of which a much more precise X-ray analysis has been carried out, and also from the behavior of the heat capacity curve, it would be reasonable to assume for the strontium salt a kind of orientational order-disorder transition with respect to the methyl groups in the propionate anions.

In the room temperature phase, each methyl group must be found at two equivalent positions with an equal probability in order to satisfy the required two-fold symmetry about the axis connecting the carboxyl- and the $\alpha$ carbon atoms. Figure 6 illustrates one of the possible models assumed for this modification, the orientational disorder of the methyl groups being indicated by broken lines.

For the lower temperature phase, only the space group has been determined by Kobayashi and Yamada.[7] However, it would be plausible to consider that such disorder would gradually disappear as the absolute zero of temperature is approached. Thus, in the ordered state, each methyl group will be located in only one of the crystallographically equivalent sites of the two possible orientations (broken lines) depicted in Fig. 6(b).

If these two different structures are assumed for the higher and the lower temperature phases, the phase transition between them may be treated, as a first approximation, by the Bragg-Williams theory. According to this theory, with $T_t=282.6$°K determined by calorimetry, the potential difference between the two possible sites of a methyl group becomes 560 cal. mol$^{-1}$. As both the upper and the lower temperature phases have a tetragonal symmetry, it may be anticipated that, among the six propionate anions in the unit cell, only four, those in which the $C_{carboxyl}$–$C_\alpha$ axes are in the c-plane of the crystal, contribute to the phase transition. The height of the jump in heat capacity and the entropy change associated with the transition can be obtained theoretically, the values being calculated to be 11.9 cal. mol$^{-1}$ deg$^{-1}$ and 5.5 e.u. respectively. The experimental values are, on the other hand, 5.7 cal. mol$^{-1}$ deg$^{-1}$ and 0.6 e.u. for the heat capacity jump and the entropy of transition. The agreement beween the theoretical and the experimental values is thus not very good; this suggests that the short range or other correlations, including the heavy atoms, should be taken into consideration in a more detailed discussion.

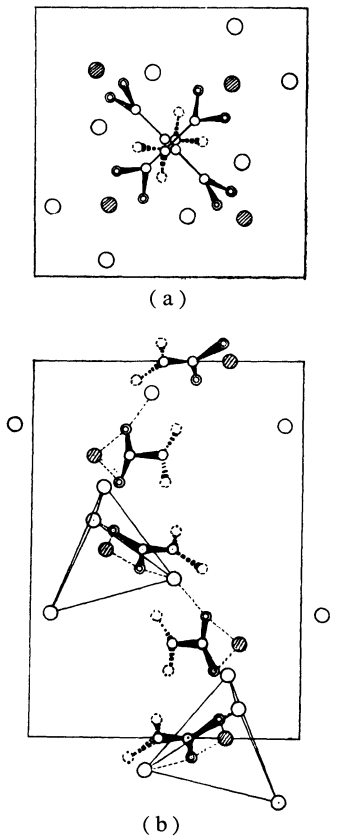

Fig. 6. Crystal structure of $SrCa_2(C_2H_5CO_2)_6$.
(a) (001) projection, (b) (100) projection
Sr Ca C O

In the next place, we should like to proceed to the problem of the temperature dependence

of the spontaneous polarization, $P_s$. The greater part of the $P_s$ value may arise from the displacement of the metallic cations relative to the negative propionate anions, and by the electronic polarization of the large oxygen atoms. However, it seems reasonable to assume as the 1st approximation, that, each propionate anion having a small dipole moment, the change in the direction of this dipole moment, accompanied by some kind of motion in the methyl group, reflects the change in the macroscopic $P_s$ value. The motions responsible for the effective change in this quantity may be assumed to consist of the torsional oscillation of the methyl group about the $C_{carboxyl}$–$C_\alpha$ axis, and also of the population difference between the two possible sites of the methyl groups mentioned above. Here we may assume that the magnitude of a dipole moment of one propionate anion, $\mu_0$, at absolute zero will decrease to $\mu_0 \cos\theta$ when the methyl group of the anion rotates about the $C_{carboxyl}$–$C_\alpha$ axis through an angle, $\theta$, around its equilibrium position at elevated temperatures. In the simple harmonic approximation, the potential function, $U$, is represented by $U=1/2\,\kappa\theta^2$; where $\kappa$ is the effective force constant for the torsional oscillation of the methyl group. According to classical statistical mechanics, the mean value of the dipole moment at a given temperature, $T$, $\overline{\mu_{vib}(T)}$, is given by:

$$\overline{\mu_{vib}(T)} = \frac{\int \mu_0 \cos\theta \exp(-U/\boldsymbol{k}T)\,d\theta}{\int \exp(-U/\boldsymbol{k}T)\,d\theta} = \frac{\int \mu_0 \cos\theta \exp(-\kappa\theta^2/\boldsymbol{k}T)\,d\theta}{\int \exp(-\kappa\theta^2/\boldsymbol{k}T)\,d\theta} = \mu_0 \exp(-\boldsymbol{k}T/2\kappa) \quad (1)$$

where $\boldsymbol{k}$ is the Boltzmann constant; the kinetic part of the partition function was not considered because it is not relevant to the present discussion.

Another contribution which decreases the mean value of the dipole moment comes from the inversion of the moment due to the order-disorder transition. In the Bragg-Williams approximation, an order parameter $x$ is introduced which varies from unity at completely ordered, to zero at completely disordered, states. Therefore, the probability of the moment being in one of the positions is given by $(1/2)(1+x)$, and that of its being in the other, inverse, position, by $(1/2)(1-x)$.

If the contributions from the torsional oscillation, as well as from the order-disorder transition, are taken into account, the effective dipole moment at $T$°K is represented by:

$$\overline{\mu(T)} = \mu_0 \exp(-\boldsymbol{k}T/2\kappa)\{1/2(1+x) - 1/2(1-x)\} = \mu_0 x \exp(-\boldsymbol{k}T/2\kappa) \quad (2)$$

where the force constant for the torsional osillation is assumed to be the same for the two sites of the methyl group. The macroscopic spontaneous polarization, $P_s(T)$, at $T$°K becomes:

$$P_s(T) = N\mu_0 x \exp(-\boldsymbol{k}T/2\kappa) = P_s(0)x \exp(-\boldsymbol{k}T/2\kappa) \quad (3)$$

by the use of Eq. 2, where $N$ is the number of those propionate anions per unit volume that have their $C_{carboxyl}$–$C_\alpha$ axes in the c-plane, and where $P_s(0)$ is the spontaneous polarization at absolute zero.

The value of $\kappa$ was evaluated semi-quantitatively from Eq. 3, using the $P_s(0)=0.6$ coulomb $cm^{-2}$ value obtained by the extrapolation of the experimental $P_s$ vs. $T$ curve[5,7] to absolute zero, and fitting the theoretical $P_s(T)$ to the experimental data at 188°K or at 262°K. The values obtained are 1.1 and $1.6\cdot10^{-3}$ md. $Å^{-1}$ respectively. Figure 7 shows the experimental[5,7] and the theoretical $P_s$ curves calculated for these two $\kappa$ values (curves 1, 2 and 3). The agreement of the experimental and the theoretical curves is fairly good if the difficulties in the accurate measurement of the spontaneous polarization are taken into account.

Now that the force constant, $\kappa$, and $\overline{\mu_{vib}(T)}$ have been obtained, we may discuss the mean maximum amplitude of the torsional oscillation of the methyl groups at each temperature on the basis of classical statistical mechanics. If the mean maximum amplitude of oscillation is represented by $\theta_1$, the mean value of the dipole moment, $\overline{\mu_{vib}(\theta_1)}$, can be given as follows:

$$\overline{\mu_{vib}(\theta_1)} = \int_{-\theta_1}^{+\theta_1} \mu_0 \cos\theta \cdot p(\theta)\,d\theta \Big/ \int_{-\theta_1}^{+\theta_1} p(\theta)\,d\theta = \mu_0 \cdot J_0(\theta_1) \quad (4)$$

where $p(\theta)$ is the probability of the dipole being rotated by an angle, $\theta$, and $J_0(\theta_1)$ the Bessel function of zeroth order. It may easily be shown that $p(\theta)$ is proportional to $(\theta_1^2-\theta^2)^{-1/2}$. By setting $\overline{\mu_{vib}(\theta_1)}$ to be equal to $\overline{\mu_{vib}(T)}$ in Eq. 1, $\theta_1$ can be calculated for each temperature. The results of the calculation for the two $\kappa$ values are shown in Fig. 7 (curves 4 and 5). The force onstant, $\kappa$, and the mean amplitude, $\theta_1$ will be discussed in a following paper.

The features of the newly-found phase transition of this crystal at 104°K were described

in the previous section. Recently, Kobayashi informed us that there is a slight, discontinuous change in $P_s$ values at about −177°C.[14] However, more detailed analyses for this transition phenomenon will require other experimental data, especially on the crystal structure of the lowest temperature phase.

**$PbCa_2(CH_3CH_2CO_2)_6$.** — In this salt, the enthalpy and entropy changes for the phase transition at 191.5°K are larger than those of the strontium salt, and it is noticeable that the value of $\Delta S_t = 5.8$ e.u. is rather close to that for the barium salt[4] (see Table IV).

If the mechanism assumed for the strontium and barium salts also applies to this salt, the calculated value of the entropy of transition, 5.5 e.u., agrees fortuitously well with the experimental value of 5.8 e.u.

The phase transition at about 60°C found by dielectric and dilatometric measurements may be due to some displacement of the metallic ions,* but no detailed discussion can be made at present.

No possibility of the appearence of ferroelectricity in the lead- and barium salts has been confirmed by Remeika below room temperature,[13] or by the present work for the phase above 60°C. The considerable difference between the dielectric properties of the strontium salt and those of the lead salt as well as of the barium salt is difficult to interpret from only the standpoint of the motions of the propionate anions assumed in the present paper.

A detailed discussion of the difference in the behavior of the propionate anions in these salts will be made in the following paper.

14) J. Kobayashi, Private communication.

* A preliminary X-ray analysis was undertaken for a powdered specimen of the lead salt, above 60°C; it was thus found that the symmetry of the phase is lower than cubic.

## Summary

Heat capacities have been measured for strontium and lead dicalcium propionates from 15 to 300°K with an adiabatic-type calorimeter in connection with the ferroelectric phase transition of strontium salt. The heat capacities, enthalpies, entropies and Gibbs energy functions in the standard state have been determined. For the strontium salt, the transition temperature, the heat of transition, and the entropy of transition for the ferroelectric phase transition are 282.6°K, 159.6 cal. $mol^{-1}$, and 0.6 e.u. respectively. Another phase transition was discovered at 104°K; the heat and entropy of this transition amount to 255 cal. $mol^{-1}$ and 3.2 e.u. respectively.

For the lead salt, a phase transition was found at 191.5°K, and the heat and the entropy of the transition are 1160.0 cal. $mol^{-1}$ and 5.8 e.u.

respectively. Low frequency dielectric constants have been measured for the lead salt from the liquid nitrogen temperature to 90°C. A discontinuous change in the dielectric constants at 183°K and another dielectric anomaly at 60°C have been observed. The absence of evidence of ferroelectricity above room temperature has also been confirmed.

The ferroelectric phase transition of the strontium salt has been treated by the Bragg-Williams theory. The temperature dependence of the spontaneous polarization has tentatively been interpreted with torsional oscillations of the methyl groups of the propionate anions.

The authors wish to express their thanks to Professor Jinzo Kobayashi of Waseda University for his helpful discussions, and to Dr. Yasusada Yamada of Osaka University for taking an X-ray photograph of the low temperature modification of the lead salt. They are also grateful to Miss Masako Ohtsuru for her help in the dielectric measurements.

# NOTES

## The Differentiation of Diastereoisomers of 1-Phenyl-2-acetamidopropane-1-ol Derivatives by Means of the NMR Spectrum

By Haruhisa SHIRAHAMA and Takeshi MATSUMOTO

(Received November 24, 1964)

During the course of studies[1] of the synthesis of 1-phenyl-2-aminopropane-1-ol derivatives, it became disirable to find a simple method for determining whether the 1-phenyl-2-acetamidopropane-1-ol derivatives belonged to the *threo* or the *erythro* series. The differentiation of these isomers by means of the infrared spectrum has been studied by Suzuki and Shindo.[2] In the present paper, we should like to show that these compounds may also be distinguished by their NMR spectra.

The hydroxyl groups of *threo* and *erythro* $\alpha$-glycols have been shown to exhibit in the NMR spectra distinctly different chemical shifts when measured in pyridine - trifluoroacetic acid.[3] Namely, the resonance line arising from the exchanging-hydroxyl group of the threo isomers appears at a higher field than that of the erythro isomer.

A similar comparison of the NMR peaks of *threo* and *erythro* 1-phenyl-2-acetamidopropane-1-ol and 1-phenyl-2-acetamido-3-ethoxypropane-1-ol[1] (Table I) also shows that the peak due to the exchanging-hydroxyl and amide protons in the threo isomer appears at the higher field. Although only two pairs have been measured, this tendency of the threo isomer to

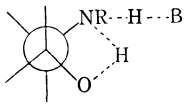
Our thanks are due to Dr. Tsuneo Ikenoue, Tohoku University, for informing us of these results prior to publication and for his valuable discussions. For the concentration shift of *threo* and *erythro* $\alpha$-glycols in pyridine and in acetic acid, see S. Fujise, G. Hazato, T. Ikenoue, S. Sasaki and Y. Senda, This Bulletin, **25**, 1742 (1962).

exhibit its resonance peak at higher fields is presumably quite general, since similar results have been obtained, without exception, with the eight $\alpha$-glycols so far examined.[3]

An explanation for the above findings may be added here, although it is only tentative. The chemical shift of an exchanging proton depends on the time-averaged environment of the active hydrogen. Assuming that all proton exchanges take place by way of hydrogen-bonded structures,[4] the interaction between the most stable form of each acetamido alcohol and surrounding species can be illustrated as follows:[5]

erythro



threo

The interaction is clearly more effective in the *erythro* isomer, and, therefore, the exchangeable proton in the erythro form is more deshielded.

# The Synthesis and Polymerization of β-Propiolactam and α-Phenyl-β-propiolactam

By Toshiyuki KODAIRA, Hideo MIYAKE*, Koichiro HAYASHI and Seizo OKAMURA

(Received November 25, 1964)

There have been several reports concerning the polymerization of α, β-substituted[1] or *N*-substituted[2] β-propiolactam. In this note, the syntheses and polymerizations of unsubstituted β-propiolactam and α-phenyl-β-propiolactam will be reported. It was found by the present study that, in the presence of such anionic catalysts as butyl lithium, sodium methoxide or potassium hydroxide, β-propiolactam and α-phenyl-β-propiolactam polymerized easily in dimethyl sulfoxide (DMSO) under mild conditions, as is shown in Tables I and II. However, a cationic catalyst, boron trifluoride, was not effective for the polymerization. Further, it was observed that the polymerization of unsubstituted lactam took place rapidly in DMSO, but very slowly when it was polymerized in the solid state. The polymer yield was slightly influenced by the reaction temperature when polymerization was carried out in DMSO (Fig. 1 and Fig. 2).

Solvent : DMSO, Temp. : 25°C

The polymerizability of β-propiolactam was larger than that of α-phenyl-β-propiolactam because of the electron-donating character of the phenyl substituent.

The infrared spectra of both polymers had characteristic absorption bands attributable to NH linkage (3300 $cm^{-1}$) and to the poly-amide structure (1655 $cm^{-1}$). The infrared spectrum of poly-β-propiolactam agreed well with those

(BuLi) : $4.3\times10^{-3}$ mol./monomer mol.
Solvent: DMSO, Polym. time: 20 min.

of the polymer obtained from the polycondensation reaction of dithiocarbonylethoxy-dicarbonyl-β-alanine.[3] Further, the polymers had higher melting points (>300°C) and larger viscosities (the $[\eta]$ values were 0.7—1.0 in a 0.5% dichloroacetic acid solution at 35°C) than those of the polymers obtained by poly-condensation[3] or by the hydrogen-transfer polymerization of acryl-amide.[4]

The results of the X-ray diffraction diagram show that the poly-β-propiolactam has a higher crystalline structure ($2\theta$: 18°46′, 26°26′, 28°40′ and 32°6′), while poly-α-phenyl-β-propiolactam has a lower one, because of the bulky substituent of the phenyl group.

## Experimental

**The Synthesis of β-Propiolactam.** — β-Alanine-ethyl ester hydrochloride (I) was prepared from β-alanine by a method similar to that used for the synthesis of α-alanine-ethyl ester hydrochloride.[5] It was recrystallized from a chloroform-ether mixture.[6] Yield 93%, m. p. 64—65°C. The β-Alanine-ethyl ester was prepared from I by a procedure similar to that used for the glycine derivative.[7] Yield 32%, b. p. 58°C/14 mmHg. β-Propiolactam (m. p. 74—75°C) was synthesized by the method of Holley.[8] The synthesis of 3-phenyl-β-propiolactam (m. p. 119—120°C) followed the method of Testa.[9] The polymerizations were carried out under a dry nitrogen stream, and the polymers obtained were precipitated in methanol.

# Basic Bile Acids. IV. On the Syntheses of 7β-Amino-, 12α-Amino-, and 3α-Hydroxy-12α-aminocholanic Acid and Their Derivatives*1

By Yasuo SATOH

(Received November 5, 1964)

In the previous papers of this series,[1] the syntheses and properties of 3α-, 3β-, 7α-, and 12α-aminocholanic acid and their derivatives have been reported. The present paper will describe the syntheses of 7β-amino-, 12α-amino-,*2 and 3α-hydroxy-12α-aminocholanic acid and their derivatives.

Derivatives of 7β- and 12α-aminocholanic acid were synthesized from the oximes of each ketone by reduction with sodium and *n*-propanol. Moreover, as a basic bile acid containing a hydroxyl group, 3α-hydroxy-12α-aminocholanic acid was synthesized. For the synthesis of this basic bile acid, deoxycholic acid was chosen as the starting material, and the reduction of the oxime was carried out according to the methods described for the cases of the 3-, 7-, and 12-positions.[1]

## Experimental*3,*4

**7β-Aminocholanic Acid Hydrochloride (II).***5— Into a boiling solution of 3.5 g. of 7-hydroxyiminocholanic acid (I) in 105 ml. of dried *n*-propanol, 10.5 g. of sodium cut into small pieces was gradually stirred. When all the sodium had been added, 15 ml. of ethanol was slowly added to the reaction mixture through the reflux condenser until the few remaining pieces of sodium had completely reacted. After the reaction mixture had then stood for 14 hr. at room temperature, 90 ml. of water was added, the separated lower layer was taken off, and 220 ml. of water was added to the upper layer. The solution, now consisting of two layers, was acidified with hydrochloric acid (1 : 1) and concentrated to half-volume under reduced pressure, and then this solution was cooled. The resultant crystals were collected, washed with water, and dried. The yield of a slightly brownish amorphous substance was 3.17 g. Attempts to crystallize the hydrochloride were unsuccessful, and so it was used for the next step without purification. IR (KBr disk): 3440, 1721, 1602 and 1508 $cm^{-1}$.

**Methyl 7β-Aminocholanate Hydrochloride (III).** —This substance was prepared according to the procedure described earlier for the synthesis of the 7α-isomer.[1] The crystallization of the resultant solid from methanol - petroleum ether gave 1.92 g. of the methyl ester from 2.7 g. of II; colorless plates, m. p. 248.5—249.5°C (which changed to needles at about 204°C), and $[\alpha]_D^{25}$ +28.5° (*c* 2.01, methanol). IR (KBr disk): 3250, 1742, 1604, 1508, and 1170 $cm^{-1}$.

**Methyl 7β-Acetamidocholanate (IV).** — The synthesis of this substance was carried out using the technique described for the synthesis of the 7α-isomer.[1] Attempts to crystallize the acetamido derivative from the ether extracts were unsuccessful. IR (KBr disk): 3264, 1732, 1636, 1559, and 1164 $cm^{-1}$.

When the syrupy material was submitted to thin-layer chromatography on Wako-gel B-5 (thickness, 0.5 mm.) with benzene-ether (1 : 2), a spot at 0.3 in $R_f$ value and another weak spot at the original point were observed. Therefore, the above-described syrupy substance was subjected to separation using a large-area layer (20×20 $cm^2$; thickness, 0.5 mm.). A separated band, which was detected with concentrated sulfuric acid, was scraped off and extracted with warm methanol. The methanolic solution was filtered, and the filtrate was evaporated under reduced pressure. Crystallization of the residue from benzene - petroleum ether afforded a crude acetamido derivative, m. p. 115—117°C; yield 165 mg. Two crystallizations of this substance from the same solvent raised the melting point to 120—121°C; $[\alpha]_D^{20}$ +22.0° (*c* 1.01, chloroform). IR (KBr disk): 3260, 1745, 1638, 1557, and 1165 $cm^{-1}$.

Found: C, 75.05; H, 10.48; N, 3.20. Calcd. for $C_{27}H_{45}O_3N$: C, 75.12; H, 10.51; N, 3.26%.

**12α-Aminocholanic Acid Hydrochloride (VIm).**— This substance was prepared according the procedure described above for the synthesis of the 7β-isomer (II). The crystallization of the resultant solid from methanol gave 2.86 g. of the amino acid hydrochloride from 3.3 g. of the oxime (V) of 12-ketocholanic acid; m. p. 285.5—287°C, $[\alpha]_D^{25}$ +42.9° (*c* 1.89, ethanol). IR (KBr disk): 3432, 1702, 1611, and 1521 $cm^{-1}$.

The melting point of this derivative was not depressed by admixture with a sample VIc prepared by the catalytic reduction of the oxime,[1] and this derivative was identical in infrared spectrum with a sample of VIc.

When the oxime was reduced with sodium and ethanol, the amino derivative formed was identical with a specimen of VIm.

---

*1 Presented at the Local Meeting of the Chemical Society of Japan, Morioka, September, 1964.

*2 The method of the synthesis of this derivative used here differs from that of the previous work.

*3 All melting points are uncorrected.

*4 The infrared absorption spectra were measured with a Shimadzu model IR-27B infrared spectrophotometer.

*5 This compound is an epimer of the 7-amino derivative described in our previous paper.[1]

**Methyl 12α-Aminocholanate Hydrochloride (VII).**—This substance was prepared according to the procedure described earlier for the synthesis of the 7α-isomer.[1] The crystallization of the resultant solid from methanol gave 810 mg. of the methyl ester from 1 g. of VIm; m. p. 205.5—207°C, $[\alpha]_D^{25}$ +40.1° (*c* 1.00, ethanol). IR (KBr disk): 3220, 1730, 1605, and 1521 $cm^{-1}$. No depression in melting point was observed upon its admixture with a sample prepared by the catalytic reduction of the oxime.[1]

**Methyl 12α-Acetamidocholanate (VIII).**—The synthesis of this substance was carried out using the technique described for the synthesis of the 7α-isomer.[1] Two-hundred and forty-four milligrams of this substance (octagonal crystals; m. p. 231—232°C, $[\alpha]_D^{28}$ +29.1° (*c* 2.00, chloroform) was obtained from 500 mg. of VII. The melting point of this substance was not depressed by admixture with methyl 12α-acetamidocholanate derived from the oxime by catalytic reduction.[1] IR (KBr disk): 3272, 1735, 1636 and 1554 $cm^{-1}$.

Found: C, 75.09; H, 10.29; N, 3.20. Calcd. for $C_{27}H_{45}O_3N$: C, 75.12; H, 10.51; N, 3.26%.

**3α-Hydroxy-12-hydroxyiminocholanic Acid (X).**—This preparation followed the general method used for the synthesis of the steroidal ketoxime from 3α-hydroxy-12-ketocholanic acid (IX): m. p. 131—132°C, $[\alpha]_D^{20}$ +149.7° (*c* 0.35, chloroform). IR (KBr disk): 3310, 1704, 1644, and 938 $cm^{-1}$.

**The Synthesis of 3α-Hydroxy-12α-aminocholanic Acid Hydrochloride (XI) from the Oxime.**—*i) Catalytic Reduction.*—The method used here was identical with that described for the 7α-isomer.[1] The crystallization of the residue from methanol yielded 751 mg. of the amino acid from 1 g. of the oxime; m. p. 279—281°C, $[\alpha]_D^{25}$ +51.5° (*c* 0.91, ethanol). IR (KBr disk): 3344, 1708, 1608, and 1518 $cm^{-1}$.

Found: C, 68.01; H, 9.91; N, 3.20; Cl, 8.20. Calcd. for $C_{24}H_{43}O_3NCl$: C, 67.37; H, 9.82; N, 3.27; Cl, 8.30%.

*ii) Reduction with Sodium and n-Propanol.*—This reaction was carried out according to the procedure described above for the synthesis of the 7β-isomer (II). The crystallization of the resultant solid from methanol gave 0.96 g. of the amino acid hydrochloride from 1.6 g. of the oxime; m. p. 280.5—282.5°C, $[\alpha]_D^{25}$ +52.7° (*c* 0.68, ethanol). IR (KBr disk): 3340, 1708, 1609, and 1518 $cm^{-1}$.

Found: C, 67.54; H, 9.82; N, 3.32; Cl, 8.23. Calcd. for $C_{24}H_{42}O_3NCl$: C, 67.37; H, 9.82; N, 3.27; Cl, 8.30%.

The melting point of this derivative was not depressed by its admixture with a sample prepared by method i.

Moreover, when the oxime was reduced with sodium and ethanol, it was found that the product was identical with the samples XIc and XIm*6.

**Methyl 3α-Hydroxy-12α-aminocholanate Hydrochloride (XII).**—This substance, m. p. 255—256°C, $[\alpha]_D^{22}$ +42.7° (*c* 0.35, chloroform), was prepared from XIc and XIm with absolute methanol and dry hydrogen chloride gas. IR (KBr disk): 3344, 1723, 1613, and 1529 $cm^{-1}$. The mixed melting point of the two esters was 254—256°C.

Found: C, 68.20; H, 9.83; N, 3.26; Cl, 7.95 (XIIc) and C, 68.06; H, 9.87; N, 3.19; Cl, 7.91 (XIIm). Calcd. for $C_{25}H_{44}O_3NCl$: C, 67.95; H, 9.97; N; 3.17; Cl, 8.04%.

**Methyl 3α-Acetoxy-12α-acetamidocholanate (XIII).**—This derivative, m. p. 248—249°C, $[\alpha]_D^{25}$ +111.9° (*c* 2.10, chloroform), was prepared from XIIc and XIIm with acetic anhydride and absolute pyridine by heating it for 4 hr. at 100°C. The mixed melting point of XIIIc and XIIIm was 247.5—249°C. IR (KBr disk): 3260, 1723, 1632, 1550, and 1250 $cm^{-1}$ (XIIIc); 3263, 1722, 1632, 1551, and 1251 $cm^{-1}$ (XIIIm).

Found: C, 71.39; H, 9.51; N, 2.86 (XIIIc) and C, 71.37; H, 9.56; N, 2.88 (XIIIm). Calcd. for $C_{29}H_{47}O_5N$: C, 71.17; H, 9.61; N, 2.86%.

# The Extraction of Thallium(III) from Hydrochloric Acid Solutions with Ethyl Acetate

By T. N. Srivastava and D. C. Rupainwar

(Received December 14, 1964)

The extraction of thallium(III) from hydrochloric acid solutions into ether and other organic solvents has been reported by several investigators.[1-4] It has been developed into an analytical method for the separation of thallium from most elements, excepting iron(III), gallium(III), gold(III), and a few others. Irving and Rossotti,[5] while studying the extraction of indium(III) from hydrochloric acid solutions, have given a comparative account of the extraction of the $HMX_4$ species (M= $Ga^{3+}$, $In^{3+}$, $Fe^{3+}$, $Au^{3+}$; X=Cl, Br, I) with various organic solvents, including ethyl acetate. However, no information is available on the extraction of the corresponding halothallic acids ($HTIX_4$). The present communication will give the details of the extraction of thallium(III) from its solutions in hydrochloric acid, using ethyl acetate as an extracting solvent.

## Experimental

Stock solutions of thallic chloride were prepared by dissolving freshly-precipitated thallium(III) oxide in hydrochloric acid solutions of the desired strength.

Ethyl acetate (British Drug House) was distilled once and used in that form. All the other reagents and solutions were prepared from "Analar" compounds, and their concentrations were ascertained by conventional methods.

Known volumes of an aqueous thallic chloride solution of the desired strength in hydrochloric acid of an appropriate concentration were shaken for a constant time (1 min.) with an equal volume of ethyl acetate (pre-equilibriated with acid of a corresponding strength), in a glass-stoppered measuring cylinder. The layers were allowed to separate, and the final volumes were recorded. Known aliquots from the organic and the aqueous layers were withdrawn and analysed volumetrically for their thallium and chloride contents.

## Results and Discussion

**Optimum Conditions for Extraction.**—The extraction yield of thallium(III) at 1.0 N hydrochloric acid was found to be as high as 72%; the percentage extraction and the distribution coefficient increase gradually with an increase in the acid concentration, attain a maxima at 6.0 N hydrochloric acid, and then fall to a lower value (Fig. 1). As the changes in the phase miscibility, due to the hydrolysis of ethyl acetate, are relatively small up to 6.0 N hydrochloric acid, the experimental conditions at this stage correspond approximately to the ideal state, but at a higher concentration of the acid, the hydrolysis of the ester becomes significant and the volume of the organic layer decreases. This consequently brings about a decrease in the activity of the extractable species, and results in the lower values for the percentage extraction and the distribution coefficient.

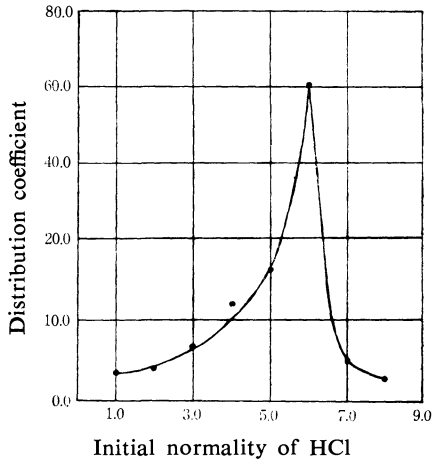

Fig. 1. Distribution of thallium(III) between ethyl acetate and hydrochloric acid.

**The Nature of the Extracted Species.**—The empirical formula of the extracted species corresponds to $HTICl_4$, because almost equimolar quantities of thallic chloride and hydrogen chloride are extracted from aqueous solutions containing less than 6.0 N hydrochloric acid.

Beyond this concentration, an increasingly greater quantity of hydrochloric acid is co-extracted. This fact cannot be attributed to the formation of a thallium complex with a larger amount of hydrochloric acid, e. g., $H_2TlCl_5$, as this species has already been shown by Horrocks and Voigt[3] to be inextractable. A plausible explanation may be a salting-out effect of thallium(III).

**The Effect of the Metal Concentration.**—The studies of the extraction of thallium(III) at various concentrations in 6 N hydrochloric acid solutions have shown that the percentage extraction and the distribution coefficient increase with the increase in the concentration of the metal. This may be due to a self-salting-out effect caused by thallium(III) itself, similar to that reported for the extraction of gallium(III) and iron(III) from hydrochloric acid solutions.[6] The mechanism of this phenomenon may be explained by assuming the formation of $[Tl(H_2O)_6]^{3+}$ ions in more concentrated solutions of thallium, which replace the protons in the species $[H^+(TlCl_4)]$, thereby giving enhanced values of the distribution coefficient and of the percentage extraction.

**Salting-out Effects.**—The extraction of thallium(III) from its solution in 2 N hydrochloric acid and in the presence of 1.0 M $MCl_x$ (where M=Li, Na, K, $NH_4$, Ca, Mg, and Al, and $x$, the valency of the cation) was studied. The presence of metal chloride results in a considerable increase in the percentage extraction and distribution coefficient. When univalent chlorides were used, the distribution coefficient followed the order Li>K—Na>$NH_4$. For other metal chlorides, an order of the Li>Al >Mg>Ca>$NH_4$ type is obtained. This may be attributed to the relative differences in the water activity in the presence of these cations. Lithium, being the most strongly hydrated, has the greatest effect.

**The Effect of the Dilution of the Solvent.**—Ethyl acetate diluted with such solvents as petroleum ether (B. range 85—100°C), benzene, chloroform and carbon tetrachloride was employed for the extraction of thallium(III). The results indicate that the distribution coefficient decreases with the increasing molar polarisation of the diluent. This happens to be in conformity with a generalisation given previously.[7]

A plot of the log of the distribution coefficient against the log of the concentration of ethyl acetate did not give a definite value of $n$, the solvation number. It appears that the solvation of the metal varies significantly with the extent of dilution; hence, a definite stiochiometric ratio can not be obtained.

**The Separation of Thallium(III) from $Al^{3+}$, $Ga^{3+}$, and $In^{3+}$.**—Experimentation on other metals of the III-B group has, however, shown that the extraction percentages of aluminum, gallium and indium are 0, 96.7, and 3.72 respectively at an initial hydrochloric acid concentration of 6.0 N. Aluminum does not from a tetrahedral-extractable species of the chloride complex in an aqueous solution, while indium under similar conditions shows a marked tendency to remain predominantly octahedral[7]; hence, very low values for the percentage extraction are obtained.

The fact that thallium(III) is extracted by 72.26% at a 1.0 N hydrochloric acid concentration, at which concentration gallium and indium are only negligibly extracted, has been utilised in separating it from these two metals. A batch-by-batch extraction with ethyl acetate at 1.0 N hydrochloric acid effects a quantitative separation of thallium from other members of the III-B group. The presence of other metals, particularly aluminum, on the other hand, results in a salting-out effect of thallium and enhances the percentage extraction.

## Summary

Ethyl acetate has been employed as a solvent for extracting thallium(III) from its hydrochloric acid solutions. The empirical formula of the extracted metal entity has been found to be $HTlCl_4$. Optimum conditions for the extraction of the metal have been determined, and the effect of various factors, e. g., metal concentration, salting-out agents, and the dilution of the solvent, have been investigated. It has been possible to separate thallium(III) from aluminum(III), gallium(III) and indium-(III) by performing a batch-by-batch extraction at a 1.0 N hydrochloric acid concentration.

1) The extracted species is an acid with an approximate formula of $HTlCl_4$, the distribution of the species between the two phases depends upon the concentration of the hydrochloric acid present in the system.

2) The extracted species is ionic and may associate in the organic phase to from ion pairs, ion triplets and higher clusters. This is evident from the fact that an increase in the metal concentration causes an increase in the distribution coefficient.

3) There is no primary solvation of thallium, which is tetrahedrally surrounded by chloride ions and which is apparently saturated. This is supported by the observation that the metal

7) Y. Marcus, *Chem. Revs.*, **63**, 139 (1963).

could not be extracted from its solution in perchloric acid.

4) The proton of the chlorothallic acid may be solvated (and possibly hydrated, too) in the organic phase, the solvation number being indefinite.

5) Ion pairing results in the formation of an extractable complex and a general mechanism of the type:

$$H(S)^+ + [Tl(S)_2Cl_4]^- \rightleftharpoons [(HS^+)(Tl(S_2)Cl_4)^-]$$

may be expected, where S is either $H_2O$ or ethyl acetate.

The above equation may well represent qualitatively various reactions at different relative water and ethyl acetate activities.

In general, the system is a simple ion-association extraction system and is quite similar to the extraction of iron(III) and gallium(III) chloride with oxygenated solvents.

# Temperature Dependence of A. C. Polarographic Waves

By G. H. Aylward and J. W. Hayes*

(Received February 23, 1965)

There are few published data on the temperature dependence of a. c. polarographic waves. The most extensive study is that of Bauer and Goodwin[1] who reported the temperature coefficients of the peak heights for the reduction of a number of metal ions and compared these values with the values for the corresponding d. c. polarographic step heights. These temperature coefficients were expressed as a percentage. Randles and Somerton[2] have reported the activation energies of electron transfer reactions involving several inorganic depolarizers. These results were obtained from faradaic impedance measurements.

Vlček[3] has proposed that the temperature dependence of d. c. polarographic step heights be expressed in terms of an activation energy obtained from an Arrhenius type plot. The values obtained should be independent of the temperature range used and activation energies have a deeper physical meaning than temperature coefficients expressed as a percentage. For a diffusion controlled limiting current, this value expresses the activation energy of diffusion. At low frequencies and high values of the electron transfer rate constant, the a. c. polarographic current is determined by mass transfer terms, and hence if this mass transfer is a diffusion process, it should be possible to obtain a value for the activation energy of diffusion from the a. c. polarographic wave height. If the mass transfer is not a diffusion process (e. g. involves a coupled chemical reaction) then this fact should be detectable from the form of Arrhenius plot obtained. Electrode processes, where the rate of electron transfer is slow enough to affect the a. c. polarographic current at low frequencies, should also show a different form of Arrhenius plot. Thus it should be possible, from the temperature dependence of the peak height, to obtain some useful information about the nature of the electrode process.

At low frequencies and high values of the electron transfer rate constant and for mass transfer by diffusion, the faradaic admittance at the peak of an a. c. polarographic wave, $Y$, is given by:[4]

$$Y=\frac{n^2F^2AC^0(\omega D)^{1/2}}{4RT} \qquad (1)$$

where $C^0$ is the concentration of depolarizer in the bulk of the solution, $\omega$ the angular

3) A. A. Vlček, *Coll. Czech. Chem. Comm.*, **24**, 3538 (1959).

4) H. H. Baure, *J. Electroanal. Chem.*, **3**, 150 (1962).

frequency, $D$ the diffussion coefficient of the depolarizer, and $n, F, A, R$, and $T$ have their usual meanings. Assuming that all quantities in Eq. 1 except $D$ and $T$ are independent of temperature, and that the temperature dependence of $D$ may be written :[3]

$$D = D_0 \exp\left(\frac{-Q_D}{RT}\right) \qquad (2)$$

where $D_0$ is a constant and $Q_D$ is the activation energy of diffusion, the temperature dependence of the faradaic admittance may be written :

$$YT = \alpha \exp\left(\frac{-1/2\, Q_D}{RT}\right) \qquad (3)^*$$

where $\alpha$ is a constant made up of the temperature independent terms. A plot of log $YT$ against $1/T$ should yield a straight line of slope $-Q_D/4.61\,R$ for cases where the above conditions are valid. The activation energy determined in this way should be comparable with that determined from the d. c. polarographic limiting current. According to Vlček[3] the values of $Q_D$ usually fall in the range 4—6 kcal. mol$^{-1}$.

Table I shows some results obtained for systems of several types. For systems numbers 1 and 2 the electrode process is known to be reversible,[5] and the values of $Q_D$ obtained from a. c. and d. c. polarography are comparable and of the expected order of magnitude. In system number 3 an irreversible chemical reaction follows the reversible electron transfer reaction[5] viz.

$$EuY^{2-} + Ca^{2+} \rightarrow Eu^{2+} + CaY^{2-}$$

where Y represents ethylenediaminetetraacetic acid (EDTA). Although the d. c. limiting current is diffusion controlled, the height of the a. c. wave is affected by the rate of the chemical reaction.[5] Consequently, the value of $Q_D$ obtained from d. c. polarography is comparable with that obtained for system number 2, whilst a linear plot is not obtained for the a. c. case. Figure 1 shows the difference in the Arrhenius plots from the a. c. polarograms in presence and absence calcium chloride.

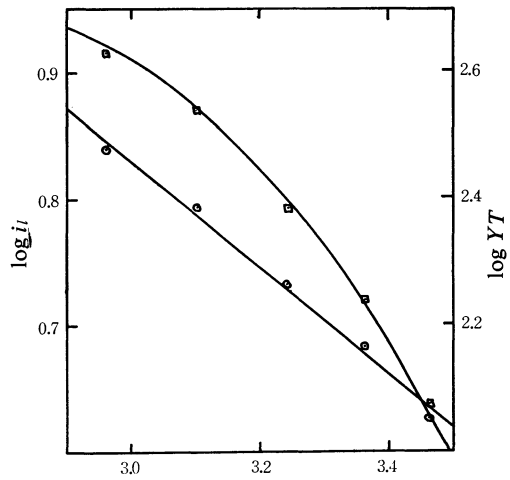

Fig. 2. Temperature dependence of limiting current ⊙, and a. c. polarographic wave height ⊡ for reduction of zinc ions (for conditions see Table I).

5) G. H. Aylward and J. W. Hayes, *Anal. Chem.*, 37, 195 (1965).

* Added in Proof : Since submission of this paper, T. Kambara and K. Kunimatsu in *Review of Polarography*, 13, 20 (1965) have published a development of Eq. 3 and its application to quasi-reversible systems.

By means of a plot of the logarithm of the rate constant against $1/T$, the activation energy of the chemical reaction has been determined.[5]

System number 4 is a well known quasi-reversible system, and the height of the a. c. wave is influenced by the rate of the electron transfer reaction. Although a linear Arrhenius plot is obtained from the d. c. polarograms, and the value $Q_D$ obtained from the limiting current is in the expected range of magnitude, marked non-linearity is found from a. c. polarograms, see Fig. 2.

Further work in this field should prove useful in the assignment of mechanisms to electrode processes.

# Interatomic and Intermolecular Scattering in Gas Electron Diffraction†

By Yonezo MORINO, Kozo KUCHITSU and R. A. BONHAM*

(Received March 29, 1965)

The effect of interatomic and intermolecular scattering on the total intensity of electrons scattered from a narrow beam of atoms or molecules in the gaseous state can be written as:

$$I_T(s) = I(s)\left\{1+4\pi\left(\frac{N}{V}\right)\times\int_0^\infty dr r^2[e^{-V(r)/kT}-1]\frac{\sin sr}{sr} +4\pi\left(\frac{N}{V}\right)\int_0^\infty dr r^2\frac{\sin sr}{sr}\right\} \quad (1)$$

in the first Born approximation, where $I(s)$ is the usual Debye intensity expression for scattering from atoms or molecules.[1] In Eq. 1, $N$ refers to the number of atoms or molecules in the volume, $V$, undergoing scattering. It should be noted that Eq. 1 is the equation previously derived by Debye and Menke[2] for the X-ray scattering from liquids. The second term on the right of the equal sign in Eq. 1 represents electron scattering from a pair of atoms separated by distances close to the position of the minimum of the interatomic or intermolecular potential, $V(r)$. The third term represents the scattering of electrons from atom pairs separated by large distances and makes no contribution to the intensity.[1] Since the second term on the right of the equal sign in Eq. 1 makes a periodic contribution to the differential scattering cross section, it is of interest to investigate this term in order to ascertain if corrections for its effect on the electron diffraction analysis are needed.

It is convenient to define a reduced molecular intensity function for interatomic or intermolecular scattering as:

$$N(s) = 9.221\times10^{-2}(P_0/T)\times\int_0^\infty dr r^2[e^{-V(r)/kT}-1]\frac{\sin sr}{sr} \quad (2)$$

where $P_0$ is the average pressure in the gas beam in fractions of an atmosphere, and $T$ is the temperature in degrees of atoms or molecules in the gas beam. In Fig. 1 $N(s)$ is calculated for an argon gas beam with $P_0=10^{-2}$ atm. and $T=300°K$. The $V(r)$ potential is approximated by a Lennard-Jones 6-12 expression using parameters obtained from Ref. 3. It is obvious from Fig. 1 that interatomic or intermolecular effects at sample pressures of the order of 10 mmHg will usually not create any difficulty in the analysis of electron diffraction data. On the other hand, an interesting question arises as to whether or not the potential function, $V(r)$, can be obtained experimentally by carrying out electron diffraction experiments with high beam pressures. This appears to be a feasible experiment provided gas pressures greater than

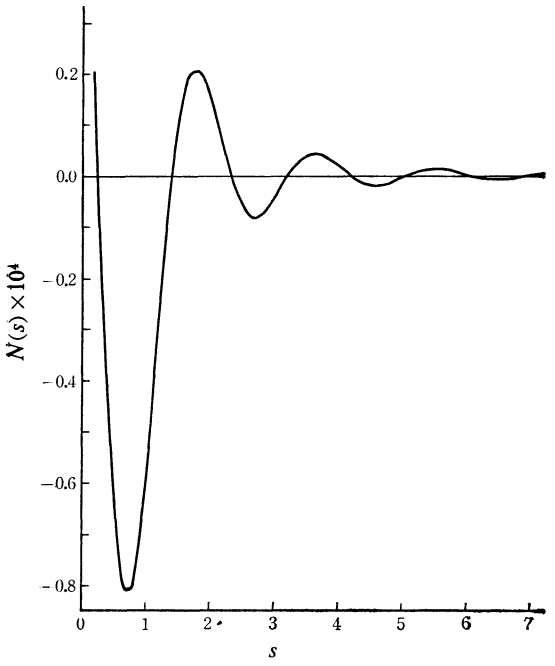

Fig. 1

1 atm. can be obtained while conditions for an optimum diffraction experiment are maintained. That is, the volume of gas undergoing scattering must be small (i. e., $10^{-3}$ cubic mm.), and the vacuum in the diffraction chamber should be at least $10^{-4}$ mm. of Hg away from the beam. At high pressures of the gas beam it is possible, in the case of many atoms and molecules, to obtain diffraction pictures in a few hundredths of a second with 40 kV. electrons. By taking a diffraction photograph during the instant following the formation of a gas beam by expansion through a small orifice (~0.1 mm.), it should be possible to maintain a reasonably good chamber pressure during the course of the exposure.

It is also important to consider the effect of multiple scattering on Eq. 1. The Karles[4] have discussed such effects previously; it appears, on the basis of their analysis, that such effects mainly contribute to the background term, $I(s)$, in a smooth fashion. It is, of course, possible for coherent contributions of these effects to the frequency such as those in Eq. 2 to arise from multiple scattering from closely-grouped clusters of three or more atoms. However, Bunyan[5] has shown that the intensity from triple scattering, for extremely heavy atoms, amounts to probably no more than 10% of the coherent scattering intensity from a cluster of three atoms in close proximity. Since in gases, even at fairly high pressures, there must be many more clusters with two atoms than with three atoms, the appearance of coherent features from multiple scattering seems rather improbable.

It is also important to note that the amplitude of $N(s)$ depends, in a sensitive manner, on the depth of the energy minimum of $V(r)$. This means that an increase in the density of the potential minimum of $V(r)$ will greatly enhance the amplitude of $N(s)$. Thus, the possibility of observing the function $N(s)$ experimentally for krypton or xenon should be even better than for argon.

# The Correction of the Relation of the Optical Density Ratio to the Stretch Ratio on the Dichroic Spectra*

By Yoshié TANIZAKI

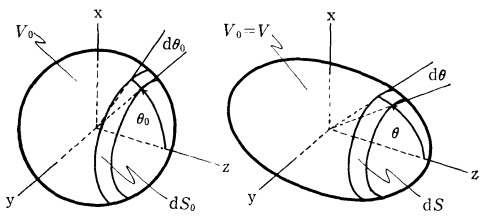
(Received April 26, 1965)

Previously,[1] in order to analyze the dichroic spectra and determine the transition directions of the electronic bands of molecules in the stretched PVA sheet, an expression was proposed for the density ratio ($R_d=D_{\parallel}/D_{\perp}$) as a function of the stretch ratio ($R_s$). In the course of the derivation, however, the author made a mistake in the description of the surface element, $\rho(\theta_0)$; therefore, the distribution function was not correct. For that reason, the proposed expression was also incorrect, though it could explain some experimental results obtained under certain conditions.[1,2]

In the present communication the author shall give the correct description of $\rho(\theta_0)$ and derive anew the distribution function $f(\theta)$ and the $R_d$ expression. Further, it will be shown how the orientation angle of the transition moment can be obtained practically.

Figure 1 illustrates schematically the previous statement[1] of the deformation of a sphere with a unit radius into a spheroid with the same volume. The long axis of the spheroid is taken as the Z axis (the stretching direction). On the assumption that the deformation is made under a constant volume, the angle $\theta_0$ of any unit vector in the sphere will be transformed into $\theta$ in the spheroid as follows:

$$\tan\theta_0=R_s\tan\theta \tag{1}$$



where both $\theta_0$ and $\theta$ are defined in the region $0-\pi/2$. The distribution function, $f(\theta)$, after stretching, is expressed as:

$$f(\theta)=\int_0^{\pi/2}G(\theta,\theta_0)F(\theta_0)\,d\theta_0$$
$$=\int_0^{\pi/2}\delta(\theta-\theta_0)\rho(\theta_0)F(\theta_0)\,d\theta_0 \tag{2}$$

where $F(\theta_0)$ $(=\sin\theta_0)$ is the distribution before stretching; $G(\theta,\theta_0)$, the transformation function, and $\delta$, the delta function. From the relation $dV_0=dV$ (Fig. 1), we have:

$$h/h_0=dS_0/dS=\rho(\theta_0)$$

hence:

$dS_0=2\pi\sin\theta_0\,d\theta_0$ $\quad dS=\dfrac{2\pi R_s^{2/3}\sin\theta\,d\theta}{\sqrt{1+(R_s^2-1)\sin^2\theta}}$

$dV_0=h_0\,dS_0$ $\quad dV=h\,dS$

Fig. 1. The schematic illustration for the deformation from a sphere to a spheroid under a constant volume.

$$\rho(\theta_0)=R_s^{-2/3}\sqrt{1+(R_s^2-1)\sin^2\theta}\,\frac{\sin\theta_0}{\sin\theta}\,\frac{d\theta_0}{d\theta}$$
$$=R_s^{1/3}\sqrt{1+(R_s^2-1)\sin^2\theta}\,\frac{\sin\theta_0}{\sin\theta}\,\frac{\cos^2\theta_0}{\cos^2\theta}$$

because, by Eq. 1, we can write $d\theta_0/d\theta=R_s\cos^2\theta_0/\cos^2\theta$. Therefore, Eq. 2 becomes:

$$f(\theta)=\int_0^{\pi/2}\delta(\theta-\theta_0)R_s^{1/3}\sqrt{1+(R_s^2-1)\sin^2\theta}\times\frac{\sin^2\theta_0\cos^2\theta_0}{\sin\theta\cos^2\theta}\,d\theta_0$$
$$=\int_0^{\pi/2}\delta(\theta-\theta_0)R_s^{1/3}\frac{\sqrt{1+(R_s^2-1)\sin^2\theta}}{\sin\theta\cos^2\theta}\times\frac{\tan^2\theta_0}{(1+\tan^2\theta_0)^2}\,d\theta_0$$

By eliminating $\tan\theta_0$ by Eq. 1, that is to say, by carrying out the integration with respect to $\theta_0$, we obtain:

$$f(\theta)=R_s^{1/3}\frac{\sqrt{1+(R_s^2-1)\sin^2\theta}}{\sin\theta\cos^2\theta}\times\frac{R_s^2\tan^2\theta}{(1+R_s^2\tan^2\theta)^2}$$

or

$$=R_s^{7/3}\sin\theta\{1+(R_s^2-1)\sin^2\theta\}^{-3/2}$$

The further integration of $f(\theta)$ with respect to $\theta$ in the region of $0-\pi/2$ gives $R_s^{1/3}$. Therefore, $R_s^{-1/3}f(\theta)$ is normalized. Rewriting this normalized function by $f(\theta)$ again, the distribution function becomes:

$$f(\theta)=R_s^2\sin\theta\{1+(R_s^2-1)\sin^2\theta\}^{-3/2} \tag{3}$$

---

* Dichroism of Dyes in the Stretched PVA Sheet. V. IV: Y. Tanizaki and H. Ono, This Bulletin, 33, 1207 (1960).

1) Y. Tanizaki, This Bulletin, 32, 75 (1959).

2) Y. Tanizaki, ibid., 33, 979 (1960).

Equation 3 is the corrected distribution function required.

The correct $R_d$ equation against $R_s$ for a parameter $r$, therefore, can be obtained as follows, using the same procedure as that described in the previous paper:[1]

$$\left.\begin{aligned} R_d &= \frac{2+2(2r^2-1)T}{(2r^2+1)-(2r^2-1)T} \\ T &= \frac{R_s^2}{R_s^2-1}\left[1-\left\{\frac{\pi}{2}-\tan^{-1}(R_s^2-1)^{-1/2}\right\}\times(R_s^2-1)^{-1/2}\right] \\ R_s &> 1 \end{aligned}\right\} \quad (4)$$

The parameter $r$ has the following meaning: $\cot^{-1} r$ provides the angle of the transition moment against the orientation axis which is considered to be peculiar to the molecular species.

If the orientation axis is peculiar to the molecular species, namely, if the $r$-value is independent of $R_s$, the orientation angle of the transition moment must be decided from Eq. 4 by substituting the observed $R_d$ and $R_s$ values. According to our experiences with the dichroic measurement, however, in some cases, the $r$-value is not invariant with $R_s$, as in the examples shown in Fig. 2. In that case, the $r$-value extrapolated to $R_s=1$ should be employed.

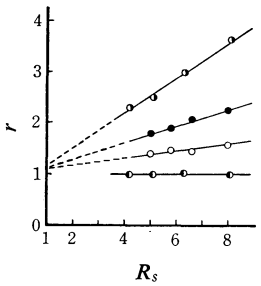


Fig. 2. Examples of the relations of $r$ vs. $R_s$.
Sodium 4'-hydroxyazobenzene-4-sulfonate:
◑ at 365 mμ, ◐ at 244 mμ
Chrysoidine:
● at 460 mμ, ○ at 240 mμ

The warrant for the appropriate deformation of the sample sheet by stretching will be given by the fact that the ratio of $(D_{\parallel}+2D_{\perp})$ for any $R_s$ to $D$ for $R_s=1$ (i.e., nonstretching) at the same wavelength is invariant for the observed region.

The author wishes to thank Dr. Yasuji Kobayashi, Assistant Professor of the Tokyo Metropolitan University, for pointing out the mistake in the distribution function in the previous paper.

## SHORT COMMUNICATIONS

# The Proton Magnetic Resonance of Thianaphthenes. III.* The Long-range Coupling Observed in Side-chain Methyl Hydrogens in Some Methylthianaphthenes

By Kensuke TAKAHASHI, Tatsuo KANDA and Yasuo MATSUKI

(Received June 2, 1965)

In this report we will discuss the coupling observed in methyl hydrogens in some methylthianaphthenes. The signal of the methyl hydrogens in 2- or 3-methylthianaphthene splits into a doublet with a splitting of about 1 c. p. s. as a result of its coupling with an adjacent ring hydrogen. However, the signal of methyl hydrogens in 4-, 5-, 6- or 7-methylthianaphthene shows a more complex structure than the doublet observed in 2- or 3-methylthianaphthene. This means that there exists some coupling between methyl hydrogens and their non-adjacent ring hydrogens in addition to the

Fig. 1. The PMR spectrum of 2,3-dimethylthianaphthene in the 5.2 mol. % solution in carbon tetrachloride at 60 Mc./sec. Applied magnetic field increasing from left to right.

coupling between the methyl hydrogens and their adjacent ring hydrogens. Similar results have already been presented for some other aromatics.[3] In the spectrum of 2, 3-dimethylthianaphthene, two methyl signals, at 0.80 and 1.00 p. p. m. with reference to cyclohexane, corresponding to 3-methyl and 2-methyl hydrogens respectively, have quartet structures, as is shown on the right side of Fig. 1. The magnitude of these splittings is about 0.7 c. p. s. This may be attributed to the coupling between two methyl hydrogens in 2, 3-dimethylthianaphthene. The present results give us some information about the mechanism of the side-chain coupling in methylthianaphthenes and indicate that it is similar to that in methylthiophenes.[4]

Hoffman described the methyl substitution technique used to check the mechanism of coupling.[5] Some compounds were taken up in order to compare the coupling of $J_{23}$ in thianaphthenes. Table I lists the observed PMR data of the first-order analyses. $J_{2\text{-H},\ 3\text{-H}}$ is about 5 c. p. s. in thianaphthenes. When we substitute a methyl group for a 2- or 3-positioned ring hydrogen, a $J_{2\text{-}CH_3,\ 3\text{-H}}$ or $J_{2\text{-H},\ 3\text{-}CH_3}$ value of about 1 c. p. s. is observed, showing a great decrease as compared with $J_{2\text{-H},\ 3\text{-H}}$. After the further substitution of a methyl group for the remaining 2- or 3-positioned ring hydrogen, we get a $J_{2\text{-}CH_3,\ 3\text{-}CH_3}$ value of about 0.7 c. p. s., which has the same order of magnitude as $J_{2\text{-H},\ 3\text{-}CH_3}$ or $J_{2\text{-}CH_3,\ 3\text{-H}}$. This leads to the conclusion that the side-chain coupling in methylthianaphthenes is mainly due to the $\pi$-electron contact contribution.

# Radiation-Induced Catalytic Activity of Nickel Oxide

By Toshiro YAMASHINA and Masakatsu SANO

(Received June 11, 1965)

The fact that the irradiation of nickel oxide with $\gamma$-rays results in changes in surface phenomena and in the reduction process by hydrogen has been suggested previously.[1] The present communication will present evidence that the induced catalytic activity with $\gamma$-irradiation leading to the decomposition of hydrogen peroxide solution is closely connected with the chemisorbed oxygen induced by radiation.

The pure nickel oxide sample was prepared in a manner identical with that described previously.[1] The samples were irradiated to total doses of $\sim 8 \times 10^8$ r. in air at room temperature, with Co-60 gamma-rays. The catalytic activity of the nickel oxide was then determined by using the decomposition of a 7.5% hydrogen peroxide solution as a model reaction, in which the rate of the reaction was followed by reading the volume of oxygen evolved per minute. A 0.2 g. catalyst sample was used for each run. The reaction temperature was 40°C. The chemisorbed oxygen was estimated by its ability to oxidize potassium iodide in a hydrochloric acid solution, in fact, the quantity of $Ni^{3+}$ ions was determined. Therefore, the results are represented as excess oxygen, two $Ni^{3+}$ ions corresponding to one $O^{2-}$ ion.

The catalytic activity and chemisorbed oxygen due to $\gamma$-irradiation are presented as a function of the radiation dose in Fig. 1. Both values were found to increase with the radiation dose, being remarkable over a total dose of about

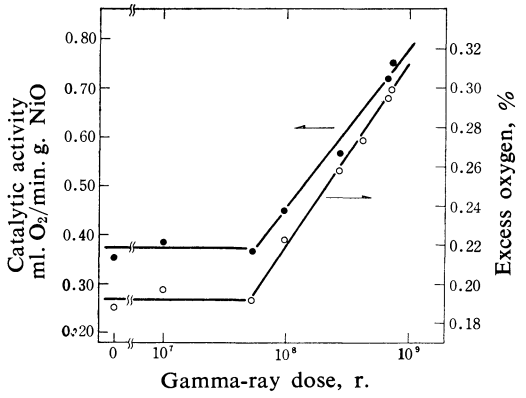

Fig. 1. Catalytic activity and excess oxygen as a function of $\gamma$-ray dose.

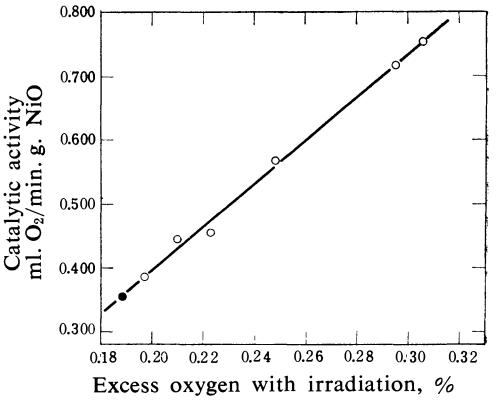

Fig. 2. Catalytic activity vs. excess oxygen with $\gamma$-irradiation.

$1 \times 10^8$ and reaching a level over twice as great as not-irradiated nickel oxide. No differences in the B. E. T. surface area with the irradiation were observed. Figure 2 shows the induced catalytic activity as a function of the oxygen chemisorbed with irradiation; a linear relationship was obtained. Similar relations have been observed in the case of oxidized chromina-alumina catalysts.[2,3] From the present results, it can be concluded that the catalytic sites on nickel oxide are closely associated with the oxygen chemisorbed on the surface with $\gamma$-irradiation.

Although some investigators[4,5] have shown the radiation induced catalytic activity on nickel oxide to be concerned with the characterization of defects with radiation damage, the mechanism of its catalysis is still not clear.

We, however, would like to suggest that catalytic action takes place preferentially at the oxygen chemisorbed with irradiation. Further study is now in progress to reveal which state of adsorbed oxygen, $O_2^-$, $O^-$ or $O^{2-}$, contributes to the catalysis.

# The Selective Debenzylation of *N*-Acyl-*O*-benzylhydroxylamines

By Mitsuo MASAKI, Junzo OHTAKE, Masatoshi SUGIYAMA and Masaki OHTA

(Received June 25, 1965)

It has been shown in our laboratory[1] that the catalytic hydrogenation of *N*-leucyl-*O*-benzylhydroxylamine (I) yields *N*-leucylhydroxylamine (II). This hydrogenolytic method was applied to *N*-acyl-*O*-benzylhydroxylamines and found to yield either hydroxamic acid or amide selectively in either the presence or absence of a trace of pyridine.

$$\underset{\text{(I)}}{\textit{iso}\text{-}C_4H_9\overset{\displaystyle NHR}{\overset{|}{C}}HCONHOCH_2C_6H_5} \rightarrow \underset{\text{(II)}}{\textit{iso}\text{-}C_4H_9\overset{\displaystyle NHR}{\overset{|}{C}}HCONHOH}$$

R=H, $C_3H_7COCH_2$

*N*-(2-Bromo-4-methylvaleryl)-*O*-benzylhydroxylamine (III-a) prepared from 2-bromo-4-methylvaleryl chloride and *O*-benzylhydroxylamine according to the usual method[1] was dissolved in 1 N sodium hydroxide, and the solution was neutralized with 1 N hydrochloric acid to afford *N*-(2-hydroxy-4-methylvaleryl)-*O*-benzylhydroxylamine (III-b), m. p. 76—77°C (Found: C, 66.04; H, 8.27; N, 6.04. Calcd. for $C_{13}H_{19}NO_3$: C, 65.80; H, 8.07; N, 5.90%). When III-b was hydrogenated with hydrogen-5% palladium on charcoal at an initial pressure of 40 kg./cm$^2$ in ethanol, only the corresponding amide (IV-b) was obtained in a 81% yield, m. p. 79—81°C (lit.[2] m. p. 51—52°C) (Found: C, 54.90; H, 9.82; N, 11.90. Calcd. for $C_6H_{13}NO_2$: C, 54.94; H, 9.99; N, 10.68%), instead of the expected hydroxamic acid (V-b).

When I is compared with III-b, the difference is found to consist only in substituents of the $\alpha$-position, amino- and hydroxyl-groups; thus some effect of the basic amino-group of I might cause the difference in the course of hydrogenation.

$$\underset{\text{(III)}}{\textit{iso}\text{-}C_4H_9\overset{\displaystyle X}{\overset{|}{C}}HCONHOCH_2C_6H_5}$$

$$\textit{iso}\text{-}C_4H_9\overset{\displaystyle X}{\overset{|}{C}}HCONH_2 \quad \text{(IV)}$$

$$\textit{iso}\text{-}C_4H_9\overset{\displaystyle X}{\overset{|}{C}}HCONHOH \quad \text{(V)}$$

a, X=Br b, X=OH c, X=H

The catalytic reduction of III-b by a similar technique was then carried out in the presence of a few drops of pyridine; this yielded exclusively the corresponding hydroxamic acid (V-b), which was isolated by conversion into the copper salt, followed by treatment of the latter with hydrogen sulfide; 73% yield, m. p. 104—105.5°C (Found: N, 9.67. Calcd. for $C_6H_{13}NO_3$: N, 9.52%). The hydroxamic acid gives a wine red color with ferric chloride.

In a similar manner, *N*-(4-methyl-2-pentenoyl)-*O*-benzylhydroxylamine (VI), prepared from 4-methylpentenoyl chloride and *O*-benzylhydroxylamine, was catalytically hydrogenated in the presence of a few drops of pyridine to yield *N*-(4-methylvaleryl)hydroxylamine (V-c) in a 56% yield, m. p. 57—58.5°C (Found: N, 10.94. Calcd. for $C_6H_{13}NO_2$: N, 10.68%), which gave a wine-red ferric reaction, while the catalytic hydrogenation of VI in the absence of pyridine gave only the corresponding amide (IV-c) in a 96% yield.

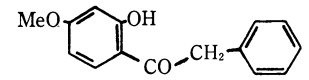
# A New Method for the Synthesis of Isoflavones



By Kenji FUKUI and Mitsuru NAKAYAMA

(Received July 1, 1965)

Of the several known methods[1] for synthesizing isoflavones, the formylation reaction, consisting of the condensation of benzyl 2-hydroxyphenyl ketones (*o*-hydroxydeoxybenzoins), is considered to be the most convenient. The Duff reaction,[2] in which formylation is effected by hexamine, has been used for the preparation of *o*-hydroxyaromatic aldehydes from phenols. The action of hexamine on the ketones has now been studied, since formylation at the reactive methylene group should lead to an isoflavone directly. Under the conditions used for the formylation of phenols, an isoflavone could be isolated in a highly pure state. This new method may be illustrated by the preparation of 7-methoxyisoflavone (I).[3] Benzyl 2-hydroxy-4-methoxyphenyl ketone (II)[4] was refluxed for several hours with an excess of hexamine in acetic acid. The resulting solution, when treated with hydrochloric acid and then poured into water, gave the isoflavone (I).

I

II

The general applicability of the method has been studied by the preparation of a number of other isoflavones, including dehydro-*O*-dimethylsophorol.[5] The results are summarized in Table I. This simple method proceeds satisfactorily when all the hydroxyl groups in the

# A New Red Platinum(II)-Platinum(IV) Compound

By Sigeo KIDA

(Received July 3, 1965)

A number of compounds, e. g., $[PtBr_2(NH_3)_2]$-$[PtBr_4(NH_3)_2]$ and $[PtCl_2en][PtCl_4en]$,[1] have been known as platinum(II)-platinum(IV) compounds, which can be regarded as consisting of platinum(II) and platinum(IV) complexes. The characteristic feature of these compounds is their intense color, which can not be expected from the component complexes. This anomalous color has been believed, on the basis of X-ray[2] and ultraviolet[3] investigations to be due to the platinum(II)-halogene-platinum(IV) interaction. Among these compounds the red Wolffram salt,[1,4] $[Ptea_4][PtCl_2ea_4]$-$Cl_4 \cdot 4H_2O$ (where "ea" denotes ethylamine), has attracted much interest; its prominent properties are its clear red color, the distinct dichroism, and the colorlessness of its aqueous solution. This compound has been believed to be unique in containing ethylamine, since, according to Reihlen and Flohr,[5] the substitution of ethylamine with other amines (or ammonia) does not lead to the formation of homologue compounds.

In this paper, in spite of Reihlen's statment, a new red platinum(II)-platinum(IV) compound, which should be one of the homologues of Wolffram's salt and which yet has no ethylamine, will be reported.

This compound was obtained in the course of synthetic work on $[Pten_3](ClO_4)_4$ (where "en" denotes ethylenediamine). Hexachloroplatinic acid was heated with an excess of ethylenediamine in 96% ethanol for 1.5 hr. The resulting light yellow precipitate was filtered and then extracted with a small amount of water. When to this solution, 60% aqueous perchloric acid was added, red crystals appeared.

This compound was found by elementary analyses to have the formula $Pten_2Cl(ClO_4)_2$ (Found: Pt, 35.80; C, 8.83; H, 3.13; N, 10.42; Calcd.: Pt, 35.49; C, 8.74; H, 2.93; N, 10.42%). The properties of this compound are similar to those of Wolffram's salt. The crystal shows a remarkable dichroism, is red (when parallel to the needle) and a very light yellow (when perpendicular to the needle). It is stable in the air, decomposes above 220°C, and is soluble in water, forming a colorless solution from which the red crystals can be recrystallized by adding concentrated perchloric acid.

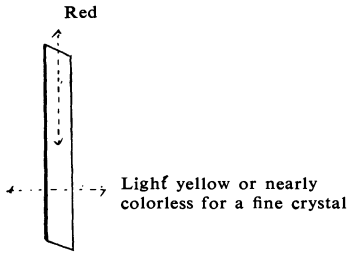

Fig. 1. Microscopic observation and dichroism of the red crystal.

The compound was directly sythesized from the colorless solution of $[Pten_2]Cl_2$ and $[PtCl_2$-$en_2]Cl_2$ at an equimolar ratio by adding 60% perchloric acid. Elementary analyses, infrared spectra, and microscopic observations indicated that the two products, obtained by different methods, are the same compound.

From the above facts, a rational formula would be $[Pten_2][PtCl_2en_2](ClO_4)_4$; this compound is undoubtedly one of the homologues of Wolffram's red salt.

A number of combinations of platinum(II) and platinum(IV) complexes are now being investigated in an attempt to obtain new compounds of this type.

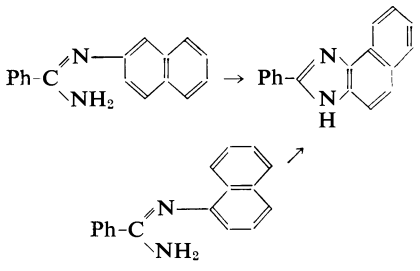
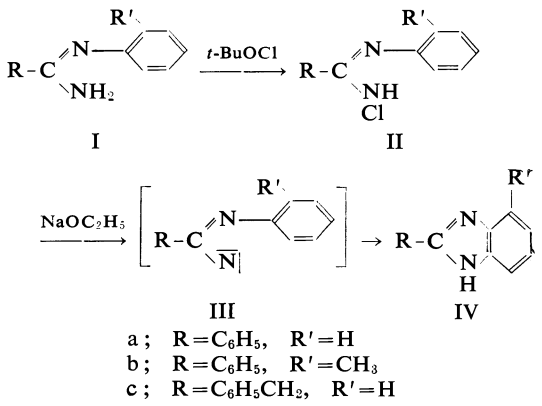
# The Preparation of 2-Substituted Benzimidazoles and 2-Phenylnaphtho-[1, 2-d]imidazole from *N*-Arylamidines



By Eiichi HARUKI, Toshihiro INAIKE and Eiji IMOTO

(Received August 2, 1965)



Grenda et al.[1] have recently reported the preparation of benzimidazoles from *N*-aryl-*N'*-haloamidines in an aqueous solvent. Independently of them, we also discovered an analogous method for the preparation of substituted benzimidazoles and 2-phenylnaphtho-[1, 2-d]imidazole during the course of a research program into the preparation and the reactivity of *N*-haloamidines. In our case, the benzimidazole derivatives and 2-phenylnaphtho[1, 2-d]-imidazole were obtained by the treatment of *N*-aryl-*N'*-chloroamidines with an equivalent amount of sodium ethoxide in benzene-ethanol.

To 3.9 g. (0.02 mol.) of *N*-phenylbenzamidine in 15 ml. of dry benzene and 15 ml. of absolute ethanol, there was added 2.3 g. of *t*-butyl hypochlorite at 0—−5°C. After the mixture had been stirred at the same temperature for two hours, 0.9 g. of sodium in 10 ml. of absolute ethanol was added; the mixture was then refluxed for three hours. When the mixture was cooled and poured into ice water, brown precipitates were obtained. Recrystallization from aqueous ethanol gave 3.1 g. (80% yield) of a pure product, m. p. 289—290°C. This compound was identified as 2-phenylbenzimidazole by means of infrared and ultraviolet spectroscopic measurements, and by a mixed melting point test with an authentic sample which had been prepared according to the method described in the literature.[2]

By the same procedure, *N*-(*o*-tolyl)benzamidine was converted to 4-methyl-2-phenylbenzimidazole in a 76% yield, and *N*-phenylphenylacetamidine, to 2-benzylbenzimidazole in a 35% yield. However, the attempt to convert *N*-phenylacetamidine to 2-methylbenzimidazole was unsuccessful. Both *N*-(α-naphthyl)benzamidine and *N*-(β-naphthyl)benzamidine afforded the same product, 2-phenylnaphtho-[1, 2-d]imidazole, in 24% and 64% yields respectively.

Our proposed mechanism for this reaction is as follows:

a; R=$C_6H_5$, R'=H
b; R=$C_6H_5$, R'=$CH_3$
c; R=$C_6H_5CH_2$, R'=H

Amidines react with *t*-butyl hypochlorite to give *N*-chloroamidines (II), which are isolated as discrete intermediates. The reaction of sodium ethoxide with *N*-haloamidines would produce the nitrene intermediate (III), which attacks the benzene nucleus to give the benzimidazole ring.

The usual syntheses of the benzimidazole ring system utilize *o*-phenylenediamine or *o*-nitroaniline as starting materials.[3] In either case, the cyclization involves a coupling at the *o*-phenylene nitrogens. It is interesting to note that the benzimidazole ring can be prepared without using *o*-phenylenediamine derivatives.

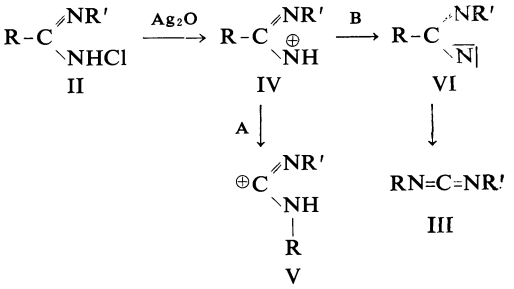
# A Novel Method for the Preparation of Carbodiimides from *N*-Haloamidine

By Eiichi HARUKI, Toshihiro INAIKE and Eiji IMOTO



(Received August 2, 1965)

In a previous communication,[1] we have shown that *N*-aryl-*N'*-haloamidines react with sodium ethoxide to form benzimidazole derivatives or 2-phenylnaphtho[1, 2-d]imidazole depending on the structure of the haloamidines. In this communication we wish to report on the reaction of *N*-aryl-*N'*-haloamidines with silver oxide. The *N*-haloamidines were mixed with silver oxide in ligroin or benzene, and these mixtures were refluxed. This treatment caused a rearrangement, thus forming the carbodiimides.

To 2.3 g. of *N*-chloro-*N'*-phenylbenzamidine in 10 ml. of dry ligroin, 5.0 g. of silver oxide was added. The mixture was stirred under reflux for two hours, and then silver oxide and silver chloride were removed by filtration. After the solvent had been evaporated from the filtrate in vacuo, diphenylcarbodiimide b.p. 140—144°C/14 mmHg, was obtained in a 80% yield. Its infrared spectrum showed the characteristic carbodiimide absorption at 2150 $cm^{-1}$ and agreed completely with that of an authentic sample prepared by the method described in the literature.[2] Chemical evidence for structure III was given by the reaction with hydrochloric acid. When refluxed in dilute hydrochloric acid, diphenylcarbodiimide was converted quantitatively into *N*, *N'*-diphenylurea.

In a similar manner, *N*-phenylphenylacetamidine (Ib) and *N*-phenylacetoamidine (Ic) yielded *N*-benzyl-*N'*-phenylcarbodiimide (IIIb, 52% yield) and *N*-methyl-*N'*-phenylcarbodiimide (IIIc, 36% yield) respectively.

The mechanism of the described conversion of *N*-chloroamidines to carbodiimides may be supposed to be as follows:

a; $R=C_6H_5$, $R'=C_6H_5$
b; $R=C_6H_5CH_2$, $R'=C_6H_5$
c; $R=CH_3$, $R=C_6H_5$

Whether the rearrangement proceeds through route A or route B is not certain. However, it is sure that this reaction involves the migration of the R group to an electron-deficient nitrogen.

# The Proton Magnetic Resonance Spectrum of Hydrogen Sulfide and HDS

By Kensuke TAKAHASHI and Genjiro HAZATO

(Received August 3, 1965)

The proton magnetic resonance spectrum of HDS has not yet been observed. Our interest is drawn to the proton-deuteron coupling constant of HDS and its isotope shift with reference to hydrogen sulfide. The equilibrium of the following exchange reaction, another point of interest, has been studied by many authors:[1]

$$H_2O+HDS \rightleftarrows H_2S+HDO$$

This equilibrium suggests one possibility of observing the multiplet spectrum of HDS if the exchange rate is not too rapid. We have estimated that the gas phase is suitable for observing the spectrum of HDS because we can easily expect a slower exchange rate in gas than in liquid.

About equal volumes of $D_2O$ and liquid hydrogen sulfide were therefore introduced into a 5 mm. glass tube in a vacuum, using a small amount of tetramethylsilane as an internal reference. Measurements for a gaseous mixture of hydrogen sulfide and HDS were carried out at about 24°C in contact with a liquid mixture of hydrogen sulfide and $D_2O$ in a sealed glass tube; we could thus estimate the total pressure of hydrogen sulfide and HDS to be about 20 atmospheres. This mixture of hydrogen sulfide and $D_2O$ gave the signal of hydrogen sulfide 0.25 p. p. m. downfield from that of tetramethylsilane in the gas phase. The triplet of HDS was centered $0.028\pm0.003$ p. p. m. upfield from the hydrogen sulfide resonance, as is shown in Fig. 1, in which one of the triplet lines of HDS seems to overlap with the signal of hydrogen sulfide. The observed proton-deuteron spin-spin coupling constant is $2.1\pm0.2$ c. p. s. The proton-proton spin-spin coupling constant for hydrogen sulfide can be readily obtained by multiplying the experimentally-determined $J_{HD}$ by the ratio of the gyromagnetic ratios, $\gamma_H/\gamma_D=6.51$; we thus get $J_{HH}=13.7\pm1.3$ c. p. s. It can be estimated that the rate of the exchange reaction between hydrogen sulfide and HDS in the gas phase, with the saturated vapor pressure at 24°C, is slower than 0.5 $sec^{-1}$, a value which is derived from the observed proton-deuteron coupling constant. Without $D_2O$, the signal of hydrogen sulfide is observed 0.89 and 0.25 p. p. m. downfield from tetramethylsilane in the liquid and gas phases respectively. The difference of 0.64 p. p. m. between the chemical shifts of the liquid and the gas of hydrogen sulfide may be due to the weak hydrogen-bonded association of hydrogen sulfide in a liquid, as has previously been discussed by Schneider et al.[2]

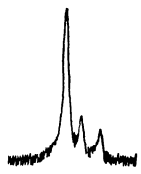

Fig. 1. The proton magnetic resonance spectrum of a gaseous mixture of $H_2S$ and HDS at 24°C in contact with a liquid mixture of $H_2S$ and $D_2O$ in a sealed glass tube. The applied magnetic field increases from left to right.

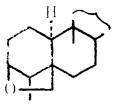
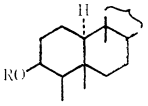
# The Synthesis of 3β-Hydroxyfriedelan-24-oic Lactone

By Toshio FUKUDA, Takahiko TSUYUKI, Yoshiaki TANAHASHI and Takeyoshi TAKAHASHI

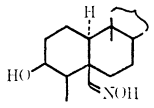


(Received August 16, 1965)

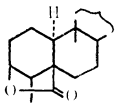
The structure of friedelin (I) has been established,[1] and the presence of a methyl group at $C_5$ has been demonstrated by degradation and by acid-catalyzed rearrangement, as well as by means of biogenetic considerations.[1] However, no direct chemical proof has yet been furnished for this methyl group.



A recent communication[2] on the structure of friedelan-*y*-al, in which the synthesis of 3β,24-oxidofriedelane (II) is registered, has prompted us to report our results in a preliminary form.



(I)



(II)

(III) R=H
(IV) R=NO

(V)

(VI)

3β-Hydroxyfriedelane (III) was, by treatment with nitrosyl chloride in pyridine, converted almost quantitatively into 3β-friedelanyl nitrite (IV); m.p. 261—263°C, $\nu_{max}^{Nujol}$ 1645 and 1610 $cm^{-1}$ (nitrite), $C_{30}H_{51}O_2N$. (Found: N, 3.02. Calcd.: N, 3.06%.) The photolysis of the nitrite (IV) in dry benzene by the Barton procedure[3] using a 100 W. mercury lamp gave 24-oximinofriedelan-3β-ol (V); m.p. 249.5—251°C, $\nu_{max}^{Nujol}$ 3570 and 3300 $cm^{-1}$, $C_{30}H_{51}O_2N$. (Found: N, 3.11. Calcd.: N, 3.06%.) This oxime (V), when treated with chromic trioxide - sulfuric acid, afforded 3β-hydroxyfriedelan-24-oic lactone (VI), m.p. 287—287.5°C, $\nu_{max}^{Nujol}$ 1765 $cm^{-1}$, $C_{30}H_{48}O_2$ (Found: C, 82.20; H, 11.19. Calcd.: C, 81.76; H, 10.98%), whose mass spectrum[4] shows a peak at *m/e* 440 ($M^+$), together with other peaks due to skeletal fragmentations.

The same γ-lactone (VI) was also obtained by an alternative route. A solution of 3β-hydroxyfriedelane (III) in cyclohexane was refluxed for 1.5 hr. with lead tetraacetate in the presence of iodine under irradiation with a 250 W. lamp. The residue obtained, when treated with chromic trioxide - sulfuric acid, gave, after separation by thin-layer chromatography, a lactone, m.p. 286—287°C, $\nu_{max}^{Nujol}$ 1765 $cm^{-1}$, identical (IR, m.p. and mixed m.p.) with 3β-hydroxyfriedelan-24-oic lactone (VI).

The synthesis of 3β-hydroxyfriedelan-24-oic lactone thus achieved furnishes chemical evidence for the presence in friedelin of an axial β-methyl group at $C_5$.

# Effect of the *N*-Substituent on the Course of the Reaction of α-Aminonitriles with Organometallic Reagents[1]

By Juji Yoshimura, Yoshiaki Ohgo and Tetsuo Sato

(Received August 12, 1964)

It is generally known that Grignard reagents or lithium alkyls react with nitriles to afford ketimines or ketones. On the other hand, one of the present authors has previously reported that the cyano group of *N*-phenyl-3, 4; 5, 6-di-*O*-isopropylidene-D-glucosaminonitrile was predominantly substituted with alkyls of various Grignard reagents or lithium alkyls to afford levo- and dextro-rotating diasteromers respectively.[2] Such substituted products have often been obtained along with the normal addition products[3] by Grignard reactions using a nitrile with an amino or a hydroxyl group on its α-carbon.

In the present work, the reactions of Grignard or lithium alkyl reagents with various *N*-substituted α-aminonitriles will be examined in order to clarify the factors governing the reaction courses, namely, the substitution and addition reactions.

## Materials

*N*-Phenyl-3,4-*O*-isopropylidene-D-threosamino- and -erythrosaminonitrile (Ib and Ic), the corresponding *N*-benzyl derivatives (Id and Ie),[4] diastereomeric mixtures of the *N*-ethyl and *N*-dimethyl derivatives (Ia and Ig), and racemic α-phenyl α-dimethylaminoacetonitrile (III)[5] were prepared by the reaction of the corresponding amines, hydrogen cyanide, and either acetone-D-glyceraldehyde or benzaldehyde.

3, 4-*O*-Isopropylidine-*N*-acetyl-*N*-benzyl-D-threosaminonitrile (If) and α-acetamido butyronitrile (II) were prepared by the acetylation of the corresponding α-aminonitriles produced by the above-mentioned procedure.

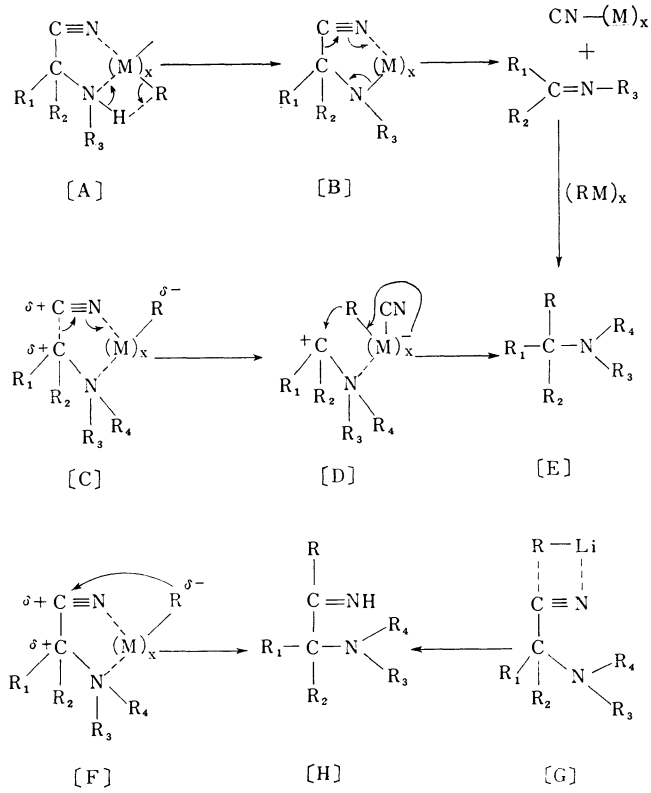
## Results and Discussion

*N*-Substituted 3, 4-*O*-isopropylidene-D-tetrosaminonitriles (Ia—Ig), $\alpha$-acetamido butyronitrile (II) and $\alpha$-phenyl $\alpha$-dimethylaminoacetonitrile (III) were treated with phenylmagnesium bromide, phenyllithium or ethyllithium in ether, and each reaction mixture was decomposed with ice-water.

The amount of cyanide ions liberated in the water layer was determined by titration with a 0.5 N silver nitrate solution; the results are summarized in Table I.

The 2, 4-dinitrophenylhydrazine test was applied to the syrup obtained from the reaction mixtures in which no detectable amount or only a very small amount of cyanide ions was produced. As shown in Table I, the test was positive in all the cases tried. Moreover, elemental analyses of each fraction isolated by high-vacuum distillation from runs 6, 8, 16 and 17 agreed with the structures of the addition products, IV (V),* VIII, VII (VIII)* and IX respectively, as shown in Scheme 1. (Yield: 20—30%; see Experimental section.)



When a considerable amount of cyanide ions was detected in the reaction mixture, the substituted products were derived to VI by treatment with hot 6 N hydrochloric acid and isolated in yields of 20—50%, as shown in Scheme 1.

Scheme 1

* The substance in parenthesis is a minor product.

$(M)_x$ means that x molecules of organometallic reagents are involved in the transition state.

Scheme 2

The structure of VId was confirmed[6] by leading it to the known *N*-acetyl-D(−)-phenylglycine, while those of VIa, VIb, VIc, VIe and VIg were presumed from the analogy of these infrared absorption spectra with that of VId and from their analytical data. VIb and VIc or VId and VIe are diastereomeric to each other.

The analytical data, physical properties, and configurational assignments of the substituted products have been shown in a previous paper.[6]

The results are summarized in Scheme 1.

As runs 1—5 and 9—13 show, both the Grignard reagent and lithium alkyl attack not nitrile carbon but α-carbon to give a substituted product when the α-aminonitrile has an active hydrogen on its aminonitrogen.

Active hydrogen is known to be highly sensitive to organometallic reagents.[3] Consequently, in the case of the α-aminonitrile with an active hydrogen on the aminonitrogen, this reagent may expel the hydrogen in the first step via coordination, thus making an *N*-metal covalent bond. The metal in this state will be coordinated with the neighboring cyano group to form a five-membered ring.

This cyclic chelation may be favored for electron migration, as shown in diagram [B], and the cyano group could smoothly migrate to the metal. The imines thus formed are attacked by another molecule of organometallic reagents to give substituted products [E].

On the other hand, a marked difference appeared in the products between Grignard and lithium alkyl reactions with α-dialkylaminonitriles; Grignard reagents attack α-carbon to give substituted products, but lithium alkyls attack nitrile carbon (runs 5, 15 and 17).

Since there is no place to make a *N*-metal covalent bond in dialkylaminonitriles, this marked differnce between Grignard and lithium alkyl reactions may be attributed to the difference in the coordination ability of the reagents. The elimination of the cyano group of α-dialkylaminonitriles in the Grignard reaction may be interpreted by assuming the initial formation of a coordinative complex [C]. The formation of the complex decreases electron density not only at the nitrile carbon but also at the α-carbon, and it may facilitate the dissociation of the $C_\alpha$–CN bond to form

6) J. Yoshimura, Y. Ohgo and T. Sato, *J. Am. Chem. Soc.*, 86, 3858 (1964).

the cyanide ion and a carbocation [D].* Lithium alkyls would not have as strong a power of attracting electron from these ligands as magnesium, and they would be considered to form the four-center transition state [G],[7] which in turn leads to ketimines. This seems to be related to the fact that the addition reaction of conjugeted carbonyl compounds with lithium alkyls gives the 1, 2 addition product predominantly, while that with Grignard reagents the 1, 4 addition product[8].

Runs 6, 8, 14 and 16 shows that the aminonitriles bearing acetyl group on its aminonitrogen are not attacked at $\alpha$-carbon but at nitrile carbon with both the reagents, thus giving the addition products.

It may be considered that the dissociation of the $C_\alpha$–CN bond of these aminonitriles does not occur, for aminonitrogen whose basicity is weakened by the acetyl group can not coordinate to the metal.

From the above mechanism concerning the Grignard reaction, it may be expected that the existence of factors to prevent the coordination of the aminonitrogen suppress the substitution reaction. In fact, certain $\alpha$-aminonitriles with oxygen in the dialkylamino portion are attacked at nitrile carbon to afford ketones predominantly.[9]

Recent investigations[10] on the composition of Grignard compounds in a solution have shown that a Grignard solution is an equilibrium mixture of several species, such as $R_2Mg$, $MgX_2$, RMgX, $(RMgX)_2$ and $R_2Mg \cdot MgX_2$, and that the natures of the alkyl group, the halogen atom and the solvent all have an effect on the equilibrium.

It would be of interest to investigate which species do play a principal role in the substitution or the addition reaction.

## Experimental

**The General Procedure for the Reaction of $\alpha$-Aminonitriles with an Organometallic Reagent.**—Into an ethereal solution of phenyllithium or phenylmagnesium bromide, prepared from 0.06 mol. of bromobenzene and 0.12 mol. of metal lithium or 0.06 mol. of magnesium, was added 0.02 mol. of aminonitrile with stirring at 0—5°C. The mixture was refluxed for about ten hours, and then it was cautiously poured into ice water covered with 100 ml. of ether. The water layer was separated from the ether layer and extracted twice 50 ml. of ether. The water layer was then titrated by a 0.5 N silver nitrate solution, using potassium iodide as an indicator, in order to determine the amount of cyanide ions liberated in the reaction mixture. In the case of the Grignard reaction, 25 ml. of a 4 N potassium hydroxide solution had previously been added to the water layer in order to prevent the cyanide ions from escaping as hydrogen cyanide; also, an amorphous precipitate was removed by filtration. The filtrate was used for the quantitative determination of the cyanide ions. The ether layer was washed with water, dried, and concentrated in vacuo to a syrup. When a considerable amount of cyanide ion were detected in the water layer, the above syrup was subjected to hydrolysis with a 6 N hydrochloric acid solution (20 ml.) at 100°C for two hours. After tar-like substances insoluble in hydrochloric acid had been removed by filtration through activated carbon, followed by steam distillation, the filtrate was decolorized with activated carbon. After the filtrate had been adjusted to pH 10 with a sodium hydroxide solution it was extracted four times with 50 ml. of ethyl acetate.

The combined ethyl acetate solution was washed twice with 50 ml. of water and dried with anhydrous sodium sulfate. After the ethyl acetate fraction had been concentrated under reduced pressure to dryness, a crude diastereomeric mixture of 1-*C*-phenyl-1-alkylamino-1-deoxy-D-glyceritol became crystals, except for the product from run 9, whose yields were from 20 to 50%.

When no remarkable amount of cyanide ion was detected in the water layer, a small portion of the syrup from the ether layer was tested for the precipitation reaction by 2,4-dinitrophenylhydrazine after the removal of isopropylidene group; in some cases the isolation of addition products from the residual syrup was attempted by high-vacuum distillation.

***N*-Ethyl-3, 4-*O*-isopropylidene-D-tetrosaminonitrile (A Diastereomeric Mixture) (Ia).**—A benzene solution (1.2 l.) of acetone-D-glyceraldehyde[11] prepared from 40 g. of diacetone-D-mannitol by oxidative scission using lead tetraacetate (70 g.) was neutralized with a 50 per cent aqueous potassium carbonate solution (50 ml.). The benzene layer was separated, dried with anhydrous sodium sulfate, and then shaken with 70 per cent ethylamine (50 ml.) for thirty minutes. The resulting reaction mixture was concentrated under reduced pressure to about 200 ml., and to it was added ethanol (100 ml.) and hydrogen cyanide (40 ml.) with cooling. The mixture was then left to stand overnight in a refrigerator and then concentrated in vacuo to a syrup; the syrup was then purified by distillation under reduced pressure.

Yield, 18.9 g. B. p. 88°C (0.35 mmHg).

solution of 50 g. of acetone-D-glyceraldehyde was shaken with 60 ml. of a 30 per cent dimethylamine solution. The mixture was concentrated to about 200 ml. under reduced pressure, mixed with 100 ml. of ethanol and 30 ml. of hydrogen cyanide with chilling, and then left to stand in a refrigerator overnight. The reaction mixture was then concentrated to a syrup, which was distilled to give 21.2 g. of the product. B. p. 81°C (0.2 mmHg).

Found: C, 58.16; H, 8.40; N, 14.21. Calcd. for $C_9H_{16}O_2N_2$: C, 58.67; H, 8.75; N, 15.21%.

**N-Benzyl-N-acetyl-3, 4-O-isopropylidene-D-threosaminonitrile (If).**—To a solution of 4 g. of *N*-benzyl-3,4-*O*-isopropylidene-D-threosaminonitrile (m. p. 86—87°C) in 40 ml. of pyridine 15 ml. of acetic anhydride was added with cooling. After the reaction mixture had been left standing at room temperature for two days, it was poured into ice water. The suspension was extracted with chloroform, and the chloroform layer was repeatedly washed with water, dried, and concentrated to a syrup. The syrup was dissolved in a suitable amount of ethanol and then left to stand overnight in a refrigerator. The crystals which appeared were recrystallized from ethanol-petroleum ether to give colorless plates (2.8 g.). M. p. 81—82°C, $[\alpha]_D$ −34° (*c* 1.03, ethanol).

Found: C, 66.03; H, 7.23; N, 9.73. Calcd. for $C_{16}H_{20}N_2O_3$: C, 66.64; H, 6.99; N, 9.72%.

**N-Acetylbutyronitrile (II).** — To a 100 ml. of ethanol containing 7.4 g. of ammonia was added 25 g. of propionaldehyde and then 40 ml. of hydrogen cyanide with chilling. After the reaction mixture had been left standing in a refrigerator for two hours, it was concentrated carefully under reduced pressure. The syrup obtained was dissolved in 50 ml. of pyridine and then 50 ml. of acetic anhydride was added to the solution with chilling. After it had stood two days at room temperature, the reaction mixture was poured into ice water and extracted with 200 ml. of ethyl acetate. The ethyl acetate layer was separated, washed with water, and dried over anhydrous sodium sulfate. After the ethyl acetate had been removed under reduced pressure, a syrup was obtained by distillation; 101°C (0.03 mmHg).

Found: C, 56.77; H, 7.93; N, 22.48. Calcd. for $C_6H_{10}N_2O$: C, 57.11; H, 7.99; N, 22.21%.

**Addition Products.**—When no cyanide ion could be detected in the reaction mixture, the isolation of the addition product from the ether fraction was attempted by high vacuum distillation in some cases. The addition products were obtained as follows.

*Addition Products from Run 6.* — Three fractions were obtained by the distillation of the syrup from run 6.

I. B. p. 125—126°C (0.01 mmHg); 0.25 g.

The analytical values of this fraction agreed with those of the imino compound (IV).

*The Addition Product from Run 8 (VIII).* — The evolution of ammonia gas was perceived from the reaction mixture of run 8 after it has stood for a week. An oily substance was obtained, besides a small amount of biphenyl, on the distillation of the syrup. Yield, 1.1 g.; b. p. 125°C (0.08 mmHg); $R_f$ 0.89 (BuOH saturated with water).

Found: C, 70.79; H, 7.17; N, 6.78. Calcd. for $C_{12}H_{17}O_2N$: C, 70.22; H, 7.37; N, 6.82%.

*The Addition Products from the Reaction Mixture of Run 16.*—The evolution of ammonia gas was perceived from the reaction mixture of run 16. The distillation of the syrup gave the following fractions.

I. B. p. 135—140°C (0.1—0.2 mmHg); 0.5 g.

The infrared spectrum of this syrup was consistent with VIII.

II. B. p. Over 150°C (0.1 mmHg); 0.3 g. The fraction became crystals. Its analytical value in nitrogen was agreed with that of VII.

Found: N, 13.12. Calcd. for $C_{12}H_{16}N_2O$: N, 13.72%.

III. A small amount of a crystalline product condensed at the top of the thermometer. This substance was identical in analytical value with the substance of fraction II.

Found: N, 13.82. Calcd. for $C_{12}H_{16}N_2O$: N, 13.72%.

*The Addition Product from Run 17 (IX).* — B. p. 111—112°C (20 mmHg).

Found: N, 14.48. Calcd. for $C_{12}H_{18}N_2$: N, 14.75%.

## Summary

The reactions between various *N*-substituted-α-aminonitriles and organometallic reagents have been investigated in order to clarify the effect of the *N*-substituent on the reaction course.

The results indicate that:

(1) Both Grignard reagent and lithium alkyl attack not nitrile carbon but α-carbon to give substituted product when the α-aminonitrile has an active hydrogen on its aminonitrogen.

(2) In the case of α-dialkylaminonitriles, Grignard reagents attack the α-carbon to give substituted products, but lithium alkyls attack the nitrile carbon.

(3) The aminonitriles bearing acetyl group on its aminonitrogen are not attacked at α-carbon but at nitrile carbon by both the reagents, thus giving addition products.

The authors wish to express their hearty thanks to the members of the Laboratory of Organic Analysis, Tokyo Institute of Technology, for their microanalysis.

# The Adsorption of Copper(II), Dichromate(II) and Oxalate(II) by Different Samples of Precipitated Hydrous Beryllium Oxide

By Rup DUTTA

(Received August 13, 1964)

In an earlier communication[1] we have described the precipitation of hydrous beryllium oxide by different alkalis, like sodium, potassium and ammonium hydroxides, from a beryllium sulfate solution. It has been shown that hydrous beryllium oxide is always associated with sulfate and sodium or potassium, according to whether the medium of precipitation is acidic or alkaline. This behavior has been attributed to the fact that at lower pH values, the precipitated hydrous oxide is basic in character and adsorbs anions, while at higher pH values it is predominantly acidic in character and preferentially adsorbs cations from the solution (Table IV). This shows, therefore, the amphoteric nature of the hydrous oxide in media of different pH values. It is worthwhile to mention here that, at different stages of precipitation, the ions adsorbed by the hydrous beryllium oxide could not be removed by washing it with hot water or even by heating the precipitated mass.

Extensive studies[2-7] of the adsorption of dyestuffs by precipitated hydrous oxides have been carried out in these laboratories. Tewari, Dey and Ghosh,[8] from a consideration of the adsorption of dyestuffs by hydrous oxides, attempted to elucidate the mechanism of the ageing of metal hydroxide.

It has been thought desirable to study the adsorption of some inorganic ions by different samples of hydrous beryllium oxide, prepared with different amounts of alkali, this paper will record the observation of the association of copper(II), dichromate(II) and oxalate(II) with the samples of hydrous beryllium oxide.

## Experimental and Results

**Materials.**—Beryllium sulfate, copper sulfate, potassium dichromate and sodium thiosulfate solutions of the desired strengths were prepared from B. D. H., AnalaR grade chemicals and standardized by the usual methods (Arthur I. Vogel).

**The Preparation of the Samples of Hydrous Oxide.**—The samples, A, B and C, of the hydrous oxide were obtained by adding calculated amounts of a standard solution of sodium hydroxide to 500 ml. of a 0.5 M beryllium sulfate solution at 25°C.

A: precipitated with an equivalent sodium hydroxide
B: precipitated with a 10% deficient sodium hydroxide
C: precipitated with a 10% excess sodium hydroxide

These samples were thoroughly washed by decantation with distilled water the washings were free from a majority of the sulfate and hydroxyl ions. (The hydroxyl ions were removed completely, but the last traces of sulfate ions could not be removed completely due to the increasing tendency of the hydrous oxide to form a colloidal solution on further washing.)

These samples were then allowed to age for a month in Jena glass bottles. The volumes of these suspensions were raised by dilution with water to 0.2 M of beryllium oxide per liter after ageing; the pH values of A, B and C were then found to be 6.1, 5.6 and 6.9 respectively.

**Adsorption Experiments.**—To 5 ml. of suspension (0.001 M), varying amounts of the electrolyte solution were added, and the volumes were raised to 15 ml. The systems were then allowed to equilibrate for 24 hr. at 30°C. In the supernatant liquids, the concentrations of the ions were estimated, copper and dichromate iodometrically and oxalate against a standard permanganate solution. The amounts of ions adsorbed, $x/m$, where $x$ is the amount of adsorbent adsorbed on $m$ g. of adsorbate, are given below.

TABLE I. ADSORPTION OF CUPRIC IONS BY VARIOUS SAMPLES OF HYDROUS BERYLLIUM OXIDE

| Initial concn. M×10⁶ | Values of cupric ion adsorbed $x/m$ | | |
|---|---|---|---|
| | Sample A | Sample B | Sample C |
| 159.6 | 88.7 | 94.2 | 43.5 |
| 128.7 | 67.2 | 71.7 | 34.2 |
| 106.0 | 52.0 | 55.0 | 25.9 |
| 85.2 | 37.5 | 39.7 | 19.9 |
| 53.3 | 17.0 | 18.2 | 10.0 |
| Total: | 262.4 | 278.8 | 133.5 |

Adsorptive capacities of samples A, B and C are in the sequence B>A>C.

TABLE II. ADSORPTION OF DICHROMATE IONS BY VARIOUS SAMPLES OF HYDROUS BERYLLIUM OXIDE

| Initial concn. $M\times10^6$ | Values of $x/m$ | | |
|---|---|---|---|
| | Sample A | Sample B | Sample C |
| 26.70 | 11.00 | 5.75 | 11.50 |
| 21.45 | 7.90 | 4.70 | 9.80 |
| 17.75 | 7.85 | 4.05 | 8.50 |
| 14.20 | 6.30 | 3.40 | 7.45 |
| Total : | 38.55 | 20.35 | 42.15 |

Adsorptive capacities of samples A, B and C in the sequence are C>A>B.

TABLE III. ADSORPTION OF OXALATE IONS BY VARIOUS SAMPLES OF HYDROUS BERYLLIUM OXIDE

| Initial concn. $M\times10^6$ | Values of $x/m$ | | |
|---|---|---|---|
| | Sample A | Sample B | Sample C |
| 79.95 | 26.40 | 11.85 | 31.50 |
| 53.30 | 22.65 | 9.40 | 25.65 |
| 42.60 | 19.75 | 7.85 | 23.40 |
| 26.65 | 13.60 | 5.70 | 17.35 |
| Total : | 82.40 | 34.80 | 97.90 |

Adsorptive capacities of samples A, B and C in the sequence are C>A>B.

## Discussion

The above tables conclusively show that in the case of the adsorption of cupric ions, the amount of adsorption reaches a maximum for sample B, prepared from deficient amount of alkali, and a minimum for sample C, prepared from an excess of alkali, and is in the order of B>A>C. In the case of oxalate and dichromate, the order of adsorption, as noted, is C>A>B, showing thereby that sample C, prepared from an excess of alkali, has the maximum adsorptive capacity for the ions.

It is well known that amphoteric bodies depend on environmental conditions to display their acidic and basic characters. A sample prepared from an excess of alkali should have an acidic character and should adsorb cations. Similarly, an acidic character and should adsorb cations. Similarly, a sample prepared from a deficient quantity of alkali should have a basic property and should preferentially adsorb anions.

In the case of beryllium hydroxide, however, the results show that the adsorption is in the reverse order; i.e., sample C displays a basic character and shows a maximum adsorption for dichromate or oxalate anions. Similarly, sample B shows an acidic character and results in a maximum adsorption for copper cation. It has been explained in an earlier communication,[1] that during the precipitation of hydrous beryllium oxide by different alkalis, the precipitated mass always contains sodium or potassium or sulfate according as the medium of precipitation is, respectively, alkaline or acidic (cf. Table IV). Moreover, as has been said earlier, these adsorbed ions could not be removed by either washing with hot water or heating the precipitated mass.

Table IV shows the amounts of beryllium oxide (in mg.) obtained in the residue and $SO_3$ obtained in the filtrate, when the precipitation of beryllium from beryllium sulfate was carried out with sodium hydroxide. The pH change during the precipitation has also been recorded. It is clear from Table IV that, when the pH of the precipitating medium is made less than 9 by the addition of deficient alkali, the adsorption of $SO_3$ is prominent on the beryllium oxide precipitate (which is represented by sample B), but that as soon as the pH

| 1 : 3.0 | 11.70 | 50 | 61.6 | 160.0 | 160.1 |
| 1 : 4.0 | 11.85 | 50 | 61.5 | 160.0 | 160.1 |

goes above 9 upon the addition of an excess of alkali, sodium ions are preferentially adsorbed by the beryllium oxide (which is represented by sample C).

These results, therefore, conclusively show that sample B, prepared from a deficient quantity of a alkali, which is already associated with anion sulfate, prevents the further association of other oxalate or dichromate anions, and showing thereby the least adsorption value for these anions. Similarly, sample C, prepared from an excess of alkali, is already associated with the cation sodium, prevents the further association of any other cation like copper from the solution.

## Summary

Three samples, A, B and C, of hydrous beryllium oxide were prepared by adding different amounts of alkali to a fixed volume of a beryllium sulfate solution.

Sample A prepared with an equivalent amount of alkali, sample B prepared with a 10% deficient amount of alkali, sample C prepared with a 10% excess amount of alkali.

These samples were washed thoroughly and allowed to age for a month. The adsorption capacities of these samples for the ions copper(II), oxalate(II) and dichromate(II) were then studied. The adsorption of copper(II) by different samples was found to be in the order B>A>C, whereas in the case of oxalate and dichromate the order of adsorption, is C>A>B.

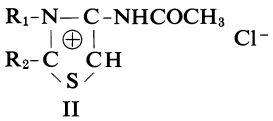
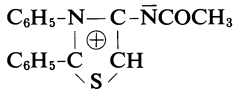
# The Reaction of "4-Thiazone Imine" Derivatives with Acetic and Benzoic Anhydride[1]



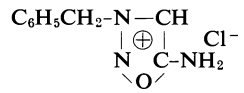
By Chung-gi SHIN and Masaki OHTA

(Received December 8, 1964)

In a previous paper of this series, the synthesis of some new meso-ionic compounds, 4-thiazone imine hydrochlorides (Ia), by the condensation of thioamides with $\alpha$-halonitriles was reported.[2] The acetylation of Ia by acetic anhydride at 100°C afforded hydrochlorides of an acetyl derivative IIa, which in turn gave a free acetyl derivative III when treated with an aqueous solution of sodium hydrogen carbonate.[2]



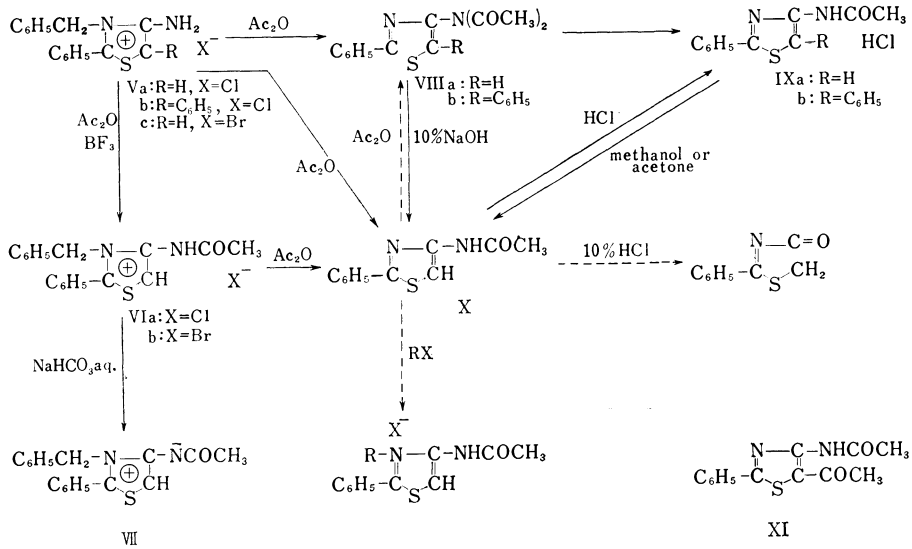
I



II

Ia : $R_1=C_6H_5$, $R_2=C_6H_5$
b : $R_1=C_6H_5$, $R_2=CH_3$
c : $R_1=CH_3$, $R_2=C_6H_5$
d : $R_1=p\text{-}ClC_6H_4$, $R_2=C_6H_5$
IIa : $R_1=C_6H_5$, $R_2=C_6H_5$
b : $R_1=C_6H_5$, $R_2=CH_3$
c : $R_1=CH_3$, $R_2=C_6H_5$
d : $R_1=p\text{-}ClC_6H_4$, $R_2=C_6H_5$

III

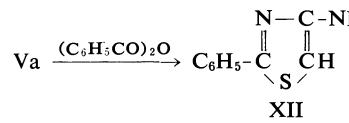


IV

Recently, the thermal instability of sydnone imine hydrochlorides possessing an aralkyl group, such as the benzyl group in the 3-position (IV), has been reported by Daeniker and Druey,[3] but the structures of the decomposition products have not yet been described.

In the course of our studies of the acylation of 4-thiazone imine salts, the present authors

1) This paper is the part XXIII of "Studies on Meso-ionic Compounds."
2) H. Chosho, K. Ichimura and M. Ohta, This Bulletin, 35, 1670 (1964).
3) H. U. Daeniker and J. Druey, *Helv. Chim. Acta*, 45, 2426 (1962).

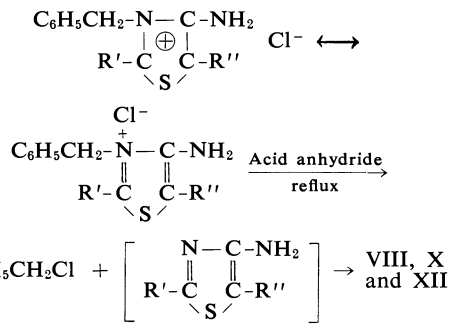


have found that 3-benzyl derivatives behave peculiarly towards acylation under special conditions. When 3-benzyl-2-phenylthiazone imine hydrochloride (Va) was treated with acetic anhydride in the presence of boron trifluoride in acetic acid at room temperature for about two weeks, until all of the solids dissolved, the monoacetyl derivative VIa was obtained in a good yield as colorless prisms. Compound VIa gave the free acetyl derivative VII upon treatment with an aqueous solution of sodium hydrogen carbonate. On the other hand, we found that when Va was refluxed with acetic anhydride, 4-diacetylamino-2-phenylthiazole (VIIIa) or a mixture of VIIIa and 4-acetylamino-2-phenylthiazole (X) was obtained, depending upon the reaction temparature and the duration of the heating. Thus, the benzyl group was eliminated and one or two acetyl groups were introduced in this reaction. The elimination of the benzyl group as benzyl chloride was confirmed by the gas chromatographic analysis of the mother liquor. The action of acetic anhydride on VIa under reflux for 45 min. gave X, also.

When an acetone solution of VIIIa was treated with 30% ethanolic hydrogen chloride at room temperature, the hydrochloride of the monoacetyl derivative IXa was obtained in an almost quantitative yield, while under a brief reflux in acetone or methanol, IXa gave the monoacetyl derivative X. This free base could also be obtained by boiling VIIIa with a 10% sodium hydroxide solution for a few minutes. Considering that 4-thiazone, with no substituent at the 5-position, is acetylated at the 5-position (XI) by heating it with acetic anhydride,[4] it is probable that one of the acetyl groups in VIIIa may be located at the 5-position, but when 3-benzyl-2, 5-diphenylthiazone imine hydrochloride (Vb) was refluxed with acetic anhydride, a diacetyl derivative VIIIb was also obtained, and it in turn gave monoacetyl derivative IXb upon hydrolysis. Only a very few 4-aminothiazole derivatives can be found in the literature. In order to establish the structure of the new acetyl derivatives, VIII and X, we tried the synthesis of X using thiobenzamide and chloroacetonitrile under various conditions; however, these attempts resulted only in the formation of resinous matter. The acetylation of Ia was reported in our previous paper,[2] in which 4-thiazone imine hydrochloride was heated with acetic anhydride at 100°C for many hours. When Ia–d were refluxed with acetic anhydride for one hour, monoacetylated thiazone imine hydrochlorides IIa–d were obtained in a good yield without the elimination of the substituent at the 3-position. The facile elimination of the benzyl group at the 3-position is, of course, due to the stability of the benzyl cation.

An attempted preparation of the 5-bromo derivative of Va with bromine in chloroform at room temperature afforded, in a high yield, yellow tablets of 3-benzyl-2-phenylthiazone imine hydrobromide (Vc), the structure of which was indicated by elemental analysis and by its infrared absorption spectrum, which was essentially identical with that of Va. It shows the same reactivity as compounds Va and Vb. Thus, by the action of acetic anhydride as in the case of Ia, Vc gave the monoacetyl derivative VIb at room temperature, while under

4) Part XVIII: M. Ohta, H. Chosho, C. Shin and K. Ichimura, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **85**, 440 (1964).



reflux, it gave X, also. An attempted preparation of VIIIa from X with acetic anhydride was not successful. Also not successful were the alkylation of X with benzyl chloride or methyl iodide and the hydrolysis of X with 10% hydrochloric acid. Moreover, we found that when Va was fused with benzoic anhydride in an oil bath for 10 min., 4-benzoylaminothiazole (XII) was obtained in a good yield.

XII

The structures of these 4-aminothiazole derivatives, VIII, IX, X and XII, were assigned on the basis of elemental analyses and their infrared absorption spectra. The elemental analysis of VIIIa is consistent with either one of two structures, VIIIa or XI; the infrared absorption spectrum showed the sharp stretching bands of two carbonyl groups, at 1700 and 1650 $cm^{-1}$, as in the case of VIIIb, which showed bands at 1720 and 1700 $cm^{-1}$. The disappearance of the $-NH_2$ stretching band at 3250 $cm^{-1}$ and the characteristic sharp absorptions of the 4-thiazone imine ring at about 1630, 1570 and 1500 $cm^{-1}$ in the cases of VIIIa and VIIIb, however, suggest the formation of *N*-diacetylated 4-aminothiazole derivatives. Compounds X and XII showed typical secondary amide absorptions, the former at 3200, 1650 and 1290 $cm^{-1}$, and the latter at 3250, 1660 and 1265 $cm^{-1}$.

Daeniker et al.[3,5] have reported the facile removal of the benzyl group of *N*-acetyl-3-benzylsydnone imine by reduction and the formation of *N*-substituted diazoacetamide. They explained its formation in terms of an intermediate formation of the 1, 2, 3-oxadiazole derivative. The formation of VIII, X and XII by reaction with acid anhydride can very possibly be explained by a similar sequence of reactions, which can be shown as follows:

5) H. U. Daeniker and J. Druey, *Helv. Chim. Acta*, **46**, 805 (1963).

We expected the reaction of acid anhydride with *N*-acyl-3-benzylsydnone imine hydrochloride to be similar and we have found that the same type of reaction does indeed take place. The details of this will be the subject of a future report.

## Experimental

**3-Benzyl-2-phenyl-*N*-acetylthiazone Imine Hydrochloride (VIa).**—A suspension of 1 g. of Va in 10 ml. of acetic anhydride and 3 drops of boron trifluoride in acetic acid was heated on a steam bath for 4—5 hr. and then kept standing for about two weeks until all the solid had dissolved. The color of the solution turned brown. The removal of acetic anhydride by evaporation under reduced pressure afforded a brown oil. Upon the addition of anhydrous acetone, colorless prisms crystallized out. Recrystallization from chloroform-ether also afforded colorless prisms. Yield, 0.7 g.; m. p. 150—151°C.

Found: C, 62.90; H, 5.01; N, 8.42. Calcd. for $C_{18}H_{17}ClN_2OS$: C, 62.70; H, 4.93; N, 8.13%.

**2, 3-Diphenyl-*N*-acetylthiazone Imine Hydrochloride (IIa).**—A suspension of 2 g. of Ia in 20 ml. of acetic anhydride was heated under reflux for one hour, until all of the solids had dissolved; the removal of half of the acetic anhydride by evaporation under reduced pressure then afforded colorless precipitates. The precipitates were collected by means of suction and washed with acetone (yield, about 1 g.). An additional 1 g. was obtained from the brown filtrate. Recrystallization from ethanol-ether gave colorless prismatic needles. The total yield of IIa was 1.6 g.; m. p. 291—292°C (decomp.). The melting point and the infrared spectrum of IIa were shown to the identical with those of an authentic sample. In exactly the same manner as in the case of IIa, *N*-monoacetylated 4-thiazone imine hydrochlorides, IIb, IIc and IId, were prepared from the corresponding thiazone imine hydrochlorides.

IIb: m. p. 228—229°C (decomp.), yellow needles.
Found: C, 53.42; H, 4.92; N, 10.74 Calcd. for $C_{12}H_{13}ClN_2OS$: C, 53.63; H, 4.84; N, 10.43%.

IIc: m. p. 215—216°C (decomp.), yellow needles.
Found: N, 10.54. Calcd. for $C_{12}H_{13}ClN_2OS$: N, 10.43%.

IId: m. p. 279—280°C (decomp.), colorless prisms.
Found: N, 7.76. Calcd. for $C_{17}H_{14}Cl_2N_2OS$: N, 7.67%.

**3-Benzyl-2-phenyl-4-thiazone Imine Hydrobromide (Vc).**—Into a solution of 10 g. of Ia in 100 ml. of chloroform, 5.3 g. of bromine in 30 ml. of chloroform were gradually added and stirred for 2 hr. at room temperature. When the chloroform was removed by evaporation under reduced pressure without heating, a brown residual oil was obtained. Yellow precipitates were crystallized out from the oil by the addition of acetone. Yield, 9.3 g.; m. p. 194—195°C (decomp.).

Found: C, 55.06; H, 4.64; N, 8.09. Calcd. for $C_{16}H_{15}BrN_2S$: C, 55.34; H, 4.32; N, 8.07%.

In the same manner as in the case of Ic, 2, 3-diphenyl-4-thiazone imine hydrobromide was obtained from the corresponding hydrochloride (Ia) (2 g.) and recrystallized from ethanol-ether as yellow needles. Yield, 1.8 g.; m. p. 209—210°C (decomp.).

Found: C, 54.26; H, 3.29; N, 8.52. Calcd. for $C_{15}H_{13}BrN_2S$: C, 54.05; H, 3.90; N, 8.41%.

**3-Benzyl-2-phenyl-*N*-acetylthiazone Imine Hydrobromide (VIb).**—A suspension of 2 g. of Vc in 20 ml. of acetic anhydride and 1 ml. of boron trifluoride in acetic acid was swirled on a steam bath for 2 hr., by which time all of the solids had dissolved. The removal of the acetic anhydride of the solution by evaporation under reduced pressure afforded a brown oil. White precipitates were crystallized out from the oil by the addition of acetone. Recrystallization from ethyl acetate-ethanol gave colorless prismatic needles. Yield, 1.5 g.; m. p. 160—161°C.

Found: C, 55.85; H, 4.70; N, 7.40. Calcd. for $C_{18}H_{17}BrN_2OS$: C, 55.52; H, 4.37; N, 7.20%.

**3-Benzyl-2-phenyl-*N*-acetylthiazone Imine (VII).**—To 20 ml. of an aqueous solution of VIa (4.5 g.), 10 ml. of a saturated aqueous solution of sodium hydrogen carbonate was added, and the mixture was shaken with benzene. The benzene layer was then washed with water and dried with sodium sulfate. The removal of the benzene afforded 3.5 g. of yellow crystals, which were then recrystallized from acetone-petroleum ether. Yield, 2.8 g.; m. p. 155—156°C.

Found: C, 69.87; H, 5.02; N, 9.43. Calcd. for $C_{18}H_{16}N_2OS$: C, 70.13; H, 5.19; N, 9.25%.

**2-Phenyl-4-diacetaminothiazone (VIIIa).**—A suspension of 7 g. of Va in 50 ml. of acetic anhydride was heated gently under reflux for 30 min.; the subsequent removal of the acetic anhydride of the solution by evaporation under reduced pressure afforded colorless needles. Recrystallization from a small amount of methanol afforded colorless prismatic needles. Yield, 3.8 g.; m. p. 98—99°C. The crystals showed $\lambda_{max}^{EtOH}$ 290 mμ (ε=11700) and 296 mμ (ε=21100).

Found: C, 60.00; H, 4.62; N, 10.77. Calcd. for $C_{13}H_{12}N_2O_2S$: C, 60.01; H, 4.55; N, 11.06%.

In the same manner as in the case of VIIIa, VIIIb was obtained from Vb (1 g.) and recrystallized from methanol as colorless needles. Yield, 0.5 g.; m. p. 108—109°C. The crystals showed $\lambda_{max}^{EtOH}$ 230 mμ (ε=18700), 240 mμ (ε=18500), 285 mμ (ε=12600) and 304 mμ (ε=13500).

Found: C, 67.44; H, 4.77; N, 8.40. Calcd. for $C_{19}H_{16}N_2O_2S$: C, 67.85; H, 4.80; N, 8.33%.

**2-Phenyl-4-acetaminothiazole Hydrochloride (IXa).**—To a solution of 0.5 g. of VIIIa in 6 ml. of anhydrous acetone, 3 ml. of a 30% ethanolic hydrogen chloride solution was added portion-by-portion at room temperature; small colorless needles were thereby crystallized out. The crystals were filtered and washed with acetone. Yield, 0.45 g.; m. p. 165—166°C (decomp.).

Found: C, 52.22; H, 4.59; N, 11.61. Calcd. for $C_{11}H_{10}ClN_2OS$: C, 51.87; H, 4.32; N, 11.01%.

In the same manner as in the case of IXa, IXb was obtained from VIII (1 g.) and recrystallized from acetone as yellow prisms. Yield, 0.6 g.; m. p. 182—183°C (decomp.).

Found: C, 61.94; H, 4.29; N, 8.75. Calcd. for $C_{17}H_{15}ClN_2OS$: C, 61.73; H, 4.54; N, 8.47%.

**2-Phenyl-4-acetaminothiazole (X).**—*a) From Va.*—A solution of 2 g. of Va in 50 ml. of acetic anhydride was heated under reflux for 1 hr.; the subsequent removal of the acetic anhydride from the solution by evaporation under reduced pressure afforded colorless precipitates, to which 8 ml. of acetone was then added and the solution filtered. To the filtrate was added, portion-by-portion, 10 ml. of a 30% ethanolic hydrogen chloride solution at room temperature. In a few minutes, small colorless needles began to separate out. After 20 min., the products were filtered and washed with acetone. Recrystallization from methanol afforded colorless tablets. Yield, 0.6 g.; m. p. 169—171°C. The crystals showed $\lambda_{max}^{EtOH}$ 238 mμ (ε=24600) and 315 mμ (ε=10900).

Found: C, 60.36; H, 4.69; N, 12.99. Calcd. for $C_{11}H_{10}N_2OS$: C, 60.54; H, 4.62; N, 12.84%.

*b) From Vc.*—A suspension of 2 g. of Vc in 20 ml. of acetic anhydride was heated under reflux for 45 min., during which time Vc was gradually dissolved in it. The removal of the acetic anhydride by evaporation under reduced pressure afforded colorless tablets. Yield, 0.6 g.; m. p. 170—171°C. This material was shown, by mixed melting point determination and by a comparison of their infrared absorption spectra, to be identical with the X obtained from Va.

*c) From VIa.*—A solution of 1 g. of VIa in 10 ml. of acetic anhydride was heated under reflux for 45 min.; then the acetic anhydride was removed by evaporation under reduced pressure. Crude colorless precipitates were obtained. Recrystallization from benzene gave colorless tablets. Yield, 0.3 g. In the same manner as in the case of c), X was obtained from VIb.

*d) From VIIIa.*—A suspension of 2 g. of VIIIa in a 10% aqueous sodium hydroxide solution was heated under reflux for a few minutes, during which time the crystal form of Va was gradually changed. After cooling, the products were collected by filtration. Recrystallization from methanol afforded colorless tablets. Yield, 1.2 g.; m. p. 170—171°C.

*e) From IXa.*—A suspension of IXa (0.45 g.) in acetone was heated under reflux for 20 min.; crude crystals were crystallized out after the removal of the acetone. Recrystallization from methanol afforded colorless tablets. Yield, 0.25 g.; m. p. 170—171°C.

**2-Phenyl-4-benzoylaminothiazole (XII).**—Two grams of Va and 1.5 g. of benzoic anhydride were fused at 200—210°C in an oil bath for 10 min. The reaction mixture turned brown, and then in a few minutes, colorless prisms were separated out. After these had cooled, anhydrous ether was added, and the products were filtered and washed with anhydrous ether. Recrystallization from ethanol gave colorless needles. Yield, 0.8 g.; m. p. 128—129°C. The material showed $\lambda_{max}^{EtOH}$ 315 mμ (ε=24100).

Found: C, 68.66; H, 4.43; N, 10.04. Calcd. for $C_{16}H_{12}N_2OS$: C, 68.58; H, 4.29; N, 10.00%.

The authors are indebted to Miss Toshiko Aoyagi for her elementary analysis.

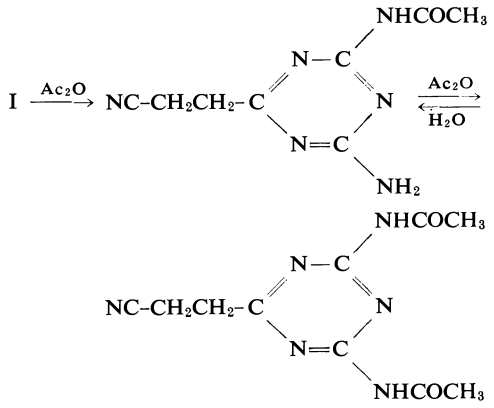
# The Reaction of Nitriles and Dicyandiamide

By Yoshio IWAKURA, Keikichi UNO and Shinsaku SHIRAISHI

(Received December 9, 1964)

Guanamine formations from dicyandiamide and nitriles[1-5] and their application to the preparation of various compounds[6,7] have been investigated by many workers, but the systematic investigation of the reaction of dinitriles with dicyandiamide has not yet been reported. This paper will, therefore, describe the formation of mono and diguanamines from dinitriles and dicyandiamide, the reaction of cyano groups in polymer molecules with dicyandiamide, and the chemical behavior of the cyano group of β-cyanopropioguanamine.

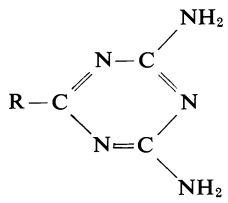


The reaction of one mole of succinonitrile and two moles of dicyandiamide with sodium methoxide as a catalyst in methanol gave an addition compound consisting of one molecule of each starting material instead of the expected succinoguanamine. The structure of the addition compound (I) was determined to be β-cyanopropioguanamine by identifying it with an authentic sample prepared from ethyl β-cyanopropionate and biguanide.

Succinoguanamine (II) was obtained by the reaction of I with dicyandiamide at 130—140°C in either dimethylformamide or methyl cellosolve in the presence of either sodium methoxide or potasium hydroxide. It was also identified with the authentic sample prepared from dimethyl succinate and biguanide. The reaction of one mole of succinonitrile and two moles of dicyandiamide at 130—140°C in methyl cellosolve in the presence of potassium hydroxide also gave succinoguanamine.

When the reaction of succinonitrile with dicyandiamide was carried out in methanol, I was precipitated from the reaction mixture in an almost pure state as a result of its insolubility to methanol, even if an excess dicyandiamide was employed. On the other hand, in methyl cellosolve, diguanamine was obtained with two moles of dicyandiamide and one mole of succinonitrile, or with one mole each of I and dicyandiamide. The reaction of each mole of succinonitrile and dicyandiamide in methyl cellosolve gave I, together with a trace amount of II.

The results suggest that mono and diguanamine selectively can be obtained from the dicyano compound and dicyandiamide, depending on the reaction temperature and solvent employed. Similar reactions of dicyandiamide with various nitriles were carried out under various reaction conditions; the results are summarized in Tables I and II. The yields of mono and diguanamines from dinitriles with odd numbers of methylene groups were comparatively low.



The acetylation of I with acetic anhydride gave mono and diacetyl derivatives. The diacetyl derivative was easily hydrolyzed to form the monoacetyl derivative by heating it in glacial acetic acid or water. This behavior is similar to that of acetoguanamine.[8]

The hydrolysis of I with 6 N hydrochloric acid or with a 1 N sodium hydroxide solution, followed by the neutralization of the reaction

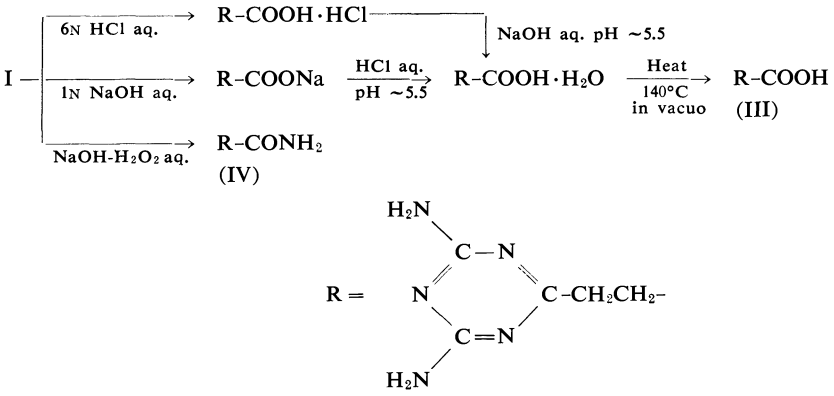
| | 1[b] | 90 | | | | |

a) Methanol and sodium methoxide were used as the reaction solvent and catalyst respectively.
b) Methyl cellosolve and potassium hydroxide were used as the reaction solvent and catalyst respectively.
1) Not characterized adduct was obtained; m. p. >330°C. When it was heated in water, mirystonitrile was separated on the surface.
2) Tar-like substance was obtained.
3) When methanol was used as the reaction solvent, guanamine was not obtained.
* MCS indicates methyl cellosolve (ethyleneglycol monomethyl ether).

TABLE II. SYNTHESIS OF DIGUANAMINES



| -R- | Reaction time hr. | Yield % | M. p. °C | N, anal. Found | N, anal. Calcd. |
|---|---|---|---|---|---|
| -$(CH_2)_2$- | 1 | 70 | >360 | *1 | |
| -$(CH_2)_3$- | 2 | 25*[2] | 265—270 | *1 | |
| -$(CH_2)_4$- | 3 | 90 | 285 (d.) | 50.57 | 50.70 |

| 6 | | 1 | 0.8 | 0.1 | 50 | 10 | 2 | — | 1*3 |

*1 The nitrogen content of starting AS resins were 8.30% (AS1), 7.30% (AS2) and 5.39% (AS3).
*2 Conversion means the ratio of the number of cyano groups converted to diamino-*sym*-triazine to those of the starting polymers.
*3 Determined from infrared spectra.

mixture up to pH 5.5, gave β-carboxypropioguanamine (III). The hydrolysis of I with an alkaline aqueous solution of hydrogen peroxide gave β-(4, 6-diamino-*sym*-triazin-2-yl) propionamide (IV). Each compound, III and IV, combines with one molecule of water, and the dehydration of the hydrates can be conducted by heating them at a temperature above 140°C under reduced pressure.

The reaction of dicyandiamide with cyano groups in polymer molecules was studied in order to modify the properties of the polymers. Polyacrylonitrile and acrylonitrile-styrene copolymers (AS resins) were used as the polymers. Copolymers containing 4, 6-diamino-*sym*-triazine were obtained from the AS resins, but not from polyacrylonitrile. The reaction mixture with polyacrylonitrile gelled and colored in the presence of potassium hydroxide. The mixture of dimethylformamide and methyl cellosolve was suitable for the reaction solvent. The infrared spectra of the modified AS resins obtained here showed new peaks at 3025—3060 (two peaks), 1630, 1545 and 824 $cm^{-1}$, the locations of the characteristic bands of guanamines.[9] The ratio of the number of cyano groups converted to diamino-*sym*-triazine to that of the starting polymer was determined by nitrogen analysis. The acrylonitrile contents of the starting copolymers were 47.3 mol.% (AS1), 42.8 mol.% (AS2) and 33.3 mol.% (AS3). The results obtained are summarized in Table III. It can be concluded that no degradation of the polymer main chain occurred in the course of the reaction; only a small change in reduced specific viscosity was observed (0.84 before to 0.78 after the reaction for the sample of Exp. No. 2).

The modified AS resins gave insoluble and infusible substances when treated with an aqueous solution of formaldehyde. However, the reaction, as well as the properties of the products, has not yet been investigated in detail.

## Experimental

**β-Cyanopropioguanamine (I).**—To a mixture of 30 g. of succinonitrile and 31 g. of dicyandiamide in 230 ml. of absolute methanol, 50 ml. of methanol containing 3 g. of sodium was added. The reaction mixture was then heated and stirred under reflux for 30 min. After the mixture had then cooled, the resulting precipitate was filtered, washed twice with 30 ml. of methanol, and dried. It was recrystallized from water; m. p. 241.5—242°C (colorless needles); yield, 40 g. (66%); IR, 3505, 3440,

3370 (N-H), 2270 (C≡N), 1672, 1645, 1543, 1425 and 818; UV, 258 mμ ($\varepsilon_{max}$=3800).

Found: C, 44.35; H, 5.05; N, 51.47. Calcd. for $C_6H_8N_6$: C, 43.89; H, 4.90; N, 51.19%.

**Succinoguanamine (II).** — Into a solution of 1.8 g. of I and 0.9 g. of dicyandiamide in 20 ml. of dimethylformamide there was added 5 ml. of a methanolic solution of sodium methoxide which had been freshly prepared from 0.1 g. of sodium; the mixture was then heated at 130—140°C for 3 hr. After the mixture had then been cooled, a white precipitate formed was filtered and washed with hot water. It did not melt at 360°C. The infrared spectrum showed the absorption bands characteristic to guanamines, but not around the 2250 $cm^{-1}$ of C≡N. When methyl cellosolve was used as the reaction solvent, potassium hydroxide was used as the catalyst.

**Guanamines.** — *o-Cyanobenzoguanamine.* — a) (In methanol) To a solution of 6.2 g. of phthalonitrile and 4.2 g. of dicyandiamide in 40 ml. of methanol, there was added a sodium methoxide solution which had been made by dissolving 0.5 g. of sodium in 10 ml. of methanol. The mixture was refluxed for 30 min. The white precipitate thus formed was filtered and recrystallized from water; yield, 8.8 g. (85%); m. p. 230.5—231.5°C.

Found: C, 56.19; H, 4.19; N, 39.85. Calcd. for $C_{10}H_8N_6$: C, 56.59; H, 3.80; N, 39.61%.

b) (In methyl cellosolve) A mixture of 1.1 g. of phthalonitrile, 0.8 g. of dicyandiamide and 0.1 g. of potassium hydroxide in 15 ml. of methyl cellosolve was heated at 130—140°C for 2 hr. The reaction mixture was then poured into cold water. A white precipitate was collected by filtration and recrystallized from water; yield, 1.6 g. (80%); m. p. 230—231°C.

*Phthaloguanamine.*—a) (From *o*-cyanobenzoguanamine) A mixture of 1.1 g. of *o*-cyanobenzoguanamine, 0.5 g. of dicyandiamide, 0.1 g. of potassium hydroxide and 20 ml. of methyl cellosolve was heated at 130—140°C for 8 hr. The white powder which was thus precipitated was filtered and washed with methanol. M. p. 340—343°C.

b) (From phthalonitrile) A mixture of 1.3 g. of phthalonitrile, 1.7 g. of dicyandiamide, 0.2 g. of potassium hydroxide and 30 ml. of methyl cellosolve was heated at 130—140°C for 7 hr. The white powder which was thus precipitated was filtered and washed with methanol. M. p. 340-343°C.

Other mono and diguanamines were synthesized by similar procedures. The results are summarized in Tables I and II.

**2-Acetamino-4-amino-6-β-cyanoethyl-1, 3, 5-triazine.**—A solution of 6 g. of I in 30 ml. of acetic anhydride was heated under reflux for several minutes, thus precipitating a white solid. This was collected by filtration and recrystallized from water; m. p. 230—231°C.

Found: N, 41.02. Calcd. for $C_8H_{10}N_6O$: N, 40.76%.

**2, 4-Diacetamino-6-β-cyanoethyl-1, 3, 5-triazine.**—When the above reaction was continued without the isolation of the monoacetate, the precipitate disappeared once, thus forming a clear solution. After another hour of reflux, however, a grayish precipitate was deposited. This was collected by filtration and recrystallized from acetic anhydride; m. p. 213—215°C.

Found: N, 33.7. Calcd. for $C_{10}H_{12}N_6O_2$: N, 33.86%.

**The Monohydrochloride of I.**—A solution of 1 g. of I in 10 ml. of cold 6 N hydrochloric acid was allowed to stand overnight in ice box. The white precipitate which was thus formed was filtered and washed with methanol; m. p. 208—209°C (decomp.); IR, 2280 (C≡N).

Found: N, 41.61; HCl, 18.5 (from the neutralization value with 0.1 N NaOH aq.). Calcd. for $C_6H_8N_6 \cdot HCl$: N, 41.90; HCl, 18.2%.

**The Acidic Hydrolysis of I.**—*β-(4,6-Diamino-sym-triazin-2-yl)propionic Acid (III).*—A mixture of 3 g. of I in 60 ml. of 6 N hydrochloric acid was heated to reflux for 5 hr. The white precipitate which was thus formed was filtered and recrystallized from water, giving colorless needles of a monohydrochloride of III. They did not melt, but they did decomposed at a temperature above 250°C, forming a black mass.

Found: N, 31.72 (Kjeldahl method). Calcd. for $C_6H_9N_5O_2 \cdot HCl$: 31.89%.

A solution of 2 g. of the monohydrochloride in 100 ml. of water was neutralized with a 1 N sodium hydroxide aqueous solution to a pH value of 5.5. The white precipitate which was thus formed was collected and recrystallized from water, giving a monohydrate of III; m. p. 262°C (decomp.). The infrared spectrum of this compound showed absorption bands at 3350 (broad), 2800—2500 $cm^{-1}$ (COOH) and other regions characteristic of guanamines.

Found: N, 35.03 (Kjeldahl method). Calcd. for $C_6H_9N_5O_2 \cdot H_2O$: N, 34.81%.

The monohydrate was dehydrated by heating it at 140°C in vacuo for 5 hr., thus forming III; m. p. 262°C (decomp.); IR, 3450, 3300 (N-H), 2800—2500 $cm^{-1}$ (COOH).

Found: N, 38.00 (Kjeldahl method). Calcd. for $C_6H_9N_5O_2$: N, 38.24%.

**The Alkaline Hydrolysis of I.**—A mixture of 2 g. of I and 1 g. of sodium hydroxide in 25 ml. of water was refluxed for 30 min. The evolution of ammonia was observed. After it had then been cooled, the mixture was neutralized with 5 N hydrochloric acid to a pH value of 5.5. The product precipitated was the same as the monohydrate of III obtained in the preceding section.

**β-(4, 6-Diamino-*sym*-triazin-2-yl)propionamide (IV).**—A solution of 2 g. of I and 0.1 g. of sodium hydroxide in 40 ml. of a 9% hydrogen peroxide aqueous solution was heated at 60—65°C for 40 min. The precipitate which was thus formed was collected by filtration and recrystallized from water, giving a monohydrate of IV; m. p. 250—251°C (decomp.).

Found: C, 36.33; H, 6.14; N, 42.26. Calcd. for $C_6H_{10}N_6O \cdot H_2O$: C, 36.00; H, 6.04; N, 41.98%.

The monohydrate was dehydrated by the same procedure as that used for III to give IV; m. p. 251—252°C (decomp.).

Found: N, 46.52. Calcd. for $C_6H_{10}N_6O$: N, 46.13%.

**The Reaction of AS Resins with Dicyandiamide.** —(Exp. No. 2). To a solution of 2 g. of AS1 in 20 ml. of dimethylformamide, 20 ml. of methyl cellosolve and 3 g. of dicyandiamide were added. The mixture was then heated at 130°C until a clear solution was obtained. To this solution there was added 0.2 g. of potassium hydroxide. The mixture was then kept at 130°C for 5 hr., after which it was poured into methanol. The polymer thus precipitated was filtered, washed with methanol, and purified by reprecipitation with a dimethylformamide-methanol system. The reduced specific viscosity of AS1 and of the modified polymer obtained here were, respectively, 0.84 and 0.78, at 30°C at the concentration of 0.2 g. of polymer in 100 ml. of dimethylformamide.

The other reactions of AS resins with dicyandiamide were carried out similarly; the results are summarized in Table III.

# The Catalytic Effect of the Support on Terpene Compounds in Gas-Liquid Chromatography

By Shûichi HAYASHI, Katsumi YANO, Naruo YOKOYAMA and Tamon MATSUURA

(Received January 22, 1965)

At the present time, diatomaceous earth or its manufactures are in general use as the solid support of a packed column in gas-liquid chromatography because these materials are porous and, consequently, have a large surface area. In the gas chromatography of terpene compounds using these solid supports, unfortunately, erroneous results due to the catalytic action of the support have occasionally been observed. Naves,[1] for instance, has observed dehydration, condensation and other reactions in the gas chromatography of essential oils by the use of diatomaceous earth or firebrick. Cartoni[2] has observed the decomposition of oxygen-containing terpene compounds in gas chromatography using Sterchamol. Using diatomaceous earth, Celite 545, Chromosorb or C-22 firebrick, Vilkas,[3] Zubyk,[4] Lukes[5] and the present authors[6] have reported the isomerisation of $\alpha$-pinene into such compounds as camphene, dipentene and *p*-cymene, and also of $\beta$-pinene into such compounds as $\alpha$-pinene, camphene, dipentene and *p*-cymene. Besides, the liquid phase on diatomaceous earth or fireblick is also rapidly decomposed,[7] as has been shown in Polyethylene glycol-1500 impregnated on Shimalite.[8] Also, the authors[6] have done preliminary research on the catalytic action of several solid materials (commercial supports, rock crystal, glass, etc.), using nearly fifty kinds of monoterpene compounds (hydrocarbons 16, alcohols 11, esters 13, carbonyl compounds 8, etc.); they have found a remarkable catalytic decomposition of terpene compounds by commercial solid supports.

Thus, in order to get a correct gas chromatogram it will be necessary to find a support possessing no catalytic action or a weak one.

In the present investigation, the catalytic action of several materials, such as glass, rock crystal, quartzite, sea sand and unglazed porcelain, and that of several commercial solid supports, such as Shimalite,*1 Diasolid-M,*2 Microsorb-W, -S, -SS and -F,*3 towards six monoterpene compounds and five sesquiterpene alcohols, which were chosen as representative compounds, will be examined in detail.

## Experimental

**Apparatus and Procedure.** — A Shimadzu Gas Chromatograph GC-2 furnished with a katharometer-type detector was used. A coiled copper tube (3 m. long, 4 mm. inner diameter) packed with the

bare material (28—48 mesh) to be examined was connected between a sample injector and a separation column (Fig. 1). The operating temperature and the flow rate of the helium carrier were set as follows: 140°C and 60 ml./min. for the monoterpene compound, 200°C and 30 ml./min. for the sesquiterpene alcohol.

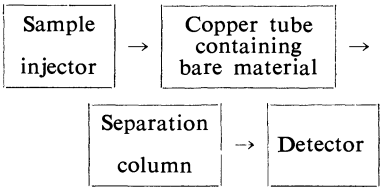

Fig. 1. Scheme of apparatus.

If an injected terpene compound suffers isomerization and/or decomposition by the bare material, its isomerization and/or decomposition products are separated by the next separation column and recorded on a chromatogram. Accordingly, by a comparison of this chromatogram with the chromatogram obtained from a blank test performed without the connection of a column packed with the bare material, one can get information about the catalytic activity and the adsorptivity of this bare material.

Crushed rock crystals (150—200 mesh) coated with 5% Thermol-1*[4] were employed in the separation column throughout this research. The sample size to be injected at one run was in the range from 0.5 to 1.5 $\mu$l.; the value was varied according to the extent of the isomerization and/or the decomposition of the sample. The electric current of the detector cell and the sensitivity of the recorder were set at 200 mamp. and 2 mV. respectively.

**The Preparation of the Solid Materials to be Examined.** — For the preparation of the solid materials (supports) to be examined, the following substances were used: soda-lime glass tubing, scraps of rock crystal from which the quartz oscillator has been cut out, quartzite ($SiO_2$ 99.88%, snow-white color) dug out in Yamanashi Prefecture, Japan, and unglazed porcelain tubing. When these substances were crushed separately in a stainless-steel mortar, 28—48 mesh particles were collected. To these particles ten portions (in volume) of aqua regia were added, and the mixture was boiled for two hours in order to dissolve any metallic impurities that entered during the crushing process. The cleaned particles were washed with water, dried, and heated at 300°C for two hours.

Sea sand ($SiO_2$ 99.02%, $Al_2O_3$ 0.52%, $Fe_2O_3$ 0.32%, trace of CaO, light brown beads), collected in Kam-ranh Bay, Viet Nam, was treated in the same way as above.

All the commercial solid supports examined are manufactured from diatomaceous earth. Of these Shimalite belongs to a usual type, Diasolid is a support which has been treated at a high temperature in order to diminish the adsorptivity for oxygen-containing compounds, and Microsorb is a firebrick precoated with Polyflon,*[5] presumably in order to diminish its adsorptivity and its catalytic activity.

**The Preparation of Terpene Compounds.** — Six monoterpene compounds, that is, $\alpha$-pinene, limonene, linalool, $\alpha$-terpineol, linalyl acetate, and geranyl acetate, were chosen from the standpoint of their sensitivity to the catalytic action. Five sesquiterpene alcohols, that is, $\alpha$- and $\beta$-santalol, $\alpha$-cadinol, patchouli alcohol and elemol, were adopted because they were easily available in our laboratory.

$\alpha$-Pinene (b. p. 156°C, $d_4^{25}$ 0.8544, $n_D^{25}$ 1.4638, $[\alpha]_D$ −39.51°) was isolated from a commercial turpentine oil, while limonene (b. p. 175.5°C, $d_4^{25}$ 0.8397, $n_D^{25}$ 1.4711, $[\alpha]_D$ +117.6°) was isolated from an essential oil of Citrus Natsudaidai Hayata. These two compounds were then each purified by repeated fractional distillation. The other monoterpene samples were commercial materials supplied by the Abrack Co., Ltd. and were used without further purification.

$\alpha$-Santalol and $\beta$-santalol were isolated from an essential oil of the sandal-wood tree through their phthalic ester; each was purified by repeated fractional distillation. The infrared absorption spectrum of $\alpha$-santalol (b. p. 160°C (10 mmHg), $d_4^{25}$ 0.9722, $n_D^{25}$ 1.4998) obtained here coincided with that reported by Herout[10] and Chakravarti[11]. $\beta$-Santalol (b. p. 164°C (10 mmHg), $d_4^{25}$ 0.9703, $n_D^{25}$ 1.5063) was recognized to be contaminated with a small amount of $\alpha$-santalol by a comparison of its infrared spectrum here with that obtained by Chakravarti.[11]

$\alpha$-Cadinol (b. p. 147°C (8 mmHg), $d_4^{25}$ 0.9375, $n_D^{25}$ 1.4960, $[\alpha]_D$ −23.63) was isolated from an essential oil of the hinoki tree,[12] by preparing its sodium alcoholate, and then fractionated. The infrared spectrum of this sample coincided with that reported by Motl et al.[13]

Patchouli alcohol was separated in the crystalline form by cooling commercial Patchouli oil in a refrigerator; it was then recrystallized three times from *n*-hexane. This preparation melted at 59—60°C, a slightly higher point than that shown in Büchi's reported (55—56°C).[14]

Elemol was isolated from Citronella oil by fractional distillation; it was then purified by elution chromatography using silica gel and *n*-hexane. This sample melted at 48—49°C, a value which coincided with that reported by Halsall,[15] and its phenyl urethane melted at 111—112°C, a value which

agreed with the melting point reported in the literature.[16]

## Results and Discussion

Gas chromatograms of monoterpene compounds and sesquiterpene alcohols, which were obtained by an apparatus furnished with a column containing the bare material to be examined, are shown in Figs. 2 and 3. Each run was carried under the same operating conditions. However, the same component did not show an identical retention time in each chromatogram on account of the difference in adsorptivity, depending on the kind of bare material. Every chromatogram shown in Figs. 2 and 3 was corrected, for the sake of convenience, by multiplying a certain factor, one which was special for each material, since the peak of the same component could be seen at an identical position in each gas chromatogram.

In these figures, the top lines represent the results of the blank test, that is, gas chromatograms of terpene compounds obtained without a column packed with the examined bare material. Therefore, if gas chromatograms regarding a certain examined material are compared with those of the corresponding blank test, information about the catalytic activity and the adsorptivity of this material can be obtained.

**Glass.** — As will be seen in Figs. 2 and 3, chromatograms obtained using a connection of a column packed with glass are simpler than chromatograms of the cases employing other bare materials. Besides, the chromatograms where glass was used closely resemble those of the blank test except for the cases of linalyl acetate and of $\alpha$-santalol. In the chromatograms of linalyl acetate and $\alpha$-santalol, several small peaks appear in addition to the main peak; these small peaks are probably due to the catalytic action of glass.

From these observations, the catalytic activity of glass seems to be the feeblest among the examined materials.

**Rock Crystal.**—When a rock crystal-packed column was used, each chromatogram of a monoterpene compound is almost identical with that obtained in the case of glass or the blank test except for the case of linalyl acetate; chromatograms of linalyl acetate and of sesquiterpene alcohols are compared with those in the case of glass. In the chromatogram of linalyl acetate, the peaks, which are small in shape in the case of glass, appear large. In the case of patchouli alcohol, new moderate-size peaks appear besides the main peak. These newly-formed or newly-enlarged peaks are perhaps due to the catalytic action of the bare material.

Therefore, the catalytic activity of rock crystal is slightly stronger than that of glass.

**The Adsorpitivity of Glass Support.** — There have been several papers[17] which have recommended glass beads as a solid support for impregnation with a liquid phase in a low concentration. The present authors[9] and Takayama[18] have, however, pointed out that glass is not suitable as a solid support, because the oxygen-containing compound has shown a broad peak and a remarkable tailing phenomenon when glass has been employed as a solid support, Takeuchi,[19] who has introduced the "tailing coefficient" as a measure to indicate quantitatively the degree of peak tailing, recently compared several solid supports by the tailing coefficient as calculated from the peak of butyl alcohol. According to his results, the tailing coefficient of glass is not small.

The uncorrected retention time of the main peak of each chromatogram involving glass and rock crystal (cf. Figs. 2 and 3) is listed in Table I. In the case of the glass-packed column, the retention time of each compound is ca. 1.5 times as large as that in the case of the rock crystal-packed column, in which the retention time is practically the same as in the blank test.

The peak width measured at half-height is shown in Table II. The peak width of each of the hydrocarbons and the esters is nearly the same in both glass and rock crystal, whereas

TABLE I. COMPARISON OF RETENTION TIME (min.) OF TERPENE COMPOUNDS

| Compound | Bare supporting material connected to the separation column | | |
|---|---|---|---|
| | Blank test | Glass | Rock crystal |
| $\alpha$-Pinene | 2.4 | 3.5 | 2.4 |
| Limonene | 3.7 | 5.3 | 3.6 |
| Linalool | 4.1 | 6.7 | 4.3 |
| $\alpha$-Terpineol | 6.7 | 11.1 | 6.8 |
| Linalyl acetate | 8.2 | 14.0 | 8.5 |
| Geranyl acetate | 14.9 | 25.1 | 14.0 |
| $\alpha$-Santalol | 9.4 | 15.2 | 9.8 |

Table II. Comparison of peak width (min.) measured at one half of peak height

| Compound | Bare supporting material connected to the separation column | | |
|---|---|---|---|
| | Blank test | Glass | Rock crystal |
| α-Pinene | 3.4 | 4.2 | 3.5 |
| Limonene | 3.6 | 4.8 | 3.8 |
| Linalool | 4.7 | 5.6 | 4.6 |
| α-Terpineol | 5.4 | 7.8 | 5.7 |
| Linalyl acetate | 6.6 | 8.7 | 6.8 |
| Geranyl acetate | 10.4 | 14.6 | 10.4 |
| α-Santalol | 13.0 | 21.0 | 13.0 |
| β-Santalol | 20.0 | 25.0 | 20.1 |
| α-Cadinol | 13.0 | 19.7 | 12.8 |
| Patchouli alcohol | 9.0 | 11.6 | 9.0 |
| Elemol | 7.5 | 8.8 | 7.3 |

the peak width of each alcohol is very much larger in glass than in rock crystal. Generally, the peak width in rock crystal is the same as in the blank test.

Such prolongation of the retention time and broadening of the peak width observed in the case of glass are probably due to the adsorption of the oxygen-containing compound on the surface of the glass used as the bare material. In fact, when the bare glass-packed column was set between the injector and the separation column, a considerable tailing phenomenon was observed in the chromatography of oxygen-containing terpene compounds, as compared with the results in the blank test.

Glass showed practically no catalytic action on terpene compounds, but it did show the adsorption or the tailing phenomenon to some extent on oxygen-containing terpene compounds. A further examination of the glass support is being attempted in our laboratory.

**Quartzite and Sea Sand.**—The chromatograms obtained by using quartzite and those in the case of sea sand are almost identical. Besides, the chromatograms in both these cases closely resemble the chromatograms obtained using rock crystal. Therefore, of rock crystal, quartzite and sea sand, it may be said that there is little difference in catalytic activity.

**Unglazed Porcelain.**—All the chromatograms in the case of unglazed porcelain are remarkably complicated compared with those of glass, rock crystal, quartzite and sea sand. Especially, linalyl acetate, α-santalol, α-cadinol and patchouli alcohol do not show the peak corresponding to the original sample in their chromatograms. On the basis of such results, it is obvious that all monoterpene and sesquiterpene compounds suffered an intense action by unglazed porcelain. That is, the catalytic activity of this material is certainly very strong, in spite of the recommendation of Lukes[5] that it has a weak activity.

**Commercial Solid Supports.**—Three groups of commercial solid supports, Shimalite, Diasolid and Microsorb, show chromatograms with characteristic features.

The chromatograms obtained with the Shimalite-packed column are the most complicated; they consist of many peaks projected on a large mountain. In these chromatograms, however, the peak corresponding to the original sample is not observed except in the chromatograms of α-pinene and limonene.

On the basis of such complex chromatograms, it may be assumed that all the terpene compounds examined suffered greatly from various catalytic actions, such as dehydration, dehydrogenation, decarboxylation, isomerization, and the cleavage of a carbon-carbon bond.

On the other hand, the chromatograms obtained by using the Diasolid-packed column show simple features, with only a few peaks, although the catalytic action of Diasolid is obviously vigorous, because the peak corresponding to the original sample is not observed in the chromatograms obtained using this material, except in the case of α-pinene and limonene. Although Diasolid has been subjected to the high temperature-treatment to diminish the catalytic activity of diatomaceous earth, it is not yet satisfactory for the gas chromatography of terpene compounds.

Regarding Microsorb, four manufactures of different grades of activity, W, F, SS and S, were examined. These materials commonly show less-tailling chromatograms than the case with Shimalite or Diasolid. Of these, Microsorb-W gives the simplest chromatograms in shape, that is, the number of peaks is the least; largely the peak corresponding to the original sample is left in these chromatograms. Therefore, the catalytic action of Microsorb-W is assumed to be the weakest among the commercial solid supports examined, and to be nearly the same as that of glass on the basis of a comparison of the two kinds of chromatograms.

**The Gas Chromatography of Terpene Compounds Using Microsorb-W.** — Microsorb-W, which showed the feeblest catalytic action among the commercial solid supports examined, was used for the gas chromatography of terpene compounds.

This support, impregnated with 7% Thermol-1, was packed into a column (4 mm. in internal diameter, 3 m. long), and the conditioning of the column was carried out at 140°C for five hours. Two chromatograms of the mixture which was prepared from ten oxygen-containing compounds are shown in Figs. 4A and 4B.

4A is a chromatogram which has been obtained immediately after the conditioning, while 4B is a chromatogram which has been obtained after 40 hr. In A, there is a large, gently sloping hill; it has been confirmed to be attributable to a trace of water contained in the terpene mixture. On the other hand, no such hill is to be seen in B. Besides, in B the peak resolution is very good, and the retention times of the peaks are also remarkably shortened in comparison with the corresponding peaks in A.

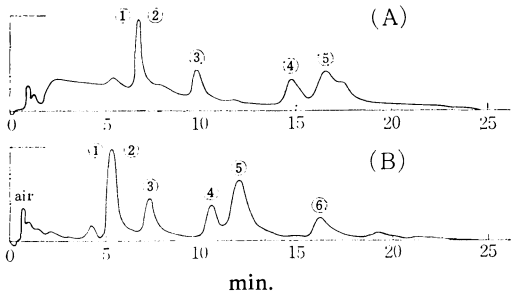

Fig. 4. Gas chromatography of terpene compounds using Microsorb-W.
A: After conditioning at 140°C for 5 hr.
B: After the use of 40 hr.
Stational liquid: Thermol-1 (7%)
Column temp.: 160°C
Flow rate of helium: 40 ml./min.
(1) Ethyl valerianate (2) Benzyl alcohol
(3) Linalool (4) Camphor
(5) Menthol (6) α-Terpineol
(7) Pulegone (8) Hydroxycitronellal
(9) α-Terpinyl acetate (10) α-Pinene

The difference observed between the two chromatograms, of A and of B, is assumed to result from an increase in the surface area of the stationary phase and from a decrease in its thickness, as a result of the evaporation and/or the decomposition of the precoating material. In such a support as Microsorb-W, the activity centers will gradually be exposed from the precoating material. Thus, this support appears unsatisfactory for the gas chromatography of terpene compounds.

**The Catalytic Action of the Stationary Phase Prepared from Diasolid-M.**—The controlling of the catalytic activity on Microsorb by precoating with a high polymer has been shown in the above section. Geranyl acetate, even when Shimalite is used, has been gas-chromatographed without decomposition by the impregnation of

TABLE III. CATALYTIC ACTION OF STATIONARY PHASE PREPARED FROM DIASOLID-M

| Compound | Stationary liquid: Termol-1 (20%) | Polycarbonate (5%) + PEG-6000 (5%) | PEG-6000 (5%) | Result in Figs. 2 and 3 |

+++: D is larger than U.
++++: Complete decomposition with no peak of original sample.

a large quantity of Polyethylene glycol-1500.[20]

In order to clarify the extent of the controlling, several monoterpene compounds were separatly gas-chromatographed using three kinds of stationary phases prepared from Diasolid-M, that is, by the impregnation of 5% Polyethylene glycol-6000 or 20% Thermol-1 into Diasolid-M, and by the impregnation of 5% Polyethylene glycol-6000 into Diasolid-M precoated with 5% polycarbonate.*6 The results are listed in Table III.*7 In the right-hand column of this table, the results regarding Diasolid-M, which has been illustrated in Figs. 2 and 3, are represented using the same symbols for convenience in comparison.

Judging from the results in Table III, it seems difficult to prepare the stationary phase, which is adequately suitable for the gas chromatography of every terpene compound, even by the impregnation of a large quantity of a stationary liquid on Diasolid-M.

20) G. Indo and H. Yukawa, *J. Japan Chem.* (*Kagaku no Ryoiki*), Addendum for Gas Chromatography, No. 3, Nankodo, Tokyo (1962), p. 105.

*6 Presented by the Teijin Kasei Co., Ltd., Matsuyama, Japan.

*7 This experiment was carried out using a flame ionization-type gas chromatograph, because Diasolid is manufactured to use when impregnated with a low concentration of a stationary liquid.

**Summary**

The catalytic action of several solid supports, that is, glass, rock crystal, quartzite, sea sand, unglazed porcelain and commercial supports, have been examined. Glass shows practically no catalytic action in the examined terpene compounds, except for linalyl acetate and $\alpha$-santalol, which were decomposed and/or isomerized slightly, but this support does show an adsorption of oxygen-containing compounds. The catalytic action of rock crystal is slightly greater than that of glass, but the adsorptivity of rock crystal is extremely small. Commercial diatomaceous earth supports show a remarkable catalytic action.

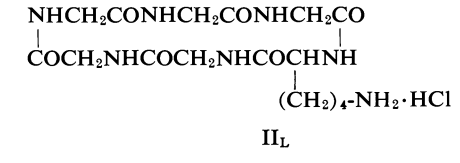
# The Synthesis of Cyclo-pentaglycyl-L-lysyl and Its Hydrolysis by Trypsin

By Motonori OHNO and Nobuo IZUMIYA



(Received January 22, 1965)

In a previous paper from this laboratory, it was shown that L-phenylalanyl- and L-valyl-L-lysine anhydrides are not hydrolyzed by trypsin at the lysine carbonyl linkage.[1] Although the reason why the dipeptide anhydrides are not susceptible to the enzyme is not yet clear, it is possible that a certain minimum ring size is necessary in order that a cyclic peptide can be hydrolyzed by the enzyme. From the literature, it appears that cyclic tri-, tetra- and pentapeptides are difficult to synthesize,[2] but cyclic hexapeptides have been prepared without difficulty.[2,3] Therefore, we attempted to synthesize a cyclic hexapeptide containing a lysine residue.

In the present investigations, the synthesis of cyclo-pentaglycyl-ε-benzyloxycarbonyl-L-lysyl ($I_L$) was studied in detail in an attempt to obtain fundamental information about the syntheses of cyclic peptides; then, cyclo-pentaglycyl-L-lysyl hydrochloride ($II_L$), which had been obtained by the hydrogenolysis of $I_L$, was tested by the trypsin.

$I_L$

$II_L$

3) T. Kato, M. Kondo, M. Ohno and N. Izumiya, This Bulletin, **38**, 1202 (1965).

Various methods for the synthesis of cyclo-pentaglycyl-ε-benzyloxycarbonyllysyl were undertaken. Since the cyclization of a linear active ester gave a better yield than the other cyclization methods,[2] we first attempted to prepare the cyclic peptide by the active ester method. In the present series of syntheses of the cyclic peptide, a benzyloxycarbonyl group was used for the selective blocking of the ε-amino group of the lysine residue.

$\text{VIII}_{\text{PR}}$

$$\varepsilon\text{-Z-}\underbrace{\text{Lys Gly}_5}_{\text{I}_{\text{PR}}} \xrightarrow[\text{HCl-MeOH}]{\text{H}_2/\text{Pd}} \underbrace{\text{Lys Gly}_5}_{\text{II}_{\text{PR}}}\cdot\text{HCl}$$

Fig. 1. Synthesis of cyclic hexapeptide via $\text{VII}_{\text{PR}}$: TRI, trityl; Z, benzyloxycarbonyl; TsOH, *p*-toluenesulfonic acid; $\text{NEt}_3$, triethylamine; M.A., mixed anhydride method; NPS, di-*p*-nitrophenyl sulfite; ONP, *p*-nitrophenoxy.

Figure 1 indicates the sequence of reactions via the linear hexapeptide *p*-nitrophenyl ester, in which ε-benzyloxycarbonyllysine was the *C*-terminal amino acid. The product obtained in a fairly good yield by the cyclization reaction of $\text{VIII}_{\text{PR}}$ was found to be a monomer with a molecular weight in agreement with that of cyclic hexapeptide ($\text{I}_{\text{PR}}$). However, it was found that the lysine residue in the compound $\text{I}_{\text{PR}}$ is partially racemized, since the specific rotation of $\text{I}_{\text{PR}}$ was +0.5, whereas that of optically-pure cyclo-pentaglycyl-ε-benzyloxycarbonyl-L-lysyl ($\text{I}_{\text{L}}$) was +0.9. When calculations are based on the specific rotation, $\text{I}_{\text{PR}}$ is found to contain about 78 per cent of the L-compound ($\text{I}_{\text{L}}$) and 22 per cent of the D-compound. Furthermore, $\text{II}_{\text{PR}}$ derived from $\text{I}_{\text{PR}}$ was not completely hydrolyzed by trypsin. The cyclo-pentaglycyllysyl which remained unchanged appeared to have a D-configuration (see Fig. 8). We assume that a partial racemization had taken place at the step of the *p*-nitrophenyl esterification of VI by di-*p*-nitrophenyl sulfite and pyridine, since Iselin and Schwyzer had reported that a partially-racemized benzyloxycarbonyl dipeptide *p*-nitrophenyl ester was obtained when benzyloxycarbonyl dipeptide was treated with di-*p*-nitrophenyl sulfite and pyridine.[4] Furthermore, since it has been reported that no racemization occurs when the benzyloxycarbonyl dipeptide *p*-nitrophenyl ester which was obtained from benzyloxycarbonyl amino acid and amino acid *p*-nitrophenyl ester is coupled with the amino acid ethyl ester,[5] no racemization may be expected at the step of the formation of $\text{I}_{\text{PR}}$ from $\text{VIII}_{\text{PR}}$ by intramolecular peptide bond formation. Therefore, a glycine or proline residue should be selected as the *C*-terminal amino acid of the *N*-blocked peptide in the case of its *p*-nitrophenyl esterification with di-*p*-nitrophenyl sulfite and a base.

Fig. 2. Synthesis of cyclic hexapeptide with IX and DCC: DCC, dicyclohexylcarbodiimide.

Figure 2 indicates an attempt to cyclize pentaglycyl-ε-benzyloxycarbonyl-L-lysine with two equivalents of dicyclohexylcarbodiimide. The yields were, however, found to be very poor. Contrary to this study, syntheses of cyclic hexa-,[6] hepta-[7] and octapeptide[8] from the pertinent linear peptides with carbodiimide have been reported.

Figures 3 and 4 indicate attempts to cyclize the linear hexapeptide azides. Although it has been reported that cyclo-hexaglycyl is obtained in a good yield by dimerization reaction from triglycine azide,[9] both triglycyl-ε-benzyloxycarbonyl-L-lysylglycylglycine azide and pentaglycyl-ε-benzyloxycarbonyl-L-lysine azide gave only a very small amount of $\text{I}_{\text{L}}$. Sheehan and McGregor reported that the cyclization of tripeptide azide did not give the desired

by the azide method, in which the *C*-terminal amino acid residue is known to be remarkably resistant to racemization.[11] Furthermore, the *p*-nitrophenyl esterification of XX does not cause any racemization since *C*-terminal amino acid is glycine. During this study, we found that the *p*-methoxybenzyloxycarbonyl group was superior to trityl or *t*-butyloxycarbonyl as a group protecting the *N*-terminal amino group of a linear peptide *p*-nitrophenyl ester. The *p*-methoxybenzyloxycarbonyl group is easily, in a few minutes, released at 0°C with trifluoroacetic acid in the absence of water, while the trityl group requires successive treatments with trifluoroacetic acid and water. The experiment, as shown in Fig. 1, indicates that the sensitive *p*-nitrophenyl ester group is degraded partially in the presence of water. Furthermore, we found that the *t*-butyloxycarbonyl peptide could not afford the desired *t*-butyloxycarbonyl peptide *p*-nitrophenyl ester with di-*p*-nitrophenyl sulfite and a base.[12] The yield of $I_L$ from XXI was fairly good, as is shown in Fig. 5. The infrared absorption spectra of $I_L$ was identical with that of $I_{PR}$ (Fig. 6), as were the $R_f$ values of $II_{PR}$ and $II_L$ in the paper chromatography. The hydrogenolysis of $I_L$ yielded the desired cyclic peptide, $II_L$. The homogeneity of $II_L$ wa asscertained by chromatography and by elemental analyses.

It was observed that cyclo-pentaglycyl-L-lysyl is completely hydrolyzed by trypsin to pentaglycyl-L-lysine. This agrees well with the fact that a linear peptide containing L-lysine is susceptible to the hydrolytic action of trypsin at the linkage of lysine carbonyl.[13] An authentic pentaglycyl-L-lysine hydrochloride (XXII) was synthesized, as Fig. 7 shows. This finding is of great interest, because this is the first example of how trypsin can hydrolyze a cyclic peptide. However, glycyl-L-lysine anhydride, a cyclic dipeptide, was found not to be hydrolyzed by trypsin, but it did not inhibit the hydrolysis of $\alpha$-benzoyl-L-arginine amide by trypsin.[14] These enzymatic experiments show that even a cyclic dipeptide containing a L-lysine residue has no affinity to trypsin, while a cyclic hexapeptide, cyclo-pentaglycyl-L-lysyl, can form an enzyme-substrate complex which is finally decomposed to the enzyme and the product. Further experiments on the preparation of cyclic peptides, cyclo-(glycyl$_n$-L-lysyl)$_2$ ($n$=2 and 4), and on their susceptibility to trypsin are in progress in this laboratory.

$$\text{IX} \xrightarrow[80\%]{\text{H}_2/\text{Pd, HCl-MeOH}} \underset{\text{XXII}}{\text{H-Gly}_5\text{-L-Lys-OH}\cdot\text{HCl}}$$

Fig. 7. Synthesis of pentaglycyl-L-lysine hydrochloride.

## Experimental

The melting points were not corrected. The optical rotations were measured on a Yanagimoto Photometric Polarimeter, OR-20 type. The paper chromatography was carried out on Toyo Roshi No. 52 chromatography paper. The thin-layer chromatography was carried out on Merck silica gel G. The developing solvents were *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2) and *t*-butanol - formic acid - water (75 : 15 : 10). Spots of materials possessing a free amino group on a thin layer plate were detected by spraying ninhydrin, and those of the amino group-blocked materials, by spraying 47 per cent hydrobromic acid and then ninhydrin.

**Trityldiglycyl - ε - benzyloxycarbonyl - L - lysine Ethyl Ester (III).**—The mixed anhydride prepared at −5°C from 18.7 g. (50 mmol.) of tritylglycylglycine,[15] 6.7 ml. (50 mmol.) of isobutyl chloroformate and 7.0 ml. (50 mmol.) of triethylamine in 150 ml. of tetrahydrofuran was coupled with 24.0 g. (50 mmol.) of ε-benzyloxycarbonyl-L-lysine ethyl ester *p*-toluenesulfonate[16] dissolved in a chilled mixture of 7.0 ml. (50 mmol.) of triethylamine and 150 ml. of chloroform. The reaction mixture was allowed to stand overnight and then evaporated to dryness in vacuo. The oily residue was dissolved in 250 ml. of ethyl acetate, and the solution was washed successively with 100-ml. portions of 0.5 N acetic acid, a 3% sodium bicarbonate solution and water, dried over sodium sulfate, and then evaporated to dryness in vacuo. The oily residue was then solidified by adding petroleum ether. Yield: 25.7 g. (77%). For analysis, the product was recrystallized from ethyl acetate - ether - petroleum ether; m. p. 107—108°C, $[\alpha]_D^{20}$ −7.1° (*c* 2, methanol).

Found: C, 70.42; H, 6.57; N, 8.45. Calcd. for $C_{39}H_{44}O_6N_4$: C, 70.46; H, 6.67; N, 8.43%.

**Diglycyl-ε-benzyloxycarbonyl-L-lysine Ethyl Ester Hydrochloride (IV).**—To a solution of 6.64 g. (10 mmol.) of III in 50 ml. of methanol, 15 ml. of N hydrogen chloride in methanol was added; then the solution was boiled for 2 min. The solution was concentrated in vacuo and ether was added to the residue. The resulting white crystals were collected by filtration and washed with ether (3.72 g.). The product was recrystallized from methanol - ether. Yield: 3.44 g. (75%); m. p. 144—146°C, $[\alpha]_D^{20}$ −13.2° (*c* 2, methanol).

Found: C, 52.17; H, 6.71; N, 11.84. Calcd. for $C_{20}H_{30}O_6N_4\cdot HCl$: C, 52.34; H, 6.59; N, 12.21%.

**Tritylpentaglycyl-ε-benzyloxycarbonyl-L-lysine Ethyl Ester (V).**—The mixed anhydride prepared at −5°C from 4.32 g. (10 mmol.) of trityldiglycylglycine,[15] 1.3 ml. (10 mmol.) of isobutyl chloroformate and 1.4 ml. (10 mmol.) of triethylamine in a mixture of 30 ml. of tetrahydrofuran and 20 ml. of chloroform was coupled with 4.59 g. (10 mmol.) of IV dissolved in a chilled mixture of triethylamine and 30 ml. of chloroform. The reaction mixture was allowed to stand overnight and then evaporated to dryness in vacuo. The oily residue was dissolved in 200 ml. of chloroform, and the solution was washed successively with 0.5 M citric acid, a 3% sodium bicarbonate solution and water, dried over sodium sulfate, and then evaporated to dryness in vacuo. The oily residue was easily solidified by adding ether and petroleum ether (6.19 g.). The product was recrystallized from acetone-ether. Yield: 5.68 g. (68%); m. p. 94—96°C, $[\alpha]_D^{20}$ −4.7° (*c* 2, dimethylformamide).

Found: C, 64.35; H, 6.56; N, 11.33. Calcd. for $C_{45}H_{53}O_9N_7$: C, 64.65; H, 6.39; N, 11.73%.

**Tritylpentaglycyl-ε-benzyloxycarbonyl-L-lysine (VI).**—To a solution of 1.80 g. (2.15 mmol.) of V in a mixture of 10 ml. of dioxane and 5 ml. of methanol, 2.5 ml. of N sodium hydroxide was added. After 2 hr., the solution was concentrated in vacuo to remove methanol, and the residual solution was diluted with water and acidified with 3.0 ml. of M citric acid under cooling. The precipitate was collected by filtration under cooling and washed with cold water. The product was recrystallized from ethanol-ether. Yield: 1.58 g. (91%). For analysis, this was further recrystallized from ethanol-ether; m. p. 109—112°C, $[\alpha]_D^{20}$ −6.5° (*c* 2, dimethylformamide).

Found: C, 63.25; H, 6.20; N, 12.22. Calcd. for $C_{43}H_{49}O_9N_7$: C, 63.92; H, 6.11; N, 12.14%.

**Tritylpentaglycyl-ε-benzyloxycarbonyllysine *p*-Nitrophenyl Ester ($VII_{PR}$).**—A solution of 1.62 g. (2 mmol.) of VI and 1.30 g. (4 mmol.) of di-*p*-nitrophenyl sulfite[4] dissolved in 10 ml. of pyridine was allowed to stand at room temperature for 15 hr. The solvent was then removed in vacuo, and the oily residue was solidified by adding a mixture of ether and petroleum ether (1 : 1) and scratching. The product was collected by filtration and washed with a mixture of ether and petroleum ether (1 : 1) until the yellow color could not be discerned upon the addition of N sodium hydroxide to the filtrate. A faintly yellow product was obtained. Yield: 1.80 g.; $[\alpha]_D^{20}$ −1.6° (*c* 2, dimethylformamide).

Found: N, 11.43. Calcd. for $C_{49}H_{52}O_{11}N_8$: N, 11.93%.

The solution of 3.04 mg. of this product in 50 ml. of methanol was diluted with N sodium hydroxide to 100 ml. ($c=3.27\times10^{-5}$ M). The absorption of this solution was measured at 404 mμ and compared with a standard curve which had been determined with the benzyloxycarbonyl-L-leucine *p*-nitrophenyl ester in the same solvent.[17] The value of the absorbance of this sample corresponded to $c=3.46\times10^{-5}$ M. Therefore, the *p*-nitrophenyl ester content of this product was estimated to be 106%.

**Pentaglycyl-ε-benzyloxycarbonyllysine *p*-Nitrophenyl Ester Trifluoroacetate ($VIII_{PR}$).**—A solution of 1.0 g. of $VII_{PR}$ dissolved in 18 ml. (25 g.) of trifluoroacetic acid was cooled to −5°C, and then 15 ml. of cold water was added slowly to this solution. After 15 min., the precipitate of triphenylcarbinol was filtered off. The filtrate was lyophilized, and the oily residue was solidified by adding ether and scratching. The powdery solid was collected by filtration and washed thoroughly with a mixture of ether and petroleum ether (1 : 1) until the yellow color could not be discerned upon the addition of N sodium hydroxide to the filtrate. A faintly yellow powder was obtained; 0.660 g. (apparent yield, 86%).

The *p*-nitrophenyl ester content of this product was estimated by the same method as has been described previously except that a mixture of dimethylformamide and N sodium hydroxide (1 : 1) was used as a solvent and the measurement was performed at 411 mμ. The *p*-nitrophenyl ester content was estimated to be 81%. Therefore, the true yield of the compound $VIII_{PR}$ was 70%.

**Cyclo-pentaglycyl-ε-benzyloxycarbonyllysyl ($I_{PR}$).**—A solution of 0.610 g. (0.762 mmol.) of $VIII_{PR}$ in a mixture of 15 ml. of dimethylformamide and 0.15 ml. of acetic acid was stirred drop by drop into 140 ml. of pyridine kept at 55—60°C over a 9-hr. period. The solution was stirred at this temperature for another 2 hr. and then evaporated to dryness in vacuo. The dried residue was dissolved in 160 ml. of a hot mixture of water and methanol (1 : 1), and insoluble materials were filtered off. The filtrate was passed successively through columns (1×14 cm.) of Dowex-50 ($H^+$ form) and Dowex-1 ($OH^-$ form) which had been washed with a mixture of water and methanol (1 : 1). The columns were then washed with a mixture of water and methanol (1 : 1). The filtrate and washings (total 400 ml.) were combined and evaporated to dryness in vacuo. The weight of the dried residue was 0.229 g. (39% from $VII_{PR}$). The crude cyclic product was recrystallized from methanol-water. Yield: 0.193 g. (33% from $VII_{PR}$); m. p. 261—262°C, $[\alpha]_D^{20}$ +0.5° (*c* 1.33, dimethylformamide).

Found: C, 51.90; H, 6.33; N, 17.19. Calcd. for $C_{24}H_{34}O_8N_7\cdot1/2H_2O$: C, 51.62; H, 6.33; N, 17.59%.

The air-dried compound lost 1.62% of its weight after being dried for 2 hr. at 130°C, 0.1 mmHg. Calcd. for $1/2H_2O$: 1.62%. The molecular weight was determined by the micro Rast method with a solvent of hexahydro-*p*-aminobenzoic acid lactam.[18] Calcd.: 549. Found: 557, 510.

**Cyclo-pentaglycyllysyl Hydrochloride ($II_{PR}$).**—A solution of 5.56 mg. (0.01 mmol.) of $I_{PR}$ dissolved in a mixture of 0.4 ml. of 0.025 N hydrochloric acid and 0.2 ml. of water was hydrogenolyzed in the presence of palladium black. After the filtrate had been evaporated to dryness, the residue was filtered with the aid of acetone; yield, 3.0 mg. The homogeneity of $II_{PR}$ was established by

17) R. Schwyzer and P. Sieber, *Helv. Chim. Acta*, **40**, 624 (1957).

18) G. Wendt, *Chem. Ber.*, **75**, 425 (1942).

chromatography ($R_f$[19] 0.27, $R_f$[20] 0.42 and $R_f$[21] 0.13). These values of $R_f$ are identical as those of analytically-pure cyclo-pentaglycyl-L-lysyl hydrochloride ($II_L$).

**Pentaglycyl-ε-benzyloxycarbonyl-L-lysine (IX).**—When 1.0 g. (1.24 mmol.) of VI suspended in 20 ml. of 50 per cent aqueous acetic acid was boiled for 2 min., it dissolved and triphenylcarbinol was deposited.[22] Ten milliliters of water was then added, and the solution was kept in a refrigerator for several hours, after which the carbinol was removed by filtration (0.298 g.). The filtrate was evaporated to dryness in vacuo. The product was filtered with the aid of ethanol (0.630 g.). This was recrystallized from water-ethanol. Yield: 0.500 g. (71%); m. p. 213—214°C (decomp.), $[\alpha]_D^{20}$ −2.4° (*c* 2, 0.2 N hydrochloric acid).

Found: C, 49.44; H, 6.28; N, 17.13. Calcd. for $C_{24}H_{35}O_9N_7 \cdot 1/2H_2O$: C, 49.39; H, 6.39; N, 16.80%.

**An Attempt to Cyclize IX by Dicyclohexylcarbodiimide.**—To a suspension of 0.234 g. (0.414 mmol.) of IX in 10 ml. of dimethylformamide, 0.170 g. (0.828 mmol.) of dicyclohexylcarbodiimide was added. The reaction mixture was kept at 0°C with stirring for 24 hr. and then evaporated to dryness in vacuo. The residue was extracted with 50 ml. of a hot mixture of water and methanol (1 : 1). After the extract had been cooled, the dicyclohexylurea deposited was removed by filtration and the filtrate was passed successively through columns of Dowex-50 ($H^+$ form) and Dowex-1 ($OH^-$ form). The filtrate and washings were then combined and evaporated to dryness in vacuo (0.011 g.). This product contained cyclo-pentaglycyl-ε-benzyloxycarbonyllysyl since the hydrogenolyzed material gave a single spot of $R_f$ 0.27[19] which was identical with $II_{PR}$.

***t*-Butyloxycarbonyltriglycyl-ε-benzyloxycarbonyl-L-lysine Ethyl Ester (X).**—To a stirred solution of 3.50 g. (20 mmol.) of *t*-butyloxycarbonylglycine[23] and 9.18 g. (20 mmol.) of IV in 200 ml. of chloroform, 2.8 ml. (20 mmol.) of triethylamine was added. The solution was then cooled to 0°C, and 4.12 g. (20 mmol.) of dicyclohexylcarbodiimide was stirred into it. The reaction mixture was stirred at 0°C for one hour and then kept in a refrigerator overnight. Dicyclohexylurea was removed by filtration. The filtrate was washed successively with 0.5 M citric acid, a 3% sodium bicarbonate solution and water, dried over sodium sulfate, and then evaporated to dryness in vacuo (9.88 g.). The product was twice recrystallized from ethyl acetate-petroleum ether. Yield: 8.88 g. (79%); m. p. 115—117°C, $[\alpha]_D^{20}$ −8.4° (*c* 2, methanol).

Found: C, 56.11; H, 7.35; N, 11.71. Calcd. for $C_{27}H_{41}O_9N_5$: C, 55.94; H, 7.13; N, 12.08%.

***t*-Butyloxycarbonyltriglycyl-ε-benzyloxycarbonyl-L-lysine (XI).**—To a solution of 8.42 g. (15 mmol.) of X in 45 ml. of methanol, 18 ml. of N sodium hydroxide was added. Saponification was carried out at room temperature for 2 hr. After the removal of the methanol in vacuo, the aqueous solution was acidified with 23 ml. of M citric acid under cooling and the oil deposited was extracted two times with 50-ml. portions of ethyl acetate. The combined ethyl acetate solution was then washed with water, dried over sodium sulfate, and evaporated to dryness in vacuo. The residue was solidified by adding petroleum ether. Yield: 7.44 g. (93%). For analysis, the product was twice recrystallized from ethyl acetate-ether; m. p. 66—67°C, $[\alpha]_D^{20}$ +2.6° (*c* 2, methanol).

Found: C, 54.11; H, 6.60; N, 12.22. Calcd. for $C_{25}H_{37}O_9N_5$: C, 54.43; H, 6.76; N, 12.70%.

***t*-Butyloxycarbonyltriglycyl-ε-benzyloxycarbonyl-L-lysylglycylglycine Benzyl Ester (XII).**—To a stirred, faintly cloudy solution of 5.52 g. (10 mmol.) of XI and 3.94 g. (10 mmol.) of glycylglycine benzyl ester *p*-toluenesulfonate in 200 ml. of chloroform, 1.4 ml. (10 mmol.) of triethylamine was added. The solution was then cooled to 0°C and 2.06 g. (10 mmol.) of dicyclohexylcarbodiimide was added to it. After the mixture had been stirred at 0°C for 4 hr., it was kept in a refrigerator for 2 days and then evaporated in vacuo. The residue was filtered with the aid of water and petroleum ether, and washed with 0.5 M citric acid, a 3% sodium bicarbonate solution and water. The dried mixture was dissolved in methanol and kept in a refrigerator for several hours, and the dicyclohexylurea was removed by filtration. These operations were repeated several times, thus removing almost all the dicyclohexylurea. Finally the filtrate was evaporated to dryness in vacuo. The oily residue was solidified by adding ether and petroleum ether. Yield: 5.80 g. (77%). For analysis, the product was twice recrystallized from methanol-ethyl acetate-ether; m. p. 132—156°C, $[\alpha]_D^{20}$ −0.5° (*c* 2, dimethylformamide).

Found: C, 56.83; H, 6.51; N, 12.38. Calcd. for $C_{36}H_{49}O_{11}N_7 \cdot 1/2H_2O$: C, 56.54; H, 6.35; N, 12.82%.

***t*-Butyloxycarbonyltriglycyl-ε-benzyloxycarbonyl-L-lysylglycylglycine Hydrazide (XIII).**—A solution of 1.51 g. (2 mmol.) of XII and 0.20 g. (4 mmol.) of hydrazine hydrate in 14 ml. of methanol was allowed to stand at room temperature for 24 hr. The solution was then evaporated to dryness in vacuo, after which the oily residue was immediately solidified by adding a mixture of ether and petroleum ether (1 : 1). This product was recrystallized from methanol-ether. Yield: 1.27 g. (93%); m. p. 159—172°C.

Found: C, 50.17; H, 6.66; N, 18.41. Calcd. for $C_{29}H_{45}O_{10}N_9 \cdot H_2O$: C, 49.92; H, 6.79; N, 18.07%.

**An Attempt to Synthesize Cyclic Hexapeptide via XIII by the Azide Method.**—A solution of 1.01 g. (1.49 mmol.) of XIII in a mixture of 8.5 ml.

19) The $R_f$ of the paper chromatography refers to the *n*-butanol-acetic acid-pyridine-water (4 : 1 : 1 : 2) system.

21) The $R_f$ of the thin layer chromatography with Merck silica gel G refers to the *n*-butanol-acetic acid-pyridine-water (4 : 1 : 1 : 2) system.
22) L. Zervas and D. M. Theodoropoulos, *J. Am. Chem. Soc.*, **78**, 1359 (1956); G. C. Stelakatos, D. M. Theodoropoulos and L. Zervas, ibid., **81**, 2884 (1959).
23) This was prepared from glycine and *t*-butyloxycarbonyl azide by the general method developed by Schwyzer et al. (R. Schwyzer, H. Kappeler, B. Iselin, W. Rittel and H. Zuber, *Helv. Chim. Acta*, **42**, 2622 (1959)).

of methanol and 20 ml. of 2.84 N hydrogen chloride in methanol was allowed to stand at room temperature for 2 hr.[24] The solution was then evaporated to dryness in vacuo, and the residue was kept under high vacuum for 2 hr. The main portion of the residue was regarded as triglycyl-ε-benzyloxycarbonyl-L-lysylglycylglycine hydrazide dihydrochloride. The residue was dissolved in 8 ml. of 0.2 N hydrochloric acid. To the solution was then added a solution of 0.111 g. (1.6 mmol.) of sodium nitrate in 1 ml. of water under cooling. After it had stood for 15 min. at 0°C, the solution was poured into 1.5 l. of cold water containing 5.6 g. of sodium bicarbonate. The solution was kept at 4°C for 24 hr., and then the pH was brought to 5 with 2 N hydrochloric acid. The solution was passed successively through columns of Dowex-50 ($H^+$ form) and Dowex-1 ($OH^-$ form). The filtrate and washings were combined and evaporated to dryness in vacuo. Only a few milligrams of $I_L$ were obtained.

**Tritylpentaglycyl-ε-benzyloxycarbonyl-L-lysine Hydrazide (XIV).**—A solution of 0.836 g. (1 mmol.) of V and 0.150 g. (3 mmol.) of hydrazine hydrate in 5 ml. of methanol was allowed to stand at room temperature for 24 hr. The solution was then concentrated in vacuo to a small volume, ether was added, and the resulting crystals were collected by filtration (0.70 g.). The product was recrystallized from methanol-ether. Yield: 0.580 g. (71%); m. p. 162—167°C, $[\alpha]_D^{20}$ −3.0° (*c* 2, dimethylformamide).

Found: C, 62.70; H, 6.36; N, 14.75. Calcd. for $C_{43}H_{51}O_8N_9$: C, 62.83; H, 6.25; N, 15.34%.

**Pentaglycyl-ε-benzyloxycarbonyl-L-lysine Hydrazide Dihydrochloride (XV).**—A solution of 0.476 g. (0.58 mmol.) of XIV in a mixture of 8 ml. of methanol and 2.4 ml. of 0.5 N hydrogen chloride in methanol was boiled for 2 min. Then the solution was evaporated in vacuo, and the resulting crystals were filtered with the aid of a mixture of ethanol and ether. The product was recrystallized from methanol-ethanol-ether. Yield: 0.292 g. (77%); m. p. 196—198°C.

Found: N, 18.33. Calcd. for $C_{24}H_{39}O_8N_9Cl_2 \cdot 2H_2O$: N, 18.29%.

**An Attempt at the Cyclization of XV by the Azide Method.**—To a cold solution of 0.255 g. (0.39 mmol.) of XV dissolved in 4 ml. of 0.1 N hydrochloric acid, a cold solution of 0.028 g. (0.40 mmol.) of sodium nitrate in 0.3 ml. of water was added. After it had stood for 15 min. at 0°C, the golden yellow solution was poured into 300 ml. of cold water containing 1.8 g. of sodium bicarbonate. The solution was kept at 4°C for 45 hr., and the pH was adjusted to 5 with 2 N hydrochloric acid. The solution was passed successively through columns of Dowex-50 and Dowex-1. The filtrate and washings were combined and evaporated to dryness in vacuo. Only a trace of $I_L$ was thus obtained.

***p*-Methoxybenzyloxycarbonylglycine (XVI).**—The synthetic procedure[25] was revised as follows. A mixture of 2.25 g. (30 mmol.) of glycine, 45 ml. of water, 45 ml. of dioxane, 6.72 g. (80 mmol.) of sodium bicarbonate and 8.07 g. (39 mmol.) of *p*-methoxybenzyloxycarbonyl azide was stirred at room temperature for 24 hr. The solution was then evaporated in vacuo in order to remove the dioxane. After it had been extracted with ethyl acetate, the solution was acidified with 80 ml. of M citric acid and then extracted with ethyl acetate. The ethyl acetate solution was dried and evaporated to dryness in vacuo. The crystals were washed with petroleum ether. Yield: 6.93 g. (97%); m. p. 95—96°C. Reported value, m. p. 94—96°C.[25]

***p*-Methoxybenzyloxycarbonyltriglycyl-ε-benzyloxycarbonyl-L-lysine Ethyl Ester (XVII).**—The mixed anhydride prepared from 3.59 g. (15 mmol.) of XVI, 1.95 ml. (15 mmol.) of isobutyl chloroformate and 2.10 ml. (15 mmol.) of triethylamine in 30 ml. of chloroform was coupled with 6.89 g. (15 mmol.) of IV dissolved in a chilled mixture of 2.10 ml. (15 mmol.) of triethylamine and 60 ml. of chloroform. After the organic solvents had been removed in vacuo, water was added to the residue and it was kept in a refrigerator. The product was collected by filtration and washed successively with M citric acid, a 3% sodium bicarbonate solution and water (9.0 g.). The product was recrystallized from methanol-ether-petroleum ether. Yield: 8.2 g. (87%); m. p. 108—112°C, $[\alpha]_D^{20}$ −6.1° (*c* 2, dimethylformamide).

Found: C, 57.19; H, 6.38; N, 10.93. Calcd. for $C_{31}H_{41}O_{10}N_5$: C, 57.84; H, 6.42; N, 10.88%.

***p*-Methoxybenzyloxycarbonyltriglycyl-ε-benzyloxycarbonyl-L-lysine Hydrazide (XVIII).**—A solution of 7.53 g. (12 mmol.) of XVII and 12 ml. (240 mmol.) of hydrazine hydrate in 24 ml. of dimethylfomamide was allowed to stand at room temperature for 2 days. The excess hydrazine was then evaporated in vacuo, and the residual solution was diluted with 400 ml. of water. The product was collected by filtration (6.30 g.). This was recrystallized from methanol-ether. Yield: 5.82 g. (79%); m. p. 182—184°C, $[\alpha]_D^{20}$ −3.9° (*c* 2, dimethylformamide).

Found: C, 55.17; H, 6.25; N, 15.79. Calcd. for $C_{29}H_{39}O_8N_7$: C, 55.31; H, 6.24; N, 15.57%.

***p*-Methoxybenzyloxycarbonyltriglycyl-ε-benzyloxycarbonyl-L-lysylglycylglycine Benzyl Ester (XIX).**—To a cooled solution of 4.30 g. (7 mmol.) of XVIII in 20 ml. of dimethylformamide and 7.7 ml. of N hydrochloric acid, a cold solution of 0.531 g. (7.7 mmol.) of sodium nitrate in 3 ml. of water was added. After it had stood for 5 min. at −5°C, the solution was diluted to a volume of 350 ml. with cold water and extracted two times with 80-ml. portions of ethyl acetate. The ethyl acetate solution was twice washed with a sodium bicarbonate solution and with water, dried over sodium sulfate, and then added to a cold solution of 2.56 g. (7 mmol.) of glycylglycine benzyl ester *p*-toluenesulfonate in 0.98 ml. (7 mmol.) of triethylamine and 4 ml. of dimethylformamide. The reaction mixture was kept at 3°C with stirring for 2 days. A gelatinous material deposited in the course of the reaction. The mixture was then evaporated in vacuo in order to remove the ethyl acetate, and the resulting solution was diluted with cold water. The product deposited was collected

24) E. Klieger and H. Gibian, *Ann.*, **649**, 183 (1961).
25) F. Weygand and K. Hunger, *Chem. Ber.*, **95**, 1 (1962).

by filtration and washed with a citric acid solution, a sodium bicarbonate solution and water (4.08 g.). The product was recrystallized from dimethylformamide - ether - petroleum ether. Yield: 4.0 g. (71%); m. p. 183—186°C, $[\alpha]_D^{20}$ −2.2° (*c* 2, dimethylformamide).

Found: C, 57.96; H, 6.27; N, 11.82. Calcd. for $C_{40}H_{49}O_{12}N_7$: C, 58.60; H, 6.02; N, 11.96%.

***p*-Methoxybenzyloxycarbonyltriglycyl-ε-benzyloxycarbonyl-L-lysylglycylglycine (XX).**—Into a suspension of 2.41 g. (3 mmol.) of XIX in 35 ml. of dioxane, 33 ml. of 0.1 N sodium hydroxide was stirred at 0°C. By thin-layer chromatography,[21] the hydrolysis was found to be complete after 1.5 hr.; it gave only one detectable product. The solution was then evaporated in vacuo in order to remove the dioxane and then further treated with a mixture of ether and petroleum ether (1 : 1) in order to extract the residual dioxane. The acidification of the aqueous solution with 4 ml. of M citric acid yielded a gelatinous product. After the solution had stood in a refrigerator overnight, the product was collected by filtration and washed with cold water (1.83 g.). The product was recrystallized from dimethylformamide - water. Yield: 1.64 g. (75%); m. p. 190—195°C, $[\alpha]_D^{20}$ −3.8° (*c* 2, dimethylformamide).

Found: C, 54.49; H, 6.06; N, 12.87. Calcd. for $C_{33}H_{43}O_{12}N_7$: C, 54.31; H, 5.94; N, 13.44%.

***p*-Methoxybenzyloxycarbonyltriglycyl-ε-benzyloxycarbonyl-L-lysylglycylglycine *p*-Nitrophenyl Ester (XXI).**—To a solution of 1.05 g. (1.43 mmol.) of XX in a mixture of 0.24 ml. (1.72 mmol.) of triethylamine and 6 ml. of dimethylformamide, 1.02 g. (3.14 mmol.) of di-*p*-nitrophenyl sulfite was added. The solution was then allowed to stand at room temperature overnight. The solvent was removed in vacuo, and the oily residue was solidified by adding a mixture of ether and petroleum ether (1 : 1) and scratching. The product was then filtered with the aid of petroleum ether (1.53 g.). The *p*-nitrophenyl ester content in this product was estimated to be 106% by means of the method described in the preparation of $VII_{PR}$. This product was used for the next reaction without further purification.

**Cyclo-pentaglycyl-ε-benzyloxycarbonyl-L-lysyl- ($I_L$).**—To a mixture of 1.53 g. of XXI and 1.3 ml. of anisole, 13 ml. of trifluoroacetic acid was added at −5°C.[25] After 10 min., the reaction mixture formed a reddish-brown solution. The removal of the trifluoroacetic acid in vacuo and the addition of ether yielded a faintly brown powder. The product was collected by filtration, washed with ether, and then dissolved in a mixture of 0.5 ml. of acetic acid and 25 ml. of dimethylformamide. A solution containing triglycyl-ε-benzyloxycarbonyl-L-lysylglycylglycine *p*-nitrophenyl ester trifluoroacetate was stirred drop by drop into 300 ml. of pyridine kept at 70—80°C over a 5.5-hr. period. The solution was then stirred at 70°C for another hour. After the solvents had been removed in vacuo, the residue was dissolved in 140 ml. of methanol and a small amount of insoluble material was filtered off. The methanolic solution was diluted with 140 ml. of water and passed successively through columns (2.5×10 cm.) of Dowex-50 and Dowex-1. The filtrate and washings were then combined and evaporated to dryness in vacuo. The residue was dissolved in 50 ml. of methanol, and insoluble materials were filtered off. The filtrate was concentrated to a small volume (0.4 ml.), and 4 ml. of ether and then 4 ml. of petroleum ether were added, to afford crystals; yield, 0.435 g. This gave only one spot in a paper chromatogram, $R_f$ 0.70.[21] Careful recrystallization from methanol - ether - petroleum ether afforded 0.335 g. (42% from XX); m. p. 262°C, $[\alpha]_D^{20}$ +0.9° (*c* 1.33, dimethylformamide).

Found: C, 52.35; H, 5.99; N, 17.77. Calcd. for $C_{24}H_{34}N_8O_7$: C, 52.54; H, 6.25; N, 17.87%.

**Cyclo-pentaglycyl-L-lysyl Hydrochloride ($II_L$).**—A solution of 0.083 g. (0.15 mmol.) of $I_L$ in a mixture of 6 ml. of methanol and 0.165 ml. of N hydrochloric acid was hydrogenolyzed in the presence of palladium black. The filtrate was then evaporated in vacuo and the concentrated solution was diluted to a volume of 0.5—0.6 ml. with water, whereupon a very small amount of an insoluble material was filtered off. After the filtrate had been concentrated to a small volume (0.3 ml.), addition of 0.3 ml. of ethanol and then 2 ml. of acetone yielded crystals. Yield: 0.045 g. (66%); m. p. 247°C (decomp.), $[\alpha]_D^{20}$ +15.6° (*c* 1.3, water); $R_f$ 0.27,[19] 0.42[20] and 0.13[21].

Found: C, 39.87; H, 6.82; N, 20.46. Calcd. for $C_{16}H_{30}O_6N_7Cl \cdot 2H_2O$: C, 39.46; H, 6.83; N, 20.13%.

**Pentaglycyl-L-lysine Hydrochloride (XXII).**—A solution of 0.300 g. (0.53 mmol.) of IX dissolved in a mixture of 7 ml. of water and 3 ml. of 0.2 N hydrochloric acid was hydrogenolyzed in the presence of palladium black. The filtrate was evaporated to a small volume, and ethanol was added to afford crystals (0.230 g.). The product was recrystallized from water - ethanol. Yield: 0.202 g. (80%); m. p. 210—212°C (decomp.), $[\alpha]_D^{20}$ 0° (*c* 1.33, water).

Found: C, 40.03; H, 6.62; N, 20.03. Calcd. for $C_{16}H_{30}O_7N_7Cl \cdot 1/2H_2O$: C, 40.29; H, 6.76; N, 20.55%.

**The Action of Trypsin on Glycyl-L-lysine Anhydride Hydrochloride, $II_{PR}$ and $II_L$.**—Hydrolysis experiments of substrates by trypsin[26] were carried out at pH 7.8, 30°C. The initial concentration of the substrates was 0.01 M, and the enzyme concentration was 0.05 mg. protein nitrogen per milliliter. The progress of the reactions was checked by thin-layer and paper chromatographies in the course of time. Table I shows the compositions of the reaction mixtures. Number 2 in Table I indicates the control experiment without the enzyme. No. 1 was performed in order to determine whether or not the trypsin autolysis took place. The control experiments (1 and 2) showed that neither the hydrolysis of cyclo-pentaglycyllysyl in the absence of the enzyme nor the autolysis of trypsin occurred. Experiment No. 3 indicated that glycyl-L-lysine anhydride hydrochloride[27] was not hydrolyzed at

26) This was a salt-free, crystalline sample from the Nutritional Biochemicals Corporation, U. S. A.

27) The synthesis of the compound (by M. Kondo and N. Izumiya) is unpublished; $R_f$ 0.34.[19]

TABLE I. COMPOSITION OF THE MIXTURES OF THE ENZYME REACTION

| Experimental No. | Substrate | Weighed amount of substrate | 0.2 M Tris buffer (pH 7.8) | Trypsin solution (0.2 mg. protein nitrogen per ml.) | Water | Total volume |
|---|---|---|---|---|---|---|
| 1 | | | 0.50 ml. | 0.25 ml. | 0.25 ml. | 1.0 ml. |
| 2 | Lys Gly$_5$·HCl ($II_{PR}$) | 0.01 mmol. | 0.50 | | 0.50 | 1.0 |
| 3 | L-Lys Gly·HCl | 0.01 | 0.50 | 0.25 | 0.25 | 1.0 |
| 4 | Lys Gly$_5$·HCl ($II_{PR}$) | 0.01 | 0.50 | 0.25 | 0.25 | 1.0 |

Authentic sample: B, cyclo-pentaglycyl-L-lysyl ($II_L$) ; C, pentaglycyl-L-lysine hydrochloride (XXII).

all by trypsin, even after 48 hrs.' incubation. Cyclo-pentaglycyllysyl hydrochloride ($II_{PR}$) was partially hydrolyzed by the enzyme (Fig. 8). After 100 hrs.' incubation, a great part of the $II_{PR}$ was hydrolyzed to the linear pentaglycyl-L-lysine, as may be seen in Fig. 8, while the rest of the material remained unchanged as the cyclic hexapeptide, presumably of the D-configuration. On the other hand, cyclo-pentaglycyl-L-lysyl hydrochloride ($II_L$) was completely hydrolyzed by trypsin after 40 hr. (Fig. 9). That the product of the two latter reactions was the corresponding linear hexapeptide, pentaglycyl-L-lysine, was proved by the chromatographic comparison of it with an authentic sample of pentaglycyl-L-lysine hydrochloride (XXII) synthesized as has been described above.

## Summary

A cyclic hexapeptide, cyclo-pentaglycyl-L-lysyl hydrochloride ($II_L$), has been synthesized in an attempt to obtain fundamental information about the syntheses of cyclic peptides; it has also been subjected to the action of trypsin.

*p*-Methoxybenzyloxycarbonyltriglycyl-ε-benzyloxycarbonyl-L-lysylglycylglycine (XX) has

been prepared by the saponification of the di-*N*-blocked hexapeptide ester which had been obtained by the condensation of *p*-methoxybenzyloxycarbonyltriglycyl-ε-benzyloxycarbonyl-L-lysine azide with the glycylglycine benzyl ester. XX has been converted to the relevant *p*-nitrophenyl ester by the action of di-*p*-nitrophenyl sulfite, and, after the removal of the *p*-methoxybenzyloxycarbonyl group with trifluoroacetic acid, the hexapeptide *p*-nitrophenyl ester has been transformed, by means of a large amount of pyridine, to the cyclic benzyloxycarbonyl-substituted hexapeptide. It has then been hydrogenolyzed in the presence of palladium black to furnish the desired product, $II_L$.

Several different synthetic methods for obtaining $II_L$ have been adopted. However, they are not satisfactory with regard to the optical purity of the L-lysine residue or the yield.

It has been observed that $II_L$ is completely hydrolyzed to pentaglycyl-L-lysine by trypsin. This appears to be the first example of how trypsin can hydrolyze a cyclic peptide. A smaller cyclic peptide, glycyl-L-lysine anhydride, could not be hydrolyzed.

# Some Reactions of Mercuridiacetaldehyde*

By Shunsuke MURAHASHI, Shun'ichi NOZAKURA and Saburo FUJI

(Received January 28, 1965)

Mercuridiacetaldehyde $Hg(CH_2CHO)_2$ was first prepared by Nesmeyanov and his group in 1955; it has since been used for the synthesis of various kinds of vinyl ethers.[1-7] Mercuridiacetaldehyde and chloromercuriacetaldehyde show O-vinylation by means of the reaction of the Hg–O with C-halogen bonds in substrates. In some cases, however, the reaction proceeds in an alternative way, one in which the C-alkylation reaction takes place by means of the Hg–C bonds.[2,8] Thus mercuridiacetaldehyde can also be regarded as divinyloxymercury, a mercuric salt of vinyl alcohol. A number of vinyloxymetal compounds have been reported in the literature, such as aluminum,[9] titanium,[10] lithium,[5] sodium,[5] iron,[5] and silicon.[6] However, the chemical behavior of the unsaturated bonds in these compounds is scarcely known at all.

In the course of their synthetic study of vinyloxymetal compounds with mercuridiacetaldehyde, the present authors noticed that the latter compound was easily converted, in various organic solvents, into an insoluble and infusible substance. This phenomenon led the authors to suspect that the insoluble substance might be a polymeric material which was formed by the addition reaction of C=C double bonds in the form of divinyloxymercury. The object of the present work is to elucidate the chemical structure of the insoluble substance, and also to obtain further information on the chemical structure of the starting material, mercuridiacetaldehyde.

As a compound closely-related to mercuridiacetaldehyde, Nef's so-called mercuric salt of vinyl alcohol was also reinvestigated in the light of recent knowledge.

## Results and Discussion

**On Mercuridiacetaldehyde.**—Two tautomeric structures, I and II, can be assumed for mercuridiacetaldehyde in view of its dual reactivities:[12]

$Hg(CH_2CHO)_2$ (I) $\quad$ $Hg(OCH{=}CH_2)_2$ (II)

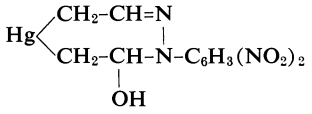
Type I should show infrared absorptions of the carbonyl group, while type II shows those of the C=C double bond. The infrared spectrum of mercuridiacetaldehyde shows a strong band at around 1645 $cm^{-1}$ (Table I). Nesmeyanov and Lutsenko[13] assigned the band to the stretching vibration of the carbonyl group, taking into account the fact that the ultraviolet spectrum of the compound showed the absorption maximum at 296 $m\mu$ ($\log \varepsilon = 2.90$) which is characteristic of the carbonyl absorption. In order to exlain both the large bathochromic shift of the carbonyl band and the dual reactivities of the compound, they proposed a $\sigma$-$\pi$ conjugated structure.[13,14]



As the infared spectrum of mercuridiacetaldehyde showed an absorption band at 2720 $cm^{-1}$ which seemed to be a normal position for the C–H stretching vibration of an aldehyde group, the reactions of the compound with typical aldehyde reagents were studied. The reactions of the compound with sodium bisulfite, 2, 4-dinitrophenylhydrazine, semicarbazide hydrochloride, and hydroxylamine hydrochloride were found to take place as follows:

$$Hg(CH_2CHO)_2 + NaHSO_3 \rightarrow$$

(III)

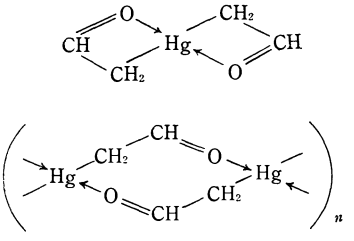
$$Hg(CH_2CHO)_2 + NH_2NHC_6H_3(NO_2)_2 \rightarrow$$

(IV)

$$Hg(CH_2CHO)_2 + NH_2NHCONH_2 \cdot HCl \rightarrow$$

$$ClHgCH_2CH{=}NNHCONH_2$$

(V)



$$Hg(CH_2CHO)_2 + NH_2OH \cdot HCl \rightarrow$$

$$ClHgCH_2CH{=}NOH$$

(VI)

The structural assignment of these products was based on analysis and on a study of their infrared spectra. Structure IV is tentatively assigned as in the case of levulinaldehyde.[15] The reaction with hydrazine hydrate led to the liberation of metallic mercury. Thus, it was shown that mercuridiacetaldehyde behaved like usual aldehydes.

The infrared spectrum of mercuridiacetaldehyde (Table I) shows a band at 553 $cm^{-1}$ which may be assigned to Hg–C. The wave number is almost the same as that reported for dimethylmercury (550 $cm^{-1}$),[16] suggesting a covalent nature of the Hg–C bond. As the carbonyl absorption at about 1645 $cm^{-1}$ corresponds to an intermediate of a metal chelate (1600—1530 $cm^{-1}$) and normal carbonyl, the carbony oxygen group in the compound might be weakly chelated to the mercury atom in the same molecule or form a polymer through coordination to the mercury atom in the next molecule. Thus, the structure may be best represented by VII, as has been suggested by Nesmeyanov.

(VII)

The structure of the decomposition product, which will be discussed below, also seems to support these chelated structures.

**The Decomposition of Mercuridiacetaldehyde in Alcohol.**—Mercuridiacetaldehyde synthesized according to the method described in the literature[3] showed a melting point of 84—86°C, which was rather low compared with the reported value (91°C).

Purification by recrystallization from various solvents was unsuccessful, because of the instability of the crude compound in solution. Table II shows the solubility of the compound in ordinary organic solvents and its stability after it has stood overnight. Water was the best solvent, and in its dilute solution the compound was considerably stable, but in a concentrated solution the compound decomposed rapidly with the separation of metallic mercury. The compound, after the solvent treatment, generally showed much higher melting points, became insoluble, and showed a higher mercury-content than the original sample. Since a survey of the infrared spectra of the high-melting sapmles thus obtained usually showed new common absorption bands, the change brought about by this treatment is considered to be due to the formation of the same decomposition product. In order to elucidate the decomposition reaction, therefore, the reaction in ethanol was then studied in more detail.

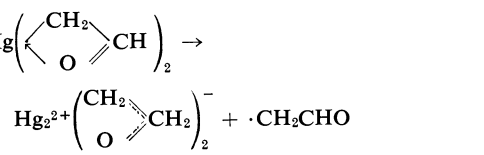
TABLE II. SOLUBILITY AND STABILITY OF MERCURIDIACETALDEHYDE IN VARIOUS SOLVENTS

| Treatment[a] | Solubility[b] | Hg% after treatment | Change of m. p. after the treatment, °C |
|---|---|---|---|
| Untreated | | 69.9 | 84 |
| Ethanol | + | | 200—250 (d) |
| Ethanol, refluxed for 5—6 hr. | | 77.3 | 200—250 (d) |
| Benzene | − | 64.7 | |
| Benzene, refluxed for 5—6 hr. | | 72.6 | 250 (d) |
| Acetone | ++ | 63.3 | |
| Acetone, 3 days | | 78.4 | 250 (d) |
| Ethyl methyl ketone | + | 78.4 | 250 (d) |
| Tetrahydrofuran | + | 74.0 | 250 (d) |
| Methanol | ++ | | 200—250 (d) |
| Water | ++ | | 78—79 |

a) A mixture of about 1 g. of sample and 1 ml. of a solvent was allowed to stand overnight and then the solvent was evaporated in vacuo.
b) −, insoluble; +, soluble; ++, readily soluble.

When an ethanol solution of mercuridiacetaldehyde was kept under reflux, a white precipitate separated after one or two hours. After the refluxing had continued for 4 hr., the mercury content of the precipitate increased to 77.3% from the original 69.9%; it remained constant thereafter. Alternatively, when a catalytic amount of an ethanol solution of sodium ethoxide was added to the solution at room temperature, the white precipitate appeared immediately. In this case, the mercury content of the product increased to 80.7%.



Associated with the decomposition phenomenon, the infrared spectra showed a marked change in some respects. The $\nu C{=}O$ band at 1645 $cm^{-1}$ and the bands at 1150 and 1050 $cm^{-1}$ diminished and new bands appeared at 1580, 1300 and 1120 $cm^{-1}$. The $\nu Hg{-}C$ band at 553 $cm^{-1}$ shifted to the doublet at 545 and 541 $cm^{-1}$. The $\nu C{-}H$ of aldehyde at 2720 $cm^{-1}$ showed no appreciable change.

When decomposition product was treated with bromine, bromacetaldehyde was obtained as a sole organic product. This fact suggests the existence of the $Hg{-}CH_2CHO$ group in the decomposition product.

$$-Hg{-}CH_2CHO + Br_2 \rightarrow -HgBr + BrCH_2CHO$$

The new band at 1580 $cm^{-1}$ is considered to be due to a carbonyl bond which is weaker than that of the original mercuridiacetaldehyde (a bathochromic shift of 60 $cm^{-1}$). A bathochromic shift of the $\nu Hg{-}C$ bond also suggests a weaker Hg–C bond in the decomposition compound than in the original compound.

From the above-mentioned facts, the authors concluded that most of the mercuridiacetaldehyde was converted into a mercurous compound, $Hg_2(CH_2CHO)_2$ by the decomposition of the Hg–C bonds.

This conclusion is supported by the fact that the $\nu C{=}O$ bands in mercuric and mercurous acetates are 1570 and 1540 $cm^{-1}$ respectively, showing a bathochromic shift of 30 $cm^{-1}$ in the change from mecuric to mercurous. The bathochloric shift of the $\nu Hg{-}C$ bond seems to be compatible with the fact that mercurous compound are generally more ionic than the corresponding mercuric compounds.

The decomposition reaction could, practically speaking, not be brought to completion, as may be seen from the analytical results and the infrared spectra, probably because of the insolubility of the product.

The decomposition of mercuridiacetaldehyde in ethanol may be interpreted in terms of a homolytic fission of the Hg–C bonds or by a nucleophilic substitution on mercury, followed by a homolytic cleavage of the $Hg{-}OC_2H_5$ bonds.

$$Hg(CH_2CHO)_2 \rightarrow HgCH_2CHO + \cdot CH_2CHO$$

or

$$Hg(CH_2CHO)_2 + C_2H_5OH \rightarrow C_2H_5OHgCH_2CHO + CH_3CHO$$

The formation of acetaldehyde was confirmed by a gas chromatographic analysis of the volatile component of the reaction mixture: about 40% of the theoretical amount of acetaldehyde was thereby detected as 2, 4-dinitrophenylhydrazone.

In the case of the base-catalyzed decomposition, it seems that the first step is a nucleophilic attack by the ethoxide anion on mercury, followed by the cleavage of the $Hg{-}OC_2H_5$ bonds. The acetaldehyde liberated during the alkaline decomposition was not detected, but it seemed to be converted into a brown polymeric material by the alkali.

As a compound closely related to mercuridiacetaldehyde, Nef's compound was reexamined. Nef[11] reported the synthesis of a mercuric salt of vinyl alcohol by the reaction of fresh mercuric oxide and aqueous acetaldehyde in the presence of sodium hydroxide. The infrared examination of Nef's compound indicated that the compound was identical with the decomposition product of the mercuridiacetaldehyde which had been obtained in the presence of sodium ethoxide.

## Experimental

**The Analysis of Mercury.** — According to the method of Hirai and Hayatsu,[17] a sample containing mercury was digested with concentrated sulfuric acid and 30% aqueous hydrogen peroxide until a colorless solution was obtained. The mercuric ion content was determined by the usual Volhard method.

**The Synthesis of Mercuridiacetaldehyde.**—The method of Nesmeyanov[3] was taken, using yellow mercuric oxide, vinyl isobutyl ether, water and a catalytic amount of mercuric acetate. The crude yield was 86—89% (m. p. 82—83°C (91°C in the literature)). It was used without further purification. The presence of mercuric acetate as a catalyst was not essential for the reaction, particularly in the small-scale preparation. The yield in this case was 76—80% (m. p. 82—84°C). However, when the synthesis was carried out on a larger scale and without the addition of merric acetate, a rapid exothermic reaction after some induction period frequently resulted in the decomposition of a part of the product.

**Reactions with the Aldehyde Reagents.** — The sodium bisulfite adduct, 2,4-dinitrophenylhydrazone and semicarbazone were prepared in the usual manner. The sodium bisulfite adduct, which was recrystallized from water, decomposed at 133—138°C; yield, 62%. The infrared spectrum showed a $\nu O{-}H$ band at 3450(s), bands of the sulfonate group at 1140(vs) and 650(s), a sulfite band at 980(s), and a $\nu Hg{-}C$ band at 530 $cm^{-1}$.

Found: Na, 10.3; Hg, 44.0. Calcd. for $C_2H_4O_7S_2Na_2Hg$: Na, 10.20; Hg, 44.50%.

The 2,4-dinitrophenylhydrazone which was recrystallized from ethanol decomposed at 138—139°C; yield, 54%. The infrared spectrum showed a $\nu O{-}H$ band at 3300(m), a $\nu C{=}N$ band at 1620(s), and a $\nu Hg{-}C$ band at 588(m) $cm^{-1}$.

Found: N, 11.4; Hg, 44.8. Calcd. for $C_{10}H_{10}O_5N_4Hg$: N, 11.99; Hg, 42.97%.

The semicarbazone recrystallized from ethanol decomposed at 159—160°C; yield, 31%. The infrared spectrum showed the $\nu N{-}H$ bands of the amide group at 3420(m) and 3320(m), a $\delta N{-}H$ band at 1540(s), and a $\nu C{=}O$ band at 1660(s) $cm^{-1}$.

Found: N, 14.56. Calcd. for $C_3H_6ON_3HgCl$: N, 14.21%.

The reaction with hydroxylamine was carried out by mixing a freshly-prepared solution of mercuridiacetaldehyde (5 g.) in water (15 ml.) and a mixed aqueous solution of 2 g. of hydroxylamine hydrochloride and 2.8 g. of potassium acetate. A white precipitate was filtered out and recrystallized from ethanol. The yield was 11.4%. M. p. 115—116°C, with decomposition. The infrared spectrm showed a chelated $\nu O{-}H$ band at 3170(m), $\nu{=}CH$ bands at 3025(m) and 3045(m), a $\nu C{=}N$ band at 1658(s), and a $\delta{=}CH$ band at 840(s) $cm^{-1}$.

Found: N, 4.60. Calcd. for $C_2H_4ONHgCl$: N, 4.76%.

**The Decomposition of Mercuridiacetaldehyde in Ethanol.**—A solution of 9.87 g. of mercuridiacetaldehyde in 80 ml. of ethanol, after filtration, was refluxed for 5 to 6 hr., yielding 8.81 g. of an insoluble white precipitate (1.06 g. of weight loss).

17) M. Hirai and R. Hayatsu, *Yakugaku Zasshi*, **70**, 76 (1956).

The volatile portion of the filtrate was found by gas chromatography to contain acetaldehyde; this acetaldehyde was converted into 2,4-dinitrophenylhydrazone in the usual manner (m. p. 163°C). The mixed melting point test with an authentic sample did not show any depression. The yield was 2.43 g., which corresponded to 0.44 g. of acetaldehyde and to a 41.5% loss of the weight of the starting material. The insoluble product was found to contain 77.3% Hg, and it decomposed at 200—250°C.

The insoluble product (3.0 g.) was decomposed by an excess of a chloroform solution of bromine at room temperature. The chloroform solution, after filtration, was found by gas chromatography to contain bromacetaldehyde; it was then converted into 2,4-dinitrophenylhydrazone, the yield being 1.48 g. (m.p. 150—152°C (from ethanol)). The mixed melting point test did not show any depression.

Found: C, 31.05; H, 2.20; N, 18.38; Br, 17.01. Calcd. for $C_8H_7O_4N_4Br$: C, 31.68; H, 2.28; N, 18.48; Br, 16.40%.

Into a solution of mercuridiacetaldehyde (3.0 g.) in 30 ml. of ethanol, a few drops of a solution of sodium ethoxide in ethanol (1 N) were added; the immediate formation of a white precipitate was observed. This precipitate (2.12 g.) contained 80.7% Hg.

**Nef's Compound.** — Nef's procedure was used, yielding 6.6 g. of the product from 8.0 g. of mercuric chloride, 4.0 g. of acetaldehyde, and 20.0 g. of sodium hydroxide. The product decomposed at about 190—210°C, changing in color from white to orange. It was soluble in oranganic solvents and in water. The infrarred spectrum is presented in Table I. It was found to contain 77.02% Hg.

## Summary

Mercuridiacetaldehyde is soluble in polar solvents and rather instable in the state of solution, yielding an insoluble and infusible substance. The decomposition reaction has been proved to include the formation of mercuri(I)-acetaldehyde $Hg_2(CH_2CHO)_2$ by the cleavage of one of the Hg–C bonds. On the other hand, mercuridiacetaldehyde reacted with aldehyde reagents as usual aldehydes. The change in the infrared spectra on these reactions has been interpreted in terms of $\sigma$-$\pi$ conjugation, as has been suggested previously by Nesmeyanov.

Nef's compound, which is considered to be a mercuric salt of vinyl alcohol, has been found to be almost identical with the mercuri-(I)-acetaldehyde.

# Kinetic Studies of Solvolysis. X.* Transition from a van't Hoff to an Arrhenius Intermediate Caused by Steric Hindrance at the Product-Formation Step of $S_N1$ Reactions

By Kunio OKAMOTO, Yoshihisa MATSUI and Haruo SHINGU

(Received February 1, 1965)

The kinetics of the two-step mechanism for the $S_N1$ reaction, in which an ion-pair is assumed as an intermediate, can well be treated by the steady-state approximation; the overall rate is then shown by Eq. 1:

$$RX \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \text{(ion-pair intermediate)} \xrightarrow{k_2[Y]} RY$$

$$d[RX]/dt = k_1k_2[RX][Y]/(k_{-1}+k_2[Y]) \quad (1)$$

In typical $S_N1$ reactions, the first ionization step is rate-determining, and $k_2$, the rate constant for the reaction of a nucleophile with the intermediate, is much larger than $k_{-1}$, the rate constant for the reversal of the ionization step. This intermediate formed at the rate-determining step can be classified as a van't Hoff intermediate.[1] If, on the other hand, $k_{-1}$ is larger than $k_2$, a pre-equilibrium will be approximately established, followed by a rate-determining step. Here the intermediate is defined as an Arrhenius intermediate[1] and the reaction obeys second-order kinetics despite its initiation by the $S_N1$ ionization mechanism:

$$d[RX]/dt = k_1k_2[RX][Y]/k_{-1} \quad (2)$$

Although the literature contains several

a) Extrapolated from data at 110 and 120°C.

references[2] to the $S_N1$ reaction involving Arrhenius intermediates, there have been reported to date no examples which clearly demonstrate such a transition of an carbonium-ion pair intermediate from a van't Hoff to an Arrhenius type.

We will report on an example of such a transition caused by a series of nucleophiles which have various steric requirements at the product-formation stage of the $S_N1$ reaction. The results of our kinetic runs and product studies[3] show that the $S_N1$ reactions of benzhydryl chloride with potassium 2,6-di-*t*-butyl-4-methylphenoxide (I), tri-*n*-butylamine, tri-*n*-butylammonium phenoxide (II), and tri-*n*-butylammonium 2,6-di-*t*-butyl-4-methylphenoxide (III) proceed through an Arrhenius intermediate and obey good second-order kinetics in acetonitrile, whereas the reaction with potassium phenoxide is a typical $S_N1$ reaction with a vant't Hoff intermediate. We will also report on the details of product studies which reveal the occurrence of a one-electron transfer reaction between the carbonium-ion intermediate and these hindered nucleophiles.

**Rate Measurements and Kinetic Interpretation.**—The titrimetric rate constants for the reaction of benzhydryl chloride with potassium phenoxide are given in Table I. The integrated first-order rate constants tended to show a slight decrease as the reaction progressed; therefore, the rate constant was calculated from the initial slope of a plot of the $\log(a-x)$ vs. the time, where $a$ is the initial concentration of the chloride and $x$ is the concentration

2) For triphenylmethyl chloride see R. F. Hudson and B. Saville, *J. Chem. Soc.*, **1955**, 4130; C. G. Swain and E. E. Pegues, *J. Am. Chem. Soc.*, **80**, 812 (1958); C. G. Swain and A. MacLachlan, ibid., **82**, 6095 (1960); L. J. Andrews and R. M. Keefer, ibid., **83**, 3708 (1961).

3) Some of the results of the product studies and kinetic runs have been published: K. Okamoto, Y. Matsui and H. Shingu, This Bulletin, **38**, 153 (1965).

of the chloride consumed. The $S_N1$ characteristic of the reaction was confirmed from the invariability of the first-order constants in the various initial concentrations (0.02—0.05 M). This is illustrated in Fig. 1. For purposes of comparison, the rate constants calculated for the second-order kinetics are included in Table I. In contrast to the first-order rate constants, the second-order rate constants display a clear trend toward larger rate constants in higher initial concentrations of the nucleophile.

Table II gives the second-order rate constants for the reactions of benzhydryl chloride with I, II, III and tri-*n*-butylamine in acetonitrile. The reactions were followed to about 70—80% completion; in all cases good second-order behaviors were observed. The plot of the log $a(b-x)/b(a-x)$ vs. the time, $t$, of a representative run is illustrated in Fig. 2, where $a$ is the initial concentration of benzhydryl chloride and $b$ is the initial concentration of the nucleophile. The definitely-curved plot for the first-order kinetics is also illustrated in Fig. 2.

An examination of the data in Tables I and II reveals that the $S_N1$ reaction of potassium phenoxide proceeds at a rate higher than any of the second-order reactions of these hindered nuclophiles. This fact evidently shows the existence of an ionized $S_N1$ intermediate, not only in the reaction medium where the first-order reaction of potassium phenoxide proceeded, but also in the environments in which the second-order reactions of the hindered nucleophiles were observed.

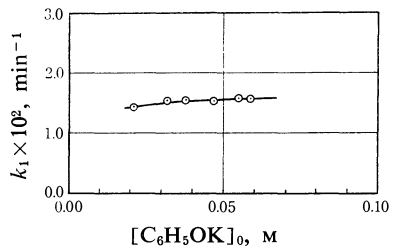

Fig. 1. First-order rate constants of the $S_N1$ reaction of benzhydryl chloride in acetonitrile in the presence of potassium phenoxide at 70.0°C. The initial concentrations of benzhydryl chloride, 0.02—0.04 M.

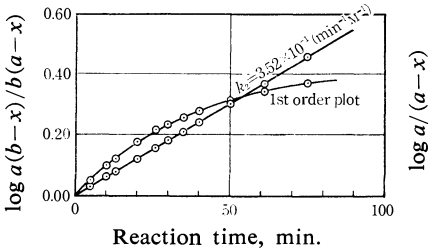

Fig. 2. Reaction rate of benzhydryl chloride in acetonitrile in the presence of tri-*n*-butylammonium phenoxide (II) at 140.0°C.
The initial concentration: the chloride, 0.0840 M; II, 0.1240 M

Thus two mechanisms for the second-order reactions of the hindered nucleophiles are possible. First, because of the large steric hindrance, the rate of a reaction between a nucleophile and the ionized intermediate became lower than the return rate of the intermediate, i.e., $k_2[Y] \ll k_{-1}$ in Eq. 1. Consequently, the reaction order changed from the first to the second, as is shown in Eq. 2, and the intermediate became an Arrhenius type. Secondly, if $k_2[Y]$ was extremely small compared with $k_{-1}$, the $S_N1$ reaction would be completely suppressed; then the $S_N2$ reactions between benzhydryl chloride and these hindered nucleophiles might appear, despite its sluggishness arising from the steric hindrance.

The first mechanism is more probable in view of the fact that a carbonium-ion type intermediate exists in acetonitrile in all the reactions of these nucleophiles. As has been briefly reported,[3] the results of product studies and of relevant control experiments have disclosed the formation of the compounds, which is unexplicable on the basis of the $S_N2$ mechanism but is conceivable as being due to a one-electron transfer reaction between the $S_N1$ intermediate and the nucleophile. Thus the $S_N1$ mechanism with an Arrhenius intermediate remains as the most probable one for the reaction with hindered nucleophiles.

**Products Studies and Mechanistic Considerations.**—The results of product studies, along with the reaction orders, are summarized in Table III. The products resulting from the $S_N1$ reaction of benzhydryl chloride and potassium phenoxide in acetonitrile at 82°C were isolated after ten half-periods; column chromatography showed that benzhydryl phenyl ether (93% yield) and *p*-benzhydrylphenol (3% yield) were formed. These are the expected products from the nucleophilic substitution of such an ambident anion.[4]

The reaction with potassium 2,6-di-*t*-butyl-4-methylphenoxide (I) was carried out in acetonitrile at 83—85°C, while the reactions with tri-*n*-butylamine and with tri-*n*-butylammouium phenoxide (III) were performed in the same solvent in a bomb at 140—160°C. The products of reactions with these hindered

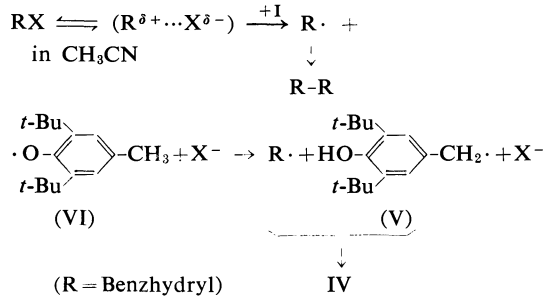
g) I, Potassium 2,6-di-*t*-butyl-4-methylphenoxide; II, Tri-*n*-butylammonium phenoxide; III, Tri-*n*-butylammonium 2,6-di-*t*-butyl-4-methylphenoxide: IV, 1-(3',5'-di-*t*-butyl-4'-hydroxyphenyl)-2,2-diphenylethane.
h) Contaminated with the ortho-isomer.

nucleophiles were also isolated after ten half-periods and separated by column chromatography.

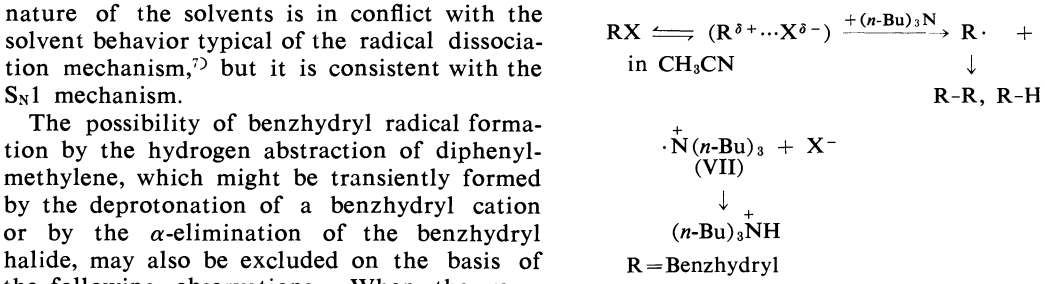


Much as with the reaction with potassium phenoxide, tri-*n*-butylammonium phenoxide and benzhydryl chloride resulted in benzhydryl phenyl ether (83% yield) and *p*-benzhydrylphenol (11.5% yield). In contrast to the reactions with these phenoxides, however, I and benzhydryl chloride yielded not the expected ether but rather *sym*-tetraphenylethane (40% yield), together with 1-(3',5'-di-*t*-butyl-4'-hydroxyphenyl)-2,2-diphenylethane (IV) (29% yield).[5] The reactions with tri-*n*-butylamine and with III gave also *sym*-tetraphenylethane as a major product in, respectively, 65% and 23% yields; in addition, a small amount of diphenylmethane (3% yield) was obtained in the former reaction.

Although kinetic runs were not carried out for benzhydryl bromide, the reaction of this bromide with I, much as in the reaction of the chloride, gave rise to no benzhydryl 2,6-di-*t*-butyl-4-methylphenyl ether in acetonitrile. Instead, IV (24% yield) and *sym*-tetraphenylethane (3% yield) were obtained at 83°C after a 23 hr. reaction. Tri-*n*-butylamine and benzhydryl bromide in the solvent also gave *sym*-tetraphenylethane (23% yield) and diphenylmethane (34% yield) in a sealed tube after 18 hr. at 90—93°C.

Evidently, the formation of both *sym*-tetraphenylethane and diphenylmethane indicates the transient existence of a benzhydryl radical in the reaction path from the benzhydryl halide. The formation of IV is also realized as being due to coupling between a benzhydryl radical and a 3,5-di-*t*-butyl-4-hydroxybenzyl radical (V). It has been known that a benzyl radical such as V can easily be formed from a 2,6-di-*t*-butyl-4-methylphenoxy radical (VI).[6] Consequently, the formation of IV indicates that, in the reaction of the benzhydryl halide and I, a one-electron transfer reaction occurs from a 2,6-di-*t*-butyl-4-methylphenoxide anion to a benzhydryl cation or to a $S_N1$ intermediate containing a benzhydryl cation. This may be formulated as follows:

5) For the structural assignment, see Ref. 3.



6) C. D. Cook, N. G. Nash and H. R. Flanagan, *J. Am. Chem. Soc.*, 77, 1783 (1955).

The possibility of benzhydryl radical formation by the radical dissociation of the benzhydryl halide in acetonitrile may be eliminated by a comparison of the rates in acetonitrile and in a non-polar solvent such as decalin. From the rate determination of the reaction of benzhydryl chloride and tri-*n*-butylamine in decalin at 150°C, it is estimated that only 4% or less of the starting chloride decomposes in 6.5 hr. Under identical reaction conditions, the reaction in acetonitrile proceeds to a more than 68% decomposition (Table III). Such rate sensitiveness to the nature of the solvents is in conflict with the solvent behavior typical of the radical dissociation mechanism,[7] but it is consistent with the $S_N1$ mechanism.

The possibility of benzhydryl radical formation by the hydrogen abstraction of diphenylmethylene, which might be transiently formed by the deprotonation of a benzhydryl cation or by the $\alpha$-elimination of the benzhydryl halide, may also be excluded on the basis of the following observations. When the reaction of benzhydryl bromide and tri-*n*-butylamine was carried out in the presence of 1, 1-diphenylethylene, a powerful scavenger of diphenylmethylene,[8] no addition product of the diphenylmethylene, i.e., 1, 1, 2, 2-tetraphenylcyclopropane, was obtained. Instead, in addition to *sym*-tetraphenylethane (13% yield) and diphenylmethane (20% yield), 1, 1, 3, 3-tetraphenyl-1-propene (VIII) was obtained in a 13% yield after a 65-hr. reaction in acetonitrile at 91°C. In the absence of tri-*n*-butylamine, benzhydryl bromide and 1, 1-diphenylethylene also yielded VIII in a 82% yield under identical reaction conditions. In the latter reaction, VIII is evidently produced by the electrophilic addition of the $S_N1$ intermediate to 1, 1-diphenylethylene and by the succeeding dehydrobromination. Therefore, the formation of VIII in the former reaction is conceivably, realized by the same addition-elimination mechanism, and the possibility of the formation of VIII as an insertion product of diphenylmethylene to 1, 1-diphenylethylene is ruled out.

In comparison with the mechanism for the reaction of hindered phenoxides, the mechanism of benzhydryl radical formation in the presence of tri-*n*-butylamine can be explained as the reduction of an $S_N1$ intermediate (i.e., a benzhydryl cation or a benzhydryl ion-pair) by the tertiary amine. It has been known that a tertiary amine such as triethylamine readily yields a charge-transfer complex with tetracyanoethylene[9a] and 7, 7, 8, 8-tetracyanoquinodimethane.[9b] Furthermore, the existence of a charge transfer complex of the amine has been suggested in certain reactions of polyhalomethane and trialkylamine, in which a homolytic cleavage of carbon-halogen bond was observed.[10] Thus, for the reaction of the benzhydryl halide and tri-*n*-butylamine in acetonitrile, the reaction scheme may be shown as follows:

A part of the amminium ion radical (VII) seems to be stabilized by forming tri-*n*-butylammonium ion, which has been identified as the halide, in a yield of 50—60% in these reactions. The source of hydrogen atoms in tri-*n*-butylammonium ions and in diphenylmethane, R–H, has not yet been established.

As for the detailed mechanism of the reduction of the $S_N1$ intermediate by tertiary amine, there seem to be two possible pathways. One is a direct reduction of the cation by the tertiary amine. The other is the reduction through a charge-transfer complex, or a complex of Weitz's quinhydrone type,[11] between the $S_N1$ intermediate and the amine. In the course of these reactions, we could not observe any deep coloration due to such complex formation. However, the possibility of the formation of such a complex between the

$S_N1$ intermediate of the carbonium-ion type and the amine can not be excluded. This will be the subject of a future paper.

## Experimental[12]

**Materials.**—Benzhydryl chloride was prepared by the reaction of thionyl chloride with benzhydryol;[13] b. p. 131.0—133.5°C/7 mmHg. Benzhdryl bromide was prepared by the reaction of bromine with diphenylmethane;[14] b. p. 139—143°C/3 mmHg. Potassium phenoxide was prepared by refluxing a mixture of potassium with a slight excess of purified phenol in dried benzene. After the potassium had completely disappeared, the phenoxide was filtered in a nitrogen stream and dried at 50°C to a constant weight in vacuo. Potassium 2,6-di-*t*-butyl-4-methylphenoxide (I) was prepared from potassium and 2,6-di-*t*-butyl-4-methylphenol (m. p. 68.0—71.0°C), by a procedure identical with that for potassium phenoxide. 1,1-Diphenylethylene (b.p. 102.5—104.5°C/2 mmHg) was prepared by the dehydration of methyldiphenylcarbinol, which had been prepared by the reaction of phenylmagnesium bromide and ethyl acetate.[15] Tri-*n*-butylamine was fractionally distilled in vacuo; b. p. 75.0—76.0°C/5 mmHg. Acetonitrile was refluxed over phosphorus pentoxide and distilled; b. p. 81.4—82.0°C. Decalin was refluxed over sodium and distilled; b. p. 190—191.5°C. Phenol was dried over calcium chloride and distilled; b. p. 178.5°C.

**Kinetic Measurements.**—A sealed-ampoule technique similar to that previously described[16] was employed. The diminution of the concentrations of the nucleophiles was followed by titration with standard perchloric acid in acetic acid, using crystal violet as an indicator. Each run was followed to 70—80% completion, and the thermostat was controlled to ±0.05—0.1°C.

**The Reaction of Benzhydryl Chloride and Potassium Phenoxide in Acetonitrile.**—A solution of potassium phenoxide was prepared in a 500-cc. round-bottomed flask equipped with a reflux condenser and a calcium chloride tube by boiling a mixture of 3.00 g. (0.0227 mol.) of potassium phenoxide and 300 cc. of acetonitrile. Benzhydryl chloride (2.94 g., 0.0145 mol.) was then added in one portion to the warm solution, and the mixture was boiled under reflux for 2.5 hr. The reaction mixture was filtered, the filtrate was concentrated by distillation, and then ether was added to the residue. The ethereal solution was washed with water, dried over magnesium sulfate, and evaporated in vacuo to give 3.79 g. of viscous oil. The potassium chloride which precipitated during the reaction was filtered after the reaction and dissolved in water, and the chloride ion concentration was determined by the Volhard method. The yield of potassium chloride based on the starting chloride was estimated as 97%. A part (0.550 g.) of the viscous oil so obtained was chromatographed over 25 g. of basic alumina. Elution with *n*-hexane afforded 0.51 g. of benzhydryl phenyl ether; m. p. 48.3—51.1°C (lit. m. p. 54°C[17] and 55°C[18]), $\lambda^{KBr}$ (infrared) 8.10 $\mu$ (C-O-C). With ethanol as the eluent, 0.04 g. of benzhydrylphenol ($\lambda^{KBr}$ (infrared) 2.73 $\mu$ (monomeric OH) and 2.80 $\mu$ (polymeric OH)) was obtained. The other part (3.24 g.) of the oil precipitated some crystals after being left overnight; the recrystallization of the crystals afforded 1.76 g. of benzhydryl phenyl ether, m. p. 51.2—53.5°C, $\lambda^{KBr}$ (infrared) identical with the sample mentioned above. When the mother liquors were chromatographed, 1.23 g. of additional benzhydryl phenyl ether (total 3.50 g., 93.2% of the starting chloride), m. p. 47.8—50.4°C (identical in the infrared spectrum), and 0.07 g. of benzhydrylphenol (total 0.11 g., 3.1%), m. p. 109.5—114.3°C (lit. m. p. 112°C) (*p*-benzhydrylphenol)[18] and 125°C (*o*-benzhydrylphenol)[17,18] almost identical in infrared spectrum with that of the authentic para isomer, were obtained.

**The Reaction of Benzhydryl Chloride and Potassium 2,6-Di-*t*-butyl-4-methylphenoxide (I) in Acetonitrile.**—A solution of 6.30 g. (0.0244 mol.) of potassium 2,6-di-*t*-butyl-4-methylphenoxide in 500 cc. of acetonitrile was prepared in a 1-l. three-necked flask with a reflux condenser, equipped with a sodalime tube, and a thermometer under a nitrogen atmosphere by refluxing the mixture. To the warm solution 4.01 g. (0.0198 mol.) of benzhydryl chloride was added; the mixture was then refluxed in a stream of nitrogen at 82—85°C for 18.3 hr. The reaction mixture was then filtered and potassium chloride was dissolved in distilled water in order to determine the chloride ion concentration by the Volhard method. The amount of the chloride ions liberated during the reaction was estimated to be 82% of the starting chloride. The filtrate was concentrated and the residue dissolved in benzene. The benzene solution was washed with water, dried with magnesium sulfate, and then concentrated in vacuo to give 7.90 g. of an oily material, which was then chromatographed over 200 g. of basic alumina. *n*-Hexane, benzene, ether and finally ethanol were used as the eluents. The first-half of the *n*-hexane fractions afforded 0.51 g. of 2,6-di-*t*-butyl-4-methylphenol, m. p. 67—70°C, identical in infrared spectrum with the authentic sample. From the second-half fractions, 2.20 g. (28.7% of the chloride) of 1-(3′,5′-di-*t*-butyl-4′-hydroxyphenyl)-2,2-diphenylethane (IV), m. p. 113—115°C (ethanol), was obtained. The structural assignment for IV has already been reported.[3] Elution with benzene afforded 1.33 g. (40.2%) of *syn*-tetraphenylethane, m. p. 207.5—208.5°C (lit. m. p. 207—208°C[19]) (identity established by m.m.p.

12) The melting points are uncorrected. The microanalyses were performed by the Microanalytical Center, Kyoto University, Kyoto. The infrared spectra were obtained from a Shimadzu model IR-27 spectrometer.

207—209°C, and the infrared spectrum). Elution with ethanol gave 1.71 g. of a brown oil, which contained a dienone, $\lambda^{neat}$ (infrared) 6.00 and 6.06 $\mu$ (doublet). This oil was not identified further. No diphenylmethane was identified from the *n*-hexane fractions.

**The Reaction of Benzhydryl Chloride and Tri-*n*-butylammonium Phenoxide (II) in Acetonitrile.**—Phenol (1.229 g., 0.0130 mol.) 2.40 g. (0.0130 mol.) of tri-*n*-butylamine, 30 cc. of acetonitrile and finally 2.00 g. (0.00985 mol.) of benzhydryl chloride were placed in a stainless-steel bomb (50 cc.). After 4 hours of heating at 143—150°C, the mixture was distilled to remove the acetonitrile; ether was added to the residue. After the ethereal solution had been washed with cold water, the titration of a part of the combined water-washings by the Volhard method indicated that 95% of the starting chloride had reacted to give chloride ions. The evaporation of the ethereal solution under reduced pressure afforded 2.71 g. of an oil, a part (0.65 g.) of which was chromatographed over 25 g. of basic alumina. Elution with benzene afforded 0.51 g. (corresponding to 83% of the starting chloride) of benzhydryl phenyl ether, m. p. 50.1—52.3°C (identity established by m.m.p. 50.1—52.5°C and the infrared spectrum). The ether fractions gave 0.07 g. (corresponding to 11.5% of the starting chloride) of benzhydrylphenol, containing mainly of the para isomer (identity established by the infrared spectrum).

**The Reaction of Benzhydryl Chloride and Tri-*n*-butylamine in Acetonitrile.**—A mixture of 1.62 g. (0.0080 mol.) of benzhydryl chloride, 1.63 g. (0.00881 mol.) of tri-*n*-butylamine and 40 cc. of acetonitrile was heated in a stainless-steel bomb at 146—156°C for 6.5 hr. The reaction mixutre was then filtered to give 0.6 g. (45% yield) of *sym*-tetraphenylethane, m. p. 208—209°C (identity established by m.m.p. 207.0—208.5°C and the infrared spectrum). The filtrate was concentrated to give an additional 0.21 g. (15.8% yield) of *sym*-tetraphenylethane, m. p. 207.0—209°C) (identity established by m.m.p. 207.0—208.5°C and the infrared spectrum). The mother liquors were washed with water and concentrated to give 1.01 g. of an oily material, which was then chromatographed on basic alumina (25 g.). Elution with *n*-hexane gave 0.04 g. (3.0% yield) of diphenylmethane (identity established by the infrared spectrum) from early fractions. Succeeding fractions gave 0.05 g. (3.7% yield) of *sym*-tetraphenylethane (total yield, 64.5%), m. p. 204.5—207.0°C (identity established by the infrared spectrum). The combined water washings were then concentrated to give 1.47 g. of hygroscopic white crystals, which was found by the Volhard method to contain 64.6% of the chloride ions of the starting chloride. These crystals were dissolved in 1 N sodium hydroxide, and an oily material was extracted with ether. The etheral solution was concentrated to give 1.05 g. of the residue, which, after distillation in vacuo, gave 0.85 g. (52.2% of the starting amine) of tri-*n*-butylamine, b. p. 84.0°C/14 mmHg (identity established by the infrared spectrum).

**The Reaction of Benzhydryl Chloride and Tri-*n*-butylammonium 2,6-Di-*t*-butyl-4-methylphenoxide (III) in Acetonitrile.**—A mixture of 1.62 g. (0.00800 mol.) of benzhydryl chloride, 1.63 g. (0.00881 mol.) of tri-*n*-butylamine and 2.12 g. (0.00881 mol.) of 2,6-di-*t*-butyl-4-methylphenol was heated in a stainless-steel bomb (50 cc.) at 141—158°C for 6.5 hr. After the mixture had been concentrated, 0.29 g. (21.8% yield) of *sym*-tetraphenylethane, m. p. 207.5—208.5°C (identity established by m.m.p. 207.5—209.0°C and the infrared spectrum) was obtained. The filtrate and the mother liquors from the recrystallization were then combined, concentrated, taken up with *n*-hexane, washed with water, and worked up to give 3.5 g. of an oily material, which was then chromatographed over 100 g. of basic alumina. Elution with benzene afforded 0.01 g. (0.7% yield) of additional *sym*-tetraphenylethane, m. p. 198—204°C (identity established by the infrared spectrum), 0.03 g. (2.1% yield) of benzophenone (identity established by the infrared spectrum), and finally 0.05 g. of 2,6-di-*t*-butyl-4-methylphenol (identity established by the infrared spectrum). A part of the water washings was titrated by the Volhard method in order to determine the chloride ion concentration; the total amount of chloride ions was estimated to be 82% of the starting chloride. The water washings were then concentrated to give 1.33 g. of hygroscopic crystals, from which 0.76 g. (46.4% of the starting amine) of tri-*n*-butylamine, (b. p. 67—73°C/17 mmHg) (identity established by the infrared spectrum) was obtained after the usual working-up.

**The Reaction of Benzhydryl Bromide and Potassium 2,6-di-*t*-butyl-4-methylphenoxide (I) in Acetonitrile.**—A solution of 2.31 g. (0.00896 mol.) of I in 250 cc. of acetonitrile was prepared in a 500-cc. round-bottomed flask equipped with a reflux condenser and a sodalime tube. After the addition of 2.01 g. (0.00850 mol.) of benzhydryl bromide, the mixture was refluxed for 6.9 hr. After the filtration of the potassium bromide, a part of the filtrate (1.000 cc.) was titrated by the Volhard method in order to determine the unchanged benzhydryl bromide. The conversion of benzhydryl bromide was estimated as 97% of the starting bromide. The filtrate was then concentrated, taken up with benzene, washed with water, dried with magnesium sulfate, and finally evaporated to give 3.26 g. of an oily material, a part (0.863 g.) of which was then chromatographed over 25 g. of basic alumina. Elution with *n*-hexane afforded 0.567 g. of an oil containing a solid, which gave 0.0104 g. of *sym*-tetraphenylethane, m. p. 197—204°C (identity established by the infrared spectrum) and 0.139 g. of IV, m. p. 116—117.5°C (identity established by m.m.p. 112—116°C, and the infrared spectrum) after fractional crystallization with ethanol. Benzene-*n*-hexane (1 : 1 by volume) fractions yielded an additional 0.057 g. of IV, m. p. 112—115°C (identity established by the infrared spectrum). From these results, the yields of *sym*-tetraphenylethane and of IV were estimated to be 3.0 and 24.1% respectively.

**The Reaction of Benzhydryl Bromide with Tri-*n*-butylamine in Acetonitrile.**—In a 100-cc. ampoule were placed 2.98 g. (0.0121 mol.) of benzhydryl

bromide, 2.45 g. (0.0132 mol.) of tri-*n*-butylamine, and 60 cc. of acetonitrile. The free space of the ampoule was then filled with nitrogen. After being sealed, the ampoule was kept at 90—93°C for 18.3 hr. Ether (100 cc.) was added to the cooled mixture, and the ethereal solution was washed with ice water. The bromide ion concentration of the water washings was determined by the Volhard method; the conversion of the starting bromide was estimated to be 91%. The dried ethereal solution was evaporated to give 2.72 g. of an oil containing some crystals. After recrystallization from ethanol, 0.10 g. (5.0% yield) of *sym*-tetraphenylethane, m. p. 196—200°C (identity established by m.m.p. and the infrared spectrum) was obtained. The mother liquors were concentrated to give 2.59 g. of an oil, a part (0.288 g.) of which was chromatographed over 25 g. of basic alumina. Some diphenylmethane (0.0775 g.) (identity established by the infrared spectrum) was left after the evaporation of the *n*-hexane fractions. Elution with *n*-hexane - benzene (7 : 3 by volume) afforded 0.0709 g. of crystals, which were then fractionally recrystallized from ethanol to give 0.0400 g. of *sym*-tetraphenylethane, m. p. 199—203°C (identity established by the infrared spectrum) and 0.028 g. of dibenzhydryl ether, m. p. 107—110°C (lit. m. p. 110°C[20]). Benzene fractions gave 0.0055 g. of benzophenone (identity established by the infrared spectrum), while ether fractions afforded 0.0185 g. of benzhydrol (identity established by the infrared spectrum). From these results, the yields of diphenylmethane and *sym*-tetraphenylethane were estimated as 22.8 and 34.4% respectively.

**The Reaction of Benzhydryl Chloride and Tri-*n*-butylamine in Decalin.**—The rate of chloride ion formation was determined at 150°C, using the sealed ampoule technique. The initial concentrations of benzhydryl chloride and tri-*n*-butylamine were 0.187 and 0.207 M respectively. The conversion of the starting chloride was estimated as 4.0% after a 6.5-hr. reaction. The conversion of the chloride under same reaction conditions was 3.0% in the absence of tri-*n*-butylamine. Product analyses for these runs were not carried out.

**The Reaction of Benzhydryl Bromide and Tri-*n*-butylamine in Acetonitrile in the Presence of 1, 1-Diphenylethylene.**—In a 100-cc. ampoule a mixture of 2.88 g. (0.0117 mol.) of benzhydryl bromide, 2.45 g. (0.0132 mol.) of tri-*n*-butylamine, 2.16 g. (0.0120 mol.) of 1, 1-diphenylethylene, and 60 cc. of acetonitrile was placed; after being sealed, the ampoule was kept at 90—91°C for 6.5 hr. To the cooled mixture was then added 100 cc. of ether, and the ethereal solution was washed with ice water. From the determination of the bromide ion concentration by the Volhard method, the conversion of starting bromide was estimated to be 95%. After the concentration of the ethereal solution, 3.69 g. of a brown oil was obtained; this was chromatographed over 145 g. of basic alumina. From *n*-hexane fractions a mixture (1.95 g., b. p. 103—107°C/3 mmHg) of diphenylmethane and 1,1-diphenylethylene was obtained. The composition of the mixture was estimated to be 0.388 g. (19.8% of the starting bromide) of diphenylmethane and 1.28 g. of 1, 1-diphenylethylene on the basis of the infrared spectrum of the mixture, taken in carbon disulfide. The characteristic bands used for the estimation were 13.5 $\mu$ for diphenylmethane and 11.1 $\mu$ for 1, 1-diphenylethylene. The first half of the benzene-*n*-hexane (1 : 9 by volume) fractions afforded 0.395 g. of a solid, which was then recrystallized from ethanol-benzene (5 : 1 by volume) to give 0.187 g. (4.5% of the starting bromide) of 1,1,3,3-tetraphenylpropene, m. p. 122—127°C (lit. m. p. 127—127.5°C[21]) (identity established by the infrared spectrum). From the second-half fractions 0.741 g. of an oil was obtained with a solid, which was then recrystallized from ethanol-benzene (5 : 1 by volume) to afford 0.212 g. (12.7% yield) of *sym*-tetraphenylethane, m. p. 203—205.5°C (identity established by the infrared spectrum). After the concentration of the mother liquors and recrystallization from ethanol-benzene (5 : 1 by volume), 0.341 g. (8.2% yield) of additional 1,1,3,3-tetraphenylpropene, m. p. 127—128°C (identity established by m.m.p. 125—126°C and the infrared spectrum) was obtained. Elution with *n*-hexane - benzene (3 : 1 by volume) gave 0.12 g. of crystals of a hydrocarbon containing a benzene nucleus (confirmed by the infrared spectrum), m. p. 165—167°C (Found: C, 93.27; H, 6.69%). The crystals showed a mixed melting point of 139—169°C on admixture with 1,1,2,2-tetraphenylcyclopropane (m. p. 164.5—166°C). Further identification for these crystals has not been carried out. From fractions eluted with ether 0.066 g. (3.1% yield) of benzophenone (identity established by the infrared spectrum) was obtained. The water washings were extracted with ether after the addition of sodium hydroxide, and the extracts were worked up to give 2.00 g. of tri-*n*-butylamine, b. p. 75—76°C/5 mmHg (identity established by the infrared spectrum).

**The Reaction of Benzhydryl Bromide and 1, 1-Diphenylethylene in Acetonitrile.**—In a 100-cc. ampoule were placed 2.98 g. (0.0121 mol.) of benzhydryl bromide, 2.16 g. (0.0120 mol.) of 1, 1-diphenylethylene and 60 cc. of acetonitrile; after it had been sealed, the ampoule was kept at 90—91°C for 63.9 hr. The white crystals (ca. 0.3 g.) which deposited on the glass wall in the upper part of the free space of the ampoule were examined in order to determine their bromide ion content by the Volhard method; Calcd. for $CH_3CN(HBr)_2$: Br, 78.8. Found: Br, 75.8%. The crystals, which precipitated in the acetonitrile solution, were filtered and washed with ether to give 2.66 g. (63.5% yield) of 1,1,3,3-tetraphenylpropene, m. p. 127—128°C (identity established by the infrared spectrum). A part of the filtrate (1.000 cc.) was added to 10 cc. of ether and washed with ice water, and the ethereal solution was titrated in order to estimate the unchanged benzhydryl bromide by the Volhard method. The conversion of the starting bromide was estimated as 97%. The mother liquors were concentrated and the residue was taken up with benzene, washed with water, dried

20) J. U. Nef, *Ann.*, **298**, 232 (1897).

21) J. E. Hodgkins and M. P. Hughes, *J. Org. Chem.*, **27**, 4189 (1962).

with magnesium sulfate and concentrated to give 1.56 g. of a solid, which in turn afforded 0.80 g. (19.2% yield) of 1,1,3,3-tetraphenylpropene, m. p. 124—126°C, (identity established by the infrared spectum) after recrystallization with benzene. The filtrate was concentrated to give 0.50 g. of an oil, which was chromatographed over 25 g. of basic alumina. Elution with *n*-hexane gave a mixture of 1,1-diphenylethylene (0.097 g.) and diphenylmethane (0.130 g., 6.4% yield). The composition was estimated by the infrared analysis mentioned above. The last fractions eluted with benzene gave 0.114 g. (5.2% yield) of benzophenone (identity established by the infrared spectrum), while those eluted with ethanol afforded 0.013 g. of benzhydrol (identity established by the infrared spectrum).

## Summary

1. The $S_N1$ reactions of benzhydryl halides and hindered nucleophiles, i. e., potassium 2, 6-di-*t*-butyl-4-methylphenoxide (I), tri-*n*-butylammonium 2, 6-di-*t*-butyl-4-methylphenoxide (III), tri-*n*-butylamine and tri-*n*-butylammonium phenoxide (II), proceed through an Arrhenius intermediate[1] and obey good second-order kinetics in acetonitrile at 110—140°C, whereas in the same solvent the reaction with potassium phenoxide is a typical $S_N1$ reaction with a van't Hoff intermediate[1] at 70—120°C. This transition of the characteristics of the intermediates from a van't Hoff to an Arrhenius type has been explained as being due to steric hindrance at the product-formation step of the $S_N1$ reactions.

2. The reactions of benzhydryl halides and some hindered nucleophiles, i. e., tri-*n*-butylamine, I and III, afford not products anticipated for the nucleophilic substitution in acetonitrile, but rather products derived from benzhydyl radicals, i. e., *sym*-tetraphenylethane, diphenylmethane and 1-(3′, 5′-di-*t*-butyl-4′-hydroxyphenyl)-2, 2-diphenylethane, whereas potassium phenoxide and II give rise to substitution products typical of the nucleophilic reactions, i. e., benzhydryl phenyl ether and *p*-benzhydrylphenol. A one-electron transfer mechanism between these hindered nucleophiles, such as tri-*n*-butylamine, I and III, and the $S_N1$ intermediate has been suggested for the formation of benzhydryl radicals.

The authors are indebted to Mrs. Yukiko Takemura, who carried out some of the kinetic measurements.

# The Solution State of Cationic Polysoap Derived from Polyallyl Chloride

By Yutaka ISHIGAMI and Hideo NARASAKI

(Received February 5, 1965)

Polysoap differs from colloidal electrolytes in exhibiting no critical micelle concentration (CMC), and in it solubilization occurs over the entire polysoap concentration range. This means that a unit polymer specy in a true molecular solution acts as a micelle.[1]

In a preceding paper,[2] one of the present authors has already reported on the synthesis and some properties of cationic polysoaps, which consist of short polymer chains with chemically-attached soap-like groups. These polysoaps were prepared by quaternizing *N*-dodecylpiperidine or dimethyl dodecylamine with polyallyl chloride, and by quaternizing *N*-dodecylpiperidine with a copolymer of allyl chloride and vinyl acetate (1 : 1 molar ratio). Their CMCs in water were determined by the three independent methods, such as conductivity, dye absorption, and surface tension. The CMC values obtained by the three methods were in good agreement. From these results, it was concluded that the micelle formation of such a polysoap in water was indeed true.

The present work was undertaken in order to examine, by means of light-scattering and surface-tension measurements, the CMC, the micellar weight, the micellar charge in water and surface excess at the air-solution interface of a cationic polysoap which consists of a

2) H. Narasaki, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **65**, 793 (1962).

relatively short polymer chain. Moreover, the results involved the effect of added sodium chloride on them.

## Experimental

**Material.** -- Polyallyl chloride was prepared by polymerizing allyl chloride at 65°C for 75 hr., using benzoyl peroxide (5% by weight of the monomer) as a polymerization initiator in an atmosphere of nitrogen, then the unreacted monomer was removed by steam distillation. The number-average molecular weight ($\overline{M}_n$) of the polyallyl chloride, as determined by freezing point depression in benzene, was 647, while the degree of polymerization ($\overline{P}_n$) calculated from $\overline{M}_n$ was 8.46. The chlorine content was 43.2% (calculated 46.4%) by a modification of the Volhard method.[3] The polysoap was prepared by quaternizing *N*-dodecylpiperidine with polyallyl chloride, using nitrobenzene as a solvent, at 150°C for 70 hr. in nitrogen. The reaction product was then isolated by precipitation into *n*-hexane. The precipitate was repeatedly washed with a large amount of benzene and dried at 55°C in a vacuum. Then it was obtained as a powder-like white material. This polysoap will be referred to as SP-100. The total chlorine content was 11.99%, as determined by a modification of the Volhard method, and the quaternized chlorine, as determined by the Volhard method, was 11.89%. Therefore, the degree of the quaternization of polyallyl chloride was calculated to be 99.2%, and the molecular weight of SP-100 was 2770.

**Light Scattering.**—Light-scattering measurements were carried out at a room temperature of about 25°C and with a wavelength of 436 m$\mu$, by using a light-scattering photometer (Shimadzu Instr. Co.). The apparatus was calibrated against redistilled benzene as a reference standard. Scattered light was measured at 45°, 90° and 135° relative to the incident beam. The dissymmetry ($Z_{45}$) was determined for all solutions, only the solutions in which $Z_{45}$ did not differ significantly from unity were used as light-scattering data. The $Z_{45}$ of the pure solvent (water) clarified in the manner described below was less than 1.03. Therefore, it is thought that the optical clarification of the solvent is accomplished.

The optical clarification of the solution to be examined was achieved as follows. Stock solutions were prepared on a weight/volume basis. The solution was centrifuged for 1 hr. at 21000 g. and the upper 2/3 parts of the solution were used for the light-scattering measurements. Then aliquots of the solution thus obtained were diluted volumetrically. Redistilled water or an aqueous sodium chloride solution clarified by the above procedure was used as the solvent. After the prepared solutions had been allowed to stand overnight in order to assure equilibrium, they were then clarified by filtration, by using suction through an ultrafine sintered glass filter directly into a light-scattering cell.

3) W. Kimura, ibid., 37, 1310 (1934).

The refractive index increments were determined with a differential refractometer (Shimadzu Instr. Co.) at a room temperature of about 25°C and with a wavelength of 436 m$\mu$. The refractometer was standardized with an aqueous potassium chloride solution. The refractive index increments, $dn/dc$, of SP-100 were found to be effectively independent of the added sodium chloride concentration in the range from 0 to 0.3 mol./l., and the value was 0.175 ml./g.

For an accurate analysis, one should treat the light scattering data as a three-component system, for the present system which was composed of SP-100, water and sodium chloride. However, Strauss and Williams,[4] and Orofino and Flory[5] have suggested that hardly any relative errors in the molecular weight of polysoaps and polyelectrolytes between two component and three component treatments, can be found. Therefore, we treated it as a two-component system composed of SP-100 and water.

In order to evaluate the micellar weight and the slope of the Debye plot of SP-100 from the light scattering data, the Debye equation below was used;

$$K(C-C_0)/(R_{90}-R_{90,\mathrm{CMC}}) = 1/M + 2A_2(C-C_0)$$

$K = 2\pi^2 n_0^2 (dn/dc)^2 / N\lambda_0^4$, where $R_{90}$ is the reduced intensity of the solution at 90°; $R_{90,\mathrm{CMC}}$ is $R_{90}$ at the CMC; $n_0$ is the refractive index of the solvent; $n$ is the refractive index of the solution; $C$ is the surfactant concentration in g./ml.; $\lambda_0$ is the wavelength of the incident light in a vacuum; $N$ is the Avogadro number; $M$ is the micellar weight; $A_2$ is the apparent second virial coefficient and $C_0$ is the CMC.

**Surface Tension.**— Surface tension measurements were carried out by the drop-weight method in a thermostat maintained at 30.0+0.2°C by using the correction of Harkins and Brown.[6] In the measurement, about one minute was allowed for the formation of each drop of the solution, since it was clear from a preliminary experiment that the solutions reached a constant value one minute after the drop formation.

## Results and Discussion

The reduced intensity of the aqueous solutions of SP-100 is plotted against the surfactant concentration in Fig. 1. The CMC was obtained from the inflection point on a curve. The scattering curve for SP-100 in water apparently shows two break points, as 0.10% and 0.22%. The CMC value in water, as determined by the minimum concentration of the surface tension, is in better agreement with 0.22% than with 0.10%, in terms of light scattering. However, this value (0.22%) gives discrepancies when compared with the system composed of added salt in the Debye plot. The Debye plot in water crosses many other

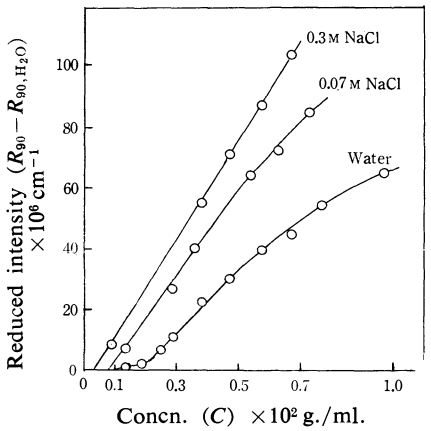

Fig. 1. Reduced intensity vs. concentration curves of SP-100 (wavelength 436 mμ, 25°C).

plots, and the extrapolation of the plot to the ordinate gives the micellar weight of about thirty thousand (Fig. 3). This means that, in the micellar weight vs. the molarity of sodium chloride relation (Fig. 4), a minimum exists at 0.03 M sodium chloride. On the other hand, the CMC value of 0.10% can easily explain the relation between the systems composed of water and of added salt in Fig. 3 and Fig. 4. Therefore, the CMC has been given as 0.10%.

The CMC of SP-100 ($3.64\times10^{-4}$ mol./l. in water) was much lower than the $10^{-2}$ mol./l. value of ordinary ionic monosoaps with the nearly same lipophilic properties, and it was of the same order of magnitude as those of nonionic monosoaps. It seems probable that a surfactant which has some soap-like groups in a molecule, such as SP-100, can more easily form a micelle than those which have only one soap group in a molecule.

As is shown in Fig. 2, when the logarithmic relation between the CMC and the total gegen ion concentration is plotted, the curve can be divided into two regions. One shows that added salt has little effect on the CMC at concentrations below about 0.07 mol./l. The other shows that the effect of added salt predominates beyond this concentration and that the CMC is linearly lowered with an increase in the total gegen ion concentration ($cl^-$). It is well known that the logarithmic relation between the CMC of a univalent ionic monosoap and the univalent gegen ion concentration can be expressed by the equation;

$$\log \mathrm{CMC} = A - B\log(\text{total gegen ion concn.})$$

where $A$ and $B$ are constants. The above phenomenon of SP-100 has never been observed for any ionic monosoaps. The dependence of the CMC of SP-100 on the total gegen ion concentration in the linear portion of the curve is given by;

$$\log \mathrm{CMC} = -4.122 - 0.547\log(cl^-)$$
$$(0.07 \leqq (cl^-) \leqq 0.6 \text{ mol./l.})$$

$K(C-C_0)/(R_{90}-R_{90,\mathrm{CMC}})$ vs. $(C-C_0)$ curves are illustrated in Fig. 3. The plots form straight lines within this range of experimental accuracy. The uncertainties in the Debye plots can be seen in water, especially at lower micellar concentration of SP-100. The slopes of the Debye plots were smaller than those of ionic monosoaps.

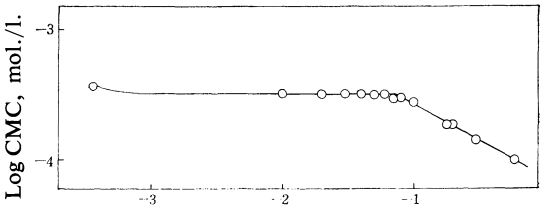

Fig. 2. Log CMC vs. log total gegen ion concentration curve of SP-100.

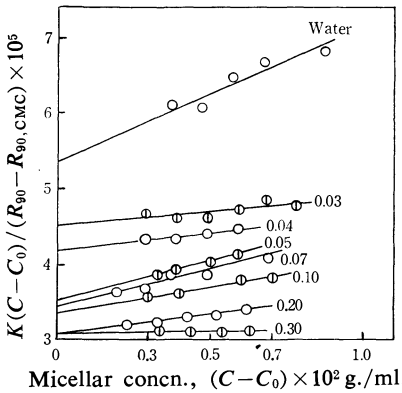

Fig. 3. Light-scattering of SP-100 in water and in aqueous sodium chloride solution (wavelength 436 mμ, 25°C). Numericals in this figure show the concn. of sodium chloride (mol./l.).

Strauss et al.[4] studied the transition from a typical polyelectrolyte to a polysoap of poly-4-vinylpyridine derivatives; they showed that a much more extended polyelectrolyte may be seen to have a much larger second virial coefficient. Inoue[7] pointed out that, in poly-2-vinylpyridine derivatives, the Huggins constant increased and the second virial coefficient decreased with an increase in their alkyl content. This reflects the interaction between their polar groups.

The micellar charge of SP-100 may, therefore, be expected to be quite small, though it may be improvable from the slope of the Debye plot. The charge on the micelle, $p$, can be

$B$: Slope of the Debye plot
$m(2)$: Aggregation number as computed from Eq. 2
$n$: Number of soap-like groups per micelle of SP-100
$p$: Micellar charge

obtained from the derived equation of Princen and Mysels[8] as follows;

$$p=[BM_1(n_1+fn_3) + \sqrt{2B(n_1+n_3)}]/A(1-AM_1E/2) \quad (1)$$
$$E=(n_1+fn_3)/(n_1+n_3)$$

where $B$ is the slope of the Debye plot; $M_1$ is the formula weight of the surfactant; $n_1$ and $n_3$ are the CMC and the added simple salt concentration both in mol./ml. respectively; $A$ is the intercept of the Debye plot, and $f$ is the ratio of the molar refractive index increment of the added salt to that of the surfactant. Once the charge has been computed, the aggregation number, $m$, is given by;

$$m=\frac{1}{2}(pE+1/AM_1) + \frac{1}{2}\sqrt{(pE+1/AM_1)^2-(p^2+p)E^2} \quad (2)$$

The results thus obtained are represented in Table I. At a lower concentration range of added salt, the $p/n$ value is much smaller than those values found for ionic monosoaps. This result may certainly be interpreted as follows. The SP-100 molecules interpenetrate each other in the interior of the micelle, and so the mutual repulsive force between the polar groups in the micelle is weakened by the shielding effect of the lipophilic groups. Many of the charged polar heads are buried so deeply in the interior of the micelle that they are effectively shielded. As a result of this shielding effect, the net charge on the micelle may be small even if the charge on single molecules is larger. On the other hand, the micellar charge increases with an increase in the added salt concentration, as is indicated in Table I. It seems probable that the micellar charge increases with the number of polar groups on the micellar surface, because the aggregated configuration of molecules in a micelle can be altered from the "*interpenetrated*" form mentioned above to a more regular one.

As Fig. 4 shows, it is noteworthy that the micellar weight of SP-100 increases much

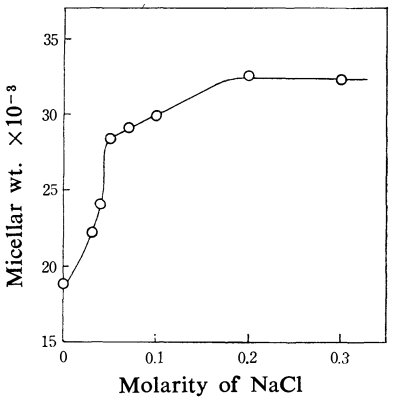

Fig. 4. Dependence of the micellar weight of SP-100 on the concentration of sodium chloride.

8) L. I. Osipow, "Surface Chemistry," Reinhold Publishing Co., New York (1962), p. 176; L. H. Princen and K. J. Mysels, *J. Colloid Sci.*, **12**, 594 (1957).

faster with an increase in the concentration of salt below about 0.06 M. On the contrary, the CMC remained essentially constant in the range from 0.01 to 0.07 M of salt. It is well known that, in ionic monosoap solutions, the addition of salt decreases the CMC and increases the micellar weight. The discrepancy between the CMC and micellar growth of SP-100 in the diluted salt solutions may be interpreted as follows. The effect of the addition of salt on the CMC and on the micellar weight of SP-100 may be distinguished as two concentration ranges. One holds in the case of the diluted SP-100 solutions below the CMC, while the other holds with solutions more concentrated than the CMC. Nakagawa and Inoue[9] considered theoretically that an intramolecular association between alkyl groups would occur in a polysoap, which did not aggregate between the molecules, even in a quite diluted solution when the cohesive power between alkyl groups was extremely strong. The degree of association between alkyl groups is large under some conditions, even in the case of a polysoap with fewer soap-like groups. In view of this, it is probable that an intramolecular association between dodecyl groups of a SP-100 molecule occurs. A small amount of added salt can not give a cohesive power level, whom SP-100 molecules require to form a micelle, to the SP-100 molecules at the lower concentrations of SP-100 just below the CMC, because the intramolecular association is expected to predominate at the lower concentrations of SP-100. Cohesive power sufficient to form a micelle may not be given to the molecules in the solution before the salt concentrtion reaches 0.07 M. On the other hand, upon the addition of a small amount of salt, the micellar weight of SP-100 increases much faster with an increase in the concentration of salt in the case of higher surfactant concentrations, because of the accessibility between the SP-100 molecules in the solution.

Surface tension vs. the logarithm of the SP-100 concentration curves are given in Fig. 5. The uppermost curve shows the system composed of water, while the lowest two curves illustrate the effect of the presence of sodium chloride on the surface activity of the surfactant. Surface tension can be regarded as entirely a linear function of $\log C$ in the concentration range of the surfactant below but near the CMC, and the $-d\gamma/d\log C$ values in these three curves are in fair agreement.

The slope of the surface tension vs. the logarithm of the concentration of an ionic surfactant has different physical meanings under

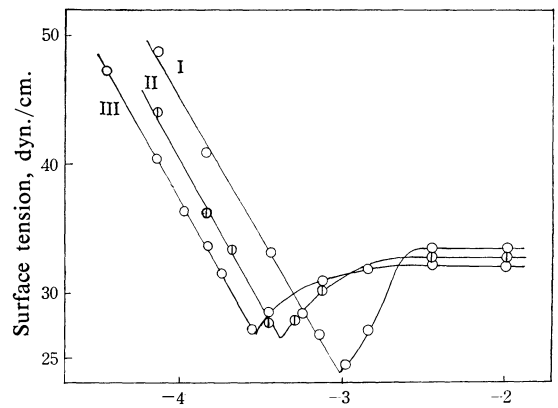

Fig. 5. Surface tension vs. log concentration curves of SP-100 at 30°C.
I Distilled water II 0.05 M NaCl
III 0.10 M NaCl

various conditions. The surface excess of SP-100 at the air-solution interface can be determined from the slope of the surface tension vs. the logarithm of the SP-100 concentration containing a definite amount of sodium chloride. In this case, Gibbs adsorption isotherm is expressed by Shinoda and Nakayama[10] as

$$-d\gamma/\boldsymbol{RT}\, d\ln X_2 = \Gamma_2 + (X_2/X_3)\Gamma_3 \qquad (3)$$

where $\gamma$ is the surface tension; $\boldsymbol{R}$ is the gas constant; $T$ is the absolute temperature; $\Gamma_2$ and $\Gamma_3$ are the surface excesses of the surfactant ion and the gegen ion at the air-solution interface respectively; and $X_2$ and $X_3$ are the mole fractions of components. Because $X_3$ is much larger than $X_2$ in the concentration region of SP-100 examined, and since $\Gamma_3$ is supposed to be at most commensurate with $\Gamma_2$, Eq. 3 reduces to

$$-d\gamma/\boldsymbol{RT}\, d\ln X_2 = \Gamma_2 \qquad (4)$$

Strictly speaking, the sample must be purified until it shows no minimum in $\gamma$ - $\log C$ curves. However, in the present system, it is difficult for us to do so; moreover, the sample itself includes fatal uncertainties in molecular weight distribution, quaternized degree distribution, and end group, etc. Therefore, we have greater interest in the comparison of the surface excesses of monosoaps and ordinary polysoaps than in the determination of the absolute value.

The $\Gamma_2$ value of SP-100, as calculated from Eq. 4 is $3.78\times10^{-10}$ mol./cm$^2$; the corresponding surface area ($A$) is obtained as 44 Å$^2$/mol. by the equation of $A=10^{16}/\boldsymbol{N}\Gamma_2$, where $\boldsymbol{N}$ is the Avogadro number. The $\Gamma_2$ value is of the same order of magnitude as those found for

9) T. Nakagawa and H. Inoue, *Kolloid-Z. u. Z. Polymere*, **195**, 93 (1964).

10) K. Shinoda and H. Nakayama, *J. Colloid Sci.*, **18**, 705 (1963).

ordinary ionic monosoaps. However, since the molecular weight of SP-100 is of the order of $10^3$, as determined on a weight basis, the surface excess of SP-100 is much larger than those of ionic monosoaps.

## Summary

Cationic polysoap (SP-100, mol. wt. 2770), consisting of a short polymer chain with chemically-attached soap-like groups, has been prepared by quaternizing *N*-dodecylpiperidine with polyallyl chloride (mol. wt. 647). Some properties of the aqueous solution of SP-100 has been investigated by the light-scattering and surface-tension methods in the absence of and in the presence of sodium chloride.

We have found that the solution of such a polysoap exhibited the CMC value and that the concentration was $3.64\times10^{-4}$ mol./l. (light scattering).

When the logarithmic relation between the CMC and the total gegen ion concentration was plotted, the curve thus obtained could be divided into two regions. Namely, the curve was almost flat at lower total gegen ion concentrations, followed by a depressed portion.

The micellar weight of SP-100 was 18800 in water and 32300 in a 0.3 M sodium chloride solution. The charges of SP-100 in aqueous solutions were calculated from the slope of the Debye plots by the derived equation of Princen and Mysels; on the basis of these results, the micellar charge of SP-100 in water is quite small.

The surface excess ($\Gamma_2$), together with the corresponding surface area ($A$), of SP-100 at the air-solution interface has been calculated from the slopes of the surface tension vs. the logarithm of polysoap concentration curve slightly below the CMC by applying the Gibbs equation. The $\Gamma_2$ value thus obtained was $3.78\times10^{-10}$ mol./cm$^2$, while $A$ was 44 Å$^2$/mol. The $\Gamma_2$ value of SP-100 in mol./cm$^2$ was of nearly the same order of magnitude as those of ionic monosoaps.

The authors wish to express their hearty thanks to Dr. Toshio Kamata for his valuable advice.

# The Electron Paramagnetic Resonance Absorption of Chromium Ions Dispersed on Silica-alumina. II. The Variation in the Spectrum under Several Chemical Treatments

By Akira MATSUMOTO, Hazime TANAKA and Nobuhisa GOTO

(Received February 5, 1965)

The structural change in chromium ions with the variation in the chemical composition of the supporting material was examined by the authors in a preceding report (Part I of this series)[1] through the analysis of the line shape in the $\gamma$-absorption on the electron paramagnetic resonance (EPR), which has been attributed to $Cr^{5+}$ ions. This paper will be concerned mainly with the spectral change in the EPR of the same materials under several chemical treatments.

A few investigators have examined the behavior of the EPR spectra of chromium ions dispersed on silica-alumina under the influence of chemical reagents. Pecherskaya and Kazanskii[2-5] have reported on a series of experiments on this problem, attaching importance to the catalytic activity in the polymerization of ethylene. They have considered that $Cr^{5+}$ ions are the catalytic-active sites. They have also examined the influence of the chemical composition of the supporting materials on the EPR spectra and the catalytic activity.

On the other hand, Cossee and Van Reijen[6] have investigated a similar substance by means

of EPR and magnetic susceptibility under the influence of hydrogen, sulfur dioxide, benzene, etc. They think that reduction at a relatively low temperature produces mainly $Cr^{4+}$ ions, and they discussed the influence of the supporting materials as well as the methods of reduction. However, they did not very much consider the nature of active sites in the polymerization of ethylene. Recently they also reported on interesting work on the same sort of material in relation to the catalytic-active sites in the dehydrogenation reactions.[7]

The authors intend in this paper to demonstrate the influence of the chemical composition of the supporting materials on the variation in EPR spectra under the action of air, water vapor, cyclohexane. The effect of evacuation will also be investigated. Then, with these results added to those of Part I, the relation between the stability of the $3d^1$ state or chromium ions and the catalytic activity in the polymerization of ethylene and in the decomposition of hydrogen peroxide will be discussed.

## Experimental

**Materials and Treatment.**—The supporting materials and the method of preparing dispersed samples were the same as those described in Part I. The calcination of samples was carried out in a stream of dry air at 500°C for 4 or 17 hr. Immediately after the calcination, the measurement of the EPR and the chemical treatments were started. The samples used in the experiment are listed in Table I.

**The Measurement of the EPR Spectra.**—The EPR spectra were observed with the K-band superheterodyne spectrometer described in the preceding paper. When the measurement was performed at elevated temperatures, a cavity equipped with a heater was employed. A small quantity of coal powder was fixed in the cavity as a standard of the relative intensity of the EPR absorption.

A silica tube which contained the sample was inserted into the cavity and connected with a vacuum system. The cavity had previously been heated at a fixed temperature. After evacuation for several minutes, each reagent was introduced and the measurement of EPR was started. Dry air was conducted from a flask containing phosphorus(V) oxide. Water vapor was then introduced from a glass tube in which a small quantity of deaerated water had been sealed off. Ethylene was taken from the same material as those used in the polymerization experiment in this laboratory. The reaction of cyclohexane was followed in the open air.

In some cases samples were treated outside the cavity and were measured in an ordinary cavity at room temperature. Especially the evacuation of the samples not calcined was carried out in another tube at room temperature for 24 hr. with an oil diffusion pump, and then the samples were transferred into a tube for measurement and sealed off. When the samples not calcined were evacuated, a color change occurred, even at room temperature.

**The Oxidation Number.**—The oxidation number was determined by the iodometry described in Part I.[1] When the determination was carried out after reduction with cyclohexane, the samples were dried, with evacuation, at room temperature. After treatment with ethylene, however, it was impossible to determine the oxidation number because the polymer covered the samples.

**The Polymerization of Ethylene.**—The activity in the polymerization of ethylene was determined at 135°C by means of the decrease in the pressure of ethylene starting from 1 atm. and from 40 kg./cm$^2$ without a solvent. About 200 mg. of the sample calcined was placed in a glass tube dipped in an oil bath at 135°C; then, after the air had been removed with a rotary vacuum pump for five minutes, ethylene was introduced up to 1 atm. The volume of the system was about 600 cc. (N.T.P.). Then the decrease in the pressure was observed. Some of the samples were taken out during this treatment and their EPR spectra measured.

When the experiment was performed starting from 40 kg./cm$^2$, about 500 mg. of the sample was placed in a stainless steel autoclave (100 cc.). After the repeated replacement of the atmosphere with nitrogen, the autoclave was heated to 135°C and ethylene was introduced up to 40 kg./cm$^2$. The decrease in the pressure was observed, and after a definite time the weight of the polymer produced was measured. The volume of the system was about 125 cc. (N.T.P.).

**Decomposition of Hydrogen Peroxide.**—The decomposition of hydrogen peroxide was investigated at 30°C, using an apparatus which was similar to that of Deren et al.[8] About 100 mg. of the sample was placed in an ampoule and 30 cc. of 30% hydrogen peroxide was added. By running water out from the burettes connected to the system, a manometer was balanced and the volume of the generated oxygen was determined nearly continuously. The decomposition proceeded linearly with time. The measurement was continued for about an hour.

## Results

**The Variation in EPR Absorption in the Atmospheres of Different Gases.**—*The Appearance of the γ-Absorption by Evacuation and Its Disappearance with Air and Water Vapor.*—Impregnated samples which had merely been dried at 120°C in open air gave a broad so-called β-absorption of EPR without a sharp line of γ-absorption or with only a very weak one. When these materials were evacuated, the γ-absorption appeared and increased, even at room temperature. This absorption, however, was more affected by air and water vapor than that of the calcined samples. Figures 1

it is calcined at 500°C for 17 hr. Concerning the $\beta$-absorption, no marked increase is seen. The decrease in the intensity of the $\gamma$-absorption is accelerated by water vapor and temperature, but the acceleration does not linearly correlate with the temperature.

*Cyclohexane and Ethylene.*—The same material was treated with cyclohexane and ethylene ;

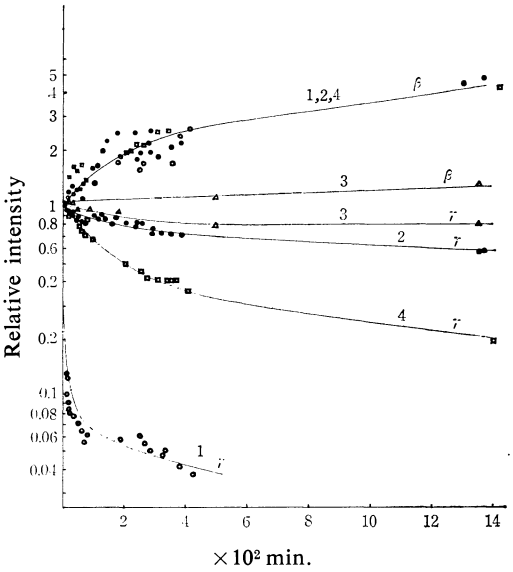

Fig. 5. The variation of the intensity of EPR absorptions by the contact of ethylene in the samples with different supporting materials at 70°C. Figures indicate sample numbers.

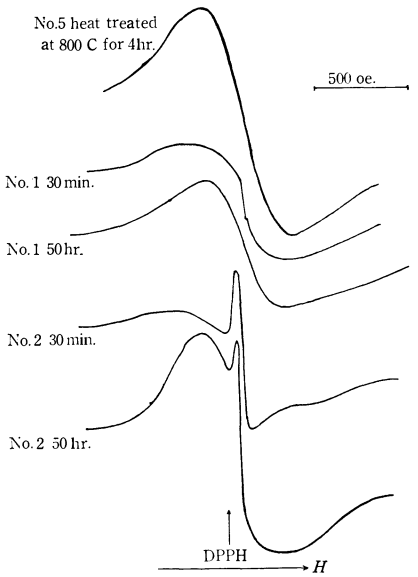

Fig. 6(a). EPR spectra after the treatment with ethylene at 1 atm. The first indicates the spectrum of the sample No. 5 heat treated in air at 800°C for 4 hr.

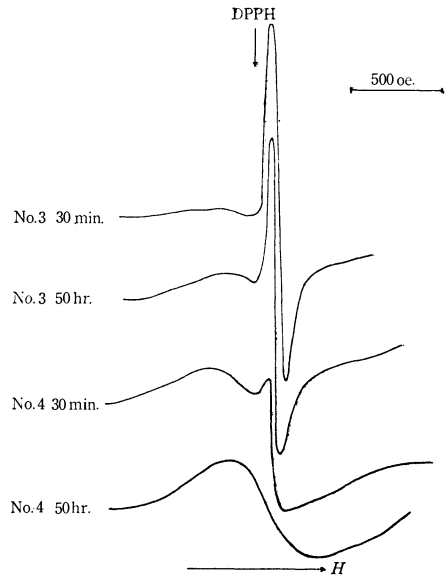

Fig. 6(b). EPR spectra after the treatment with ethylene at 1 atm.

the results are shown in Fig. 4. Another series of experiments was carried out in order to compare the samples with different supporting materials. Figure 5 shows the intensity variation in each sample at 70°C in an atmosphere of ethylene. Figure 6 shows the line shapes of the EPR of samples which were picked out in the course of the polymerization experiment to be described below.

It may be seen that in these atmospheres the $\beta$-absorption grows rapidly and that the decrease in $\gamma$-absorption is also remarkable. The variation does not depend on temperatue very much, from 50°C to 120°C, in the atmosphere of ethylene. The supporting material markedly affects the behavior of the $\gamma$-absorption. As may be seen in Figs. 5 and 6, the

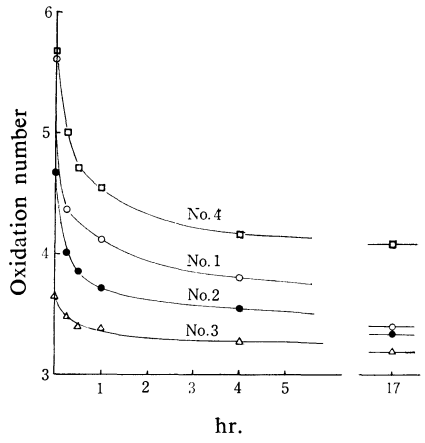

Fig. 7. The variation of the oxidation number by the treatment with cyclohexane at 60°C.

sample with a silica gel base loses the $\gamma$-absorption quite rapidly, with the sample with a gamma-alumina base next. In the sample with a silica-alumina I (silica : alumina=4 : 1) base, the $\gamma$-absorption is rather stable, and in the sample of silica-aluminaII (silica : alumina= 1 : 1) the $\gamma$-absorption hardly changes at all during the measurement.

Figure 7 indicates the variation in the oxidation number of the four kinds of samples by the treatment with cyclohexane at 60°C. The oxidation number of the silica-gel-base sample also decreases quickly. The sample with a silica-alumina II base keeps a low oxidation number from the beginning. It may be noticed that the sample with a gamma-alumina base keeps a relatively high oxidation number, even after long treatment.

**The Polmerization of Ethylene.** — When the samples calcined at 500°C for 4 hr. were brought into contact with ethylene of 1 atm. at 135°C, a decrease in the pressure was observed in the cases of the samples with a silica gel base and with a silica-alumina I base, as is shown in Fig. 8. The polymers which

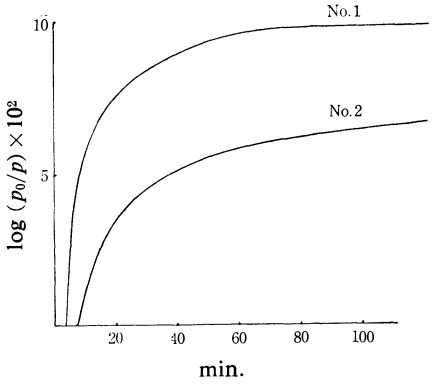

Fig. 8. The pressure decrease of the ethylene with the contact of the samples (at 135°C, from 1 atm.).

melted during the reaction, including the particles of the samples, formed a plate. The reproducibility of the experiment was not very good, but the relative inclination was always similar. Figure 8 indicates the average curves of several runs. In all cases a short period of induction was observed. This period was shorter in the silica-gel-base sample than in the silica-gel-alumina I base sample, and the initial rate of the reaction was faster in the former. After about an hour of the rapid decrease in the pressure, a gradual drop continued for a long time.

For the samples with a silica-alumina II base and with a gamma-alumina base, no decrease in the pressure could be observed. The

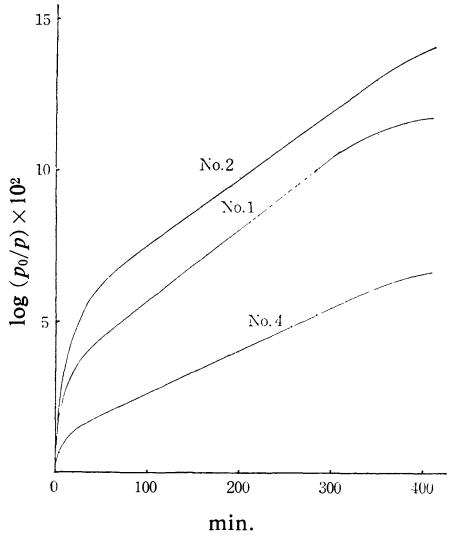

Fig. 9. The pressure drop of the ethylene with the contact of the samples (at 135°C, from 40 kg./cm$^2$).

color of the samples turned green from the initial orange or orange yellow for the samples with a silica gel base and with a silica-alumina I base, but for the sample with a silica-alumina II base the color changed little remaining brown.

Figure 9 shows the results of the experiments with an autoclave. In this case decrease in the pressure was observed even with the sample with a gamma-alumina base, but the rate was slower than with the samples with a silica gel base and with a silica-alumina I base. The difference between the latter two samples was not as clear as in the experiment started from 1 atm. The polymer produced after 20 hr. was 4—5 g. per 1 g. of the sample in the cases of silica gel and silica-alumina I, and about 1.5 g. per 1 g. of the sample in the case of a gamma-alumina base. However, as the polymerization proceeds, the samples are covered with the molten polymer and the diffusion of ethylene into the polymer becomes important in the reaction. Also, the heat of the reaction necessarily elevates the temperature at the surface of the sample, so it is difficult to decide the activity directly on the basis of these values. The sample with a silica-alumina II base did not bring about the pressure drop at 40 kg./cm$^2$ either.

**The Decomposition of Hydrogen Peroxide.**— In Table II the amount of oxygen liberated in one minute per gram of chromium in the sample and that oxidation number are shown for the four kinds of samples, each of which was measured before and after treatment with cyclohexane. This treatment was the same as

that for the determination of the variation in the oxidation number, and the duration was fixed at thirty minutes.

The activities per chromium differ, but if the activity is expressed by the value per oxidation number, they are not very different. Even after the reduction, these values remain constant, except for the sample with a silica gel base, where the activity per oxidation number becomes more than two times as large.

TABLE II. THE CATALYTIC ACTIVITY IN THE DECOMPOSITION OF $H_2O_2$

| Sample | Before reduction | After reduction* |
|---|---|---|
| Liberated $O_2$ cc./min./g. of Cr | | |
| 1 | $9.79\times10^{12}$ | $7.98\times10^{12}$ |

## Discussion

**The Stability of $\gamma$-Absorption Sites Against Chemical Reagents.** — The authors showed in Part I of this series that thermal stability of $\gamma$-absorption sites in the dispersed chromia was affected by the chemical composition of the supporting material. The sample with a silica gel base held a high mean oxidation state and showed the $\gamma$-absorption up to a higher temperature of the heat treatment. The addition of alumina to the base material lowered the thermal stability of the high oxidation state and $\gamma$-absorption sites. Pure gamma-alumina had a somewhat different inclination as a supporting material.

On the contrary, the reduction with chemical reagents proceeds most easily in the sample with a silica gel base, and the disappearance of the $\gamma$-absorption upon contact with ethylene occurs most rapidly in this sample. The sample with a silica-alumina II base, which has a relatively low oxidation number from the beginning and which shows a strong $\gamma$-abserption, is quite inert; the $\gamma$-absorption is hardly changed at all by the treatment with ethylene, as is shown in Figs. 5 and 6. The absorption of the sample with a gamma-alumina base behaved in an intermediate manner under this treatment.

As was mentioned in Part I, the $\gamma$-absorption site of the pure silica-gel-base sample must be present in the cluster of chromia, possibly at the surface. Its concentration is low, and the coordination field around the $Cr^{5+}$ ions is a symmetric. It may be considered that under such conditions chromium ions react easily with chemical reagents.

When alumina is added to the supporting material, isolated chromium ions appear. The concentration of $Cr^{5+}$ ions increases, and the coordination field around them becomes more symmetric. The chemical stability of these sites increases, though they are not very stable against heat treatment. It is natural to think that this effect is caused by aluminum ions or by the defects made by aluminum ions. It is, however, not clear at present whether the $\gamma$-absorption sites are present at the isolated chromium or in the clusters of chromia, but at least there are several $\gamma$-absorption sites which are different in the chemical stability, and the addition of alumina to the supporting material makes for an increase in the number of chemically-stable sites or for an increase in the general stability of the sites against chemical reagents.

Gamma-alumina acts as an intermediate supporting material. The line shape of the $\gamma$-absorption is most symmetric in the sample with this base and the coordination is most regular. Unlike silica-alumina, gamma-alumina is rather a regular substance, so the dispersion of chromia on this material is more regular, though the interaction between chromia and alumina is strong. The fact that the oxidation number does not go below four upon treatment with cyclohexane indicates the different state of the chromium ions on this material.

Kazanskii et al.[5] reported similar findings concerning variation in the line shape of the EPR in different supporting materials, though they thought mainly in terms of a substitution of the chromium atom for the silicon atom. The interaction of chromium with silica-alumina has also been discussed by a few investigators.[9-11] Topchiev et al.[9,10] considered the formation of aluminum chromate, with reference to the work of Pode et al.,[12] and concluded that the stability of the high oxidation state of chromium is determined by the form of the chromates.

As has been seen earlier, the evacuation of a sample not calcined produces $\gamma$-absorption

sites which easily disappear upon contact with air, even, at room temperature. Perhaps the nature of these sites is similar to that on silica gel. The EPR spectra of the samples calcined do not change very much in a vacuum or in dry air. Particularly the $\beta$-absorption does not increase. This means that the ionic state of chromium in the dispersed clusters of chromia does not essentially change. On the contrary, in the samples not calcined, a rise in the $\beta$-absorption is seen in response to a fall in the $\gamma$-absorption. The effect of water vapor is more rapid and clear, and the $\beta$-absorption appears gradually, even in the calcined sample. These phenomena correlate with the process of stabilization, indicating the formation of certain coordination states.

**The Activity in the Polymerization of Ethylene.**—The initial reaction rate of ethylene at 1 atm. is the fastest with a silica gel base, but the chromium ions on the same base are most easily reduced. This may correlate with the fact that when used as the supporting material the pure silica gel makes the catalyst most easily deactivated.[13] The addition of alumina produces the more stable active sites. However, addition in excess increases the number of inactive chromium ions.

The nature of the active sites in these substances in the polymerization of ethylene is not yet clear. It is, however, possible to consider that such sites exist in the dispersed clusters of chromia, where chromium ions are placed in a field of distorted octahedron. In the course of the present experiment, it was established that the samples become yellow or orange yellow when subjected to heat treatment in dry air. If the activation was carried out in wet air, the samples turned green. After the polymerization, the color generally turned green. The green samples played no part in the polymerization, as is well known. The teatment of the activated samples by cyclohexane caused a color change to brown and not to green.

Van Reijen et al.[7] also paid attention to the color change of chromia-alumina and chromia-silica. They measured the EPR and the magnetic susceptibility and concluded that, in a light blue sample, chromium ions become $Cr^{2+}$ and active in the dehydrogenation of cyclohexane, while in a green sample chromium ions are $Cr^{3+}$ and inactive.

These colors reflect the electronic state of the active chromium ions. From the facts that the oxidation state of chromium easily changed by the treatment with cyclohexane and that, in general, the catalyst is dispersed in some hydrocarbon before coming in contact with the solution of ethylene, the valence state of chromium has to be below $5^+$ at the moment of reaction. Accordingly, the existence of chromium ions which are easily reduced to a low valence state, but yet keep some coordination condition, may be essential for the polymerization.

The life of the active site is decided by the ease of the transfer from an active to an inactive coordination state. The effect of the addition of alumina can be understood from the increase in the symmetry of the coordination field and from the subsequent increase in the stability of the state, which is reflected by the increase in the symmetry and width of the $\gamma$-absorption.

About the poisoning of the activity by water, Kazanskii and Pecherskaya[4] proposed a mechanism of the strong attaching of water to $Cr^{5+}$ sites, which they considered to be the active sites in the polymerization reaction. This is a possibility, but at the same time it is possible to consider that water accelerates the transfer of chromium ions into an inactive state. This is because, if the air of the heat treatment is wet, the color of the sample becomes green, the presence of water produces a green sample both in a reductive atmosphere and in an oxidative.

There are a few articles about the mechanism of the polymerization of ethylene with this sort of catalyst.[10,14-19] Clark et al.[20] reported that the treatment of the catalyst by carbon monoxide above 250°C or by ethylene above 15°C produces a complex of the carboxylate type on the surface, and that only the catalyst accompanying this complex is active in the polymerization of ethylene at low temperature. The role of this complex has not yet been made clear.

Before the catalyst is introduced into the reactor, it is dispersed and held in the solvent. This procedure may, like the penetration of the solvent, be useful in making the complex. As may be seen in Fig. 8, the polymerization at 1 atm. shows an induction period, which may correspond to the complex formation. Topchiev et al.[21] have shown that the pretreatment of the catalyst by ethylene or isooctane reduces this induction period.

The dispersion of chromia in the form of thin-layer clusters is convenient for the multi-point adsorption; also, if this assembly of chromia has the character of an *n*-type semiconductor in the reducing atmosphere, the $d^1$ or $d^2$ state of chromium is conductive to the adsorption from the point of view of the ligand field stabilization energy. The adsorption is also possible in a Zeise-type $\pi$-complex, such as Cossee suggested in the case of the Zieglar-type catalyst.[23] In any case, ethylene monomers are adsorbed on the surface of the cluster of chromia collectively. If the carboxylate ions cited above serve to initiate the process, the polymerization proceeds in a manner like that proposed by Duck[23] in a Ziegler-type catalyst or by Friedlander[24,25] in a standard-type catalyst. It is interesting that Eishens observed the same type of carboxylate ions on the Ni–NiO treated with CO.[26]

**The Decomposition of Hydrogen Peroxide.**— There have been several reports concerning the activity of chromia dispersed on the supporting materials in the decomposition of hydrogen peroxide. Voltz and Weller[27] and Matsunaga[28] have shown that the activity of the chromia-alumina system depends on the excess oxygen over a wide range of the chromium concentration; the activity per excess of oxygen is constant. Tarama et al.[29] have reported that the $Cr^{6+}$ site and the $Cr^{5+}$ site both have catalytic activity. On the other hand, Deren et al.[8,30] showed that the aggregative state of $Cr^{6+}$ affects the activation energy in the decomposition reaction. From the low concentration range of chromium where an atomic dispersion occurred, to the higher concentration which resulted in the clusters, the activation energy gradually lowered and the activity increased as a whole.

In the present experiment, the decomposition activity is related to the excess oxygen of the samples in many cases. The difference in the supporting material does not produce a great difference in the specific activity. The reduction by cyclohexane lowers the total activity, but the activity per excess unit of oxygen remains constant. Only in the case of the sample with a silica gel base is the activity per excess unit of oxygen about two times larger after the reduction; the lowering of the activity is not so great as that of the oxidation number.

This phenomenon may be correlated with the coordination state of the chromium ion. If the decomposition of hydrogen peroxide by these materials proceeds via the cycle of oxidation-reduction mentioned in the case of $MnO_2$,[31] the quantity of the excess oxygen is only a measure of the sites in the oxidation state. In general, the rate-determining step of the reaction involves only the acceptor site. There are two possibilities in the case of the sample with a silica gel base. First, the reduction does not destroy the active site, though its oxidation state is changed. Second, both the acceptor site and the donor site contribute to the rate determination step in some coordination state. The former enlarges the finding of Tarama et al. that $Cr^{4+}$ is also a reactive site. The results of Deren et al. are also useful in understanding special features of the chromia cluster. It would be expected that the assembly would produce an lowering of the activation energy. This must be a characteristic of this dispersion.

## Summary

The dispersed state of chromium and the effect of heat treatment have been compared in Part I in chromium dispersed on different supporting materials. The behavior of the EPR absorption of the same materials in the reaction of several chemical reagents have been observed in the present work. The catalytic activities of these samples in the polymerization of ethylene and in the decomposition of hydrogen peroxide have also been measured.

The $\gamma$-absorption sites of the samples had different stabilities. In the sample with a silica gel base, this absorption disappeared quite easily in a reductive atmosphere, but that of the sample with a silica : alumina 1 : 1 base was stable in the same atmosphere. The former showed the greatest initial reaction rate in the polymerization of ethylene at 1 atm., while the latter had no catalytic activity in the polymerization, even at 40 kg./cm$^2$. The sample with a gamma-alumina base showed an intermediate character in many respects. The activity in the decomposition of hydrogen peroxide generally corresponded to the oxidation number of the samples, even after reduction with cyclohexane, but in the case of the silica gel base different behavior was observed.

Taking the present and the preceding results into account, the character of this type of catalyst has been discussed. Its nature must essentially be due to the cluster-form dispersion of chromia; the addition of alumina to the supporting material gives an effect of stabilization to the active site, which extends the life of the catalyst, though an excess in the addition results in an inactive material. The $3d^3$ state of the chromium ions is inactive in the polymerization of ethylene, probably because of the lack of a beneficial adsorptive property to the monomer. The ease in the transfer among $d^0$, $d^1$ and $d^2$ states of chromium ions may decide the activity, while the transfer into the $d^3$ state may decide tha life of the catalyst. Water accelerates the latter and deactivates the catalyst.

# The Preparation of Hydride-free Triethylaluminum and Its Reaction with Titanium Tetrachloride

By Yukichi TAKASHI and Itsuho AISHIMA

(Received February 6, 1964)

In order to clarify the mechanism of the Ziegler catalysis for the polymerization of $\alpha$-olefins, many investigations concerning the reaction between the catalyst components, namely, triethylaluminum and titanium tetrachloride, have been reported. All authors have observed the rapid reduction of titanium tetrachloride to the lower valency states.

Roha et al.[1] proposed that the reduction of titanium tetrachloride during the reaction with triethylaluminum was due to the effect of the diethylaluminum hydride present in the triethylaluminum. They stated that the diethylaluminum hydride present as an impurity in triethylaluminum has a strong reducing power and that the triethylaluminum, which had been treated with ethylene at a high pressure in an attempt to decrease the hydride content, did not show any appreciable reduction of titanium tetrachloride, although a clear orange solution was obtained.

In order to study the true behavior of triethylaluminum, hydride-free triethylaluminum was prepared and the reactivity of trialkylaluminum with titanium tetrachloride was investigated.

## Experimental

**Material.**—*Crude Triethylaluminum.*—A commercial reagent (Texas Alkyls Corp.) was used.

*Diethylzinc.*—A commercial reagent (Sankyo Yuki Co.) was distilled at 50°C/64 mmHg.

*Titanium Tetrachloride.*—A commercial reagent (Kishida Chem. Co.) was distilled at 136—137°C.

*n-Hexane.*—Commercial-grade *n*-hexane (Phillips Petroleum Co.) was refluxed on sodium wire, distilled, and stored over a molecular sieve.

*Ethylene.*—Commercial high-purity ethylene (Nihon Sekiyu Co.) was used after having been dried with a molecular sieve.

*Analysis.*—Elemental analysis was done according to the standard methods as follows: aluminum, gravimetric oxine method; zinc, titration method using ethylenediamine tetraacetic acid; carbon and hydrogen, microcombustion method. The determination of the alkyl group or hydrogen bound to aluminum or zinc was accomplished by the hydrolysis and the volumetric measurement of the alkane and hydrogen evolved. The above gaseous hydrolysis products were analyzed by gas chromatography at room temperature using a column 5 m. long×4.5 mm. diameter packed with alumina containing 25% acetonylacetone (for hydrogen) and with "C-22" (Shimadzu Seisakusyo) containing 25% liquid paraffin (for hydrocarbons). Furthermore, the trace of diethylaluminum hydride in triethylaluminum was analyzed qualitatively by means of the infrared spectrum and the isoquinoline test. Diethylaluminum hydride shows a deep infrared absorption at about 5.7 $\mu$[2] and forms a deep red complex with isoquinoline.[3] For the measurement of the infrared spectrum, a Perkin-Elmer model 137 was used.

2) G. Schomberg and E. C. Hoffman, *Z. Elektrochem.*, 61, 1110 (1957).

3) F. Bonitz, *Chem. Ber.*, **88**, 742 (1955).

**The Preparation of Hydride-free Triethylaluminum.**—Crude triethylaluminum (45 cc.) and 100 cc. of *n*-hexane were introduced, under a nitrogen atmosphere, into a 200 cc. flask equipped with a dropping funnel, a stirring bar, and a gas outlet connected to a nitrogen surge tube. The flask was set in a bath kept at −30°C using dry ice - *n*-hexane. Diethylzinc (5 cc.) dissolved in 100 cc. of *n*-hexane was dropped into the stirred solution of crude triethylaluminum. A white precipitate was thus formed. After the dropping was completed, the temperature of the flask was gradually raised to room temperature. The white precipitate then turned dark gradually. At about 20°C the precipitate instantaneously turned black. The supernatant colorless liquid was distilled under reduced pressure. A main fraction (a colorless liquid), distilled at 64—66°C/6 mmHg, was analyzed as follows: Found: Al, 23.56; C, 63.27; H, 13.21; Zn, 0.00; Calcd. for $Al(C_2H_5)_3$: Al, 23.63; C, 63.12; H, 13.24%. The results of the determination of the hydride by means of the infrared spectrum, the isoquinoline test and hydrolysis are shown in Table I.

Table I. The analysis of triethylaluminum

| $AlEt_3$ | | | Crude | Purified |
|---|---|---|---|---|
| Infrared spectrum (5.7 $\mu$) | | | + | − |
| Isoquinoline test | | | + | − |
| Hydrolysis | Gas evolved | mol./mol. $AlEt_3$ | 2.98 | 2.98 |
| | Ethane | vol. % | 93.16 | 98.44 |
| | Ethylene | vol. % | 0.33 | 0.00 |
| | *n*-Butane | vol. % | 3.14 | 1.56 |
| | Hydrogen | vol. % | 3.37 | 0.00 |

**The Reaction of Crude Triethylaluminum with Diethylzinc.**—Crude triethylaluminum (9.2 g., 0.081 mol.) was introduced under a nitrogen atmosphere into a 50 cc. test tube equipped with a magnetic stirrer, a gas outlet connected to a gas burette, and a dropping funnel. The test tube was then set in an oil bath kept at 60°C. To the stirred crude triethylaluminum, 10.0 g. (0.088 mol.) of diethylzinc was added from the dropping funnel over a 10 min. period, after which stirring was continued for a further 20 min. The reaction thus proceeded, separating a black metallic powder, and 6.2 mmol. of gas was evolved during the reaction. The composition of the gaseous products, as determined by gas chromatographic analysis, is shown in Table II.

Table II. The composition of the gaseous products evolved during the reaction between crude $AlEt_3$ and $ZnEt_2$

| Component | Vol. % |
|---|---|
| Hydrogen | 70.0 |
| Ethane | 29.1 |
| *n*-Butane | trace |

When the black precipitate was filtered, washed with dried *n*-hexane, and dried, 0.46 g. of a matallic solid was obtained. It was 97.37% zinc and 0.24% aluminum, and so it seems to be almost pure zinc metal. (Zn, 6.85 m atom).

To the filtrate a few drops of diethylzinc were then added. No further change was observed. On the other hand, when a few drops of crude triethylaluminum were added to the filtrate, a black precipitate separated again.

**The Treatment of Crude Triethylaluminum with Ethylene.**—A solution of 10 g. (0.088 mol.) of triethylaluminum in 50 cc. of dry *n*-hexane was treated with ethylene at 40—60 kg./cm² at 90°C for 18.5 hr. in an autoclave. Ethylene (0.56 mol.) was absorbed smoothly. *n*-Hexane was then stripped from the resultant to obtain 25.7 g. of a colorless liquid. The average chain length (carbon number) was calculated as 6.3 on the assumption that all the ethylene absorbed was consumed in the "Aufbau Reaktion." The reaction product was hydrolyzed as usual. The composition of the evolved gas was analyzed by gas chromatography. Table III shows the composition of the evolved gas.

Table III. The composition of the gas evolved upon hydrolysis

| Component | Composition vol. % |
|---|---|
| Ethane | 11.3 |
| *n*-Butane | 86.7 |
| Hydrogen | 2.0 |
| (Total gas | 1.73 mmol./g.-Product) |

Table IV. The distribution of the groups bound to aluminum

| Group | Composition mol. % |
|---|---|
| Ethyl | 1.9 |
| *n*-Butyl | 14.6 |
| Hydride | 0.3 |
| Longer alkyls | 83.2* |

* Calculated as 100 minus the sum of the percentages of the above groups.

Table V. The reaction of trialkylaluminum with titanium tetrachloride

| Run No. | $AlR_3$ | Ethylene* treatment | Reaction |
|---|---|---|---|
| 1 | Crude $AlEt_3$ | − | A dark brown precipitate was formed instantaneously |
| 2 | Crude $AlEt_3$ | + | A dark brown precipitata was formed instantaneously |
| 3 | Pure $AlEt_3$ | − | A dark brown precipitata was formed instantaneously |
| 4 | Pure $AlEt_3$ | + | A dark brown precipitate was formed instantaneously |
| 5 | $AlEt_3$ treated with ethylene at a high pressure | − | Clear yellow solution (slightly orange-colored) |
| 6 | $AlEt_3$ treated with ethylene at a high pressure | + | Clear yellow solution |

* Ethylene was passed into the $AlR_3$ benzene solution at atmospheric pressure and at room temperature for 30 min.

The distribution of the groups bound to aluminum is shown in Table IV.

**The Reaction of Various Trialkylaluminum Species with Titanium Tetrachloride.**—To trialkylaluminum (0.274 g.) dissolved in 200 cc. of dry benzene in a 300 cc. conical flask, titanium tetrachloride (3 cc.) in benzene (1 mmol./cc.) was added drop by drop at room temperature.

The same procedure was then repeated using a benzene solution of trialkylaluminums which had been treated with ethylene bubbled in at atmospheric pressure and at room temperature for 30 min.

The results of the reactions are shown in Table V.

## Discussion

**The Preparation of Hydride-free Triethylaluminum.**—Triethylaluminum free from hydride can be prepared by treating triethylaluminum containing the hydride with diethylzinc. It is postulated that the reaction proceeds according to the following equations:

$$Et_2AlH + Et_2Zn \longrightarrow Et_3Al + EtZnH \quad (1)$$

$$Et_2AlH + EtZnH \longrightarrow Et_3Al + ZnH_2 \quad (2)$$

$$2EtZnH \longrightarrow Et_2Zn + ZnH_2 \quad (3)$$

$$EtZnH \longrightarrow Zn + EtH \quad (4)$$

$$ZnH_2 \longrightarrow Zn + H_2 \quad (5)$$

Equations 4 and 5 are supported by the fact that the reaction gives metallic zinc and a nearly equimolar quantity of a gas consisting mainly of hydrogen and ethane.

The gas evolved during the reaction contained 70 mol. % of hydrogen. However, it is uncertain that the second-step alkylation shown in Eq. 2 can proceed. The disproportionation of ethylzinc hydride as shown in Eq. 3 should also be considered.

Assuming that the reactions of 1—5 proceeded quantitatively, the hydride-group content in the groups bound to the aluminum of crude triethylaluminum was calculated to be 4.3%. This value nearly coincided with the analytical value of 3.4% (Table I).

**The Reaction of Ziegler-catalyst Components.**—In order to clarify the mechanism of Ziegler catalysis, many investigations concerning the reaction of the catalyst components, e. g., triethylaluminum and titanium tetrachloride, have been reported. All the authors agree that titanium tetrachloride is alkylated by triethylaluminum and that then the alkyl-titanium bond is decomposed to yield titanium species of lower valency states. Although some catalysts which are comprised only quadrivalent titanium species have been proposed,[2] the reduction of titanium in the case of a Ziegler catalyst consisting of triethylaluminum and titanium tetrachloride is noticeable as a reaction important to an analysis of the catalytic mechanism. However, the mechanism of the reduction of titanium tetrachloride has not yet been clarified in detail.

Roha et al.[1] found that the triethylaluminum treated with ethylene at a high pressure and temperature does not reduce titanium tetrachloride; they therefore proposed that the reduction of titanium tetrachloride is due to the effect of the diethylaluminum hydride present as an impurity in triethylaluminum, which hydride has a stronger reducing ability.

Sinn et al.[4] proposed that the presence of a small quantity of water is necessary for Ziegler catalysis.

In fact, it is important to notice the effects of the components present in small quantities in the catalyst system.

In order to study the role of the impurities present in trialkylaluminum, we studied the reactions between titanium tetrachloride and various trialkylaluminums, namely, commercial crude triethylaluminum which contained a small quantity of the hydride (diethylaluminum hydride), purified triethylaluminum free from hydride, and trialkylaluminum which had been obtained by the treatment of commercial triethylaluminum with ethylene at a high pressure and temperature.

The experimental results showed that even when the purified triethylaluminum was used, the instantaneous reduction of titanium tetrachloride occured, just as in the case of crude triethylaluminum containing diethylaluminum hydride.

On the other hand, trialkylaluminum with longer alkyl chains, which had been obtained by treating crude triethylaluminum with ethylene at a high pressure and temperature, could not reduce titanium tetrachloride to the lower valency states; rather, a clear yellowish-orange solution was obtained.

The fact that the triethylaluminum treated with ethylene at a high pressure and temperature, even though with a detectable amount of an aluminum-hydrogen bond, did not reduce titanium tetrachloride might be explained in terms of the steric hindrance of its long alkyl groups.

We might also conclude that the reduction of titanium tetrachloride with triethylaluminum is not caused only by the hydride present in it as an impurity.

## Summary

Hydride-free triethylaluminum has been prepared by destroying diethylaluminum hydride by reaction with diethylzinc.

4) Hj. Sinn, H. Winter and W. v. Tirpitz, *Makromol. Chem.*, **48**, 59 (1961).

The reaction of hydride-free triethylaluminum and titanium tetrachloride in benzene shows the instantaneous reduction of titanium tetrachloride. It has been concluded that the reduction of titanium tetrachloride is not caused only by the presence of diethylaluminum hydride as an impurity in triethylaluminum, as has been proposed by Roha. Triethylaluminum treated with ethylene at a high pressure does not reduce titanium tetrachloride under ordinary conditions, even though it contains appreciable amounts of the hydride.

On the basis of the above facts, the reaction of Ziegler-catalyst component has been discussed.

# The Interaction of Cumulene Systems with Organometallic $\pi$-Complexes. III.[1] Iron Carbonyl Complexes of Hexapentaene and of Tetra- and Dimethylbutatriene*

By Akira NAKAMURA**

(Received February 16, 1965)

The stabilization of unstable organic compounds by the formation of organometallic $\pi$-complexes has provided a base for the occurrence of such unstable reaction intermediate species as cyclobutadiene.[2] We have reported the formation of a very stable tetraphenylcyclobutadiene complex of cobalt by the reaction of diphenylacetylene with some organocobalt compounds. In continuation of our study of the stabilization of unstable organic compounds by $\pi$-complex formation, we have found that the unsubstituted butatriene, a very unstable compound, can be stabilized by the formation of a stable iron carbonyl complex, $C_4H_4Fe_2(CO)_5$.[3] A brief communication describing the preparation of a tetraphenylbutatriene complex of iron carbonyl has also been published.[4] Unsubstituted hexapentaene, one of the unknown higher homologues of the butatriene, seems to be much more unstable than the unsubstituted butatriene. The successful isolation of the butatriene iron carbonyl complex led us to investigate the corresponding iron carbonyl complexes of the hexapentaene. We also investigated the preparation of alkyl derivatives of the butatriene complexes in order to get a better understanding of their structures and bonding by a study of their electronic, vibrational and NMR spectra.

**Hexapentaene Complexes.**—By an extension of the method of the preparation of the unsubstituted butatriene complex, which involves the dehalogenation of dihalobutyne, an analogous dehalogenation of dihalohexadiyne with zinc powder in the presence of tri-iron dodecacarbonyl was attempted:

$$\underset{\displaystyle X \quad X}{H_2C\text{-}C{\equiv}C\text{-}CH_2} + Fe_3(CO)_{12} + Zn \rightarrow (H_2C{=}C{=}C{=}CH_2)Fe_2(CO)_5$$

$$\underset{\displaystyle X \qquad X}{H_2C\text{-}C{\equiv}C\text{-}C{\equiv}C\text{-}CH_2} + Fe_3(CO)_{12} + Zn \rightarrow (H_2C{=}C{=}C{=}C{=}C{=}CH_2)Fe_3(CO)_{7-8}$$

Thus, 1,6-dichlorohexadiyne was treated with an excess of zinc powder and tri-iron dodecacarbonyl in refluxing benzene. A vigorous gas evolution was observed during the reaction. From the reaction mixture, the product was purified by chromatography, followed by crystallization, to give deep purple-red crystals. The main difficulty in obtaining the product was its exceedingly small yield (1.2%) and the separation from the remaining tri-iron dodecacarbonyl. The product I was found to have the composition: $C_6H_4Fe_3(CO)_{7-8}$.

The number of carbonyl groups in the complex is rather ambiguous considering the accuracy of the elemental analysis. Moreover, the molecular weight of I is not very accurate as a result of its slight solubility in many organic solvents. The infrared spectrum of I was found to have very strong carbonyl bands at 2088, 2065, 2045 and 2005 $cm^{-1}$, thus indicating some similarity with that of the corresponding butatriene complex. The electronic spectrum of I had its maximum at 567 m$\mu$. The position of this maximum is, significantly, at a longer wavelength than that of the butatriene complex. The NMR spectrum was very similar to that of the butatriene complex in that it showed two signals at 5.20 and 5.71 $\tau$, although the very low solubility of I prevented the obtaining of a well-resolved spectrum. Therefore, no splitting of the signals were observed.

The most interesting property of I is its thermal and air stability. For example, it is stable up to 250°C in nitrogen, stable in air as crystals, and also stable as a solution in carbon tetrachloride. Since unsubstituted butatriene has been reported[5] to be stable only at very low temperatures in nitrogen, unsubstituted hexapentaene, if prepared, will probably be much more unstable than the butatriene. Hence, the preparation of unsubstituted hexapentaene has not been reported to date and a comparison of the stability of the free and the complexed hexapentaene is impossible. However, the stabilization of the hexapentaene by means of the $\pi$-complex formation is apparent; it is another example of such stabilization.

In order to furnish further evidence for the presence of a hexapentaene system in the complex, tetraphenylhexapentaene was reacted with iron pentacarbonyl and with tri-iron dodecacarbonyl. A very deep brown solid II was obtained; it was stable in air. However, it was very difficult to obtain the product in a crystalline state, and attempts to purify it by chromatography on activated or deactivated alumina resulted in decomposition in the column. The infrared spectrum of II showed a similarity with that of I in the absorption pattern of the terminal metal carbonyl-stretching region (maxima at 2071, 2036, 2009 and 2001 $cm^{-1}$). The absence of an uncomplexed tetraphenylhexapentaene system in the product was shown by the absence of any maxima in the visible region. The structures of these hexapentaene complexes are difficult to infer, but they are probably similar to those of the butatriene complexes described below. Attempts to prepare analogous hexapentaene complexes of cobalt and chromium have all failed. Now, however, it may be said with considerable certainty that the interaction of cumulene systems with iron carbonyls is great enough to give stable $\pi$-complexes generally.

**1, 1, 4, 4-Tetramethyl- and 1, 4-Dimethylbutatriene Iron Carbonyl Complexes.**—Unsubstituted butatriene and tetraphenylbutatriene complexes of iron carbonyl have already been prepared and described in detail in a previous paper of this series.[3] We have here attempted to prepare methyl-substituted analogues by the application of the dehalogenation method to methyl-substituted dihalobutynes. The preparation of the methyl analogues will allow us to compare the electronic and vibrational spectra of the complexes and will give us very interesting NMR spectra, which might in turn lead to the determination of the correct structure of the complexes. 2, 5-Dichlorohexyne-3 (1, 4-dimethyl-1, 4-dichlorobutyne-2) was reacted with an excess of zinc powder in the presence of tri-iron dodecacarbonyl in just the same way as in the preparation of butatriene di-iron pentacarbonyl (III). A reddish-orange, air-stable crystalline compound IV was obtained in a 4.1% yield (based on the iron carbonyl used). It was very similar to the butatriene complex III in appearance, solubility, volatility and stability. The close similarity to III in its infrared metal carbonyl-stretching absorption pattern and also in its electronic spectrum, together with the elemental analysis and molecular weight data, showed it to be a dimethyl derivative of III.

$$\begin{matrix} R_1 \\ R_2 \end{matrix}\!\!>\!C(X)\!-\!C\equiv C\!-\!C(X)\!<\!\!\begin{matrix} R_1 \\ R_2 \end{matrix} + Zn + Fe_3(CO)_{12} \rightarrow$$

$$\left(\begin{matrix} R_1 \\ R_2 \end{matrix}\!\!>\!C=C=C=C<\!\!\begin{matrix} R_1 \\ R_2 \end{matrix}\right)Fe_2(CO)_5$$

III: $R_1=R_2=H$, X=Br
IV: $R_1=H$, $R_2=CH_3$, X=Cl
V: $R_1=R_2=CH_3$, X=Cl

2, 5-Dichloro-2, 5-dimethylhexyne-3 (1, 1, 4, 4-tetramethyl-1, 4-dichlorobutyne-2) was used to prepare an analogous tetramethyl derivative in the same way. The reddish-orange, air-stable compound V obtained in this way, in a 4.4% yield, was also very similar to III and IV in many ways. Apart from the similarity in the infrared and electronic spectra of these compounds, their NMR spectra provided the confirmation of IV and V as, respectively, di- and tetramethyl derivatives of III.

## Discussion

The method of preparation, the yield and various physical constants of the cumulene

complexes prepared by us are listed in Table I. The successful preparation of the di- and tetramethyl derivatives of III showed that the preparation of such derivatives is possible by the same dehalogenation route and that the alkyl derivatives have a stability similar to that of the unsubstituted compound III. The preparation of the tetraphenyl derivative VI, as has been reported previously, also shows that the tetra-aryl derivatives will be similarly stable and can be prepared by the direct route in good yields.

A comparison of the infrared spectra of butatriene complexes, III—VI, also seems of interest. A small but significant lowering of the metal carbonyl-stretching frequency in the III to VI series is apparent. This lowering is obviously caused by the introduction of the substituents into the butatriene system. A lowering of the metal carbonyl-stretching frequency has been attributed to the increase in electron density around the metal atom,[6] because such an increase results in the enhanced contribution of the resonance species of M=C=O, as is shown below:

$$\left[L\text{-}\overset{(-)}{M}\text{-}C\equiv\overset{(+)}{O} \longleftrightarrow L\text{-}M=C=O\right]$$

It is conceivable that, in the case of the substituted butatriene complexes, electron-donating methyl groups on the butatriene part push the electron to the iron atom through the butatriene part and cause the lowering of the metal carbonyl-stretching frequency. Phenyl groups are known to have an electron-attracting inductive effect, but they are also known to have an electron-releasing resonance polar effect. The tetraphenylbutatriene complex VI has the lowest metal carbonyl-stretching

6) R. D. Fischer, *Chem. Ber.*, **93**, 165 (1960); E. O. Fischer and H. Werner, *Angew. Chem.*, **75**, 60 (1963).

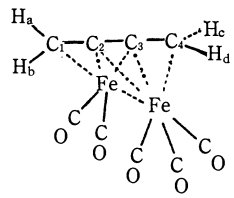
frequency among the butatriene complexes prepared heretofore. Therefore, the electron-releasing resonance polar effect may be operating here. The complexes, III—VI, resemble each other in metal carbonyl-stretching pattern so closely that only difference in the frequency distinguish them.

The electronic spectra of the butatriene compounds are also very similar. Here again, only small differences in the position of the absorption maxima are observed. The longest wavelength maxima of these complexes shift towards even longer wavelengths upon the successive introduction of methyl groups. The introduction of two methyl groups shifts the maximum by 4 m$\mu$, and that of four methyl groups, by 22 m$\mu$. This shifts reminds us of the mell-known Woodward rule,[7] which states that the introduction of one methyl group into the conjugated diene system results in a shift of 5 m$\mu$ in the K-band.

The NMR spectrum of III has already been discussed in the previous paper. No definite conlusion concerning the structure of III was there obtained, however. The spectrum indicated that two kinds of protons are present and that the coupling constant of the two protons is small (ca. 1.5 c. p. s.). As expected, two kinds of methyl signals were observed in the NMR spectrum of the tetramethyl derivative V. The difference in the chemical shift (0.17 p. p. m.) between the methyl signals is significantly smaller than that between the two proton signals of III (0.63 p. p. m.). In the NMR spectrum of the corresponding dimethyl derivative IV, only one methyl signal is observed; it is split into a doublet by an adjacent olefinic proton. The olefinic proton signal is split into a symmetrical quartet (ratio of areas: 1 : 3 : 3 : 1) by the adjacent methyl group. The coupling constant between these methyl and olefinic protons was, as expected, found to be 6.0 c. p. s. These results show that the two methyl groups are equivalent, and so are the two olefinic protons.

From an examination of the NMR spectra of these three compounds, III—V, the following conclusions can be drawn:

i) The Ha and Hb protons (also Hc and Hd) are not equivalent.



$$\left(\begin{matrix}Ha\\Hb\end{matrix}\right)C=C=C=C\left(\begin{matrix}Hc\\Hd\end{matrix}\right)Fe_2(CO)_5$$

(III)

ii) The splitting observed in the spectrum of III probably arises from the geminal coupling between Ha and Hb.

iii) No appreciable long-range coupling is observed between the terminal protons of III.

A planar structure of the butatriene part and a symmetrical attachment of the iron carbonyl groups do not easily explain the difference between Ha and Hb. A twisted structure, as shown below, explains the observed NMR spectrum more easily than the other possible

structures. In the twisted structure, the two terminal protons are not equivalent because of the unsymmetrical attachment of the two iron carbonyl groups, $Fe(CO)_3$ and $Fe(CO)_2$. However, a repeated intramolecular transfer of one of the CO groups from the iron tricarbonyl group to the iron dicarbonyl group would make the two terminal protons equivalent. The Ha and Hb protons are made non-equivalent by the attachment of the iron carbonyl group on one side of the plane defined by Hc–$C_4$–Hd. Therefore, Hb and Hd may be expected to be nearer to the iron carbonyl groups than Ha and Hc. The difference in the environment will make the protons, Ha and Hb, non-equivalent. For the tetramethyl compound V, the situation is quite similar, and two methyl signals are observed. In the dimethyl compound IV, the two methyl groups probably occupy the positions of Ha and Hc because of the bulkiness of the methyl group, and they remain equivalent.

The NMR results obtained so far can be explained, as above, on the assumption of a straight C4 chain, but there is no clear indication of the straightness of the C4 chain. Actually, it might well be a bent structure. The NMR results are not very sensitive to such a deformation, and, unfortunately, they do not definitely establish the correct structure for the butatriene complexes. Therefore, an X-ray structure analysis of these complexes is necessary in order to establish the correct structure.*

## Experimental

All melting points are uncorrected; they were measured by a micro-melting point apparatus, Yanagimoto Model MP-S2. The melting points and decomposition points in nitrogen were measured in a sealed capillary filled with nitrogen. The infrared spectra were obtained by Hitachi Model EPI-2

7) R. B. Woodward, *J. Am. Chem. Soc.*, **64**, 72 (1942).

* A private communication from Professor O. S. Mills told us that he and his co-workers were carrying out an X-ray analysis of the tetraphenyl butatriene iron carbonyl complex.

and Jasco Model DS-402G grating spectrophotometers. The visible and ultraviolet spectra were taken by a Beckman DK-2 spectrophotometer. The NMR spectra were recorded by a Varian Model A-60 instrument using tetramethylsilane as an internal standard in carbon tetrachloride. The alumina used for the chromatography had an activity grade of I and was of a 200—300 mesh size. The elemental analysis was performed by Mr. T. Shibano of this Institute. The elemental analysis for oxygen was performed by Mr. I. Shimidzu of the Japan Synthetic Rubber Company. The molecular weights were measured in a benzene solution using a Mechrolab Vapor Pressure Osmometer Model 301A.

**Materials.**—Dichloro- and dibromohexadiyne-2, 4,[8] 2, 5-dichlorohexyne-3,[9] 2, 5-dimethyl-2, 5-dichlorohexyne-3,[10] tetraphenylhexapentaene,[11] butatriene di-iron pentacarbonyl[3] and tetraphenylbutatriene di-iron pentacarbonyl[3] were prepared in manners described in the literature.

**The Preparation of the Hexapentaene Iron Carbonyl Complex (I).**—A mixture of 3.0 g. of freshly prepared and distilled dichlorohexadiyne-2, 4, 4.2 g. of tri-iron dodecacarbonyl, 5.0 g. of zinc powder in 25 ml. of isooctane and 20 ml. of benzene was heated, with vigorous magnetic stirring, under nitrogen for 4 hr. at 80—90°C. During the reaction period, a total of about 1250 ml. of a gas evolved. The deep green solution was then filtered by gravity in air, and the brown precipitates were washed well with benzene. The evaporation of the filtrate and the wash gave almost black crystalline solids, which were then dissolved again in benzene and purified by chromatography on alumina. Elution with benzene gave a deep purple-red eluate. (A considerable decomposition of the product was observed when the elution was carried out with *n*-hexane.) The evaporation of the eluate gave almost black crystals (0.1 g.), which were purified further by crystallization from benzene (5 ml.) to give deep purple-red crystals (45 mg.) (I). The insoluble part in benzene consists mainly of tri-iron dodecacarbonyl

Found: C, 35.73; H, 1.19; O, 30.05±3%; mol. wt., 500—700. Calcd. for $C_{14}H_4Fe_3O_8$: C, 35.94; H, 0.87; O, 27.36%; mol. wt. 467.6.

**The Preparation of the Tetraphenylhexapentaene Iron Carbonyl Complex (II).**—Tetraphenylhexapentaene was reacted with an excess of iron pentacarbonyl in *p*-xylene for 3.5 hr. under nitrogen. The color turned deep brown upon heating at 140°C. The reaction mixture was then evaporated under reduced pressure to give a deep-reddish-brown semisolid (II), m. p. (decomp.) ca. 220°C in air. This semisolid did not crystallize from the solution in benzene or in a *n*-hexane-benzene mixture. A similar reaction using tri-iron dodecacarbonyl in benzene at 90°C for 3 hr. gave similar results.

**Tetramethylbutatriene Di-iron Pentacarbonyl (V).**—A mixture of 1.2 g. of freshly distilled 2, 5-dimethyl-2, 5-dichlorohexyne-3, 2.2 g. of tri-iron dodecacarbonyl and 3.0 g. of zinc powder in 20 ml. of dry isooctane was stirred magnetically under nitrogen and heated at 90—100°C on a water bath. During the 3 hr. of the reaction, the evolution of a gas continued. After 150 ml. of the gas had evolved, however, the evolution almost stopped. The brownish suspension was filtered by gravity in air, and the precipitates were washed with a small amount of benzene. The deep brown filtrate was then evaporated under reduced pressure at room temperature to give a deep brown semisolid.

The semisolid was then dissolved in a small amount of *n*-hexane and chromatographed on alumina. Elution with *n*-hexane gave a deep red eluate, which in turn gave a red viscous oil upon evaporation under reduced pressure. Most of the oil crystallized when the mixture was chilled to −20°C in a refrigerator overnight. The red crystals (52 mg.) (V) were collected on a clay plate and washed well with a small amount of *n*-hexane. The crystals were purified further by sublimation at 80°C/3 mmHg to afford an analytical sample. A further crop (12 mg.) of the crystals could be obtained from the oily part of the eluate through fractional sublimation and through drying on a clay plate.

Found: C, 43.56; H, 3.35; mol. wt., 357. Calcd. for $C_{13}H_{12}Fe_2O_5$: C, 43.38; H, 3.36%; mol. wt., 360.

**Dimethylbutatriene Di-iron Pentacarbonyl (IV).**—The title compound IV was obtained by essentially the same method as that described for the tetramethyl compound V, using 0.9 g. of 2, 5-dichlorohexyne-3, 2.0 g. of tri-iron dodecacarbonyl and 3.0 g. of zinc powder in 20 ml. of isooctane. The analytical sample (31 ml.) was obtained from 38 mg. of the crude product by sublimation. A further crop (16 mg.) was obtainable by working up the oily part in the manner described above for V.

Found: C, 40.22; H, 2.33; O, 23.04; mol. wt., 360. Calcd. for $C_{11}H_8Fe_2O_5$: C, 39.85; H, 2.43; O, 24.10%; mol. wt., 332.

## Summary

The reaction of 1, 6-dihalohexadiyne-2, 4 with tri-iron dodecacarbonyl in the presence of an excess of zinc powder have given a hexapentaene iron carbonyl complex, $C_6H_4Fe_3(CO)_{7-8}$, as deep purple-red, air-stable crystals in a 1.2% yield. Essentially the same reaction using methyl-substituted 1, 4-dichlorobutyne-2 have given substituted butatriene iron carbonyl complexes, $(R_1R_2C{=}C{=}C{=}CR_1R_2)Fe_2(CO)_5$, where $R_1{=}R_2{=}CH_3$ (V), $R_1{=}H$, and $R_2{=}CH_3$ (IV), in low yields. The vibrational, electronic and NMR spectra of these new complexes have been discussed in connection with their structures.

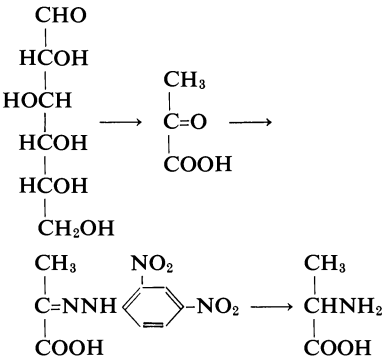
# Studies on the Chemical Decomposition of Simple Sugars. XVI. Pyruvic Acid Formation from D-Glucose-1-$^{14}$C*



By Sinichi OTANI**

(Received February 20, 1965)

The fragmentation reaction of reducing sugars is well known in both acid and alkaline media,[1,2] but the mechanism of this reaction has not been satisfactorily elucidated. Especially, the formation of pyruvic acid has remained to be studied on account of its instability, its low yield, and the difficulty of isolating it. Nodzu et al.,[2,3] however, obtained pyruvic acid from a weakly alkaline and a weakly acid solution of glucose, and proposed a mechanism which included acetylformoin as a direct precursor of pyruvic acid. Recently, Hayami et al. effectively used the $^{14}$C-labeled sugars[4,5] and the methylated sugars[6] for the investigation of the mechanism of the acetol formation, and presented another mechanism in which they inferred the formation of pyruvic acid, though they had no experimental evidence.

The present purpose was to obtain pyruvic acid by the decomposition of D-glucose-1-$^{14}$C in a weakly acid phosphate solution, and to determine the relative distribution of a label in pyruvic acid in order to elucidate the mechanism of the pyruvic acid formation.

The present author obtained a mixture of pyruvic acid 2, 4-dinitrophenylhydrazone and other kinds of acid hydrazone or osazone; he then reduced them to amino acids, while the pyruvic acid 2, 4-dinitrophenylhydrazone was reduced to alanine.[7] The alanine was separated[8] and subjected to the degradation, by which means the relative distribution of a label in pyruvic acid was determined.

Scheme 1.

The alanine was decomposed with ninhydrin in nitrogen gas after some modification of the method of Virtanen et al.[9] The methyl part and the center carbon of the alanine were converted into acetaldehyde, and the carboxylic acid part was converted into carbon dioxide,

* The present work was presented at the Symposium on the Mechanism of Organic Chemical Reaction of the Chemical Society of Japan, Nagoya, October, 1964.

which was then caught in a sodium hydroxide solution and counted in the form of barium carbonate. Acetaldehyde was caught as an adduct of sodium bisulfite and converted into iodoform and formic acid. From the combustion of the iodoform, the radioactivity of the methyl carbon of the alanine was determined.

By the method mentioned above, the radioactivity of both terminal carbons of the alanine was determined, but it was impossible to determine of the center carbon directly. Therefore, the radioactivity of the center carbon was indirectly deduced from the results of the two terminal carbons and from that of the three carbon atoms of the alanine.

## Experimental

**Radioactive Sugars and Assay Method.** — D-Glucose-1-$^{14}$C was prepared from D-arabinose by a cyanohydrin synthesis.[10]

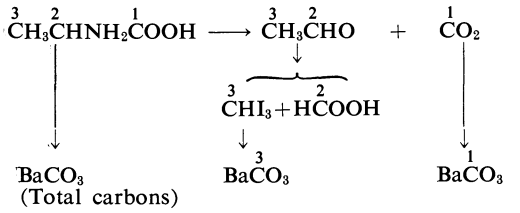
For an assay, all samples were converted into barium carbonate by the Van Slyke-Folch wet combustion method. Barium carbonate was collected on a filter paper and counted, mostly in an infinite thickness, with a $2\pi$-gas flow counter. In the case of the combustion of iodoform, the barium carbonate obtained was counted in a medium thickness and corrected for an infinite thickness.

**The Decomposition of D-Glucose-1-$^{14}$C.**—A solution of 20 g. of the labeled D-glucose in 200 ml. of a concentrated potassium acid phosphate buffer solution (40%, pH 6.6) was heated and distilled. Water was added drop by drop in order to maintain a constant volume. About 100 ml. of the distillate was collected every 45 min., and the distillation was continued for 9 hr.

**The Isolation of Crude Pyruvic Acid 2, 4-Dinitrophenylhydrazone.** — The distillation residue was made up to one and a half in volume by the addition of 6 N hydrochloric acid; the precipitate formed was then removed by filtration after having been kept overnight. To the filtrate was added 2 l. of a saturated solution of 2, 4-dinitrophenylhydrazine in 2 N hydrochloric acid, and the precipitate formed was collected and dried in a vacuum. About ten grams of the precipitate were extracted with about 20 l. of isopropyl ether. The ether solution was then extracted with an equal volume of a 6% aqueous solution of sodium bicarbonate. After the extract had been slightly acidified with 6 N hydrochloric acid, it was again extracted with about an equal volume of isopropyl ether. The ether solution was evaporated under reduced pressure to give a brown residue (1.2 g.). It was shown by paper chromatography (solvent; *n*-butanol - 0.1 N aqueous ammonium hydroxide - methanol 4 : 1 : 1 v/v) that the residue contained pyruvic acid 2, 4-dinitrophenylhydrazone in a considerably high concentration.

**The Reduction of the Crude Pyruvic Acid 2, 4-Dinitrophenylhydrazone to Alanine.**—2, 4-Dinitrophenylhydrazone (600 mg.) was suspended in water (ca. 40 ml.) and hydrogenated with Adams' catalyst, platinum dioxide (147 mg.) under the atmospheric pressure of hydrogen gas.

**The Isolation of the Crude Alanine.**— After the removal of the catalyst by filtration, the filtrate and washings (25 ml.) were passed through a column (1.6×18 cm.) of Dowex 50W-X8 in the H form (200—400 mesh). Hydrochloric acid (1.5 N) was used as the eluting solvent. The effluent, which was positive for a ninhydrin test,[11] was then concentrated and passed through a column of Amberlite IR-400 (acetate form) in order to remove the chloride anions, using 0.5 N acetic acid as the eluting solvent. The effluent was then collected, concentrated under reduced pressure, and dried to a yellow powder.



**The Purification of Alanine.**—This part was a modification of the method of Hirs, Moore and Stein.[8] An ammonium formate buffer solution (pH 3.7) was made by mixing 375 ml. of 2 N formic acid, 200 ml. of 1 N ammonium hydroxide, 400 ml. of ethanol and water to 1 l. Dowex 50W-X8 (200—400 mesh, 500 ml.) was placed in a column (3.5×55 cm.) with the aid of an ammonium formate buffer solution, which was used as an eluting solvent, and the crude alanine (ca. 50 mg.) was charged. The effluent was collected in about 10 ml. fractions with a flow-rate about 30 ml./hr. Aliquots (0.5 ml.) of the effluents were then analyzed by means of the ninhydrin test after the sublimation of ammonium formate. The fractions showing a positive reaction were collected and concentrated under reduced pressure. A yellow residue was obtained after the sublimation of ammonium formate. This residue was decolorized with active carbon and crystallized from a thick aqueous solution by adding anhydrous ethanol.

**The Degradation of Alanine.** — The procedure was carried out under a stream of nitrogen and under oxygen-free conditions. In a three-necked flask, 62.6 mg. of alanine, 168 g. of ammonium sulfate, and 11.5 g. of citric acid were dissolved in 150 ml. of water; the solution was then heated. After it had been boiled, 60 ml. of a 1% aqueous solution of ninhydrin was added drop by drop from a dropping funnel; the solution was then kept boiling for 90 min. The acetaldehyde formed was swept into 40 ml. of a 1% aqueous solution of sodium bisulfite passing through the Allihn condenser and caught in the form of an adduct. Carbon dioxide was introduced into 20 ml. of a 0.1 N sodium hydroxide solution, which was connected to the sodium bisulfite solution. The sodium bisulfite solution was treated with a 10% sodium hydroxide solution and a 10% iodine solution, and the iodoform formed was collected using a centrifugal separator, washed with water, and converted in a wet condition into barium carbonate by the Van Slyke-Folch wet combustion method. The carbon dioxide, caught in a sodium hydroxide solution, was treated with 360

*6 Probable error was less than 15%.

## Results and Discussion

The results reported herein indicate that, in the case of D-glucose-1-$^{14}$C, the radioactivity is mostly found in the methyl carbon of the alanine. This means that the C-1 of the glucose was converted into the methyl carbon of the pyruvic acid.

In the case of the formation of acetol,[5-6] accompanied by pyruvic acid, the C-1 and C-6 of the original glucose were converted into the methyl carbon of the acetol, while the C-3 and C-4 of the original glucose were converted into the hydroxymethyl carbon of the acetol. In addition, the acetol-1-$^{14}$C, which was formed from D-glucose-3, 4$^{14}$-$C_2$, was found to preserve the molar radioactivity of the original glucose. This indicates that, in the formation of acetol, the C-1, 2, and 3 and the C-4, 5, and 6 of the original glucose behaved as units, and that no skeletal rearrangement in these $C_3$ units was involved. In the case of pentoses,[5] both terminal carbons were converted into the methyl carbon of the acetol. Hayami[6] has determined the mechanism of the formation of acetol on the basis of findings concerning labeled sugars and methylated sugars; he inferred that pyruvic acid should be formed by a similar mechanism. His inference consisted of two essential points, which he applied also to the case of the formation of acetol. One was $\beta$-hydroxy-carbonyl elimination, after the isomerization to 3-ketose or 4-ketose; the other was hydrolytic cleavage between the C-3 and C-4 of glucose. The present results support Hayami's inference.

From the common finding of these experiments with pyruvic acid and acetol, it may be deduced that the C-6 of glucose is converted into the methyl carbon of pyruvic acid, while the C-3 and C-4 are converted into the carbon of the carboxylic acid group of pyruvic acid.

From this point of view, comparing the molar radioactivity of the original D-glucose-1-$^{14}$C with that of the alanine found in the present study, the results show that the lower half of the glucose skeleton contributes more than the upper half to the formation of pyruvic acid.

Further experiments using other labeled sugars are, however, necessary to explain the mechanism of the formation of pyruvic acid.

The author wishes to express his thanks to Professor Ryozo Goto for his constant guidance and encouragement and to Dr. Jun'ichi Hayami for his kind suggestions throughout the course of this work. The author wishes also to thank Dr. Yo Miyagi for his assistance in synthesizing the labeled sugar.

# The Absorption Spectrum of the Cobalt(II) Ion Catalyst in the Reaction of Methanol with Carbon Monoxide and Hydrogen under a High Pressure

By Tsutomu MIZOROKI and Mikitake NAKAYAMA

(Received February 22, 1965)

The treatment of methanol with carbon monoxide or carbon monoxide - hydrogen mixtures under a high temperature and pressure results in the formation of acetic acid, acetaldehyde and ethanol, as in the following equations:

$$CH_3OH + CO = CH_3COOH + 33.0^{*1} \quad (1)$$

$$CH_3OH + CO + H_2 = CH_3CHO + H_2O + 24.6 \quad (2)$$

$$CH_3OH + CO + 2H_2 = C_2H_5OH + H_2O + 51.2 \quad (3)$$

In the acetic acid synthesis from methanol and carbon monoxide represented by Eq. 1, mixtures of the salts of transition metals (nickel, iron, cobalt etc.) and iodine or the iodides of these metals have been used as the catalyst,[1,2] and a mixture of cobalt(II) acetate and iodine had been reported as a catalyst of the homologation of methanol[3], as is represented by Eqs. 2 and 3. On the other hand, no works have been reported on reaction mechanisms with these catalysts, because the complex intermediates from these catalysts are too unstable to be isolated at room temperature and pressure.

The present authors investigated in detail these reaction, in the presence of a mixture of cobalt(II) acetate ($Co(AcO)_2 \cdot 4H_2O$*2) and with an iodide (lithium iodide, sodium iodide, potassium iodide, etc.) as the catalyst, by using an autoclave lined with Ti-Mn alloy. It was reported that the conversion of methanol into acetic acid or acetaldehyde increased with the amount of an iodide added and that ethanol was estimated to be formed from the hydrogenation of the acetaldehyde produced.[4,5] On the other hand, it is well known that the soluble salts of cobalt(II) ions form blue or green tetrahedral complex ions $[CoX_4]^{2-}$ ($X=Cl^-$, $Br^-$, $I^-$, $AcO^-$, $NCS^-$, etc.[6]) in organic solvents (glacial acetic acid, acetone, nitromethane, etc.). From these facts, it was assumed that, during the course of the reaction, most of cobalt(II) ions were surrounded with iodide ions, thus forming tetrahedral complex ions of the $[Co(AcO)_{4-n}I_n]^{2-}$ type ($n=1$—4), with which carbon monoxide was then activated.[7]

This work was undertaken in order to study the behavior of cobalt(II) ions and iodide ions in the course of the reaction of methanol with carbon monoxide and hydrogen by measuring the absorption spectra. For this purpose, a special autoclave, with which absorption spectra could be observed under a high temperature and pressure, was made of Ti-Mn alloy and a couple of thick pieces of quartz glass.

## Experimental

**The Apparatus for Taking an Electronic Absorption Spectrum under a High Temperature and Pressure.**—The special autoclave is illustrated in Fig. 1. A couple of thick quartz glass windows (15 mm. thick, 20 mm. in diameter) were set in teflon packings and pressed uniformly hard against the autoclave by high internal pressure introduced through a valve (1 in Fig. 1). These pieces of glass were proof against pressure lower than 250 kg./cm² at a temperature of 200°C. The inner volume of this autoclave was about 6 ml., and the thickness of a liquid sample was about 5.5 mm. The autoclave was heated by the electric furnace shown in Fig. 1. The temperature of the autoclave was kept constant (within ±0.5°C) by using an electronic thermo-controller (P. I. D. method), because the absorption spectrum of cobalt(II) ion was very dependent on the temperature. The autoclave was then placed with the electric furnace into the sample box of an automatic recording spectrophotometer (IV-50A type, Shimadzu Seisakusho Ltd.), and absorption spectra were recorded over the range from 340 to 1000 mμ.

**The Reaction Conditions.**—The reaction rate of the acetic acid synthesis by Eq. 1 was very slow at 200°C under pressure lower than 250 kg./cm². However, the reaction of the acetaldehyde synthesis

7 Electric furnace

by Eq. 2 proceeded smoothly under the endurable condititons of the special autoclave, even if the amount of cobalt(II) acetate added was less than 0.10 mol. %. A preliminary experiment showed that the lowest partial pressures of carbon monoxide and hydrogen reacting with methanol to form acetaldehyde were, respectively, 70 and 30 kg./cm² at 200°C. From these experimental results, it was found that the following conditions were suitable for investigating the variation in the absorption spectrum of the cobalt(II) ion catalyst. The solution used was a mixture of methanol 9 and acetic acid*3 1 (mole ratio) containing 0.05 mol. % of cobal(II) acetate and a given amount of sodium iodide. After the solution of 3.0 ml. had been charged into the autoclave through inlet 6 in Fig. 1, carbon monoxide and hydrogen were introduced, up to 70 and 30 kg./cm² respectively (the total pressure, 100 kg./cm²). The autoclave was then heated up to 180—190°C within one hour. The methanol, acetic acid, cobalt(II) acetate and sodium iodide used were obtained from commercial sources, while the hydrogen and carbon monoxide were obtained from the electrolysis of water and the decomposion of formic acid respectively.

No attempt was made to evaluate the base line of a high temperature and pressure spectrum. Only the positions of the bands and the relative magnitude of the intensities of the recorded absorption spectra are important, since the transmittances, $I/I_0$ ($=T$), were determined at 840 mμ, at which point that of the liquid sample was nearly constant. The formation of acetaldehyde was confirmed by subjecting the liquid sample, after an experiment had been finished to gas chromatography.

*3 Acetic acid was added to prevent the catalyst from precipitating.

## Results and Discussion

**Visible Absorption Spectra.**—The variation in the absorption spectra due to the d-d transitions of cobalt(II) ions in the course of the reaction is recorded in Fig. 2. The amounts of the iodide ions of I, II, and III added in Fig. 2 are, respectively, 5, 10 and 20 times that of the cobalt(II) ion. IV shows a variation in the absorption spectrum of the cobalt(II) ion ($I^-/Co^{2+}=10$) in ethanol, with which carbon monoxide and hydrogen do not react under these conditions. V shows an absorption spectra of $[CoI_4]^{2-}$ and $[Co(AcO)_4]^{2-}$ in glacial

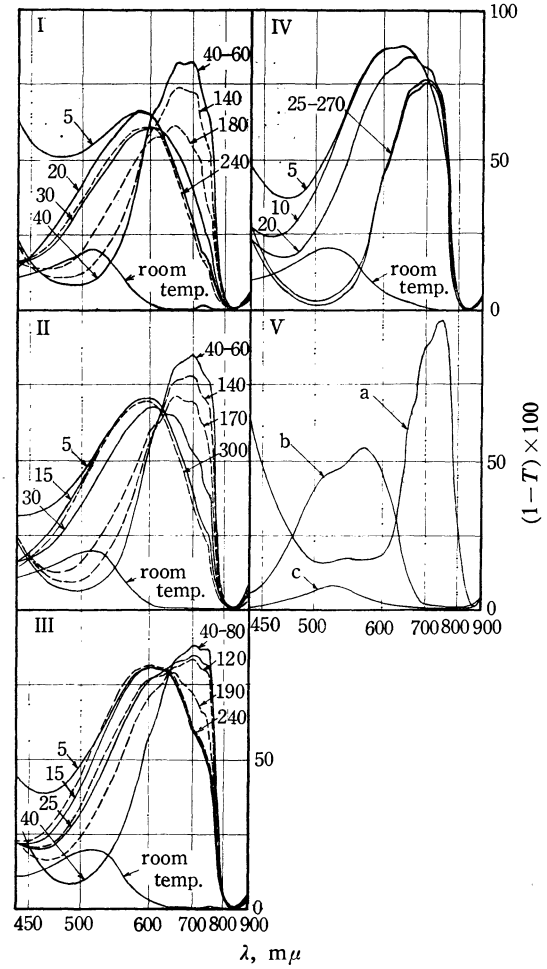

Fig. 2. The variation in the absorption spectra of cobalt(II) ions ($Co(AcO)_2 \cdot 4H_2O$ of 0.050 mol. %) in course of the reaction.

Numbers in the figure are the times (min.) after the temperature of the autoclave having reached 180°C. (I) $I^-/Co^{2+}=5$, (II) $I^-/Co^{2+}=10$, (III) $I^-/Co^{2+}=20$, (IV) $I^-/Co^{2+}=10$ in ethanol 9 : acetic acid 1 sol. and (V) the absorption spectra of $[CoI_4]^{2-}$ (a), $[Co(AcO)_4]^{2-}$ (b) and $[Co(H_2O)_6]^{2+}$ (c).

c) P. J. Proll, L. H. Sutcliffe, *J. Phy. Chem.*, **65**, 1993 (1961).
d) P. J. Proll, L. H. Sutcliffe, J. Walkley, ibid, **65**, 455 (1961).
e) T. Mizoroki, Y. Andō, S. Furumi, The 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

acetic acid: (a) is that of $[CoI_4]^{2-}$ formed at a room temperature from cobalt(II) acetate (2.0 mmol./l.) and sodium iodide (0.10 mol./l.); (b) is that of $[Co(AcO)_4$*4$]^{2-}$ formed at 150°C from cobalt(II) acetate (6.0 mmol./l.) and lithium acetate (0.10 mol./l.), and (c) is that of the hexaquo cobalt(II) ion $[Co(H_2O)_6]^{2+}$ (6.0 mmol./l.) in water.

Tetrahedral cobalt(II) complex ions of the $[CoX_4]^{2-}$ type, where X is $AcO^-$, $NCS^-$, $Cl^-$, $Br^-$ or $I^-$, have absorptions in a visible range, their extinction coefficients being about one hundred times stronger than that of the hexaquo cobalt(II) ion. According to the ligand field theory,[8] their absorptions are due to the electronic transitions of $d_\gamma \rightarrow d_\varepsilon$. The decrease in the strength of a ligand field decreases the difference between $d_\gamma$ and $d_\varepsilon$; the absorption, therefore, shifts toward longer wavelengths. The absorption spectra of $[CoX_4]^{2-}$ are represented in Table I. The decrease in the strength of a ligand field becomes larger in the order of $AcO^-$, $NCS^-$ $Cl^-$, $Br^-$ and $I^-$.

I, II and III of Fig. 1 show that the absorption corresponding to that of $[CoI_4]^{2-}$ obviously increases with the increase in the amount of iodide ions added. The extinction coefficient of $[Co(AcO)_4]^{2-}$ ($\varepsilon=1700$) is larger than that of $[CoI_4]^{2-}$. It seems, therefore, unreasonable that the absorption corresponding to $[CoI_4]^{2-}$ becomes stronger than that corresponding to $[Co(AcO_4)]^{2-}$. It is considered that those complex ions that have methanol, acetic acid or water as the ligand L are present in considerable quantities, together with $[Co(AcO)_4]^{2-}$, although it is nearly impossible to distinguish their absorption spectra from those of $[Co(AcO)_4]^{2-}$ and $[Co^{2+}(L)_6]$. Their extinction coefficients are probably smaller than that of $[Co(AcO)_4]^{2-}$. Therefore, the absorption corresponding to $[Co(AcO)_4]^{2-}$ recorded in Fig. 2 is not as strong as expected.

The variation in the absorption spectra may be divided into three parts. The first part lasts for about 20 min. after the temperature has reached 180°C, within which period no variation in the absorption of cobalt(II) ion is observed except that the absorption in the short-wavelength region gradually decreases. The second part lasts from about 20 to 100 min., within which period, as soon as the absorption from 500 to 650 mμ has started decreasing, that from 600 to 800 mμ goes on increasing until it reaches its maximum. The third part lasts from about 100 to 300 min., within which period the variation is the inverse of that of the second part. The absorption spectrum recorded after 200 to 300 min. becomes nearly the same as that of the first part. In the case of IV, the absorption from 500 to 650 mμ decreases very much within 25 min. after the temperature reaches 180°C; however, that from 600 to 800 mμ scarcely increases at all, and no variation is observed after 25 min. These are large differences from I, II and III.

The present authors would like to give the following estimates of these three parts of the variation. In the first part, most of the iodine molecules formed from iodide ions have been

*4 The octahedral species of the $[Co^{2+}(L)_6]$ type, where L represents $AcO^-$, AcOH or $H_2O$, are present in considerable quantities, together with $[Co(AcO)_4]^{2-}$.

8) L. E. Orgel, "An Introduction to Transition Metal Chemistry (Ligand Field Theory)," Methuen & Co. Ltd., London (1960).

reduced to iodide ions once again,*5 and the reaction does not start (an induction time). The second part is that in which the reaction starts and its rate reaches its maximum. The third part is that in which the partial pressure of carbon monoxide decreases in proportion as the reaction proceeds, until it nearly stops after 200 to 300 min. These estimates are supported by the following experimental results.

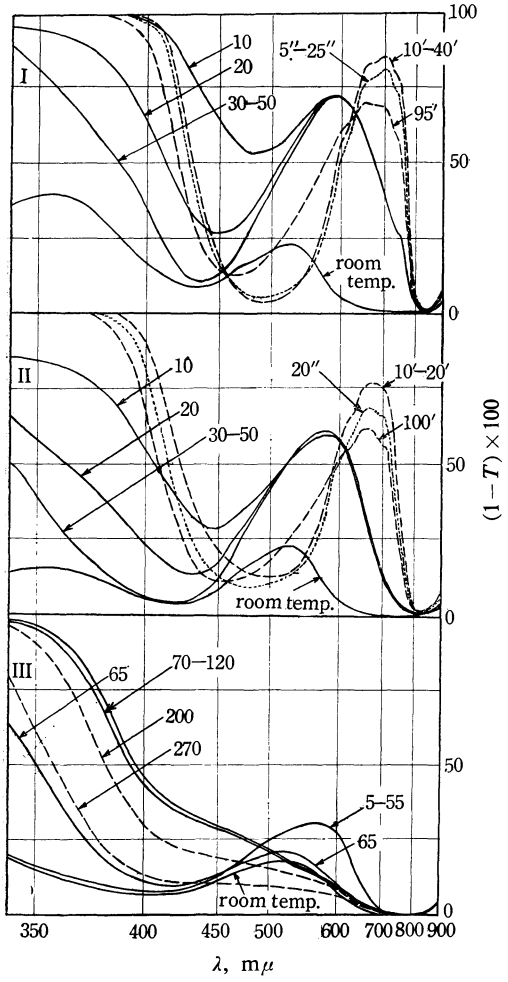

Fig. 3. The variation in the absorption spectra in course of the reaction under 200—220 kg./cm² ($CO/H_2=1$) at 185°C.
(I) $I^-/Co^{2+}=10$, (II) $I^-/Co^{2+}=2$ and (III) $I^-/Co^{2+}=0$. Numbers in the figure are the time (min.) since the temperature of the autoclave has reached 185°C and dashed numbers ($t'$ and $t''$) are those since the higher pressure gases have been introduced up to 220 kg./cm² at 185°C.

*5 The absorption in the short wavelengths is observed to decrease. See the near ultraviolet absorptions recorded in I and II of Fig. 3. It may be considered that most of the iodine molecules are formed according to the following reactions:

$$I^- + AcOH \rightleftarrows AcO^- + HI, \quad 2HI \rightleftarrows H_2 + I_2$$

The gases ($CO/H_2=1$) with a lower pressure (60 kg./cm²) than that in Fig. 2 were introduced at room temperature into the autoclave, in which the same solution as that of II in Fig. 2 had previously been placed. After the temperature had been kept constant at 185°C for about one hour (the variation in the absorption spectra within this period is shown by the full lines in I and II of Fig. 3), higher-pressure gases ($CO/H_2=1$) were introduced up to 220 kg./cm² at this temperature and the absorption spectra were taken (the broken lines). The results are summarized as I in Fig. 3. When the higher-pressure gases were introduced, most of the iodine molecules formed had already been reduced to iodide ions. The reaction, therefore, starts without exhibiting any induction time; the absorption from 600 to 800 mμ goes on increasing so fast that it reaches its maximum after about 10 min. After about 3 hr., the absorption spectrum returns to become nearly the same as it was before the reaction started. It may be expected that, if the higher pressure gases are once more introduced up to 220 kg./cm², nearly the same variation will again be observed. This is shown by the dotted lines in Fig. 3. II of Fig. 3 shows the results obtained when a small number of iodide ions are present in the solution ($I^-/Co^{2+}=2$).

These experimental results show that the reaction of methanol with carbon monoxide-hydrogen starts at the time that the iodine molecules formed have been mostly reduced to iodide ions, and that it is accompanied by an increase in the number of tetrahedral iodocobalt(II) complex ions.

**Near Ultraviolet Absorption Spectra.**—There may be expected to be five kinds of absorptions in a near ultraviolet region. 1) The absorption of an iodine. The strong absorption of an iodine molecule takes place from a visible part to a near ultraviolet one. This is due to the transition of non-bonding electrons in the iodine molecule ($n \rightarrow \sigma^*$).[9] This absorption is observed from 600 mμ toward the near ultraviolet region*6 of these absorption specra that are taken immediately after the temperature of the autoclave has reached 185°C (I and II of Fig. 3). 2) An electronic charge transfer from a coordinated iodine ion to the cobalt(II) ion. Whenever the reaction starts and the number of iodo-cobalt(II) complex ions increases, a new strong absorption takes place from 480 mμ to the shorter wavelengths, as is shown in I and II of Fig. 3. This absorption is probably due to an electronic charge

9) C. N. Rao, "Ultraviolet and Visible Spectroscopy," Butterworths, London (1961).

*6 This was confirmed by a preliminary experiment.

transfer of the $Co^{2+} + I^- \rightarrow Co^+ + I$ type, which may be correlated with the oxidation-reduction potential of cobalt(II) ions.[7] 3) An electronic charge transfer of the Mulliken type. If an iodine molecule or an iodide ion makes a weak bond with a solvent molecule, it may be expected that an electronic charge transfer of the Mulliken type[10] will take place in a near ultraviolet region. 4) The absorptions of cobalt carbonyls. III of Fig. 3 shows the variation in the absorption spectrum of the solution (methanol 9 : acetic acid 1) containing only cobalt(II) acetate (0.020 mol.%) under the same conditions as those of I, II and III of Fig. 2. After 50 to 60 min. since the temperature has been increased up to 180°C, the absorption corresponding to that of $[Co(AcO)_4]^{2-}$ decreases rapidly, while a new strong absorption takes place in the near ultraviolet region, although its intensity continues to decrease. This new absorption may be considered to be that of the cobalt carbonyl*7 formed from the following equations: $Co^{2+} + H_2 \rightarrow Co + 2H^+$, $2Co + 8CO \rightarrow Co_2(CO)_8$, $H_2 + Co_2(CO)_8 \rightarrow 2HCo(CO)_4 \rightarrow 2H^+ + 2[Co(CO)_4]^-$; it may also be considered that its decomposition into metallic cobalt[11] causes its absorption to decrease. 5) The absorption of acetaldehyde. Acetaldehyde formed has an absorption from 330 mμ to the shorter wavelengths ($n \rightarrow \pi^*$, $\varepsilon = 10—100$). However, the intensity of the near ultraviolet absorption due to the electronic charge transfer from iodine ions to cobalt(II) ions was so strong that it was difficult to confirm the formation of cobalt carbonyls during the course of the reaction.

From the variation in the visible absorption spectra of cobalt(II) ions in the course of the reaction of methanol with carbon monoxide and hydrogen, it may be considered that, when a comparatively large number of iodide ions are added to the solution, most of the cobalt(II) ions do not form cobalt carbonyls, but tetrahedral cobalt(II) complex ions, and that the equilibrium of the equation represented apparently by $[Co(AcO)_{4-n}I_n]^{2-} + I^- \rightleftarrows [Co(AcO)_{3-n}I_{n+1}]^{2-} + AcO^-$ inclines much toward the right side in the course of the reaction. This is greatly different from an oxo-reaction.

10) R. S. Mulliken, *J. Am. Chem. Soc.*, **74**, 811 (1952).

*7 This absorption is estimated to be the transition of the bonding electrons between a cobalt atom and carbon monoxides to an anti-bonding orbital (H. B. Gray et al., *J. Am. Chem. Soc.*, **84**, 3404 (1962); R. J. Angelici and F. Basolo, *Inorg. Chem.*, **2**, 728 (1963)).

## Summary

The absorption spectra during the course of the reaction of methanol with carbon monoxide-hydrogen mixtures in the presence of a mixture of cobalt(II) acetate and sodium iodide as the catalyst under high temperatures and pressures (180—185°C, 200—220 kg./cm²) have been taken, using an automatic recording spectrophotometer and special autoclave made of Ti-Mn alloy and a couple of thick pieces of quartz glass. Whenever the reaction starts, the absorption corresponding to that of $[Co(AcO)_4]^{2-}$ goes on decreasing, while that corresponding to $[CoI_4]^{2-}$ increases in place. It has been difficult to confirm the formation of cobalt carbonyls as $Co_2(CO)_8$ and $HCo(CO)_4$ during the course of the reaction, because their absortions overlap with those of the strong electronic charge transfer of tetrahedral iodocobalt(II) complex ions. From the experimental results and subsequent considerations, it has been shown that, when a comparatively large number of iodide ions are present in the solution, most of the cobalt(II) ions do not form cobalt carbonyls, but tetrahedral cobalt(II) complex ions of the $[Co(AcO)_{4-n}I_n]^{2-}$ type ($n = 1—4$) during the course of the reaction, and that the reaction is accompanied by an increase in the number of tetrahedral iodocobalt(II) complex ions.

The authors wish to express their thanks to Professor Yukio Yoneda, Faculty of Engineering, The University of Tokyo, for his discussions on the visible absorption spectra, and to Dr. Hiroshi Uchida for his invaluable advice.

# A New Method of Analyzing Thermogravimetric Data

By Takeo Ozawa

(Received February 23, 1965)

Various kinds of materials have been studied by thermogravimetric analysis, in which is recorded the weight-change of a sample heated at a constant rate of heating. Thermogravimetry has an advantage over measurement at a constant temperature, because in the latter a part of the sample may change while the sample is heated to the desired temperature. Especially at the degradation of high polymers, this initial structure change in the sample complicates the isothermal data and makes it difficult to analyze.

The many methods proposed for obtaining the kinetic parameters from the thermogravimetric data, though rather complicated, may be classified into two classes, in both of which the rates of decomposition must have the following form:

$$-\frac{dW}{dt}=A\exp\left(-\frac{\Delta E}{RT}\right)W^n \qquad (1)$$

where $W$ is the fractional residual weight of the sample; $T$, the absolute temperature; $R$, the gas constant; $t$, the time, and $A$, $\Delta E$ and $n$, the pre-exponential factor, the activation energy and the order of the reaction respectively.

In the first class of the analyzing method,[1-5] Eq. 1 is treated as a differential equation, and the fractional weight is derived by integration as a function of the temperature. In the other method,[6-10] from the plots of the logarithms of the terms of Eq. 1 the kinetic constants are obtained. These analyses are usually cumbersome. Complex quantities must be derived from the data or the trial-and-error fitting of the curve is required in the former cases, while the weight-temperature curve must be differentiated graphically in the latter cases. Furthermore, these methods are applicable only to the decomposition expressed by Eq. 1.

This paper will propose an approximate integral method similar to, but even simpler than, that of Doyle.[2] This method is more widely applicable than the others. For example, the random degradation of high polymers[11] can be analyzed by this treatment.

A few methods of estimating the thermal stability of polymeric materials have been reported.[12,13] In these papers, however, the effect of the heating rate has not been considered. In this paper these methods will be revised, considering the effect of heating rates, and it will be shown that a master curve may be derived from the data at different heating rates.

The applications of the method to the decomposition of calcium oxalate and to the degradation of nylon 6 will be shown. Finally, the applicability of the method to other types of thermal analyses and the possibility of extending it to thermal behavior under various conditions of temperature change will be discussed.

## Theoretical Consideration

Generally, the fractional weight, $W$, of a reacting material is expressed as a function of the fraction of a structural quantity, such as a group, a constituent, a broken bond, etc., which is represented by $x$:

$$W=f(x) \qquad (2)$$

where $x$ changes according to the ordinary kinetic equation:

$$-\frac{dx}{dt}=A\exp\left(-\frac{\Delta E}{RT}\right)g(x) \qquad (3)$$

By integration,

$$-\int_{x_0}^{x}\frac{dx}{g(x)}=A\int_{t_0}^{t}\exp\left(-\frac{\Delta E}{RT}\right)dt \qquad (4)$$

where $x_0$ is the value of $x$ at $t=t_0$. In most cases, the kinetics of the weight-change can be expressed as Eq. 1, where $x$ is equal to $W$.

TABLE I. SEVERAL FORMS OF $f(x)$, $g(x)$ AND $\int dx/g(x)$

| Type of reaction | $f(x)$ | $g(x)$ | $\int dx/g(x)$ |
|---|---|---|---|
| 0th order reaction | $W$ | 1 | $W$ |
| 1st order reaction | $W$ | $W$ | $\ln W$ |
| 2nd order reaction | $W$ | $W^2$ | $-1/W$ |
| 3rd order reaction | $W$ | $W^3$ | $-2/W^2$ |
| Random degradation[11] | $(1-x)^{L-1}\left\{1+x\frac{(N-L)(L-1)}{N}\right\}$* | $-(1-x)$ | $-\ln(1-x)$ |

* $N$ is the initial degree of polymerization and $L$ is the least number of repeating units of polymer not volatilized. Following approximation can be made for $N \gg L$:
$f(x)=(1-x)^{L-1}\{1+(L-1)x\}$

In the random degradation of high polymers,[11] $x$ is a fractional number of the broken bond.

When the temperature of the sample is raised at a constant rate, $a$, the change in $x$ is given by Eq. 5:

$$-\int_{x_0}^{x}\frac{dx}{g(x)}=\frac{A}{a}\int_{T_0}^{T}\exp\left(-\frac{\Delta E}{RT}\right)dT \qquad (5)$$

where $T_0$ is the value of $T$ at $t=t_0$. Ordinarily, the rate of the reaction is very low at low temperatures. Therefore, the next approximation is valid:

$$\int_{T_0}^{T}\exp\left(-\frac{\Delta E}{RT}\right)dT=\int_{0}^{T}\exp\left(-\frac{\Delta E}{RT}\right)dT \qquad (6)$$

The value of the right side of Eq. 6 is expressed and tabulated by Doyle[2] as the following function, $p$:

$$\frac{\Delta E}{R}p\left(\frac{\Delta E}{RT}\right)=\int_{0}^{T}\exp\left(-\frac{\Delta E}{RT}\right)dT \qquad (7)$$

If $\Delta E/RT$ is larger than 20, $p(\Delta E/RT)$ can be approximated by the following formula:[3]

$$\log p\left(\frac{\Delta E}{RT}\right)\fallingdotseq -2.315-0.4567\frac{\Delta E}{RT} \qquad (8)$$

Now, for a given value of $W$, a single-valued function of $x$, the left side of Eq. 5 is a constant which does not depend on the heating rate. Therefore, if the weight decreases to a given fraction at the temperature, $T_1$, for the heating rate of $a_1$, at $T_2$ for $a_2$, and so on, the following equations can be obtained;

$$\frac{A\Delta E}{a_1 R}p\left(\frac{\Delta E}{RT_1}\right)=\frac{A\Delta E}{a_2 R}p\left(\frac{\Delta E}{RT_2}\right)=\cdots \qquad (9)$$

Using Eq. 8, the following linear relations can easily be derived:

$$-\log a_1-0.4567\frac{\Delta E}{RT_1}=-\log a_2-0.4567\frac{\Delta E}{RT_2}=\cdots \qquad (10)$$

Thus, the plots of $\log a$ versus the reciprocal absolute temperature for a given value of $W$ must give a straight line, the slope of which gives the activation energy. In other words, if the thermogravimetric curves are given as a plot of $W$ versus the reciprocal absolute temperature for various heating rates, the curves can be superposed upon each other by shifting them along the abscissa. The length of the lateral shift is proportional to the logarithm of the corresponding heating rate of the curve. By these superpositions there is obtained the master thermogravimetric curve, which is a standard and more accurate curve than individual ones; this procedure makes possible the mutual comparison of the thermogravimetric data at different heating rates.

The next step of the analysis is the determination of $A$, $f(x)$ and $g(x)$. For some typical kinetic processes, $f(x)$, $g(x)$ and $\int dx/g(x)$ are given in Table I, where $L$ is the

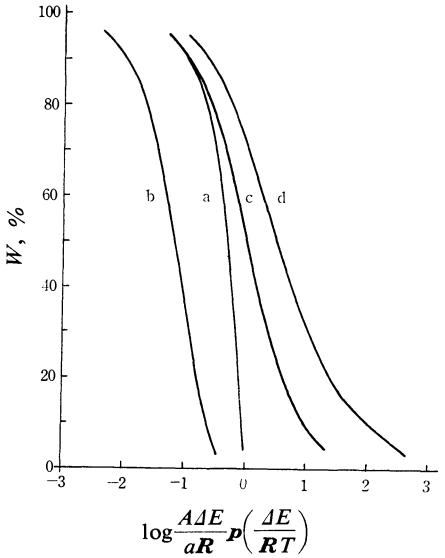

Fig. 1. The theoretical thermogravimetric curves for;

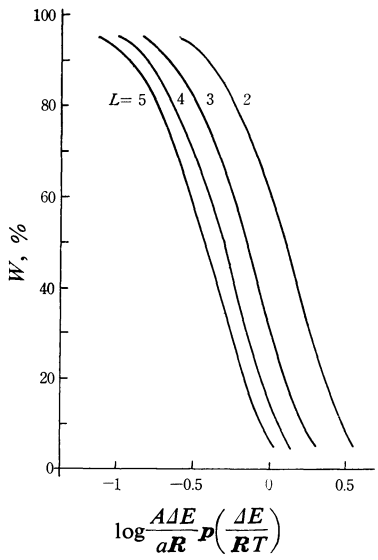

Fig. 2. The theoretical thermogravimetric curves of the random degradation of high polymers with the indicated values of $L$. Approximation is made for $N \gg L$.

least number of repeating units of the polymer not volatilized.[11] As $\int dx/g(x)$ is a function of $x$, which is equal to $(A\Delta E/aR)p(\Delta E/RT)$, and $W$ is a single-valued function of $x$, $W$ can be calculated as a function of $\log\{(A\Delta E/aR)p(\Delta E/RT)\}$, as is shown in Figs. 1 and 2. The plots of $W$ against $\log\{(A\Delta E/aR)p(\Delta E/RT)\}$ by using the experimental master thermogravimetric curve and the activation energy determined as shown above must be superposed upon one of the curves in Figs. 1 and 2 by a lateral shift. By this procedure the forms of $f(x)$ and $g(x)$ are determined, and the length of the lateral shift is found to be equal to $\log A$. An analogous, but more precise determination of $A$ can be made by the subtraction of $\log\{(\Delta E/aR)p(\Delta E/RT)\}$ from the $\int dx/g(x)$ of the determined form of $g(x)$, as is shown in Tables II and III.

| mean | 36.2±0.5 | 10.91±0.014 |

* The dimension of $A$ is $min^{-1}$.

Thus, the kinetic parameters, e.g., $\Delta E$, $A$, $f(x)$ and $g(x)$, are determined; from these parameters, a theoretical curve can be drawn and compared with the experimental master thermogravimetric curve. If the successive adjustments of the parameters are made, more accurate values will be obtained.

## Experimental

The method was applied to two reactions: the decomposition of calcium oxalate into calcium carbonate and carbon monooxide, and the degradation of nylon 6. The calcium oxalate monohydrate was of a G.R. grade, purchased from the Showa Chemical Co., Ltd., and used without further purification. The nylon 6, kindly supplied by the Toyo Rayon Co., Ltd., was dissolved in formic acid, reprecipitated by water, and dried in vacuo. The viscosity-average molecular weight of 10300,

was obtained from the intrinsic viscosity as measured in formic acid at 25°C. The amino groups at the chain ends of the polymer were partly acetylated.

A 300 mg. sample of calcium oxalate monohydrate or a 100 mg. sample of nylon 6 was weighed in a glass sample pan 15 mm. in diameter and 10 mm. in depth. The sample of nylon 6 was dried in the sample pan at 180°C for one hour under a pressure of less than $1\times10^{-3}$ Torr. prior to the measurements.

A null-type continuously-recording thermobalance supplied by the Ohyo Rika Kogyo Co., Ltd., was employed for the thermogravimetric measurements. A chromel-alumel thermocouple was located directly above the sample. The linear increase in the furnace temperature was regulated by a PI-type program controller and a SCR regulator purchased from the Ohkura Electric Co., Ltd. The pyrolysis of calcium oxalate monohydrate was carried out in air at an ambient pressure, and that of nylon 6, under a pressure of less than $1\times10^{-3}$ Torr. The heating rates were varied from 12°C per hour to 140°C per hour. The samples were weighed before and after heating by an analytical balance.

## Results and Discussion

The results of the thermogravimetry at various heating rates are plotted against the reciprocal absolute temperature in Figs. 3 and 4. It is apparent that these curves can be superposed by lateral shifts. The logarithms of the heating rates are plotted against the reciprocal absolute temperature, until which point the weight of the sample decreases to a

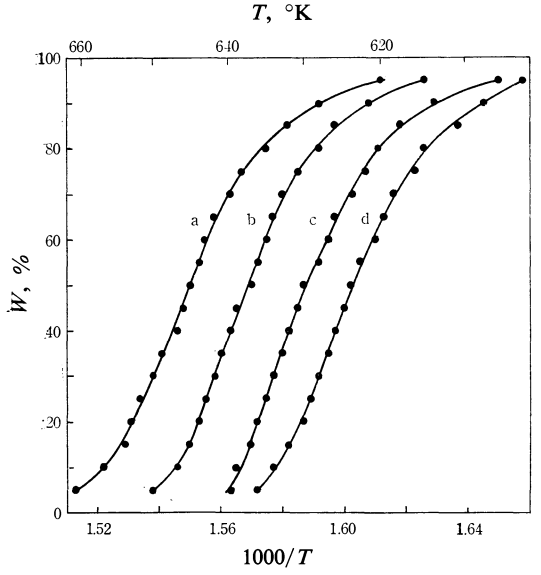

Fig. 3. The thermogravimetric curves of decomposition of calcium oxalate plotted against the reciprocal absolute temperature. Heating rate; a, 108°C/hr.; b, 54°C/hr.; c, 24.4°C/hr.; d, 12.5°C/hr.

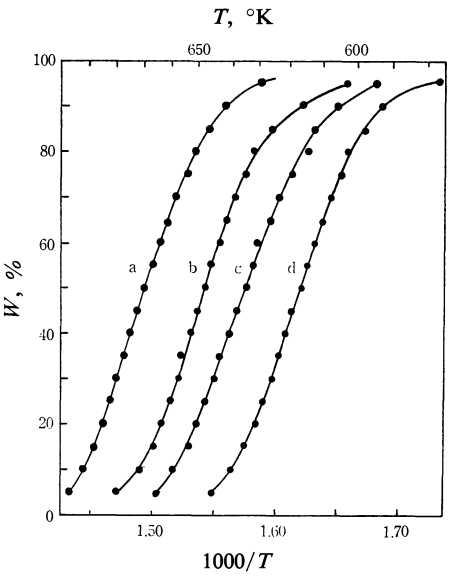

Fig. 4. The thermogravimetric curves of nylon 6 plotted against the reciprocal absoute temperature. Heating rate; a, 140°C/hr.; b, 48°C/hr.; c, 28°C/hr.; d, 14.3°C/hr.

given fraction, as Figs. 5 and 6 show. Straight lines are drawn by the method of the least squares; from these lines the activation energies are determined as listed in Tables II and III.

By using the activation energies thus determined, the weight changes are plotted against $\log\{(\Delta E/aR)p(\Delta E/RT)\}$ and compared with the curves in Figs. 1 and 2. From these comparisons, the mechanism of the decomposition of calcium oxalate may be elucidated to be of the 1st order; it is also found that the

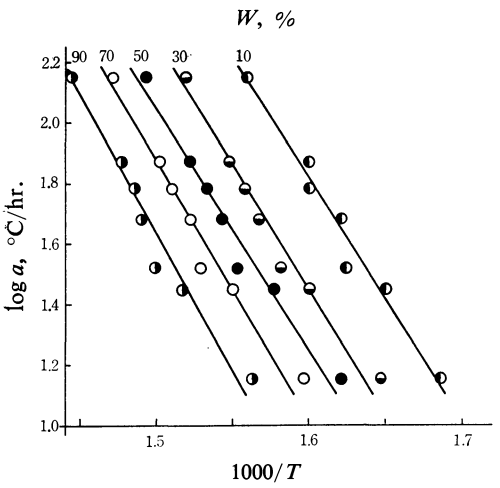

Fig. 6. The plots of logarithms of heating rate versus the reciprocal absolute temperature for indicated conversions of the degradation of nylon 6.

theoretical curve of random degradation with $L=2$ is best fitted to the experimental curve of nylon 6. A is determined by comparing $\log\{(\Delta E/aR)p(\Delta E/RT)\}$ with $\log\int dx/g(x)$ at every 5% of conversion; this tabulation is also in Tables II and III. In Freeman and Carrol's paper,[7] the activation energy and the order of the reaction of the decomposition of calcium oxalate were reported to be 74 kcal./mol. and 0.7 respectively, but the pre-exponential factor could not be evaluated by their method. The agreement between the results of this paper and theirs is good. For nylon 6, the activation energy and the order of the reaction were evaluated to be 37.0 kcal./mol. and 0 in Inoue and Sumoto's paper,[14] in which the mechanism of the unzipping of the monomer from carboxyl ends was postulated, whereas Straus and Wall[15] reported a mechanism of random degradation in which the activation energy is about 30 kcal./mol., the pre-exponential factor is of the order of $10^5$—$10^7$, and $L$ is 5. In both papers, the results were obtained by isothermal measurements, which contain some errors, as has been pointed out above. Considering these facts, the agreement seems fairly good. The experimental master curves at the heating rate of 60°C per hour are shown in Figs. 7 and 8, where they are also compared with the theoretical curves on the basis of the kinetic parameters obtained by the above analyses. The agreements between them are also good.

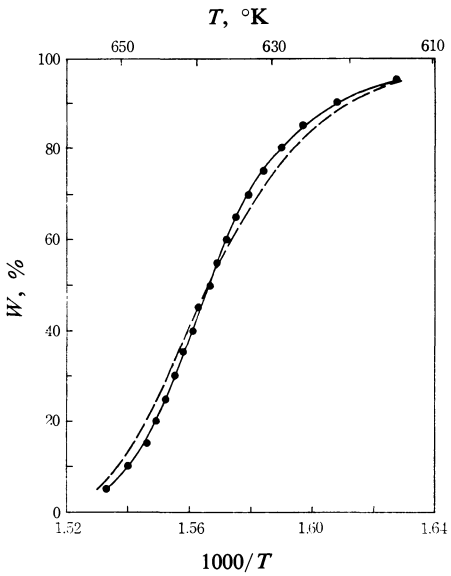

Fig. 7. The comparison of the experimental master curve (——) and the theoretical curve (----) of the decomposition of calcium oxalate.

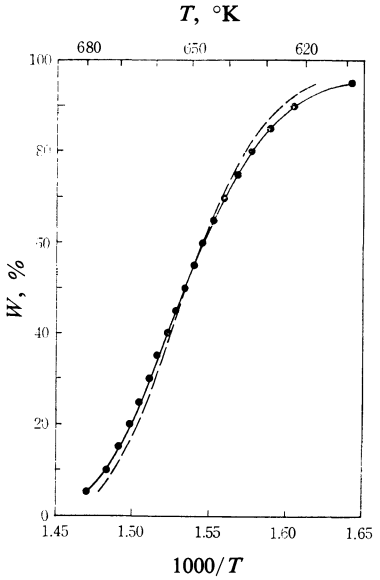

Fig. 8. The comparison of the experimental master curve (——) and the theoretical curve (----) of the degradation of nylon 6.

As may be seen in the above procedure, the method described in this paper is simple and applicable to the random degradation of polymers and other complicated reactions which can not be analyzed by other methods. However, if the weight changes in the manner of parallel reactions or consecutive reactions (in other words, if the weight-change is governed by two or more activation energies), the curves of the weight versus the reciprocal

absolute temperature at different heating rates can not be superposed, and the analysis mentioned above can not be applied. This is also the case for the other methods of analyzing thermogravimetric data.

Now we would like to discuss the applicability of the method to other types of thermal analyses, in which is recorded the change, or the rate of the change, of some property of the material heated at a constant rate.[16,17] If the property measured is a function of $x$ only, the change in the property can be treated similarly to the change in weight at the random degradation of polymers, and even if the exact form of $f(x)$ and/or $g(x)$ is unknown, the activation energy of the thermal behavior of the property can be estimated by a plot similar to Figs. 5 and 6. Furthermore, the change in the property under different conditions of temperature change can be predicted. Namely, the conversion of the property depends on the integral of the right side of Eq. 4, which has the dimension of time and which could be called "reduced time," $\theta$:

$$\theta = \int_{t_0}^{t} \exp\left(-\frac{\Delta E}{RT}\right) dt \tag{11}$$

When the change in the property is plotted against the logarithm of the reduced time by using the activation energy thus determined, the master curve of the change in the property under the various conditions of temperature change will be obtained. Below are shown the expressions of the reduced time, some of which have already been calculated in the literature.[18] (i) If the temperature is maintained at $T$ from time 0 to time $t$:

$$\theta = t \exp(-\Delta E/RT) \tag{12}$$

(ii) If the temperature is raised from $T_1$ to $T_2$ at the rate of $a$ and cooled from $T_2$ to $T_3$ at the rate of $b$:

$$\theta = (\Delta E/aR)\{p(\Delta E/RT_2) - p(\Delta E/RT_1)\} + (\Delta E/bR)\{p(\Delta E/RT_2) - p(\Delta E/RT_3)\} \tag{13}$$

(iii) If the temperature is changed from $T_1$ to $T_2$ according to Eq. 14:

$$T = a + b\exp(-\alpha t) \tag{14}$$

$$\theta = \left(\frac{1}{\alpha}\right)\left\{Ei\left(-\frac{\Delta E}{RT_2}\right) - Ei\left(-\frac{\Delta E}{RT_1}\right)\right\} - \left(\frac{1}{\alpha}\right)\exp\left(-\frac{\Delta E}{aR}\right)\left\{Ei\left(\frac{\Delta E}{aR} - \frac{\Delta E}{RT_2}\right) - Ei\left(\frac{\Delta E}{aR} - \frac{\Delta E}{RT_1}\right)\right\} \tag{15}$$

where:

$$Ei(x) = \frac{\exp(x)}{x}\left\{1 + \frac{1}{x} + \frac{2!}{x^2} + \frac{3!}{x^3} + \cdots\right\} \tag{16}$$

(iv) If the temperature is changed from $T_1$ to $T_2$ according to Eq. 17:

$$1/T = 1/T_0 - at \tag{17}$$

$$\theta = \left(\frac{R}{a\Delta E}\right)\left\{\exp\left(-\frac{\Delta E}{RT_2}\right) - \exp\left(-\frac{\Delta E}{RT_1}\right)\right\} \tag{18}$$

For the more complicated changes in the temperature, $\theta$ can be calculated according to its additivity, or according to its linearity in integration. It is also apparent from the above discussions that the thermal stability of the materials should be defined by using $\theta$ and $\Delta E$.

## Summary

A new method of obtaining the kinetic parameters from thermogravimetric curves has been proposed. The method is simple and applicable to reactions which can not be analyzed by other methods. The effect of the heating rate on thermogravimetric curves has been elucidated, and the master curve of the experimental curves at different heating rates has been derived.

The applications of the method to the pyrolyses of calcium oxalate and nylon 6 have been shown; the results are in good agreement with the reported values.

The applicability of the method to other types of thermal analyses has been discussed, and the method of the conversion of the data to other conditions of temperature change has been suggested. From these discussions, the definition of the thermal stability of materials has been criticized.

# A New Colorimetric Method for the Determination of Minute Amounts of Bromide by Means of Its Catalytic Effect*

By Norinobu YONEHARA, Satori UTSUMI and Iwaji IWASAKI

(Received February 24, 1965)

A rapid and sensitive method for the determination of a minute amount of bromide is desirable. Two of the present authors (S. U. and I. I.) and Shiota[1] have previously reported a colorimetric method for the determination of bromide which is based on the catalytic effect of bromide on the oxidation of iodine to iodate by potassium permanganate in a sulfuric acid solution. Fishman and Skougstad[2] have studied this method further. However, it has been observed that some inevitable technical difficulties occur in keeping the reaction time and temperature constant, because this oxidation reaction proceeds fairly rapidly, even below room temperature.

By a further investigation of the oxidation of iodine to iodate employing various oxidizing agents, it was found that, when ceric ammonium sulfate is used as the oxidizing agent, this oxidation reaction is catalytically promoted by a minute amount of bromide in the presence of large amounts of potassium dichromate in a nitric acid solution. This reaction proceeds fairly slowly at room temperature, thus, favorable conditions for the procedure can be realized. In this paper a new method for the determination of a minute amount of bromide using this reaction will be described.

This oxidation reaction proceeds more rapidly in the presence of bromide than in its absence. Consequently, when this reaction was carried out at a given temperature for a given time, the higher the concentration of bromide was, the lower that of the unreacted iodine became. Thus, the determination of bromide can be made by determining the amount of this unreacted iodine. The oxidation reaction is stopped after a given time by the extraction of the unreacted iodine with carbon tetrachloride; the amount of iodine in the extract is then determined by adding an alcoholic solution of mercuric thiocyanate and a ferric ammonium sulfate solution and by measuring the absorbance of the resulting ferric thiocyanate.[3]

## Experimental

**Apparatus.**—A Hirama photoelectric-colorimeter with a 460 filter (with maximum transmission at 460 mμ) and 10 mm. cells was used to measure the absorbance.

The reactions were carried out at given temperatures (±0.1°C) using a water bath with a Taiyo Thermo Unit.

**Reagents.** — All the chemicals used were of guaranteed-reagent quality.

*The Ceric Ammonium Sulfate Solution (0.2 M in 2 N Sulfuric Acid).*—Dissolve 33.42 g. of ceric ammonium sulfate $[Ce(SO_4)_2 \cdot 2(NH_4)_2SO_4 \cdot 4H_2O]$ in a sulfuric acid solution (14 ml. of concentrated sulfuric acid +115 ml. of redistilled water) and dilute to 250 ml. with redistilled water.

*The Potassium Dichromate Solution (0.2 M).*—Dissolve 15.21 g. of potassium dichromate in redistilled water and dilute to 250 ml.

*The Potassium Iodide Solution (1 mg. of iodide per ml.).*—Recrystallized potassium iodide was used. Prepare about a 0.1 M potassium iodide solution, standardize by Volhard's method, and then dilute this solution to give 1000 p. p. m. of iodide.

*Concentrated Nitric Acid (sp. gr. 1.38).*

*The Mercuric Thiocyanate Solution.*—Solid mercuric thiocyanate[4] was prepared in our laboratory. Dissolve 0.3 g. of mercuric thiocyanate in 100 ml. of absolute ethyl alcohol.

*The Ferric Ammonium Sulfate Solution.*—Dissolve 6 g. of ferric ammonium sulfate in 100 ml. of a 6 N nitric acid solution and store in a brown glass bottle.

*The Standard Bromide Solution.*—Prepare about a 0.1 M potassium bromide solution using redistilled water and standardize by Volhard's method. Prepare the working solutions by diluting this solution adequately.

*The Standard Chloride Solution.*—Dissolve 1.649 g. of sodium chloride in redistilled water and dilute to exactly 1 l. This solution contains 1 mg. of chloride per milliliter. Prepare the working solutions by successive dilutions.

**Procedure and Calibration Curve.** — To 10.0 ml. of the sample in a 30 ml. glass tube with a glass

stopper add 1.5 ml. of the potassium iodide solution, 1.0 ml. of the potassium dichromate solution and 2.0 ml. of the nitric acid solution, and mix thoroughly. Place the glass tube in the water bath at 30°C for about 10 min. Start the reaction by adding 2.0 ml. of the ceric ammonium sulfate solution (at the same temperature), mixing thoroughly, and replacing the glass tube in the water bath.

Exactly 20 min. after the addition of the ceric ammonium sulfate solution, add 5 ml. of carbon tetrachloride and immediately shake the glass tube for 30 sec. After the layers have completely separated, remove the aqueous layer by using the pipet with a rubber bulb. As even a small amount of the remaining aqueous layer disturbs the subsequent procedure, it is necessary to remove it completely by the following procedure. Add about 5 ml. of redistilled water to the glass tube containing carbon tetrachloride along the inside wall of the tube, and then remove this water again in the manner described above. The aqueous layer that initially remains can be removed almost completely by repeating this procedure three times. To the carbon tetrachloride thus obtained in the glass tube, add 5.0 ml. of redistilled water, 1.0 ml. of the ferric ammonium sulfate solution and 0.5 ml. of the mercuric thiocyanate solution, and shake the glass tube for about one minute. Thus, the aqueous layer is colored with ferric thiocyanate. Measure the absorbance of this aqueous layer at 460 mμ using redistilled water as a reference.

Concn. of bromide, p. p. m.

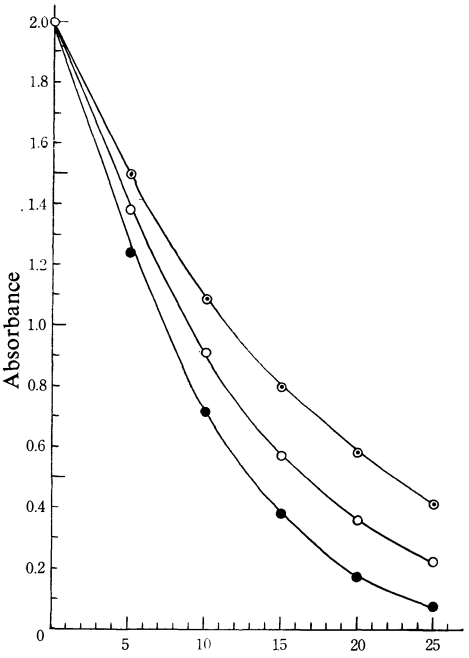

Fig. 1. Calibration curve.
30°C, 20 min.

The calibration curve shown in Fig. 1 was obtained by the procedure described above, using standard bromide solutions of known concentrations. The same calibration curve as that for bromide is obtained by using standard bromate solutions with the concentrations given as bromine.

This method is especially suitable for the determination of concentrations lower than 0.05 p. p. m.; concentrations of bromide as low as 0.005 p. p. m. can thus be determined.

## Results and Discussion

**The Reaction Rate Curves.** — The catalytic reactions were carried out in the same way using 10.0 ml. of a 0.10 p. p. m. bromide solution. After various intervals, the color was developed by using 10.0 ml. of redistilled water, 2.0 ml. of the ferric ammonium sulfate solution and 1.0 ml. of the mercuric thiocyanate solution. The reaction rate curve I shown in Fig. 2 was obtained by this experiment.

Time, min.

Fig. 2. Reaction rate curves.
30°C, Color reaction of $FeSCN^{2+}$ is done by using 10 ml. of $H_2O$, 2 ml. of ferric solution and 1 ml. of $Hg(SCN)_2$ solution.
—●— 0.10 p. p. m. $Br^-$ (I)
—○— 0.02 p. p. m. $Br^-$ (II)
—⊙— Redistilled water (III)

Curves II and III in Fig. 2 were obtained by using a 0.02 p. p. m. bromide solution and redistilled water. As can be seen from Fig. 2, the reaction rate increased with an increase in the concentration of bromide, and the differences in absorbances among the three curves increased with the reaction time. These results indicate that the sensitivity of the method increases with the reaction time. However, in the solution with 0.10 p. p. m. bromide, the reaction has been almost completed after 25 min. and the sensitivity became small. A reaction time of 20 min. was adequate at 30°C.

**The Amount of Iodide, the Reaction Time and the Temperature.**—Curves I and II in Fig. 3 show the combined effect of the reaction time and the temperature. Similar calibration curves were obtained when shorter periods of time were used for higher temperatures.

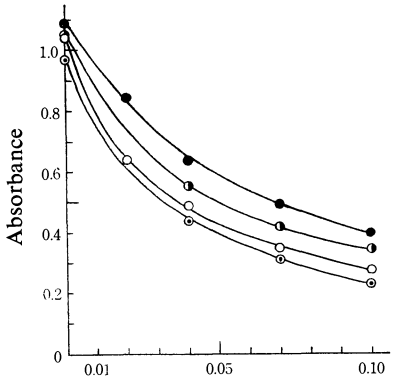

Fig. 3. Effects of reaction time, temperature and amounts of iodide.
—○— 30°C, 20 min., 1.5 ml. of iodide (I)
—●— 35°C, 10 min., 1.5 ml. of iodide (II)
—⊙— 30°C, 15 min., 1.0 ml. of iodide (III)
—◑— 30°C, 25 min., 2.0 ml. of iodide (IV)

The results with different amounts of iodide and different reaction times are shown by curves I, III and IV in Fig. 3. Similar curves were also obtained when longer periods of time were used for larger amounts of iodide. It was thought most favorable to use the reaction time of 20 min., the temperature of 30°C, and 1.5 ml. of the iodide solution.

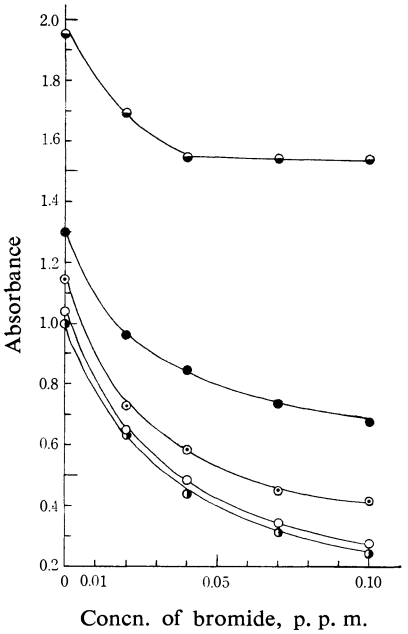

Fig. 4. Effect of amount of ceric solution.
30°C, 20 min., 0.2 M ceric solution is used.
—◒— 0.5 ml. —○— 2.0 ml.
—●— 1.0 ml. —◑— 2.5 ml.
—⊙— 1.5 ml.

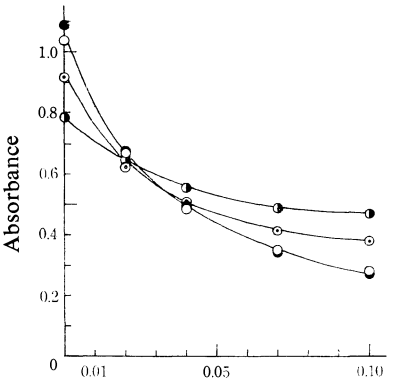

Fig. 5. Effect of amount of nitric acid.
30°C, 20 min., concentrated nitric acid is used.
—◑— 1.0 ml. —○— 2.0 ml.
—⊙— 1.5 ml. —●— 2.5 ml.

**The Concentration of Reagents.**—The effects of the ceric solution are shown in Fig. 4. The sensitivity increased with an increase in the amount of ceric solution added, but when more than 2.0 ml. of the ceric solution was used, no increase in sensitivity was obtained.

Figure 5 shows the effects of nitric acid. The larger the amount of nitric acid, the higher the absorbance of the blank solution and the lower that of the 0.10 p. p. m. bromide solution. However, by using 2.5 ml. of nitric acid, almost the same curve as that of 2.0 ml. was obtained. It appears that the nitric acid is necessary for this catalytic reaction. When sulfuric acid was used instead of nitric acid, no difference in absorbances between blank solution and 0.10 p. p. m. bromide solution was observed.

Dichromate is essential for this catalytic reaction. In its absence no difference in absorbance was obtained between blank and bromide solutions. In order to examine the

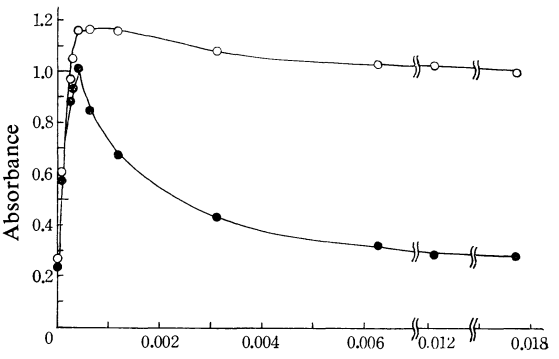

Fig. 6. Effect of concentration of dichromate.
30°C, 20 min.
—○— Redistilled water (I)
—●— 0.10 p. p. m. $Br^-$ (II)

effects of dichromate, the reactions were performed in the presence of various amounts of dichromate using the blank solution and the solution containing 0.1 p. p. m. of bromide. The results are shown in Fig. 6. The presence of small amounts of dichromate caused a sharp decrease in the reaction rate and only a slight difference in absorbance between the two curves I and II. However, at higher concentrations than 0.0004 M in the reaction solution, curve II deviated remarkably from curve I with the increase in the concentration of dichromate; they then ran parallel to each other.

In order to ascertain the most suitable conditions, the effects of the amount of the dichromate solution were further determined, as shown in Fig. 7.

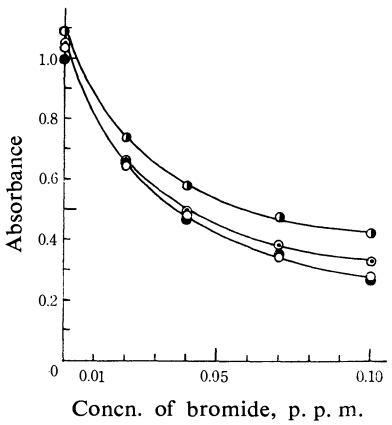

Fig. 7. Effect of amount of dichromate solution.
30°C, 20 min., 0.2 M dichromate solution is used.
—◑— 0.25 ml. —○— 1.0 ml.
—⊙— 0.5 ml. —●— 1.5 ml.

The sensitivity increased with an increase in the amount of dichromate solution added, but by using more than 1.0 ml. almost the same curves were obtained.

**The Effect of Diverse Ions.** — In order to make clear the effect of diverse ions on this method, some experiments were made in the presence of 0.04 p. p. m. of bromide ion and in its absence. The experimental results are given in Table I.

Nitrate and sulfate ions do not interfere at considerably high concentrations, but chloride ions interfere at 1 p. p. m. The effects of chloride ions will be described in detail in the following section. Iodide ions interfere slightly at 10 p. p. m. However, even if the sample contains more than 10 p. p. m. of iodide ions, the total amount of iodide in the reaction solution at the start of the oxidation can be

kept at the constant concentration by decreasing the amount of the iodide reagent to be used. Permanganate and manganese(II) ions interfere at relatively low concentrations. Silver and mercuric ions interfere remarkably.

**The Determination of Bromide in the Presence of Chloride.**—This method is affected by 1 p.p.m. of chloride. As natural waters always contain small amounts of chloride, the effects of chloride were examined.

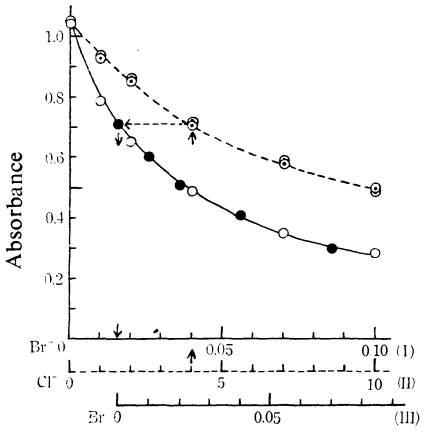

Fig. 8. Calibration curves.
30°C. 20 min.
—○— $Br^-$ (I)
--⊙-- $Cl^-$ (II)
—●— $Br^-$ in the presence of 4 p. p. m. $Cl^-$ (III)
←---- 4 p. p. m. $Cl^-$ (↑) is equivalent to 0.016 p. p. m. $Br^-$ (↓).

Curve II in Fig. 8 was obtained by this method by using standard chloride solutions of known concentrations. Curve I, the calibration curve of this method, is shown in Fig. 1. Chloride gives a curve similar to bromide when the concentrations of chloride are a hundred times larger than those of bromide. The experiments were also made by using standard bromide solutions containing 4 p. p. m. of chloride. The absorbances obtained are plotted against the concentrations of bromide on the abscissa III with solid circles. All these solid circles fall just on curve I. The concentration of bromide on the abscissa I minus that equivalent to 4 p. p. m. of chloride gives the value on the abscissa III. The same results were also obtained in the presence of different amounts of chloride. Thus, in samples containing small amounts of chloride, the concentration of bromide can be obtained by correcting the value for the chloride.

The concentration of chloride in the sample is first determined by the mercuric thiocyanate method.[4] By means of curves I and II in Fig. 8, a concentration of bromide ($A$ p. p. m.) equivalent to the concentration of chloride is obtained. Then the sample is treated by this method, and the value ($B$ p. p. m.) is obtained by curve I. Thus, the concentration of bromide in the sample is calculated as the difference between $B$ and $A$ [$(B-A)$ p. p. m.].

The bromide contents in several natural waters were also determined by this method. The results are given in Table II.

Table II. Determination of bromide contents in natural waters

| | Sample | Concn. of bromide p. p. m. | Concn. of chloride p. p. m. |
|---|---|---|---|
| No. 1 | Rain water*1 (I) | 0.005 | 0.17 |
| No. 2 | River water*2 (II) | 0.070 | 16.2 |
| No. 3 | River water*3 (III) | 0.060 | 15.2 |
| No. 4 | | 0.062 | |
| No. 5 | Sample added bromide*4 | 0.082 | |

*1 The sample was taken at Meguro-ku, Tokyo, July, 1963.
*2 The sample was taken in River Tamagawa, Noborito-bashi, Tokyo, June, 1963.
*3 The sample was taken in River Tamagawa, Futako-bashi, Tokyo, June, 1963.
*4 The sample contains 0.020 p. p. m. of added bromide and 0.061 p. p. m. of originally present bromide.

Sample I was analyzed by using 10 ml., while samples II and III were analyzed by using samples diluted 3 ml. to 10 ml. The results given in Table II are calculated to original concentrations. The value listed in No. 4 was obtained by using sample III diluted 5 ml. to 10 ml. The comparison of the two results of sample III shows a good agreement. The method was also checked by adding a known amount of bromide to sample III. The determination of the total bromide concentration of this sample was made by using a sample diluted 3 ml. to 10 ml. The original concentration was calculated from the value thus obtained; it is listed in No. 5. This result shows that the known amount of bromide added is satisfactorily determined.

By this method, minute amounts of bromide in natural waters can be determined rapidly and sensitively.

# Chemical Effects Associated with the $\beta$-Decay Process. II. A Kinetic Study of the Chemical Behavior of $^{144}Pr$ in the EDTA Complex System

By Takanobu SHIOKAWA and Takashi OMORI

(Received March 5, 1965)

Unusual chemical behavior of a radioactive daughter atom may result from an increase in the nuclear charge produced by $\beta^-$-decay.[1] The effects of the increase include such secondary processes as an electronic excitation due to a sudden change in the nuclear charge, and rotational and vibrational excitations due to recoil. It is very difficult to evaluate the effects associated with $\beta^-$-decay in the liquid system, in contrast to those taking place in the gas phase. In the Ce-Pr-144 system, however, the probability of a bond-rupture arising from the recoil by $\beta^-$-decay is expected to be much smaller, since the maximum recoil energy imparted to a free, isolated $^{144}Pr$ atom is only 1.6 eV. It was also suggested in the preceding paper[2] that the thermodynamical instability of a $^{144}Pr$ atom plays an important role in determining its chemical behavior. Accordingly, the experimental results could be explained qualitatively by a mechanism which includes the decomposition of an intermediate complex produced by intramolecular electron-transfer, in addition to the substitution reaction between the liberated $^{144}Pr$ ion and the cerium(III) ethylenediaminetetraacetate (Ce(III)-EDTA) complex.

More experimental evidence is needed to substantiate this model. The present authors have, therefore, attempted to elucidate quantitatively the chemical behavior of $^{144}Pr$ atoms in terms of the per cent yield of the $^{144}Pr$(III)-EDTA complex (the $^{144}PrY^-$-yield). Moreover, in order to study the kinetics of the $^{144}PrY^-$-yield, the substitution reactions of the cerium(III) ion and the Pr(III)-EDTA complex were investigated in an aqueous solution using $^{144}Ce$ as a tracer.

## Experimental

The chemicals employed were the same as those described previously.[2]

The kinetic runs were carried out as follows: an aqueous solution of the Pr(III)-EDTA complex was mixed with praseodymium(III) chloride containing $^{144}Ce$ at 25±0.1°C. The ionic strength was adjusted using 0.50 M sodium chloride, and then 0.04 M sodium acetate was added as a buffer. As will be mentioned later, the exchange rate is affected by the presence of acetate ions, so the total concentration of acetate ions was maintained at 0.04 M in order to minimize such effect. At suitable times, samples were withdrawn rapidly through a Dowex 50W-X8 column (0.5 g. of resin) which had been previously treated with an appropriate buffer. The column was then washed with a known amount of buffer, and the combined eluates (that is, the fraction containing the complex) were collected in a test tube. The separate experiments ensured that the free-ion fraction was separated quantitatively from the complex fraction.

The $^{144}PrY^-$-yield, which was defined as the ratio of the $\gamma$-activity of the eluate to the total activity, was obtained similarly, after a complete equilibration with respect to $^{144}Ce$ had been attained chemically.

The $\gamma$-activity of each liquid sample was determined with a well-type scintillation spectrometer. The $^{144}Ce$ and $^{144}Pr$ were assayed by essentially the same methods as had been employed previously.[2] The pH of the solution at the equilibrium was measured by a glass-electrode pH meter, with an accuracy of 0.01 pH.

## Results and Discussion

**The Substitution Mechanism.**—In the preliminary experiments on the isotopic exchange reaction of $^{144}Ce$(III) ion and Ce(III)-EDTA complex, it was found that the rate of the exchange reaction, $R$, may be expressed as:

$$R = k_{Ce,\,app}\,[CeY^-]\,[H^+] \qquad (1)$$

where $k_{Ce,\,app}$ is the apparent rate constant, depending on the concentration of acetate ions, and $Y^{4-}$ indicates a tetravalent EDTA anion. The main path leading to exchange is the acid-catalyzed dissociation of the Ce(III)-EDTA complex, which is in accordance with the mechanism suggested by Betts et al.[3]

The substitution reaction of the cerium(III)

ion and the Pr(III)-EDTA complex may be expressed stoichiometrically as follows:

$$^{144}Ce^{3+} + PrY^{-} \rightleftarrows {}^{144}CeY^{-} + Pr^{3+} \quad (2)$$

On the basis of the isotopic exchange reaction, the path of the substitution will be:

$$PrY^{-} + H^{+} \xrightarrow{k_{Pr,\,app}} Pr^{3+} + HY^{3-} \quad (3)$$

followed by a very fast reaction:

$$Ce^{3+} + HY^{3-} \xrightarrow{k'_{Ce}} CeY^{-} + H^{+} \quad (4)$$

The reverse reactions, whose rate constants are designated by $k'_{Pr}$ for Eq. 3 and $k_{Ce,\,app}$ for Eq. 4, would take place simultaneously. In these expressions, $Pr^{3+}$ and $Ce^{3+}$ represent the species in the cationic form, including acetate complexes. These, however, may be allowed, since the exchange rate is independent of the nature of the free metal ion. It is also permissible to set $k'_{Ce}=k'_{Pr}$. Hence, the overall rate equation is given by:

$$\frac{d[CeY^{-}]}{dt} = k_{Pr,\,app}[PrY^{-}][H^{+}]\frac{[Ce^{3+}]}{[Ce^{3+}]+[Pr^{3+}]} - k_{Ce,\,app}[CeY^{-}][H^{+}]\frac{[Pr^{3+}]}{[Ce^{3+}]+[Pr^{3+}]} \quad (5)$$

Since the kinetic measurements are carried out with solutions containing both the praseodymium(III) ion and the Pr(III)-EDTA complex in a large excess over carrier-free $^{144}Ce$, the substitution reaction can be treated as a pseudo-first order reaction; the reaction rate may thus be simplified as follows:

$$\frac{d[^{144}CeY^{-}]}{dt} = k_{Pr,\,app}[H^{+}]\frac{[PrY^{-}]_0}{[Pr^{3+}]_0}[^{144}Ce^{3+}] - k_{Ce,\,app}[H^{+}][^{144}CeY^{-}] \quad (6)$$

where the subscript $_0$ denotes the initial state. The concentrations of the praseodymium(III) ion and the Pr(III)-EDTA complex remain unchanged during the reaction; therefore, the following relation may be satisfied at equilibrium:

$$K_{app} = \frac{[PrY^{-}]_e[^{144}Ce^{3+}]_e}{[Pr^{3+}]_e[^{144}CeY^{-}]_e} = \frac{k_{Ce,\,app}}{k_{Pr,\,app}} \quad (7)$$

where $K_{app}$ corresponds to the reciprocal of the apparent equilibrium constant of Eq. 2 at a specified acetate concentration, and the subscript e denotes the equilibrium state. The apparent equilibrium constant, $K_{app}$, was found to be $2.10\pm0.08$ in the presence of 0.04 M acetate at 25°C.

The integration of Eq. 6, then, gives:

$$\ln\left\{\frac{[^{144}CeY^{-}]_e}{[^{144}CeY^{-}]_e-[^{144}CeY^{-}]}\right\} = \left\{k_{Pr,\,app}\frac{[PrY^{-}]_0}{[Pr^{3+}]_0}+k_{Ce,\,app}\right\}[H^{+}]t = k_{app}\cdot t \text{ (at a constant pH)} \quad (8)$$

| ① : | $1.82\times10^{-4}$ M ; | $1.64\times10^{-4}$ M |

Typical plots of the logarithmic term in Eq. 8 against $t$ are shown in Fig. 1. The zero-time exchange appears to be negligible. The apparent rate constant, $k_{app}$, is obtained from the slope of the straight line shown in Fig. 1. The dependence of $\log k_{app}$ on pH is given in Fig. 2, indicating the first order dependence of $k_{app}$ on the hydrogen ion concentration. Equation 7 also gives the relation:

$$k_{Ce,\,app} = K_{app}\cdot k_{Pr,\,app} = 2.10\,k_{Pr,\,app} \quad (7')$$

indicating that the exchange rate constants are in inverse order with regard to the stability constants of the EDTA complexes. Hence, as long as the substitution mechanism proposed

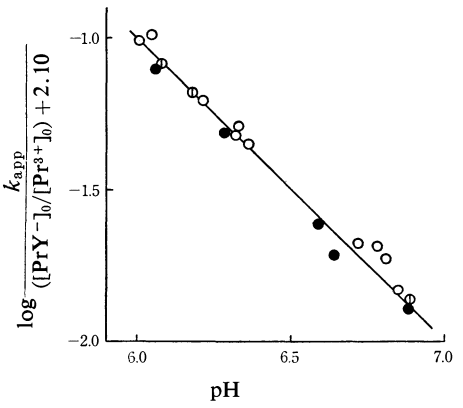

Fig. 3. $\log\frac{k_{app}}{([PrY^-]_0/[Pr^{3+}]_0)+2.10}$ vs. pH.

is valid, the plot of $\log k_{app}/\{([PrY^-]_0/[Pr^{3+}]_0)+2.10\}$ against the pH value must normalize the experimental values obtained under different conditions, giving a straight line with a unit slope. The value of $k_{Pr,\,app}$ can be determined from the intercept. The results are satisfactory, as Fig. 3 shows, and lend support to the kinetic mechanism proposed. The exchange rate constant, $k_{Pr,\,app}$, was determined to be:

$$k_{Pr,\,app}=1.0_1\times10^5\ \text{l. mol}^{-1}\text{min}^{-1}$$

and from the relation expressed by Eq. 7', $k_{Ce,\,app}$ was calculated as follows:

$$k_{Ce,\,app}=2.1_1\times10^5\ \text{l. mol}^{-1}\ \text{min}^{-1}$$

**The Chemical Behavior of $^{144}$Pr.**—In order to estimate the contribution of the thermal exchange reaction, the dependence of the $^{144}PrY^-$-yield on the pH value was investigated. As is shown in Fig. 4, the $^{144}PrY^-$-yield decreases gradually with the pH, indicating that the departure from the equilibrium value is large in higher pH regions.

If the $^{144}$Pr atoms which escape from the parent molecule distribute thermally between the praseodymium(III) ion and the Pr(III)-EDTA complex, the fraction of exchange that has taken place during the time, $t$, can be expressed as:

$$\ln\left\{\frac{[^{144}PrY^-]_e}{[^{144}PrY^-]_e-[^{144}PrY^-]}\right\}=k_{Pr,\,app}\left\{\frac{[Pr^{3+}]_0+[PrY^-]_0}{[Pr^{3+}]_0}\right\}[H^+]t \quad (9)$$

Of course, one must take into consideration the fact that, even in the case of the transformation of the $^{144}$Ce(III)-EDTA complex to the $^{144}$Pr(III)-EDTA complex without any net chemical change, a re-distribution of the praseodymium ions takes place because of the difference in the formation constants of their EDTA complexes.

First, let us assume that the extent of the bond-rupture by the $\beta^-$-decay process is insensitive to the pH, viz., that $t$ in Eq. 9 is a constant. When one plots the logarithmic fraction of the exchange vs. the pH, a straight line with a slope of -1 should be obtained. On the other hand, the value of $t$ in Eq. 9 can be determined by introducing the rate constants obtained in the preceding section. These results are given in Figs. 5 and 6. The non-unit slope, as shown in Fig. 5, means that the extent of formation of free $^{144}$Pr ions varies with the pH; that is, the reaction time

| ●: | $9.52\times10^{-5}$ M; | $7.62\times10^{-5}$ M |

The dashed lines were calculated by Eq. 9.

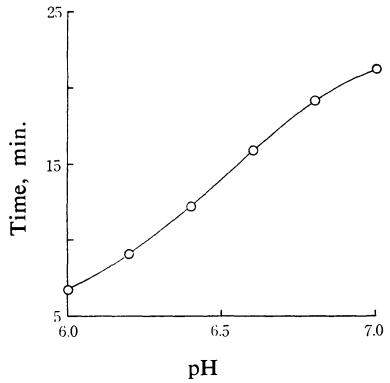

Fig. 6. Reaction time vs. pH.
$[PrY^-]_0=1.82\times10^{-4}$ M
$[Pr^{3+}]_0=7.62\times10^{-5}$ M

is not constant. However, even if the concept that the extent of bond rupture is sensitive to pH is valid, the values of the reaction time obtained are fairly small in the lower pH region, as compared with the average life of $^{144}Pr$, $\tau$, which is defined as:

$$\tau=t_{1/2}/0.693=25.3 \text{ min.}$$

These facts are strong evidence in support of the presence of an intermediate with a measurable lifetime produced by the $\beta^-$-decay of the $^{144}Ce$(III)-EDTA complex.
