Before we consider the physical and chemical meanings of the intermediate complex, an attempt to treat the decomposition of this complex on the basis of kinetics will be discussed. The deviation of the $^{144}PrY^-$-yield from the equilibrium values leads to an assumption that the irreversible decomposition of the intermediate complex to produce the free $^{144}Pr$ ions is promoted by the action of either hydroxide ions or protonated EDTA anions ($HY^{3-}$), which are supplied steadily by the acid-catalyzed dissociation of the Pr(III)-EDTA complex. The latter mechanism is substantially analogous to the decomposition of the Mn-(III)-EDTA complex in the presence of an excess of EDTA.[4] The proposed mechanism excludes a direct bimolecular reaction between the intermediate and Pr(III)-EDTA complex to afford $^{144}Pr$-EDTA complex, because $^{144}Pr$ atoms were considerably enriched in the free-ion fraction. Hence, the decomposition process may be expressed as:

$$^{144}PrZ \xrightarrow[k_1]{OH^-,\ HY^{3-}} {}^{144}Pr^{3+} \underset{k_2}{\rightleftarrows} {}^{144}PrY^- \qquad (10)$$

where $^{144}PrZ$ represents the intermediate complex.

4) K. A. Schroeder and R. E. Hamm, *Inorg. Chem.*, **3**, 391 (1964).

The fraction of the $^{144}Pr$(III)-EDTA complex, $Z$, at the time, $t$, can be obtained by the following equation:

$$Z=\frac{[PrY^-]_0}{([Pr^{3+}]_0+[PrY^-]_0)2\sqrt{\alpha^2-\beta}} \times (r_2e^{r_1t}-r_1e^{r_2t}+2\sqrt{\alpha^2-\beta}) \qquad (11)$$

where:

$$k_1+k_2=2\alpha, \quad k_1k_2=\beta$$
$$r_1=-\alpha+\sqrt{\alpha^2-\beta} \quad r_2=-\alpha-\sqrt{\alpha^2-\beta}$$
$$k_1=k'[OH^-]+k''[H^+][PrY^-]_0/[Pr^{3+}]_0 \qquad (12)$$
$$k_2=k_{Pr,\ app}[H^+]([Pr^{3+}]_0+[PrY^-]_0)/[Pr^{3+}]_0$$

$k'$ and $k''$ are the rate constants for the hydroxide ion- and the protonated EDTA anion-dependent terms respectively. If one chooses suitable values for $k'$ and $k''$, the $^{144}PrY^-$-yield can be calculated from Eqs. 9 and 11, provided that the $^{144}Pr$ atoms produced by the $\beta^-$-decay of free $^{144}Ce$(III) ions are reduced instantaneously to stable $^{144}Pr$(III) ions through electron-transfer with surrounding substances.

By using the rate constants, $k'=10^{6.1}$ l. mol$^{-1}$. min$^{-1}$ and $k''=10^{4.4}$ l. mol$^{-1}$ min$^{-1}$, and the reaction time of $t=25.3$ min., the $^{144}PrY^-$-yields were calculated as in Fig. 7. The agreement

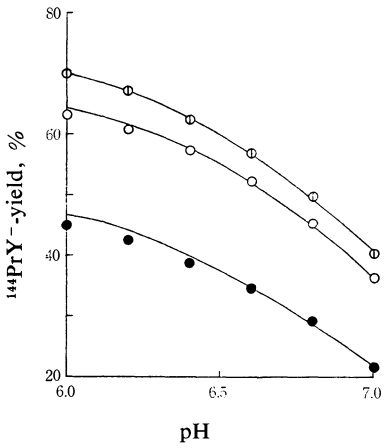

Fig. 7. The $^{144}PrY^-$-yield calculated by Eqs. 9 and 11.

| | $[PrY^-]_0$ | $[Pr^{3+}]_0$ |
|---|---|---|
| ① : | $2.40\times10^{-4}$ M ; | $8.00\times10^{-5}$ M |
| ○ : | $1.82\times10^{-4}$ M ; | $7.62\times10^{-5}$ M |
| ● : | $9.52\times10^{-5}$ M ; | $7.62\times10^{-5}$ M |

The circles indicate the experimental values obtained from the curves in Fig. 4.
The solid curves were calculated by Eqs. 9 and 11.

between the observed and calculated $^{144}PrY^-$-yields is satisfactory.

To confirm this mechanism, a similar experiment was carried out with the cerium(III) ion and Ce(III)-EDTA complex system. The

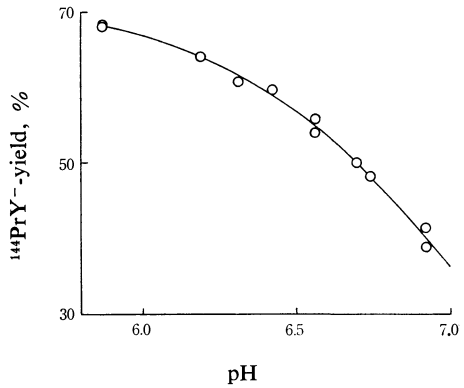

Fig. 8. Dependence of the $^{144}PrY^-$-yield on pH at 25°C in the $Ce^{3+}$-$CeY^-$ system.
$[CeY^-]_0=1.00\times10^{-4}$ M;
$[Ce^{3+}]_0=8.08\times10^{-5}$ M

relation between the $^{144}PrY^-$-yield and the pH is shown in Fig. 8. The substitution reaction for a $^{144}Pr$(III) ion and a Ce(III)-EDTA complex is expressed as follows:

$$\ln\left\{\frac{[^{144}PrY^-]_e}{[^{144}PrY^-]_e-[^{144}PrY^-]}\right\}=\left\{k_{Ce,\,app}\frac{[CeY^-]_0}{[Ce^{3+}]_0}+k_{Pr,\,app}\right\}[H^+]t \quad (13)$$

In this system, Eq. 11 will be rewritten as:

$$Z=\frac{2.10[CeY^-]_0}{([Ce^{3+}]_0+2.10[CeY^-]_0)2\sqrt{\alpha^2-\beta}}\times(r_2e^{r_1t}-r_1e^{r_2t}+2\sqrt{\alpha^2-\beta}) \quad (14)$$

and the rate constants for the processes in Eq. 10 are expressed, respectively, as follows:

$$k_1=k'[OH^-]+2.10k''[H^+][CeY^-]_0/[Ce^{3+}]_0$$

$$k_2=\{k_{Ce,\,app}[CeY^-]_0/[Ce^{3+}]_0+k_{Pr,\,app}\}[H^+] \quad (15)$$

As Fig. 9 shows, the excellent agreement between the $^{144}PrY^-$-yield calculated by Eqs. 13 and 14 and the experimental values further supports the proposed decomposition process of the intermediate complex.

These results indicate that at least the intermediate can not be regarded as the EDTA complex, the chemical behavior of which is treated reasonably by Eq. 9 or Eq. 13. EDTA is a reducing agent, one which reduces permanganate, chromate and cerium(IV) ions in an acidic solution,[5] but EDTA bound in a metal complex is not oxidized by permanganate ions.[6] Recently, it has been found that the photodecomposition of acid aquoethylenediaminetetraacetatoferrate(III) produces both iron(II) ions by electron-transfer and carbon

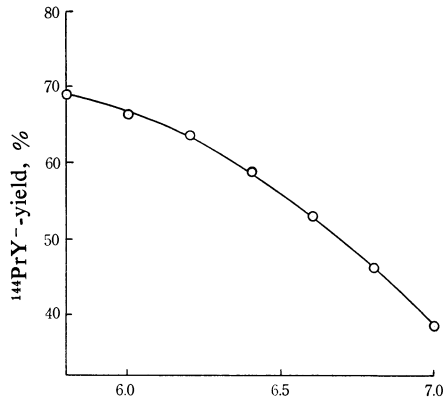

Fig. 9. The $^{144}PrY^-$-yield calculated by Eqs. 13 and 14.

The solid curve was calculated by Eqs. 13 and 14.

dioxide by the decarboxylation of a coordinated carboxylate group.[7] Schroeder and Hamm[4] also found that carbon dioxide and formaldehyde were produced in the case of the decomposition of the Mn(III)-EDTA complex. By taking into consideration the fact that the praseodymium(IV) ion is very unstable in solution, it is apparent that an intramolecular electron-transfer between the tetravalent praseodymium and the EDTA molecule will take place at the time of the $\beta^-$-decay of $^{144}Ce$ complexed with EDTA, as has been proposed in the previous paper.[2] The trivalent $^{144}Pr$ ion remains complexed with an oxidized EDTA radical, which is probably produced by the loss of one chelating carboxylate group; it does not escape from the molecule.

According to the formation constant of the cerium(III) acetate complex,[8] about 80 per cent of the cerium(III) ions complex with acetate ions under the experimental conditions. The tetravalent praseodymium produced by the $\beta^-$-decay of the $^{144}Ce$ acetate complex may be either reduced by the intramolecular electron-transfer or by the action of the surrounding substances. The reduced praseodymium(III) ion will escape easily from the molecule, because the acetate ion is a monodentate ligand and it forms labile complexes with praseodymium(III) ions. The process of the deactivation of the $^{144}Pr$ produced by the $\beta^-$-decay of $^{144}Ce$ is illustrated schematically in Fig. 10.

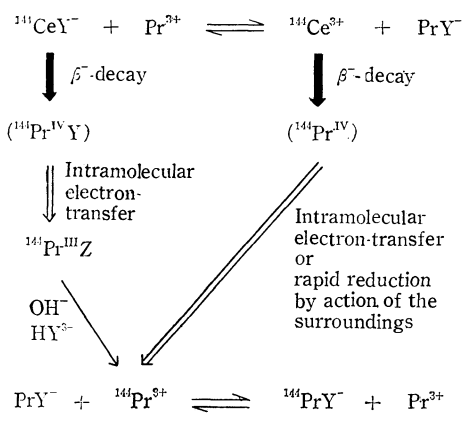

Fig. 10. De-activation proceses of $^{144}Pr$ atom produced by $\beta^-$-decay of $^{144}Ce$ in the EDTA complex system.

A satisfactory explanation for the experimental results can be offered on the assumption that all the decay events of the complexed $^{144}Ce$ lead to the formation of the intermediate. Nevertheless, the excited $^{144}Pr$ atoms may be stabilized by a different route; namely, the multiple charging due to internal conversion, at least in part, may cause an exhaustive decomposition, thus liberating the free $^{144}Pr$ ion. It must be noted, therefore, that the values obtained for the rate constants, $k'$ and $k''$, are not absolute, but include the various accompanying effects resulting from the $\beta^-$-decay process.

## Summary

The substitution reaction of $^{144}Ce$(III) ions with the $^{144}Pr$(III)-EDTA complex in an aqueous solution at 25°C has been investigated; the rate-determining step has been found to be the acid-catalyzed dissociation of the Pr(III)-EDTA complex.

On the basis of the above substitution mechanism, the chemical behavior of the $^{144}Pr$ atoms produced by the $\beta^-$-decay of $^{144}Ce$ has been satisfactorily explained in terms of a model which involves the formation of an intermediate complex. The kinetic treatment leads to the conclusion that the intermediate, produced as a results of an increase in the nuclear charge by the $\beta^-$-decay of the complexed $^{144}Ce$, is available for attack by hydroxide ions and protonated EDTA anions and, consequently, produces free $^{144}Pr$(III) ions.

The authors wish to thank Mr. Michio Hoshi* for his assistance in the experimental work.

# Studies of Hydrogenolysis. XLIX.[1] The Selective Hydrogenolysis of $\alpha, \beta$-Epoxyketones*1

By Sekio MITSUI, Yasuhisa SENDA, Takashi SHIMODAIRA*2 and Hiroshi ICHIKAWA*3

(Received March 6, 1965)

It has been reported that the mechanism of catalytic hydrogenolysis depends on the adsorbed state of organic compounds,[2] especially on the orientation of molecules at the catalyst surface which is in turn determined by the chemical and steric structure of the molecules and by the nature of the catalysts.[3,4] We can now report that some $\alpha, \beta$-epoxyketones have been hydrogenated to give isomeric products at room temperature and at atmospheric pressure with different catalysts.

When benzalacetophenone oxide (I)[5] was

hydrogenated with either palladium charcoal-A[6],*4 (abbr. Pd-C-A) or palladium charcoal-B[7],*4 (abbr. Pd-C-B), 2-hydroxy-1, 3-diphenylpropan-1-one (II) (m. p. 66°C)[8] was produced with absorption of one mole of hydrogen, and 1, 3-diphenylpropane-1, 2-diol (III and III') (III: m. p. 84.5°C, III': m. p. 70°C),[9] with the absorption of two moles of hydrogen. The catalytic hydrogenation of III with Pd-C-A, to which small portions of concentrated hydrochloric acid had been added, yielded 1, 3-diphenylpropan-2-ol (IV) (*p*-nitrobenzoate (m. p. 79°C)).[10] The Raney nickel hydrogenation of I gave 1, 3-diphenylpropane-1, 3-diol (V and V') (V, racemic isomers; m. p. 130°C. V', meso isomer, m. p. 97°C).[11] V was converted into 1, 3-diphenylpropane (VI) (b. p. 126°C/0.6 mmHg)[12] by hydrogenation over Pd-C-A which contained a small amount of concentrated hydrochloric acid. I was also hydrogenated with platinum oxide; in this case both III' and V were reaction products.

The NMR spectrum of I shows that the signals of the epoxide protons are a doublet at 4.06 p.p.m. and 4.27 p.p.m.[13] The coupling constant for these protons in I is 1.7 c.p.s. This epoxide is confirmed as the trans isomer by the published data for simple epoxides.[14] The structures of II, III, III', IV, V, V' and VI were confirmed by analyses of them and of their benzoates and *p*-nitrobenzoates (except the VI) and by a comparison of their physical properties with those reported in the literature.[8-10,11a,12]

Differences similar to those observed in the hydrogenation of I with different catalysts, were also found in the hydrogenation of *cis*-dypnone oxide (VII).[15] The hydrogenation of VII over Pd-C-A or Pd-C-B gave 1, 3-diphenylbutane-1, 2-diol (VIII) (m. p. 90°C), while over Raney nickel 1, 3-diphenylbutane-1, 3-diol (IX) (m. p. 91°C) was obtained. The structures of VIII and IX were confirmed by analyses and by the reaction with periodic acid.

On the other hand, when benzalacetone oxide (X)[16] was hydrogenated with Pd-C-A, the hydrogen uptake ceased after one mole of hydrogen had been absorbed and 3-hydroxy-4-phenylbutan-2-one (XI) (b. p. 93.5°C/0.75 mmHg)[17] was obtained. XI was hydrogenated to give 1-phenylbutane-2, 3-diol (XII) (b. p. 118°C/0.18 mmHg)[16] with Raney nickel. Similarly, the hydrogenation of X over Raney nickel gave mainly XI when one mole of hydrogen was absorbed and XII when two moles of hydrogen were absorbed.

The X formed from benzaldehyde and chloroacetone under normal Darzen condensation was confirmed to be the trans isomer by Kwart and Kirk.[18] The structures of XI and XII were established by analyses of the semicarbazone of XI (m. p. 179°C)[17] and di-*p*-nitrobenzoate of XII (m. p. 130°C) and by a comparison of several of their physical properties with those of an authentic sample of 1-hydroxy-1-phenylbutan-3-one (XIII) (b. p. 106°C/0.11 mmHg, semicarbazone; m. p. 173°C), prepared by the reaction of benzaldehyde with acetone.[19]

XI and XII were recovered unchanged when they were shaken with hydrogen over Pd-C-A containing a small amount of concentrated hydrochloric acid. This fact also supports the theory that XI and XII are not benzyl-type alcohols.

It has been shown by Herz[9c] that the catalytic hydrogenation of benzalacetophenone oxide (I) yielded two dihydroxydiphenylpropanes, which he considered to be the diastereoisomeric $\alpha$-glycols.[20] From the present results, it is obvious that, on the hydrogenation of I and VII, the two isomeric products resulting from the cleavage of the carbon-oxygen bonds of the epoxide ring at different position were obtained according to the species of the catalysts. On the other hand, on the hydrogenation of X, which includes an acetyl group instead of the benzoyl group in I and VII, the cleavage of the $\beta$-carbon-oxygen bond

20) H. E. Zimmerman and J. English, Jr. described in their work (Ref. 7a) that one of the diastereoisomeric $\alpha$-glycols, the 128° compound derived from benzalacetophenone oxide which was reported by W. Herz was assigned to 1, 3-diphenyl-1, 3-propanediol.

occurred irrespective of the kind of catalyst, giving an $\alpha$-hydroxyketone.

We have reported that the hydrogenolysis of optically active benzyl-type alcohols and alkyl ethers took different courses of reaction according to the species of the catalysts; it is considered that, on hydrogenolysis over Raney nickel, hydrogen may attack the asymmetric carbon atom from the same direction as the C*–O bond and that the reaction may proceed with the retention of the original configuration. On the other hand, over palladium catalyst the hydrogen may attack from behind the C*–O bond and the reaction may proceed with an inversion of the configuration; this would be caused by the differences, in the affinities of the catalysts for the oxygen atom.[3,4]

By taking account of the different properties of the nickel and palladium catalysts mentioned above, together with the consideration that the phenyl group may be adsorbed more strongly on the surface of the catalyst than the acetyl group, the adsorbed states of X on the catalyst may be assumed to be as shown in Figs. 1 and 2; it may also be assumed that the hydrogen adsorbed on the surface of the catalyst may attack the $\beta$-carbon atom.

On the other hand, as it is considered that the benzoyl group may be adsorbed more strongly than the phenyl group on the surface of the catalyst by means of its $\pi$ and lone-pair electrons of the carbonyl group, the adsorbed states of I and VII may be assumed to be as shown in Figs. 1 and 3. On this occasion, the surface-adsorbed hydrogen may attack the $\beta$-carbon atom, in the case of Fig. 1, and the $\alpha$-carbon atom, in the case of Fig. 3 so that in each case the corresponding products are obtained on the hydrogenation of I and VII. Besides, it may also be assumed that the hydrogenation of I, VII and X proceeds with a carbonium ion mechanism[2] (Fig. 4) to give $\alpha$-hydroxyketones; however, it is not possible to conclude whether or not this mechanism is responsible.

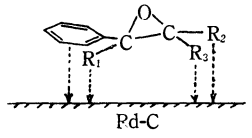

Fig. 1.

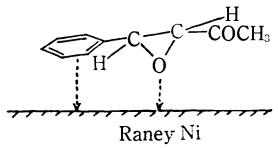

Fig. 2.

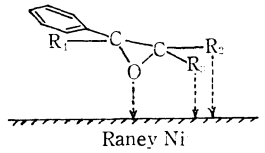

Fig. 3.

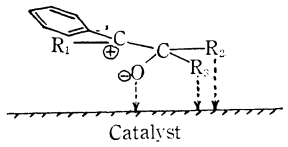

Fig. 4.

I: $R_1=H$, $R_2=H$, $R_3=COC_6H_5$
VII: $R_1=CH_3$, $R_2=COC_6H_5$, $R_3=H$
X: $R_1=H$, $R_2=H$, $R_3=COCH_3$

These considerations are also supported by the following experimental evidence: Optically-active $\alpha$-methyl or $\alpha$-ethylstyrene oxide was hydrogenolyzed, with the retention of the original configuration over Raney nickel and with an inversion over palladium charcoal, to give corresponding optically-active products.[21] On the hydrogenolysis of *trans*-dimethylstilbene oxide, the reaction products were *erythro*-2, 3-diphenylbutan-2-ol over palladium charcoal and the threo isomer over Raney nickel.[22]

The experimental results of the platinum oxide hydrogenation suggest that it possesses the characteristics of both nickel and palladium.

## Experimental

**Starting Material.**—$\alpha,\beta$-Epoxyketones (I,[5] VII[15] and X[16]) were prepared by the procedures reported in literatures.

**Catalytic Hydrogenation.**—The following general procedure was used. 1/100 mol. of the compounds, 0.2 g. of Pd-C or 1 g. of Raney nickel and 100 ml. of ethanol were stirred into hydrogen at an ordinary temperature and at atmospheric pressure. After the theoretical amount of hydrogen had been absorbed, the catalyst was filtered out and the ethanol was distilled off.

*Benzalacetophenone Oxide (I) over Pd-C (with 1 mol. of Hydrogen).*—The residue was recrystallized from ligroin to give 2-hydroxy-1,3-diphenylpropan-1-one (II) in an 86% yield. The melting point was 66°C.

Found: C, 79.41; H, 6.28. Calcd. for $C_{15}H_{14}O_2$: C, 79.62; H, 6.19%.

*Benzalacetophenone Oxide (I) over Pd-C (with 2 mol. of Hydrogen).*—The residual sirup was dissolved in hot ligroin and then cooled in an ice bath. Isomer-A-rich crystals of 1,3-diphenylpropane-1,2-diol were obtained (m. p. 65—77°C); they were

21) S. Mitsui and S. Imaizumi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **86**, 219 (1965); *Chem and Ind.*, in press.
22) S. Mitsui and Y. Nagahisa, Presented at the 15th Symposium of Reaction Mechanism of Organic Compounds, Nagoya, October, 1964.

then recrystallized from ligroin to give the pure isomer-A (III) in a 59% yield (m. p. 85°C). When the mother liquor was concentrated and also cooled in an ice bath, isomer-B-rich crystals of 1,3-diphenylpropane-1,2-diol were obtained; they were recrystallized from ligroin to give the pure isomer-B (III') in a 7% yield (m. p. 70°C).

Found (for III): C, 78.83; H, 7.63. Calcd. for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%. Found (for III'): C, 78.81; H, 7.29. Calcd. for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%.

The dibenzoate of III melted at 157°C.

Found: C, 79.66; H, 5.33. Calcd. for $C_{29}H_{24}O_4$: C, 79.79; H, 5.54%.

*Benzalacetophenone Oxide (I) over Raney Nickel.*—The residual sirup was dissolved in a hot benzene-ligroin (1:1) mixture and then cooled in an ice bath. Crystals rich in the racemic isomer of 1,3-diphenylpropane-1,3-diol were obtained; they were recrystallized from ligroin to give the pure racemic isomer (V) in a 40% yield (m. p. 130°C). The mother liquor was concentrated and also cooled in an ice bath. Crystals rich in the meso isomer of 1,3-diphenylpropane-1,3-diol were obtained; they were recrystallized from ligroin to give the pure meso isomer (V') in 24% yield (m. p. 97°C).

Found (for V): C, 79.17; H, 7.22. Calcd. for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%. Found (for V'): C, 78.83; H, 7.35. Calcd. for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%.

The dibenzoate of V melted at 123—124°C.

Found: C, 79.61; H, 5.56. Calcd. for $C_{29}H_{24}O_4$: C, 79.79; H, 5.54%.

*Benzalacetophenone Oxide (I) over Platinum(IV) Oxide.*—The residual sirup was dissolved in hot petroleum benzine and then cooled to room temperature. The crystals obtained were recrystallized from petroleum benzine to give pure V in a 40% yield (m. p. 130°C). The mother liquor was concentrated to give III' in a 47% yield (m. p. 70°C).

*cis-Dypnone Oxide (VII) over Pd-C.*—The residue was recrystallized from a benzene-petroleum ether (1:1) mixture to give pure 1,3-diphenylbutane-1,2-diol (VIII) in a 70% yield. The melting point was 90°C.

Found: C, 79.21; H, 7.21. Calcd. for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

*cis-Dypnone Oxide (VII) over Raney Nickel.*—The residue was recrystallized from a benzene-petroleum ether (1:1) mixture to give pure 1,3-diphenylbutane-1,3-diol (IX) in a 50% yield. The melting point was 91°C.

Found: C, 79.72; H, 7.49. Calcd. for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

The mixed melting point of VIII and IX was 62—65°C.

*Benzalacetone Oxide (X) over Pd-C.*—The residual oil was distilled under reduced pressure to give 3-hydroxy-4-phenylbutane-2-one (XI) in an 88% yield (b. p. 93.5°C/0.75 mmHg). XI was identified as the semicarbazone (m. p. 174°C).

Found: C, 59.72; H, 7.35; N, 19.26. Calcd. for $C_{11}H_{15}O_2N_2$: C, 59,71; H, 6.83; N, 18.99%.

The mixed melting point of the semicarbazone of XI and of 1-hydroxy-1-phenylbutan-3-one (XIII) was 162—163.5°C.

*Benzalacetone Oxide (X) over Raney Nickel.*—The residual sirup was distilled under reduced pressure to give 1-phenylbutane-2,3-diol (XII) in a 72% yield (b. p. 118°C/0.18 mmHg), and di-*p*-nitrobenzoate, which melted at 130°C and which was recrystallized from ethanol.

Found: C, 62.00; H, 4.28; N, 5.93. Calcd. for $C_{24}H_{20}O_8N_2$: C, 62.06; H, 4.34; N, 6.03%.

*3-Hydroxy-4-phenylbutan-2-one (XI) over Raney Nickel.*—The residual sirup was distilled under reduced pressure to give 1-phenylbutane-2,3-diol (XII) in a 79% yield (b. p. 118°C/0.17 mmHg), and di-*p*-nitrobenzoate, which was recrystallized from ethanol and which melted at 129°C.

Found: C, 62.24; H, 4.38; N, 5.94. Calcd. for $C_{24}H_{20}O_8N_2$: C, 62.06; H, 4.34; N, 6.03%.

The mixed melting point of the di-*p*-nitrobenzoates of XII which was obtained by the hydrogenation of XI over Raney nickel and of X over Raney nickel remained undepressed.

*1,3-Diphenylpropane-1,2-diol (III) over Pd-C-A Containing Three Micro Drops of Concentrated Hydrochloric Acid.*—The residual oil was distilled under reduced pressure to give 1,3-diphenylpropan-2-ol (IV) in a 67% yield (b. p. 130—140°C/0.5 mmHg). The *p*-nitrobenzoate, which was recrystallized from ethyl acetate, melted at 79.5°C.

*1,3-Diphenylpropane-1,3-diol (V) over Pd-C-A Containing Three Micro Drops of Concentrated Hydrochloric Acid.*—The residual oil was distilled under reduced pressure to give 1,3-diphenylpropane (VI) in a 50% yield (b. p. 126—127°C/0.6 mmHg).

Found: C, 91.29; H, 8.19. Calcd. for $C_{15}H_{16}$: C, 91.78; H, 8.22%.

The infrared spectrum of VI showed that $\nu_{OH}$ vanished completely.

**1-Hydroxy-1-phenylbutan-3-one (XIII).**—XIII was prepared from acetone and benzaldehyde by the alkaline condensation reported by Noyce and Reed.[18] B. p. 106°C/0.11 mmHg; semicarbazone, m. p. 180—181.5°C.

Found: C, 59.91; H, 6.47; N, 18.84. Calcd. for $C_{11}H_{15}O_2N_2$: C, 59.71; H, 6.83; N, 18.99%.

**Periodic Acid Oxidation.**—This experiment was carried out by the method of Jackson.[23] Sample VIII consumed 1.09 equivalents of periodic acid, while sample IX did not consume any at all, after three hours of mixing diols with periodic acid.

The derivatives, such as benzoate, *p*-nitrobenzoate and semicarbazone, which are mentioned above were prepared by the usual procedure.

The authors are indebted to Misses Ayako Iwanaga and Mutsuko Suzuki and Mrs. Hide Arai of the Department of Chemistry of this University for their elementary microanalyses. They wish also to thank Dr. Shin-ichi Sasaki of the Department of Chemistry of this University for his kindness in measuring the infrared and NMR spectra.

# Some Acetylene Complexes of Vanadium*

By Ryuichiro TSUMURA** and Nobue HAGIHARA

(Received March 8, 1965)

It was previously reported[1] that $\pi$-dicyclopentadienyl-vanadium causes the catalytic polymerization of various acetylenes. Much attention was then drawn to a possible isolation of acetylene complexes of vanadium in an effort to elucidate the catalysis of the vanadium complex, which seems to be different from that of such nickel compounds as $(PPh_3)_2Ni(CO)_2$[2] and $NiCl_2 \cdot 2PPh_3$[3] in the catalytic polymerization of acetylenes. We will now report on the preparation, some properties and a proposed structure of some new acetylene complexes of vanadium, such as $\pi$-$C_5H_5(RC_2H)V(CO)_2$, prepared from the reactions of $\pi$-cyclopentadienyl-vanadium tetracarbonyl[4] with several acetylenes. The infrared and nuclear magnetic resonance spectra of the acetylene complexes are used as the basis of discussion of their structure and of the type of bonding by which the acetylenes may be bonded to metal. Regarding the bonding of the acetylenes to vanadium, the acetylene complexes described here are probably related to an intermediate in the catalytic polymerization mentioned above. Although a wide variety of acetylene complexes of such transition metals as manganese,[5,6] iron,[7] cobalt,[7-9] nickel,[7,9,10] tungsten,[11] and platinum[6,12,13] have been reported, some acetylene complexes described here are the first examples of vanadium.

## Preparation and Properties

$\pi$-Cyclopentadienyl-vanadium tetracarbonyl[4] (I) reacted with pressured acetylene in benzene near room temperature under the influence of the irradiation of light from a tungsten lamp. The reaction solution turned from orange to green to form an acetylene complex. Similar photochemical reactions of I with an excess of such 1-alkynes as 1-pentyne, 1-hexyne and *t*-butylacetylene proceeded with the evolution of approximately 2 mol. of carbon monoxide per atom of vanadium present and gave green acetylene complexes. On the other hand, in the interactions of an excess of I with 1-alkynes 2 mol. of carbon monoxide per mole of the alkynes present were evolved, and also the corresponding acetylene complexes were obtained. It is, therefore, reasonable to assume from these facts and from the results of the elemental and spectroscopic analyses to be described later, that the resulting compounds are acetylene complexes of vanadium (II) in which two carbonyl groups of the starting material, I, have been replaced by the corresponding acetylene molecule by the following reaction:

$$\underset{(I)}{\pi\text{-}C_5H_5V(CO)_4} + RC{\equiv}CH \xrightarrow{h\nu} \underset{(II)}{\pi\text{-}C_5H_5(RC_2H)V(CO)_2} + 2CO$$

(R=H, $n$-$C_3H_7$, $n$-$C_4H_9$ and $(CH_3)_3C$)

Acetylene complexes of vanadium II were purified through chromatography over alumina, followed by vacuum distillation. They are either viscous oils or low melting solids which crystallize spontaneously on cooling. All of them are quite sensitive to air, so they must be handled under oxygen-free nitrogen. These properties make it difficult to obtain satisfying values from the elemental analyses. The acetylene complexes II are easily soluble in most organic solvents. Their infrared and nuclear magnetic resonance spectra are shown in the Experimental section and in Table I respectively, together with some assignments.

TABLE I. NMR SPECTRA OF ACETYLENE COMPLEXES OF VANADIUM II[a]

| Compound[b] | Solvent | Band position ($\tau$)[c,d] | | | | |
|---|---|---|---|---|---|---|
| | | $\pi$-$C_5H_5$- | $HC_2$- | $-C_2CH_2$- | $-CH_2$- | $-CH_3$ |
| M($HC_2H$) | $CCl_4$ | 4.46(s)[e] | 4.92(s) | | | |
| | $C_6H_6$ | 4.88(s) | 5.63(s) | | | |
| M($HC_2C_3H_7$) | $CHCl_3$ | 4.50(s) | 4.93(s) | 6.61(t)[e] | 8.18(m)[e] | 9.01(t) |
| M($HC_2C_4H_9$) | $C_6H_6$ | 4.78(s) | 5.60(s) | 6.46(t) | 8.37(m) | 9.01(t) |
| M($HC_2CMe_3$) | $CCl_4$ | 4.48(s) | 4.90(s) | | | 8.76(s) |
| | $CHCl_3$ | 4.45(s) | 4.90(s) | | | 8.73(s) |

a) Measured at 60 Mc./sec. at room temperature.
b) M = $\pi$-$C_5H_5V(CO)_2$.
c) Relative to $SiMe_4$ ($\tau$ = 10) as the internal standard.
d) The relative intensities were essentially consistent with those to be expected from the assigned structure. The decomposition during the measurements sometimes also showed complex spectra containing absorptions of free acetylene molecules.
e) (s), (t) and (m) indicate multiplicity, singlet, triplet and complex multiplets respectively.

Attempts to make the complex I interact with phenylacetylene and tolane were made in order to obtain more stable and higher melting acetylene complexes than the complex II itself. The reactions occurred with the evolution of carbon monoxide and presumably formed the corresponding acetylene complexes of vanadium, but their isolation was unsuccessful because of the great difficulty of purifying them. Seeking to obtain a more stable and crystalline acetylene complex, we have investigated the preparation of a complex in which at least one of the two remaining carbonyl groups of the acetylene complexes II obtained above is replaced by triphenylphosphine.

The photochemical reaction of the carbonyl compound I with triphenylphosphine in a benzene solution at room temperature proceeded quantitatively, with the evolution of a mole of carbon monoxide equal to the mole of the vanadium compound present, and it gave orange crystals of a mono-substituted product (III) by the following reaction:

$$\pi\text{-}C_5H_5V(CO)_4 + PPh_3 \xrightarrow{h\nu} \pi\text{-}C_5H_5V(PPh_3)(CO)_3 + CO$$
(III)

The phosphine derivative III is completely air-stable in the solid state, and it is only slowly oxidized by air in solutions; these characteristics indicate that the stability of the new compound III is higher than that of I. It is fairly soluble in hot benzene and carbon tetrachloride, but poorly soluble in *n*-hexane, ethers and alcohols.

The reaction between III and tolane gave yellow crystals of the expected acetylene complex (IV):

$$\pi\text{-}C_5H_5V(PPh_3)(CO)_3 + PhC{\equiv}CPh \xrightarrow{h\nu} \pi\text{-}C_5H_5(PhC_2Ph)V(PPh_3)(CO) + 2CO$$
(IV)

The tolane complex IV could be recrystallized from *n*-hexane in a careful operation, though it is still sensitive to air. It is easily soluble in most organic solvents in the same manner as is II.

## Discussion

In general, acetylenes are known[14] to give many kinds of organometallic complexes upon reaction with transition metal carbonyl compounds. On the basis of the chemical and physical properties of the acetylene complexes of vanadium reported here, it is clear that they are monomeric compounds obtained through the replacement of two carbonyl groups in the complex I by the acetylene, and that the acetylene molecule is bonded to a single vanadium atom as a bidentate ligand. On the other hand, there are some examples of the $\pi$-bonding of acetylenes as monodentate ligands through a single electron pair of their triple bond to a metal, for instance, in such manganese complexes as $\pi$-$C_5H_5(PhC_2Ph)$-$Mn(CO)_2$,[5] which is prepared from the reaction of $\pi$-cyclopentadienyl-manganese tricarbonyl with tolane. It is very interesting that the bonding of acetylenes to the vanadium atom is assumed to be different from that in the manganese complexes even though the same types of acetylene complexes are derived from the similar reaction of $\pi$-cyclopentadienyl-metal carbonyl compounds with acetylenes.

The infrared spectra of all of the acetylene complexes II indicate that the wave numbers of the two carbonyl bands are a little smaller than those in the original compound, I, as a result of the replacement of two carbonyl groups in I by the acetylene. The infrared

14) M. A. Bennet, *Chem. Revs.*, **62**, 611 (1962); R. G. Guy and B. L. Shaw, "Advances in Inorganic Chemistry and Radiochemistry," Vol. 4, Academic Press Inc., New York (1962), p. 78.

spectra of the alkyne complexes II (R=alkyl) showed no absorptions in the region of 3300 $cm^{-1}$ due to the presence of the acetylenic hydrogen atoms and of the band at 2100 $cm^{-1}$ arising from the stretching vibrations of the terminal triple bonds. The lack of the characteristic absorptions of 1-alkynes suggests that their triple bond nature is weakened in the acetylene complexes. The stretching absorptions of the coordinated acetylenic bond are reported to be situated at 1919 $cm^{-1}$ in the manganese complex, $\pi$-$C_5H_5(CF_3C_2CF_3)Mn(CO)_2$,[6] in which the acetylene is merely acting as a donor. In contrast, they have been found in the 1700 $cm^{-1}$ region in such complexes of platinum, rhenium and tungsten as $(RC_2R)Pt(PPh_3)_2$,[12] $(PhC_2H)_2ReCl$,[15] and $(RC_2R)_3W(CO)$[11] respectively, in which the acetylenes are considered to be $\sigma$-bonded or doubly $\pi$-bonded to the metal, apparently as a bidentate ligand. In the vanadium compounds II, however, it was impossible to assign any band to the stretching vibration of the coordinated multiple bond with certainty. The two broad, strong absorptions of the carbonyls could also be presumed to cover the absorption band in question.

The nuclear magnetic resonance spectra of the acetylene complexes II given in Table I indicate what the property of the coordinated acetylenic bond might be. All of the compounds II possess essentially the same chemical shifts for the acetylenic hydrogens, at $\tau$ 4.9 in carbon tetrachloride and chloroform or at $\tau$ 5.6 in benzene. In carbon tetrachloride and chloroform, the spectra of the acetylenic protons of the coordinated acetylenes are shifted about $\tau$ 2.7 toward the lower-magnetic field than those of the corresponding free acetylenes; they are thus located in the region of olefinic protons. As a result of the coordination of the acetylenes to vanadium metal, the chemical shift of the acetylenic hydrogens is expected to be mainly influenced by a diamagnetic effect due to d-electrons of the metal on the one hand, and, on the other hand, by a paramagnetic effect which is brought about through the loss of the diamagnetic anisotropy of the triple bond. In this case, the great paramagnetic shift observed might be presumed to result from the more remarkable effect of the latter than the former.

These facts, consistent with the results of the infrared spectra described above, suggest that the triple bond of the acetylenes in II may be reduced effectively to a double bond by their bonding to vanadium metal. The higher shielding of the acetylenic protons in benzene than that in the other chlorinated hydrocarbons may be considered to result from a solvent effect due to the remarkable diamagnetic anisotropy and plane form of the benzene molecule. Such a shielding due to the solvent effect of benzene is seen also in the chemical shifts of the cyclopentadienyl ring protons, though it is not so great as in those of the acetylenic hydrogens. A comparison of the spectra in the different solvents tested indicates that of all kinds of hydrogens present in the acetylene complexes II, the acetylenic protons are affected by solvents most sensitively.

On the basis of these experimental results, various possible structures of the acetylene complexes of vanadium II might be considered: The structure formulated in Fig. 1(A), in which the acetylene is $\pi$-bonded to the metal by only a single $\pi$-electron pair, as in the above-mentioned complexes[5,6] of manganese; the structure presented in Fig. 1(B), in which the acetylenic carbon atoms are substantially rehybridized toward the $sp^2$ configuration and the acetylene is bonded to the metal through two $\sigma$-bondings, as in the above-described complexes of platinum[12] and rhenium[15], and a possible intermediate structure, one between structures A and B.

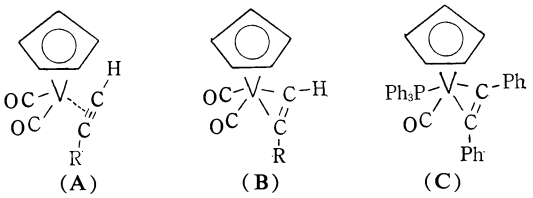

Fig. 1. Acetylene complexes of vanadium.

It may be concluded from the experimental evidence that the most probable structure of the vanadium complexes II is consistent with, or at least near, structure B, even if it may be intermediate between structures A and B. The tolane complex IV prepared from the phosphine derivative III is presumed in the same way to have the structure given in Fig. 1(C).

In the catalysis of dicyclopentadienyl-vanadium for the polymerization of acetylenes, it appears reasonable to assume that the polymerization proceeds through the initial formation of an acetylene complex in which the acetylene molecule is bonded to a vanadium atom by a bonding similar to that in the structure B of the isolated complexes II.

Further investigation has led to the successful preparation of a few acetylene complexes in which an acetylene molecule is probably $\sigma$-bonded to a vanadium metal, one simultaneously having two coordinated cyclopentadienyl

15) R. Colton, R. Levitus and G. Wilkinson, *Nature*, **186**, 233 (1960).

rings. The findings on such acetylene complexes will be soon presented elsewhere.

## Experimental

All preparations, chromatographic separations, distillations and analytical measurements were carried out under an atmosphere of dry, oxygen-free nitrogen or in a vacuum. Solvents were distilled and saturated with nitrogen before use. All melting points are uncorrected.

**Preparation.** —*π-Cyclopentadienyl - acetylene - vanadium Dicarbonyl.*—In a 70ml. glass autoclave acetylene was pressured into a solution of 0.58 g. (2.5 mmol.) of π-cyclopentadienyl-vanadium tetracarbonyl[4] (I) in 30 ml. of benzene up to about 5 kg./cm². The resultant orange solution was irradiated with a 500 W. tungsten lamp for ca. 4 hr. while being cooled with running water; it thus turned dark green and had an evolution of small bubbles from the bottom of the vessel. After the solvent had been removed at room temperature, the oily residue was chromatographed over alumina which had been treated with nitrogen before use. The elution of the column with benzene gave, at first, a light orange solution of the unchanged material I and then a clear green solution. When the green fraction was concentrated in vacuo at room temperature, a green oil was left; this was then distilled in 0.1 mmHg at ca. 70°C. The resulting green viscous distillate crystallized spontaneously upon being cooled, yielding 0.10 g. of green crystals, m. p. 27—30°C.

Found: C, 55.7; H, 3.7; mol. wt. (cryoscopic in benzene), 183. Calcd. for $C_9H_7O_2V$: C, 54.6; H, 3.6%; mol. wt., 198.

The yield of the isolation procedure virtually depended upon the decomposition of the product during the manipulations. The discrepancy in the elemental analysis for the acetylene complex may be due to the instability of the complex, which could not be purified by recrystallization.

*π-Cyclopentadienyl-(1-pentyne)-vanadium Dicarbonyl.*—Into a 100 ml. fiask connected to a gas-measuring vessel a solution of 0.815 g. (3.57 mmol.) of I in 30 ml. of benzene and 2.0 ml. of 1-pentyne was placed. The reaction system was then magnetically stirred and irradiated with a tungsten lamp while being cooled with running water. The color of the solution gradually turned from orange to green, and was a gas evolved. Irradiation was continued for 8 hr., until the evolution of the gas had ceased. The carbon monoxide evolved amounted to approximately 165 ml. (7.05 mmol.). The reaction mixture was then chromatographed and distilled as has been described above, yielding 0.35 g. of a green oil.

Found: C, 61.0; H, 5.6. Calcd. for $C_{12}H_{13}O_2V$: C, 60.0; H, 5.5%.

*π-Cyclopentadienyl-(1-hexyne)-vanadium Dicarbonyl and π-Cyclopentadienyl-(t-butylacetylene)-vanadium Dicarbonyl.*—A mixture of I and the 1-alkyne in benzene was treated in the manner described for the pentyne complex.

Hexyne gave a green oil of the acetylene complex.

Found: C, 62.1; H, 6.3. Calcd. for $C_{13}H_{15}O_2V$: C, 61.4; H, 6.0%.

Tertiary butylacetylene gave green crystals of the acetylene complex, m. p. 31—32°C.

Found: C, 62.0; H, 5.9; CO, 21.7. Calcd. for $C_{13}H_{15}O_2V$: C, 61.4; H, 6.0; CO, 22.0%.

*π-Cyclopentadienyl-triphenylphosphine-vanadium Tricarbonyl.*—A mixture of 5.85 g. (25.5 mmol.) of I and 7.02 g. (26.8 mmol.) of triphenylphosphine, dissolved in 80 ml. of benzene, was photochemically treated in a manner similar to that described above. A gas evolved smoothly, and fine orange crystals separated. Irradiation was then continued for about 15 hr., until the evolution of the gas almost ceased. The carbon monoxide evolved amounted to 570 ml. (24.4 mmol.). The reaction mixture was then filtered, and the precipitate washed well with cold benzene and dried under reduced pressure to yield 9.40 g. (87.8%) of orange crystals of a mono-substituted product III, m. p. 160—161°C.

Found: C, 67.38; H, 4.53; V, 11.23. Calcd. for $C_{26}H_{29}O_3PV$: C, 67.55; H, 4.36; V, 11.02%.

Furthermore, 0.50 g. of III was recovered by recrystallization from the orange filtrate.

*π-Cyclopentadienyl - tolane - triphenylphosphine - vanadium Carbonyl.*—A mixture of 0.658 g. (1.42 mmol.) of III and 0.267 g. (1.49 mmol.) of tolane in 50 ml. of benzene was worked up in the same way. The carbon monoxide evolved amounted to 50 ml. (2.14 mmol.), though there was a slower evolution of the gas. The reaction mixture was then evacuated and chromatographed over alumina with benzene, and the resulting yellow-green eluate was evaporated to dryness under reduced pressure. The residue was recrystallized from *n*-hexane at the temperature of dry ice to yield 0.25 g. of a yellow crystalline powder, m. p. 35—37°C.

Found: C, 78.02; H, 5.35; mol. wt. (cryoscopic in benzene), 559. Calcd. for $C_{38}H_{30}OPV$: C, 78.08; H, 5.17%; mol. wt., 584.

**Infrared Spectra.** — Measurements were made with a Hitachi EPI-2 spectrophotometer. The spectra and some assignments are shown below:

## Summary

Some acetylene complexes of vanadium of the $\pi$-$C_5H_5(RC_2H)V(CO)_2$ (R=H, *n*-$C_3H_7$, *n*-$C_4H_9$ and $(CH_3)_3C$) and $\pi$-$C_5H_5(PhC_2Ph)V(PPh_3)(CO)$ types have been prepared by the photochemical reaction of the corresponding acetylene with $\pi$-cyclopentadienyl-vanadium tetracarbonyl and its phosphine derivative respectively. It has been proposed, on the basis of their infrared and nuclear magnetic resonance spectra, that the acetylene complexes of vanadium have a structure in which the acetylene molecule is bonded via two $\sigma$-bondings to a vanadium atom.

We wish to thank Mr. Shibano of our laboratory for his elemental analyses, and Mr. Ishikawa and Mr. Naoki, Faculty of Science, Osaka University, for their spectroscopic measurements.

# The Preparation and Polymerization of Divinyl Carbonate*

By Shunsuke MURAHASHI, Shun'ichi NOZAKURA, Saburo FUJI and Kiyoshi KIKUKAWA

(Received March 15, 1965)

Since Butler[1] found the principle of the intra-inter polymerization of divinyl compounds, many divinyl compounds have been reported to undergo cyclopolymerization, yielding soluble polymers.

Divinyl carbonate seems, considering its structural analogy to divinyl thiocarbonate,[2] to be a monomer with the possibility of cyclopolymerization. The hydrolysis of the cyclized polymer might yield polyvinyl alcohol, which in turn might show some features of the cyclopolymer with stereoregularity.[3] The present study started from such point of view.

Divinyl carbonate has not previously been successfully prepared. In the present paper we wish to report the synthesis of divinyl carbonate and its polymerization, emphasis being laid on the cyclopolymerization of the monomer under various conditions. The identification of cyclic units in the polymer and the estimation of the degree of cyclization have been made by means of infrared analysis based on the study of model compounds.

## Experimental

**The Preparation of Divinyl Carbonate.**—Divinyl carbonate was synthesized by the reaction of mercuridiacetaldehyde with phosgene in tetrahydrofuran. A mixture of 220 g. of mercuridiacetaldehyde,[4] 150 ml. of tetrahydrofuran, and 0.5 g. of hydroquinone was placed in a 500 ml. three-necked flask equipped with a reflux condenser with a calcium chloride tube, a stirrer and a glass gas inlet tube, the flask was then cooled with an ice bath. Phosgene (29 ml.), which had been condensed in a graduated trap cooled in a dry ice-acetone bath, was gradually evaporated through a phosphorus pentoxide tube into the flask while its contents were being stirred. The flask was then kept at 0°C for 1 hr. while being stirred, kept at room temperature for another hour, and then warmed slowly up to 60°C. The reaction, which was not complete at 0°C, yielded vinyl chlorocarbonate as a main product. The volatile components of the reaction mixture were collected by vacuum distillation at room temperature, and then the distillate was subjected to fractional distillation at reduced pressure using a fractional column of about 30 theoretical plates. The yield was 17 g., 40% based on mercuridiacetaldehyde. Colorless liquid, b. p. 103.5—104.5°C, 49.0—49.2°C/98 mmHg, m. p. −38.0—−38.5°C, $n_D^{25}$ 1.4135, $d_4^{25}$ 1.0095.

Found: C, 51.92; H, 5.22. Calcd. for $C_5H_6O_3$: C, 52.63; H, 5.25%.

**The Synthesis of Carbonates.** — Trimethylene carbonate was prepared by a known method[5] from 45 g. of diethyl carbonate, 25 g. of 1,3-propanediol and 0.2 g. of sodium. B. p. 115—116°C/2 mmHg; m. p. 47.0—47.5°C (recrystallized from ether). Yield 27%.

2,3-Butanediol cyclic carbonate was prepared from 25 g. of 2,3-butanediol, 45 g. of diethyl carbonate and 0.1 g. of sodium. The mixture was then heated for 5 hr. at 120°C, the ethanol thus formed being distilled through a Vigreux column. After the distillation of ethanol had ceased, the reaction mixture was distilled under reduced pressure twice, thus yielding 19 g. of the product (60%), b. p. 78—79°C/4 mmHg.

Found: C, 51.78; H, 6.88. Calcd. for $C_5H_8O_3$: C, 51.72; H, 6.89%.

2,4-Pentanediol cyclic carbonate was prepared in a manner similar to that used for 2,3-butanediol cyclic carbonate, using 10 g. of 2,4-pentanediol, 15 g. of diethyl carbonate and 0.1 g. of sodium. The yield was 7 g. (54%). B. p. 129—130°C/7 mmHg, m. p. 12.5—13.0°C.

Found: C, 55.37; H, 7.78. Calcd. for $C_6H_{10}O_3$: C, 55.39; H, 7.75%.

For the preparation of ethyl vinyl carbonate, a mixture of 60 g. mercuridiacetaldehyde, 15 g. of ethyl chlorocarbonate and 30 ml. of tetrahydrofuran was stirred in a three-necked flask equipped with a reflux condenser and a stirrer, first at room temperature for several hours, and then at gradually increased temperatures up to 65°C. The volatile component of the reaction mixture was collected in a trap cooled by a dry ice - acetone bath in a vacuum, and then fractionally distilled, yielding 11 g. of the product (69%), b. p. 71—72°C/176 mmHg.

Found: C, 50.98; H, 6.75. Calcd. for $C_5H_8O_3$: C, 51.72; H, 6.89%.

Propylene carbonate, a commercial product, was used after distillation and the gas chromatographic comfirmation of its purity.

The solvents for the polymerization experiments were purified by standard procedures.

**Polymerization.**—An ampoule containing a monomer, a solvent and benzoylperoxide (0.5 mol.% of the monomer) or 2,2'-azobisisobutyronitrile was degassed three times in a high-vacuum manipulation and then sealed. Polymerization was carried out in a thermostat at 60±0.05°C.

In the photo-sensitized polymerization, a solution of the monomer and 2,2'-azobisisobutyronitrile in benzene was irradiated with a ultraviolet lamp (Toshiba SHL 100-UV) in a vacuum, using a vessel with a fused silica window.

After polymerization, a small amount of an inhibitor, *p-t*-butylcatechol, was introduced into the polymerization mixture, and then the residual monomer and the solvent are stripped in a vacuum at room temperature. The residual crude polymer was treated with acetone. The acetone-soluble fraction was precipitated with petroleum ether. In some experiments the polymerization mixture was poured into a large amount of hexane, yielding a precipitate of the polymer. The polymer was dried at room temperature in vacuo.

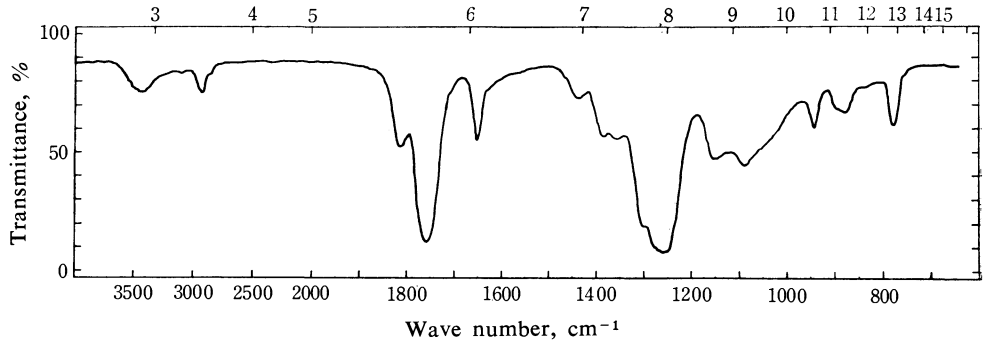
A typical example of the analysis of the polymer is shown below for the sample of Exp. No. 1 in Table V.

Found: C, 52.61; H, 5.29. Calcd. for $C_5H_6O_3$: C, 52.62; H, 5.31%.

**Infrared Spectra.**—The absorption coefficients of the model compounds were determined in chloroform, as it was confirmed that the Lambert-Beer law was applicable at concentrations from 0.02 to 0.5 mol./l. The infrared spectra of the polymer were taken by the KBr-tablet method.

## Results

**The Infrared Analysis of the Polymer Structure.**—An infrared spectrum of the polymer, shown in Fig. 1, has two carbonyl absorptions, at 1810 and 1760 $cm^{-1}$, and a double bond absorption at 1660 $cm^{-1}$. To identify these absorptions, the infrared spectra of model compounds were studied, they are listed in Table I. It can there be seen that the band at 1810 $cm^{-1}$ in the polymer corresponds to 2,3-butanediol cyclic carbonate (1810) and closely corresponds to propylene carbonate (1800), thus indicating that the 1810 band may be due to the presence of a 5-membered carbonate. The band at 1760 $cm^{-1}$ of the polymer corresponds to 2,4-pentanediol cyclic carbonate (1750), trimethylene carbonate (1755), and also to ethyl vinyl carbonate (1760), indicating that this band may originate from the unsaturated carbonate of 1,2-addition type, presumably being overlapped with a 6-membered cyclic carbonate. Thus, the structure of the polymer may be represented by Formula I:



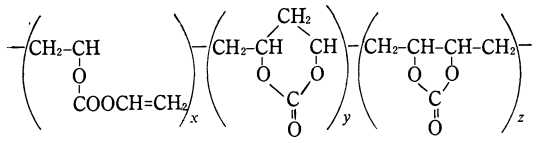


Fig. 1. Infrared spectrum of polydivinylcarbonate.

I

Using the following notations:

| Polymer structure | Molar concn. | Absorption coefficient | | Observed absorbance |
|---|---|---|---|---|
| Unsaturated carbonate | $C_1$ | C=C | $\varepsilon_1$ | $D_1$ (1660 $cm^{-1}$) |
| | | C=O | $\varepsilon_2$ | |
| 6-Membered carbonate | $C_2$ | | $\varepsilon_3$ | $D_2$ (1760 $cm^{-1}$) |
| 5-Membered carbonate | $C_3$ | | $\varepsilon_4$ | $D_3$ (1810 $cm^{-1}$) |

the molar concentrations of the three structural units can be expressed as;

$$C_1 = D_1/\varepsilon_1 l$$
$$C_2 = (D_2 - \varepsilon_2 D_1/\varepsilon_1)/\varepsilon_3 l$$
$$C_3 = D_3/\varepsilon_4 l$$

where $l$, denotes the thickness of a specimen. Assuming that the absorption coefficients of the three structural units can be represented by those of the corresponding model compounds in solution, the following expressions result:

$$C_1 = D_1/494l$$
$$C_2 = (D_2 - 2.97D_1)/1819l$$
$$C_3 = D_3/1960l$$

The relative amounts of $C_1$, $C_2$ and $C_3$ can be calculated independently of the thickness, $l$. The absorption bands at 1810 and 1760 $cm^{-1}$ in the polymer, which overlapped each other, were separated as shown in Fig. 2. The 6-membered cyclic carbonate content was not determined directly, but it was calculated on the basis of the difference in the observed absorbance of unsaturated carbonate as calculated from the $\nu_{C=C}$ band at 1660 $cm^{-1}$. Therefore, its value is likely to have some error and to be less reliable. Cross-linking due to the pendant unsaturation may not be large,

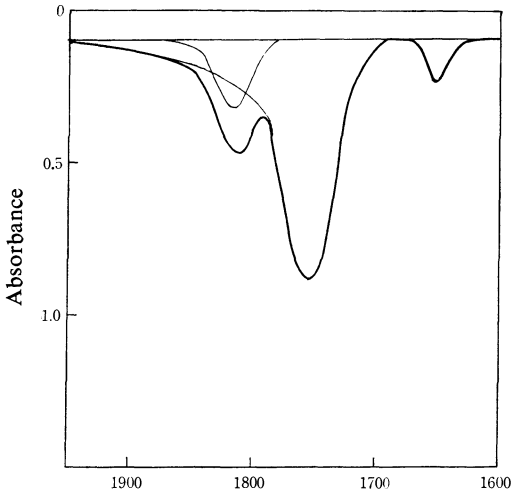

Fig. 2. Analysis of an infrared spectrum of polydivinyl carbonate.

but its increase will result in the overestimation of the 6-membered carbonate in the above calculations. This is another source of error in the estimation of the 6-membered carbonate.

**The Effect of Polymerization Variables on Polymer Properties.**—Gel point conversion may represent a qualitative measure of the degree of cyclization.[2] The effect of the monomer concentration on the gel point conversion is shown in Table II. When a visible gellation had taken place, almost the entire polymer was found to become insoluble; the monomer concentration in this case did not have any appreciable effect on the gel point conversion.

As it has been shown that, at a gel point conversion, almost the entire polymer becomes insoluble, the solubility of the polymers was examined at various points of conversion. The polymer was fractionated into a soluble part and an insoluble part by digesting the precipitated polymer with acetone at room temperature. The results are shown in Table III. The first appearance of gellation was observed after about 75 min. polymerization, but the insoluble

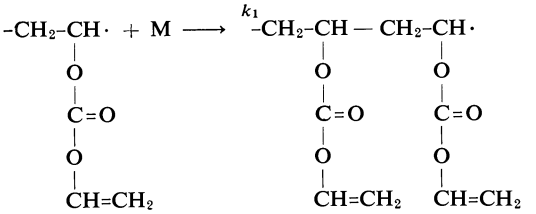
c) Temperature was kept constant within ±0.5°C.

polymer had been formed prior to the apparent gellation. At a conversion as low as 6%, the polymer was soluble in acetone, and thereafter the fraction of the insoluble polymer increased rapidly with conversion. The soluble part softened at 250—270°C with a slight discoloring. The polymer structure did not show appreciable change during the course of polymerization.



The solvent was expected to influence the solubility and the structure of the resulting polymer because of the differences in the chain transfer reaction and in the polarity, the latter of which might have some special influence on the conformation of the monomer molecule and of the polymer end in solution. The results are listed in Table IV. Even carbon tetrachloride, which is known to have a large chain transfer constant in the vinyl acetate polymerization, could not prevent the gel formation. However, polymerization in acetonitrile gave a polymer of a relatively high solubility. The extraordinary high yield of the polymer in carbon tetrachloride was unexpected: the reason can not be determined at present. Hydrocarbon solvents with high chain transfer constants, such as toluene and cumene, did not have any effect on the polymer structure, but a polar solvent, acetonitrile, showed such an effect, increasing the relative content of the 5-membered cyclic carbonate structure.

**The Effect of the Polymerization Temperature on the Polymer Structure.**—The formation of the 5-membered cyclic structure means the head-to-head addition of two vinyl groups in the same molecule. Head-to-head addition in usual vinyl monomers is known to have a higher activation energy than that of head-to-tail addition, and so it is to be expected that the polymerization temperature will have an effect on the content of cyclic units. The results are shown in Tables V and VI. The ratios of $C_3/C_1$, that is, the mole ratio of the 5-membered cyclic unit to the unsaturated carbonate units, is taken in an Arrhenius plot, giving the difference in the activation energies (Fig. 3):

$$E_3-E_1=6.21\pm0.29 \text{ kcal./mol. in a 50\% benzene solution}$$
$$=8.44\pm0.48 \text{ kcal./mol. in bulk polymerization}$$

## Discussion

The experimental facts concerning the polymerization of divinyl carbonate at low conversions may be summarized thus:

i) The polymer structure has been found to be composed of a 5-membered cyclic carbonate unit, a 6-membered cyclic carbonate unit, and an unsaturated carbonate unit.

ii) Cyclopolymerization is not a predominant mode of propagation, leaving not less than half a mole of unsaturation per unit structure. Hence, the polymers are likely to be cross-linked.

iii) The polymerization variables, i.e., the concentrations of the monomer, the conversion, and the solvent, had no appreciable effect on the polymer structure except for the polymerization in acetonitrile (Table IV).

iv) The polymerization temperature had a strong influence on the polymer structure, raising temperature resulting in an increased content of the 5-membered cyclic carbonate unit.

Divinyl compounds which undergo cyclopolymerization may be classified into two types. The one is compounds with unsaturated groups relatively inactive towards a radical, such as diallyl compounds and divinyl acetals. The other one is monomers with the reactive double bonds, like acrylic anhydride and its derivatives. Recently, it has been suggested, from a study of the electronic spectra, that two double bonds in a molecule of the latter type have a mutual interaction in solution and that the molecule takes a special conformation favorable to cyclization.[6] The vinyl groups in divinyl carbonate belong to the latter type, its reactivity is not very different from that of vinyl acetate.[7] The fact that divinyl carbonate is unlikely to undergo genuine cyclopolymerization might be due to the lack of a conformation favorable to cyclopolymerization in this case.

Gellation at the stage of low conversion is explained as being due simply to the prior existence of a large amount of the pendant vinyl groups in the polymer and to the high reactivity of the vinyl group.

The temperature dependency of the polymer structure is significant. The intramolecular formation of the 5-membered cyclic unit has a larger activation energy, from 6 to 8 kcal./mol., than the intermolecular propagation. The difference in the activation energies between the head-to-head addition and the head-to-tail addition of the usual monomers is reported to be 1 to 3 kcal./mol.[8] The formation of the 5-membered cyclic unit of divinyl carbonate implies an intramolecular cyclization as well as a head-to-head addition. Therefore, the cyclization reaction may need an additional activation energy to be able to take a conformation favorable to the ring closure.

The frequency factor of the 5-membered cyclization reaction ($A_3$) is larger than that of the intermolecular propagation ($A_1$) by a magnitude of $10^4$ to $10^5$. The ratios observed in other vinyl monomers range from 0.1 to 0.7.[8] This large difference may not be unreasonable when it is considered that the reacting vinyl group in the cyclization reaction always exists in the vicinity of the reacting polymer radical. In other words, the intramolecular cyclization needs less decrease of entropy at the activated state than does the intermolecular propagation.

## Summary

The preparation of divinyl carbonate has been described. The cyclopolymerization of the monomer has been studied under various reaction conditions, and it has been found that cyclopolymerization is not a predominant mode of propagation, for it leaves not less than half a mole of unsafuration per unit structure. The polymer structure has been analyzed by the infrared method and found to contain the 5-membered cyclic carbonate unit, the 6-membered cyclic carbonate unit and the pendant unsaturated carbonate unit.

The polymerization temperature has been shown to have a significant effect on the 5-membered cyclic unit content, increasing the temperature resulting in an increase in the 5-membered unit. The activation energy difference between the intramolecular 5-membered cyclization and the intermolecular propagation has been estimated to be $6.21 \pm 0.29$ kcal./mol. in the polymerization in a 50% benzene solution and $8.44 \pm 0.48$ kcal./mol. in bulk polymerization.

# The Electrodeposition of Ruthenium from a Ruthenium(III) and Ruthenium(IV) Solution and a Fission Products Solution

By Yoshii KOBAYASHI,* Hideo YAMATERA and Hisateru OKUNO

(Received March 20, 1965)

Ruthenium in an aqueous solution may be present as a variety of chemical species, and its chemical behavior is affected by various factors. Thus the complete separation of ruthenium is one of the most difficult problems in the separation of fission products. In order to solve this problem, various separation methods, including solvent extraction,[1,2] ion exchange[3] and ruthenium-tetroxide distillation[4], have been proposed. Since ruthenium is one of the noble metals, the electrochemical method should be useful for the separation of ruthenium from fission products. Although some electrochemical studies of ruthenium have been reported (they will be described below), no electrochemical method has yet been applied successfully to the separation of ruthenium from fission products.

The electrochemical studies of ruthenium were carried out by Griess and Lietzke,[5,6] by Haissinsky and El Guebely[7,8] and by other investigators. Griess and Lietzke reported that the complete electrodeposition of ruthenium was possible from a ruthenium nitrosyl chloride solution at concentrations higher than $5\times10^{-5}$ M, while an 80% deposition was obtained at concentrations of $5\times10^{-6}$ M or less. Haissinsky and Guebely investigated the electrodeposition of ruthenium on the cathode and the anodic oxidation of ruthenium sulfate using a sulfuric acid solution.

In this study, we will attempt to find an electrochemical method of separating ruthenium from fission products. For this purpose, the electrodeposition will be investigated with sample solutions containing $^{106}$Ru-labeled ruthenium in the form of ruthenium chloride and ruthenium nitrosyl chloride. Moreover, the electrodeposition method will be successfully applied to the separation of ruthenium from fission products. The ruthenium deposited on a platinum electrode is easily recovered into a solution by anodic oxidation, using sodium hydroxide as the electrolyte.

## Experimental

**Cells for Electrolyses.**—Cells of two types were used for the electrolyses: one of them was a Joliot cell[9] made of Plexiglass, while the other, shown in Fig. 1, was a cylindrical glass cell clamped on the cathode plate by a brass stand. The latter was used for the electrolyses at elevated temperatures and for the separation of ruthenium from fission products. Silver-coated copper ($20\times0.5$ mm.) and platinum ($20\times0.05$ mm.) plates were used as the cathode, and a platinum wire ($0.50\times100$ mm.), as the anode. As the reference electrode, a saturated calomel electrode was used for the Joliot cell and a silver-silver chloride electrode for the cylindrical glass cell. The cathode potential was kept at a given potential against the reference electrode by a potential regulator.

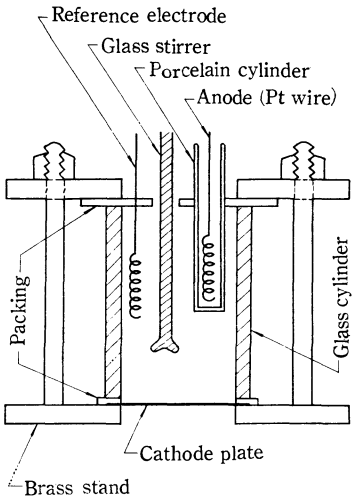

Fig. 1. Cylindrical glass cell.

**The Preparation of a Ruthenium Sample Solution and the General Procedure.**—Radioruthenium-106 (as ruthenium chloride) in a hydrochloric acid

solution was imported from the Radiochemical Center, Amersham, England. A $1\times10^{-7}$ M ruthenium chloride sample solution was prepared by evaporating the radioruthenium chloride and by dissolving the residue in 0.1 M hydrochloric acid. A $2\times10^{-4}$ M ruthenium chloride solution was prepared by the following method. Radioruthenium was added to a ruthenium chloride solution of an appropriate concentration ($\sim10^{-3}$ M), and then ruthenium tetroxide was distilled. The distilled ruthenium tetroxide, containing radioruthenium, was absorbed in dilute hydrochloric acid containing a small amount of hydrogen peroxide. The solution was then evaporated to dryness, and the residue was dissolved in 0.1 M hydrochloric acid. The ruthenium concentration was determined by the colorimetric method with a ruthenium thiourea complex. Ruthenium nitrosyl chloride was prepared according to the method of Griess; the resulting ruthenium nitrosyl chloride was dissolved in 0.1 M hydrochloric acid.

Five milliliters of the sample solution was placed in a cell equipped with a silver-coated copper plate as the cathode, a platinum wire as the anode, and a motor-driven glass stirrer. The solution was then electrolyzed while being continuosly stirred for a given period of time. In some cases, a Geiger counter was placed close to the outside of the cathode plate, which constituted a part of the wall of the cell, in order to measure the radiation from the inside. The rate of increase in the counting rate was directly related to the rate of electrodeposition. The activity of the electrolyte solution was measured with a well-type NaI(Tl) scintillation counter, and the activity of the electrodeposited ruthenium on the cathode plate, with a Geiger counter.

**The Electrolysis of the Fission Products.**—The gross fission products in a nitric acid solution were imported from the Oak Ridge National Laboratory, U. S. A., and aged for about 3.5 years, until they consisted mainly of $^{144}$Ce-$^{144}$Pr, $^{90}$Sr-$^{90}$Y, $^{137}$Cs, and $^{106}$Ru-$^{106}$Rh. An aliquot of this sample was evaporated to dryness and dissolved in 0.1 M hydrochloric acid. Ten milliliters of the solution was electrolyzed in the cylindrical glass cell by the general procedure except that a platinum plate was used as the cathode and the cathode and anode electrolytes were separated.

**The Determination of the Total Ruthenium Activity in the Fission Products.**—Aliquots of the fission products solution before and after electrolysis were converted from a hydrochloric into a sulfuric acid solution and mixed with a ruthenium carrier (0.5 mg.) in a sulfuric acid solution. Then the solution was made alkaline with some sodium hydroxide solution, and antiformine (a commercial sodium hypochlorite solution) was added in order to oxidize the ruthenium to ruthenate or perruthenate. To this solution, carbon tetrachloride was then added, after which the solution was slightly acidified with sulfuric acid. After the solution had been shaken for about two minutes, the ruthenium was completely extracted with carbon tetrachloride as ruthenium tetroxide, while the other fission products remained in the aqueous phase. In this method, the activity of the ruthenium extracted in carbon tetrachloride was measured on the fission products solution before and after the electrolysis, and the percentage of ruthenium electrodeposited from fission products was calculated.

**The Dissolution of the Ruthenium Deposited on a Platinum Plate.**—In order to remove the ruthenium deposited on a platinum plate, anodic oxidation was performed by the following procedure. An electrolytic cell was equipped with the platinum plate carrying the ruthenium deposit as the anode (and a copper wire as the cathode). With 0.1 M hydrochloric acid as the electrolyte, electrolysis was carried out for ten minutes at room temperature. The anode potential was maintained at a given potential (each of the potentials presented in Fig. 8) against a silver-silver chloride electrode.

The anodic oxidation was also carried out with a 0.1 M sodium hydroxide solution without controlling the anode potential. In this case, the current was supplied by a six-volt storage battery and controlled to give a rapid evolution of oxygen gas at the anode. By this method, the deposited ruthenium was completely removed from the platinum in ten minutes; the cleaned platinum plate was thereafter used repeatedly.

## Results

**Ruthenium Chloride and Ruthenium Nitrosyl Chloride.**—Figure 2 shows the results of the electrolysis of $1\times10^{-7}$ M ruthenium chloride in 0.1 M hydrochloric acid for 90 min. There was no deposition of ruthenium at the cathode potential of $-0.2$ V. vs. SCE. The ruthenium deposition increased with the decrease in the cathode potential until it reached a maximum at $-0.55$ V. vs. SCE; it decreased with the further decrease in the cathode potential. The deposition curve for $2\times10^{-4}$ M ruthenium

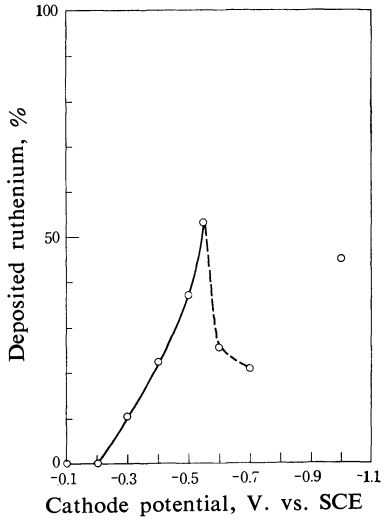

Fig. 2. Deposition curve of $1\times10^{-7}$ M ruthenium chloride (0.1 M HCl, room temperature, 90 min.).

chloride is presented in Fig. 3. This curve is unlike the cuve for $1\times10^{-7}$ M ruthenium chloride and has no maximum. In Figs. 4 and 5, the activity of the ruthenium deposited on the cathode plate is plotted against the loss of ruthenium activity from the electrolyte. The findings on $2\times10^{-4}$ M ruthenium chloride at cathode potentials between $-0.4$ and $-0.8$ V. fell on a straight line, as would naturally be expected, but the findings on $1\times10^{-7}$ M deviated from the linear relationship at cathode potentials lower than $-0.6$ V.

Figure 6 shows the results on electrolyses of $1\times10^{-7}$ M ruthenium nitrosyl chloride in 0.1 M hydrochloric acid for 60 min. The deposition curve has a maximum at $-0.6$ V. vs. SCE. A comparison of Fig. 6 with Fig. 2 will indicate that ruthenium nitrosyl chloride more easily produces a metal deposit than does ruthenium

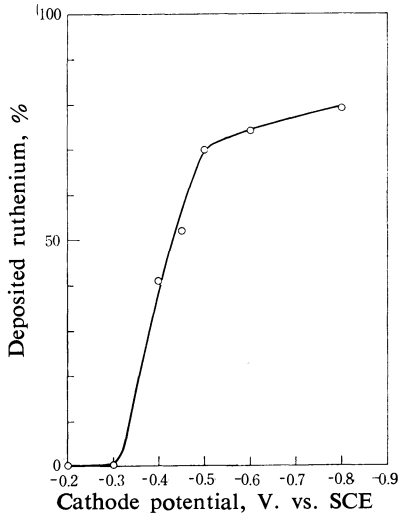

Fig. 3. Deposition curve of $2\times10^{-4}$ M ruthenium chloride (0.1 M HCl, room temperature, 30 min.).

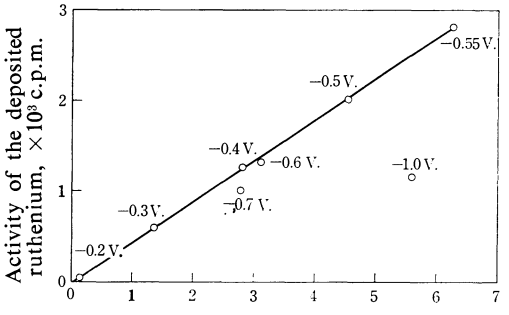

Fig. 5. Relationship between the deposited and the lost ruthenium from a $2\times10^{-4}$ M ruthenium chloride electrolyte.

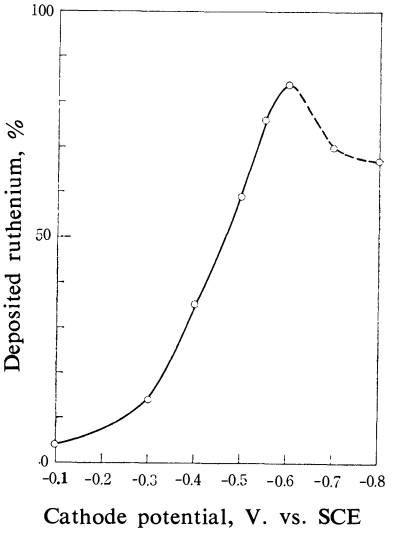

Fig. 6. Deposition curve of $1\times10^{-7}$ M ruthenium nitrosyl chloride (0.1 M HCl, room temperature, 60 min.).

Fig. 4. Relation ship between the deposited and the lost ruthenium from a $1\times10^{-7}$ M ruthenium chloride electrolyte.

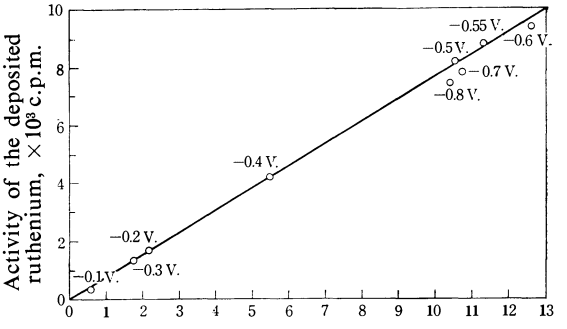

Fig. 7. Relationship between the deposited and the lost ruthenium from a $1\times10^{-7}$ M ruthenium nitrosyl chloride electrolyte.

TABLE I. ELECTRODEPOSITION OF Ru FROM Ru NITROSYL NITRATE IN 0.1 M $HNO_3$ (one hour)

| Cathode pot. vs. SCE | % Ru deposited |
|---|---|
| −0.3 | 15.8 (14.4) |
| −0.4 | 18.6 (36.4) |
| −0.5 | 36.3 (69.2) |
| −0.6 | 34.6 (84.0) |
| −0.7 | 21.1 (70.8) |

Values in parentheses are data of Ru nitrosyl chloride in 0.1 M hydrochloric acid.

chloride. The relationship between the activity of the ruthenium deposit on the cathode plate and the loss of ruthenium activity from the electrolyte is presented in Fig. 7, which also shows deviation from a linear relationship at lower cathode potentials.

Experiments with a 0.1 M nitric acid solution were also carried out, since nitrosyl ruthenium normally occurs in a nitric acid solution. The results are given in Table I. The ruthenium depositions were not as good as those from a 0.1 M hydrochloric acid solution.

Since about six hours were required to obtain a 90% deposition of ruthenium from a $1\times10^{-7}$ M ruthenium chloride solution at a cathode potential of −0.5 V. vs. SCE at room temperature, some experiments were attempted in an attempt to speed up the rate of ruthenium deposition. The results showed that a platinum plate was more useful as the cathode than a silver-coated copper plate; it gave an 85% deposition in two hours at 45°C. When 100 $\gamma$ of hexachloroplatinic(IV) acid was added to the electrolyte as the carrier, 97% of the ruthenium was deposited in one hour at room temperature using a platinum plate as the cathode.

**The Dissolution of the Deposited Ruthenium.**—The results of the anodic oxidation are presented in Fig. 8. The ruthenium deposited on a platinum plate was completely removed from the plate in a 0.1 M hydrochloric acid solution in ten miutes at anode potentials higher than 1.2 V. vs. a silver - silver chloride electrode. At these potentials, oxygen gas evolved at the anode plate. The dissolution of the ruthenium deposited on a platinum plate was also complete within ten minutes when electrolysis without the anode potential control was carried out in 0.1 M sodium hydroxide with a current strong enough to produce a violent evolution of oxygen gas at the anode.

**Fission Products.**—On the basis of the experimental results described above, the separation of ruthenium from fission products was carried out under the following conditions: the cathode potential was −0.5 V. vs. a silver - silver chloride electrode, and the cathode electrolyte solution (fission products solution) and the anode electrolyte solution (0.1 M hydrochloric acid) were separated by a diaphragm in order to prevent the oxidation of ruthenium-(III) or ruthenium(IV) to higher oxidation states. The results are presented in Table II. The nuclide separated by this method was identified as ruthenium-106 by gamma-spectrometry.

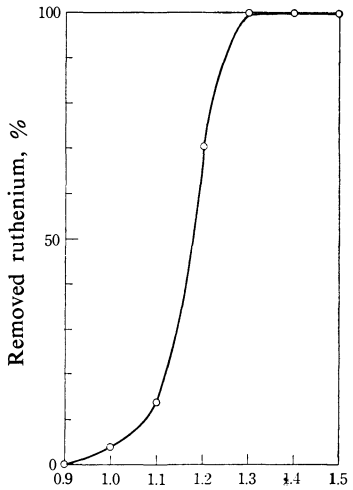

Fig. 8. Anodic oxidation of deposited ruthenium on platinum electrode (0.1 M HCl, room temperature, 10 min.).

TABLE II. ELECTRODEPOSITION OF Ru FROM FISSION PRODUCTS

| Temperature | % Ru deposited |
|---|---|
| Room temp. | 72.8 |
| Room temp. | 73.0 |
| 75°C | 97.5 |
| 75°C | 95.5 |
| Room temp. | 100 (Ru carrier; 0.5 mg.) |

## Discussion

Haissinsky and Guebely carried out experiments on the electrodeposition of ruthenium from solutions at the concentration of $5\times10^{-9}$ g.equiv./l. in sulfuric acid without separating the cathode and the anode electrolyte; they found that the ruthenium deposited on the cathode decreased at lower cathode potentials. They thought that this decrease in the electrodeposition might be attributed to the rapid evolution of hydrogen gas at the cathode at lower potentials partially preventing the ruthenium deposition, although they also found, in their experiments on anodic oxidation, that the ruthenium oxide or hydroxide was deposited on the wall of the cell. On the other

hand, Griess, who carried out electrolyses using a salt bridge to separate the cathode and the anode electrolyte, did not report any decrease in the ruthenium deposition on the cathode at lower potentials.

In the present study, the same tendency as had been reported by Haissinsky and Guebely was observed in experiments with a $1\times10^{-7}$ M ruthenium solution, while a different tendency was observed at the concentration of $2\times10^{-4}$ M.

If the decrease in ruthenium deposition had been effected mainly by the evolution of hydrogen gas at the cathode, the abnormal decrease should have been observed not only in the experiments at $1\times10^{-7}$ M and in those by Haissinsky and Guebely, but also in the experiments at $2\times10^{-4}$ M and in those by Griess, and a linear relationship would naturally exist between the activity of the deposited ruthenium and the activity of the ruthenium lost from the electrolyte, even at lower cathode potentials (−0.6 V.) Actually, however, no mention was made of any such abnormality by Griess, and a deviation from the linear relationship was observed in some of the present experiments (Fig. 4, 5 and 7).

From these facts, the abnormal phenomenon can be explained as follows. At lower cathode potentials, especially at −1.0 V., where gases rapidly evolved from the cathode and anode, an appreciable portion of the ruthenium in a $1\times10^{-7}$ M solution disappeared from the electrolyte, probably due to oxidation to higher oxidation states, followed by deposition on the wall of the cell and the anode and/or by volatilization as ruthenium tetroxide. With a $2\times10^{-4}$ M ruthenium solution, the portion of ruthenium oxidized was negligible as compared with the total, and a normal deposition curve resulted. Although no decisive conclusion could be derived from the present study, it seems very probable that the anodic oxidation of ruthenium, as well as the evolution of hydrogen gas at the cathode, is responsible for the abnormality in the deposition of ruthenium from the $1\times10^{-7}$ M solution.

Griess and Lietzke reported the dissolution of the ruthenium deposited on a gold or platinum electrode. When they carried out electrolysis in a strong sodium cyanide solution using a gold or platinum electrode as the anode, the ruthenium deposited on the gold or platinum plate was completely removed from the plate by the electrochemical dissolution of the base gold or platinum metal. In the present study, however, our tentative conclusion is that the removal of the ruthenium that had been deposited on a platinum plate was effected by the anodic oxidation of the ruthenium, for an electrolytic solution (acidic or alkaline) took on an orange-yellow color when ruthenium in a macro amount was electrolytically removed from a platinum plate, whereas the solution was colorless with ruthenium in a micro amount.

It has been shown that this electrochemical method for the separation of ruthenium may be successfully applied to fission products. Unlike other methods, such as tetroxide distillation method and some solvent extraction methods, this method does not require the addition of an oxidizing, a reducing or a complexing agent and is free from trouble in the subsequent steps needed for the separation of other nuclides.

## Summary

The electrodeposition of ruthenium from ruthenium chloride and ruthenium nitrosyl chloride solution has been studied and has been applied to the separation of the radioactive ruthenium contained in fission products. When the amount of the ruthenium deposited in a given time was plotted against the cathode potential, the curves for $1\times10^{-7}$ M solutions of chloride and nitrosyl chloride showed a maximum. The decrease in the electrodeposition at lower cathode potentials may be due to the anodic oxidation of ruthenium as well as to the evolution of hydrogen gas at the cathode. The rate of electrodeposition was found to depend on the material used as the cathode, and to be increased by an increase in the temperature and by the addition of the carrier platinum or ruthenium. A complete separation of radio-ruthenium from fission products resulted when electrolysis was carried out with a 0.1 M hydrochloric acid solution of fission products containing carrier ruthenium under the appopriate conditions mentioned in the text. The ruthenium electrodeposited on the platinum electrode was completely recovered into the solution by anodic oxidation.

The authors wish to express their deep thanks to Professor Niro Matsuura (The University of Tokyo) for his invaluable suggestions and for providing the Joliot electrolysis cell. They are also indebted to Professor Tatsujiro Ishimori and Professor Kunihiko Mizumachi (St. Paul's University) for their useful discussions. The expenses of the work were partly defrayed by a grant from the Ministry of Education, to which the authors' thanks are due.

# The Photolysis of Ethyl Chloroformate in Hydrocarbons

By Chyongjin PAC and Shigeru TSUTSUMI

(Received March 22, 1965)

It has been reported that alkoxycarbonyl radicals are produced by the reactions of alkyl formates with alkyl[1,2] or methoxy[3] radicals, and by those of methyl chloroformate with methyl radicals.[4] In the peroxide-induced reaction of methyl formate with an olefin such as oct-1-ene, the formation of methyl pelargonate can arise from the addition of methoxycarbonyl radicals to the olefin.[5] Although the alkoxycarbonyl radicals would also be produced in some of the primary steps in the photolysis of alkyl formates[6] or esters of aliphatic carboxylic acids,[7] this photolytic decomposition mainly takes place in the formyl- or acyl-alkoxy bond fission. An illustration is provided by the fact that the photolysis of methyl formate in cyclohexane gives cyclohexylcarbinol as the major product.[8] The photolysis of esters of formic and other aliphatic carboxylic acids, therefore, is not suitable for the generation of alkoxycarbonyl radicals. Photolyses of ethyl cyanoformate and diethyl oxalate have been reported from this laboratory to give ethoxycarbonyl radicals, though the photolyses are related to the cyanation[9] and the $\alpha$-ketocarboxylation[10] of the substrates respectively.

Although the thermodynamic properties of alkoxycarbonyl radicals have been discussed by Gray and Thynne,[2] little information concerning the stability and the reactivity of the radicals has been given for lack of convenient methods for the generation of such radicals. In a previous communication,[11] we have reported that the photolysis of ethyl chloroformate affords ethoxycarbonyl radicals and supplies a method for the direct carboxylation of hydrocarbons. The present paper will show the full results of the photolysis of ethyl chloroformate (ECF) in hydrocarbons; these results indicate the occurrence of selective carbon-chlorine bond breaking to give ethoxycarbonyl radicals. The reactivity of the radical in such hydrocarbons as cyclohexane, cyclohexene, oct-1-ene, and benzene will also be discussed in some detail.

## Results and Discussion

The photolysis of ECF was carried out with an unfiltered high pressure mercury arc without a solvent, or in cyclohexane, cyclohexene, oct-1-ene, and benzene. During the course of the

*** The amounts were negligible.

irradiation, hydrogen chloride and the other gases were evolved; small amounts of the condensable products were trapped at −60°C at the end of the irradiation. The condensable products, which were analyzed by gas chromatography, mainly consisted of ethyl chloride, along with traces of acetaldehyde, while *n*-butane could not be detected. The gases formed, which were also analyzed by gas chromatography, included carbon monoxide, carbon dioxide, ethane, and ethylene. Both in cyclohexane and in the absence of a solvent, carbon dioxide and ethane were the major products, while carbon monoxide and ethylene were found to be the minor products. In the case of cyclohexene, the yields of gaseous products were very small, and the product-ratios were different from those found in the case of cyclohexane. The results concerning gaseous products obtained from the photolysis of ECF in cyclohexane and cyclohexene are summarized in Table I. The liquid products found in the photolysis of ECF in cyclohexane, cyclohexene, oct-1-ene, and benzene are listed in Table II.

**Primary Processes of the Photolysis of ECF.** —On the basis of the suggestions regarding the photolysis of esters of formic or aliphatic carboxylic acids,[7] the possible primary processes of the photolysis of ECF might be shown as follows:

(1)
(2)
(3)

The ethoxycarbonyl radical I, produced by the breaking of the carbon-chlorine bond (Eq. 1), is decomposed into carbon dioxide and an ethyl radical (Eq. 4-a) with an activation energy somewhat greater than 1—2 kcal./mol.[2] The chloroformyl radical II produced by the homolysis of the chloroformyl-ethoxy bond (Eq. 2) breaks down into carbon monoxide and a chlorine atom (Eq. 4-b) with the activation energy of 6.3 kcal./mol.[12]

$$\underset{\text{I}}{\cdot COOC_2H_5} \rightarrow CO_2 + \cdot C_2H_5 \qquad (4\text{-a})$$

$$\underset{\text{II}}{\cdot COCl} \rightarrow CO + \cdot Cl \qquad (4\text{-b})$$

According to schemes 1, 3, and 4-a, if ethyl radicals are quantitatively converted to ethane

12) W. G. Burn and F. S. Dainton, *Trans. Faraday Soc.*, **48**, 39 (1952).

and/or ethylene by their hydrogen-abstraction from a substrate or by disproportionation, the stoichiometric relationship between $C_2$-hydrocarbons and carbon dioxide must be given by Eq. 5:

$$([C_2H_4] + [C_2H_6])/[CO_2] = 1 \quad (5)$$

where $[C_2H_4]$, $[C_2H_6]$, and $[CO_2]$ indicate the moles of the corresponding compounds. It has been suggested that the disproportionation of ethyl radicals is suppressed by the use of organic solvents and that, in some cases, it does not take place at all.[13] The proportion of ethylene in gaseous products, therefore, might be expected to determine how process 3 participates in the photolysis of ECF. As is shown in Table I, with the increase in the amount of cyclohexane added. the values of the $C_2$-hydrocarbons/$CO_2$ ratio were changed from 0.62 to unity. When ECF was sufficiently diluted with cyclohexane, equal amounts of ethane and carbon dioxide were obtained, and the formation of ethylene became negligible. The dilution with cyclohexane apparently completes the conversion of ethyl radicals to ethane:

$$\cdot C_2H_5 + \bigcirc \rightarrow C_2H_6 + \cdot\bigcirc \quad (6)$$

and Eq. 5 is satisfied. These results, therefore, strongly suggest that process 3 does not play an important role in the primary processes of the photolysis of ECF in cyclohexane.

On the other hand, the amounts of carbon monoxide might indicate the extent of the primary process 2. The findings in Table I show that the amounts of carbon monoxide are very small in all cases; hence process 2 would be negligible. From a comparison of the activation energy for the decomposition of the radical II with that for the decomposition of the radical I, however, it might be expected that a significant amount of the former radical might be likely to react with the other species before the decomposition. Contrary to the above expectation, however, the liquid products obtained from the photolysis of ECF in excess cyclohexane were not contaminated with cyclohexanecarbonyl chloride. Moreover, the amounts of acetaldehyde and diethyl carbonate which are derived from ethoxy radicals produced through process 2 are very small:

$$C_2H_5O\cdot + R\cdot \rightarrow CH_3CHO + RH \quad (7)$$

$$2C_2H_5O\cdot \rightarrow CH_3CHO + C_2H_5OH \quad (7')$$

$$C_2H_5O\cdot \xrightarrow{\text{hydrogen donor}} C_2H_5OH \quad (8)$$

$$C_2H_5OH + ClCOOC_2H_5 \rightarrow (C_2H_5O)_2CO + HCl \quad (9)$$

13) J. Smid, A. Rembaum and M. Szwarc, *J. Am. Chem. Soc.*, 75, 3315 (1956); M. Matsuoka, P. S. Dixon, A. P. Stefani and M. Szwarc, *Proc. Chem. Soc.*, **1962**, 304; J. N. Bradley, *J. Chem. Phys.*, 35, 748 (1961).

$$C_2H_5O\cdot + \cdot COOC_2H_5 \rightarrow (C_2H_5O)_2CO \quad (10)$$

These results are consistent with the conclusion that the primary process 2 plays a negligible role in the photolysis of ECF.

Thus we may decide that, in the photolysis of ECF, the breaking of the carbon-chlorine bond occurs in a selective manner, and that the photolysis of ECF can serve for the generation of ethoxycarbonyl radicals.

**The Reactions of Ethoxycarbonyl Radicals.** —As Table II shows, the liquid products from the photolysis of ECF in cyclohexane consisted of ethyl cyclohexanecarboxylate, bicyclohexyl, and traces of a mixture of chlorocyclohexane, ethylcyclohexane, and diethyl carbonate, while cyclohexanecarbonyl chloride could not be detected in any liquid fraction.

With respect to the formation of ethyl cyclohexanecarboxylate, two alternative interpretations are possible, as is shown in schemes 11 and 12, the radical-association scheme and the chain-reaction scheme. In the latter scheme, if a cyclohexyl radical is generated, the ester

$$\bigcirc\cdot + \cdot COOC_2H_5 \rightarrow \bigcirc\text{-}COOC_2H_5 \quad (11)$$

$$\bigcirc\cdot + \begin{matrix} Cl \\ | \\ C{=}O \\ | \\ OC_2H_5 \end{matrix} \rightarrow \bigcirc\text{-}COOC_2H_5 + \cdot Cl \quad (12)$$

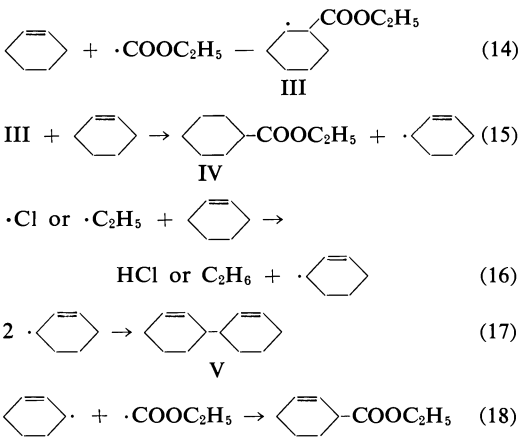
must be produced. When the dibenzoyl peroxide-catalyzed reaction of ECF in cyclohexane was carried out, the ester was not observed, but bicyclohexyl was produced. Therefore, the latter interpretation (chain reaction) is ruled out; the association scheme 11 can be adopted in this case.

Assuming that the radical I diffuses in the solvent and associates with a cyclohexyl radical, the dimerization product, diethyl oxalate, may be expected to be formed, since carbamoyl radicals, $\cdot CONH_2$, can dimerize to give oxamide.[14] The difference in these reactions must be ascribed to the difference in stability between the radical I and the carbamoyl radical, not to a difference in electronic properties. The radical I might not have life time enough to dimerize. Therefore, it is very unlikely that the radical I diffuses in the solvent; it should be considered that ethyl cyclohexanecarboxylate might be produced in a solvent cage, involving the cage wall.

$$\left[\bigcirc + \cdot Cl + \cdot COOC_2H_5\right] \rightarrow \left[\bigcirc\cdot + \cdot COOC_2H_5 + HCl\right] \rightarrow \bigcirc\text{-}COOC_2H_5 + HCl \quad (13)$$

14) D. Elad and J. Rochach, *J. Org. Chem.*, 29, 1855 (1964).

Gray and Thynne have shown that the activation energies for the decomposition of alkoxycarbonyl radicals are somewhat greater than those for the decomposition of acyloxy radicals.[2] An acetyloxy radical, even in the liquid phase, does not attack alkanes; the entity of the radical reaction in such a system has been suggested to be a methyl radical,[15] though acetyloxy radicals are scavenged by iodine molecules.[16] In our experiments, the ratio of the association of the radical I with a cyclohexyl radical to the decomposition exhibits values of 0.1 or less, showing, in the liquid phase, fairly good accordance with the above authors' suggestion. The radical I might have life time enough to associate with a cyclohexyl radical in the solvent cage.



In order to observe the reactivity of the radical I to double bonds, cyclohexene and oct-1-ene were employed as solvents. The dilution with cyclohexene suppressed the formation of gases to a great extent, but the amounts of gases formed did not vary, though the concentration of ECF in cyclohexene was greatly changed. These results might indicate that a facile addition of the radical I to cyclohexene takes place, and that the decomposition is greatly suppressed. This interpretation is well supported by the results in Table II and by the well-known fact that olefins are good scavengers of various radicals.

The ratio of ethyl cyclohexanecarboxylate to carbon dioxide might give a measure of the reactivity of the radical I to cyclohexene. The value of the ratio, 2.5, indicates that the addition of the radical I to cyclohexene predominates over the decomposition at least 2.5 times. It is, however, difficult to explain why the amount of $C_2$-hydrocarbons were much less than that of carbon dioxide, and why ethylcyclohexane was not detected. It is most likely that ethyl radicals add to cyclohexene, and that the resulting species react further with cyclohexene to give unreclaimed, heavier compounds.

In the photolysis of esters of formic and aliphatic carboxylic acids[6] it has been suggested that the migration of a hydrogen atom (process 3) takes place in the excited singlet state. Therefore, the formation of ethylene via process 3 might not be quenched by cyclohexene. On the other hand, the formation of carbon dioxide might be much suppressed by the facile addition of the radical I to cyclohexene, and some of the ethyl radicals from the decomposition of the radical I might be trapped by cyclohexene. Thus, the proportion of ethylene in gaseous products is increased, and that of ethane is decreased compared with the results in the case of cyclohexane or in the absence of a solvent.

It was expected that the radical I would associate with a cyclohexen-3-yl radical in a manner similar to that in the case of cyclohexyl radicals to give an amount of ethyl cyclohexene-3-carboxylate comparable with that of ethyl cyclohexanecarboxylate obtained from the photolysis of ECF in cyclohexane. However, the amount of ethyl cyclohexene-3-carboxylate was negligible. These unexpected results can be explained by assuming that the addition of the radical I to cyclohexene is very rapid. Since the radical I is almost scavenged by cyclohexene, the concentration of the radical I might be so lowered that the association with the cyclohexen-3-yl radical, even in a solvent cage, can not take place to any appreciable extent.

The reaction scheme is shown as follows:

According to the above scheme, a stoichiometry is given by Eq. 19:

$$([HCl] + [C_2H_6] + [IV])/2[V] = 1 \quad (19)$$

where [HCl], [$C_2H_6$], [IV], and [V] indicate the moles of the corresponding products. Since the number of chlorine atoms is equivalent to the amount of the radical I, [HCl] can be approximately replaced by [$CO_2$]+[IV]:

$$([CO_2] + [C_2H_6] + 2[IV])/2[V] \sim 1 \quad (20)$$

The observed values of the ratio in Eq. 20 are 1.05, showing good accordance with those expected from the scheme.

Another possible product, ethyl 2-chlorocyclohexanecarboxylate, could not be detected in any appreciable amounts. Although a methyl radical has been reported to abstract the chlorine atom in methyl chloroformate in the vapor phase,[4] the species III might not abstract the chlorine atom in ECF. The above finding can be interpreted in three ways: 1) The chlorine

15) L. Herk and M. Szwarc, *J. Am. Chem. Soc.*, **82**, 3558 (1960).
16) H. J. Shine and D. H. Hoffman, ibid., **83**, 2782 (1961).

atom-abstraction may be sterically hindered by the configuration of the cyclohexane ring. 2) Since cyclohexene has highly labile allylic hydrogen atoms, the species III may predominantly abstract the hydrogen atoms. 3) The chlorine atom in ECF may be insensitive to abstraction with radical species other than a methyl radical in the liquid phase.

A chain terminal olefin, such as oct-1-ene, eliminates such steric hindrance and does not have so reactive hydrogen atoms. When the photolysis of ECF in oct-1-ene was carried out, a variety of products was formed, including a moderate amount of ethyl pelargonate and traces of ethyl 3-chloropelargonate. Moreover, the amount of ethyl chloride found was very small in all cases. Therefore, it is likely that the third possibility is correct, that is, that the chlorine atom in ECF is insensitive to abstraction with the species III and VI and with ethyl radicals in the liquid phase.

$$C_6H_{13}\text{-}\dot{C}HCH_2COOC_2H_5$$

VI

The formation of a variety of products is ascribed to the competing reactions of various radicals formed primarily and secondarily. All of the liquid fractions obtained, however, showed essentially identical infrared absorption spectra, exhibiting strong bands corresponding to esters of aliphatic carboxylic acid without any other carbonyl bands. Moreover, the amounts of gases formed and the product ratios were comparable to those in the case of cyclohexene. These results show that the radical I adds not only to cyclohexene, but also to oct-1-ene, and with less decomposition.

In the case of benzene, the effective light for the photolysis of ECF appears to be quenched by benzene, since the absorption maximum of ECF lies below 2500 Å. Therefore, a precise investigation could not be undertaken, though small amounts of ethyl benzoate and traces of biphenyl were detected.

## Experimental

**Materials.**—ECF, cyclohexane, and benzene were obtained commercially and purified in usual ways. Cyclohexene was prepared by the dehydration of cyclohexanol,[17] and oct-1-ene, by the pyrolysis of *n*-octyl acetate.[18] All of the materials were distilled before use.

**The Analysis of Gaseous and Condensable Products.**—In the study of gaseous products for Table I, the photolysis of ECF was carried out in a quartz cell (50 cm. long, 2 cm. in diameter) immersed in a water bath maintained at room temperature, and with a high-pressure mercury arc (600 W.) mounted 1 cm. from the cell. The gases formed were passed through an aqueous alkaline solution after a trap at −60°C and were collected in a gas buret, with which the volumes of the neutral gaseous products were measured. The product ratios were determined by gas chromatographic measurements (silica-gel column: 1 m. at 25°C). At the end of the irradiation, a slow stream of nitrogen was bubbled into the irradiated mixture, and the condensable products collected in the trap were subjected to gas chromatography (tricresyl phosphate column: 3 m. at 25°C). Acetaldehyde was identifed by the paper chromatography of its 2,4-dinitrophenylhydrazone.

**The Photolysis of ECF in Cyclohexane.**—A mixture of ECF (83 g.) and an excess of cyclohexane (168 g.) was irradiated with an internally-mounted high-pressure mercury arc (600 W.) at room temperature for 6 hr. in an atmosphere of nitrogen. During the course of the irradiation, 1400 cc. of neutral gaseous products was evolved. After the unchanged materials had been removed from the irradiated mixture, the remaining oil was distilled under reduced pressure to yield traces of a mixture of chlorocyclohexane, ethylcyclohexane, and diethyl carbonate (b. p. 30—60°C/35 mmHg), 1 g. of ethyl cyclohexanecarboxylate (b. p. 93—96°C/35 mmHg, $n_D^{26}$ 1.4510) and 1.5 g. of bicyclohexyl (b. p. 65—70°C/3 mmHg, $n_D^{26}$ 1.4743). The mixture of chlorocyclohexane, ethylcyclohexane, and diethyl carbonate was analyzed by gas chromatography (silicone-oil column: 3 m. at 80°C). The fraction of ethyl cyclohexanecarboxylate showed only one peak in its gas chromatogram (silicone-oil column: 3 m. at 170°C) and an infrared absorption spectrum identical with that of an authentic sample. An anilide derived from this fraction showed no melting point depression upon admixture with an authentic anilide; melting point and mixed melting point 143—143.5°.

(Found: C, 76.69; H, 8.06. Calcd. for $C_{18}H_{17}ON$: C, 76.81; H, 8.43%)

The fraction of bicyclohexyl was analyzed by gas chromatography (silicone-oil column: 3 m. at 170°C); it was contaminated with only a small amount of ethyl cyclohexanecarboxylate (3.8 wt.%).

**The Photolysis of ECF in Cyclohexene.**—The photolysis of ECF (83 g.) in cyclohexene (164 g.) for 14 hr. gave 50 cc. of neutral gaseous products and two fractions, one of them with a b. p. of 88—99°C/28 mmHg ($n_D^{26}$ 1.4570, 3.1 g.) and the other with a b. p. of 110—132°C/28 mmHg ($n_D^{26}$ 1.4953, 2.9 g.); both of these showed two peaks in their gas chromatograms (silicone-oil column: 3 m. at 170°C). One of the peaks had the same retention time as that of ethyl cyclohexanecarboxylate, while the other was considered to be the peak of 3,3'-bicyclohexenyl on the basis of findings to be described later. The area-ratios of the former peak to the latter in two fractions showed the values of 5.7 and 0.15 respectively; thus the yields of ethyl cyclohexanecarboxylate and 3,3'-bicyclohexenyl were each calculated to be 3 g. The lower boiling fraction was further analyzed by gas chromatography under

17) G. H. Coleman and H. F. Johnstone, "Organic Syntheses," Coll. Vol. 1, 183 (1956).
18) W. J. Bailey and W. H. Hale, *J. Am. Chem. Soc.*, **81**, 647 (1959).

different conditions (dioctyl sebatate column: 4 m. at 120°C); this analysis showed the presence of a trace of ethyl cyclohexene-3-carboxylate.[19] This fraction showed an infrared absorption spectrum essentially identical with that of ethyl cyclohexanecarboxylate, and an anilide derived from the fraction showed no melting point depression upon admixture with anilide of cyclohexanecarboxylic acid (m. p. 143.5°C and mixed m. p. 143—143.5°C). The higher boiling fraction showed the absorption bands characteristic of double bonds at 3040 and 1640 $cm^{-1}$ and, on treatment with bromine, afforded two white crystals, the one (m. p. 153—156°C) more soluble and the other (m. p. 187—189°C) less soluble in chloroform; these were considered to be tetrabromides of 3, 3'-bicyclohexenyl (lit.[20] the more soluble isomer, m. p. 159—162°C, and the less soluble one, m. p. 188—190°C).

**The Photolysis of ECF in Oct-1-ene.**—The photolysis of ECF (60 g.) in oct-1-ene (178 g.) for 12 hr. gave 100 cc. of neutral gaseous products and the following fractions; b. p. 109—115°C/27 mmHg, 1.7 g. and b. p. 125—149°C/1 mmHg, 1.9 g. These two fractions exhibited infrared absorption spectra essentially identical with the strong bands of the aliphatic carboxylic acids at 1740 (C=O) and 1160 (C-O) $cm^{-1}$ respectively. The lower boiling fraction showed five peaks in its gas chromatogram (silicone oil column: 1.5 m. at 165°C), in which the largest peak had the same retention time as that of ethyl pelargonate, while the retention time of the smallest one was identical with that of ethyl 3-chloropelargonate. An anilide derived from the lower boiling fraction showed no melting point depression upon admixture with anilide of pelargonic acid; m. p. 56.5—57.5°C and mixed m. p. 56.5—58°C.

(Found: C, 77.33; H, 9.91. Calcd. for $C_{15}H_{23}ON$: C, 77.25; H, 9.87%)

The higher boiling fraction was analyzed by gas chromatography (silicone oil column: 1.5 m. at 165°C) and found to consist of seven or more components; these were not, however, identified.

**The Photolysis of ECF in Benzene.**—When a mixture of ECF (80 g.) and benzene (22 g.) was photolyzed for 50 hr., 100 cc. of neutral gaseous products and 100 mg. of a fraction (b. p. 65—75°C/10 mmHg) were obtained. The liquid fraction, when analyzed by gas chromatography (silicon oil column: 3 m. at 160°C), was found to consist of ethyl benzoate, along with traces of biphenyl and only a small amount of another, unidentified component. Further investigations were not carried out.

**The Dibenzoyl Peroxide-Catalyzed Reaction of ECF in Cyclohexane.**—A mixture of ECF (18 g.) and cyclohexane (40 g.) containing 2 g. of dibenzoyl peroxide was refluxed at 83—85°C for 24 hr. under a nitrogen atmosphere. During the course of the reaction, carbon dioxide was evolved, but no other gaseous products were observed. After the unchanged materials had been removed, the remaining oil was distilled under reduced pressure to yield 0.2 g. of a fraction (b. p. 100—130°C/25 mmHg). During the distillation, benzoic acid was sublimed. In the gas chromatogram of the fraction, a peak showed the same retention time as that of bicyclohexyl, but there was no peak with a retention time the same as or near the same as that observed in ethyl cyclohexanecarboxylate (silicone oil column: 3 m. at 170°C).

## Summary

The photolysis of ECF in cyclohexane, cyclohexene, oct-1-ene, and benzene has been carried out. It has been concluded that carbon-chlorine bond breaking has occurred to give ethoxycarbonyl radicals in a selective manner. The reactions of the radical in hydrocarbons have been qualitatively discussed, and it has been suggested that the radical had a life long enough to associate with a cyclohexyl radical in a solvent cage, but not a life long enough to dimerize and be added to carbon-carbon double bonds with less decomposition. Thus, cyclohexane, cyclohexene, oct-1-ene, and benzene were carboxylated. No chain reactions were observed in light- and dibenzoyl peroxide-induced reactions of ECF in hydrocarbons; i. e., ECF was unreactive to alkyl radicals and radicals bearing an ethoxycarbonyl group on their $\alpha$-carbon. The photolysis of ECF supplies a convenient method for the generation of ethoxycarbonyl radicals.

The authors wish to express their hearty thanks to Dr. Yoshinobu Odaira for his kind advice and encouragement throughout this work. Thanks are also due to Mr. Kikuhiko Koyama for his kind advice.

# The Copolymerization of the Vinyl Monomer with a Cyclic Compound. I. The Cationic Copolymerization of Some Vinyl Monomers with 3, 3-Bis(chloromethyl)oxetane*

By Shuzo AOKI, Yoshiyuki HARITA, Takayuki OTSU and Minoru IMOTO

(Received March 25, 1965)

Several attempts to copolymerize the vinyl monomer with cyclic ether have been made. Recently, Tsuruta and Fujio[1] prepared the copolymer of methyl vinyl ketone with propylene oxide or epichlorohydrin, using aluminum isopropoxide as an anionic catalyst. The acrylonitrile - ethylene oxide[2] and - propylene oxide[3] copolymers have been prepared in the radiation-induced copolymerization at a low temperature. The cationic copolymerizations of cyclic ethers with vinyl monomers have also been patented.[4,5] Höhr et al.[6] have reported a detailed mechanism of the cationic copolymerization of trioxane with styrene.

The present investigation was undertaken to evaluate the reactivities of vinyl monomers and cyclic ether in their copolymerizations by Lewis acids. Styrene (St), $\alpha$-methylstyrene ($\alpha$-MeSt) and isobutyl vinyl ether (IBVE), having different reactivities for cationic polymerization, were used as the vinyl monomers. 3, 3-Bis(chloromethyl)oxetane (BCMO) was adopted as the cyclic ether, and boron trifluoride-diethyl etherate ($BF_3 \cdot Et_2O$), stannic chloride ($SnCl_4$) and triethylaluminum-water ($AlEt_3$-$H_2O$) were used as the cationic catalysts. The copolymerizations were carried out in methylene chloride at 0°C.

## Experimental

**Materials.**—Commercial St, $\alpha$-MeSt and IBVE were distilled over calcium hydride under reduced pressure. BCMO was prepared by the method described by Farthing[7] and distilled over calcium hydride under reduced pressure; b. p. 80.5—81.5°C/10 mmHg, $n_D^{20}$ 1.4858 (lit.[7] b. p. 80.2—81.5°C/10 mmHg, $n_D^{20}$ 1.4858).

Commercial $BF_3 \cdot Et_2O$ and $SnCl_4$ were purified by distillation before use. $AlEt_3$ (Ethyl Corp.) was used without further purification. The $AlEt_3$-$H_2O$ catalyst was prepared in methylene chloride ($AlEt_3$/$H_2O$=1 in mole).

Methylene chloride was shaken with a sodium carbonate solution, washed with pure water, and then distilled over phosphorous pentoxide. The other materials were purified by ordinary methods.

**Copolymerization Procedure.**—The copolymerizations were carried out in a glass-stoppered tube, except in the case of the $AlEt_3$-$H_2O$ catalyst, for which a serum type-stoppered tube was used as the reaction vessel. The initial concentrations of the total monomer mixture and of the catalyst were kept constant at 3.0 and 0.07 mol./l. respectively. After the monomers and the solvent had been charged, dry nitrogen gas was flashed into the tube, which had previously been chilled in an ice-water bath. A known quantity of the catalyst solution in methylene chloride was then added to this tube, and it was sealed off. After it had been polymerized for a given time, the reaction mixture was poured into a large amount of methanol in order to stop the reaction and isolate the polymer produced. In the cases of $SnCl_4$ and $AlEt_3$-$H_2O$ catalysts, methanol containing a small amount of hydrochloric acid was used as the precipitant in order to avoid the precipitation of metal hydroxide. The resulting polymer was washed by methanol and dried under reduced pressure at room temperature.

**The Analysis and Fractionation of the Polymer.**—The compositions of the polymers were determined from their chlorine contents. In order to check whether or not the copolymer was obtained, the polymer was separated with chloroform into insoluble and soluble fractions. The chloroform-soluble fraction was then fractionated into several fractions by the successive addition of methanol.

The molecular weight of the polymer was determined by the cryoscopic method in benzene. The infrared spectra of the polymers were determined in a KBr disk.

## Results

**The St-BCMO-$BF_3 \cdot Et_2O$ System.**— The results of the copolymerization of St and BCMO as catalyzed by $BF_3 \cdot Et_2O$ are tabulated in Table I. The rate of the polymerization ($R_p$) of St was remarkably lowered by the presence of BCMO. As is indicated in Table I, the reactivity of St for the copolymerization with BCMO

* In mole fraction
** Molecular weight of $CHCl_3$-soluble part was 724 (Cl: 5.07%), while that of homopolyα-MeSt (Exp. No. 47) was 1270.

was extremely low, and the homopolymer of BCMO was obtained.

**The α-MeSt - BCMO - $BF_3 \cdot Et_2O$ System.**— The results of the copolymerization of α-MeSt and BCMO by $BF_3 \cdot Et_2O$ are summarized in Table II. The rate of copolymerization decreased as compared with the respective homopolymerization rates. Colorless, powdered polymers, composed of both monomer units, were obtained. The monomer-polymer composition curve in this system is shown in Fig. 1.

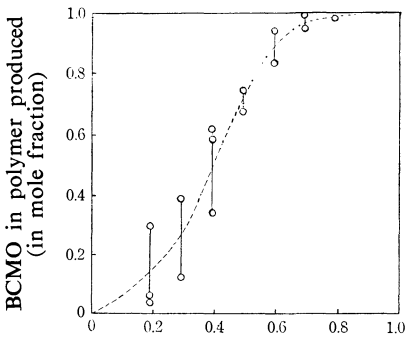

Fig. 1. Monomer-polymer composition curve for the copolymerization of α-MeSt and BCMO by $BF_3 \cdot Et_2O$ in methylene chloride at 0°C.

Since the molecular weights of the polymers obtained under the present conditions were low (see Table III), it may be assumed that the low molecular weight polymer mainly consisted of α-MeSt units is partly soluble in methanol as a precipitant. Accordingly, the curve in Fig. 1 should be shifted in a small extent, however, any further discussion will be not disturbed.

In order to check whether or not the copolymer was produced, some of the polymers obtained were fractionated into several fractions. The analytical results of these fractions are shown in Table III, while their infrared spectra are indicated in Fig. 2.

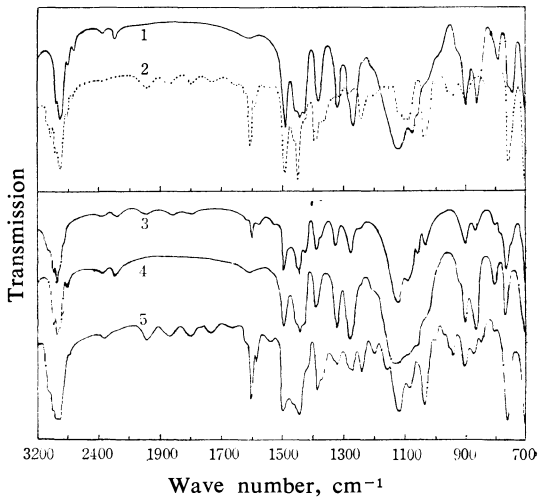

Fig. 2. Infrared spectra of the polymer (Exp. No. 37) obtained in the system of α-MeSt - BCMO - $BF_3 \cdot Et_2O$ in methylene chloride at 0°C. 1. PolyBCMO, 2. Polyα-MeSt, 3. Unfractionated polymer, 4. Chloroform-insoluble fraction, 5. Chloroform-soluble fraction

Because the infrared spectra and chlorine contents of the chloroform-insoluble fractions were nearly identical with those of polyBCMO, it was obvious that this fractions were homopolymers of BCMO. On the other hand, the infrared spectrum of the chloroform-soluble fraction showed the absorption bands due to the α-MeSt unit and the C-O-C band at 1120 $cm^{-1}$ from the BCMO unit, as is shown in Fig. 2. This fraction was, therefore, further fractionated into several fractions which contained considerable amounts of chlorine. The molecular weight of the chloroform-soluble fraction (Exp. No. 37) was found to be 724 (Cl: 5.07%). This value corresponds approximately to the calculated value (746) of the

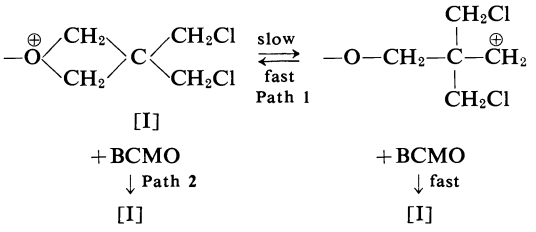
** $CHCl_3$-insoluble part: 18.42 wt.% (Cl: 41.74%); $CHCl_3$-soluble part: 81.58 wt.% (Cl: 0.68%)

polymer, which consisted of five α-MeSt units and one BCMO unit (Cl: 9.5%). Therefore, this soluble fraction may be taken as a mixture of the homopolymers of α-MeSt and of polyα-MeSt containing one terminal BCMO unit.

**The α-MeSt - BCMO - $SnCl_4$ System.**—The results of the copolymerization of α-MeSt and BCMO with $SnCl_4$ as the catalyst are tabulated in Table IV. BCMO was hardly polymerized at all by $SnCl_4$, and only a polyα-MeSt was obtained in this system.

**The α-MeSt - BCMO - $AlEt_3$-$H_2O$ System.**—The results of the copolymerization of α-MeSt and BCMO by the $AlEt_3$-$H_2O$ catalyst are tabulated in Table V. The polymer, mainly consisting of BCMO units, was obtained in the copolymerization of various monomer compositions, though the homopolymerizations of both α-MeSt and BCMO proceeded without difficulty when this catalyst system was used.

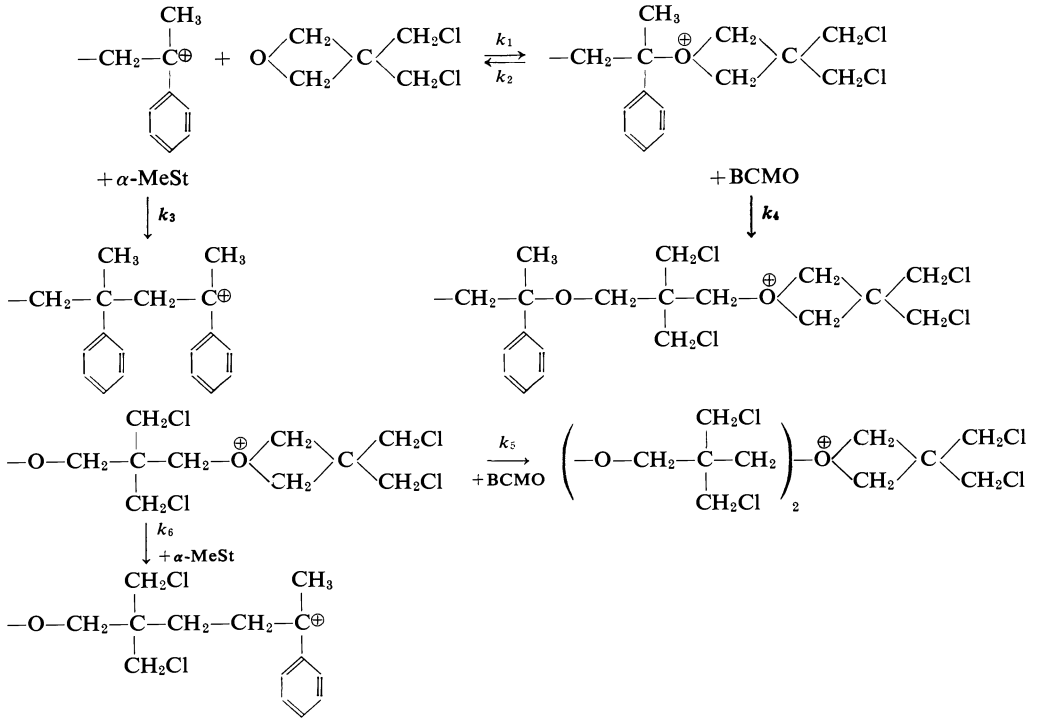


**The IBVE-BCMO-$BF_3 \cdot Et_2O$ System.** — The results of the copolymerization of IBVE and BCMO by $BF_3 \cdot Et_2O$ are tabulated in Table VI. Tacky and pale yellow polymers were obtained from this system. The homopolyIBVE was obtained in the copolymerization at a higher concentration of IBVE, while a polymer containing both IBVE and BCMO units was obtained through the system which used a higher concentration of BCMO. This polymer, containing both IBVE and BCMO units, was fractionated with chloroform, and a polymer mainly consisting of BCMO units and homopolyIBVE were separated.

## Discussion

In the cationic copolymerizations of the St-BCMO-$BF_3 \cdot Et_2O$, α-MeSt - BCMO - $SnCl_4$ and α-MeSt - BCMO - $AlEt_3$-$H_2O$ systems, only the homopolymer of a vinyl or a cyclic compound was obtained (Tables I, IV and V). On the other hand, in the copolymerization of α-MeSt or IBVE by $BF_3 \cdot Et_2O$, the composition analyses showed that the resulting polymer contained both monomer units (Tables II and VI, and Fig. 1). The S-shaped monomer-polymer composition curve in the copolymerization of α-MeSt and BCMO (Fig. 1) indicated that both monomer reactivity ratios ($r_1$ and $r_2$) were larger than unity, and that the homopropagating reactivities of both growing chain ends were very important. Furthermore, from the fractionation experiments of the resulting polymers

(see Table III), it was clarified that no copolymer was obtained, although a mixture of the homopolymers of BCMO and $\alpha$-MeSt, and of poly$\alpha$-MeSt containing one BCMO unit which might be attached as an end group, was obtained. Similar results were obtained in the case of IBVE-BCMO copolymerization (see Table VI). The phenomenon in which a mixture of homopolymers was produced through the copolymerization (this is expressed in terms of independent copolymerization) may be observed when the reactivities of the two monomers are close to each other.



The following two paths may be considered in the propagation of BCMO:

The rate of propagation should be proportional to the concentration of the propagating cation in path 1 and to the concentrations of both the propagating cation and the monomer in path 2. Penczek and Penczek[8] proved kinetically that the propagation in BCMO polymerization was a bimolecular reaction of the propagating cation and the monomer. Therefore, path 1 may be eliminated. The propagation takes place through the reaction of the terminal oxonium ion with the monomer molecule.

The reaction scheme of the cationic copolymerization of $\alpha$-MeSt and BCMO is expressed below.

The reactions of $k_3$ and $k_5$ are the homopolymerizations of $\alpha$-MeSt and BCMO respectively; their rates must be larger than that of cross propagation, if only a mixture of both homopolymers is produced. The stability of the $\alpha$-MeSt cation participates in this copolymerization fairly importantly. If the growing carbonium ion from the vinyl monomer is unstable, it is very easy in the reaction with ether to form a stable oxonium ion, and the polymerization of the vinyl monomer is inhibited by the presence of ether. It is understandable, in view of this, that the greater reactivity of $\alpha$-MeSt for cationic polymerization by $BF_3 \cdot Et_2O$ was much depressed, being it close to that of BCMO in its copolymerization with BCMO. In the St-BCMO system, the polymerization reactivity of St by $BF_3 \cdot Et_2O$ was also greatly depressed, and scarcely any polymers containing St units were obtained. The inhibiting effect of ethers in the cationic

8) I. Penczek and S. Penczek, *Makromol. Chem.*, **67**, 203 (1963).

polymerization of St has been reported previously.[9]

The phenomenon that the copolymer was not obtained in the cationic copolymerization of α-MeSt and BCMO may result from the difference in reactivity based on the structures of the propagating cations; namely, the poly-α-MeSt cation is the carbonium ion, while the polyBCMO cation is the oxonium ion. A similar consideration was postulated by Yamashita et al.[10] for the cationic copolymerization of BCMO and β, β-dimethyl-β-propiolactone.

In the $SnCl_4$-catalyzed copolymerization, only a homopolymer of α-MeSt was obtained, because the polymerization reactivity of BCMO by this catalyst is quite small. In the $AlEt_3$-$H_2O$- catalyzed copolymerization, homopolyBCMO was obtained, though the homopolymerization of α-MeSt proceeded without difficulty when this catalyst system was used. Recently it was proposed by Furukawa et al.[11] that this catalyst system could act as does Lewis acid for the polymerization of BCMO.

These differences in the results according to the kind of catalyst may result from the fact that the effect of the gegen ion in the cationic polymerization is very important.

The relationship between the monomer and the resulting polymer compositions in the copolymerization is expressed by Eq. 1[12];

$$\frac{[m_1]}{[m_2]}=\frac{[M_1]}{[M_2]}\frac{r_1[M_1]+[M_2]}{[M_1]+r_2[M_2]} \qquad (1)$$

where $m_1$ and $m_2$ are the monomer units in the copolymer, and $M_1$ and $M_2$ are those in the monomer mixture. If $r_1$ and $r_2$ are infinity, Eq. 1 is converted into Eq. 2:

$$\frac{[m_1]}{[m_2]}=\frac{[M_1]^2}{[M_2]^2} \qquad (2)$$

However, if absolutely no cross propagation occurs (independent copolymerization), $[m_1]/[m_2]$ must be proportional to the ratio of the rates of homoplymerizations of $M_1$ and $M_2$. On the basis of the postulations of the rate equations and the rate constants, including the term of the catalyst concentration in the homopolymerizations of $M_1$ and $M_2$, the relation between monomer and polymer compositions in the independent copolymerization is shown in Fig. 3a—c.

As can be seen from Fig. 3, the relation of Eq. 2 is only an example of independent copolymerization; the S-shaped composition

curve is not essential. However, in actuality, no clear relation such as is shown in Fig. 3 is observed because of the complicated effects in the ionic polymerization.

It is known that the block copolymer is obtained occasionally in the ionic copolymerization. Tada, Saegusa and Furukawa[13] proved that this phenomenon occurs with the cationic copolymer of BCMO and β-propiolactone.

Equation 1 can be simply adopted for a copolymerization in which the monomer units are distributed statistically in the resulting copolymer chain. Therefore, if a block copolymer or a mixture of copolymer and homopolymer was obtained through the copolymerization, the resulting monomer reactivity ratios ($r_1$ and $r_2$), which indicate the ratio of the rate constants of homo- and cross-propagation, may become less significant.

**Summary**

The copolymerization of several vinyl monomers, such as styrene, α-methylstyrene and isobutyl vinyl ether, with 3,3-bis(chloromethyl)oxetane catalyzed by Lewis acids (boron trifluoride-diethyl etherate, stannic chloride and triethylaluminum-water) in methylene chloride at 0°C has been investigated. In these copolymerizations, the copolymers were not obtained, though a mixture of the corresponding homopolymers was obtained in some cases. The results have been explained on the basis of the differences in reactivity resulting from the structures of the two propagating chain ends.

# The Copolymerization of the Vinyl Monomer with a Cyclic Compound. II. The Cationic Copolymerization of Some Vinyl Monomers with β-Propiolactone*

By Shuzo AOKI, Yoshiyuki HARITA, Takayuki OTSU and Minoru IMOTO

(Received March 25, 1965)

In a preceding paper,[1] the cationic copolymerization of some vinyl monomers with 3, 3-bis(chloromethyl)oxetane catalyzed by Lewis acids was investigated. It was found that the copolymers were not obtained in all systems, but that mixtures of the corresponding homopolymers were produced in some cases. The present paper is concerned with the cationic copolymerization of vinyl monomers with β-propiolactone (β-PL) catalyzed by Lewis acids.

It is interesting to prepare the copolymer of the vinyl monomer with β-PL, which gives the ester linkage in the main chain of the resulting copolymer. With such a purpose in mind, Okamura et al.,[2] for instance, attempted the radiation-induced copolymerization of styrene (St), acrylonitrile and methyl methacrylate with β-PL. Shimosaka, Tsuruta and Furukawa[3] prepared the copolymer of acrylonitrile with β-PL through the copolymerization catalyzed by organometallic compounds. Yamashita et al.[4] reported the copolymerization of St with β, β-dimethyl-β-propiolactone by stannic chloride.

In the present paper, St, α-methylstyrene (α-MeSt) and isobutyl vinyl ether (IBVE) will be used as vinyl monomers. Boron trifluoride-diethyl etherate ($BF_3 \cdot Et_2O$), stannic chloride ($SnCl_4$) and triethylaluminum-water ($AlEt_3$-$H_2O$) will be used as cationic catalysts. From the copolymerization results, the reactivity of β-PL with vinyl monomers will be evaluated and discussed.

## Experimental

**Materials.**—Commercial β-PL, St, α-MeSt and IBVE were distilled over calcium hydride under reduced pressures.

2) S. Okamura, K. Hayashi, Y. Kitanishi and M. Nishii, *Isotopes and Radiation* (*Doitai to Hoshasen*), 3, 510 (1960).

3) Y. Shimosaka, T. Tsuruta and J. Furukawa, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **66**, 1498 (1963).

4) Y. Yamashita, T. Tsuda, Y. Ishikawa and T. Shimizu, ibid., **66**, 1493 (1963).

$BF_3 \cdot Et_2O$, $SnCl_4$ and methylene chloride were purified and the $AlEt_3$-$H_2O$ catalyst was prepared in the methods described in the preceding paper.[1] The other materials were purified by the ordinary methods.

**Copolymerization Procedure.**—The copolymerization procedure was the same as that described in the preceding paper.[1]

**The Fractionation of the Polymer.**—The polymer obtained in the copolymerization of β-PL and St was fractionated to determine whether this polymer was the copolymer or a mixture of the homopolymers. Since polySt was isoluble in acetic acid, while polyβ-PL was soluble, the chloroform solution of the resulting polymer was poured into a large amount of acetic acid in order to separate it into acetic acid-soluble and acetic acid-insoluble fractions. Both fractions were then further fractionated by the chloroform-methanol system.

**The Analysis of the Polymer.**—The compositions of the polymers obtained in various monomer compositions were determined by means of their infrared spectra and by means of elementary analyses on carbon.

The molecular weight of the polymer was determined with a Mechrolab vapor pressure osmometer, model 301-A.

The inherent viscosity of the polymer was measured in a one per cent solution of it in choroform at 30°C.

## Results

**The β-PL - St - $BF_3 \cdot Et_2O$ or - $SnCl_4$ System.**—The results of the copolymerization of β-PL with St catalyzed by $BF_3 \cdot Et_2O$ or $SnCl_4$ are summarized in Tables I and II. The copolymerization proceeded without difficulty with both catalysts, and a colorless, powdered polymer was obtained. The infrared spectra of the resulting polymer showed the characteristic absorption bands at 1725 and 1603 $cm^{-1}$ based on the ester linkage (β-PL unit) and

the benzene nucleus (St unit) respectively (see Fig. 2). The monomer-polymer composition curve for this copolymerization is shown in Fig. 1.

No difference between $BF_3 \cdot Et_2O$ and $SnCl_4$ catalysts was observed in the monomer-polymer composition relation. The apparent monomer reactivity ratios were estimated, by the curve-fitting method, to be $r_{(\beta\text{-PL})}=0.2$ and $r_{(St)}=20$ respectively.

In order to determine whether the polymer obtained here was the copolymer or a mixture of the corresponding homopolymers, the resulting polymer was fractionated into several fractions. The results are given in Table III, while the infrared spectra of soluble and insoluble fractions in acetic acid are shown in Fig. 2.

It was proved, by infrared spectra and elementary analysis, that the insoluble fraction of the resulting copolymer in acetic acid, which is known to be a solvent for only polyβ-PL, contained the β-PL unit; while its soluble fraction contained the St unit. The molecular weight of the fractionated copolymer was not very low (see Table III). These results indicated that the copolymer of β-PL with St was produced in their copolymerizations with such Lewis acids as $BF_3 \cdot Et_2O$ and $SnCl_4$.

Some of the infrared spectra of the unfractionated and fractionated copolymers showed absorption bands at 1680 and 1710 $cm^{-1}$ in addition to the characteristic bands mentioned above (see Fig. 2). It is assumed that the structure of the β-PL - St copolymer contains the following four types of repeating units:

The structures I and II are the repeating units of polyβ-PL and polySt, and show the characteristic absorption bands in the infrared spectra at 1725 and 1603 $cm^{-1}$ respectively. The structure III must be formed through the copolymerization in which the opening of the β-PL ring, followed by an attack on the vinyl double bond of St, takes place to form carbonyl cations as the propagating species. Since the infrared absorption band at 1710 $cm^{-1}$ agreed with that of a carbonyl group of aliphatic ketone, it was obvious that this copolymer contained the structure III. If the

carbonyl cation formed from β-PL attacks the benzene nucleus of monomeric or polymeric St through the chain-transfer reaction, the structure IV may be formed. The absorption band at 1680 $cm^{-1}$ may be assigned to a carbonyl group of aromatic ketone. It was therefore concluded that this copolymer contained the structure IV.

In order to obtain further evidence for the existence of the structure IV in the copolymer, the polymerization of β-PL in the presence of ethylbenzene in place of St was performed. The existence of the ketonic carbonyl group in the resulting polymer was also confirmed by the reaction with 2, 4-dinitrophenylhydrazine.

**The β-PL - St - $AlEt_3$-$H_2O$ System.**—The results of the copolymerization of β-PL with St catalyzed by $AlEt_3$-$H_2O$ are summarized in Table IV. In contrast with the case of the $BF_3 \cdot Et_2O$ or the $SnCl_4$ catalyst, no copolymer was obtained in this catalyst system.

**The β-PL - α-MeSt - $BF_3 \cdot Et_2O$ or - $SnCl_4$ System.**—The results of the copolymerization of β-PL with α-MeSt by the $BF_3 \cdot Et_2O$ or the $SnCl_4$ catalyst are summarized in Tables V and VI. The absence of the β-PL unit in the resulting polymers was confirmed by their infrared spectra.

**The β-PL - α-MeSt - $AlEt_3$-$H_2O$ System.**—The results of the copolymerization of β-PL and α-MeSt by the $AlEt_3$-$H_2O$ catalyst are shown in Table VII. The resulting polymers were found to be homopolymers of β-PL, much as in the case of β-PL - St - $AlEt_3$-$H_2O$.

**The β-PL - IBVE - $SnCl_4$ System.**—The results of the copolymerization of β-PL and IBVE by $SnCl_4$ are tabulated in Table VIII. The polymerization was very rapid, and the resulting

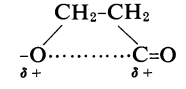
polymer was confirmed by infrared spectra to be polyIBVE.

## Discussion

The results of the copolymerization of vinyl monomers with β-PL are summarized in Table IX. As this table shows, the β-PL - St - $BF_3 \cdot Et_2O$ or - $SnCl_4$ system gave copolymer. This copolymer contained infrared absorption bands at 1680 and 1710 $cm^{-1}$ which could be assigned to the carbonyl groups of aromatic and aliphatic ketones respectively. These results indicate that the ring-opening of β-PL takes place at the acyl-oxygen bond, as has been reported by Cherdron et al.[5] The presence of aromatic and aliphatic ketones also indicates that the copolymers obtained here include a graft copolymer of polySt containg a pendant polyester chain derived from β-PL.



In our previous paper,[1] it was suggested that the copolymer was not obtained in the copolymerization of monomers which propagate via different propagating species, carbonium and oxonium ions. Accordingly, the fact that the copolymer is formed in the present case may lead to the conclusion that the propagating species of β-PL in this cationic polymerization is that of carbonium ions, although an oxonium-ion mechanism was proposed by Yamashita et al.[6]

In order to clarify this ambiguity, the homopolymerization of β-PL was undertaken. The results are tabulated in Table X. The rate of polymerization increased with an increase in the concentration of the monomer, but the molecular weight of the resulting polymer, as deduced from its inherent viscosity, was little affected. The propagation scheme in β-PL polymerization may, then, be expressed by the following two paths:

In path 1, an oxonium ion of the propagating β-PL directly attacks the β-PL monomer. On the other hand, in path 2, the propagation includes a carbonium-ion intermediate. From the difference in the stabilities of the oxonium and carbonium ions, it may reasonably be assumed that, in path 2, the rate-determining step is the formation of the carbonium-ion intermediate. If the termination of the β-PL polymerization is an unimolecular reaction of the growing cation, the molecular weight of the resulting polymer is proportional to the monomer concentration in path 1, while it is independent of it in path 2.

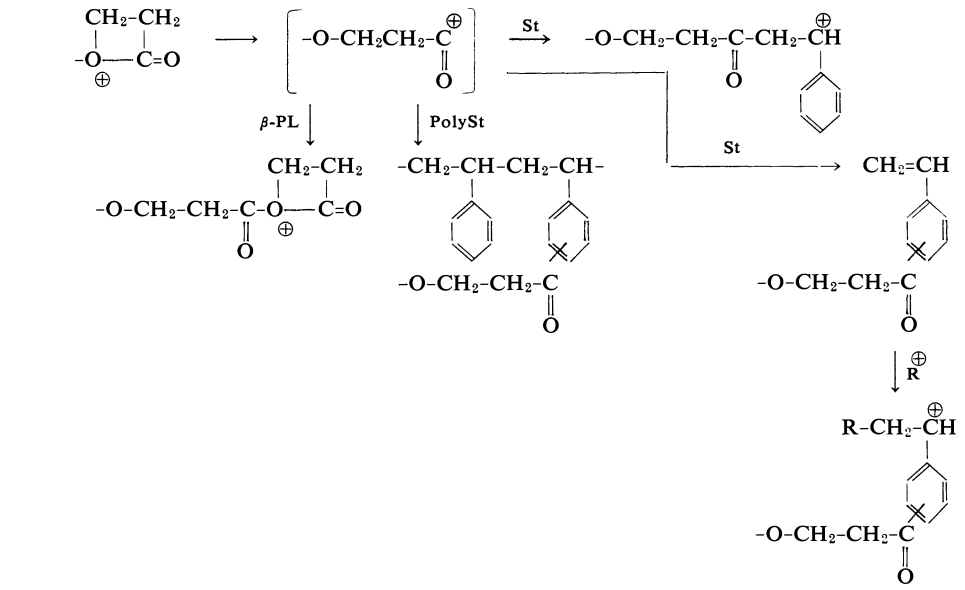
The results in Table X support the mechanism of path 2. In practice, however, the carbonyl cation derived from β-PL may be considered to exist as an intramolecular-solvated state, an intermediate between oxonium and carbonium ions. Therefore, the β-PL-growing cation contains an intermediate structure of both oxonium and carbonium ions (V):

(V)

In a polar solvent the character of the carbonium ion may be emphasized, but the reverse holds in a nonpolar solvent. Thus, it may be concluded that β-PL copolymerizes with St via β-PL carbonium ions and with 3, 3-bis(chloromethyl)oxetane[7] via oxonium ions.

The reaction scheme of the copolymerization of β-PL and St can be given as follows:

TABLE IX. COPOLYMERIZATION BEHAVIOR OF β-PL



| Catalyst | Comonomer | | |
|---|---|---|---|
| | St | α-MeSt | IBVE |
| $BF_3 \cdot Et_2O$ | Copolymer | Polyα-MeSt | — |
| $SnCl_4$ | Copolymer | Polyα-MeSt | PolyIBVE |
| $AlEt_3$-$H_2O$ | Polyβ-PL | Polyβ-PL | — |

([$SnCl_4$] = 0.07 mol./l.)

| [β-PL] mol./l. | Time min. | Conversion, % | $R_p \times 10^3$ mol./l. min. | $\eta_{sp}/C$* dl./g. |
|---|---|---|---|---|
| 0.5 | 270 | 36.5 | 0.7 | 0.07 |
| 1.0 | 150 | 28.3 | 1.9 | 0.07 |
| 2.0 | 250 | 35.2 | 2.8 | 0.09 |
| 2.0 | 345 | 46.6 | 2.7 | 0.09 |
| 3.0 | 80 | 29.3 | 11.0 | 0.09 |

* In 1% chloroform solution at 30°C.

5) H. Cherdron, H. Ohse and F. Korte, *Makromol. Chem.*, **56**, 179 (1962).
6) Y. Yamashita, Y. Ishikawa, T. Tsuda and S. Miura, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **66**, 104 (1963).
7) K. Tada, T. Saegusa and J. Furukawa, *Makromol. Chem.*, **71**, 71 (1964).

It should be noted that the copolymerization results on $\alpha$-MeSt and IBVE by $BF_3 \cdot Et_2O$ or $SnCl_4$, as shown in Table IX, may be understood to be caused by the higher reactivity of these vinyl monomers than that of St. The difference between the results obtained using $BF_3 \cdot Et_2O$ and $SnCl_4$, and $AlEt_3$-$H_2O$ as catalysts may result from the difference in the effect of gegen ions.

## Summary

The copolymerization of several vinyl monomers, such as styrene (St), $\alpha$-methylstyrene and isobutyl vinyl ether, with $\beta$-propiolactone ($\beta$-PL) as catalyzed by Lewis acids has been investigated in methylene chloride at 0°C. In the copolymerization of $\beta$-PL and St using boron trifluoride-diethyl etherate or stannic chloride as a catalyst, the copolymer was obtained. The apparent monomer reactivity ratios were estimated to be as follows:

$$r_{(\beta\text{-PL})}=0.2\,;\ r_{(St)}=20$$

In the other copolymerization systems, the copolymer was not obtained. The mechanism of these copolymerizations has been discussed.

# The Effect of Hydrogen-Bonding on the g-Value of Diphenyl Nitric Oxide

By Takashi KAWAMURA, Shoichi MATSUNAMI, Teijiro YONEZAWA and Kenichi FUKUI

(Received March 29, 1965)

The solvent effects on the hyperfine structure of the ESR spectra of semiquinones,[1,2] nitro-compounds[3-5] and aromatic nitric oxides[6,7] have been reported on. However, only a few studies of the solvent effect upon the g-value have been reported.[8] Stone has derived the gauge-invariant g-tensor[9] and an equation as for calculating the g-value of a π-radical.[10] His work suggests that the g-value of a π-radical which contains an oxygen atom in conjugated systems would deviate considerably from the g-value of a free electron (2.00232) because of the large L-S coupling of oxygen as well as the small difference in energy between the odd-electron orbital and the oxygen lone-pair orbital. This has also been pointed out qualitatively by McConnell and Robertson.[11]

It may be expected that the formation of a hydrogen bond to an oxygen atom in a conjugated system would diminish the contribution of the oxygen atom to the g-value through lowering the lone-pair orbital energy and decreasing the odd-electron density on the oxygen atom, thus causing a variation in the g-value. In the present paper we will investigate the effect of the hydrogen bond on the g-value of diphenyl nitric oxide (DPNO); we will attempt a precise analysis.

## Experimental

**Materials.**—DPNO was synthesized by employing the method of Wieland and Roth,[12] recrystallized from methanol (m. p. 62—63°C), sealed in an ampoule under $10^{-4}$ mmHg vacuum, and stored in liquid nitrogen.[6] Carbon tetrachloride, chloroform, ethanol and toluene were purified by following the directions described in "Organic Solvents."[13] Phenylacetylene was purified by distillation from Drierite in a vacuum. Phenol was purified by the freezing method.

**The Measurement of the ESR Spectra.**—Several solvents were employed in preparing a dilute solution of DPNO. The solvents were dried over Drierite for at least one day and then distilled from Drierite under a $10^{-4}$—$10^{-5}$ mmHg vacuum into sample tubes which had previously been charged with DPNO. In the case of a phenol-toluene mixed solvent, a dilute solution of DPNO was prepared under ordinary atmospheric conditions, charged into a sample tube, and then degassed. The ESR spectrometer employed was a JES-3BX-type instrument with a 100 kc. modulation, made by the Japan Electron Optics Co. The static magnetic field was generated by a JES electro-magnet with 300 mmφ pole pieces, with a homogeneity of $1\times10^{-5}$. For the measurement of the g-value and hyperfine splittings, a glass capillary was attached to a sample. The capillary, as in the usual procedure, was filled, as a reference compound, with an aqueous solution of potassium peroxylamine disulfonate, the g-value and the hyperfine coupling constant of the $^{14}N$ of which had been reported to be $2.00550\pm0.00005$ and $13.0\pm0.1$ gauss.[14]

All the measurements of the ESR spectra and the visible spectra were performed at room temperature (10—20°C).

## Results

The numbering of the positions in the DPNO molecule is shown in Fig. 1c. The ESR spectrum of DPNO in carbon tetrachloride is shown in Fig. 1a, and a constructed spectrum with coupling constants of $a_{1\text{-H}}=a_{3\text{-H}}=1.845$, $a_{2\text{-H}}=0.810$ and $a_N=9.559$ gauss, in Fig. 1b. Figure 1b shows a good agreement with the observed spectrum in Fig. 1a. The g-value of DPNO in carbon tetrachloride proved to be $2.00572\pm0.00005$.

The g-value and hyperfine coupling constants of 1- and 3-protons are listed in Table I, together with the changes in them caused by

TABLE I. THE OBSERVED $g$-VALUE AND HYPERFINE COUPLING CONSTANTS OF 1- AND 3-PROTONS AND THEIR SHIFTS

| Solvent | $(g-g_{POA})\times10^5$ a) | $a_{1\text{-H}}=a_{3\text{-H}}$ b) Gauss | $\delta\Delta g\times10^5$ | $\delta a_{1\text{-H}}$ Gauss |
|---|---|---|---|---|
| Carbon tetrachloride | +22±1 | 1.845±0.008 | 0 | 0 |
| Phenylacetylene | +10±2 | 1.879±0.006 | −12 | +0.034 |
| Chloroform | +6±1 | 1.890±0.003 | −16 | +0.045 |
| Ethanol | +4±1 | 1.913±0.014 | −18 | +0.068 |
| Methanol | +0±1 | 1.917±0.002 | −22 | +0.072 |
| Phenol in toluene (4.4 mol./l. soln.) | −35±1 | 2.068±0.007 | −57 | +0.223 |
| Water | −42±1 | 2.105±0.003 | −64 | +0.260 |

a) The measurement of $g$-value is performed by employing peroxylamine disulfonate as a reference. The $g$-value of peroxylamine disulfonate is notated as $g_{POA}$.
b) Experimentally found values of $a_{1\text{-H}}$ and $a_{3\text{-H}}$ are equal in all solvents employed, although 1- and 3-protons are non-equivalent.

the variation in solvents employed. The differences of these values from those in carbon tetrachloride are denoted by $\delta\Delta g$ and $\delta a_{1\text{-H}}$ respectively, where $\Delta g$ means the difference in $g$-value from that of free spins, which is indicated in Eq. 1.

The visible spectra of DPNO in carbon tetrachloride, chloroform, ethanol and methanol are shown in Fig. 2.

In the visible spectrum of DPNO in carbon tetrachloride, the absorptions at 578 m$\mu$ (shoulder) ($\log\varepsilon=1.97$), 537 m$\mu$ (2.24) and 512 m$\mu$ (2.26) are taken to be the $n$-$\pi^*$ transition, and the absorptions at 473 m$\mu$ (2.66) and 395 m$\mu$ (3.17) are taken to be the $\pi$-$\pi^*$ transition, because the former three shift toward blue and the latter two, toward red when dissolved in hydrogen-bond-forming solvents.[15] Although the observed spectra show that the magnitude of the blue shift of the $n$-$\pi^*$ transition is parallel with the hydrogen-bonding ability of the solvents, and also with the shift of the $g$-value and the hyperfine coupling constants, the position of $n$-$\pi^*$ absorption in hydrogen-bonding solvents, unfortunately, can not be determined with accuracy.

15) H. McConnell, *J. Chem. Phys.*, 20, 700 (1952).

## Discussion

**Stone's Theory for the $g$-Value.**—Considering only one-center integrals and using the two-center $\sigma$-molecular orbital model, Stone has derived the following equation to give the $g$-value of a $\pi$-radical:[10]

$$g=2.00232+\Delta g \quad (1)$$

$$\Delta g=\sum_i \Delta g_i+\sum_j \Delta g_{nj} \quad (2)$$

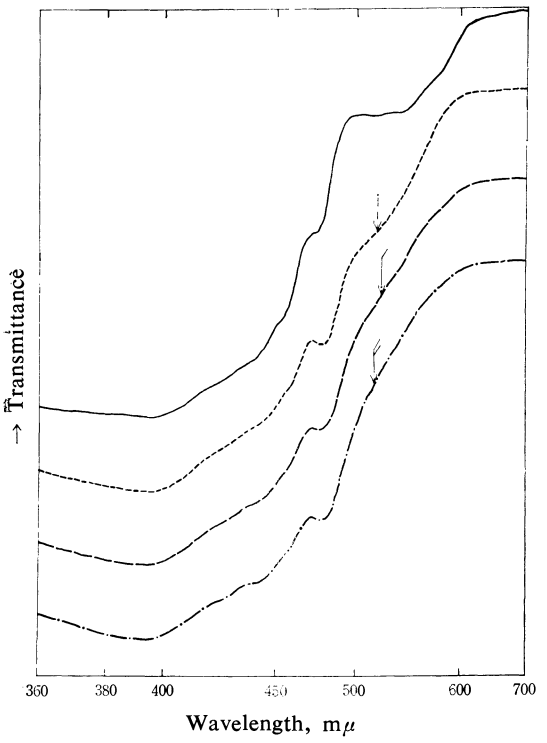

Fig. 2. Visible spectra of DPNO in carbon tetrachloride ——, in chloroform - - - -, in ethanol — — — and in methanol —·—·—. Arrows ↓, ↓ and ↓ show the position of $n$-$\pi^*$ transition of DPNO in chloroform, in ethanol and in methanol calculated from the $g$-value (see text).

$$\Delta g_i = \frac{2}{3}\sum_{m}^{a,b} \frac{\zeta_r(C^m_{rx})^2(C^p_r)^2+\zeta_s(C^m_{sx})^2(C^p_s)^2+(\zeta_r+\zeta_s)C^m_{rx}C^m_{sx}C^p_rC^p_s}{\varepsilon^p-\varepsilon^m_i} + \frac{2}{3}\sum_{m}^{a,b} \frac{\zeta_r(C^m_{ry})^2(C^p_r)^2+\zeta_s(C^m_{sy})^2(C^p_s)^2+(\zeta_r+\zeta_s)C^m_{ry}C^m_{sy}C^p_rC^p_s}{\varepsilon^p-\varepsilon^m_i} \quad (3)$$

$$\Delta g_{nj} = \frac{2}{3}\frac{\zeta_j\{(C^n_{jx})^2+(C^n_{jy})^2\}(C^p_j)^2}{\varepsilon^p-\varepsilon^n_j} \quad (4)$$

where $\Delta g_i$ and $\Delta g_{nj}$ are the contributions to $\Delta g$ from $i$th $\sigma$-bond and the $j$th lone-pair orbital respectively; the notation $\sum_i$ and $\sum_j$ in Eq. 2 indicate the sums over $\sigma$-bonds and over lone-pairs respectively. Throughout this paper, $g$ and all the $\Delta g$'s are the average with respect to three spatial axes. In Eq. 3, $a$ and $b$ indicate the bonding and the anti-bonding orbitals of the $i$th $\sigma$-bond between atoms $r$ and $s$. When the nodal plane of the $\pi$-orbital is the xy-plane, $C^p_r$ is the coefficient of the $P_z$ atomic orbital (AO) of the atom $r$ in the odd-electron orbital; $C^m_{rx}$ and $C^m_{ry}$ are coefficients of the $P_x$ and $P_y$ AO's of the atom $r$ in the $m$th $\sigma$-orbital, and so on. The notations $\zeta_r$ and $\zeta_s$ are L-S coupling constants about the $r$ and $s$ nuclei. The notations $C^n_{jx}$ and $C^n_{jy}$ in Eq. 4 are the coefficients of the $P_x$ and $P_y$ AO's in the $j$th lone-pair orbital, while $C^p_j$ and $\zeta_j$ are the coefficient in the odd-electron orbital and the L-S coupling constant of the atom which has the $j$th lone-pair. When many-center integrals are neglected, fully-occupied or vacant $\pi$-orbitals do not mix into the half-occupied $\pi$-orbital by means of the perturbation of the L-S coupling. Thus, the summation in Eq. 2 is only required over all of the $\sigma$-bonds and lone-pair orbitals.

**The Calculation of the $g$-Value of DPNO in Carbon Tetrachloride.**—The $\pi$-orbitals of DPNO were obtained by the Hückel molecular orbital method, with parameters of $\alpha_O=\alpha+\beta$, $\alpha_N=\alpha+2\beta$, $\beta_{NC}=0.7\beta$ and $\beta_{NO}=0.7\beta$.[16] The calculated odd-electron orbital energy, the odd-electron densities, $\rho_r=(C^p_r)^2$, and the odd-electron orbital bond-orders, $p^p_{rs}=C^p_r\times C^p_s$, are as follows:

$\varepsilon^p=\alpha+0.5090\beta=-8.33$ eV.[17],

$\rho_1=0.0551$, $\rho_2=0.0036$,

$\rho_3=0.0418$, $\rho_4=0.0268$,

$\rho_5=0.2160$, $\rho_6=0.4389$,

$p^p_{45}=-0.0761$, $p^p_{56}=-0.3079$

To obtain N–O and N–C $\sigma$-orbitals, an extended Hückel molecular orbital calculation[18] of $((CH_2)_2C)_2NO$ was performed, on the assumption that all bond angles were 120°, and that the C–H, C–C, C–N and N–O distances were 1.084 Å, 1.397 Å, 1.40 Å and 1.35 Å respectively in the co-planar structure. Then, by slightly modifying the $\sigma$-molecular orbitals, which are mainly localized in N–O and N–C bonds obtained by an extended Hückel method, we got:

the N–C anti-bonding orbital and its orbital energy:

$$\varphi^a_{NC}=0.9120\chi_{Ny}+0.1248\chi_{Cs}-0.3556\chi_{Cx}+0.6916\chi_{Cy}$$

$\varepsilon^a_{NC}=+4.25$ eV.

the N–C bonding orbital and its orbital energy:

16) A. Streitwieser, Jr., "Molecular Orbital Theory for Organic Chemists," John Wiley & Sons, Inc., N. Y. (1961), p. 135. A small $\beta_{NC}$ is used, because the phenyl ring plane would be somewhat twisted from the nodal plane of N–O $\pi$-orbital.

17) $\alpha=-7.06$ eV. and $\beta=-2.49$ eV. are used. Teijiro Yonezawa, Chikayoshi Nagata, Hiroshi Kato, Akira Imamura and Keiji Morokuma, "Ryōshikagaku Nyūmon (Introduction to Quantum Chemistry)," Kagaku Dōjin Co., Tokyo (1964), p. 130.

18) R. Hoffmann, *J. Chem. Phys.*, **39**, 1397 (1963); **40**, 2474, 2480, 2745 (1964).

$$\varphi^{b}_{NC}=0.7777\chi_{Ny}+0.0718\chi_{Cs}+0.3627\chi_{Cx}-0.2823\chi_{Cy}$$

$$\varepsilon^{b}_{NC}=-14.33\ \text{eV}.$$

the N–O anti-bonding orbital and its orbital energy:

$$\varphi^{a}_{NO}=0.5456\chi_{Os}+0.7031\chi_{Ox}-0.2846\chi_{Ns}+1.0517\chi_{Nx}$$

$$\varepsilon^{a}_{NO}=+0.10\ \text{eV}.$$

the N–O bonding orbital and its orbital energy:

$$\varphi^{b}_{NO}=-0.1804\chi_{Os}+0.8247\chi_{Ox}+0.0555\chi_{Ns}-0.3623\chi_{Nx}$$

$$\varepsilon^{b}_{NO}=-19.02\ \text{eV}.$$

Here $\chi_{Ns}$ and $\chi_{Ox}$ are the 2S AO of nitrogen and $2P_x$ AO of oxygen, and so on. These $\sigma$-orbitals would not be bad for N–C and N–O $\sigma$-orbitals in DPNO. In the present treatment, we assumed that a $2P_y$ AO is a lone-pair orbital of the oxygen atom. We estimated $\varepsilon^{p}-\varepsilon^{n}$ as 18620 $cm^{-1}$ from the observed $n$-$\pi^*$ absorption spectrum.

With the above-mentioned orbitals and by putting $\zeta_N=70\ cm^{-1}$ and $\zeta_O=152\ cm^{-1}$,[19] $\Delta g_i$'s and $\Delta g_{nj}$ were calculated as follows:

$$\Delta g_{NC}=+9.7\times10^{-5}$$

$$\Delta g_{NO}=+53.2\times10^{-5}$$

$$\Delta g_{n}=+238.8\times10^{-5}$$

For the sum of the $\Delta g_i$'s over the hydrocarbon part, which may be denoted by $\Delta g_{h.c.}$, Stone has proposed formula 5 semiempirically[10]:

$$\Delta g_{h.c.}=\sum_{i}^{carbons}\rho_i(24.7-19.3\lambda)\times10^{-5} \qquad (5)$$

where $\lambda$ is the coefficient of the odd-electron orbital energy, $\alpha+\lambda\beta$, and $\rho_i$ is the odd-electron density on the $i$th carbon. With Eq. 5, $\Delta g_{h.c.}$ of DPNO becomes:

$$\Delta g_{h.c.}=+5.1\times10^{-5}$$

The calculated $g$-value of DPNO is, therefore:

$$g_{calcd}=2.00232+2\Delta g_{NC}+\Delta g_{NO}+\Delta g_{n}+\Delta g_{h.c.}=2.00549$$

This value shows a good agreement with the $g$-value observed in carbon tetrachloride:

$$g_{obs}=2.00572\pm0.00005$$

**The Calculation of the Hydrogen-bond Effect on the $g$-Value.**—Bolton[20] has considered the protonation effect on the hyperfine structure of the ESR spectra of semiquinones as a perturbation which causes changes in the coulomb integral of the oxygen atom and the resonance integral of the C–O bond. In a similar way, in explaining the difference in the hyperfine coupling constants of semiquinones in dimethylsulfoxide and in an ethanol-water mixed solvent, Gendell and Fraenkel[2] regarded the solvent effect as a perturbation which causes a change in the coulomb integral of the oxygen atom.

Here we take the hydrogen-bond effect to be a perturbation which increases the coulomb integral of the oxygen atom. In the Hückel molecular orbital theory the perturbation, which increases the coulomb integral of the $t$th atom from $\alpha_t$ to $\alpha_t+\delta\alpha_t$, also increases the odd-electron density on the $r$th atom from $\rho_r$ to $\rho_r+\delta\rho_r$, the odd-electron orbital bond order between $r$th and $s$th atoms from $p^{p}_{rs}$ to $p^{p}_{rs}+\delta p^{p}_{rs}$, and the odd-electron orbital energy from $\varepsilon^{p}$ to $\varepsilon^{p}+\delta\varepsilon^{p}$, as is indicated in Eqs. 6—10.

$$\delta\rho_r=\pi^{p}_{r,t}\times\delta\alpha_t \qquad (6)$$

$$\delta p^{p}_{rs}=\pi^{p}_{rs,t}\times\delta\alpha_t \qquad (7)$$

$$\delta\varepsilon^{p}=\rho_t\times\delta\alpha_t \qquad (8)$$

$$\pi^{p}_{r,t}=2\sum_{k\neq p}\frac{C^{k}_{r}C^{k}_{t}C^{p}_{r}C^{p}_{t}}{\varepsilon^{p}-\varepsilon^{k}} \qquad (9)$$

$$\pi^{p}_{rs,t}=\sum_{k\neq p}\frac{C^{k}_{t}C^{k}_{r}C^{p}_{t}C^{p}_{s}+C^{k}_{t}C^{k}_{s}C^{p}_{t}C^{p}_{r}}{\varepsilon^{p}-\varepsilon^{k}} \qquad (10)$$

Here $C^{k}_{r}$ and $C^{p}_{r}$ are the coefficients of the AO of the $r$th atom in the $k$th and the odd-electron $\pi$-orbitals. The notations $\varepsilon^{k}$ and $\varepsilon^{p}$ are the orbital energies of the $k$th and the odd-electron $\pi$-orbitals. Calculated with the parameters mentioned in the preceding section, the values of $\pi^{p}_{r,t}$'s and $\pi^{p}_{rs,t}$'s are tabulated in Table II.

TABLE II. $\pi^{p}_{r,t}$ AND $\pi^{p}_{rs,t}$ (in unit of $1/\beta$)

| $\pi^{p}_{1,6}$ | $\pi^{p}_{2,6}$ | $\pi^{p}_{3,6}$ | $\pi^{p}_{4,6}$ |
|---|---|---|---|
| +0.1074 | +0.0139 | +0.0574 | +0.0932 |
| $\pi^{p}_{5,6}$ | $\pi^{p}_{6,6}$ | $\pi^{p}_{45,6}$ | $\pi^{p}_{56,6}$ |
| +0.0831 | −0.7696 | −0.1392 | +0.2297 |

From Eq. 6, in this connection we get:

$$\frac{\delta a_{1\text{-H}}}{a_1}=\frac{\delta\rho_1}{\rho_1}=\frac{\pi^{p}_{1,6}}{\rho_1}\times\delta\alpha_6$$

$$\frac{\delta a_{3\text{-H}}}{a_3}=\frac{\delta\rho_3}{\rho_3}=\frac{\pi^{p}_{3,6}}{\rho_3}\times\delta\alpha_6$$

where $a_1$ and $a_3$ are the coupling constants of 1- and 3-protons of DPNO dissolved in carbon tetrachloride respectively, and where $\delta a_{1\text{-H}}$ and $\delta a_{3\text{-H}}$ are their increases in hydrogen-bond solvents. It was observed that $a_1=a_3$ and $\delta a_{1\text{-H}}=\delta a_{3\text{-H}}$. Hence, for the purpose of obtaining the value of $\delta\alpha_6$, we may write approximately:

19) D. S. McClure, *J. Chem. Phys.*, **17**, 905 (1949).
20) J. R. Bolton, A. Carrington and J. dos Santos-Veiga, *Mol. Phys.*, **5**, 465 (1962).

$$\delta\alpha_6=(\delta a_{1\text{-H}}/a_1)/\{(1/2)(\pi^{p}{}_{1,6}/\rho_1+\pi^{p}{}_{3,6}/\rho_3)\} \quad (11)$$

In this way, we can calculate the increase in the coulomb integral of the oxygen atom, $\delta\alpha_6$, by means of formula 11. The results are listed in Table III.

Table III. Increase of the coulomb integral of the oxygen atom due to hydrogen bonding

| Solvent | $\delta\alpha_6$ ($\beta$) |
|---|---|
| Carbon tetrachloride | +0 |
| Phenylacetylene | +0.0111 |
| Chloroform | +0.0147 |
| Ethanol | +0.0222 |
| Methanol | +0.0235 |
| Phenol in toluene (4.4 mol./l. soln.) | +0.0728 |
| Water | +0.0848 |

The contribution to $\delta\Delta g$ from each $\sigma$-bond, the lone-pair and the hydrocarbon part are obtained from Eqs. 3—5 by considering their changes due to the increase in the coulomb integral of the oxygen atom, by considering, that is Eqs. 6—8. The results are as follows:

$$\delta\Delta g_{NC}=+14.5\times10^{-5}\times\delta\alpha_6/\beta \quad (12)$$

$$\delta\Delta g_{NO}=-55.3\times10^{-5}\times\delta\alpha_6/\beta \quad (13)$$

$$\delta\Delta g_{h.c.}=+7.0\times10^{-5}\times\delta\alpha_6/\beta \quad (14)$$

$$\delta\Delta g_{n}=-418.8\times10^{-5}\times\delta\alpha_6/\beta \quad (15)$$

Using these equations, $\delta\Delta g_i$'s are estimated to be as cited in Table IV.

Table IV. The variation of contribution to $\Delta g$ from $\sigma$-bonds and the lone-pair

| Solvent | $\delta\Delta g_{NO}$ $\times10^5$ | $\delta\Delta g_{NC}$ $\times10^5$ | $\delta\Delta g_{h.c.}$ $\times10^5$ | $\delta\Delta g_{n}$ $\times10^5$ |
|---|---|---|---|---|
| Carbon tetrachloride | 0 | 0 | 0 | 0 |
| Phenylacetylene | −0.6 | +0.2 | +0.1 | −4.6 |
| Chloroform | −0.8 | +0.2 | +0.1 | −6.2 |
| Ethanol | −1.2 | +0.3 | +0.2 | −9.3 |
| Methanol | −1.3 | +0.3 | +0.2 | −9.8 |
| Phenol in toluene (4.4 mol./l. soln.) | −4.0 | +1.1 | +0.5 | −30.5 |
| Water | −4.7 | +1.2 | +0.6 | −35.5 |

The values of the $\delta\Delta g_i$'s obtained from Eqs. 12—15 are the variations in $\Delta g_i$'s which are caused by the redistribution of the odd electron through the increase in the coulomb integral of the oxygen atom. Hence, the difference, $\delta'\Delta g_n$, as defined by the equation:

$$\delta'\Delta g_n=\delta\Delta g_{obs}-(2\delta\Delta g_{NC}+\delta\Delta g_{NO}+\delta\Delta g_{h.c.}+\delta\Delta g_n)$$

would be the change in $\Delta g_n$ caused by the increase in the difference between the odd-electron orbital and the lone-pair orbital energies, which brings out the blue shift of the $n$-$\pi^*$ transition. The blue shift of the $n$-$\pi^*$ transition can be represented by Eq. 16[21]:

$$\delta(\varepsilon^{p}-\varepsilon^{n})=-\frac{\delta'\Delta g_n}{\Delta g_n}\times18620\ \text{cm}^{-1} \quad (16)$$

The value of $\delta'\Delta g_n$ and the blue shift of the $n$-$\pi^*$ transition, $\delta(\varepsilon^{p}-\varepsilon^{n})$, are tabulated in Table V.

Table V. The blue shift of the $n$-$\pi^*$ transition calculated from the $g$-value

| Solvent | $\delta'\Delta g_n$ $\times10^5$ | $\delta(\varepsilon^{p}-\varepsilon^{n})$ cm$^{-1}$ |
|---|---|---|
| Carbon tetrachloride | 0 | 0 |
| Phenylacetylene | −7 | +550 |
| Chloroform | −9 | +700 |
| Ethanol | −8 | +600 |
| Methanol | −11 | +850 |
| Phenol in toluene (4.4 mol./l. soln.) | −24 | +1900 |
| Water | −26 | +2000 |

The positions of the $n$-$\pi^*$ transition as calculated from the $g$-value of DPNO in chloroform, ethanol and methanol are shown in Fig. 2. The agreement between the calculated $n$-$\pi^*$ transition energy and the observed spectra seems passable. The following factors might cause deviation. The value of $\delta'\Delta g_n$ is very sensitive to parameters in the Hückel calculation. Intermolecular forces other than hydrogen-bonding, orientation forces, inductive forces, dispersion forces and so on, might change the coulomb parameters of the conjugated system, and the solvation might cause a change in the $\beta_{NC}$ through the distortion of the phenyl ring. Thus, the value of $\delta'\Delta g_n$ obtained is only qualitatively reliable.

## Summary

The decrease in the $g$-value of diphenyl nitric oxide in hydrogen-bonding solvents has been examined. This decrease has been analyzed on the basis of Stone's theory for the $g$-value of a $\pi$-radical. The decrease in the $g$-value has been shown to be caused mainly by the decrease in the odd-electron density on the oxygen atom and the increase in the energy difference between the odd-electron and lone-pair orbitals. We have also attempted to

21) Thus determined $n$-$\pi^*$ transition energy is a weighted mean value of solvated and not solvated DPNO, because when the equilibrium is established with rapid exchange between two states, the observed ESR spectrum is a weighted mean spectrum of ones of the two states. H. M. McConnell, *J. Chem. Phys.*, **28**, 430 (1958).

estimate the blue shift of the $n$-$\pi^*$ transition from the $g$-value.

The authors are indebted to Professor Hideo Takaki and Professor Yasuo Deguchi for offering them a chance to use the ESR spectrometer. They also wish to express their thanks to Dr. Hiroshi Kato and Dr. Keiji Morokuma for their valuable discussions throughout this work.

# A Geochemical Study of Selenium in Volcanic Exhalation and Sulfur Deposits. II.* On the Behavior of Selenium and Sulfur in Volcanic Exhalation and Sulfur Deposits

By Tetsuro SUZUOKI

(Received April 1, 1965)

It has been reported by the present author that selenium is contained in the volcanic exhalations and sulfur deposits collected at the Nasudake and Kuju volcanoes. It has also been observed that the variations in the selenium content and in the sulfur/selenium ratio are closely related to the change in the temperature of fumarolic gases.[1] The main purpose of the previous study was to examine the content and the distribution of selenium in the matters emitted from volcanoes in Japan. From the results of the previous study, it is anticipated that the estimation of the conditions in natural vents from their inside to the outlets of the fumaroles may be possible by means of studying the change in the sulfur/selenium ratio with the temperature and with the concentration of selenium.

It has already been found, in the previous studies of the chemical equilibrium in volcanic gases, that some of the chemical constituents in volcanic gases are in equilibrium with respect to several chemical reactions associated with the volcanic activity.[2,3] It is also possible that a phase change such as vaporization plays an important role in the process of the occurrence of selenium and sulfur in volcanic gases because of the greater volatility of these substances. In the case of sulfur, as is well known, the hydrogen sulfide and sulfur dioxide which are in equilibrium with free sulfur are important in the transfer of sulfur in volcanic gases. As to the selenium, however, the chemical form of this element in volcanic gases is unknown. Therefore, it is necessary to estimate the chemical form of selenium by considering the chemical equilibria in the reactions with which selenium is possibly concerned. The effect of vapor pressure on the transfer of selenium into volcanic gases should also be studied.

Mizutani[4] found a linear relationship between the concentration of gaseous components and the temperature at the Showashinzan volcano; for this he gave the explanation that the low-temperature fumarolic gases are formed by the mixing of the original gases with water vapor. In this study, the author intends to examine whether or not similar processes are controlling the concentration of selenium in volcanic exhalations emitting from the Nasudake volcano.

From the above points of view, a thermodynamic consideration will be made in order to find the factors controlling the concentration of selenium and the sulfur/selenium ratio in volcanic matters. The cause and the mechanism producing the distribution of selenium and sulfur in the effusion process in the Nasudake volcano will also be discussed.

## Theoretical Considerations

**The Relation between the Temperature and the Equilibrium Constants.**—By combining the chemical components whose presence may be expected in volcanic gases, we find four possible reactions for selenium:

$$3/2Se_2 + 2H_2O = 2H_2Se + SeO_2 \quad (1)$$

*. Part I of this series: This Bulletin, 37, 1200 (1964).

1) T. Suzuoki, ibid., 37, 1200 (1964).

2) K. B. Krauskoph, *Econ. Geol.*, 52, 786 (1957).

3) S. Matsuo, *Bull. Volcanologique*, 24, 59 (1962).

4) Y. Mizutani, *J. Earth Sci., Nagoya Univ.*, 10, 135 (1962).

$$1/2Se_2+2SO_3=SeO_2+2SO_2 \quad (2)$$

$$Se_2+2H_2=2H_2Se \quad (3)$$

$$3H_2+SeO_2=H_2Se+2H_2O \quad (4)$$

The equilibrium constants of the above reactions were calculated; the thermodynamical data were refferred chiefly to Kubaschewski et al.,[5] Latimer,[6] Palmer et al.,[7] and Altschuller.[8] The equations expressing the relation between the equilibrium constants and the temperature in these reactions are as follows:

$$\log K_1=\frac{1.25\times10^4}{T}-88.16-0.3314\log T-0.2470\times10^{-3}T+0.5279\times10^{-7}T^2 \quad (5)$$

$$K_1=\frac{(SeO_2)\,(H_2Se)^2}{(Se_2)^{3/2}(H_2O)}$$

$$\log K_2=\frac{1.125\times10^4}{T}-81.45+7.432\log T-10.36\times10^{-3}T+2.396\times10^{-7}T^2-0.0038\times10^{-9}T^3 \quad (6)$$

$$K_2=\frac{(SeO_2)\,(SO_2)^2}{(Se_2)^{1/2}(SO_3)^3}$$

$$\log K_3=\frac{2.023\times10^3}{T}-22.94+1.220\log T-0.7526\times10^{-3}T+1.105\times10^{-7}T^2 \quad (7)$$

$$K_3=\frac{(H_2Se)^2}{(Se_2)\,(H_2)^2}$$

$$\log K_4=\frac{8.855\times10^3}{T}-64.11-1.264\log T+0.8798\times10^{-3}T-1.158\times10^{-7}T^2 \quad (8)$$

$$K_4=\frac{(H_2Se)\,(H_2O)^2}{(H_2)^3(SeO_2)}$$

The relations between the equilibrium constants and the temperature are illustrated in Fig. 1, in which the $K$-$T$ relations for sulfur are also shown for the sake of comparison. The reactions for sulfur are:

$$3/2S_2+2H_2O=2H_2S+SO_2 \quad (9)$$

and:

$$3H_2+SO_2=2H_2O+H_2S \quad (10)$$

where the $K$-$T$ relations are as follows:

$$\log K_9=-\frac{4.26\times10^4}{T^{2.}}+\frac{0.2031\times10^4}{T}+0.68-1.37\log T+4.77\times10^{-4}T \quad (11)$$

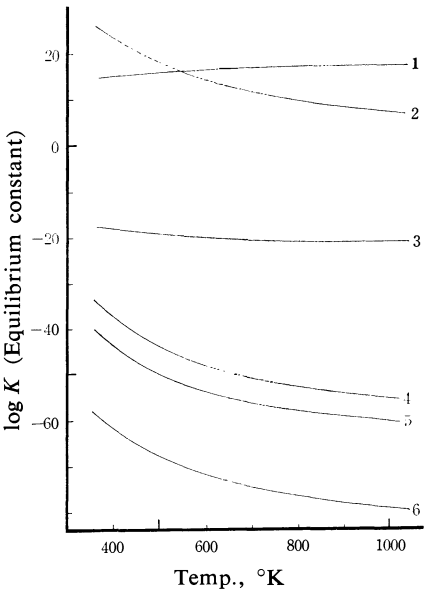

Fig. 1. Relation between temperature and equilibrium constant.

1, $\frac{[H_2Se]^2}{[Se_2][H_2]^2}$ 2, $\frac{[H_2S][H_2O]^2}{[H_2]^3[SO_2]}$

3, $\frac{[H_2S]^2[SO_2]}{[S_2]^{3/2}[H_2O]^2}$ 4, $\frac{[SeO_2][SO_2]}{[Se_2]^{1/2}[SO_3]^2}$

5, $\frac{[H_2Se][H_2O]^2}{[H_2]^3[SeO_2]}$ 6, $\frac{[H_2Se]^2[SeO_2]}{[Se]^{3/2}[H_2O]}$

$$K_9=\frac{(S_2)^{3/2}(H_2O)^2}{(H_2S)^2(SO_2)}$$

and

$$\log K_{10}=\frac{1.041\times10^4}{T}+5.45-2.82\log T-5.24\times10^{-4}T+3.28\times10^{-7}T^2-4.9\times10^{-11}T^3 \quad (12)$$

$$K_{10}=\frac{(H_2O)^2(H_2S)}{(H_2)^3(SO_2)}$$

**The Relation between the Vapor Pressure of Selenium and the Temperature.**—As to the data of the vapor pressure of selenium and sulfur, papers by Kubaschewski et al.,[5] West et al.,[9] and others[10] may be referred to. The empirical formulae for expressing the relation between the temperature and the vapor pressure of selenium and sulfur are given by the above authors as follows: For selenium:

$$\log P_{Se}=8.0886-4989.5/T \quad (13)$$

and for sulfur:

$(598°K>T>393°K)$

$$\log P_S=14.7-6.2238\times10^{-3}T-5405.1/T \quad (14)$$

5) O. Kubaschewski and E. Evans, "Metallurgical Thermochemistry," Pergamon Press, London (1956).
6) W. M. Latimer, "The Oxidation States of the Elements and their Potential in Aqueous Solution," Prentice Hall, New York (1952).
7) K. J. Palmer and N. Elliott, *J. Am. Chem. Soc.*, **60**, 1309 (1938).
8) A. P. Altschuller, *J. Phys. Chem.*, **61**, 509 (1957).
9) W. A. West and A. W. Menzies, ibid., **33**, 1880 (1929).
10) "International Critical Tables of Numerical Data," McGraw-Hill, London, **3**, 201 (1933).

($T>598$°K)

$$\log P_S = 7.4329 - 3268.2/T \quad (14')$$

where $P$ and $T$ are, respectively, the vapor pressure in mmHg and the absolute temperature, °K.

From the above equations, the ratios of the vapor pressure of sulfur to that of selenium are given by the following equations as functions of the temperature:

($598$°K$>T>393$°K)

$$\log P_S/P_{Se} = 6.6114 - 6.2238\times10^{-3}T - 415.6/T \quad (15)$$

($T>598$°K)

$$\log P_S/P_{Se} = -0.6557 + 1.7213/T \quad (15')$$

## Discussion

**The Chemical Form of Selenium and Sulfur in Volcanic Gases.**—As is shown in Fig. 1 the calculated equilibrium constants in reactions 1, 2, 3 and 4 at temperature between 400 and 1000°K range from $10^{-60}$ to $10^{-56}$, from $10^{-56}$ to $10^{-34}$, from $10^{14}$ to $10^{18}$, and from $10^{-60}$ to $10^{-40}$ respectively. The chemical equilibrium constants in reactions 1, 2 and 4 show that a gaseous form of selenium is most stable in the temperature range quoted above. On the contrary, the higher value of the equilibrium constants in reaction 3 shows that hydrogen selenide is more stable than gaseous selenium. However, it is known that hydrogen selenide tends to be unstable in the presence of much water. The volcanic gases usually contain an excess amount of water vapor (more than 99% of the total). Therefore, the hydrogen selenide would not remain stable in the volcanic gases. Thus, the most probable chemical form of selenium in volcanic gases near the outlet of a fumarole is gaseous, perhaps such elementary forms as $Se_2$ and $Se_6$. The value of the $Se_2/Se_6$ ratio depends on the equilibrium constants in the dissociation reaction, $Se_6=3Se_2$, which is given by the following equation as a function of the temperature: $\log K=-13000/T+18.40$, where $K=(Se_2)^3/(Se_6)$.[11] On the other hand, as is well known, most sulfur exists in the forms of sulfur dioxide and hydrogen sulfide in volcanic gases.

It should be noted that in volcanic gases the stable form of selenium is different from that of sulfur despite the similarity of these elements.

**The Vapor Pressure of Selenium and Sulfur in Their Respective Chemical Forms.**—It may be said that an abundance of selenium and sulfur in volcanic gases depends on the volatility of these chemical elements. Therefore, the effect of vapor pressure on the behavior of selenium and sulfur in volcanic gases must be examined.

The ratio of the vapor pressures of free sulfur and selenium is expressed by Eqs. 15 and 15′ as a function of the temperature. The relation between the temperature and the sulfur/selenium ratio is illustrated in Fig. 3 as a

TABLE I. THE S-Se ABUNDANCE RATIO FROM OBSERVATIONS AND DATA OF VAPOR PRESSURE

| Temp., °K | S/Se ratio | |
|---|---|---|
| | Observed | Estimated |
| 694 | $2.0\times10^4$ | 66.7 |
| 683 | 2.0 | 73.1 |
| 659 | 2.4 | 90.4 |
| 653.5 | 2.7 | 95.1 |
| 569 | 6.7 | 278 |
| 539 | 14 | 306 |

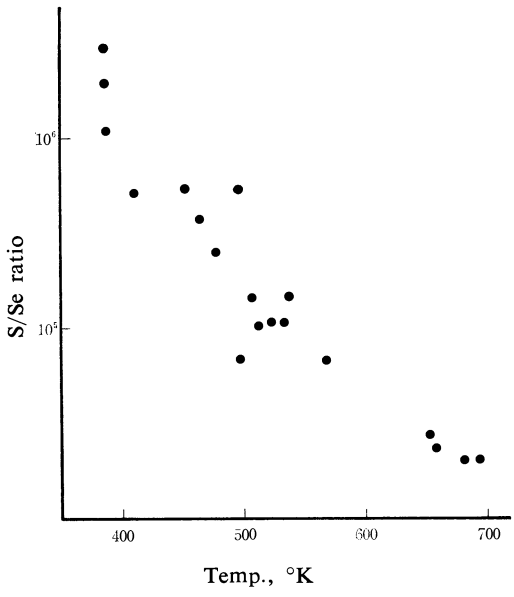

Fig. 2. Relation between S/Se ratio in fumarolic gases and gas temperature.

11) O. V. Al'tshuller, G. N. Zwinadadze and D. M. Chizhikow, *Zhur. Neorg. Khim.*, **2**, 1581 (1957).

straight line extending from about $10^2$ to $10^3$. As is shown in Table I and Fig. 2, however, the abundance ratio of sulfur to selenium in volcanic gases is much higher than the sulfur/selenium ratio shown in Fig. 3. This discrepancy is doubtless due to the presence of much sulfur dioxide and hydrogen sulfide. Therefore, the amount of $S_2$ vapor was calculated by using Eq. 11, putting into it the observed values of hydrogen sulfide and sulfur dioxide; the ratio of the elementary sulfur to selenium was thus obtained. It was found that the ratio of $S_2$ sulfur to selenium is nearly equal to or little less than the theoretical value of the sulfur/selenium ratio, as is shown in Fig. 3.

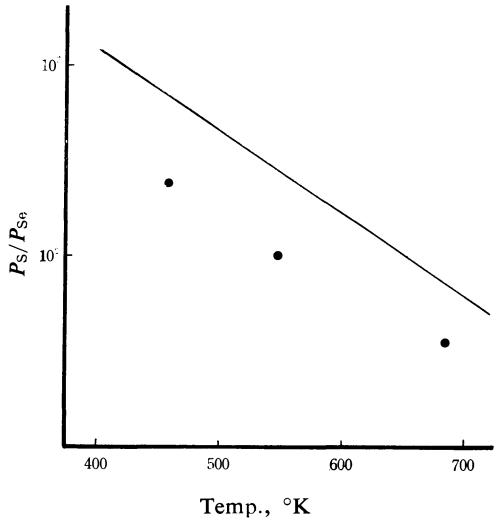

Fig. 3. Comparison of vapor pressure ratio $(P_S/P_{Se})_{saturation}$ with the ratio calculated from observations.
——: Vapor pres. of S/vapor pres. of Se
●: Calculated from observations

The above results suggest that the main part of the sulfur is present and is transferred in form other than that of free gaseous sulfur. Thus, it may be concluded that the behavior of selenium and sulfur in the transfer process is determined by the differences in their chemical forms and in the vapor pressure of each substance.

**The Absolute Concentration and the Distribution of Sulfur and Selenium.**—Regarding the vapor pressure of selenium and sulfur, the observed vapor pressure in volcanic gases have been compared with the saturated vapor pressure obtained by Eqs. 13, 14 and 14′ respectively. As Table II and Fig. 4 show, both selenium and sulfur in volcanic gases are present in quantities very much less than the saturation point. For instance, the degrees of saturation at 800°K for selenium and sulfur are as small as $10^{-6}$ and $10^{-4}$ respectively.

Table II. The degree of saturation for selenium and sulfur in volcanic gases (saturation=1)

| Temp., °K | Ratio to saturation: Sulfur | Selenium |

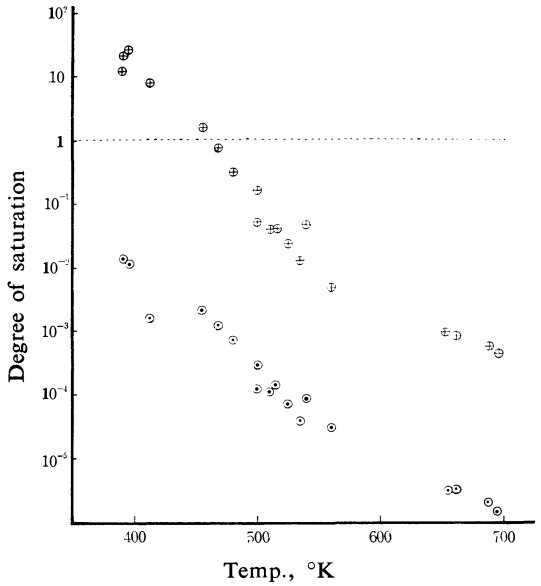

Fig. 4. The degree of saturation for selenium and sulfur in volcanic gases.
⊕: Sulfur
⊙: Selenium

Regarding the scantiness of both chemical elements in volcanic gases, two interpretations are possible. One is based on the static process, and the other, on the dynamic process. In the former, it is supposed that the vapors of selenium and sulfur in primary gases are

once in the equilibrium condition with their solid or liquid phases, that these are quenched in situ, and that the gases are then isolated from the source and transported. The unsaturation may result from the addition of water vapor to the primary gas mixtures. In the second interpretation, it is supposed that the gaseous selenium and sulfur have never been in equilibrium with other phases of the same elements because of the dynamic process of transfer. If the unsaturation results, as in the first interpretation, from only the dilution with water vapor with a temperature of 373°K, the mixing ratio of the latter to the primary gases will be about $10^5$. The addition of such a large amount of water vapor will decrease the temperature very much below the observed value. Therefore, the interpretation based on the static process is inadequate to explain the selenium and sulfur deficiency. It may, therefore, be said that the dynamic process is more probable than the static one in bringing about a deficiency of these elements at a high temperature.

**The Dilution of the Primary Gases with the Water Vapor near the Surface.**—As has been mentioned above, the gas emitted from each fumarole is considered to derive from a common source. In addition, if selenium and sulfur enter into the gases through, for instance, distillation taking place at certain zones in natural vents, and if there is no change in the composition of volcanic gases near the surface, the partial pressure of each component may not vary despite the temperature lowering, provided that the concentration is far below the saturation point. It was found from observation that the concentrations of selenium and sulfur show, respectively, a gradual decrease and a gradual increase with the decrease in the temperature, as is shown in Figs. 5 and 6. The decrease in selenium may be the result of dilution with recyclic water vapor near the surface. Here, the fumarolic gas with the highest temperature is assumed to represent the primary gas.

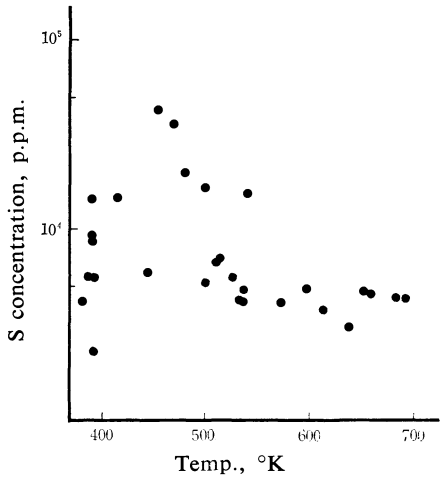

Fig. 6. Relation between temperature and sulfur content in fumarolic gases from Nasudake.

When the primary gases with a temperature of 873°K is diluted with a different amount of water vapor with a temperature of 373°K, the change in the fraction of the primary gases or in the concentration of selenium will be linear with respect to the temperature of the mixture as may be seen in Fig. 7. The calculation is made on the basis of the thermal balance in mixing the respective gases with different temperatures, as is represented in the following equation:

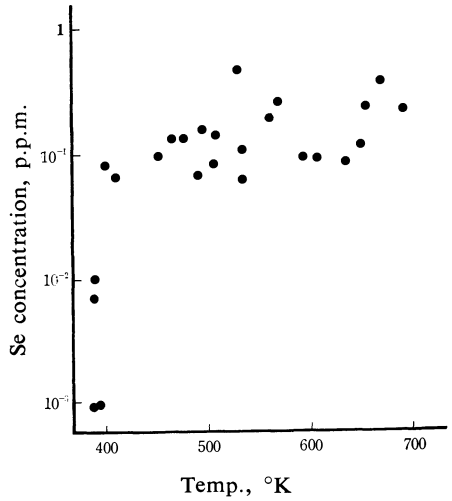

Fig. 5. Relation between temperature and selenium content in fumarolic gases from Nasudake.

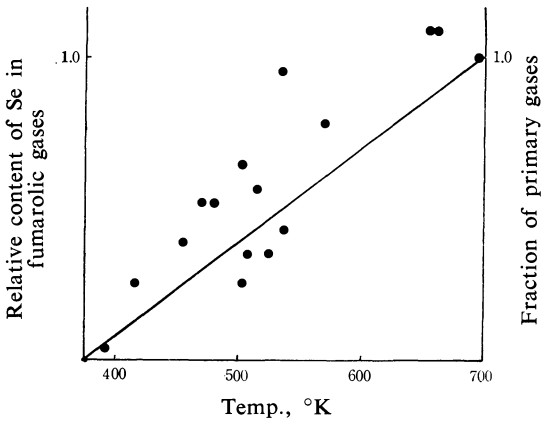

Fig. 7. Relation of selenium concentration and fraction of primary gases to gas temperature.

$$F(T)=\frac{\int_{T}^{873} Cp_{H_2O}dT}{\int_{373}^{T} Cp_{H_2O}dT+\int_{T}^{873} Cp_{H_2O}dT}$$

where $F(T)$ and $Cp_{H_2O}$ are a fraction of the primary gas in the observed mixture at the temperature $T$°K and the heat capacity of water respectively. The selenium contents are also plotted in Fig. 7 in a relative scale. As Fig. 7 shows, the agreement between the calculated and the observed changes in the fraction of selenium suggests that the decrease in the selenium concentration with the decrease in the temperature is mainly due to dilution by water vapor supplied near the earth surface (in the respective vents). As for sulfur, the increase with the decrease in the temperature may result from the addition of sulfur near the surface. This problem will be discussed in the following paper.

The addition or removal of the components in the primary gas may take place in the process of mixing it with water vapor. It may be possible to obtain useful information on the mixing problem by examining the variation in the concentrations of some constituents with the temperature. It may be said that selenium is one of the most promising constituents or indicators for this purpose.

Mizutani explained the origin of low-temperature fumarolic gases of the showashinzan volcano on the basis of the linear relation between the concentration of some gaseous components and the temperature.[4] The linear relation as found at the Showashinzan volcano was not observed at the Nasudake volcano for such components as chlorine, fluorine and boron. It is, therefore, necessary to determine the one component among others, in the primary and secondary gases which is applicable to the study of the mixing processes.

## Conclusion

Regarding the presence of selenium and sulfur in volcanic exhalations and sulfur deposits, it may be concluded that the different behavior of selenium and of sulfur is mainly due to the differences in the vapor pressures and in the chemical forms of these elements in volcanic gases. From thermodynamic considerations, it may also be concluded that the most probable chemical form of selenium in volcanic gases is free selenium.

It may be said that the amount of selenium and sulfur in fumarolic gases is controlled not only by the above factors but also by other factors, judging from the fact that these elements are seldom saturated in volcanic gases, especially at high temperature. It is thought that the undersaturation may occur in the course of the transfer of both elements through fractional distillation, which is controlled by the rates of flow and vaporization. Such dynamic processes may be important as controlling factors in the introduction of selenium and sulfur into volcanic gases in natural vents.

Unlike the Showashinzan volcano, the Nasudake volcano exhibits no linear relation between the temperature and the concentration of most of the gaseous components, except for selenium. The dilution process through mixing with water vapor of a ground-water origin seems to be the cause of the apparent variation in selenium content with the temperature at or near the surface.

Generally, the variation in the concentrations of the chemical components in volcanic gases gives valuable information for a study of the alteration of volcanic exhalation through the mixing of the other components and so on. However, in such a study, careful consideration is required in selecting components which are as practical indicators of the above processes.

It is found in the study of the Nasudake volcano that the selenium and sulfur in volcanic gases are useful indicators for the study of the mixing processes in the course of the alteration of volcanic gases. In this connection, the selenium content and the variation in its concentration in volcanic gases may be regarded as an interesting problem in the study of volcanoes in other areas.

## Summary

With regard to the temperature dependency of the sulfur/selenium ratio in volcanic gases, the factors which control the behavior of selenium and sulfur have been considered from the viewpoints of the chemical equilibrium, the vapor pressure and the thermal balance.

It has been found, from the examination of the equilibrium constants, that, unlike the case with sulfur, the most probable form of selenium in volcanic gases is free selenium. The effect of the vapor pressuse is significant in controlling the transfer of selenium and sulfur into volcanic gases. The results of the calculation of the thermal balance show that the observed wide variation in selenium concentration is due to the addition of water vapor.

On the other hand, it has been found that selenium and sulfur are extremely unsaturated at higher temperatures. This lack of saturation is caused by the dynamical processes of the introduction of these gases into volcanic gases.

The author wishes to thank Professor Yasuo Miyake and Dr. Sadao Matsuo, Department of

chemistry, Faculty of Science, Tokyo Kyoiku University, who gave him valuable advice on many points throughout this study.

Thanks are also due to Dr. Yoshihiko Mizutani, the Institute of Earth Sciences, Faculty of Science, Nagoya University, and Mr. Eitaro Wada and Mr. Osamu Matsubaya, Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, for their help in the collection of samples.

# A Geochemical Study of Selenium in Volcanic Exhalation and Sulfur Deposits. III. On the Relation between Selenium and Certain Other Constituents, and on the Behavior of Volcanic Gases

By Tetsuro SUZUOKI

(Received April 1, 1965)

Regarding the relation beween selenium and other constituents in volcanic exhalations, it has been reported in previous papers[1,2] that the gas temperature at the outlets of fumaroles is one of the factors controlling the selenium content in volcanic gases and the amount of sulfur deposits. On the other hand, though the ratio of sulfur to selenium is correlated with the gas temperature at the outlets of fumaroles, the selenium content in the gases has little correlation with the contents of sulfur and chlorine. For instance, it was found that the sulfur content in gases of a certain area was several times higher than that in gases of other areas.

It has also been reported that difference in the behavior of sulfur and selenium in the transfer process of these chemical elements into volcanic gases is mainly caused by the difference in such of their characteristics as the chemical form and the vapor pressure. In addition, the variation of selenium and other constituents in volcanic gases is found to be due to the dilution process.

A continuous observation over a short period was undertaken in order to study the time variation in the contents of sulfur and selenium in volcanic gases from a fumarole at the Nasudake volcano. It was found that the time variation of the sulfur content in volcanic gases was small, while the selenium content showed a considerable variation.

It is necessary, therefore, to study the time variation of selenium in more detail, in connection with other components (sulfur, chlorine, fluorine and boron), by means of a continuous observation. It is also desirable to study the variation in the contents of these elements with the temperature in order to clarify the behavior of selenium and other elements in the effusion process of volcanic gases.

This study was carried out in order to examine the behavior of volcanic gases by observing the variation in the chemical nature of volcanic gases at the sub-surface of the Nasudake volcano.

## Sampling Site and Samples

Samples were collected during the years from 1961 to 1964 at the Nasudake volcano (36°07'N, 139°57'E). The condition of the field has been previously described, and a part of the data for the selenium and sulfur contents, previously reported.[1]

Two kinds of samples were collected; one was used to examine the variation in the constituents in fumarolic gases with the temperature and the other, to observed continuously the concentration of several components in the fumarolic gases.

The samples for the former purpose were collected from many fumaroles with different temperatures over a wide area of Nasudake. The samples for the latter purpose were collected at several fumaroles over a short period of time at intervals of 40 or 60 min. Simultaneous and continuous observation was made at two different fumaroles, representative ones in the NA and NB areas respectively.[1] The distribution of fumaroles at Nasudake is shown in Fig. 1.

## Analytical Methods

The selenium, sulfur, chlorine, fluorine and boron in volcanic gases, which were collected as condensed water (alkaline solution), were determined by the following methods.

**Selenium.** — A colorimetric method using 3,3′-diaminobenzidine. A solution of 10—20 ml. containing 5—25 $\mu$g. of selenium is oxidized with hydrogen peroxide, followed by the reduction of the selenium in 6 M hydrochloric acid solution and neutralization with ammonia.[1]

**Sulfur.**—The total amount of sulfur is determined by the gravimetric method as barium sulfate. A solution of 2—5 ml. is oxidized by hydrogen peroxide and acidified with a dilute hydrochloric acid solution. The $SO_2$-sulfur is determined in the same way as the total sulfur after the sulfide has been removed as cadmium sulfide. The filtrate is oxidized by hydrogen peroxide. Sulfide-sulfur is obtained by the subtraction of the $SO_2$-sulfur from the total sulfur.

**Chlorine.**—Mohr's titration method, or the colorimetric method using iron alum and mercury thiocyanate.[3] A solution of 1—2 ml. is oxidized with hydrogen peroxide.

**Fluorine.**—The colorimetric method using alizarin sodium monosulfonate and thorium nitrate. A solution of 1—2 ml. is oxidized, and then 100—300 mg. of silver oxide is added to avoid the disturbance from chlorine: fluorine is then distilled as hydrofluorosilicic acid.[4,5] The distillation apparatus is a little modified in order to apply it to volcanic samples.

**Boron.** — The titration method using a 0.002 N sodium hydroxide solution and mannitol. A solution of 10—20 ml. is oxidized and acidified by a dilute hydrochloric acid solution in order to expel the carbon dioxide, bicarbonate and carbonate; then the pH of the solution is adjusted to 7.0 with a sodium hydroxide solution before titration.[6]

## Results

A) The following results of analysis were obtained for condensed water from various fumarolic gases of the Nasudake volcano collected in 1964: The sulfur and selenium contents range from 2350 to 8730 p.p.m. and from 0.01 to 0.31 p.p.m. respectively. The chlorine,

fluorine and boron contents range from 295 to 1350 p.p.m., 2.0 to 26.0 p.p.m. and 20 to 81 p.p.m. respectively. The results are listed in Table I.

The fluorine content in the NB area is higher than that in other areas. The boron content is a little higher in the NA area than that in other areas. Regarding the variation in chlorine, little correlation was found with the gas temperature or with the location of the fumarole. The correlation with the temperature found in the case of selenium content was not observed for some of the other elements over a wider area of Nasudake. The

fluorine and boron contents, however, are likely to show the linear relation with the temperature in the NA area shown in Figs. 2 and 3.

B) The following results of analysis were obtained by the continuous observation of fumarolic gases at the Nasudake volcano in 1962, 1963 and 1964:

*Continuous Observation.* — The contents of sulfur, selenium, chlorine, fluorine and boron in condensed water samples, which were collected at several fumaroles at time intervals of 40 and 60 min., were determined in order to examine the time variations in the contents of those elements. As is shown in Figs. 4, 5 and 6, the contents of selenium, chlorine, fluorine and boron in volcanic gases show comparatively wide variations, while the sulfur content shows a smaller variation, as in the previous observation at the Nasudake volcano.

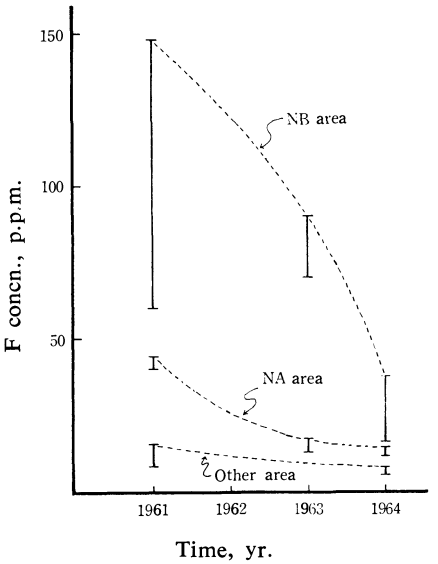

Fig. 8. Year to year variation of fluorine content in fumarolic gases from Nasudake.

*Simultaneous and Continuous Observations.*— A continuous observation for several hours was done simultaneously at two different fumarole areas (NA and NB) in order to examine the differences in several gaseous components with the location. As is shown in

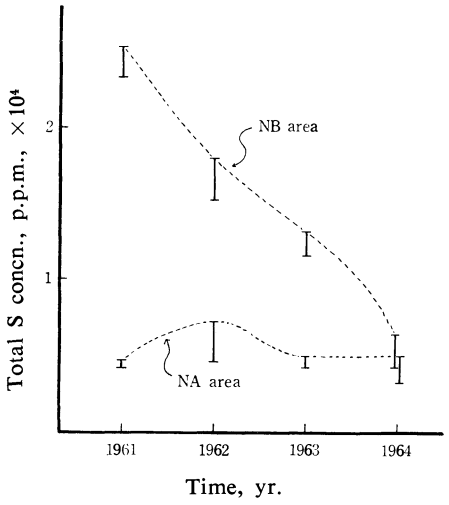

Fig. 7. Year to year variation of total sulfur content in fumarolic gases from Nasudake.

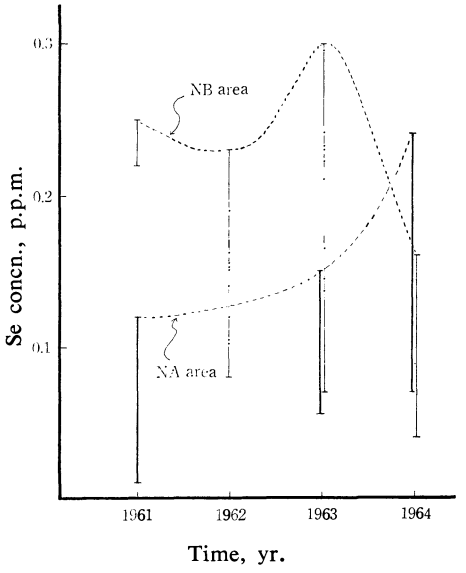

Fig. 9. Year to year variation of the selenium content in fumarolic gases from Nasudake.

Fig. 6, the mode of time variation in the contents of the constituents in gases were considerably different according to the fumarolic area of the volcano.

C) The following results were obtained concerning the year-to-year variations in the contents of sulfur, selenium and fluorine, and in the gas temperature.

As is shown in Figs. 7 and 8, it was found that the contents of sulfur and fluorine remarkably decrease with four years' lapse of time, except that the sulfur in the NA area and the fluorine in the NC and ND areas may be regarded as constant. On the other hand, the selenium content slightly decreased in the NA area and increased in the NB area, as is shown in Fig. 9. In 1964, it was found that the gas temperature in the NB area rose from 195°C to 300°C. It was also noted that the sulfur/selenium ratio in gases decreased slightly in the NA area and increased in the NB area, and that the local variation in the sulfur and fluorine contents in fumarolic gases through the wider areas became smaller during the four years' period.

## Discussion

It may be said that, in addition to the study of the behavior of selenium and sulfur, the study of the behavior of other chemical constituents is important in order to elucidate the effusion process of volcanic gases. Both selenium and boron form volatile compounds with halogens, especially with fluorine. However, there is no indication that these compounds play an effective role in controlling the respective concentrations of these elements in volcanic exhalations. It has already been found that the chemical composition of fumarolic gases gives an average value which is fairly reproducible with the repeated collection of samples when a sample of more than about 200 ml. of condensed water is collected. The results of continuous observation, however, show that the chemical composition varies considerably over a short period of time (i.e., several hours) when a small fraction of gases (less than about 50 ml.) is collected as condensed water. It was also found that the patterns of the time variations of several components are different; this finding indicates that there are some causes of the different patterns of the time variation with each components, besides the common effect over the wider area of the Nasudake volcano. Thus, it is likely that the observed time variation is due to a local effect superposed on the general and common change. The following local effects are to be considered as factors producing the time variation in each constituent in fumarolic gases: i) an accidental addition of particulated matters from wall rocks constituting the vents to volcanic gases, ii) the intermittent addition of water, in which some components are dissolved, and iii) a change in the fumarolic activity.

It is, however, difficult to give a right answer to the question of the variation in the content of substances in the volcanic gases, because of the insufficient data obtained so far.

It was reported in a previous paper[2] that the dilution effect of mixing the primary gases with water vapor is important in the content variation of selenium in fumarolic gases. In this paper, "primary gas" means the source gas of the Nasudake volcano, not a magmatic gas. If the same is true for the variations of sulfur, fluorine, chlorine and boron, a relation similar to that in the case of selenium of each component and the mixing ratio with the temperature should be obtained. The total sulfur content, however, increases with the decreasing temperature, as is shown in Fig. 10. Regarding boron, fluorine and chlorine, no intimate relation was found with respect to the temperature. As has been mentioned above, only the boron and fluorine contents have a linear relation with the temperature, and they only in the NA area, not in the NB area. It is also found that sulfur, boron and fluorine contents, except for chlorine, show a tendency to increase in the NB area. In the effusion process, it is not reasonable to expect that these components will be enriched in the lower-temperature gases if the presence of a single source for each

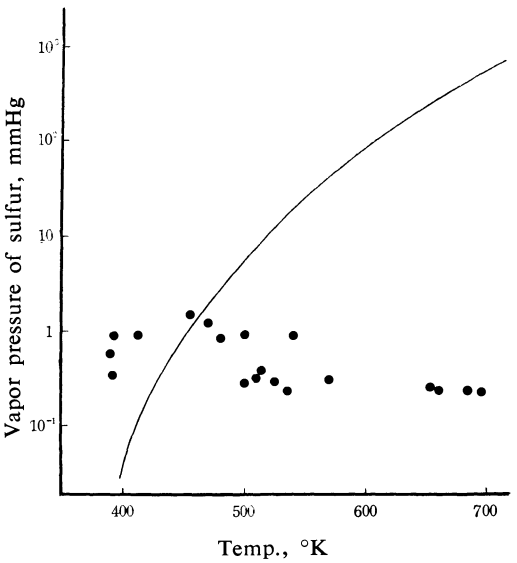

Fig. 10. Relation between vapor pressure ot sulfur and temperature.

● Obtained from observation

fumarolic gas is considered. Judging from the distribution and the year-to-year variation of these components, it may be expected that a part of the components is derived from the secondary source in the sub-surface, and also that the high-temperature gas from the NA area is closely related to the primary gas of Nasudake. In other words, it is likely that the source gas in the NB area is almost the same as that in the NA area, and that the sulfur, fluorine and boron in fumarolic gases of the NB area are concentrated in the sub-surface in this area when primary gas is encountered with the secondary source near the sub-surface. In the case of sulfur, the additional sulfur is derived from the distillation of the underlying sulfur deposits, which are the products of the past effusion process.

The results of the observation of year-to-year variation of sulfur (Fig. 7) show that the sulfur content in the NA area may be regarded as constant compared with that in the NB area, and that the lowest sulfur/selenium ratio in the NA area is close to the sulfur/selenium ratio in the primary gas. The fluorine content also shows a year-to-year variation like sulfur, whereas a gradual decrease in the fluorine content in the NA area is observed, as Fig. 8 shows. These results may be taken to indicate that the amount of the underlying source of sulfur and fluorine decreased during the four years' lapse of time. The result for selenium, on the other hand, indicates that the selenium in the NB area increases during the four years, as is shown in Fig. 9, while the temperature of the gases in this area is found to rise from 200 to 300°C as is listed in the second column of Table II. The increase in the selenium content might not be regarded as being due to the secondary source, unlike the sulfur and fluorine, but rather to the increase in the temperature of gases in the NB area. This fact also indicates that the selenium concentration has a strong temperature dependency, which reflect the peculiar nature of selenium and which is followed by a change in the fumarolic activity. As one of the causes of the higher concentration of fluorine in lower-temperature gases, it may be expected that fluorine has accumulated in the sub-surface in the form, like calcium fluoride, through the past effusion process of volcanic gases and that it is derived to the fumarolic gases by a leaching of calcium fluoride with water vapor or volcanic gases according to the change in fumarolic activity, for it is known that the reaction rate of calcium fluoride with water vapor increases with a lowering of the temperature and an increase of the silica content in the gases.[7,8]

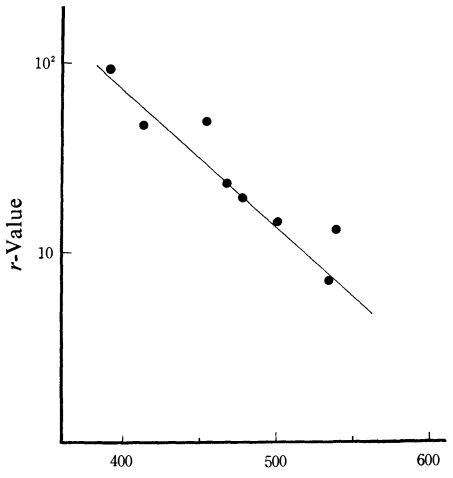

Fig. 12. Relation between gas temperature and S-Se fractionation factors ($r$).

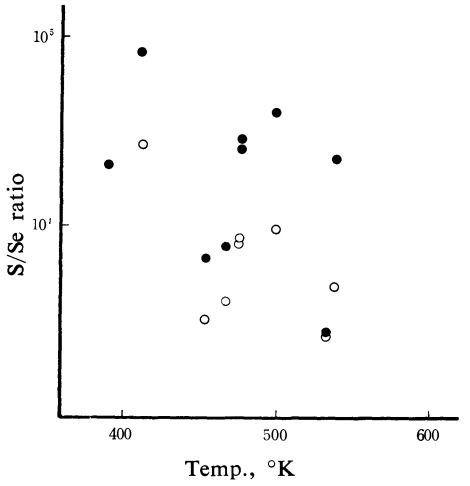

Fig. 13. Relation between S/Se ratio in sulfur deposits and gas temperature.

● Observed
○ Obtained by eliminating excess sulfur

On the basis of the above considerations, the observed sulfur/selenium ratio over the four-year period is corrected by eliminating the effect of the secondarily-added sulfur. The result gives the relation between the sulfur/selenium ratio and the gas temperature, as is shown in Fig. 11; this relation may represent the change in the ratio of sulfur/selenium with the temperature of primary gases. As Fig. 12 shows, it should be noted that a log-linear relation with the temperature is still maintained for the fractionation factors of selenium and sulfur between fumarolic gases and sulfur sublimates, regardless of the content variation of these elements in exhalations and in a dynamical process such as volcanic emission. The sulfur/selenium ratio in sulfur deposits from the primary gases is estimated to be as shown in Fig. 13 by using the above two relations. Accordingly, the proportion of the primary sulfur in the sulfur deposits can be estimated. The gas temperature and the sulfur/selenium ratio in gases co-existing at the time when the separation of sulfur deposits as free sulfur begins from the gaseous phase, can be estimated by means of sulfur/selenium ratio in the sulfur, solidified from the outflowing liquid, and by using the sulfur/selenium ratio in the curves, as is shown in Figs. 11, 12 and 13, which were obtained by the least-square method. Consequently, $1.0—1.7\times10^4$ were obtained for the sulfur/selenium ratio in the source gases from which the above-mentioned sulfur deposit was formed in the NA and NB areas. These data are consistent with the sulfur/selenium ratio ($1.8\times10^4$) which is estimated from the data for fumarolic gases.[1] This supports the supposition that the source gases in both areas are the same and suggests that the sulfur/selenium ratio in the original gases will be between $1—2\times10^4$. It might even be possible to guess the conditions of the formation of sulfur in the past effusion processes by means of the sulfur/selenium ratios in the deposits available at present.

The year-to-year variations in several components suggest that a certain mechanism through fractional distillation or occlusion process by the primary volcanic gases occurs in the sub-surface. It is thought that sulfur and selenium are derived by fractional distillation. In this case, it may be expected that the sulfur/selenium ratio will increase during the process, the stages of which may be divided into 4 steps as follows: I. The first step of distillation, in which only the sulfur content increases; II. The second step, in which the sulfur/selenium ratio remains nearly constant; III. The third step, in which the sulfur content decreases and the selenium content increases (decrease in the sulfur/selenium ratio); and IV. the last one, in which both sulfur and selenium contents decrease. It was mentioned above that there was the difference in sulfur and selenium content between the NA and NB area, and also that there has been a slight variation in the selenium content during the last four years. It may be said, on the basis of observation and the above considerations, that the process of fractional distillation certainly takes place in the sub-surface and the process in the NB area has proceeded from step II to III, and that in the NA area, from III to IV, during the last four years. In addition, it may also be said that the proportion of the secondary

to the primary origin is much higher in the cases of sulfur and fluorine than in that of selenium.

Regarding the differences in the chemical nature of gases among fumarole areas, two interpretations may be given. One is that, as there is originally no secondary source in a certain area (i. e., the NA area), the entry of several components through distillation or occlusion process has not occured in the course of the effusion process. The other is that, after the secondary process has been carried out over a broader area at the same time, an apparent difference in the evolution stages among fumarole areas is brought about at the present time on account of the difference in each fumarolic activity, which corresponds to the temperature conditions of each fumarolic gas. Our consideration and our field observation of several gaseous constituents show that the latter interpretation is more probable.

In connection with the behavior of the several constituents mentioned above, the movement of volcanic gases and the possible process occurring in the sub-surface are illustrated schematically in Fig. 14, which is based on the results obtained thus far.

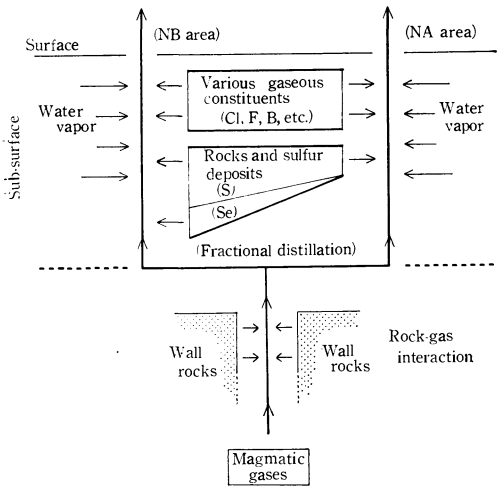

Fig. 14. Schematic diagram of behavior of volcanic gases at the sub-surface of volcano.

## Conclusion

Unlike the case of the Showashinzan volcano,[9] the gaseous components at the Nasudake volcano show no linear relation with the gas temperature with the exception of selenium.

It is to be expected that, at an old solfataric volcano like Nasudake, certain constituents will have been accumulated in the sub-surface during the past effusion processes. It may also be possible that the constituents thus accumulated are leached by the volcanic gases with the change in volcanic activity, and that the observed variations in sulfur, chlorine, fluorine and boron with temperature and time are brought about through such effects. On the other hand, the variation in the selenium content as a result of local effects is much smaller than those of other components; it can be regarded as characteristic in the primary gases. In the cases of a volcano with secondary effects of a considerable extent on the content variations, it may be concluded that the behavior of selenium and the fractionation of selenium and sulfur are applicable to the study of the behavior of volcanic gases according to the stages of the effusion processes and the changes in the chemical nature of volcanic gases in the sub-surface.

The variation in the content of some gaseous constituents with time is an interesting problem to study before we can study in detail the behavior of fumarolic gases near the surface in relation to the change in volcanic activity, the accidental addition of fine particles from wall rocks, and the intermittent addition of water vapor. The problem, however, is still unsolved because not enough data are available for us to make a detailed discussion. Thus, it is necessary to obtain more data with sampling method device suitable to this purpose, one which would make possible the successive collection of fumarolic gases.

As has been mentioned in a previous paper,[2] it may be concluded, from the results of geochemical work on selenium and sulfur, that the entry and transfer of selenium and sulfur into the primary volcanic gases are controlled by certain dynamic factors, such as the rate of vaporization, the rate of gas flow, the ratio of the amounts of gases and rocks, and the reaction time in the rock-gas interactions. It is likely that these processes contribute to the common and general change in the contents of several constituents in volcanic gases. On the other hand, it has also been concluded, from the present study, that the several constituents accumulated in the sub-surface are occluded by primary gases after volcanic gases have branched into smaller vents on the way to the surface. It is likely that the local change in the contents of several constituents is caused by these processes. It may be expected that the above two processes will superpose on each other in the volcanic processes and that, consequently, the distributions of several components at the outlet of fumaroles are as has now been observed.

9) Y. Mizutani, *J. Earth Sci., Nagoya Univ.*, **10**, 135 (1962).

**Summary**

Continuous observations of fumarolic gases have been made in order to study the chemical nature of volcanic gases. A very wide variation in the content of some gaseous constituents has been observed in continuous observation over several hours, and over four years.

Judging from the field observation and the mode of the content variation of several components with the time and the temperature, it is likely that process of the alteration of volcanic gases occurring in the sub-surface plays an important role in producing the difference in the chemical nature of fumarolic gases among the fumarole areas. In addition, the year-to-year variation of the contents of some constituents might provide an indication of the stage of some processes, such as distillation and occlusion, which have occurred in the sub-surface.

It has been found that components like selenium are useful in an examination of the behavior of volcanic gases at an old solfataric volcano like Nasudake, because it is expected that most of the constituents except for selenium have been accumulated in the sub-surface by the past effusion processes and that the accumulated constituents have been occluded in the primary volcanic gases with the change in volcanic activity.

The author wishes to thank Professor Yasuo Miyake and Dr. Sadao Matsuo, Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, both of whom gave him valuable advice on many points throughout this study.

Thanks are also due to Dr. Yoshihiko Mizutani, Institute of Earth Sciences, Faculty of Science, Nagoya University, and author's colleagues, Messrs. Eitaro Wada, Osamu Matsubaya and Minoru Kusakabe, Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, for their help in the collection of samples for present study.

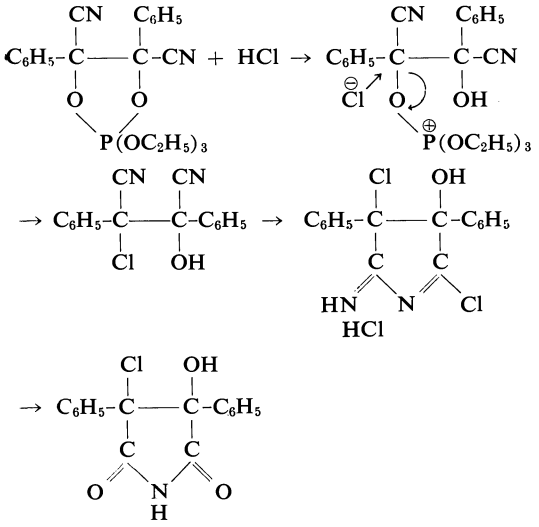
# The Reactions of Benzoyl Cyanide with Trivalent Phosphorus Compounds

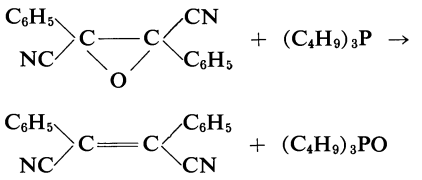
By Teruaki MUKAIYAKA, Isao KUWAJIMA and Kiyotaka OHNO

(Received April 2, 1965)

The deoxygenation reactions of isocyanates,[1] diphenyl ketone,[1] and benzil[2] by means of trivalent phosphorus compounds have been described in previous papers. In the present study, the reactions of benzoyl cyanide with trivalent phosphorus compounds will be examined. When triethyl phosphite is added to two equivalents of benzoyl cyanide in anhydrous benzene at room temperature, the reaction takes place exothermically. After the mixture is warmed to 50°C for 30 min., a white solid is obtained in a high yield. An elemental analysis shows that this product is a 2 : 1 adduct.



(I) or (II)

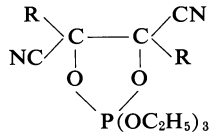


In order to confirm this structure, it was hydrolyzed in concentrated hydrochloric acid; 3,4-diphenyl-3-chloro-4-hydroxysuccinimide, whose infrared spectrum has characteristic bonds for carbonyl (1790 and 1720 $cm^{-1}$), for NH (3270 $cm^{-1}$) and for OH (3430 $cm^{-1}$), was thus obtained in a 62% yield. Mark[3] and Ramirez[4] reported that tris-dimethylamino phosphane or triethyl phosphite reacts with 2 mol. of aldehydes to form 2 : 1 adducts which

1) T. Mukaiyama, H. Nambu and M. Okamoto, *J. Org. Chem.*, **27**, 3651 (1962).
2) T. Mukaiyama, H. Nambu and T. Kumamoto., ibid., **29**, 2243 (1964).
3) V. Mark, *J. Am. Chem. Soc.*, **85**, 1884 (1963).
4) F. Ramirez, A. V. Patwardhan and S. R. Heller, ibid., **86**, 514 (1964).

posses phosphorus-carbon bond. However, in the present case the structure of the adduct may be designated as I, since the hydrolysis product obtained adove may be expected only from I through decomposition as is sketched below:

When the adduct was heated in xylene, it decomposed into $\alpha,\alpha'$-dicyanostilbene oxide (70%) and triethyl phosphate (100%). The former compound could be identified by its infrared spectrum which has characteristic absorption bonds attributable to the epoxide ring (1260, 870 and 790 $cm^{-1}$), and by the fact of its conversion to *cis*-$\alpha,\alpha'$-dicyanostilbene when treated with tri-*n*-butylphosphine at 160°C.



It has been reported by Wittig[5] that an inverted olefin is a predominant product when the epoxide is deoxygenated by tertiary phosphine. This suggests that the epoxide obtained above is in the trans-form. Similar adducts were obtained in the cases of *p*-nitro, *p*-chloro and *p*-methyl phenyl derivatives; they decomposed into the corresponding epoxides when they were refluxed in toluene or xylene (see Tables I and II).

In the case of *p*-anisoyl cyanide, however, a similar adduct was not obtained; rather $\alpha,\alpha'$-dicyano-*p*,*p'*-dimethoxystilbene was formed in a 64% yield.

Next, the reaction was attempted by using tri-*n*-butylphosphine in place of the triethyl phosphite used in the above experiment. When tri-*n*-butylphosphine was added drop-by-drop to an equimolar amount of benzoyl cyanide at room temperature, a red color was formed with a violent evolution of heat. After the solvent had been removed, a large amount of white crystals were obtained from the tarry reaction mixture. This product was shown to be *cis*-$\alpha,\alpha'$-dicyanostilbene by means of elemental analysis, its melting point[6] and its infrared spectrum (2400 $cm^{-1}$ for nitrile; 1600, 1580, 1500, 1470, 770 and 700 $cm^{-1}$ for the

monosubstituted benzene ring). In order to ascertain whether the epoxide is an intermediate of this reaction, the deoxygenation of $\alpha,\alpha'$-dicyanostilbene oxide by tri-*n*-butylphosphine was next attempted under similar moderate conditions. However, the expected deoxygenation could not be observed, and the epoxide was recovered almost quantitatively. The results show that the epoxide is not a probable intermediate in this olefin formation. Similar results were observed in the cases of various *p*-substituted benzoyl cyanides, where the corresponding $\alpha,\alpha'$-dicyano olefines were obtained in 18—40% yields (see Table III).

The mechanisms of these reactions may be considered to be as follows; initially, benzoyl cyanide reacts with the trivalent phosphorus compound to form an adduct such as III, which may be stabilized by the strong electron-attracting effect of the cyano group. This is in turn transformed into 2 : 1 adduct by the electrophilic attack of another molecule of benzoyl cyanide. The electrophilic attack may occur at this stage so that two large groups, e. g., the phenyl group, conform in trans-position. Thus, the triethyl phosphite adduct, which is pyrolyzed, gives *trans*-epoxide, as is shown below.

In the case of tri-*n*-butylphosphine, the reaction may proceed through a similar adduct. The substitution reaction is expected to occur by the nucleophilic attack of the tertiary phosphine, accompanied by the elimination of the phosphine oxide. In the intermediate IV,

since the $\geqslant P^+$ part and $-O^-$ part are situated on opposite sides, it is necessary to rotate along the central carbon-carbon bond in order to accomplish the Wittig-type elimination of the tertiary phosphine oxide. Thus, *cis*-olefin may be formed predominantly.

## Experimental

**The Reaction of Benzoyl Cyanide with Triethyl Phosphite.** — A solution of triethyl phosphite (0.415 g., 0.0025 mol.) in 10 ml. of anhydrous benzene was added slowly to benzoyl cyanide (0.655 g., 0.005 mol.) in 20 ml. of anhydrous benzene at 50°C under nitrogen atmosphere. After this mixture had stood for 30 min. at 50°C, the benzene was distilled off in vacuo, and the solidified residue was recrystallized from ligroin. The 2 : 1 adduct (1.04 g., 97% ; m. p. 117°C) was obtained.

By a similar procedure, the corresponding adducts were obtained from *p*-methyl, *p*-chloro and *p*-nitro phenyl derivatives.

**The Reaction of Benzoyl Cyanide with Tri-*n*-butylphosphine.**—A solution of tri-*n*-butylphosphine (6.06 g., 0.03 mol.) in 10 ml. of anhydrous ether was added drop-by-drop to benzoyl cyanide (3.93 g., 0.03 mol.) in 20 ml. of anhydrous ether under cooling in an ice-salt bath. Then the bath was removed and the reaction mixture was kept for one day at room temperature. After the evaporation of the ether at reduced pressure, the deposited solid was filtered and recrystallized from ethanol. $\alpha,\alpha'$-Dicyanostilbene (1.35 g., 39% ; m. p. 160°C) was thus obtained. By the distillation of the residue, tri-*n*-butylphosphine oxide (4.00 g., 61% ; b. p. 125—130°C/0.5 mmHg) was then obtained.

**The Decomposition of the Adduct.**—The benzoyl cyanide-triethyl phosphite adduct (4.30 g.) was dissolved in anhydrous xylene and refluxed for 1.5 hr. Then the solvent was removed in vacuo and the reaction mixture was distilled, giving triethyl phosphate (1.80 g., 98% ; b. p. 105—107°C/22 mmHg). The residue was solidified by cooling it and then recrystallized from ethanol. $\alpha,\alpha'$-Dicyanostilbene oxide (1.75 g., 70% ; m. p. 162°C) was thus obtained.

**The Hydrolysis of the Adduct.**—When 10 ml. of concentrated hydrochloric acid was added to the adduct (1.00 g.), it turned into a yellow oil. After it had then been refluxed for an hour, the deposited white solid was filtered and recrystallized twice from benzene.

Found : C, 63.11 ; H, 4.37 ; N, 5.03. Calcd. for $C_{16}H_{12}NO_3Cl$ : C, 63.68 ; H, 3.98 ; N, 4.64%.

**The Conversion of $\alpha,\alpha'$-Dicyanostilbene Oxide into $\alpha,\alpha'$-Dicyanostilbene.**—A mixture of $\alpha,\alpha'$-dicyanostilbene oxide and tri-*n*-butylphosphine was heated at 160°C for 5 min. in nitrogen atmosphere. The reaction took place violently, and the reaction mixture turned black. After it had then been washed with ether, $\alpha,\alpha'$-dicyanostilbene (m. p. and m. m. p. 158—160°C) was obtained in a 48% yield.

No similar reaction could be observed at room temperature or at 100°C.

## Summary

The reactions of various *p*-substituted benzoyl cyanides with trivalent phosphorus compounds have been studied. They react with triethyl phosphite to form 2 : 1 adducts which, upon being heated in xylene, decomposed into the corresponding dicyanostilbene oxide and triethyl phosphate. The reaction with tri-*n*-butylphosphine, on the other hand, gives *cis*-dicyanostilbene derivatives. These reactions can be explained by a mechanism through similar intermediates.

# The Switch-over from the D–R to the D–D Mechanism in the Photoreduction of Methylene Blue

By Nobuo KOSUI, Kengo UCHIDA and Masao KOIZUMI

(Received April 3, 1965)

One of the present authors (M. K.) and his collaborators have found that some thiazine dyes undergo photoreduction in the absence of any reducing agents,[1,2] and that the primary process is an electron transfer between the triplet dye and the ground-state dye.[3,4] This finding has led to the expectation that the photoreduction of thiazine dyes may in general be classified into two types according to their primary processes. The first type begin with an electron transfer (or a hydrogen transfer) from the reductant to the dye (the D–R mechanism), whereas the second type is initiated by an electron transfer between the excited dye and the ground-state dye molecules (the D–D mechanism). However, evidence for a switch-over from one mechanism to the other has recently been presented for the first time in connection with the photoreduction of eosine by allythiourea (ATU).[5] The purpose of the present paper is to report a similar switch-over of mechanisms taking place in the photoreduction of methylene blue with such reductants as ATU and EDTA. The evidence was obtained in two ways, from an investigation of the rate formula for a run and from the effect of the dye concentration on the quantum yield of the photoreduction. In addition, an attempt was made to determine $\varphi_{S-T}$, the probabilities of a transition from the singlet-excited state to the triplet state.

## Experimental

**Material.** — *Methylene Blue.* — Grübler's special-grade sample was recrystallized three times from *n*-butanol. $\varepsilon_{max}=6.0\times10^4$.

ATU and EDTA and the other inorganic reagents were recrystallized three times from water.

**Apparatus and Procedure.**—The pH of the sample solution was controlled by a phosphate buffer solution (1/50 M), and most experiments were performed at pH 7.2. The sample was degassed thoroughly, freezing and thawing being repeated six times.

The apparatus and procedure were the same as have already reported on,[3] apart from the method of following the reaction.

The reactions were carried out in an apparatus equipped with a microammeter and photocell; the light beam entered through a cut-off filter, and passed through the reaction cell and then via an interference filter ($\lambda_{max}=669$ m$\mu$; half-width=18 m$\mu$) to the photocell.

When the shift in the absorption peak was observed, a new absorption spectrum in the 600 m$\mu$ to 700 m$\mu$ region was recorded on a Hitachi spectrophotometer (EPU-2A), and the kinetics were investigated by employing Blaisdell's method. The light intensity was measured by using a thermopile (Kipp & Zonen Co.). The reactions were all carried out at 30.0°C.

Both EDTA and ATU scarcely affect the absorption spectra of methylene blue at all. Usually photobleaching occurred without a shift of the absorption peak. When air was introduced at the end of the reaction, coloration was restored in a few minutes in the methylene blue - EDTA system, whereas a longer time was required in the case of the methylene blue - ATU system, about ten minutes being necessary for an 80% recovery of the original dye.

## Results and Discussion

**Rate Formula for a Run.**—In the case of EDTA, the relation between $\ln(e^{\alpha cd}-1)$ and time, $t$, ($\alpha$, $c$ and $d$ are, respectively, the average

molar absorption coefficient, the concentration of dye, and the thickness of the cell) is satisfactorily linear for all the experiments when the concentration of EDTA is larger than $1.0\times10^{-4}$ M and when the dye concentration is less than $10^{-5}$ M. As Fig. 1 shows, the linear relation holds in most cases until two-thirds or more of the dye had been bleached. This means that the rate is simply proportional to the absorption of light, for in this case the rate is given by:

$$\frac{-\mathrm{d}[\mathrm{D}]}{\mathrm{d}t}=\Phi I_{abs}=\frac{10^3 I_0\Phi}{d}(1-\mathrm{e}^{\alpha[\mathrm{D}]d}) \qquad (1)$$

where $\Phi$ is the quantum yield and $I_0$ is the intensity of the exciting light (expressed in moles per $cm^2$ per sec.), and one obtains, by integrating (1):

$$\ln(\mathrm{e}^{\alpha d[\mathrm{D}]}-1)-\ln(\mathrm{e}^{\alpha d[\mathrm{D}]_0}-1)=10^3\Phi I_0\alpha t \qquad (2)$$

where $[\mathrm{D}]_0$ is the initial concentration of dye. From the plots in Fig. 1 one can evaluate the quantum yield, $\Phi$, since $I_0\alpha$ is obtained easily by measuring the light absorption.

When the concentration of EDTA is reduced to $1\times10^{-4}$ M, the situation becomes a little different. Thus, when the original dye concentration is $5.6\times10^{-6}$—$1.6\times10^{-5}$ M relation 2 still holds until two-thirds of the original dye has been bleached, whereas when the dye concentration is higher, Eq. 2 ceases to be applicable and deviations become apparent when one-third of the dye has been bleached.

When ATU is the reducing agent, its concentration must be higher than $\sim4\times10^{-2}$ M for formula 2 to express a run down to a two-thirds bleaching of the original dye. When the concentration of ATU is decreased, although relation 2 still holds in the earlier stages down to $4.0\times10^{-3}$ M of ATU, it becomes less applicable as the reaction proceeds, until at a concentration of $\sim1\times10^{-3}$ M ATU it becomes entirely unsatisfactory. Parallel with this, the plot of 1/O.D. against $t$ becomes more linear, and when the concentration of ATU is $\sim10^{-3}$ M the linearity of the 1/O.D. versus $t$ plot becomes almost satisfactory. This implies that, with the decrease in ATU, the second-order reaction with regard to the dye becomes predominant. Thus, in this case:

$$\frac{1}{[\mathrm{D}]}-\frac{1}{[\mathrm{D}]_0}=kt \qquad (3)$$

or

$$\frac{1}{\mathrm{O.D}}-\frac{1}{(\mathrm{O.D})_0}=\frac{k}{\varepsilon d}t \qquad (3')$$

The above tendency is quite evident and always exists irrespective of the dye concentration, apart from the fact that the larger the dye concentration, the larger the concentration of ATU at which Eq. 2 deteriorates. Figures 2a and 2b show typical examples of the above tendency. The effect of the dye concentration on the rate formula will be discussed later.

●: $1.4\times10^{-2}$ M ⊙: $4.0\times10^{-2}$ M

An attempt to determine $\varphi_{S-T}$ from the effect of the reductant concentration on $\Phi$ was made as follows. When the concentration of reductant is large enough for Eq. 2 to hold, there is scarcely any doubt that the reaction proceeds as follows:

(P denotes the photoproduct, perhaps leuco dye)

On the basis of this scheme, the following rate formula is derived:

$$-\frac{d[D]}{dt}=\frac{\varphi_{S-T}k_R^r[R]I_{abs}}{k_d+k_R^S[R]+k_D[D]_0}$$

where $\varphi_{S-T}$ is the transition probability for the singlet excited state to the triplet state and $k_R^S$ is the sum of $k_R^r$ and $k_R^d$ (the rate constant for mere deactivation by R). Further, it is assumed that the ground-state dye and the leuco dye deactivate the triplet state at a diffusion-controlled rate.

From the above formula, it follows that:

$$\Phi=\frac{\varphi_{S-T}k_R^r[R]}{k_d+k_R^S[R]+k_D[D]_0} \quad (4)$$

Taking the inverse of Eq. 4, one gets:

$$\frac{1}{\Phi}=\frac{1}{\varphi_{S-T}}\frac{k_R^S}{k_R^r}+\frac{1}{\varphi_{S-T}}\left\{\frac{k_d}{k_R^r}+\frac{k_D[D]_0}{k_R^r}\right\}\frac{1}{[R]} \quad (5)$$

If one assumes that $k_R^S=k_R^r$, then the value of $\varphi_{S-T}$ can immediately be obtained by applying Eq. 5 to the experimental data. This was attempted first for the case of EDTA. Some of the necessary data are given in Table I, while the $1/\Phi$—$1/[R]$ plots are given in Fig. 3.

Table I

a) $[MB]=9.0\times10^{-6}$ M, pH=6.7

| $[EDTA]\times10^3$ M | $\Phi$ | $[EDTA]\times10^3$ M | $\Phi$ |
|---|---|---|---|
| 20 | 0.154 | 3.0 | 0.102, 0.099 |
| 10 | 0.144 | 2.0 | 0.080 |
| 6.0 | 0.127 | 1.6 | 0.067 |
| 5.0 | 0.133 | 1.4 | 0.061 |

b) $[MB]=9.0\times10^{-6}$ M, pH=7.2

| $[EDTA]\times10^3$ M | $\Phi$ | $[EDTA]\times10^3$ M | $\Phi$ |
|---|---|---|---|
| 20 | 0.170 | 3.0 | 0.103 |
| 10 | 0.165 | 2.0 | 0.080 |
| 5.0 | 0.133 | 1.4 | 0.066 |

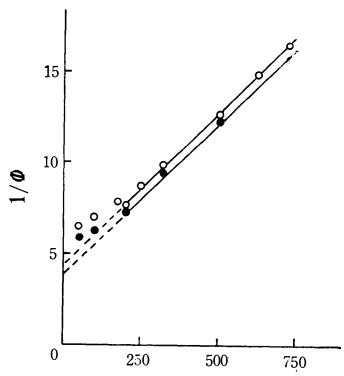

Fig. 3. Plots of $1/\Phi$ against EDTA concentration.
$[MB]_0=9.0\times10^{-6}$ M
○ : pH=6.7, ● : pH=7.2

As may be seen in Fig. 3 the linearity holds satisfactorily except in the region of very high concentrations of EDTA. The values of $\varphi_{S-T}$ obtained are 0.22 and 0.24, for pH=6.7 and 7.2 respectively. These values agree quite well with Oster's value of 0.21[6] at pH=7.0. Although there is some doubt concerning the assumption that $k_R^r=k_R^S$, we would like tentatively to take this value as a real value of $\varphi_{S-T}$. Besides, from the slope of the curves one gets:

$$\frac{k_d}{k_R^r}+\frac{k_D[D]_0}{k_R^r}=3.7\times10^{-3}\text{ M}$$

In the case of ATU, Eq. 2 holds when $[ATU]\gtrsim4\times10^{-3}$ M, at least in the earlier stages of bleaching; hence, as in the above case, an attempt was made to apply Eq. 2 to the results obtained under such experimental conditions. The necessary data are given in Table II, while the $1/\Phi$—$1/[R]$ plot is shown in Fig. 4.

Table II

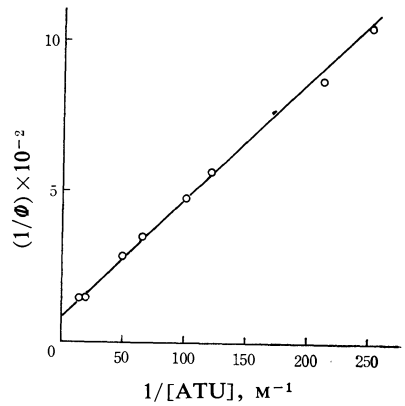

Fig. 4. Plot of $1/\Phi$ against $1/[ATU]$.
pH=7.2, $[MB]_0=(8.2\pm0.2)\times10^{-6}$ M

As can be seen from Fig. 4, the plot is linear, and from its slope and the intercept one gets $(k_d+k_D[D]_0)/\varphi_{S-T}k_R^r=3.9$ M and $k_R^S/k_R^r\varphi_{S-T}=80$. If one assumes that $k_R^S=k_R^r$, then one gets $\varphi_{S-T}=1.3\times10^{-2}$, which is very small compared with that for EDTA. The mere deactivation of the triplet dye by an ATU molecule seems quite plausible.

6) N. Wotherspoon and G. Oster, *J. Am. Chem. Soc.*, 79, 4836 (1957).

**The Effect of the Dye Concentration on $\Phi$.**— This can be dealt with in one of two different ways, depending on the situation. The first method is used in cases in which the D–R mechanism predominates. As may be judged from Eq. 2, the mere deactivation of the triplet dye by the ground state dye causes a decrease in the quantum yield with the increase in the dye concentration. However, when the D–D mechanism begins to take part, a deviation from Eq. 2 is to be expected. The other method is used in cases in which both D–R and D–D mechanisms participate and at the same order of magnitude. In these cases, since the kinetic features of the later steps of D–D mechanism are not clear, it is desirable to discuss the experimental data from a different angle.

Judging from the applicability of Eq. 2, the D–R mechanism is considered to hold for EDTA in general, while for ATU it is dominant only when $[ATU]>1.4\times10^{-2}$ M.

*EDTA.*—The effect of the dye concentration was examined at two fixed concentrations of EDTA. The results are given in Table III, while the $1/\Phi$—$[D]_0$ plot is given in Fig. 5.

TABLE III

| 7.2 | 1.85 | 12.7 | 1.41 |

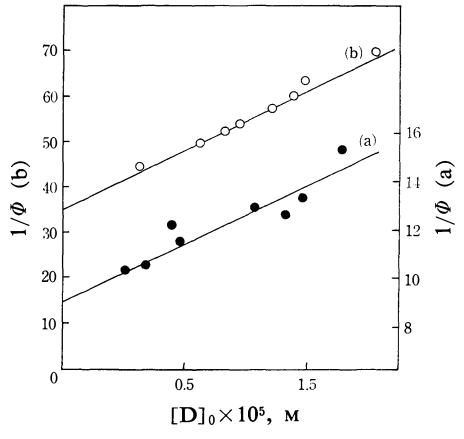

Fig. 5. Plots of $1/\Phi$ against initial dye concentration.
pH=7.2
○ : $[EDTA]=4.0\times10^{-4}$ M
● : $[EDTA]=2.0\times10^{-3}$ M

From Eq. 4, one gets (R is denoted as E) :

$$\frac{1}{\Phi}=\left\{\frac{1}{\varphi_{S-T}}+\frac{1}{\varphi_{S-T}}\frac{k_d}{k_R{}^r}\frac{1}{[E]}\right\}+\frac{1}{\varphi_{S-T}}\frac{k_D}{k_R{}^r[E]}[D]_0 \qquad (6)$$

and from the intercept and the slope of the line b in Fig. 5, one gets:

$$\frac{1}{\varphi_{S-T}}\left(1+\frac{k_d}{k_R{}^r[E]}\right)=9.0$$

$$\frac{1}{\varphi_{S-T}}\frac{k_D}{k_R{}^r[E]}=4.8\times10^5\ M^{-1}$$

With the value of $\varphi_{S-T}$ (0.24) obtained above and by putting $k_d=3.0\times10^4\ sec^{-1}$,[4] one can determine $k_R{}^r$ and $k_D$ separately.

From the results in a),

$$k_R{}^r=1.3\times10^7\ M^{-1}\ sec^{-1}$$

$$k_D=3.0\times10^9\ M^{-1}\ sec^{-1}$$

while from the results in b),

$$k_R{}^r=1.0\times10^7\ M^{-1}\ sec^{-1}$$

$$k_D=2.5\times10^9\ M^{-1}\ sec^{-1}$$

It is worth noting that, when $[D]_0=9.0\times10^{-6}$ M, $k_R{}^r[E]$, $k_D[D]_0$ and $k_d$ are, respectively, $2.6\times10^4$, $2.7\times10^4$ and $3.0\times10^4\ sec^{-1}$ and are of the same order of magnitude. The value of $\frac{1}{\varphi_{S-T}}\left(\frac{k_d}{k_R{}^r}+\frac{k_D}{k_R{}^r}[D]_0\right)$ (see Eq. 5), as calculated by using the above rate constants and by putting $[D]_0=9.0\times10^{-6}$ M, is $1.8\times10^{-2}$ M, which is in good agreement with the experimental value, $1.6\times10^{-2}$ M, obtained from the plot in Fig. 3. At $[EDTA]=1.0\times10^{-4}$ M, a wider range

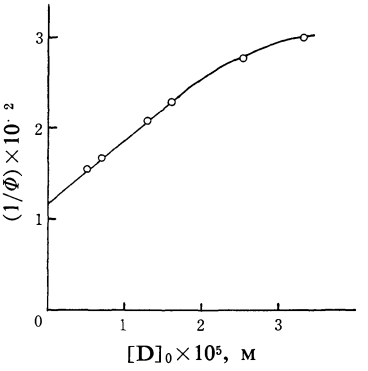

Fig. 6. Polt of $1/\Phi$ against initial dye concentration.
pH=7.2, $[EDTA]=1.0\times10^{-4}$ M

of dye concentrations was chosen, i.e., from $5.6\times10^{-6}$ to $3.3\times10^{-5}$ M. In the case of the higher concentrations of dye, a spacer (7 mm. thick) was used to measure the optical density accurately. Equation 2 holds until one-third of the original dye has been bleached, even when the dye concentration is $\sim2.5\times10^{-5}$ M. A $1/\Phi$—$[D]_0$ plot is shown in Fig. 6. It may be seen that the deviation from a linear plot begins at $2.5\times10^{-5}$ M of dye. By extrapolating the linear part, one gets from the intercept:

$$\frac{k_R^r[E]+k_d}{\varphi_{S-T}k_R^r[E]}=120$$

and from the slope:

$$\frac{k_D}{\varphi_{S-T}k_R^r[E]}=6.4\times10^6\ M^{-1}$$

With $\varphi_{S-T}=0.24$ and $k_d=3.0\times10^4\ sec^{-1}$, one gets:

$$k_R^r=1.1\times10^7\ M^{-1}\ sec^{-1}$$
$$k_D=1.7\times10^9\ M^{-1}\ sec^{-1}$$

From the above results, it may be concluded that as long as the concentration of EDTA is moderate, only the D–R mechanism prevails.

*ATU.*—Different behaviours are expected in the higher and the lower concentration regions of ATU, because the rate formula for a run is Eq. 2 in the former case and Eq. 3 in the latter case. Therefore, rather extensive studies were made by varying the concentration of ATU over a wide range.

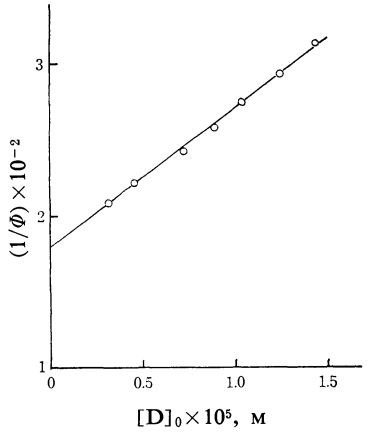

Fig. 7. Plot of $1/\Phi$ against initial dye concentration.
pH=7.2, $[ATU]=4.4\times10^{-2}$ M

Table IV

$[ATU]=4.4\times10^{-2}$ M, pH=7.2

| $[MB]\times10^6$ M | $\Phi\times10^3$ | $[MB]\times10^6$ M | $\Phi\times10^3$ |
|---|---|---|---|
| 14.4 | 3.21 | 7.1 | 4.15 |
| 12.5 | 3.4 | 4.6 | 4.51 |
| 10.3 | 3.65 | 3.2 | 4.8 |
| 8.8 | 3.9 | 2.6 | 5.80 |

When the concentration of ATU is $8.0\times10^{-2}$ or $4.4\times10^{-2}$ M, Eq. 2 fits as a rate formula. A plot of $1/\Phi$ against the original dye concentration is given in Fig. 7. Only the data for $[ATU]=4.4\times10^{-2}$ M are given in Table IV.

From the intercept and the slope of the plot shown in Fig. 8, one obtains:

$$\frac{1}{\varphi_{S-T}}\left\{\frac{k_R^S}{k_R^r}+\frac{k_d}{k_R^r[A]}\right\}=180$$

$$\frac{k_D}{\varphi_{S-T}k_R^r[A]}=9.0\times10^6\ M^{-1}$$

Using the value of $k_R^S/k_R^r\varphi_{S-T}=80$, one gets $k_D/k_R^r=9.5\times10^4$, and, further, by the use of the $k_d$-value;

$$k_R^r=1.1\times10^5\ M^{-1}\ sec^{-1}$$
$$k_D=1.0\times10^{10}\ M^{-1}\ sec^{-1}$$

$k_R^r$ can also be obtained by applying Eq. 5 to the plot in Fig. 4 and by using the value of $k_D/k_R^r$ obtained above. The value thus obtained is $1.8\times10^5\ M^{-1}\ sec^{-1}$, which is in good agreement with the above value. Although the values for $[ATU]=8\times10^{-2}$ M are not so accurate, the value of $k_R^r$ obtained is of the order of $10^5$.

To examine the dye concentration effect more extensively, the concentration of dye was varied over a wider range at a fixed ATU

Table V

$[ATU]=4.0\times10^{-2}$ M, pH=7.2

concentration ($4.0\times10^{-2}$ M). The results are given in Table V. Figures 8a and 8b show that with the increase in the dye concentration, the applicability of Eq. 2 gets worse, while that of 3 gets better.

Figuare 9, which gives the $1/\Phi$—$[D]_0$ plot, shows that deviation becomes appreciable at $2\times10^{-5}$ M of dye. From the intercept and the slope of the straight part,

$$\frac{1}{\varphi_{S-T}}\left\{\frac{k_R^S}{k_R^r}+\frac{k_d}{k_R^r[A]}\right\}=185$$

$$\frac{k_D}{\varphi_{S-T}k_R^r[A]}=8.5\times10^6\ M^{-1}$$

With the use of $\varphi_{S-T}=0.24$ and $k_R^S/k_R^r=20$, one gets:

$$k_R^r=1.1\times10^5\ M^{-1}\ sec^{-1}$$

and $$k_D=9.0\times10^9\ M^{-1}\ sec^{-1}$$

When the concentration of ATU is low, Eq. 3′ instead of Eq. 2 becomes applicable, as Fig. 10 shows. At the same time, a slight shift in the main absorption peak of the dye becomes apparent. The kinetics were investigated, therefore, by employing Blaisdell's method.

Under such conditions, there is scarcely any doubt that, in addition to a D–R mechanism, a D–D mechanism plays a large part in the reaction. Hence, the total quantum yield should consist of two parts, $\Phi_{D-R}$ and $\Phi_{D-D}$, which are, respectively, the quantum yields due to the D–R and the D–D mechanisms. One can estimate $\Phi_{D-R}$ by inserting the values of the rate constants obtained above and the concentrations of ATU and dye into Eq. 4. $\Phi_{D-D}$, then, is obtained as the difference between $\Phi$ and $\Phi_{D-R}$. The results are shown in Table VI and in Fig. 11 and 12, which show that the curves for $\Phi_{D-D}$ are quite similar in the two series of experiments.

Thus, $\Phi_{D-D}$ increases with the dye concentration until it reaches its maximum at $[D]_0\approx(5—8)\times10^{-6}$ M, where $\Phi_{D-D}=(4—6)\times10^{-4}$, and then decreases again.

The results can be interpreted by assuming the analogous scheme proposed for the photoreduction in the absence of any reducing agent:[4]

From this scheme, one gets:

$$\Phi_{D-D}=\frac{\varphi_{S-T}k_D^r[D]k_R'[A]}{\{k_R^S[A]+k_d+k_D[D]_0\}\{k_R'[A]+k_D'[D]_0+k_d'\}} \quad (7)$$

At very low concentrations of D, $\Phi$ at the initial stage is approximated by:

$$\Phi_{D-D}\frac{\varphi_{S-T}k_D^r[D]_0k_R'[A]}{\{_R^S[A]+k_d\}\{k_R'[A]+k_d'\}}$$

which increases with $[D]_0$, while at high concentrations of D,

$$\Phi_{D-D}\frac{\varphi_{S-T}k_D^rk_R'[A]}{k_Dk_D'[D]_0}$$

which decreases with $[D]_0$.

If the second factor in the denominator in Eq. 7 is missing, then $\Phi_{D-D}$ should increase monotonously with $[D]_0$, without showing any maximum. Thus, in order to interpret the present results, it is necessary to take into account the deactivation of the redox intermediate, $D^+\cdots D^-$, by the ground state dye and (perhaps) by the leuco dye produced.

## Conclusions

It may be concluded from the present results that a switch-over in mechanism really does take place in the photoreduction of methylene blue by EDTA and ATU. This was verified consistently from the rate formula for a run and from the dye concentration effect on the quantum yield. The rate constants of the elementary reactions obtained in the present paper are summarized in the following table:

| | $\varphi_{S-T}$ | $k_R^r/k_R^S$ | $k_R^r M^{-1}sec^{-1}$ | $k_D M^{-1}sec^{-1}$ |
|---|---|---|---|---|
| EDTA | (0.23) | (1) | $1.2\times10^7$ | $2.4\times10^9$ |
| ATU | (0.23) | (0.052) | $1.1\times10^5$ | $9.5\times10^9$ |

These values were obtained by assuming that

$$k_d=3.0\times10^4\ sec^{-1}$$

It is seen from the above table that EDTA is a hundred times more efficient as a reducing agent than is ATU. The reason for the rather large difference in the values of $k_D$ for the two reducing agents is unknown.

As to the switch-over of the mechanism, it does not take place very easily in the case of EDTA; thus, even when the concentration of EDTA is $\sim 1\times10^{-4}$ M, the D–D mechanism only operates to a slight extent when the dye concentration is as high as $2.5\times10^{-5}$ M. On the other hand, in the case of ATU, the D–D mechanism becomes appreciable even with $4\times10^{-2}$ M of reductant and $2.5\times10^{-5}$ M of dye. When the concentration of ATU is $\sim 1\times10^{-3}$ M, the D–D mechanism operates to a large extent.

From these results it may be inferred that the proportion of leuco dye formed by the D–D mechanism is only one hundredth, or less, of that from the entire reaction between $D^T$ and D. This is consistent with a small value of $\Phi_{D-D}$.

Moreover, the rate of the reaction proceeding by the D–D mechanism is greatly reduced at higher concentrations of dye. Hence, it is rather difficult to study the D–D reaction separately. This is consistent with the scheme, proposed in the previous paper, in which the D–D intermediate or $D^+\cdots D^-$ is deactivated by the ground state dye as well as by the leuco dye.[3] Were this not the case, $\Phi_{D-D}$ would have reached a constant limiting value when the dye concentration was increased.

Another notable finding in the present paper is that, at a lower concentration of dye, $\Phi_{D-D}$ increases with the dye concentration. This is naturally to be expected from the scheme, but it was not observed in the photoreduction of toluidine blue and methylene blue in the absence of a reducing agent. This is perhaps due to the fact that the minimum dye concentration then used was $0.7\times10^{-5}$ M, while in the present investigation a concentration as low as $0.2\times10^{-5}$ M was employed.

Although the occurence of a switch-over in the mechanism of the photoreduction of methylene blue has now been proved, it is not so clear-cut as in the case of eosine.[5] This seems rather strange at first sight, because eosine, in contrast to thiazine dyes, does not bleach photochemically in the absence of a reducing agent. However, the reason is that, in the case of eosine, only the reverse reaction of $D^-\cdots D^+$ follows its formation on account of the absence of a simultaneous reaction, such as demethylation, to make the forword reduction feasible. On the other hand, there appear to be at least two reasons why eosine shows this change of mechanism more clearly than thiazine dyes. First, the triplet state of eosine has a longer life than thiazine dyes, so it has a greater chance to be attacked by the ground state dye. Second, its redox intermediate seems to be more easily attacked by ATU and less effectively attacked by the ground state dye than in the case of thiazine dyes.

Summarizing the results obtained so far on xanthene dyes and thiazine dyes, one may state, that as far as the primary processes of the D–D and the D–R mechanisms are concerned, there seems to be no essential difference between xanthene dyes and thiazine dyes.

# The Zeeman Effect of Nuclear Quadrupole Resonance Spectrum in $\alpha$-BHC Crystal

By Gen SODA, Masaharu TOYAMA and Yonezo MORINO

(Received April 17, 1965)

Pure quadrupole resonances of the $^{35}Cl$-nuclei for crystals of various isomers of benzene hexachlorides (BHC) have been studied by Duchesne, Monfils and Depireux,[1] and by Morino and others,[2-4] and the assignments of each spectral line to one of the six chlorine atoms have been carried out for $\alpha$- and $\gamma$-isomers, with reference to the crystal structure obtained by van Bommel[5] by the X-ray diffraction method. The apparatus and the method of analysis have been so greatly improved that the Zeeman study enables us to determine the

exact locations of the principal axes of the field-gradient tensors at the chlorine nuclei. For instance, for $\delta$-BHC the direction of each axis was determined with an uncertainty of only 0.1° to 0.5°.[6] It has also been revealed that some of the C-Cl bonds are considerably distorted from the directions to be expected from the tetrahedral bond angles for each carbon atom. The purpose of the present study is to locate the field-gradient tensors in the racemic $\alpha$-BHC crystal by the use of the refined technique that was used for $\delta$-BHC.

The molecule of $\alpha$-BHC has two axial C-Cl bonds and four equatorial C-Cl bonds, one for each carbon atom in the cyclohexane ring. The configuration, which is shown in Fig. 1, is expressed as "*aaeeee*", where *a* and *e* denote the axial and equatorial C-Cl bonds respectively. The crystal is monoclinic, and the four molecules contained in a unit cell are all equivalent, although they are different in orientation. They may be classified into two groups; two molecules in each group are arranged antiparallel to each other, while the molecules in one group are located symmetrically with the molecules in the other group with respect to the crystal ac-plane.

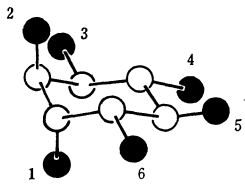

Fig. 1. Model structure of the $\alpha$-BHC molecule. Black and white circles denote the chlorine and carbon atoms respectively. The locations of hydrogen atoms are omitted.

## Experimental and Results

**Apparatus and Material.** — The spectrometer used was the same as that described in a previous paper on $\delta$-BHC.[6] The absorption spectra were detected by using a self-quenched super-regenerative spectrometer similar to that described by Dean, the modulation and the quench frequencies being 230 cycle/sec. and about 50 kc./sec. respectively. The magnetic field for the Zeeman study was supplied by an air-cooled Helmholtz coil. The field strength was continuously variable from zero to 162 gauss. All the Zeeman studies were carried out at room temperature.

The $\alpha$-BHC was recrystallized from a benzene solution. A single crystal with dimensions of $0.6\times2.0\times4.0$ cm$^3$ was prepared from the saturated solution by carefully evaporating the solvent. The crystal thus obtained was a good single crystal, as was supported by the fact that the spectra of this crystal did not show, even under a strong magnetic field, any unexpected disturbance, such as line-splitting and broadening, due to the coexistence of crystals with a different orientation.

**Principle of the Measurement.**—The principle used for the measurement was exactly the same as that used for $\delta$-BHC in the preceeding paper. The direction of the principal z-axis of the field-gradient tensor was determined by the method of "no-splitting locus" proposed by Das and Hahn.[7] The no-splitting locus is expressed by the formula of the first order with respect to $\eta$:

$$(\boldsymbol{H}\cdot\boldsymbol{Z})=\frac{1}{\sqrt{3}}\left\{1+\frac{\eta}{3}[1-3(\boldsymbol{X}\cdot\boldsymbol{H})^2]\right\} \qquad (1)$$

where $\boldsymbol{H}$ represents a unit vector in the direction of the generating line of the locus, and $\boldsymbol{Z}$ and $\boldsymbol{X}$, those in directions parallel to the principal z- and x-axes of the field-gradient $q$-tensor respectively. Equation 1 shows that, in the case of $\eta=0$, the no-splitting locus is a circular cone whose axis is parallel to $\boldsymbol{Z}$, and that the first-order term in $\eta$ represents a distortion from the circular cone. It would, therefore, be possible to determine not only the direction of $\boldsymbol{Z}$ from the axis of the observed cone, but also the asymmetry parameter, $\eta$, and the direction of $\boldsymbol{X}$ from its distortion. This method was, however, not applicable to the latter purpose in the present case, because our apparatus, because of its construction, does not give the whole locus; furthermore, the distortion of the locus from the circular cone is small for $\alpha$-BHC. Thus, $\eta$ and $\boldsymbol{X}$ were obtained by the measurement of the splitting and the intensity ratio of the outer and inner components of the Zeeman pattern when the magnetic field was applied nearly parallel to the direction of the intersection between the crystal ac-plane and the principal xy-plane of the field-gradient $q$-tensor.[6] At this setting of the magnetic field, the relative intensity, $P_r$, of the outer and the inner components of the Zeeman pattern is expressed by these formulae;

$$P_r=P(-)/\{P(+)+P(-)\}$$
$$=\frac{1}{2}\{1-(\eta/\Delta\nu)\cos 2\varphi_r\} \qquad (2)$$

and

$$\Delta\nu=(\eta^2+9\cos^2\theta_s)^{1/2} \qquad (3)$$

where $P(-)$ and $P(+)$ indicate the intensities

6) Y. Morino, M. Toyama and K. Itoh, *Acta Cryst.*, **16**, 129 (1963); M. Toyama, *J. Phys. Soc. Japan*, **14**, 1727 (1959).

7) T. P. Das and E. L. Hahn, Nuclear Quadrupole Resonance Spectroscopy," Academic Press, New York (1958).

of the outer and the inner components respectively, and $(\theta_r, \varphi_r)$ and $(\theta_s, \varphi_s)$ indicate, respectively, the directions of the r. f.-field and of the static magnetic field with reference to the principal coordinate system. $\Delta\nu$ designates a half of the difference between the frequency separations of the two pairs in units of $\nu_H = \gamma H/2\pi$, where $\gamma$ is the gyromagnetic ratio and $H$, the strength of the applied magnetic field.

**No-splitting Loci and the Principal z-Axes of Field-gradient Tensors.**—An approximate location of the no-splitting locus was first determined by observing the Zeeman pattern of each spectral line at various orientations of a relatively weak magnetic field (50—70 gauss). Next, a magnetic field of a suitable strength, from 100 to 160 gauss, was applied in directions near the locus thus roughly determined; the directions giving a no-splitting Zeeman component were determined within an uncertainty of about 0.2°. A no-splitting locus was drawn by tracing the directions thus obtained at intervals of 3—5°.

| E | 35.693 | 35.878 | 36.081 | 0.185 | 0.203 |
| F | 35.608 | 35.813 | 36.038 | 0.205 | 0.225 |

The six absorption lines are designated, for convenience, A, B, C, D, E and F, in the order of decreasing frequency, as is shown in Table I. The no-splitting loci of the spectral lines A, B, E and F were first determined with a single crystal mounted in such a way that the crystal b-axis was nearly parallel to the $Z_l$-axis of the laboratory coordinate system. The loci of the spectral lines C and D were not determined, because the frequency difference between the two lines was so small that the Zeeman pattern was complicated at this mounting. This run is called Experiment 1. Next, the crystal was remounted at such a position that the b-axis was located nearly parallel to the $X_l$-axis. At this mounting the no-splitting loci of the spectral lines from A through F were all determined. This run is called Experiment 2.

Figures 2a and 2b illustrate the no-splitting loci in a stereographic projection; they are projected on a horizontal plane, namely, on the $X_lY_l$-plane which passes through the center of the crystal as its origin. The symbols $\Theta$ and $\Phi$ denote the polar coordinates with reference to the laboratory coordinate system. The figures show that two no-splitting loci were found for each spectral line. This means that each line corresponds to two distinct field-gradient tensors which are equal in magnitude but different in direction; in other words, one

spectral line corresponds to two distinct C-Cl bonds which are different in direction. As will be seen later, the principal z-axes of the two field-gradients determined by two no-splitting loci were found to be symmetrical with respect to an axis which is common to all the six lines. This axis is the crystal b-axis. These results agree with those obtained by X-ray diffraction;[5] four equivalent C-Cl bonds in a unit cell are classified into two groups, as has been described in the introduction. All principal z-axes of the field-gradient tensors determined above were, therefore, uniquely classified into two groups according to the criterion that the mutual angles between the two directions of the principal z-axes which belong to the same group were nearly 180° or close to the tetrahedral angle. These two groups are distinguished by the suffixes 1 and 2; for example, $A_1$ and $A_2$ denote the field-gradient tensors belonging to group 1 and group 2 respectively.

There are two symmetry planes with respect to which two principal z-axes of the $q$-tensors of each spectral line are equivalent. One is the crystal ac-plane, and the other is a plane which is perpendicular to it. The latter symmetry planes intersect, on the crystal b-axis, with those for other field-gradient tensors. Accordingly, a bisecting line of the angle between the z-axes of $A_1$ and $A_2$ should be either on the ac-plane or parallel to the b-axis. This gives a method for determining the b-axis; that is, a direction common to either one of the bisecting lines for all of the six spectral lines, A to F, is parallel to the b-axis. As the observed directions of these bisecting lines deviated from A to F within a possible range of experimental error, an average of them was taken and designated as the $Z_c$-axis, the suffix c denoting a crystal-fixed coordinate system.

The $X_cY_c$-plane was easily given by a plane perpendicular to the $Z_c$-axis thus determined. The $X_c$- and $Y_c$-axes were defined, for the sake of convenience, by taking the direction of a bisecting line between the projections of the z-axes of the E and F tensors on the $X_cY_c$-plane. As the $X_cY_c$-plane does not exactly coincide with the ac-plane of the crystal because of experimental uncertainties, the projections of the two z-axes belonging either to the E or to the F tensors on the $X_cY_c$-plane are slightly different from each other. Thus, the $Y_c$-axis was determined by taking an average of them. The $X_c$-axis was determined as perpendicular to both the $Y_c$- and $Z_c$-axes.

Table II shows the final values of the directions of the principal axes referred to the crystal-fixed coordinate system. The details of the elimination of one of the two choices of $\varphi_r$ will be described later.

**Asymmetry Parameters and the Principal x- and y-Axes of Field-gradient Tensors.**—When a static magnetic field is applied in a direction which is in either of the two symmetry planes mentioned above, then the Zeeman pattern is reduced to a simple four-line pattern. For example, Fig. 3 shows a Zeeman pattern of a spectral line, F, for such a setting of the magnetic field. The spectra were recorded from the right to the left, with the magnetic field applied 12′ and 44′, respectively, from the intersection of the crystal ac-plane and the principal xy-plane of the $q$-tensor. The asymmetry parameter of $\alpha$-BHC is so small that the outer and the inner components of the Zeeman pattern overlap appreciably, as is shown in Fig. 3, and the apparent peak-to-peak separation recorded in the first derivative form is smaller than the correct value. Therefore, the values of $P(+)/P(-)$ and $\Delta\nu$ were determined from the observed Zeeman pattern in the following way.

If the shape of a single spectral line is

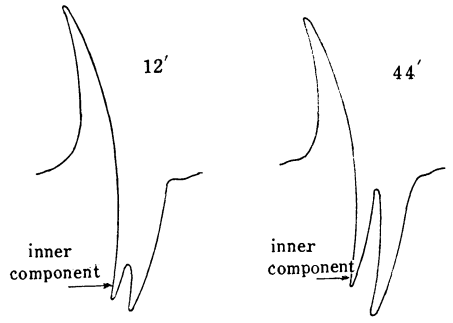

Fig. 3. Typical patterns of the Zeeman splittings of the spectral line F when the static magnetic field is applied near the principal xy-plane in the crystal ac-plane. Zeeman components on the higher frequency side were recorded in the first derivative form. The frequency increase from the left to the right.

assumed to be expressed by a Gaussian distribution function, then the first derivative curve of a doublet is given by the following equation:

$$g(x)=\frac{\{P(+)(x+\Delta\nu)e^{-a(x+\Delta\nu)^2}+P(-)xe^{-ax^2}\}}{(P(+)+P(-))} \quad (4)$$

where $\Delta\nu$ denotes the frequency separation. The two lines are assumed to have the same width, $(2/a)^{1/2}$. The three parameters, $a$, $\Delta\nu$ and $P(+)/P(-)$, involved in this formula were obtained by comparing the calculated curve with the observed one, with reference to the peak-to-peak separation and the widths at half-height positions of the two peaks. The asymmetry parameters of the six field-gradient tensors thus determined are given in Table III.

Table III. Asymmetry parameters of field-gradient tensors

| Absorption line | Asymmetry parameter $\eta$ |
|---|---|
| A | 0.0166±0.0014 |
| B | 0.0231±0.0031 |
| C | 0.0286±0.0031 |
| D | 0.036 ±0.010 |
| E | 0.0220±0.0025 |
| F | 0.0311±0.0031 |

The angle, $\theta_r$, of the r. f.-field with respect to the principal axes was determined, with an uncertainty of 10°, on the assumption that the r. f.-field was parallel to the axis of the r. f.-coil. The values of $\varphi_r$ are obtained from the intensity ratio, $P_r$, by the use of Eq. 2. However, the sign of $\varphi_r$ was not determined uniquely, because $\varphi_r$ is involved in Eq. 2 in the form of $\cos 2\varphi_r$. One of the alternatives was discarded by the following procedure. The approximate directions of the principal z-axes obtained above were refined for the first-order term given in Eq. 1, the magnitude of which depended on the choice of the direction of the principal x-axes. By using one of the values of the principal x-axes, the corrected directions of the principal z-axes for the two experiments, 1 and 2, coincided within the range of experimental error, whereas, for the other choice, they did not coincide beyond the range of experimental error. The former direction was, therefore, taken as the correct one. The measurements at different mountings were thus efficient in excluding the alternative choice of $\varphi_r$.

This method, however, could not be used for the spectral lines, C and D, not measured in Experiment 1. Nevertheless, in the case of D the direction of the principal x-axis was determined, because $|\varphi_r|$ was accidentally close to 90°. In the case of C, the directions of the principal axes were examined by the same method as was employed in a previous report:[6] first, two directions of the principal z-axes of the $q$-tensors were calculated, corresponding to the choices of the two principal x-axes, which are designated by $C_I$ and $C_{II}$, and then two directions of the intersection between the principal xy-plane and the crystal ac-plane were determined. The directions of the intersections for the other spectra were similarly calculated; the mutual angles between these

Table IV. Observed and calculated angles between the intersections of the principal xy-planes of field-gradient tensors with the crystal ac-plane

| $\angle AC_I$ | 22°22′ | 22°32′ | 10′ |
| $\angle AC_{II}$ | 22°22′ | 22°51′ | 29′ |
| $\angle BC_I$ | 25°54′ | 26°05′ | 11′ |
| $\angle BC_{II}$ | 25°54′ | 26°25′ | 31′ |

Table V. Direction cosines of the principal x- and y-axes of the field-gradient tensors with reference to the crystal-fixed coordinate system (molecule 1)

| | | $X_c$ | $Y_c$ | $Z_c$ |
|---|---|---|---|---|
| A | x | 0.25 | −0.61 | −0.75 |
| | y | 0.91 | 0.41 | −0.03 |
| B | x | 0.90 | 0.44 | −0.07 |
| | y | 0.25 | −0.64 | −0.73 |
| C | x | 0.62 | −0.32 | 0.72 |
| | y | −0.78 | −0.32 | 0.54 |
| D | x | 0.17 | 0.34 | −0.92 |
| | y | 0.30 | −0.91 | −0.28 |
| E | x | 0.28 | −0.92 | 0.28 |
| | y | 0.76 | 0.39 | 0.52 |
| F | x | 0.68 | 0.26 | 0.68 |
| | y | 0.24 | −0.96 | 0.13 |

directions of the intersections are listed in Table IV, along with the values obtained in the course of the determination of $\eta$. If the choice is correct, the mutual angles among these calculated intersections should agree with those among the observed intersections. As Table IV shows, this requirement was actually satisfied for both assignments; of these, however, $C_I$ seems to be preferable because in it the deviation was found to be smaller. The final values of the directions of the principal z-axes and those of the principal x- and y-axes are tabulated in Tables II and V respectively.

## Discussion

**Assignment.**—Six absorption lines are assigned to six chlorine atoms by comparing the directions of the principal z-axes of the field-gradient tensors determined by the present study with those of the C-Cl bonds obtained by X-ray diffraction. Table VI shows the

TABLE VI. COMPARISON OF THE RESULTS OF THE ZEEMAN STUDY WITH THOSE OF X-RAY DIFFRACTION

| | Mutual angles between the two principal z-axes of the field-gradient tensors | Mutual angles between the C-Cl bonds by the X-ray diffraction by van Bommel | |
|---|---|---|---|
| A | 82°57′ | $C_3$-$Cl_3$ | 82°36′ |
| B | 85°43′ | $C_6$-$Cl_6$ | 86°22′ |
| C | 53°37′ | $C_4$-$Cl_4$ | 49°56′ |
| D | 30°02′ | $C_5$-$Cl_5$ | 30°36′ |
| E | 108°13′ | $C_2$-$Cl_2$ | 106°48′ |
| F | 92°48′ | $C_1$-$Cl_1$ | 92°48′ |

angles between the two principal z-axes of the field-gradient tensors belonging to each spectral line obtained by the Zeeman study and the angles between the C-Cl bonds which are symmetric with respect to the ac-plane. It may easily be seen that a mutual agreement is attained between the corresponding angles, if the absorption lines from A through F are assigned to the bonds shown on the same line in the table. The assignment of A and B has not yet been established because of the experimental error, ±4°, which accompanies the X-ray diffraction. The reliability factor proposed in the previous paper,

$$\langle \Delta\theta^2 \rangle^{1/2} = \left\{ \frac{1}{6} \sum_{i=1}^{6} (\Delta\theta_i)^2 \right\}^{1/2} \qquad (5)$$

decreases when the assignments A and B are interchanged, as is shown in Table VII. Here $\Delta\theta_i$ denotes the angle between the direction of the $i$-th C-Cl bond and that of the principal z-axis of the corresponding field-gradient tensor. For calculating $\Delta\theta_i$, it is necessary to describe the directions of the C-Cl bonds and those of the principal z-axes of

TABLE VII. PROBABLE ASSIGNMENT OF THE ABSORPTION LINES TO THE C-Cl BONDS OF α-BHC AND THE RELIABILITY FACTOR

| Spectral line | A | B | C | D | E | F | $\langle \Delta\theta^2 \rangle^{1/2}$ |
|---|---|---|---|---|---|---|---|
| Assignment 1 | 3 | 6 | 4 | 5 | 2 | 1 | 2°58′ |
| Assignment 2 | 6 | 3 | 4 | 5 | 2 | 1 | 2°44′ |

the $q$-tensors on the same coordinate system. The direction of the $Z_c$-axis as determined by X-ray diffraction coincides well with that obtained by the Zeeman study, because, as a result of the symmetry, the crystal b-axis was determined accurately in comparison with the other axes. On the other hand, the $Y_c$-axis which is obtained from the directions of the principal z-axes of the spectra E and F does not always coincide with the $Y_c$-axis as determined from the directions of the corresponding C-Cl bonds, 2 and 1, by X-ray diffraction. Because of the experimental errors, the directions of the two $Y_c$-axes thus determined might have a small deviation between them. The description of the results on a common coordinate system may be obtained by rotating either of the two coordinate systems about the $Z_c$-axis so as to minimize $\langle \Delta\theta^2 \rangle^{1/2}$. This minimum value of $\langle \Delta\theta^2 \rangle^{1/2}$ was calculated for each probable assignment as in Table VII. Here again the difference in $\langle \Delta\theta^2 \rangle^{1/2}$ between the two assignments is so small compared with the error, ±4°, that it would be premature to eliminate one of the two assignments.

The assignment obtained here agrees with the tentative one reported previously, and it is consistent with the temperature dependence of the resonance frequencies listed in Table I. According to Bayer's theory,[8] the absorption lines coming from the parallel C-Cl bonds should have the same temperature gradient. Two pairs of lines, A and B, and E and F, have nearly the same temperature gradients, but the curves of the C and D spectral lines cross each other slightly below room temperature. This indicates that the lines, A and B or E and F, may be assigned to the pair of C-Cl bonds which are parallel to each other, whereas C and D may be assigned to a pair of C-Cl bonds which are not parallel, in accord with the results obtained above.

**Molecular Structure.**—The α-BHC molecule in the gaseous state has a two-fold symmetry axis which passes through the middle point of the $C_1$-$C_2$ bond and that of the $C_4$-$C_5$ bond, as is shown in Fig. 1, and each of the pairs of chlorine atoms, ($Cl_1$-$Cl_2$), ($Cl_3$-$Cl_6$), or ($Cl_4$-$Cl_5$), is disposed symmetrically with respect to this axis. The molecules in the crystal are appreciably distorted from the configuration in

8) H. Bayer, *Z. Physik*, **130**, 227 (1951).

the gaseous state. Still, the molecules retain a pseudo-two-fold symmetry, as is easily shown by the fact that the principal z-axes of the $q$-tensors belonging to each of the above chlorine pairs are symmetrically oriented about the axis; the deviations were found to be within 45′ for the pairs, A and B, or E and F, and 3°, for the pair of C and D. The location of the x-axes is also another test for this symmetry; it shows a tendency to satisfy the symmetry, though fairly large errors were unavoidable in determining the x-axes.

Table VIII. Mutual angles between the principal z-axes of the field-gradient tensors in the α-BHC molecule

| | B (6) | C (4) | D (5) | E (2) | F (1) |
|---|---|---|---|---|---|
| A (3) | 2°59′ | 70°51′ | 71°12′ | 72°32′ | 72°08′ |
| B (6) | — | 73°43′ | 68°31′ | 72°40′ | 73°53′ |
| C (4) | — | — | 74°06′ | 62°51′ | 72°59′ |
| D (5) | — | — | — | 71°18′ | 61°51′ |
| E (2) | — | — | — | — | 11°18′ |

Table VIII shows the mutual angles of the directions of the principal z-axes of the $q$-tensors within a molecule, as calculated from the results listed in Table II. It exhibits considerable distortions of bond angles from 180° or from the tetrahedral angle. For instances, neither the opposite equatorial bonds, 3 and 6, nor the opposite axial bonds, 1 and 2, are parallel to each other; the deviations amount to 2°59′, or even to 11°18′. For the bond pairs, 2 and 4, and 1 and 5, which consist of an axial bond and an equatorial bond, the deviations from the tetrahedral angle (70°32′) amount to 7°41′ and 8°41′ respectively. A closer examination indicates that the distorting force tends to make the skeleton of the molecule planar, keeping the symmetry of the molecule at a maximum. Therefore, it is likely that the distortions are mainly due to intramolecular forces which act in accordance with the molecular symmetry, and only partly due to intermolecular forces which are not connected with the symmetry of the molecule.

The asymmetry parameters shown in Table III are of the same order of magnitude as those observed in the δ-BHC crystal.[6] This is another case in which the asymmetry parameters of the chlorine nuclei substituted to a saturated hydrocarbon have been measured. Two effects have been pointed out concerning the origin of the asymmetry of the field-gradient. One is the intramolecular effect, such as the deviation of the hybridization of carbon atoms from $sp^3$, which would be anticipated from the distortion of bond angles. The other is the effect of the crystal field; the electric charge on the neighboring atoms distorts the charge cloud around the chlorine nucleus, thus producing asymmetry in the field-gradient. For δ-BHC, the asymmetry parameters were of the same order of magnitude as that produced by the crystal field. For α-BHC it is likely that, in addition to the crystal field, the intramolecular effect also makes a considerable contribution to the asymmetry parameters, because the principal x-axes tend to satisfy the symmetry of the free molecule. In the δ-BHC crystal, the orientation of the x-axes were not examined except for line B, because the assignment was accompanied by a large uncertainty originating from the errors of the X-ray study, and because two choices between x-axes remained undetermined for the D, E and F spectra. The α-BHC reported here is a fortunate case where the directions of the x-axes have been determined by the pursuit of the measurement at two different mountings of the crystal.

## Summary

The Zeeman effect of the nuclear quadrupole resonance has been studied on the $^{35}Cl$-nuclei in the racemic α-BHC single crystal at room temperature. The directions of the principal x-, y- and z-axes of the field-gradient tensor at each nucleus have been determined through two runs of measurements of the no-splitting loci of each absorption line. The asymmetry parameters of the field-gradient tensor have also been determined. The C–Cl bonds have been found to be considerably distorted from the directions to be expected from the tetrahedral bond angles for each carbon atom. The distortion takes place in such a way that the skeleton of each molecule approachs a planar configuration. Since the principal axes show a tendency to satisfy the two-fold symmetry, the distorting force has been attributed mainly to the intramolecular forces, and only partly to the intermolecular forces. The previous assignment of the six absorption lines to the six chlorine atoms in the molecule has thus been confirmed.

The authors wish to express their deep thanks to Dr. Hideo Sueta, of the Research Laboratory of the Mitsubishi Chemical Industries, Ltd., for kindly supplying the pure sample of α-BHC. The expenses of the work were defrayed by the Ministry of Education of Japan, to which their thanks are also due.

# Studies of the Liquid-Liquid Partition Systems. III. The Solvent Extraction of Americium(III) and Europium(III) Thiocyanate Complexes with Tributylphosphate

By Tatsuya SEKINE

(Received April 19, 1965)

Two different liquid-liquid partition methods have been applied to the determination of the stability constants of various metal complexes in aqueous solutions.

By the first method, the metal ion is extracted with an organophilic chelating acid in the organic phase. The complex formation is determined from the decrease in the chelate extraction caused by the complex formation in the aqueous phase.

By the second method, the metal ion is extracted, as an adduct of the neutral complex, with an organophilic neutral ligand in the organic phase. The complex formation is determined from the change in the metal extraction caused by the change in the relative concentration of the neutral complex in the aqueous phase.

The principles of these two methods are quite different, and the stability constants of metal complexes in an aqueous solution may be determined quite independently by the two methods.

The chelate extraction method has been applied to various complex formation systems; the stability constants thus determined have been found to agree with the constants determined by various other methods. On the other hand, the adduct extraction method has not often been applied except in some recent studies of the mononuclear hydrolysis of metal ions,[1] and no attempt seems to have been made to compare the results given by this method with the results given by the other methods.

The present work studied the thiocyanate complexes of trivalent americium and europium by the adduct extraction method.

As was reviewed in the previous paper,[2] a remarkable difference in ion-exchange behavior has been observed between the trivalent actinide and lanthanide ions in thiocyanate media; this has been explained in terms of the stronger complexing of actinides than of lanthanides with thiocyanate ions. The stability constants of these complexes in 5 M Na(SCN, $ClO_4$) were determined by the chelate extraction method at 25°C.[2] The results showed that americium(III) forms more stable thiocyanate complexes than does europium(III).

The extraction of the neutral metal thiocyanate complexes as an adduct of various extractants has been reported by many authors.[3] Yoshida[4] reported that europium(III) was extracted with tributylphosphate (TBP) from ammonium thiocyanate solutions and that the distribution ratio was quite different when the inert diluent of TBP was different; he concluded that the metal complex in the organic phase was a tetrasolvate of TBP.

In the present work, the distribution of americium(III) and europium(III) between hexane solutions of TBP and aqueous solutions of sodium thiocyanate will be studied. The stability constants of the complexes will be calculated from the distribution data and compared with the results given in Ref. 2. Some discussion will also be made of the salting-out of the metal ions by the electrolytes in the aqueous phase.

## Statistical Treatment

The formation of the metal thiocyanate complexes and the over-all stability constants can be described as follows:

$$M^{3+} + nSCN^- \rightleftarrows M(SCN)_n^{3-n} \quad (1)$$

$$\beta_n = [M(SCN)_n^{3-n}]/[M^{3+}][SCN^-]^n \quad (2)$$

In the present paper, the net distribution ratio of the metal ions between the organic and aqueous phases is always defined as:

$$D = [M(III)]_{org,total}/[M(III)]_{total} \quad (3)$$

The subscript " org " denotes a chemical species in the organic phase, while the absence of a

2) T. Sekine, *J. Inorg. Nucl. Chem.*, **26**, 1463 (1964). The full paper will be published in *Acta Chem. Scand.*

3) The previous work is reviewed in G. H. Morrison and H. Freiser, " Solvent Extraction in Analytical Chemistry," John Wiley & Sons Inc., New York (1957); L. G. Sillén, and A. E. Martell, " Stability Constants," spec. pub. No. 17, The Chemical Society, London (1964). and revised edition to be published.

4) H. Yoshida, *J. Inorg. Nucl. Chem.*, **24**, 1257 (1962).

subscript denotes a chemical species in the aqueous phase.

**The Metal Chelate Extraction Method.**—The details of this method were given in Ref. 2; only the final equation will be given in the present paper:

$$D_0/D=K_0/K=1+\sum_1^n \beta_n[SCN^-]^n \quad (4)$$

In Eq. 4, the subscript "0" denotes the net distribution ratio of the metal or the metal chelate extraction constant when no complexes are formed in the aqueous phase. The metal chelate extraction and the extraction constant are described as:

$$M^{3+} + 3HA_{(org)} \rightleftarrows MA_{3(org)} + 3H^+$$

$$K_0=D_0[H^+]^3[HA]^{-3}{}_{org} \quad (5)$$

where HA denotes an organophilic chelating acid.

Equation 4 shows that the stability constants of the thiocyanate complexes, $MSCN^{2+}$, $M(SCN)_2{}^+$,$\cdots$ can be determined from the decrease in the metal chelate extraction and in the concentration of the ligand.

**The Adduct Extraction Method.**—In an aqueous solution where the metal complexes are formed with thiocyanate ions, the metal concentration can be written as:

$$[M(III)]_{total} = [M^{3+}] + [MSCN^{2+}] + [M(SCN)_2{}^+] + [M(SCN)_3] + [M(SCN)_4{}^-] + \cdots \quad (6)$$

When the neutral complex, $M(SCN)_3$, is extracted with an organophilic neutral ligand, N, the equilibrium constant is described as:

$$M(SCN)_3 + nN_{(org)} \rightleftarrows M(SCN)_3N_{n(org)} \quad (7)$$

$$K_n = [M(SCN)_3N_n]_{org}/[M(SCN)_3][N]^n{}_{org} \quad (8)$$

The total metal concentration in the organic phase is written as:

$$[M(III)]_{org,total}=[M(SCN)_3N]_{org} + [M(SCN)_3N_2]_{org} + \cdots \quad (9)$$

$$= \sum_1^n K_n[M(SCN)_3][N]^n{}_{org} \quad (10)$$

When the concentration of the extracting ligand, N, in the organic phase is constant, Eq. 10 can be written as:

$$[M(III)]_{org,total} = K_{DM}[M(SCN)_3] \quad (11)$$

From Eqs. 6 and 10, the net distribution ratio of M(III) in Eq. 3 can be written as:

$$D=K_{DM}[M(SCN)_3]/([M^{3+}] + [MSCN^{2+}] + [M(SCN)_2{}^+] + [M(SCN)_3] + [M(SCN)_4{}^-] + \cdots) \quad (12)$$

From Eqs. 2 and 12, the distribution of M(III) can be written as:

$$D = K_{DM}\beta_3[SCN^-]^3/(1 + \beta_1[SCN^-] + \beta_2[SCN^-]^2 + \beta_3[SCN^-]^3 + \beta_4[SCN^-]^4 + \cdots) \quad (13)$$

or it can also be written as:

$$D=K_{DM}/(\beta_3{}^{-1}[SCN^-]^{-3} + \beta_1\beta_3{}^{-1}[SCN^-]^{-2} + \beta_2\beta_3{}^{-1}[SCN^-]^{-1} + 1 + \beta_4\beta_3{}^{-1}[SCN^-] + \cdots) \quad (14)$$

Thus we can determine the stability constants, $\beta_n$, from the net distribution ratio, $D$, and the concentration of thiocyanate ions if the concentration of the extracting ligand in the organic phase is kept constant.

## Experimental

**Reagents.** — The europium 152+154 tracer was obtained from the Oak Ridge National Laboratory as a hydrochloric acid solution. The americium 241 tracer was obtained from the Radiochemical Center, Amersham, also as a hydrochloric acid solution. They were then diluted with 5 M sodium perchlorate or 5 M sodium thiocyanate and used as the stock solutions. All of the reagents used were of analytical grade. Sodium perchlorate was prepared from sodium carbonate and perchloric acid and recrystallized two times. Tributylphosphate (TBP) was washed with 0.1 M perchloric acid, water and 0.1 M sodium hydroxide, and then with water until the washed solution gave a neutral color on an indicator paper. Stock solutions of sodium perchlorate and sodium thiocyanate were also prepared. The concentration of the sodium perchlorate stock solution was determined from the difference in the weight of a portion of the stock solution before and after it had been dried in an air-bath at 120°C. The concentration of the thiocyanate stock solution was determined by argentimetry.

**Procedures.**—All of the procedures were carried out in a thermostatted room at 25±0.5°C. The tracer solution, various amounts of the sodium thiocyanate solution, the sodium perchlorate solution and the TBP hexane solution were placed in stoppered glass tubes. The aqueous phase was buffered at pH 4 to 5 with a small amount of acetate. The initial volume of both the organic and aqueous phases was 5.0 ml. The initial concentration of the tracer in the aqueous phase was less than $10^{-6}$ M.

The two phases in the tubes were agitated with a mechanical rotator at 20 r.p.m. for about two hours and centrifuged at 1500 r.p.m. for about three minutes. Two milliliters of the solution was then pipetted from both phases and transferred into small tubes. The $\gamma$-radioactivity of the solutions was determined with a well-type (NaI) scintillation counter, and the net distribution ratio of M(III) was determined to be:

$$D=\frac{\gamma\text{-count-rate per 2 ml. of the organic phase}}{\gamma\text{-count-rate per 2 ml. of the aqueous phase}} \quad (15)$$

## Results

In the present study, the hydrogen ion concentration of the aqueous solution was buffered at pH 4 to 5. This was enough to prevent the association of $SCN^-$ with $H^+$ and the hydrolysis of the metal ion. In the preliminary experiments, is was confirmed that the change in the pH value within this range did not change the metal distribution. The expression "5% TBP in hexane" will always mean a 5% TBP hexane solution as expressed by the volume percentage. The temperature was always 25±0.5°C. The description "5 M Na(SCN, $ClO_4$)" denotes that the concentration of sodium ions is always 5 M; the sum of the thiocyanate and perchlorate concentrations is also kept at 5 M.

**The Extraction of Americium(III) and Europium(III) from Sodium Thiocyanate Solutions.**—Figure 1 gives the plot of log $D$ vs. log [$SCN^-$] when the organic phase was 5% TBP in hexane and when the aqueous phase was sodium thiocyanate solutions (the total electrolyte concentration was not kept constant). We may see in the figure that the distribution of the metal ions increases drastically with the increase in the thiocyanate concentration. The slope d log $D$/d log [$SCN^-$] also increases with the increase in the thiocyanate concentration.

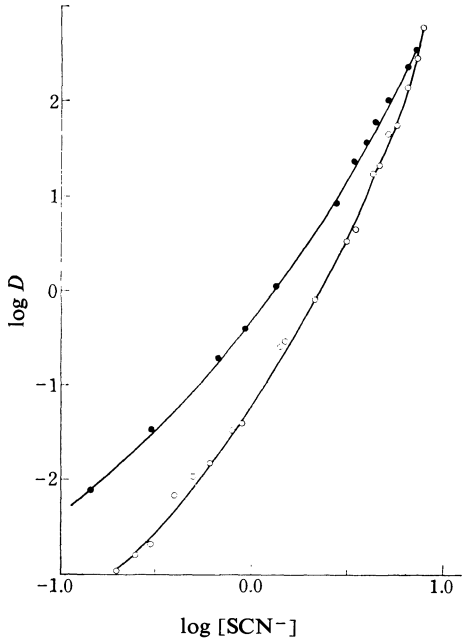

Fig. 1. Distribution of americium(III) (●) and europium(III) (○) between 5% TBP (by volume) in hexane and sodium thiocyanate solutions at pH 4 to 5 (total electrolyte concentration is not constant).

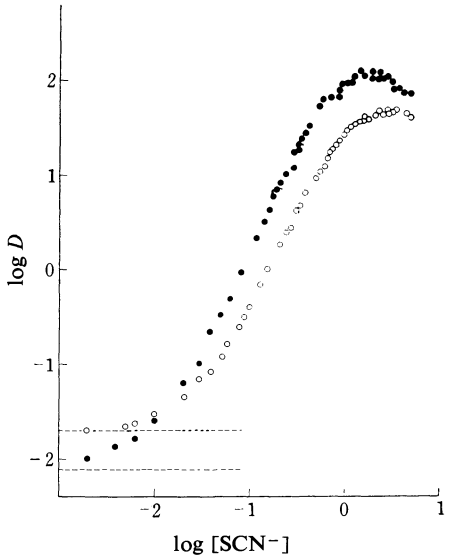

Fig. 2. Distribution of americium(III) (●) and europium(III) (○) between 5% TBP (by volume) in hexane and 5 M Na(SCN, $ClO_4$) at pH 4 to 5. The dotted lines give the distribution ratio of Am(III) (log $D=-2.10$) and Eu(III) (log $D=-1.70$) when the aqueous phase is 5 M $NaClO_4$ at pH 4 to 5.

The separation factor of americium(III) and europium(III), $D_{Am}/D_{Eu}$, is largest in the lowest thiocyanate concentration region; it decreases to unity in the highest region.

**The Extraction of Americium(III) and Europium(III) from 5 M Na(SCN, $ClO_4$).**—Figure 2 gives the plot of log $D$ vs. log [$SCN^-$] of americium(III) and europium(III) when the organic phase was 5% TBP in hexane and when the aqueous phase was 5 M Na(SCN, $ClO_4$). In the figure, we see that the distribution ratio of the metal ions is constant in the lowest thiocyanate concentration region. The distribution ratio increases with the increase in the thiocyanate concentration until it reaches a maximum, and then it decreases slightly in the highest concentration region.

From Eqs. 12 to 14 we may see that the slope d log $D$/d log [$SCN^-$] changes from +3 to $3-n$ with the change in the thiocyanate concentration corresponding to the dominant metal complex species, $M^{3+}$, $MSCN^{2+}$,…, $M(SCN)_n^{3-n}$ in the aqueous phase. It seems that the constancy of the distribution ratio in the lowest thiocyante concentration region can be explained by the extraction of the ion-pair of the metal ion with the perchlorate ion, $M^{3+}(ClO_4^-)_3\cdot(TBP)_n$. It may be also possible that mixed complexes are extracted from the aqueous solutions at a lower thiocyanate concentration and that the distribution ratio of the metal ions may generally be described as:

$$D=\sum_{0}^{3}[M(SCN)_a(ClO_4)_{3-a}]_{org}/\sum_{0}^{n}[M(SCN)_n^{3-n}] \quad (16)$$

The separation factor, $D_{Am}/D_{Eu}$, changes from 0.4 to 10 between a 0.1 M and a 1.0 M thiocyanate solution and decreases in the highest thiocyanate concentration region.

**The Calculation of the Stability Constants.**— From the results in the Fig. 2, we can calculate the stability constants of the metal thiocyanate complexes in 5 M Na(SCN, $ClO_4$).

For the calculation of the stability constants, the data should be taken from the thiocyanate concentration region, where the extraction of the mixed complexes is practically negligible. In Fig. 2, we see that the slope d log $D$/d log [SCN⁻] is about +2 above log [SCN⁻]= −1.3, and so it may be possible to say that the $MSCN^+$ complex is dominant in this region and that only the $M(SCN)_3$ species is extracted into the organic phase. The results in Ref. 2 also seem to support this estimate.

From this, the data used for the calculation were taken from the thiocyanate concentration region above 0.1 M. The data are given in Table I.

In the present study, Eq. 14 was used for the calculation because it is not possible to calculate the $\beta_1$ without the distribution data in the region where both of the $M^{3+}$ and the $MSCN^{2+}$ species exist in the aqueous phase (and where the slope in Fig. 2 should be from

Table II. Equilibrium constants of americium(III) and europium(III) thiocyanate complexes in 5 M Na(SCN, $ClO_4$) at 25°C

$\beta_n=[M(SCN)_n^{3-n}]/[M^{3+}][SCN^-]^n$
$\beta_1\beta_3^{-1}=[MSCN^{2+}][SCN^-]/[M(SCN)_3]$
$\beta_2\beta_3^{-1}=[M(SCN)_2^+][SCN^-]/[M(SCN)_3]$
$\beta_4\beta_3^{-1}=[M(SCN)_4^-]/[M(SCN)_3][SCN^-]$
$K_{DM}=[M(SCN)_3]_{org}/[M(SCN)_3]$
(organic phase: 5% (by volume) TBP in hexane)

(A) Equilibrium constants obtained by the adduct extraction method (present work).

| | Am(III) | Eu(III) |
|---|---|---|
| $\beta_1\beta_3^{-1}$ | 1.68±0.84 | 2.48±0.24 |
| $\beta_2\beta_3^{-1}$ | no evidence | ∼0.9(<0.75) |
| $\beta_4\beta_3^{-1}$ | 0.74±0.51 | 0.34±0.07 |
| $K_{DM}$ | 321±146 | 113±10 |

(B) Equilibrium constants obtained by the chelate extaction method in Ref. 2.

| | Am(III) | Eu(III) |
|---|---|---|
| $\beta_1$ | 7.02±0.28 | 2.08±0.14 |
| $\beta_2$ | no evidence | ∼0.9(<1.5) |
| $\beta_3$ | 3.57±0.41 | 0.44±0.15 |
| $\beta_4$ | 1.00±0.12 | no evidence |
| $\beta_1\beta_3^{-1}$ | 2.0 | 4.7 |
| $\beta_2\beta_3^{-1}$ | no evidence | erroneous |
| $\beta_4\beta_3^{-1}$ | 0.28 | no evidence |

(the limit of error is $3\sigma$)

+3 to +2). The equilibrium constants thus calculated show the following:

$$\beta_1\beta_3^{-1}=[MSCN^{2+}][SCN^-]^2/[M(SCN)_3]$$

$$\beta_2\beta_3^{-1}=[M(SCN)_2^+][SCN^-]/[M(SCN)_3]$$

$$\beta_4\beta_3^{-1}=[M(SCN)_4^{-1}]/[M(SCN)_3][SCN^-]$$

The constants were first estimated graphically, and then the estimates were refined by a generallized least-squares method using the computer program "LETAGROP VRID."[5] The details of the calculation were the same as those given in previous work.[1,2] The equilibrium constants thus determined are given in Table II, together with the constants calculated from the results in Ref. 2. In the table, the limit of the error is $3\sigma$. The expression for the $\beta_2\beta_3^{-1}$ of europium(III), $\sim$0.3 ($<$0.75), means that the calculated value is 0.3 but it may range in the region $0 \leq \beta_2\beta_3^{-1} < 0.75$ if $3\sigma$ is employed as the limit of the error.

**The Change in the Distribution Ratio upon the Addition of Perchlorate.**—Figure 3 gives the plot of the distribution of europium(III), log $D$ vs. log [$SCN^-$], when the organic phase was 5% TBP in hexane and when the aqueous phase was (i) sodium thiocyanate, (ii) 3 M Na(SCN, $ClO_4$) and (iii) 5 M Na(SCN, $ClO_4$).

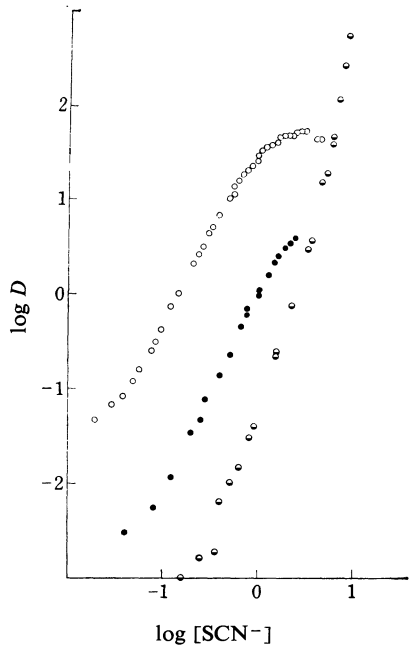

Fig. 3. Distribution of europium(III) between 5% TBP hexane (by volume) and (i) sodium thiocyanate (◒), (ii) 3 M Na(SCN, $ClO_4$) (●), (iii) 5 M Na(SCN, $ClO_4$) (○). pH of the aqueous phase is 4 to 5.

5) N. Ingri and L. G. Sillén, *Acta Chem. Scand.*, **16**, 173 (1962); *Arkiv Kemi*, **23**, 97 (1964).

In the figure we can see that the slope d log $D$/d log [$SCN^-$] increases drastically with the increase in the thiocyanate concentration when the aqueous phase contains only sodium thiocyanate, but that the slope changes only gradually when the total electrolyte concentration is kept constant at 3 M Na(SCN, $ClO_4$) or 5 M Na(SCN, $ClO_4$).' This indicates that the metal distribution is very much increased

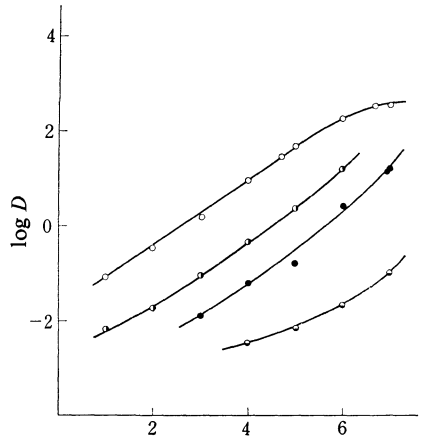

Fig. 4. Increase of the distribribution ratio of europium(III) by addition of sodium perchlorate. Organic phase: TBP 5% (by volume) in hexane. Aqueous phase: at pH 4 to 5
○ [$SCN^-$]=1.0 M, ◑ [$SCN^-$]=0.28 M,
● [$SCN^-$]=0.10 M, ◒ [$SCN^-$]=0 M.
The abscissa gives the total electrolyte concentration in the aqueous phase (the sum of the concentrations of sodium perchlorate and sodium thiocyanate).

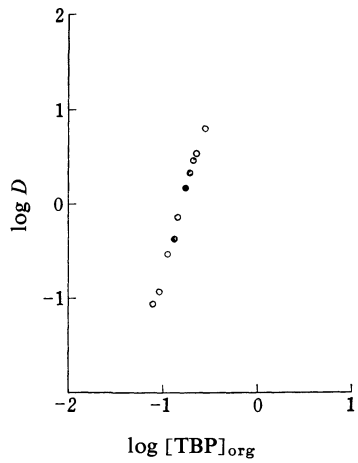

Fig. 5. Dependency of the distribution ratio of europium(III) on the concentration of tributylphosphate.
Organic phase: TBP in hexane.
Aqueous phase: 1 M NaSCN+2 M $NaClO_4$ at pH 4 to 5.

by the addition of sodium perchlorate, even when the concentration of thiocyanate ions is kept constant.

Figure 4 gives the change in the log $D$ when various amounts of sodium perchlorate are added to the solutions while the concentration of thiocyanate ion is kept constant.

In the figure we can see that the addition of perchlorate increases the distribution greatly.

Europium(III) is extracted with TBP, even from a sodium perchlorate solution, and the distribution ratio is also greatly increased by the increase in the perchlorate concentration.

**The TBP Dependency of the Metal Distribution.**—Figure 5 gives the plot of log $D$ vs. log$[TBP]_{org}$ when the aqueous phase contains 1 M sodium thiocyanate and 2 M sodium perchlorate. In this figure we can see that the TBP dependency of the metal distribution is between 3 and 4 in the TBP concentration range.

## Discussion

**The Stability Constants of the Metal Thiocyanate Complexes.**—The results in Fig. 2 and the equilibrium constants in Table II may be summarized as follows.

The constants determined by the chelate extraction method in Ref. 2 indicate that:

(i) The americium(III) thiocyanate complexes are always more stable than the europium(III) thiocyanate complexes.

(ii) No evidence of the complex $Am(SCN)_2^+$ can be observed. The stability constants for the $Eu(SCN)_2^+$ is erroneous, and it is not possible to recognize this species definitely.

(iii) The stability constants for the $Am(SCN)_4^-$ species can be determined, but no evidence of the $Eu(SCN)_4^-$ complex is observed when the thiocyanate concentration is below 5 M.

On the other hand, the results obtained by the present TBP adduct extraction method indicate that:

(i) In the lower thiocyanate concentration region, both americium(III) and europium(III) are extracted with perchlorate ions, and it is not possible to determine the constant for the equilibrium, $M^{3+} + SCN^- \rightleftarrows MSCN^{2+}$.

(ii) It is also not possible to determine the stability constants of the other complexes in Eq. 2. The equilibrium constants obtained are only for the formation of the $M(SCN)_3$ complex from the $MSCN^{2+}$, $M(SCN)_2^+$ and $M(SCN)_4^-$ complexes.

(iii) No evidence of the complex $Am(SCN)_2^+$ can be observed. The equilibrium constant, $\beta_2\beta_3^{-1} = [Eu(SCN)_2^+][SCN^-]/[Eu(SCN)_3]$, is very erroneous, and it is not possible to confirm this complex definitely.

(iv) The formation of the $Eu(SCN)_4^-$ complex, which was not observed in the chelate extraction method, is here observed in the heighest thiocyanate concentration region. The stability constant for the $Am(SCN)_4^-$ complex is higher than that obtained by the chlate extraction method.

(v) The distribution constant of the $Am(SCN)_3$ species between the aqueous and the organic phases, $K_{DM}$ in Eq. 11, is higher than that of the $Eu(SCN)_3$ species.

Thus, from Table II, we may conclude that the equilibrium constants as determined by these two methods nearly agree with each other except for the constant for the formation of the $Eu(SCN)_4^-$ complex.

In the highest thiocyanate concentration region, the anion in the aqueous phase is almost entirely changed from $ClO_4^-$ to $SCN^-$; this may cause some change in the activity of the chemical species in the aqueous phase, even when the total electrolyte concentration is kept constant.

However further information on these systems seems to be necessary in order for us to be able to explain the difference in the constants obtained by these two methods.

**The Effect of the Electrolyte Concentration on the Metal Distribution.**—The increase in the distribution of the metal ions by the addition of various amounts of perchlolate is very remarkable. The increase can be caused by: (i) the extraction of the mixed complexes with thiocyanate and perchlorate ions; (ii) the increase in the stability of the $M(SCN)_3$ species in the aqueous phase, or (iii) the increase in the distribution constant of the $M(SCN)_3$ complex, $K_{DM}$ in Eq. 11.

The extraction of the mixed complexs may not always be important, because the stability constants in Table II, obtained by calculations which neglect the mixed complexs, seem to be reasonable.

The increase in the stability of the $M(SCN)_3$ may also not be very important, because we see in Fig. 3 that the plot of log $D$ vs. log $[SCN^-]$ of the metal extraction from 3 M Na(SCN, $ClO_4$) is nearly parallel to that of the extraction from 5 M Na(SCN, $ClO_4$). If the difference in the distribution ratio is caused by the increase in the relative concentration of the $M(SCN)_3$, the shape of the extraction curve should be different (cf. Eqs. 12 to 14). However, it is not possible to discuss this problem in more detail before we know the equilibrium constants in 3 M Na(SCN, $ClO_4$).

The final explanation, that the addition of sodium perchlorate increases the $K_{DM}$ in Eq. 11, seems to be most reasonable. The increase in

the $K_{DM}$ can be caused both by the increase in the thermodynamical activity of the $M(SCN)_3$ species and by the decrease in the activity of water in the aqueous phase. The decrease in the activity of water may be favorable for the dissociation of the hydrated water of the $M(SCN)_3$ moleculces when they pass through the intersurface between the two phases. However, further information seems to be necessary before we can discuss this problem further.

In Fig. 1 we see that the distribution ratios always increase with the increase in the thiocyanate concentration. When the total electrolyte concentration is kept constant with sodium perchlorate, a slight decrease is observed in the highest thiocyanate concentration region for both americium and europium; this can be explained in terms of the formation of the negative charged species, $M(SCN)_4^-$. The continuous increase in the distribution ratios in Fig. 1, even above 5 M sodium thiocyanate, may be explained in terms of the salting-out effect of the sodium thiocyanate. The formation of the negative charged species by the increase in the thiocyanate concentration should decrease the relative concentration of the $M(SCN)_3$ species in the aqueous phase, and this in turn should decrease the metal distribution. However, as we see in Figs. 3 and 4, the salting-out in these systems is very large, and even though the relative concentration of the $M(SCN)_3$ is decreased by the increase in the thiocyanate concentration (which is not favorable for the metal distribution), the increase in the distribution constant of the $M(SCN)_3$, $K_{DM}$, by the salting-out exceeds the decrease by the former.

Thus, we may conclude that the addition of sodium thiocyanate in the experiment in Fig. 1 causes both the complex formation and the salting-out effect.

**The Solvation Number of TBP in the Adduct Complexes.**—The TBP dependency of the distribution ratio of europium(III) was estimated to be between 3 and 4. This means that if the activity coefficient of TBP in the organic phase can be assumed to be constant, the adduct complexes in the organic phase are a mixture of $Eu(SCN)_3(TBP)_3$ and $Eu(SCN)_3(TBP)_4$. This is a little different from the conclusion of Yoshida.[4] The difference in the composition of the aqueous phase can cause this difference.

## Summary

The two-phase distribution of americium(III) and europium(III) has been studied between the hexane solution of tributylphosphate (TBP) and the aqueous solution of sodium thiocyanate at 25°C. From the distribution data when the organic phase was 5% (by volume) TBP in hexane and the aqueous phase was 5 M Na(SCN, $ClO_4$), the following equilibrium constants have been obtained by a least-squares method:

| | Am(III) | Eu(III) |
|---|---|---|
| $\beta_1\beta_3^{-1}$ | 1.68±0.84 | 2.53±0.24 |
| $\beta_2\beta_3^{-1}$ | no evidence | ~0.3 (<0.75) |
| $\beta_4\beta_3^{-1}$ | 0.74±0.51 | 0.34±0.07 |
| $K_{DK}$ | 321±146 | 113±10 |

(The limit of error is $3\sigma$)

A remarkable salting-out effect has been observed when sodium perchlorate is added to the aqueous phase. This salting-out effect has been discussed, as has the solvation number of TBP in the adduct complexes in the organic phase.

Some part of this work was carried out at the Department of Inorganic Chemistry, the Royal Institute of Technology, Stockholm. The author is very grateful to Professors Lars-Gunnar Sillén and David Dyrssen. Another of this work was carried out at the Laboratory of Nuclear Chemistry, Institute of Physical and Chemical Research, Tokyo. The author is very grateful to Profesor Nobufusa Saito, the head of that laboratory. Some experimental work was carried out by Miss Yuko Hasegawa and Messrs. Mitsuo Sakairi and Takeshi Hamada in the present laboratory. The author is very grateful to them also.

# The Trifluoroacetate Method of Peptide Synthesis. I. The Synthesis and Use of Trifluoroacetate Reagents

By Shumpei SAKAKIBARA and Noriyoshi INUKAI*

(Received April 24, 1965)

In a preceding paper,[1] a new method for the preparation of the *p*-nitrophenylesters of ordinary carboxylic acids, using *p*-nitrophenyl trifluoroacetate (I) as a reagent, has been reported. Reagent I reacts smoothly with carboxylic acids in pyridine to give the *p*-nitrophenylesters by an ester-exchange reaction. In the present investigation, various active esters of trifluoroacetic acid were synthesized

as possible reagent, and the above-mentioned method was extended to the synthesis of the respective esters of acylated amino acids. In addition, a new procedure for the synthesis of peptides using these new reagents was developed.

First, various compounds, such as phenol, thiophenol and *N*-hydroxyimide derivatives, which are known to be hydroxylic partners of various active carboxylic acid esters, were converted to their respective trifluoroacetates by the procedure used for synthesizing reagent I. The physical constants of and analytical data on the trifluoroacetate reagents obtained are listed in Table I. Since these reagents were rather unstable against water, they had to be kept in sealed tubes or in tightly-closed bottles. Attempts to synthesize the trifluoroacetates of 2, 4-dinitrophenol, 2, 4, 6-trinitrophenol and 2, 4-dinitrothiophenol were unsuccessful under the present experimental conditions. Moreover, the trifluoroacetates of common alcohols, such as ethanol and benzyl alcohol, were found to be inactive as ester-exchange reagents in pyridine.

The reagents cited in Table I were each subjected to reaction with acylated amino acids in pyridine for the ester-exchange reactions;

TABLE I. PHYSICAL CONSTANTS AND ANALYTICAL VALUES OF THE TRIFLUOROACETATE REAGENTS

| Compound No. | Name | [m. p.] or (b. p.)[a] °C | Anal. % Found C | Found H | Found N | Calcd. C | Calcd. H | Calcd. N |

No decomposition of these compounds was detectable by thin-layer chromatography during the period except in the cases with b) as a suffix.
a) See Table II for the abbreviations used.
b) Partial decomposition of this material was detected during the period by thin-layer chromatography.

the results are listed in Table II. In addition, the *p*-nitrophenylesters of some fatty acids and keto acid were also prepared. In general, the trifluoroacetates of 2, 4, 5-trichlorophenol (V), pentachlorophenol (VI), *p*-nitrothiophenol (IX) and *N*-hydroxysuccinimide (X) gave good results in the reaction. Reagents II, III, IV, VII and VIII, however, were found to be less reactive, and the reaction mixture had to be heated in order to accelerate the reaction. In the case of XI, a remarkable decomposition of the reagent was observed in pyridine, and the yield of the desired product was poor. Since amino acids with free functional groups on the side chains, such as serine, threonine, tyrosine and histidine, showed complicated side reactions with these trifluoroacetate reagents, these functional groups had to be protected before the compounds could be subjected to the reaction. Carbobenzoxy-L-asparagine also gave a poor yield. This may be due to intramolecular dehydration by the reagent.

No racemization was observed during the ester-exchange reaction of these reagents with phthalylamino acids or urethane-type acylamino acids. In the following cases, however, apparent racemization was observed: (1) When carbobenzoxy-L-phenylalanine was treated with VIII in boiling pyridine, and (2) when acetyl-L-alanine was treated with I at room temperature. The latter case seemed to be general for any of the reagents when usual acylamino acids, such as acetyl or benzoyl derivatives, were treated. Therefore, if racemization is to be avoided, the procedure should be limited to amino acids which are acylated through a phthalyl- or urethane-type group, since these are known to be resistant to racemization. Reagent VIII seemed to be exceptional in causing racemization with carbobenzoxy-L-phenylalanine. The thiophenylester of the compound, when once formed, may readily racemize in hot pyridine during the procedure. To check this possibility, authentic carbobenzoxy-L-phenylalanine thiophenylester was prepared by the dicyclohexylcarbodiimide method; the complete racemization of the compound was observed after treatment with boiling pyridine for one hour.

As can be seen in Table III and Fig. 1, the optical stabilities of other carbobenzoxy-L-phenylalanine active esters were measured in pyridine at room temperature; a distinct decrease in rotation was observed only with the pentachlorophenylester. This may be due not only to the partial racemization, but also to

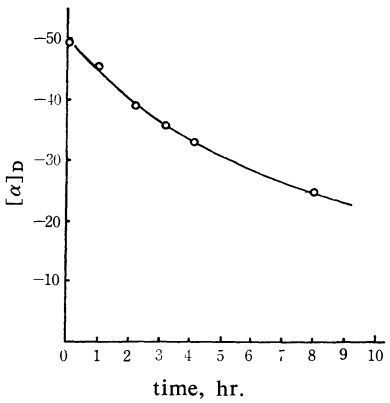

Fig. 1. Optical rotation change of carbobenzoxy-L-phenylalanine pentachlorophenylester in pyridine. $c=1$, 22°C.

the partial decomposition (probably the oxazolon formation) of the compound. Serious decomposition was also observed with the *p*-nitrothiophenylester wtihin two hours. Therefore, care should be taken with prolonged treatment of the materials with VI or IX. Finally, it was concluded that the *p*-nitrophenylesters, 2, 4, 5-trichlorophenylesters and *N*-hydroxysuccinimidesters of phthalyl or urethanetype acyl-L-amino acids can safely be prepared by the new procedure.

Next, the direct syntheses of peptides using the trifluoroacetate reagents I, V and X were studied. One advantage of the trifluoroacetate method in the preparation of active esters of acylamino acids is that the only co-product of the ester-exchange reaction is water-soluble trifluoroacetic acid, which can be removed from the product very easily. Therefore, in preparing peptides, a direct method becomes possible, a method in which the isolation of the active ester of the acylamino acid is not necessary before it is condensed with an amino component. This procedure is considered to be similar to that of the mixed anhydride method, in which the acylamino acid is activated by an acyl chloride reagent, and then the activated intermediate is condensed with an amino acid or peptide ester without being isolated from the reaction mixture.

As examples of the direct method, carbobenzoxy-L-phenylalanyl-L-phenylalanine benzylester, carbobenzoxy-L-phenylalanylglycine ethylester and carbobenzoxyglycyl-L-tyrosine ethylester were prepared, and the optimum conditions of each reaction were investigated. The relationship between the reactivity of each active ester and the amount of triethylamine added to a reaction mixture was interesting. In the cases of reaction with I or V, two equivalents of triethylamine were necessary to proceed the

reaction; these may be consumed for liberating the free ester from the hydrochloride or tosylate and for neutralizing the trifluoroacetic acid formed. In the case of reaction with X, however, the addition of triethylamine was not necessary for the completion of the reaction, even if ester hydrochloride or tosylate was used, and the only contribution of the triethylamine to the reaction was to reduce the reaction period. The pyridine in the reaction mixture should act as the necessary base for the reaction (Table IV). The yields of the reaction products were excellent, and their purities were also quite satisfactory. The procedure should be useful for the step wise elongation method of peptide synthesis.

One advantage of the direct method for peptide synthesis is that the procedure can be applied whether or not the acylamino acid active ester can be crystallized. For the same reason, it should also be useful for the synthesis of long peptides by the fragment-condensation method or for the synthesis of cyclic peptides. Studies of these possibilities will be published in subsequent papers.

## Experimental

All melting points given were uncorrected, and all were determined by the capillary method in a sulfuric acid bath. The completion of the reaction was checked by simplified thin-layer chromatography[2] using Merck's silica gel G and with a mixture of chloroform, methanol and acetic acid (95 : 5 : 3 v/v) as the solvent. *N*-Carbobenzoxy or *t*-butoxycarbonyl compounds were developed on the plates by heating with hydrobromic acid, followed by treatment with ninhydrin.

**Materials.**—Trifluoroacetic anhydride was prepared according to the procedure of Bourne.[3] *p*-Nitrothiophenol was prepared according to the procedure of Price and Stacy,[4] as was 2, 4-Dinitrothiophenol. *N*-hydroxysuccinimide was prepared by the procedure of Anderson et al.[5] *N*-hydroxyphthalimide was prepared by the method of Nefkens and Tesser.[6] *p*-Chlorophenol, *p*-bromophenol, 2, 4, 5-trichlorophenol, pentachlorophenol, *p*-methoxyphenol and thiophenol were obtained from the Tokyo Kasei Co., Ltd., Tokyo. Acyl amino acids were prepared by standard procedures, and their physical constants were checked before the reactions. Pyridine was dried over potassium hydroxide pellets before use.

**The General Procedure for the Preparation of Trifluoroacetate Reagents.**—A mixture of trifluoroacetic anhydride (0.15 mol.) and a phenolic compound or an *N*-hydroxyimide derivative (0.1 mol.) in benzene (30 ml.) was refluxed for about 5 hr. until all the crystals had disappeared. The solution was then concentrated to dryness in order to obtain the product. The yield was generally quantitative, and the product was used without further purification in subsequent reactions. The trifluoroacetates of 2, 4, 5-trichlorophenol, *p*-nitrothiophenol, *N*-hydroxysuccinimide and *N*-hydroxyphthalimide did not give correct analytical data, because all the purification procedures tested, such as recrystallization and distillation, caused their partial decomposition. Other trifluoroacetates could, however, be purified for analysis by sublimation or distillation. Their physical constants and analytical data are listed in Table I.

**The General Procedure for the Preparation of Acylamino Acid-active Esters Using Trifluoroacetate Reagents.**—A solution of an acylamino acid (0.005 mol.) in pyridine (3 ml.) was treated with a trifluoroacetate reagent (0.006 mol.) until the starting material had disappeared; this was checked by thin-layer chromatography. After the reaction was complete, water (about 20 ml.) was added to the reaction mixture in order to precipitate the product as crystals; these were then separated by filtration and recrystallized from a suitable solvent system. The yields, properties and analytical data on these products are listed in Table II.

**The General Procedure for the Preparation of Carbobenzoxy Dipeptide Esters by the Direct Method.**—A solution of carbobenzoxy-amino acid (0.005 mol.) in pyridine (4 ml.) was treated with a trifluoroacetate reagent (0.006 mol.), I, V or X, as has been described above, and then water (0.018 ml.) was added to the reaction mixture in order to destroy the excess reagent. A solution of amino acid ester hydrochloride or tosylate (0.005 mol.) and triethylamine (2 mole equivalents) in chloroform (4 ml.) was added to the reaction mixture. After an adequate period, water was added to the solution, and the oil precipitated was extracted with ethyl acetate. The extract was washed successively with a 10% sodium bicarbonate solution or, if necessary, with N ammonia and N hydrochloric acid, and then dried over anhydrous magnesium sulfate. The dried solution was concentrated to dryness, and the residue was crystallized from a suitable solvent system. The data are listed in Table IV.

## Summary

The trifluoroacetates of various phenol, thiophenol and *N*-hydroxyimide derivatives, which are known as hydroxylic partners of various active carboxylic acid ester, have been synthesized, and it has been found that they are good reagents for the preparation of the respective active esters of acylamino acids by the ester-exchange reaction in pyridine. The new method is especially effective in the preparation of *p*-nitrophenyl, 2, 4, 5-trichlorophenyl and *N*-hydroxysuccinimide esters of acylamino acids, which are well known to be useful intermediates for peptide synthesis. The direct

# The Relative Reactivities of Different C–H Bonds in the Photochemical Sulfoxidation of *n*-Hexane[1]

By Yoshiro OGATA, Yasuji IZAWA and Takao TSUDA

(Received April 30, 1965)

The present authors have previously postulated,[2] in the photochemical sulfoxidation of *n*-hexane, a mechanism involving the simultaneous steps of a chain reaction via persulfonate radical and a molecular mechanism via excited sulfur trioxide; the primary process in the radical chain seems to involve two simultaneous processes, i. e., energy transfer and hydrogen abstraction with excited sulfur dioxide.

The relative reactivities of different C–H bonds in *n*-heptane towards ultraviolet light-excited sulfur dioxide have recently been estimated by Asinger, Fell and Pöttkamper.[3] In order to estimate the relative reactivities, the heptanesulfonic acids produced were converted to the corresponding methyl heptanesulfonates, which had been determined by gas chromatography.

The present paper will describe the results obtained in a study of the relative reactivities of different C–H bonds towards excited sulfur dioxide and sulfur trioxide in the photochemical sulfoxidation of *n*-hexane, together with the results of the comparison of these data with those of the photochemical chlorination.

## Experimental

**Materials.**—*n*-Hexane was purified by a previously reported procedure.[2] Acetic anhydride, dichloromethane, sulfur dioxide and oxygen were of commercial materials of an extra pure grade. Thionyl chloride (b. p. 78—79°C) and dimethyl formamide (b. p. 75—77°C/63 mmHg) were purified by the fractionation of commercial materials of an extra pure grade. Authentic 2-hexanesulfonyl chloride was prepared as follows: 2-hexanol (b. p. 79—80°C/81 mmHg; $n_D^{25}$ 1.4133 (lit.[4] $n_D^{25}$ 1.4136); its 3,5-dinitrobenzoate, m. p. 37.8—38.5°C (lit.[5] m. p. 38°C)) was prepared by Grignard synthesis from *n*-butyl bromide and acetaldehyde; it was converted by phosphorous tribromide to 2-hexyl bromide, which was then converted to 2-hexanesulfonyl chloride (b. p. 60—62°C/4.5 mmHg; $n_D^{25}$ 1.4630 (lit.[6] $n_D^{25}$ 1.4610)) via 2-hexyl thiocyanate.[7,8] Authentic 1-hexanesulfonyl chloride (b. p. 92—93°C/4 mmHg; $n_D^{25}$ 1.4612 (lit.[9] $n_D^{25}$ 1.4563)) and 3-hexanesulfonyl chloride (b. p. 64°C/5.5 mmHg; $n_D^{25}$ 1.4637) were similarly prepared from 1-hexanol (b. p. 156—157°C) and 3-hexanol (b. p. 134—135°C; $n_D^{25}$ 1.4134 (lit.[10] $n_D^{25}$ 1.4139); its 3,5-dinitrobenzoate, m. p. 75.2—75.5°C (lit.[5] m. p. 77°C)) respectively. The purities of all the alcohols, bromides, thiocyanates and sulfonylchlorides examined were confirmed by gas chromatography.

**The Sulfoxidation of *n*-Hexane.**—Sulfur dioxide (0.5—2 l./hr.) and oxygen (0.3—2 l./hr.) were introduced simultaneously into a mixture of *n*-hexane (0.3 mol., 40 ml.) and acetic anhydride (0.016 mol.) under ultraviolet light (Toshiba SHL-100 UV) at 1—28°C for 1 hr. After irradiation had ended, treatment in a way similar to that described in a previous paper[2] gave sodium hexanemonosulfonates.

**The Conversion of Sodium Hexanesulfonates to Their Sulfonyl Chlorides.**—The procedure employed was similar to that reported by Kirkland.[11] A mixture of the resulting sodium hexanesulfonates

(1.5 g.) and fresh thionyl chloride (50 ml.) in the presence of dimethyl formamide (1.5 ml.) was refluxed until the evolution of sulfur dioxide had subsided (1—2 hr.); then it was cooled. Dichloromethane (about 50 ml.) was added to the reaction product, and the precipitate of sodium chloride was filtered off. The unreacted thionyl chloride and the solvent were carefully removed by evaporation under moderately reduced pressure, and dichloromethane (3—5 ml.) was added to the remaining sulfonyl chloride. The isomeric hexanesulfonyl chloride content of the solution was determined by gas chromatography.

**The Determination of the Isomeric Hexanesulfonyl Chlorides by Gas Chromatography.**—The vapor-phase chromatographic determination of the isomers was carried out using a 5 m. column (diameter 4 mm.) containing polyethylene glycol 4000 (1% by weight)/C-22 (40—60 mesh), and with helium as a carrier gas (54 ml./min.) at 130°C (Fig. 1); the similarity of the retention times of the peaks of the authentic material to those of the peaks of the sample established their identity. The molar ratio of the isomers was calculated by means of the paper-peak-weight ratio. No appreciable decomposition of hexanesulfonyl chlorides to the corresponding hexyl chlorides was observed under these conditions.

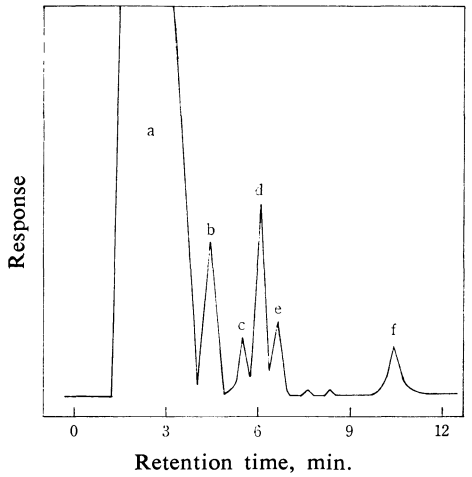

Fig. 1. Typical chromatogram of 1-, 2- and 3-hexanesulfonyl chlorides.
a: Dichloromethane, b: Dimethylformamide, c: Unknown, d: 3-Hexanesulfonyl chloride, e: 2-Hexanesulfonyl chloride and f: 1-Hexanesulfonyl chloride.

**The Photochlorination of *n*-Hexane.**—Chlorine (0.3—0.5 l./hr.) was introduced into *n*-hexane (0.3 mol., 40 ml.) under ultraviolet light at −10—+28°C for 1 hr. After the irradiation had ended, nitrogen was bubbled into the reaction mixture in order to remove the free chlorine and hydrogen chloride in the mixture. The resulting solution was washed with 1 N aqueous sodium hydrogen carbonate and then with water, and dried with sodium sulfate. The isomeric hexyl monochloride content was determined by gas chromatography, using a column similar to that used for hexanesulfonyl chloride at 37°C. The hexyl monochloride content as a whole in the resulting chlorinated hexane was about 83%.

## Results and Discussion

The sodium 1-, 2- and 3-hexanesulfonates obtained by the sulfoxidation of *n*-hexane were converted to the corresponding sulfonyl chlorides, and then the latter were estimated by gas chromatography. The relative reactivity ($R$) of different C–H bonds towards excited $SO_2$ and $SO_3$ is given by:

$$R=\left(\frac{\text{Mol.\% of the isomer in the product}}{\text{Total number of C–H bonds at the corresponding position}}\right)\Big/R_1$$

where

$$R_1=\frac{\text{Mol.\% of 1-isomer}}{\text{Total No. of C–H bonds at the 1-position}}$$

Table I summarizes the relative reactivities of different C–H bonds in the photochemical sulfoxidation and chlorination of the *n*-hexane in our hands, together with the results in the literature. As Table I shows, the relative reactivity, 2.1—3.6, for the secondary vs. the primary C–H bond of *n*-hexane approximates those in the photochemical sulfoxidation[12] and sulfochlorination[13] of *n*-dodecane and the photochlorination of *n*-heptane[14] and *n*-dodecane.[15,16] In contrast, it has recently been reported[3] that the relative reactivity for C(secondary) vs. $C_1$ in the photochemical sulfoxidation of *n*-heptane without acetic anhydride is about 30, although this value is very different from those obtained in photochemical reactions by other workers. At any rate, the increase in the relative reactivity of C(secondary) may be accounted for by the stability of the secondary carbon radical being greater than that of the primary radical.

On the other hand, since it may be expected that the $C_3$–H bond is more sterically hindered, it is surprising to observe that the reactivity of the $C_2$–H bond is lower than that of the $C_3$–H bond. This fact may be explained by assuming temporarily the tentative formation of a six-membered ring[17,18] of the 2-hexyl radical, which results in the inhibition of the approach of $SO_2$ or $SO_3$ to the 2-position, thus

TABLE II. EFFECT OF THE RATIO $[SO_2]/[O_2]$ ON THE RELATIVE REACTIVITIES OF C-H BONDS ($[n\text{-}C_6H_{14}]/[Ac_2O]$ : 19; Irradiation time: 1 hr.)

| $[SO_2]/[O_2]$ | Temp. °C | Relative reactivity | | | |
|---|---|---|---|---|---|
| | | $C_1$-H | $C_2$-H | $C_3$-H | $2_{ry}C$-H/$1_{ry}C$-H |
| 0.5 | 18—19 | 1 | 0.8 | 4.0 | 2.4 |
| 2 | 11—18 | 1 | 1 | 3.3 | 2.2 |
| 10 | 18—19 | 1 | 0.9 | 6.2 | 3.6 |

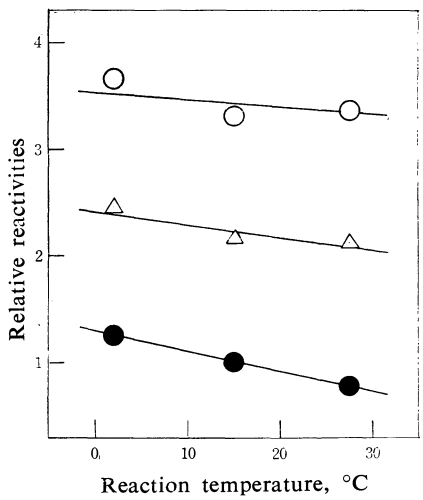

Fig. 2. Temperature dependence of the relative reactivities in photochemical sulfoxidation of *n*-hexane.
●: $C_2$-H, ○: $C_3$-H
△: (Secondary C-H)/(Primary C-H)

lowering the reactivity of $C_2$-H bonds compared with that of $C_3$-H bonds. This assumption may also explain the fact that the temperature dependence of the reactivity of $C_2$-H bonds is somewhat greater than that of $C_3$-H bonds (Fig. 2), for rings are formed more easily at a higher temperature. Since the C-H bond length is short, the five-membered ring from the 3-hexyl radical may approach the four-membered ring, which is less stabilized. Although the temperature effect on the reactivity is small in the 0—30°C range, an increase in the temperature results in a small decrease in the reactivity for photochemical sulfonates by sulfur trioxide, as is shown in Fig. 2. Furthermore, the ratio of $SO_2$ vs. $O_2$ also affects the relative reactivity, particularly for $C_3$-H bonds (Table II).

Table III shows the findings on the photochemical chlorination of *n*-hexane, where such steric hindrance of the six-membered ring seems to be small. In this case, the difference in the relative reactivities of $C_2$-H and $C_3$-H bonds is small. Such a difference in the behavior of chlorine and sulfur dioxide has been reported in the photochemical chlorination of

TABLE III. RELATIVE REACTIVITIES OF C-H BONDS IN THE PHOTOCHLORINATION OF *n*-HEXANE (Flow rate of $Cl_2$: 0.3—0.5 l./hr.; Irradiation Time: 1 hr.)

| Temp. °C | Relative reactivity | | |
|---|---|---|---|
| | $C_1$-H | $C_2$-H | $C_3$-H |
| −7—−5 | 1 | 3.5 | 3.0 |
| 21— 22 | 1 | 2.9 | 3.2 |
| 27— 28 | 1 | 3.4 | 3.8 |

isobutane, giving *t*-butyl chloride,[19] and the sulfochlorination of the same substrate, giving isobutanesulfonyl chloride alone.[20]

## Summary

The product mixture of isomeric hexanesulfonic acids in the ultraviolet light-induced sulfoxidation of *n*-hexane under various conditions has been analyzed by gas chromatography. On the basis of the data thus obtained, the relative reactivities of different C–H bonds in *n*-hexane towards light-excited sulfur dioxide and sulfur trioxide have been estimated. The ratio of the reactivities of $C_1$–H : $C_2$–H : $C_3$–H has been calculated to be 1 : 0.8—1.3 : 3.2—6.2. The higher reaction temperatures tend to lower the reactivity of $C_2$–H. The mole ratio of $SO_2$ vs. $O_2$ has an appreciable effect on the composition of the isomers. The lower reactivity of $C_2$–H than that of $C_3$–H may be explained by the intermediary formation of a six-membered ring.

The authors are grateful to the Seitetsu Chemical Co. for their gift of sulfur dioxide.

# Traube's Rule for Soluble Monolayers of Homologous Strong Electrolytes

By Kunio TAMAKI

(Received May 8, 1965)

On the surface tension of dilute aqueous solutions of a homologous series of aliphatic alcohols or carboxylic acids, Traube[1] showed that the concentrations required for an equal lowering of the surface tension diminished by a constant factor for each additional methylene group in the hydrocarbon chain. This relation, commonly called Traube's rule, is conveniently expressed as;

$$C_n/C_{n+1}=K \tag{1}$$

where $C_n$ and $C_{n+1}$ are, respectively, the concentrations for successive members of the series with $n$ and $n+1$ methylene groups at the equal lowering of surface tension, and $K$, termed "Traube's factor" in this paper, is a constant. Many experimental data for the homologous series of nonelectrolytes, such as aliphatic alcohols, or of weak electrolytes, such as aliphatic carboxylic acids, indicate that $K$ is about 3.

On the other hand, Traube's factor for a homologous series of strong electrolytes seems to be about 2. The object of this paper is to interpret the significance of Traube's factor for soluble monolayers of homologous strong electrolytes, especially for perfluoro acids.

**Traube's Factor for Nonelectrolytes and Weak Electrolytes.**—Langmuir,[2] Tamamushi,[3] Ward[4] and Davies[5] interpreted Traube's rule in terms of the free energy of the adsorption of each additional methylene group.

The chemical potentials of a solute, $\mu$, in the surface film and in the water may be written, respectively, as;

$$\left.\begin{aligned}\mu_s&=\mu_s^\circ+\boldsymbol{R}\boldsymbol{T}\ln C_s\\ \mu_b&=\mu_b^\circ+\boldsymbol{R}\boldsymbol{T}\ln C_b\end{aligned}\right\} \tag{2}$$

where $\boldsymbol{R}$ is the gas constant; $T$, the absolute temperature, and $C$, the concentration; the superscript $\circ$ is used to identify the standard state, while the subscripts $s$ and $b$ refer to the surface and the bulk phases respectively. The activity coefficients are omitted in this paper. When surface and bulk are in equilibrium, $\mu_s=\mu_b$; therefore,

$$C_s=C_b\exp\frac{\mu_b^\circ-\mu_s^\circ}{\boldsymbol{R}\boldsymbol{T}}=C_b\exp\frac{-\Delta F^\circ}{\boldsymbol{R}\boldsymbol{T}} \tag{3}$$

where $\Delta F^\circ$ $(=\mu_s^\circ-\mu_b^\circ)$ is the standard free energy of the adsorption of the solute molecule from the bulk to be the surface, which is written as;

$$\Delta F^\circ=W_0+nW \tag{4}$$

1) I. Traube, *Ann. Chem. Liebigs*, **265**, 27 (1891).

2) I. Langmuir, *J. Am. Chem. Soc.*, **38**, 1948 (1917).

3) B. Tamamushi, This Bulletin, **9**, 363 (1934).

4) A. F. H. Ward, *Trans. Faraday Soc.*, **42**, 399 (1946).

5) J. T. Davies and E. K. Rideal, "Interfacial Phenomena," Academic Press, New York and London (1961), p. 154.

where $W$ is the free energy of the adsorption of an additional methylene group from the bulk to the surface and $W_0$ is the free energy contribution of a polar group. Then, from the great resemblance of the surface tension versus the logarithm of concentration curve for each homologous compound, it may be assumed that the surface concentration, $C_s$, is approximately equal at the equal lowering of surface tension for each compound. From the two equations corresponding to Eq. 3 for successive members of the series with $n$ and $n+1$ methylene groups, one obtains;

$$\frac{C_n}{C_{n+1}} = \exp\left(\frac{\Delta F_n^\circ - \Delta F_{n+1}^\circ}{RT}\right) \quad (5)$$

From Eqs. 1, 4 and 5, we obtain;

$$K = \exp(-W/RT) \quad (6)$$

At the air-water interface, the interchain cohesion increases with the adsorption and the standard free energy of the adsorption of long-chain molecules is dependent on the surface concentration, as has been discussed by Tamamushi[6] in his early work and by Davies[7] in recent years. If, however, we set $W=-650$ cal./mol. at 25°C, as an approximate value, in Eq. 6, Traube's factor becomes 3.0.

**Traube's Factor for Strong Electrolytes.**—For soluble ionized monolayers, one must take into consideration the electrical repulsive potential of the surface, which tends to make the adsorbed long-chain ions repel each other; the standard free energy of the adsorption per mole, $\Delta F^\circ$, is expressed as;

$$\Delta F^\circ = nW + NZe\phi \quad (7)$$

where $N$ is the Avogadro number; $Z$, the valency of the long-chain ion; $e$, the proton charge, and $\phi$, the electrical potential of the surface. According to Gouy's theory, $\phi$ may be given as;

$$\phi = \frac{2kT}{Ze}\sinh^{-1}\left(\sigma\sqrt{\frac{500\pi}{CDRT}}\right) \quad (8)$$

where $k$ is the Boltzmann constant; $\sigma$, the surface charge density; $C$, the molar concentration, and $D$, the dielectric constant of the solvent. Further, at a high potential, Eq. 8 may be simplified to;

$$\phi = \frac{kT}{Ze}\ln\frac{2000\sigma^2\pi}{CDRT} \quad (9)$$

The combination of Eqs. 7 and 9 gives;

$$\Delta F^\circ = nW + RT\ln\frac{2000\sigma^2\pi}{CDRT} \quad (10)$$

From the two equations corresponding to Eq. 10 for successive members of the series with $n$ and $n+1$ methylene groups, and by assuming that the surface charge density, $\sigma$, is approximately equal at equal lowerings of the surface tension for homologous compounds, as has been mentioned above, we obtain;

$$\Delta F_n^\circ - \Delta F_{n+1}^\circ = -W + RT\ln C_{n+1}/C_n \quad (11)$$

By the substitution of Eq. 11 into Eq. 5, we find that;

$$C_n/C_{n+1} = K = \exp(-W/2RT) \quad (12)$$

Table I summarizes the values of Traub's factor calculated from the published data of Kling and Lange[8] on the heptane-water interfacial tensions for sodium alkyl sulfates at 50°C. From this table Traube's factor is found to be about 2. With $W=-810$ cal./mol. as the free energy of the adsorption for each methylene group at the oil-water interface, Eq. 12 gives $K=1.9$. It may, therefore, be concluded that Eq. 12 can be used to obtain a very good approximation of Traube's factor for soluble monolayers of homologous strong electrolytes.

Table I. Calculation of the Traube's factor for sodium alkyl ($C_8$–$C_{16}$) sulfates at the heptane-water interface at 50°C using data of Kling and Lange[8]

| Substance | Concn. required to give interfacial tension of 30 dyne/cm., M | $K^2$ |
|---|---|---|
| $C_8$ | 0.021 | $(1.8)^2$ |
| $C_{10}$ | 0.0063 | $(2.0)^2$ |
| $C_{12}$ | 0.0016 | $(2.0)^2$ |
| $C_{14}$ | 0.00042 | $(2.0)^2$ |
| $C_{16}$ | 0.00011 | |

**Traube's Factor for Perfluoro Acids.**—Aranow and Witten[9] proposed a theory of Traube's rule on the assumption that on the surface each methylene group has 3 equal energy potential minima with respect to the torsion whose effect contributes $R\ln 3$ to the entropy, and that if the enthalpy increment per methylene group is zero, the increment in the free energy per methylene group is given by $RT\ln 3$. Further, they pointed out, as an example of the applicability of their theory, that Traube's factor for homologous series with perfluorochains is found to be about 3, and that this can be explained by similarily assuming that each $CF_2$ group has 3 positions of potential minima about carbon-carbon bonds, regardless of the different strengths of the interactions between water-$CF_2$ and water-$CH_2$.

According to our view, however, Traube's

9) R. H. Aranow and L. Witten, *J. Chem. Phys.*, **28**, 405 (1958), **35**, 1504 (1961).

rule for homologous perfluoro acids can be interpreted using Eq. 12, because perfluoro acids are of the strong electrolyte type. Phillips[10] obtained the free energy of the transfer of the $CF_2$ group from the water phase to the oil phase as about $-1300$ cal./mol. By the substitution of this value into Eq. 13, Traube's factor $K$ becomes 3.3 Therefore, it is a fortuitous fact that Traube's rule with the same constant holds for molecules with fluorocarbon chains as well as for hydrocarbon chains.

Recently, Kauzmann,[11] and Némethy and Scheraga[12] evaluated the thermodynamic parameters pertaining to the transfer of such nonpolar molecules as hydrocarbons from the water phase to the oil phase, termed the "hydrophobic bond" or "hydrophobic interaction"; they concluded that the entropy increment caused by the change of the "iceberg" around the nonpolar molecules to the original water is the most important part of the process. The entropy effect may be a main contribution to the free energy of the adsorption of nonpolar molecules from the water phase to the surface phase; however, this effect would not originate from the potential minima of the internal rotation about carbon-carbon bonds, but probably from the hydrophobic interaction. More recently, Spaull and Nearn[13] have discussed the thermodynamic parameters of the adsorption of fatty alcohols at the air-water interface along the same lines.

## Summary

By using the free energy of the adsorption of the $CH_2$ or the $CF_2$ group from water to the surface, $W$, and the surface potential of Gouy's theory, Traube's factor, $K$, that is, the ratio of the respective concentrations, $C_n$ and $C_{n+1}$, required to effect the equal lowering of surface or interfacial tension for successive homologous strong electrolytes with $n$ and $n+1$ $CH_2$ or $CF_2$ groups, has been derived as;

$$K=C_n/C_{n+1}=\exp(-W/2\boldsymbol{R}T)$$

where $\boldsymbol{R}$ is the gas constant and $T$, the absolute temperature. This equation has been shown to be applicable also in obtaining a very good approximation for homologous sodium alkyl sulfates or perfluoro acids.

The author wishes to express his sincere gratitude to Professor Bun-ichi Tamamushi, of Tokyo Woman's Christian College, for his many helpful discussions throughout this work.

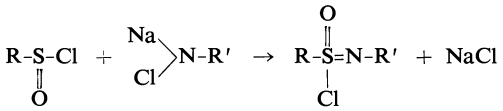
# The Preparation of Iminosulfonic Acid Derivatives by Means of Sulfinamides and *N*-Bromosuccinimide

By Hisashi TAKEI, Itaru WATANABE and Teruaki MUKAIYAMA



(Received May 15, 1965)

The preparation of *N*-alkyl and *N*-aryliminosulfonic acid derivatives by the reaction of sulfinamides with bromine or *N*-bromosuccinimide in the presence of amines or sodium *p*-nitrophenolate has been attempted on the assumption that the iminosulfonic acid derivatives might be useful as intermediates in the field of synthetic chemistry.

In this connection, Levchenko and his coworkers[1] have recently reported that *N*-sulfonyl, *N*-ethoxycarbonyl or *N*-acetyl iminosulfonyl chlorides may be prepared by the reaction of arylsulfinyl chlorides with sodium *N*-chlorosulfonamides, sodium ethyl *N*-chlorocarbamate or sodium *N*-chloroacetamide. The amides and esters of iminosulfonic acid are synthesized from the chlorides, and amines and sodium phenolate respectively:[2]

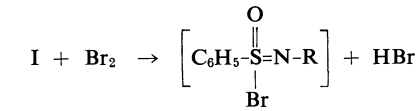
R=aryl
R'=arylsulfonyl, ethoxycarbonyl or acetyl

However, the method is not applicable to the synthesis of *N*-alkyl or *N*-aryliminosulfonic acid derivatives, because the sodium *N*-chloroalkyl or aryl amides are difficult to handle in the isolated state.

Iminochlorides are generally obtained by the reaction of carboxylic acid amides with phosgene, thionyl chloride or phosphorus pentachloride.[3] However, sulfonamides do not give the corresponding iminosulfonyl chlorides[4] when treated with the above-mentioned chlorinating reagents except in the case of diarylsulfonylimides[5] and *N*-dichlorophosphorylarylsulfonamides.[4a]

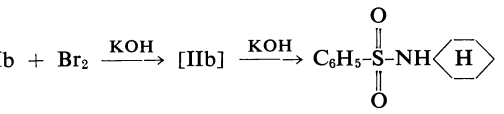
In the present experiment, the preparation of benzene-*N*-phenyliminosulfinyl chloride from benzenesulfinanilide (Ia) and thionyl chloride was attempted first. When a benzene solution of Ia and excess thionyl chloride was refluxed for half an hour, a 87% yield of be benzenesulfinyl chloride and a 88% yield of *N*-sulfinylaniline were obtained instead of the expected iminosulfinyl chloride. *N*-Cyclohexylbenzenesulfinamide (Ib) reacted with thionyl chloride to yield 11% of benzenesulfinyl chloride and 13% of *N*-sulfinylcyclohexylamine, along with a large amount of a dark-colored tarry product.

Similarly, the reaction of Ia with phosgene gave a 55% yield of benzenesulfinyl chloride and a 42% yield of phenyl isocyanate.

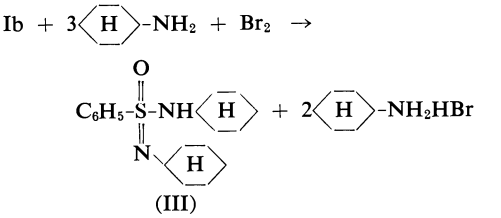


(Ia) R=$C_6H_5$

(Ib) R= 



Since the preparation of iminosulfonyl halide or iminosulfinyl halide by a method similar to those used for iminochloride had proved unsuccessful, it was thought advisable to investigate the method of preparing the iminosulfonyl bromide by the oxidation of sulfinamides with bromine, a method shown in the following equation:



(II)

The expected product, benzene-*N*-cyclohexyliminosulfonyl bromide (IIb), could not be isolated by the addition of bromine to a suspension of Ib in carbon tetrachloride, but cyclohexylamine hydrobromide was obtained in a good yield. It is known that sulfinamides are unstable towards acid;[6] therefore, it seemed reasonable to assume that the hydrogen bromide initially produced rapidly react with Ib, thus giving cyclohexylamine hydrobromide. On the other hand, when bromine was added drop-by-drop to a solution of Ib and potassium hydroxide in 50% aqueous ethanol, *N*-cyclohexylbenzenesulfonamide, the oxidized product of Ib, was obtained in a 60% yield. This may be produced by the hydrolysis of the IIb initially formed.

It is to be expected that if the above reaction is carried out in the presence of primary or secondary amine instead of potassium hydroxide, IIb will rapidly react with the amine to yield iminosulfonamide. Indeed, when the reaction of Ib with bromine in carbon tetrachloride was attempted at 0°C in the presence of three times as many moles of cyclohexylamine, *N*-cyclohexylbenzene-*N*-cyclohexyliminosulfonamide (III) was obtained in a 32% yield, along with cyclohexylamine hydrobromide. The III was identified by elemental analyses and by means of its infrared spectrum, which has the characteristic bonds of the nitrogen hydrogen bond (3250 $cm^{-1}$) and of the iminosulfonyl group (1272 $cm^{-1}$, 1255 $cm^{-1}$ and 1135 $cm^{-1}$).[7]

(III)

3) These reactions have been reported by many workers, for example, O. Wallach, *Ann.*, **184**, 1 (1877); J. v. Braun and W. Pinkernelle, *Ber.*, **67**, 1218 (1934).

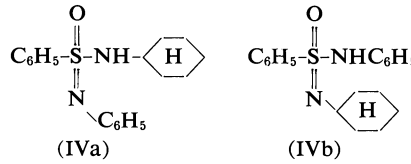
7) E. S. Levchenko, E. S. Kozlov, A. A. Kisilenko and A. V. Kirsanov, *Zhur. Obscheĭ. Khim.*, 33, 3065 (1963); *Chem. Abstr.*, **60**, 2451h (1964).

When *N*-bromosuccinimide (NBS) was used instead of bromine in the above experiment, III was obtained in a 69% yield, along with succinimide and cyclohexylamine hydrobromide. This reaction is considered to proceed through an initial formation of IIb and succinimide by a reaction of Ib with NBS similar to that of Ib with bromine. The IIb in turn reacts with cyclohexylamine to yield III.

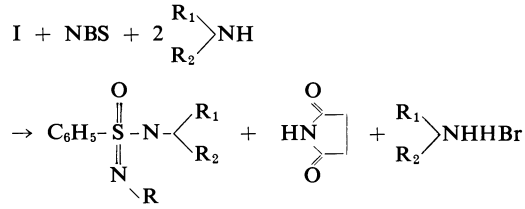


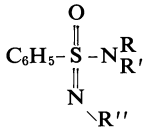
However, the treatment of Ib and NBS in the presence of aniline did not give *N*-cyclohexylbenzene-*N*-phenyliminosulfonamide (IV), presumably because of the facile reaction of NBS with aniline. Instead, IV was obtained in a 73% yield, along with succinimide and aniline hydrobromide, when NBS and Ib were stirred at 0°C for forty minutes in carbon tetrachloride and then two times as many moles of aniline were added to the reaction mixture. On the other hand, the yield of IV decreased to 39% when Ib and NBS were treated for three hours before the addition of aniline. Thus, it seemed reasonable to assume that the intermediate, *N*-cyclohexyliminobenzenesulfonyl bromide (IIb), may be unstable even at 0°C.

On the other hand, IV was also obtained in a 84% yield by the reaction of Ia with NBS in the presence of cyclohexylamine.

There may be two tautomeric forms of IVa and IVb for IV. The phenyl group has a greater tendency to attract electrons and IV should, therefore, tend to exist as formula IVa:

The results of the reactions of Ia or Ib and NBS in the presence of various amines are summarized in Table I.





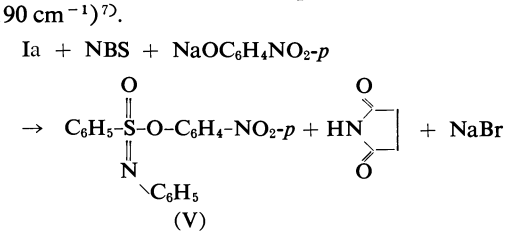


Table I. Preparation of benzeneiminosulfonamides

| $R\diagdown R'\diagup N-$ | R'' | Yield % | M. p. °C | Formula | C, % Found | C, % Calcd. | H, % Found | H, % Calcd. | N, % Found | N, % Calcd. |

a) B. p. 168—172°C/0.13 mmHg. b) Recrystallized from petroleum ether. c) Recrystallized from alcohol. d) Recrystallized from ligroin.

Next, the preparation of the *p*-nitrophenyl ester of iminosulfonic acid by the reaction of Ia with NBS and sodium *p*-nitrophenolate was attempted. When the suspension of Ia, NBS and sodium *n*-nitrophenolate in carbon tetrachloride was stirred at 0°C for about 10 hr., *p*-nitrophenyl benzene-*N*-phenyliminosulfonate (V) was obtained in a 48% yield. The infrared spectrum of V contains characteristic bands assignable to a nitro group (1349 $cm^{-1}$) and a iminosulfonyl group (1250 $cm^{-1}$ and 1190 $cm^{-1}$)[7].

(V)

When the reaction of Ib, NBS and sodium benzoate was carried out, colorless needles were obtained in a high yield, along with succinimide and sodium bromide. These needles were identified as *N*-benzoyl-*N*-cyclohexylbenzenesulfonamide (VI) by elementary analyses and by a comparison of them with an authentic sample prepared by the reaction of sodium *N*-cyclohexylbenzenesulfonamide with benzoyl chloride. This finding suggests that an initially-formed IIb reacted with sodium benzoate to give the intermediate, iminosulfonic benzoic anhydride, which in turn rearranged to yield VI.[8]

(VI)

## Experimental

**Benzenesulfinanilide (Ia) and *N*-Cyclohexylbenzenesulfinamide (Ib).**—These compounds were prepared, according to the method of Klaman et al.,[6] from phenylmagnesium bromide and the corresponding *N*-sulfinylamine.

**The Reaction of Ia with Thionyl Chloride.**—To a suspension of Ia (2.17 g., 0.01 mol.) in anhydrous benzene, excess thionyl chloride (3.0 g., 0.025 mol.) was added, the mixture was then refluxed for half an hour. After the solvent and the excess thionyl chloride had been removed, benzenesulfinyl chloride (1.42 g., 88%; b. p. 90—93°C/4 mmHg) and *N*-sulfinylaniline (1.20 g., 87%; b. p. 96—98°C/18 mmHg) were obtained.

When Ib (2.23 g., 0.01 mol.) was used in place of Ia in the above experiment, benzenesulfinyl chloride (0.17 g., 11%) and *N*-sulfinylcyclohexylamine (0.19 g., 13%; b. p. 55°C/4 mmHg) were obtained, along with a large amount of a tarry product.

**The Reaction of Ia with Phosgene.**—To a suspension of Ia (2.17 g., 0.01 mol.) in anhydrous benzene, 30% phosgene in toluene (3.3 g., 0.01 mol.) was added drop-by-drop under cooling; the mixture was then refluxed for half an hour. A 55% yield of benzenesulfinyl chloride (0.88 g.) and a 42% yield of phenyl isocyanate (0.50 g.) were obtained by fractional distillation.

***N*-Cyclohexylbenzenesulfonamide.**—To a solution of Ib (2.23 g., 0.01 mol.) and potassium hydroxide (1.34 g., 0.034 mol.) in 50% aqueous ethanol, bromine (1.60 g., 0.01 mol.) was added drop-by-drop under cooling. The mixture was evaporated to dryness under reduced pressure, and the residue was extracted with hot ligroin to give colorless needles (1.43 g. (60%); m. p. 89—90°C (undepressed by admixture with an authentic sample)).

***N*-Cyclohexylbenzene-*N*-cyclohexyliminosulfonamide (III).**—a) To a mixture of Ib (2.23 g., 0.01 mol.) and cyclohexylamine (3.07 g., 0.031 mol.) in 30 ml. of carbon tetrachloride, bromine (1.60 g., 0.01 mol.) was added drop-by-drop under cooling; cyclohexylamine hydrobromide and succinimide were thus precipitated. The filtrate was evaporated, and the dark-colored residue was chromatographed on alumina. III was eluted with ether and recrystallized from petroleum ether (1.02 g. (32%); m. p. 100—101°C).

Found: C, 67.39; H, 8.81; N, 8.50; S, 10.18. Calcd. for $C_{18}H_{28}N_2OS$: C, 67.47; H, 8.81; N, 8.74; S, 9.99%.

b) A mixture of cyclohexylamine (3.07 g., 0.031 mol.), Ib (2.23 g., 0.01 mol.) and *N*-bromosuccinimide (NBS) (1.78 g., 0.01 mol.) in carbon tetrachloride was stirred for 3 hr. at 0°C and then for an additional 3 hrs. at room temperature. III was obtained from the filtrate in a 69% yield (2.20 g.; m. p. 100—101°C). Similarly, when *N*-bromophthalimide was used instead of NBS in the above experiment, III was obtained in a 50% yield.

***N*-Cyclohexylbenzene-*N*-phenyliminosulfonamide (IV).**—a) A mixture of Ia (2.17 g., 0.01 mol.) and NBS (1.78 g., 0.01 mol.) in carbon tetrachloride (30 ml.) was stirred for 40 min. at 0°C; then aniline (2.05 g., 0.022 mol.) was added, and the mixture was stirred for 3 more hr. The precipitate was collected and washed with water and weighed; 1.20 g., m. p. 140—143°C. The filtrate, after the solvent had been removed, gave an additional IV (1.10 g.); total yield, 2.30 g. (73%). The IV was recrystallized from ethanol (m. p. 149—150°C).

8) A similar rearrangement is observed in the case of the carboxylic imidic anhydride produced by the reaction of sodium carboxylate with imidoyl chloride; it yields diacylamides. O. Mumm, H. Hesse and H. Volquartz, *Ber.*, **48**, 388 (1915); F. Cramer and K. Baer, ibid., **93**, 1231 (1960).

Found: C, 68.63; H, 7.16; N, 8.92. Calcd. for $C_{18}H_{22}N_2OS$: C, 68.77; H, 7.05; N, 8.91%.

When a mixture of Ib and NBS in carbon tetrachloride was stirred for 3 hr. at 0°C before the addition of aniline as in the above experiment, the yield dropped to 1.22 g. (39%).

b) Similarly, when a mixture of Ib (2.17 g., 0.01 mol.), NBS (1.78 g., 0.01 mol.) and cyclohexylamine (3.07 g., 0.031 mol.) was stirred for 2 hr. at 0°C and then for an additional 3 hr. at room temperature, IV was obtained in a 84% yield (2.65 g.).

The other iminosulfonamides were prepared by the reaction of Ia or Ib, NBS and 2 mol. of the corresponding amines. The results are listed in Table I.

***p*-Nitrophenyl Benzene-*N*-phenyliminosulfonate (V).**—A mixture of Ia (2.23 g., 0.01 mol.), NBS (1.78 g., 0.01 mol.) and sodium *p*-nitrophenolate (1.78 g., 0.011 mol.) in 30 ml. of carbon tetrachloride was stirred for 10 hr. at 0°C. The filtrate, after the solvent had been removed, gave a dark-colored syrup. When a small portion of ethanol was added to the syrup, pale yellow V was crystallized out (1.70 g., 48%; m. p. 70—72°C). When it was recrystallized from ethanol, its m. p. was 72—73°C.

Found: C, 60.75; H, 3.91; N, 8.07. Calcd. for $C_{18}H_{14}N_2O_4S$: C, 61.01; H, 3.98; N, 7.91%.

***N*-Benzoyl-*N*-cyclohexylbenzenesulfonamide (VI).**—A mixture of Ib (2.23 g., 0.01 mol.), NBS (1.78 g., 0.01 mol.), and sodium benzoate (1.44 g., 0.01 mol.) in 30 ml. of carbon tetrachloride was stirred for 3 hrs. at 0°C and then for an additional 3 hr. at room temperature. The precipitate was collected and washed with water to give VI (2.44 g. (71%), m. p. 140—142°C). When it was then recrystallized from ethanol, its m. p. was 143—144°C. The infrared spectrum (KBr) showed strong absorptions at 1650 $cm^{-1}$ (C=O of amide linkage) and at 1330 $cm^{-1}$ and 1160 $cm^{-1}$ ($SO_2$ linkage).

Found: C, 66.18; H, 6.13; N, 3.82; S, 9.40. Calcd. for $C_{19}H_{21}NO_3S$: C, 66.46; H, 6.16; N, 4.08; S, 9.32%.

When the same reaction was carried out in tetrahydrofuran, methylene chloride or ether, the yield of VI decreased to 58%, 17% or 5% respectively.

This compound VI can also be prepared by the reaction of sodium *N*-cyclohexylbenzenesulfonamide with benzoyl chloride.

## Summary

It has been found that *N*-substituted benzenesulfinamides (I) react with thionyl chloride to give benzenesulfinyl chloride and the corresponding *N*-sulfinylamines, and that they are oxidized by treatment with bromine in an alkaline solution to give *N*-substituted sulfonamides.

When these benzenesulfinamides are treated with bromine or *N*-bromosuccinimide (NBS) in the presence of various primary or secondary amines, the corresponding benzeneiminosulfonamides are obtained in high yields. Similarly, the reaction of I, NBS and sodium *p*-nitrophenolate or sodium benzoate yields *p*-nitrophenyl benzeneiminosulfonate or *N*-benzoylbenzensulfonamide. These reactions are considered to proceed through the benzeneiminosulfonyl bromides formed by the oxidation of sulfinamides with bromine or NBS.

# A Study of Zinc Oxide - Chromium Oxide Catalysts. VI. The Changes Brought about by Heat Treatment in the Activity for Methanol Synthesis and in the Structure of the Raw Catalysts

By Hiroshi UCHIDA, Masaaki OBA and Michio ARAKI

(Received May 24, 1965)

A number of papers have appeared dealing with those methanol-synthesis catalysts which consist of the oxides of zinc and chromium.[1] However, most of these papers have described mainly the relation of the activity and of the catalyst structure to the chemical composition. The only exception is a series of papers by Kawamura and his associates,[3-6] who investigated the reduction process of the catalysts in detail and also the changes in the activity and in the structure of the reduced catalysts brought

about by heat treatment. In the course of our previous study[7] of the catalysts, it became evident that the activity declined considerably if a dry preparation from a slurry of zinc oxide powder in aqueous chromic acid was preheated in the air in the hope that the shrinkage of the catalyst bed during the synthesis might be avoided. This observation makes us suspect that a change in the catalyst structure might accompany this decline in activity. However, in order that a better understanding of the dependence of the catalyst performance upon the history of a catalyst may be obtained, a more detailed study on this subject is required.

## Experimental

**Catalyst Preparation and Activity Measurement.**—Catalysts with different chromium/zinc atomic ratios were prepared from commercial zinc oxide powder and chromic acid in the following way. A slurry of the zinc oxide powder in aqueous chromic acid was spread over a glass plate and evaporated to dryness in the air at room temperature. The resulting cake was then ground to a 100-mesh powder, and the powder was pelleted (4 mm. in diameter by 4 mm. high). The chromium/zinc atomic ratios in the catalysts thus prepared were 0.1, 0.5, and 1.0. Also, a catalyst not containing chromic acid was prepared by pelleting the zinc oxide powder to the same size.

Every kind of catalyst was treated as follows. A lot of the catalyst was divided into two parts. One part was reduced in a vessel different from the methanol synthesis reactor[7] and then immediately tested in the reactor for catalytic activity. The other part was first heated in the air at 400°C for 5 hr., and then reduced in the methanol synthesis reactor and tested for catalytic activity in situ. In this paper, the former class of catalysts will be denoted by the symbol "A," and the latter class, by the symbol "B." Also, if necessary, the numerals, 1, 2, 3, and 4, will be attached to the above symbols to indicate the chromium/zinc ratios of 0, 0.1, 0.5, and 1.0 respectively. Thus we will have A-1, A-2, etc.

In all cases, the reduction was carried out in a current of $2H_2$-1CO synthesis gas under atmospheric pressure; in the earlier stages of reduction, the temperature was gradually raised to 350°C over a 1.5 hr., period so that the glow phenomenon due to the rapid reduction of sexivalent chromium might be prevented in the catalyst bed. This final temperature was maintained for 4 hr.

The activity for methanol synthesis was measured by the use of the same apparatus as has been described previously.[8] Five milliliters of a catalyst sample (1—2 mm.) was placed to the reactor in order to fill the annular space between the walls of the reactor and the centrally-placed stainless-steel thermocouple protection tube (4 mm. in OD and 2 mm. in ID). The catalyst bed formed was 18 mm. in OD, 4 mm. in ID, and 22 mm. high. The longitudinal temperature difference throughout the whole catalyst bed remained within 2°C when the activity measurements were made with a $2H_2$-1CO synthesis gas containing 4% nitrogen under the following conditions; pressure=150 kg./cm$^2$, space velocity based on the feed rate (vol./hr. at S. T. P.) of synthesis gas=$1\times10^4\pm50$ hr$^{-1}$, and temperature range=300—390°C.

In the experiments with the catalyst samples A-3 and B-3, the samples, once they had been used in the methanol synthesis, were heated in a hydrogen stream at 500°C for 8 hr.; then activity measurements were again made on these hydrogen-treated samples (designated as A'-3 and B'-3).

**The Investigation of Catalyst Structures.**—The specific surface area, $S$, was determined by applying the BET equation to the argon adsorption isotherm at −196°C. The density, $\rho_t$, was measured by the helium displacement method. From the values of $S$ and $\rho_t$, the average particle diameter, $\bar{d}$, was calculated according to the formula $\bar{d}=6/\rho_t S$, on the basis of the assumption that the particles have the form of a sphere or cube. Moreover, the particle size and shape in catalyst granules were examined under an electron microscope of the JEM-6 type. The samples for the electron microscopic observation were prepared by grinding the catalyst with castor oil in a mortar.

The X-ray diffraction patterns for powdered samples of the catalysts were obtained with an

Table I. Samples used for the investigation of catalyst structures

| Sample | Cr/Zn atomic ratio | Remarks |
|---|---|---|
| $A_0$-1 | 0 | Catalysts as prepared from slurries. (These are the original samples for the preparation of the othe series of samples listed in this table.) |
| $A_0$-2 | 0.1 | |
| $A_0$-3 | 0.5 | |
| $A_0$-4 | 1.0 | |
| $A_1$-1 | 0 | Reduced in $2H_2$-1CO gas stream under atmospheric pressure at temperatures below 350°C after the preparation from slurries. |
| $A_1$-2 | 0.1 | |
| $A_1$-3 | 0.5 | |
| $A_1$-4 | 1.0 | |
| $A_2$-1 | 0 | Reduced under the afore-mentioned conditions after the preparation from slurries and subsequently used for methanol synthesis. |
| $A_2$-2 | 0.1 | |
| $A_2$-3 | 0.5 | |
| $A_2$-4 | 1.1 | |
| $B_0$-1 | 0 | Heated in air at 400°C for 5 hr. after the preparation from slurries. |
| $B_0$-2 | 0.1 | |
| $B_0$-3 | 0.5 | |
| $B_0$-4 | 1.0 | |
| $B_1$-1 | 0 | Treated in the same manner as samples $B_0$ after the preparation from slurries and then used for methanol synthesis. |
| $B_1$-2 | 0.1 | |
| $B_1$-3 | 0.5 | |
| $B_1$-4 | 1.0 | |
| A'$_2$-3 | 0.5 | Obtained by heating samples $A_2$-3 and $B_1$-3 in hydrogen stream at 500°C for 8 hr. |
| B'$_1$-3 | 0.5 | |

7) If reduced in the reactor, the catalyst bed shrinks with the progress of reduction and, consequently cannot be tested for catalytic activity in situ.

8) M. Oba, Y. Ogino and H. Uchida, *Rpt. Gov't, Chem. Ind. Research Inst., Tokyo*, **60**, 121 (1965).

X-ray diffractometer of the Geigerflex D-3F type. The nickel-filtered Cu$K\alpha$ radiation from a sealed-off X-ray tube equipped with beryllium windows and operated at 40 kV. and 18 mamp. was used.

The above measurements and observations were conducted on catalyst samples taken at various stages of catalyst treatment. These samples are listed in Table I. In the nomenclature used here, subscript numbers are attached to the catalyst class symbols A and B in order to indicate the different treatments to which the catalysts, A and B, were subjected. Thus the symbols $A_1$ and $B_{1,}$, for example, stand for those samples of a catalyst of Class A or B which were subjected to a specified treatment.

## Results

**Activity for Methanol Synthesis.**—The methanol concentration in the exit gas is plotted against the reaction temperature in Fig. 1 for the synthesis runs conducted with the catalysts of two series, A and B.[9] Also, for the purpose of a quantitative comparison of activities, the values of the rate constant of methanol synthesis at 330°C, $k_{330}$, taken as a measure of the activity are listed in Table II. The $k_{330}$ values for synthesis with the catalysts A'-3 and B'-3 are also included in this table. The $k_{330}$ values were calculated according to Eq. 1, which was in turn derived from Rate Eq. 2.[10]

$$k=\frac{SV}{273\boldsymbol{R}}\times \int_0^z \frac{\left[\nu_{CO}\nu_{H_2}{}^2 4P^3\{1+(1-n)z\}\left(\frac{n}{2}-z\right)\right]^{0.3}}{(1+2z)^2\left[\nu_{CO}\nu_{H_2}{}^2\frac{4P^3\{1+(1-n)z\}}{(1+n)^3}-\frac{\nu_{CH_3OH}Pz}{K}\right]} \quad (1)$$

$$r=k\{(f_{CO}f_{H_2}{}^2)^{0.7}-f_{CH_3OH}(f_{CO}f_{H_2}{}^2)^{-0.3}/K\} \quad (2)$$

In these equations, $SV$ ($hr^{-1}$) is the space velocity based on the feed rate of the synthesis gas; $\boldsymbol{R}$, the gas constant; $\nu_i$, the fugacity coefficient of the $i$th component; $P$ (atm.), the total pressure of the $H_2$-CO gas; $n$ the $H_2$/CO mol. ratio; $z$, the mole fraction of methanol in the exit gas; $r$ (mol./hr.), the rate of methanol formation; $f_i$ (atm.), the fugacity of the $i$th component, and $K$, the equilibrium constant of reaction. Both Fig. 1 and Table II show that the optimum chromium/zinc atomic ratio is 0.5 for each series of catalysts, and that all the catalysts of series A have higher activities than the corresponding catalysts of series B.

A comparison of the activity difference between catalysts A-3 and A'-3 with the difference between the catalysts B-3 and B'-3 (Fig. 2 and Table II) may give an approximate concept of the relative thermal stability of the two series, A and B. The stronger thermal stability of the catalysts of series A may be seen from the data.[11]

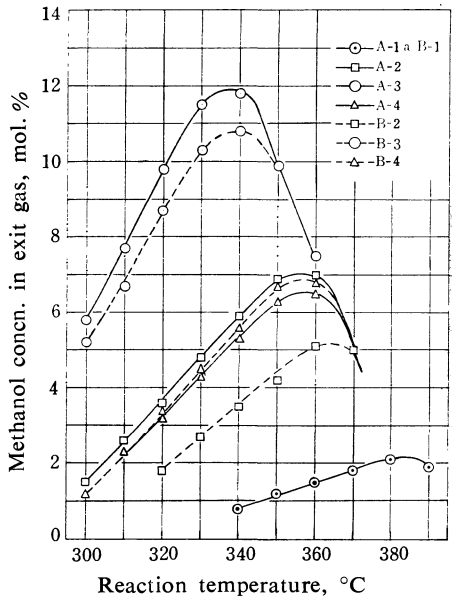

Fig. 1. Catalyst activity for methanol synthesis.

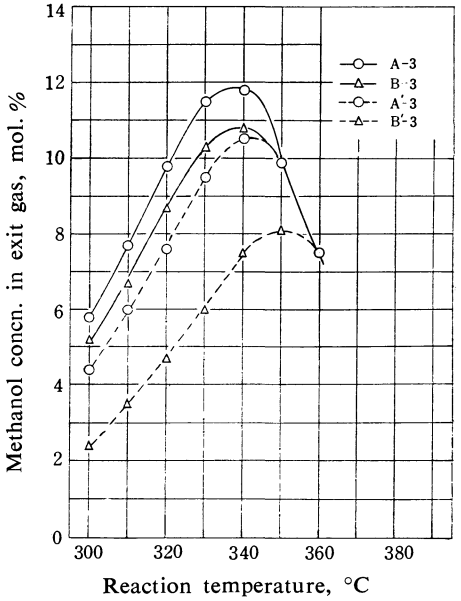

Fig. 2. Catalyst activity for methanol synthesis.

9) According to the nomenclature in Table I, these catalysts should be denoted by the symbols $A_1$ and $B_0$. However, for the sake of simplicitys, the symbols with the subscript numbers will not be used unless necessary.

10) H. Uchida and Y. Ogino, This Bulletin, 31, 45 (1958).

11) When catalysts A-3 and B-3 were heated in hydrogen for only 2 hr., their activities decreased to the same extent as when the catalysts were heated in the same medium for 8 hr.

TABLE II. RATE CONSTANT OF METHANOL SYNTHESIS AT 330°C ($k_{330}$), SPECIFIC RATE CONSTANT ($k'_{330}$), ACTIVATION ENERGY ($E$), AND FREQUENCY FACTOR PER UNIT SURFACE AREA ($A'$)

| Catalyst | $k_{330}$ $atm^{-2.1}hr^{-1}$ | $k'_{330}$ $atm^{-2.1}ml.hr^{-1}m^{-2}$ | $E$ kcal./mol. | $A'$ $atm^{-2.1}ml.hr^{-1}m^{-2}$ |
|---|---|---|---|---|
| A-1 | $0.50\times10^{-2}$ | $1.65\times10^{-4}$ | 33 | $1.44\times10^{8}$ |

b) The symbols Z and S stand for zinc oxide and zinc chromite while I$\beta$ and III$\beta$ for zinc hydroxychromates I$\beta$ and III$\beta$ respectively.

The liquid product of methanol synthesis, in general, contains small amounts of such by-products as dimethyl ether, methylformate, water, formaldehyde, and isobutanol. Therefore, the liquid products obtained in the synthesis runs conducted at 380°C with different catalysts were analyzed for such by-products.[12] The results show that the proportion of water in the liquid product obtained with a catalyst of a lower activity is greater than in the product obtained with a catalyst of a higher activity (e.g., 5% water in the case of the catalyst A-3 and 1.1% in the case of the catalyst A-1), whereas the proportions of the other by-products are nearly in dependent of catalyst species or of chromium content (0.7—1.5% dimethyl ether, 0.5—0.6% methylformate, and 0.1% formaldehyde).[13]

**Surface Area and Average Particle Diameter.** —The results of the surface-area determination are summarized in Table III. The surface areas of three original catalysts containing chromium, $A_0$-2, $A_0$-3, and $A_0$-4, are very small, even

12) The by-products were determined gas chromatographically except for formaldehyde, which was determined iodometrically.

13) The percentages are based on the weight of the liquid product. In no cases was isobutanol detectable.

smaller than the surface area of the original zinc oxide catalyst, $A_0$-1. If these chromium-containing catalysts are reduced in the synthesis gas, the reduced catalysts ($A_1$-2, $A_1$-3, and $A_1$-4) show quite large surface areas, 30—50 times as large as the surface areas before reduction. However, when these reduced catalysts are used for methanol synthesis, the surface area decreases more or less according to the chromium content; the smaller the chromium content, the smaller the surface area. (Compare the surface areas of the samples $A_1$ with those of the samples $A_2$.) On the other hand, if the original catalysts are heated in the air at 400°C, the surface area of the chromium-containing catalysts is slightly increased (see the data for the samples $B_0$), while when these heat-treated catalysts are used for methanol synthesis, the surface areas of such samples ($B_1$) are greater than those of the samples $A_2$. It is worth noting here that the surface area is nearly the same for all the samples $B_1$, being independent of the chromium content. On the other hand, when two catalyst samples once used for methanol synthesis, $A_2$-3 $B_1$-3, are heated in hydrogen at 500°C for 8 hr., the surface areas are markedly decreased, the extent of decrease being greater in the case of the sample $B_1$-3 (see the data for $A_2'$-3 and $B_1'$-3).[14]

The density, $\rho_t$, is the highest for the catalyst samples with no chromium; it tends to decrease with an increase in the chromium content.

The values of the average particle diameter are also listed in Table III. Particles in the chromium-containing original catalysts ($A_0$) are quite large, much larger than the particles in the original zinc oxide catalyst. However, when these catalysts are reduced in the synthesis gas, the particles are split into very fine particles.

**X-Ray Diffraction.**—The results obtained are summarized in Table III. In the case of the chromium-containing catalysts $A_0$, if the chromium/zinc ratio is smaller than the ratio for zinc hydroxychromate I$\beta$ ($ZnCrO \cdot Zn(OH)_2$, $Cr/Zn=0.5$), all the chromic acid added will react with zinc oxide to form zinc hydroxychromates. In fact, the X-ray diffraction pattern of the sample $A_0$-2 shows the presence of hydroxychromate III$\beta$ ($ZnCrO_4 \cdot 3\text{-}4Zn(OH)_2$), together with zinc oxide, whereas the diffraction pattern of the sample $A_0$-3 shows the presence of hydroxychromate I$\beta$ alone. If the proportion of chromic acid is further increased, there appears another diffraction pattern which has not yet been identified. Kawamura et al.,[3] however, attributed this diffraction pattern to a bichromate.

When the chromium-containing original catalysts ($A_0$) are reduced in the synthesis gas or are used for methanol synthesis, the resultant catalysts give diffraction diagrams quite different from those for the original catalysts. In such diagrams, no crystalline phase other than those of zinc oxide and zinc chromite is observed. This indicates that hydroxychromates has undergone decomposition in the synthesis gas. The decomposition of hydroxychromates is also caused by the heat treatment of the same original catalysts in the air at 400°C, as is evidenced by the diffraction data obtained with the $B_0$ catalysts. However, the results of the differential thermal analysis and the thermogravimetric analysis of the sample $A_0$-3 (Fig. 3)[15] show that the decomposition occurring

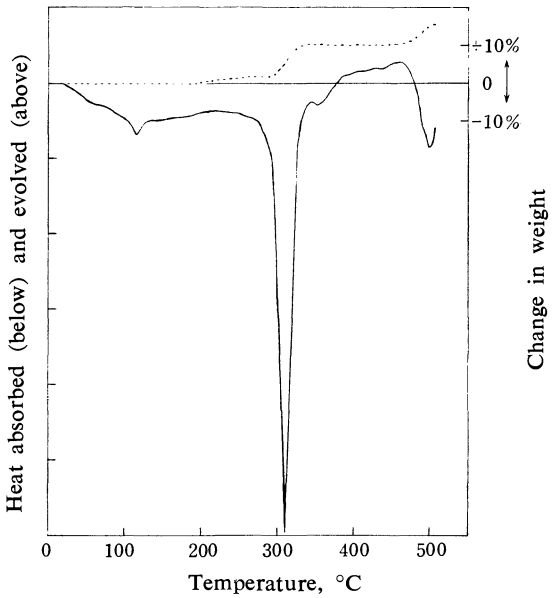

Fig. 3. Differential thermal analysis curve and thermogravimetric analysis curve.
—— D. T. A. ---- T. G. A.

in the air is different in type from the decomposition in the synthesis gas. The former type of decomposition is endothermic and takes place at ca. 310°C, whereas the latter type is exothermic and, according to Kawamura and Irie,[5] begins to take place at a much lower temperature, i. e., 200°C. The endothermic peak observed is due to the conversion of sexivalent chromium oxide by oxygen removal into the

14) When the catalysts A-3 and B-3 were heated in hydrogen for only 2 hr., the surface areas decreased to the same extent as when the catalysts were heated in the same medium for 8 hr.

15) Similar results, though not the same as those reported here, were presented by Kawamura et al.[3] for a variety of zinc oxide-chromium oxide catalysts, but their results for a catalyst similar to the present one are not identical with ours.

trivalent oxide, which combines with zinc oxide to form zinc chromite.

Besides the diffraction patterns due to zinc oxide and zinc chromite, the diffraction diagram of the sample $B_0$-4 shows complicated patterns, which, though not identified, give evidence for the formation of intermediates in the decomposition process.

On the basis of diffraction lines due to the (110) plane of zinc oxide and the (400) plane of zinc chromite, the lattice constants for the two components have been calculated; they are listed in Table III. The lattice constants calculated for the zinc oxide in the catalyst samples vary little among the samples and agree with the literature value (a=3.249 Å).[16] whereas the lattice constants found for the zinc chromite[17] in the catalyst samples are, in general, greater than the literature values[18] ($a$=8.32, 8.20 Å).[16] According to Irie and Shiraishi,[6] the zinc chromite produced by the reduction of the hydroxychromates at low temperatures occludes zinc oxide, and its lattice is enlarged to form a stressed structure. By taking their view into consideration, the present observation may be interpreted as follows: Where there is a non-stoichiometric structure of zinc chromite, $Zn^{2+}$ will enter the structure to occupy the empty interstices; as a result, the lattice will be enlarged, with stresses set up on it. The zinc chromite retains the enlarged lattice even when heated for a prolonged time in hydrogen at 500°C.

**Electron Microscopic Picture.**—Upon the addition of aqueous chromic acid to zinc oxide powder (Micrograph 1), the reaction between the two reagents takes place around the periphery of the powders. This fact can be seen, though not directly, from Micrograph 5 with reference to a low-chromium sample once used for the synthesis (the sample $A_2$-2). As the amount of chromic acid is increased, the reaction extends into the interior of the powders, producing large crystals of zinc hydroxychromate I$\beta$ (see Micrograph 2 for the sample $A_0$-3). According to Feitknecht and Hugi-Carmes,[19] the crystal of this hydroxychromate grows to a thin hexagonal plate of large dimensions. The present observation is in agreement with their statement in that the crystal grows in the form of a layer-structure; the only difference is that the crystal is a thin plate of an irregular shape. The crystals here observed may be the fragments into which the original hexagonal plate has been broken as a result of grinding the catalyst in the preparation of samples for electron microscopic observation. On the other hand, the electron microscopic picture of a reduced catalyst (the sample $A_1$-3) is entirely different from that of the original (the sample $A_0$-3). Micrograph 3 for the sample $A_1$-3 shows a number of caterpillar-like particles within the original fringe of the hydroxychromate crystal, particles which are as fine as about 50 Å wide. Seemingly, the particle is an aggregate of a few crystallites of a spheroid structure (ca. 50 Å in diameter). When the reduced catalyst is used for methanol synthesis, the particles become greater and more gaps are formed between them, with no substantial change in the pattern visible in the original fringe of the crystal. (Compare Micograph 4 for the sample $A_2$-3 with Micrograph 3.) This phenomenon may be simply due to the progress of sintering during the synthesis run. It should here be noted that these electron microscopic pictures are quite different from that of the catalyst prepared from a mixed solution of the nitrates and ammonia (see Refs. 8 and 20).

In spite of the fact that zinc hydroxychromate undergoes thermal decomposition in the heat treatment of catalysts in the air at 310°C,

17) Irie and Shiraishi[6] designated this structure as R and distinguished it from zinc chromite.

18) A sample with a chromium/zinc ratio of 1.98 was found to give the value of 8.331 Å after it was reduced and then heat-treated in the air at 800°C for 40 hr.

19) W. Feitknecht and L. Hugi-Carmes, *Helv. Chim. Acta*, 37, 2093 (1953).

the electron microscopic picture of a heat-treated catalyst (the sample $B_0$-3) is not essentially different from the original catalyst (the sample $A_0$-3). The only differences are that the crystal fragments are smaller and that massive fragments of an irregular shape are more abundant in the case of the sample $B_0$-3 than in the case of the sample $A_0$-3.

In contrast to the structural difference observed between the samples $A_0$-3 and $A_1$-3, no remarkable difference is found between the electron microscopic pictures of the samples $B_0$-3 and $B_1$-3 (i.e., the sample once used for methanol synthesis after heat treatment in the air). In the sample $B_1$-3, such a pattern as is observed in the micrograph for the sample $A_2$-3 appears only within a very small portion of the original fringe of the thin plate-like crystal; the major part remains so homogeneous that the individual particles, if present, are indistinguishable. This is also the case with the two samples of a high chromium content, $B_0$-4 and $B_1$-4 (see Micrograph 9).

When two samples once used for methanol synthesis, $A_2$-3 and $B_1$-3, are heated in hydrogen at 500°C, a marked crystal growth occurs, leading to the production of large crystals (compare Micrograph 10 with Micrograph 4), the growth being more pronounced in the sample $B_1$-3.[20]

**The Composition of Individual Particles.**—It yet remained unclarified whether the catalyst particles in a sample once used for methanol synthesis consist of the single component, zinc oxide or zinc chromite, or whether each particle is a composite substance made up of the two. For the study of this problem, two samples containing a large excess of zinc oxide, $A_2$-3 and $B_1$-3, in which the $ZnO/ZnCr_2O_4$ mol. ratio was 3, were treated with an aqueous ammonium acetate solution for half an hour at room temperature and the free zinc oxide removed;[22] the residues were then examined under an electron microscope.

The residue from the sample $A_2$-3 was found to have a chromium/zinc ratio of 1.79, which is approximately the ratio for zinc chromite. Its electron microscopic picture does not differ essentially from that of the initial sample (compare Micrograph 11 with Micrograph 4), although the caterpillar-like particles in the residue are thinner than in the initial sample and more white areas are observed. Therefore, it follows that most of the particles are aggregates of zinc oxide and zinc chromite crystallites, whereas the others consist of zinc oxide

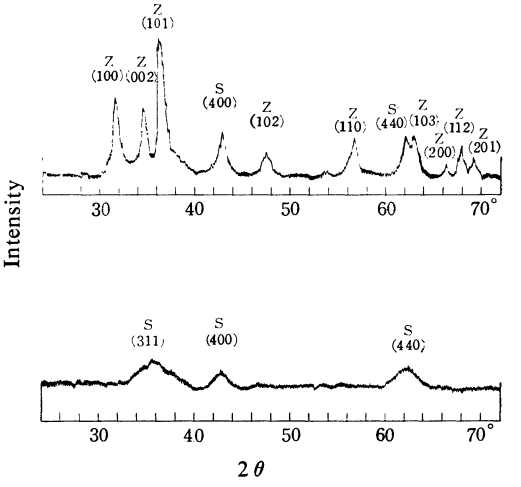

Fig. 5. X-Ray diffraction diagrams.
Above, sample $A_3$-3. Below, residue from sample $A_3$-3 after removal of zinc oxide.

alone or mainly of zinc oxide. This inference is also supported by a comparison of the X-ray diffraction diagram of the residue with that of the initial sample (Fig. 5). The X-ray diffraction diagram shows the presence of zinc chromite alone, and the diffraction lines due to zinc chromite are greatly broadened. The line-broadening effect is probably due to the stress imposed on the chromite lattice as a result of the removal of the zinc oxide initially present in the zinc chromite in excess of its stoichiometric proportion.

The electron microscopic picture of the residue from the sample $B_1$-3 (Micrograph 12) is somewhat different from that of the initial sample (Micrograph 8). Within the original fringe of the crystal there appear wide openings, in which presumably zinc oxide particles have predominated. Accordingly, either zinc oxide crystallites or zinc chromite crystallites are more or less concentrated locally within the fringe, and the mutual penetration of the two components seems to have been achieved not as thoroughly as in the case of the sample $A_2$-3.

## Discussion

**The Size and Shape of Particles.**—In general, the average particle diameter, $\bar{d}$, as calculated by use of the formula $\bar{d}=6/\rho_t S$, greatly differs from the size as estimated by electron microscopic observations. The shape one can imagine from the $\bar{d}$ for the particles in the sample $A_0$-3 is a sphere or cube about 4000 Å in diameter or in linear dimension. Similarly, the particle in the $A_2$-3 is considered to be a sphere or cube of the 160 Å size. However, electron

20) J. E. Germain and L. Ponsole, *Bull. soc. chim. France*, 1961, 1572.
21) Other electron micrographs will be presented elsewhere.
22) G. H. Osborn, *Analyst*, **76**, 114 (1951).

micrographs show a thin plate-like particle of several thousands Å size for the former sample, and a caterpillar-like particle about 50 Å in width for the latter. Such a discrepancy is also found in the case of the sample $A_2$-4. Particularly in the case of the sample $B_1$-3, the particle shape imaginable from the $\bar{d}$ differs markedly from the shape observed under the electron microscope. The $\bar{d}$ for the particles in this sample is calculated to be 70 Å. This size would be sufficiently large for the individual particles to be distinguished from one another in the electron micrograph if they could be assumed to be, for instance, spherical. However, most of the particles seen in the electron micrograph are relatively large and thin plates of a homogeneous structure.

These seemingly contradictory results may be interpreted as follows. In the sample $A_0$-3, thin plates of large dimensions are piled up, with no gaps between them, to form particles as thick as several thousand Å. These particles are more or less similar in shape to the one assumed in the calculation of $\bar{d}$; however, under the influence of the grinding action in the preparation of samples for electron microscopic observations, they collapse to yield thin plate-like particles. On the other hand, in the sample $A_2$-3, the particles are in the form of caterpillars and apparently different in shape from the one assumed in the calculation of $\bar{d}$; in the sample $A_2$-4, particles are of two different types, caterpillar-like particles and particles of irregular shape, whereas the particle shape assumed in the calculation is of a single type, a sphere or a cube. These considerations will account for the discrepancies noted above. However, it is not possible to give a satisfactory interpretation of the results for the sample $B_1$-3. At any rate, the $\bar{d}$ value is of minor significance for us in drawing the picture of individual particles.

The sum of the surface areas of all the particles in one gram of a catalyst, when calculated from their linear dimensions as estimated from the electron micrograph, can be considerably greater than the specific surface area of the same catalyst as measured by the BET method. In this respect, Nielsen[23] points out that the interfacial layers are apt to coalesce with the particles to a coherent surface, and that only where the distance between two particles, or the orientation, is too divergent does the interfacial layer split up in two surface areas. This coherent surface should be taken into consideration in attempting to understand the $k$ in terms of the specific activity and the specific surface area, because this is the surface where the reactants in the methanol synthesis reach.

**Specific Activity.**—The specific activity based on unit accessible surface area at a given reaction temperature, $k'$, is calculated by the following formula:

$$k' = k/\rho_b S \qquad (3)$$

where $\rho_b$ is the catalyst bed density (the values are listed in Table III). The $k'$ depends on the chromium/zinc ratio in nearly the same manner as the $k$ does.[24] From the Arrhenius plot of $k'$, the activation energy, $E$, and the frequency factor per unit surface area, $A'$, are calculated for each catalyst. The calculated values of $k'$ at 330°C ($k'_{330}$), $E$, and $A'$ are given in Table II.

In the case of the catalysts A, both the high $k'$ value and the moderately large $S$ value are responsible for the high $k$ value. On the other hand, in the case of the catalysts B, $k'$ is the sole factor affecting the $k$ value, because the surface area, $S$, in this particular case is almost the same for all the catalysts.

A comparison of the data for $k'$ values of the two series of catalysts show that the heat treatment of chromium-containing catalysts (the original catalysts, designated as $A_0$ in Tables I and III) in the air at 400°C results in a considerable decrease in $k'$. However, the heat-treated catalysts, after having been used for methanol synthesis, have a much greater surface area than the corresponding catalysts used for the synthesis without previous heat treatment in the air (see the data for $S$ of the samples $B_1$ and $A_2$ in Table III). Therefore, the decrease in $k'$ due to heat treatment is the main reason why the catalysts B have lower activities ($k$) than the catalysts A.

**Structural Factors Affecting the Specific Activity.**—The catalysts A have higher specific activtiies ($k'$) than the corresponding catalysts B. Moreover, the two series of catalysts are quite different in their electron microscopic pictures. The structural difference between the two series of catalysts may stem from the difference in the way of the decomposition of zinc hydroxychromate into zinc oxide and zinc chromite. The decomposition of, or the removal of excess oxygen from, the hydroxychromate proceeds more slowly but to a greater extent in the heat treatment of catalysts in the synthesis gas than in the treatment in the air.

23) A. Nielsen, "An Investigation on Promoted Iron Catalysts for the Synthesis of Ammonia," Jul. Gjellerups Forlag. Copenhagen (1956), p. 167.

24) The correlation between $k'$ and the chromium/zinc ratio in the range of high chromium/zinc ratios is different from that described in the previous paper.[25] This is mainly due to the different values of $S$ for the catalyst samples with a chromium/zinc ratio of 1.

25) Y. Ogino, M. Oba and H. Uchida, This Bulletin, 32, 284 (1954).

According to Irie and Shiraishi,[6] the decomposition of the hydroxychromate in the synthesis gas begins to take place at a temperature as low as 200°C, and the rate of decomposition gradually increases as the temperature is raised. The excess oxygen, in this case, is removed exothermically as carbon dioxide. Therefore, it is here considered that, in the earlier stages of the heat treatment of catalysts in the synthesis gas (i. e., treatment at low temperatures), a number of fine crystallites of zinc oxide and zinc chromite appear in the layer-structure of hydroxychromate and that, in the latter stages (i. e., treatment at higher temperatures), these crystallites will serve as nuclei for the formation of large particles by the aggregation of newly-born crystallites. In these particles, the mutual penetration of zinc oxide and zinc chromite is likely to be achieved as thoroughly as possible.

On the other hand, in the treatment of catalysts in the air, the decomposition of the hydroxychromate, as is exemplified in Fig. 3 for the catalyst A-3, occurs suddenly at a higher temperature, i. e., at 310°C. In this case, the whole layer-structure of hydroxychromate will be decomposed instantaneously into a great number of very fine crystallites of zinc oxide and zinc chromite, the crystallites being scattered within the initial fringe of the layer-structure; the removal of excess oxygen will remain rather incomplete. Accordingly, once this structure appears in the heat treatment of a catalyst in the air, the complete transformation of this structure into one capable of forming large particles in the heat treatment in the synthesis gas may be difficult, even though the catalyst is subsequently heated in the synthesis gas at temperatures not much higher.

The lattice constant of zinc chromite in catalysts is, in general, considerably greater than the normal value,[26] it varies a little among the catalysts studied. However, the specific activities of the chromium-containing catalysts of Series A greatly differ, from the specific activities of the corresponding catalysts of Series B. Hence, the specific activity can, by no means, be correlated with the lattice constant. The difference in specific activity is considered attributable to the difference in the degree of the mutual penetration of zinc oxide and zinc chromite rather than to the difference in the lattice constants.

This consideration is not contradictory to the observation that the specific activity of the catalyst B'-3 can be increased to the level of specific activity for the catalyst A-3 by heat treatment in hydrogen at 500°C, because the heat treatment favors the progress of the mutual penetration of zinc oxide and zinc chromite.

26) Irie and Shiraishi[6] state that the zinc chromite of the normal lattice constant shows scarcely any activity for methanol synthesis.

## Summary

The activity for methanol synthesis has been determined for two series of catalysts prepared from zinc oxide and chromic acid with and without subsequent heat treatment in the air. Also, the correlations between catalytic activity and other catalyst properties have been studied. Each catalyst series has consisted of four catalysts, three of them prepared from slurries of zinc oxide powder in aqueous chromic acid, and the other prepared directly from zinc oxide powder. The chromium/zinc ratios in the catalysts made from the slurries are 0.1, 0.5, and 1.0. The catalysts of one series have been heated in the air at 400°C after their preparation (the "heated series").

In both series, the activity and the specific activity have been found to be influenced by the chromium/zinc ratio. The catalysts not heated in the air after their preparation (the "unheated series") show higher activities than the corresponding catalysts of the heated series, though the former catalysts have much smaller surface areas.

The results of electron microscopic examination show that the two series of catalysts, after having been used for methanol synthesis, are structually different. The structural difference has been ascribed to the difference in the way of the decomposition of the layer-structure of zinc hydroxychromate. In the case of the unheated series, the layer-structure is decomposed into crystallites of zinc oxide and zinc chromite by reduction in the synthesis gas, whereas in the case of the heated series the layer-structure is decomposed by heat treatment in the air.

X-Ray diffraction data show that, in all cases, the lattice constant for the zinc oxide in catalysts is normal, whereas the lattice constant for the zinc chromite is larger than the normal value.

The average particle diameter as calculated from the surface area and density of catalysts does not agree with the size as estimated by electron microscopic observations.

The difference in specific activity between the two series may be due to the difference in the degree of the mutual penetration of zinc oxide and zinc chromite crystallites rather than to the variation in the zinc chromite lattice constant.

In addition, the effects upon the activity and

upon the catalyst structure of catalyst treatment in hydrogen at 500°C after methanol synthesis have been discussed.

# The Effect of Temperature on Electrodialytic Demineralization

By Susan A. WEINER

(Received May 25, 1965)

Saline water conversion, a relatively new field, has shown considerable progress in the past ten years although the conversion of sea water by simply boiling it and collecting the vapors was practiced over two centuries ago. Among the various desalination techniques, distillation is still the most feasible one for highly saline waters. For the conversion of slightly brackish waters, however, electrodialysis is considered to be one of the most promising methods.

**Electrodialysis.**—In this process demineralization is achieved with the aid of electrical energy. Salt ions, confined into compartments bounded by ion-selective polymer membranes, move towards the oppositely charged electrodes from compartments 1, 3, 5, ···, etc. (see Fig. 1). Ions from compartments 2, 4, 6, ···, etc. cannot pass through the membranes because of the repulsion between the like charges on the ions and membranes. As a result, demineralization of the feed solution occurs in the odd numbered cells while the even numbered ones increase in concentration.

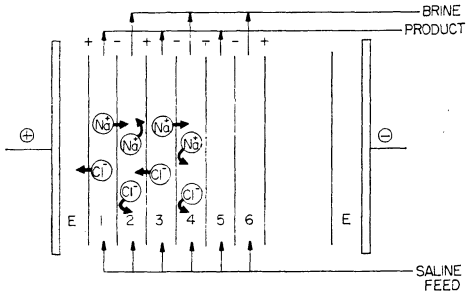

Fig. 1. Schematic of a multicompartment electrodialysis stack.

One of the major factors which limits the practical and economical application of electrodialysis is polarization. This phenomenon arises when a certain limiting current density is exceeded.[1] Under severe polarization conditions the current is used partly to transport salt ions, partly to transport $H^+$ and $OH^-$ ions. This not only results in decreased coulomb efficiency, but can give rise to harmful scale formation.

Polarization is a function of several variables: throughput velocity, stack geometry, feed concentration, temperature and others. This paper describes the changes observed when the feed solution temperature was varied from 5°C to 35.5°C and 40°C.

**Prior Work.** — Several variables influencing polarization characteristics were investigated at our Laboratory[2,3] using a modified Aquafresh stack (manufactured by the American Machine and Foundry Company). It was found that under 4 cm./sec. velocity a straight line correlation existed between the polarization parameter $J_{lim}/N_{do}$, (mamp./cm²)/(eq./l.) and the throughput velocity, but over 4 cm./sec. no such correlation could be established. In this region the limiting current density was found to be a function of the product normality and could be expressed as

$$J_{lim}=6400\ (N_{do})^{1.65}$$ for countercurrent NaCl solutions

$$J_{lim}=3000\ (N_{do})^{1.55}$$ for countercurrent San Francisco Bay water

where $J_{lim}$ = limiting current density (mamp./cm²) and $N_{do}$ = dialyzate stream concentration at the stack outlet (eq./l.) Feed solution temperatures in these experiments were all around 20°C.

## Experimental Procedure

The modified Aquafresh stack was used with 8 cell pairs in series. To obtain higher temperatures

the brine and dialyzate feed tanks were equipped with immersion heaters; Fenwal thermoswitches served as regulators. Constant air agitation was used to insure uniform temperature throughout the five-gallon capacity containers. The dialyzate stream flow was approximately constant in all runs at around 6.5 cm./sec. Feed concentrations were varied from 0.0148 to 0.246 N.

A very simple but effective arrangement was used to obtain the desired low temperature. Water was placed in a three-gallon plastic pail which was embedded in a salted, crushed-ice bed. Circulation of the cooling water was achieved by a small Eastern pump. Four coils, constructed from 3/8" copper tubing, were immersed in each feed tank, connections were made from flexible plastic tubing. The recirculation created enough turbulence in the bucket to prevent ice formation next to the walls. Crushed ice was also added to the water directly. Temperatures as low as 3.5°C could easily be maintained with very little deviation. Our experiments were conducted around 5.3°C; the concentration of the feed solutions ranged from 0.0168 N to 0.245 N. For the complete set of experimental data see table below.

## Discussion and Results

The role of temperature in electrodialytic demineralization cannot be dismissed by simply stating that the total resistance of the system changes about 2% per °C. True, one of the advantages of operating at elevated temperatures is the reduced resistance, or in other words the decreased power consumption, but there is another very important factor to be considered. This is the variation of the limiting current density with temperature. Our experiments revealed that the limiting current density is increased at elevated temperatures. The straight line relationship between current density and product normality could be expressed as

$$J_{lim}=5500(N_{do})^{1.53} \text{ at } 40°C$$

$$J_{lim}=4600(N_{do})^{1.53} \text{ at } 35.5°C$$

and is plotted on Fig. 2. Should one operate at elevated temperatures, the current density could be increased (required membrane area decreased) or keeping the area constant a greater degree of demineralization could be achieved. The estimated 20—30% power reduction is another favorable feature. Experiments with a pilot-plant size stack, that was constructed at the University of California, yielded similar results.

In many parts of this country and abroad, well waters have considerably lower temperatures than 18—20°C. A good example is Webster, South Dakota, where the Office of Saline Water electrodialysis demonstration plant has to cope with a 9°C feed water. It was of interest, therefore, to examine the effect of low temperatures on the electrodialytic desalination process. Our experiments yielded the following observations: (a) while the limiting current density was found to be a function of product normality over 4 cm./sec. at feed temperatures of 15°C and over, no such correlation could be established for runs at approximately 5°C (Fig. 2); (b) with feeds more concentrated than 0.05 N (3000 p.p.m. sodium chloride) very strong back pressure in the electrode compartments was noticeable (in

the run with $N_0 = 0.245$ N this was so pronounced that the electrode rinse flow was completely stopped); (c) polarization occurred at decreased current densities; (d) by comparing power consumptions at 40°C and 5°C (Fig. 3) it can be seen that while there is no significant increase for feeds of 1000 p.p.m., the increase is considerable at $N_0 > 2000$ p.p.m.

## Conclusions

Our experiments quantitatively demonstrated that electrodialytic demineralization at elevated temperatures has two attractive features: higher limiting current density and lower power consumption. These savings cannot, however, be achieved without the installation (and maintenance) of expensive heat exchange equipment. The question arises: would the additional cost in equipment be counterbalanced by the gains resulting from elevated temperature operation. Only an extensive economic analysis could give a definite answer to this important question.

## Summary

The process of electrodialysis, as a means of demineralizing brackish water, is briefly described. Polarization, a limiting factor in the practical application of the process, is a function of several variables, one of which is temperature. In this study the temperature dependence of limiting current density and power consumption was examined. Experiments conducted at elevated temperatures (35.5°C and 40°C) showed that the limiting current densities are increased and the power consumption is decreased. At low temperatures (5°C) marked decrease in limiting current density was observed. Comparison of power consumption data at 40°C and 5°C show that significant differences occur with feeds more concentrated than 2000 p.p.m.

NOTES

# The Determination of Formaldehyde by Means of 3-Methyl-2-benzothiazolone Hydrazone. A New Procedure, Involving Extraction

By Eijiro KAMATA

(Received January 16, 1965)

A new solvent extraction procedure for the determination of formaldehyde with 3-methyl-2-benzothiazolone hydrazone (MBTH)[1] will be described. This procedure is particularly advantageous in the determination of a minute amount of the aldehyde in colored and/or turbid sample solutions.

## Experimental

**Reagents.**—*A Standard Solution of Formaldehyde.*—The stock solution of formaldehyde is standardized by the dimedon method.[2] The aliquot portion of the stock solution is then diluted in order to prepare the standard solution (1 $\mu$g./ml.).

*3-Methyl-2-benzothiazolone Hydrazone Hydrochloride (MBTH) Reagent.*—0.4% aqueous solution.

*1% Ferric Chloride Solution.*

*Saturated Sodium Chloride Solution.*

*Anhydrous Sodium Sulfate.*

*A Mixed Solvent, (1+1) Acetone-Chloroform.*

**Instruments.**—A Beckman model DU spectrophotometer. A Coleman model 14 spectrophotometer.

**Procedure.**—To 9 ml. of test solution, 1 ml. of a saturated sodium chloride solution is added, and then 2 ml. of a 0.4% MBTH aqueous solution is added. After the mixture has stood for 20 min., 0.5 ml. of a 1% ferric chloride solution is added. After an additional 10 min., 12.5 ml. of a (1+1) acetone-chloroform solvent is added to the mixture. Then the mixture is transferred into a separatory funnel and shaken twenty times.* The extract is poured into a 10 ml. measuring flask, and the flask is filled up to the mark with the solvent. Then the extract is quickly dehydrated in a stoppered test tube with 6 g. of anhydrous sodium sulfate.** The extract is filtered through a dry filter paper. The absorbance is read at the wavelength of 670 m$\mu$. The color is stable for at least two hours.

## Results and Discussion

In the reaction of MBTH with formaldehyde, a maximum coloration is obtained in the range of the concentration of sodium chloride from 0.5 mol. to 1.0 mol. The molar absorptivity is $6.9\times10^4$ in the sodium chloride solution, while it is $6.1\times10^4$ in a solution without sodium chloride. The absorbance is increased by 1.13 times in the sodium chloride solution. On the other hand, Sawicki et al.[1] give $6.5\times10^4$ as the molar absorptivity in a solution without

* After shaking the solvent decreases in volume to about 9.8 ml.

** The color is not stabilized for a longer period by using a smaller amount of sodium sulfate. Any decrease of the absorbance is not noticed by treating the extract with sodium sulfate and then a filter paper.

sodium chloride, while Hünig et al.[3] gives 7.6 $\times 10^4$ as the molar absorptivity of the pure product in acetone. A similar increase in the absorbance is also noticed in the reaction of acetaldehyde with MBTH. Sodium chloride seems to be effective in raising the yield of the color reaction of MBTH with aldehyde. Potassium chloride is less effective than sodium chloride for the enhancement of the sensitivity of the present method.

The addition of sodium chloride to the reaction mixture has another advantage. In the presence of sodium chloride, the extraction of the colored product is quantitative, while in a solution without sodium chloride more than 10% of the colored product remains in the aqueous phase (Fig. 1). Extraction is also advantageous for the determination of a minute amount of aldehyde in colored or turbid solutions, because the colored product of aldehyde is concentrated in a small volume of the organic phase. A prolonged contact of the organic phase with the aqueous phase reduces the absorbance. The extract must be rapidly dehydrated after extraction; delayed dehydration also causes a decrease in the absorbance.

The presence of 20 mg./l. of ferrous ions or 50 mg./l. of manganese ions does not interfere. The presence of 1 mg. of sugar gives only a minimum detectable absorbance. This is one of the advantages of the MBTH method here presented. By means of the method using chromotropic acid, a small amount of formaldehyde in the presence of a larger amount of sugar cannot be determined because sugar and formaldehyde are likely to react with the reagent.

# Catalytic Tritium Exchange Reactions with Tritiated Active Methylene Compound

By Ken-ichi KUDO, Takayoshi ADACHI, Masaaki HAZUE and Michio ENDO

(Received February 18, 1965)

Although the isotopic hydrogen exchange reactions of a number of organic compounds catalyzed by a transition-metal have been investigated by many workers,[1] these exchange reactions have dealt almost exclusively with deuterium oxide,[1] deuterium,[1] and tritium oxide[2] as an isotope source.

The present paper will describe the catalytic tritium-hydrogen exchange using ethyl malonate-(active methylene-T) (I) as a tritium source. Table I shows that the alkyl hydrogens are, by the use of a catalyst, exchanged with I more easily than with tritium oxide. The catalytic activity of the transition-metal for benzene is in the following order: with I, Raney Ni>Pd-black>Pt-black; with tritium oxide, Pt-black>Pd-black>Raney Ni.

TABLE I. EXCHANGE BY TRITIUM OXIDE OR I*

| Catalyst | Substrate | % Approach to statistical equilibrium | |
|---|---|---|---|
| | | $T_2O$ | I |
| Pd-Black | *p*-Xylene | 4 | 99 |
| Pd-Black | Benzene | 77 | 10 |
| Pd-Black | Cyclohexane | 0 | 11 |
| Pt-Black | *p*-Xylene | 0 | 0 |
| Pt-Black | Benzene | 100 | 6 |
| Pt-Black | Cyclohexane | 0 | 3 |
| PtO | *p*-Xylene | 3 | 17 |
| PtO | Benzene | 98 | 45 |
| Raney Ni | *p*-Xylene | 2 | 90 |
| Raney Ni | Benzene | 62 | 76 |
| Raney Ni | Cyclohexane | 0 | 2 |

* At 130°C for 17 hr.

The results in Table II show that the exchanges of toluene and *m*-xylene catalyzed by Pd-black and Raney Ni occur mainly in the alkyl groups. Figure 1 indicates that the

2) J. L. Garnett and W. A. Sollich, *J. Catalysis*, 2, 350 (1963).

TABLE II. TRITIUM DISTRIBUTION IN THE COMPOUNDS LABELED WITH I*

| Substrate | Catalyst | % of tritium | |
|---|---|---|---|
| | | Methyl | Ring |
| Toluene | Pd-Black | 100 | 0 |
| Toluene | Raney Ni | 89 | 11 |
| *m*-Xylene | Pd-Black | 98 | 2 |
| *m*-Xylene | Raney Ni | 97 | 3 |

* At 130°C for 17 hr.

TABLE III. EXCHANGES OF ORGANIC COMPOUNDS WITH I*

| Substrate | % Approach to statistical equilibrium | | |
|---|---|---|---|
| | Pd-Black | Pt-Black | Raney Ni |
| *m*-Xylene | 96 | 1 | 82 |
| *p*-Xylene | 99 | 0 | 91 |
| Toluene | 100 | 16 | 83 |
| Benzene | 10 | 6 | 76 |
| Diphenyl | 0 | 90 | 1 |
| *n*-Heptane | 5 | 0 | 2 |
| Cyclohexane | 11 | 3 | 2 |
| Tetralin | 67 | 77 | 85 |

* At 130°C for 17 hr.

extent of the isotopic exchanges with I is decreased considerably by the addition of water. Judging from the above results in this reaction, it may be expected that the mechanism of the exchange with I will be different from that with tritium oxide. The extent of the exchange of some organic compounds with I are shown in Table III.

These results indicate that the catalytic exchange of hydrogen with I is a good method for labeling an organic compound with hydrogen isotopes.

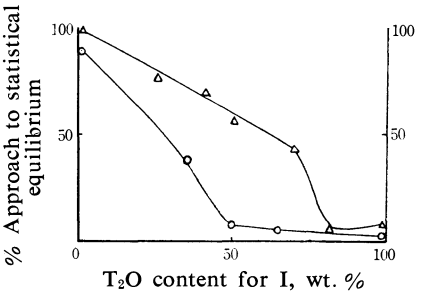

Fig. 1. Effects of water on exchange reaction of *p*-xylene by I at 130°C for 17 hr.
—△— With Pd-black
—○— With Raney Ni

## Experimental

**The Exchange of *p*-Xylene by Pd-Black.** — A mixture of 30 ml. of *p*-xylene, 1 ml. of I (41.1 μc./ml.), and 0.3 g. of Pd-black in an ampoule was shaken at about 130°C for 17 hr. After it had then been cooled, Pd-black was filtered off, the filtrate was hydrolyzed with 20 ml. of a 10% aqueous sodium hydroxide solution to give sodium malonate, and the reaction mixture was washed repeatedly with water, dried with sodium sulfate, and distilled to give 24 ml. (80%) of tritiated *p*-xylene (specific activity 1.36 μc./ml.) (99% approach to statistical equilibrium).

**The Determination of the Tritium Distribution in Toluene.**—A mixture of 2 ml. of tritiated toluene (0.179 mc./mM), 8 g. of potassium permanganate, and 96 ml. of water was heated under reflux for 3 hr. After it had cooled, the mixture was filtered and the filtrate was acidified with hydrochloric acid. The precipitate was then recrystallized from alcohol to give pure benzoic acid (specific activity $1.93\times10^{-2}$ μc./mM). Thus, the distribution of tritium in toluene was as follows: methyl, 89%; ring, 11%.

# The Anomalous Thermal Expansion of Hematite at a High Temperature

By Tatsuo SAITO

(Received February 20, 1965)

It has long been known that magnetic and specific heat anomalies are shown by hematite, $\alpha$-$Fe_2O_3$, in the 650—700°C region.

Néel[1] has suggested that this magnetic change comprises a transition from an antiferromagnetic state below 675°C to a paramagnetic one above this temperature.

However, when Willis and Rooksby[2] examined the crystal structure of hematite at elevated temperatures from 20°C to 950°C by means of a high temperature X-ray powder camera, they did not find any crystallogaphic phase transitions. However, at a temperature near 675°C the expansion coefficient of the $c_h$-axis in the hexagonal system showed a sudden increase. These results were interpreted in terms of the magnetic transition of pure hematite.

Finch and Sinha[3] observed the surface of a hematite single crystal by electron diffraction after heating it in air at 700°C; they concluded that $\gamma$-$Fe_2O_3$ was the stable form of $Fe_2O_3$ at high temperatures.

Blackman and Kaye[4] examined single crystals of hematite between 700°C and 1000°C by electron diffraction; they claimed that, in some cases, oriented layers of $Fe_3O_4$ occurred, but, in contrast to the results of Finch and Sinha, they found no evidence for the presence of $\gamma$-$Fe_2O_3$.

In view of these differences in the high temperature structural behavior of hematite, the present investigations were undertaken in order to determine the change in the unit cell of hematite precisely.

## Experimental

The materials used in this experiment were specular hematite, obtained from the Quebec-Cartier Company of Canada, and reagent grade hematite, $\alpha$-$Fe_2O_3$, obtained from the Fisher Scientific Company. The specular hematite, which was ground in a small tungsten carbide ball mill, contained about 2.5% $Fe_3O_4$ and a small percentage of $SiO_2$. This hematite ore powder was pre-heated at about 1000°C for 1 hr. because the original powder has lattice strains resulting from the grinding. Minus 325 mesh fractions of powder samples of both hematite ore and Fisher reagent were taken for X-ray measurements.

The equipment used was a Norelco X-ray difractometer, with, attached, a Materials Research Corporation Model X86-N furnace using a platinum ribbon heater.

The spacings of (10.4), (11.0) and (30.0) of hematite were measured at 50°C intervals, from room temperature to 1100°C, through the heating and cooling cycles. Both the heating and cooling rates of the furnace were 10°C per minute, and the specimens were kept at a constant temperature for 10 min. before performing the X-ray measurements.

The thermocouple measurements were calibrated by the data of the lattice parameter changes for magnesium oxide as a function of the temperature;[5] moreover, in this experiment the lattice strain of magnesium oxide due to the distorsion of the sample holder during heating was checked at each temperature by the above data of the lattice parameter for magnesium oxide.[5] The temperature control of the furnace was maintained within ±5°C.

The lattice parameters of the hexagonal cell, $a_h$ and $c_h$, at each temperature were computed from the measured average reflection angles, without taking corrections by the extraporation method. The rhombohedral unit cell dimensions, the cell edge, $a_R$, and the angle, $\alpha$, were computed from the hexagonal lattice parameters.

## Results and Discussion

The lattice parameter values at each temperature during heating and cooling are plotted in Figs. 1 and 2 as functions of the temperature. Figure 1 compares the thermal expansions of both $a_h$- and $c_h$-axes with one together. The values shown are $\Delta a_{ht}/a_{h20}$ and $\Delta c_{ht}/c_{h20}$ in percent for $a_h$- and $c_h$-axes expansions respectively. $a_{h20}$ or $c_{h20}$ means the lattice parameter value at 20°C, while $\Delta a_{ht}$ or $\Delta c_{ht}$ means the difference between each parameter value at 20°C and at $t$°C. In this case, the lattice parameter values at each temperature in the cooling stage were slightly larger than those in the heating stage. Figure 2 shows the expansion of the rhombohedral cell edge, $\Delta a_{Rt}/a_{R20}$, in percent. $a_{R20}$ is the value

of the cell edge at 20°C. $\Delta a_{Rt}$ is the difference between the cell edge values at 20°C and at $t$°C. Figure 3 shows the rhombohedral angle-temperature curve for the expansion of the rhombohedral unit cell.

As may be seen in these figures, two anomalies, at about 300°C and 700°C, are observed for the thermal expansion curve of hematite.

The hexagonal lattice parameters increase uniformly from room temperature to about 300°C, and they also increase almost uniformly above about 700°C; however, in the temperature range from about 300°C to 700°C, the two axes show different expansion behavior.

Similar behavior is also observed in the experiment with Fisher hematite.

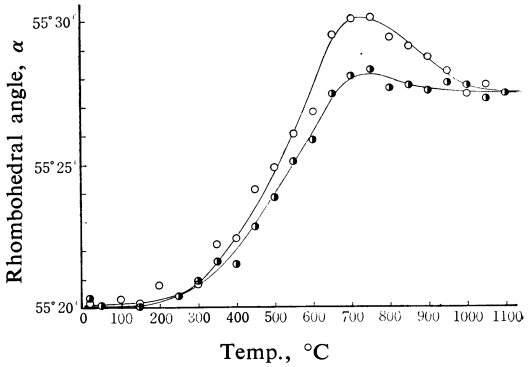

Fig. 3. Rhombohedral angle variation with temperature for hematite ore.

○—○ Heating stage
◑—◑ Cooling stage

It has, therefore, been found that the rhombohedral hematite has three stages of thermal expansion. Below about 300°C and above about 700°C the rhombohedral angle is almost constant, but in the temperature range from about 300°C to 700°C the rhombohedral angle increases. On the other hand, as may be seen in Fig. 3, the values of $\alpha$ in the 700—800°C range during heating are slightly larger than during cooling above 700°C. This irreversibility of the rhombohedral cell expansion at high temperatures during the heating and cooling cycles was also observed in the experiment with Fisher hematite. X-ray measurements were also performed in a nitrogen atmosphere, but no distinct differences were observed. On further heating above 1100°C, the rhombohedral unit cell of hematite underwent a complete deformation because of its dissociation to magnetite.

The work was done at the Institute of Mineral Research, Michigan Technological University, U. S. A., with financial support provided by that university. The author wishes to express his appreciation to Mr. M. E. Volin, Director of the Institute of Mineral Research, for his permission to publish this paper. The author also wishes to Thank Mr. W. A. Hockings, Research Engineer of the Institute of Mineral Research, for his helpful discussions.

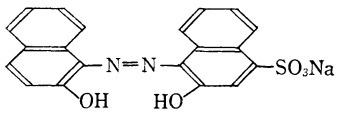
# The Spectrophotometric Determination of Chromium with 2-Hydroxy-1-(2-hydroxy-4-sulfo-1-naphthylazo)-naphthalein (Sodium Salt)



By Katsuya UESUGI and Yukiteru KATSUBE

(Received March 18, 1965)

2-Hydroxy-1-(2-hydroxy-4-sulfo-1-naphthylazo)-naphthalein (Sunchromine blue black R) has been examined spectrophotometrically in order to determine the molybdenum,[1] zirconium[2] and titanium[3] in a methanol-hydrochloric acid solution; it has also been examined as an indicator of the complexometric titration of calcium in the presence of magnesium.[4]

In this paper, a new method will be described for the spectrophotometric determination of trace amounts of chromium(III). The method is based on the stable blue complex formed by the reaction between chromium ions and 2-hydroxy-1-(2-hydroxy-4-sulfo-1-naphthylazo)-naphthalein.

The structure of the reagent is as follows:

## Experimental

**Reagents.**—The reagent solution was prepared by dissolving 0.1 g. of Sunchromine blue black R in 100 ml. of distilled water.

The standard solution, containing 100 $\mu$g. of chromium(III) per milliliter, was prepared by dissolving chromium alum (analytical grade) in 0.01 N sulfuric acid. The other reagents used were also of analytical grade.

**The Procedure for the Determination of Chromium.**—Transfer the solution containing 5 to 75 $\mu$g. of chromium to a 50 ml. volumetric flask, and add 5 ml. of the 0.1% reagent solution. Then add 10 ml. of a borax-sodium hydroxide buffer solution (pH 10), and make up to the mark with distilled water. After ten minutes, measure the absorbance at 630 m$\mu$, using a reagent blank solution as a reference.

## Results and Discussion

**Absorption Spectra.**—The absorption spectra of the complex are shown in Fig. 1. At pH 10, the maximum absorbance is at 630 m$\mu$.

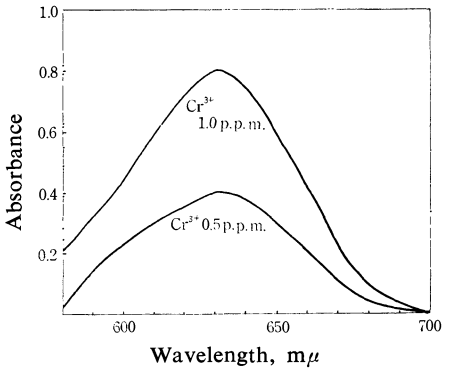


Fig. 1. Absorption spectra of the Cr-complex. pH 10, reagent 80 p. p. m., against reagent blank.

**The Effect of pH.**—A borax-sodium hydroxide buffer was satisfactory for the determination of chromium. The effect of pH on the color intensity of the complex is shown in Fig. 2. The complex has a maximum intensity in the pH range from 9.8 to 10.3.

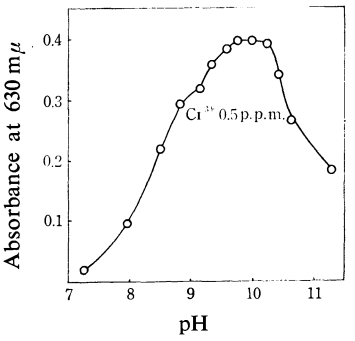

Fig. 2. Effect of pH on the Cr-complex.

**Rate of Color Formation.**—The color intensity reaches a maximum in ten minutes and remains constant for about an hour.

**Beer's Law.**—Beer's law is obeyed up to about 1.2 p. p. m. of chromium at 630 m$\mu$ (see Fig. 3).

**Sensitivity.**—The molar extinction coefficient is about 42000 at 630 m$\mu$, and the spectrophotometric sensitivity is 0.0013 $\mu$g. Cr/cm$^2$ for $\log I_0/I = 0.001$.

4) G. P. Hildebrand and C. N. Reilley, *Anal. Chem.*, **29**, 259 (1957).

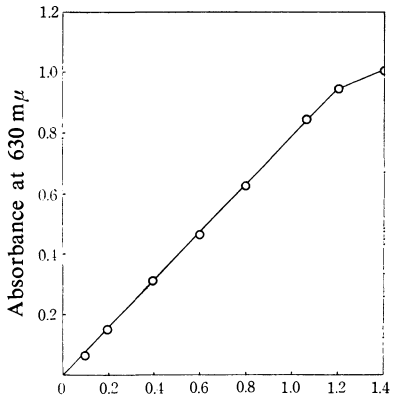

Fig. 3. Beer's law curve, pH 10.

**Interfering Ions.** — The effect of various cations was studied; it was found that aluminum, beryllium, iron(III), scandium, and large amounts of calcium, cobalt, zinc and titanium interfere. The presence of these interfering metal ions gives the smaller absorbance at 630 mμ. Hexavalent chromium, chloride and sulfate are without effect; 50 μg. of chromium(III) can thus be successfully determined in the presence of 100 mg. of any of these ions. The interfering metals must be removed or masked prior to the determination. Aluminum[5,6] and iron(III)[6] can be removed by the 8-hydroxyquinoline chloroform extraction method from chromium. The acetylacetone chloroform extraction method[7] effected a good separation of aluminum, iron(III) and beryllium from chromium.

## Summary

A spectrophotometric method for the determination of traces of chromium(III) with 2-hydroxy-1-(2-hydroxy-4-sulfo-1-naphthylazo)-naphthalein has been described. Beer's law is obeyed up to 1.2 p. p. m. of chromium. The spectrophotometric sensitivity is 0.0013 μg. Cr/cm$^2$ based on an absorbance of 0.001 unit at 630 mμ. The accuracy and precision are satisfactory. The interference of foreign ions can be avoided by 8-hydroxyquinoline chloroform extraction or by acetylacetone chloroform extraction.

# The Preparation of Triorganosilyl Derivatives of Hydroquinone, Resorcinol, Bisphenol-A and Terephthalic Acid

By Minoru Abe, Masaru Niwano, Hideaki Kobuna and Toshio Akiguchi

(Received April 5, 1965)

In the course of the preparation of phenylene- and phthalate-siloxy copolymers with $-C_6H_4O-Si-$ and $-O_2CC_6H_4CO_2Si-$, di-triorganosilyl derivatives of hydroquinone and resorcinol, *1,4(1,3)-di-triorganosiloxy benzene* ($R_3HQ$ and $R_3RC$), those of bisphenol-A (BPA), *2,2-bis-(4-triorganosiloxyphenyl)-propane* ($R_3BPA$), and terephthalic acid, *bis-triorganosilyl terephthalate* ($R_3TPA$) were isolated in pure states. $R_3HQ$ and $R_3RC$ were prepared from the reaction of triorganochlorosilane with the diphenols; $R_3BPA$, from the reaction of chlorosilane with BPA in the presence of aniline as a hydrogen chloride acceptor, or with the sodium salt of BPA in an inert solvent, and $R_3TPA$, from the reaction of chlorosilane with dipotassium terephthalate. $R_3TPA$ was found to be extremely sensitive towards solvolysis, while the phenolic silyl-ethers, the former three, were rather stable in both hydrolysis and alcoholysis.

## Experimental

**Triorganochlorosilanes.** — A pure sample of trimethylchlorosilane (b. p. 58°C) was obtained from the Shinetsu Chemical Industrial Co. Dimethylbutylchlorosilane (b.p. 139—140°C), dimethylphenylchlorosilane (b. p. 76—78°C/2 mmHg) and diphenylmethylchlorosilane (b. p. 145—146°C/2.5 mmHg) were prepared by the Grignard route.[1] Triphenylchlorosilane (m. p. 98—99°C) was isolated from high

1) T. Takiguchi and M. Abe, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **66**, 625 (1963).

boiling residue[2] of the direct synthesis of phenylchlorosilanes. All the compounds were further purified by conventional methods just before use.

**The Preparation of $R_3HQ$ and $R_3RC$.** — The general procedure will be described using 1,4-bis-trimethylsiloxy-benzene ($Me_3HQ$) as an example. A mixed sample of hydroquinone (33 g., 0.3 mol.) and trimethylchlorosilane (54 g., 0.5 mol.) was refluxed until the hydroquinone dissolved completely to give a clear yellow solution. The resultant solution was evaporated to remove the excess chlorosilan and then distilled under a vacuum. The distillate at 107—110°C/4 mmHg was a viscous liquid which solidified on standing. Recrystallization from ether gave 59 g. (77%) of pure $Me_3HQ$ (m. p. 48°C) (lit. m. p. 46°C,[3] 52°C,[4] 48.9—49.3°C[5]); b. p. 239°C (lit. b. p. 252°C,[6] 246°C[3]). The following disilyl ethers of the diphenols were obtained by a very similar procedure: $Me_3RC$, b. p. 235—236°C, 92—93°C/2 mmHg (lit. b. p. 239°C,[6] 243°C[4], 237—240°C,[7] 116°C/7 mmHg[3]); $n_D^{20}$ 1.4755; $d_4^{20}$ 0.947. $Me_2BuHQ$, b. p. 158—195°C/1.5 mmHg; $n_D^{20}$ 1.4765; $d_4^{20}$ 0.925. $Me_2BuRC$, b. p. 161—162°C/3 mmHg; $n_D^{20}$ 1.4798; $d_4^{20}$ 0.923. $Me_2PhHQ$, b. p. 137—139°C/0.5 mmHg; $n_D^{20}$ 1.5720; $d_4^{20}$ 1.087. $MePh_2HQ$, b. p. 237—238°C/0.5 mmHg; $n_D^{20}$ 1.5882; $d_4^{20}$ 1.113. $Ph_3HQ$, m. p. 225—226°C (lit. m. p. 215.8—216.0°C[5]). ($Ph_3HQ$ was prepared from the reaction in aniline.)

*$Me_3HQ(RC)$.* — Found: Si, 21.0 (21.7); mol. wt., 238 (244) (in benzene); $MR_D$,[8] — (75.35). Calcd. for $C_{12}H_{22}O_2Si_2$: Si, 22.0%; mol. wt., 254; $MR_D$, 74.38.

*$Me_2BuHQ(RC)$.*—Found: Si, 16.4 (16.0); mol. wt., 318 (326); $MR_D$, 104.7 (104.3). Calcd. for $C_{18}H_{34}O_2Si_2$: Si, 16.6%; mol. wt., 339; $MR_D$, 104.7.

*$Me_2PhHQ$.* — Found: Si, 14.5; mol. wt., 377, 373; $MR_D$, 111.4. Calcd. for $C_{22}H_{26}O_2Si_2$: Si, 14.8%; mol. wt., 379; $MR_D$, 112.7.

*$MePh_2HQ$.* — Found: Si, 10.7; mol. wt., 491; $MR_D$, 152.2. Calcd. for $C_{32}H_{30}O_2Si_2$: Si, 11.2%; mol. wt., 503; $MR_D$, 150.9.

*$Ph_3HQ$.*—Found: Si, 8.2; mol. wt., 633 (1,4-dioxane). Calcd. for $C_{42}H_{34}O_2Si_2$: Si, 8.9%; mol. wt., 627.

$R_3HQ$ was fairly stable in hydrolysis; e.g., $Me_3HQ$ recovered unchanged even after 2 hr.' boiling with distilled water. $R_3RC$ was less stable than $R_3HQ$. However, both were hydrolyzed gradually by prolonged heating with 1/20 N sulfuric acid, yielding the diphenols and the corresponding disiloxanes. The produts were also characterized by their infrared absorption spectra.[9] X-Ray powder patterns for crystalline ethers are given below:

| $I/I_0$: | 1.00 | 0.39 | 0.29 | 0.14 | 0.24 | 0.29 | 0.26 |
| | 0.14 | 0.13 | | | | | |

$Ph_3HQ$

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| $d, kX$: | 12.26 | 8.51 | 7.76 | 6.92 | 6.15 | 4.70 | 4.53 |
| | 4.37 | 4.17 | 4.02 | 3.59 | 3.48 | 3.39 | |
| $I/I_0$: | 0.19 | 0.45 | 0.36 | 0.28 | 0.93 | 1.00 | 0.48 |
| | 0.98 | 0.63 | 0.36 | 0.26 | 0.24 | 0.25 | |

**The Preparation of $R_3BPA$.**—A typical procedure will be detailed for 2,2-bis-(4-dimethylphenylsiloxyphenyl)-propane ($Me_2PhBPA$). A mixture of BPA (46 g., 0.2 mol.) and dimethylphenylchlorosilane (85 g., 0.5 mol.) was refluxed for 5 hr. After it had then been cooled to room temperature, a solution of aniline (37 g., 0.4 mol.) in 300 ml. of ether was vigorously stirred into the mixture, after which the mixture was refluxed for an additional 2 hr. The resultant solution was filtered to remove aniline hydrochloride and concentrated to a clear viscous liquid, from which crude $Me_2PhBPA$ boiling at 266—285°C (1.5 mmHg) was obtained by distillation. The redistillation of the fraction gave 74 g. (74%) of pure $M_2PhBPA$; b. p. 286—287°C/1.5 mmHg, $n_D^{20}$ 1.5746, $d_4^{20}$ 1.117.

It was found that the use of aniline as a hydrogen chloride acceptor was essential for the successful preparation; otherwise, the reaction was not completed, it was always accompanied by the formation of considerable amounts of mono-silyl ether, and the yield of bis-silyl ether was less than 40%.

In another preparation, an ethereal solution of dimethylphenylchlorosilane (85 g., 0.5 mol.) was added to a stirred slurry of sodium salt of BPA (54 g., 0.2 mol.) in ether. After it has been stirred for 2 hr. under refluxing, the mixture was filtered to remove sodium chloride; then the filtrate was evaporated to give an oily viscous liquid, which gave 66 g. (66%) of $Me_2PhBPA$ by fractionation under a vacuum. The following were obtained analogously in a consistent yield of 65—70%. $Me_3BPA$, b. p. 179—180°C/1.5 mmHg, $n_D^{20}$ 1.5178, $d_D^{20}$ 0.981; $Me_2BuBPA$, b. p. 211—214°C/1.5 mmHg, $n_D^{20}$ 1.5102, $d_4^{20}$ 0.976; and $MePh_2BPA$, b. p. 297—300°C/0.5 mmHg, $n_D^{20}$ 1.5777, $d_4^{20}$ 1.084.

Triphenylchlorosilane was found to be much less reactive to BPA than the other chlorosilanes. Therefore, a reaction in a high boilng solvent (toluene, xylene, etc.) using aluminum chloride as a catalyst was necessary; otherwise, the yield of bis-silyl-ether always remained below 20%. $Ph_3BPA$ was a fine crystalline substance melting at 151—152°C; it was obtained in a 47% (mean) yield by preparation in xylene. It was readily soluble in benzene, toluene and xylene, and insoluble in hexane, acetone, ethanol and methanol.

X-Ray powder diffraction data of $Ph_3BPA$:

| | | | | | | | |

*$Me_2PhBPA$*.—Found: Si, 11.0; mol. wt., 506 (benzene); $MR_D$, 147.0. Calcd. for $C_{31}H_{36}O_2Si_2$: Si, 11.3%; mol. wt., 497; $MR_D$, 146.9.

*$Me_3BPA$*.—Found: Si, 14.7; mol. wt., 366; $MR_D$, 115.2. Calcd. for $C_{21}H_{32}O_2Si_2$: Si, 15.1%; mol. wt., 373; $MR_D$, 112.0.

*$Me_2BuBPA$*. — Found: Si, 11.9; mol. wt., 455; $MR_D$, 140.1. Calcd. for $C_{27}H_{44}O_2Si_2$: Si, 12.3%; mol. wt., 457; $MR_D$, 139.8.

*$MePh_2BPA$*. — Found: Si, 8.83; mol. wt., 617; $MR_D$, 191.3. Calcd. for $C_{41}H_{40}O_2Si_2$: Si, 9.1%; mol. wt., 621; $MR_D$, 188.5.

*$Ph_3BPA$*.—Found: Si, 7.1; mol. wt., 750. Calcd. for $C_{51}H_{44}O_2Si_2$: Si, 7.5%; mol. wt., 745.

The identifications of these bis-silyl ethers were further established by their hydrolytic cleavage. The hydrolysis of $Me_2BuBPA$ (22.8 g., 0.05 mol.) with 1/20 N sulfuric acid by refluxing it for 10 hr. afforded BPA (10.0 g., 0.044 mol.) and 1,3-dibutyltetramethyldisiloxane (b. p. 207—208°C; 11.3 g., 0.046 mol.). Infrared absorption data[9] were also recorded.

Throughout the infrared absorption spectra of all silyl ethers ($R_3BPA$, $R_3HQ$ and $R_3RC$), a very strong and characteristic absorption band in the 910—925 $cm^{-1}$ region was found to exist. Its assignment still remains uncertain; however, it is very probably due to the existence of phenylene- or phenyl-silyl ether bonding (-$C_6H_4$-O-Si- or $C_6H_5$-O-Si-) in these compounds. An entire absence of the band in BPA, diphenols and in phenol, and its appearance in the silyl derivatives of BPA, in diphenols and in all phenoxysilanes[10] seems to support this assignment strongly.

**Bis-triphenylsilyl Terephthalate.**—In a manner similar to that employed for $R_3TPA$ ($R_3$=$Me_3$, $Me_3Bu$, $Me_2Ph$ and $MePh_2$) in the preceding paper,[11] bis-triphenylsilyl terephthalate ($Ph_3TPA$) was obtained in 67% yield from the reaction of dipotassium terephthalate with triphenylchlorosilane in boiling toluene.

$Ph_3TPA$ was a fine acicular crystal melting at 242—243°C, hardly soluble in ordinary solvents at room temperature, and fairly soluble in boiling toluene, xylene, dioxane and chlorobenzene.

Found: Si, 7.7; mol. wt., 688, 692 (Rast method). Calcd. for $C_{44}H_{34}O_4Si_2$: Si, 8.2%; mol. wt., 683.

X-Ray powder diffraction data of $Ph_3TPA$:

# A New Cobalt(III) Complex: $K[Co(CN)_2dg_2] \cdot 3/2\ H_2O$

By Nobufumi MAKI

(Received April 9, 1965)

The dicyano-bis(dimethylglyoximato)cobaltate(III) complex, $K[Co^{III}(CN)_2dg_2] \cdot 3/2\ H_2O$,[1] has been prepared, and its absorption spectrum compared with those of the related dicyanocobalt(III) complexes.

A solution (200 ml.) containing 13.7 g. of potassium cyanide was mixed with a solution of 50 g. of bis(dimethylglyoximato)diamminecobalt(III) chloride, $[Co\ dg_2(NH_3)_2]Cl \cdot 5H_2O$,[2] under continuous stirring, and then heated on a water bath until the reaction mixture was evaporated to one-third of its former volume. From the smell of the ammonia evolved, it could be discerned that the following mild reaction was in progress:

$$[Co\ dg_2(NH_3)_2]Cl \cdot 5\ H_2O + 2\ KCN \rightarrow K[Co(CN)_2dg_2] \cdot 3/2\ H_2O + 2\ NH_3 + KCl$$

During the course of the reaction, an insoluble yellow matter was deposited. These crystalline deposits were eliminated from the solution quickly while it was in a hot state. These insoluble orange yellow crystals are probably tris(dimethylglyoximato)cobalt(III), $[Co(dgH)_3]$,[3] formed from the rupture of the hydrogen bonding due to the alkalinity of the cyanide solution.

After cooling, the lusterous silky yellow crystals which had been deposited were filtered and washed with cold 85% ethanol and ether.

1) N. Maki, *Nature*, **188**, 227 (1960).
2) L. Tschugaeff, *Z. anorg. u. allgem. Chem.*, **46**, 160 (1905).
3) J. Fujita, A. Nakahara and R. Tsuchida, *J. Chem. Phys.*, **23**, 1541 (1955).

When the mother liquor was concentrated on a water bath, more crystals were obtained and recrystallized from hot water. Large needle-shaped crystals were thus obtained.

Found: Co, 15.49; C, 31.60; N, 21.99; K, 10.22. Calcd. for $K[Co(C_8H_{14}O_4N_4)(CN)_2]$: Co, 15.50; C, 31.58; N, 22.10; K, 10.28%.

The anhydrous salt (dried at 110°C for 3 hr.) was hygroscopic.

*cis*-Dicyano-bis(ethylenediamine)cobalt(III) chloride[4] and dicyano-bis(propylenediamine)-cobalt(III) thiosulfate were prepared by the method of Rây and Sarma[5] or that of Gupta[6].

The visible and ultraviolet absorption spectra measurements were made manually by a Beckmann DU spectrophotometer in an aqueous solution.

## Results and Discussion

The absorption spectra of dicyano-cobalt(III) complexes are shown in Fig. 1. It can be seen that the first band in the visible region shifts towards the shorter wavelength in the following order of ligands:

tn en pn dg.

Table I shows the absorption maxima for dicyano-cobalt(III) complexes. These data were reported recently by Ohkawa, Fujita and Shimura[7] except for that of a dimethylglyoxime complex.

Figure 2 shows the absorption spectra for bis(dimethylglyoximato)cobalt(III) complexes of the $[Co^{III}dg_2X_2]$-type.[8] The order of the spectrochemical series of ligands is as follows:

$CN^-$ $NO_2^-$ $NH_3$ $dgH^-$ $Cl^-$

As for the dicyano complex, two dimethylglyoximes co-ordinate with the central cobalt(III) ion in a planary manner as a pair of chelate rings with two hydrogen bonds, and two dicyano ligands co-ordinate with it at position above and below its coplanar structure. Each co-ordinate bond appears to have a strong $\pi$-bonding character in its co-ordination sphere. Therefore, this complex has a configuration similar to that of cobalamine (vitamin $B_{12}$) and shows a quite analogous behavior in solution.[1] This stable complex, in view of this, will be useful for the study of a catalytic reaction.

The author wishes to thank Professor Akitsugu Nakahara (Osaka University) and Dr. Junnosuke Fujita (Tohoku University) for their kindness to give him the data and suggestions throughout this work.

# The Electrical Properties of the Poly(*N*-vinyl Carbazole) - Antimony(V) Chloride (or Iodine) Charge Transfer Complexes*

By Yoshihisa YAMAMOTO, Seiichi KANDA, Shigekazu KUSABAYASHI
Takeshi NOGAITO, Kazuo ITO and Hiroshi MIKAWA

(Received April 21, 1965)

Many investigations have been made of solid molecular complexes containing polycyclic aromatic hydrocarbons as donors and halogens[1,2] or antimony(V) chloride as acceptors.[3] Most of these complexes are good semiconductors and have a high conductivity, and they often show ESR absorption. Charge transfer complexes derived from polyvinylanthracene,[4] polyvinylpyridine,[5] polyvinylnaphthalene,[6] polyvinylmesitylene[6] and polyvinylcarbazole[7] have already been reported.

It may be expected that vinyl polymer with a $\pi$-electron system of aromatic amines may form a charge transfer complex with antimony(V) chloride or iodine. Although vinyl polymers are real insulating materials, some electrical conductivity may be expected in the resulting complex. It may also be hoped that plastic properties can be retained in the product complex. The present paper will deal with the electrical conductivity, ESR absorption and optical absorption of the charge transfer complexes between poly(*N*-vinyl carbazole) (abbreviated as PVCa) and antimony(V) chloride or iodine.

**Preparation.** — The PVCa used was Luvican M170 (Badische Anilin u. Soda Fabrik A. G.). The antimony(V) chloride was purified twice by distillation.

*Poly(N-vinyl Carbazole) - Antimony(V) Chloride Complexes.*—The preparation of sample No. 2 (Table I), which will serve as an example, was as follows. PVCa (0.4 g.) was dissolved in chloroform (20 cc.), and then 5 cc. of $1\times10^{-3}$ mol./l. antimony(V) chloride solution in chloroform was stirred in at room temperature. The solution turned green, and precipitation occured. The mixture was kept overnight in a desiccator, after which precipitated complex was filtered and washed repeatedly with chloroform in order to remove the excess antimony(V) chloride. The complex thus obtained was powdered and dried under reduced pressure until a constant weight was obtained. All procedures were carefully carried out free from moisture in order to avoid the decomposition of antimony(V) chloride. In the cases of samples No. 6 and 7, precipitation did not occur, although they turned green when the two components were mixed. The solution was evaporated to dryness to give the complex as a film, which was then washed repeatedly with chloroform and petroleum ether.

*N-Ethylcarbazole - Antimony(V) Chloride and Carbazole - Antimony(V) Chloride Complexes.*— The methods used were the same as those used in the case of PVCa. The complexes were soluble in chloroform.

*N*-Ethylcarbazole - antimony(V) chloride complexes; m. p. 129—132°C. Found: C, 29.8; H, 2.45; N, 2.40; Sb, 30.40. Calcd. for $(C_{14}H_{13}N)_2(SbCl_4)_3$: C, 28.4; H, 2.2; N, 2.37; Sb, 30.93%. Although the mole ratio of *N*-ethylcarbazole and antimony was found to be 2 : 3, Sb : Cl ratio was 1 : 4.

Carbazole - antimony(V) chloride complex; m. p. 179—183°C. Found: C, 44.38; H, 2.79; N, 4.40; Sb, 19.30. Calcd. for $(C_{12}H_9N)_2(SbCl_5)$: C, 45.54; H, 2.84; N, 4.40; Sb, 19.30%.

*Poly(N-vinyl Carbazole) - Iodine Complexes.*— PVCa and iodine in chloroform were mixed, the stirring was continued for two hours at room temperature, and then they were refluxed for another hour, after which the mixture was allowed to stand overnight. The green colored complex was then precipitated by petroleum ether.

*Electric Properties.* — Two disk electrodes, 0.2—0.3 mm. thick and 8 mm. in diameter, were prepared first by pressing graphite powder at $5\times10^3$ kg./cm$^2$. The powder of the material was packed between these two graphite electrodes in a mold with a diameter of 13 mm. and pressed at $6\times10^3$ kg./cm$^2$. The thickness of the specimen between the electrodes was about 0.7 mm. The d. c. conductivity was measured in the temperature range between 20 and 60°C.

An almost linear relationship was observed between the current and the applied voltage up to 4600—7000 V./cm. The temperature dependence of the resistivity obeyed the $\rho = \rho_0 \exp(\varepsilon/2kT)$ equation (Fig. 1). The resistivity at 20°C ($\rho_{20}$) and the apparent energy gap ($\varepsilon$) as calculated from the above equation are tabulated in Table I. The $\rho_{20}$ values of PVCa - antimony(V) chloride complexes and PVCa - iodine complexes were found to be $10^5$—$10^9$ and $10^{11}$—$10^{13}$ Ωcm. The $\varepsilon$ values were

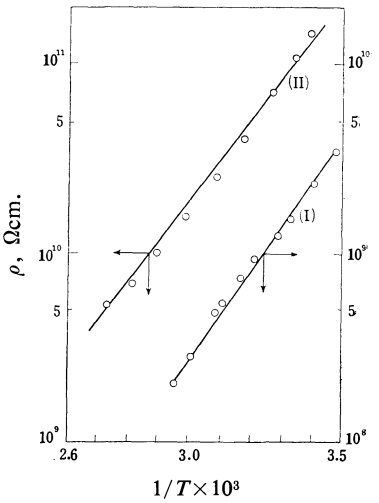

Fig. 1. Specific resistivity vs. $1/T\times10^3$.

| 1 | PVCa only | | $>10^{17}$ | | |
| 2 | 1 : 2.5 | 4.5 : 1 | $5.0\times10^7$ | 0.92 | $2\times10^{19}$ |
| 3 | 2 : 3 | | $2.0\times10^5$ | 0.50 | $6\times10^{19}$ |
| 4 | 1 : 1 | 7.3 : 1 | $8.0\times10^6$ | 0.62 | |
| 5 | 2 : 1 | 5.3 : 1 | $4.0\times10^5$ | 0.47 | $4\times10^{19}$ |
| 6 | 5 : 1 | 5.6 : 1 | $2.5\times10^9$ | 0.80 | $4\times10^{19}$ |
| 7 | 10 : 1 | 11.3 : 1 | $8.0\times10^7$ | 1.0 | |
| *N*-Ethylcarbazole - $SbCl_5$ | | | | | |
| 8 | 1 : 2.5 | 3.0 : 2 | $1.9\times10^6$ | 0.60 | $2\times10^{19}$ |
| Carbazole-$SbCl_5$ | | | | | |
| 9 | 1 : 2.5 | 2.0 : 1 | $1.5\times10^7$ | 1.18 | |
| Poly(*N*-vinyl carbazole) - $I_2$ | | | | | |
| 10 | 1 : 5 | 7.6 : 1 | $1.5\times10^{11}$ | 0.93 | $5\times10^{17}$ |
| 11 | 1 : 2 | 14 : 1 | $1.8\times10^{13}$ | 1.14 | $6\times10^{16}$ |
| 12 | 1 : 1 | 45 : 1 | $3.3\times10^{12}$ | 0.94 | $6\times10^{16}$ |
| 13 | 2 : 1 | 73 : 1 | $2.6\times10^{13}$ | 0.88 | $8\times10^{16}$ |

0.50—1.0 eV. for PVCa - antimony(V) chloride complexes and 0.88—1.22 eV. for PVCa - iodine complexes.

As a reference, the *N*-ethylcarbazole - antimony(V) chloride complex and the carbazole-antimony(V) chloride complex were also measured; there $\rho_{20}$ values were found to be $10^6$ and $10^7$ Ωcm. respectively.

**ESR Absorption.**—The ESR absorption was examined at room temperature with a Hitachi MPS-2C spectrometer. The observed values are shown in Table I in spin/g. All the measured samples showed ESR absorption, indicating the existence of unpaired electrons. In the PVCa - antimony(V) chloride complex the number of unpaired spins is about one-tenth of the number of antimony(V) chloride present in the complex. On the other hand, in the PVCa - iodine complex the number of unpaired spins is only $10^{-3}$—$10^{-4}$ of the number of iodine molecules in the complex.

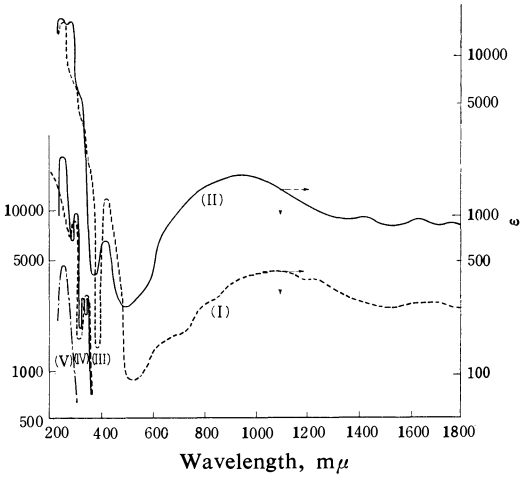

Fig. 2. Absorption spectra of some complexes.
(I) Poly(*N*-vinyl carbazole) - $SbCl_5$
(II) Ethyl carbazole - $SbCl_5$
(III) Poly(*N*-vinyl carbazole)
(V) Ethyl carbazole
(IV) $SbCl_5$

**Optical Absorption.**—The absorption spectra of the complexes are shown in Fig. 2. The absorption bands of the complexes in chloroform exist in four regions: <400, 420, 1000 and >1300 mμ of these, the <400 mμ bands are due to the components. The spectrum of antimony(V) chloride in chloroform did not show any absorption above 400 mμ. The 400, 1000 and >1300 mμ bands are, therefore, due to complexing between the components. The values of the energy gap as obtained from the temperature dependence of the resistivity are calculated to correspond to 1300—2500 mμ.

The authors wish to thank Mr. Takuzo Fujino and Mr. Tsuneyo Shishido for their elementary analyses.

SHORT COMMUNICATIONS

# The Reactivities of Hydrated Electrons and OH Radicals in an Aqueous Hexacyanoferrate(II) Solution

By Shin-ichi OHNO

(Received June 28, 1965)

As has been reported previously,[1] the irradiation of aqueous hexacyanoferrate(II) solutions at 2537Å results in the formation of hexacyanoferrate(III) ions and hydrated electrons, $e^-_{aq}$:

$$Fe(CN)_6^{4-} \rightarrow Fe(CN)_6^{3-} + e^-_{aq} \quad (1)$$

The limiting quantum yield, obtained at high concentrations of an electron scavenger, $N_2O$ or $NO_3^-$, was 0.35 at 25°C. This communication will present some results of the investigations into the reactivities of hydrated electrons and OH radicals using the above photochemical system.

In the $Fe(CN)_6^{4-}-N_2O$ systems, the photochemical reaction 1 is followed by:

$$e^-_{aq} + N_2O \rightarrow N_2 + OH + OH^- \quad (2)[2]$$

$$Fe(CN)_6^{4-} + OH \rightarrow Fe(CN)_6^{3-} + OH^- \quad (3)$$

The addition of other solutes which compete efficiently with $N_2O$ for $e^-_{aq}$ reduces the $N_2$ yields:

$$e^-_{aq} + S \rightarrow S^- \quad (4)$$

Thus, the relative rates can be obtained. In those cases where the $S^-$ produced reduces the $Fe(CN)_6^{3-}$ ion, the ratio of the rate constants, $k_4/k_2$, can also be calculated from the measured hexacyanoferrate(III) yields. Some results obtained are shown in column a of Table I.

In the $Fe(CN)_6^{4-}-NO_3^-$ systems containing other electron acceptors, the observed yields of nitrite[1,3] permit us to calculate the rates relative to nitrate. Table I, column b, shows some of these results.

Table I. Relative reactivity of various solutes towards $e^-_{aq}$, normalized to $k(e^-_{aq}+N_2O)=100$ or $k(e^-_{aq}+NO_3^-)=100$

| a | | b | |
|---|---|---|---|
| $N_2O$ | =100 | $NO_3^-$ | =100 |
| $H^+$ | 220 | $N_2O$ | 35 |
| $NO_3^-$ | 286 | $O_2$ | 250 |
| $Fe(CN)_6^{3-}$ | 120 | $CO_2$ | 38 |
| Acetone | 150 | $H_2O_2$ | 210 |
| $H_2PO_4^-$ | 1.6 | Acetone | 45 |
| $HPO_4^{2-}$, $ClO_4^-$ | Unreactive | $Cl^-$, Methanol | Unreactive |

The solutes, RH, which compete with $Fe(CN)_6^{4-}$ in the reaction with OH to yield the reducing radicals, R;

$$RH + OH \rightarrow R + H_2O \quad (5)$$

$$Fe(CN)_6^{3-} + R \rightarrow Fe(CN)_6^{4-} + R^+$$

reduce the yields of hexacyanoferrate(III), and the rate constant ratios, $k_5/k_3$, can be calculated. Table II shows some of these results, $k(OH+Fe(CN)_6^{4-})$ being taken as 100.

Table II. Reactivity of some solutes towards OH radicals, normalized to $k(OH+Fe(CN)_6^{4-})=100$

# The Non-catalytic Fusion Reaction of Acylated Sugars with Some Purines and Phenols[1]

By Yoshiharu ISHIDO, Teruo MATSUBA, Akira HOSONO, Kiyoshi FUJII
Hisayuki TANAKA, Koichi IWABUCHI, Sadanori ISOME, Akira MARUYAMA
Yasuhiko KIKUCHI and Tetsuo SATO

(Received July 12, 1965)

The authors wish to report on a new type of non-catalytic fusion of ordinary acylated sugars with some purines and phenols.

Helferich and Gootz[2] have reported that 1-*O*-trichloroacetyl-2, 3, 4, 6-tetra-*O*-acetyl-β-D-glucopyranose (I) is reactive enough in the non-catalytic fusion reaction with phenol to give phenyl 2′, 3′, 4′, 6′-tetra-*O*-acetyl-β-D-glucopyranoside.

When 2, 6-dichloropurine (II)[3] and theophylline (III) are applied to the reaction, only II gave 2, 6-dichloro-9-(2′, 3′, 4′, 6′-tetra-*O*-acetyl-β-D-glucopyranosyl)-purine (in a 57% yield) under the same conditions.[4] Moreover, II gave the corresponding 2′, 3′, 5′-tri-*O*-acetyl-β-D-ribofuranoside in a good yield[5] by the reaction with 1, 2, 3, 5-tetra-*O*-acetyl-β-D-ribofuranose (IV) in the presence of any catalyst, even though the reaction period was very short.[4]

These facts suggest that the non-catalytic reaction might be caused not only by the activation on the $C_{(1)}$-*O*-acyl group, as in the case of I, but also by that of the acidic hydrogen which is attached to the reaction center of such purines as II, as a result of the polar effect of the electron-withdrawing substituents, and that, therefore, the reactivity of purine derivatives can not simply be ascribed to their fusibility[1b] in the reaction with acylated sugars, as has been reported before.

6-Chloro-(V),[6] 6-iodo-,[6] 6-cyano-,[6] II, 2(6)-chloro-6(2)-iodo-,[6] and 2, 6, 8-trichloro-purine,[7] by non-catalytic fusion reaction with IV at 150—155°C in vacuo, gave the corresponding ribonucleosides in yields of 10,[8] 12,[8] 21,[9] 50,[10] 67,[10] and 64%[10] respectively. On the other hand, 6-methoxypurine[11] gave no corresponding product by the same reaction. In these cases, the fusibility of purine derivatives and their thermostability seem also to exert a considerable effect.

*p*-Nitrophenol, whose p*K*a value is almost the same as that of V,[12] also gave *p*-nitrophenyl 2′, 3′, 4′, 6′-tetra-*O*-acetyl-β-D-glucopyranoside[14] (in a 65% yield) by reaction with 1, 2, 3, 4, 6-penta-*O*-acetyl-β-D-glucopyranose at 175—195°C in vacuo. Similarly, IV gave two kinds of *p*-nitrophenyl tri-*O*-acetyl-D-ribofuranosides: *m*-Nitophenol gave *m*-nitrophenyl 2′, 3′, 4′, 6′-tetra-*O*-acetyl-β-D-glucopyranoside (m. p. 138—139.5°C, $[\alpha]_{578}^{27}$ −38.1°, $[\alpha]_{546}^{27}$ −40.1° in chloroform) in 47% yield, but neither *o*-nitro- nor 2, 4-dinitrophenol gave a corresponding product.

In view of these facts, the interpretation[15] of the polar effects of substituents on the reaction center requires further study. The fusion reaction of deoxy- and unsaturated-sugar derivatives with these purines and phenols is also under investigation.

A kinetic study of this reaction has been carried out by means of ultraviolet absorption spectroscopy; it has been found that the reaction of II with IV is of the second order. Detailed results will be published in the near future.

# Studies of the Absorption of Hydrogen on a Palladium Carbon Catalyst

By Sadao SUZUKI and Tsutomu SUZUKI

(Received July 20, 1965)

The platinum-carbon-hydrogen-system has been investigated by several groups[1-3] in recent years. The absorption of hydrogen on a palladium carbon catalyst (Pd-C) has been studied and some interesting information gained. It is known that hydrogen is only physically adsorbed on carbon at room temperature. Above 600°C hydrogen is chemisorbed on carbon.[4]

In this study, extraordinary absorption of hydrogen on Pd-C has been found. That is, the net amount absorbed on carbon (the amount absorbed on Pd-C minus that absorbed on palladium alone) is several hundred times that adsorbed physically at the same temperature. The measurements were made in a constant-volume apparatus. Carbon had been soaked in a 10% hydrofluolic acid solution in order to eliminate impurities. The required amount of palladium chloride solution was dispersed impartially over carbon to make a Pd-C catalyst. The catalyst, after it had been fully washed by ion-exchanged and distilled water, was put into the cell in a wet state and evacuated at 250°C.

The hydrogen for absorption measurements was made by the electrolysis of a 20% sodium hydroxide solution and purified by passing it through a palladium asbestos tube heated to 200°C.

A typical run of experiments is shown in Fig. 1. From this figure, it is evident that the amount absorbed on Pd-C is much larger than that which would be adsorbed phycically. The correlation between the over-all amount of hydrogen absorbed and the pressure at equilibrium is shown in Fig. 1 also.

Apparently the amount absorbed is proportional to the square root of the pressure at equilibrium over the range from 0 mmHg to 80. This pressure dependence indicates a dissociative absorption of hydrogen. The effect of the amount of palladium on the absorption rate is illustrated in Fig. 2. This figure suggests that the initial rate of absorption is

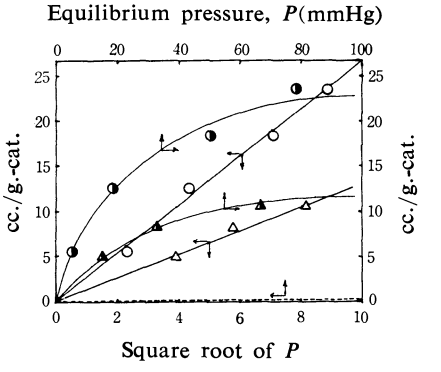

Fig. 1. Dependence of the amount absorbed on 5%Pd-C on equilibrium pressure.
Experimental results: ◑ at 150°C, ◭ at 200°C, ····· the amount physically absorbed on Pd only (the amount on C only is negligible). Avanged values with $\sqrt{P}$: ○ at 150°C, △ at 200°C.

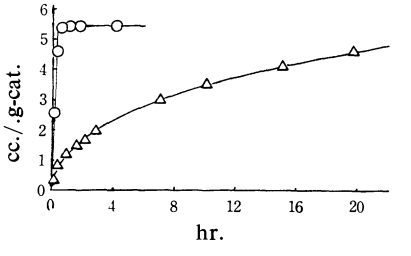

Fig. 2. Effect of the amount of Pd on the absorption rate at 150°C.
○ 5%Pd-C, △ 1%Pd-C

roughly proportional to the amount of palladium in the catalyst under the same initial pressure of hydrogen, and that the amounts absorbed at equilibrium are the same, irrespective of the palladium content.

The above information leads to several conclusions. The palladium in the catalyst plays the role of dissociating the hydrogen, which then migrates to the carbon surface and is stored there. The kinetic data predict that the rate-determining step of this absorption process is the diffusion of hydrogen from palladium to the carbon surface.

Gases other than hydrogen were found in the desorbed gas at 250°C.

# The Photo-Ionization of *N*, *N*, *N'*, *N'*-Tetramethyl-*p*-phenylenediamine in Organic Matrices

By Hiroshi TSUBOMURA, Naoto YAMAMOTO, Katsumi KIMURA, Toru SATO Hikoichiro YAMADA, Masahiko KATO, Gentaro YAMAGUCHI and Yoshinori NAKATO

(Received August 13, 1965)

The photolytic formation of Wurster's blue cation from *N*, *N*, *N'*, *N'*-tetramethyl-*p*-phenylenediamine (TMPD) in an organic rigid matrix is well known after the pioneering research of Lewis and his collaborators.[1] Not much investigation has been made, however, into the behavior of the electron ejected in the matrix, except for the interesting work reported by Dolan and Albrecht.[2]

We have made flash-photolytic experiments of TMPD, using two argon-filled flash lamps, with a total discharge energy of 200—400 joules and the duration of which is less than 4 $\mu$sec. In deoxygenated liquid paraffin at room temperature, the flash photolysis of TMPD showed the transient absorption spectrum shown in Fig. 1a. From this result, although there is some difference in spectral position between the curves shown in Fig. 1, it seems certain that Wurster's blue cation is formed in the liquid paraffin solution at room temperature.

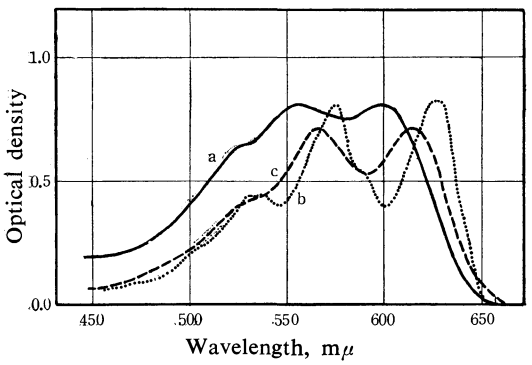

Fig. 1. Absorption spectra of Wurster's blue cation formed

a) by the fiash photolysis of TMPD in liquid paraffin at room temperature
b) by the ultraviolet illumination of TMPD in ethanol at 77°K.
c) Absorption spectrum of Wurster's blue perchlorate in ethanol at room temperature.

The transient spectrum decayed exponentially with $\tau_e = 82$ $\mu$sec. With deaerated *n*-heptane solutions, and also with aerated liquid paraffin solutions, no transient spectrum was obtained.

We have measured the fluorescence and phosphorescence spectra of TMPD at 77°K in ethanol, EPA and MP. These spectra, together with the absorption spectrum, may well be understood as those of the substituted benzenes.[3] In other words, no special band, such as the charge-transfer absorption band or the charge-transfer fluorescence band, appears at all in these solutions. The life-times of the phosphorescence spectrum for ethanol and MP solutions at 77°K have been found to be 1.57 and 2.12 sec. respectively. These life-times are also normal for substituted benzenes. From these results, we can conclude that, on excitation, TMPD goes first into its singlet excited level, and that then some of the molecules return to the ground state, either emitting fluorescence and phosphorescence or radiationlessly, while others are transferred into the ionized state.

The TMPD cation produced by the flash illumination of deoxygenated ethanol solutions has been found to have a surprisingly long life. It returns to the original state after two days, and the experiment can be repeated for several times. In aerated ethanol, only very few cations were formed by a flash with approximately the same energy as that used for deoxygenated solutions, and no transient absorption spectrum was photographed, even if the spectral flash lamp was fired at 10 $\mu$sec. after the photolysis flash.[4] We also photo-ionized the deoxygenated ethanol solution by the flash, and then introduced oxygen into the colored solution. The color did not change at all. These results show that oxygen quenches the photo-ionization at the initial stage.

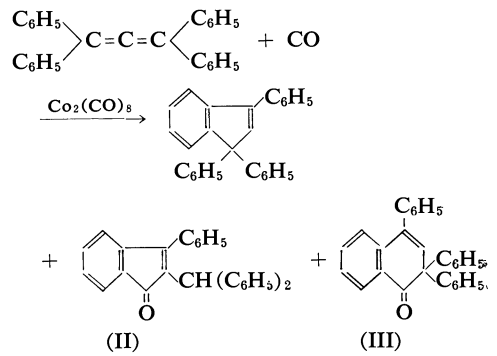
# The Carbonylation of Cumulenes

By Pu-Jun KIM and Nobue HAGIHARA

(Received August 16, 1965)



It has previously been shown that cumulenes interact with transition metal carbonyls to yield some new $\pi$-complexes.[1] In this paper we wish to describe the carbonylation of tetraphenyl-butatriene and -allene in the presence of dicobalt octacarbonyl.

Tetraphenylbutatriene (2.0 g.) in benzene (50 ml.) was treated with carbon monoxide (150 kg./cm$^2$) in the presence of dicobalt octacarbonyl (0.2 g.) at 230—250°C. Upon cooling after 6 hr., a red solution was obtained. The reaction mixture was separated by chromatography on alumina with benzene to give 1-diphenylmethylene-3-phenylindene[2] in a 0.04% yield and red prisms (I) (m. p. 147—148°C) in a 70% yield. The elemental analysis and molecular weight determination indicated that I has this composition: (tetraphenylbutatriene)·(CO), I (Found: C, 90.02; H, 5.55; mol. wt. (Rast), 365.5. Calcd. for $C_{29}H_{20}O$: C, 90.59; H, 5.24%; mol. wt., 384.5). The infrared spectrum of I showed the presence of a ketonic carbonyl group (1714 cm$^{-1}$). The NMR spectrum of I showed a singlet at 3.57$\tau$ and a multiplet at 2.67—3.08$\tau$, with a relative intensity of 1 : 19. I absorbed 2 mol. of hydrogen over a Raney-nickel catalyst and was oxidized with chromium trioxide in acetic acid to give *o*-benzoylbenzoic acid and benzophenone. On the basis of this evidence and the melting point described in the literature, I was shown to be 2-($\beta$, $\beta$-diphenylvinyl)-3-phenyl-indone (lit.[3] m. p. 147—148°C) as is shown below:

(I)

Analogously, tetraphenylallene in benzene was heated with carbon monoxide (150 kg./cm$^2$) in the presence of dicobalt octacarbonyl at 230—250°C for 6 hr. After the reaction, a yellow solution was obtained on cooling. The reaction mixture was separated by chromatography on alumina to give 1, 1, 3-triphenylindene (m. p. 133—134°C)[2] in a 41.5% yield, yellow plates (II) (m. p. 155.5—156.5°C) in a 23% yield, and yellow prisms (III) m. p. 172—174°C) in a 17% yield. These compounds were recrystallized from benzene and petroleum-ether. The elemental analyses and molecular weight determinations indicated that both II and III have this composition: (tetraphenylallene)·(CO), II (Found: C, 89.96; H, 5.33; mol. wt. (Rast), 367.0. Calcd. for $C_{28}H_{20}O$: C, 90.29; H, 54.1%; mol. wt., 372.4), III (Found: C, 89.80; H, 5.34%; mol. wt. (Rast), 367.4). The infrared spectra of II and III showed the presence of ketonic carbonyl groups (1714 and 1690 cm$^{-1}$ respectively in Nujol). The NMR spectrum of II showed a singlet at 4.81$\tau$ and a multiplet at 2.58—3.09$\tau$, with a relative intensity of 1 : 19. On the basis of this evidence and the melting point described in the literature, II was shown to be 2-diphenylmethyl-3-phenylindone (lit.[4] m. p. 154°C), while III, an isomer of II, seemed to be 2, 2, 4-triphenylnaphthalenone from its infrared spectrum, as is shown below:

# The Anomalous Temperature Dependence of the Electrical Conductivity of Phenanthrene

By Shoichi MATSUMOTO and Tomomichi TSUKADA

(Received August 16, 1965)

A relatively large anisotropy in the electrical conductivity of the phenanthrene single crystal,[1] and the current-voltage characteristics of the single crystal,[2] characteristics which might be attributable to space-charge-limited currents phenomena, have previously been reported. In the course of an extensive study of the electrical properties of polycrystalline phenanthrene, the present authors have found an anomaly at around 64—71°C in the temperature dependence of the electrical conductivity. In this paper, the observed anomaly and a probable cause for it will be presented.

The powdered phenanthrene, purified by a combination of recrystallization and zone melting, was packed in a polytetrafluoroethylene cylinder with a small exhaust-path and compressed between the metal ends used as electrodes. The pressure of compression was 120 kg./cm$^2$, and the electrical measurements were carried out under a pressure of $10^{-3}-10^{-4}$ mmHg.

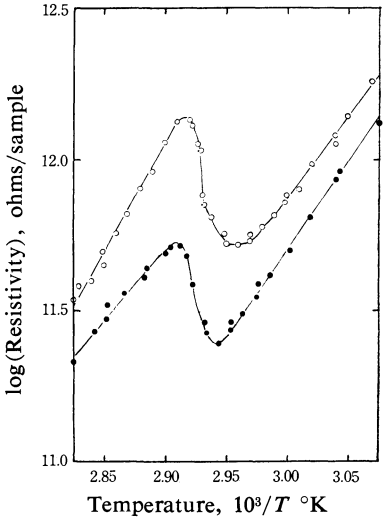

Fig. 1. One example of the temperature dependence (○ for heating, ● for cooling) of the electrical resistivity of phenanthrene, showing an anomaly at around 64—71°C.

A typical example of the temperature dependence of the electrical resistivity measured by the d. c. method is shown in Fig. 1, where an anomaly is observed at around 64—71°C. The linear relationship between the logarithm of resistivity and the reciprocal absolute temperature was broken in this temperature range, after which the resistivity increased abruptly with the rising temperature until it became approximately 6—7 times greater than that below 64°C. However, the linear relationship remained both below and above the anomaly, and there is no significant change in the slopes of each relationship. The anomalous phenomena were quite reversible. The reproducibility of the phenomena for different specimens is good within the range of experimental error.

Hence, the above-mentioned anomaly must be associated with a certain intrinsic property of phenanthrene itself. The large increase in resistivity at the anomalous point may be attributable to the influence of the differences in the molecular arrangement below and above the point; that is, it is probable that phenanthrene has a phase transition at around 64—71°C. However, this transition may not be great in itself, because the anomalous phenomena were quite reversible and no significant change of the activation energy for conduction can be admitted.

A preliminary investigation by differential thermal analysis showed an apparent endothermic peak at about 67°C on a thermogram. This may present evidence on a phase transition of phenanthrene suggested by the above-mentioned anomaly. This study is now in progress.

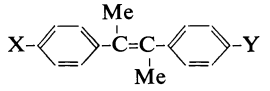
# The Substituent Effect on the Ultraviolet Spectrum of 1, 2-Diphenyltetramethyldisilane[1]



By Hideki SAKURAI, Hisayoshi YAMAMORI and Makoto KUMADA

(Received August 19, 1965)

It has previously been reported from this laboratory[2] that polysilanes with phenyl or vinyl groups, unlike monosilanes, have a very intense absorption in the ultraviolet region. This interesting ultraviolet property of polysilanes has been studied by several groups of workers in recent years.[3-5] These investigations are in accord with the view that the silicon-silicon bond is essential as a chromophore in making an enhanced conjugation with pi-electron systems.

(I)

(II)

TABLE I. UV SPECTRA OF SOME 1, 2-DIPHENYLTETRAMETHYLDISILANES[a]

| Substituent X | Substituent Y | $\lambda_{max}$ mμ | $\varepsilon \times 10^{-4}$ |
|---|---|---|---|
| none | | 238.0 | 1.85 |
| *p*-$CH_3$ | *p*-H | 238.5 | 2.11 |
| *p*-$CH_3$ | *p*-$CH_3$ | 239.0 | 2.49 |

| *p*-Cl | *p*-Cl | 242.5 | 2.80 |
| *p*-$CH_3$ | *p*-Cl | 240.5 | 2.46 |

a) Spectra were obtained in *n*-hexane with Shimadzu SV-50A automatic recording spectrophotometer.

We have now prepared several derivatives of 1, 2-diphenyltetramethyldisilane (I)[6] and examined their ultraviolet absorption spectra (Table I).

Bathochromic shifts of the first intense band of the parent compound are observed with all the available *para*-substituted derivatives; apparently the bathochromic effects of substituents are additive.

It is of considerable interest to compare the ultraviolet spectra of these compounds with those of the correspondingly-substituted *trans*-$\alpha, \alpha'$-dimethylstilbenes (II).[7] As may be seen in Fig. 1, there is a linear correlation between

# The Circular Dichroism of Tris(L-prolinato)cobalt(III)

By Takaji YASUI, Jinsai HIDAKA and Yoichi SHIMURA

(Received August 23, 1965)

It is shown by the construction of molecular models that the tris(L-prolinato)cobalt(III) molecule can not exist in any one of the mer-$\Delta$, mer-$\Lambda$ and fac-$\Delta$ configurations but only in the fac-$\Lambda$ configuration, as a result of the steric hindrance among the three coordinated L-prolinate ions. The complex was prepared as purplish-pink crystals by the reaction of diaquotetramminecobalt(III) perchlorate with L-proline in the presence of activated charcoal. Found: C, 44.17; H, 6.02; N, 10.37. Calcd. for $Co(C_5H_8NO_2)_3$: C, 44.88; H, 6.04; N, 10.47%. The absorption spectrum confirms that it is the facial form.[1]

The circular dichroism (CD) and the rotatory dispersion (ORD) curves,* shownin Fig. 1, confirm the absolute configuration ($\Lambda$) of the complex.[2] A similar CD behavior was observed in tris(L-hydroxyprolinato)cobalt(III).

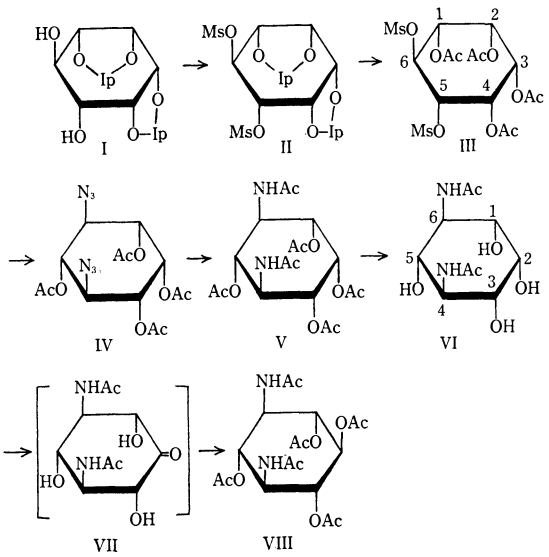
# Aminocyclitols. IX. The Facile Synthesis of Streptamine



By Tetsuo SUAMI and Seiichiro OGAWA

(Received September 4, 1965)

In connection with the previous studies of this series,[1] a new synthetic route to streptamine has been established in our laboratory.

Streptamine has been found to be a component of the antibiotic streptomycin,[2] and its structure has been shown to be *scyllo*-inosadiamine-1, 3.[3] This compound has been synthesized by Wolfrom et al.[3] from natural glucosamine and by Heyns et al.[4] from *myo*-inositol.

(±)-1 : 2-3 : 4-Di-*O*-isopropylidene-*epi*-inositol (I) has been prepared by the method of Angyal et al.[5] from *epi*-inositol[6] and used as the starting material in the present experiment. When I is treated with an excess amount of methanesulfonyl chloride in pyridine, di-*O*-mesyl derivative (II), m. p. 147.5—148.5°C, is formed. Then II is heated in 50% acetic acid solution on a boiling water bath for 2 hr. in order to remove the acetone, and the product is acetylated to give (±)-5, 6-di-*O*-mesyl-*epi*-inositol tetraacetate (III), m. p. 166.5—168.5°C). When III is treated with sodium azide in boiling aqueous 2-methoxyethanol for 40 hr. and subsequently acetylated, 4, 6-diazido-4, 6-dideoxy-*myo*-inositol tetraacetate (IV), m. p. 147—149°C, is obtained as the main product in 28% yield. The catalytic hydrogenation of IV in ethanol and the acetylation of the reduction product give hexaacetyl-*myo*-inosadiamine-4, 6 (V), m. p. 290—292°C. The NMR spectrum of V in deuteriochloroform exhibits a sharp signal at 8.07 $\tau$ for two equatorial acetamido groups, and three sharp signals of a 2 : 1 : 1 relative intensity at 7.98, 7.92 and 7.79 $\tau$ for

Ac=$CH_3CO$- Ms=$CH_3SO_2$- Ip=isopropylidene

three equatorial groups and an axial acetoxy group respectively.

The selective deacetylation of V gives the di-*N*-acetyl derivative (VI). Now VI is expected to be oxidized at C-2 selectively, since there is only one axial hydroxyl group on C-2.[7] Therefore, VI is oxidized in the presence of platinum black in a stream of oxygen at 40°C for 24 hr.[8] Then the ketone (VII) is immediately reduced by sodium amalgam[9] in a slightly acidic solution. The reduction product is acetylated to give hexaacetyl-streptamine (VIII) in 12.5% yield. The transition point of VIII is 243—248°C. The infrared spectrum of VIII is superimposable on that of an authentic sample which has been prepared from streptomycin by the method of Peck et al.[2]

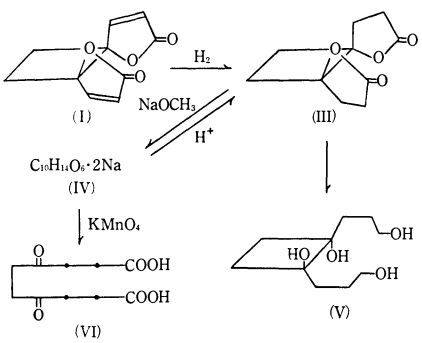
# The Photo-synthesis of Anemonin from Protoanemonin



By Hiroshi KATAOKA, Kazutoshi YAMADA and Noboru SUGIYAMA

(Received September 7, 1965)

In 1914, Asahina proposed a structure for anemonin[1]; later he confirmed it by the dimerization of synthesized protoanemonin.[2] Later other authors[3] have not, however, paid any attention to the effect of light on the dimerization of protoanemonin.

We have attempted to dimerize protoanemonin to anemonin with radiation of light; we succeeded in getting anemonin in a much better yield than those of the previous reports. As the configuration of anemonin had never been described, we propose that anemonin has a configuration[4] (I).

A methanol solution of protoanemonin[5] (II) was irradiated at $-50°C$ by a high-pressure mercury lamp. The crystals of I deposited were collected (yield, 75%). Colorless needles (from ethanol; m. p. 153°C). IR: 1780, 1755, 935, 900, 810 $cm^{-1}$. I was catalytically reduced, and tetrahydroanemonin (III) was obtained (from hot water; m. p. 154.5°C). IR: 1775, 930, 900, 810 $cm^{-1}$. NMR: 7.30 $\tau$ (triplet, 4H), 7.89 $\tau$ (triplet, 4H), 7.48 $\tau$ (quartet, 4H). III was hydrolyzed with sodium methoxide to give sodium dicarboxylate (IV), which was again converted into the lactone III in an acidic solution. The permanganate oxidation of IV gave dilevulinic acid (VI). From these results it was clear that the photodimerization product was identical with Asahina's anemonin.

By letting a methanol solution of I stand at $-50°C$ without irradiation, the formation of I was observed, but the yield was very poor.

Tetrahydroanemonin III was further reduced with lithium aluminum hydride to a tetraol (V). V could not be oxidized by lead tetraacetate and was recovered quantitatively. V showed a shift of the stretching vibration bands of hydroxyl groups when treated by a dilution method. This suggest the existence of a weak inter-molecular hydrogen bond of hydroxyl groups. V had no signal less than 4 $\tau$ in the NMR spectrum, indicating the absence of a strong hydrogen bond. These data support the speculation that two hydroxyl groups on the cyclobutane ring of V have a trans configuration. From the trans configuration of V and the fact of the formation of VI, the configuration of I was concluded to be trans and head to head.

# Altenin, a New Phytopathologically-toxic Metabolite from *Alternaria Kikuchiana*

By Noboru SUGIYAMA, Choji KASHIMA, Makoto YAMAMOTO and Ryotaro MOHRI[1]

(Received September 13, 1965)

*Alternaria Kikuchiana* Tanaka is a fungus which produces black spots on leaves and fruits of the pear, especially the improved species *Pyrus Ussuriensis var. Aromatica* Rehder (Japanese name *Nijusseiki*).[2] This fungus had been cultivated on a Czapek-Dox medium containing 4 per cent sucrose.[3] For the large-scale preparation it has now been cultivated in a 200-l. fermenter on a sucrose, ammonium phosphate, potassium phosphate and potassium chloride medium for 8 days at 30°C.

A factor which developed black spots on the leaf of the pear was isolated from the culture filtrate; this was designated "Altenin." Only one drop of an aqueous $2\times10^{-5}$ mg./ml. solution of altenin exhibited the phytopathologic effect. Thin-layer chromatography indicated that no other active substance was present in this filtrate. After the adjustment of the culture filtrate to pH 3.0, the active substance was adsorved on active charcoal and then eluted with acetone. The acetone was evaporated, and the altenin was purified by passing it through columns of silica gel and alumina.

One milligram of altenin was obtained from about 4 l. of the culture filtrate. Altenin is a yellow liquid, giving only one spot on silica-gel thin-layer chromatography with a benzene-acetone (1 : 1 v/v) mixture; the $R_f$ value is 0.76, while that of methyl red, a pilot dye, is 0.37. On alumina thin-layer chromatography with a methanol-water (5 : 1 v/v) mixture, the $R_f$ value is 0.87, while that of methyl red is 0.41.

Altenine is unstable at high temperatures and loses its biological activity in 10 min. at 80°C, or in an hour at 60°C. At 40°C, however, the activity continues for several hours, while at room temperature it is stable for 2 days, even when a stream of air is blown into the aqueous solution.

A molecular formula of $C_9H_{14}O_6$, (M. W. 218) was indicated by elementary analysis and mass spectrometry. Altenin is soluble in water, alcohol, ethyl ether, acetone and chloroform, and moderately soluble in benzene. It is extracted from acidic solutions with ethyl ether, but it is not extracted from alkaline solutions. A $pK_a$ value of 7.75 is indicated by potentiometry. The infrared absorption spectrum shows OH and carbonyl bands, but no carboxylic acid bands. The nuclear magnetic resonance spectrum shows a multiplet equivalent to two hydrogens, which disappears upon deuterium exchange. Altenin has a levo specific rotation at the D line.

Structural studies of altenin are now in progress; the details will be reported in the near furture.

# 3,4-Benzotropolone and Related Compounds. IV.[1] Azo- and Hydroxy-3,4-benzotropolones*

By Seiji EBINE

(Received September 12, 1964)

There have been a few reports describing benzotropolones whose seven-membered ring carries an azo or hydroxy group, such as *x*-(*p*-tolylazo)-3,4-benzotropolone,[2] 3-(*p*-nitrophenylazo)-4,5-benzotropolone,[3] its 7-phenyl derivative,[4] and 3-hydroxy-4,5-benzotropolone.[5] The present work is undertaken in order to obtain such a type of compound by means of azo-coupling and the hydroxylation of 3,4-benzotropolone (I) and its halogen derivatives (II, III and IV).

It has been found that monocyclic tropolones, like phenols, undergo azo-coupling with ease to give 5-arylazotropolones in fair yields.[6] On the other hand, I, II, III, and IV reacted sluggishly with diazotized amines to afford azo-compounds or rearrangement products, along with a considerable amount of tar, as is summarized in Table I. An attempted azo-coupling of I in an alkaline solution gave only a resinous product, no definite product being isolated. The azo-coupling of I with diazotized aniline was effected in an acetic acid solution in the presence of sodium acetate to yield phenylazo-3,4-benzotropolone (V), whose infrared absorption spectrum exhibited a carbonyl band in the region below 1650 $cm^{-1}$ (Experimental), agreeing with a spectral feature of troponoid compounds.[7] V is either the 5- or the 7-phenylazo-compound, based upon the *o*, *p*-directing effect of its hydroxyl group; it seems more likely to be the former because its ultraviolet absorption spectrum resembles that of the 5-phenylazo-compound (VII, described below), as is shown in Fig. 1. The azo-coupling of I with diazotized aniline proceeded in a different mode when carried out in a pyridine solution; then it yielded an uncharacterized azo-compound (VI), the infrared absorption spectrum of which showed no carbonyl band (Experimental).

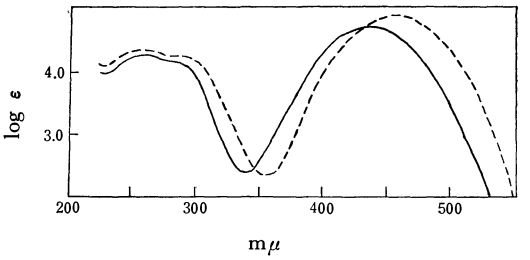

Fig. 1. Ultraviolet absorption spectra of 5-phenylazo-3,4-benzotropolone (V, ——) and 5-phenylazo-7-bromo-3,4-benzotropolone (VII, ----) in methanol.

The azo-coupling of 7-bromo-3,4-benzotropolone (IIa) with diazotized aniline in an acetic acid solution gave 5-phenylazo-7-bromo-3,4-benzotropolone (VII). However, when carried out in a pyridine solution, the same reaction resulted in the formation of rearrangement products, 2-phenyl-2*H*-benz[g]indazole-4,5-dione (VIIIa) and 2-phenylazo-1-naphthol (IX). Similarly, the azo-coupling of IIa with diazotized *p*-toluidine in a pyridine solution gave 2-(*p*-tolyl)-2*H*-benz[g]indazole-4,5-dione (VIIIb), but it did not produce an isolable amount of an azonaphthol. When the coupling component was *p*-methoxybenzenediazonium chloride, the products were 2-(*p*-anisylazo)- and 2,4-bis(*p*-anisylazo)-1-naphthols, no indazole derivative being produced. The azo-coupling of 7-chloro-3,4-benzotropolone (IIb) with diazotized aniline in a pyridine solution gave only IX, no indazole derivative again being isolated. The structure of VIII was established by the following reactions: (a) VIII was reduced to a leuco compound, which easily regenerated the original material on exposure to air; (b) VIII produced a diacetate (XII) on reductive acetylation and a quinoxaline derivative on treatment with *o*-phenylenediamine; (c) VIII was oxidized with peracetic acid to 1-phenyl- or 1-(*p*-tolyl)-3-(*o*-carboxyphenyl)pyrazole-4-carboxylic acid (XIIIa or XIIIb), and then XIIIa was decarboxylated by heating it with copper powder to give 1,3-diphenylpyrazole (XIV), whose melting point was undepressed on admixture with an authentic sample[8]; the infrared spectra of the two samples were also identical in all respects. Although it is not clear why the reaction of IIa with a diazotized amine gives rearrangement products

in a pyridine solution, whereas it gives a normal azo-coupling product in an acetic acid solution, possible courses for the formation of VIII and IX are tentatively illustrated by Schemes 1 and 2 respectively. III coupled with diazotized aniline to yield $C_{17}H_{11}O_2N_2Br$ (X), which showed an infrared absorption band at 1685 $cm^{-1}$, suggesting the presence of a non-troponoid carbonyl group. 5,7-Dibromo- and 5,7-dichloro-3,4-benzotropolones (IVa and IVb) reacted with diazotized aniline and *p*-toluidine, undergoing azo-coupling followed by rearrangement to the corresponding 2-arylazo-4-halogeno-1-naphthols (XI). This reaction is also illustrated by Scheme 2.

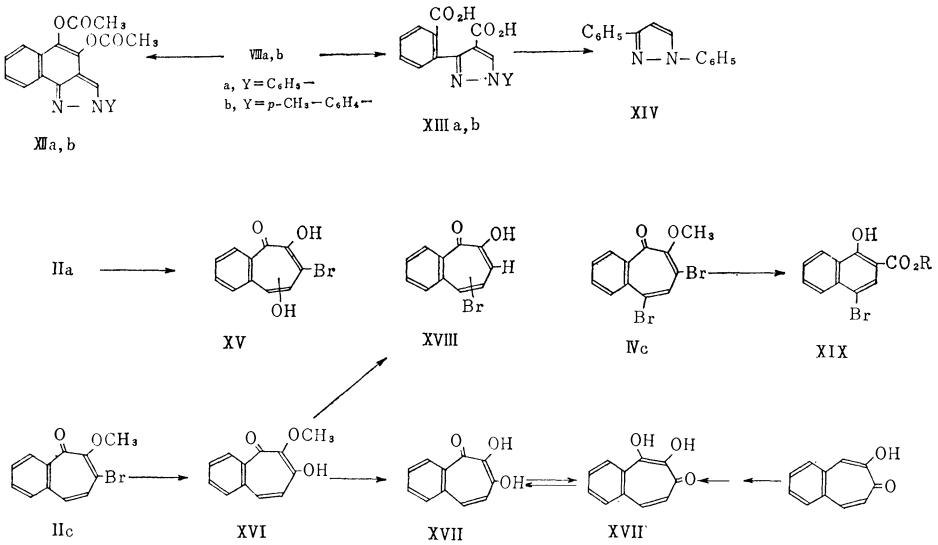

TABLE I. AZO-COUPLING PRODUCTS OF 3, 4-BENZOTROPOLONE AND ITS DERIVATIVES

| 3, 4-Benzotropolone and its derivative | Product (in acetic acid) | Product (in pyridine) |
|---|---|---|
|  I |  V | $C_{16}H_{12}ON_2$ VI |
|  IIa, X=Br IIb, X=Cl |  VII |  VIIIa, Y=$C_6H_5$ VIIIb, Y=*p*-$CH_3C_6H_4$ |  IX |
|  III | $C_{17}H_{11}O_2N_2Br$ X | X |
|  IVa, X=Br IVb, X=Cl |  XIa, X=Br, Y=$C_6H_5$ XIb, X=Cl, Y=$C_6H_5$ XIc, X=Br, Y=*p*-$CH_3C_6H_4$ | XI |

Scheme 3, IVc $\xrightarrow{KOH}$  XIX

Attempts were then made to obtain hydroxybenzotropolones. According to the method of hydroxylation of monocyclic tropolones,[9] I and IIa were subjected to persulfate oxidation; the former failed to give a definite product, but the latter furnished 5(?)-hydroxy-7-bromo-3,4-benzotropolone (XV). 7-Bromo-3,4-benzotropolone methyl ether (IIc) reacted with methanolic alkali, affording 6-hydroxy-7-methoxy-2,3-benzotropone (XVI). The treament of IIc with alkali results in the hydrolysis of the bromine atom, giving XVI, whereas monocyclic 2-methoxy-7-bromotropone with alkali results in the hydrolysis of the methoxyl group, giving 3-bromotropolone.[10] Such a difference has been pointed out previously.[11] The further hydrolysis of XVI with concentrated hydrochloric acid gave 6,7-dihydroxy-2,3-benzotropone (XVII), which was identical with Fernholz and his co-workers' 3-hydroxy-4,5-benzotropolone (XVII'),[5] obtained by the bromination and subsequent hydrolysis of 4,5-benzotropolone. The bromination of XVI yielded 4(?)-bromo-6,7-dihydroxy-2,3-benzotropone (XVIII) or its tautomer. 5,7-Dibromo-3,4-benzotropolone methyl ether (IVc), unlike IIc, reacted with methanolic alkali to yield rearrangement products, 1-hydroxy-4-bromo-2-naphthoic acid and its methyl ether (XIX). It is of interest that 3,4-benzotropolone and its derivatives have a tendency to undergo azo-coupling and other reactions, accompanied with rearrangement.

## Experimental

**The Azo-coupling of 3,4-Benzotropolone (I).**—*5-Phenylazo-3,4-benzotropolone (V).*—A solution of 175 mg. of aniline in 2.3 ml. of 2.4 N hydrochloric acid was diazotized with 1.1 g. of 10% sodium nitrite. The benzenediazonium chloride solution was then dropped into an ice-cooled mixture of 250 mg. of I dissolved in 25 ml. of acetic acid and 4.5 g. of sodium acetate dissolved in 13.5 ml. of water. After the mixture had been stirred for 1 hr., the red precipitate was collected and crystallized from acetone to yield 120 mg. (30%) of V; red plates; m. p. 148—150°C; infrared spectrum in the 1800—1500 $cm^{-1}$ region (KBr): 1622, 1587, 1560 $cm^{-1}$.

Found: C, 73.59; H, 4.19; N, 9.95. Calcd. for $C_{17}H_{12}O_2N_2$: C, 73.90; H, 4.38; N, 10.14%.

*An Uncharacterized Azo-compound (VI).*—Aniline (350 mg.) dissolved in 4.6 ml. of 2.4 N hydrochloric acid was diazotized with 2.2 g. of 10% sodium nitrite; the resulting solution was dropped into an ice-cooled solution of 500 mg. of I in 15 ml. of pyridine. After standing overnight in an ice-chest, the solution was concentrated below 30°C under reduced pressure to give a dark red, tarry residue. The residue was then dissolved in benzene and chromatographed on silica gel, affording 100 ml. (14%) of VI; brownish red needles; m. p. 171.5—172.5°C after recrystallization from ethanol; infrared spectrum (Nujol): 3333, 1595, 1580, 1536, 1511, 1429, 1319, 1163, 1020, 821, 757 $cm^{-1}$.

Found: C, 77.61; H, 4.64; N, 11.44. Calcd. for $C_{16}H_{12}ON_2$: C, 77.40; H, 4.87; N, 11.28%.

**The Azo-coupling of 7-Bromo- and 7-Chloro-3,4-benzotropolones (IIa and IIb).**—*5-Phenylazo-7-bromo-3,4-benzotropolone (VII).*—A solution of 200 mg. of IIa and 2.5 g. of sodium acetate in 80 ml. of acetic acid was treated with a benzenediazonium chloride solution prepared from 96 mg. of aniline in a manner described above. The product was recrystallized from petroleum ether to yield 80 mg. (28%) of VII as brownish orange needles; m. p. 168—169°C; infrared spectrum in the 1800—1500 $cm^{-1}$ region (KBr): 1615, 1584, 1547, 1522 $cm^{-1}$.

9) T. Nozoe, S. Seto and S. Ito, *Proc. Japan Acad.*, **28**, 488 (1952); T. Nozoe, S. Seto, S. Ito, M. Sato and T. Katono, *Sci. Repts. Tohoku Univ., I*, **37**, 191 (1953).

10) T. Nozoe, Y. Kitahara and S. Masamune, *Proc. Japan Acad.*, **27**, 649 (1951).

11) S. Ebine, This Bulletin, **34**, 887 (1961).

Found: C, 57.55; H, 3.21; N, 7.62. Calcd. for $C_{17}H_{11}O_2N_2Br$: C, 57.48; H, 3.12; N, 7.89%.

*2-Phenyl- and 2-(p-Tolyl)-2H-benz[g]indazole-4, 5-diones (VIIIa and VIIIb).*—To an ice-cooled solution of 500 mg. of IIa in 15 ml. of pyridine there was added, drop by drop, a solution of benzenediazonium or *p*-toluenediazonium chloride prepared by the action of 1.4 g. of 10% sodium nitrite on 240 mg. of aniline or 280 mg. of *p*-toluidine dissolved in 3.2 ml. of 2.4 N hydrochloric acid. Dilution with an equal volume of water gave a precipitate, which was then filtered and recrystallized from ethanol to yield 160 mg. (29%) of VIIIa or 400 mg. (69%) of VIIIb, along with a 20% recovery of IIa. The pyridine filtrate contains azonaphthols as will be described below.

VIIIa; yellow needles; m. p. 251°C; infrared spectrum (Nujol): 3160, 1678, 1603, 1545, 1330, 1275, 1247, 910, 757, 700 $cm^{-1}$.

Found: C, 74.35; H, 3.85; N, 10.29. Calcd. for $C_{17}H_{10}O_2N_2$: C, 74.44; H, 3.68; N, 10.21%.

VIIIb; orangeish yellow needles; m. p. 273°C; infrared spectrum (Nujol): 3150, 1670, 1600, 1560, 1510, 1408, 1275, 1245, 1230, 957, 907, 863, 814, 772, 697 $cm^{-1}$.

Found: C, 74.78; H, 4.50; N, 9.98. Calcd. for $C_{18}H_{12}O_2N_2$: C, 74.99; H, 4.20; N, 9.72%.

*Azonaphthols.*—The pyridine filtrate obtained from VIIIa of the above experiment was concentrated under reduced pressure to a tarry residue; this was then dissolved in benzene and chromatographed on silica gel, yielding 45 mg. (9%) of 2-phenylazo-1-naphthol (IX). (Found: C, 77.59; H, 4.90; N, 11.44. Calcd. for $C_{16}H_{12}ON_2$: C, 77.40; H, 4.87; N, 11.28%; m. p. 134°C, the melting poing being undepressed on admixture with an authentic sample prepared by the condensation of 1, 2-naphthoquinone with phenylhydrazine.)

The pyridine filtrate from VIIIb, unlike that from VIIIa, gave no azonaphthol.

The azo-coupling of 500 mg. of IIa with a 1-mole equivalent of diazotized *p*-anisidine in a pyridine solution gave 65 mg. (12%) of 2-(*p*-anisylazo)-1-naphthol as red needles, m. p. 124°C (Found: C, 73.40; H, 4.99; N, 9.90. Calcd. for $C_{17}H_{14}O_2N_2$: C, 73.36; H, 5.07; N, 10.07%) and 30 mg. (3.6%) of 2, 4-bis(*p*-anisylazo)-1-naphthol as dark-brown fibrous needles, m. p. 182.5°C (Found: N, 13.40. Calcd. for $C_{24}H_{20}O_3N_4$: N, 13.59%), after the same work-up as above.

A pyridine solution of IIb (500 mg.) was coupled with benzenediazonium chloride in the same way as above, and the crude product was dissolved in benzene and chromatographed on silica gel to afford IX (85 mg., 14%), m. p. and mixed m. p. 134°C, with no benzindazoledione derivative.

**Reaction of VIIIa and VIIIb.**—*Hydrogenation.*—VIIIa or VIIIb (100 mg.) in 40 ml. of dioxane was hydrogenated over 50 mg. of 5% palladium-on-charcoal at atmospheric pressure until no further uptake of hydrogen was observed. The yellow solution faded during hydrogenation, but colored again on exposure to air. The removal of the catalyst and solvent left the original material (identified by a mixed melting point determination) in a quantitative recovery.

*Reductive Acetylation.*—A suspension of 100 mg. of VIIIa (or VIIIb) and 500 mg. of fused sodium acetate in 20 ml. of acetic anhydride was treated with 300 mg. of zinc powder. After the reaction mixture had become nearly colorless, the excess acetic anhydride was decomposed with water, the precipitate was extracted with boiling alcohol, the extract was concentrated, and the product was recrystallized from ethanol.

2-Phenyl-4, 5-diacetoxy-2*H*-benz[g]indazole (XIIa); colorless, fibrous needles; m. p. 191°C; yield 100 mg. (85%).

Found: C, 70.20; H, 4.20; N, 7.66. Calcd. for $C_{21}H_{16}O_4N_2$: C, 69.99; H, 4.48; N, 7.77%.

2-(*p*-Tolyl)-4, 5-diacetoxy-2*H*-benz[g]indazole (XIIb); colorless, fibrous needles; m. p. 167—168°C; yield 100 mg. (77%).

Found: C, 70.59; H, 4.95; N, 7.44. Calcd. for $C_{22}H_{18}O_4N_2$: C, 70.58; H, 4.85; N, 7.48%.

XIIa and XIIb underwent hydrolysis, followed by autoxidation, to regenerate VIIIa and VIIIb respectively when 10 mg. of the sample was heated in 1.5 ml. of ethanol containing 3 drops of concentrated hydrochloric acid.

*Reaction with o-Phenylenediamine.*—*o*-Phenylenediamine (120 mg.) and 80 mg. of VIIIa (or VIIIb) in 10 ml. of acetic acid were refluxed for 10 min.; the precipitate which separated on cooling was recrystallized from benzene.

Quinoxaline derivative of VIIIa; pale yellow needles; m. p. 233—234°C.

Found: C, 79.92; H, 3.90; N, 15.90. Calcd. for $C_{23}H_{14}N_4$: C, 79.75; H, 4.07; N, 16.18%.

Quinoxaline derivative of VIIIb; pale yellow needles; m. p. 252°C.

Found: C, 79.83; H, 4.52; N, 15.50. Calcd. for $C_{24}H_{16}N_4$: C, 79.98; H, 4.48; N, 15.55%.

*Oxidation with Permanganate.*—Aqueous potassium permanganate (10%, 15 ml.) was dropped into a solution of 200 mg. of VIIIa (or VIIIb) in 20 ml. of pyridine while the solution was being heated on a water bath. After 1 hr.'s heating, the pyridine was removed under reduced pressure, and the manganese dioxide was dissolved with sulfurous acid. The resulting solution was saturated with sodium chloride and extracted with ether. The evaporation of the solvent from the extract gave 90 mg. (74%) of phthalic acid, which was identified by converting it to phthalanil; m. p. and mixed m. p. 205—206°C.

*Oxidation with Peracetic Acid.*—To a solution of 200 mg. of VIIIa (or VIIIb) in 80 ml. of acetic acid containing 6 ml. of concentrated sulfuric acid there was added, drop by drop, 5 ml. of 30% hydrogen peroxide over a period of 1 hr. at 40°C. After being kept at the same temperature for another hour, the solution was concentrated to 10 ml. below 40°C under reduced pressure. Dilution with an equal volume of water gave a precipitate, which was then recrystallized from acetic acid.

1-Phenyl-3-(*o*-carboxyphenyl)pyrazole-4-carboxylic acid (XIIIa): colorless needles; m. p. 284—285°C (with decomposition); yield 180 mg. (80%).

Found: C, 66.34; H, 4.19; N, 9.09. Calcd. for $C_{17}H_{12}O_4N_2$: C, 66.23; H, 3.92; N, 9.09%.

1-(*p*-Tolyl)-3-(*o*-carboxyphenyl)pyrazole-4-carboxylic acid (XIIIb): colorless needles; m. p. 300—302°C (with decomposition); yield 160 mg. (71%).

Found: C, 66.94; H, 4.14; N, 8.80. Calcd. for $C_{18}H_{14}O_4N_2$: C, 67.07; H, 4.38; N, 8.69%.

*The Decarboxylation of XIIIa.*—A mixture of 200 mg. of XIIIa and 200 mg. of copper powder was heated at 285—295°C under 5-mmHg pressure for 10 min., the sublimate was then recrystallized from dilute ethanol to give 130 mg. (91%) of 1,3-diphenylpyrazole (XIV) melting at 84—84.5°C. (Found: C, 81.43; H, 5.70; N, 12.59. Calcd. for $C_{15}H_{12}N_2$: C, 81.79; H, 5.49; N, 12.72%.) The melting point was not depressed on admixture with an authentic sample, and infrared spectra of the two samples were superimposable.

**The Azo-coupling of 5-Bromo-3,4-benzotropolone (III).**—III (500 mg.) in acetic acid or pyridine was coupled with benzenediazonium chloride prepared from 240 mg. of aniline. After the same work-up as before, there was obtained an uncharacterized azo-compound (X) as red plates; m. p. 160—161°C; yields 150 mg. (21%) in an acetic acid solution and 110 mg. (16%) in a pyridine solution; infrared spectrum (KBr): 1685, 1614, 1587, 1506, 1459, 1384, 1192, 1168, 940, 758 $cm^{-1}$.

Found: C, 57.65; H, 2.99; N, 7.89. Calcd. for $C_{17}H_{11}O_2N_2Br$: C, 57.48; H, 3.12; N, 7.89%.

**The Azo-coupling of 5,7-Dibromo- and 5,7-Dichloro-3,4-benzotropolones (IVa and IVb).**—A solution of 500 mg. of IVa and 5 g. of sodium acetate in 75 ml. of acetic acid was treated with a diazonium chloride solution prepared from 185 mg. of aniline or 212 mg. of *p*-toluidine, and the azo-compound which resulted was recrystallized from ethanol. Azo-coupling carried out in a pyridine solution gave the same result. When IVb was substituted for IVa, the corresponding azo-compound was produced.

2-Phenylazo-4-bromo-1-naphthol (XIa); red needles; m. p. 178.5°C; yields 140 mg. (28%) in acetic acid, and 110 mg. (22%) in pyridine.

Found: C, 58.56; H, 3.43; N, 8.32. Calcd. for $C_{16}H_{11}ON_2Br$: C, 58.73; H, 3.39; N, 8.56%.

2-Phenylazo-4-chloro-1-naphthol (XIb): fibrous red needles; m. p. 160°C; yield 170 mg. (29%) in acetic acid.

Found: C, 68.04; H, 3.74; N, 9.50. Calcd. for $C_{16}H_{11}ON_2Cl$: C, 67.97; H, 3.92; N, 9.91%.

2-(*p*-Tolylazo)-4-bromo-1-naphthol (XIc): fibrous, reddish orange needles; m. p. 183—184°C; yield 150 mg. (29%) in a pyridine solution.

Found: C, 60.08; H, 3.97; N, 8.48. Calcd. for $C_{17}H_{13}ON_2Br$: C, 59.84; H, 3.84; N, 8.21%.

XIc showed no melting point depression on admixture with the sample (Found: C, 61.00; H, 4.05; N, 8.50%) prepared by the azo-coupling of 4-bromo-1-naphthol with *p*-toluenediazonium chloride in a pyridine solution.

The above azonaphthols were then subjected to reductive acetylation. To a suspension of 100 mg. of XIa or XIb and 500 mg. of fused sodium acetate in 3 ml. of acetic anhydride there was added 300 mg. of zinc powder in small portions. After the excess acetic anhydride had been decomposed with water, the precipitate was extracted with ethyl acetate. Upon cooling, the extrct gave the product, which was recrystallized from the same solvent.

1-Acetoxy-2-acetamino-4-bromonaphthalene: stout colorless needles; m. p. 232°C; yield 65 mg. (65%).

Found: C, 51.95; H, 3.85; N, 4.63. Calcd. for $C_{14}H_{12}O_3NBr$: C, 52.18; H, 3.75; N, 4.35%.

1-Acetoxy-2-acetamino-4-chloronaphthalene: fibrous colorless needles; m. p. 195—200°C; yield 67 mg. (68%).

Found: C, 60.20; H, 4.03; N, 4.70. Calcd. for $C_{14}H_{12}O_3NCl$: C, 60.55; H, 4.36; N, 5.04%.

**5(?)-Hydroxy-7-bromo-3,4-benzotropolone (XV).**—IIa (500 mg.) was dissolved in a mixture of 20 ml. of 0.4 N potassium hydroxide and 8 ml. of pyridine; to this there was added, drop by drop, a solution of 450 mg. of potassium persulfate in 15 ml. of water over a 2-hr. period with ice-cooling. After it had stood in an ice-chest for 3 days, the reaction mixture was strongly acidified with 100 ml. of concentrated hydrochloric acid to give a precipitate, whose recrystallization from ethanol gave 210 mg. of unchanged material (m. p. and mixed m. p. 147°C) and 150 mg. (28%) of XV; yellow needles; m. p. 317—320°C, with a darkening at 180°C; infrared spectrum in the 1800—1500 $cm^{-1}$ region (Nujol): 1616, 1606, 1585 $cm^{-1}$.

Found: C, 49.67; H, 2.87. Calcd. for $C_{11}H_7O_3Br$: C, 49.46; H, 2.64%.

**6-Hydroxy-7-methoxy-2,3-benzotropone (XVI).**—7-Bromo-3,4-benzotropolone methyl ether (IIc) (300 mg.) was dissolved in methanolic alkali prepared from 15 ml. of methanol and 1.2 g. of 50% potassium hydroxide, and then allowed to stand at room temperature for 10 hr. The reaction mixture was acidified with dilute hydrochloric acid and concentrated; after the inorganic salt had been removed by washing the mixture with water, the precipitate was recrystallized from dilute ethanol to give 165 mg. (86%) of pale yellow scales; m. p. 103.5—104.5°C; infrared spectrum in the 1800—1500 $cm^{-1}$ region (KBr): 1632, 1570, 1525 $cm^{-1}$; ultraviolet spectrum (MeOH): $m\mu$ (log $\varepsilon$), 260(4.55), 268(4.56), 350(3.90).

Found: C, 65.53; H, 5.56. Calcd. for $C_{12}H_{10}O_3 \cdot H_2O$: C, 65.44; H, 5.49%.

An anhydrous sample, m. p. 115—116°C, was obtained by drying over phosphorous pentoxide for 2 days at room temperature.

Found: C, 71.56; H, 5.06. Calcd. for $C_{12}H_{10}O_3$: C, 71.28; H, 4.99%.

Benzylamine salt: pale yellow scales; m. p. 165—169°C.

Found: C, 73.88; H, 6.32; N, 4.82. Calcd. for $C_{12}H_{10}O_3 \cdot C_7H_9N$: C, 73.76; H, 6.19; N, 4.53%.

**6,7-Dihydroxy-2,3-benzotropone (XVII).**—A solution of 100 mg. of XVI in 2 ml. of concentrated hydrochloric acid was heated in a sealed tube at 135—140°C for 5 hr. Dilution with an equal volume of water and the recrystallization of the precipitate from water yielded 65 mg. (70%) of yellow needles; m. p. 133.5°C; infrared spectrum in the 1800—1500 $cm^{-1}$ region (Nujol): 1640, 1595, 1522 $cm^{-1}$; ultraviolet spectrum (MeOH): $m\mu$ (log $\varepsilon$), 248(4.50), 270(4.56), 370(3.90); (Found: C, 70.07; H, 4.15. Calcd. for $C_{11}H_8O_3$: C, 70.21; H, 4.29%).

*4(?)-Bromo-6,7-dihydroxy-2,3-benzotropone (XVIII).*—Bromine (320 mg.) was dropped into a solution of 200 mg. of XVI in 2 ml. of acetic acid, whereupon a reddish-violet powder precipitated immediately. The whole was heated on a water bath for 1 hr. and then diluted with 20 ml. of water, giving 100 mg. (38%, after recrystallization from ethanol) of XVIII as yellow needles; m. p. 198.5°C; infrared spectrum in the 1800—1500 $cm^{-1}$ region (Nujol): 1604, 1540, 1510

$cm^{-1}$: ultraviolet spectrum (MeOH): $m\mu$ (log $\varepsilon$), 280(4.74), 328(3.70), 380(3.74).

Found: C, 49.33; H, 2.71. Calcd. for $C_{11}H_7O_3Br$: C, 49.46; H, 2.64%.

The reddish-violet powder described above was an intermediate product which regenerated XVI upon being heated with water.

Dimethyl ether: colorless needles from methanol; m. p. 73—75°C.

Found: C, 53.15; H, 3.75. Calcd. for $C_{13}H_{11}O_3Br$: C, 52.91; H, 3.76%.

**The Action of Alkali on 5, 7-Dibromo-3, 4-benzotropolone Methyl Ether (IVc).**—A solution of 300 mg. of IVc in 60 ml. of methanol containing 1.2 g. of 50% of potassium hydroxide was set aside overnight at room temperature. After acidification with dilute hydrochloric acid, the solvent was distilled, and the residue was then recrystallized from methanol to give 180 mg. (73%) of methyl 1-hydroxy-4-bromo-2-naphthoate (XIX, R=$CH_3$) (m. p. 120—121°C) (Found: C, 51.08; H, 3.42. Calcd. for $C_{12}H_9O_3Br$: C, 51.27; H, 3.23%); when treated with diazomethane, this gave methyl 1-methoxy-4-bromo-2-naphthoate, (m. p. 94°C) (Found: C, 53.09; H, 3.71. Calcd. for $C_{13}H_{11}O_3Br$: C, 52.90; H, 3.76%). When carried out under reflux, this reaction gave 1-hydroxy-4-bromo-2-naphthoic acid (XIX, R=H) (m. p. and mixed m. p. 237°C with decomposition).

Grateful acknowledgement is hereby made to Professor Tetsuo Nozoe of Tohoku University for his guidance throughout this work. Thanks are also due to Miss Ayako Iwanaga of Tohoku University for her microanalyses.

# Compounds Related to Acridine. III.*,[1] The Formation of Acridone in the Reaction of 9-Methylacridine with *p*-Nitrosodimethylaniline

By Otohiko TSUGE and Minoru NISHINOHARA**

(Received July 23, 1965)

In a previous paper[2] dealing with the condensations of the acridine with an active methyl group and of the aromatic nitroso compound, it was shown that the presence of a catalytic amount of hydrochloric acid (HA) revealed interesting features regarding the yields and the amounts of the anil and of the nitrone compound relative to those in the presence of the alkaline catalyst usually used in such reactions.

It was also reported there that in the reaction of 9-methylacridine (I) with *p*-nitrosodimethylaniline (II), a higher-melting substance, m. p. over 300°C, whose structure was not identified, came to be formed as the amount of HA increased, and that its maximum yield was obtained when equimolar amounts of I and of HA were used.

Since the structure of the higher-melting substance has now been clarified, further investigation was undertaken in order to elucidate the course of the formation of the compound.

## Results and Discussion

After the higher-melting substance obtained in the previous paper[2] was washed with hydrochloric acid, recrystallization from a large amount of benzene or sublimation afforded pale yellow prisms, m. p. 354°C. This compound was proved, by the admixed melting point and by the infrared spectrum, to be identical with acridone (III), which was prepared from 9-chloroacridine.[3]

It may be supposed that *N*-(*p*-dimethylaminophenyl)-$\alpha$-(9-acridyl)nitrone (IV), which is the main product when a catalytic amount of HA was used, and acridine-9-carboxaldehyde *N*-(*p*-dimethylaminophenyl)anil (V) could be formed at an initial stage of the reaction when a sufficient amount of HA was used.

It is well known that both IV and V are almost quantitatively hydrolyzed by dilute hydrochloric acid to afford acridine-9-carboxaldehyde (VI), and we found that the nitroso compound (II) was also formed in the hydrolysis of IV. The treatment of IV with an equimolar amount of HA in ethanol, however, afforded III, and the similar treatment of V resulted only in the formation of VI. Further, III was formed not only from IV but also

Chart 1

from V in the heating with II in the presence of HA, as is depicted in Chart 1.

These observations indicate that both II and HA play an important role in the formation of III. It could be postulated that both IV and V will be hydrolyzed to afford VI in the presence of sufficient amounts of HA, and that III is formed from VI by a secondary reaction. In fact, it was found that the treatment of VI with II in the presence of HA in ethanol gave III in a high yield, besides a small amount of *p,p'*-bis(dimethylamino)azoxybenzene (VII). However, III was not formed from VI when treated with II or with HA alone.

On the basis of the facts mentioned above, the possible courses of the formation of III from VI are shown in Chart 2. It has been established that acridine *N*-oxide (VIII) rearranges to III in the heating with acetic anhydride.[4] As VIII was not rearranged to III under the reaction conditions, the possibility that VIII, which might be formed through the courses a and /or b by the oxidative property of II, may be rearranged to III was excluded. It was also recognized that III was not formed from either acridine-9-carboxlic acid (XI) or acridine (X) under similar conditions.

Now, the replacement of the formyl group by the hydroxyl group by the action of a peroxide has been known as the Dakin hydroxylation reaction, which proceeds through the formate.[5] If III is formed through 9-acridyl formate (XI), as is shown in the course c, the treatment of VI with a peroxide should give III.

The treatment of VI with hydrogen peroxide in ethanol or with perbenzoic acid in chloroform really gave III with a good yield. Furthermore, the formate (XI) was isolated when the reaction of VI with hydrogen peroxide was quenched after a short while. Although XI could not be isolated

R= $p$-$C_6H_4N(CH_3)_2$

Chart 3

in the reaction of VI with II in the presence of HA in ethanol, ethyl formate was identified by the gas chromatographic analysis of the distillate of the reaction mixture, as in the case of the reaction with hydrogen peroxide.

On the basis of these observations, it is reasonable to conclude that the formation of III from VI in the presence of II and HA proceeds through the course c.

The results of the effect of the amounts of II and of HA on the yield of III are shown in Fig. 1. It is notable that III was formed with a high yield even if an amount of II equimolar to VI and a catalytic amount of HA were used.

On the other hand, it was found that, in the treatment of VI with II in the presence of sodium hydroxide in ethanol, a small amount of the anil compound (V) was obtained, besides the azoxy compound (VII). Similar treatment in the presence of acetic acid in place of sodium hydroxide gave III, V and VII. The formation of V indicates that II was in part reduced to the corresponding amine in the reactions, since V can be formed only by the condensation of VI and the amine. Such a reduction of II to the amine would take place in the presence of HA. The above scheme is shown in Chart 3.

Further investigation of the oxidative property of II in the presence of HA will be published elsewhere in the near future.

## Experimental[6,7]

**The Reaction of 9-Methylacridine (I) with $p$-Nitrosodimethylaniline (II).**—A solution of 1.0 g. of I, 1.6 g. of II and 0.4 ml. of HA in 50 ml. of ethanol was refluxed for 2 hr. and then allowed to stand overnight. Filtration gave crystals which, on being washed with hot benzene (5 ml.×2), left 0.6 g. (35.4%) of the nitrone compound (IV) as reddish-brown prisms, m. p. 243°C (decomp.).[2] The benzene washings were then evaporated to give a small amount of the anil (V) as red prisms, m. p. 248°C.[2] The ethanol filtrate after the reaction was concentrated in vacuo, and then the residue was washed with concentrated hydrochloric acid to leave 0.46 g. of the higher-melting compound, m. p. over 300°C. Recrystallization from a large amount of benzene or sublimation gave pale yellow prisms, m. p. 354°C. This compound was proved, by the admixed melting point and by the infrared spectrum, to be identical with the acridone (III) which was obtained by the hydrolysis of 9-chloracridine.

Found: C, 79.93; H, 4.73; N, 7.05. Mol. wt. 191.[8] Calcd. for $C_{13}H_9ON$: C, 79.98; H, 4.65; N, 7.17%. Mol. wt. 195.2.

The results of other reactions under varying conditions have been reported in a previous paper.[2]

**The Formation of Acridone (III) from the Nitrone (IV) or Anil Compound (V).**—i) A mixture of 1.7 g. of IV and 0.4 ml. of HA in 50 ml. of ethanol was refluxed for 3 hr. After a large part of the ethanol had been evaporated in vacuo, the residue was washed with concentrated hydrochloric acid (5 ml.×2), aqueous ammonia, and then water to leave 0.38 g. (39%) of yellow crystals, m. p. 335—340°C. Recrystallization from a large amount of benzene gave yellow prisms, m. p. 354°C, whose infrared spectrum was superimposable on that of acridone.

The similar treatment of 0.8 g. of V and 0.2 ml. of HA in 30 ml. of ethanol afforded 0.37 g. (71%) of acridine-9-carboxaldehyde (VI), m. p. 147°C (lit.[9] 147°C).

ii) A mixture of 1.0 g. of IV, 1.0 g. of II and 0.3 ml. of HA in 30 ml. of ethanol was refluxed for 3 hr. and then cooled. Filtration gave 0.37 g. of brown crystals, m. p. 225—230°C, which, on recrystallization from benzene, afforded pale brown prisms, m. p. 240—241°C. This compound was proved by a study of its infrared spectrum to be identical with an authentic sample of $p,p'$-bis(dimethylamino)azoxybenzene (VII), m. p. 241—242°C.[10]

After the filtrate had been evaporated in vacuo, the residue was washed with hydrochloric acid, aqueous

6) All melting points are uncorrected.

7) HA used in this experiment: $d^{27}$ 1.1748.

8) Molecular weight was measured by the cryoscopic method, using dimethylsulfoxide (molecular depression constant=4.24) as the solvent.

9) L. Chardonnens and P. Heinrich, *Helv. Chim. Acta*, **32**, 656 (1949).

10) H. von Pechmann and W. Schmitz, *Ber.*, **31**, 295 (1898).

ammonia and then water to leave 0.34 g. (60%) of III.

A similar reaction of 0.5 g. of V with 0.5 g. of II in the presence of 0.15 ml. of HA in 20 ml. of ethanol afforded 0.18 g. (60%) of III and 0.18 g. of VII.

**The Reaciton of the Formyl Compound (VI) with II.**—*In the Presence of HA.*—A mixture of 0.52 g. of VI, 0.56 g. of II and 0.23 g. of the hydrochloride of II in 25 ml. of ethanol was refluxed for 3 hr., and then the ethanol was evaporated in vacuo. The residue was treated with hydrochloric acid, aqueous ammonia and water to give 0.37 g. (76%) of III, m. p. 350—353°C.

The results of other reactions under varying conditions are shown in Fig. 1.

*In the Presence of Sodium Hydroxide.* — A mixture of 0.52 g. of VI, 0.75 g. of II and 0.50 g. of sodium hydroxide in 25 ml. of ethanol was refluxed for 3 hr. and then allowed to stand overnight. Filtration gave 0.12 g. of crystals, m. p. 195—230°C, which were found to be a mixture of V and VII by a study of the infrared spectrum. The recrystallization of the crystals from ethanol gave a small amount of V, m. p. 248°C. From the filtrate, III was not isolated.

*In the Presence of Acetic Acid.* — A mixture of 0.52 g. of VI, 0.75 g. of II and 0.5 ml. of glacial acetic acid in 30 ml. of ethanol was refluxed for 3 hr. Treatment similar to that described above gave 0.10 g. of reddish brown crystals, m. p. 200—225°C, which were found to be a mixture of V and VII by a study of the infrared spectrum. From the filtrate, 0.13 g. of II was obtained.

**The Reaction of the Formyl Compound (IV) with Hydrogen Peroxide.**—*i*) To a solution of 0.52 g. of VI in 25 ml. of ethanol there was added 0.5 ml. of 30% of hydrogen peroxide. The refluxing of the reaction mixture resulted in the precipitation of yellow crystals in several minutes: then it turned into a complete solution. After it had been refluxed for 2 hr., the ethanol was evaporated in vacuo. The residue was washed with hydrochloric acid, aqueous ammonia and then water to obtain 0.44 g. (90%), m. p. 247—250°C, of III.

*ii*) *The Isolation of the Formate (XI).*—After a mixture of 0.25 g. of VI and 0.25 ml. of hydrogen peroxide in 25 ml. of ethanol had been refluxed for 10 min., 0.13 g. of yellow crystals, m. p. 254°C (decomp.), was obtained by filtration. Recrystallization from ethanol then afforded yellow prisms, m. p. 254°C (decomp.).

Found: C, 74.98; H, 4.39; N, 6.22. Calcd. for $C_{14}H_9O_2N$ (XI): C, 75.34; H, 4.04; N, 6.27%.

**The Reaction of the Formyl Compound (VI) with Perbenzoic Acid.**—To 30 ml. of a chloroform solution of perbenzoic acid,[11] 2.0 g. of VI was added under ice-cooling. After the reaction mixture had been stirred under ice-cooling for 3 hr., filtration gave 0.90 g. of III. The filtrate was not examined further.

The authers are deeply grateful to the staff of the Analytical Service Centre of this university of their elemental analyses.

# Compounds Related to Acridine. IV.[1,2] The Condensation of 9-Ethylacridine and *p*-Nitrosodimethylaniline

By Otohiko TSUGE, Minoru NISHINOHARA*[1] and Kunio SADANO[2]*

(Received July 23, 1965)

Recently[3] we found that the condensation of the acridine with an active methyl group and the aromatic nitroso compound, under the influence of a catalytic amount of hydrochloric acid (HA), afforded as condensation products an anil and a nitrone in fairly good yields compared with the yield when an alkaline catalyst is used.

Since, however, no informationn has been available regarding the condensation of the ethyl group and the aromatic nitroso compound, it appeared of interest to investigate whether 9-ethylacridine (I) can be condensed with *p*-nitrosodimethylaniline (II).

## Results and Discussion

The condensation of I and II did not take place in the presence of potassium carbonate, but a small amount of *p*,*p*'-bis(dimethylamino)azoxybenzene (III), m. p. 240—241°C (lit.[4] 241—242°C) was formed.

However, the presence of HA as a catalyst in

1) Preliminary communication: This Bulletin, **37**, 436 (1964).
2) Part III: O. Tsuge and M. Nishinohara, **38**, 2034 (1965).

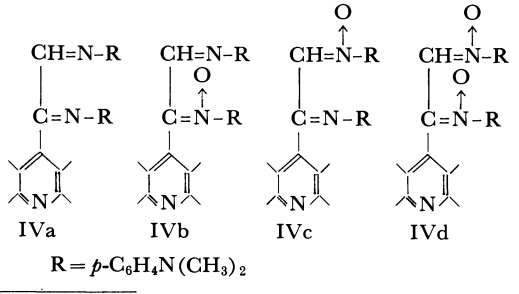
4) H. von Pechmann and W. Schmitz, *Ber.*, **31**, 295 (1898).

place of an alkaline catalyst afforded condensation products (IV) as reddish crystals, m. p. about 260°C (decomp.).

The effect of different amounts of HA on the yield of IV was investigated; the results are shown in Table I. The maximum yield of IV was obtained when the molar ratio of HA to I was about 1.1 (0.2 ml. in Table I); a fairly large amount of HA was needed, in contrast with the case of the condensation of the 9-methylacridine and II. Also, acridone was not formed, even if the amount of HA was increased.

Table I. The effect of differents of HA on the yield of condensation products (IV)*

| HCl ml. | Yield g. | HCl ml. | Yield g. |
|---|---|---|---|
| 0.01 | trace | 0.3 | 1.05 |
| 0.03 | trace | 0.4 | 0.70 |
| 0.1 | 0.96 | 0.8 | 0.01 |
| 0.2 | 1.28 | | |



* Mixtures of I (1.0 g.), II (1.4 g.) and the specified amounts of HA in ethanol (20 ml.) were refluxed for 3 hr.

The hydrolysis of IV with 12% aqueous hydrochloric acid afforded acridine-9-carboxaldehyde (V), m. p. 147°C (lit.[5] 147°C), in a high yield. On the other hand, the treatment of IV with cold 10% aqueous sulfuric acid gave orange prisms (VI), m. p. 208°C (decomp.). The elemental analytical data of VI were in agreement with the formula $C_{23}H_{19}O_2N_3$, whose infrared spectrum exhibited the sharp bands at 1662 and 1604 $cm^{-1}$ ascribed to the carbonyl group and the C=N bond respectively. Also, the qualitative test for the formyl group by the Tollens reagent was positive.

Furthermore, VI was oxidized with silver oxide to give *N*-(*p*-dimethylaminophenyl)-$\alpha$-(9-acridyl)-nitrone (VII),[3] m. p. 243°C (decomp.), which was then easily hydrolyzed with dilute hydrochloric acid to V. VI was also easily hydrolyzed with the dilute acid to give V.

These observations indicate that VI is 9-acridylglyoxal-$\alpha$-*N*-(*p*-dimethylaminophenyl)nitrone.

In view of the fact that V and VI were obtained by the hydrolysis of IV, it seems most reasonable to assume that IV is either one of the compounds (IVa—IVd) whose structrues correspond with those of the condensation products of one mole of I and two moles of II, or a mixture of them.

R = *p*-$C_6H_4N(CH_3)_2$

The condensation of VI and *p*-aminodimethylaniline afforded 9-acridylglyoxal-$\alpha$-*N*-(dimethylaminophenyl)nitrone-$\beta$-*N*-(*p*-dimethylaminophenyl)anil (IVb), which was identified by an elemental analysis, as reddish-brown prisms, m. p. 265°C (decomp.). The infrared spectrum of IVb in KBr is given in Fig. 1.

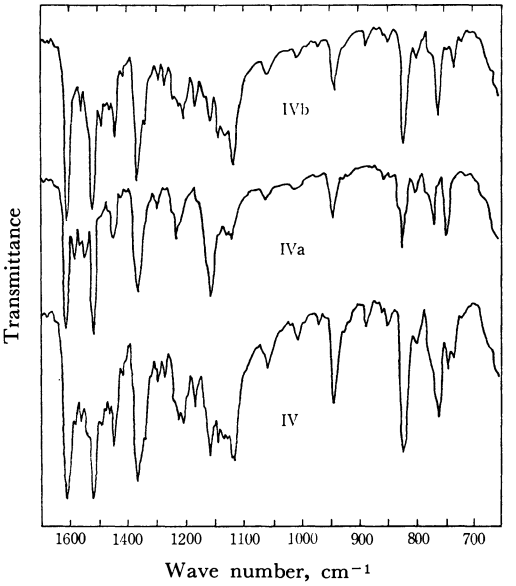


Fig. 1. Infrared spectra of IV, IVa and IVb in KBr.

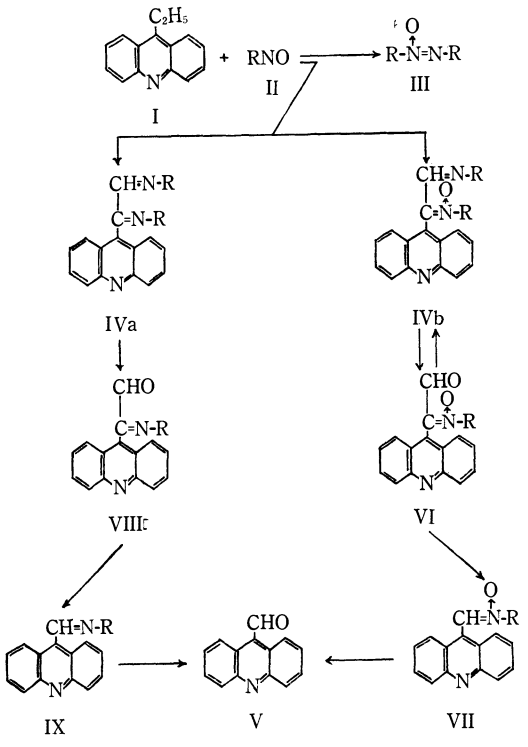

On the other hand, 9-acridylglyoxal-$\alpha$, $\beta$-*N*-(*p*-dimethylaminophenyl)dianil (IVa) was obtained as red prisms, m. p. 283°C (decomp.), by several fractional recrystallizations of IV from pyridine, or by the deoxygenation of IVb with triethyl phosphite. The infrared spectrum of IVa is also shown in Fig. 1.

On the basis of the infrared spectrum of IV, which revealed all the distinctive bands of IVa and IVb to be as shown in Fig. 1, and of the elemental analysis of IV,[6] it may be supposed that IV is a mixture of IVa and IVb only.

Moreover, it seems most reasonable to conclude that the hydrolysis of IV to V proceeds successively through the course depicted in Chart 1: IVa→VIII→IX→V; IVb→VI→VII→V, although 9-acridylglyoxal-$\alpha$-*N*-(*p*-dimethylaminophenyl)anil (VIII) and acridine-9-carboxaldehyde *N*-(*p*-dimethylaminophenyl)anil (IX) could not be isolated.

5) L. Chardonnens and P. Heinrich, *Helv. Chim. Acta*, **32**, 656 (1949).

6) As will be shown in the Experimental section, the elemental analysis of IV showed the intermediate values between those of IVa and IVb (or IVc), but these values were considerably different from those of IVd (C, 73.93; H, 5.80; N, 13.91%).

$R = p\text{-}C_6H_4N(CH_3)_2$

Chart 1

It is known that anil and nitrone compounds are difficult to separate. As the $\alpha$, $\beta$-dianil (IVa) and $\alpha$-nitrone-$\beta$-anil (IVb) have similarities in their chemical structures and properties, the separation was very difficult.

Although no chracteristic bands between IVa and IVb were observed in their infrared spectra, as is shown in Fig. 2, the quantitative estimation of IVa and IVb in IV was established by using of the ratio method,[7] which was carried out by the measurement of the absorbances $A_1$ and $A_2$ for the bands at 1120 and 1592 $cm^{-1}$ respectively.

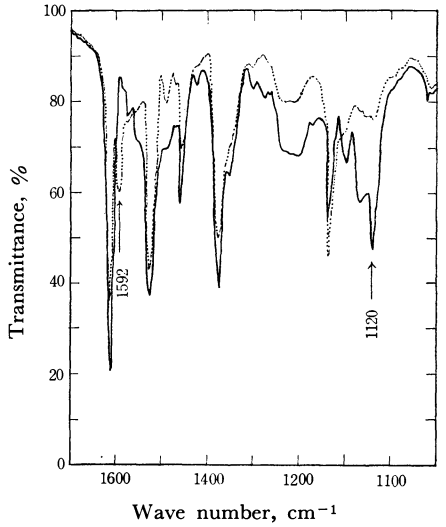

Fig. 2. Infrared spectra of IVa and IVb in chloroform.
..... IVa, —— IVb

Thus, samples of a mixture consisting of specified amounts of IVa and IVb were prepared and the absorbances $A_1$ and $A_2$ were measured according to the baseline method. The calibration curves plotting the relationship between $A_1/A_2$ or $A_2/A_1$ and the concentration (wt.%) of IVb are shown in Fig. 3.

According to the calibration curves thus obtained, the effect of reaction conditions on the yields of IVa and of IVb was examined. The results are given in Tables II and III.

When the molar ratio of HA to I was about 1.1 (Table III), the main product was the $\alpha$-nitrone-$\beta$-anil IVb, whose yield was increased with an increment in the nitroso compound II. While the

yield of $\alpha$, $\beta$-dianil IVa was little affected by II, it was low. In particular, it is interest that IVa and IVb were formed, even when an equimolar amount of II was used.

## Experimental[8]

9-Ethylacridine (I) was prepared by the condensation of diphenylamine and propionic acid in the presence of anhydrous zinc chloride, m. p. 116°C.[9]

**The Reaction of I with *p*-Nitrosodimethylaniline (II).**—To a solution of 1.0 g. of I and 1.4 g. of II in 20 ml. of ethanol, 0.20 ml. of HA was added.[10] After having been refluxed for 3 hr., the mixture was allowed to stand overnight. Filtration gave 1.28 g. of reddishbrown crystals (IV), m. p. 260—262°C (decomp.).

Found: C, 77.51, 77.74; H, 6.04, 6.10; N, 14.11, 14.36%.

Several fractional recrystallizations of IV from pyridine afforded a small amount of 9-acridylglyoxal-$\alpha$, $\beta$-*N*-(*p*-dimethylaminophenyl)dianil (IVa) as red prisms, m. p. 283°C (decomp.).

Found: C, 78.87; H, 6.19; N, 14.65. Calcd. for $C_{31}H_{29}N_5$: C, 78.95; H, 6.20; N, 14.85%.

The results of other reactions under varying conditions are shown in Tables I, II and III.

**The Hydrolysis of IV.** — *With Dilute Hydrochoric Acid.*—A mixture of 2.0 g. of IV in 7.5 ml. of 12% aqueous hydrochloric acid was heated on a water bath for several minutes. After the mixture had cooled, the precipitated crystals were filtered and washed with the saturated sodium chloride aqueous solution - dilute hydrochloric acid mixture. The insoluble crystals were dissolved in a large amount of hot water and then filtered. To the filtrate, a sodium acetate aqueous solution was then added to give yellow crystals. Filtration gave 0.95 g. of yellow crystals, m. p. 141—143°C. Recrystallization from the petroleum benzine - benzene mixture afforded yellow needles, m. p. 146—147°C. This compound was proved, by the admixed m. p. determination and its infrared spectrum, to be identical with an authentic sample of acridine-9-carboxaldehyde (V), m. p. 147°C.[4]

*With Cold 10% Aqueous Sulfuric Acid.*—Ten milliliters of 10% sulfuric acid was added to 0.5 g. of IV under ice-cooling. Immediately, the reaction mixture was filtered by suction to give yellow crystals, which, upon being washed with aqueous ammonia, afforded 0.12 g. of orange crystals, m. p. 204°C (decomp.). Recrystallization from benzene gave 9-acridylglyoxal-$\alpha$-*N*-(*p*-dimethylaminophenyl)nitrone (VI) as orange needles, m. p. 208°C (decomp.).

Found: C, 74.85; H, 5.18; N, 11.13. Calcd. for $C_{23}H_{19}O_2N_3$: C, 74.78; H, 5.18; N, 11.37%. IR (KBr): $\nu_{C=O}$ 1662 $cm^{-1}$.

**The Oxidation of VI with Silver Oxide.**—A mixture of 0.26 g. of VI in 170 ml. of the Tollens reagent was heated on a water bath for 4 hr. During the heating, the reaction mixture resulted in the precipitation of silver and yellow brown crystals. After it had been cooled, the mixture was extracted with chloroform. The chloroform solution was then evaporated in vacuo to give 0.10 g. of reddish-brown crystals, m. p. 239°C (decomp.). Recrystallization from chlorobenzene afforded reddish-brown prisms, m. p. 243°C (decomp.). This compound was proved, by a study of its infrared spectrum, to be identical with the *N*-(*p*-dimethylaminophenyl)-$\alpha$-(9-acridyl)-nitrone (VII)[3] obtained from the condensation of 9-methylacridine and II.

**9-Acridylglyoxal-$\alpha$-*N*-(*p*-dimethylaminophenyl)-nitrone-$\beta$-*N*-(*p*-dimethylaminophenyl)anil (IVb).**—A mixture of 0.1 g. of VI, 0.2 g. of *p*-aminodimethylaniline and 1 drop of acetic acid in 5 ml. of ethanol was refluxed for 2 hr. After the mixture had cooled, filtration afforded 0.12 g. (93%) of IVb as red crysals, m. p. 265°C (decomp.). Recrystallization from benzene gave red prisms, m. p. 265°C (decomp.).

Found: C, 76.67; H, 6.24; N, 14.10. Calcd. for $C_{31}H_{29}ON_5$: C, 76.36; H, 6.00; N, 14.36%.

**The Reaction of IVb with Triethyl Phosphite.**—A mixture of 0.5 g. of IVb and 2.0 g. of triethyl phosphite[11] was gently refluxed under a nitrogen atmosphere on an oil bath (160—165°C) for 20 hr. After the mixture had stood overnight, the precipitated crystals were filtered and then washed with ethanol to give 0.38 g. (80%) of red crystals, m. p. 279°C (decomp.). Recrystallization from pyridine gave red prisms, m. p. 283°C (decomp.), these were proved, by a study of their infrared spectrum, to be identical with the IVa obtained by the fractional recrystallization of IV from pyridine.

**The Spectroscopic Determination of IVa and IVb in IV.**—The infrared absorption measurements were made with a Koken IR-S double beam spectrophotometer with a sodium chloride prism.

Chloroform solutions containing IVa and IVb, in which the weight percentages of IVb were 0, 22.2, 26.3, 41.6, 58.8, 63.1, 77.4, 84.6, 90.2 and 100% respectively, were prepared. The absorbances $A_1$ and $A_2$ for the bands at 1120 and 1592 $cm^{-1}$ respectively were measured by the baseline method. The absorbances $A_1$ and $A_2$ in the order of the above concentrations of IVb were as follows. $A_1$: 0.064, 0.083, 0.085, 0.091, 0.135, 0.143, 0.166, 0.196, 0.207 and 0.238. $A_2$: 0.199, 0.192, 0.170, 0.161, 0.133, 0.127, 0.096, 0.080, 0.043 and 0.038.

# Studies on Mixture Dyeing. III.[1] The Absorption Spectra of Direct Dye Mixtures in an Aqueous Solution

By Zenzo MORITA and Minoru SEKIDO

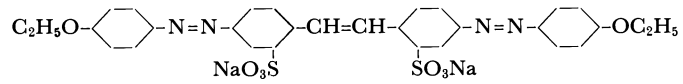
(Received December 22, 1964)

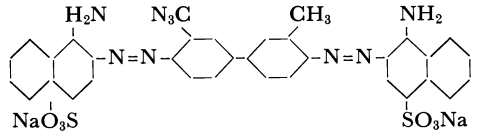
Since Neale and Stringfellow[2] discovered that most of the binary mixtures of dyes in an aqeous solution showed non-additive spectra, the interaction between molecules of different kinds of dyes in an aqueous solution has been studied extensively.[3-10]

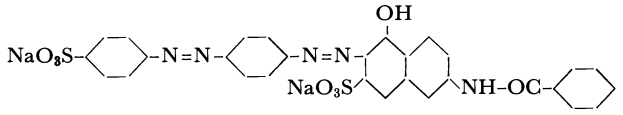
Derbyshire and Peters[3] have investigated the interaction between Chrysophenine G and Sky Blue FF, for which pair Neale and Stringfellow[2] found the strongest interaction in an aqueous solution, measured the heat of the formation of the 1:1 complex of the two dyes to be −15 kcal./mol. by direct colorimetry, and concluded that the formation of the 1:1 complex occurred in an aqueous solution to an appreciable extent, even at 90°C.

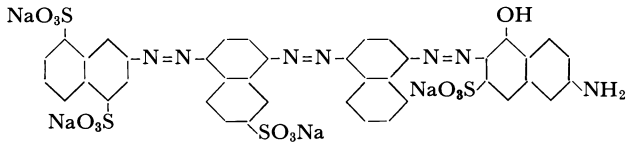
Tanizaki, Kobayashi and Ando[4] have confirmed the non-additivity of the absorption spectra of a binary mixture with Sky Blue FF in an aqueous solution. Kobayshi Tanizaki and Ando,[5-7] and Kobayshi, Saito, Tanizaki and Ando[8] obtained the equilibrium constants for a 1:1 complex with many kind of two dyes. Inscore, Gould, Corning and Brode[9] observed the absorption spectra of binary dye mixtures in an aqueous solution and discussed qualitatively the relation between the structure of these dyes and the strength of the interaction between them. Very recently, Hoshi[10] has investigated spectroscopically the interaction in an aqueous solution between Chrysophenine G and the blue dyes derived from dianisidine as diazo components.

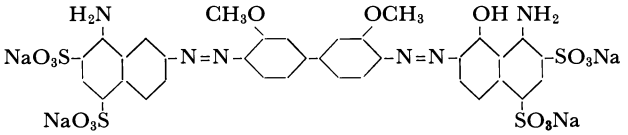
The investigations above quoted,[3-8,10] however, have some limitations in terms of the chemical structure of dyes. For the present paper, therefore, five typical dyes (cf. Table I) were selected in order to extend the scope of the study of the interaction, this study revealed that the interaction of Chrysophenine G and Sky Blue 6B is very strong and that the absorption spectra of the mixture of Chrysophenine G and Sirius Supra Blue BRR are almost additive.[2] Sirius Red 4B and Sirius Supra Blue BRR are typical unsymmetrical, direct dyes, and in terms of dyeability the other three dyes have been investigated as typical models of direct dyes. These five dyes may, then, be assumed to be representative so far as their shape, structure, dyeability, and molecular weight are concerned. In view of the above-mentioned reasons, the study of the interaction between every two of these five dyes would be helpful in obtaining a general idea of the combinations of most direct dyes commercially available.











In the present paper the equilibrium constants for the complexes of six combinations among the ten will be obtained spectroscopically at room temperature. Because of the overlapping of their absorption spectra, the equilibrium constants of the other combinations were unobtainable.

## Experimental

Purified dyes were used throughout. The samples of Chrysophenine G, Benzopurpurine 4B, Sirius Red 4B and Sky Blue 6B were the same as those used before.[1,11]

Table I. Dye structures

| Name (C. I. Direct No.) | Structure |
|---|---|
| Chrysophenine G (Yellow 12) |  |
| Benzopurpurine 4B (Red 2) |  |
| Sirius Red 4B* (Red 81) |  |
| Sirius Supra Blue BRR* (Blue 71) |  |
| Sky Blue 6B (Blue 1) |  |

* Although Chlorazol Fast Red K and Chlorazol Fast Blue 2BN, used by Neale and Stringfellow,[2] are not listed in "Colour Index 2nd ed.," they are similar to Sirius Red 4B and Sirius Supra Blue BRR, respectively by "Colour Index 1 st ed." and "Schultz's Farbstofftabellen 7 th ed."

Sirius Supra Blue BRR were purified from commercial dyes (Sumilight Supra Blue BRR (NSK)) by the method of Robinson and Mills.[12] The absence of colored impurities was checked by paper chromatography.

All the concentrations were determined by weight. All of the absorption spectra were mesured in a 1.0 cm. cell by a Hitachi EPB-V type spectrophotometer at room temperature.

## Results and Discussion

The absorption spectra of two combinations among the six investigated are shown in Figs. 1 (Chrysophenine G - Sirius Supra Blue BRR) and 2 (Benzopurpurine 4B - Sky Blue 6B). These spectra show the same non-additivity as those early investigated,[2-9] but when the concentration of a component increases, no second isosbestic point, which corresponds to the formation of a 1:2 complex, is found.[7,10] It follows that only a 1:1 complex is formed in all the concentrations. Though the absorption spectra of the mixtures of Chrysophenine G and Sirius Supra Blue BRR were found to be almost additive by Neale and Stringfellow,[2] Fig. 2 shows the non-additive spectra and the presence of an isosbestic point.

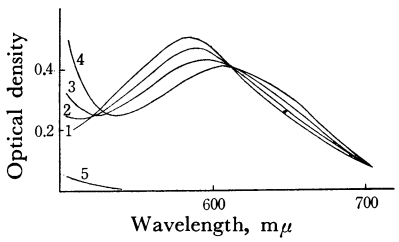

Fig. 1. Absorption spectra of the mixture of Chrysophenine G and Sirius Supra Blue BRR in aqueous solution at 16°C.

determination of the equilibrium constants of dye-dye complexes.[5,10,17] In this paper Nash's method,[18] which permits a direct evaluation of the equilibrium constant with a minimum of computational labor, has been used.

Following Nash's presentation, it is assumed that there are chemical equilibria of the forms:

$$S + D = SD \quad (1)$$

$$SD + D = SD_2 \quad (2)$$

where D is any donor dye molecule; S, an acceptor substrate and SD and $SD_2$, 1:1 and 1:2 complexes respectively. The equilibrium constants appropriate to reactions 1 and 2 are given in concentration units by:

$$K_1=\frac{C_{SD}}{C_S\cdot C_D} \quad (3)$$

$$K_2=\frac{C_{SD_2}}{C_{SD}\cdot C_D} \quad (4)$$

where $C_{SD}$ and $C_{SD_2}$ are the equilibrium concentrations of SD and $SD_2$, and $C_S$ and $C_D$ are the final concentrations of S and D respectively.

In order to obtain the equilibrium constant of the complex between the S and D dyes, the spectroscopic measurement of mixture solutions containing a constant concentration of the S dye and various concentrations of the D dye is required. $A°$ denotes the optical density at a wavelength when the concentration of the D dye is zero, while $A$ denotes the optical density of the mixture solution when the final concentration of the D dye is $C_D$. When the reciprocal of the donor dye concentration is plotted against the reciprocal of (one minus the absorbance ratio) (i. e., $1/C_D$ vs. $A°/(A°-A)$), a straight line results if a 1 : 1 complex is formed. The intercept of this line is equal to the negative of the equilibrium constant.

However, it is necessary that the absorbance of the D dye at the wavelength be zero, and that the difference between $A°$ and $A$ be as large as possible. With these points in mind, the wavelength of 680 mμ was used. The results are shown in Figs. 3

Table II. Equilibrium constants for the complex between dyes

| Dye (1) | Dye (2) | $K_1$ l./mol. | Temp. °C |
|---|---|---|---|
| Sky Blue 6B | Chrysophenine G | $1.7\times10^7$ | 18 |
| | Benzopurpurine 4B | $1.8\times10^5$ | 18 |
| | Sirius Red 4B | $5.0\times10^4$ | 18 |
| Sirius Supra Blue BRR | Chrysophenine G | ca. $1.0\times10^4$ | 16 |
| | Benzopurpurine 4B | $5.0\times10^4$ | 16 |
| | Sirius Red 4B | $1.4\times10^5$ | 16 |

and 4, while the equilibrium constant, $K_1$ is given in Table II. When the other wavelength was used, similar results were obtained.

The equilibrium constant for the complex of Chrysophenine G and Sky Blue 6B, as determined by Kobayashi, Tanizaki and Ando,[7] is different from that as determined by Hoshi;[10] this is due to the dissimilar concentrations of Sky Blue 6B. The absorption spectra of the mixture of Chrysophenine G and Sky Blue 6B are shown in Fig. 5. In this case, the equilibrium constant for the 1 : 1 complex could not be calculated by Nash's method because of the smaller concentration of Chrysophenine G (D) than of Sky Blue 6B (S), against the assumption $S \ll D$. Moreover, the equilibrium constants, $K_1$ and $K_2$, can be calculated by the method using the two isosbestic points corresponding to formations of 1 : 1 and 1 : 2 complexes.[10] The evaluation of the molar extinction coefficient of the $SD_2$ complex at the wavelength of the first isosbestic point is

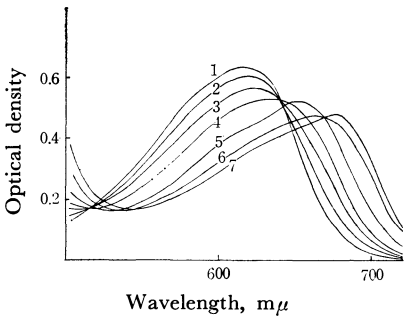

Fig. 5. Absorption spectra of the mixture of Chrysophenine G and Sky Blue 6B in aqueous solution at 18°C.

| | Sky Blue 6B | Chrysophenine G, mol./l. |
|---|---|---|
| 1 | $6.46_8\times10^{-6}$ | 0 |
| 2 | $6.46_8\times10^{-6}$ | $1.22_7\times10^{-6}$ |
| 3 | $6.46_8\times10^{-6}$ | $2.69_0$ |
| 4 | $6.46_8\times10^{-6}$ | $4.38_7$ |
| 5 | $6.46_8\times10^{-6}$ | $8.60_2$ |
| 6 | $6.46_8\times10^{-6}$ | $18.6_6$ |
| 7 | $6.46_8\times10^{-6}$ | $36.7_9$ |

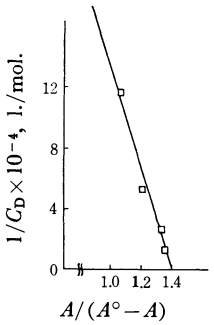

Fig. 6. The interaction of Sky Blue 6B with Chrysophenine G.
The concn. of Sky Blue 6B=$6.46_8\times10^{-6}$ mol./l.; 640 mμ

not easy by this method. At this wavelength, however, $K_2$ can be obtained with ease by Nash's method (Fig. 6). Here $A^\circ$ for Eq. 2 (the optical density of SD when the concentration of dye D is zero) corresponds to the first isosbestic point. $K_1$ and $K_2$ are $1.7_4\times10^7$ and $4.2_5\times10^5$ respectively, and they are in the range of values investigated earlier.[7,10]

The $K_1$ values for Chrysophenine G and Sky Blue 6B complexes are extremely large compared with those in Table II while the $K_1$ values for Chrysophenine G and Sirius Supra Blue BRR complexes are small. This can be supposed on the basis of the results reported earlier.[2] The strength of the interaction is of the following order: Chrysophenine G - Sky Blue 6B > Benzopurpurine 4B - Sky Blue 6B > Sirius Red 4B - Sirius Supra Blue BRR > Sirius Red 4B - Sky Blue 6B = Benzopurpurine 4B - Sirius Supra Blue BRR > Chrysophenine G - Sirius Supra Blue BRR. It follows that the combination of Chrysophenine G and Sky Blue 6B is a typical one in direct dyes, and that the equilibrium constants for dye-dye complexes in an aqueous solution at room temperature are in the $10^7$—$10^4$ range. The order of the magnitude of $K_1$ may confirm the qualitative observations by Inscore, Gould, Corning and Brode.[9]

Some factors influencing the interaction between dyes have been studied. The exact nature of the forces operative in the interaction and the manner how these dyes form complex have not yet been determined. However, since it is clear that the interaction between unlike dye molecules is stronger than that between like molecules, the aggregation of like dye molecules is less favorable than the complex formation between unlike molecules, such as Chrysophenine G and Sirius Supra Blue BRR. It follows that the equilibrium constant for a complex between like dye molecules is very much smaller than $10^4$.

## Summary

The absorption spectra of a binary mixture of five representative direct dyes in solution have been investigated. The equilibrium constants for complex formation are in the $10^7$—$10^4$ range and are in the order: Chrysophenine G - Sky Blue 6B > Benzopurpurine 4B - Sky Blue 6B > Sirius Red 4B - Sirius Supra Blue BRR > Sirius Red 4B - Sky Blue 6B = Benzopurpurine 4B - Sirius Supra Blue BRR > Chrysophenine G - Sirius Supra Blue BRR. The combination of Chrysophenine G and Sky Blue 6B is a typical one in direct dyes. The equilibrium constant for an aggregation of like dye molecules is very much smaller than the value of $10^4$ at room temperature.

# Studies on Reactions of Polypropylene. V. On the Thermal Degradation Accelerated by Vinyl Polymers

By Yukio MIZUTANI, Seishiro MATSUOKA and Keiichi YAMAMOTO

(Received February 12, 1965)

A few drawbacks are encountered in the use of polypropylene, for example, the poor flow properties resulting from its very high molecular weight and the poor dyeability resulting from its nonpolarity and high crystallinity. The former drawback has been solved either by the improvement of the polymerization process,[1-3] in which the molecular weight of polypropylene can be controlled, or by the degradation of polypropylene in order to reduce its very high molecular weight.[4-9]

As for the latter drawback, the modification of polypropylene has been much studied: graft polymers have been prepared,[10-15] dyeable polymers have been blended,[16-18] and some functional groups have been introduced to the polypropylene chain.[19,20] Also, two thermally degradative methods have been proposed for the modification of polypropylene: the thermal degradation of polypropylene in the presence of vinyl monomers,[21] and the thermal treatment of polypropylene containing 5—95% specified polymers.[22]

For this paper, the thermal degradation of polypropylene accelerated by vinyl polymers was studied in an attempt to overcome the drawbacks described above. The fundamental idea of this study was as follows: A vinyl polymer generally degrades easily to a monomer by the chain reaction mechanism,[23] but polypropylene degrades by the random scission mechanism.[4,5] As a vinyl polymer is more susceptible to thermal degradation than polypropylene, if the mixture of polypropylene and a vinyl polymer is heated at an elevated temperature, the active radical generated by the scission of a vinyl polymer chain may be effective as an accelerator in the degradation of polypropylene and the modification of polypropylene may be expected because of the interaction among a vinyl monomer, a vinyl polymer radical, a polypropylene radical and a polypropylene molecule. The vinyl polymers used in this study were polystyrene, polymethyl methacrylate, the 2-methyl-5-vinylpyridine - styrene copolymer, and the acrylonitrile - styrene copolymer. As had been expected, it was proved that the vinyl polymers added were effective not only in accelerating the thermal degradation of polypropylene, but also in forming graft or block polymers.

## Experimental

**Polypropylene.** — Polypropylene (PP) was polymerized at 80°C in *n*-heptane by a catalyst consisting of titanium trichloride, dicyclopentadienyl titanium dichloride, sodium and hydrogen.[24] Polypropylene thus obtained was soaked in an excess methanol-isopropanol mixture (1:1) overnight after it had been separated from hot *n*-heptane under a nitrogen atmosphere, then it was filtered, washed with methanol, and soaked in methanol - concentrated hydrochloric acid mixture (10:1) overnight. Then polypropylene was

filtered, washed with a methanol-water mixture (10:1) and methanol, and dried under a vacuum. Polypropylene used contained no stabilizer. The properties are shown in Table I.

**The Preparation of Samples.**—The vinyl polymers used were polystyrene [PSt; intrinsic viscosity in a benzene solution at 25°C : 1.05 dl./g.], polymethyl methacrylate [PMMA; intrinsic viscosity in an acetone solution at 25°C : 1.22 dl./g.], and the 2-methyl 5-vinylpyridine - styrene copolymer [P(MVP-St); (2-methyl-5-vinylpyridine/styrene) in the copolymer : 1.2 by weight], and the acrylonitrile-styrene copolymer [P(A-St); (acrylonitrile/styrene) in the copolymer : 1.4 by weight]. All the vinyl polymers used were purified by reprecipitation.

The samples were prepared as follows: PP powder was stirred into a PMMA-acetone solution, a P(MVP-St)-acetone solution, a P(A-St)-acetone solution or a PSt-toluene solution. In the case of the acetone solution, the acetone was evaporated by stirring under a vacuum. The slurry of PP powder and the PSt-toluene solution was poured into excess methanol in a mixer. The polymer precipitated was filtered, washed with methanol and dried under a vacuum. The quantity of PSt, PMMA, and P(MVP-St) added to polypropylene was regulated at 3% by weight, while the quantity of P(A-St) was 4.7% by weight.

**The Viscosity Measurements and the Calculation of the Scission Number.**—The viscosity of the tetraline solution of the polymer sample containing 0.2 g. of 2, 6-di-*t*-butyl *p*-cresol per 100 ml. of tetralin was determined at 135°C with an Ubbelohde viscometer under a nitrogen atmosphere. The intrinsic viscosity was determined from the three-point measurement by extrapolation. The scission number of the polypropylene chain ($S$) per molecule, with the molecular weight calculated by Parrini's equation[25] $[[\eta]=0.80\times10^{-4}M^{0.80}]$, was calculated by the following equation:

$$S=(1/0.524)\{([\eta]_0/[\eta]_t)^{1/0.80}-1\}$$

$[\eta]_0$: The intrinsic viscosity of a sample before thermal degradation

$[\eta]_0$: The intrinsic viscosity of a sample after thermal degradation for $t$ hr.

This equation was derived from Matsumoto's equation[26] and Parrini's equation,[25] and it was previously applied to the analysis of the thermal degradation of polypropylene by Oshika.[9]

**Thermal Degradation in a Glass Ampoule.**—The sample (0.3 g.) was transferred into an ampoule of 6 mm. in diameter and 10 cm. in length. The ampoule was then evacuated by the use of an oil diffusion pump for one hour after three cycles of evacuation-nitrogen substitution. The ampoule was sealed off and dipped into a salt bath of sodium nitrate - potassium nitrate. The hot ampoule was rapidly cooled in water, and the viscosity of the polymer was determined.

**Thermal Degradation by the Use of an Extruder.** — The thermal degradation by the use of an extruder was studied under a nitrogen stream in order to consider the practical utility of the thermal degradation of polypropylene accelerated by vinyl polymers. Figure 1 gives a rough sketch of the extruder. The extruder was a modification of type MK-1 from Modern Machinery Co., Ltd., the heating zone of which was divided into three parts.

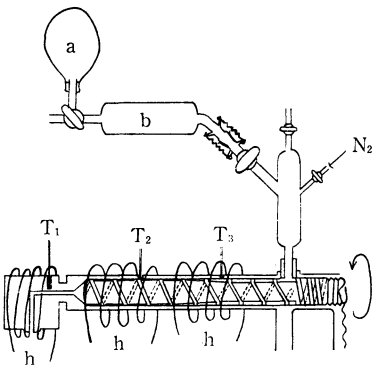

Fig. 1. The rough sketch of the extruder.
a : Nitrogen-balloon

$T_1$, $T_2$ and $T_3$: Thermo-couple
h : Heater

**Volatilization Curves.**—Volatilization curves of the samples were determined under a nitrogen stream with a differential thermal analysis apparatus DT-1A from Shimadzu Seisakusho, Ltd., in order to compare the thermal stability of the samples. The heating rate was 2°C/min.

**The Acetone-Extraction of Degraded Samples.**—The sample degraded by the use of the extruder was in the shape of a pellet. The sample was dissolved in *p*-xylene under a nitrogen atmosphere, and the hot solution was slowly cooled overnight, then the slurry obtained was poured into methanol [for the PP(A)-PSt sample, the PP(A)-PMMA sample, and the PP(D)-P(A-St) sample] or petroleum ether [for the PP(D)-P(MVP-St) sample] in a mixer. The precipitate was filtered, washed with methanol or petroleum ether, and dried under a vacuum. The powder obtained was extracted by acetone[12] with a Soxhlet extractor for 20 hr. under a nitrogen atmosphere. The residue was dried under a vacuum, and the vinyl polymer content of the residue was determined by infrared spectrum analysis, using a spectrophotometer, type AR-275, from Shimadzu Seisakusho Co., Ltd. The determination was carried out by the base-line method[27] using the following analytical wavelengths: PSt 14.4 $\mu$, PMMA 5.8$\mu$, and PMVP 13.6 $\mu$.

## Results and Discussion

**Volatilization Curves.**—Figures 2 and 3 show the volatilization curves of the PP(C), PP(D), PSt, PMMA, P(A-St), P(MVP-St), PP(C)-PSt, PP(C)-PMMA, PP(D)-P(A-St), and PP(D)-P(MVP-St)

samples. The volatilization curves of the PP(C)-PSt, PP(C)-PMMA, PP(D)-P(A-St), and PP(D)-P(MVP-St) samples were between the volatilization curves of PP(C) or PP(D) and those of PSt, PMMA, P(A-St), and P(MVP-St) respectively. These relations of the volatilization curves may be considered as suggesting the accelerating effect of vinyl polymers for the thermal degradation of polypropylene.

**Thermal Degradation in a Glass Ampoule.** —Figures 4—9 show the changes in the relative intrinsic viscosity with the reaction time at 280—345°C. Apparently, the changes in the relative intrinsic viscosity of the PP(A)-PSt, PP(A)-PMMA, PP(D)-P(A-St), and PP(D)-P(MVP-St) samples were larger than those of PP(A) and PP(D). Figures 10—15 show the changes in the scission number of the polypropylene chain with the reaction time, but it is necessary to note that the effect of addition of the vinyl ploymers was neglected. The scission rate was constant at a definite temperature, and the vinyl polymers were proved to be effective as accelerators for the thermal degradation of polypropylene. Judging from the fact that

the straight lines in Figs. 10—15 did not pass the origins, the scission rate at the initial step of the reaction should be larger than that at the stationary step of the reaction, and this should be attributed to the weak bond in the polymers.[5,9]

Figure 16 shows a plot of the logarithm of the scission rate versus the reciprocal of the absolute

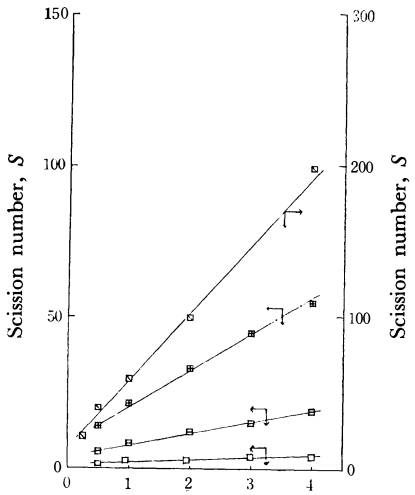

Fig. 12. Scission number of PP(A)-PSt sample vs. reaction time.

temperature, and the response to the Arrehenius law is considered to be good. From the gradient of the straight line as determined by the method of the least squares, the activation energies for the scission reaction of the samples were calculated to be as follows:

57.2 kcal./mol. for PP(A),
58.4 kcal./mol. for PP(D),
46.8 kcal./mol. for the PP(A)-PSt sample,
43.5 kcal./mol. for the PP(A)-PMMA sample,
46.9 kcal./mol. for the PP(D)-P(A-St) sample,
and 38.6 kcal./mol. for the PP(D)-P(MVP-St) sample.

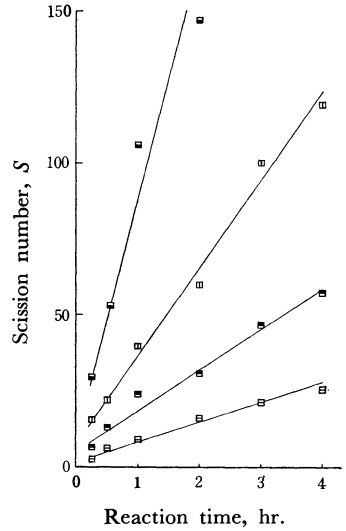

Fig. 14. Scission number of PP(D)-P(MVP-St) sample vs. reaction time.
Reaction temperature;
-⊟-: 300°C, -■-: 315°C
-◫-: 330°C, -▬-: 345°C

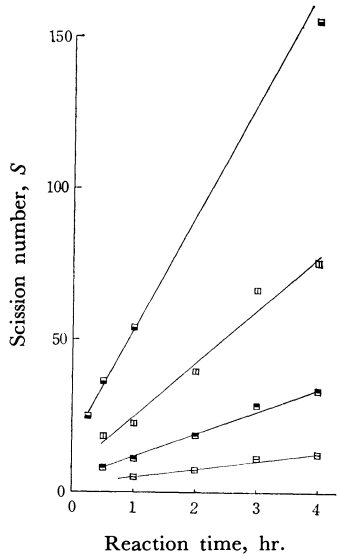

Fig. 15. Scission number of PP(D)-P(A-St) sample vs. reaction time.
Reaction temperature;
-⊟-: 300°C, -■-: 315°C
-◫-: 330°C, -▬-: 345°C

The activation energies for PP(A) and PP(D) could be cosidered to be consistent, but the reason for the difference between the scission rate of PP(A) and that of PP(D) is not clear. The values for PP(A) and PP(D) were larger than the value obtained by Hamada[5] (51.4 kcal./mol. at 250—320°C), while they were smaller than the value obtained by Davies et al.[4] (65 kcal./mol. at 250—300°C). The values for the PP - vinyl polymer

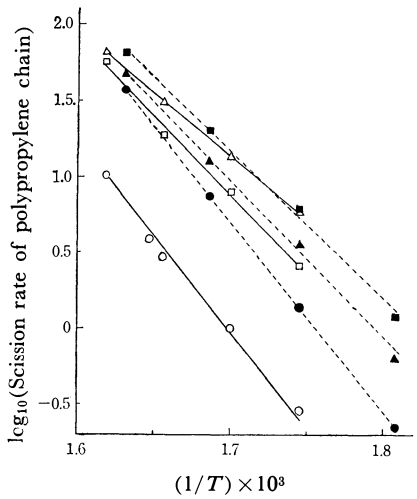

Fig. 16. $\log_{10}$(Scssion rate of polypropylene chain) vs. (1/T).
--●--: PP(A), --▲--: PP(A)-PSt,
--■--: PP(A)-PMMA, -○-: PP(D),
-△-: PP(D)P(MVP-St), -□-: PP(D)-P(A-St)

samples were smaller than the values for PP(A) and PP(D). This difference may be attributed to the accelerating effect of the vinyl polymers added.

The orders of the activation energies of the PP(A) series or the PP(D) series were consistent with the order of thermal stabilities, as is shown in Figs. 2 and 3 respectively.

The value of the PP(D)-P(A-St) sample could not be compared with the values of the other PP-vinyl polymer samples, because of the difference in the quantity of the vinyl polymers added.

In this study, the degradation process was regarded as only the scission process of the polypropylene chain. However, as the formation of graft or block polymers was observed, as will be described later, such reactions as the degradations of a vinyl polymer chain and of a polypropylene chain and the interaction among a vinyl monomer liberated by the thermal degradation, a vinyl polymer radical, a polypropylene radical, and a polypropylene molecule must be considered simultaneously. The study of these reactions would be an interesting theme in the future.

**Thermal Degradation by the Use of an Extruder and Acetone-Extraction.**—Table II shows the results of the thermal degradation of PP(C)-PMMA and PP(D)-P(MVP-St) samples by the use of an extruder. The accelerating effect of PMMA and P(MVP-St) may easily be observed from Table II. When these results are compared with those of the thermal degradation in the glass ampoule, it is clear that the reaction time needed here for modification to the appropriate intrinsic viscosity of polypropylene by the use of the extruder is shorter than that in the glass ampoule. As plausible reasons for this difference, the following factors may be listed: the mechanical shearing effect of the extruder, the mechanical mixing effect of the extruder, and the effect of a trace of oxygen which could not be eliminated because of the imperfect air-tightness of the extruder.

Regarding the mechanical shearing effect, it was well known that the mechanical degradation process has a negative temperature coefficient, since the bulk viscosity decreases and since, therefore, the degradative effect of the mechanical shear is reduced at higher temperatures until it finally become negligible. For example, the mechanical shearing effect is negligible for natural rubber at about 120°C.[28] In order to judge whether the mechanical shearing effect was negligible or not, PP([η]: 4.30 dl./g., specific gravity: 0.911) was extruded in a nitrogen atmosphere under these conditions: $T_1$: 190°C, $T_2$: 240°C, $T_3$: 200°C, and

Table III. The result of acetone extraction

| Sample | Thermal degradation conditions: Temp. of the extruder, °C $T_1$ | $T_2$ | $T_3$ | Rotation speed of screwing shaft round/min. | Quantity of vinyl polymer added % | Intrinsic viscosity dl./g. | Content of vinyl polymer in the residue after acetone-extraction % | Vinyl polymer in the residue / Vinyl polymer added |
|---|---|---|---|---|---|---|---|---|
| PP(C)-PMMA | 220 | 340 | 320 | 30 | 3 | 1.79 | 0.23 | 0.08 |
| PP(C)-PSt | 220 | 335 | 315 | 35 | 3 | 1.75 | 1.47 | 0.49 |
| PP(D)-(MVP-St) | 200 | 330 | 275 | 10 | 3 | 1.58 | 0.50 {PMVP: 0.20 PSt: 0.30} | 0.17 {PMVP: 0.12 PSt: 0.22} |

rotation speed of the screwing shaft: 30 round/min. Since the thermal degradation under these conditions was found to be negligible and since no degradation was observed ([$\eta$] of PP extruded: 4.29 dl/g.), the mechanical shearing effect was judg ed to be negligible. Therefore, it is reasonable to say that the shearing effect was negligible for the degradation shown in Table II.

The effect of the trace of oxygen was negligible in the results described above, but this fact can not assure that the effect of the trace of oxygen is negligible for the degradation shown in Table II, as the temperature of the above experiment is considerably lower than that shown in Table II. Also, the mechanical mixing effect may be effective, because the diffusion of the active radicals generated in the viscous polymer phase will probably not be easy and so the mechanical mixing might be effective in promoting the diffusion and the reaction of active radicals.

Table III shows the results of acetone-extraction. The formation of graft or block polymers was confirmed from the fact that a considerable quantity of the vinyl polymers was detected in the residue after acetone-extraction, while, no vinyl polymer was detected in the residue from PP-P(MVP-St) and PP-PSt mixtures after acetone-extraction. Furthermore, the monomer unit ratio (MVP/St) in the residue from the PP(D)-P(MVP-St) sample was 0.67, smaller than that of P(MVP-St) itself (MVP/St=1.2). This interesting finding may be a key to a solution of the question of whether or not the vinyl polymers degrade to monomers in the thermal degradation process.

The thermal degradative process of the vinyl polymers to the monomers may, therefore, be considered to accelerate the polypropylene degradation. The details should be elucidated by a study using a fractionated vinyl copolymer with a narrow molecular weight distribution and a difinite monomer unit ratio.

**Dyeability.**—The fibers spun from the modified polymers showed a good dyeability by dispersed dyes, such as Celliton Blue Extra Type, Latyl Cerise B, and Diacelliton Fast Yellow G. It was established by the microscopic observation of the cross section of dyed fibers that the colored vinyl polymer was dispersed in the shape of a granule and that the dispersed state of the colored vinyl polymer in the modified polypropylene was finer and more preferable to that of polypropylene fibers blended only with the vinyl polymer. The graft or block polymers formed in the thermal degradation should play an important role in improving the dispersion state of the colored vinyl polymer in the modified polypropylene.

## Summary

The thermal degradation of polypropylene in the presence of such vinyl polymers as polystyrene, polymethyl methacrylate, the 2-methyl-5-vinylpyridine-styrene copolymer, and the acrylonitrile-styrene copolymer has been studied at 280—345°C by the use of glass ampoules and an extruder.

1) The vinyl polymers added were effective as accelerators for the thermal degradation of polypropylene. The activation energies for the scission reaction of the polypropylene chain were 57.2 and 58.4 kcal./mol. for the two polypropylene samples, and 46.8, 43.5, 46.9 and 38.6 kcal./mol. for polypropylenes containing 3% polystyrene, 3% polymethyl methacrylate, 4.7% the acrylonitrile-styrene copolymer, and 3% the 2-methyl-5-vinylpyridine-styrene copolymer respectively.

2) The reaction time needed for the modification of polypropylene to an appropriate intrinsic viscosity by the use of an extruder is shorter than that in glass ampoules.

3) Graft or block polymers have been detected in the residue after the acetone-extraction of the extruded polypropylene. They could be used in the modification of the polypropylene dyeability.

4) It has been concluded that the simple process of the thermal degradation of polypropylene accelerated by vinyl polymers can be used for the modification of polypropylene with a very high molecular weight and, simultaneously, for the preparation of graft or block polymers.

# Studies of the Decomposition Products of Ethereal Blue Perchromate by Ion-exchange Resins. II. The Open Bottle Decomposition Product

By B. S. RAJPUT and R. C. RAI

(Received February 19, 1965)

The blue perchromate decomposes in different manners, yielding different compounds under different conditions. Rai and Prakash[1] and Rajput and Rai[2] have shown, for instance, that in contact with water it gives $Cr_2(Cr_2O_7)_3$.

No serious attempt has, however, yet been made to ascertain the composition of and to assign a chemical formula to the decomposition product of the ethereal blue perchromate obtained when it is allowed to decompose in uncorked Erlenmeyer flasks (the open bottle decomposition product). According to Schwarz and Giese,[3] ethereal blue perchromate gives $CrO_3$ in presence of silver oxide. Rai, Rajput and Rai[4] have seen that if the ethereal blue perchromate is allowed to decompose under tightly-corked conditions (the closed bottle decomposition product), its titration value becomes nearly double when this product is oxidised with 30% hydrogen peroxide in a strongly alkaline medium (NaOH). They have thus tried to show that, under such conditions, a compound with the formula $CrCrO_4$ seems to be formed. The same compound has been reported by Vauquelin and others.[5]

In the present paper, the composition of the open bottle decomposition product of the ethereal blue perchromate will be studied, and, on the basis of the observations obtained, a chemical formula will be assigned to it. It will further be shown how the formation of this product supports the formula suggested by Rai for the ethereal blue perchromate.

## Experimental

Blue perchromate was prepared by mixing ice-cold solutions of 5% w/v potassium dichromate (50 ml.), 2 N sulphuric acid (5 ml.) and 6% hydrogen peroxide. The blue compound thus formed was then extracted with ice-cold ethyl ether (100 ml.), washed several times with ice-cold distilled water, and placed in a tightly-corked flask in the refrigerator in order to freeze out the water. After about three hours, it was transferred to a previously-dried and cooled flask and kept in ice. Five milliliters of it was then allowed to decompose in each of two dry, 100-ml. Erlenmeyer flasks; the rest of it was allowed to decompose in a 250-ml. Erlenmeyer flask under open conditions. After about 12 to 14 hr., only a brown residue was left in all the flasks. The contents of one of the 100-ml. Erlenmeyer flasks were titrated after potassium iodide and sulphuric acid had been added; that of the other was so titrated after the contents had been oxidised with 30% hydrogen peroxide in an alkaline medium (NaOH). The excess peroxide was then removed by prolonged boiling. The brown residue left in the third flask was dissolved in water with the aid of a few milliliters of dilute sulphuric acid.

Several columns (6/75 mm.) were prepared for the different ion-exchangers and washed thoroughly with distilled water. Cations and anions separated from the solution of the open bottle decomposition product prepared above. It was found, with the aid of a spot test, that chromium was present in cationic as well as in anionic portions of the product solution. The amount was then estimated quantitatively iodometrically. In the case of cationic chromium, it was oxidised with 30% hydrogen peroxide as above after elution and then titrated iodometrically. Anionic chromium was titrated iodometrically, as usual. In the case of anion exchangers, a final elution was made with a few milliliters of 1 N hydrochloric acid in order to elute any chromium formed due to some reaction[6] between the resin and the anion of the effluent. The elutriant so obtained did not liberate iodine with acid; hence it was oxidised as above with 30% hydrogen peroxide and titrated iodometrically after the excess peroxide had been removed. The titration value so obtained was added to the titration value of the anionic portion of the product solution. The experimental results are noted in Tables I—III:

## Discussion

According to Schwarz the ethereal blue perchromate decomposes in the presence of silver oxide, giving $CrO_3$:

$$CrO_5 \xrightarrow{Ag_2O} CrO_3 + 2O$$

When the ethereal blue perchromate is decomposed in an open bottle in the absence of any foreign substance, a brown substance is formed. It liberates iodine in the presence of acid; the

quantity of iodine liberated increases if the product is oxidised with 30% hydrogen peroxide in a strongly alkaline medium (NaOH) before the iodometric titration. This increase in titration value can be understood if the product is considered to have chromium in the cationic portion as well. In an attempt to verify this, the product was dissolved in water with the aid of dilute sulphuric acid, and then cationic and anionic portions were separated with the help of different ion-exchangers. Chromium was found to be present in both portions; when this was estimated quantitatively and iodometrically, it was found that the cationic and anionic chromium are present in the ratio of 1 : 1.5 (Tables II and III). The increase in the titration value of the unexchanged product solution may, therefore, be considered to be due only to the conversion of chromium(III) to chromium(VI).

On the basis of the above ratio (1 : 1.5) between cationic and anionic chromium, it can easily be found that the compound formed is $Cr_2(CrO_4)_3$, as otherwise this ratio can not be explained. Moreover, the insolubility of the compound in water also agrees with the known properties of $Cr_2(CrO_4)_3$.

An attempt will now be made to show how this product can be formed from the blue compound, and in what manner it is related to the parent compound (blue perchromate). It will also be seen which formula, the $CrO_5$ of Schwarz or the $Cr_2(Cr_2O_{10})_3$ and $CrCrO_8$ of Rai best explains the results obtained above.

If the blue perchromate is $CrO_5$, it is difficult to presume the formation of trivalent chromium from it without the presence of any reducing agent. However, omitting all this and admitting that it does happen, $CrO_5$ may be taken to decompose in the following manner to give chromium chromate:

$$10CrO_5 \rightarrow 2Cr_2(CrO_4)_3 + 26O \quad (1)$$

and the total oxidising capacity of the blue compound as expressed in the number of available oxygen atoms may be given in this case as:

$$10CrO_5 \rightarrow 5Cr_2O_3 + 35O \quad (2)$$

and from chromium chromate:

$$2Cr_2(CrO_4)_3 \rightarrow 5Cr_2O_3 + 9O \quad (3)$$

The ratio between the total available oxygen atoms from the blue perchromate and chromium chromate will, in this case, be 35 : 9, i. e., 3.88 : 1 (Eqs. 2 and 3). However, the ratio obtained in Table III, Column 'e' does not exceed 2.84 : 1.

On the contrary, if the formulae suggested by Rai are accepted, the above relation can be shown as follows:

$$5Cr_2(Cr_2O_{10})_3 \rightarrow 8Cr_2(CrO_4)_3 + 54O \quad (4)$$

and

$$20CrCrO_8 \rightarrow 8Cr_2(CrO_4)_3 + 64O \quad (5)$$

The total available oxygen atoms in these cases will be:

$$5Cr_2(Cr_2O_{10})_3 \rightarrow 20Cr_2O_3 + 90O \quad (6)$$

and

$$20CrCrO_8 \rightarrow 20Cr_2O_3 + 100O \quad (7)$$

and from chromium chromate:

$$8Cr_2(CrO_4)_3 \rightarrow 20Cr_2O_3 + 36O \quad (8)$$

The corresponding ratios in these cases will be 90 : 36 and 100 : 36, i. e., 2.5 : 1 and 2.77 : 1 (Eqs. 6, 7 and 8), values which agree fairly well with the ratios obtained in Table III, Column 'e' on the basis of experimental results.

When the open bottle decomposition product is oxidised with hydrogen peroxide in an alkaline medium, it is converted into sodium chromate:

$$8Cr_2(CrO_4)_3 + 80NaOH + 24H_2O_2 \rightarrow 40Na_2CrO_4 + 64H_2O \quad (9)$$

When titrated iodometrically, this gives:

$$40Na_2CrO_4 \rightarrow 40Na_2O + 20Cr_2O_3 + 60O \quad (10)$$

The ratios between the available oxygen atoms of the blue perchromate and those obtained from the sodium chromate so formed will be:

1) on the basis of $CrO_5$: 35 : 15, i. e., 2.33 : 1
2) on the basis of $Cr_2(Cr_2O_{10})_3$: 90 : 60, i. e., 1.50 : 1
3) on the basis of $CrCrO_8$: 100 : 60, i. e., 1.66 : 1

The values obtained in Column 'f' of Table III are, again, nearer to those obtained by Rai's formulae.

The formula, $Cr_2(Cr_2O_{10})_3$, suggested by Rai[7] for the blue perchromate has been shown by him[8] to be in equilibrium with the other formula, $CrCrO_8$:

$$Cr_2(Cr_2O_{10})_3 + 2H_2O_2 \rightleftarrows 4CrCrO_8 + 2H_2O$$

He has further shown that $CrCrO_8$ is formed when hydrogen peroxide is present in excess.

The observations noted above, therefore, prove that the ethereal blue perchromate gives chromium chromate, $Cr_2(CrO_4)_3$, when decomposed in an open bottle and that its formation can be explained on the basis of Rai's formulae for the blue perchromate.

8) R. C. Rai, D. Sc. Thesis, University of Allahabad, 1962 on 'On the Constitution of Blue Peroxy Chromic Acid,' page 214.

**Summary**

The composition of the open bottle decomposition product has been studied and a chemical formula $Cr_2(CrO_4)_3$ has been assigned to it. It has been shown that the formation of this product can be explained successfully if we accept the formula suggested by Rai for the ethereal blue perchromate.

# The Dehydrogenation of All-*cis*-5, 11, 14-Eicosatrienoic Acid to Arachidonic Acid

By Toru TAKAGI

(Received March 5, 1965)

Early investigators have indicated, as a result of studying the feeding of linoleate concentrates to rats, that linoleate is transformed to arachidonate.[1] The transformation was confirmed by Mead and his co-workers using $^{14}C$-labeled linoleate.[2] The transformations of all-*cis*-6,9,12-octadecatrienoic acid[3] and all-*cis*-8,11,14-eicosatrienoic acid[4] to arachidonic acid were also confirmed by Mead and his co-workers.

Recently the present author reported that the unique fatty acid of *Podocarpus nagi* seed oil may be characterized as all-*cis*-5,11,14-eicosatrienoic acid.[5] The all-*cis*-acid was also found in *Ginko biloba*[6] and pinewood and tall oil.[7] The dehydrogenation of this acid to arachidonic acid in animals could be expected, because the structure of the acid differed from that of arachidonic acid only in lacking the double bond in the 8-position. Therefore, the metabolism of the eicosatrienoate has been investigated in our laboratory. This paper will present the results of the feeding experiments; an analysis of the fatty acid composition will follow.

## Results and Discussion

Twenty male rat weanlings (20 days old) of the Wister strain were kept on a basic fat-free-diet[8] obtained from the Nutrition Biochemical Co. After 100 days feeding, a gas chromatographic analysis of the fatty acids in the rat livers showed the presence of less than 1.1% linoleate and 2.0% arachidonate respectively of the total of the fatty acids. The rats were then divided into three groups of five rats in each. One gram portions of ethyl linoleate and ethyl all-*cis*-5,11,14-eicosatrienoate were fed daily intragastrically, by means of a syringe equipped with a round-end needle, to the first group and the second, respectivly. No fat was given to the third group. The fat-free-diet was fed to each group continuously. After 5 days, the rats were killed and the livers were quickly removed and immediately frozen. The fatty acid compositions of the liver lipids analyzed by the gas chromatographic method are given in Table I. A "shorthand designation" of the structure of each acid is included in the table; e.g., 18:2 is a C-18 acid with 2 double bonds, and 18:0 a saturated

C-18 acid. Each acid shown in the table was identified by internal standards. The low level of linoleate (18:2) and arachidonate (20:4) and the high level of eicosatrienoate in the fatty acid from the fat-free-diet group were consistent with the results of metabolic studies of the fatty acids reported by Mead and his co-workers.[9] The linoleate percentage was affected only to a slight degree by the dietary 5,11,14-eicosatrienoate, while it was significantly elevated by the dietary linoleate. On the contrary, the eicosatrienoate percentage was significantly elevated by the dietary 5,11,14-eicosatrienoate, while it was slightly decreased by the dietary linoleate. In spite of such differences, the arachidonate percentages were elevated in both cases. It is plausible that the dehydrogenation of 5,11,14-eicosatrienoate at the 8-position directly produced arachidonic acid in this experiment, because there was probably no other source for arachidonic acid except such dehydrogenation.

As the arachidonic acid detected by gas chromatography was identified only by the retention time, a structural confirmation was sought by a spectrophotometric analysis of alkali-isomerized products and by a gas chromatographic analysis of the degraded products. The eicosatrienoate and the eicosatetraenoate were therefore isolated from the liver lipids of rats fed with 5,11,14-eicosatrienoate by elution chromatography using silver-nitrate impregnated silicic acid as the stationary phase. The specific extinction coefficents at the maxima in the spectrophotometric absorption of the alkali-isomerized products of the eicosatrienoic acid and the eicosatetraenoic acid shown in Table II. The accordance of the specific extinction coefficients of the alkali-isomerized eicosatetraenoic acid with those of the alkali-isomerized arachidonic acid indicates that the greater part of the double bond in the

* Reported data for arachidonic acid in Ref. 14.

eicosatetraenoate belongs to the divinyl methylene system, for a double bond separated by more than 2 carbons can not be isomerized to the conjugated position with an adjacent double bond by alkali treatment. The oxidation of the eicosatrienoate by the periodate-permanganate reagent[10] gave mainly glutaric acid (96%) indicating the insertion of five carbon atoms between the carboxyl group and the first double bond in the eicosatetraenoate. The eicosatetraenoate fraction did not indicate the peak of a trans double bond in infrared spectrophotometric analysis. We may conclude, then, that the eicosatetraenoic acid from the liver lipids of rats of group II consists chiefly of arachidonic acid.

The data in Table II shows that more than 80% of the eicosatrienoate was changed to conjugated diene, not triene, by alkali isomerization; these data support the idea that the triene consisted chiefly unchanged 5,11,14-eicosatrienoate.

Further studies using the isotopic tracer technique are being planned in this laboratory in order to get direct evidence for the dehydrogenation and reliable knowledge concerning the effect of 5,11,14-eicosatrienoic acid as a new essential fatty acid.

## Experimental

**Materials.**—*Ethyl All-cis-5,11,14-Eicosatrienoic Acid.*—The ether extract (1.4 kg.) from *Podocarpus nagi* seeds was saponified with 4 l. of 10% ethanolic potassium hydroxide, and the free acids were esterified by refluxing them with 4 l. of 1% sulfuric acid - ethanol for 1 hr. The ethyl ester (1362 g.) was fractionally distilled through a glass column packed with stainless steel helices (1.5 cm. in diameter, 1 m. long) and with a heated jacket under 0.5—1 mmHg. Each fraction was analyzed by gas chromatography; a C-20 fraction (251 g.) containing less than 0.5% C-18 acid was collected. Further fractionation at 0—−20°C by the urea adduct method,[5] followed by distillation, yielded 70 g. of the eicosatrienoate, which was found to be 99.6% pure by gas chromatography.

*Ethyl Linoleate.* — Linoleate was prepared from safflower oil by the urea adduct method.[11] A gas

10) E. von Rudloff, *Can. J. Chem.*, **34**, 1413 (1956); C. G. Youngs, *J. Am. Oil Chem. Soc.*, **38**, 62 (1961).

11) J. G. Keppler, S. Sparreboom, J. B. A. Strorick and J. D. von Mikusch, *J. Am. Oil Chem. Soc.*, **36**, 38 (1959); A. R. Johnson and G. M. Ali, ibid., **38**, 453 (1961).

chromatographic analysis of the ester exhibited no peak other than that of linoleate.

*The Analysis of Fatty Acids.*—The livers were homogenized and extracted with chloroform-methanol (2:1 v/v) according to Folch's method.[12] The lipid extracted was then saponified by refluxing it for 1 hr. with 10% ethanolic potassium hydroxide. The fatty acids obtained from the saponified mixture were esterified by refluxing for 1 hr. with a 1% sulfuric acid - methanol solution. The esters obtained were then analyzed by gas chromatography using a stainless steel column, 6 min. in diameter and 2.25 m. long, packed with diethyleneglycol succinate-Celite 545 (60—80 mesh) (1 : 5 w/w) and with a hydrogen-flame-ionization detector. The remaining esters were separated according to column chromatography by the de Vries method.[13] The adsorbent was prepared by impregnating 100 g. of silicic acid with 200 ml. of 50% of an aqueous solution of silver nitrate. It was then filtered to remove the excess of the solution and activated at 120°C for 16 hr. Twenty grams of the adsorbent was packed into the glass tube using hexane and a hexane solution of the methyl ester (300 mg.) was added to the column. The sample was fractionated by step-by-step elution with 0—100% diethyl ether - hexane, and then the eicosatrienoate and the eicosatetraenoate were collected from the eluates. Their purities were found to be higher than 97% by gas chromatography. A portion was then isomerized by heating it with 11 g. of potassium hydroxide-ethyleneglycol for 15 min., after which the methanol solution of the products was subjected to spectrophotometric measurements according to the Herb method.[14] The other portion was oxidized by the periodate-permanganate method.[10] Ten milligrams of the sample in 20 ml. of *t*-butanol was added to 13.5 ml. of the periodate-permanganate reagent, which contained sodium periodate (284 mg.), potassium permanganate (1.10 mg.) and potassium carbonate (16.7 mg.), and the solution was refluxed for 1 hr. After the excess oxidizing reagent and *t*-butanol had been removed, the products were acidified and extracted with ether. The methyl esters were then analyzed by gas chromatography.

## Summary

Ethyl 5,11,14-eicosatrienoate has been fed to fat-deficient rats. The gas chromatographic analysis of the fatty acids in the liver lipids and the alkali isomerization and oxidation scission of the eicosatetraenoate separated from the fatty acid has given evidence for the transformation of all-*cis*-5,11,14-eicosatrienoate to arachidonate.

# The Condensation Product of Monomethylammonium 6-Aminosalicylate with Acetone[1),*]

By Kazutoshi YAMADA and Noboru SUGIYAMA

(Received March 15, 1965)

In previous papers it has been demonstrated that the 8-quinolinecarboxylic acid derivative was obtained by the reaction between the ammonium salt of 6-amionsalicylic acid (II) and $\beta$-diketone at room temperature,[2)] and that the reaction of ammonium salt of II with ethyl acetoacetate gave 4,7-dihydroxy-2-methyl-8-quinolinecarboxylic acid as a major product.[3)]

While the reaction of ammonium or ethylammonium 6-aminosalicylate with acetone has been demonstrated to give a compound I (R=H or $C_2H_5$),[4,5] the reaction of methylammonium 6-aminosalicylate with acetone has not yet been

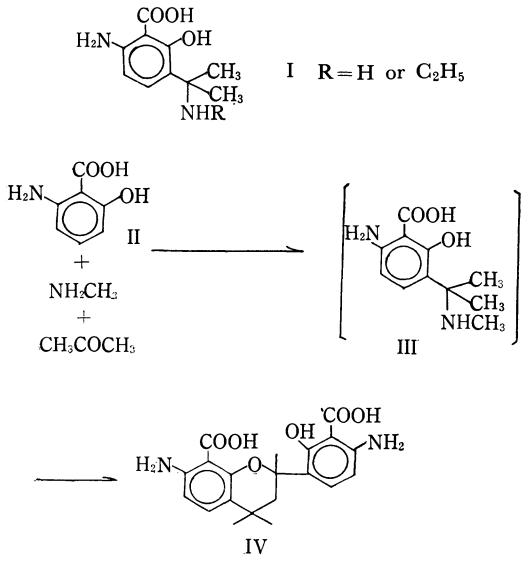

Fig. 1

studied. If the latter reaction proceeds as does the former, the III substance may be expected. Actually, however, the reaction product has not proved to be III.

Monomethylammonium 6-aminosalicylate was dissolved in acetone, and the solution was allowed to stand at room temperature. From this solution a solid was obtained. By purification with petroleum ether - ether, IV was obtained. IV could not be recrystallized from any solvents unless ether was added. IV was, however, readily susceptible to air-oxidation. The fact that flavan derivatives give a crystalline complex with ether is well-known.[6] This fact, plus the analogy of the reaction of ammonium or ethylammonium 6-amionsalicylate with acetone, suggests that this compound is a flavan derivative such as IV.

The structure of IV was established as follows. It showed positive ferric chloride and Ehrlich-Herter tests. In addition, it was soluble in a sodium bicarbonate solution. The ultraviolet absorption spectrum of IV in ethanol had two absorption maxima, at 285 and 312 m$\mu$, which indicates no radical change from the ultraviolet spectrum of I. The infrared absorption spectrum in the KBr disk contained an amino band (3350 cm$^{-1}$), a hydroxyl band (3500—3200 cm$^{-1}$), a carbonyl band (1695 cm$^{-1}$) and a C–H out-of-plane deformation vibration band of the benzene ring (with two adjacent hydrogen atoms) (820 cm$^{-1}$). Its p$K_a'$ values were 3.9 (COOH) and 7.2 (COOH) in 55% methanol.[7] By treatment with pyridine - acetyl chloride, it afforded a diacetyl derivative, the infrared absorption spectrum of which contained a $\nu$C=O (acetamido) band (1665 cm$^{-1}$). Therefore, it was presumed that the condensation product has no conjugated system except benzene, and that it has one hydroxyl, two amino and two carboxyl groups.

When IV was refluxed in 10% hydrochloric acid, V was obtained. Its infrared absorption spectrum contained bands of amino and hydroxyl groups (3350 cm$^{-1}$), and a C–H out-of-plane deformation vibration of the benzene ring (with one and two adjacent hydrogen atoms) (840 cm$^{-1}$), but the carbonyl band had disappeared. The Ferric chloride and Ehrlich-Herter tests were positive. Therefore, it was found to be a decarboxylated amino-hydroxyl compound. V was easily oxidized by air and changed to a sticky substance.

The diazotization of the amino-hydroxy compound V, followed by the Sandmeyer reaction,[8] resulted in the formation of the dichloro compound (VI). VI was then catalytically reduced with palladium black to a halogen-free compound (VII). The infrared absorption spectrum of VII showed a hydroxyl band (3300 cm$^{-1}$) and a C–H out-of-plane deformation band (with four adjacent hydrogen atoms) (750 cm$^{-1}$). The molecular weight of VII was 260 (by Rast method). Therefore, the compound IV is probably a dimer of 3-isopropenyl-6-aminosalicylic acid. The $\lambda_{max}$ value (282 m$\mu$) of VII in ethanol was shifted to 290 m$\mu$ in a 0.5 N sodium hydroxide solution. Since hindered or partially-hindered phenols usually show a bathochromic shift of 10—20 m$\mu$ in a 0.5 N alkaline solution,[9,10] the structure VII with a hindered hydroxyl group is sufficient to explain the 8 m$\mu$ shift. The NMR spectrum in carbon tetrachloride had a sharp singlet at 8.67 $\tau$ (6 : methyl protons of *gem*-dimethyl groups),[11,12] a singlet at 8.45 $\tau$ (3: methyl protons) and a singlet at 5.01 $\tau$ (hydroxyl proton), as well as complex multiplets at 8.2—8.4 $\tau$ (2: aliphatic protons) and 2.8—3.2 $\tau$ (8: aromatic protons).[13] Thus, the NMR data are consistent with the structure of 2'-hydroxy-2,4,4-trimethylflavan. The behavior of forming crystalline adducts with ether was characteristic of flavans.[14,15] The methylation of

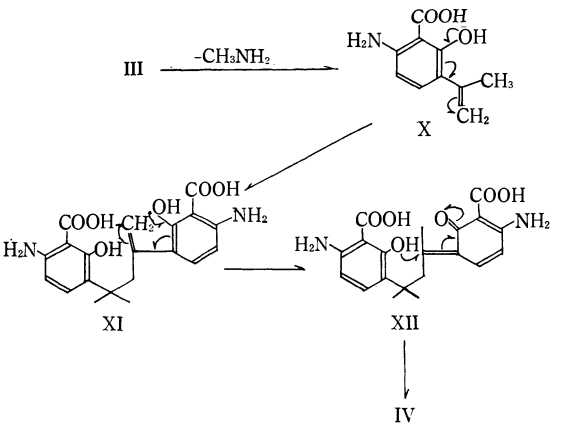

Fig. 3

VII with diazomethane gave a monomethoxy compound. Its infrared absorption spectrum did not show a hydroxyl band.

Compound VII was oxidized with potassium permanganate to an acid VIII. If the structure of VII is hydroxyflavan, the oxidized compound VIII should be chromancarboxylic acid. Its infrared absorption spectrum showed the group frequencies which characterize an acid carbonyl group, and a C–H out-of-plane deformation vibration of the benzene ring (with four adjacent hydrogen atoms). The ultraviolet absorption maxima in ethanol appeared at 226.5, 274.5 and 281.5 m$\mu$. The melting point of VIII coincided well with that of the literature.[16]

The decarboxylation of the acid VIII by the usual method was very difficult. When, however, a mixture of VIII and copper chromite in quinoline was heated, the compound $C_{12}H_{16}O_2$ (IX) was formed by the loss of carbon monoxide. The melting point and infrared absorption spectrum of this compound were identical with those of 2-hydroxy-2,4,4-trimethylchroman. The loss of carbon monoxide by heating in quinoline with copper chromite is frequently observed in this type of compound.[14] These degradation reactions and physical properties are consistent with the structure of IV, 7, 4'-diamino-2'-hydroxy-2, 4, 4-trimethylflavan-8, 3'-dicarboxylic acid.

It is known that the flavan derivative is obtained by the reduction of naturally-occurring flavon derivatives or by the cyclization of allyl ethers. The reaction of methylammonium 6-aminosalicylate with acetone presents another new method of preparing the flavan derivative.

The mechanism of the condensation reaction of monomethylammonium 6-aminosalicylate with acetone is considered to be following. Much as in the reaction of ammonium 6-aminosalicylate with acetone, it is probable that at the first stage 6-aminosalicylate produces an unstable intermediate III. III can readily lose its methylamino on account of its hyperconjugation by methyl group to give the 3-isopropenyl derivative X, which, in turn, can dimerize by means of proton transfer and electron rearrangement. The ready dimerization of 3-isopropenyl salicylic acid[5] and its derivatives would support this mechanism. The dimer XI (enol form), is probably in keto-enol equilibrium with the reactive form, XII, containing the more highly-substituted (and the more sterically-hindered) double bond. The process of cyclization is shown in Fig. 3. This is supported by the fact that the dimerization of the vinyl compound is promoted by an acid catalyst.

## Experimental

**4', 7-Diamino-2'-hydroxy-2, 4, 4-trimethylflavan-3', 8-dicarboxylic Acid (IV).**—A solution of methylammonium salt of 6-aminosalicylic acid,[17] which had been obtained from 10 g. of II, as has been described before,[2] in 50 ml. of dry acetone was allowed to stand at room temperature for one week. During this time, crystals were gradually separated. These crystals were then collected and dissolved in a 1 N sodium hydroxide solution. After neutralization with dilute hydrochloric acid, the solution was extracted with ether. The ether solution was dried with anhydrous sodium sulfate, and the ether was removed. The residue was recrystallized from petroleum ether with a small amount of ether. Pale yellow fine needles, m. p. 97°C (decomp.) were obtained. Yield, 3 g.

Found: C, 62.4; H, 6.98; N, 5.98. Calcd. for $C_{20}H_{22}O_6N_2 \cdot (C_2H_5)_2O$: C, 62.6; H, 7.01; N, 6.08%.

It was very sensitive to oxygen. Even in the crystalline state, it soon changed from colorless to red. A ferric chloride test was positive (dark red). Ehrlich-Herter and sodium nitroprusside tests were positive. UV: $\lambda_{max}^{EtOH}$ 265, 330 m$\mu$. IR: 3500—3200, 3350, 1695

16) W. Baker and J. C. McGowan, *J. Chem. Soc.*, **1952**, 1781; **1938**, 347.

17) K. Yamada, K. Taya and S. Seki, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **83**, 107 (1962).

820 $cm^{-1}$.[18] $pK_a'$: 3.9 (COOH) and 7.2 (COOH) in 55% methanol.[19] IV gave a diacetyl derivative with pyridine-acetyl chloride. IR: 1665 $cm^{-1}$ (acetamido carbonyl).

**4', 7-Diamino-2'-hydroxy-2, 4, 4-trimethylflavan (V).**—A suspension of 1.3 g. of IV in 20 ml. of 10% hydrochloric acid was refluxed for 5 hr. Carbon dioxide thus evolved vigorously. The neutralization of the resulting solution with a dilute sodium hydroxide solution separated precipitates, which were then recrystallized from petroleum ether-ether. Pale yellow needles, m. p. 177—180°C (decomp.), were obtained. Yield, 0.8 g.

Found: C, 70.6; H, 8.59; N, 7.30. Calcd. for $C_{18}H_{22}O_2N_2 \cdot (C_2H_5)_2O$: C, 71.0; H, 8.74; N, 7.41%.

Ferric chloride and Ehrlich-Herter tests were positive. UV: $\lambda_{max}^{EtOH}$ 235, 325 m$\mu$. IR: 3350, 840 $cm^{-1}$.

**4', 7-Dichloro-2'-hydroxy-2, 4, 4-trimethylflavan (VI).**—To a solution of 2 g. of V in a mixture of 15 ml. of concentrated hydrochloric acid and 15 ml. of water was dropped a solution of 0.6 g. of sodium nitrite in 2 ml. of water at 0—5°C with shaking. To the reaction mixture was then added a cuprous chloride solution, prepared from 9 g. of copper sulfate. After it had been kept at 60°C for 5 min., this solution was cooled in an ice bath. The precipitates were collected and recrystallized from light petroleum. Rhombic crystals, m. p. 135°C, were obtained. Yield, 1.1 g.

Found: C, 64.1; H, 5.3; Cl, 20.8. Calcd. for $C_{18}H_{18}O_2Cl_2$: C, 64.1; H, 5.3; Cl, 21.1%.

IR: 3380, 850 $cm^{-1}$. A ferric chloride test was positive.

**2'-Hydroxy-2, 4, 4-trimethylflavan (VII).**—A solution of 0.5 g. of dichloro-flavan (VI) in 10 ml. of methanol was reduced with hydrogen at an atmospheric pressure of 10 in the presence of 0.5 g. of palladium black and 0.3 g. of powdered anhydrous sodium acetate for 8 hr. To the filtered solution water was then added until all the precipitates had been separated. The recrystallization of the precipitates from petroleum ether gave prisms, m. p. 99°C. Yield, 0.25 g.

Found: C, 80.1; H, 7.6; mol. wt. (Rast), 260. Calcd. for $C_{18}H_{20}O_2$: C, 80.6; H, 7.5%; mol. wt. 268.

A ferric chloride test was positive. IR: 330, 750 $cm^{-1}$.

This compound was characterised as the $-OCOCH_3$ derivative; hexagonal prisms; m. p. 96°C.

Found: C, 81.8; H, 7.3. Calcd. for $C_{20}H_{22}O_2$: C, 81.6; H, 7.53%.

UV: $\lambda_{max}^{EtOH}$ 230, 282 m$\mu$.

**2, 4, 4-Trimethylchroman-2-carboxylic Acid (VIII).**—A solution of 1 g. of VII in 10 ml. of acetone was oxidized by the rapid addition of potassium permanganate in 300 ml. of acetone. The mixture boiled spontaneously, and the oxidation reaction was completed in 5 min. After the acetone had been removed, 50 ml. of water, 13 g. of sodium pyrosulfite and 13 ml. of 2 N hydrochloric acid were added to the residue. Sulfur dioxide was then passed in until the mixture became colorless. The mixture was extracted with ether. The ether solution was washed with water and extracted with four 5 ml. portions of a saturated sodium bicarbonate solution. The aqueous layer was washed with 10 ml. of ether and then acidified with hydrochloric acid. Pale yellow solid precipitates were collected at 0°C. Recrystallization from benzene gave an acid, VIII; 0.15 g.; rhombs; m. p. 172°C. UV: $\lambda_{max}^{EtOH}$ 226.5, 274.5, 281.5 m$\mu$. IR: 1695, 758 $cm^{-1}$. $pK_a'$: 4.6 (COOH) in 62% methanol. The structures of VIII and its methyl derivative were confirmed by their melting point infrared and ultraviolet absorption spectra.

**The Reaction of 2, 4, 4-Trimethylchroman-2-carboxylic Acid with Copper Chromite-Quinoline.**—A mixture of 0.3 g. of the acid VIII, 0.5 ml. of freshly-distilled quinoline, and 0.5 g. of copper chromite were refluxed for 20 min. The cooled mixture was then poured into 15 ml. of concentrated hydrochloric acid. After the mixture had been heated on a boiling water-bath for 15 min., 20 ml. of water was added. The solid precipitates which separated were filtered off through sand and washed with 30 ml. of ether. The aqueous layer was then extracted with three 10 ml. portions of ether. After the substance had been shaken with 10 ml. of a saturated sodium bicarbonate solution, the ether was removed. The oily residue, which soon solidified, was recrystallized from petroleum ether. Prisms, m. p. 90°C, were obtained. The melting point of IX was the same as that of the literature.[16]

Found: C, 75.5; H, 8.6. Calcd. for $C_{12}H_{16}O_2$: C, 75.0; H, 8.3%. UV: $\lambda_{max}^{EtOH}$ 274, 279 m$\mu$. IR: 3440, 750 $cm^{-1}$.

The authors wish to thank Professor Kunisaburo Tamura and Dr. Shigeo Seki for their helpful discussions.

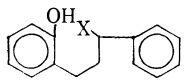
18) The IR absorption spectra were recorded with a Nihon Bunko Model DS 301 and Hitachi Model S-2 spectrophotometers. The UV absorption spectra were recorded with a Hitachi Model EPS-2 spectrophotometer; a pair of 1 cm. quartz cell was used. The NMR spectra were measured with a Nihon-denshi type NMR spectrometer equipped with a 60 Mc.

19) All p*Ka'* measurements were carried out at 25±1°C with a Radiometer (Copenhagen) type SBR-2/SBU-1/TTT-1/TTA-2 titration equipment.



# The Condensation Products of Acetamidophenol with Acetone[1),*]

By Kazutoshi YAMADA and Noboru SUGIYAMA

(Received March 15, 1965)

In a previous paper,[2)] the reaction of methylammonium 6-aminosalicylate with acetone at room temperature was found to afford the aminoflavan derivative. The process of the formation of this derivative was explained by a dimerization mechanism of the intermediate isopropenyl compound.

Though it is known that flavan derivatives are synthesized through the dehydration of phenyl-(*o*-hydroxyphenylethyl)-carbinol derivatives (Ia) or through the dehydrohalogenation of halogen compounds such as Ib, these methods are accompanied by too many side reactions and too many difficulties for purification to be possible. In 1905 Fabinyi and Szeky obtained the so-call "Dragon's blood" by reacting phenols with acetone in an acidic medium.[3)] Their structures were studied by Baker

Ia X=OH
Ib X=halogen

Fig. 1.

and explained as flavan derivatives.[4)] Both of these projects, however, reported methods of obtaining flavan derivatives which are not satisfactory for practical purposes.

It has been found that aminoflavan derivatives are obtained easily by the acidic condensation of acetamidophenols with acetone. *m*-Acetamidophenol (II) was, therefore, dissolved in a large amount of acetone and heated at 50°C, and then dry hydrogen chloride gas was passed in. From the reaction mixture, a crystalline substance IV was obtained. Its ultraviolet absorption spectrum showed $\lambda_{max}$ 250, 287 m$\mu$. Compared with the absorption of II ($\lambda_{max}$ 246, 284 m$\mu$), no radical change was observed. Its infrared absorption spectrum showed absorptions at 1670 cm$^{-1}$ ($\nu$C=O, acetamido), 3380 cm$^{-1}$, and 3240 cm$^{-1}$ ($\nu$OH, $\nu$NH). As the ferric chloride test is positive, the existence of phenolic hydroxyl is evident. The position of each substituent can easily be estimated by the C–H out of plane deformation vibration band of the benzene ring (with one or two adjacent H atoms).[5)]

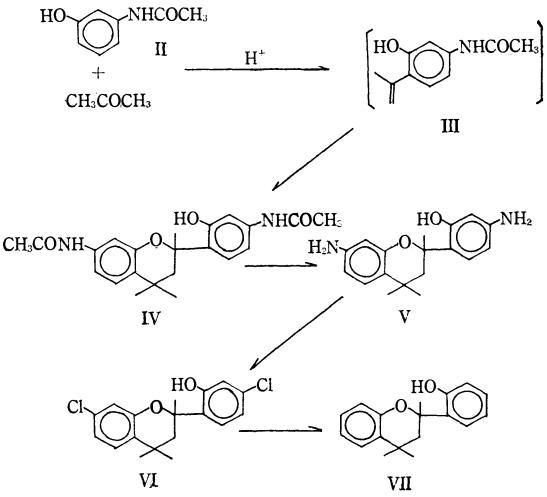


Fig. 2.

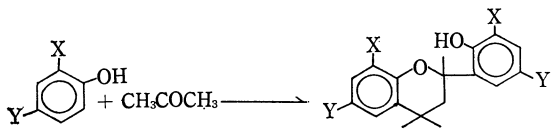

In order to determine the structure of IV, the following experiments were carried out. The refluxing of a suspension of IV in 10% hydrochloric acid for 5 hr. yielded a compound V. The ferric chloride test and Ehrlich-Herter test of V were positive, and its infrared absorption spectrum showed hydroxyl and amino groups. The ultraviolet absorption maximum of V coincided with that of 4', 7-diamino-2'-hydroxy-2, 4, 4-trimethylflavan. V was not stable in the air, however, it turned black at room temperature.

V was deaminated to a stable derivative as follows. It was diazotized, and then chlorinated to VI by the Sandmeyer method.[6)] VI was then catalytically dechlorinated to VII at room temperature with palladium black, which did not show any melting point depression when mixed with authentic 2'-hydroxy-2, 4, 4-trimethylflavan.[2)] Moreover, its infrared sbsorption spectrum also coincided completely with that of this authentic sample. Therefore, the structure of IV was identified as 4',7-diacetamido-2'-hydroxy-2, 4, 4-trimethylflavan. Furthermore, the NMR spectrum of IV in carbon tetrachloride had a sharp singlet at 8.67$\tau$ (6: methyl protons of *gem*-dimethyl groups), a singlet at 8.54$\tau$ (3: methyl protons), singlet at 5.01$\tau$ (a hydroxyl proton), a doublet at 7.85$\tau$ (6: methyl protons of *N*-acetyl groups),[7)] a multiplet at 8.3—8.5$\tau$ (2:

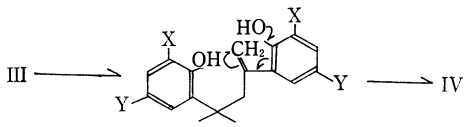
aliphatic protons) and complex multiplets at 2.8—3.2$\tau$(6: aromatic protons).[8] Thus, the NMR data also was consistent with the structure of 4', 7-diacetamido-2'-hydroxy-2, 4, 4-trimethylflavan.

A similar condensation reaction was applied to the *o*- and *p*-isomers of II. When *o*-acetamidophenol (VIII) and acetone were subjected to condensation by hydrogen chloride, a condensate (IX) was obtained. Its ultraviolet absorption maxima were at 248 and 286 m$\mu$. Infrared absorptions were observed at 1668 $cm^{-1}$ ($\nu$C=O), 3389 $cm^{-1}$ ($\nu$OH), and 3300 $cm^{-1}$ ($\nu$NH) respectively. From these results, IX was identified as 3', 8-diacetamido-2'-hydroxy-2, 4, 4-trimethylflavan.



VIII X=NHCOCH$_3$, Y=H  IX X=NHCOCH$_3$, Y=H
X X=H, Y=NHCOCH$_3$  XI X=H, Y=NHCOCH$_3$

Fig. 3.

From *p*-acetamidophenol (X) and acetone 5', 6-diacetamido-2'-hydroxy-2, 4, 4-trimethylflavan (XI) was obtained. Its ultraviolet and infrared absorption were similar to those of IX.

As an intermediate product of the condensation reaction of II with acetone, III was considered. This process is supported by the formation of the flavan derivative from isopropenyl phenol in an acidic medium.[9] If Schnell's polymerization mechanism of vinyl compounds holds true, XII may be produced by the dimerization of III, and, further, will form a ring to yield IV. According to this mechanism, it is probable that isomeric acetamido-2-isopropenylphenol will be produced, however, due to the steric effect of the acetamido group, it is very difficult to produce it. The fact that the yields of the IX, IV, and XI condensates from *o*-, *m*- and *p*-acetamidophenol were 1.4, 5.2 and 4.7% respectively also supports the isopropenyl intermediate mechanism.

XII X=H or NHCOCH$_3$, Y=NHCOCH$_3$ or H

## Experimental

**4', 7-Diacetamido-2'-hydroxy-2, 4, 4-trimethylflavan (IV).**—A mixture of *m*-acetamidophenol and 30 ml. of acetone was saturated with dry hydrogen chloride, and then kept at 50°C for 2 days. After the acetone had been removed, a dark red substance was obtained. After an excess of 20% sodium hydroxide solution had then been added to this substance, the mixture was stirred vigorously overnight. After filtration, the sodium hydroxide solution was acidified and next extracted with 250 ml. of ethyl acetate. The ethyl acetate solution was dried with sodium sulfate. After the distillation of ethyl acetate, the residue became a sodid. It was then purified by chromatography (alumina-acetone). After the acetone had been removed, the residual solid substance was recrystallized from ether-petroleum ether. Small rhombic crystals (IV), m. p. 165°C (decomp.), were obtained. Yield, 1.6 g.

Found: N, 6.01. Calcd. for $C_{22}H_{26}O_4N_2\cdot(C_2H_5)_2O$: N, 6.14%. This substance has 1 mol. of the ether of crystallization. It loses the ether of crystallization even upon standing in air, becoming opaque and sticky. UV: $\lambda_{max}^{EtOH}$ 250, 287 m$\mu$. IR: 3380, 3240, 1670, 870, 830 $cm^{-1}$.

**4', 7-Diamino-2'-hydroxy-2, 4, 4-trimethylflavan (V).**—A suspension of 1 g. of IV in 20 ml. of 10% hydrochloric acid was refluxed for 5 hr. Neutralization with an aqueous sodium hydroxide solution produced percipitates. Recrystallization from petroleum ether-ether then gave pale yellow needles (V), m. p. 179.5°C (decomp.). Yield, 0.3 g.

Found: N, 7.23. Calcd. for $C_{18}H_{22}O_2N_2\cdot(C_2H_5)_2O$: N, 7.41%. The ferric chloride test and Ehrlich-Herter test were positive. UV: $\lambda_{max}^{EtOH}$ 236, 325 m$\mu$. IR: 3400, 3100, 880, 830 $cm^{-1}$.

**2'-Hydroxy-2, 4, 4-trimethylflavan (VII).**—Diaminoflavan (V) was converted into a dichloro compound according to the method described in a previous paper.[2] The dichloroflavan in methanol was dechlorinated with hydrogen at an atmospheric pressure of 5 in the presence of palladium black and powdered anhydrous sodium acetate for 10 hr. The dechlorinated substance (VII) was then recrystallized from petroleum ether-ether. M. p. 98°C.

Found: C, 80.3; H, 7.4. Calcd. for $C_{18}H_{20}O_2$: C, 80.6; H, 7.5%. A mixed melting point determination with an authentic sample showed no depression (98°C), and its infrared and ultraviolet absorption spectra were identical with those of 2'-hydroxy-2, 4, 4-trimethylflavan.

**3', 8-Diacetamido-2'-hydroxy-2, 4, 4-trimethylflavan (IX).**—A mixture of 10 g. of *o*-acetamidophenol and 30 ml. of acetone was saturated with dry hydrogen chloride, and then kept at 50°C for a week, after which time the solution was treated in a manner similar to that described for IV. Yellow needles (IX), m. p. 146.5°C (decomp.), were obtained.

Found: N, 5.92. Calcd. for $C_{22}H_{26}O_4N_2\cdot(C_2H_5)_2O$: N, 6.14%. UV: $\lambda_{max}^{EtOH}$ 248, 286 m$\mu$. IR: 3340, 1668, 750 $cm^{-1}$. On standing in air, the crystals lost some of the ether of crystallization and became sticky. Yield, 0.4 g.

10) UV, IR, NMR and p$K_a'$ were measured with the same apparatus as the previous paper.[2]

**5′, 6-Diacetamido-2′-hydroxy-2, 4, 4-trimethylflavan (XI).**—The reaction of 5 g. of *p*-acetamidophenol with acetone under the same conditions as above afforded 5′,6-diacetamido-2′-hydroxy-2, 4, 4-trimethylflavan (XI), m. p. 85°C (decomp.). Yield, 0.7 g.

Found: N, 6.02. Calcd. for $C_{22}H_{26}O_4N_2 \cdot (C_2H_5)_2O$: N, 6.14%. UV: $\lambda_{max}^{EtOH}$ 250, 291 m$\mu$. IR: 3390, 1664, 875 (w.), 825 cm$^{-1}$.

The authers wish to thank Dr. Yoshimori Omote and Miss Yo Saiga for their helpful discussions.

# Studies on Geometric Isomerism by Nuclear Magnetic Resonance. II.[1] Geometric Configurations of Alkylidenecyanoacetic Esters

By Toshio HAYASHI, Minoru IGARASHI, Shoichi HAYASHI and Hiroshi MIDORIKAWA

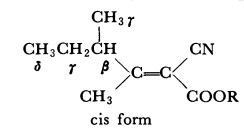
(Received March 30, 1965)

A number of studies of the mechanism of the Knoevenagel reaction has been published,[2-9] but little information is available concerning the stereochemistry of the reaction. Baker and Howes[10] have shown that the condensation of salicylaldehyde or its methyl ether with cyanoacetic acid or its ester gives only the isomers with the trans configuration.[11] However, this study has so far not been extended to alkylidenecyanoacetic esters.

In the preceding paper, the present authors have reported the successful application of the NMR technique to the configurational determinations of the compounds of the $R_1(R_2O)C=C(CN)\cdot COOR_3$ type. Therefore, it seems that it would be interesting to apply this technique to alkylidenecyanoacetic esters of the $R_1MeC=C(CN)COOR_2$ type.

For the present purpose, it is assumed that the $\beta$-methyl[12] signal of an isomer of these esters consists of only one peak, due to the absence of any resolved spin-spin coupling across the C=C bond. Hence, the esters of this type are believed to be a class of compounds which is suitable for studies of cis-trans isomerism. However, since no stereoisomer of a known configuration was available, the assignment of each of two signals for the $\beta$-methyl group to the correct stereoisomer had to be based on the previous assumption,[1] which states that the chemical shift for the $\beta$-methyl group occurs at a higher field in the trans- than in the cis-configuration with respect to the alkoxycarbonyl group, whereas the reverse is true for the $\gamma$-methyl group. The results obtained have been supported by the relative stability of the isomers.

## Experimental



**Materials.**—All the alkylidenecyanoacetic esters examined were prepared according to the method of Cope.[9] Each compound was distilled under reduced pressure at least twice, and the boiling points and nitrogen contents were checked against the literature values.

An equilibrium mixture of cis-trans isomers was obtained by the addition of a trace amount of sodium ethoxide, after which the mixture was allowed to stand at room temperature for at least one week.

**NMR Spectra.**—All NMR spectra were taken with a JNM-C-60 high-resolution NMR spectrometer working

11) By a trans isomer is meant the form in which the phenyl and carbonyl groups are on opposite sides of the C=C bond.

12) The notations used here to distinguish the various methyl and methylene groups are shown below, each group being referred to as cis or trans with respect to the alkoxycarbonyl group. The isomer in which the $\beta$-methyl group and alkoxycarbonyl groups are on the same side of the C=C bond is referred to as the isomer.

cis form

at 60 Mc. and at a temperature of 19—20°C. The samples were examined in a ca. 8 per cent (w/v) solution in carbon tetrachloride, using tetramethylsilane as an internal reference. The chemical shifts are given as p. p. m. downfield from tetramethylsilane.

The data recorded in Table II were obtained by averaging the results of at least three measurements. The values are accurate to ±0.025 p. p. m,; the relative values between *cis*- and *trans*-β-methyl protons are accurate to ±0.005 p. p. m.

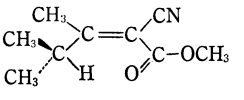
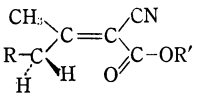
## Results and Discussion

The esters studied in this work are listed in Table I, together with the pertinent physical and chemical data, while the chemical shifts are shown in Table II. The isomeric compositions of fourteen esters are shown in Table III, together with the equilibrium ratios. Representative NMR spectra of the esters are shown in Figs. 1 and 2.



The resonance line-positions of the methyl protons of the methoxycarbonyl group were constantly located in the 3.80+0.01 p.p.m. range, while those of the methyl and methylene protons of the ethoxycarbonyl group always appeared in the 1.33+0.01 and 4.23+0.01 p.p.m. ranges respectively. The replacement of the methoxycarbonyl group by the ethoxycarbonyl group has practically no effect on the chemical shifts of the $\beta$-methyl and $\beta$-alkyl protons in the corresponding ester. This fact was often useful in assigning signals superimposed upon by signals of the alkoxycarbonyl group.

The fact that the spectra show two signals of an unequal intensity, separated by about 0.08 p.p.m., for the $\beta$-methyl group was ascribed to the co-existence of cis and trans isomers. As has been mentioned previously, the assignment of the configuration was made on the basis of a previous assumption.[1] This leads to the assignment of the $\beta$-methyl resonance at the higher field to the group which is in a position trans to the alkoxycarbonyl group.



In the case of these esters, the relative stabilities of the stereoisomers may be expected to be determined by simple steric interactions between the $\beta$-alkyl substituent and the alkoxycarbonyl group. An examination of molecular models suggests that the cis configurations are to be favored over the trans. On the basis of this consideration, the more intense of the two signals of the $\beta$-methyl group is assigned to the cis isomer, and the less intense, to the trans. The conclusions reached by the two methods of assigning the peaks in the NMR spectrum are consistent with each other.

As a typical example, the present authors analyzed the spectrum of ethyl $\alpha$-cyano-$\beta$-neopentylcrotonate (XIII, Fig. 1A). The $\beta$-methyl signal appears as a doublet* of an unequal intensity, with the more intense signal at the lower field (2.28 and 2.35 p.p.m.). The $\beta$-methylene signal also appears as a doublet of an unequal intensity, with the more intense signal at the higher field (2.45 and 2.86 p.p.m.). On the basis of the arguments just given, the more intense signals are assigned to those of the cis isomer, and the weaker signals, to those of the trans. Since the $\beta$-methylene group of the cis isomer is in a position trans to the ethoxycarbonyl group, the results show that both the $\beta$-methyl and the $\beta$-methylene groups are more deshiedled by 0.08 p.p.m. in the cis- than in the trans-arrangement with respect to the ethoxycarbonyl group. The $\gamma$-methyl protons appear as a doublet of an unequal intensity, with the more intense signal at the lower field (0.98 and 1.06 p.p.m.), indicating that, contrary to the case of the $\beta$-methyl protons, the $\gamma$-methyl protons occur at the higher field when located cis to the ethoxycarbonyl group. Similar observations have already been made in the case of $\alpha$-cyano-$\beta$-alkoxy-$\beta$-alkylacrylic esters.[1]

It may be noticed in Table II that, in general, the peak separation of the $\beta$-methylene protons, except for III and IV, is much larger than that of the $\beta$-methyl protons, and that the peak separation of the $\beta$-methine proton (0.65 p.p.m. for VII and VIII) is much larger than that of the $\beta$-methylene protons. These facts suggest that the VIIa and XIIa conformations are heavily populated, as has been pointed out by Jackman and

Wiley in the case of methyl β-methylglutaconate.[13]

The isomeric compositions of fourteen esters, as evaluated from the integration of the area under the appropriate NMR signals, are given in Table III. The composition is little affected by the temperature, as was determined by heating it to 71°C, except in the case of XIII. (As may be seen from Fig. 1B, the trans isomer of XIII was surprisingly much increased by heating it to 71°C (trans per cent, 61).) Attempts to separate the stereoisomers of these esters by gas chromatography were unsuccessful.

It seemed to be important to ascertain whether or not the isomeric compositions of the condensation products are the same in the equilibrium state. It is known that the isomerization of the esters is induced by a trace amount of base.[14,15] A sample which contained sodium ethoxide was allowed to stand at room temperature for a week and then distilled in vacuo. The results (Table III) show that the cis-trans ratios of the equilibrium mixtures are almost the same as those of the products ratios within the limit of experimental error, except for XIII. Accordingly, it is open to question whether or not the products were formed in these ratios. The present authors rather prefer the explanation that the products, once formed in some unidentified ratios, reached, by isomerization, a thermodynamic equilibrium. These circumstances would make it difficult to elucidate the steric course of the Knoevenagel reaction. However, these considerations are only tentative; they are now being investigated further.

It is interesting to note that the percentage of the cis isomer gradually increases with an increase in the size of the β-substituted alkyl group in the order; *t*-butyl > neopentyl > isobutyl > isopropyl > *n*-propyl > ethyl > methyl > hydrogen. This observation agrees with what would be expected on steric grounds, because this order is almost parallel with the magnitude of the steric requirement of the β-substituted alkyl group. Therefore, this finding supports the assumption suggested in Part I.[1]

## Summary

The Knoevenagel reaction of a methyl alkyl ketone with cyanoacetic ester gives a stereoisomeric mixture of α-cyano-β-alkylcrotonic ester. The NMR technique has been applied to the study of the geometric configurations of the mixture. It has been found that the isomer with a β-methyl group cis to the alkoxycarbonyl group always occurs predominantly. The magnitude of the cis-trans composition of the mixture is parallel to the steric requirement of the β-substituted alkyl group.

The authors wish to express their thanks to Mr. Jun Uzawa of this Institute for his measurements of the NMR spectra.

# Kinetic Studies of the Solution Polymerization of Trioxane Catalyzed by $BF_3 \cdot O(C_2H_5)_2$. I. The Effect of the Catalyst and the Water Concentration on the Rate of Polymerization

By Toshinobu HIGASHIMURA, Tetsuro MIKI and Seizo OKAMURA

(Received April 5, 1965)

It has been considered that, in the case of the cationic polymerization of cyclic oxygen compounds such as ethylene oxide, the chain carrier (active center) is a *t*-oxonium ion rather than a carbonium ion.[1-3] The reason for this is as follows: as the carbonium ion produced from cyclic monomers is generally unstable in comparison with that of vinyl monomer, the carbonium ion is transformed to the more stable oxonium ion by solvation at the ether group of the monomer whose concentration in the reaction system is very large. It is also inferred that, because of its stability, the oxonium ion is less reactive than the carbonium ion in vinyl polymerization.

Many patents on the cationic polymerization of trioxane (TO) have been presented, but only a few papers have been published on the kinetic study

1) H. Meerwein, E. Battenberg, H. Glod, E. Pfeil and G. Willfang, *J. Prakt. Chem.*, **154**, 83 (1939); K. Hamann, *Angew. Chem.*, **63**, 231 (1951).
2) J. B. Rose, *J. Chem. Soc.*, **1956**, 546.
3) D. J. Worsfold and A. M. Eastham, *J. Am. Chem. Soc.*, **79**, 897 (1957).

of the solution polymerization of TO catalyzed by cationic catalyst.[4-6] Recently, however, reports on the nature of the induction period of the solution polymerization[7] and on the kinetics of polymerization of molten TO[8-11] have been published, the results of the latter differing from those of solution polymerization. Kern et al.[4] suggested that the active center was a zwitter ion, unlike as in the usual polymerization mechanism of vinyl monomers.

In this series of reports we will try to establish the characteristics of the cationic polymerization of cyclic monomers. As such a monomer, trioxane was selected. Up to the present, none of the published papers on the cationic polymerization of TO has dealt with the quantitative relation between the polymerization condition and the rate of polymerization or the molecular weight of the resultant polymer. Therefore, we tried to mesaure the rate of polymerization and the molecular weight of the resultant polymer under various conditions, using $BF_3 \cdot O(C_2H_5)_2$ as the catalyst because it is most often used in cationic polymerizations. Even with the limitation of a single catalyst, the polymerizations in the different kinds of solvents were very dissimilar and it was difficult to infer the reaction mechanism.

In this first report the dependence of the rate of polymerization of the concentrations of the catalyst and the water will be discussed. In a non-polar solvent, a small amount of water acts as a co-catalyst. On the other hand, in a polar solvent water does not accelerate the polymerization reaction. It will also be found that the kinetic order of the catalyst concentration to the rate of polymerization varies with the kind of solvent in a complicated manner.

## Experimental

**Procedures.**—The polymerization was initiated by adding the catalyst solution from a syringe through a rubber stopper into a flask containing the monomer solution. Here the effects of air were not considered, and the polymerization solution was not stirred. In the course of the polymerization the polymers produced were suspended in the medium (when the water concentration was small) or precipitated (when the water concentration was large), and at longer times the whole reaction system gelled. The polymerization was stopped by adding methanol containing a small amount of ammonia to the reaction system. The resultant polymer was washed by methanol, dried in a vacuum at 40°C, and weighed. The initial rate of polymerization in this paper means the maximum rate at a range of 5—15% conversion. The induction period was determined from the intersection between the time axis and the extrapolated part of the maximum inclination of a time-conversion curve.

The water concentration in the reaction system was measured by the Karl-Fischer method. The reproducibility of the induction period and the rate of polymerization was fairly good as long as the water concentration was controlled.

**Materials.** — Trioxane (Celanese Co.) was twice recrylstallized in methylene chloride and stored in a desiccator over potassium hydroxide in a cool and dark place. The water content in the refined monomer was less than 0.008 wt.% (by the Karl-Fischer method), and the content of methylene chloride was less than 0.3% (by the gas chromatographic method).

The solvents were washed, dried, and distilled by the usual method; then they were refluxed and distilled on $CaH_2$ just before use. The water concentration was controlled by adding distilled water to a polymerizing solution.

$BF_3 \cdot O(C_2H_5)_2$ was refined by distilling commercial material.

## Results

**The Effects of the Catalyst Concentration.** —The effects of the catalyst concentration on the induction period and the rate of polymerization were studied at fixed concentrations of monomer and water.

Here benzene was used as the non-polar solvent, ethylene dichloride as the polar solvent, and nitrobenzene as the more polar solvent. As the polymerization in each solvent was characteristic and complicated, the time-conversion curves of each solvent are shown in the figures.

Figure 1 shows the time-conversion curve in benzene. The initial rate, as is shown in Fig. 2,

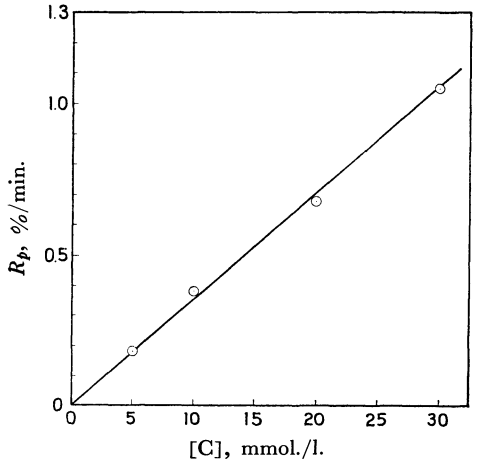

Fig. 2. Relationship between the catalyst concentration and the initial rate in benzene at 30°C. (Calculated from Fig. 1).

was proportional to the catalyst concentration. The decrease in the catalyst concentration increased the induction period. No simple relationship between the catalyst concentration and the induction period could be obtained.

Figure 3 shows the relation between the reaction time and conversion in the ethylene dichloride solvent. The initial rate was, as Fig. 4 shows, proportional to the square root of the catalyst concentration. No such phenomenon has been found in the cationic polymerization of vinyl monomers. When the catalyst concentration was more than the water concentration in the reaction system, the induction period of polymerization was less than 5 min. and was inversely proportional to the catalyst concentration, as is shown in Fig. 5.

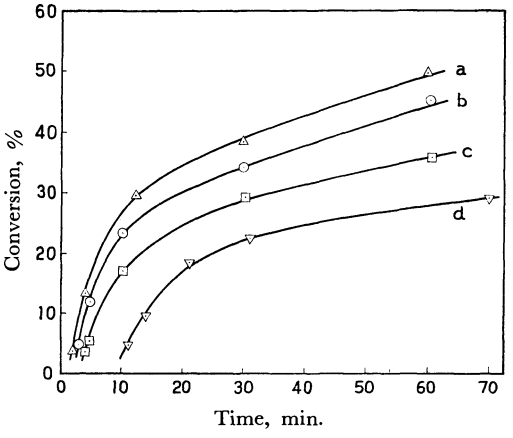

Fig. 3. Effect of the catalyst concentration on the rate of polymerization in ethylene dichloride at 30°C.
$[M]_0$; 3.3 mol./l, $[H_2O]$; 2.9 mmol./l., $[BF_3 \cdot O(C_2H_5)_2]$; a(△): 20, b(○): 10, c(□): 5.0 and d(▽): 2.5 mmol./l.

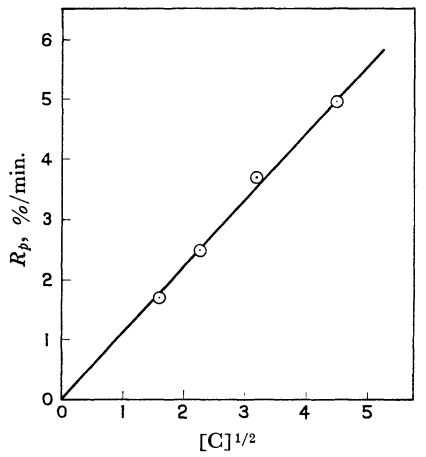

Fig. 4. Relationship between the catalyst concentration and the initial rate in ethylene dichloride at 30°C.
(Calculated from Fig. 3.)

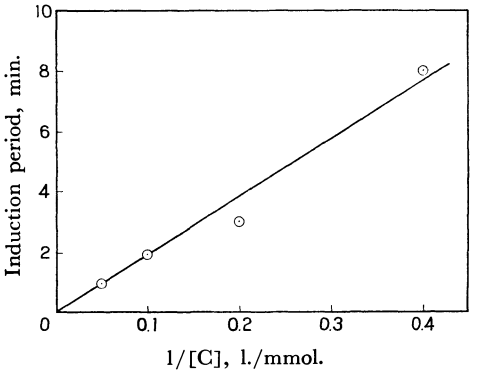

Fig. 5. Relationship between the reciprocal of the catalyst concentration and induction period in ethylene dichloride solution at 30°C.
(Calculated from Fig. 3.)

In the polymerization in nitrobenzene, the relation between the catalyst concentration and the polymerization rate was unusual. At a high monomer concentration, the polymerization reaction proceeded too fast for the rate of polymerization in nitrobenzene to be measured. Such an example is shown by the dotted line in Fig. 6. In order to ascertain the relation between the catalyst concentration and the polymerization rate, the polymerization was carried out at lower monomer concentrations. As Fig. 6 shows, the polymerization rate in nitrobenzene was almost independent of the catalyst concentration. The induction period tended to decrease with an increase in the catalyst concentration, being roughly proportional to the inverse square of the catalyst concentration.

**The Effects of the Water Concentration.**— At fixed concentrations of catalyst and monomer, the effects of the concentration of added water were

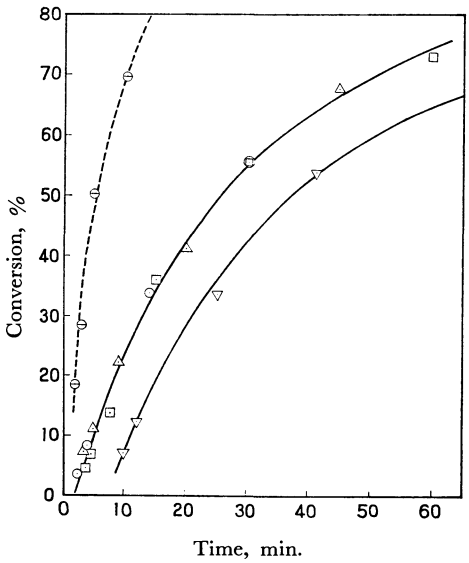

Fig. 6. Effect of the catalyst concentration on the rate of polymerization in nitrobezene at 30°C.
$[M]_0$; 1.1 mol./l., $[H_2O]$; 2.4 mmol./l., $[BF_3 \cdot O(C_2H_5)_2]$; (○): 20, (△): 10, (□): 5 and (▽): 2.5 mmol./l. Dotted line (—); $[M]_0$; 3.3 mol./l., $[H_2O]$; 1.8 mmol./l., $[BF_3 \cdot O(C_2H_5)_2]$; 1.0 mmol./l.

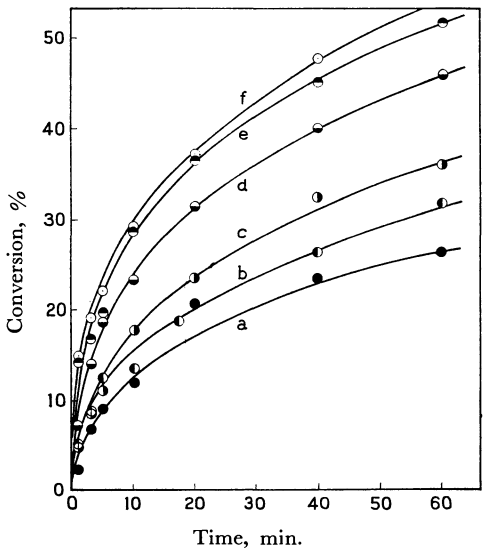

Fig. 7. Effect of the water concentration on the rate of polymerization in *n*-hexane at 30°C.
$[M]_0$; 0.37 mol./l., $[BF_3 \cdot O(C_2H_5)_2]$; 9.4 mmol./l., $[H_2O]$; a(●): 0.4, b(◐): 0.9, c(◑): 1.1, d(◒): 1.7, e(◓): 2.2 and f(○): 3.4 mmol./l.

studied. Here, *n*-hexane was used as the non-polar solvent, since it could dissolve less water than benzene.

Figure 7 shows the effects of water in *n*-hexane. At this range of water concentration, the polymerization proceeded entirely without an induction period, and even a small amount of water accelerated the reaction. However, the rate of polymerization decreases if more water is added.

Similar phenomena were found for the polymerization in the benzene solvent. A small amount of water accelerated the polymerization, but the rate of polymerization decreased upon the addition of a larger amount of water.

In the ethylene dichloride solvent, as is shown in Fig. 8, the induction period increased almost proportionally to the water concentration; the initial rate of polymerization reached its maximum at $[H_2O]/[BF_3 \cdot O(C_2H_5)_2] \simeq 1/2$.

As can be seen in Fig. 8, the time-conversion curve consisted of the initial part, where the rate of polymerization was large, and the subsequent part, where the rate was small. It is interesting that the initial part lasts longer at higher water concentrations.

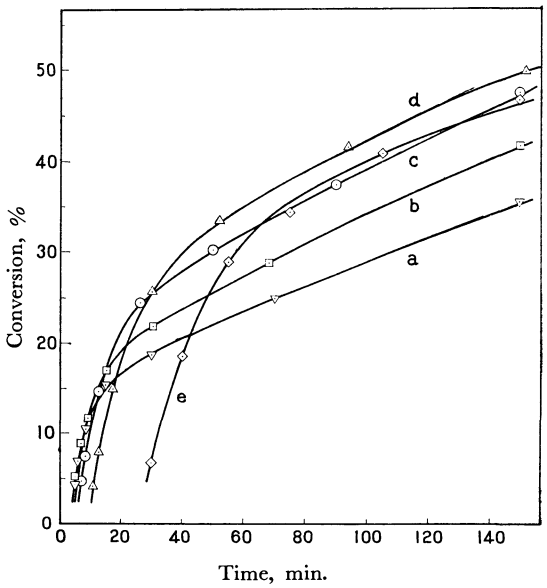

Fig. 8. Effect of the water concentration on the rate of polymerization in ethylene dichloride at 30°C.
$[M]_0$; 3.3mol./l., $[BF_3 \cdot O(C_2H_5)_2]$; 10mmol./l., $[H_2O]$; a(▽): 0.3, b(□): 1.6, c(○): 3.7, d(△): 5.9 and e(◇): 10.8 mmol./l.)

In nitrobenzene, where the water concentration was larger than that of the catalyst, the rate of polymerization was, as Fig. 9 shows, almost independent of the water concentration and only the induction period varied remarkably. On the other hand, where the water concentration was less than that of the catalyst, neither the induction period nor the rate of polymerization was affected, as is shown in Fig. 10.

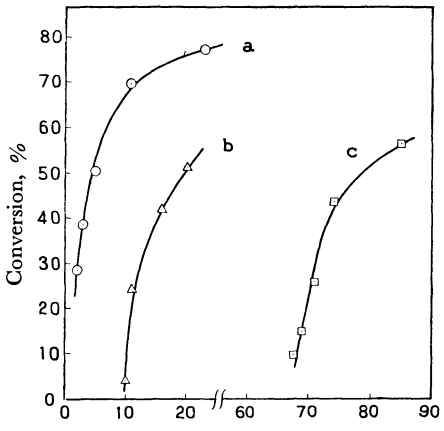

Fig. 9. Effect of the water concentration on the rate of polymerization in nitrobenzene at high concentrations of monomer and water at 30°C.
$[M]_0$; 3.3 mol./l., $[BF_3 \cdot O(C_2H_5)_2]$; 1.0 mmol./l., $[H_2O]$; a(○): 1.8, b(△): 4.7 and c(□): 8.3 mmol./l.

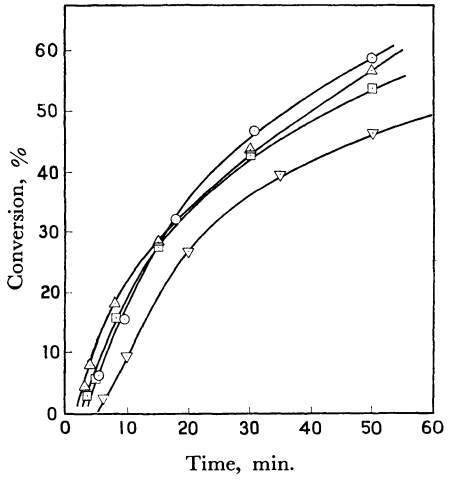

Fig. 10. Effect of the water concentration on the rate of polymerization in nitrobenzene at low concentrations of monomer and water at 30°C.
$[M]_0$; 1.1 mol./l., $[BF_3 \cdot O(C_2H)_2]$; 10 mmol./l., $[H_2O]$; (△): 2.2, (□): 4.0, (○): 5.9 and (▽): 7.8 mmol./l.

**The Effects of Added Methanol.**—As has been shown above, a small amount of water did not affect the polymerization in nitrobenzene. In order to clarify this point, the effects of the addition of methanol in nitrobenzene and in ethylene dichloride were compared.

In ethylene dichloride, as Fig. 11 shows, methanol equivalent to half the amount of the catalyst accelerated the polymerization, while an amount of methanol equal to the catalyst decreased the rate of polymerization. The addition of methanol

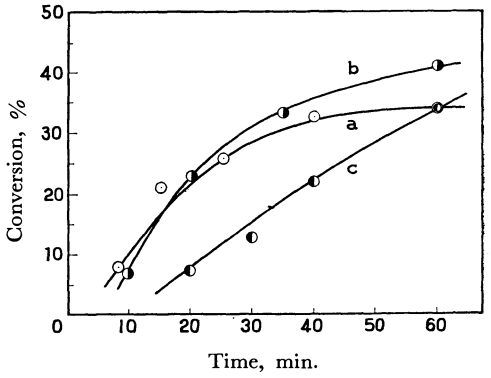

Fig. 11. Effect of the methanol concentration on the rate of polymerization in ethylene dichloride at 30°C.
$[M]_0$; 3.3 mol./l., $[BF_3 \cdot O(C_2H_5)_2]$; 20 mmol./l., $[H_2O]$; 2.7 mmol./l., $[CH_3OH]$; a(○): 0, b(◑): 10 and c(◑): 20 mmol./l..

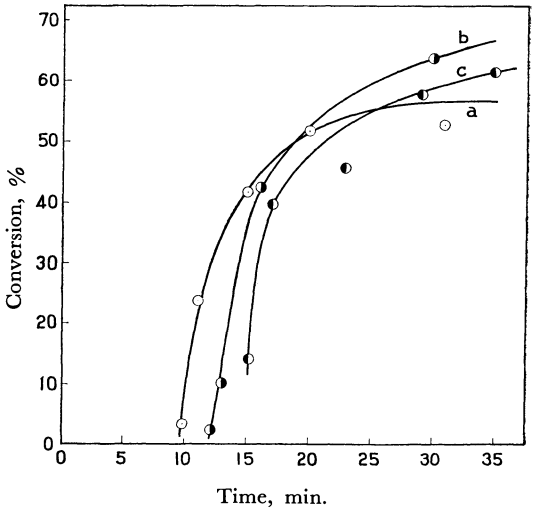

Fig. 12. Effect of the methanol concentration on the rate of polymerization in nitrobenzene at 30°C.
$[M]_0$; 3.3 mol./l., $[BF_3 \cdot O(C_2H_5)_2]$; 1.0 mmol./l., $[H_2O]$; 4.7 mmol./l., $[CH_3OH]$; a(○): 0, b(◑): 2.5 and c(◐): 5.0 mmol./l.

increased the induction period, as did the addition of water.

On the other hand, in nitrobenzene, as is shown in Fig. 12, even the addition of five times as much methanol to the catalyst tended to accelerate the rate, and its effect was very small, much as in the case of the addition of water.

## Discussion

Table I summarizes the effects of the catalyst concentration on the rate of polymerization. In Fig. 13 the effect of the water concentration on the rate of polymerization is schematically shown.

TABLE I. SUMMARY OF THE EFFECT OF CATALYST CONCENTRATION OF THE RATE OF POLYMERIZATION ($R_p$) IN VARIOUS SOLVENTS AT 30°C ($[BF_3 \cdot O(C_2H_5)_2] > [H_2O]$)

| Solvent | $R_p$ |
|---|---|
| $C_6H_6$ | $R_p \propto [C]^{1.0}$ |
| $(CH_2Cl)_2$ | $R_p \propto [C]^{0.5}$ |
| $C_6H_5NO_2$ | $R_p \propto [C]^0$ |

Figure 13 was obtained from the results of Figs. 7, 8 and 10. In a non-polar solvent such as *n*-hexane, the polymerization seems not to proceed when water is strictly excluded. Therefore, it may be concluded that water is necessary as a co-catalyst for the polymerization in a non-polar solvent. Even in this case, however, the rate of polymerization decreased when more water than a limited quantity was added. A similar tendency was found in the benzene solvent, also.

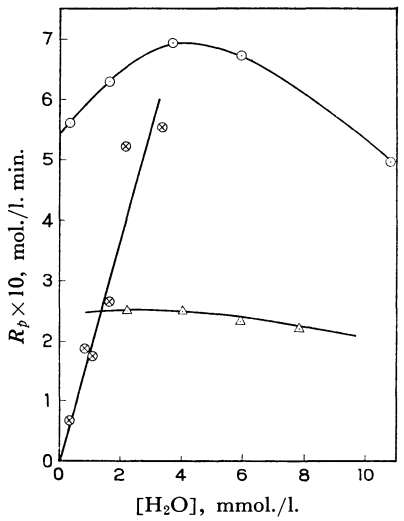

Fig. 13. Effect of the water concentration on the initial rate in various solvents at 30°C.
a(⊗); *n*-hexane solvent (from Fig. 7),
b(○); ethylene dichloride solvent (from Fig. 8),
c(△); nitrobenzene solvent (from Fig. 10)

On the other hand, in nitrobenzene the rate of polymerization was not affected by the water concentration within the range of our experiment, and water is not considered to act as a co-catalyst. In ethylene dichloride the rate of polymerization was slightly increased by a small amount of water, but the effect was very small and the polymerization seems to occur even without water.

In a polar solvent the catalyst $BF_3 \cdot O(C_2H_5)_2$, as is well known, dissociates according to Eq. 1, thus producing the ethyl cation.[12,13] The latter can initiate the polymerization of trioxane. On the contraty, in a non-polar solvent the catalyst $BF_3 \cdot O(C_2H_5)_2$ canont dissociate by itself according to Eq. 1; it needs water as a co-catalyst;

$$BF_3 \cdot O(C_2H_5)_2 \rightarrow BF_3 \cdot O(C_2H_5)^- \ (C_2H_5)^+ \quad (1)$$

$$BF_3 \cdot O(C_2H_5)_2 + H_2O \rightarrow (BF_3OH)^- \ H^+ + O(C_2H_5)_2 \quad (2)$$

as is shown in Eq. 2, to produce an ionizable species which has the ability to initiate the polymerization. In ethylene dichloride, it is inferred that the two processes (Eq. 1 and Eq. 2) took place simultaneously; and a behavior between that in *n*-hexane and that in nitrobenzene was observed. This consideration is supported by the thermodecomposition rate of the resultant polymer in each solvent, whose ends were not chemically treated and whose molecular weights ($\eta_{sp}/c$) were nearly equal. That is, the decomposition of the polymer obtained in *n*-hexane was 5 to 10 times faster than the rate of the polymer produced in nitrobenzene. The polymer obtained in ethylene dichloride had an intermediate value. The relationship between the co-catalytic effect of water and the thermodecomposition rate of the resultant polymer can be reasonably explained. The polymer produced in the presence of water as a co-catalyst, both of whose ends were –OH groups may be easily decomposed, while the polymer obtained by the initiation of the ethyl cation, one of whose ends was the ethoxyl radical, decomposes with more difficulty.

Kern et al.[4] have found that, in the cationic polymerization of trioxane by boron fluoride gas in methylene chloride, the rate of polymerization decreases with an increase in the concentration of added water; they have proposed that the polymerization of this system proceeds without a co-catalyst and that the active center is a zwitter ion. However, in the polymerization catalyzed by $BF_3 \cdot O(C_2H_5)_2$ the mechanism of the zwitter ion is considered to be impossible for the above-mentioned reasons; that is, a co-catalyst was necessary in the non-polar solvent, the thermodecomposition rate of polymers was affected by the kind of solvent, and the alkoxyl-end group was detected in the produced polymer.[14] On the other hand, it has been considered that water as a co-catalyst is necessary in the polymerization of trioxane by tin(IV) chloride.[5] The idea of the zwitter ion has also been rejected in the polymerization of 3, 3-bis-(chloromethyl)-oxetane by boron fluoride.[15] Therefore, it may be concluded that, under the conditions of our experiments, the polymerization reaction does not proceed through the zwitter ion. The above considerations also lead to the conclusion that the polymerization of trioxane catalyzed by $BF_3 \cdot O(C_2H_5)_2$ is initiated by the attack of the proton or the ethyl cation on trioxane.

15) I. Penczek and S. Penczek, *Makromol. Chem.*, **67**, 213 (1963).

This interpretation of the co-catalysis was confirmed by the addition of not only water but also methanol. As is shown in Fig. 11 and Fig. 12, a small amount of methanol accelerated the polymerization in ethylene dichloride but scarcely affected that in nitrobenzene.

In the case of the cationic polymerization of vinyl monomers, the rate of polymerization is generally proportional to the catalyst concentration. As Table I shows, in the polymerization of trioxane in a non-polar solvent such as benzene, the polymerization rate is proportional to the catalyst concentration. However, it is difficult to explain the experimental fact that the kinetic order of the catalyst concentration to the rate of polymerization is equal to 0.5 in ethylene dichloride and to zero in nitrobenzene. It has been found that, in the polymerization of trioxane catalyzed by tin(IV) chloride, the final yield in both polar and non-polar solvents is not dependent on the catalyst concentration when the concentration of the catalyst is larger than that of water.[5] A similar result has been obtained in the polymerization of isobutene catalyzed by tin(IV) chloride[16] and aluminum chloride[17]. In our experiment, however, $BF_3 \cdot O(C_2H_5)_2$ can cause the polymerization reaction of trioxane in nitrobenzene without water as a co-catalyst; consequently, it is impossible to explain the above-mentioned phenomena only in terms of the relation between the water and catalyst concentrations.

Rose[2] has proposed, on the basis of the relation between the reaction rate and kinetic order of the concentration of the reagents, that, in the polymerization of cycloxabutane, the active center is an oxonium ion. However, in our experiment the relationship between the rate of polymerization and the catalyst concentration was very complicated; the nature of the active center can not be discussed on the basis of our kinetic results.

## Summary

In the solution polymerization of TO catalyzed by $BF_3 \cdot O(C_2H_5)_2$, water acted as a co-catalyst in *n*-hexane, a non-polar solvent; in ethylene dichloride, a polar solvent, water slightly accelerated the rate of polymerization, and in nitrobenzene, a more polar solvent, water did not affect the rate at all. The kinetic order of the catalyst concentration to the polymerization rate was 1.0 in benzene, 0.5 in ethylene dichloride, and zero in nitrobenzene. The induction period was very short when water was excluded as much as possible, but it increased with an increase in the water concentration and with a decrease in the catalyst concentration.

On the basis of these results, it may be concluded that the polymerization of TO by $BF_3 \cdot O(C_2H_5)_2$ is initiated by the attack of the proton or the ethyl cation on the monomer.

# Investigations on Some Amine Complexes of Cobalt(II) Phthalimide. II. Infrared Spectroscopic Measurements

By Gopal NARAIN

(Received April 9, 1965)

The preparation of a series of amine complexes of cobalt(II) phthalimide and some preliminary investigations, such as their analysis and studies of their molecular weight and conductivity, have been reported in Part I.[1] It has there been pointed out that the non-electrolytic nature of the complexes shows that two phthalimide ions are co-ordinated along with the amine ligands, and that the co-ordination of the phthalimide ion to the metal can be either through the negatively-charged nitrogen or the oxygen of the carbonyl group. The present communication, related to infrared spectroscopic measurements, will attempt further to confirm and establish that both the amine and phthalimide ligands are co-ordinated to the cobalt atom.

## Experimental

The spectra were obtained on a small infracord, using potassium bromide prisms.

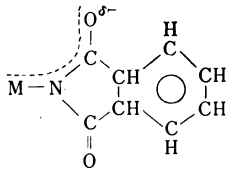
## Results

The spectra have been examined over the entire infrared range from 400—3500 $cm^{-1}$; the various bands obtained for individual complexes are listed in Table I.

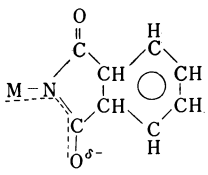
## Discussion

The examination of the spectra shows that there are two interesting regions, the NH and C:O stretching frequency regions.



As has been mentioned earlier, the phthalimide ion has the possibility of being coordinated to the metal atom either through the nitrogen or through the oxygen of the carbonyl group. The infrared spectra cannot make a sharp distinction between these two conditions, because any change in phthalimide nitrogen, which is directly linked to the carbonyl group, will alter the molecular environment and, accordingly, the frequency of the latter, even if it is not co-ordinated.[2] However, on the basis of the Lewis concept, it may be expected that the nitrogen, which is negatively-charged, will have better possibilities of being co-ordinated than the oxygen.[3] In the co-ordination through oxygen, steric hindrance will be effective, as is exemplified by the unsuccessful attempt to prepare some metal complexes with phthalimide as the ligand, complexes which would be analogous to acetamide complexes.[4]

All complexes (except those prepared by using 2, 2-'dipyridyl or *o*-phenanthroline as the ligand) show a single sharp absorption band in the vicinity of 3300 $cm^{-1}$; this is taken to be the NH-stretching frequency band. In free ammonia the band occurs at 3414 $cm^{-1}$. This negative shift of the frequency is a result of the co-ordination of the amine to the cobalt atom, thus resulting in the formation of a highly covalent M–N bond, which weakens the NH bond order. In the case of the ethylene diamine complex also, there is a considerable shift; this is again because of the co-ordination of the amine. In the case of 2, 2'-dipyridyl and *o*-phenanthroline complexes, there is no band in the above region. However, a comparison of the positions of the various bands with those of free ligands[5,6] shows that the frequencies are shifted to higher values in complexes, which clearly shows that the ligands are co-ordinated.[5]



The band observed in the carbonyl-stretching frequency region is of interest. In phthalimide, the band occurs at 1745 $cm^{-1}$, and in cobalt phthalimide it shifts to 1725 $cm^{-1}$, while in complexes it shifts to 1700—1710 $cm^{-1}$. The cause of this negative shift of frequency appears to be the electron density of nitrogen. In the case of cobalt(II) phthalimide, which is supposed to possess a partial covalent character, exhibited by its low solubility in polar solvents, the band shifts by only 25 $cm^{-1}$. This negative nitrogen has an orbital covalently bonding to the metal and an orbital perpendicular to the plane to the phthalimide. This filled orbital on nitrogen would help to direct a greater electron density towards the C=O bond; this would tend to increase the frequency. However, other factors, such as the $\infty$-mass effect and hydrogen bonding, tend to decrease the frequency; hence, an intermediate value is obtained. In the case of complexes, the direction of the added electron density reaches a saturation point, beyond which any added electron density tends to reduce the C=O double bond to a single bond and reduce the frequency. The addition of additional ligands to the cobalt(II) ion causes the metal ions to attempt to "back donate" into the available orbitals on the nitrogen of phthalimide. The filled orbital of the phthalimide nitrogen is made available by a quasiaromatic delocalisation. Thus, the following formulae would give a lower bond

order to C=O and a lower frequency:

(I)

(II)

(III)

Another cause of the shift may be the ∝-mass effect.[7] In phthalimide, the nitrogen is linked to a very light hydrogen atom; hence, there is no hindrance in the normal motion of the CO group. In the case of complexes, the phthalimide nitrogen is linked to a heavy metal atom, which may cause a hindrance in its normal vibration, thus displacing the carbonyl frequency band to a lower value, although the magnitude of this shift would be small because, due to the cyclic nature of the ligand, the oxygen is vibrating against essentially the whole ligand. Hence, it appears that it is as a result of these factors that a negative shift of CO frequency is observed, although the oxygen of the carbonyl group is not co-ordinated.

## Summary

Infrared measurements of a series of complexes prepared with cobalt(II) phthalimide and some amines of the $[Co(Phthalimide)_2(amine)_{2or1}]$ type have been made. The spectra confirm that both phthalimide ions and amine molecules are co-ordinated; they further suggest that the co-ordination of phthalimide is through the nitrogen.

# An Isotopic Exchange Reaction between Oxygen and Carbon Dioxide on Zinc Oxide

By Toshizo TITANI, Tadamitsu KIYOURA and Akira ADACHI

(Received April 15, 1965)

Zinc oxide has been extensively studied by many investigators in terms of semiconductivity, and there are several works on the isotopic exchange between oxygen and zinc oxide.[1-6] However, only a little information is available on the isotopic exchange between oxygen and carbon dioxide on zinc oxide, or on that between carbon dioxide and zinc oxide. We have recently investigated the exchange reaction over the temperature range from 350 to 550°C in a rather qualitative way in order to provide preliminary data for further tracer studies. It appears worthwhile, therefore, to publish our results at this time. In this paper we shall discuss the general features of the isotopic exchange between carbon dioxide and zinc oxide, and that between oxygen and carbon dioxide on zinc oxide.

## Experimental

Zinc oxide was prepared by the thermal decomposition of zinc oxalate at 500°C for 15 hr. in the presence of air; the B. E. T. area of the zinc oxide was 5.8 $m^2$/g. Zinc oxalate was obtained by the addition of an aqueous solution of ammonium oxalate to a solution of zinc chloride. The precipitate was washed so that it was free from chloride ions and then dried in the

air 110°C for 8 hr. prior to its thermal decomposition. Heavy oxygen, $O^{18}O$, was prepared in our laboratory by the thermal diffusion method;[7] its concentration was 1.81 atom.%. Carbon dioxide enriched in $^{18}O$, $CO^{18}O$ (3.01 atom.%) was obtained by equilibrating ordinary carbon dioxide with $^{18}O$ enriched water, $H_2{}^{18}O$. As the source of ordinary oxygen and carbon dioxide, commercial gases were used with some purification. All the gases used were dried through a train of traps at −78°C. The search for an impurity in the gases used was made by using a mass spectrometer up to mass 100. They contained about 0.3 to 0.5% of one impurity, giving rise to mass 28 (nitrogen); none other was found in any detectable amount.

The exchange reaction was studied by the static batch method. The reaction vessel was made of borosilicate glass. For the exchange between carbon dioxide and zinc oxide, an accurately-weighed 400 mg. portion of zinc oxide was placed in the reaction vessel and was then outgassed at 500°C for 3 hr., using a mercury diffusion pump, through a liquid nitrogen trap. Then the temperature of the reaction vessel was adjusted to the desired temperature, and 1.5 ml. (N. T. P.) of $^{18}O$-enriched carbon dioxide was introduced. The temperature range studied was from 350 to 550°C, with 50°C intervals. At desired time intervals, all the carbon dioxide was collected by a Toepler pump and the $^{18}O$ content of the carbon dioxide was analyzed by the use of a mass spectrometer. For the exchange between oxygen and carbon dioxide on zinc oxide, 2.7 ml. (N. T. P.) of the gas mixture of enriched oxygen and normal carbon dioxide or of normal oxygen and enriched carbon dioxide in a ratio of 1 to 1 was used. The amount of zinc oxide and the out-gassing and other procedures were the same as those in the exchange between carbon dioxide and zinc oxide. In order to maintain a constant pressure of the gas at each reaction temperature (14 cmHg for the $CO_2$-ZnO system and 25 cmHg for the $O_2$-$CO_2$-ZnO system), a reaction vessels of different volumes were chosen for the different temperatures; 19.0 ml. for 350°C, 20.0 for 400°C, 21.5 for 450°C, 23.0 for 500°C, and 25.0 for 550°C. The pressure change due to adsorption was ignored, since the accompanying pressure changes were less than 10% of the total pressure. In all the experiments, the pressure of the carbon dioxide was kept lower than the decomposition pressure of zinc carbonate (76 cmHg at 300°C).[8]

## Results and Discussion

First, the isotopic oxygen exchanges between carbon dioxide and the surface of the reaction vessel, and between oxygen and the surface, and also the catalytic action of the surface were examined. It was found that, within the limits of experimental error, the reaction vessel surface did not participate in the exchange reaction.

**Exchange between Carbon Dioxide and Zinc Oxide.**—The extent of the exchange reaction is shown in Fig. 1. The rate of the exchange was rapid, and within a few minutes after the introduction of the enriched carbon dioxide into the reaction vessel, the $^{18}O$ content of the carbon dioxide reached a definite value. This value was characteristic of the reaction temperature. At this stage of the reaction, an isotopic equilibrium was established between the carbon dioxide in the gas phase and a certain part of the zinc oxide. After the initial fast reaction had finished, there was a slow downward drift of the $^{18}O$ content of the carbon dioxide. From Fig. 1, we obtained the definite $^{18}O$ content by the extrapolation of the drift line to time zero. From these quantities, we obtained the amount of the rapidly-exchangeable oxygen of the zinc oxide, $n_s$ (gram atom per gram of zinc oxide). The calculation of $n_s$ was carried out using Eq. 1,[2] where $^{18}O_0$ and $^{18}O_\infty$ were the initial and the definite $^{18}O$ content of the carbon dioxide respectively; the numerical constant, 0.204, was the $^{18}O$ natural abundance; $n_g$ was the number of oxygen atoms in the amount of carbon dioxide used, and $w$ was the weight of the zinc oxide used.

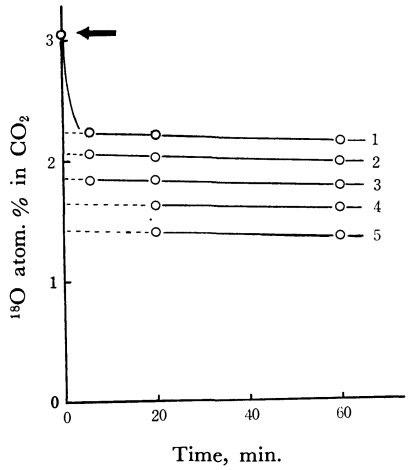

Fig. 1. Extent of the exchange reaction between $CO^{18}O$ and ZnO.
The arrow indicates the initial content of $^{18}O$ in $CO_2$.
1, 350°C 2, 400°C 3, 450°C 4, 500°C
5, 550°C

$$n_s w(^{18}O_\infty - 0.204) = n_g(^{18}O_0 - {}^{18}O_\infty) \quad (1)$$

The values of $n_s$ at various temperatures are listed in Table I. A random exposure of the crystalline face being assumed, the number of rapidly-exchangeable surface layers of the zinc oxide at various temperatures was obtained through the value of $n_s$, the surface area of zinc oxide, and the lattice constant of zinc oxide; they are also listed in Table I.

The pretreatment of the zinc oxide was changed from the normal evacuation at 500°C for 3 hr. to that at 600°C for 5 hr. However, no difference in the value of $n_s$ was observed after this change.

7) Y. Horibe, *Isotopes and Radiation*, **2**, 25 (1959).
8) K. Friedlich, *Stahl und Eisen*, **31**, 1901 (1911).

Table I. The value of $n_s$ and the number of rapidly-exchangeable surface layers of the zinc oxide

| Temp., °C | 350 | 400 | 450 | 500 | 550 |
|---|---|---|---|---|---|
| $n_s$ (g. atom./g.)·$10^5$ | 12.8 | 18.0 | 24.1 | 28.2 | 44.3 |
| Number of exchangeable layers | 0.7 | 0.9 | 1.2 | 1.5 | 2.3 |

Therefore, the rapidly-exchangeable oxygen of the zinc oxide was probably not a residual water nor a residual oxalate.

Below 400°C a part of the monolayer or the surface oxygen, between 400 to 450°C a monolayer, and above 450°C more than a monolayer participate in the fast initial exchange reaction.

**The Exchange between Oxygen and Zinc Oxide.**—The results are shown in Fig. 2. The experimental conditions were the same as those used with carbon dioxide.

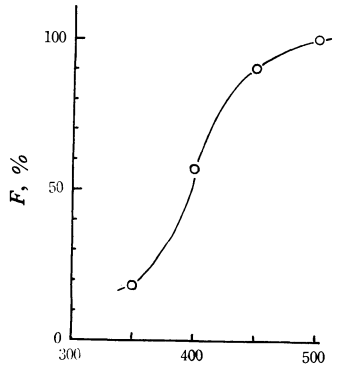

Fig. 2. Fractional attainment of the exchange between $O^{18}O$ and ZnO. Reaction time, 15 min.
$F=100(^{18}O_0-^{18}O_t)/(^{18}O_0-^{18}O_\infty)$
$^{18}O_0$ and $^{18}O_t$ are the initial and the after 15 min. $^{18}O$ content in $O_2$. $^{18}O_\infty$ is the equilibrium content of $^{18}O$ in $O_2$, calculated from the amounts of $O_2$ gas used and value of $n_s$.

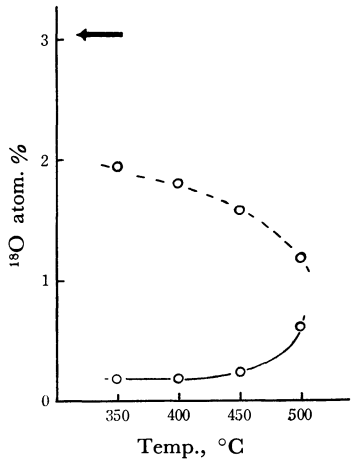

Fig. 4. $^{18}O$ in $CO_2$ and $O_2$. Reaction time, 1 hr.
Full line, $O^{18}O$. Broken line, $CO^{18}O$.
The arrow indicates the initial content of $^{18}O$ in $CO_2$.

**The Exchange between Oxygen and Carbon Dioxide on Zinc Oxide.**—The exchange of oxygen occurred at a measurable rate around 450°C. The decrease in the $^{18}O$ content in oxygen and the increase in carbon dioxide are shown in Fig. 3. The number of $^{18}O$'s that the carbon dioxide had gained was less than that which the oxygen had lost. This difference may be ascribed to the exchange with zinc oxide. In the above-mentioned experiments, $^{18}O$-enriched oxygen and normal carbon dioxide were used as the starting materials. The results of the exchange experiments, in which the $^{18}O$-enriched carbon dioxide and normal oxygen were used as the starting materials, are shown in Fig. 4. A considerable decrease in the $^{18}O$ content in the carbon dioxide was observed at 350°C, but no increase in the $^{18}O$ content of the oxygen was observed up to 400 to 450°C. This finding indicates that the $^{18}O$ which were transferred from carbon dioxide to zinc oxide were not transferred to oxygen up to 400 to 450°C. On the other hand, the exchange between oxygen and zinc oxide took place, even at 350°C, in the absence of carbon dioxide (see Fig. 2).

Schwab,[9] and Matsuura et al.[10] have reported that carbon dioxide inhibits the oxidation of carbon monoxide on zinc oxide. In our experiments also, carbon dioxide acts as an inhibitor of the exchange between oxygen and zinc oxide. For that reason, no exchange is observed up to 400 to 450°C in the presence of carbon dioxide. Figures. 1, 2, and

9) G. M. Schwab, *Z. Physik. Chem. (Neue Folge)*, **1**, 42 (1954).
10) I. Matsuura, Y. Kubokawa and O. Toyama, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **81**, 997 (1960).

3 indicate that the rate of the isotopic exchange decreases in the following order;

$$CO_2\text{-}ZnO > O_2\text{-}ZnO > O_2\text{-}CO_2$$

According to these results, it was concluded that the isotopic exchange between oxygen and carbon dioxide takes place through the exchange between these gases and the oxygen atoms of zinc oxide, and that the limiting step is the exchange with oxygen.

## Summary

Isotopic oxygen exchange reactions between carbon dioxide and zinc oxide, and between oxygen and carbon dioxide on zinc oxide, have been studied by the static method in the temperature range from 350 to 550°C. At any temperature carbon dioxide exchanges its oxygen atoms with those of zinc oxide rapidly. Within a few minutes after the initiation of the reaction, an isotopic equilibrium is established between the carbon dioxide in the gas phase and a certain part of the zinc oxide. It has been found that the isotopic exchange between oxygen and carbon dioxide on zinc oxide takes place through the exchange between these gases and the oxygen atoms of the zinc oxide, that the limiting step is the exchange with oxygen, and that the carbon dioxide acts as an inhibitor of the exchange between oxygen and zinc oxide.

# The Reaction of *C*-Substituted Ethylenediamine with the Ester of α-Halo Acid

By Kuniyoshi MASUZAWA, Mitsuo MASAKI and Masaki OHTA

(Received April 20, 1965)

In a previous report[1] it has been shown how 3,6-disubstituted 2-oxopiperazines were first synthesized by the reaction of α-chloro oximes with the esters of amino acids, followed by the reductive cyclization of the products. Recently Iwanami et al.[2] have described the synthesis of 3-ethoxycarbonylmethylene-6-methyl-2-oxopiperazine by the reaction of diethyl acetylenedicarboxylate with 1,2-propanediamine. 3-Substituted 2-oxopiperazines are usually synthesized by Aspinall's method,[3] which consists of the reaction of ethylenediamine with the ester of α-halo acid. The application of this method to the synthesis of disubstituted 2-oxopiperazine will involve the condensation of *C*-substituted ethylenediamine (III) with the ester of α-halo acid (IV). In such a case condensation may occur in one or both of two directions. Thus, the condensation of III with IV might give 3,6-disubstituted 2-oxopiperazine (V) or 3,5-disubstituted 2-oxopiperazine (VI), or a mixture of the two.

The present paper will describe the reaction of 1-phenylethylenediamine (IIIa) with ethyl α-bromo-β-phenylpropionate (IVa) and that of 1,2-propanediamine (IIIb) with ethyl α-bromopropionate (IVb), reactions yielding, as the main products, the corresponding 3,6-disubstituted 2-oxopiperazines (V). Although 1-phenylethylenediamine (IIIa) is usually prepared by reducing phenylaminoacetonitrile,[4] phenylglyoxime,[5] or phenylglycineamide,[6] these methods of preparation are troublesome or have defects in yield. The conversion of phenacylamine hydrochloride (I) to the oxime is usually in a low yield, because the former cyclizes rapidly to 2,5-diphenylpyrazine in the course of the reaction.[7] The oximination of α-halo and α-amino ketones have been known to be successfully carried out in the presence of acetic acid liberated from sodium acetate.[8] Phenacylamine hydrochloride (I) was converted to the oxime in a good yield by reaction with hydroxylamine hydrochloride and an excess of sodium acetate, and the resulting oxime was hydrogenated in the presence of Raney-nickel to IIIa. Ethyl α-bromo-β-phenylpropionate (IVa) was treated with an excess of IIIa in benzene to give, as the main product, crystals with a m. p. of 170—171.5°C

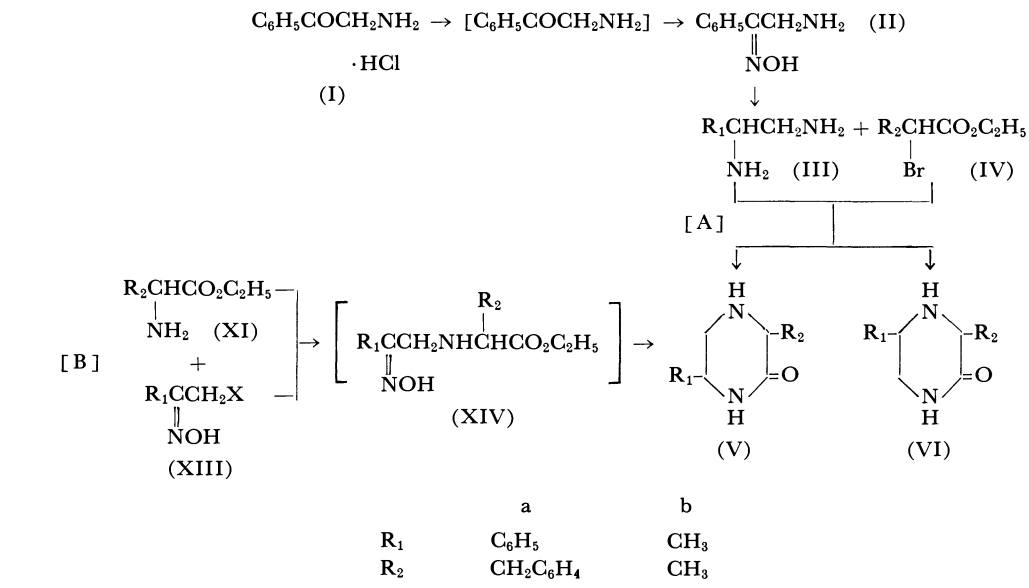

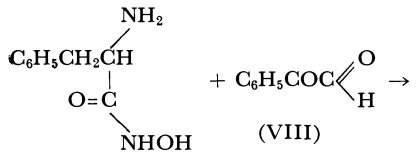

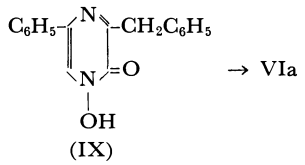

Fig. 1.

and a trace of a crystalline substance with an m. p. of 152—154°C, which was isolated from the mother liquor of the recrystallization of the former by means of column chromatography. The main product (m. p. 170—171.5°C) was easily identified as 3-benzyl-6-phenyl-2-oxopiperazine (Va) by a mixed

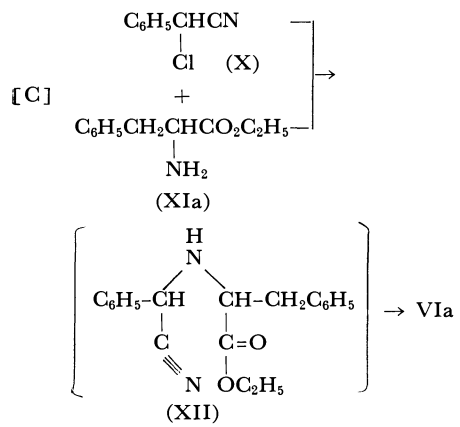

Fig. 2

melting point determination with an authentic sample.[10]

The structure of the substance with an m. p. of 152—154°C was indicated as being the 3,5-isomer by an elementary analysis of it and by its infrared spectrum. In order to confirm this, 3-benzyl-5-phenyl-2-oxopiperazine (VIa) was then synthesized through other two routes. It has been shown by Dutcher[9] that Aspergillic acid (1-hydroxy-3-isobutyl-6-*s*-butyl-2-pyrazinone) can be reduced to the corresponding 3,6-disubstituted 2-oxopiperazine by zinc and acetic acid. In a similar manner, 1-hydroxy-3-benzyl-5-phenyl-2-pyrazinone (IX) which had been synthesized by the reaction of DL-phenylalanylhydroxylamine (VII) with phenylglyoxal (VIII) was reduced, yielding the required 3-benzyl-5-phenyl-2-oxopiperazine (VIa), which was also synthesized by alternative route. By the treatment of α-chlorophenylacetonitrile (X) with DL-phenylalanine ethyl ester (XIa) in the presence of equimolar triethylamine, the *N*-(α-cyanobenzyl)-phenylalanine ethyl ester was obtained as an oily product. The product, without purification, was hydrogenated at 80°C in the presence of Raney-nickel; a simultaneous cyclization then occurred, giving VIa. The crystalline by-product with an m. p. of 152—154°C, which was obtained in the reaction of IIIa with IVa, showed no depression in a mixing test with the 3-benzyl-5-phenyl-2-oxopiperazine (VIa) prepared above.

In a manner analogous to the above case, the reaction of 1,2-propanediamine (IIIb) with ethyl α-bromopropionate (IVb) in benzene gave an oily product; this was converted to crystalline hydrochloride and a phenylureido derivative, which were

9) J. D. Dutcher, *J. Biol. Chem.*, **171**, 321 (1947).

characterized as 2-oxopiperazine derivatives by an elementary analysis of them and on the basis of their infrared spectra. These derivatives showed no depression in a mixing test with the corresponding derivatives of the 3,6-dimethyl-2-oxopiperazine (Vb) synthesized by an alternative method, which consisted of the reaction of $\alpha$-chloroacetone oxime (XIIIb) with the DL-alanine ethyl ester in ether, followed by the reductive cyclization of the product. In the case of the reaction of IIIb with IVb, the formation of the 3,5-isomer was not observed.

It is of interest that 3,6-disubstituted 2-oxopiperazine is formed exclusively either in the reaction of *C*-substituted ethylenediamine with the ester of $\alpha$-halo acid or in the reaction of 1,2-propanediamine with diethyl acetylenedicarboxylate.

## Experimental

**Phenacylamine Oxime (II).** — A hot solution of sodium acetate (24.8 g., 300 mmol.) in water (50 ml.) was added with stirring to solution of hydroxylamine hydrochloride (7.0 g., 100 mmol.) and I[10] (8.6 g., 50 mmol.) in water (50 ml.). The temperature was then raised from 20°C to 55°C. After it had been stirred for several hours, the pale yellow solution was allowed to stand overnight. The solution was made alkaline with a saturated solution of sodium carbonate in water under cooling by ice water, and then the crystals which separated from the solution were collected by filtration, washed with cold water, and recrystallized from ethanol to give colorless plates (5.3 g., 70.6%), m. p. 142—144°C (lit.[7a] m. p. 138—140°C).

**DL-1-Phenylethylenediamine (IIIa).** — To a solution of II (3.2 g., 21 mmol.) in ethanol (100 ml.) Raney-nickel (2 g.) which had previously been rinsed with ethanol (25 ml.) was added. The mixture was then stirred with hydrogen at an initial pressure of 40 kg./cm$^2$ at 70°C. Hydrogen absorption ceased after 2 hr.; the catalyst and the solvent were thereafter removed by the usual procedures. The residue was distilled under a nitrogen stream, yielding DL-1-phenylethylenediamine (2.1 g., 72.7%), b. p. 101—103°C/5.5 mmHg. Dry hydrogen chloride was introduced to the solution of IIIa in ethanol in order to precipitate crystalline solids which, after recrystallization from methanol, afforded pure dihydrochloride, m. p. 295—300°C (decomp., lit.[6] 300—301°C).

Found: C, 45.89; H, 6.95; N, 13.11. Calcd. for $C_8H_{12}N_2 \cdot 2HCl$: C, 45.94; H, 6.75; N, 13.39%.

**The Reaction of IIIa with IVa.**—A solution of IVa (3.6 g., 14 mmol.) in benzene (5 ml.) was vigorously stirred, drop by drop, into a solution of IIIa (5.7 g., 42 mmol.) in benzene (11 ml.), and the mixture was heated at 80°C for 4 hr. To the reaction mixture, a solution of potassium hydroxide (0.79 g.) in ethanol (15 ml.) was added, and the separated potassium bromide was filtered off, when the filtrate was concentrated under reduced pressure and the residue was dissolved in benzene (25 ml.), the insoluble crystals in the benzene were removed completely. The filtrate was then dried over anhydrous sodium sulfate and evaporated to dryness at 100°C under diminished pressure in order to recover the original IIIa and IVa. Carbon tetrachloride (6 ml.) was added to the residue; thereupon small needles slowly crystallized out. They were collected (1.4 g., 37.6%) and recrystallized from methanol to give colorless needles, m. p. 170—171.5°C, which showed no depression in a mixing test with authentic Va. After Va had separated, the above carbon tetrachloride was evaporated to dryness. The residue was dissolved in benzene (10 ml.), and the solution was dried over anhydrous sodium sulfate and passed through a column of activated alumina. The column was then washed with additional benzene (20 ml.). The evaporation of the combined benzene eluate yielded pale yellow solids, which were recrystallized from methanol to give the isomer of Va (0.06 g.) as colorless needles, m. p. 152—154°C. IR (KBr disk): 3430, 3300, 3180, 3050, 1655 and 1454 cm$^{-1}$.

Found: C, 76.80; H, 6.89; N. 10.79. Calcd. for $C_{17}H_{18}ON_2$: C, 76.66; H, 6.81; N, 10.52%.

**1-Hydroxy-3-benzyl-5-phenyl-2-pyrazinone (IX).** —IX was prepared by the use of the procedure of Dunn et al.[11] A solution of phenylglyoxal (2.68 g., 20 mmol.) in methanol (30 ml.) was added drop by drop to a suspension of DL-phenylalanylhydroxylamine[12] (3.6 g., 20 mmol) in methanol (30 ml.) and water (20 ml.) at −30°C. A sodium hydroxide solution (12.5 ml.; 2 N) was added during a 5—10 min. period, and then mixture was stirred at −30°C for 15 min. The temperature was raised to 0°C during the next 10 min., at the end of which period dissolution was complete. Stirring was continued at 5°C for 3 hr. The solution was acidified with a dilute solution of acetic acid to give yellow solids. These were collected, washed with water, and recrystallized from a small amount of ethyl acetate to yield yellowish needles (2.8 g., 50.0%), m. p. 165—166°C. The product gives a wine red color with a methanolic ferric chloride solution.

Found: N, 10.23. Calcd. for $C_{17}H_{14}O_2N_2$: N, 10.23%.

**The Reductions of IX.** — 1-Hydroxy-3-benzyl-5-phenyl-2-pyrazinone (IX) (1.25 g., 4.5 mmol.) was added to a solution of acetic acid (12.5 ml.) and water (12.5 ml.); zinc dust was then added in three 0.5 g. portions during 4 hr. of refluxing. The solution was cooled, and diluted with 70 ml. of water, and hydrogen sulfide was introduced to the solution until no more zinc sulfide precipitated. After the filtration of the zinc sulfide, the solution was neutralized with sodium hydroxide and extracted with three 30 ml. portions of benzene. The benzene was washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure, yielding crystalline, pale yellow solids. Carbon tetrachloride (4 ml.) was added to the solids, and insoluble crystals in carbon tetrachloride were collected (0.8 g., 66.7%) and recrystallized from methanol to yield colorless needles, m. p. 152—153°C (unchanged by admixture with VIa obtained by the reaction of X with XIa).

**3-Benzyl-5-phenyl-2-oxopiperazine (VIa).** — Triethylamine (2.1 g., 21 mmol.) was added to a solution of X (3.1 g., 20.5 mmol.) and XIa (4.0 g., 20.5 mmol.) in benzene (30 ml.), and the mixture was

10) C. Mannich and F. L. Hahn, *Ber.*, **44**, 1542 (1911).

11) G. Dunn, J. A. Elvidge, G. T. Newbalt, D. W. C. Ramsey, F. S. Spring and W. Sweeny, *J. Chem. Soc.*, **1949**, 2707.

heated at 80°C for 16 hr. The clear solution gradually became dark brown. After the mixture had been kept overnight, the triethylamine hydrochloride which had separated was filtrated off. The filtrate was washed twice successively with water with 3% hydrochloric acid, and twice more with water, and then dried over anhydrous sodium sulfate. After the solution of benzene had been saturated with hydrogen chloride under cooling, the resultant solution was allowed to stand for several hours. The separated crystals were collected, and dissolved in water (10 ml.), and the solution was filtered to remove a small amount of an insoluble substance. The filtrate was then neutralized with potassium carbonate, and the oily free base (XII) separated and it was extracted twice with benzene; the combined extracts were dried over anhydrous sodium sulfate and concentrated under reduced pressure to give XII as an brown residue (2.0 g.). A solution of crude XII (2.0 g.) in ethanol (100 ml.) was shaken with a Raney-nickel catalyst (1.0 g.) at an initial pressure of 100 kg./cm$^2$ of hydrogen at 70—80°C. The product was separated from the catalyst, the filtrate was evaporated to dryness under reduced pressure, and ligroin (5 ml.) was added to the residue. After several hours, 3-benzyl-5-phenyl-2-oxopiperazine precipitated; they were collected and washed with ligroin. The yield was 0.48 g. An analytical sample was obtained by recrystallization from methanol as colorless needles, m. p. 152—154°C. No depression of the melting point was observed on admixture with VIa synthesized by the reaction of IIIa with IVa. IR (KBr disk): 3400, 3300, 3180, 3060, 1660 and 1457 cm$^{-1}$.

Found: C, 76.63; H, 7.20; N, 11.10. Calcd. for $C_{17}H_{18}ON_2$: C, 76.66; H, 6.81; N, 10.52%.

**The Reaction of IIIb with IVb.**—A mixture of IIIb (14.8 g., 200 mmol.) and IVb (6.0 g., 33.2 mmol.) in benzene (50 ml.) was heated at 80°C for 3 hr. while being stirred. The mixture was concentrated to a half of the initial volume, and then a solution of potassium hydroxide (2.1 g.) in ethanol (30 ml.) was added. After the precipitate had separated, the solution was distilled under reduced pressure to yield a viscous liquid (2.0 g., 47%), b. p. 115—118°C/1 mmHg. The oil solidified spontaneously upon standing.

*Hydrochloride:* Colorless needles, m. p. 285—287°C (decomp.). IR (KBr disk): 3270, 2950, 2780—2250, 1685, 1465 and 1348 cm$^{-1}$.

Found: C, 44.10; H, 7.87; N, 17.02%.

*Phenylureido Derivative:* Colorless prisms, m. p. 202—203°C (unchanged by admixture with the phenylureido derivative synthesized by the reaction of XIb with XIIIb).

Found: N, 17.06%.

**3, 6-Dimethyl-2-oxopiperazine (Vb).**—A solution of chloroacetone oxime (8.3 g., 77 mmol.) in absolute ether (40 ml.) was added drop by drop to a solution of XIb (18 g., 154 mmol.) in absolute ether (180 ml.), after a few minutes amino acid ester hydrochloride began to precipitate. The mixture was then allowed to stand for 3 days at room temperature until the reaction was complete. The precipitated salt (11.1 g., 93.8%) was filtered off and washed with absolute ether. The combined ethereal solution, concentrated to about 100 ml., was extracted with 20 ml. of 3 N hydrochloric acid three times. The extracts were washed with ether, and then potassium carbonate was added until a yellow oil had separated completely. This oil was repeatedly extracted with ether, and then all the extracts were washed with saturated solution of sodium chloride and dried over anhydrous sodium sulfate. After the ether had been removed, a crude brown oil (7.0 g., 48.5% of the theoretical amount) was obtained; it was used for the next reduction step without further purification. A solution of crude XIVb (6.0 g., 32 mmol.) in ethanol (60 ml.) was shaken with Raney-nickel (2.0 g.) at an initial pressure of 100 kg./cm$^2$ of hydrogen. The reaction was then allowed to proceed for 5 hr. at room temperature. The catalyst was removed by filtration, and the brown oil was obtained by the concentration of the filtrate under reduced pressure. The oily products were distilled under a nitrogen stream to give 3,6-dimethyl-2-oxopiperazine (2.5 g., 61.0%), b. p. 129 — 132°C/2 mmHg.

*Hydrochloride:* Colorless needles, m. p. 285—286.5°C (decomp.). Its infrared spectrum in a potassium bromide pellet was superimposable with that of the hydrochloride of Vb obtained above.

Found: C, 43.90; H, 7.96; N, 17.12. Calcd. for $C_6H_{12}ON_2 \cdot HCl$: C, 43.77; H, 7.95; N, 17.02%.

**3, 6-Dimethyl-4-phenylcarbamoyl-2-oxopiperazine.**—Vb was treated with phenyl isocyanate, yielding the phenylureido derivative. This was crystallized from dilute ethanol to give colorless prisms; m. p. 202—203°C.

Found: N, 17.06 Calcd. for $C_{13}H_{17}O_2N_3$: N, 16.99%.

# The Copolymerization of Cyclic Olefins with Maleic Anhydride*

By Shunsuke MURAHASHI, Shun'ichi NOZAKURA and Katsutoshi YASUFUKU

(Received April 23, 1965)

Olefins with an internal double bond are known to homopolymerize reluctantly. This is believed to be due to steric interaction, in the propagating transition state, between monomer substituents and the propagating polymer end.[1] It is conceivable that, in addition to steric effects, resonance and polar effects are also operative here, as in the case of vinyl polymerization. The present authors hope to elucidate the reactivities of internal olefins in terms of these and other unknown factors. Cyclic olefins are considered to be simple internal olefins, since both polar and resonance factors can be regarded as constant, with their relative reactivities governed mainly by steric factors.

Some polymerization reactions of cyclic olefins are known. It has been reported that cyclic olefins gave oily low polymers by a radical mechanism under high pressure.[2] Recently, a new type of the ring-opening polymerization of cyclopentene has been reported.[3] As for the copolymerization of cyclic olefins, the formation of polysulfones is a well-known example of radical polymerization.[4] The copolymerization of cyclic olefins with ethylene, using Ziegler catalysts, has also been reported.[5]

The reaction of cyclic olefins with maleic anhydride was reported, by Alder et al.[6] and by Barltrop and Robson[7], to give an 1:1 adduct. More recently, Imoto et al. described the copolymerization of butenes with maleic anhydride.[8]

The present paper will compare the reactivity of cyclic olefins and butene-2 isomers in the copolymerization with maleic anhydride (MAn). The kinetics of the formation of the cyclopentene-MAn copolymer will also be described.

## Experimental

**Materials.** — Cyclobutene was synthesized by the pyrolysis of the adduct of cycloöctatetraene and acetylenedicarboxylic acid according to a known method.[9] The yield of the pyrolysis, which was carried out at 220°C (10 mmHg), was 98%. The infrared spectrum of the product was identical to that reported in the literature.[10] Cyclopentene (b. p. 44—44.5°C), cyclohexene (b. p. 81.5—82.0°C) and cycloheptene (b. p. 115°C) were synthesized by the usual methods. *cis*-Cyclooctene (b. p. 73.5—74.5°C (85 mmHg)) was a commercial product and was purified by rectification. All the monomers were checked for purity by gas chromatography.

MAn was distilled and stored in a desiccator as a benzene solution. 2,2'-Azobis-isobutyronitrile was recrystallized from ethanol.

**Polymerization.** — Polymerization was carried out in a sealed tube and/or in a dilatometer. Into a 20 ml. glass ampoule was placed a known amount of a monomer solution in benzene, together with an initiator solution. The solution was then degassed, using three freeze-thaw cycles, and sealed under a vacuum, after which the sealed ampoule was kept in a thermostat at 60±0.05°C. In the case of the butenes, a known volume of liquified butene was distilled, under a vacuum, into the ampoule, which contained the other reactants and the solvent. The mixture after polymerization was dissolved in a small amount of dry acetone and reprecipitated with dry ether. This procedure was repeated three times. The polymer was then extracted with ether and dried in vacuo at room temperature.

Dilatometers had a capillary 2 mm. in inside diameter and a total volume of about 13 ml. The volume contraction was read to $10^{-2}$ mm. by a cathetometer, and the relation between the volume contraction and the conversion was obtained by precipitating the polymer after polymerization.

**The Esterification of Copolymers.** — When a cyclopentene-MAn copolymer (soft. p. 195—200°C) was refluxed in methanol for 3 days, the result was a homogeneous solution of half esters, which softened at 145—150°C. These half esters were soluble in methanol, acetone and dioxane, but insoluble in ether, benzene, haxane and water. A dioxane solution of the half ester was treated with an ether solution of diazomethane at room temperature to yield the dimethyl esters of the copolymer, which softened at 100—110°C. The dimethyl ester was soluble in acetone and benzene, and insoluble in ether. The infrared spectra of the anhydride copolymer and its dimethylester are shown in Fig. 1.

Found for cyclopentene-MAn copolymer: C, 64.15; H, 6.29. Calcd. for $C_5H_8 \cdot C_4H_2O_3$: C, 65.04; H, 6.06%.

Found for dimethyl ester of the copolymer: C, 62.43; H, 7.57. Calcd. for $C_5H_8 \cdot C_6H_8O_4$: C, 62.24; H, 7.59%.

**An Analysis of Copolymer Composition.**—The copolymers thus obtained were found to have been partly hydrolyzed because of unavoidable contact with moisture, and so the copolymer composition was calculated from an analysis of both carbon and hydrogen, using a calibrated composition formula: $[\text{cycloolefin}]_x [\text{MAn}]_y [\text{H}_2\text{O}]_z$.

The molecular weight of the copolymers was determined in acetone, and that of the dimethyl ester of the copolymer, in benzene, using a Mechrolab Vapor Pressure Osmometer.

## Results

**The Reactivity of Cyclic Olefins.**—In order to compare the reactivity of cyclic olefins in the copolymerization with MAn, copolymerization was carried out in benzene at an equimolar monomer concentration; the results are shown in Table I.

Table I. Copolymerization of cyclic olefins ($M_2$) with MAn ($M_1$)

$[\text{MAn}] = [\text{Olefin}] = 1.54$ mol./l.; $[\text{AIBN}] = 3.2 \times 10^{-2}$ mol./l. in benzene; 60±0.05°C

| $M_2$ | Time hr. | Yield % | %/hr. | Soft. p. °C | MW |
|---|---|---|---|---|---|
| Cyclobutene | 0.32 | 13.2 | 41.8 | 180—190 | Insol. |
| Cyclopentene | 1.25 | 26.2 | 21.0 | 190—195 | 1600 |
| Cyclohexene | 23 | 17.7 | 0.8 | 170—185 | 500 |
| Cycloheptene | 19 | 18.3 | 1.0 | 240—245 | 700 |
| Cyclooctene (*cis*) | 14 | 19.7 | 1.4 | 250—255 | 1600 |

The copolymers obtained in Table I were white brittle solids and were soluble in acetone, dioxane, dimethylformamide, dimethylsulfoxide, pyridine

and methanol (except for the copolymer of cyclobutene), but insoluble in hexane, benzene, chloroform and ether. The cyclobutene copolymer swelled in these solvents. Although a comparison of the relative overall reactivities of cyclic olefins can be made on the basis of these relative rate data, these data do not measure reactivity in propagation because of the inclusion of initiation and termination rates. To obtain a stricter measure of the reactivity in the propagation reaction, monomer reactivity ratios were calculated by the usual procedure from a set of copolymerizations for each monomer. Since cyclic olefins did not homopolymerize under these conditions, the following simplified copolymer composition equation can be used: $(m_1/m_2)-1=r_1M_1/M_2$, where $m_1$, $m_2$, $M_1$ and $M_2$ denote the concentrations of MAn and cyclic olefin in the copolymer and the monomer mixture respectively. The results are listed in Table II,

TABLE III. MONOMER REACTIVITY RATIOS IN THE COPOLYMERIZATION OF CYCLIC OLEFINS ($M_2$) WITH ($M_1$)

| $M_2$ | $r_1$ | $1/r_1$ |
|---|---|---|
| Cyclopentene | 0.010±0.003 | 100 |
| Cyclohexene | 0.083±0.005 | 12 |
| Cycloheptene | 0.068±0.002 | 14.5 |
| Cyclooctene (*cis*) | 0.067±0.006 | 15 |
| *cis*-Butene-2 | 0.016±0.005 | 63 |
| *trans*-Butene-2 | 0.030±0.009 | 33 |

together with data on butene-2 isomers. The $r_1$ values are summarized in Table III. The $1/r_1$ value measures the relative reactivity of cyclic olefins towards the MAn radical of the growing polymer end.

In calculating the copolymer composition from carbon and hydrogen analysis, a correction was made for the partial hydrolysis of the anhydride group. This treatment was found to give a better straight line with less standard deviation than that which did not consider partial hydrolysis. In fact, the infrared spectra of the copolymers showed a weak shoulder at 1720 $cm^{-1}$ indicating the existence of free acid. Even the same sample yielded different analyses after storage in air, but after correcting for hydrolysis the calculated compositions remained constant.

The copolymer composition curve should go through the point of origin if the simplified copolymer equation represents the system adequately. An intercept at the ordinate might indicate either the existence of a systematic error in the analysis or a penultimate effect.[11] In the present treatment, however, the slope was taken as $r_1$, with the small intercept at the ordinate ignored.

The data illustrate that *cis*-butene-2 is about twice as reactive as the trans-isomer. The relative reactivity is:

cis/trans = 1.91 from $1/r_1$ values

cis/trans = 1.84 from dilatometric measurements

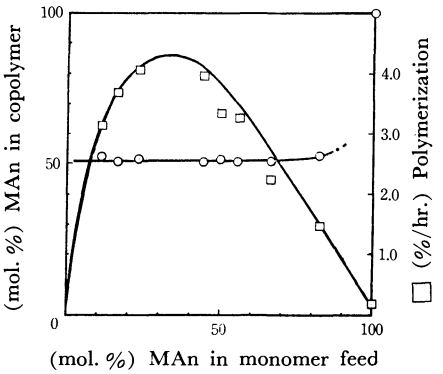

Fig. 2. Copolymer composition and rate in the cycloheptene-MAn copolymerization, 60°C in benzene.
[AIBN] = $1.05\times10^{-2}$ mol. $l^{-1}$
[MAn+Cyclopentene] = 1.72 mol. $l^{-1}$

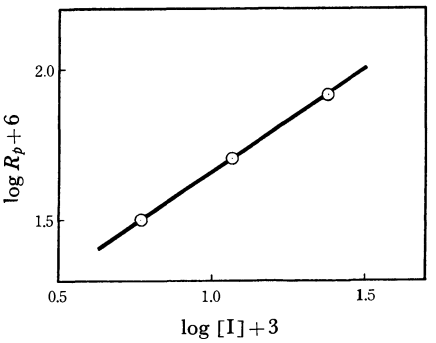

Fig. 3. Dependence of rate on initiator concentration in cyclopentene-MAn copolymerization, at 60°C in benzene.
[MAn] = [Cyclopentene] = 1.186 mol. $l^{-1}$

11) C. H. Bamford, W. G. Barb, A. D. Jenkins and P. F. Onyon, "The Kinetics of Vinyl Polymerization by Radical Mechanisms," Butterworth Scientific Pub., London (1958), p. 162.

The two values are in good agreement.

**The Kinetics of the Cyclopentene-MAn Copolymerization.**—The rate data for the copolymerization of cyclopentene and MAn, together with the copolymer composition curve, are shown in Fig. 2. MAn homopolymerizes slightly (0.18%/hr.) under the reaction conditions. A maximum rate was observed at 30 to 40 mol.% of MAn. The dependency of the rate on the initiator concentration (Fig. 3) and on the monomer concentration (Fig. 4) was measured, giving the expression:

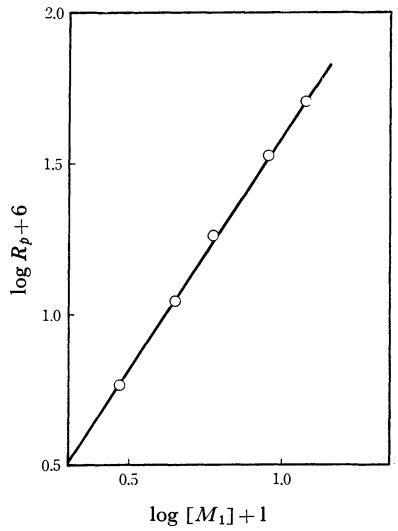

Fig. 4. Dependence of rate on the monomer concentration at 60°C in benzene.
[AIBM] = $1.14\times10^{-2}$ mol. $l^{-1}$
[MAn]/[Cyclopentene] = 1

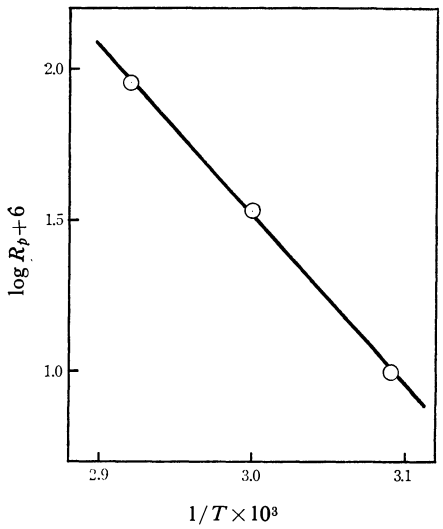

Fig. 5. Dependence of rate on temperature.
[MAn] = [Cyclopentene] = 0.895 mol. $l^{-1}$
[AIBN] = $1.14\times10^{-2}$ mol. $l^{-1}$

$$-(dM_1+dM_2)/dt=k[I]^{0.68\pm0.005}[M_1]^{1.54\pm0.018}$$

when $[M_1]=[M_2]$

$$k=(8.57\pm0.78)\times10^{-4}\ \text{mol.}\ l^{-1}\ \text{sec}^{-1}$$

An Arrhenius plot of the copolymerization rate data (Fig. 5) yielded an overall activation energy of 24.2±0.35 kcal./mol. Thus the overall rate constant, $k$, at 60°C is:

$$k=Ae^{-E/RT}=5.83\times10^{12}\,e^{-24.2kcal/RT}$$

No thermal polymerization was observed without the initiator for this monomer pair.

The molecular weights of the dimethylated copolymer were measured using a vapor pressure osmometer; values ranged from 3300 to 4400, i. e., the degree of polymerization was 30 to 40. Slight decreases in the molecular weight were observed with increasing monomer concentrations and initiator concentrations.

## Discussions

**The Copolymers of Cyclic Olefins and MAn.**—It may be seen from Table I that cyclobutene is much more reactive than the other cyclic olefins. Although the monomer reactivity ratio was not determined for cyclobutene because of insufficient data, Table II suggests that cyclobutene may add to its own radical. Cyclobutene has not been considered to homopolymerize by a radical mechanism.[5] It may also be noted that the copolymer was not soluble, and that even its dimethyl ester only swelled in organic solvents. This fact suggests that cross-linking had taken place during the polymerization, presumably due to opening of the cyclobutene ring.

Upon the dimethylation of the cyclopentene-MAn copolymer, the $\nu$C=O band at 1860 and 1780 $cm^{-1}$ and the $\delta$C–O–C band at 1220 $cm^{-1}$, which are due to the 5-membered cyclic acid anhydride group, disappeared; instead the $\nu$C=O of the ester appeared at 1720 $cm^{-1}$ (Fig. 1). The bands due to the cyclopentane ring at 970 and 920 $cm^{-1}$ became discernible in the dimethylated copolymer. There was a weak band at 1635 $cm^{-1}$; the fact that it increased in intensity upon methylation suggests that the $\nu$C=C band may be assigned to a double bond of the maleic anhydride type. The formation of that type of unsaturation may result from a chain transfer reaction. It has also been suggested by Joshi that the hydrogen atom of MAn is likely to be abstracted by a radical.[12] In fact, the molecular weight of the copolymer is always low, the degree of polymerization being at most 40.

**The Copolymerization of MAn ($M_1$) and Cyclopentene ($M_2$).**—Cyclopentene was chosen as representative of the cyclic olefins, and the kinetics

12) R. M. Joshi, *Makromol. Chem.*, **53**, 33 (1962).

of its copolymerization were sutdied. The rate of copolymerization was found to be of about the 0.7 th order with respect to the initiator. The value was significantly larger than one half, indicating some contribution of an unimolecular termination to the usual bimolecular one. The degradative chain transfer may partly account for the low molecular weight of the copolymers.

The rate was also found to be of the 1.5th order with respect to the monomer. A theoretical expression for the rate of copolymerization can be reduced to the following simple form in the case of $r_2=0$ and $[M_1]=[M_2]$:

$$R_p=kR_i^{1/2}[M_1]$$

The observed 1.5th order dependency might suggest that the monomer plays a role in the initiation reaction.

The monomer pair was found qualitatively to show a charge transfer band in the ultraviolet absorption spectrum.[13] In such an alternating copolymerization system, a question arises as to whether the two monomers behave as a complexed species in the propagation, as has been suggested in polysulfone formation.[14,15] If so, the rate of copolymerization should be at least of the second-order with respect to the monomer in the above expression, since the concentration of the complex molecule is low enough to be represented by $K_c[M_1][M_2]$.

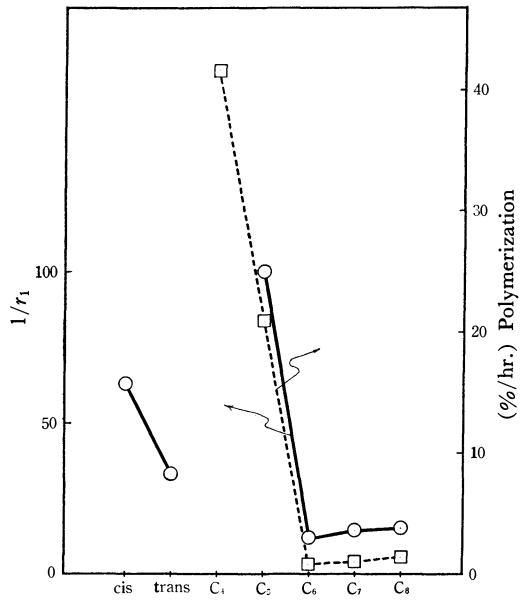

Fig. 6. Reactivities of cyclic olefins in the copolymerization with MAn.

$K_c$ denotes an equilibrium constant of the charge transfer reaction. The observed monomer dependency suggests that the present system is not such an extreme case.

**The Reactivity of Cyclic Olefins.**—The results listed in Tables I and III are reproduced in Fig. 6. The relative reactivity as determined by the $1/r_1$ value and the rate data are in good agreement. The features may be summarized as: i) The relative reactivities of cyclic olefins towards the growing MAn radical had a minimum at cyclohexene, higher members had slightly higher reactivities, and lower members had markedly higher reactivities.

ii) *cis*-Butene-2 is twice as reactive as the trans-isomer. *trans*-1, 2-Disubstituted ethylenes usually show higher reactivities than the cis-isomer.[16] This was rationalized by assuming that the resonance stabilization of the transition state is favored in the trans-isomers. The explanation could not, however, be applied to the present case.

iii) The reactivities of cyclohexene, cycloheptene and *cis*-cyclooctene were even lower than that of *trans*-butene-2, indicating that ring formation does not always activate the double bond.

The main factors which will control the reactivity of cyclic olefins are considered to be: 1) the difference in the strain energy in an olefin and the corresponding paraffin, 2) the strain energy of olefins, 3) steric hindrance due to ring bulkiness. Factors 1 and 2 will contribute to the activation energy of the propagation reaction, while factor 3 contributes mainly to the entropy term. If it is assumed that there is not much difference in the transition states for all the cyclic olefins, the difference between the strain energy in an olefin and that in the corresponding paraffin might reflect on the activation energy and, hence, on the relative reactivity. The energy difference can be approximated by the heat of the hydrogenation of these olefins.[17] Cyclohexene has the largest heat of hydrogenation, and so it should be the most reactive. However, this was not the case. Thus, factor 1 is not considered to be the predominant one.

A better correspondency was found between factor 2 and the observed reactivity. The strain energy of olefins is reproduced from the literature in Fig. 7.[18] The strain energy of *cis*-butene-2 is larger than that the of trans-isomer, and it is also in good agreement with the observed reactivity. Thus, the strain energy is considered to be one of the main factors which govern the reactivity of cyclic olefins.

Factor 3 may also make some contribution to

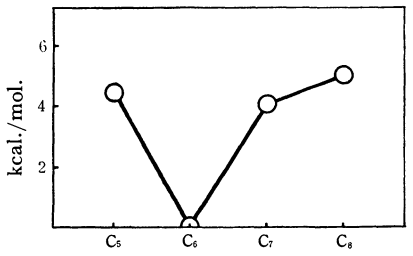

Fig. 7. Strain energy difference of cyclic olefin based on cyclohexene.[18]

the relative reactivity. In a study of methyl affinities,[17] cycloheptene and cyclooctene showed comparable reactivities to cyclopentene. In copolymerization with MAn, the attacking polymer radical is much larger than a methyl radical, and so the steric hindrance of higher cyclic olefins might have been enhanced in the copolymerization.

## Summary

The relative reactivities of cyclo-butene, -pentene, -hexene, -heptene, -octene(*cis*), *cis*- and *trans*-butene-2 have been compared in the copolymerization with MAn. The reactivity showed a minimum at cyclohexene, with the higher members having slightly higher reactivities and the lower members having markedly higher reativites than cyclohexene. *cis*-Butene-2 was found to be twice as reactive as the trans-isomer. These facts have been explained by a combination of the effects of the strain energy of olefins and of steric hindrance.

The kinetics of the copolymerization of cyclopentene and MAn was studied at 60°C in benzene, the overall rate being expressed by:

$$R_p = k[\mathrm{I}]^{0.7}[\mathrm{M}_1]^{1.5} \quad \text{when} \quad [\mathrm{M}_1]=[\mathrm{M}_2]$$

$$k = 5.83 \times 10^{12}\, e^{-24.2kcal/RT}$$

# Studies of the Liquid-Liquid Partition Systems. IV. The Solvent Extraction Study of Europium(III) Adduct Chelate Complexes with Six Acetylacetone Derivatives and Tributylphosphate

By Tatsuya SEKINE and Masaru ONO

(Received April 24, 1965)

The enhancement of metal chelate extractions by the addition of a neutral organophilic ligand has attracted the attention of many authors and has very often been called the "synergic effect."

The synergic effect has been found in many metal extraction systems with various chelating acids and neutral ligands; the enhancement of the extraction has been explained by the adduct formation of the metal chelates with the neutral ligand in the organic phases. A short review of this problem is given in Ref. 1.

The synergic enhancement of the metal extraction has been most extensively studied in metal extraction systems with thenoyltrifluoroacetone (TTA) and various organic phosphate esters. Some of the results in the previous work may be summarized briefly as follows: (i) The TTA metal chelate extraction systems show a much larger synergic effect than many other metal chelate extraction systems. (ii) The synergic effect is larger when the neutral adduct-forming ligand is an organic phosphate ester than when it is any other neutral ligand. (iii) The synergic effect is quite different when the central metal ion in the TTA chelate is different. TTA chelates of trivalent lanthanides and actinides or uranyl ions show larger synergic effects than many other metal TTA chelates. (iv) The synergic effect is different in different inert organic solvents. The effect is usually larger when water has a smaller solubility in the solvent.

The mechanism of the synergic enhancement of the metal chelate extraction seems not to be very simple, and even though some discussion has been presented to explain this phenomenon, the details seem not to have been understood completely.

In our laboratory, a systematic study has been carried out to obtain further information on the synergic effect of metal chelates. For the present paper, the authors have studied the differences

in the adduct formation of europium(III) chelates with six acetylacetone derivatives and tributylphosphate (TBP) in chloroform. These six β-diketones were chosen in order to determine if the large synergic effect in the metal TTA extraction systems is a character of metal chelates with (a) common β-diketones, (b) β-diketones with a trifluoromethyl group, (c) β-diketones with a large organic group such as a thenoyl group, or (d) β-diketones with both a trifluoromethyl group and a thenoyl group.

Europium(III) was chosen as the central metal ion in the chelate, TBP was chosen as the adduct-forming ligand, and chloroform was chosen as the inert organic solvent. The choices were made in order to make it possible to compare the results with previous results.[1]

Acetylacetone and its five derivatives, benzoylacetone, trifluoroacetylacetone, benzoyltrifluoroacetone, froyltrifluoroacetone and thenoyltrifluoroacetone, were chosen as the chelating acids.

The chemical properties of these β-diketones and the previous work on the metal extraction with these β-diketones were summarized by Morrison and Freiser,[2] Poskanzer and Foreman,[3] and Stary.[4] In the present study, the aqueous phase was always 0.1 M sodium perchlorate solutions with a small amount of a buffer. The influence of the concentration of the electrolytes in the aqueous phase on the synergic enhancement will be reported in another paper of this series.

## Experimental

**Reagents.**—The europium 152+154 tracer was obtained from the Oak Ridge National Laboratory as europium chloride in a dilute hydrochloric acid solution. It was diluted with 0.1 M perchloric acid and used as the stock solution. The six β-diketones were obtained from the Dojin Yakukagaku Co. The other reagents were of reagent grade. Sodium perchlorate was prepared from perchloric acid and sodium carbonate. It was recrystallized two times from water. Tributylphosphate was washed with 0.1 M perchloric acid, water and 0.1 M sodium hydroxide respectively, and then several times with water until the washed solution gave a neutral color on an indicator paper. Chloroform was washed three times with water to remove the alcohol which had been added as the stabilizer.

**Procedures.**—All of the procedures were carried out in a thermostatted room at 25±0.5°C. The tracer solution, the buffer solution and 0.1 M sodium perchlorate solution were placed in stoppered glass tubes, and then chloroform solutions of the chelating acid and TBP were added to the tubes. The aqueous phase was buffered with sulfanilate, acetate, or triethanolamine. The initial concentration of the buffer was 0.01 M. The initial volumes of the organic and the aqueous phases were 5.0 ml., and the volume of the glass tubes was about 20 ml. All of the solutions were left standing overnight before use. The two phases in the tubes were agitated by a mechanical rotator at 20 r. p. m. for about two hours and centrifuged. Two-milliliter portions were pipetted from both phases and transferred into small test tubes. The γ-radioactivity of the solutions was measured with a well-type (NaI) scintillation counter. A small portion of the aqueous phase was transferred into a small vessel, and the hydrogen ion concentration was determined potentiometrically using a 0.010 M $HClO_4$+0.090 M $NaClO_4$ solution as the standard ($-\log[H^+]=2.00$).

The net distribution ratio of europium(III) was calculated as follows:

$$D=\frac{\gamma\text{-count-rate per 2 ml. of org. phase}}{\gamma\text{-count-rate per 2 ml. of aq. phase}} \quad (1)$$

## Statistical Treatment

In the present paper, the subscript "org" denotes a species in the organic phase, while the absence of a subscript denotes a species in the aqueous phase. The suffix "0" denotes the distribution ratio or the extraction constant when no adduct is formed in the organic phase.

**Metal Extraction with a Chelating Acid.**—The extraction of a trivalent metal ion $M^{3+}$ with an organophilic chelating acid, HA, can be described as follows:

$$M^{3+}+3HA(org)\rightleftarrows MA_3(org)+3H^+ \quad (2)$$

$$K_0=([MA_3]_{org}/[M^{3+}])[H^+]^3[HA]^{-3}{}_{org} \quad (3)$$

The net distribution ratio obtained by Eq. 1 is generally described as:

$$D=[M(III)]_{org,\ total}/[M(III)]_{total} \quad (4)$$

From the organic phase, a small amount of the chelating acid is distributed into the aqueous phase, and the metal ion in the aqueous phase may form chelate complexes, $MA^{2+}$, $MA_2{}^+$,… The total metal ion content in the aqueous phase is generally described as:

$$[M(III)]_{total}=[M^{3+}]+[MA^{2+}]+[MA_2{}^+]+\cdots \quad (5)$$

and Eq. 4 is described as:

$$D_0=[MA_3]_{org}/([M^{3+}]+[MA^{2+}]+[MA_2{}^+]+\cdots) \quad (6)$$

When the aqueous chelate complexes are negligible, the distribution ratio is :

$$D_0=[MA_3]_{org}/[M^{3+}] \quad (7)$$

Then the extraction constant in Eq. 3 is expressed as:

1) T. Sekine and D. Dyrssen, *J. Inorg. Nucl. Chem.*, **26**, 1727 (1964). Three more papers on this subject are to be published in the same journal.

2) G. H. Morrison and H. Freiser, "Solvent Extraction in Analytical Chemistry," John Wiley & Sons Inc., New York (1957).

3) A. M. Poskanzer and B. M. Foreman, Jr., *J. Inorg. Nucl. Chem.*, **16**, 323 (1961).

4) J. Stary, "The Solvent Extraction of Metal Chelates," Pergamon Press, Oxford (1964).

$$K_0 = D_0[H^+]^3[HA]^{-3}_{org} \quad (8)$$

or:

$$D_0 = K_0[HA]^3_{org}[H^+]^{-3} \quad (9)$$

Thus when aqueous complexes are negligible, Eq. 8 or 9 describes the distribution equilibrium of the metal ion.

The aqueous chelate complexes in Eq. 6 can be treated as follows. When the distribution constant and the dissociation constant of a chelating acid are defined as:

$$K_D = [HA]_{org}/[HA] \quad (10)$$

$$K_a = [H^+][A^-]/[HA] \quad (11)$$

then the following equation can be introduced:

$$[A^-] = (K_a/K_D) \times ([HA]_{org}/[H^+]) \quad (12)$$

When the stability constants of the aqueous chelates are defined as:

$$\beta_{aq,n} = [MA_n^{3-n}]/[M^{3+}][A^-]^n \quad (13)$$

then the following equation is introduced on the basis of Eqs. 6, 12 and 13:

$$D_0 = [MA_3]_{org}[M^{3+}]^{-1} \times \{1 + \sum_1^n \beta_{aq,n}(K_a/K_D)^n([HA]_{org}/[H^+])^n\}^{-1} \quad (14)$$

From Eqs. 7 and 9, Eq. 14 can be written as:

$$D_0 = K_0[HA]^3_{org}[H^+]^{-3} \times \{1 + \sum_1^n \beta_{aq,n}(K_a/K_D)^n([HA]_{org}/[H^+])^n\}^{-1} \quad (15)$$

When we can assume that

$$[HA]_{org} - ([HA] + [A^-]) \cong [HA]_{org}$$

we can use the initial concentration of the chelating acid in Eqs. 14 and 15 instead of the concentration at the equilibrium.

**The Adduct Formation of a Metal Chelate with a Neutral ligand.**—When a metal chelate complex, $MA_3$, in the organic phase forms adduct complexes with an organophilic neutral ligand, L, the equilibrium is described as:

$$MA_3(org) + n\,L(org) \rightleftarrows MA_3L_n(org) \quad (16)$$

$$\beta_n = [MA_3L_n]_{org}/[MA_3]_{org}[L]^n_{org} \quad (17)$$

The distribution ratio in Eq. 4 is then:

$$D = ([MA_3]_{org} + [MA_3L]_{org} + [MA_3L_2]_{org} + \cdots)/([M^{3+}] + [MA^{2+}] + \cdots) \quad (18)$$

From Eqs. 17 and 18 we can introduce:

$$D = [MA_3]_{org}(1 + \sum_1^n \beta_n[L]^n_{org})/([M^{3+}] + [MA^{2+}] + \cdots) \quad (19)$$

then from Eqs. 6 and 19 we can introduce:

$$D/D_0 = 1 + \sum_1^n \beta_n[L]^n_{org} \quad (20)$$

Here the $D_0$ is the distribution ratio of the metal ion when no adduct is formed in the system.

When we can assume that there is no chelate formation in the aqueous phase, we can define the extraction constant, $K$, when the concentration of the neutral ligand is $[L]_{org}$ as:

$$K = D[H^+]^3[HA]^{-3}_{org} \quad (21)$$

$$= \{1 + \sum_1^n \beta_n[L]^n_{org})[MA_3]_{org}/[M^{3+}]\} \times [H^+]^3[HA]^{-3}_{org} \quad (22)$$

We can then obtain the following equation from the extraction constant, $K_0$, in Eq. 8:

$$K/K_0 = 1 + \sum_1^n \beta_n[L]^n_{org} \quad (23)$$

## Graphical Expression

**Metal Extraction with a Chelating Acid.**—When no complexes are formed in the aqueous phase, Eq. 9 is valid and the $D_0$ vs. $-\log[H^+]$ plot ($[HA]_{org}$ is constant) is a straight line with a slope of $+3$. The plot of $\log D_0[H^+]^3[HA]^{-3}_{org}$ vs. $\log[HA]_{org}$ or vs. $\log[H^+]^{-1}$ should be a straight line parallel to the abscissa.

On the other hand, when chelate complexes are formed in the aqueous phase, Eq. 6 or 15 is valid and the plot deviates downward from the straight line with a slope of $+3$. The plot of $\log D[H^+]^3 \cdot [HA]^{-3}_{org}$ vs. $\log[H^+]^{-1}$ or vs. $\log[HA]_{org}$ deviates downward from the straight line parallel to the abscissa, as we can see from Eq. 15.

**Adduct Chelate Complex Formation in the Organic Phase.**—When adduct chelate complexes with an organophilic neutral ligand are formed, Eqs. 18 and 19 are valid. The increase in the extraction with the increase in the ligand concentration can be expressed by Eq. 20.

When the formation of chelate complexes in the aqueous phase is negligible, Eq. 23 can also be used.

The formation constants of the adduct complexes, $\beta_1, \beta_2, \cdots$ can be determined graphically by a curve-fitting method.[1,5,6] It may be possible to describe the problem generally, but in the present study the description will be limited to the $MA_3L$- and the $MA_3L_2$-type complexes because we have encountered only these two complexes in the present study.

(i) When only the $MA_3L$ complex exists in the porganic hase, Eq. 20 can be described as:

$$\log D/D_0 = \log(1 + \beta_1[L]_{org}) \quad (24)$$

When a parameter

$$v = \beta_1[L]_{org}$$

is introduced, Eq. 24 can be described as:

$$\log D/D_0 = \log(1 + v) \quad (25)$$

This plot can be fitted with a standard curve:

5) D. Dyrssen and L. G. Sillén, *Acta Chem. Scand.*, **7**, 663 (1953).
6) L. G. Sillén, ibid., **10**, 186 (1956).

$$Y=\log(1+v) \qquad (26)$$
$$X=\log v$$

Equation 24 has two asymptotes:

$$[L]_{org}\to\infty \qquad Y=\log\beta_1+\log[L]_{org} \qquad (27)$$
$$[L]_{org}\to 0 \qquad Y=0 \qquad (27')$$

From the intersect of these two asymptotes, $Y=0$ and $X=\log x_1$, the $\beta_1$ can be determined as:

$$\log\beta_1=-\log x_1$$

(ii) When both the $MA_3L$ and the $MA_3L_2$ complexes are formed in the organic phase, Eq. 20 is described as:

$$\log D/D_0=\log(1+\beta_1[L]_{org}+\beta_2[L]^2_{org}) \qquad (28)$$

When we introduce two parameters:

$$v=\beta_2^{1/2}[L]_{org}$$

and

$$p=\beta_1\beta_2^{1/2}$$

Equation 28 can be described as:

$$\log D/D_0=\log(1+pv+v^2) \qquad (29)$$

and Eq. 28 can be fitted with a family of standard curves:

$$Y=\log(1+pv+v^2) \qquad (30)$$
$$X=\log v$$

Equation 28 has two asymptotes:

$$[L]_{org}\to\infty \qquad Y=\log\beta_2+2\log[L]_{org} \qquad (31)$$
$$[L]_{org}\to 0 \qquad Y=0 \qquad (31')$$

When the intersects of these two asymptotes is $Y=0$ and $X=\log x_2$, the $\beta_2$ can be determined as:

$$\log\beta_2=-2\log x_2$$

Figure 1 gives the standard curves obtained by Eq. 30 when the $p$ values are 0, 1, 2, 3, 5, 10, 20, and 50 respectively.

When the plot in Eq. 28 is fitted with one of the standard curves, the $\beta_1$ can be obtained from the $p$ and from the $\beta_2$ as:

$$\beta_1=p\beta_2^{1/2}$$

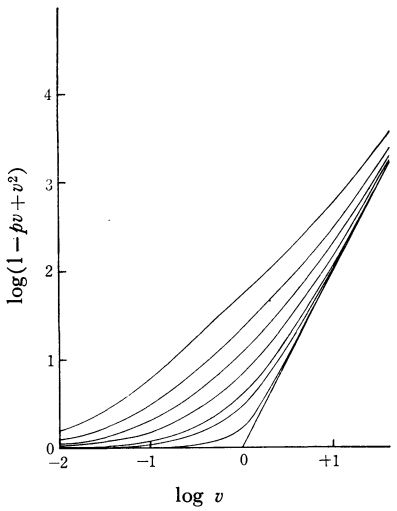

Fig. 1. Standard curves used for the graphical determination of the formation constants of the adducts, $Y=\log(1+pv+v^2)$, $X=\log v$. Each of the curves corresponds to the value of $p$, 50, 20, 10, 5, 3, 2, 1 and 0 respectively.

## Results

Figure 2 gives the plot of $\log D$ vs. $\log[H^+]^{-1}$ when the organic phase contained 0.1 M (initial) of the chelating acids.

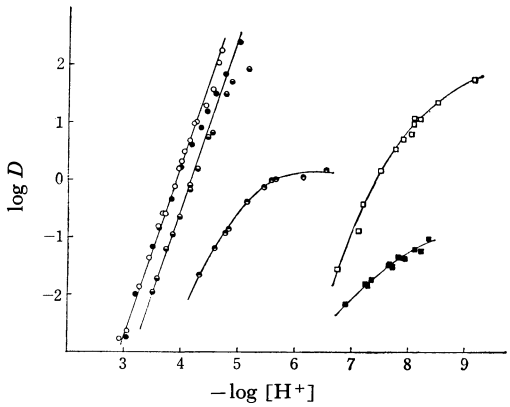

Fig. 2. The hydrogen ion concentration dependence of the distribution of europium(III). Aqueous phase: 0.1 M $NaClO_4$; Organic phase: Chloroform with 0.1 M of acetylacetone(■), benzoylacetone(□), trifluoroacetylacetone(◓), benzoyltrifluoroacetone(◒), froyltrifluoroacetone(●) and thenoyltrifluoroacetone(○).

Figures 3 to 8 give the plot of $\log D/D_0$ vs. $\log[TBP]_{org}$ when the chelating acid was acetylacetone (AA), benzoylacetone (BZA), trifluoroacetylacetone (TAA), froyltrifluoroacetone (FTA), or thenoyltrifluoroacetone (TTA) respectively.

The extraction constants of europium(III) with

Organic phase: 0.1 M of chelating ligand in $CHCl_3$. Aqueous phase: 0.1 M $NaClO_4$.

1) R and R' indicate the functional group in the $\beta$-diketone as indicated in the figure.

2) $K_0=[MA_3]_{org}[H^+]^3/[M^{3+}][HA]^3_{org}$

3) $\beta_1=[MA_3L]_{org}/[MA_3]_{org}[L]_{org}$

4) $\beta_2=[MA_3L_2]_{org}/[MA_3]_{org}[L]^2_{org}$ HA: a chelating ligand L: TBP

5) The extraction is always less than 10% over the entire pH range.

6) Metal chelate complexes are also formed in the aqueous phase and the $K_0$ cannot be determined definitely.

7) No evidence of the second adduct $EuA_3L_2$ is observed.

8) The concentration of TTA is 0.05 M for the experiments of the adduct formation.

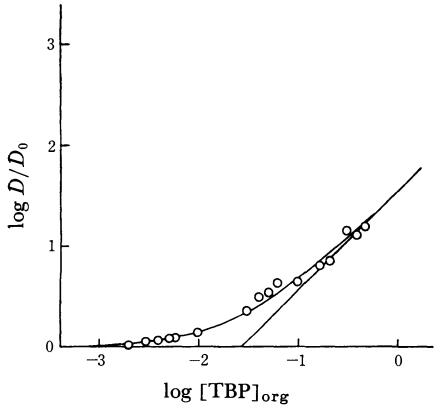

Fig. 4. 0.1 M benzoylacetone - TBP system. The curve fitted is $Y=\log(1+v)$, $X=\log v$. The intersect of the two asymptotes is (−1.60, 0).

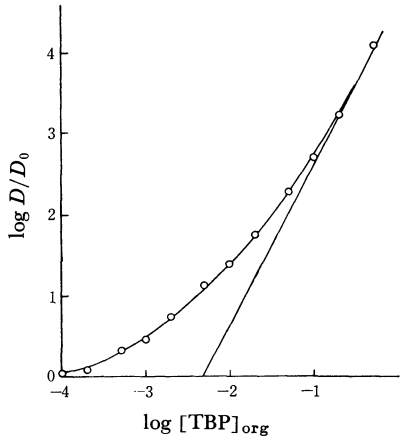

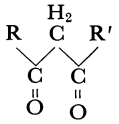

Fig. 5. 0.1 M trifluoroacetylacetone - TBP system. The curve fitted is $Y=\log(1+10v+v^2)$, $X=\log v$. The intersect of the two asymptotes is (−2.32, 0).

these chelating acids were calculated from the distribution data. The formation constants of the TBP adducts were obtained by the curve-fitting method.

The constants thus determined are given in Table I.

## Discussion

The six $\beta$-diketones in the present study can be described as:

In this discussion, the $\beta$-diketones will be classified into two groups and will be called the $CH_3$-group $\beta$-diketones and the $CF_3$-group $\beta$-diketones.

| | $\beta$-Diketone | R | R' |
|---|---|---|---|
| $CH_3$-group | Acetylacetone (AA) | $CH_3$- | $CH_3$- |
| | Benzoylacetone (BZA) | $CH_3$- | Benzoyl |
| $CF_3$-group | Trifluoroacetylacetone (TAA) | $CF_3$- | $CH_3$- |
| | Benzoyltrifluoroacetone (BFA) | $CF_3$- | Benzoyl |
| | Froyltrifluoroacetone (FTA) | $CF_3$- | Froyl |
| | Thenoyltrifluoroacetone (TTA) | $CF_3$- | Thenoyl |

A $\beta$-diketone exists in the keto form and in the enol form. A metal ion is extracted into the organic

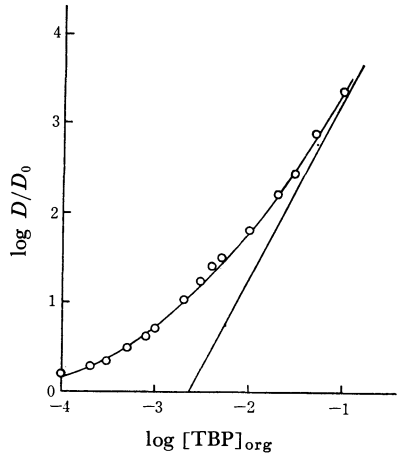

Fig. 6. 0.1 M benzoyltrifluoroacetone-TBP system. The curve fitted is $Y=\log(1+10v+v^2)$, $X=\log v$. The intersect of the two asymptotes is $(-2.64, 0)$.

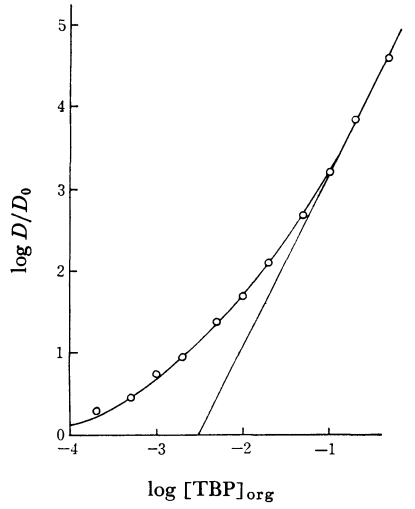

Fig. 7. 0.1 M froyltrifluoroacetone-TBP system. The curve fitted is $Y=\log(1+10v+v^2)$, $X=\log v$. The intersect of the two asymptotes is $(-2.50, 0)$.

phase as a metal chelate with only the enol-form ligand.

Adduct chelate complexes are sometimes also formed with the undissociated chelating acid, HA, as:

$$MA_3(org)+n\,HA(org)\rightleftarrows MA_3(HA)_n(org)$$

However, the formation of adducts of this type may be negligible when the concentration of the chelating acid is 0.1 M in chloroform (cf. Ref. 1, Paper III).

**Metal Extraction with Chelating Acids.**— The pH of 50% extraction increases in the following order:

$$TTA\cong FTA<BFA<TAA<BZA<(AA)$$

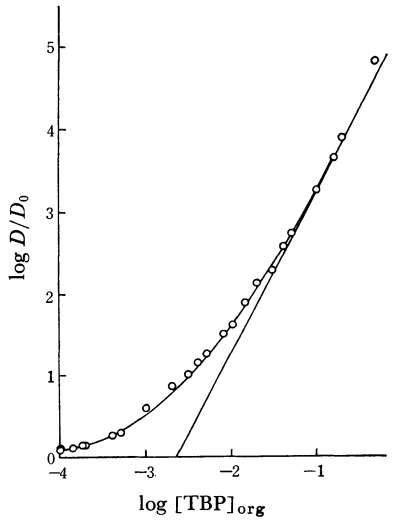

Fig. 8. 0.1 M thenoyltrifluoroacetone-TBP system. The curve fitted is $Y=\log(1+5v+v^2)$, $X=\log v$. The intersect of the two asymptotes is $(-2.64, 0)$.

Acetylacetone showed the least extraction of europium(III). With it the extraction was always less than 10%. The low extraction of trivalent lanthanide ions with this reagent has been reported by several authors.[7]

Benzoylacetone extracts europium(III) much better than acetylacetone, but the pH of 50% extraction is higher than that of the $CF_3$-group $\beta$-diketones. This agrees with previous observations.[8]

The extraction with thenoyltrifluoroacetone seems to agree with the results of the previous work.[1-4,9]

Most of the plots in Fig. 2 deviate from the straight line with a slope of +3. The deviation may be explained as resulting from the formation of aqueous complexes, as is shown in Eq. 15.

In the figure we can see that the deviation is larger in the order:

AA>TAA>BZA>FTA>BFA>TTA

In Eq. 15 we can see that the formation of aqueous complexes at a certain $[HA]_{org}/[H^+]$ is larger when the stability constants, $\beta_{aq,n}$, are larger and /or the $K_a/K_D$ ratio is larger.

Tables II and III summarize some data of the distribution constants and the dissociation constants of these $\beta$-diketones in the literature. In the tables we can see that the dissociation constants of the protons of acetylacetone and benzoylacetone are

| | 2.12 | $C_6H_6$ | 25°C $\mu=1.0$ | 16 |

Table III. Dissociation constants of β-diketones as an acid[4]

$K_a = [H^+][A^-]/[HA]$

| | $-\log K_a$ | Remarks | Ref. |
|---|---|---|---|
| Acetylacetone | 8.82 | 25°C $\mu=0.1$ | 11 |
| | 8.76 | 25°C $\mu=0.1$ | 12 |
| Benzoylacetone | 8.74 | 20°C $\mu=1.0$ | 17 |
| | 8.24 | 25°C $\mu=1.0$ | 14 |
| | 8.96 | 25°C $\mu=1.0$ | 13 |
| Trifluoroacetylacetone | 6.3 | 25°C | 18 |
| Benzoyltrifluoroacetone | 6.3 | 25°C | 18 |
| Thenoyltrifluoroacetone | 6.23 | 25°C $\mu=0.1$ | 19 |

nearly the same, but that the distribution constant of acetylacetone is much smaller than that of benzoylacetone (this can easily be understood in terms of the higher organophilic tendency of the larger organic group). We can also see in the tables that the dissociation constants of the $CF_3$-group β-diketones are nearly the same, but that the distribution constant of trifluoroacetylacetone is much lower than those of the others. This shows that the $K_a/K_D$ value of acetylacetone or trifluoroacetylacetone is larger than that of their homologues; we can thus understand why these two β-diketones form much more aqueous chelate complexes and show a lower ability of metal extraction.*

From these results, we may assume that the $K_0$ values (cf. Eq. 3) for the metal extraction with these two β-diketones are not very far from those of their homologues, even though the apparent metal extraction is quite different.

**Adduct Formation of the Metal Chelates with TBP.**—The formation constants of the adduct chelate complexes in Table I may be summarized as follows:

1) The formation constants of the first adducts of the metal chelates with the $CH_3$-group β-diketones are much lower than those of the metal chelates with the $CF_3$-group β-diketones.

2) The metal chelates with the $CH_3$-group β-diketones do not form the second adduct, $MA_3 \cdot (TBP)_2$, but the metal chelates with the $CF_3$-group β-diketones form the second adducts.

3) There is no large difference in the formation constants between the adducts of the acetylacetone chelate and those of the benzoylacetone chelate. There is also no large difference in the formation constants among the adducts of the four metal chelates with the $CF_3$-group β-diketones.

Thus the substitution of a methyl group in a metal chelate with a trifluoromethyl group changes the stability of the metal chelates, as we can see in Fig. 2; this substitution should change the interaction between the central metal ion and the ligands.

When the interaction between the metal ion and the chelating ligand is changed, the residual coordination power of the metal ion which makes the adduct formation possible may be changed. However, as the mechanism of the adduct formation in a synergic extraction system has not yet been clarified, further information on the structrue of the complexes seems to be necessary before this problem can be discussed in more detail.

## Conclusion

From the results of this study, we may conclude the following for the extraction of europium(III) in 0.1 M sodium perchlorate with the six β-diketones in chloroform and the adduct formation of these chelates in the organic phase with tributylphosphate:

1) The substitution of a methyl group in acetylacetone or trifluoroacetone with a benzoyl, froyl or thenoyl group increases the possibility of metal extraction, because the substitution increases the organophilic tendency of the molecules and prevents the formation of metal chelates in the aqueous phase. However, the substitution does not seem to change the metal extraction equilibrium,

$$M^{3+} + 3\,HA(org) \rightleftarrows MA_3(org) + 3\,H^+,$$

very much.

2) The β-diketones with one trifluoromethyl group extract the metal ion from aqueous solutions at a lower pH than those without a trifluoromethyl group.

* In the synergic extraction systems, the deviation caused by the formation of aqueous complexes becomes smaller. The details of this have been discussed in another paper.[10]

19) D. Dyrssen, *Svensk. Kem. Tidskr.*, **68**, 212 (1956).

3) The substitution of one methyl group in acetylacetone or benzoylacetone with one trifluoromethyl group increases the ability of metal chelates with these β-diketones to form adduct complexes with TBP in chloroform.

4) The substitution of one methyl group in acetylacetone chelate or that in trifluoroacetylacetone chelate with one benzoyl, froyl or thenoyl group does not change the adduct formation with TBP very much.

5) The high stability of TBP adducts observed in the metal TTA chelates seems to be similar to that in the TBP adducts of metal chelates with β-diketones which have a trifluoromethyl group.

## Summary

The extraction of europium(III) in 0.1 M sodium perchlorate with acetylacetone, benzoylacetone, trifluoroacetylacetone, benzoyltrifluoroacetone, froyltrifluoroacetone and thenoyltrifluoroacetone in chloroform and the adduct formation of these metal chelates with tributylphosphate have been studied at 25°C.

It has been concluded that: (i) The β-diketones which have one trifluoromethyl group extract europium(III) better than those which have no trifluoromethyl group. The difference in the metal extraction with acetylacetone or trifluoroacetylacetone and the metal extraction with the homologues of these β-diketones seems to be mainly due to the aqueous chelate complex formation. (ii) A metal chelate with a β-diketone which has a trifluoromethyl group is a much better acceptor of tributylphosphate to form adduct complexes than a metal chelate with a β-diketone which has no trifluoromethyl group. (iii) The ability of the acetylacetone chelate or the trifluoroacetylacetone chelate to form an adduct is not very much changed by the replacement of the methyl group with a benzoyl, froyl, or thenoyl group.

Some part of this work was carried out at the Laboratory of Nuclear Chemistry, Institute of Physical and Chemical Research, Tokyo. The authors are so grateful to Professor Nobufusa Saito, the head of the laboratory. Some of the experiments were made by Miss Tomoe Taira and by Messers Tatsuo Sato and Mitsuo Sakairi. The authors are also grateful to them.

# The Catalytic Hydrogenation of Aniline[1)]

By Hiroshi HAGIHARA and Etsuro ECHIGOYA

(Received April 24, 1965)

A few reports and a number of patents have previously been published on the hydrogenation of aniline, but most of them have reported on the catalytic hydrogenation in the liquid phase.[2-4)] The present authors have investigated this subject, using a number of types of catalysts, and this report will describe the development of the catalysts, and their selectivity in the vapor-phase hydrogenation of the benzene nucleus of aniline.

Catalysts consisting of single or mixed metals, or of supported metals, were used for this reaction. The catalyzed main reaction is the hydrogenation of aniline to cyclohexylamine:

$$C_6H_5NH_2 + 3H_2 \rightarrow C_6H_{11}NH_2$$

The side reactions of cyclohexylamine or aniline occur as follows:

$$2C_6H_{11}NH_2 \rightarrow (C_6H_{11})_2NH + NH_3$$

$$C_6H_{11}NH_2 + C_6H_5NH_2 \rightarrow C_6H_5NHC_6H_{11} + NH_3$$

Also, on a smaller scale, the hydrogenolysis reactions of cyclohexylamine to cyclohexane and ammonia, and of aniline to benzene and ammonia, took place under 250°C, as follows:

$$C_6H_{11}NH_2 \xrightarrow{H_2} C_6H_{12} + NH_3$$

$$C_6H_5NH_2 \xrightarrow{H_2} C_6H_6 + NH_3$$

## Experimental

**Procedure of Catalyst Preparation.**—Reagents of a chemically-pure grade were used as starting materials in the preparation of the catalysts. The

3) J. C. Jungers and G. Debus, *Chem. Abstr.*, **48**, 6975 (1954).
4) H. Yamamoto and T. Kwan, presented at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

catalysts were prepared by co-precipitation, by impregnation followed by subsequent precipitation, by mixing, by impregnation, and by precipitation followed by hydrothermal treatment under pressure in an autoclave.

*The Catalyst Preparation of Single or Mixed Metal Oxide.*[5]—Single or mixed metal catalysts were precipitated by slowly adding, with rapid agitation, a dissolved equivalent quantity of ammonium carbonate to a solution of nitrates at 20°C. After washing the filtered precipitates, they were dried at 100°C and calcined at 500°C, for 2 hr.

*Catalyst Preparation by the Impregnation Method with Subsequent Precipitation.*—The powdered support was added to a solution of nickel or cobalt nitrate. The slurry was stirred for some time, and then a solution of ammonium carbonate was slowly added to it until there was a slight excess at 20°C. After the precipitate had been filtered and washed, it was dried at 100°C and then calcined at 500°C for 2 hr.

*Catalyst Preparation by the Co-precipitation Method.*—The catalysts were prepared by co-precipitation with vigorous stirring from a mixed solution of nickel, or cobalt, and aluminum nitrate, or sodium silicate, and ammonium carbonate at 20°C. The precipitates were washed with distilled water, dried at 100°C, powdered, and calcined at 500°C for 2 hr. in an electric furnace.

*Catalyst Preparation by the Impregnation Method.*—The powdered support was added to a solution of nickel or cobalt nitrate and was in the solution for 5 hr. The slurry was then evaporated to dryness on a water bath, and the residue was dried in an oven at 100°C, washed with distilled water to remove nitrate ions, and dried again at 100°C. Then it was calcined at 500°C for 2 hr. in an electric furnace.

*Catalyst Preparation by the Mixing Method.*—The powdered support and the slurry of nickel or cobalt-basic carbonate were mixed mechanically in a beaker. The mixture was vacuum-filtered, and then it was dried at 100°C and calcined at 500°C for 2 hr.

*Catalyst Preparation by Hydrothermal Treatment.*[6]—Basic nickel carbonate or basic cobalt carbonate (prepared from a nickel or cobalt nitrate solution and an ammonium carbonate solution at 20°C) was mixed with silica gel or aluminum oxide gel and then heated in an autoclave to 250°C for 25 hr. with water. It was then cooled, filtered, washed with distilled water, dried at 100°C, and then calcined at 550°C for 2 hr.

**Experimental Method of the Hydrogenation of Aniline.**—The hydrogenation experiments were performed in a fixed-bed apparatus of the flow type in the temperature range from 150°C to 300°C. Figure 1 shows its flow diagram. The mixture of aniline and hydrogen was introduced into a reactor which was immersed in a fluidized thermal bath.

The gaseous products leaving from the reaction zone were caught in a condenser trap cooled with dry ice-methanol, from which trap condensates were drawn every thirty minutes for gas chromatographic analyses.

The oxide catalysts (5 ml.) were in the same fixed-bed apparatus used for the reaction, reduced to the metals in hydrogen according to a definite reduction

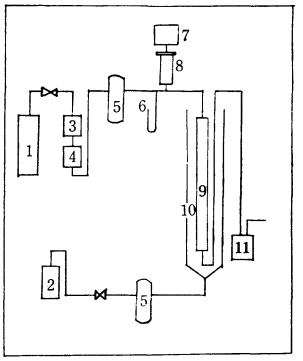

Fig. 1. Flow sheet for the hydrogenation reaction of aniline.

schedule. The flow rate of hydrogen was 250 ml./min. The temparature of the catalyst bed was raised to 200°C in one hour, and then raised at the rate of 2.5°C per minute until 400°C or 450°C was reached. After the temperature had been held at 400°C or 450°C for two hours, the catalyst was cooled in the hydrogen stream to the reaction temperature, and then a run of the hydrogenation of aniline was carried out.

After a steady state of activity was achieved, the activity of the catalyst was estimated as follows:

$$\text{Conversion} = \frac{\text{The amount of reacted aniline (mol./hr.)}}{\text{Total aniline introduced (mol./hr.)}}$$

$$\text{Selectivity} = \frac{\text{Cyclohexylamine yield (mol./hr.)}}{\text{Reacted aniline (mol./hr.)}}$$

$$\text{Yield of benzene} = \frac{\text{Benzene yield (mol./hr.)}}{\text{Total aniline used (mol./hr.)}}$$

$$\text{Yield of secondary amine} = \frac{\text{Secondary amine yield (mol./hr.)}}{\text{Total aniline used (mol./hr.)}}$$

## Results

**The Activity of Various Metals for This Reaction.**—The catalysts were reduced by hydrogen at 400°C. The results of the activity tests are shown in Fig. 2. The single-metal catalysts are sharply divided into three classes. Ruthenium is active at low temperatures. Cobalt is more active than nickel. Iron and copper are inactive in this reaction.

It must be emphasized that the inactivity of iron or copper is not due to insufficient reduction or to the sintering of the metal. Especially in the case of copper, the reduction was carried out at a low temperature (about 200°C) to prevent it from sintering. It was found through experiments that the activity of a metal prepared by reduction

from the oxide is dependent on the length of the reduction time and on the temperature. The effects of the reduction temperature of cobalt on the activity were also investigated. The results are shown in Fig. 3.

**The Activity of the Mixed Metal Catalysts.**—The catalysts were reduced by hydrogen at 400°C. The results of the activity tests are shown in Fig. 4. The activity of the Co-Ni series showed a decrease as the nickel content increased. However, in the Co-Fe series, when the Fe content became 50%, the Co-Fe catalyst lost its activity almost completely. A similar results was obtained by Long et al.[7,8] in the hydrogenation of benzene.

Long et al. ascribed this to the different crystsl structures of mixed metal catalysts. They found that as the mixture becomes richer in cobalt, the more probable it is that the catalyst will have more of a face-centered cubic lattice, and will hence be active.

**The Activity of Supported Metal Catalysts.**—The activities of metal catalysts supported on the same oxide carrier, although prepared by different methods, show almost the same tendency in the relative abundance of the various products.

1) The maximum activity of catalysts for the hydrogenation reaction was obtained in the temperature range from 180 to 200°C, and 2) The production of secondary amine was affected by the kind of carrier-oxide used.

**The Activity of Supported Cobalt Catalysts.**—The catalysts were reduced by hydrogen at 450°C for 2 hr. The results of the activity tests are presented in Figs. 8 and 9.

From these data, it may be concluded that:

1) The maximum activity of catalysts for the hydrogenation reaction was obtained in the temperature range from 180 to 200°C, and 2) The production of secondary amine was less with a cobalt catalyst than with nickel catalysts. 3) The selectivity of this reaction was influenced by the kind of carrier-oxide.

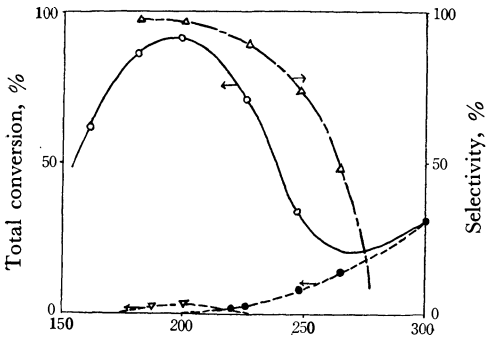

Fig. 8. The activity and selectivity of Co-$Al_2O_3$ (50% cobalt) for the hydrogenation.
LHSV=1.0 $hr^{-1}$, $H_2$/aniline 10 (mole ratio)
-▽- yield of dicyclohexylamine
-●- yield of benzene

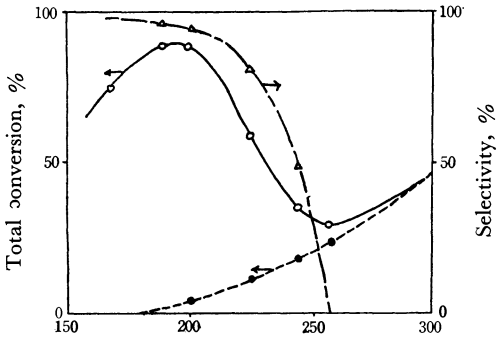

Fig. 9. The activity and selectivity of Co-MgO-Kieselguhr (45 : 10 : 45) for the hydrogenation.
LHSV=1.0 $hr^{-1}$ $H_2$/aniline 10 (mole ratio)
-●- yield of benzene

On the basis of the above data, we have concluded that the kind of carrier-oxide used has an effect on the activity of nickel, as well as on the cobalt. The production of dicyclohexylamine is especially affected by the kind of carrier used.

**The Activity of Catalysts Prepared by the Hydrothermal Treatment.**—The catalyst were reduced by hydrogen at 550°C. The results are presented in Fig. 10. It may be concluded that the catalysts produced by the hydrothermal treatment are less active.

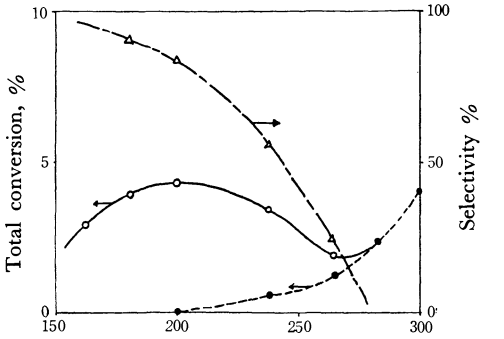

Fig. 10. The activity and selectivity of Co-$SiO_2$* cat. (20% cobalt) for the hydrogenation.
* The catalyst was treated at 250°C in an autoclave in the presence of water.

**The Effect of the Carrier-oxide Content of Metallic Catalysts on the Hydrogenation Reaction of Aniline.**—The results are summarized

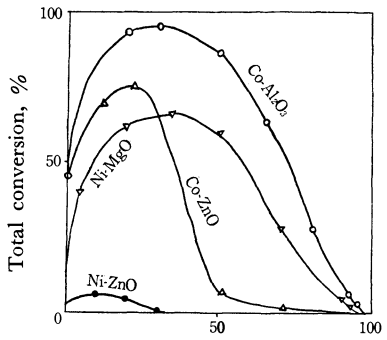

Fig. 11. Effect of the oxide carrier contents of metallic catalysts on the hydrogenation.
Reaction temp. 200°C
LHSV=1.0 $hr^{-1}$, $H_2$/aniline 10 (mole ratio)

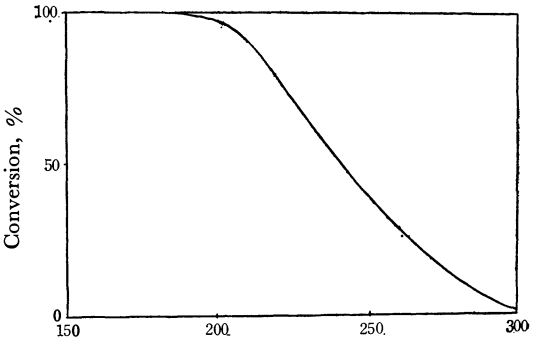

Fig. 12. Relation between temperature and equilibrium conversion.
$H_2$: aniline=10 : 1

in Fig. 11. The activity of the catalysts was found to be influenced by its carrier-oxide, and their activity is highest at a certain metal-to-carrier ratio.

In the Co-ZnO and Ni-ZnO series, the activity was found to be very low. This was attributed to the formation of a complex between the metal and its carrier. From X-ray analysis, it was concluded that $ZnCo_2O_4$ was formed.

**The Relationship between the Activity and the Metal Content of the Catalyst in the Hydrogenolysis Reaction of Aniline.**—Table I shows the relation between the conversion and the metal content of the catalyst in the hydrogenolysis reaction. From the data presented, it may be concluded that the rate of the hydrogenolysis reaction of aniline is related to the amount of metal on the oxide carrier, the activity of the catalyst was found to be proportional to the metal content of the catalyst.

TABLE I. THE RELATION BETWEEN CONVERSION AND THE METAL CONTENT OF THE CATALYST IN THE HYDROGENOLYSIS REACTION

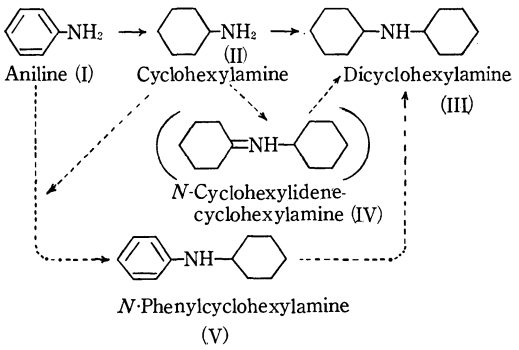
Reaction temp. 300°C, LHSV=1.0 $hr^{-1}$
$H_2$/aniline 10 (mole ratio)

| Metal content, % | Catalyst | |
|---|---|---|
| | Ni-MgO | Co-$Al_2O_3$ |
| 10 | 11% | 14% |
| 20 | 19% | 17% |
| 30 | 28% | 24% |

## Discussion

**The Relationship between the Activity and the Reaction Temperature.**—As is shown in Figs. 6—9, in the hydrogenation reaction of aniline in the vapor phase the highest conversion of aniline into cyclohexylamine was obtained in the temperature range from 180 to 200°C. At high temperatures, the degree of hydrogenation decreased. This phenomenon of a negative temperature coefficient can be explained in terms of the thermodynamic chemical equilibrium calculated using the Nernst equation at the $H_2$ to aniline mole ratio of 10 to 1.

Since the hydrogenation is carried out in a dynamic (flow) system, the conversion is most probably controlled not only by the equilibrium constant, but also by the rate of the surface reaction. It was concluded from the kinetic study with cobalt and nickel of the vapor-phase hydrogenation of aniline that the results obtained may be expressed satisfactorily by the following rate equation in the 150—210°C temperature range.



$$r=k\theta_A\theta_H^3$$

$r$: reaction rate
$k$: reaction rate constant
$\theta_A$: the fractions of the surface covered by the aniline
$\theta_H$: the fractions of the surface covered by hydrogen

A more detailed report of the kinetic study will be presented later.

**A Relationship between the Activity and the Structrue of the Catalyst.**—The chemical states of metal on the supported catalyst may be classified into two types. The one is the type in which the metal is not combined with the carrier but remains free on the surface of the carrier. In the other type, the metal oxide forms a complex with the carrier resists reduction by hydrogen. Generally speaking, catalysts of the first type (supported free metal) show a higher activity for the hydrogenation and hydrogenolysis reaction of aniline. A more detailed report on this will be presented in the near future.

**The Mechanism of the Production of Secondary Amine.**—In the course of the hydrogenation reaction, dicyclohexylamine and phenylcyclohexylamine are also found in the product. The course of the formation of those products may be described as follows.

(The main course is presented by a full line, the less important course is presented by dotted lines)

The cyclohexaneimine was not found in the product, but *N*-cyclohexylidene-cyclohexylamine could be isolated. However the quantity of IV found is small compared with that of III.

The main course of the production of dicyclohexylamine may consist of two paths, the one through *N*-cyclohexylidene-cyclohexylamine, and the other through the condensation of two cyclohexylamine molecules. We also found that the rate of the condensation of two cyclohexylamines into dicyclohexylamine is fast compared with the rate of the condensation of aniline and cyclohexylamine.

**The Properties of the Carrier-oxides.**—We have found that the properties of the carrier-oxides have a great influence on the selectivity of the catalyst.

According to Sanderson,[9] oxides have thier own partial charge on oxygen and this value is an important parameter for determining the acidic character of oxides. We used the values given by Sanderson for $Al_2O_3$, $SiO_2$, MgO, CaO, ZnO, and $K_2O$ and correlated these values with the $-\Delta H_0°$ values of the oxides given by Tamaru[10]

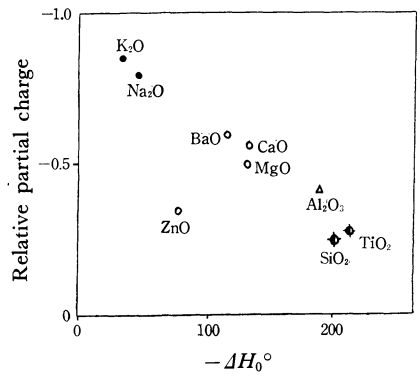


Fig. 13. Correlation between R.P.C. and $-\Delta H_0°$ of oxide.

9) R. T. Sanderson, "Chemical Periodicity," Reinhold Pub. Comp., N. Y. (1960), p. 106.

10) K. Tamaru and K. Tanaka, *Shokubai* (*Catalyst*), **4**, 328, (1962).

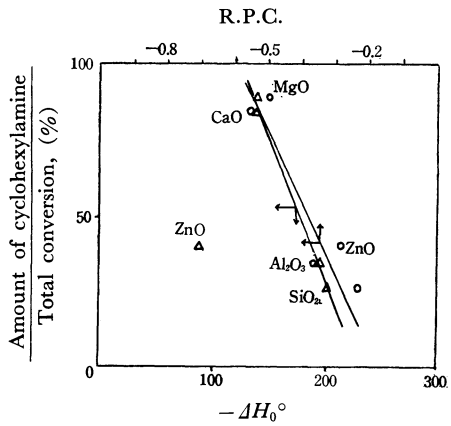

Fig. 14. Relationship between selectivity and oxide carrier of nickel catalysts (50% nickel). Reaction temp. 200°C, LHSV=1.0 $hr^{-1}$ SV=3000 $hr^{-1}$, $H_2$/aniline 10 (mole ratio)

(see Fig. 13).

There is a relationship between the r. p. c. and $-\Delta H_0°$ values. As Fig. 14 shows, the selectivity of the catalysts was proportional to the value of $-\Delta H_0°$. Thus, we have concluded that the acidic and basic property of the carriers has a great influence on the production of secondary amine. The property of the oxide carrier is probably related to the elimination of ammonia from the cyclohexylamine and aniline molecules. The electron-donating property of the nitrogen of the amino group suggests that the amino group strongly interacts with the metal surface.[11] This effect may be considered to play an important role in the formation of the secondary amine. The adsorption of amine may be weakened on that metal which is supported by basic oxides.

## Summary

1) The order of the activity of a metal catalyst for the hydrogenation of aniline is Co>Ni>Fe, Cu. The order of their selectivity is Co>Ni.

2) The activity of the mixed metals (Co-Ni, Co-Fe) is lower than that of a cobalt single catalyst.

3) The rate of hydrogenation increases with the temperature up to 180—200°C, and then decreases at higher temperatures. This phenomenon may be explained in terms of the kinetics of the reaction.

4) The catalyst which consists of a complex between the metal and its carrier-oxide is less active than the free metal catalyst for the hydrogenation reaction, and it almost completely loses its activity for the hydrogenolysis reaction.

5) The production of cyclohexylamine is affected by the property of the carrier oxide.

6) The main course of the production of dicyclohexylamine is considered to proceed through the

11) Y. Y. Yao, *J. Phys. Chem.*, **67**, 2055 (1963).

condensation of two cyclohexylamine molecules and through *N*-cyclohexylidene-cyclohexylamine.

Notation: r. p. c.=relative partial charge on the oxygen of oxide (reported by R. T. Sanderson)
$-\Delta H_0°$=standard heat of formation of the highest oxide per metal g.-atm.

The authors wish to thank Professor Kiyoshi Morikawa for his guidance and discussions in the course of this study.

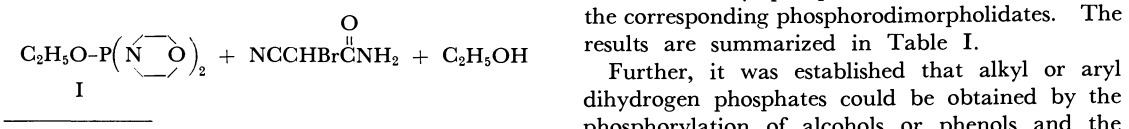
# Phosphorylation by Means of Ethyl Phosphorodimorpholidite and $\alpha$-Bromoamides

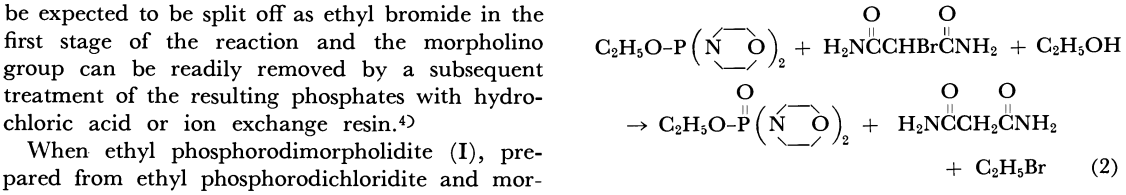
By Oyo MITSUNOBU, Teisuke OBATA, Yoshiharu SUGAYA and Teruaki MUKAIYAMA



(Received April 24, 1965)

Preceding papers[1,2] have described a selective phosphorylation of alcohols and phosphates by means of monobromocyanoacetamide or monobromomalonamide with trialkyl phosphites, thus forming mixed esters of phosphoric acid and unsymmetrical pyrophosphates.

When this phosphorylation method was applied to the preparation of some naturally-occurring phosphorus compounds, tribenzyl phosphite was employed[3] since the benzyl group can be readily removed from the resulting phosphates by catalytic hydrogenation after phosphorylation has been performed.



In the present study, another phosphite, ethyl phosphorodimorpholidite (I), was prepared and treated with monobromocyanoacetamide and alcohols. The ethyl group of the phosphite would be expected to be split off as ethyl bromide in the first stage of the reaction and the morpholino group can be readily removed by a subsequent treatment of the resulting phosphates with hydrochloric acid or ion exchange resin.[4]

When ethyl phosphorodimorpholidite (I), prepared from ethyl phosphorodichloridite and morpholine, was reacted with monobromocyanoacetamide in ethanol at $-40°C$, ethyl phosphorodimorpholidate (II) was obtained in a 46% yield by fractionation (Eq. 1).

(1)

Since a small amount of cyanoacetamide contaminates the fraction of ethyl phosphorodimorpholidate, monobromomalonamide was used in place of monobromocyanoacetamide in the above reaction. In this case, the resulting malonamide may be expected to be removed more readily than cyanoacetamide from the reaction mixture, while pure phosphate may be isolated by distillation. Actually, when ethyl phosphorodimorpholidite was reacted with monobromomalonamide in ethanol at room temperature, ethyl phosphorodimorpholidate was obtained in a 54% yield (Eq. 2).

(2)

Similarly, methyl alcohol, *n*-propyl alcohol, isopropyl alcohol, phenol and *p*-nitrophenol were phosphorylated by means of monobromomalonamide and ethyl phosphorodimorpholidite to yield the corresponding phosphorodimorpholidates. The results are summarized in Table I.

Further, it was established that alkyl or aryl dihydrogen phosphates could be obtained by the phosphorylation of alcohols or phenols and the subsequent hydrolysis of the reaction mixture with Amberlite IR-120 ($H^+$ form) ion exchange resin. For example, phenol was reacted with monobromocyanoacetamide and ethyl phosphorodimorpholidite

at −40°C. After the cyanoacetamide had been removed by filtration, the filtrate was subsequently treated with Amberlite IR-120 ($H^+$ form) ion exchange resin, and phenyl dihydrogen phosphate was isolated as anilinium salt in a 47% yield.

Similarly, ethyl dihydrogen phosphate and *p*-nitrophenyl dihydrogen phosphate were obtained by the reaction of either ethanol or *p*-nitrophenol with monobromocyanoacetamide and ethyl phosphorodimorpholidite.

Further, this method of preparing monoesters of phosphoric acid was applied to the synthesis of adenosine 5′-phosphate. A mixture of 2′,3′-isopropylidene adenosine, monobromocyanoacetamide and ethyl phosphorodimorpholidite in dimethyl formamide was kept standing for 3 days at room temperature. After the solvent, had been promoved, the residue was treated with 1 N hydrochloric acid in order to remove protecting groups from the resulting 2′,3′-isopropylidene adenosine 5′-phosphorodimorpholidate. Adenosine 5′-phosphate was isolated as barium salt in a 54% yield and identified by paper chromatography and paper electrophoresis with an authentic sample. In the course of the hydrolysis, the glycosyl linkage was cleaved and a small amount of adenine was formed (as detected by paper chromatography).

(3)

## Experimental

Monobromocyanoacetamide,[1] monobromomalonamide,[2] ethyl phosphorodichloridite[5] and 2′,3′-isopropylidene adenosine[6] were prepared by the literature procedures.

**The Preparation of Ethyl Phosphorodimorpholidite.**—A solution of ethyl phosphorodichloridite (73.5 g., 0.5 mol.) in 100 ml. of ether was added drop by drop over a period of 1 hr. to a solution of triethylamine (101 g., 1 mol.) and morpholine (87.1 g., 1 mol.) in 500 ml. of ether cooled in an ice bath. The reaction mixture was refluxed for an additional 30 min. and triethylamine hydrochloride was removed by filtration. After the ether had been removed from the filtrate, 81 g. (65%) of ethyl phosphorodimorpholidite was obtained by fractionation, b. p. 120—124°C/5 mmHg. Redistillation gave an analytical sample, b. p. 118°C/0.35 mmHg.

Found: N, 11.37. Calcd. for $C_{10}H_{21}N_2O_3P$: N, 11.33%.

**The Phosphorylation of Ethanol by Means of Ethyl Phosphorodimorpholidite and Monobromocyanoacetamide.** — A solution of ethyl phosphorodimorpholidite (2.48 g., 0.01 mol.) in 5 ml. of ethanol was added drop by drop to a solution of monobromocyanoacetamide (1.63 g., 0.01 mol.) in 15 ml. of ethanol at −70°C. After the reaction mixture had been kept standing overnight at room temperature, ethanol was removed under reduced pressure. Chloroform was added to the residue and undissolved cyanoacetamide was filtered off, 0.76 g., 91%; m. p. 99—112°C. The filtrate was then concentrated to a syrup. This syrup was distilled to give 1.20 g. (46%) of ethyl phosphorodimorpholidate, b. p. 129—131°C/0.008 mmHg, along with a small amount of cyanoacetamide.

**The Phosphorylation of Ethanol by Means of Ethyl Phosphorodimorpholidite and Monobromomalonamide.**—To a suspension of monobromomalonamide (1.81 g., 0.01 mol.) in 13 ml. of ethanol was added, drop by drop, a solution of ethyl phosphorodimorpholidite (2.48 g., 0.01 mol.) in 3 ml. of ethanol at room temperature. The reaction started soon with the liberation of heat and a white precipitate, malonamide, appeared. After the reaction mixture

5) N. Menshutkin, *Ann.*, **139**, 343 (1866).
6) A. Hampton, *J. Am. Chem. Soc.*, **83**, 3640 (1961).

had been kept standing overnight, malonamide was removed by filtration. From the filtrate, ethyl phosphorodimorpholidate was obtained by fractionation; 1.54 g. (58%), b. p. 130—132°C/0.01 mmHg. When this stood at room temperature, the product solidified.

Found: N, 10.02. Calcd. for $C_{10}H_{21}N_2O_4P$: N, 10.06%.

Similarly, methyl alcohol, *n*-propyl alcohol and isopropyl alcohol were phosphorylated to give the corresponding alkyl phosphorodimorpholidates, as is shown in Table I.

**The Phosphorylation of Phenol by Means of Ethyl Phosphorodimorpholidite and Monobromomalonamide.**—To a suspension of monobromomalonamide (1.81 g., 0.01 mol.) and phenol (0.93 g., 0.01 mol.) in 15 ml. of ether there was added a solution of ethyl phosphorodimorpholidite (2.48 g., 0.01 mol.) in 5 ml. of ether at room temperature. The reaction started soon with the liberation of heat, and a white crystalline compound, malonamide, appeared. After the reaction mixture had been kept standing overnight, the malonamide was removed by filtration. From the filtrate, phenyl phosphorodimorpholidate was obtained by fractionation; 2.16 g. (69%), b. p. 168—169°C/0.005 mmHg.

Found: N, 9.00. Calcd. for $C_{14}H_{21}N_2O_4P$: N, 8.97%.

**The Phosphorylation of *p*-Nitrophenol by Means of Ethyl Phosphorodimorpholidite and Monobromomalonamide.**—A solution of ethyl phosphorodimorpholidite (2.48 g., 0.01 mol.) in 5 ml. of tetrahydrofuran (THF) was added drop by drop to a solution of monobromomalonamide (1.81 g., 0.01 mol.) and *p*-nitrophenol (1.39 g., 0.01 mol.) in 15 ml. of THF cooled in a water bath. After the reaction mixture had been kept standing overnight, the malonamide was removed by filtration; 1.00 g., 97%, m. p. 151—164°C. The removal of the solvent from the filtrate gave 3.80 g. of a solid residue which was recrystallized from ethyl acetate to give 3.10 g. (87%) of *p*-nitrophenyl phosphorodimorpholidate, m. p. 118.5—120°C.

Found: N, 12.09. Calcd. for $C_{14}H_{20}N_3O_6P$: N, 11.76%.

**The Phosphorylation of Morpholine by Means of Ethyl Phosphorodimorpholidite and Monobromomalonamide.**—A solution of ethyl phosphorodimorpholidite (2.48 g., 0.01 mol.) in 5 ml. of THF was added drop by drop to a solution of monobromomalonamide (1.81 g., 0.01 mol.) and morpholine (0.87 g., 0.01 mol.) in 15 ml. of THF at room temperature. After the reaction mixture had been kept standing overnight, the malonamide was removed by filtration. The filtrate was concentrated under reduced pressure, and 15 ml. of chloroform was added to the residue. A small amount of undissolved malonamide was filtered off. The removal of the solvent from the filtrate gave a solid residue which was recrystallized from acetone to give 0.98 g. (32%) of phosphorotrimorpholidate, m. p. 185—186°C.

Found: N, 13.48. Calcd. for $C_{12}H_{24}N_3O_4P$: N, 13.76%.

**The Preparation of Ethyl Dihydrogen Phosphate.**—A solution of ethyl phosphorodimorpholidite (2.48 g., 0.01 mol.) in 5 ml. of ethanol was added drop by drop to a solution of monobromocyanoacetamide (1.63 g., 0.01 mol.) in 10 ml. of ethanol cooled at −40—−30°C. After the reaction mixture had been kept standing overnight, the ethanol was removed under reduced pressure. Chloroform (20 ml.) was added to the residue, and the undissolved cyanoacetamide was removed by filtration. The filtrate was concentrated to a syrup, which was then dissolved in 30 ml. of water. The solution was passed slowly (1 hr.) through a column (18×150 mm.) of Amberlite IR-120 resin ($H^+$ form) at 60°C, and the column was washed with 100 ml. of water. After the water had been removed from the eluate under reduced pressure, the residue was dissolved in acetone and 1.4 ml. of cyclohexylamine was added to the solution, giving 0.88 g. (27%) of bis cyclohexylammonium ethyl phosphate. Recrystallization from *n*-propyl alcohol gave an analytical sample, m. p. 201—203°C (decomp.).

Found: N, 8.35. Calcd. for $C_{14}H_{33}N_2O_4P$: N, 8.63%.

**The Preparation of *p*-Nitrophenyl Dihydrogen Phosphate.**—The mixture which resulted from the reaction of *p*-nitrophenol (2.78 g., 0.02 mol.), ethyl phosphorodimorpholidite (4.96 g., 0.02 mol.) and monobromocyanoacetamide (3.26 g., 0.02 mol.) in 30 ml. of THF at −40°—−30°C was concentrated to give a solid residue. Chloroform (40 ml.) was then added, and the undissolved cyanoacetamide was removed by filtration. The removal of chloroform from the filtrate under reduced pressure gave a crystalline compound; this was then dissolved in acetonitrile (15 ml.) and water (30 ml.). The solution was passed through a column of Amberlite IR-120 resin ($H^+$ form), as in the above experiment, and the column was washed with a mixture of acetonitrile (50 ml.) and water (10 ml.). By a manner analogous to that mentioned above, bis(anilinium) *p*-nitrophenyl phosphate was obtained in a 49% (1.05 g.) yield. An analytical sample was obtained by recrystallization from acetone and water, m. p. 165—167°C.

Found: N, 10.41. Calcd. for $C_{18}H_{20}N_3O_6P$: N, 10.35%.

Similarly, anilinium phenyl hydrogen phosphate was obtained in a 47% yield, m. p. 180—182°C.

**The Preparation of Adenosine 5′-Phosphate.**—A solution of ethyl phosphorodimorpholidite (0.25 g., 0.001 mol.) in 0.4 ml. of dimethyl formamide (DMF) was added drop by drop to a suspension of 2′,3′-isopropylidene adenosine (0.15 g., 0.0005 mol.; dried over phosphorus(V) oxide at 115°C, 0.05 mmHg for 11 hr.) and monobromocyanoacetamide (0.16 g., 0.001 mol.; dried over phosphorus(V) oxide at room temperature, 20 mmHg for 11 hr.) in 1.8 ml. of DMF. The reaction started soon, with the liberation of heat. The reaction mixture was then kept standing for 3 days at room temperature. After the solvent had been removed under reduced pressure, 3 ml. of 1 N hydrochloric acid was added to the residue and it was heated at 40°C for 8.5 hr. in order to remove the protecting groups. After the pH had been adjusted to 7.5 with 1 N ammonium hydroxide, the water was removed under reduced pressure (50°C/4 mmHg). Ammonium hydroxide was added to the residue to pH 10, and then a saturated solution of barium chloride was added. After the mixture had been kept standing in a refrigerator, the precipitate was collected by centrifugation, washed with two portions of water

(5 ml.) and dried over phosphorus(V) oxide at room temperature to give 0.14 g. (54%) of the barium salt of adenosine 5′-phosphate. The product was found to be identical with an authentic adenosine 5′-phosphate by a comparison of $R_f$ values; 0.70 (5% $Na_2HPO_4$, isoamyl alcohol, 1 cm.: 0.5 cm.), and 0.33 (1% ammonium sulfate - isopropyl alcohol, 1 : 2 V/V). By paper electrophoresis, the product was also identified with an authentic sample (citrate buffer, pH 3.5, 4 hr. at 800 V.).

## Summary

The phosphorylation of alcohols or phenols by means of ethyl phosphorodimorpholidite and either monobromocyanoacetamide or monobromomalonamide has been studied. Further, adenosine 5′-phosphate has been prepared by the reaction of ethyl phosphorodimorpholidite and monobromocyanoacetamide with 2′,3′-isopropylidene adenosine.

# The Kinetics of the Acid-Catalyzed Formation of Peracetic Acid from Acetic Acid and Hydrogen Peroxide*

By Yasuhiko SAWAKI and Yoshiro OGATA

(Received April 30, 1965)

It has been established that the formation and hydrolysis of peracetic acid is acid-catalyzed,[1] and also that the equilibrium constant for reaction 1 increases with an increase in the concentration of catalytic acid.[2,3]

$$CH_3CO_2H + H_2O_2 \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} CH_3CO_3H + H_2O \quad (1)$$

In order to clarify these phenomena, the dependence of the rate and equilibrium constants on the concentration of mineral acid over a wider range has been studied, and the dependence has been correlated with Hammett's acidity function.

## Experimental

**Materials.**—Commercal aetic acid was refluxed with potassium permanganate and rectified over phosphorus pentoxide; b. p. 117—118°C. Hydrogen peroxide (30%) and sulfuric acid were both of guaranteed grade. *p*-Nitro- and *o*-nitroanilines were recrystallized from water containing a small amount of methanol.

**Kinetic Measurements.** — A definite amount of aqueous acetic acid of a known concentration containing an appropriate amount of surfuric acid was thermostated and the reaction was started by adding 30% hydrogen peroxide. (Water had been added previously in order to prevent the evolution of the heat of neutralization when 30% hydrogen peroxide was added.)

Aliquots were taken out at appropriate intervals of time and analyzed for hydrogen peroxide and peracid by means of an unique method. The aliquot was poured into ca. 50 ml. of ice-cooled ca. 0.4 N sulfuric acid containing three drops of 1% aqueous manganese sulfate. The hydrogen peroxide was quickly titrated with potassium permanganate until a pink color appeared, and then the remaining peracid was titrated iodometrically after the addition of potassium iodide. The peracid content was calculated from the ratio of the titres of permanganate and thiosulfate consumed, since the decomposition of hydrogen peroxide and peracid was found to be negligible under these reaction conditions. This novel method, which does without the weighing of aliquots, gave an adequate accuracy in a blank test.

**The Calculation of Rate Constants.**—Since the decomposition of hydrogen peroxide and peracid under these conditions was unappreciable, the rate constants may be calculated as follows. By representing the initial concentrations of acetic acid, hydrogen peroxide and water as $a$, $b$ and $c$, respectively, and the concentration of the peracid produced as $x$, the rate of the formation of peracetic acid may be expressed as:

$$v = k_1(a-x)(b-x) - k_{-1}(c+x)x$$

This equation is transformed to:

$$v = k_1(1-1/K_1)(\alpha-x)(\beta-x) \quad (2)$$

Here, $K_1 = k_1/k_{-1}$ and

$$\alpha, \beta = \frac{1}{2(1-1/K_1)}\left\{(a+b+c/K_1) \pm \sqrt{(a+b+c/K_1)^2 - 4ab(1-1/K_1)}\right\}$$

The rate constant $k_1$ thus calculated, has a good constancy, as is shown in Table I.

Table I. A typical rate constant for the formation of peracetic acid in 80 vol.% acetic acid at 25°C

Initial concn.: $a=[CH_3CO_2H]=13.77$ M; $b=[H_2O_2]=1.014$ M; $c=[H_2O]=9.831$ M; $[H_2SO_4]=0.30$ M.

| Time min. | $x=[CH_3CO_3H]$ M | $k_1\times10^6$ a) $M^{-1}\,sec^{-1}$ |
|---|---|---|
| 10 | 0.115 | 15.9 |
| 17 | 0.186 | 16.0 |
| 27 | 0.272 | 15.8 |
| 40 | 0.358 | 15.3 |
| 50 | 0.421 | 15.4 |
| 60 | 0.483 | 16.0 |
| 75 | 0.530 | 15.0 |
| 100 | 0.612 | 15.3 |
| 1800 | 0.800 | —b) |

a) $\alpha=26.04$; $\beta=0.777$
b) Calculated equilibrium constant ($K_1$) was 3.045.

**The Measurement of $H_0$.** — Hammett's acidity function of the reaction media (water was added in place of hydrogen peroxide) was measured using *o*- and *p*-nitroanilines as indicators. The absorption peaks were measured at 410 mμ for *o*-nitroaniline and at 370—380 mμ for *p*-nitroaniline; the shift of $\lambda_{max}$ was observed upon varying the ratio of acetic acid to water. The $H_0$'s were calculated from the equation; $H_0=pK_{BH^+}-\log(c_{BH^+}/c_B)$, where $pK_{BH^+}$ is an indicator constant and $c_{BH^+}$ is the concentration of the conjugate acid of the indicator and $c_B$ is that of the neutral form of the same indicator. The values of $pK_{BH^+}$ cited are −0.29 for *o*-nitroaniline and 0.99 for *p*-isomer.[4] These results are listed in Tables II and III.

## Results and Discussion

**The Rate Law.**—The acid-catalyzed formation of peracetic acid follows Rate Eq. 2, while a typical run is shown in Table I. The rate law coincides with the data reported previously in the literature.[3,5] The rate of peracid formation in the absence of mineral acid was too slow to measure.

**The Effect of the Acidity of the Media.**—The rates and equilibrium constants for the formation of peracetic acid are shown in Table II, where it is obvious that they increase with an increase in the concentration of sulfuric acid. These facts have been reported as the proportionalities of rate and equilibrium constants to the concentration (<0.5 M) of mineral acid.[2-4] However, this is not true at higher concentrations of mineral acid (>0.5 M), and the polts of $k_1$ or $K_1$ vs. $[H_2SO_4]$ lie not on a straight line but on a curve (Fig. 1).

This departure from linearity may be corrected for by plotting log $k_1$ or log $K_1$ against Hammett's acidity function; the plots then give a straight line with a solpe of 0.82 for log $k_1$ and 0.22 for log $K_1$ (Fig. 2).

former slope (0.82). It should be noted that different indicators are used for the determination of the acidity function, and that this may cause a small difference in the observed acidity function.

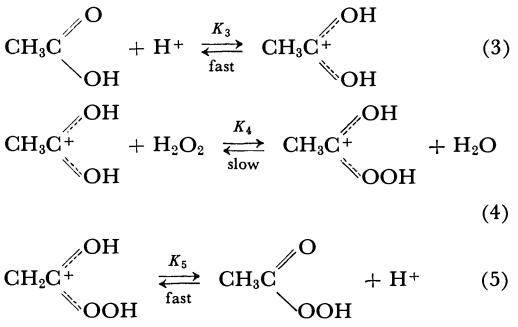
**Temperature Dependence.**—The effect of the temperature on the rate was studied in 60 and 80 vol.% acetic acid; the results, together with the calculated activation parameters, are summarized in Table IV. The change in the energy and entropy of activation is unappreciable in going from 60% to 80% acetic acid.

Table IV. Apparent energies and entropies of activation for the acid-catalyzed formation of peracetic acid



| Acetic acid vol.% | Temp. °C | $K_1$ | $k_1\times10^6$ M$^{-1}$ sec$^{-1}$ | $E_a$ kcal.·mol$^{-1}$ | $\Delta S^{\neq}$ e. u. |
|---|---|---|---|---|---|
| 80[a)] | 18.0 | 2.948 | 5.04 | 15.0 | −35.7 |
| | 25.0 | 2.907 | 9.54 | | |
| | 18.0 | 2.828 | 16.5 | | |
| 60[b)] | 18.0 | 2.589 | 1.84 | 15.1 | −33.2 |
| | 25.0 | 2.537 | 3.36 | | |
| | 32.0 | 2.453 | 6.10 | | |

a) Initial concn.: $[H_2SO_4]=0.20$ M; $[CH_3CO_2H]=12.36$ M; $[H_2O_2]=1.014$ M; $[H_2O]=9.831$ M.
b) Initial concn.: $[H_2SO_4]=0.20$ M; $[CH_3CO_2H]=8.611$ M; $[H_2O_2]=2.028$ M; $[H_2O]=19.66$ M.

The value for the entropy of activation (−33—−36 e.u.) implies a mechanism similar to that in the case of acid-catalyzed second-order esterification (−15——30 e.u.).[6)] The value for the energy activation (15.1 kcal. mol$^{-1}$) also suggests a second-order mechanism resembling the ester hydrolysis. Both the energy and the entropy of activation are close to the activation parameters in an oxygen-exchange reaction between water and benzoic acid (16 kcal. mol$^{-1}$ and −30 e.u. respectively).[7)]

**The Reaction Mechanism.**—The logarithm of the rate constant for peracid formation is proportional to $-H_0$. The energy and the entropy of activation are close to those in acid-catalyzed esterification. The substituent effect in acetic acid in dioxane was found to depend mostly on the steric factor, and to be little affected by the polar factor of the substituents.[8)] Tracer studies of the hydrolysis of peracid also reveal that the mechanism is analogous to the acyl-oxygen fission mechanism of ester hydrolysis.[9)] These facts suggest this probable mechanism for the peracid formation:

The position of the protonation of the carboxyl group has been found to be mainly at carbonyl oxygen,[10] as has been described above. The rate-determining step is Eq. 4; hence, the rate of peracid formation should be proportional to the product of the concentrations of acetic acid and hydrogen peroxide, the logarithm of the rate constant being proportional to $-H_0$; this is indeed the case. The reaction of acetic acid with hydrogen peroxide in the absence of catalytic mineral acid was too slow to measure; hence, the reaction path through unprotonated acetic acid may be considered to be negligible.

Although the details of the mechanism are still unknown on the basis of the above results alone, a mechanism similar to those in the acid-catalyzed esterification may be assumed. Our data, together with those in the literature,[7,11] show a similarity of mechanisms in the esterification, the oxygen-exchange, and the peracid formation. Hence, a nucleophilic attack of hydrogen peroxide on protonated carboxylic acid is a probable course for the reaction.

**The Effect of the Acidity on the Equilibrium Constants.** — The equilibrium constant increased with an increase in the concentration of sulfuric acid. The plots of log $K_1$ vs. $-H_0$ gave a straight line, with a slope of 0.22 (Fig. 2). This fact may well be explained by assuming the elimination of free water from the reaction system by the protonation, since water is the strongest base among the components in Eq. 1.

$$K_1=\frac{[CH_3CO_3H][H_2O]}{[CH_3CO_2H][H_2O_2]}$$

It is known that water is a thousandfold stronger as a base than hydrogen peroxide;[12] hence, the protonation occurs only to water. The stoichiometric concentration of water is the sum of the free and the protonated water, the latter having little ability to make a uncleophilic attack on carboxyl carbon. The net concentration of free water, an effective nucleophile, decreases with an increase in the acidity much more rapidly than hydrogen peroxide does. Hence, the appearent equilibrium constant should increase with an increase in the acidity of the medium.

The protonation of acetic acid has been reported,[13] but no data is available on the protonation of peracetic acid. However, the extent of the protonation of acetic and peracetic acids should be much smaller than that of water and hydrogen peroxide, both of which are stronger as bases. Therfore, the protonation of these acids may be neglected in examining the effect of the acidity on the equilibrium constant, $K_1$.

## Summary

The sulfuric acid-catalyzed reversible formation of peracetic acid from acetic acid and hydrogen peroxide in aqueous acetic acid has been studied kinetically. The rate of peracid formation is proportional to the product of the concentrations of acetic acid and of hydrogen peroxide, increasing with an increase in the concentration of sulfuric acid. The plot of the logarithm of the rate constant vs. $-H_0$ gives a straight line, with a slope of 0.82 and 1.10. The mechanism has been discussed in connection with the analogous acid-catalyzed esterification. The equilibrium constants for the present reaction also increase with an increase in the acidity, and the similar plot of log $K_1$ vs. $-H_0$ gives a straight line with a slope of 0.22. These facts are explicable by considering the protonation of water.

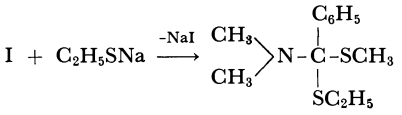
# Reactions of the Iodomethylate of *N, N*-Dimethylthiobenzamide with Nucleophilic Reagents

By Teruaki MUKAIYAMA, Tatsuaki YAMAGUCHI and Hiroyuki NOHIRA

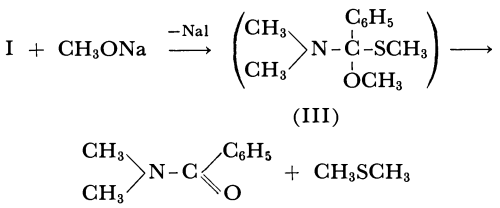
(Received April 30, 1965)

It has been reported that α-dialkylaminomethylene compounds can be prepared by the condensation of *N,N*-dialkylformamide acetals[1,2] with active hydrogen compounds, such as active methylene compounds. In the present study, the preparation of various α-dimethylaminobenzylidene compounds by reactions of the iodomethylate (I) of *N,N*-dimethylthiobenzamide with nucleophilic reagents will be examined.



Recently, Böttcher and Bauer have isolated the iodomethylate (I) of *N,N*-dimethylthiobenzamide by treating *N*-methylisothiobenzamide-*S*-methylether with methyl iodide.[3] The iodomethylate (I) is easily hydrolyzed with alkali to give *N,N*-dimethylbenzamide and methyl mercaptan.

(I)

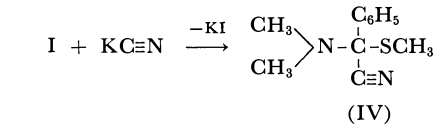


This result suggests that the iodomethylate (I) would yield condensation products when it is treated with nucleophilic reagents, such as sodium ethylmercaptide, potassium cyanide, amines, and the monosodium salts of active methylene compounds.

With this in mind the reaction of sodium ethylmercaptide with the iodomethylate (I) was attempted first. Sodium ethylmercaptide easily reacted with the iodomethylate (I) in dry ether at room temperature, and *N,N*-dimethylbenzamide methylethylmercaptol (II) was obtained in a fairly good yield.

(II)

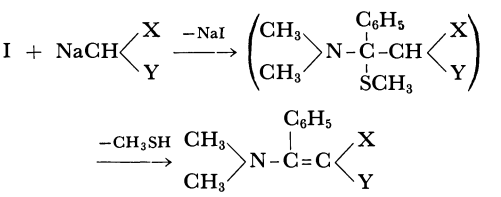
On the other hand, sodium methoxide could hardly react at all with the iodomethylate (I) at room temperature. When they were refluxed in dry benzene for 1 hr., however, *N,N*-dimethylbenzamide was obtained in a 41.5% yield, along with dimethyl sulfide, instead of the expected product, *N,N*-dimethylbenzamide monothioketal (III).



(III)

The results of the reactions of other sodium alkoxides with the iodomethylate (I) are listed in Table I.

Table I. Reactions of I with sodium alkoxides



| Sodium alkoxide | Reaction condition | | | Yield, % | |
|---|---|---|---|---|---|
| | Solvent | Temp. °C | Time hr. | Amide | Sulfide |
| Methoxide | Benzene | 80 | 1.0 | 41.5 | — |
| Ethoxide | Benzene | 80 | 1.0 | 46 | — |
| Cyclohexyloxide | Toluene | 110 | 2.0 | 33 | 16 |
| Benzyloxide | Dioxane | 100 | 3.0 | 79 | 65 |

In addition, when potassium cyanide and the iodomethylate (I) were refluxed in dry benzene for 1 hr., α-dimethylamino-α-methylthiobenzyl cyanide (IV) was obtained in a 64% yield, while potassium iodide was eliminated.

(IV)

Next, it was found that α-dimethylaminobenzylidene malonate was produced in a 56% yield, with the evolution of methyl mercaptan, when a suspension of the iodomethylate (I) and the monosodium salt of ethyl malonate in dry dioxane was stirred at 80°C for 2 hr. Similar results were obtained by treating the iodomethylate (I) with the monosodium salts of other active methylene compounds, such as ethyl acetoacetate, ethyl cyanoacetate, acetylacetone and nitromethane (see Table II).

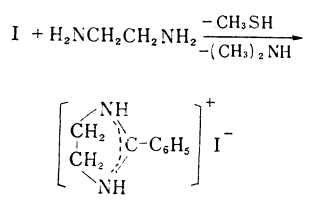
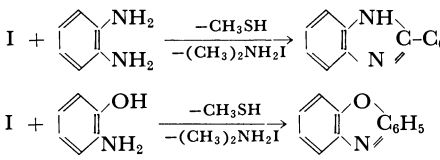
a) Recrystallized from benzene-ligroin. b) from ethyl acetate. c) from ethanol or benzene.

Further, the reactions of the iodomethylate (I) with primary amines were examined. When an ethanol solution of aniline was added to a suspension of the iodomethylate (I) in ethanol at room temperature, the evolution of methyl mercaptan was observed, and after stirring had been continued for 3 hr., *N*, *N*-dimethyl-*N'*-phenylbenzamidine hydroiodide was obtained in a 68% yield. Similarly, cyclohexylamine reacted with the iodomethylate (I) at room temperature to give *N*,*N*-dimethyl-*N'*-cyclohexylbenzamidine hydroiodide in a high yield.





On the other hand, when a mixture of 2 mol. of cyclohexylamine and 1 mol. of the iodomethylate (I) was refluxed in ethanol for 2 hr., *N*, *N'*-dicyclohexylbenzamidine hydroiodide was given in a 49% yield, along with methyl mercaptan and dimethylamine.

Further, when ethylenediamine and the iodomethylate (I) were refluxed in ethanol for 2 hr., 2-phenylimidazoline hydroiodide was produced in a high yield. Free 2-phenylimidazoline was obtained by treating the hydroiodide with alkali.

*o*-Phenylenediamine reacted with the iodomethylate (I) at room temperature in ethanol to give 2-phenylbenzimidazole in a good yield, with the elimination of methyl mercaptan and dimethylamine hydroiodide. In a similar way, 2-phenylbenzoxazole was prepared in a good yield by the reaction between *o*-aminophenol and the iodomethylate (I).

## Experimental[4]

**The Iodomethylate (I) of *N*, *N*-Dimethylthiobenzamide.**—This compound was prepared by the following method. A solution of 83 g. (0.5 mol.) of *N*, *N*-dimethylthiobenzamide and 100 g. (0.7 mol.) of methyl iodide in 400 ml. of acetone was refluxed on a water-bath for 1 hr. After the mixture had then been cooled, the iodomethylate (I) was separated and recrystallized from acetone. Yield, 140 g. (92%); m. p. 148—149°C.

4) All melting points and boiling points are uncorrected.

**The Reaction of I with Sodium Ethylmercaptide.**—A suspension of 28 g. (0.1 mol.) of I and 9.8 g. (0.11 mol.) of sodium ethylmercaptide in 150 ml. of dry ether was stirred at room temperature for 1 hr. The precipitate of sodium iodide was then removed by filtration and washed with dry ether. After ether had been evaporated from the filtrate, the residual liquid was distilled in vacuo to give 11.1 g. (52%) of *N*, *N*-dimethylbenzamide methylethylmercaptol (II). B. p. 94—97°C/0.08 mmHg.

Found: C, 59.93; H, 8.14; N, 6.08. Calcd. for $C_{11}H_{19}NS_2$: C, 59.73; H, 7.94; N, 5.81%.

**The Reaction of I with Sodium Methoxide.**—A suspension of 3.0 g. (0.01 mol.) of I and 0.6 g. (0.01 mol.) of sodium methoxide in 20 ml. of dry benzene was refluxed for 1 hr. Then the reaction mixture was filtered to remove the precipitate of sodium iodide. After the benzene had been removed from the filtrate, the residual liquid was distilled under reduced pressure to give 0.62 g. (41.5%) of *N*, *N*-dimethylbenzamide. B. p. 133°C/12 mmHg.

By similar procedures, *N*, *N*-dimethylbenzamide and sulfides were obtained by the reactions of I with sodium ethoxide, sodium cyclohexyloxide and sodium benzyloxide (see Table I).

**The Reaction of I with Potassium Cyanide.**—A suspension of 3.0 g. (0.01 mol.) of I and 0.65 g. (0.01 mol.) of potassium cyanide in 20 ml. of dry benzene was refluxed for 1 hr. After the solution had cooled, the precipitated potassium iodide was filtered off and the benzene was removed from the filtrate in vacuo. The distillation of the residue under reduced pressure gave 1.33 g. (64%) of $\alpha$-dimethylamino-$\alpha$-methylthiobenzyl cyanide (IV). B. p. 93—94°C/2 mm Hg.

Found: C, 63.82; H, 7.13; N, 13.55. Calcd. for $C_{11}H_{14}N_2S$: C, 64.06; H, 6.84; N, 13.58%.

The infrared spectrum showed an absorption at 2230 $cm^{-1}$(C≡N).

**The Reactions of I with the Monosodium Salts of Active Methylene Compounds.**—Into a solution of an excess amount of an active methylene compound in 20 ml. of dry dioxane, 0.23 g. (0.01 mol.) of sodium metal was added in portions. Then the mixture was heated to the boiling point, when all the sodium parts disappeared. To the resulting suspension of the monosodium salt of the active methylene compound in dioxane was then added 3.0 g. (0.01 mol.) of I and the mixture was stirred for 2 hr. at 80°C. The $\alpha$-dimethylaminobenzylidene derivatives (V) of the active methylene compounds obtained were purified by distillation or recrystallization. Their properties are listed in Table II.

**The Reaction of I with Aniline.**—A solution of 0.9 g. (0.01 mol.) of aniline in 20 ml. of ethanol was added to a suspension of 3.0 g. (0.01 mol.) of I in 20 ml. of ethanol. Soon the evolution of methyl mercaptan was observed and the suspended I was dissolved. After the solution had been stirred for 3 hr. at room temperature, the ethanol was removed in vacuo, giving *N*, *N*-dimethyl-*N'*-phenylbenzamidine hydroiodide as a white crystal; this was then recrystallized from ethanol-ether. Yield, 2.3 g. (68%). m. p. 122—124°C. Free *N*, *N*-dimethyl-*N'*-phenylbenzamidine (m. p. 72°C) was obtained by treating the hydroiodide with a 20% aqueous solution of potassium hydroxide.

**The Reaction of 1 mol. of I with 1 mol. of Cyclohexylamine.**—A suspension of 3.0 g. (0.01 mol.) of I and 1.0 g. (0.01 mol.) of cyclohexylamine in 20 ml. of ethanol was stirred at room temperature. The suspended I was soon dissolved completely, and the evolution of methyl mercaptan was observed. After stirring had been continued for 3 hr., the ethanol was evaporated and *N*, *N*-dimethyl-*N'*-cyclohexylbenzamidine hydroiodide was obtained as a white crystal. The hydroiodide was then recrystallized from ethanol-ether. Yield, 3.4 g. (91.5%); m. p. 189—190°C.

Found: C, 50.33; H, 6.17; N, 7.85. Calcd. for $C_{15}H_{23}N_2I$: C, 50.37; H, 6.41; N, 7.81%.

**The Reaction of 1 mol. of I with 2 mol. of Cyclohexylamine.**—A suspension of 3.0 g. (0.01 mol.) of I and 2.0 g. (0.02 mol.) of cyclohexylamine in 20 ml. of ethanol was refluxed for 3 hr. Then the ethanol was removed from the reaction mixture, and the resulting *N*, *N'*-dicyclohexylbenzamidine hydroiodide was recrystallized from ethanol-ether. Yield, 2.0 g. (49%); m. p. 173—174°C.

Found: C, 55.50; H, 7.04; N, 7.02. Calcd. for $C_{19}H_{29}N_2I$: C, 55.34; H, 7.08; N, 6.79%.

**The Preparation of 2-Phenylimidazoline from I and Ethylenediamine.** — Into a suspension of 3.0 g. (0.01 mol.) of I in 20 ml. of ethanol was added a solution of 0.6 g. (0.01 mol.) of ethylenediamine in 10 ml. of ethanol; the mixture was then refluxed on a water-bath. Soon the I was dissolved completely, and the evolution of methyl mercaptan was observed. After 2 hr., the solvent was removed and the resulting 2-phenylimidazoline hydroiodide monohydrate was recrystallized from acetonitrile-ether. Yield, 2.4 g. (89%); m. p. 105—107°C.

Found: C, 37.44; H, 4.50; N, 9.89. Calcd. for $C_9H_{13}N_2OI$: C, 37.00; H, 4.45; N, 9.59%.

Free 2-phenylimidazoline (m. p. 100—101°C) was obtained by treating the hydroiodide with a 10% aqueous solution of potassium hydroxide.

**The Preparations of 2-Phenylbenzimidazole and 2-Phenylbenzoxazole from I.**—A suspension of 3.0 g. (0.01 mol.) of I and 1.0 g. (0.01 mol.) of *o*-phenylenediamine in 20 ml. of ethanol was stirred at room temperature. The suspended I was thus dissolved completely, and methyl mercaptan was evolved. After stirring had been continued for 4 hr., about 50 ml. of water was added to the reaction mixture giving 1.45 g. (74.5%) of 2-phenylbenzimidazole. This was then recrystallized from acetonitrile. M. p. 285—286°C.

Similarly, when a suspension of 3.0 g. (0.01 mol.) of I and 1.1 g. (0.01 mol.) of freshly-refined *o*-aminophenol in 20 ml. of ethanol was stirred for 3 hr. at room temperature, 1.3 g. (67%) of 2-phenylbenzoxazole was obtained; it was then recrystallized from ethanol-ether. M. p. 101—102°C.

## Summary

The reactions of the iodomethylate (I) of *N*, *N*-dimethylthiobenzamide with nucleophilic reagents have been examined. The iodomethylate I reacted with sodium ethylmercaptide and potassium

cyanide to give *N*,*N*-dimethylbenzamide methylethylmercaptol and α-dimethylamino-α-methylthiobenzyl cyanide respectively. When primary amines and the monosodium salts of active methylene compounds were treated with the iodomethylate I, benzamidine hydroiodides and α-dimethylaminobenzylidene derivatives of the active methylene compounds were, respectively, obtained, and methyl mercaptan was eliminated. Further, it has been found that diamines, such as *o*-phenylenediamine, easily condensed with the iodomethylate I to yield such heterocyclic compounds as 2-phenylbenzimidazole, while methyl mercaptan and dimethylamine were eliminated.

# A Study of the Charge-Transfer Complexes. II. The Complexes of Pyromellitic Dianhydride with Polycyclic Aromatic Compounds*

By Taku MATSUO

(Received May 4, 1965)

Many interesting properties of the solid complexes formed between pyromellitic dianhydride and polymethylbenzenes were reported in the preceding paper of this series.[1] In fact, pyromellitic dianhydride is characterized by the special ease with which it forms solid complexes with many aromatic compounds. Relatively few papers have, however, been published on the spectroscopic study of such charge-transfer complexes in the solid state.[2] In studying the complexes in solution, it has been quite common to consider the variation in the absorption maximum of the charge-transfer band as changing the donor molecule for a given acceptor. The results of such experiments are generally used to estimate the electron affinity of the acceptor molecule.[3] Dewar and Lepley showed that essentially the same technique can be fruitfully applied to the case of solid complexes.[4] The same type of experimental results will be presented here on charge-transfer complexes with pyromellitic dianhydride employed as the common acceptor. Polycyclic aromatic compounds were used as donors in order to cover a wide range of ionization potential for the donor molecule. Some other aromatic compounds were also used in the experiment in order to observe the donor dependence of the charge-transfer band in more detail. It may be adequate to mention here that the KBr disk method or something similar has been the most popular technique for measuring the absorption spectra of solid complexes.[2,4,5] In the present experiment, use was made of the diffuse reflectance method, which had been proven to be quite successful in studying solid molecular complexes.[6]

## Experimental

**Materials.**—Naphthalene and anthracene were purchased from the Wako Pure Chemical Industry Co., while chrysene, pyrene and phenanthrene were provided by the Tokyo Kasei Organic Chemicals Co. All of these compounds were purified by repeated recrystallization from various solvents, such as ethanol, acetic acid and toluene. The m. p.'s and ultraviolet spectra agreed well with those reported in the literature. *trans*-Stilbene was synthesized from benzaldehyde through benzoin.[7] $\alpha$-Methylnaphthalene was made by catalytic dehydrogenation following the dehydration of 1-methyltetralol.[8] Anisole was purchased from the Wako Pure Chemical Co. *para*-Methylanisole and *p*-dimethoxybenzene were synthesized by the usual method from the corresponding sodium phenolate and dimethylsulfate. All the liquid samples were found pure by gas chromatography and were identified by means of the infrared and NMR spectra. Reagent-grade ethylacetate was washed with a saturated aqueous sodium carbonate solution and then dried over calcium chloride. Further purification was made by repeated fractional distillation in the presence of phosphorus pentoxide. Pyromellitic dianhydride was obtained by dehydrating pyromellitic acid, as supplied by the Tokyo Kasei Organic Chemicals Co., in boiling acetic anhydride; it was then recrystallized from purified ethylacetate before use (m. p. 299.8—300.0°C).[1]

**Spectroscopic Measurements.**—Solutions of the complexes were prepared by dissolving pyromellitic

dianhydride ($10^{-2}$ mol./l.) and the donor compounds into ethylacetate. The donor concentration varied from $10^{-2}$ to $10^{-1}$ mol./l., depending on the stability and on the solubility of the complex. The spectra were measured in 1 cm. cells in the visible range on a Hitachi model EPS-2U recording spectrophotometer. Solid molecular complexes were prepared by the method described in the previous paper.[1] The complex was dispersed in talcum powder, and it relative diffuse reflectance was measured with a Hitachi model EPU-2A photoelectric spectrophotometer equipped with an integrating sphere.[1]

## Results and Discussion

Examples of the appearance of the charge-transfer absorption band of the complex in an ethyl acetate solution are shown in Fig. 1 for the cases of $\alpha$-methylnaphthalene and anthracene. The spectra were measured using ethyl acetate as the reference; the absorptions due to the components are not substracted from the data. The absorption of pyromellitic dianhydride (abbreviated as PMDA hereafter) itself, however, is small enough to be neglected in the visible region.[1] The bands indicated by the arrows in Fig. 1 may, then, be easily identified as the charge-transfer absorption, as they are clearly separated from the bands mainly due to the donor absorption on the higher frequency side. There are cases, however, where the charge-transfer band appears as just a weak shoulder superimposed on the tail of a strong absorption on the higher frequency side. Such overlapping bands were resolved graphically, as is illustrated in Fig. 2 for the case of a PMDA-stilbene complex. The absorption maxima obtained by these methods for various donors are summarized in Table I, together with the errors involved in the resolution.

By definition, the Kubelka-Munk remission function, $f(R)$, is the ratio of the absorption to the scattering coefficients, $k/S$, of the powdered sample;

it is expressed in terms of the measured diffuse reflectance, $R$, by the following equation:[9]

$$f(R)=\frac{k}{S}=\frac{(R-1)^2}{2S} \quad (1)$$

Assuming that the scattering coefficient, $S$, is independent of the wavelength, $f(R)$ is taken to reproduce the absorption band in the region under investigation. This treatment is not entirely valid from the theoretical point of view. Experimental observation has, however, shown that the remission function is good enough to estimate the absorption maxima of molecular complexes in the solid state.[1,6] In addition, no violent treatment is applied to the molecular complexes in preparing the sample for diffuse reflectance measurement, in contrast to the KBr disk method. The remission functions of PMDA complexes with anthracene and naphthalene are shown in Fig. 3. The absorption maxima thus obtained for the solid complexes are given in the fourth column of Table I. The frequency of the charge-transfer absorption band is correlated with the electron affinity of an acceptor, $E_A$, and the ionization potential of the donor, $I_P$, by the following well-known equation:

$$h\nu_{CT}=I_p-E_A+\Delta \quad (2)$$

where $\Delta$ stands for a correction mainly due to the Coulombic interaction in the complex. The ionization potentials of polycyclic aromatic compounds are known to be linearly dependent on the energy level of the highest-occupied MO's, as calculated by the Hückel MO method.[10] Thus the following equation may be expected to hold:

$$h\nu_{CT}=am-E_A+\Delta \quad (3)$$

where the energy of the highest occupied MO is expressed as:

$$E=\alpha+m\beta \quad (4)$$

If the correction factor, $\Delta$, is assumed to be the same for a series of complexes with a common acceptor, Eq. 3 may be rewritten as:

$$h\nu_{CT}=am+b \quad (5)$$

The relationship expressed by Eq. 5 has been verified to hold in various series of complexes.[4,11] An attempt will be made here to treat the data of PMDA complexes given in Table I by the same method. The energies of the highest-occupied MO's in $\beta$ units are given in the second column of Table I. The values for ordinary polycyclic aromatic compounds are those calculated with the Hückel MO. The values for the substituted compounds were estimated by using the relationship $\tilde{\nu}_{CT}$ and $m$ for the chloranil complexes of polycyclic aromatic hydrocarbons reported by Kuboyama.[11g] The method of estimation is illustrated in Fig. 4.

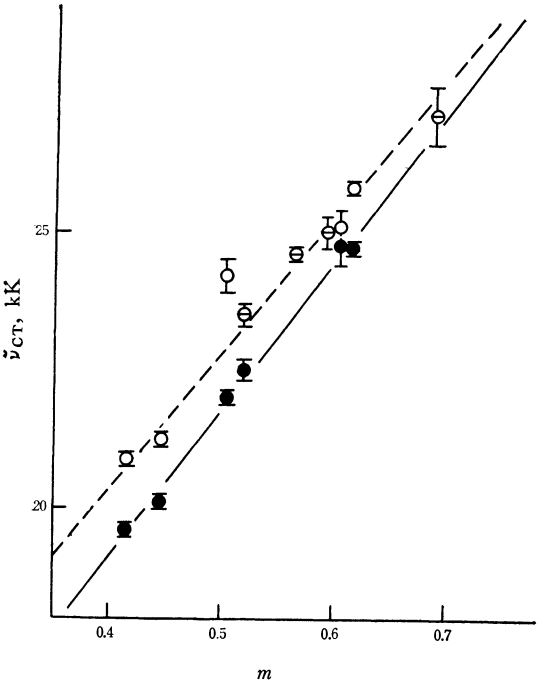

Fig. 5. Correlation of $\tilde{\nu}_{CT}$ and $m$ in the cases of the PMDA complexes with aromatic compounds.
● Solid complex,
○ Complex in solution ($m$ as calculated by Hückel MO)
⊖ Complex in solution ($m$ as estimated from Fig. 4)

The data in Table I are used in Fig. 5 to illustrate the close correlation between $\tilde{\nu}_{CT}$ and $m$ for the PMDA complexes of aromatic compounds, both solution and in the solid state. The charge-transfer band shows a bathochromic shift going from the solution to the solid state. The extent of the shift varies depending on the particular donor in question. The overall linear relationships observed between $\tilde{\nu}_{CT}$ and $m$ in both phases, however, are almost parallel each other.

The PMDA complex of *trans*-stilbene presents an anomalous example. In contrast to the fact that the experimental point for the solid complex rests exactly on the line, the corresponding $\tilde{\nu}_{CT}$ in the solution is located at much higher frequency than might be expected from the $m$ value. A similar situation is also met in the chloranil complex of stilbene, as is shown in Fig. 4. A part of the reason for this anomalous behavior may be that the $m$ value is calculated by means of the Hückel MO. The calculation is made by assuming that all the $\alpha$'s and $\beta$'s are the same in the conjugate system. It is obvious from the structure that the assumption would hold to a lesser extent in the case of *trans*-stilbene than in the cases of ordinary polycyclic aromatic hydrocarbons. In addition, the suggestion may be made that *trans*-stilbene can be slightly twisted around its essential single bond in a solution. As a result, the conjugation in the molecule is reduced and the energy level of the highest-occupied MO is lower than expected. In the solid state, a coplanar structure would be restored for *trans*-stilbene to enable it to form a strong molecular complex with PMDA. Other donor molecules attached to a conjugate group through an essential single bond seem to show behavior more or less similar to that of *trans*-stibene.

The linear relationships between $\tilde{\nu}_{CT}$ and $m$ observed above (excluding the point for the *trans*-stilbene complex in a solution) are expressed by the following equations:

in a solution,

$$\tilde{\nu}_{CT}=24.6\,m+10.5 \quad \text{(in kK)}, \tag{6}$$

and in the solid state,

$$\tilde{\nu}_{CT}=26.5\,m+\ 8.5 \quad \text{(in kK)}. \tag{7}$$

By comparing Eqs. 6 and 7 with Eq. 5 and by also remembering that

$$b=-E_A\ +\ \Delta, \tag{8}$$

one may estimate that the electron affinity of PMDA in ethyl acetate is lower than that in the solid state by 0.25 eV. The value can not be taken too seriously because an assumption is made here that the correction factor, $\Delta$, is the same for both phases. It should be remembered at this point that all of the molecules and the complexes under consideration are solvated at both their

ground and excited states. Due to this solvation effect, the equilibrium and the Franck-Condon states concerning the charge-transfer absorption will not be the same in various media. Consequently, it is quite unlikely that the correction factor, $\Delta$, is the same for an ethyl acetate solution and solid state. The parallel relation observed between Eqs. 6 and 7 indicates, however, that the difference in $\Delta$ value between the complexes in the two phases is almost constant in this series and nearly independent of the donor property. Thus, it appears that the electron affinity of PMDA in the solid state is higher than that in ethyl acetate by the before-mentioned amounts. As is clear from the above discussion, 0.25 eV. is the upper limit of the value of the change in the electron affinity of PMDA since the solvent effects on the donor and complex are also included in that number. No attempt will be made here to estimate the latter effects because too many unknown factors are involved for a successful reasoning to be carried out. A similar zero-order treatment suggests that PMDA in ethyl acetate behaves as an electron acceptor weaker by 0.53 eV. than chloranil in carbon tetrachloride.[11c] The difference in the electron affinity of these compounds has previously been given by Briegleb as 0.52 eV.[3] The agreement between these two results is surprisingly close in spite of the possible difference in the media.

**Summary**

The frequency of the charge-transfer absorption of the PMDA complex has been found to be linearly dependent on the energy level of the highest-occupied MO of the aromatic donor as estimated by the Hückel MO method. The behavior of the complex in the solid state is almost parallel to that in a solution. On the basis of these linear relationships, it has been suggested that PMDA in ethyl acetate behaves as if it is an electron acceptor weaker than that in a solid complex and chloranil in carbon tetrachloride by about 0.2 eV. and 0.53 eV. respectively in the zero order approximation.

Another suggestion has been made that *trans*-stilbene may be slightly twisted around its essential single bond in a solution but not in the solid complex.

The author wishes to express his gratitude to Mrs. Katsumi Aoyagi for measuring the spectra. He is also grateful to Miss Mizue Moritomo for both operating the spectrometer and for helping in the preparation of the manuscript.

# The Reaction of Ions in the Radiolysis of *n*-Butane in the Gas Phase

By Tetsuo MIYAZAKI and Shoji SHIDA

(Received May 7, 1965)

The reaction of ions produced in the radiolysis of *n*-butane has been reported in previous papers by the present authors. In the first paper[1] it was shown, from a comparison of the results of radiolysis, photolysis and mass spectrum study, that the fragmentation of the excited butane ion is quite different from that of the excited butane molecule. In the second paper[2] the deactivation of the excited butane ion was discussed from the point of view of the effect of density in the radiolysis. The present work will concern the role of several ions in the radiolysis of *n*-butane in the gas phase. Since excited molecules and radicals are produced by irradiation in addition to ionic species, the role of ions in radiation chemistry is sometimes obscure. Futrell[3] explained the distribution of products in the radiolysis of *n*-hexane by using the mass-spectrometric cracking pattern, working on the assumption that the fragment ions form the products by hydride-ion transfer reactions with *n*-hexane. Ausloos et al.[4] studied the radiolysis of a $n$-$C_4H_{10}$ - $n$-$C_4D_{10}$ - $I_2$ mixture and found that $C_3H_7D$ and $C_3D_8$ were produced in comparable amounts. They concluded that 95% of propane is formed by hydride ion transfer reaction, and they assumed that hot radicals were not produced in the radiolysis.

In the present study ammonia was used as a proton transfer reagent, since ammonia has a high proton affinity (202 kcal./mol.)[5] and since products from ammonia by irradiation can be discriminated

from those from *n*-butane. Ammonia is expected to react with ions to give alkene by the following proton transfer reaction:

$$C_nH_{2n+1}^+ + NH_3 \rightarrow C_nH_{2n} + NH_4^+$$

In the absence of ammonia, an alkyl ion forms alkane by hydride-ion transfer reaction with *n*-butane:

$$C_nH_{2n+1}^+ + n\text{-}C_4H_{10} \rightarrow C_nH_{2n+2} + C_4H_9^+$$

## Experimental

The *n*-Butane was the same as that used before.[1] The $C_5H_{10}$-1 was 99.99% pure. The water and ammonia were also of high purity. The samples were irradiated with $\gamma$-rays from Co-60 of 16000 c. at a total dose of $2.5\times10^{21}$ eV. $g^{-1}$. Most of the analytical procedures were identical with those described before.[1,2] The $C_2$—$C_4$ hydrocarbon products were analyzed by gas chromatography (benzyl ether column, 20 m.).

## Results and Discussion

The effect of ammonia in the radiolysis of *n*-butane in the gas phase is shown in Table I. The yields given in the table are expressed in moles per 1000 mol. of *n*-butane. This value is proportional to the *G*-value, and for Run 2-1 the yields are given also in *G*-value units. Since iodine has the unfavorable property[6] of reacting with unsaturated products, $C_5H_{10}$-1 was used as a radical scavenger in spite of its low reactivity to radicals. The yield of $C_4H_8$-1 was determined in Run 2-1 and Run 4-1 by separating *n*-butane before the analysis, since the peak of $C_4H_8$-1 in the gas chromatography was not separated from a large peak of *n*-butane. The electron fraction of ammonia in Table I indicates that the direct absorption of radiation energy by ammonia is small compared with that of *n*-butane.

The effect of ammonia is clearly shown in Fig. 1. Each product is affected in quite different ways. The effects may be classified into three types: A) $C_2$-products and $C_3H_8$ decrease upon

b) Mol. per 1000 mol. of $n$-$C_4H_{10}$.
c) $C_2$ represents the sum of $C_2H_6+C_2H_4$.

6) T. Kudo and S. Shida, Symposium on Radiation Chemistry, Nagoya (1964).

the addition of ammonia: the latter decreases more markedly.

B) $C_3H_6$ and $C_4H_8$ increase upon the addition of ammonia. The latter increases sharply upon the addition of a small amount of ammonia, and then gradually decreases in the high concentrations.

C) $H_2$ and $CH_4$ are not significantly affected by ammonia. Although methane and propane are formed by the rupture of the first C–C bond, only propane is affected by ammonia. This shows that the methyl radical produced by the fragmentation of the butane ion does not react with ammonia, while $C_3H_7^+$ does react with it.

**The Reaction of $C_3H_7^+$.**—The rate of the non-radical formation of $C_3H_8$ decreases sharply upon the addition of ammonia (Fig. 1). One the contrary, the yield of $C_3H_6$ increases complementally. This may be due to the high proton affinity of ammonia, which has been described above. Similar phenomena were observed in the radiolysis of mixtures of isobutane and some organic compounds, such as nitromethane, acetone or methyl iodide.[7]

$$n\text{-}C_4H_{10} \xrightarrow{I'(C_3H_7^+)_0} C_3H_7^+ + CH_3 + e \qquad (1)$$

$$C_3H_7^+ + n\text{-}C_4H_{10} \xrightarrow{k_2} C_3H_8 + C_4H_9^+ \qquad (2)$$

$$C_3H_7^+ + NH_3 \begin{cases} \xrightarrow{k_3} C_3H_6 + NH_4^+ & (3) \\ \xrightarrow{k_4} C_3H_7NH_3^+ & (4) \end{cases}$$

N. B. $I'(C_3H_7^+)_0$: Rate of reaction 1, expressed in moles per 1000 mol. of *n*-butane.

$k$: Rate constant

$C_3H_7^+$ produced by irradiation forms propane via the hydride-ion transfer reaction with *n*-butane, but in the presence of ammonia it forms propylene via the proton transfer reaction. Since the increment of propylene is smaller than the decrement of propane, the condensation reaction 4 with ammonia may also occur. Though this type of ion-molecule reaction is seldom observed with a low pressure mass spectrometer, it is possible in the present use because of the deactivation of the condensed ion at 250 mmHg. The steady-state treatment leads to Eq. 1 for the decrease in propane and to Eq. 2 for the increase in propylene:

$$\frac{[NH_3]}{-\Delta G'(C_3H_8)} = \frac{k_2[C_4H_{10}]}{(k_3+k_4)I'(C_3H_7^+)_0} + \frac{1}{I'(C_3H_7^+)_0}[NH_3] \qquad \text{(Eq. 1)}$$

$$\frac{[NH_3]}{\Delta G'(C_3H_6)} = \frac{k_2[C_4H_{10}]}{k_3 I'(C_3H_7^+)_0} + \frac{(k_3+k_4)}{k_3 I'(C_3H_7^+)_0}[NH_3] \qquad \text{(Ep. 2)}$$

N. B. $G'$ is expressed in moles per 1000 mol. of *n*-butane: it is proportional to *G*-value. $\Delta G'$ represents the increment in the product.

Thus, there must be a linear relationship between $[NH_3]/-\Delta G'(C_3H_8)$ and $[NH_3]$, and between $[NH_3]/\Delta G'(C_3H_6)$ and $[NH_3]$. As may be seen in Fig. 2 and Fig. 3, satisfactory straight lines are obtained. From the slopes and the intercepts

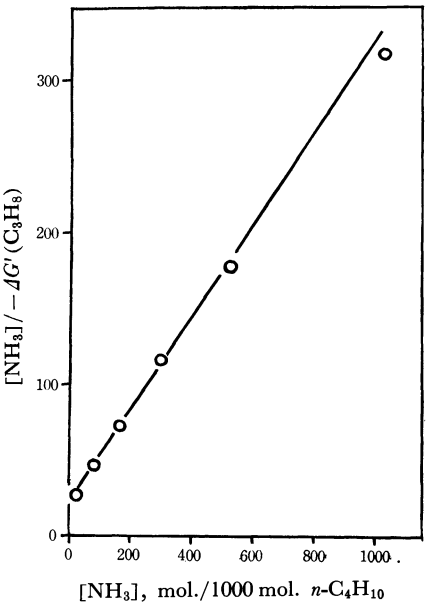

Fig. 2. Relation between $[NH_3]/-\Delta G'(C_3H_8)$ and $[NH_3]$.

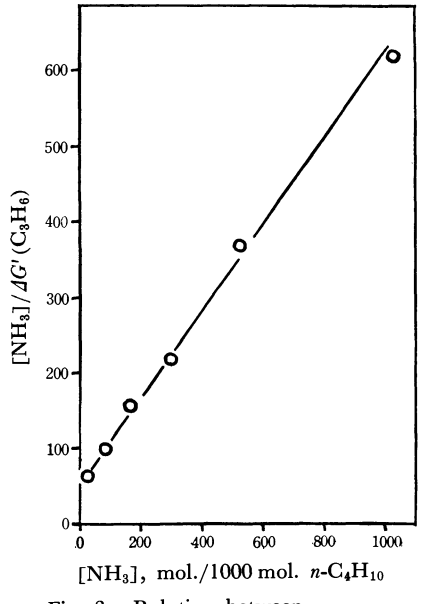

Fig. 3. Relation between $[NH_3]/\Delta G'(C_3H_6)$ and $[NH_3]$.

7) R. P. Borkowski and P. J. Ausloos, *J. Chem. Phys.*, **40**, 1128 (1964).

of Fig. 2 and Fig. 3, the following relationships are obtained:

$$\frac{1}{I'(C_3H_7^+)_0}=0.306$$

1000 mol. of $n$-$C_4H_{10}$/mol. (Eq. 3)

$$\frac{k_2[C_4H_{10}]}{I'(C_3H_7^+)_0(k_3+k_4)}=20 \quad \text{(Eq. 4)}$$

$$\frac{(k_3+k_4)}{k_3I'(C_3H_7^+)_0}=0.574$$

1000 mol. of $n$-$C_4H_{10}$/mol. (Eq. 5)

$$\frac{k_2[C_4H_{10}]}{k_3I'(C_3H_7^+)_0}=52 \quad \text{(Eq. 6)}$$

From the above four equations, we get $k_3=6.0k_2$ and $k_4=7.1k_2$ as the average values.

**The Reaction of $C_4H_9^+$.**—As is shown in Fig. 1, $C_4H_8$ increases sharply upon the addition of a small amount of ammonia, and then it decreases gradually upon any further addition. This increase may be due to the proton transfer reaction between $C_4H_9^+$ and $NH_3$. Since the following fragmentation is not known to occur from the mass spectrum of $n$-butane:

$$C_4H_{10}^{+*} \rightarrow C_4H_9^+ + H \quad (5)$$

the $C_4H_9^+$ in the radiolysis may be formed by the following secondary reactions:

$$C_4H_{10} \xrightarrow{I(Fr^+)_0} Fr^+ + N + e \quad (1)$$

$$Fr^+ + C_4H_{10} \xrightarrow{k_6} FrH + C_4H_9^+ \quad (6)$$

$$C_4H_9^+ \rightarrow P \quad (7)$$

$$C_4H_9^+ + NH_3 \begin{cases} \xrightarrow{k_8} C_4H_8 + NH_4 & (8) \\ \xrightarrow{k_9} C_4H_9NH_3^+ & (9) \end{cases}$$

$$Fr^+ + NH_3 \rightarrow \text{Products} \quad (10)$$

N. B. $Fr^+$: Fragment ions from the excited butane ion, such as $C_2H_5^+$ and $C_3H_7^+$.
N: Neutral fragments from the excited butane ion
P: A product
Reaction 10 represents the reaction of fragment ions and ammonia; cf., for example, reactions 3 and 4.

While the yield of $C_4H_8$ is increased by reaction 8 in a low concentration of ammonia, in a high concentration the reactions of ammonia with fragment ions cause a decrease in $C_4H_9^+$ (cf. reactions 10 and 6), that is, a depression of reaction 8.

We are able to estimate the life time of $C_4H_9^+$. As seen in Fig. 1, the concentration of ammonia where the rate of reaction 7 is about the same magnitude as that of reaction 8 is 5—10 mol./1000 mol. $n$-$C_4H_{10}$. Assuming that

$R(7)\simeq R(8)$ at $[NH_3]=7.5$ mol./1000 mol. $n$-$C_4H_{10}$
$=7.5$ mol./$7.42\times10^4$ l.

the life time of $C_4H_9^+$ is given as follows;

$$t(C_4H_9^+)=\frac{1}{k_8[NH_3]} \quad \text{(Eq. 7)}$$

If $k_8$ is assumed to be equal to $k_3$ and if $k_2$ is taken as $1.3\times10^{-9}$ cc. molec$^{-1}$ sec$^{-1}$,[8] we get $t(C_4H_9^+)=2.1\times10^{-9}$ sec., a value which is much shorter than the time of neutralization ($10^{-2}$—$10^{-3}$ sec.) in the gas-phase radiolysis.[9] Therefore, it seems that $C_4H_9^+$ reacts with $n$-butane or with the unsaturated products, including $C_5H_{10}$-1, before the neutralization.

**The Yields of $C_4H_{10}^{+*}$.**—One of the most important problems in the radiolysis is how to estimate the relative importance of the excited ion and the molecule. Their importance in the C–C rupture of $n$-butane will, therefore, now be considered in spite of some uncertainty.

We get, from Eq. 3, Eq. 4, Eq. 5 and Eq. 6: $I'(C_3H_7^+)_0=3.52$ mol./1000 mol. $n$-$C_4H_{10}$, which is the initial yield of $C_3H_7^+$. Since $-\Delta G'(C_3H_8)=3.24$ at the concentration of 1030 mol./1000 mol. $n$-$C_4H_{10}$ of ammonia, more than 90% of the ions react with ammonia at this concentration. Now we may assume that all of the fragment ions are eliminated by the proton transfer and condensation reactions with ammonia at 1030 mol./1000 mol. $n$-$C_4H_{10}$, and that the rate constants of the two reactions are the same. Since the total decreases in the $C_2$ and $C_3$ products upon the addition of ammonia are due to the condensation reaction, the yields of ions which react with ammonia should be twice the decrement:

$$-\Delta G'(C_3)=1.58 \text{ at } 1030 \text{ mol. } NH_3/1000 \text{ mol. } n\text{-}C_4H_{10}$$

$$-\Delta G'(C_2)=1.56 \text{ at } 1030 \text{ mol. } NH_3/1000 \text{ mol. } n\text{-}C_4H_{10}$$

Thus, $G'(C_4H_{10}^{+*})_{C_3}=3.2$ and $G'(C_4H_{10}^{+*})_{C_2}=3.1$ respectively. Therefore, $G'(C_4H_{10}^{+*})=6.3$ or $G(C_4H_{10}^{+*})=2.6$, as expressed in usual $G$-value units.

Most of the fragment ions form $C_4H_9^+$ via the hydride-ion transfer reaction with $n$-butane (cf. reaction 6); therefore, the yields of $C_4H_9^+$ may be considered to be approximately equal to that of $C_4H_{10}^{+*}$. The increment in $C_4H_8$ in Fig. 1 represents that of reaction 8. Assuming that $k_8/k_9\simeq k_3/k_4\simeq1$ as before, the yields of $C_4H_9^+$ are twice the increment of $C_4H_8$ (cf. reactions 8 and 9):

$$G(C_4H_9^+)=2\Delta G(C_4H_8)_{at\ [NH_3]=81.5}/0.6 \quad \text{(Eq. 8)}$$

The denominator is the correction factor as calculated from the decrease in $C_3H_8$ at 81.5 mol. $NH_3$/

8) F. H. Field and F. W. Lampe, *J. Am. Chem. Soc.*, **80**, 5587 (1958).
9) D. P. Stevenson, *J. Phys. Chem.*, **61**, 1453 (1957).

1000 mol. $n$-$C_4H_{10}$, since some of the fragment ions are lost by the reaction with ammonia at this concentration. Therefore, we get $G(C_4H_9^+)=2.4$. The agreement with $G(C_4H_{10}^{+*})$, as estimated from the decrement of products, is satisfactory.

Since the total $G$-value of the products from the C–C rupture, that is, $G(\sum C_1—C_3, C_5—C_7)$, is 6.5 (as determined by a previous study by the present authors[1]), the contribution of the excited molecule to the C–C rupture can be estimated by using $G(C_4H_{10}^{+*})$. As may be seen in Table II, the ionic C–C rupture is important in the radiolysis of gaseous $n$-butane. This result supports the conclusion of previous studies.[1,4]

TABLE II. THE CONTRIBUTION OF EXCITED ION AND MOLECULE IN THE C–C RUPTURE REACTION

| | A | B | C |
|---|---|---|---|
| $G(C_4H_{10}^{+*})$ | 2.6 | 2.4 | 2.6 |
| $G(C_4H_{10}^{*})$ | 0.7 | 0.9 | 0.8 |

A: Estimated from the reaction between fragment ions and $NH_3$.
B: Estimated from the reaction between $C_4H_9^+$ and $NH_3$.
C: Estimated from the analysis of products in the radiolysis of $n$-$C_4H_{10}$ - $n$-$C_4D_{10}$ - $I_2$ mixture.[4]

**$C_4H_{10}^+$ at High Pressure.**—Williams[10] used $ND_3$ as a proton scavenger in studying the ionic processes in the radiolysis of liquid cyclohexane. Since the saturation solubility of $ND_3$ in liquid cyclohexane is limited to a small percentage, however, he could not succeed in discussing the mechanism in detail. The present authors reported in a previous paper[2] that the radiolysis of $n$-butane near the critical state is similar to that in the liquid phase. Since we can get homogeneous mixtures of $n$-butane and the additive (water or ammonia) at any arbitrary concentration near the critical state, the effect of water or ammonia in high concentrations (up to 20%) has been studied near the critical state. The results in Table III show that all products by the C–C rupture decreases upon the addition of water or ammonia. Methane decreases to 70% upon the addition of 200 mol./1000 mol. $n$-$C_4H_{10}$ of ammonia though it does not decrease upon the addition of even 500 mol./1000 mol. $n$-$C_4H_{10}$ in the radiolysis at a low pressure (cf. Fig. 1). This fact suggests that the C–C rupture near the critical state may occur from the $C_4H_{10}^+$ produced by the deactivation of the excited butane ion:

$$C_4H_{10}^{+*} + C_4H_{10} \longrightarrow C_4H_{10}^+ + C_4H_{10} \quad (11)$$

$$C_4H_{10}^+ \xrightarrow[\text{or neutralization}]{\text{Thermal cracking}} CH_4, C_2H_6, \text{etc.} \quad (12)$$

$$C_4H_{10}^+ + NH_3 \longrightarrow Q \quad (13)$$

A more detailed study will be needed in order to discuss the mechanism of the effect of water or ammonia at high pressures.

TABLE III. EFFECT OF AMMONIA (OR WATER) IN THE RADIOLYSIS OF $n$-BUTANE AT HIGH PRESSURE

Yields of Products[a] at the density of 0.12 g. $cc^{-1}$ of $n$-butane

b) Mol. per 1000 mol. of $n$-$C_4H_{10}$.

## Summary

The effect of ammonia in the radiolysis of $n$-butane has been investigated. In low pressure radiolysis, $C_3H_8$ and $C_2$-products decrease upon the addition of ammonia while $C_3H_6$ increases. $C_4H_8$ increases sharply upon the addition of a small amount of ammonia, but it gradually decreases upon further addition. $CH_4$ and $H_2$ are not significantly affected by ammonia. These results have been interpreted in terms of the proton transfer reaction of ammonia with ions, and their rate constants have been estimated. The contribution of the excited ion to the C–C rupture has been concluded to be much more important than that of the excited molecule in low-pressure radiolysis.

In high-pressure radiolysis all the products from the C–C rupture, including $CH_4$, decrease upon the addition of ammonia (or water).

We appreciate the help of the Japan Atomic Energy Institute in performing the irradiation.

# The Hydroxide-Blacks of Ruthenium and Rhodium as Catalysts for the Hydrogenation of Organic Compounds. I. Their Catalytic Activity and Selectivity in the Hydrogenation of Some Aromatic Compounds*[1]

By Yuzuru TAKAGI, Takatoshi NAITO and Shigeo NISHIMURA*[2]

(Received May 7, 1965)

Recently it has been shown in many studies that ruthenium and rhodium catalysts or those containing these metals are outstanding in catalytic activity and selectivity in the hydrogenation of various organic compounds. High activities and/or high selectivities have been reported, for instance, in the hydrogenation of aromatic and heterocyclic compounds,[1] olefins,[2] carbonyl compounds,[1c,1e,3] nitriles,[4] and carboxylic acids to alcohols,[5] in the selective production of alicyclic primary amines,[6] in the selective hydrogenation of the compounds susceptible to hydrogenolysis,[1e,4,7] and in the selective cis-hydrogenation of substituted aromatic compounds.[8] There are also many other examples in which these catalysts have been shown to be useful.

The hydrogenations mentioned above are mostly concerned with the use of either the catalysts from the oxides of ruthenium and rhodium, those prepared by the reduction of the chlorides of ruthenium and rhodium with sodium borohydride, or the ruthenium and rhodium catalysts supported on various carriers. It appears that no study has yet been concerned with the use of the hydroxide-black catalysts of ruthenium and rhodium. The hydroxide of ruthenium or rhodium is easily prepared as, respectively, a black or a yellow precipitate, by adding a slight excess of a sodium hydroxide solution to a hot aqueous solution of ruthenium or rhodium chloride. The hydroxides of ruthenium and rhodium thus prepared have been found to exhibit excellent catalytic activity in the hydrogenation of various organic compounds when they are reduced to the metals in the presence of the compounds to be hydrogenated.

In this paper the activity and/or the selectivity of these hydroxide-black catalysts have been studied in the hydrogenation of toluene, benzoic acid, *o*-xylene, hydroquinone dimethyl ether and phenyl ether. The results are summarized in Tables I to V, along with those obtained with the oxides of ruthenium and rhodium. The mixed ruthenium-rhodium hydroxides were also prepared from mixtures of ruthenium chloride and rhodium chloride by the same method; the results with these catalysts are also included in the tables.

The hydroxide-catalyzed hydrogenations of the aromatic compounds proceed rapidly at 85 to 100°C under a high hydrogen pressure. Usually only a very small amount of the hydroxide is required for hydrogenation to be completed within a short time. Though a small amount of acetic acid was added in each hydrogenation in order to neutralize the trace of alkaline substances remaining in the catalysts, the hydroxide-catalyzed hydrogenations generally proceed smoothly without the addition of acetic acid (see the example shown in Table I). This fact, together with other observations,*[3] suggests that the hydroxides of ruthenium and rhodium

*[3] A marked difference in selectivity in the hydrogenation of nitriles and aniline was observed between the hydroxides and the oxides; this difference may be attributed to the difference in the alkali contents of the catalysts (to be described in following papers).

TABLE I. HYDROGENATION OF TOLUENE[a]

| Catalyst | Amount mg. | Additive, ml. | Time for hydrogenation[b] min. |
|---|---|---|---|
| Ru hydroxide | 25 | AcOH, 0.05 | 28 |
| Ru hydroxide | 10 | $H_2O$, 1 | 9 |
| Ru hydroxide | 10 | $H_2O$, 3 | 6 |
| Ru hydroxide | 10 | $H_2O$, 6 | 4 |
| Ru hydroxide | 5 | $H_2O$, 1 + AcOH, 0.05 | 12 |
| Ru hydroxide | 1 | $H_2O$, 1 + AcOH, 0.05 | 17 |
| Rh hydroxide | 5 | $H_2O$, 1 + AcOH, 0.05 | 11 |
| Ru dioxide | 5 | $H_2O$, 1 + AcOH, 0.05 | 18 |
| Rh oxide | 5 | $H_2O$, 1 + AcOH, 0.05 | 11 |

a) Toluene (9.2 g.) was hydrogenated at 85°C and 80 to 100 kg./cm² of hydrogen pressure.
b) The product consisted exclusively of methylcyclohexane throughout the runs, containing neither toluene nor any other compound.

TABLE II. HYDROGENATION OF BENZOIC ACID[a]

| Catalyst | Amount mg. | Solvent ml. | Time for hydrogenation[b] min. |
|---|---|---|---|
| (1:1) Ru-Rh hydroxide | 4 | $H_2O$, 15 | 180 |
| Rh hydroxide | 4 | $H_2O$, 15 | 130 |
| Rh oxide | 4 | $H_2O$, 15 | 120 |

a) Benzoic acid (12 g.) was hydrogenated at 100°C and 70 to 100 kg./cm² of hydrogen pressure.
b) The product (cyclohexanecarboxylic acid) was not isolated, but the hydrogen uptake was quantitative in each run.

contain much less alkali than do the oxides of ruthenium and rhodium, even though the hydroxides were precipitated from an alkaline solution.

The promoting action of water reported in the hydrogenation with a supported ruthenium catalyst[9] was also observed in the ruthenium hydroxide-catalyzed hydrogenations (see Tables I and IV). In the presence of water the ruthenium hydroxide was nearly as active as or even more active than the rhodium hydroxide in the hydrogenation of toluene and *o*-xylene, whereas the addition of water slightly retarded the hydrogenation of hydroquinone dimethyl ether with rhodium hydroxide. Generally the catalytic activity of ruthenium hydroxide is considerably greater than that of ruthenium dioxide,*4 and rhodium hydroxide is nearly as active as the rhodium oxide of the Adams type.[11] No appreciable co-activation effect of ruthenium and rhodium was observed in hydrogenation with the mixed ruthenium-rhodium hydroxides, although such an effect was reported with a supported ruthenium-rhodium catalyst.[12]

As may be seen from Tables III and IV, ruthenium hydroxide is more selective than the rhodium catalysts in the cis-hydrogenation of *o*-xylene*5 and hydroquinone dimethyl ether. It should be noted that the presence of water increases the yield of *cis*-1, 4-dimethoxycyclohexane in the hydrogenation of hydroquinone dimethyl ether. Both ruthenium and rhodium hydroxides give good yields of the corresponding saturated ethers in the hydrogenation of hydroquinone dimethyl ether and phenyl ether, which are both very easily susceptible to the hydrogenolysis of the C–O linkage (Table

TABLE III. HYDROGENATION OF *o*-XYLENE

| Catalyst | Amount, mg. | Additives, ml. | Time for hydrogenation min. | cis/trans ratio of 1,2-dimethylcyclohexane[b] |
|---|---|---|---|---|
| Ru hydroxide | 5 | $H_2O$, 1 + AcOH, 0.05 | 16 | 12.3 |
| (3:1) Ru-Rh hydroxide | 5 | $H_2O$, 1 + AcOH, 0.05 | 16 | 10.3 |
| (1:1) Ru-Rh hydroxide | 5 | $H_2O$, 1 + AcOH, 0.05 | 16 | 10.2 |
| (1:3) Ru-Rh hydroxide | 5 | $H_2O$, 1 + AcOH, 0.05 | 18 | 9.3 |
| Rh hydroxide | 5 | $H_2O$, 1 + AcOH, 0.05 | 23 | 9.5 |
| Ru dioxide | 5 | $H_2O$, 1 + AcOH, 0.05 | 26 | 11.2 |

a) *o*-Xylene (10.6 g.) was hydrogenated at 85°C and 80 to 100 kg./cm² of hydrogen pressure.
b) The yield of 1,2-dimethylcyclohexane was quantitative in each run.

9) P. N. Rylander, N. Rakoncza, D. Steele and M. Bollinger, *Engelhard Ind. Tech. Bull.*, **4**, 95 (1963).

*4 The ruthenium dioxide used in this study was prepared by the method of Pichler and Buffleb.[10] The oxide of ruthenium may also be prepared by the Adams method (cf. G. C. Bond and D. E. Webster, *Proc. Chem. Soc.*, **1964**, 398), but the resulting catalyst was far less active than the oxide of Pichler and Buffleb in the hydrogenation of toluene. The oxide obtained by the Adams method shows peaks at $2\theta = 28°$ and 35° in the X-ray diffraction analysis using Cu-$K\alpha$ radiation; these peaks are consistent with those of ruthenium dioxide reported in the literature. Pichler's dioxide and ruthenium hydroxide do not show any distinct diffraction patterns corresponding to the oxide of ruthenium. The oxide obtained by the Adams method does not dissolve in hot concentrated hydrochloric acid, whereas Pichler's dioxide partly, and ruthenium hydroxide rather easily, dissolve in the acid. These facts suggest that Pichler's dioxide is probably a mixture of the oxide and the hydroxide of ruthenium.

10) H. Pichler and H. Buffleb, *Brennstoff-Chem.*, **21**, 257 (1940).

12) P. N. Rylander and D. R. Steele, *Engelhard Ind. Tech. Bull.*, **3**, 91 (1962).

*5 Since rhodium oxide gives a better yield of *cis*-1, 2-dimethylcyclohexane than platinum oxide under similar conditions (unpublished; cf. Ref. 8), the order of selectivity in the cis-hydrogenation of *o*-xylene will be as follows: ruthenium>rhodium>platinum.

Table IV. Hydrogenation of hydroquinone dimethyl ether[a)]

| Catalyst | Amount, mg. | Additives, ml. | Time for hydrogenation min. | 1,4-Dimethoxycyclohexane | |

b) Addition of water caused the hydrolysis of phenyl ether to a large extent.

IV and V). The rhodium hydroxide is somewhat more selective than the ruthenium hydroxide in these hydrogenations, the results with it being consistent with those reported previously for the oxides of ruthenium and rhodium.[7b)] As can be seen from Tables III to V, the selectivities of the mixed ruthenium-rhodium hydroxides are generally those which would be expected from their compositions and not greater than that of either ruthenium hydroxide or rhodium hydroxide.

The results described above show that the hydroxide-black catalysts of ruthenium and rhodium are excellent catalysts in their activity and selectivity in the hydrogenation of the aromatic compounds. The method of preparing the hydroxides is very simple, and the resulting catalysts are nearly as active as or even more active than the corresponding oxide catalysts. Moreover, the catalysts containing much less alkali than the oxides may easily be obtained. Further studies will be reported in following papers.

## Experimental

**Catalysts.**—The hydroxides of ruthenium, rhodium, and ruthenium-rhodium were prepared by vigorously stirring a slight excess of a 10% sodium hydroxide solution into an about 1% aqueous solution of the metal chloride at 85 to 90°C. The precipitate thus formed was collected on a filter paper, washed with distilled water many times until the pH of the filtrate finally became 7.8, and then dried in a vacuum at room temperature. The yields were quantitative as judged on the basis of the metal contents of the hydroxides (see below). Ruthenium dioxide was

prepared according to the method of Pichler and Buffleb[10] by the fusion of ruthenium metal powder with potassium hydroxide and potassium nitrate, followed by reduction with methyl alcohol. Rhodium oxide was prepared by a modified Adams method[11] by the fusion of rhodium chloride with sodium nitrate at 460 to 480°C. The metal contents of the hydroxides and the oxides were estimated from the decrease in their weights when they were reduced to the metals in an atmosphere of hydrogen, using a thermobalance. The metal contents of ruthenium hydroxide, ruthenium dioxide, rhodium hydroxide, and rhodium oxide were 65, 75, 57, and 69% respectively.

**Hydrogenation.** — A 100 ml. bomb of an electromagnetically-stirring-type was used in all the hydrogenations. The bomb was charged with a 100 kg./cm$^2$ pressure of hydrogen and immersed in water maintained at 85°C during the hydrogenation, except in the case of benzoic acid. The hydrogenation of benzoic acid was carried out at 100°C with the use of water as the solvent, because at temperatures below 100°C the rate was too slow, probably because of the low solubility of benzoic acid in water. All the products, except cyclohexanecarboxylic acid, were analyzed by means of gas chromatography using a column containing PEG-6000.

# Electrochemical Syntheses. V. The Direct Synthesis of Methyl Esters of $\alpha, \beta$-Unsaturated Carboxylic Acids from Some Arylated Olefins and Carbon Monoxide*

By Tadao INOUE and Shigeru TSUTSUMI

(Received May 12, 1965)

Although various reactions of olefins with carbon monoxide in the presence of proton-catalysts[1] and/or metal-carbonyls[2] or their-complexes[3] have been reported, the synthesis of $\alpha, \beta$-unsaturated carboxylic acids or esters from olefins and carbon monoxide has been unsuccessful as yet.

The present investigation deals with the first direct synthesis of methyl esters of $\alpha, \beta$-unsaturated carboxylic acids from olefins and carbon monoxide by a unique electrochemical method in the presence of a certain platinum carbonyl compound.

In the last previous paper[7] in this series,[4-7] the present authors have shown that the anodic oxidation of methanol in the presence of arylated olefins produced $\alpha, \beta$-dimethoxylated derivatives, and that the reaction involved a methoxy radical as an intermediate. In order to utilize the radicals produced in the electrolysis for organic synthesis, the electrolysis was carried out in these systems in the presence of carbon monoxide; consequently, we have observed that the platinum used as a cathode was easily dissolved into the solution during the electrolysis of methanol containing sodium methoxide, thus giving a certain platinum carbonyl compound. We have also found that this carbonyl compound reacted with olefins catalytically as well as electrolytically in the presence of carbon monoxide to give a methyl ester of the corresponding $\alpha, \beta$-unsaturated carboxylic acid as the main product. In order to provide some information with regard to the reaction mechanism and the synthetic usefulness of this curious electrochemical reaction, various experiments were carried out regarding the formation of the platinum carbonyl compound, its catalytic action on carboxylations of olefins, the influence of the concentration of the carbonyl compound, and the effect of the steric factor in olefins. Thus, styrene, $\alpha$-methylstyrene and 1, 1-diphenylethylene were chosen as the starting olefins.

## Results and Discussion

**1) The Carbomethoxylation of Olefins (Method A).**—The electrolyses were carried out

by using two platinum-plate electrodes in a cylindrical glass cell placed in an autoclave under a pressure of 70 kg./cm² of carbon monoxide. The apparatus used is shown in Fig. 1. The current was controlled at nearly 1.0 amp., the temperature being kept at −10——15°C. The electrolysis of a methanolic solution containing sodium methoxide and styrene for 9 hr. gave methyl *trans*-cinnamate (I) as the main product in a 14% yield based on the styrene used; it also gave methyl β-methoxy-β-phenyl propionate (II) (3.6%), methyl β-phenyl propionate (III) (3.1%), dimethyl *meso*-β, γ-diphenyl adipate (IV) (a trace) and styrene glycol dimethyl ether (V) (5.6%), and unreacted styrene (57%). However, during the course of this electrolysis, the platinum plate used as a cathode (1.3 g.) was dissolved into the solution, and the electrolyzed solution turned a greenish-blue. The results obtained under various conditions are summarized in Table I, where the yield is calculated from the results of gas chromatographic analysis. When the electrolysis was carried out by using copper or carbon as the cathode and a platinum plate as the anode, styrene glycol dimethyl ether (V) was obtained as the sole product (23%), as is shown in Table I.

The electrolysis in the presence of α-methylstyrene instead of styrene for 9 hr. gave methyl *trans*-β-methyl cinnamate (VI) (14.8%), methyl 3-phenyl-3-butenoate (VII) (4.9%), methyl β-methyl-β-phenyl propionate (VIII) (1%) and α-methylstyrene glycol dimethyl ether (IX) (2.2%). When 1, 1-diphenylethylene was used, methyl β-phenyl cinnamate (X) was also obtained in a 17.2% yield as the main product, as is shown in Table II. In these electrolyses, the platinum used as a cathode was also dissolved into the electrolyzed solution.

**2) One Platinum Compound.**—When the electrolysis of methanol containing sodium methoxide was carried out by using two platinum-plate electrodes in the absence of olefins under the pressure of carbon monoxide, the platinum used as the cathode was also easily dissolved into the solution, giving a certain platinum carbonyl compound; this compound was then isolated by the removal

of methanol from the electrolyzed solution under a dry nitrogen atmosphere. This carbonyl compound was very sensitive to air and was greenish-blue. Its infrared spectrum has the characteristic absorption bands at about 2015 (v. s.) and 2145 cm$^{-1}$ (w.) (terminal carbonyl group), and at about 1860 (m. s.) and 1840 cm$^{-1}$ (m. s.) (the bridged carbonyl group); it also has strong absorption bands at about 1642, 1280 and 1180 cm$^{-1}$, as is shown in Fig. 2. Although the structure of this carbonyl compound has not yet been completely elucidated, the latter strong absorption bands may be due to the ester group attached to platinum metal, as has been reported in other metal-carbonyl compounds.[8]

**3) The Carbomethoxylation of Olefins in the Presence of the Platinum Carbonyl Compound (Method B).**—At first, the platinum carbonyl compound was produced in methanol containing sodium methoxide by electrolysis in a cylindrical glass cell in a manner similar to the procedure described above 2); then, after the plate of cathode had changed to copper($2\times3$ cm$^2$), electrolyses were carried out in the presence of olefins and carbon monoxide for 16 hr. (1.0 amp., $-10$——$-15$°C).

In these electrolyses, methyl esters of $\alpha,\beta$-unsaturated carboxylic acids were also obtained as the main products. Examples of the yields of these unsaturated esters and of other products are given in Table III.

**4) The Carbomethoxylation of Styrene in the Presence of Platinous Potassium Chloride.**—When the electrolysis was carried out in the presence of platinous potassium chloride or sodium cholride under similar conditions 3), it gave as products I (1%), II (3.3%) and V (18%).

The products obtained from these reactions were identified by the infrared spectroscopic, gas chromatographic and elemental analysis and, some of them, by NMR data; they were also identified as free acids by mixed melting points determinations with authentic specimens.

8) T. Kruck and M. Noack, *Chem. Ber.*, **97**, 1693 (1964).

*The Participation of the Platinum Carbonyl Compound.*—In these electrochemical reactions, the formation of unsaturated esters proceeds by the catalytic action of the platinum carbonyl compound, which is cathodically generated from the platinum used as the cathode and from sodium methoxide in the presence of carbon monoxide. The above statement was supported by the following experimental results: (a) Without the platinum carbonyl compound, the electrolysis of styrene using copper or carbon as the cathode and platinum as the anode gave styrene glycol dimethyl ether (V), and the formation of esters I—IV was not observed, as is shown in Table I (R-5 and 6); on the other hand, in the presence of the platinum carbonyl compound, these esters were mainly obtained, as Tables I—III show. (b) The electrolysis under a nitrogen atmosphere with catholyte and anolyte which contained the platinum carbonyl compound and styrene in each separated compartment resulted in the formation of the esters I and II from the anode compartment, although no product was detected from the cathode compartment. (c) With the increase in the concentration of the platinum carbonyl compound, the yield of these esters increased. On the contrary, the yield of styrene glycol dimethyl ether (V) decreased, as is shown in Table III. (d) The formation of these esters may proceed catalytically as well as electrolytically in the presence of the platinum carbonyl compound and carbon monoxide, for the electrolysis of styrene (0.15 mol.) give I (0.031 mol.), II (0.020 mol.) and III (0.003 mol.) in the presence of a catalytic amount of the platinum carbonyl compound (0.007 mol.), as Table III-R-2 shows.

Thus, it can be considered that the esters I and II are produced by the anodic reaction of styrene with the platinum carbonyl compound and carbon monoxide:

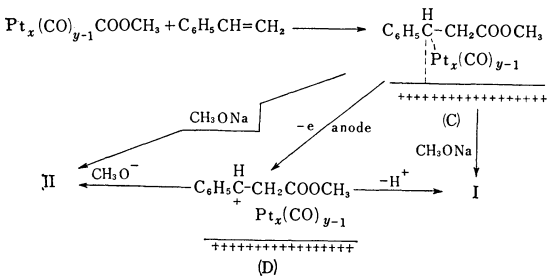
$$C_6H_5CH{=}CH_2 + CO + CH_3O^- \xrightarrow[[Pt_x(CO)_y]^n]{\text{anode}} C_6H_5CH{=}CHCOOCH_3\ (\textit{trans}\text{-})\ \text{(I)} + C_6H_5\underset{\displaystyle OCH_3}{\underset{|}{C}}HCH_2COOCH_3\ \text{(II)} \quad (1)$$

*Other Products.*—Styrene glycol dimethyl ether (V) is produced by the reaction of the methoxy radical, which is formed by the anodic oxidation of methanol as an intermediate, with styrene, as has been reported before.[7] Methyl $\beta$-phenyl propionate (III) and dimethyl *meso*-$\beta$, $\gamma$-diphenyl adipate (IV) are probably produced by the cathodic reduction of the methyl cinnamate (I) generated in the first step at a low concentration of the platinum carbonyl compound, since I was partly reduced to III and IV in, respectively, the absence of and presence of the platinum carbonyl compound under conditions similar to those described above 3), and since it is well known that cinnamic acid or its derivatives are easily reduced to propionic acid and adipic acid or their derivatives at mercury cathode.[9]

*Mechanistic Aspects.*—In this new electrochemical reaction, the above-mentioned carbomethoxy platinum carbonylate was assumed to be the active species for the carboxylation, preserving the olefinic double bond, of olefins. The experimental evidence for the above assumption included the facts that the carbomethoxy platinum carbonylate was isolated in the solid state, the infrared spectrum of which showed the presence of the ester group attached to platinum-metal, the terminal and the bridged carbonyl group, and that it reacted with olefins upon electrolysis to give methyl esters of $\alpha$, $\beta$-unsaturated carboxylic acids. Although the precise mechanism of the formation of this carbomethoxy platinum carbonylate is still open to question, it may be considered, as a possible rationalization, that the cathodically-generated platinum carbonyl compound immediately reacts with the methoxy radical or sodium methoxide via the anodic process to give the carbomethoxy platinum carbonylate (Eq. 2 or 3):

$$CH_3O^- \xrightarrow[\text{anode}]{-e} CH_3O\cdot \quad (2)$$

$$[Pt_x(CO)_y]^n + CH_3O\cdot \longrightarrow Pt_x(CO)_{y-1}COOCH_3$$
or
$$[Pt_x(CO)_y]^n \xrightarrow[\text{anode}]{-e} [Pt_x(CO)_y]^{n-1} \xrightarrow{CH_3ONa} \uparrow \quad (3)$$

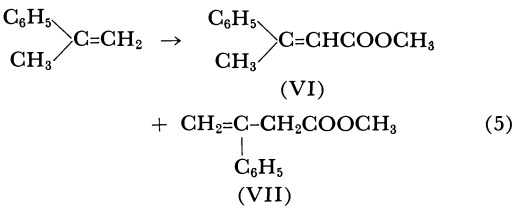


Equation 2 may be expected, since the environment around the electrode might have a particularly high concentration of the methoxy radical. The reaction scheme of Eq. 3 may be analogous to the formation of carbomethoxy manganese and rhenium carbonyl compound using manganese or rhenium carbonyl and sodium methoxide,[8] but in our case the reaction of Eq. 3 proceeded via the anodic process.[10] In any case, it is interesting that the platinum carbonyl or its derivatives, the preparation of which by other methods was difficult, was easily prepared by the electrochemical method.[11]

Thus, the esters of $\alpha$, $\beta$-unsaturated carboxylic acids may be considered to be produced by the addition of the Pt–$COOCH_3$ group in the platinum carbonyl compound to the olefinic double bond via the electrode process, followed by further anodic oxidation or decomposition with sodium methoxide, as is indicated below:

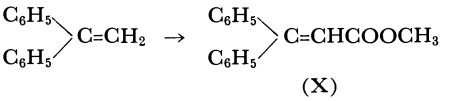
9) C. L. Wilson and K. B. Wilson, *Trans. Electrochem. Soc.*, **84**, 153 (1943); C. L. Wilson, ibid., **92**, 369 (1947).

10) This statement is supported by the experiment in which nickel carbonyl was easily oxidized at the anode surface by the electrolysis of methanol containing sodium methoxide.



11) For example, the synthesis of manganese cyclopentadienyl tricarbonyls has been reported by the electrolysis of a mixture of a manganese compound, a cyclopentadiene, carbon monoxide and a transition metal-carbonyl. (Ethyl Corp., Brit 845074 (1960); *Chem. Abstr.*, **55**, 4205 (1961).)

The addition of the metal-carbon $\sigma$-bond to the olefinic double bond has recently been reported by several workers. For example, acyl and alkyl cobalt- and manganese-carbonyl compounds react with olefins,[12] diene[13] and fluoro-olefins.[14]



The complex C may be decomposed in the presence of sodium methoxide to give I and II as final products, as has been shown in other metal-carbonyl complexes.[12,13] Alternatively, the possibility of the oxidation of C to carbonium ions, which are then converted to I and II as final products, cannot be excluded, since it has been reported that benzylic carbonium ions can be easily produced as intermediates in electrolysies.[15,16]

*The Electrolyses of α-Methylstyrene or* 1, 1-*Diphenylethylene.*—When $\alpha$-methylstyrene was used instead of styrene, methyl 3-phenyl-3-butenoate (VII), besides methyl *trans*-$\beta$-methyl cinnamate (VI) as the main product, was obtained in a fairly high yield, as Table III shows. The NMR spectrum of

(5)

VII ($CCl_4$ as the solvent) showed peaks at 2.75 ($C_6H_5$), 4.55 ($CH_2$=), 4.85 ($CH_2$=), 6.47 ($OCH_3$) and 6.59 $\tau$ (-$CH_2$-); the peak areas were in the ratio of 5 : 1 : 1 : 3 : 2, as was to be expected from the presumed structure. In addition, VII could be easily hydrolyzed with an aqueous alkali solution to give *trans*-$\beta$-methyl cinnamic acid in the same way as methyl vinyl acetate.[17] The formation of these esters of unsaturated products VI and VII can be reasonably explained by $\alpha$- or $\gamma$-proton elimination from the intermediate complex C or the carbonium ion D in according to the hypothetical scheme described above. Similar electrolysis in the presence of 1, 1-diphenylethylene gave methyl $\beta$-phenyl cinnamate (X) and 1, 1-diphenylethylene glycol dimethyl ether (XI).

(6)

In these electrolyses, however, the corresponding methyl $\beta$-methoxy carboxylates were not detected in the products from $\alpha$-methylstyrene or in 1, 1-diphenylethylene, while methyl $\beta$-methoxy-$\beta$-phenyl propionate (II) was obtained from styrene, as has been mentioned above, and the corresponding dimethyl ether derivatives were obtained from these olefins. This may be due to the steric factor ($CH_3$-, $C_6H_5$-) with methoxide ions approaching the complex C or carbonium ion D as intermediates. More confirmations, however, are required with respect to this matter.

It is interesting to note that methyl esters of $\alpha$, $\beta$-unsaturated carboxylic acids were directly synthesized from olefins and carbon monoxide in fairly high yields in the presence of the platinum carbonyl compound.

## Experimental

All melting points and boiling points are uncorrected. The electrolyses were carried out with the apparatus shown in Fig. 1.

**Materials.** — Styrene and $\alpha$-methylstyrene were carefully purified in a usual manner,[18] stored in an ice-box, and distilled before use. 1, 1-Diphenylethylene was prepared by the dehydration of the alcohol formed by the action of phenylmagnesium bromide and ethyl acetate[19]; b. p. 97—97.5°C/0.5 mmHg, $n_D^{15}$= 1.6098. Methanol was purified in a manner described earlier.[4] These materials were confirmed to be pure by gas chromatography. Carbon monoxide (99.5% pure) was purchased from the Takatiho Co. The platinum plate (99.99% pure, 2×3 $cm^2$, 0.3 mm. thick) used as an electrode was prepared by carefully treating commercial material with dilute nitric acid and with distilled water; it was weighed before and after use. Commercially-available platinous potassium chloride was used.

**The Anodic Oxidation of Methanol in the Presence of Styrene and Carbon Monoxide (Method A).**—The reaction conditions and the yields of the products are summarized in Table I. R-3 may be illustrated as follows: Metallic sodium (0.5 g., 0.022 mol.) was dissolved in 80 g. of absolute methanol (2.5 mol.) in a cylindrical glass cell, and then 15.6 g. of freshly distilled styrene (0.15 mol.) was added to the mixture. After dry nitrogen had been bubbled through the mixture for about 1 hr., the cell was placed in an autoclave and the platinum plate as cathode was weighed. Carbon monoxide was then introduced (70 kg./$cm^2$), and the mixture was electrolyzed at −10—−15°C for 9 hr., with the current

18) A. Weissberger, "Technique of Organic Chemistry," Vol. VII, Interscience Publ., New York (1955), p. 331.
19) "Organic Syntheses," Coll. Vol. I (1956), p. 226.

maintained at nearly 1.0 amp. (current density, ca. 8.3 amp./cm$^2$). The electrolyzed solution turned a greenish-blue, and 1.32 g. of the platinum used as a cathode was dissolved into the electrolyzed solution. After the methanol had been removed from the reaction mixture under 25—30 mmHg pressure, the residue was poured into water (50 ml.), neutralized with 3 N hydrochloric acid, and extracted with ether; the extract was then dried over magnesium sulfate. After the ether had been removed, the oily residue (17.5 g.) was fractionated by distillation under diminished pressure into the following fractions:

| Fraction | B. p. | Weight, g. |
|---|---|---|
| 1 | ~50°C/25—28 mmHg | 4.1 |
| 2 | 70—120°C/0.7 mmHg | 6.9 |
| 3 | 120—150°C/0.7 mmHg | 1.0 |
| 4 | Residue | 2.0 |

By gas chromatographic analysis (conditions: column, Poly Ethylene Glycol 6000, 3 m. and Poly Ester DA., 3 m.; column temperature, 190°C; carrier gas, $H_2$), it was shown that Fraction 1 was unreacted styrene, while Fractions 2 and 3 were mixtures of styrene glycol dimethyl ether, methyl β-methoxy-β-phenyl propionate, methyl β-phenyl propionate, and methyl *trans*-cinnamate. The total amounts of these products were as follows: styrene glycol dimethyl ether, 1.4 g.; methyl β-methoxy-β-phenyl propionate, 1.0 g.; methyl β-phenyl propionate, 0.7 g.; methyl *trans*-cinnamate, 3.4 g. (14% yield based on the styrene used.)

Fraction 2 was submitted to preparative gas chromatography (column, Poly Ethylene Glycol 6000, 3 m.; column temperature, 190°C; carrier gas, $N_2$), and the respective products were isolated:

(a) methyl *trans*-cinnamate, m. p. 35—36°C.

Founds: C, 74.25; H, 6.46. Calcd. for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22%.

The infrared spectrum of this ester showed the chracteristic bands at about 1735 (C=O) and 1640 cm$^{-1}$ (C=C), and it was identical with that of an authentic sample. The hydrolysis of this ester with an aqueous alkali solution gave *trans*-cinnamic acid (m. p. 132—133°C) from ligroin; a mixed melting point determination with an authentic sample showed no depression.

Found: C, 72.67; H, 5.57. Calcd. for $C_9H_8O_2$: C, 72.96; H, 5.44%.

(b) Methyl β-methoxy-β-phenyl propionate, b. p. 125—127°C/12—13 mmHg. The infrared spectrum of this compound showed the characteristic bands at about 1750 (C=O) and 1100 cm$^{-1}$ (C-O-C), and it was identical with that of an authentic sample prepared as described below; the hydrolysis of this ester with a cold 3 N potassium hydroxide solution gave β-methoxy-β-phenyl propionic acid, m. p. 98—98.5°C, from ligroin. A mixed melting point determination with an authentic sample showed no depression.

Found: C, 66.66; H, 6.77. Calcd. for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%.

With a boiling aqueous alkali solution, this ester was easily hydrolyzed to give *trans*-cinnamic acid, m. p. 132—133°C; a mixed melting point determination with an authentic sample showed no depression.

(c) Methyl β-phenyl propionate, b. p. 132—135°C/30 mmHg, $n_D^{15}=1.4997$. The hydrolysis of this compound with a boiling alkali solution gave β-phenyl propionic acid, m. p. 47.5—48°C, from petroleum ether; a mixed melting point determination with an authentic sample showed no depression.

Found: C, 72.18; H, 6.75. Calcd. for $C_9H_{10}O_2$: C, 71.98; H, 6.71%.

The infrared spectrum of this acid showed the characteristic band at about 1730 cm$^{-1}$ (C=O), and it was identical with that of an authentic sample.

(d) Styrene glycol dimethyl ether, b. p. 75—76°C/2 mmHg.

Found: C, 72.49; H, 8.88. Calcd. for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

The infrared spectrum of this ether showed the characteristic absorption band at 1105 cm$^{-1}$ (C-O-C), it was identical with that of an authentic sample prepared as described earlier.[7]

Fraction 3 was chromatographed over silica gel (2.5×45 cm). After the elusion of methyl *trans*-cinnamate (0.1 g.) with benzene, elusion with methanol gave a material which was then hydrolyzed with a methanolic alkali solution to give *meso*-β,γ-diphenyl adipic acid, m. p. 270—272°C, from methanol; a mixed melting point determination with an authentic sample prepared as described below showed no depression.

Found: C, 72.48; H, 6.14. Calcd. for $C_{18}H_{18}O_4$: C, 72.46; H, 6.08%.

The infrared spectrum of this acid was identical with that of an authentic sample.

**The Anodic Oxidation of Methanol in the Presence of Styrene, Carbon Monoxide and the Platinum Carbonyl Compound (Method B).**—The reaction conditions and the yields of the products are summarized in Table III.

R-2 may be illustrated as follows: Metallic sodium (0.5 g., 0.022 mol.) was dissolved in 90 g. of absolute methanol in a cylindrical glass cell, and dry nitrogen was bubbled through the mixture for about 1 hr. The cell was placed in an autoclave, carbon monoxide was introduced (70 kg./cm$^2$), and then the mixture was electrolyzed at −10—−15°C for 5 hr. (1.0 amp., 16—45 V.), using two weighed platinum plates. The platinum used as a cathod (1.5 g.) was dissolved into the solution in order to give a certain platinum carbonyl compound; the solution then turned to greenish-blue. After the carbon monoxide had been removed, the plate of cathode was changed to a copper one (2×3 cm$^2$), and then 15.6 g. of freshly-distilled styrene (0.15 mol.) was added to the electrolyzed solution. Carbon monoxide was again introduced (70 kg./cm$^2$) and the mixture was electrolyzed for 16 hr. under the conditions described above. The electrolyzed solution was worked up in a manner similar to the procedure described above (method A), and the oily residue was fractionated by distillation under reduced pressure into the following fractions:

| Fraction | B. p. | Weight, g. |
|---|---|---|
| 1 | ~39°C/15—17 mmHg | 2.5 |
| 2 | 64—75°C/0.3 mmHg | 3.5 |
| 3 | 75—85°C/0.3 mmHg | 10.5 |
| 4 | 85—125°C/0.3 mmHg | 1.8 |
| 5 | Residue | 3—4 |

By gas chromatographic analysis (conditions: described above), it was shown that Fraction 1 was unreacted styrene, while Fractions 2—4 were mixtures of

styrene glycol dimethyl ether (5.7 g.), methyl β-phenyl propionate (0.4 g.), methyl β-methoxy-β-phenyl propionate (3.9 g.) and methyl *trans*-cinnamate (5.0 g., 21% yield). The hydrolysis of the Fraction 5 (residue) with an aqueous alkali solution gave a small amount of *meso*-β,γ-diphenyl adipic acid (0.1 g.).

**The Anodic Oxidation of Methanol in the Presence of α-Methylstyrene, Carbon Monoxide and Platinum Carbonyl Compound (Method B).**—According to the procedure described above, the platinum carbonyl compound (2.9 g., wt. of Pt) was produced in a methanol solution containing sodium methoxide (metallic sodium (0.5 g.) in 90 g. of methanol) by electrolysis for 13.5 hr., and then freshly-distilled α-methylstyrene (17.7 g., 0.15 mol.) was added to the mixture. The electrolysis of the mixture was carried out, by using copper copper plate as a cathode, under the pressure of carbon monoxide (70 kg./cm²) for 16 hr. (1.0 amp., −10—−15°C). The electrolyzed solution was worked up in a manner similar to the procedure described above (method A), and the oily residue was fractionated by distillation under reduced pressure into the following fractions:

| Fraction | B. p. | Weight, g. |
|---|---|---|
| 1 | ~49°C/12—13 mmHg | 4.9 |
| 2 | 65—85°C/2—3 mmHg | 2.0 |
| 3 | 85—125°C/2—3 mmHg | 7.4 |
| 4 | 125—185°C/2—3 mmHg | 1.0 |
| 5 | Residue | 5.9 |

By gas chromatographic analysis (conditions: column, Poly Ester DA, 3 m.; temperature, 182°C; carrier gas, $H_2$), it was shown that Fractions 1—4 were mixtures of methyl *trans*-β-methyl cinnamate, methyl 3-phenyl-3-butenoate, methyl β-methyl-β-phenyl propionate, α-methylstyrene glycol dimethyl ether and acetophenone and that the total amount of these products were as follows: methyl *trans*-β-methyl cinnamate, 4.5 g. (18% yield, based on the α-methylstyrene used); methyl 3-phenyl-3-butenoate, 2.7 g.; methyl β-methyl-β-phenyl propionate, 0.6 g.; α-methyl-styrene glycol dimethyl ether, 2.5 g.; acetophenone, 1.1 g. Fractions 3 and 4 were chromatographed over silica gel (2.5×45 cm.). Elusion with benzene led to the isolation of the following products:

(a) Methyl *trans*-β-methyl cinnamate, b. p. 80—81°C/0.8 mmHg, m. p. 28—29°C; from ligroin.

Found: C, 74.88; H, 6.97. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86%.

The infrared spectrum of this unsaturated ester showed the characteristic absorption bands at about 1735 (C=O) and 1642 $cm^{-1}$ (C=C), and it was identical with that of an authentic sample. The hydrolysis of this ester with an aqueous alkali solution gave *trans*-β-methyl cinnamic acid, m. p. 96.5—97.5°C, from ligroin; a mixed melting point determination with an authentic sample prepared as described below showed no depression.

Found: C, 74.22; H, 6.22. Calcd. for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22%.

(b) Methyl 3-phenyl-3-butenoate, b. p. 125—126°C/12—13 mmHg.

Found: C, 75.17; H, 6.89. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86%.

The infrared spectrum of this ester showed the characteristic absorption bands at about 1755 (C=O) and 1645 $cm^{-1}$ (C=C), and the NMR spectrum of this unsaturated ester ($CCl_4$ as solvent) showed peaks at 2.75($C_6H_5$), 4.55($CH_2$=), 4.85($CH_2$=), 6.47($OCH_3$) and 6.59 τ(−$CH_2$−); the peak areas were in the ratio of 5 : 1 : 1 : 3 : 2, as would be expected from the structure. The hydrolysis of this ester with a 3 N potassium hydroxide solution gave *trans*-β-methyl cinnamic acid, m. p. 96.5—97.5°C; a mixed melting point determination with an authentic sample showed no depression.

(c) α-Methylstyrene glycol dimethyl ether, b. p. 67—69°C/1.5 mmHg, $n_D^{14}$=1.5022.

Found: C, 73.57; H, 9.27. Calcd. for $C_{11}H_{16}O_2$: C, 73.39; H, 8.95%.

The infrared spectrum of this dimethyl ether showed the characteristic absorption bands at about 1110 and 1128 $cm^{-1}$ (C-O-C), and it was identical with that of an authentic sample prepared as earlier.[7]

Methyl β-methyl-β-phenyl propionate was identified by gas chromatographic analysis (conditions as described above). From Fraction 2, acetophenone was identified as its 2,4-dinitrophenylhydrazone: m. p. 237—238°C; a mixed melting point determination with an authentic sample was not depressed.

Found: C, 56.17; H, 3.93. Calcd. for $C_{14}H_{12}N_4O_4$: C, 56.00; H, 4.03%.

**The Anodic Oxidation of Methanol in the Presence of 1, 1-Diphenylethylene, Carbon Monoxide and the Platinum Carbonyl Compound (Method B).**—After the platinum carbonyl compound (1.0 g., wt. of Pt) had been produced in methanol containing sodium methoxide (metallic sodium 0.5 g in 90 g. of methanol) by electrolysis for 3 hr., 18.0 g. of freshly-distilled 1,1-diphenylethylene was added to the mixture; then the mixture was electrolyzed by using copper plate as the cathode for 16 hr. under carbon monoxide pressure (70 kg./cm²). The electrolyzed solution was worked up in a manner similar to that described above, and the oily residue was fractionated by distillation under diminished pressure into the following fractions:

| Fraction | B. p. | Weight, g. |
|---|---|---|
| 1 | ~125°C/0.2 mmHg | 2.5 |
| 2 | 125—145°C/0.2 mmHg | 17.3 |
| 3 | Residue | 2—3 |

10.0 g. of a mixture of Fractions 1 and 2 was chromatographed over silica gel (2.5×50 cm.). Elution with benzene led to the isolation of methyl β-phenyl cinnamate (4.0 g.), 1, 1-diphenylethylene glycol dimethyl ether (2.5 g.), unidentified products (3.5 g.) and unreacted 1,1-diphenylethylene (0.5 g.): (a) methyl β-phenyl cinnamate, b. p. 133—134°C/0.3 mmHg.

Found: C, 80.83; H, 6.19. Calcd. for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92%.

The infrared spectrum of this ester showed the characteristic absorption bands at about 1745 (C=O) and 1625 $cm^{-1}$ (C=C). The hydrolysis of this ester with an alcoholic alkali solution gave β-phenyl cinnamic acid, m. p. 161—162°C, from methanol; a mixed melting point determination with an authentic sample prepared as described below showed no depression.

Found: C, 80.54; H, 5.15. Calcd. for $C_{15}H_{12}O_2$: C, 80.33; H, 5.39%.

(b) 1,1-Diphenylethylene glycol dimethyl ether, m. p. 64.5—65.5°C, from ligroin; a mixed melting point determination with an authentic sample prepared as described earlier[7] showed no depression.

Found: C, 79.06; H, 7.25. Calcd. for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

9.5 g. of the mixture of Fractions 1 and 2 was hydrolyzed with a 10% potassium hydroxide - ethanol solution to give 3.5 g. of β-phenyl cinnamic acid with a m. p. of 158—161°C.

**The Anodic Oxidation of Methanol in the Presence of Styrene, Carbon Monoxide and Platinous Potassium Chloride.** — Metallic sodium (0.5 g.) was dissolved in 90 g. of absolute methanol in a cylindrical glass cell, and then 3.0 g. of platinous potassium chloride and 33 g. of freshly-distilled styrene were added to the mixture. The mixture was electrolyzed by using carbon as the cathode and platinum as the anode for 17 hr. under a carbon monoxide pressure of 70 kg./cm². The reaction mixture was worked up in a manner similar to the procedure described above, and the oily residue was distilled under diminished pressure to give the following fractions:

| Fraction | B. p. | Weight, g. |
|---|---|---|
| 1 | ~49°C/20 mmHg | 8.7 |
| 2 | ~75°C/1 mmHg | 6.2 |
| 3 | 75—100°C/1 mmHg | 5.8 |
| 4 | 100—145°C/1 mmHg | 2.5 |
| 5 | Residue | 5.5 |

By gas chromatographic analysis (conditions: column, Poly Ethylene Glycol 6000, 3 m.; column temperature, 177°C; carrier gas, $H_2$), it was shown that the total amount of the products were as follows: styrene-glycol dimethyl ether, 9.3 g.; methyl β-methoxy-β-phenyl propionate, 1.8 g.; methyl *trans*-cinnamate, 0.4 g.; unidentified products, 3.5 g.

Fraction 3 was hydrolyzed with a cold 3 N potassium hydroxide solution to give 1.7 g. of β-methoxy-β-phenyl propionic acid with a m. p. of 97—98.5°C from ligroin; a mixed melting point determination with an authentic sample showed no depression.

**The Syntheses of the Authentic Samples.**— *trans*-Cinnamic acid and β-phenyl propionic acid or their esters were commercial; they were then purified from ligroin.

Methyl β-methoxy-β-phenyl propionate was prepared by the reaction of methyl α-acetoxymercury-β-methoxy-β-phenyl propionate, which had been prepared by the action of methyl *trans*-cinnamate with mercury acetate in methanol,[20] with hydrogen sulfide and ammonia[20]; b. p. 125—127°C/12—13 mmHg. β-Methoxy-β-phenyl propionic acid was obtained by the hydrolysis of methyl β-methoxy-β-phenyl propionate with a cold aqueous alkali solution; m. p. 97—98°C (lit.,[20] m. p. 98°C). *meso*-β,γ-Diphenyl adipic acid was prepared by the electrolytic reduction of *trans*-cinnamic acid at the mercury cathode[21]; m. p. 270—272°C (lit.,[21] m. p. 270—273°C). *trans*-β-Methyl cinnamic acid was synthesized from *t*-butyl acetate[22] and acetophenone by the action of lithium amide[23]; m. p. 97.5—98°C (lit.,[23] m. p. 98—98.5°C). Methyl β-methyl-β-phenyl propionate was prepared by the electrolytic reduction of methyl *trans*-β-methyl-cinnamate[24]; b. p. 133—134°C/22 mmHg. β-Phenyl cinnamic acid was prepared by the reaction of 1,1-diphenylethylene with oxalyl chloride[25]; m. p. 161—162°C (lit.,[25] m. p. 162°C).

We should like to thank Dr. Yoshinobu Odaira and Dr. Menbo Ryang for their useful suggestions and encouragement.

# The Optical Properties of Colored Colloidal Systems. III. A Theory of Spherical Particles, with Especial Attention to Systems Dispersed in Colored Media*

By Masayuki NAKAGAKI

(Received April 14, 1965)

In a previous paper,[1] the extinction, scattering and absorption of light by a colloidal sytem of colored spherical particles dispersed in a colorless medium was studied theoretically; it was concluded that the scattering is affected by the absorption, and that the absorption is affected by the scattering. In another paper,[2] the apparent refractive index of the same system was studied theoretically, and the results were applied to a solution of dye, Acid Orange R, the system being treated as a dispersed system of infinitesimally small particles. In the present paper, the theoretical treatment will be extended to cases where either the particle or the medium is colored, or both; the results will be discussed in detail for the case of a relatively small absorption.

## Theoretical

**Complex Refractive Index.**—The refractive index of a colored phase is usually expressed by a complex quantity. For the dispersion medium;

$$\mu_1 = \mu_{10}(1 - ik_2) \tag{1}$$

and for the dispersed phase;

$$\mu_2 = \mu_{20}(1 - ik_2) \tag{2}$$

may be used, where $\mu_{10}$ and $\mu_{20}$ are the usual refractive indices of the respective bulk phases, while $k_1$ and $k_2$ are related to the optical densities per unit of thickness, $E_i'$, of the respective bulk phases by the following equation,[3] with $i=1$ or 2;

$$E_i' = -[\ln(I_i'/I_0')]/l_i' = 4\pi\mu_{i0}k_i/\lambda_0 \tag{3}$$

Here $l_i'$ is the thickness of the phase $i$, $I_0'$ and $I_i'$ are the intensities of the incident and transmitted light, and $\lambda_0$ is the wavelength of the light in a vacuum.

When phase 2 is dispersed as small spherical particles in phase 1, the optical properties of the dispersed system are determined by the relative radius, $\alpha$, the relative refractive index, $m$, the number of particles in a unit volume, $N$, and the wavelength of light in the medium, $\lambda$. The relative radius is defined by:

$$\alpha = 2\pi a/\lambda \tag{4}$$

where $a$ is the radius of the sphere and where

$$\lambda = \lambda_0/\mu_{10} \tag{5}$$

If the concentration $c$ (g./ml.) is used instead of $N$;

$$c = \alpha^3\lambda^3\rho_2 N/6\pi^2 \tag{6}$$

where $\rho_2$ is the density of the dispersed phase.

The relative refractive index, $m$, defined by:

$$m = \mu_2/\mu_1 \tag{7}$$

is also a complex quantity in our case; it is separated into real and imaginary parts as follows:

$$m = m_0 - ik_0 \tag{8}$$

where $i$ is $\sqrt{-1}$ and

$$m_0 = (\mu_{20}/\mu_{10})(1+k_1k_2)/(1+k_1^2) \tag{9}$$

$$k_0 = (\mu_{20}/\mu_{10})(k_2-k_1)/(1+k_1^2) \tag{10}$$

or

$$k = k_0/m_0 = (k_2-k_1)/(1+k_1k_2) \tag{11}$$

If the medium is colorless and the particles are colored,

$$\left.\begin{array}{l} m_0 = \mu_{20}/\mu_{10} \\ k_0 = m_0k_2 \text{ or } k = k_2 \end{array}\right\} \text{ (if } k_1=0) \tag{12a}$$

Therefore, $m_0$ is equal to the ratio of the usual refractive indices and $k_0$ is positive. This is the case discussed in the previous papers.[1,2]

On the contrary, if the medium is colored and the particles are colorless,

$$\left.\begin{array}{l} m_0 = (\mu_{20}/\mu_{10})/(1+k_1^2) \\ k_0 = -m_0k_1 \text{ or } k = -k_1 \end{array}\right\} \text{ (if } k_2=0) \tag{12b}$$

Therefore, $m_0$ is smaller than the ratio of the usual refractive indices $(\mu_{20}/\mu_{10})$ and $k_0$ is negative. Finally, if both the medium and the particles are colored, the situation is different depending on whether $k_1$ or $k_2$ is the greater. If $k_1<k_2$, then $m_0>(\mu_{20}/\mu_{10})$ and $k_0>0$, but if $k_1>k_2$, then $m_0>(\mu_{20}/\mu_{10})$ and $k_0<0$. The case when $k_1=k_2$ is especially interesting because $m_0=\mu_{20}/\mu_{10}$ and $k_0=0$. This means that the effect of the particles on the optical properties of the dispersed system for which $k_1=k_2$ can be treated theoretically as if the system is colorless, although actually the system is colored.

* Presented at the 16th Colloid Symposium held by the Chemical Society of Japan, Osaka, November, 1963; and the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

1) M. Nakagaki, This Bulletin, **31**, 980 (1958).

2) M. Nakagaki and T. Fujii, ibid., **34**, 433 (1961).

3) The optical density is usually defined by a common logarithm, but the natural logarithm is used throughout this paper.

**Optical Density, Absorption and Scattering.**—The optical density per unit layer thickness of the colored colloidal system is set as $E_0$, which may be measured, for example, by a Beckman-type photometer, using distilled water as the reference for an aqueous colloidal system. The difference in the optical densities per unit layer thickness between the colored colloidal system, $E_0$, and the colored medium, $E_1$, is set at $E$, which may be measured by using the colored medium (instead of distilled water) as the reference solution. Therefore,

$$E=E_0-E_1=-[\ln(I/I_1)]/l \tag{13}$$

where $l$ is the layer thickness, $I$ is the transmitted light through the colloidal system, and $I_1$ is the transmitted light through the dispersion medium. On the other hand,

$$E_0=-[\ln(I/I_0)]/l=E+4\pi k_1/\lambda \tag{14}$$

where $I_0$ is the intensity of the incident light and where the last term is obtained from Eqs. 3 and 5. The quantity $E$ means the increment in the optical density as a result of the existence of the colloidal particles.' In the special case where the medium is colorless ($k_1=0$), $E$ is equal to $E_0$. When $k_0<0$ (that is, $k_2<k_1$), $E$ will take a negative value, as will be shown later, except when the effect of scattering is sufficiently large.

The optical density increment per particle, $E/N$, is considered to be the sum of the scattering, $R$, and the absorption, $A$.

$$E/N = R + A \tag{15}$$

The parameters $\varepsilon$, $\kappa$, and $\varepsilon_a$ will, however, be used because the concentration, $c$, is experimentally more convenient than the number of particles, $N$. Here,

$$\left.\begin{aligned}\varepsilon &= E/c\\ \kappa &= RN/c\\ \varepsilon_a &= AN/c\end{aligned}\right\} \tag{16}$$

The parameters $x$, $y$ and $z$ will be used, as in a previous paper.[1]

$$\left.\begin{aligned}x &= (\lambda\rho_2/3\pi)\varepsilon\\ y &= (\lambda\rho_2/3\pi)\kappa\\ z &= (\lambda\rho_2/3\pi)\varepsilon_a=x-y\end{aligned}\right\} \tag{17}$$

The theoretical values of the parameters $x$, $y$ and $z$ can be calculated according to the Mie theory.[4] The equations expanded in a power series of $\alpha$ and $k_0$ have already been given in a previous paper.[1] Numerical calculations according to these equations have been made for $\alpha=0$ (0.2) 0.8, $m_0=0.50$ (0.05) 1.50 and $k_0=-0.3$ (0.1) 0.3. The $m_0$-values smaller than 1.00 were included because, first, those values may be smaller than unity if $k_1$ is sufficiently greater than $k_2$ (cf. Eq. 9), even when $(\mu_{20}/\mu_{10})$ is greater than unity, and, second, $(\mu_{20}/\mu_{10})$ itself may be smaller than unity in such a case, as when, for examples, bubbles are dispersed in a liquid. The negative $k_0$-values were included because sometimes the medium is colored, as has been mentioned before. The results are shown in Fig. 1 for $x$, in Fig. 2 for $y$, and in Fig. 3 for $z$, although only the results for $m_0=1.50$, 1.00,

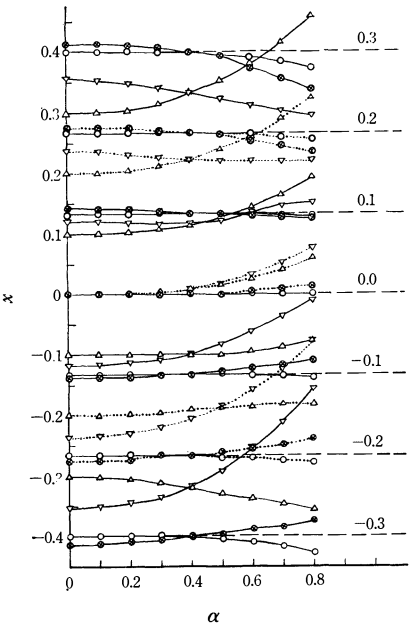

Fig. 1. Relation between $x$ and $\alpha$.
Parameter: $k_0$. $m_0=1.50(\triangle)$, $1.00(\bigcirc)$, $0.8165(\otimes)$ and $0.50(\triangledown)$. $k_0=0$ and $\pm 0.2(\cdots)$; $\pm 0.1$ and $\pm 0.3(—)$

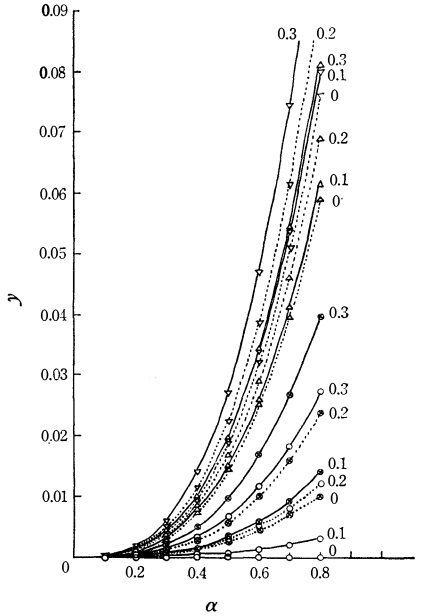

Fig. 2. Relation between $y$ and $\alpha$.
Parameter: $|k_0|$. $m_0=1.50(\triangle)$, $1.00(\bigcirc)$, $0.8165(\otimes)$ and $0.50(\triangledown)$. $|k_0|=0$ and $0.2(\cdots)$, 0.1 and $0.3(—)$

4) G. Mie, *Ann. Phys.*, (4), **25**, 377 (1908).

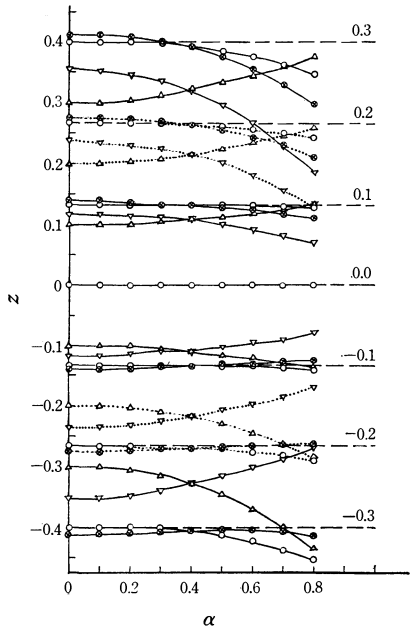

Fig. 3. Relation between $z$ and $\alpha$.
Parameter: $k_0$. $m_0=1.50(\triangle)$, $1.00(\bigcirc)$, 0.8165 ($\otimes$) and $0.50(\triangledown)$. $k_0=0$ and $\pm$ 0.2(···), $\pm$ 0.1 and $\pm$ 0.3(—)

0.8165 (corresponding to the maximum of $\zeta_0$, as will be discussed later) and 0.5 will be shown in order to keep the figures simple. The horizontal broken lines in Figs. 1 and 3 are the limitting values where $m_0$ is 1.00 and $\alpha$ is sufficiently small; that is:

$$\left.\begin{aligned} x(m_0=1.00;\ \alpha=0)=z(m_0=1.00;\ \alpha=0)=(4/3)k_0 \\ y(m_0=1.00;\ \alpha=0)=0 \end{aligned}\right\} \tag{18}$$

When the medium is colorless, these values are equal to the values for the bulk phase of the dispersed material;

$$\left.\begin{aligned} x_2(\text{bulk})=z_2(\text{bulk})=(4/3)\,(\mu_{20}/\mu_{10})k_2 \\ y_2(\text{bulk})=0 \end{aligned}\right\} \tag{19}$$

but when the medium is colored, the limiting value of Eq. 18 is not equal to the values of Eq. 19 for the bulk phase.

After the author had published a previous paper,[1] Chromey[5] made computations based on the exact Mie theory for $\alpha=0.2$ (0.2) 2.0; $m_0=0.50$ (0.25) 3.00, and $k=(k_0/m_0)=0.0$ (0.1) 1.0. The results agree with each other in the range discussed in the present paper as far as comparison is possible, although Chromey never treated the case of $k_0<0$.

The effect of $k_0$ on the quantities $x$, $y$ and $z$

5) F. C. Chromey, *J. Optical Soc. Am.*, **50**, 730 (1960). The symbols $\Omega$, $(\Omega-\Omega')$, $\Omega'$ and $x$ in his paper correspond, respectively, to $x$, $y$, $z$ and $k$ in our notation, although he erroneously states that $\Omega'$ is pure scattering.

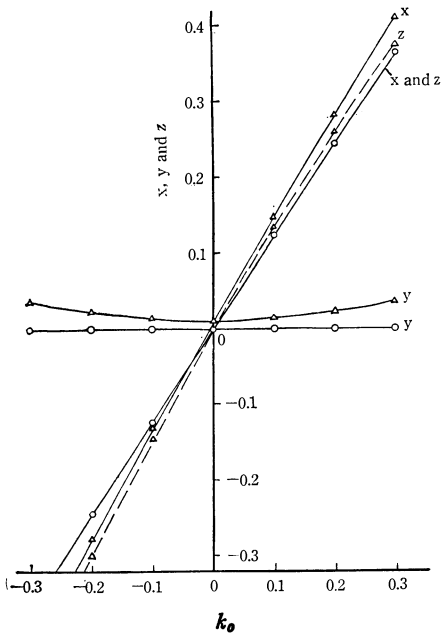

Fig. 4. Relation between $x$, $y$ and $z$ vs. $k_0$
$\alpha=0(\bigcirc)$ and $0.8(\triangle)$; $m_0=1.20$

can be seen from Fig. 4. The figure illustrates the case of $m_0=1.20$, which is close to the $m_0$-values for a polymer latex dispersed in an aqueous solution. In the range of small $k_0$-values, both $x$ and $z$ are approximately linear with regard to $k_0$. The line for $z$ passes the origin, but the line for $x$ does not, because $x$ is the sum of $y$ and $z$, and $y$ is not zero, even when $k_0$ is zero, if $\alpha\neq 0$.

If $k_0$ is small, the value of $z$ is proportional to $k_0$. The proportionality constant, $\zeta$, is defined by:

$$\zeta = \lim_{k_0\to 0}(z/k_0) \tag{20}$$

If there were no effect of scattering, $\zeta$ should be equal to 4/3, as is shown in Eq. 18. The actual

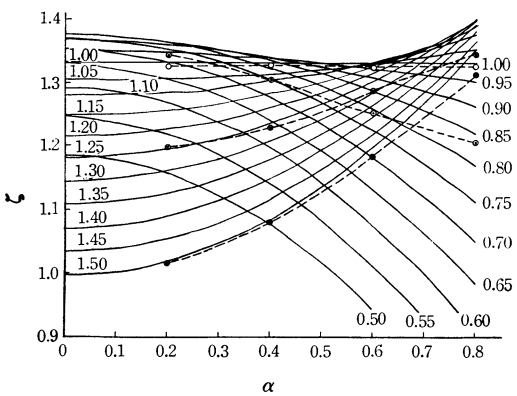

Fig. 5. Relation between $\zeta$ and $\alpha$.
Parameter: $m_0$. Chromey's date for $m_0=0.75$ ($\odot$), $1.00(\bigcirc)$, $1.25(\otimes)$, $1.50(\bullet)$

$\zeta$-value, however, depends on both the relative particle size, $\alpha$, and the relative refractive index, $m_0$, as is shown in Fig. 5. The results of the numerical calculation may be compared with the values obtained by extrapolating Chromey's data.[6] Fairly good agreement is observed, except when $\alpha$ exceeds 0.6. The value of $\zeta$ for very small particles, $\zeta_0$, depends on $m_0$, as is shown in Fig. 6. $\zeta_0$ takes a maximum value ($\zeta_0(\max)=1.377838$)

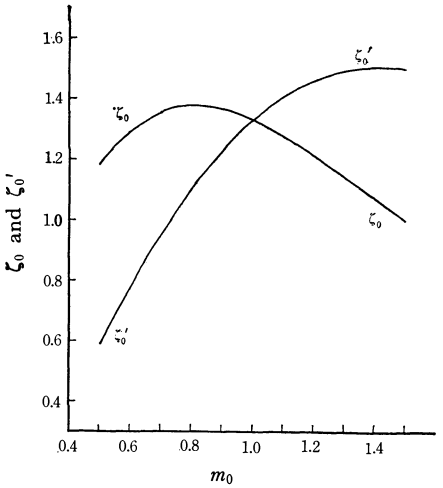

Fig. 6. Relation between $\zeta_0$ and $\zeta_0'$ vs. $m_0$.

at $m_0=\sqrt{2/3}$. Sometimes the quantity $k$, instead of $k_0$, is taken as the variable. Then:

$$\zeta_0' = \lim_{\substack{k\to 0 \\ \alpha\to 0}} (z/k) \tag{21}$$

should be used instead of $\zeta_0$. The value of $\zeta_0'$, too, is shown in Fig. 6, which takes a maximum value ($\zeta_0'(\max)=3/2$) at $m_0=\sqrt{2}$. The values of $\zeta_0$ and $\zeta_0'$ are the same and are equal to 4/3 at $m_0=1$, since $k_0=m_0k$.

The scattering (expressed by the quantity $y$ as has already been shown in Fig. 2) is proportional to the cube of the relative particle radius, as far as the present approximation is concerned.

$$y = Y\alpha^3 \tag{22}$$

The coefficient $Y$ depends on both $m_0$ and $k_0$, as is shown in Fig. 7, and its value is the greater, the greater $|m_0-1|$ is and the greater $|k_0|$ is. The scattering is, thus, caused by the refraction and absorption. The $Y$-value for $k_0=0$ is considered to represent the scattering caused by the refraction and is expressed by $Y_m$, while the $Y$-value for $m_0=1$ is considered to represent the scattering caused by the absorption and is expressed by $Y_k$. The actual $Y$-value is, however, not equal to the sum of $Y_m$ and $Y_k$; a cross term, $Y_{mk}$, is also required.

$$Y = Y_m+Y_k+Y_{mk} \tag{23}$$

6) His data for $m_0=1.25$, $k=0.2$ and $\alpha=0.2$ are in error. These values were, therefore, disregarded in the extrapolation.

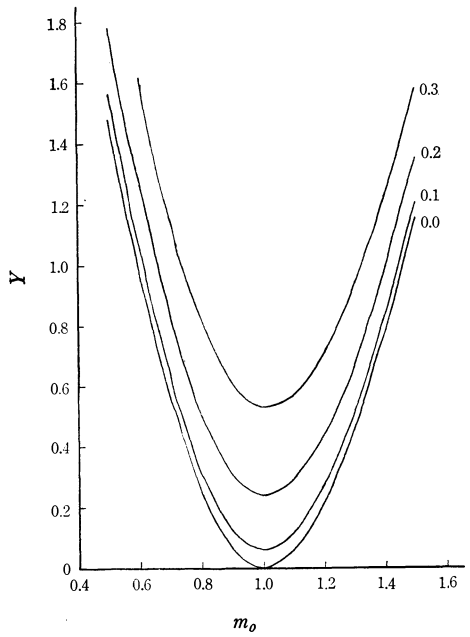

Fig. 7. Relation between $Y$ and $m_0$. Parameter: $|k_0|$

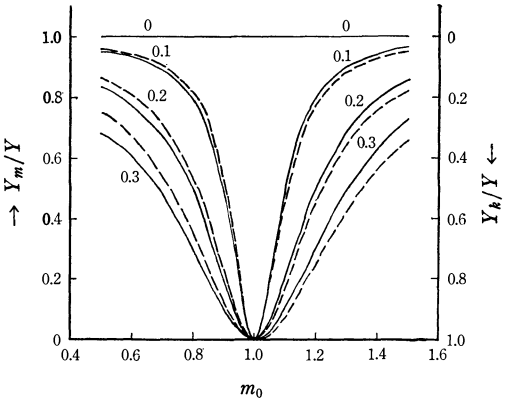

Fig. 8. Dependence of $Y_m/Y(-)$ and $Y_k/Y(\cdots)$ on $m_0$. Parameter: $|k_0|$

In Fig. 8, the ratio $Y_m/Y$ (solid lines) is shown on the left ordinate in an upward direction, while the ratio $Y_k/Y$ (broken lines) is shown on the right ordinate in a downward direction. It may be seen from Fig. 8 that the cross term, $Y_{mk}$, is negative when $m_0>1$ and positive when $m_0<1$. The value of $Y_{mk}/Y$ is not large, although it is not equal to zero except when $m_0=1$ or $k_0=0$.

**The Refractive Index of the Dispersed System.**—It has been well established experimentally that the refractive index of a dispersed system, $\mu_{12}$, is linear to the concentration, $c$, (g./ml.), at least within the concentration range of the usual experimental conditions. This can be explained by the mixture rule:

$$\mu_{12} = \mu_{10}\varphi_1 + \mu_{20}'\varphi_2 \quad (24)$$

because the rule yields the following equation, which states that $\partial\mu_{12}/\partial c$ is constant:

$$\partial\mu_{12}/\partial c = (\mu_{20}'-\mu_{10})/\rho_2 \quad (25)$$

where $\varphi_1$ and $\varphi_2$ are the volume fractions of the medium and the dispresed phase respectively, and where $\rho_2$ is the density of the dispersed phase. The apparent refractive index of the particle $\mu_{20}'$ is, however, not equal to the refractive index of the dispersed phase, $\mu_{20}$ (the real part of the complex refractive index as defined by Eq. 2) because the refractive index is affected by light scattering, as has already been stated by the author and Heller.[7]

The value of the apparent relative refractive index

$$m' = \mu_{20}'/\mu_{10} \quad (26)$$

can be calculated on the basis of the Mie theory, as has been stated in previous papers.[2,7] In the case of $\alpha \ll 1$ and $|k_0| \ll m_0$, the equation was expanded in a power series of $k_0$ and the coefficients of the power series were expressed[2] as known functions of $m_0$ and $\alpha$. Numerical calculation has been made for $\alpha=0$ (0.1) 0.8, $m_0=0.85$ (0.05) 1.50 and $k_0=-0.3$ (0.1)$+0.3$. The $m_0$-values smaller than unity and the negative $k_0$-values were included in order to consider the case where the medium is colored. Only some of the results, for $k_0=-0.3$, 0 and $+0.3$, are shown in Fig. 9 in order to keep the figure simple. When $k_0$ is equal to zero, or when the system is colorless, the value of $m'$ increases[8] with the $\alpha$, and the increment is the greater, the greater $|m_0-1|$ is. When $k_0$ is not equal to zero, or when the system is colored, the value of $m'$ increases or decreases with $\alpha$, depending on the values of $m_0$ and $k_0$. When $\alpha$ approaches zero, the value of $m'$ depends on the absolute value of $k_0$. When $\alpha$ is not so small, the value of $m'$ depends not only on the absolute value but also on the sign of $k_0$. If $k_0$ is so small that the term $k_0^2$ can be neglected, then:

$$m' = m_0'(1-fk_0) \quad (27)$$

where $m_0'$ is the $m'$-value for $k_0=0$. The value of the coefficient $f$ is shown in Fig. 10. The value of $f$ is positive for $m_0>1$ and negative for $m_0<1$, and the absolute value of $f$ increases with the $\alpha$.

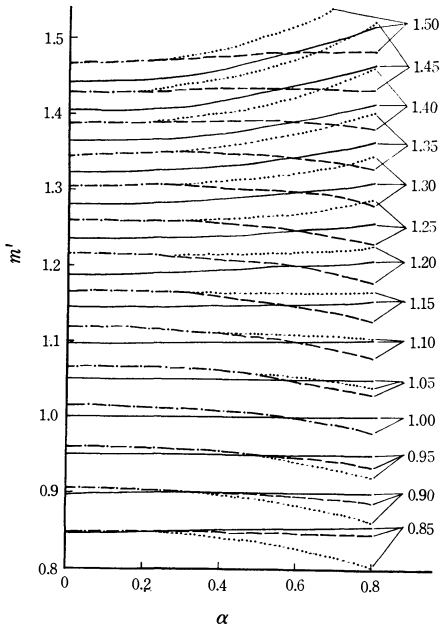

Fig. 9. Relation between $m'$ and $\alpha$.
Parameter: $m_0$. $k_0=+0.3$(---), 0(—), $-0.3$(···)

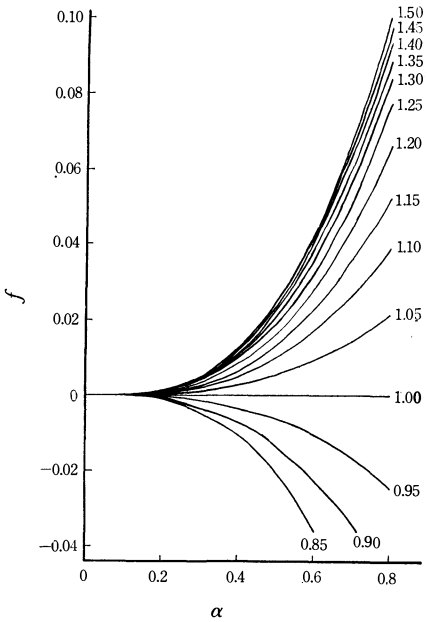

Fig. 10. Relation between $f$ and $\alpha$.
Parameter: $m_0$

**A Note on the Usual Experimental Conditions for the System of a Colored Medium.**— The value of $k_0$ may be very large if the particles are colored. It may even be infinitely large if the particles are made of a good conductor, but the extinction of the dispersed system as a whole can be made as small as possible in experimental work by diluting the dispersed system. If, however, the medium is colored and the particles are colorless, the absolute value of $k_0$ cannot be very large, because a certain detectable amount of light must pass through the layer of the dispersed system. If $k_0$ is not small, an extremely strong light source is needed.

Considering a layer of a colored medium, the value of, for example, $k_1=0.76\times10^{-4}$ is obtained

7) M. Nakagaki and W. Heller, *J. Appl. Phys.*, **27**, 975 (1956).

8) The value of $m'$ passes a maximum point when $\alpha$ increases further. (Cf. Ref. 7)

according to Eq. 3, if the optical density $-\log(I_1'/I_0')$ is 3.00, the layer thickness is 0.30 cm., the refractive index of the medium is $\mu_{10}=1.333$ (water), and the wavelength of the light is $\lambda_0=555\,\mathrm{m}\mu$ (the most sensitive wavelength for the human eye). This gives the result that $k_0=-0.91\times10^{-4}$ if $k_2=0$ and if $\mu_{20}/\mu_{10}=1.20$. Therefore, extremely small $k_0$-values are interesting experimentally.

The scattered-light intensity of a colored colloidal system, of course, decreases by the term $\exp.(-E_0l)$ according to the Lambert law, where $l$ is the path length of light in the colloidal system. However, after this decrease in light intensity ash been corrected properly, the scattered-light intensity of a colored colloidal system should be almost exactly equal to that of a colorless system which has the same $m_0$ and $\alpha$ values. This is obvious because, according to Fig. 4, the $x$, $y$ and $z$ values for such small $k_0$ value as $10^{-4}$ are practically equal to those for $k_0=0$. According to Eq. 27 and the $f$ value shown in Fig. 10, it is obvious that the value of the refractive index of the colored system is also practically equal to that of the colorless system if $k_0$ is as small as $10^{-4}$.

## Summary

In the expression of the complex refractive index of a colored colloidal system ($m=m_0-ik_0$), the value of $m_0$ may be smaller than unity and $k_0$ may be negative if the medium is colored. Including these cases, the values of $x$ (corresponding to the optical density), $y$ (scattering) and $z$ (absorption) have been calculated for relatively small $\alpha$ and $k_0$ values. The values of the apparent relative refractive index, $m'$, have been calculated also. These results have been discussed in detail in order to show the effect of the scattering and absorption on the scattering, absorption and apparent refractive index. It has been concluded that the data of a system in which colorless particles are dispersed in a colored medium will be practically equal to those in a colorless medium if the extinction of light according to the Lambert law is corrected properly.

# The Determination of Micro Amounts of Polythionates. II.* A Photometric Method for the Determination of Hexathionate by Means of Its Cyanolysis[1]

By Tomozo Koh and Iwaji Iwasaki

(Received May 18, 1965)

In the preceding paper[2] of this series, the methods in current use for analyzing polythionates have been reviewed. So far, there has not been any procedure for the determination of micro quantities of hexathionate. One of the present authors (T. K.)[2] has, however, reported an excellent method for the determination of a small amount of pentathionate, a method which depends upon the reaction:

$$S_5O_6^{2-}+4CN^-+H_2O=$$
$$S_2O_3^{2-}+SO_4^{2-}+2HCN+2SCN^-$$

followed by the photometric measurement of the thiocyanate thus formed with ferric iron. The above study establishes the feasibility of a method for the determination of hexathionate, because the higher polythionate, hexathionate, reacts more easily with cyanide to form thiocyanate.

The present authors have investigated, in detail, a photometric method for the determination of a micro amount of hexathionate, a method which is based on the reactions:

$$S_6O_6^{2-}+5CN^-+H_2O=$$
$$S_2O_3^{2-}+SO_4^{2-}+2HCN+3SCN^-$$
$$SCN^-+Fe^{3+}=FeSCN^{2+}$$

they have established an excellent method, finding the most suitable conditions for the reaction of hexathionate with cyanide to proceed completion by varying the cyanide amount, the pH, the reaction time, and the temperature.

In the present investigation, it was observed that hexathionate also is quantitatively converted

* Part I: This Bulletin, **38**, 1510 (1965)

2) T. Koh, This Bulletin, **38**, 1510 (1965).

into thiocyanate under the same conditions as are used for the determination of pentathionate.

The proposed method is sufficiently rapid, precise, and accurate to be used for the determination of a small amount of hexathionate.

## Experimental

**Apparatus and Materials.**—Unless stated particularly, the apparatus and materials used in this investigation are the same as those described in the previous paper.[2]

*Potassium Hexathionate.*—This salt was prepared according to the directions of Goehring and Feldmann.[3] The hexathionate obtained was then recrystallized twice with 2 N hydrochloric acid and dried at room temperature for 6 days.

In order to obtain pure hexathionate, it is of great importance to recrystallize the raw hexathionate as fast as possible, because it undergoes thermal decomposition easily, even in a strong acid solution. In the present study, much purer hexathionate could be obtained than that described in the literature (96%).[3]

The water content physically adsorbed on the hexathionate was estimated to be 1.2% by the Karl Fischer method.

*The Purity of the Potassium Hexathionate.*—The purity of this salt was estimated by determining the total potassium and sulfur contents as follows.

The potassium hexathionate was decomposed into potassium sulfate by heating it at around 800°C; $K_2S_6O_6 \rightarrow K_2SO_4$. The potassium was determined by weighing[4] the potassium sulfate thus formed.

As for the sulfur, the hexathionate was oxidized[4,5] by bromine in an alkaline medium on heating and, the sulfate ion content formed was determined by the usual gravimetric method. Tables I and II show that

Table I. Determination of K for the potassium hexathionate* used in the present study

Table II. Determination of S for the potassium hexathionate* used in the present study

| Sample taken mg. | As $K_2S_6O_6$ mg. | Found as $BaSO_4$ mg. | S found for $K_2S_6O_6$ % | S calcd. for $K_2S_6O_6$ % |
|---|---|---|---|---|
| 212.0 | 209.4 | 796.1 | 52.22 | 52.48 |
| 173.4 | 171.3 | 651.0 | 52.20 | |

* Water content was estimated to be 1.2%.

the results obtained are within the limits of experimental error and that this potassium hexathionate is pure enough for the purposes of this study.

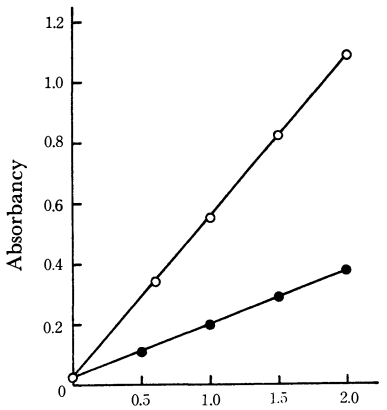
5) C. Mishima, *Bull. Tokyo Inst. Tech.*, No. 1, 27 (1951).

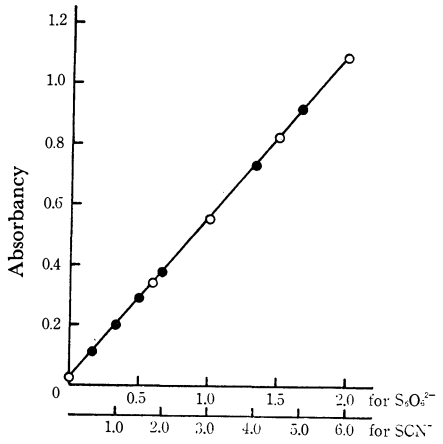
*The Standard Hexathionate Solution.*—The standard solution, a $1.0 \times 10^{-3}$ M concentration of hexathionate, was prepared by dissolving 185.6 mg. of the potassium hexathionate (water content: 1.2%) in redistilled water and by then diluting it to 500 ml. This stock solution proved to be stable; even after two months, no measurable change was found by the present method when it was kept at 5±2°C in a refrigerator. The working standard solutions were prepared by then diluting this stock solution properly.



**Procedure.**—A standard hexathionate solution of 10.0 ml. is placed in a 25 ml. volumetric flask. To this solution are added first 4.0 ml. of the buffer solution of pH 7.4, and then 2.6 ml. of 0.05 M sodium cyanide, whereupon the pH of the solution is brought to 8.6.

The volumetric flask is kept in the thermostat at 40±1°C for 30 min.; hexathionate is thus converted into thiocyanate quantitatively. Then 3.0 ml. of a 1.5 M ferric nitrate - perchloric acid solution is added. After the flask has been filled to the mark with redistilled water, its contents are mixed well. The absorbancy of the solution of the ferric-thiocyanate complex thus formed is measured at the wavelength of 460 mμ, using distilled water as a reference.

## Results and Discussion

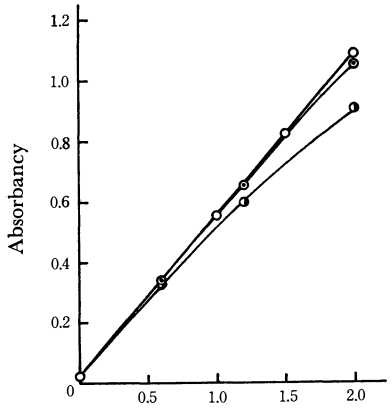


**Calibration Curves.**—The solutions containing various amounts of hexathionate and thiocyanate were treated by the procedure mentioned above; the experimental results are plotted in Figs. 1 and 2.

As can be seen in Figs. 1 and 2, the absorbancy and concentration were in a good linear relationship. When one ion of hexathionate undergoes cyanolysis, three ions of thiocyanate are formed. Consequently, if the hexathionate is pure enough and if it is, moreover, converted into thiocyanate quantitatively, the sensitivity of hexathionate should be just three times as high as that of thiocyanate when plotted by the mole concentration for hexathionate and thiocyanate. In fact, Fig. 1 shows that the calibration curve for hexathionate is three

Concn. of $S_6O_6^{2-}$ and $SCN^-$, $\times 10^{-4}$ M

Fig. 1. Calibration curves.
○ Hexathionate ● Thiocyanate



Concn. of $S_6O_6^{2-}$ and $SCN^-$, $\times 10^{-4}$ M

Fig. 2. Calibration curves.
○ Hexathionate ● Thiocyanate

times as sensitive as that for thiocyanate. As can also be seen in Fig. 2, the calibration curve of hexathionate exactly coincides with that of thiocyanate when the scale of the thiocyanate concentration is made one-third of that of the hexathionate concentration, demonstrating that the stoichiometric reaction has occurred.

**The Effect of the Amount of Sodium Cyanide.**—The preliminary experiments led the authors to the conclusion that pH has a great effect on the cyanolysis and that hexathionate, just like pentathionate,[2] undergoes a partial alkaline decomposition as a result of the higher pH caused by the addition of the cyanide.

As will be described below, it was observed that the optimum pH for the reaction of hexathionate with cyanide is over the range of 7.8 to 8.9 under the conditions of the preceding procedure. 0.5 ml. of 0.025 M sodium cyanide and 0.5 to 4.0 ml. of 0.05 M sodium cyanide were employed, and in all cases the solution was buffered to the optimum pH value. The resulting effect of the amount of sodium cyanide on the cyanolysis is shown in Fig. 3.

Concn. of hexathionate, $\times 10^{-4}$ M

Fig. 3. Effect of sodium cyanide amount. The pH was adjusted to the range from 7.8 to 8.9 in all cases.
Cyanolysis time: 30 min. at 40°C
◑ 0.025 M NaCN 0.5 ml. (I)
⊙ 0.05 M NaCN 0.5 ml. (II)
○ 0.05 M NaCN 1.0, 2.0, 2.6 and 4.0 ml. (III)

The calibration curves with 0.5 ml. portions of 0.025 and 0.05 M sodium cyanide solutions do not form straight lines (see I and II), indicating that hexathionate is not quantitatively converted into thiocyanate because of insufficient amounts of cyanide. It can be concluded from Fig. 3 that 1.0 ml. of a 0.05 M sodium cyanide solution is sufficient for the quantitative conversion of hexathionate into thiocyanate, and that the amount of sodium cyanide does not have any effect on the method, so long as it is sufficient and the pH is adjusted to an optimum value.

**The Effect of pH.**—At higher pH levels, hexathionate undergoes an alkaline decomposition besides cyanolysis; therefore, the procedure should be carried out below a pH value of 8.9. Figure 4 shows the dependence of the rate of cyanolysis on the pH of the solution at 20°C.

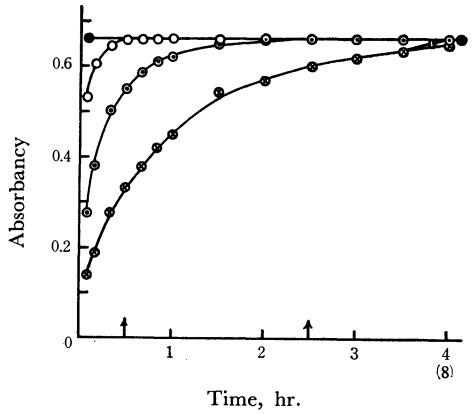


Fig. 4. Effect of pH on the rate of cyanolysis at 20°C.
● $3.6\times10^{-4}$ M $SCN^-$
○ pH 8.7 (I)
⊙ pH 8.0 (II) } $1.2\times10^{-4}$ M $S_6O_6^{2-}$
⊗ pH 7.5 (III)

The maximum absorbancy, which corresponds to the complete and stoichiometric reaction of hexathionate with cyanide, is reached in 30 min. at pH 8.7; it then remains constant (see I), while the reaction at pH 8.0 goes to completion in two hours and a half (see II). On the other hand, the reaction at pH 7.5 does not go to completion even within 4 hr.; however, it goes stoichiometrically to completion in 8 hr. (see III).

In order to accelerate the rate of cyanolysis, the reaction temperature was raised from 20°C to 40°C and 70°C. Figure 5 shows how the pH

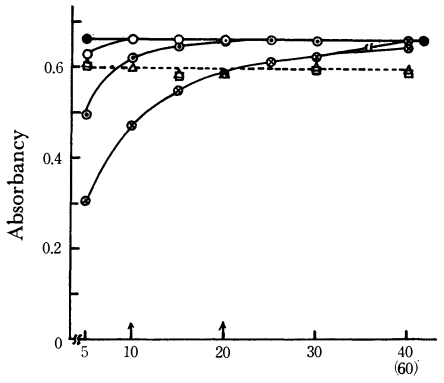

Fig. 5. Effect of pH on the rate of cyanolysis.
—●— $3.6\times10^{-4}$ M $SCN^-$
—○— pH 8.7 (I) } at 40°C
—⊙— pH 8.0 (II) } at 40°C
—⊗— pH 7.5 (III) } at 40°C
--△-- pH 8.7 (IV) } at 70°C
--□-- pH 8.0 (IV) } at 70°C
$1.2\times10^{-4}$ M $S_6O_6^{2-}$

of the solution affects the rate of cyanolysis at 40°C and 70°C.

At 40°C, the reaction goes well to completion and is stoichiometric in 10 min. at pH 8.7 (see I), while the reactions at pH 8.0 and 7.5 go to completion in 20 min. and 1 hr. respectively (see III). At 70°C, the thermodecomposition occurs in addition to cyanolysis, so hexathionate is not completely converted into thiocyanate (see IV).

The reaction of hexathionate with cyanide at various pH values was carried out, both at 20°C for 60 min. and at 40°C for 30 min., for the purpose of studying the effect of pH on the cyanolysis. The results are shown in Fig. 6, where the reaction

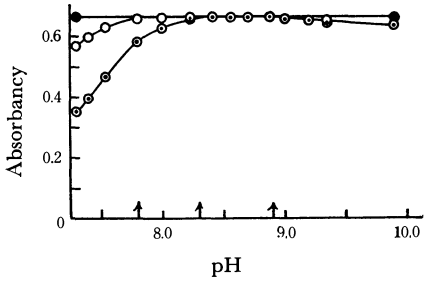

Fig. 6. Effect of pH.
● $3.6\times10^{-4}$ M $SCN^-$
○ 30 min. at 40°C (II) } $1.2\times10^{-4}$ M $S_6O_6^{2-}$
⊙ 60 min. at 20°C (I) }

at 20°C for 60 min. gives maximum absorbancies over the pH range from 8.9 to 8.3 (see I), and that at 40°C, for 30 min. over the pH range from 8.9 to 7.8 (see II). The decrease in absorbancy above the pH value of 9.0 may be attributed to the alkaline decomposition of hexathionate. The optimum pH range for the stoichiometric reaction can be extended from both 7.8 and 8.3 to a lower pH value by making the cyanolysis time longer, because the rate of cyanolysis decreases with the lowering of the pH.

A similar method which is available for the determination of micro amounts of tetrathionate under the same conditions as those used here for the determination of pentathionate and hexathionate will be reported on in another paper.

## Summary

A photometric method for the determination of a small amount of hexathionate has been developed, a method depending on the formation of thiocyanate equivalent to the hexathionate, and on the determination of thiocyanate with an excess of ferric iron. A buffer solution is first added to a standard hexathionate solution in order that the pH of the mixed solution after the addition of the cyanide solution may be within an optimum range; otherwise the hexathionate undergoes alkaline decomposition as a result of the higher pH value caused by the addition of the cyanide. The conditions under which the reaction of hexathionate with cyanide is rapid and proceeds well to completion, have been established by varying the cyanide amount, the pH, the reaction time, and the temperature. Hexathionate can be determined by exactly the same procedure as that used for phentathionate.

The authors wish to thank Dr. Satori Utsumi of Nihon University, and Mr. Takejiro Ozawa and Dr. Minoru Yoshida of the Tokyo Institute of Technology, for their many valuable discussions and suggestions during the course of this study. Thanks are also due to Dr. Kaname Muroi, Central Research Laboratory of the Mitsubishi Chemical Industries, Ltd., for estimating the water content in the hexathionate by the Karl Fischer method.

# Studies of Peptide Antibiotics. III. Cyclo-(L-valyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl)$_2$[1]

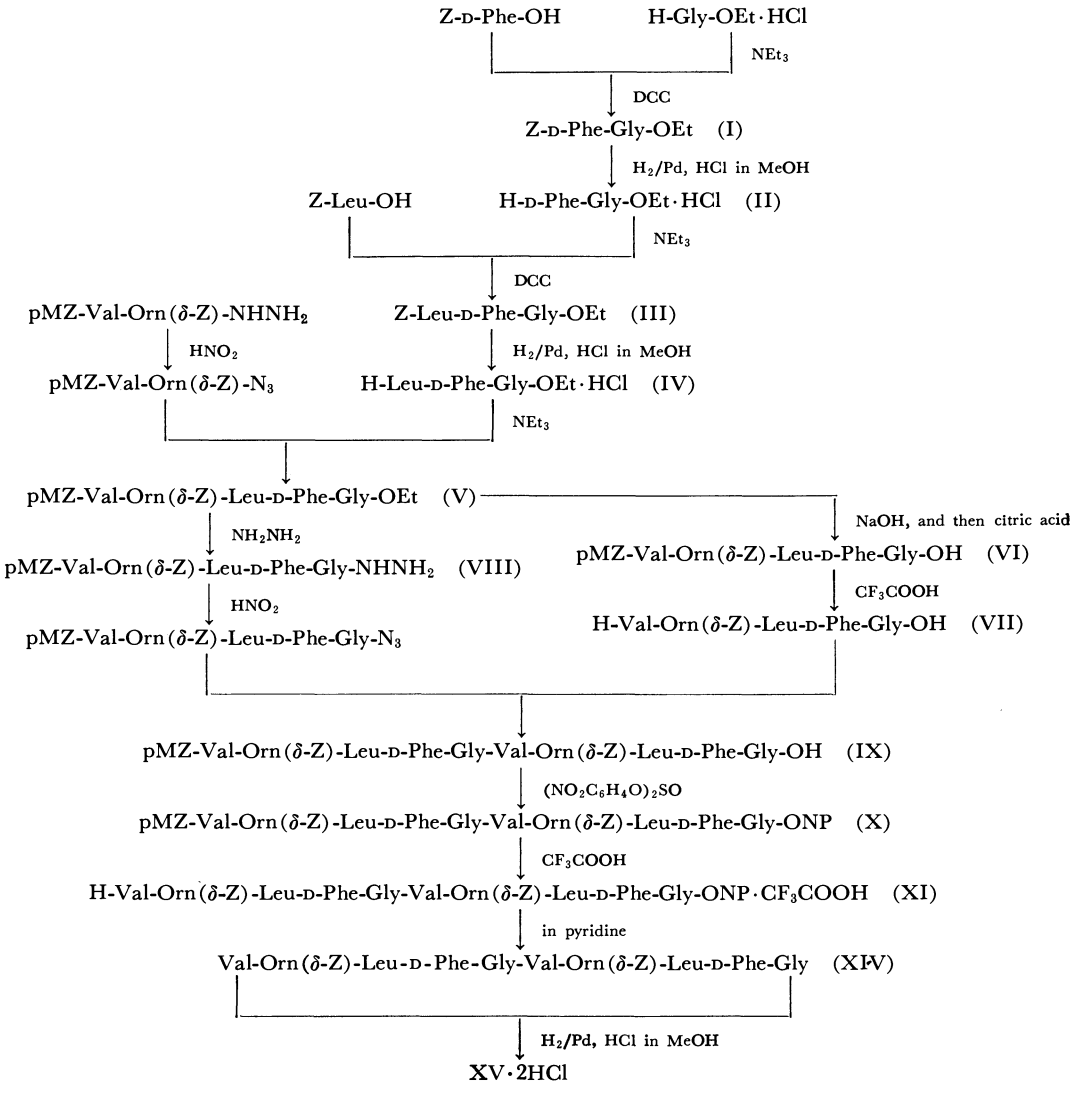
By Haruhiko Aoyagi, Tetsuo Kato, Motonori Ohno, Michio Kondo
Michinori Waki, Satoru Makisumi and Nobuo Izumiya

(Received May 24, 1965)

Certain peptide antibiotics, such as gramicidin S,

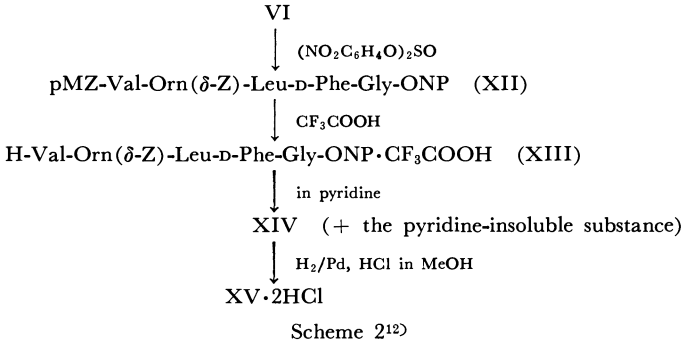
L-Val-L-Orn-L-Leu-D-Phe-L-Pro
↑ ↓
L-Pro-D-Phe-L-Leu-L-Orn-L-Val
Gramicidin S

possess several characteristic features in common. These features include a cyclic structure, D-amino acid residues, and a basic character due to the presence of diamino acid residues. The necessity of a cyclic structure for antibacterial activity is indicated by the finding that the activity of a synthetic linear decapeptide, with the same sequence of amino acid residues as that found in gramicidin S, is markedly less than that of gramicidin S.[2] In a previous paper from this laboratory,[3] a cyclic hexapeptide, cyclo-L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolyl-glycyl, which contains a partial sequence found in gramicidin S, was prepared and its antibacterial activity was tested. The cyclic hexapeptide was, however, found to be devoid of antibacterial activity. Recently, another cyclic hexapeptide, cyclo-L-valyl-D-ornithyl-L-prolyl-D-phenylalanyl-D-leucyl-L-ornithyl, has been synthesized; it also was found to possess no antibacterial activity.[4] From these findings, it appears that, in addition to the characteristics mentioned above, other structural features, such as a ring size larger than that of the cyclic hexapeptide and/or specific amino acid sequence, are necessary in this type of molecule for an activity to be exhibited. Therefore, it became of interest to examine the effect on bacterial growth of a larger synthetic cyclic peptide than the cyclic hexapeptide.



Syntheses of relatively large cyclic peptides have been reported from several laboratories in recent years. Cyclic hepta-[5] and octapeptide[6] related to polymyxin have been synthesized from the respective linear peptide via the carbodiimide. However, cyclic decapeptides have generally been obtained in better yields from the respective linear decapeptide active ester.[7,8] Furthermore, the cyclization reaction of linear pentapeptide active esters, wherein proline residues are C-terminuses, gave cyclic decapeptide in good yields by the dimerization reaction.[9,10] For these reasons, we have decided to attempt the synthesis of a cyclic decapeptide with the appropriate amino acid sequence.

It is well known that, in many polypeptides, a proline residue causes a kink in a peptide chain.[11] It has been reported that, in gramicidin S, the presence of proline might facilitate the formation of a stable conformation.[10] Therefore, it appeared of interest to synthesize an analog (XV) of the cyclic decapeptide gramicidin S, wherein proline residues are replaced by glycines, in order to determine to what degree the proline side chains contribute to the biological activity.



L-Val-L-Orn-L-Leu-D-Phe-Gly
↑ ↓
Gly-D-Phe-L-Leu-L-Orn-L-Val
XV

The reaction sequences employed for the synthesis of XV are shown in Schemes 1 and 2. The cyclic benzyloxycarbonyl-substituted decapeptide (XIV) was obtained both by the cyclization reaction of the decapeptide active ester (XI) (Scheme 1) and by the dimerization reaction of the pentapeptide active ester (XIII) (Scheme 2). It was found that the yield of XIV by the cyclization of XI was satisfactory, but that that by the dimerization reaction was only 10—15%, because a considerable amount of the unidentified pyridine insoluble product was formed. It should be noted that Schwyzer and Sieber, by the dimerization reaction, obtained tosyl-substituted gramicidin S in a satisfactory yield for the pertinent pentapeptide active ester, wherein a proline residue is the C-

Scheme 1[12]

Scheme 2[12]

12) The abbreviations used are: pMZ, *p*-methoxybenzyloxycarbonyl; Z, benzyloxycarbonyl; DCC, dicyclohexylcarbodiimide; ONP, *p*-nitrophenoxy ester. An amino acid residue except Gly and D-Phe is of L-configuration.

terminus.[10] The final product (XV) was obtained as colorless crystals with six moles of the water of crystallization, and its homogeneity was demonstrated by chromatography in many solvent systems.

The cyclic decapeptide (XV) was found to be much more active than gramicidin S against *B. subtilis* in a synthetic medium (Table I). This finding shows that the replacement of the proline residues by glycines in the sequence of gramicidin S does not reduce the activity, demonstrating that not all the original amino acid sequences in the natural peptide are necessary for the full activity; e.g., the side chain of proline is not required. It should be noted that homo-gramicidin S, wherein the ornithine residues are replaced by lysines, exhibits an activity nearly equal to that of the natural gramicidin S.[10] On the other hand, it appears that the valine residues in gramicidin S are of importance in the activity.[13]

In order to extend further the study of the relationship between the chemical structure and the biological activities of peptide antibiotics, experiments on the preparation of and studies in the properties of several cyclic and linear peptides are in progress in this laboratory.

## Experimental

All melting points are uncorrected.

**Benzyloxycarbonyl-D-phenylalanylglycine Ethyl Ester (I).** — To a solution of benzyloxycarbonyl-D-phenylalanine (2.99 g.) and glycine ethyl ester hydrochloride (1.40 g.) in chloroform (40 ml.), triethylamine (1.4 ml.) and dicyclohexylcarbodiimide[14] (2.06 g.) were added at 0°C. After it had been permitted to stand overnight at 0°C, the mixture was evaporated in vacuo, the residue diluted with ethyl acetate (50 ml.), and the dicyclohexylurea formed was filtered off. The filtrate was washed successively with 4% sodium bicarbonate, 3% hydrochloric acid, and water and dried over anhydrous sodium sulfate. The filtered solution was evaporated in vacuo. The residual oil solidified after ether and petroleum ether had been added. Recrystallization from ethyl acetate - petroleum ether gave 3.18 g. (83%); m. p. 109—110°C; $[\alpha]_D^{18}$ +20.5° (*c* 2, methanol).

Found: C, 65.86; H, 6.56; N, 7.33. Calcd. for $C_{21}H_{24}O_5N_2$: C, 65.61; H, 6.29; N, 7.29%.

This compound had been previously obtained by the acid chloride method; m. p. 109—111°C.[15]

**D-Phenylalanylglycine Ethyl Ester Hydrochloride (II).**—I (2.69 g.) was subjected to hydrogenolysis in the presence of palladium black and 0.31 N methanolic hydrogen chloride (24.8 ml.). The filtrate from the catalyst was then evaporated to dryness in vacuo. The product was obtained as a hygroscopic powder; yield, 2.01 g. (100%); $R_f$ 0.88[16] and 0.74[17].

**Benzyloxycarbonyl-L-leucyl-D-phenylalanylglycine Ethyl Ester (III).**—Benzyloxycarbonyl-L-leucine (1.86 g.) was coupled with II (2.01 g.) by dicyclohexylcarbodiimide (1.44 g), following the procedure described for the preparation of I. Recrystallization from ethyl acetate - ether gave 2.79 g. (80%); m. p. 122—124°C; $[\alpha]_D^{25}$ +13.0° (*c* 2, methanol).

Found: C, 64.75; H, 7.07; H, 7.07; N, 8.33. Calcd. for $C_{27}H_{35}O_6N_3$: C, 65.17; H, 7.09; N, 8.45%.

**L-Leucyl-D-phenylalanylglycine Ethyl Ester Hydrochloride (IV).**—III (1.99 g.) was subjected to hydrogenolysis in the presence of palladium black and 0.46 N methanolic hydrogen chloride (9.6 ml.), and then treated as described in the preparation of II. Yield of oily product: 1.61 g. (100%); $R_f$ 0.90[16] and 0.77[17].

***p*-Methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycine Ethyl Ester (V).**—The following operations were carried out in a cold room. Into a chilled solution of *p*-methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithine hydrazide[3] (0.98 g.) in glacial acetic acid (12 ml.), N hydrochloric acid (4 ml.) and sodium nitrite (136 mg.) in water (2 ml.) were stirred. After 6 min., cold water (100 ml.) was added to the solution. The azide which precipitated as a white mass was collected by filtration and washed with water, 4% sodium bicarbonate, and water, and then dried under a vacuum in a desiccator. The azide was added to a solution of IV (0.72 g.) and triethylamine (0.25 ml.) in dimethylformamide (20 ml.), and then the mixture was stirred for 3 days at 0°C. The precipitate which formed upon the addition of water (300 ml.) to the solution was collected, washed with 4% sodium bicarbonate, 0.5 M citric acd and water, and dried. The product was recrystallized from dioxane-ether; yield, 1.30 g. (83%); m. p. 206—208°C; $[\alpha]_D^{25}$ −23.5° (*c* 1, acetic acid); $R_f$ 0.87.[17]

Found: C, 63.02; H, 7.15; N, 9.94. Calcd. for $C_{46}H_{62}O_{11}N_6$: C, 63.14; H, 7.14; N, 9.61%.

***p*-Methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycine (VI).**—To a solution of V (872 mg.) in a mixture of methanol (50 ml.) and dioxane (20 ml.), N sodium hydroxide (1.5 ml.) was added; the solution was then allowed to stand overnight at room temperature. After the addition of 0.5 M citric acid (6 ml.) under cooling, the solution was concentrated in vacuo at low temperature, and the residue was treated with water (100 ml.). After they had been stored in a refrigerator, the crystals were collected by filtration, washed with water, and dried. Recrystallization from dioxane-ether gave 712 mg. (84%) of VI; m. p. 214—215°C; $[\alpha]_D^{25}$ −21° (*c* 1, acetic acid); $R_f$ 0.82.[17]

Found: C, 61.95; H, 6.88; N, 10.00. Calcd. for $C_{44}H_{58}O_{11}N_6$: C, 62.39; H, 6.90; N, 9.92%.

16) The $R_f$ of the paper chromatography with Toyo Roshi No. 52 refers to the *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2, v./v.) system.

17) The $R_f$ of the thin layer chromatography with Merck silica gel G refers to the *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2, v./v.) system. Compounds possessing a free amino group were detected by spraying with ninhydrin, and those with blocked amino groups, by spraying with 47% hydrobromic acid, and then ninhydrin.

**L-Valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycine (VII).**—To a mixture of VI (434 mg.) and anisole (0.16 ml.) trifluoroacetic acid (2 ml.) was added at 0°C.[18] After being permitted to stand for 20 min. at 0°C, the solution was evaporated in vacuo. The residue was triturated with ether (20 ml.) and washed repeatedly with ether by decantation. The residual crystals were dissolved in water. After triethylamine (1 ml.) had been added, the solution was evaporated to dryness in vacuo. The crystalline product was collected by filtration with the aid of water; yield, 260 mg. (76%); m. p. 191—192°C; $[\alpha]_D^{25}$ −4.2° (*c* 1, acetic acid); $R_f$ 0.85.[17]

Found: C, 60.96; H, 7.37; N, 12.05. Calcd. for $C_{35}H_{50}O_8N_6 \cdot 1/2H_2O$; C, 60.76; H, 7.43; N, 12.15%.

***p*-Methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenyalanylglycine Hydrazide (VIII).**—To a solution of V (440 mg.) in dimethylformamide (4 ml.) hydrazine hydrate (0.5 ml.) was added; the solution was allowed to stand for 2 days at room temperature. The reaction mixture was evaporated in vacuo. The hydrazide which precipitated upon the addition of water (20 ml.) was filtered, washed with water, and dried. It was recrystallized from methanol-ethyl acetate-ether; yield, 372 mg. (87%); m. p. 217—219°C; $[\alpha]_D^{25}$ −20° (*c* 1, acetic acid); $R_f$ 0.91.[17]

Found: C, 60.84; H, 7.15; N, 12.89. Calcd. for $C_{44}H_{60}O_{10}N_8$: C, 61.38; H, 7.02; N, 13.02%.

***p*-Methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycine (IX).**—Into a solution of VIII (345 mg.) in dimethylformamide (7 ml.), N hydrochloric acid (1.2 ml.) and sodium nitrite (30 mg.) in water (0.5 ml.) were stirred. After 5 min., cold water (100 ml.) was added to the solution. The azide which precipitated was filtered and treated as described in the preparation of V. The azide was added to a solution of VII (273 mg.) in a mixture of dimethylformamide (8 ml.) and triethylamine (0.055 ml.), and then the mixture was stirred for 3 days at 0°C. The insoluble material was removed by by filtration, and the filtrate was concentrated in vacuo. The precipitate which was formed upon the addition of ethyl acetate (10 ml.) and ether (4 ml.) to the concentrated filtrate was collected, washed with 0.5 M citric acid and water, and dried. Recrystallization from dimethylformamide-ethyl acetate-ether did not raise the melting point. The yield was 495 mg. (82%); m. p. 253—257°C; $[\alpha]_D^{25}$ −48° (*c* 0.5, acetic acid); $R_f$ of hydrogenated product of IX, 0.60.[17]

Found; C, 61.77; H, 7.18; N, 10.94. Calcd. for $C_{79}H_{106}O_{18}N_{12} \cdot H_2O$; C, 62.02; H, 7.12; N, 10.99%.

**Cyclo-(L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl)$_2$ (XIV).**—*XIV (from deca).*—To a solution of IX (612 mg., 0.4 mmol.) in a mixture of dimethylformamide (3 ml.) and pyridine (0.95 ml.) di-*p*-nitrophenyl sulfite[19] (1.30 g., 4 mmol.) was added; the reaction mixture was then allowed to stand for 24 hr. at room temperature. After evaporation, the oily product was triturated with petroleum ether and washed repeatedly with a mixture of ether and petroleum ether (1:1) by decantation until no yellow color could be discerned on the addition of a sodium hydroxide solution to the washings. The product was filtered, washed with a mixture of ether and petroleum ether (1:1), and dried. It weighed 648 mg. This product was dissolved in dimethylformamide-N sodium hydroxide (1:1 v./v.), and the content of *p*-nitrophenyl ester was estimated by measuring the optical density of the solution at 412 mμ.[7] The purity of the compound was estimated to be 70%.

To the *p*-nitrophenyl ester X (638 mg.) anisole (0.5 ml.) and trifluoroacetic acid (3.5 ml.) were added at 0°C. The solution was evaporated in vacuo at 0°C, and the residue was triturated with ether. The decapeptide *p*-nitrophenyl ester trifluoroacetate (XI) was collected, washed with ether, and dissolved in dimethylformamide (12 ml.) containing glacial acetic acid (0.1 ml.). The solution was then stirred drop by drop into pyridine (120 ml.) which had been kept at 55—60°C over a period of 5 hr.; the stirring was then continued for an additional 2 hr. at the same temperature. After the solvent had been removed, the residual oil was dissolved in a mixture of methanol (150 ml.) and water (60 ml.). The insoluble substance was removed by filtration, and the filtrate was passed successively through columns of Dowex 1 ($OH^-$ form, 2.7×11 cm.) and Dowex 50 ($H^+$ form, 2.5×10 cm.). The columns were then washed with the same solvent (200 ml.), the combined effluent was evaporated to dryness in vacuo, and the product was suspended in water (30 ml.), filtered, and dried (246 mg.). The product was recrystallized from methanol-ether; yield, 211 mg. (38%) (named as XIV (from deca)); m. p. 248—250°C; $[\alpha]_D^{17}$ −127° (*c* 0.5, acetic acid); $R_f$ 0.93.[17]

Found: C, 60.62; H, 7.40; N, 12.25. Calcd. for $C_{70}H_{96}O_{14}N_{12} \cdot 3H_2O$: C, 60.76; H, 7.43; N, 12.15%.

The molecular weight of XIV (from deca) was determined by a Model 301A osmometer, Mechrolab Inc. solvent methanol).

Found: 1420. Calcd. for $C_{70}H_{96}O_{14}N_{12} \cdot 3H_2O$: 1384.

The air-dried compound lost 3.4% of its weight after it had been dried over phosphorus pentoxide for 2 hr. at 100°C; 2 mmHg. Calcd. for $3H_2O$: 3.9%.

*XIV (from penta).*—To a solution of VI (508 mg., 0.6 mmol.) in dimethylformamide (2 ml.) pyridine (0.2 ml.) and di-*p*-nitrophenyl sulfite (778 mg., 2.4 mmol.) were added. The reaction mixture was allowed to stand for 24 hr. at room temperature and treated as has been described above. The product (XII) obtained weighed 548 mg. The purity of the compound was estimated to be 78%.

To the *p*-nitrophenyl ester XII (538 mg.) anisole (0.5 ml.) and trifluoroacetic acid (3 ml.) were added. The solution was evaporated in vacuo, and the residue was triturated with ether. The pentapeptide *p*-nitrophenyl ester trifluoroacetate (XIII) was filtered, and then dissolved in dimethylformamide (10 ml.) containing glacial acetic acid (0.1 ml.). The solution was stirred drop by drop into pyridine (100 ml.) at 55—60°C as has been described above. During the stirring a crystalline precipitate appeared. After the completion of the reaction, the mixture was cooled to room temperature, and the crystals were filtered and washed with pyridine. It weighed 173 mg.[20] The filtrate was

18) F. Weygand and K. Hunger, *Chem. Ber.*, **95**, 1 (1962).
19) B. Iselin and R. Schwyzer, *Helv. Chim. Acta*, **43**, 1760 (1960).
20) Experiments on the properties of this pyridine-insoluble substance are in progress in this laboratory.

evaporated in vacuo. The residue was dissolved in a mixture with methanol (120 ml.) and water (40 ml.), and the solution was treated with the columns of Dowex 1 and 50 as has been described above. Recrystallization from methanol-ether gave 40 mg. (10%); m. p. 247—251°C[21]; $[\alpha]_D^{17}$ −123° (*c* 0.5, acetic acid); $R_f$ 0.93.[17]

Found: C, 61.31; H, 7.30; N, 12.20. Calcd. for $C_{70}H_{96}O_{14}N_{12}\cdot 3H_2O$: C, 60.76; H, 7.43; N, 12.15%.

When the procedure with the same scale was repeated, the yields of XIV (from penta) and the pyridine-insoluble substance were 62 mg. (15%) and 170 mg. respectively.

**Cyclo-(L-valyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl)$_2$ Dihydrocloride (XV).** — *XV (from deca).*— XIV (from deca) (82 mg., 0.06 mmol.), dissolved in methanol (1 ml.) and 0.065 N methanolic hydrogen chloride (2 m.), was subjected to hydrogenolysis in the presence of palladium black. After it had been filtered from the catalyst, the solution was evaporated to dryness in vacuo, The crystals which remained were then filtered with the aid of a mixture of acetone and ether (4: 1); yield of air-dried product, 66 mg. (88%); m. p. 227—230°C; $[\alpha]_D^{17}$ −190° (*c* 0.5, ethanol); $R_f$ 0.90,[16] 0.77,[17] 0.91[22] and 0.78[23].

Found: C, 52.06; H, 7.98; N, 13.28. Calcd. for $C_{54}H_{86}O_{10}N_{12}Cl_2\cdot 6H_2O$: C, 52.20; H, 7.95; N, 13.53%.

The air-dried product lost 2.9% of its weight when it was left in a desiccator with calcium chloride at room temperature. Calcd. for $2H_2O$: 2.9%. The air-dried product lost 8.8% of its weight after it had been dried over phosphorus pentoxide for 2 hr. at 120°C; 2 mmHg. Calcd. for $6H_2O$: 8.7%. The product was treated with dinitrofluorobenzene in the usual manner.[24] After the hydrolysis of the dinitrophenylated compound (DNP-XV), only one DNP-amino acid identified as δ-DNP-ornithine was detected on the paper chromatogram; $R_f$ 0.64.[16]

*XV (from penta).* — XIV (from penta) (6.9 mg., 5 μmol.) was dissolved in methanol (0.5 ml.) and 0.05 N methanolic hydrogen chloride (0.22 ml.) and treated as has been mentioned above. Crystals were obtained; yield, 4.5 mg. (80%). $R_f$ values of the crystals (XV (from penta)) were identical with those of XV (from deca). 0.90,[16] 0.77,[17] 0.91[22] and 0.77[23]. Furthermore, the identity of XV (from deca) with XV (from penta) was confirmed by paper electrophoresis carried out with 500 V. for 2 hr., using a solvent of formic acid - acetic acid - methanol - water (1: 3: 6: 10, v./v.; pH 1.8) and Toyo Roshi No. 52 paper.

**The Amino Acid Analysis of XV.**—Quantitative amino acid analysis was performed as follows. XV (ca. 0.6 mg.) was hydrolyzed with 6 N hydrochloric acid at 110°C for 48 hr. Each of the hydrolysates of XV from deca and penta was dissolved in 0.1 ml. of

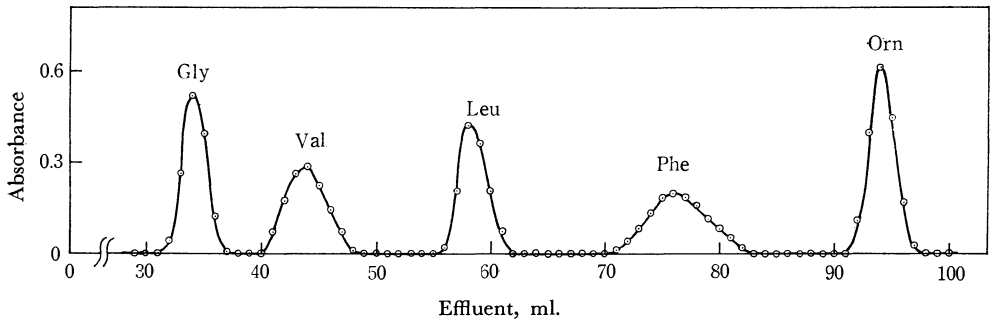

Fig. 1. Chromatogram of the hydrolysate of XV (from deca).

Table I. Amount of compound necessary for complete inhibition of growth (μg./ml.)

| Compound | Synthetic medium[a] | | Bouillon agar medium[b] | |

a) Stephenson-Whetham's medium (modified); $KH_2PO_4$ 1g., NaCl 1 g., $FeSO_4\cdot 7H_2O$ 0.7 g., Na-glutamate 4 g., glucose 5 g./1000 ml. and agar 20 g.
b) Usual bouillon agar medium, pH 7.0.
c) *Escherichia coli IRO 3044.*
d) *Bactllus subtilis PCI 219.*
e) A product of Astra Co., U. S. A. This contains eight moles of water of crystallization.

21) The melting point was not depressed by admixture with XIV (from deca).
22) The $R_f$ of the paper chromatography with Toyo Roshi No. 52 refers to the *t*-butanol - formic acid - water (75 : 15 : 10, v./v.) system.
23) The $R_f$ of the thin layer chromatography with Merck silica gel G refers to the *t*-butanol - formic acid - water (75 : 15 : 10, v./v.) system.
24) F. Sanger and E. O. P. Thompson, *Biochem. J.*, **53**, 353 (1953).

a 0.1 M citrate buffer (pH 3.1),[25] the solution was applied to a column (0.9×15 cm.) with Aminex Q-150 (31—45 microns, $Na^+$ form), and development was continued with the same solvent. Elution was carried out at about 20°C, the flow rate was 20—25 ml. per hr., and 1-ml. fractions were collected. The eluting solvent was replaced with a 0.1 M citrate buffer of pH 4.25[26] at fraction 35, and with a 0.2 N buffer of pH 9.2[26] at fraction 75. The amino acid contents in the fractions were determined by the modified ninhydrin reagent described by Yemm and Cocking.[27] A typical chromatogram is shown in Fig. 1. Quantitative amino acid determinations of XV from deca and penta gave the molar ratios of 1.0: 1.1: 1.0: 1.1: 1.1 and 1.0: 0.9: 1.0: 1.0: 1.0 for valine, ornithine, leucine, phenylalanine and glycine respectively.

**Microbiological Assays.**—The microrganisms employed are shown in Table I. A minimum amount of the compounds necessary for the complete inhibition of growth was determined by a dilution method with a bouillon agar medium and with a synthetic medium. As is shown in Table I, the cyclodecapeptide was found to be much more active than natural gramicidin S against *B. Subtilis* in a synthetic medium.

## Summary

A cyclic decapeptide, cyclo-(L-valyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl)$_2$, has been synthesized in an attempt to obtain information about the relation of the structure to the antibacterial activity of gramicidin S.

The synthesis of the cyclic decapeptide was achieved in two ways. The condensation of *p*-methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycine azide with L-valyl-δ-benzyloxycarbonyl-L-ornithyl L-leucyl-D-phenylalanylglycine afforded the corresponding N-blocked decapeptide, which was converted to the *p*-nitrpohenyl ester by the action of di-*p*-nitrophenyl sulfite. After the *p*-methoxybenzyloxycarbonyl group had been removed with trifluoroacetic acid, the decapeptide *p*-nitrophenyl ester was transformed to the cyclic benzyloxycarbonyl-substituted decapeptide by treatment with pyridine. On the other hand, this compound was also obtained by a dimerization reaction of L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycine *p*-nitrophenyl ester. In the latter case, however, the yield was poor. The cyclic benzyloxycarbonyl-substituted decapeptide was hydrogenated in the presence of palladium black to give the desired cyclic decapeptide dihydrochloride.

The effects of the synthesized cyclic decapeptide on bacterial growth have also been examined. It was observed that the compound was about ten times as active as gramicidin S against *B. subtilis* in a synthetic medium; however, it showed silghtly less activity than gramicidin S in a bouillon agar medium.

The authors wish to express their thanks to Dr. Motoo Shibata of the Takada Chemical Industries, Ltd., for his microbiological assays. Thanks are also due to Ajinomoto Co., Inc., and Kyowa Hakko Kogyo Co., Ltd., for supplying some amino acids.

# The Electronic Structure of Some Hydrides, Halides and Alkyl Compounds of Boron and Aluminum. I. Monomers and Ions

By Hiroshi KATO, Kaichiro YAMAGUCHI, Teijiro YONEZAWA and Kenichi FUKUI

(Received May 24, 1965)

Boron and aluminum atoms are known as typical group III elements of the periodic table which are very electro-positive and which are strong electron acceptors. Many experimental studies have been performed on compounds containing these two elements,[1] and theoretical investigations have been performed, especially on the basis of the valency theory.[2]

In the present paper, some boron and aluminum compounds, i.e., hydrides, halides, alkyl compounds, and their related ions will be treated by

the extended Hückel method proposed by Hoffmann.[3] The electronic structures and some physico-chemical properties of these compounds, such as their electron-accepting characters, and the stabilities of these monomers will be investigated. In addition, a problem of stereochemical interest—the two configurations of the $B_2Cl_4$ molecule—will be briefly discussed.

The electronic structure of the dimers will be treated in Part II, while the aspects of the chemical behavior which are important in the synthetic process will be discussed in Part III.

## The Parameters Used

In the present method, the values of the Coulomb integral, $H_{ii}$ are given by changing the sign of the valence-state ionization potentials of valence electrons, and the values of the resonance integral, $H_{ij}$, are evaluated by the following equation:[3]

$$H_{ij}=0.875(H_{ii}+H_{jj})S_{ij}$$

where $S_{ij}$ is the overlap integral between the $i$th and the $j$th atomic orbitals (AO). The adopted values of the Coulomb integrals and the effective nuclear charges of various AO's are collected in Table I, where the notations $s$ and $p$ denote the values of $H_{ii}$ of the 2s and 2p orbitals for the second row elements and of the 3s and 3p orbitals for the third row elements of the periodic table respectively.

The bond distances and the bond angles are determined with reference to those cited in Ref. 4. Those values which have not yet been measured are estimated on an assumption that, for example, the B–H bond distance in the monomeric $BH_3$ is equal to the terminal B-H distance in the dimer. These values are cited in Table II, together with their symmetry groups.

Table II. The adopted values of the bond distances, bond angles and symmetries of various compounds

| Compounds | Sym. | Bond distance (Å) and bond angle (deg.)* |
|---|---|---|
| $BH_3$ | $C_{3v}$ | B-H=1.187 |
| $BH_4^-$ | $T_d$ | B-H=1.25 |
| $BCl_3$ | $D_{3h}$ | B-Cl=1.75 |
| $BF_3$ | $D_{3h}$ | B-F=1.30 |
| $BF_4^-$ | $T_d$ | B-F=1.40 |
| $B_2Cl_4$ | $D_{2d}$, $D_{2h}$ | B-B=1.77, B-Cl=1.73, ∠ClBCl=120 |
| $BH(CH_3)_2$ | $C_{2v}$ | B-H=1.20, B-C=1.56, ∠HBC=120 |
| $B(CH_3)_3$ | $C_{3v}$ | B-C=1.56 |
| $BC_2H_3(CH_3)_2$ / $B(C_2H_3)_2CH_3$ | $C_{2v}$ | B-C=1.56, ∠CBC=120 |
| $B(C_2H_3)_3$ | $C_{3v}$ | B-C=1.56, ∠CBC=120 |
| $AlH_3$ | $C_{3v}$ | Al-H=1.65 |

| $Al(C_2H_5)_3$ | $C_{3v}$ | Al-C=2.0 |

* As to the methyl, ethyl and vinyl groups, the used values are as same as ones in these parent molecules.

## Results and Discussion

The calculated values of the atomic population of an atom X, $M(X)$, and the atom bond populations between X atoms and Y atoms, $M(X–Y)$, for various monomers and ions are summarized in Fig. 1.

**The Charge Distribution in Monomers.**—By referring to the values of $M(X)$ in Fig. 1, it may be seen that boron atoms have positive charges and that aluminum atoms are more positive in these monomers. That is to say, even in the $BH_3$ and $AlH_3$ molecules, each hydrogen atom bears more than one unit charge, and, in their alkyl compounds, the boron-carbon and aluminum-carbon bond are polarized in such a way as $B^{+\delta}$–$C^{-\delta}$ and $Al^{+\delta}$–$C^{-\delta}$. The atomic population of the methylene carbon atom in triethyl aluminum, 4.897, is larger than that of the methyl carbon atom, 4.386. This finding agrees with that of the NMR study described in Ref. 1. In the halides of boron and aluminum, the polarization of M–X bonds (M=boron or aluminum and X=halogens) is more remarkable than in alkyl compounds. An example is presented by the aluminum trichloride monomer, in which the value of $M(Al)$ is calculated to be 1.029 and that of $M(Cl)$ as 7.657. In this connection the result of Casabella et al. is worth our attention. They estimated, by the PQR

measurement, that the total electronic densities of various atoms in the aluminum tribromide dimer are 1.26 on the aluminum atom, 7.65 on the terminal bromine atom, and 7.44 on the bridged bromine atom.[5] With these values in mind, our results are not very extreme.

(s: 2s or 3s AO; x, y, z: 2px or 3px, 2py or 3py, 2pz or 3pz AO's)

5) P. A. Casabella, P. J. Bray and R. G. Barnes, *J. Chem. Phys.*, **30**, 1393 (1959).

The atomic orbital populations of the $r$th AO, $N(r)$, are collected in Table III(a) for the boron atoms and in Table III(b) for the aluminum atoms in various monomers, where the pz orbitals of these atoms consist of the $p\pi$ orbitals of these monomers. In $BH_3$ and $AlH_3$ molecules, the values of $N$(s) (the s denotes the 2s orbital on boron or the 3s orbital on aluminum) are almost comparable to those of $N$(x) and $N$(y), and $N$(z) is zero at both atoms (x, y, and z denote 2px, 2py, and 2pz AO's on boron or 3px, 3py, and 3pz AO's on aluminum). This result may be interpreted as meaning that in these atoms the promotion of the valence eletrons occurs from the $s^2p$ ground state to the $sp^2$ valence state. The strong electron-accepting ability of these compounds may also partly be attributed to the existence of pure, or almost-unfilled $\pi$ orbitals on the metal atom.

**The Energy Levels of Monomers.**—The calculated energy values of the highest-occupied orbitals (HO) and the lowest-vacant orbitals (LV) are presented in Table IV(a) for the boron compounds and in Table IV(b) for the aluminum compounds. The LV energies fall in a definite range, i. e., $-9$——$-6$ eV. for the boron compounds and $-7$——$-5$ eV. for the aluminum compounds; these values are considerably lower than those of the carbon atoms of saturated bonds. (The LV energies calculated by Hoffmann[3] are $+3.13$ eV. for the ethane and $-8.23$ eV. for the ethylene molecule.) Thus, these compounds might easily accept the electrons of donors and are very liable to the attack of nucleophilic reagents. Furthermore, these LV orbitals are $p\pi$ type orbitals, and the electron in them is almost localized on the $p\pi$ orbital of the boron or aluminum atom. For example, the atomic orbital population in the LV orbital is calculated to be 1.00 on the boron or aluminum atom in the hydrides (a pure $p\pi$ orbital), 0.97 on the aluminum atom in trimethylaluminum, and 0.94 on the aluminum atom in the aluminum trichloride monomer.

TABLE IV. THE HO AND LV ORBITAL ENERGY (eV.) OF VARIOUS MONOMERS

| | HO | LV |
|---|---|---|
| (a) B-Compounds | | |
| $BH_3$ | $-13.91$ | $-8.53$ |
| $BF_3$ | $-20.71$ | $-6.25$ |
| $BH(CH_3)_2$ | $-12.50$ | $-6.97$ |
| $B(CH_3)_3$ | $-12.36$ | $-6.23$ |
| $BC_2H_3(CH_3)_2$ | $-12.08$ | $-8.91$ |
| $BCl_3$ | $-14.58$ | $-5.91$ |
| (b) Al-Compounds | | |
| $AlH_3$ | $-13.86$ | $-6.67$ |
| $Al(CH_3)_3$ | $-12.14$ | $-5.01$ |
| $Al(C_2H_5)_3$ | $-11.54$ | $-5.08$ |
| $Al(CH_3)_2Cl$ | $-12.12$ | $-4.91$ |
| $AlCl_3$ | $-14.94$ | $-4.73$ |

With regard to the value of the HO energy, unfortunately, there seem to be no experimental results available to compare it with.

**$\pi$-Conjugation in Monomers.**—The magnitude of the $\pi$-conjugation has been supposed to be a measure of the stability of these monomer molecules. For instance, Mulliken described how the existence of trimethyl and trihalogenated boron monomers depends on the extent of stabilization due to $\pi$-conjugation in these monomers (hyperconjugation in the trimethylborane monomer).[6] Similarly, Ritter and his co-workers discussed the relation between the $\pi$-conjugation energy and the acid strength or the rate of disproportionation in vinyl boron derivatives.[7]

According to Table III, the orders of the magnitude of the $N(z)$ of boron atoms in various monomers are $BCl_3 > B(C_2H_3)_3 > B(C_2H_3)_2(CH_3) > BC_2H_3(CH_3)_2 > B(CH_3)_3 > BH(CH_3)_2 > BF_3 > BH_3$. Except for $BF_3$,* this order is reasonable, since it is known that $BH_3$ and $BH(CH_3)_2$ exist as in the dimeric form, and trimethyl boron and trihalogenated boron, as in the monomeric form.[6] The magnitude of $N(z)$ in aluminum compounds is smaller than that of the respective boron compounds, and the $N(z)$ of aluminum in the $AlCl_3$ monomer, which is the largest of the aluminum compound monomers presented here, is comparable to the $N(z)$ of boron in the $BH(CH_3)_2$ monomer; in fact, these two compounds are known to form dimers at room temperature.

Good and Ritter[7] treated the $\pi$ systems of vinyl boron compounds by a simple LCAO method. The calculated total $\pi$ electron densities for the $C_1{=}C_2{-}B$ system (dimethylvinylborane) are 0.84 on atom $C_1$, 1.05 on $C_2$, and 0.11 on the boron atom, whereas the $N(r)$ values of these $\pi$ orbitals in the present treatment are 0.941, 1.003, and 0.150 respectively. Furthermore, they obtained the $\pi$ densities of the boron atom as 0.21 in monomethyl divinylborane and as 0.29 in trivinylborane, while our values are 0.175 in the former and 0.207 in the latter.

The $\pi$-conjugation energies were also calculated by Good and Ritter.[7] These values were 4 kcal./mol. in dimethylvinylborane, 8.0 kcal/mol. in monomethyl divinylborane, and 11.8 kcal./mol. in trivinylborane. The results of our calculations are 2.4, 7.4, and 15.0 kcal./mol. respectively (our values are obtained as the differences between the $\pi$ orbital energy of the isolated ethylene molecule and those in methyl vinylboranes.). These two sets of results seem to be comparable with one other. The $\pi$-conjugation energies of the $BCl_3$, $BF_3$ and $AlCl_3$ monomers are obtained as 18.2, 6.7, and 7.4 kcal./mol. respectively. In $BF_3$, the value seems somewhat too small.

**The Electronic Structure of the Monomer and the Ion.**—Now the change in the electronic structure between the monomer ($MX_3$) and its ion ($MX_4^-$) will be discussed. A remarkable difference is indicated in the following two points. One is concerned with the LV orbital energy, and the other, with the $N(z)$ value of the boron and aluminum atoms. The energies of HO and LV orbitals are listed in Table V, while the $N(r)$ values of the boron and aluminum atoms in various compounds are given in Table VI.

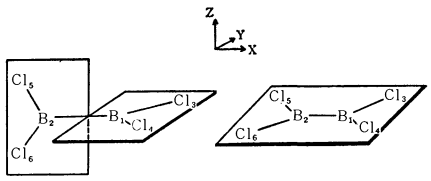
Table V. The HO and LV orbital energies of some monomers ($MX_3$) and corresponding ions ($MX_4^-$)

| | HO | LV |
|---|---|---|
| $BH_3$ | −13.91 | − 8.53 |
| $BH_4^-$ | −13.71 | +10.02 |
| $BF_3$ | −20.71 | − 6.25 |
| $BF_4^-$ | −20.71 | + 8.82 |
| $AlH_3$ | −13.86 | − 6.67 |
| $AlH_4^-$ | −13.71 | + 6.98 |
| $AlCl_3$ | −14.94 | − 4.73 |
| $AlCl_4^-$ | −14.81 | +13.21 |

Table VI. The $N(r)$ values of boron and aluminum atoms in monomers and ions

| | $N$(s) | $N$(x) | $N$(y) | $N$(z) |
|---|---|---|---|---|
| $BH_3$ | 0.912 | 0.825 | 0.825 | 0.0 |
| $BH_4^-$ | 0.847 | 0.816 | 0.816 | 0.816 |
| $BF_3$ | 0.295 | 0.122 | 0.122 | 0.082 |
| $BF_4^-$ | 0.298 | 0.110 | 0.110 | 0.110 |
| $AlH_3$ | 0.850 | 0.497 | 0.497 | 0.0 |
| $AlH_4^-$ | 0.808 | 0.480 | 0.480 | 0.480 |
| $AlCl_3$ | 0.505 | 0.206 | 0.206 | 0.111 |
| $AlCl_4^-$ | 0.504 | 0.202 | 0.202 | 0.202 |

(s: 2s or 3s AO; x, y, z: 2px or 3px, 2py or 3py, 2pz or 3pz AO's)



The difference in HO orbital energy between the monomer and its ion is small, whereas the LV level of ions lies much higher than that of the monomers, corresponding to the weak electron-accepting ability of these ions. The most important change in $N(r)$ value between the monomer and its ion occurs on the pz orbital of the boron and aluminum atoms. The $N(z)$ value of the ions is much larger than that of the corresponding monomers, naturally indicating that the electron-accepting abilities of monomers disappears in ions.

These saturation phenomena can be recognized from the charge migrations. In the $MX_3 + X^- \rightarrow MX_4^-$ (M = boron or aluminum) process, for instance the magnitude of the charge migration from $X^-$ to $MX_3$ may be roughly estimated by the unit charge in $X^-$ minus the net charge of X

* The calculated $\pi$ overlap values are 0.179 for the B-F bond in $BF_3$ and 0.124 for B-Cl in $BCl_3$, but the obtained $\pi$ charge of the boron atom in $BF_3$ is smaller than that of $BCl_3$.

in $MX_4^-$. This quantity is calculated as 0.824e in $BH_3$, as 0.157e in $BF_3$, as 0.561e in $AlH_3$ and as 0.277e in $AlCl_3$. Many of these transferred electrons enter into the vacant $p\pi$ orbitals of the boron or aluminum atom, as has been shown above.

**The Electronic Structures of the Two Configurations of the $B_2Cl_4$ Molecule.**—Two configurations of the tetrachlorodiborine, $B_2Cl_4$, have been considered.[8] The one is the planar configuration belonging to the symmetry group, $D_{2h}$, while the other has a $D_{2d}$ configuration in which two $BCl_2$ planes are perpendicular to each other. These two configurations are shown in Fig. 2. The molecule with the $D_{2d}$ symmetry exists in liquid and gas phases, and the $D_{2h}$ molecule, in the crystal form.[8]

$D_{2d}$ $D_{2h}$

* The LV levels.
** The HO levels.
*** The lone pair orbitals of the chlorine atoms.

The energies of all of the occupied orbitals and lowest-unoccupied orbitals of the molecules in these two configurations are listed in Table VII, together with their irreducible representations. The correspondence of irreducible representations between these two groups is as follows:

| $D_{2d}$ (perpendicular) | $D_{2h}$ (planar) |
|---|---|
| $a_1$ | $a_g$ |
| $b_2$ | $b_{1u}$ |
| e | $b_{2g}$, $b_{3g}$, $b_{2u}$, $b_{3u}$ |

The differences between the corresponding orbital energies of these two groups are seen to be very small. (The same values of the bond distances are adopted for these two forms as is shown in Table II.) The energy of the e orbital in the $D_{2d}$ may be compared with the sum of the two split orbital energies in the $D_{2h}$. The LV orbital is the e orbital in the $D_{2d}$, while the lowest is $b_{2u}$ and the next is $b_{3g}$ in the $D_{2h}$ molecule. The difference in the LV orbital energy between these two forms will be discussed later, again from the point of view of the electronic structrue.

The $M(X)$, $N(r)$ and $M(X\text{-}Y)$ values for the two forms are collected in Table VIII. The corresponding data for these two are almost equal to each other. The atomic orbital bond population between the $r$th and $s$th AO's is here denoted by $N(r\text{-}s)$. The $N(z(B_1)\text{-}z(B_2))$ value is −0.001 in the $D_{2d}$ form and +0.002 in the $D_{2h}$, while the $N(y(B_1)\text{-}y(B_2))$ value is −0.001 in the $D_{2d}$ form and −0.009 in the $D_{2h}$ form. Accordingly, the B–B bond in these two configurations is almost purely of a $\sigma$ type and does not exhibit the double-bond character. This result leads to the conclusion that the rotation about the B–B bond is very easy and that the conversion between two forms may be carried out without a great hindrance.

However, as was discussed above, the situation is remarkably different in the LV orbitals. That is, the LV e orbital of the $D_{2d}$ molecule splits into $b_{2u}$ and $b_{3g}$ in the $D_{2h}$ molecule, where $b_{2u}$ is the lowest. The calculated coefficients of the AO's in these orbitals are collected in Table IX, together with those of the HO orbitals. It may be seen from the table that the LV orbitals in the $D_{2d}$ molecule, which is twofold degenerate, are nonbonding orbitals localized on the $B_1$ and

(a) The $D_{2d}$ molecule

LV e $1.03z_{B1}+0.02z_{B2}-0.33(z_{C13}+z_{C14})-0.06(s_{C15}-s_{C16})-0.09(x_{C15}-x_{C16})+0.04(z_{C15}+z_{C16})$

LV e $1.03y_{B2}+0.02y_{B1}-0.33(y_{C15}+y_{C16})-0.06(s_{C12}-s_{C14})+0.09(x_{C12}-x_{C14})+0.04(y_{C12}+y_{C14})$

HO $a_1$ $0.23(s_{B1}+s_{B2})-0.44(x_{B1}-x_{B2})+0.32(x_{C13}+x_{C14}-x_{C15}-x_{C16})-0.07(s_{C13}+s_{C14}+s_{C15}+s_{C16})$
$+0.05(y_{C13}-y_{C14}+y_{C15}-y_{C16})$

(b) The $D_{2h}$ molecule

$b_{3g}$ $0.84(z_{B1}-z_{B2})-0.23(z_{C13}+z_{C14}-z_{C15}-z_{C16})$

LV $b_{2u}$ $0.65(z_{B1}+z_{B2})-0.25(z_{C13}+z_{C14}+z_{C15}+z_{C16})$

HO $a_g$ $0.24(s_{B1}+s_{B2})-0.44(x_{B1}-x_{B2})+0.31(x_{C13}+x_{C14}-x_{C15}-x_{C16})-0.07(s_{C13}+s_{C14}+s_{C15}+s_{C16})$
$+0.07(y_{C13}-y_{C14}+y_{C15}-y_{C16})$

$B_2$ atoms respectively, whereas the LV orbital of the $D_{2h}$ molecule is a $\pi$ type B–B bonding and the next LV is a $\pi$ type B–B anti-bonding. Thus, if a $D_{2d}$ molecule receives two electrons, these will enter into the LV orbitals, localizing on the 2pz orbital of the $B_1$ atom and on the 2py orbital of the $B_2$ atom, so that this compound will behave like a biradical. In the $D_{2h}$ molecule, these added electrons will serve to strengthen the B–B $\pi$ conjugation, behaving like tetrachloroethylene.

It is hoped that these results will be examined by future experiments.

The calculations have been carried out on an IBM 7090 computer at Japan IBM Co., with the permission of the UNICON committee, whom the authors wish to thank.

By Nobuo Mori, Satoshi Ōmura,*2 Norihiko Kobayashi and Yojiro Tsuzuki

(Received May 24, 1965)

In a previous paper,[2] it was reported that an intramolecular hydrogen bond is formed in some $\alpha$- and $\beta$-hydroxy-carboxylates in a dilute carbon tetrachloride solution, mainly on to the carbonyl-oxygen atom, rather than to the ether-oxygen of the ester group; the bonded OH-stretching frequencies were about 3540 $cm^{-1}$ in the $\alpha$-hydroxy esters and about 3559—3586 $cm^{-1}$ in the $\beta$-hydroxy esters. In addition to this strong band, a completely resolved or an unresolved weak band or shoulder appeared in the range from ca. 3610 to 3625 $cm^{-1}$ in both cases. It has, however, not yet been settled whether this band or shoulder is due to the free OH group or to the OH group bonded to the ether-oxygen atom. Flett[3] has suggested that it comes from the free OH group and has attributed the lowering in frequency (by ca. 10 to 20 $cm^{-1}$ from the free OH frequencies of alcohols) to the electron-attracting effect of the ester group. This point has now been elucidated with reference to the rotational isomerism around the C–OH bond, by means of infrared measurements of a series of $\alpha$- and $\beta$-hydroxy-carboxylates. Further, this paper will report on the limitation of intramolecular hydrogen bonding through the length of an alkylene chain intervening between the hydroxyl and the ester group in the $\omega$-hydroxy $HO(CH_2)_nCOOR$ series, as well as in isomeric hydroxycyclohexane-carboxylates.

## Experimental

**Samples.**—All the esters used are listed in Table I. The esters 1, 3, 5, 7, 9, 15, 16, 19 and 21 were those previously[2] used, while the esters 2, 4, 6, 8, 18 and 20 were prepared in similar manners. Ester No. 10 was prepared by Reformatsky reaction from acetone and methyl bromoacetate; No. 11 by the reduction of

a) The frequencies are different from those previously[2] reported, but more exact.

* Band I denotes the band of the OH group bonded to the carbonyl-oxygen atom as in form I shown in Fig. 2, band II that of the OH group bonded to the ether-oxygen atom as in form II, and bands IIIa and IIIb are of the free OH groups as in forms IIIa and IIIb, respectively, and band IIIab consists of both the bands IIIa and IIIb.

** $D=\log I_0/I$

ethyl levulinate with sodium borohydride; Nos. 12 and 13 by the oxidation of the corresponding cycloalkanones with potassium persulfate in ethanol; No. 14 by the Bouveault-Blanc reduction of the corresponding $\alpha,\omega$-dicarboxylic acid monoester, followed by esterification; No. 17 by the hydrolysis of cyclohexanone-cyanohydrin followed by esterification, and Nos. 22 to 25 by the catalytic hydrogenation of the corresponding methyl hydroxybenzoates. The $\gamma$-hydroxyvalerate (11) was considerably contaminated by its lactone, which was formed during vacuum distillation. The physical constants of these esters agreed with those reported in the literature (cf. Table I).

**Infrared Measurements.**—These were carried out with solutions of ca. 0.004 mol./l.*3 in carbon tetrachloride at 25°C, in the OH-stretching region from 3300 to 3700 cm,$^{-1}$ using a Perkin-Elmer 21 spectrophotometer equipped with a lithium fluoride prism and with a cell 3 cm. in length. The slit width was constantly 0.029 mm. The observed frequencies were calibrated against that of the atmospheric vapor. The OH spectra observed were apparently those of an unresolved or a resolved doublet or triplet and were graphically separated*4 into two or three symmetric components, assuming that they consist of symmetric bands. The infrared data of the separated band-components are summarized in Table I.*5 The frequencies of the peaks of the components were identical with those of the apparent bands, but most of their absorbances were somewhat or much lower than those of the latter bands.

## Results and Discussion

The infrared data of the esters investigated are listed in Table I.

**$\alpha$-Hydroxy Esters.**—All the esters, without exception, show a strong symmetric band at 3540—3550 cm$^{-1}$ (band I) and a weak symmetric band at 3606—3618 cm$^{-1}$, as Fig. 1 shows. The

*3 At this concentration, intermolecular hydrogen bonding was entirely absent; a very weak band due to the overtone of a carbonyl group appeared in all the spectra at ca. 3445 cm$^{-1}$, in addition to the strong bands listed in Table I.

*4 The graphical separation was made by reflecting the major component of a doublet or a triplet about the ordinate at the apparent maximum and by subtracting the mirror image from the observed spectrum. In the triplet, the residual minor part, unsymmetric on the lower or on the higher frequency side, was then similarly separated into two. The process was repeated by the trial and error method, until the components were symmetric.

*5 Each ester in the cyclohexane series herein investigated can take two interconvertible chair-conformations; therefore, the OH band should consist of two bands due to the axial and the equatorial OH group, which are somewhat different in frequency (see A. R. H. Cole, P. R. Jefferies and G. T. A. Müller, *J. Chem. Soc.*, **1959**, 1222 and previous papers). This difference in frequency is too small to separate the observed OH band into the two components, and, at any rate, such separation is not very significant in this investigation. Accordingly, such a distinction has not drawn herein.

Fig. 2. Possible rotational isomers around the C-OH axis.

frequency of the latter band decreases with the increasing number of methyl groups attached to the $\alpha$-carbon atom. In assigning this band, it is convenient to take into account the rotational isomers possible by rotation around the $C_\alpha$–O axis, as is shown with the four possible forms, I—IIIa,b, and their mirror images, in Fig. 2. In this figure, form I is hydrogen-bonded with the carbonyl-oxygen atom, and form II, with the ether-oxygen atom, while forms IIIa and IIIb do not form any hydrogen bond.

According to the infrared study of alcohols by Ōki and Iwamura,[11] the OH frequency depends on the number of methyl groups skew to the OH group with respect to the C–O bond, as is shown by forms A—C:

$\nu_{OH}$ cm$^{-1}$ Form A: 3640 Form B: 3627 Form C: 3617

wherein R represents a hydrogen atom or an alkyl group.

As examples of compounds capable of taking a hydrogen-bonded form such as form I ($n$=1 in the figure) we may mention such $\alpha$-ketols as acylmethyl carbinol[12] and 2-hydroxycyclohexanones[13], whose bonded and free OH frequencies are ca. 3490 and 3615 cm$^{-1}$ respectively. The latter frequency is lower by 12 cm$^{-1}$ than the OH frequency of 3627 cm$^{-1}$ in form B of alcohols; this lowering in frequency may be caused by the electron-attracting effect of the ketone group.

In the case of the $\alpha$-hydroxy esters, the electron-attracting effect of the ester group exercised on the OH frequency, if there is any at all, is probably much smaller than that of the ketone group. The weak band of glycolate 1 appears at 3618 cm$^{-1}$, lower by 22 cm$^{-1}$ than the OH frequency of 3640 cm$^{-1}$ in form A of alcohols; therefore, it can not be due to the free OH group in form IIIb corresponding to form A. This indicates, further, the absence of the non-bonded form IIIa, which should be thermodynamically less stable than IIIb. Accordingly, the band must be assigned to the bonded OH group in the residual form II. In this case, the lowering in frequency is 9 cm$^{-1}$ from the OH frequency of 3627 cm$^{-1}$ in form B, corresponding to form II.

In the lactates 2, 3 and 4, similarly, the weak band whose frequency is lower by ca. 13 cm$^{-1}$ than the 3627 cm$^{-1}$ of the OH band for form B and lower by ca. 3 cm$^{-1}$ than the 3617 cm$^{-1}$ for form C, may consist of a major component due to the bonded OH group in form II and a minor component due to one in the less stable rotational isomer II ($R_1$=H; $R_2$=Me). With $\alpha$-hydroxyisobutyrate 5 and 1-hydroxycyclohexane-carboxylate 17, since the lowering in the frequency of the weak band is ca. 10 cm$^{-1}$ from the 3617 cm$^{-1}$ in form C, comparable to the above cases, this band may be predominantly due to the bonded OH group in form II. Consequently, the OH group other than that in form I may hydrogen-bond with the ether-oxygen atom to a much larger extent than it remains free.

Further evidence for this assignment is provided by the fact that the frequencies of the esters 1,

2—4 and 17 are in good agreement with the bonded OH frequencies of 3622, 3614 and 3607 $cm^{-1}$, respectively, of the monoacetates[14] of ethylene glycol, *trans*-cyclohexane-1, 2-diol and 1-hydroxy-cyclohexylcarbinol in a hydrogen-bonded form such as form II. These frequencies are higher by 10—21 $cm^{-1}$ than the bonded OH frequencies of 3612,[15] 3602[15] and 3586[14] of the respective free diols; this rise in frequency may be attributed to the decreased electron-density on the ether-oxygen atom resulting from the resonance of the ester group. A similar finding is afforded in the case of diaxial *cis*-cyclohexane-1, 3-diols and their monoacetates.[16]

The ratio of the absorbance of the weak band to that of the strong band ($D_{II}/D_I$) is substantially constant in the esters, 1—5, except 17, irrespective of the number of methyl groups on the $\alpha$-carbon atom, but it tends to decrease as the alcoholic alkyl portion of the ester group increases in bulk or in number of carbon atoms, as is positively shown for lactates 2, 3 and 4, The relatively high ratio of the ester 17 may be explained in terms of the possible steric repulsion between the axial hydrogens on $C_2$ and $C_6$ and the alkoxy group in form I; by this means this form can be partially converted into form II, as is shown, e. g., by the following equilibrium between conformations containing an OH group axial:

Form I Form II

**β-Hydroxy Esters.**—The β-hydroxy-propionates and -butyrates 6—9 show, in each case, a strong band in the range from 3559 to 3586 $cm^{-1}$; this band is considerably broadened on the higher frequency side, and it also has a shoulder at ca. 3620—3640 $cm^{-1}$ on this side, as is shown in Fig. 3. On the other hand, the isovalerate 10 shows a strong, almost symmetric band at 3537 $cm^{-1}$, with a broad shoulder on the bottom of the band on the higher frequency side; the latter can be separated into two components, as is shown in Fig. 4. However, the spectra of the cyclic esters 18—21 are somewhat different; the cis esters show a strong band at 3544 $cm^{-1}$, with a weak shoulder on the higher frequency side, and the trans isomers, an unresolved triplet with a maximum at 3596 $cm^{-1}$, as is shown in Figs. 5 and 6.

In a previous paper,[2] which dealt with ethyl β-hydroxy-propionate and -butyrate (7 and 9), it could not be concluded whether the shoulder of the band was due to the free OH group. This point has now been solved by separating each of the complicated bands into three components, as is shown in Fig. 3. The separated components have maxima at 3585, 3622 and 3639 $cm^{-1}$ in the case of the esters 6 and 7; the lowest frequency

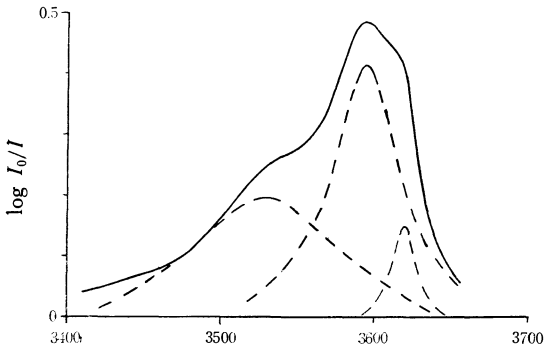

Fig. 6. OH spectrum of methy *trans*-2-hydroxy-cyclohexane-carboxylate (20).

band may be due to the bonded OH group in form I (band I). The other two may be assigned to the free OH groups in forms IIIa and IIIb, rather than to the bonded OH group in form II, because their relative intensities and frequencies are comparable to those of the other $\omega$-hydroxy esters 12—16.

In the $\beta$-hydroxybutyrates 8 and 9, the band at 3624 $cm^{-1}$ may consist predominantly of two bands due to the free OH groups in forms IIIa ($R_1$=Me ; $R_2$=H) and IIIb, probably with a weaker band due to the free OH in another form IIIa ($R_1$=H ; $R_2$=Me), because the frequency is comparable to the 3627 $cm^{-1}$ of the OH group in form B corresponding to the former two forms, while it is higher than the 3617 $cm^{-1}$ of the OH group in form C corresponding to the latter IIIa. Subsequently, the band at 3590 $cm^{-1}$ may be due to the bonded OH group in form II. This assignment can be supported also by the fact that the intensity of this band relative to the band IIIab of 3624 $cm^{-1}$ is higher than those of the band IIIa to IIIb for all the $\omega$-hydroxy esters. The same assignments can be given for the separated band-components in the cyclic series, 18—21. In this series, it is of interest that the cis-esters almost exclusively take form I, while the trans-isomers prefer form II, though the reason for this is not clear.

In the $\beta$-hydroxyisovalerate 10, the three bands can similarly be assigned to two bonded groups and one free OH group, as Table I shows.

Further evidence for the assignment of band I is given by the fact[3] that diacetone-alcohol and hydroacetylacetone, capable of forming a ring similar to form I through intramolecular hydrogen-bonding, exhibit the bonded OH frequencies of 3532 and 3557 $cm^{-1}$ respectively; these frequencies are comparable to those of the esters 10 and 8. A hydrogen-bonded form similar to form II can be realized in the diaxial conformations of *cis*-1, 3-diol monoacetates in cyclohexane systems; the bonded OH frequencies are lower by ca. 20 $cm^{-1}$ than the corresponding free OH ones;[16] this affords additional support for the assignment of band II.

From the above informations and reasoning, we are led to the conclusion that the methyl groups on the $\beta$-carbon atom sterically serve to make the hydroxyl and the ester group closer together; the non-bonded forms, IIIa and IIIb, thereby decrease in proportion, and instead the hydrogen-bonded form, II, comes into existence. Further, this effect results in strengthening the hydrogen bond in form I, as is indicated by the facts that the degree of the lowering in frequency of band I resulting from the introduction of one or two methyl groups is unexpectedly large (i. e., ca. 30 $cm^{-1}$ per methyl group) and that, simultaneously, the relative intensity of band I tends to increase. Such an effect is, however, not observed in the $\alpha$-hydroxy esters.

**The Other Esters.**—Higher $\omega$-hydroxy esters do not form a hydrogen bond with the ether-oxygen atom in form II. However, some of them are hydrogen-bonded with the carbonyl-oxygen atom. In the $\gamma$-hydroxyvalerate 11, the bonded OH band I has almost the same intensity as that of the free OH band, but in the $\varepsilon$-hydroxy ester 12 (see Fig. 7) it is very weak, and in the other $\omega$-hydroxy esters, it entirely disappears. It is interesting that the ester 12 is hydrogen-bonded and a nine-mumbered ring is formed, although the largest ring hitherto known contains at most eight members (in 5-methoxypentanol[17] and 5-phenylpentane-1,5-diol[18]). In addition to this, these esters have, in cach case, a strong free OH band broadened on the lower frequency side; the two components separated may be due to the free OH groups in forms IIIa and IIIb respectively.

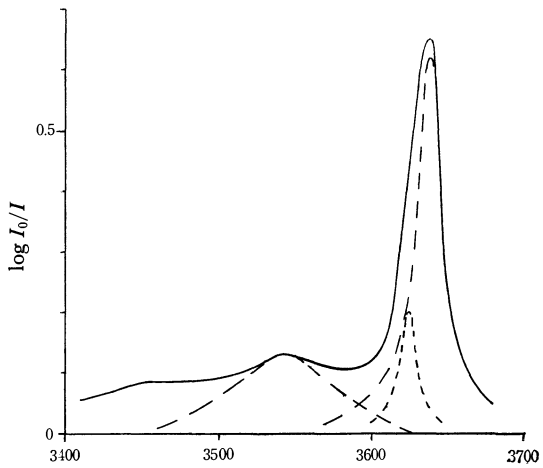

Fig. 7. OH spectrum of ethyl 5-hydroxycapronate (12).

17) A. B. Foster, A. H. Haines and M. Stacey, *Tetrahedron*, **16**, 177 (1961).
18) N. Mori, S. Ōmura and Y. Tsuzuki, This Bulletin, **38**, 1631 (1965).

In the case of the ester 11, the lower frequency band is due to the free OH group in form IIIa ($R_1$=H ; $R_2$=Me), while the higher frequency band is due to that in forms IIIa ($R_1$=Me; $R_2$=H) and IIIb. The intensity ratios of band IIIa to band IIIb (or IIIab) are ca. 0.25.

3- and 4-Hydroxycyclohexane-carboxylates (22—25) are not internally hydrogen-bonded. The absence of any hydrogen bonding in the *cis*-4-hydroxy ester 24 can be explained in view of the fact that even if the hydrogen bonding were possible, the stabilization*6 resulting from it would be much lower than the instabilization*7 resulting from taking the boat or twist conformation required for ordinary hydrogen-bondings between 1- and 4- cis groups.[19] In the case of the *cis*-3-hydroxy ester 22, the reason for the absence of hydrogen-bonding seems to be that the orientation of the ester group in its 1, 3-diaxial chair-conformation is unfavorable for hydrogen-bonding. If the ester group could take an orientation favorable for hydrogen-bonding with the OH group, the stabilization*6 resulting from the hydrogen-bonding could exceed the difference in free energy (ca. 2.0 kcal./mol.*8) between the non-bonded diaxial and the diequatorial chair-conformation and, therefore, molecules taking the diaxial conformation which is hydrogen-bonded should be present to a considerable extent.

**Comparison with Other Hydrogen-bonded Systems.**—As has been described above, the bonded OH frequencies may reasonably be assigned on the basis of a comparison with those of some ketols and alkane-diol monoacetates. In this paragraph, they will be compared with those of $\alpha$, $\omega$-alkane-diols[15,17] and $\omega$-methoxyalkanols[17] of the series $RO(CH_2)_nOH$, wherein R is a hydrogen atom or a methyl group. As is shown in Table II, only when the number of members in a ring to be formed through hydrogen-bonding is equal to 5, the bonded OH frequncies I in the $\alpha$-hydroxy esters are much lower, but the frequencies II are slightly higher than those of the other series. This seems to indicate this decreasing order in proton-accepting power: ester C=O>MeO>HO>ester –O–,† if the distances between the hydroxyl-hydrogen and the proton-accepting oxygen atoms in all the series are almost equal in such probable geometries that the OH and the ester group in the esters are oriented as in forms I and II (in I, the C=O bond almost eclipses the $C_\alpha$–O bond and the C–OR bond is situated between the $C_\alpha$–$R_1$ and the $C_\alpha$–$R_2$ bond, while in II, the C=O bond almost eclipses the $C_\alpha$–$R_1$ bond and the C–OR bond is skew to the $C_\alpha$–O and the $C_\alpha$–$R_2$ bond.); the OH and the OR group in both the alkanol series are skew to one another with respect to the $C_\alpha$–$C_\beta$ axis.

Table II. A comparison of bonded OH frequencies ($\nu_{bonded OH}$ $cm^{-1}$)

| Number of ring-memers | Hydroxy ester: Ester No. | Band I | Band II | $RO(CH_2)_nOH$[17]: R=H | R=Me |
|---|---|---|---|---|---|
| 5 | 1 | 3550 | 3618 | 3619, 3612[15] | 3610 |
| | 3 | 3543 | 3613 | | |
| 6 | 7 | 3584 | — | 3565, 3558[15] | 3554 |
| | 9 | 3560 | 3590 | | |
| 7 | 11 | 3544 | — | 3484, 3478[15] | 3460 |
| 8 | | | | — | 3500 |
| 9 | 12 | 3542 | — | — | — |

When the ring consists of six members or more, however, the frequencies I and II of the ester series are higher than those of both the alkanol series; this indicates that the OH group in the former series is more apart from the proton-accepting atoms than in the case of the latter. Further, in the hydrogen-bonded esters with $n$=1—5 (except 2,) the OH–O=C distances are almost equal and with $n$=2 it is longer, if the bonded OH frequencies directly reflect the distances, as has been recognized in the alkane-diol system.[15]

# The Metal-catalyzed Autoxidation of Tetralin. V. The Effect of Fatty Acid Solvents

By Yoshio KAMIYA

(Received May 31, 1965)

Recently, the solvent effect on the autoxidation of hydrocarbons has attracted much attention. Hendry and Russell,[1] and Howard and Ingold[2,3] have studied the several hydrocarbons and tried to correlate the rate constant value of $k_3/k_6^{1/2}$ with the dielectric function, $(D-1)/(2D+1)$. The present author, in a previous paper,[4] derived $k_3/k_6^{1/2}$ from the limiting rate of the metal-catalyzed oxidation of tetralin. Mostly, his values showed good agreement with those obtained by a quite different method, that is, azobisisobutyronitrile-catalyzed oxidation.

For this paper the effect of fatty acid solvents, from acetic to myristic acids, on the rate of the cobalt-catalyzed oxidation of tetralin, and also the effect of small amounts of stronger organic acids, were studied.

A possible kinetic scheme[5] describing the overall reaction is:

$$\mathrm{ROOH} + n\mathrm{Me} \xrightarrow{k_1'} \text{radical} \xrightarrow{\mathrm{RH}} \mathrm{R}\cdot \quad (1)$$

$$\mathrm{R}\cdot + \mathrm{O_2} \rightarrow \mathrm{RO_2}\cdot \quad (2)$$

$$\mathrm{RO_2}\cdot + \mathrm{RH} \xrightarrow{k_3} \mathrm{ROOH} + \mathrm{R}\cdot \quad (3)$$

$$\mathrm{RO_2}\cdot + \mathrm{RO_2}\cdot \xrightarrow{k_6} \text{non-radical} + \mathrm{O_2} \quad (4)$$

Under stationary conditions:

$$-\mathrm{dO_2}/\mathrm{d}t = k_3(k_1'/2k_6)^{1/2}(\mathrm{ROOH})^{1/2}(\mathrm{Me})^{n/2}(\mathrm{RH}) - k_1'(\mathrm{ROOH})(\mathrm{Me})^n/2 \quad (5)$$

When the rate of the decomposition of hydroperoxide equals its rate of formation, the limiting rate of oxidation is given by:

$$-\mathrm{dO_2}/\mathrm{d}t = k_3^2(\mathrm{RH})^2/2k_6 \quad (6)$$

## Experimental

The purification of tetralin and the oxygen absorption apparatus have been described previously.[5,6] All the experiments described in this work were performed at 50°C. The cell-cleaning procedure was that of Chalk and Smith.[7] Tetralin hydroperoxide was prepared and analyzed by the method of Woodward and Mesrobian.[8]

Cobalt decanoate prepared by the method of Heaton and Uri[9] was used as a catalyst. The fatty acids used as solvents were acetic, propionic, butyric, pentanoic, octanoic, nonanoic, decanoic, lauric and myristic acids.

## Results and Discussion

**The Decomposition of Tetralin Hydroperoxide by Cobalt Salt in Fatty Acid Solvents.** —The decomposition of tetralin hydroperoxide by cobalt decanoate was carried out in a fatty acid-benzene solution (1 : 1 by volume); its rate was found to be first order with respect to hydroperoxide and second order with respect to cobalt, regardless of fatty acids, from acetic to myristic, which were used, at cobalt concentrations from $5\times10^{-4}$ to $5\times10^{-3}$ mol./l.; i. e.:

$$-\mathrm{dROOH}/\mathrm{d}t = k_1'(\mathrm{Co})^2(\mathrm{ROOH}) \quad (7)$$

The values of $k_1'$, as Table I shows, increased markedly with the increase in the carbon number of the fatty acid.

Table I. The rate constants of the cobalt-catalyzed decomposition of tetralin hydroperoxide in a 1 : 1 by volume fatty acid - benzene solution

| Fatty acid | $k_1'$ mol$^{-2}$ l$^2$ sec$^{-1}$ | $k''$ sec$^{-1}$ |
|---|---|---|
| Acetic | 244 | 18600 |
| Propionic | 495 | 22000 |
| Butyric | 754 | 22100 |
| Pentanoic | 963 | 20500 |
| Heptanoic | 1440 | 18000 |
| Nonanoic | 2440 | 20000 |

However, further experiments confirmed that the decomposition rate is inversely proportional to the square of the concentration of acid, as has been shown in the case of acetic acid;[5] i. e.:

$$-\mathrm{dROOH}/\mathrm{d}t = k''(\mathrm{CO})^2(\mathrm{ROOH})/(\mathrm{Acid})^2 \quad (8)$$

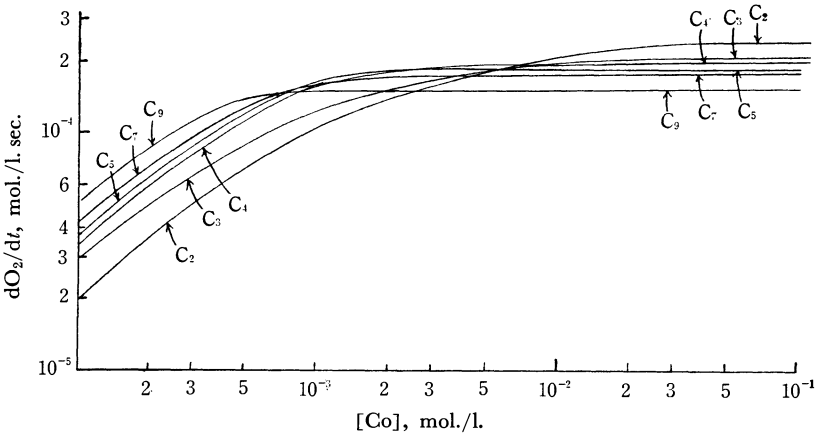

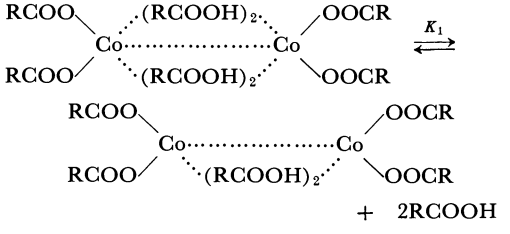

Fig. 1. The rate of oxidation of tetralin in the fatty acid as a function of cobalt concentration.

is that the calculated rate constant, $k''$, of Eq. 8 was nearly $2\times10^4$ $sec^{-1}$; it was independent of the molecular weight of the acid given in Table I. Each cobalt salt in an acid solvent may be complexed with two molecules of acids, and the active form of cobalt might be written as follows:

Thus,

$$\text{Active cobalt}=K_1(\text{Co})^2/(\text{acid})^2$$

Therefore, it can be concluded that the rate constant of the decomposition of tetralin hydroperoxide in an acid solvent may be attributed mainly to the kind of metal[2] and very little to the acid.

**The Oxidation of Tatralin in the Fatty Acid Solvent.**—Previously,[4,5] it was proved that the rate of the oxidation of tetralin reaches a limiting rate at high catalyst concentrations; this was explained by the mechanism suggested by Tobolsky;[10]

$$-dO_2/dt=k_3^2(RH)^2/2k_6$$

The rates of the oxidation of tetralin against the cobalt concentration in several fatty acids are shown in Fig. 1. At cobalt concentrations higher than $5\times10^{-2}$ mol./l., the rate reaches a limiting value according to the solvent used. The lower the dielectric constant of the acid, the lower the limiting rate. In contrast, the order of the rate of oxidation was completely reversed at low catalyst concentrations; this is due to the effect of the higher initiation rate caused by the solvent. Recently, the rate of autoxidation has been correlated as a dielectric function by several workers.[1,2,11] Hendry showed that the oxidation rate could be roughly correlated with the dielectric constant ($D$) of the solvent by means of the function $(D-1)/(2D+1)$, which describes the bulk effect of solvents on dipole-forming reactions.

That is, the rate constant, $k'$, for a reaction in a solution[13] is given by:

$$\ln k'=\ln k_0'-\frac{1}{kT}\frac{D-1}{2D+1}\left(\frac{\mu^2_A}{a^3_A}+\frac{\mu^2_B}{a^3_B}-\frac{\mu^2_{M^*}}{a^3_{M^*}}\right)+\frac{\phi_A+\phi_B-\phi_{M^*}}{kT}$$

$k_0'$ is the specific rate constant in a solvent with a unit dielectric constant, while $\mu$ and $a$ are the dipole moment and the radius of the reactants (A and B) and transition state (M). $\phi$ is a correction factor for non-electrostatic forces between the solvent and the reactants, and the solvent and transition state (e. g., dipole quadruple forces, van der Waals forces, and other specific solvation effects). Provided the non-electrostatic terms are small enough to be neglected, a plot of $\log k'$ against $(D-1)/(2D+1)$ should be linear.

Howard and Ingold[2] obtained a rather more linear correlation with styrene than was obtained by Hendry[1] with cyclohexene, but there was still the same sharp increase in the rate for the solvents with very high dielectric constants. The correlation between $\log(k_3/k_6^{1/2})$ and $(D-1)/(2D+1)$ is not significantly improved by multiplying the dielectric function by the ratio of the density

10) A. V. Tobolsky, D. J. Metz and R. B. Mesrobian, *J. Am. Chem. Soc.*, **72**, 1942 (1950).

12) Y. Kamiya and K. U. Ingold, *Can. J. Chem.*, **42**, 1027 (1964).

to the molecular weight of the solvent. Later, Howard and Ingold also studied the oxidation of $\alpha$-methylstyrene, tetralin, 4-methyl cyclohexene and cumene, and plotted the $k_3/k_6^{1/2}$ values for the first three hydrocarbons against the $k_3/k_6^{1/2}$ value for styrene. They concluded that the increase in the oxidation rate with an increase in the solvent dielectric constant results mainly from the interaction of the solvent with the dipolar transition state of the propagation reaction.

The values of $k_3/k_6^{1/2}$ calculated in this work from the limiting rate of the oxidation of tetralin in the fatty acid solution, are plotted against $(D-1)/(2D+1)$ in Fig. 2; an excellent linear correlation is obtained. The very good result in the case of the fatty acid solvent can be attributed to the lack of any deactivation of the catalyst and also, presumably, to little difference in the correction factor, $\phi$, upon a change in solvent.

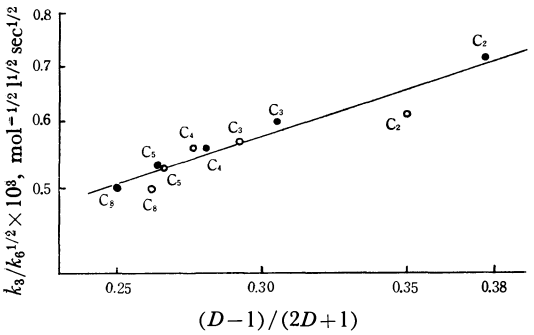

Fig. 2. Plot of $k_3/k_6^{1/2}$ for the oxidation of tetralin in the fatty acid against dielectric function, $(D-1)/(2D+1)$.
$C_n$: $n$ represents the carbon number of fatty acid.
● Tetralin 1.22 mol./l.
○ Tetralin 3.67 mol./l.

As a result, the limiting rate of the oxidation of tetralin in an acid solvent can easily and accurately be estimated when its dielectric constant is known.

At low catalyst concentrations, the rate of oxidation can be written by Eq. 5. When the hydroperoxide concentration is high enough compared with cobalt, the term $(Co)(ROOH)^{1/2}$ nearly equals (Co), because, as has been suggested by many workers,[5] cobalt and hydroperoxide form an intermediate complex. Therefore, Eq. 5 can be simplified as follows:

$$-dO_2/dt = k_3(k_1'/k_6)^{1/2}(RH)(Me) - k_1'(Me)^2/2$$

$k'_1$ can be obtained by the direct determination of the decomposition rate of hydroperoxide, or from $k''$, which is nearly $2\times10^4$ sec$^{-1}$, while $k_3/k_6^{1/2}$ can be obtained from the dielectric constant or the limiting rate of oxidation. The rate of oxidation calculated by Eq. 5 and the observed values at cobalt concentrations of $3\times10^{-4}$ and $1\times10^{-4}$ mol./l. in the six fatty acids are shown in Table II.

Table II. The calculated and observed values of the rate of oxidation of tetralin

| Solvent | $-dO_2/dt\times10^5$ (mol./l. sec.) | | | |
|---|---|---|---|---|
| | $CoDe_2$ $3\times10^{-4}$ mol./l. | | $CoDe_2$ $1\times10^{-4}$ mol./l. | |
| | Calcd. | Obs. | Calcd. | Obs. |
| Acetic | 6.1 | 5.2 | 2.3 | 2.0 |
| Propionic | 7.6 | 6.5 | 3.0 | 2.9 |
| Butyric | 8.0 | 8.5 | 3.4 | 3.2 |
| Pentanoic | 8.4 | 9.0 | 3.8 | 3.5 |
| Heptanoic | 8.8 | 10.1 | 4.7 | 4.1 |
| Nonanoic | 11.0 | 12.0 | 5.2 | 5.1 |

The calculated values showed an excellent agreement with the experimental results, thus justifying the limiting-rate theory.

It may be concluded that not only the limiting rate of tetralin oxidation, but also the rate of tetralin oxidation at low catalyst concentrations, can be estimated with very good accuracy.

**The Effect of Stronger Organic Acids on the Rate of Oxidation.**—When dichloro- or trichloro-acetic acids were used as solvents, the oxidation of tetralin did not proceed at all at cobalt concentrations lower than $5\times10^{-2}$. However, monochloroacetic acid gave a limiting rate of $2.62\times10^{-4}$ mol./l. sec., as compared with that of $2.5\times10^{-4}$ mol./l. sec. in acetic acid, which is a quite reasonable value in view of its dielectric constant. In the case of monochloroacetic acid, a slow but steady deactivation of the catalyst took place, probably due to the formation of an inactive complex between cobalt and monochloroacetic acid. Incidentally, no oxygen absorption was observed at $5\times10^{-3}$ mol./l. (Co) in a monochloroacetic acid solution. Even a small amount of monochloroacetic acid reduced the rate of the cobalt-catalyzed oxidation of tetralin in acetic acid. The effect of a small amount of various organic acids on the oxidation rate of tetralin in acetic acid was studied in the limiting-rate region, i. e., $5\times10^{-2}$ mol./l. (Co).

Benzene carboxylic acids produced in a slight decrease of the rate of oxidation, but oxalic acid, which showed the strongest effect of all acids tested, was found to deactivate an equimolar amount of cobalt. The solvent effect of chloroacetic acids was studied by Ohta[14] for $p$-xylene and by Levanevskii[15] for $n$-decane; they found a marked increase in the rate of oxidation compared with the rate in acetic acid. The difference between their results and those of experiment can be attributed to the strong temperature-dependency of the metal-deactivating effect of chloroacetic acids.

15) O. E. Levanevskii and T. Zhumabylov, *Neftkhim*, **1963**, 264; *Chem. Abstr.*, **60**, 13111 (1963).

**The True Limiting Rate of the Oxidation of Tetralin.**—The limiting rate of the oxidation of tetralin was, in the previous paper, calculated from the limiting rate of the oxidation in acetic acid to be $1\times10^{-3}$ mol./l. sec.; just the dilution effect due to the $(RH)^2$ term was considered. It was concluded that it showed an excellent agreement with the theoretical value of $1\times10^{-3}$ mol./l. sec. However, as has been described above, the dielectric effect should be taken into consideration. After correcting for the dielectric effect, the measured limiting rate of the oxidation of tetralin is $7.8\times10^{-4}$ mol./l. sec. The difference between the theoretical rate and observed rate after the correction may be attributed to the non-radical decomposition of hydroperoxide. The products of the decomposition of tetralin hydroperoxide by cobalt salt have been shown by gas chromatography to be composed of 50% $\alpha$-tetralone and 50% a mixture of $\alpha$-tetralol and dihydronaphthalene. Dyer et al.[16] obtained similar results by chemical analysis.

In the limiting-rate region, as has been described previously, the expected ratio of alcohol to ketone is 2 : 1. The non-radical decomposition of hydroperoxide may yield $\alpha$-tetralone as follows:

$$ROOH + n\text{Me} \xrightarrow{k^*} \alpha\text{-tetralone} + H_2O + n\text{Me}$$

Therefore, the radical-producing decomposition may be calculated to be 75%; i. e.: $k_1'/k_1'+k^*=0.75$

Accordingly, the limiting rate of the oxidation of tetralin at 50°C becomes $0.75\times10^{-3}=7.5\times10^{-4}$, which agrees excellently with the theoretical value of $7.8\times10^{-4}$.

## Summary

The rate of the cobalt-catalyzed decomposition of tetralin hydroperoxide in fatty acid solvents was first order with respect to hydroperoxide and second order with respect to the cobalt, and it was inversely proportional to the square of the acid concentration; i. e., $-\mathrm{dROOH}/\mathrm{d}t=k''(\mathrm{Co})^2\cdot(\mathrm{ROOH})/(\mathrm{Acid})^2$. The rate constant, $k''$, was found to be almost constant, regardless of the molecular weight of the acid. The values of $k_3/k_6^{1/2}$ obtained from the limiting rate of the oxidation showed an excellent linear correlation against the dielectric function of $(D-1)/(2D+1)$. The rate of the oxidation of tetralin calculated by $-\mathrm{dO}_2/\mathrm{d}t=k_3(k_1'/2k_6)^{1/2}(\mathrm{RH})(\mathrm{Co})-k_1'(\mathrm{Co})^2/2$ showed an excellent agreement with the value observed at cobalt concentrations lower than $3\times10^{-4}$ mol./l. Strong organic acids such as chloroacetic acids deactivated the cobalt catalyst, and oxalic acid, which has shown the strongest deactivating effect of all the acids tested, deactivated equimolar cobalt salt.

The author wishes to express his thanks to Professor Shingo Ando and Dr. K. U. Ingold for their continued advice and encouragement in this work.

# Studies of Halogenoacetato Cobalt(III) Complexes. III.*,[1] The Preparation and Some Properties of Trifluoroacetato Cobalt(III) Complexes

By Kashiro KURODA and Philip S. GENTILE

(Received June 7, 1965)

In the preceding communications[1,2] the present authors have reported on the preparation of and some properties of pentammine-, tetrammine- and bis(ethylenediamine)-cobalt(III) complexes with chloroacetato and bromoacetato ligands—$[Co(halac)(NH_3)_5]X_2$, *cis*- and *trans*-$[Co(halac)_2(NH_3)_4]X$ and *cis*- and *trans*-$[Co(halac)_2(en)_2]X$, where halac$=CH_3CO_2$, $CH_2ClCO_2$, $CHCl_2CO_2$, $CCl_3CO_2$, $CH_2BrCO_2$ and $CHBr_2CO_2$. There we pointed out several regularities found in their properties. It was there considered to be very interesting that in each series of complexes the basicity of the halogenoacetato ligands is the main factor determining the maxima of their absorption spectra, and that the volume of the ligands and the sort of halogen in the halac's are minor ones.

* This work was mostly done in the laboratory of Chemistry Department, Fordham University, New York 58, N. Y., U. S. A., when the former of the authors was a visiting chemist to the university.

1) Parts I and II of this series: K. Kuroda and P. S. Gentile, This Bulletin, **38**, 1362, 1368 (1965).

2) K. Kuroda and P. S. Gentile, *J. Inorg. Nucl. Chem.*, **27**, 155 (1965).

Although the trifluoroacetato-pentammine-cobalt(III) complex, $[Co(CF_3CO_2)(NH_3)_5]X_2$, has previously been studied,[3,4] bis(trifluoroacetato)-cobalt(III) complexes have so far not been prepared. Since trifluoroacetic acid is a stronger acid than any other halogenoacetic acid (it is virtually a strong electrolyte), the basicity of the trifluoroacetato ligand is the smallest among all of the halogenoacetato ligands, the spectral features of trifluoroacetato complexes should be the most extreme in each member of the above series. With such an expectation, several new cobalt complexes with trifluoroacetato ligand, *cis*-$[Co(CF_3CO_2)_2(NH_3)_4]ClO_4$, *trans*-$[Co(CF_3CO_2)_2(NH_3)_4]Cl$, *cis*-$[Co(CF_3CO_2)_2(en)_2]ClO_4$ and *trans*-$[Co(CF_3CO_2)_2(en)_2]ClO_4$, have been prepared, and some physical and chemical properties have been examined. In consequence, the expected results have been obtained, and also a few special noteworthy phenomena have been observed.

## Experimental

**Materials.** — Trifluoroacetic acid (K & K Laboratories, Inc.) and all the other reagent-grade chemicals were used without further purification.

**Analysis.**—Cobalt was analyzed by EDTA direct titration, using murexide as an indicator,[5] after a complex had been decomposed with hot concentrated sulfuric and nitric acids. The other elements were analyzed microquantitatively by the Schwarzkopf Microanalytical Laboratory (Woodside, New York, U. S. A.).

**Apparatus and Measurements.**—The visible and ultraviolet absorption spectra of the complexes were measured with a Cary 15 spectrophotometer, using a pair of one-cm. quartz cells. The measurements were carried out in a way which has been described previously.[1] The infrared spectra were also taken with a Perkin-Elmer Infracord in order to help verify the composition of the compounds. All of the complexes showed the characteristic absorptions of CO and $ClO_4$ (except for 3) below). The procedure of the solubility measurement, as well as that of the precipitation test, have also been described previously.[1]

**The Assignment of Configuration.**—It has been settled both experimentally[6,7] and theoretically[8,9] that the 1st band of a trans-isomer splits much more significantly than that of the corresponding cis-isomer. As may be seen in Fig. 1, two isomers exhibited such absorption curves; by this means geometrical configurations were assigned.

**Preparations.** — *1) Trifluoroacetato-pentammine-cobalt(III) Perchlorate, $[Co(CF_3CO_2)(NH_3)_5](ClO_4)_2$.*—The nitrate was prepared by a procedure similar to that used for the acetato-complex described in "Inorganic Syntheses."[10] The nitrate was transformed to the perchlorate by the addition of perchloric acid to its solution.

*2) cis-Bis(trifluoroacetato)-tetrammine-cobalt(III) Perchlorates, cis-$[Co(CF_3CO_2)_2(NH_3)_4]ClO_4$.*—A mixture of $[CoCO_3(NH_3)_4]ClO_4$ (2 g.), $CF_3CO_2H$ (1.7 g.) and water (2 ml.) was evaporated to almost complete dryness at 65°C. To the reaction product was then added 5 ml. of a 20% sodium perchlorate solution; the precipitate thus formed was collected and washed with the sodium perchlorate solution. The product was recrystallized from 20 ml. of warm (~40°C) water, and the resulting crystals were collected on a glass filter and washed with ether in order to remove the attached aqueous phase mechanically as completely as possible, and then with an ethanol (80%) - ether mixture and with ether. (The complex is very soluble in ethanol, especially when it is wet.) Yield: 0.5 g.

Found: Co, 12.76; C, 10.85; H, 2.83; N, 12.14. Calcd. for *cis*-$[Co(CF_3CO_2)_2(NH_3)_4]ClO_4$: Co, 13.02; C, 10.62; H, 2.67; N, 12.38%.

*3) trans-Bis(trifluoroacetato)-tetrammine-cobalt(III) Chloride, trans-$[Co(CF_3CO_2)_2(NH_3)_4]Cl$.*—A product was obtained by the evaporation of a mixture of $[CoCO_3(NH_3)_4]ClO_4$ (3 g.), $CF_3CO_2H$ (9.5 g.) and water (5 ml.) at 75—80°C. Ten milliliters of a 20% sodium perchlorate solution was added to the cooled product, and the precipitate formed was separated and extracted by 10 ml. of warm water. After combining the extracted solution with the first filtrate, 20 ml. of a 6 N hydrochloric acid was added and the mixture was kept at 0°C for an hour. The light brownish-violet crystals which formed, which were the acidic chloride of the complex *trans*-$[Co(CF_3CO_2)_2(NH_3)_4]Cl \cdot HCl$, were then washed with a cold 6 N hydrochloric acid until the filtrate became colorless. To convert to a neutral salt, the crystals were dissolved in 10 ml. of ethanol containing a few drops of water; then 10 ml. of ether was added to the solution. The resulting pale violet precipitate was washed with an ethanol (50%) - ether mixture and with ether. The neutral salt can also be obtained if the *dry* acidic chloride is treated with absolute ethanol, but the *wet* one is very soluble in ethanol. Yield: 0.5 g.

Found: Co, 14.94; C, 12.23; H, 3.46; N, 14.07. Calcd. for *trans*-$[Co(CF_3CO_2)_2(NH_3)_4]Cl$: Co, 15.17; C, 12.36; H, 3.34; N, 14.42%.

*4) cis-Bis(trifluoroacetato)-bis(ethylenediamine)-cobalt-(III) Perchlorate, cis-$[Co(CF_3CO_2)_2(en)_2]ClO_4$.* — This complex was prepared by a procedure similar to 2). The yield of the recrystallized product was 1 g. from 2 g. of $[CoCO_3(en)_2]ClO_4$.

Found: Co, 11.50; C, 18.91; H, 3.66; N, 10.93. Calcd. for *cis*-$[Co(CF_3CO_2)_2(en)_2]ClO_4$: Co, 11.68; C, 19.04; H, 3.20; N, 11.10%.

*5) trans-Bis(trifluoroacetato)-bis(ethylenediamine)-cobalt-(III) Perchlorate, trans-$[Co(CF_3CO_2)_2(en)_2]ClO_4$.*—A mixture of $[CoCO_3(en)_2]ClO_4$ (3 g.), $CF_3CO_2H$ (10 g.) and water (5 ml.) was evaporated at 75°C to a small volume; the solution was then carefully boiled for a few minutes with a small flame until the color suddenly changed from dark red to deep reddish-violet. As soon as this process had finished, the mixture was

cooled. The resulting solid was crushed, and 20 ml. of a dilute sodium perchlorate solution was added and thoroughly mixed in. The precipitate which formed, after being washed with a cold sodium perchlorate solution, was recrystallized from 40 ml. of warm water. A concentrated solution which contained 2 g. of sodium perchlorate was added in order to complete the precipitation. The pale violet crystals which formed were washed with ethanol and ether. Yield: 1.5 g.

Found: Co, 11.64; C, 18.84; H, 2.86; N, 11.45. Calcd. for *trans*-$[Co(CF_3CO_2)_2(en)_2]ClO_4$: Co, 11.68; C, 19.04; H, 3.20; N, 11.10%.

## Results and Discussion

Table I shows the solubilities of the complexes prepared and their precipitation reactions with various common anions. The salts are, in general, readily soluble in water; this is in contrast to the corresponding trichloroacetato-complexes.[1] On the other hand, they are soluble in ethanol or even in an ethanol-ether mixture, especially when they are wet, as are the trichloroacetato-complexes.[1] One must take remember this quality in washing the complexes in preparing them.

Among the reactions with various anions, the precipitation of *cis*-$[Co(CF_3CO_2)_2(en)_2]^+$ with acetate ions is considered to be the most important, because there is as yet no precipitant for acetate ions. It has already been reported[11] that this reaction may be used as a new method for detecting acetate in the qualitative analysis of anions. The reactions in which trichloroacetic acid makes precipitates with the trans-isomers but not with the cis-isomers are similar to those with other halogenoacetato-complexes already reported.[1]

Table II and Fig. 1 show the absorption spectra of the complexes. Previously,[1] it has been pointed out that, in the absorption spectra of each series of halogenoacetato-complexes—the pentammine-, *cis*- and *trans*-tetrammine- and *cis*- and *trans*-bis-(ethylenediamine)-series of complexes—, the basicity of halogenoacetato ligands is the predominant factor in determining spectral characteristics, and that the other factors—the volume of the ligands and the oxidation-reduction property of halogen atoms—are minor.

Thus, the relative position of $CF_3CO_2$ in the spectrochemical series is expected to be:

$$I < \cdots < CH_3CO_2 < \left\{ \begin{array}{c} \\ CH_2ClCO_2 < CHCl_2CO_2 < CCl_3CO_2 \\ CH_2BrCO_2 < CHBr_2CO_2 \end{array} \right\} < \cdots < CN$$

($CF_3CO_2$ above $CCl_3CO_2$)

(increasing ligand field)

since the basicity of $CF_3CO_2^-$ is the smallest of

all of the halogenoacetate ions. This expectation was statisfactorily verified by the experimental results that the absorption maxima of the present complexes (except for the split 1st bands of the trans-isomers) were found at the highest frequencies in each series of complexes.[1]

The splitting of the 1st bands of the *trans*-isomers is worth noticing because of its magnitude. As may be clear from a comparison of Fig. 1 and Figs. 1 and 2 in Part II (Ref. 1), the degree of the splitting of the present trans-isomers is rather larger than that of trichloroacetato complexes. This result confirms the previous suggestion that the distance in the spectrochemical series between the "a" and "b" of a complex *trans*-$[Coa_4b_2]$ is not the sole factor determining the magnitude of the splitting.

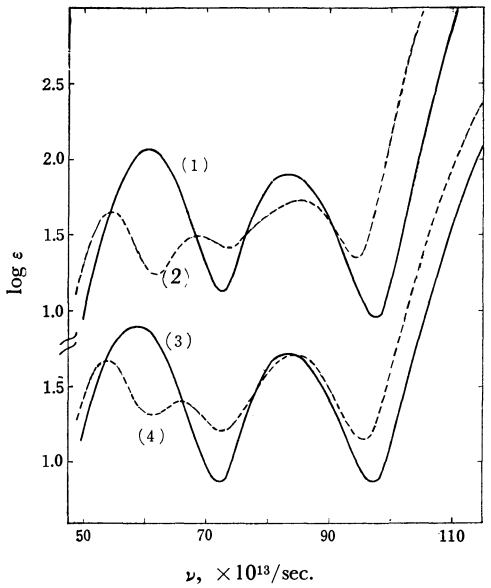

Fig. 1. Absorption spectra of trifluoroacetato cobalt(III) complexes.

(1) *cis*-$[Co(CF_3CO_2)_2(en)_2]ClO_4$
(2) *trans*-$[Co(CF_3CO_2)_2(en)_2]ClO_4$
(3) *cis*-$[Co(CF_3CO_2)_2(NH_3)_4]ClO_4$
(4) *trans*-$[CO(CF_3CO_2)_2(NH_3)_4]Cl$

The shape of the 2nd band of *trans*-$[Co(CF_3CO_2)_2(en)_2]^+$ is considered to be noteworthy. It is well known[12] that, in a pure single band, the half-width of the left branch, $\delta$-, is usually about 10% smaller than that of the right branch, $\delta_+$; this generality is preserved in the lst and 2nd bands of $[Co(CF_3CO_2)(NH_3)_5]^{2+}$, *cis*-$[Co(CF_3CO_2)_2(NH_3)_4]^+$, and *cis*-$[Co(CF_3CO_2)_2(en)_2]^+$ and in Ia bands of the trans-isomers, as in the bands of many other cobalt complexes. Contrary to this rule, however, the 2nd band of *trans*-$[Co(CF_3CO_2)_2(en)_2]^+$ is abnormally asymmetric in a direction the reverse of the ordinary cases, as may be observed in Fig. 1. Indeed, the right branch of the Ib band might influence the left branch of the 2nd band, but because Ib is so small and so separated from the 2nd that it is not possible to deform for it the band to such a large extent. A similar deformation can be observed in the spectra of the *trans*-$[Co(halac)_2(en)_2]^+$ series previously reported[1]; that is, the left branch of the 2nd band broadens steadily with an increase in the chlorine content of the halac-ligands, and the deformation of *trans*-$[Co(CCl_3CO_2)_2(en)_2]^+$ is as large as that of *trans*-$[Co(CF_3CO_2)_2(en)_2]^+$. The same trend, but to a lesser degree, is also observable in the *trans*-$[Co(halac)_2(NH_3)_4]^+$ series. These facts may indicate a splitting of the 2nd bands.

It has been pointed out[13] that the 2nd band of a *trans*-$[Coa_4b_2]$-type complexes should split into two parts by the tetragonal distortion of the ligand field, as the 1st band does. However, no cobalt complex has ever been found which exhibits such splitting in the band. The reasons for this are considered to be that, in many cases, the 2nd band is greatly influenced by adjacent bands and/or ligand specific bands; there have been very few examples in which both the branches of the band could be compared over a sufficient frequency range free from the influence of other bands. Fortunately, the 2nd bands of the present complexes are satisfactorily pure and can be examined with accuracy. A precise analysis of the spectral curves is undoubtedly necessary for a decision on the splitting phenomena; this research will be reported on shortly in a separate paper.

# The Structure and Properties of Supported Cobalt Catalysts

By Hiroshi HAGIHARA and Etsuro ECHIGOYA

(Received June 8, 1965)

In experiments previously reported by the present same authors[1], it was observed that the catalytic activity of supported metal catalysts in the hydrogenation reaction of aniline varied greatly for different types of catalyst. In order to understand this phenomenon, it is necessary to know the structure and properties of these catalysts.

Many reports[2-5] have been published with respect to the structure and properties of supported nickel catalysts, but few regarding supported cobalt catalysts. Anderson et al.[6] have reported on the structure and properties of the catalyst for Fisher-Tropsch synthesis. However, their study was restricted to the chemical properties of a cobalt-diatomaceous earth system.

The present investigation has been undertaken in an attempt to obtain some information about the structure and properties of cobalt oxide as supported on various kinds of oxide carriers, and also on the relationship between the hydrogenation activity and the catalyst structure.

## Experimental

**The Preparation of Catalysts.** — The standard procedures of catalyst preparation were as follows:

*The Impregnation Method:* The powdered support was added to a solution of cobalt nitrate. The slurry was stirred for some time, and then to it was slowly added, at 20°C, a quantity of dissolved ammonium carbonate in a slight excess. After the precipitate has been filtered and washed, it was dried at 100°C and then calcined at 500°C for 2 hr.

*The Coprecipitation Method:* The catalyst was prepared by coprecipitation, from a mixed solution of cobalt nitrate and aluminum nitrate or sodium silicate, by ammonium carbonate solution at 20°C with vigorous stirring. The slurry was stirred for some time, and then it was vacuum-filtered. The precipitate was washed with distilled water on the filter, dried in a drying cabinet at 100°C, powdered, and calcined at 500°C for 2 hr. in air.

*The Hydrothermal Treatment:* Basic cobalt carbonate (prepared from cobalt nitrate and ammonium carbonate solutions at 20°C) was mixed with silica gel or aluminum oxide gel, and then heated with water in an autoclave at 200°C for 25 hr. It was then cooled, filtered, washed with distilled water, dried at 100°C, and calcined at 550°C for 2 hr.

*The Mixing Method:* The powdered silica gel and cobalt basic carbonate were mechanically mixed in water in a beaker. The mixture was vacuum filtered, and then it was dried at 100°C and calcined at 500°C for 2 hr.

**Surface Area Measurements.**—The area of the samples was estimated by the BET method.

**The Reduction of the Catalysts in Hydrogen.**—*Hydrogen consumption measurement.*—The volumetric apparatus shown in Fig. 1 was used for this attempt. Hydrogen was continuously circulated through the catalyst at the flow rate of 100 cc./min., and the water produced by reduction was removed using a dry-ice methanol trap and a silica gel drier placed behined the catalyst bed. The pressure was held manually at one atmosphere by adjusting the leveling (L). Thus the pressure difference of the manometer showed directly the volume of hydrogen consumed; this volume was then plotted as a function of the heating-up temperature and of the time (Fig. 1). The apparent $H_2$ consumption as measured as described above was then corrected for the changes in volume caused by heating.

* The color is given for the catalyst which was calcined at 500°C for 2 hr.

*The change in the X-ray diffraction pattern of the catalyst upon being reduced in a stream of $H_2$, using a high temperature X-ray camera.* The heating unit of this X-ray camera consists of a Pt-Rh plate, which serves as a support for the powdered sample and also as a heating element by means of the passage of the electric current through it. The sample temperature was measured by a alumel-chromel thermocouple inserted in the center of the Pt-Rh plate. The whole assembly was placed inside a container, through which $H_2$ gas was then passed. The X-ray tube irradiates the specimen attached to the Pt-Rh plate, as in the ordinary powder method, and produces an overlapping X-ray pattern of the specimen and platinum. After a one-hour reduction with a 50 cc./min. flow rate of $H_2$ at a definite temperature, X-ray diffraction pattern was obtained. This technique was previously described by Kubo[7]; it was only slightly modified in this investigation.

**Differential Thermal Analysis.**—The differential thermal analysis was performed in air at a heating rate of 7—10°C/min. The reference junction of the differential couple was embedded in an inserted fused quartz. Fifty milligrams of the sample was sandwiched between two 200 mg. layers, of the fused quartz or $\alpha$ alumina, each in a platinum cell. The thermocouple employed was alumel-chromel.

**Infrared Spectra.** — The infrared spectra in the NaCl and KBr prism regions (5000—600 $cm^{-1}$) were obtained by using a Hitachi EPI-2G infrared spectrophotometer. The wavelength calibration was made with polystyrene. Spectra were measured by the KBr disk and Nujol methods.

**The Solubility of the Catalysts in 2 N Hydrochloric Acid.**—0.2 g. of the powdered catalyst was added to 50 ml. of 2 N hydrochloric acid. The slurry was then stirred vigorously at 30°C for 8 hr. by a magnetic stirrer. The resulting slurry was decanted, and 50 cc. of 2 N hydrochloric acid was added to the remaining slurry. After this process had been repeated three times, the filtered solution was collected and the amount of cobalt oxide was determined by EDTA titration. The fraction dissolved was calculated as follows:

$$\text{Dissolved (\%)} = \frac{\text{the amount of Co in the soln. (g.)}}{\text{the initial amount of Co in the cat. (g.)}}$$

**Activity Test.**—The experiments were performed in a fixed bed apparatus of the flow type in the temperature range from 150 to 300°C.

## Results and Discussion

**Surface Area Data.**—The surface areas of the unreduced and reduced catalysts are given in Fig. 2 and in Table II. From these data, it can be seen that the surface area of all the catalysts studied decreased by upon reduction. The areas of the cobalt-silica, cobalt-alumina and cobalt-celite catalysts decreased to 90%, to 80—70% and to 60% of those before reduction respectively. It was shown, however, that the area of celite did not change appreciably when it was subjected to the usual reduction procedures[8]. From the data in Table II and Fig. 2, silica or alumina carriers appear to be more effective in preventing the sintering of Co during reduction than diatomaceous earth (celite). This may be attributed to the

TABLE II

| Catalyst | Surface area $m^2/g.$ |
|---|---|
| $Co_3O_4$ | 90 |

state of cobalt oxide on the carriers, i. e., to the oxide distribution on the carrier-surface and to the nature of the carrier-oxide bond. The decrease in the surface area of the catalysts produced by hydrothermal treatment during reduction was comparatively small. This may be caused by the low reducibility of cobalt oxide in the catalyst (i. e., the small fraction reduced to the metal.)

**Reducibility by $H_2$.**—The reduction curves are presented in Figs. 3, 4, and 5. The method of preparation bears a direct relationship to the reducibility of the supported cobalt oxide. For the cobalt diatomaceous earth system, Craxford[9] reported a decreasing reducibility as the formation of hydrosilicates progresses. The same phenomenon was reported for supported Ni-oxide by Van Eijk van Voorthujsen[2] and Morikawa et al.[5] Taking all these facts into consideration, it seems that an interaction has most probably occured between cobalt oxide and alumina or silica gel.

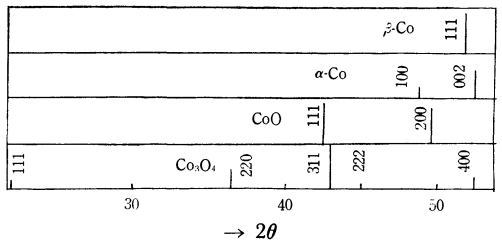

Fig. 6. The X-ray diffraction pattern of related materials.

In cobalt oxide - alumina catalysts,[10] prepared by the various methods described above, the degree of the formation of a complex structure was found to decrease in the following sequence: the hydrothermal > coprecipitation > impregnation methods. The same conclusion was obtained from a study of the effect of the hydrothermal treatment, which brought about an improvement in the complex structure. From the curves (Figs. 3 and 4), it is also apparent that the reducibility of cobalt oxide and the supported compounds decreases

10) J. T. Richardson and L. W. Vernon, *J. Phys. Chem.*, **62**, 1153 (1958).

with an increase in the quantity of the carrier. This may be related to the high degree of dispersion and to the strong interaction between the metal and carrier used.

**The Course of Catalyst Reduction in $H_2$, Seen by Using an X-Ray Camera.**—As Figs. 7 and 8 show, the temperatures of the reduction to cobalt(II) oxide and cobalt-metal varied greatly with the cobalt oxide contents, the methods of preparation, and the kinds of carriers used. In cobalt-alumina catalysts, cobalt-metal was first observed in the temperature range from 300°C to 500°C. The different temperature of the formation of the cobalt-metal on the carrier is related to the structure and to the cobalt-oxide content of the catalyst. The preparation by the coprecipitation methods results in an improvement of the formation of the complex between cobalt oxide and the carrier. In the cobalt-silica system, the catalyst produced by impregnation and the coprecipitation method also showed a high resistance to reduction by $H_2$. The cobalt metal was first observed at 500°C. This phenomenon suggested a complex formation between cobalt-oxide and silica gel. In cobalt-celite, the temperature of the reduction to cobalt-metal was about 300°C. This may be related to the low degree of dispersion of cobalt oxide and to the less complex formation in this case. In the range from 200 to 300°C, the cobalt-(II, III) oxide in the catalyst is mainly reduced to cobalt(II) oxide; later it is reduced to $\beta$-cobalt between 300 and 500°C (Fig. 9).

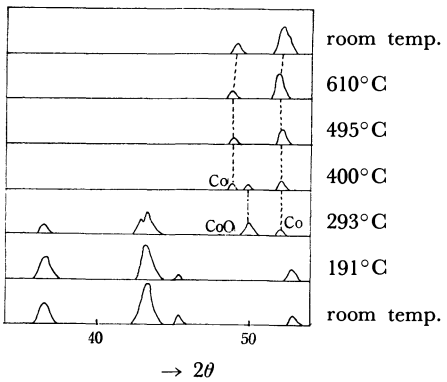

Fig. 7. X-Ray diffraction pattern in a stream of $H_2$. Sample: 49% Co-$Al_2O_3$-p

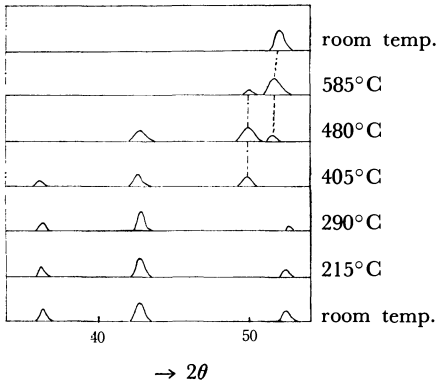

Fig. 8. X-Ray diffraction pattern in a stream of $H_2$. Sample: 25% Co-$Al_2O_3$-cp

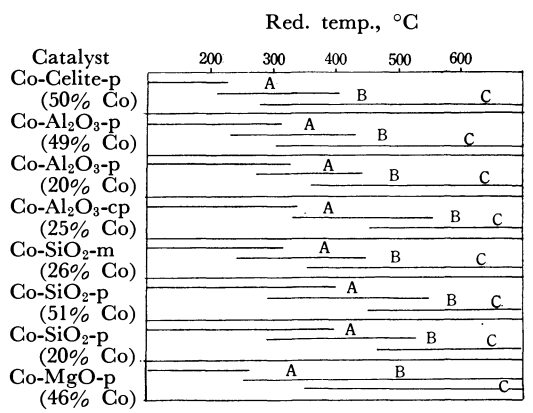

Fig. 9. Summary of the X-ray diffraction pattern of the catalyst being reduced in a stream of $H_2$. A: $Co_3O_4$, B: CoO, C: $\beta$-Co

**Differential Thermal Analysis.**—All the thermograms of cobalt oxide catalysts are given in Fig. 10 for purposes of comparison. The basic cobalt carbonate exhibited two endothermal and one exothermal peaks. The endotherm at 100—150°C refers principally to dehydration, when most of the water is lost without any changes in structure. The endotherm at 250—350°C corresponds to the decarboxylation and dehydration which results in the change in structure from basic carbonate to cobalt monoxide. The exotherm at 350—400°C corresponds to the oxidation from cobalt(II) oxide to cobalt(II, III) oxide. Thus the changes in basic cobalt carbonate upon heating follow each other in the following manner:

$$2CoCO_3 \cdot 3Co(OH)_2 \cdot nH_2O \xrightarrow{100-150^\circ C} 2CoCO_3 \cdot 3Co(OH)_2$$

$$2CoCO_3 \cdot 3Co(OH)_2 \xrightarrow{250-300^\circ C} CoO \xrightarrow{350-400^\circ C} Co_3O_4 \longrightarrow CoO^{11)}$$

Except for the Co-$SiO_2$ catalyst produced by the coprecipitation method, the DTA curves exhibited by the various supported cobalt-oxide catalysts were almost identical with that of the basic cobalt-carbonate. For the Co-$SiO_2$ catalyst prepared by coprecipitation, however, only one broad endothermal peak was clearly observed between 500 and 700°C above the dehydration temperature. This may be attributed to the decomposition of hydrosilicate (orthotype) into cobalt oxide, silica and water.

**The Infrared Spectrum.**—Several applications of this technique to the study of catalyst

11) K. Kubo and M. Kato, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **67**, 1502 (1964).

structures have been reported.[12-15] The results of our investigation are shown in Fig. 11. In the spectral region examined, three bands were found: near 3400 cm,$^{-1}$ 1600 cm,$^{-1}$ and 1000 cm$^{-1}$. The 3400 cm$^{-1}$ and 1600 cm$^{-1}$ bands are attributed to the O-H bond. The band near 1000 cm$^{-1}$ may generally be attributed to the silicon oxide or aluminum oxide.[16] In the catalysts produced by hydrothermal treatment, these three bands diminished in intensity or were shifted compared with

those of catalysts prepared by impregnation. These changes may also be due to the complex formation between cobalt oxide and the carriers.

**Solubility in 2 N Hydrochloric Acid.**—Applications of this test to the supported nickel catalysts have been reported by Morikawa and Nozaki. They found that only the free metal in the catalyst is soluble in 2 N hydrochloric acid. This technique was then applied to the supported cobalt-oxide in order to find the chemical state of cobalt oxide in the catalyst. The results are summarized in Table III. The catalysts which dried at 100°C were fully soluble in 2 N hydrochloric acid. In the cobalt-alumina system, when it was calcined at 700°C for 2 hr. the cobalt(II, III) oxide in the catalyst almost became insoluble. This shows that the interaction between cobalt oxide and alumina carrier progressed further as the calcining temperature was raised. The structure of the complex was probably that of cobalt aluminate ($CoAl_2O_4$) and a solid solution. In the cobalt-silica catalyst prepared by coprecipitation, the cobalt oxide was fully soluble in 2 N hydrochloric acid, even after calcination. This may be attributed to the formation of a soluble compound, like ortho hydrosilicate.[17]

**The Relationship between Activity and Structure.**—The results of activity tests are summarized in Table IV. From the data given above, generally speaking, the catalysts of the supported free-metal type showed a higher activity in the hydrogenation and hydrogenolysis reaction of aniline. For example, in the cobalt alumina series, the activity of the catalyst produced by hydrothermal treatment is about one-fifth that of that made by the impregnation method.

17) J. A. A. Ketelaar, "Chemical Constitution," Elsvier (1958), p. 61.

## Summary

1) The chemical states of cobalt in the supported catalysts may be classified into two types. One is the type in which the cobalt is not combined with the carrier but remains free on its surface. In the other type, cobalt oxide forms a complex with the carrier and resists reduction by hydrogen.

2) The ratio of the amounts of the two types varied both with the kind of carrier and with the method of preparation used.

3) The hydrothermally-formed cobalt-alumina and cobalt-silica catalysts form $CoAl_2O_4$ and cobalt hydrosilicate compounds respectively.

4) The course of the reduction of cobalt oxide in the catalyst is as follows: In the temperature range from 200 to 300°C, the cobalt(II, III) oxide is mainly reduced to cobalt(II) oxide, and later cobalt(II) oxide is reduced to $\beta$-Co between 300 and 500°C. The reduction temperature of cobalt(II, III) oxide is different for the various types of catalysts.

5) The catalyst which consists of a complex between the metal and its carrier-oxide is less active than the free metal catalyst for the hydrogenation reaction, and it is almost completely inactive in the hydrogenolysis reaction.

6) The results of the various analyses of the supported cobalt catalysts are in good agreement with one other.

The authors wish to thank Professor Kiyoshi Morikawa for his valuable discussion, and Mr. Masaki Kato, Mr. Kaku Ishizima, Miss Keiko Irie, and Mr. Daiziro Ohata for their kind assistance.

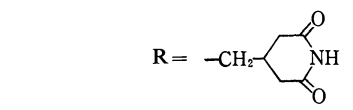
# Studies of Cycloheximide-Related Compounds. II. The Acid-catalyzed Condensation of Glutarimide-β-acetaldehyde with Ketones*

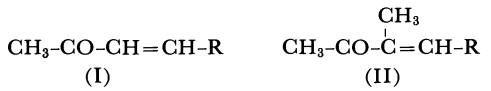
By Yoshiyuki EGAWA and Sumio UMEZAWA

(Received June 14, 1965)

Cycloheximide, a mold metabolite, has been known for many years, having been first isolated from the culture of streptomycin-producing Streptomyces griseus by Whiffen et al.[1] The antibiotic has been used as an agricultural fungicide and possesses antitumor and rodent-repellent activities. We have now undertaken a program of synthesis with the intention of preparing new compounds related to cycloheximide, meanwhile improving the biological activities of the antibiotic.

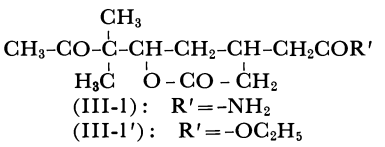


One approach to the synthesis of cycloheximide-related compounds is to condense carbonyl compounds with glutarimide-β-acetaldehyde (GAA) by aldol reaction. Lawes[2] successfully synthesized anhydrocycloheximide by condensing 2,4-dimethyl-6-formylcyclohexanone with GAA in the presence of potassium carbonate. However, since our preliminary experiments showed that basic catalysts, such as sodium hydroxide, carbonate, bicarbonate and cyanides of sodium and potassium, caused a cleavage of the imide ring in GAA during the aldol reaction, it was thought advisable to investigate condensation by the aid of acid catalysts.



We have successfully condensed GAA with ketones by the use of dry hydrogen chloride (method A) or concentrated sulfuric acid in acetic acid (method B) to give cycloheximide-related compounds. When GAA is sparingly soluble in ketone component, method B is preferable to A.

The glutarimide-β-acetaldehyde was prepared from diethyl β-ketoglutarate and cyanoacetic acid by way of diethyl β-cyanomethylglutarate by the method of Egawa et al.[3]



The condensation of acetone and ethyl methyl ketone with GAA by method A gave 3-(4-oxo-2-*n*-pentenyl)glutarimide (I) and 3-(3-methyl-4-oxo-2-*n*-pentenyl)glutarimide (II) respectively. Woodward's ultraviolet rule[4] predicted the values of the absorption maxima of I and II.

The reaction of methyl isopropyl ketone with GAA by method A resulted in the formation

* Methanol solution

of δ-(1, 1-dimethyl-2-oxo-*n*-propyl)-β-carbamoylmethyl-δ-valerolactone (III-1) and 3-(2-hydroxy-3, 3-dimethyl-4-oxo-*n*-pentyl)glutarimide (III-2) in yields of 37 and 2.7% respectively. When the reaction was carried out by method B, III-2 was obtained as the main product. The ultraviolet spectrum of III-1 indicated the absence of the α, β-unsaturated ketone system. The infrared spectrum of III-1 showed the disappearance of bands at 3200 and 3100 $cm^{-1}$ characteristic of glutarimide moiety and the appearance of new bands at 3442, 3225 and 1630 $cm^{-1}$ and at 1737 $cm^{-1}$ which indicate the presence of primary amide and of a δ-lactone ring respectively. The presence of a terminal $CH_3CO$-group in III-1 was demonstrated by a positive iodoform reaction. In order to further establish that III-1 contains the carbamoyl group, the ethanolysis of III-1 in the presence of a catalytic amount of concentrated sulfuric acid was carried out; an ester derivative (III-1′) was thus obtained.

It is noteworthy that either method, A or B, resulted in the formation of an isomer (III-2) of 3-(2-hydroxy-5-methyl-4-oxo-*n*-hexyl)glutarimide (III-3), the product which was obtained by Nielsen's aldol condensation procedure.[3] The latter (III-3) easily afforded an anhydro-derivative, 3-(5-methyl-4-oxo-2-*n*-hexenyl)glutarimide (III-4) on dehydration with phosphorus pentoxide in dry benzene and showed a negative iodoform reaction, while the former (III-2) resisted dehydration, showed a positive iodoform reaction, and afforded an *O*-acetate derivative (III-2′) by the usual acetylation.

In a preliminary attempt to synthesize cycloheximide,[5] DL-2, 4-dimethylcyclohexanone was caused to react with GAA by method B, however no stereoisomers of cycloheximide were obtained, while DL-anhydrocycloheximide (IV-1) and two stereoisomers (IV-2, IV-3) of DL-*gem*-cycloheximide were produced in poor yields. An analogous condensation of (2R : 4R)-2, 4-dimethylcyclohexanone[6] prepared from natural cycloheximide by alkaline degradation with GAA afforded anhydrocycloheximide[2] (V-1) and two stereoisomers (V-2, V-3) of *gem*-cycloheximide.

The resorcinol color reactions[7] of IV-2, IV-3, V-2 and V-3 were negative, suggesting the presence of the –CO–C(OH)–CH(OH)– ketol system, while those of IV-1 and V-1 were positive, indicating the presence of the –CO–C=CH– anhydro-system, which was further judged to be present by the absorption band near 240 mμ in the ultraviolet spectra. The melting points of these compounds corresponded well to those previously reported for the substances prepared by an alternative method.[3,8] The ketol compounds (IV-2, IV-3, V-2, V-3) were additionally characterized by having been led to their acetates. The identities were ascertained by analyses, by infrared spectra determination and by their failure to depress the melting points of authentic samples respectively.

Table I lists the melting point, absorption maxima, analyses and yields of the above-mentioned products.

5) The total synthesis of cycloheximide was recently achieved by F. Johnson, N. A. Starkovsky, A. C. Paton and A. A. Carlson, *J. Am. Chem. Soc.*, **86**, 118 (1964).
6) T. Okuda, *Chem. Pharm. Bull.* (*Tokyo*), **7**, 659 (1959).
7) M. Takeshita, H. Takahashi and T. Okuda, ibid., **10**, 304 (1962).
8) M. Suzuki, Y. Egawa and T. Okuda, ibid., **11**, 582 (1963).

In connection with the above synthesis, several attempts were made to effect the hydration of the ethylene linkage of the anhydrocycloheximide (V-1); however, this attempt resulted in no more than the formation of a small quantity of *α-epi*-isocycloheximide[8] (VI).

The results of preliminary screening studies of the antimicrobial, antitumor and rodent-repellent activities of the above-mentioned compounds will be reported elsewhere.

## Experimental

**General Procedures.**—*Method A* (Condensation by hydrogen chloride). — Glutarimide - β - acetaldehyde (GAA) was dissolved in excess ketone saturated with dry hydrogen chloride at room temperature, and then the mixture was allowed to stand overnight. After the excess ketone and hydrogen chloride had been removed by evaporation under reduced pressure, the residue was washed with ether and further purified by chromatography.

*Method B* (Condensation by concentrated sulfuric acid in acetic acid).—A large excess of a ketone and GAA (5—10 mmol.) were dissolved in glacial acetic acid (2—4 ml.). Into the solution, concentrated sulfuric acid (0.3 ml.) was added drop by drop under stirring at room temperature, and the mixture was allowed to stand overnight. Volatile ketones were removed by evaporation under reduced pressure. In the case of nonvolatile ketones, the reaction mixture was diluted with water, and, after neutralization with sodium carbonate, the solution was extracted with ethyl acetate. The removal of the solvent after drying over anhydrous sodium sulfate, gave a residue; this residue was then washed with *n*-hexane and further purified by chromatography.

**Acetylation.**—By the usual procedure, using acetic anhydride and pyridine at room temperature overnight.

**3-(4-Oxo-2-*n*-pentyl)glutarimide (I).**—The crude product (2.83 g.) obtained from GAA (1.55 g., 10 mmol.) and acetone (14 g.) by method A was dissolved in acetone (2 ml.), poured onto a column of acid-treated alumina (42 g.), and eluted with 3% methanol-benzene. After the eluate had been concentrated, dry ether was added and the mixture was kept standing in a refrigerator; thereupon separated crude crystals, which were washed with a small quantity of ether (yield 658 mg. (34%)). Recrystallization from ethyl acetate gave colorless prisms, m. p. 112.5—113°C. Infrared bands (Nujol): 3210, 3100 (NH), 1732, 1700, 1685 (C=O), 1652 $cm^{-1}$ (conjugated C=C).

2, 4-*Dinitrophenylhydrazone*: Red prisms, m. p. 203.5—205°C. Found: C, 50.90; H, 4.60; N, 18.50. Calcd. for $C_{16}H_{17}O_4N_5$; C, 51.20; H, 4.53; N, 18.67%.

**3-(3-Methyl-4-oxo-2-*n*-pentenyl)glutarimide (II).**—The crude product (806 mg.) obtained from GAA (775 mg., 5 mmol.) and ethyl methyl ketone (14.4 g., 0.5 mol.) by method A was dissolved in benzene (3 ml.) and chromatographed over acid-treated alumina (16 g.) using 3% methanol-benzene as a solvent. After the solvent had been removed by evaporation, the resulting syrup (642 mg.) was mixed with ether and allowed to stand in a refrigerator to give crude crystals (288 mg., 28%). Recrystallization from ethyl acetate gave colorless prisms, m. p. 81—81.5°C. Infrared bands (Nujol): 3200, 3100 (NH), 1732, 1702, 1675 (C=O), 1650 $cm^{-1}$ (conjugated C=C).

2, 4-*Dinitrophenylhydrazone*: Red prisms, m. p. 242—244°C (decomp.). Found: C, 52.74; H, 4.88; N, 17.99. Calcd. for $C_{17}H_{19}O_4N_5$: C, 53.00; H, 4.76; N, 17.75%.

**δ-(1, 1-Dimethyl-2-oxo-*n*-propyl)-β-carbamoylmethyl-δ-valerolactone (III-1).**—GAA (1.55 g., 10 mmol.) in acetic acid (2 ml.) was added drop by drop into methyl isopropyl ketone (8.6 g., 100 mmol.) containing hydrogen chloride (1.8 g., 51 mmol.) and stirred at room temperature. The crude product (3.65 g.) was then dissolved in acetone-benzene (1 : 1), poured onto a column of acid-treated alumina (50 g.), and eluted with 3% methanol-benzene. The viscous residue (985 mg.) obtained was caused to crystallize from acetone; yield 890 mg. (37%). Two recrystallizations from hot acetone gave colorless prisms, m. p. 164—164.5°C. Infrared bands (Nujol): 3442, 3225 (NH), 1737, 1685, 1665 (C=O), 1630 $cm^{-1}$ (NH).

Found: C, 59.90; H, 7.73; N, 5.87. Calcd. for $C_{12}H_{19}O_4N$: C, 59.73; H, 7.94; N, 5.81%.

**δ-(1, 1-Dimethyl-2-oxo-*n*-propyl)-β-ethoxycarbonylmethyl-δ-valerolactone (III-1′).**—A sample (120 mg.) of III-1 was dissolved in 95% ethanol (4 ml.). A solution of concentrated sulfuric acid (0.4 ml.) in 95% ethanol (2 ml.) was then added to the solution, and the mixture was allowed to stand at room temperature. After evaporation under reduced pressure, the resulting residue was diluted with a small amount of water, neutralized with 5% aqueous sodium carbonate, and extracted with ethyl acetate. Washing this with water, drying it over anhydrous sodium sulfate, and evaporating it left a syrup, which was then dissolved in *n*-hexane and allowed to stand in a refrigerator. There were deposited colorless prisms of III-1′ (35 mg.), m. p. 52—53°C. The infrared spectrum (Nujol) contained bands at 1750, 1740, 1715 (C=O), 1245, 1130 $cm^{-1}$ (C-O).

Found: C, 62.32; H, 8.68. Calcd. for $C_{14}H_{22}O_5$: C, 62.20; H, 8.20%.

2, 4-*Dinitrophenylhydrazone*: Red prisms, m. p. 166—166.5°C (decomp.).

Found: C, 53.11; H, 5.82; N, 12.15. Calcd. for $C_{20}H_{26}O_8N_4$: C, 53.33; H, 5.82; N, 12.44%.

**3-(2-Hydroxy-3,3-dimethyl-4-oxo-*n*-pentyl)glutarimide (III-2).**—*By Method A.*—A syrup (810 mg.) obtained by the evaporation of the mother liquor left after isolation of III-1 was chromatographed over acid-treated alumina (16 g.) with 3% methanol-benzene. After concentration under reduced pressure, the resulting syrup (450 mg.) was dissolved in ethyl acetate - ether and kept standing in a refrigerator to give crude crystals of III-2 (150 mg., 2.7%). Recrystallization from ethyl acetate gave colorless prisms, m. p. 112—112.5°C.

*By Method B.*—The crude product (660 mg.) obtained from GAA (775 mg., 5 mmol.) and methyl isopropyl ketone (4.3 g., 50 mmol.) was dissolved in acetone-benzene (1 : 1) and chromatographed on acid-treated alumina (16 g.). Elution with 3% methanol-benzene gave crude crystals of III-3 (190 mg., 16%). Recrystallization from ethyl acetate gave colorless prisms, m. p. 112.5—113°C. No depression in melting point

was observed upon its admixture with the sample prepared by method A.

*2, 4-Dinitrophenylhydrazone*: Red prisms, m. p. 227—227.5°C (decomp.). Found: C, 51.59; H, 5.56; N, 16.75. Calcd. for $C_{18}H_{23}O_7N_5$: C, 51.30; H, 5.50; N, 16.62%.

**Acetate of III-2 (III-2′).**—A crude sample (28 mg.) of III-2 was acetylated to give the acetate (11 mg.). Recrystallization from isopropanol gave colorless prisms, m. p. 143.5—144°C.

**3-(2-Hydroxy-5-methyl-4-oxo-*n*-hexyl) glutarimide (III)-3.**—The ethyl acetate solution obtained from *N*-methylanilinomagnesium bromide (33 mmol.), methyl isopropyl ketone (3.01 g., 35 mmol.) and GAA (1.86 g., 12 mmol.) by the procedure previously[3] reported was concentrated to give a syrup; this syrup was then washed with *n*-hexane to remove the unchanged ketone. The insoluble residue (900 mg.) was chromatographed on acid-treated alumina (18 g.). Elution with 3% methanol-benzene again gave a syrup (150 mg.); when this syrup was taken up in dry ether and kept in a refrigerator, it gave crude crystals (28 mg., 1.0%). Recrystallization from ethyl acetate afforded colorless prisms, m. p. 96.5—97°C. The ultraviolet spectrum in methanol showed end absorption. The infrared spectrum (Nujol) contained bands at 3540 (OH), 3220, 3110 (NH), 1733, 1708 and 1685 $cm^{-1}$ (C=O).

**3-(5-Methyl-4-oxo-2-*n*-hexenyl) glutarimide (III-4) (Anhydro-derivative of III-3).**—A sample of III-3 (20 mg.) dissolved in benzene (5 ml.) was mixed with phosphorus pentoxide (100 mg.), slowly heated to boiling, and then cooled. Evaporation under reduced pressure gave a residue which was recrystallized from dry ether to afford colorless prisms (3 mg.), m. p. 46—48°C. The ultraviolet spectrum in methanol showed a maximum at 224 mμ (ε 15200). The infrared spectrum (KBr) contained bands at 3200, 3080 (NH), 1737 sh, 1715, 1675 (C=O) and 1630 $cm^{-1}$ (conjugated C=C).

**DL-Anhydrocycloheximide (IV-1).**—A crude product (2.84 g.) prepared from DL-2, 4-dimethylcyclohexanone[9] (6.3 g., 50 mmol.) and GAA (1.55 g., 10 mmol.) by method B was dissolved in benzene-methanol (8 : 1), and the solution was poured onto acid-treated alumina (56 g.) and eluted with 3% methanol-benzene. When a syrup obtained from the early fractions was taken up in dry ether and allowed to stand in a refrigerator, it afforded crude IV (yield 30 mg., 1.1%). Recrystallization from ethyl acetate gave colorless prisms (12 mg.), m. p. 113—114°C. No depression in melting point was observed in admixture with an authentic specimen (m. p. 114—115°C) previously[3] reported.

**DL-*gem*-Cycloheximide I (IV-2).**—The mother liquor left after the isolation of IV-1 was concentrated under reduced pressure. The resulting syrup (1.01 g.) was charged on a column of silica gel (50 g.) and eluted with isopropyl ether - ethyl acetate (9 : 1, 7 : 3, 1 : 1 and 1 : 3) and ethyl acetate successively. The early fractions obtained with 30% ethyl acetate - isopropyl ether were concentrated to give a syrup which was caused to crystallize from ether; yield, 40 mg., m. p. 112—113°C. The product was identical with VI-1 in all respects.

A syrup (108 mg.) obtained from the early fractions with 50% ethyl acetate - isopropyl ether was caused to crystallize from ethyl acetate to give crude IV-2 (42 mg., 1.5%). Two recrystallizations from the same solvent gave colorless prisms, m. p. 142.5—143°C, which showed a negative resorcinol reaction.[7] The product has a higher melting point than that of a sample of DL-*gem*-cycloheximide I previously obtained,[3] which has now been found to be impure. The identity was ascertained by both samples leading to the same acetate, as will be described below.

**Acetate of IV-2 (IV-2′).**—A sample of IV-2 (15 mg.) was acetylated to give colorless prisms (10 mg.), m. p. 174—175°C. The acetate was found to be identical with the DL-*gem*-cycloheximide I acetate (reported m. p. 174—175°C) previously reported[3] by a mixed melting point determination and by a comparison of the infrared spectra.

**DL-*gem*-Cycloheximide II (IV-3).**—The later fractions with 3% methanol - benzene and all fractions with 5% methanol - benzene (see DL-anhydrocycloheximide (IV-1)) were collected and concentrated to dryness, and the residue (783 mg.) was caused to crystallize from ethyl acetate to give crude crystals of IV-3 (280 mg., 10%). Recrystallization from methanol gave colorless prisms, m. p. 182—182.5°C, which showed a negative resorcinol reaction. The product has a higher melting point than that of DL-*gem*-cycloheximide II previously obtained,[3] a product which has now been found to be impure. The identity was confirmed by both products leading to acetate, as will be described below.

**Acetate of IV-3 (IV-3′).**—A sample of IV-3 (26 mg.) was acetylated to give crude acetate (22 mg.). Recrystallization from isopropanol gave colorless prisms (15 mg.), m. p. 207—208°C, undepressed by admixture with an authentic specimen (m. p. 200—202°C) previously obtained.[3]

**Anhydrocycloheximide (V-1).**—The crude product (1.93 g.) obtained by the reaction of optically-active (2R : 4R)-2, 4-dimethylcyclohexanone (3.2 g., 25 mmol.) with GAA (775 mg., 5 mmol.) was chromatographed over acid-treated alumina (38 g.) with 3% methanol - benzene. The eluate was then evaporated under reduced pressure, and the resulting residue (481 mg.) was dissolved in ethyl acetate, poured onto a column of silica gel (25 g.) and eluted with the same solvent systems as were used for the isolation of IV-1. A syrup obtained from the early fractions with ethyl acetate - isopropyl ether (1 : 1) was caused to crystallize from ether; crude crystals (12 mg.) (1.0%). Recrystallization from methanol gave colorless prisms, m. p. 135—136°C. The product was found to be identical with anhydrocycloheximide (reported m. p. 136.5—138°C) by a mixed melting point determination. Additionally, they had identical ultraviolet and infrared spectra.

***gem*-Cycloheximide II (V-2) and Its Acetate (V-2′).**—When a residue (197 mg.) obtained from the middle fractions with 50% ethyl acetate - isopropyl ether in the above chromatography was taken up in ether and allowed to stand at room temperature, there separated crystals of V-2 (60 mg., 4%). Recrystallization from ethyl acetate afforded colorless prisms, m. p. 156—156.5°C. The product showed a negative resorcinol color reaction, indicating that the product

9) H. E. Ungnada and A. D. McLaren, *J. Org. Chem.*, **10**, 29 (1945).

was a diastereoisomer[10] of the *gem*-cycloheximide. The product has been led to its acetate (colorless prisms; m. p. 145—147°C) by the general procedure. The infrared spectrum (KBr) contained bands at 3270, 3100w (NH), 1745sh, 1715, 1700 (C=O) and 1250 $cm^{-1}$ (C-O).

***gem*-Cycloheximide (V-3) and Its Acetate (V-3′).** —The mother liquor left after the isolation of V-2 was evaporated to give crude V-3, which could not be caused to crystallize. Then, the residue (50 mg.) was acetylated by the general procedure to give a crude solid (20 mg.). Recrystallization from isopropanol gave colorless prisms of V-3′ (10 mg.), m. p. 164.5—165°C. The product was found to be identical in all respects with the *gem*-cycloheximide I acetate (reported m. p. 166—166.5°C) previously[8] reported.

***α-epi*-Isocycloheximide (VI) and Its Acetate (VI′) (The Hydration of Anhydrocycloheximide).** —Into a mixture of anhydrocycloheximide (V-1) (4.21 g., 16 mmol.) and acetic acid (12 ml.), 75% sulfuric acid (2.34 g., 17.6 mmol.) was added drop by drop and stirred at room temperature. Stirring was continued for 2 hr. to give a clear solution, and then the mixture was stirred for an additional 3 hr. The reaction mixture was diluted with water (12 ml.) and neutralized with sodium carbonate, followed by extraction with ethyl acetate. After it had been washed with water, aqueous 5% sodium bicarbonate and water, and dried over anhydrous sodium sulfate, the extract was evaporated to remove the solvent. The resulting yellow syrup was treated with ether in order to precipitate unchanged anhydrocycloheximide (2.2 g., m. p. 133—135°C). The ethereal solution was evaporated to give a residue (2.45 g.), which was then taken up in dry benzene, poured onto acid-treated alumina (60 g.), and eluted with 3% methanol-benzene. The later fractions showed a significant activity in reaction to *Saccharomyces sake*. The resulting residue (950 mg.) was similarly rechromatographed to afford crude VI (240 mg.), which was taken in ethyl acetate and again chromatographed over silica gel (32 g.) with ethyl acetate - isopropyl ether (1 : 1). The evaporation of the later fractions again afforded a gummy solid (210 mg.). The minimum inhibitory concentration of the product against *S. sake* was found to be 30 mg./ml. by a dilution method.

Found: C, 63.95; H, 8.06; N, 4.95. Calcd. for $C_{15}H_{23}O_4N$: C, 64.03; H, 8.24; N, 4.98%.

10) M, Suzuki et al. described a diastereomer with a m. p. of 141—145°C. See Ref. 8.

The product (100 mg.) was acetylated by the general procedure. The crude acetate was purified by chromatography over silica gel (3 g.) with 30% ethyl acetate - isopropyl ether. Recrystallizations from ether and isopropyl ether gave colorless prisms, 30 mg., m. p. 177.5—178°C. No depression in melting point was observed upon admixture with an authentic specimen of *α-epi*-isocycloheximide acetate.[8] Additionally, the product was identical in infrared spectra with the authentic specimen.

## Summary

1) Glutarimide-β-acetaldehyde has been condensed with several aliphatic ketones by acid-catalysts to give mainly α, β-unsaturated keto-derivatives. The condensation with methyl isopropyl ketone has given δ-(1, 1-dimethyl-2-oxo-*n*-propyl)-β-carbamoylmethyl-δ-valerolactone (III-1) and 3-(2-hydroxy-3, 3-dimethyl-4-oxo-*n*-pentyl)-glutarimide (III-2). It has been found that the latter is an isomer of the product prepared by Nielsen's aldol condensation procedure.

2) An analogous condensation with DL-2,4-dimethylcyclohexanone has given DL-anhydrocycloheximide and two stereoisomers of DL-*gem*-cycloheximide. The condensation with (2R:4R)-2, 4-dimethylcyclohexanone has given a similar result.

3) It has been shown that the acid-catalyzed hydration of anhydrocycloheximide affords *α-epi*-isocycloheximide.

The authors are grateful to Dr. Tomoharu Okuda. Director of the Microbial Chemistry Research Laboratories of Tanabe Seiyaku Co., for his helpful advice. The authors also wish to thank Mr. Saburo Nakada for his microanalyses and Mr. Hajime Miki and Mr. Tatsuo Hasue for their technical assistance. The support of this work by a cancer research grant of the Ministry of Education is hereby gratefully acknowledged.

# The Cross-linking Reaction of the Polybutadiene Binder for Composite Propellants

By Kiroku YAMAZAKI and Harusuke TOKUI

(Received June 14, 1965)

The monomer or prepolymer of the fuel binder should have a suitable fluidity at an ambient temperature in order to secure a high holding capacity of solid ingredients and a high castability. On the other hand, a propellant grain should have good mechanical and combustion characteristics. Polyurethane is an excellent binder, one which fulfills such requirements; its physical properties can be widely controlled by means of the reaction conditions and the type of starting materials.[1] Polybutadiene also seems to give a grain with a high ballistic performance and a good low temperature property due to its low heat of formation, its high hydrogen/carbon ratio and its low second-order transition point.

In view of these points, a polybutadiene fuel binder with good mechanical properties was studied using "telechelic polybutadiene" (carboxy-terminated polybutadiene) as the starting material.[2] "Telechelic polybutadiene" has a relatively uniform molecular weight distribution and is cross-linked with terminal groups, so that the resultant polymer network will be essentially uniform, containing no terminal sections. Unlike conventionally-vulcanized rubbers, which are randomly cross-linked, the strain would be distributed uniformly upon each elastic chain of the cross-linkage and the mechanical strength might be improved remarkably. Moreover, it is possible to control to some extent the reaction of the chain extension and the cross-linking because this compound functions as a dicarboxylic acid.

Tris[1-(2-methyl)aziridinyl] phosphine oxide [MAPO] was used as the cross-linking agent in this work.[3] Usually a curing temperature as high as 100—150°C is recommended; however, we preferred here to suppress the temperature as much as possible toward the ambient temperature in view of the volume contraction of the cured material and the inferior heat resistance of the additives. An effective accelerator was found which enables cross-linkage even at the relatively low temperatures of 50—70°C without the sacrifice of the properties of the cured products.

3) U. S. Pat. 3087844.

## Raw Materials

"Telechelic polybutadiene" HC-434 (Thiokol Chem.) and Butarez CTL (Phillips Pet. Co.) were used as received. The number-average molecular weights were 3770 and 5500 respectively.

## Experimental Results

**An Accelerator for the Curing Reaction.**— Reaction mixtures were poured into a 40×40×5 mm. glass cell, made of two 40×40 mm. glass plates standing face to face with a 5 mm. spacer with tin foils lining the inside surfaces; these plates served as a pair of electrodes. The loaded cell was put into a constant temperature oven, and the specific resistivity at 50°C was measured continuously. Figure 1 shows the curve of the specific resistivity versus the reaction time. The time required until the specific resistivity become constant is cut by the addition of the accelerator.

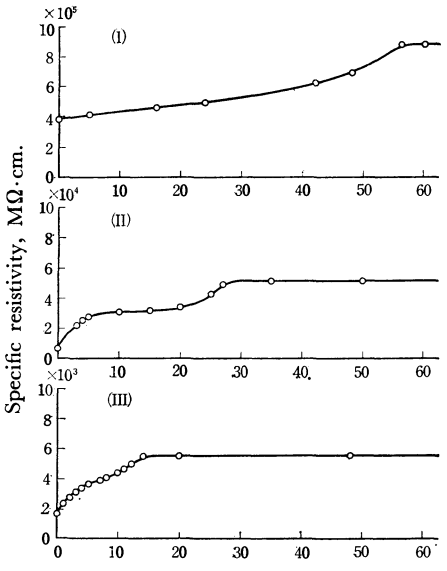

Fig. 1. Specific resistivity versus reaction time (50°C cure).

| 4.0 | — | — | — | — | — | 14130 | 14.67 |

Even though the changes of the electric property could not indicate the degree of the chemical cross-linking exactly, it may be expected that the increase in specific resistivity is still be related to the process of the curing reaction; it is evident that the addition of the accelerator is very effective.

However, the time required for a perfect cure is remarkably affected by the type of vessel used for the curing. For example, the composition shown on Fig. 1 was cast and cured at 50°C in a 60 mm.$\phi \times$90 mm.H polyethylene cup, and the progress of the curing reaction was followed by hardness measurements with a durometer. The hardness increased as the reaction proceeded, but more than 2 weeks were required for a perfect cure. It is reasonable for the heat transfer to the inside of the reaction mixture in a large vessel to be slower than in a smaller one, but this difference alone can not explain the result. Although no decisive interpretation can yet be made, the difference may be attributed to the differences in the area of contact with the atmosphere from vessel to vessel. However, the addition of an accelerator was effective in both cases. In the end, for the purpose of lowering the curing temperature for the carboxy-terminated polybutadiene-MAPO system, some effective accelerators were found.

**The Elastomer Preparation.**—The required amounts of the ingredients were mixed manually at 75—80°C, degassed, and cast into the cavity formed by two parallel glass plates in order to form elastomer sheets about 2—3 mm. thick. After some preliminary tests, the curing time of 7 days was taken.

**The Measuring Process.**—The tensile stress-strain data were obtained using "Tensilon" with dumbbell-shaped specimens. Following the standard "Physical Testing Methods for Vulcanized Rubber" (JIS-K-6301), a strain rate of 500 mm./min., a cross-head distance of 50 mm. and No. 3 type dumbbell-shaped specimens die-cut from the elastomer were used.

The hardness was measured using an Asker durometer J.

All the experiments were performed in an air-conditioned room at a constant temperature of 20°C and at a constant relative humidity of 60%.

The data are shown in Tables I and II.

**Equilibrium Swelling.**—If a two-functional carboxy-terminated polybutadiene reacts quantitatively with an equivalent amount of a three-functional cross-linking agents [MAPO], the resultant network will have no terminal sections. In this case, each segment of the network structure

acts in an elastic manner, and the length of each segment should be same as that of the initial two-functional polybutadiene molecule. However, the actual curing reaction will be more complicated because of some undesirable side reactions. The average molecular weight for the chain of the network and the degree of cross-linking are very important factors in describing a three-dimensional polymer network model; therefore, the equilibrium swelling was measured in order to clarify these indexes.

When the volume fraction, $Q_m$, of the polymer present in the swollen gel is rather small, it can be approximately represented by Eq. 1.[4]

$$Q_m=[(1/2-\mu)M_c/\rho_2 V_1]^{3/5} \quad (1)$$

where $\rho_2$ : the polymer density
$V_1$ : the molar volume of the solvent
$\mu$ : the polymer-solvent interaction constant
$M_c$ : the average molecular weight between cross-links

$Q_m$ can be determined directly by Eqs. 2 and 3.

$$W=W_1+W_2 \quad (2)$$

$$Q_m=1+(\rho_2/\rho_1)(W'/W_1-1) \quad (3)$$

where $\rho_1$ : the density of the solvent
$W$ : the weight of the specimen before swelling
$W_1$ : the weight of gel in the specimen
$W_2$ : the weight of sol in the specimen
$W'$ : the weight of the specimen on equilibrium swelling

The calibration term for terminal chains could be neglected because its fraction would be very small from the standpoint of the reaction scheme.

Small pieces of elastomers about 0.4—0.5 g. were immersed in carbon tetrachloride at 20°C. After 7 days, the swollen gel was removed from the solvent, quickly blotted with dry filter paper, and reweighed in a stoppered weighing bottle. The specimen was then transferred to an electric oven at 50°C in order to remove the imbibed solvent; the $W_1$ was thus determined. The weight difference, $W_2$, between $W$ and $W_1$ was taken as the weight of the sol. It is impossible for all of the sol to be extracted by such a simple procedure; however, the measured value is useful as a semi-quantitative measure of the sol fraction.

The polymer density at 20°C was measured by the pycnometer method, using distilled water as the sealant.

The $Q_m$ was determined from Eq. 3; then $M_c$ was calculated by Eq. 1. The data obtained are shown in Table I and Table II, together with the sol fraction, which was measured by the procedure described.

4) J. Furukawa and S. Yamashita, *J. Soc. Rubber Ind. Japan (Nippon Gomu Kyokai-shi)*, **30**, 955 (1957).

The polymer-solvent interaction parameter, $\mu$, was calculated as 0.264 (at 20°C) by means of the data shown by Shvarts.[5]

## Discussion

From the data illustrated on Table I and Table II, it is evident that the chain length between cross-links, $M_c$, is strongly influenced by the cross-linking agent, the accelerator and the curing temperature. In general, as the addition of the cross-linking agent increases, the tensile strength and the modulus of the elastomer pass through a maximum. Namely, there is a peak in the curve of the tensile modulus versus the quantity of the cross-linking agent added. If this was due to only the "dilution effect" of an excess cross-linking agent, $M_c$ would not decrease even if the tensile modulus decreased.

Though the data observed are negative for such a relation, $M_c$ was inversely proportional to the tensile modulus; and this shows that the optimum molar ratio of the cross-linking agent should be determined with the maximum tensile modulus and it was found that a 100—200% excess of equivalence is required.

Assuming that the ideally cross-linked HC-434 polymer has a network model as has been described previously, its $M_c$ should be same as the average molecular weight 3800 of the HC-434 polymer. However, the minimum $M_c$ value obtained is about 6000, which is about one and a half times the chain length for an ideal network. Therefore, it is reasonable to assume that a considerable chain extending reaction occurs inevitably; this may be the reason why an excess of the cross-linking agent is required in order to obtain the maximum tensile modulus.

The kinetic theory of rubber elasticity predicts that the tensile stress-strain will be given by Flory's equation:

$$S=\nu \boldsymbol{R} T(\alpha-1/\alpha^2) \quad (4)$$

where $S$ : the stress based on the original cross-sectional area
$\nu$ : moles of effective chain per unit volume
$\boldsymbol{R}$ : the gas constant
$T$ : the absolute temperature
$\alpha$ : the principal extension ratio

In Eq. 4 $\nu$ can be replaced by $1/M_c$, for the polymer density is almost equal to 1.00; the tensile stress, $S$, should then be inversely proportional to the chain length, $M_c$. As $\boldsymbol{R}$ and $T$ are known quantities, the tensile stress at 100% elongation ($\alpha=2$) can be calculated by means of Eq. 5:

$$S_{100}=0.426\times 10^5(1/M_c) \text{ kg./cm}^2 \quad (5)$$

Figure 2 shows the relationship between the tensile stress at 100% elongation and the chain length, $M_c$.

5) A. G. Shvarts, *Rubber Chem. and Tech.*, **31**, 691 (1958).

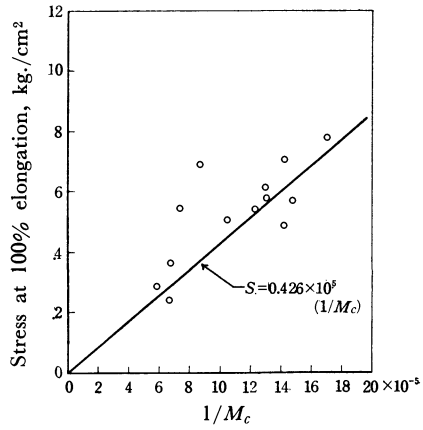

Fig. 2. Plot of tensile stress at 100% elongation versus $M_c$ (HC-434 - MAPO - Accelerator).

Although there are a few exceptions, in general, the observed data agree well with the theoretical quantities.

It can readily be assumed that the quantity of an ingredient which makes no contribution to the cross-linking reaction (which would be proportional to the sol fraction) might be at a minimum at the optimum mixing ratio of the polybutadiene, the cross-linking agent and the accelerator for the maximum tensile modulus of an elastomer. The longer the chain length, the greater the quantity of the sol fraction. These relationships are illustrated in Fig. 3.

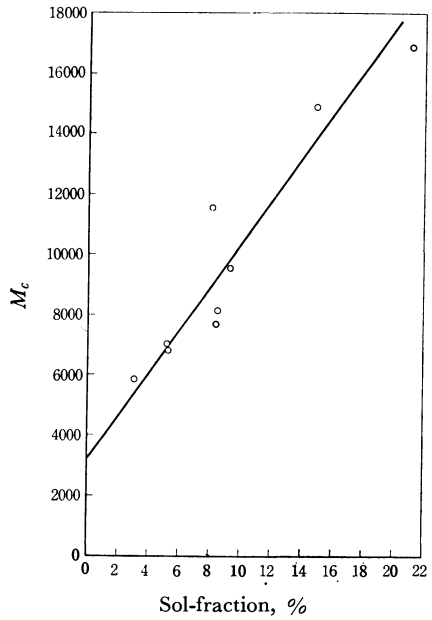

Fig. 3. Plot of sol fraction versus $M_c$ (HC-434 - MAPO - Accelerator 5 phr.).

Figure 4 shows the chain length, $M_c$, versus the elongation at the break point of the elastomer.

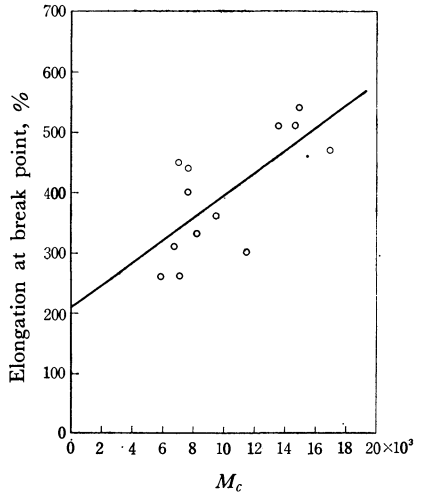

Fig. 4. Plot of elongation at break point versus $M_c$ (HC-434 - MAPO - Accelerator).

Breaking phenomena can scarcely give reliable data, because they are strongly influenced by the internal defects in the molecular structure of the specimens. However, it is shown that the elongation at the break point increases with the chain length, $M_c$. As the cross-linking reaction proceeds so effectively that the chain length, $M_c$, becomes short, the internal stress per unit of the chain of the network should be increased; this may be what happens in the breaking of the elastomer.

Equation 4 shows that the stress, $S$, should be proportional to $(\alpha - 1/\alpha^2)$ and that the slope of this line, $\nu RT$, equals the shear modulus. These relationships are illustrated in Fig. 5 and Fig. 6; plots of $S$ versus $(\alpha - 1/\alpha^2)$ show a good linearity.

(II) MAPO 2.5 eq. (IV) MAPO 4.0 eq.

On the other hand, as $M_c$ was determined from swelling data, the stress-strain data could be calculated by means of Eq. 4. These are represented in Fig. 5 and Fig. 6 with dotted lines. (The polymer density was assumed to be 1.00.)

Of course, there is a considerable amount of sol occluded in the network structure, and if the sol fraction has no role to play in the networks, the tensile stress can be calculated by considering the term of the "dilution effect" for the swelling data; however, the observed value is higher than that calculated from $M_c$. Therefore, a dilution effect of the sol fraction is not conceivable, while a reinforcing effect such as chain entanglement is plausible.

Table I shows the effects of the curing temperature. As is shown by the table, the increase in the temperature for the cross-linking reaction from 50°C to 70°C causes a decrease in the sol fraction, the chain length, $M_c$, and the quantity of cross-linking agent required for the maximum tensile modulus. These tendencies seem quite reasonable, since the reactivity and the mobility of the ingredients would increase with the reaction temperature.

Table III compares the cross-linking reactions of the Butarez CTL and HC-434 polymers. The average molecular weight of Butarez CTL is larger than that of HC-434, so the $M_c$ of the cured products of the former is longer than that of those of the latter. However, not only are the ratios of $M_c$ divided by the average molecular weight of respective raw materials almost the same; the sol fractions are also almost the same. Hence, it may be concluded that there is no noticeable difference between the reactivities of these two raw materials.

## Conclusion

The cross-linking reactions of "telechelic polybutadiene" at relatively low temperatures have been studied, and some kinds of accelerator have been found to be effective.

In general, a 100—200% excess of cross-linking agent was required in order to obtain cured elastomers of the maximum tensile modulus.

As the curing temperature rose, the excess quantity of the cross-linking agent was diminished.

The measured stress-strain data of the elastomers closely fit Flory's equation for the rubber elasticity theory. The swelling data were in line with the stress-strain data.

## Summary

The cross-linking reactions of carboxy-terminated polybutadiene with tris[1-(2-methyl)aziridinyl] phosphine oxide have been studied in order to obtain an excellent fuel binder of good mechanical properties as well as good combustion characteristics.

The tensile strength and elongation at the break point, as shown by the elastomer studied, were about 10—15 kg./cm.² and 250—500% respectively. For high tensile modulus of the elastomer, an 100—200% excess of the cross-linking agent over the equivalent ratio was required.

The reaction temperature for cross-linking was lowered to the 50—70°C range by the addition of a suitable accelerator.

The stress-strain curve of the elastomer closely fit the equation for the rubber elasticity theory, and these stress-strain data was in accordance with the measured swelling data.

# Palladium(II) Complexes of β-Ketoamines Derived from Acetylacetone and Amines

By Emiko YOSHIDA and Shoichiro YAMADA

(Received June 14, 1965)

In previous papers from this laboratory,[1] transition metal complexes of Schiff bases derived from salicylaldehyde and various amines were discussed. A similar study was then made of nickel(II) and copper(II) complexes of β-ketoamines[2] derived from acetylacetone and amines in order to compare the results with those of the corresponding salicylideneimine complexes previously studied.[3,4] Most of the papers about this and similar topics were, however, concerned mainly with complexes of the first transition elements, such as cobalt, nickel and copper. It seemed, therefore, worthwhile to study the corresponding complexes of the second or the third transition elements and to compare them with those of the first transition elements. The present paper will describe palladium(II) complexes of β-ketoamines derived from acetylacetone and monoamines. No palladium(II) complexes of these ketoamines have yet been described in the literature.

## Experimental

**Materials.** — The palladium(II) complexes, Pd(Aca.R)$_2$, were prepared according to either of the following two methods. (A) To a solution of bis(acetylacetonato)palladium(II)[5] in ethanol, a calculated amount or a slight excess of one of the amines was added. The mixture was then stirred while being heated at about 50—60°C for five hours. (B) To a solution of a β-ketoamine in ethanol there was gradually added an aqueous solution of potassium tetrachloropalladate(II) and potassium hydroxide. The mixture was then stirred while being heated at about 40—50°C for about five hours. The yield was generally higher by the method B than by the method A. The method B was, therefore, applied to the preparation of the complexes with aryl amines, ammonia, methyl amine and benzyl amine. Since, however, it was difficult to prepare the β-ketoamines by condensation in the case of alkyl amines (with the exception of methyl amine), the metal complexes with alkyl amines were prepared according to the method A.

A typical example of preparation by the method A is that for bis(*N*-methyl-acetylacetoneaminato)palladium(II), Pd(Aca.$CH_3$)$_2$. To 1.0 g. (1/300 mol.) of Pd(acac)$_2$ in 10 ml. of ethanol, was added 0.67 g. of a 30% solution of methyl amine (2/300 mol.).[6] The reaction mixture was then stirred while being heated at abbut 60°C for about five hours. The coluor of the solution gradually changed from yellow to reddish brown. Then the solution was filtered and allowed to stand at room temperature. Reddish-brown crude crystals were obtained and recrystallized from chloroform.

A typical example of preparation by the method B is that for bis(*N*-phenyl-acetylacetoneaminato)palladium(II), Pd(Aca.$C_6H_5$)$_2$. To a slight excess of a β-ketoamine in 10 ml. of ethanol were added 1.0 g. (1/300 mol.) of potassium tetrachloropalladate(II) in 10 ml. of water and 0.38 g. of potassium hydroxide in 5 ml. of water. An orangish-yellow precipitate was produced at once, but the resulting mixture was incessantly stirred at 45—50°C for five hours. Then it was allowed to stand at room temperature. The product was filtered, washed with ether, and recrystallized from benzene-ethanol.

These palladium(II) complexes are all yellow or yellow-orange, with the exception of the *N*-methyl-substituted complex, for which two isomers were obtained as pure crystals, one being yellow and the other orange-red. The yellow form was prepared by the method B, and the orange-red form, by the method A. All the complexes prepared were stable in the atmosphere and were readily soluble in benzene and chloroform and moderately soluble in acetone, ethanol and methanol. The solvents used for the recrystallization of the complexes are shown in Table I, together with elemental analyses of the compounds.

**Measurements.**—The visible and ultraviolet absorption spectra of the complexes in solution were determined with a Shimadzu QR-50 spectrophotometer and a Beckman DU spectrophotometer. The infrared spectra of the compounds were determined with a Hitachi EPU-2A infrared spectrophotometer. The X-ray diffraction diagrams were obtained with a Toshiba ADX-103 X-ray diffractometer.

## Results and Discussion

Many new palladium(II) complexes have been synthesized in the present work with β-ketoamines

1) S. Yamada, H. Nishikawa and K. Yamasaki, This Bulletin, **36**, 483 (1963); S. Yamada and H. Nishikawa, ibid., **36**, 755 (1963); S. Yamada, H. Nishikawa and E. Yoshida, *Proc. Japan* Academy, **40**, (1964); etc.

2) As a matter of convenience, these ligands will be referred to as β-ketoamines, although their electronic state in the metal complexes may be somewhere between the ketoamine and the enolimine.

3) These metal complexes are abbreviated in this paper as M(Sal. R)$_2$ and M(Aca. R)$_2$, R being an alkyl or an aryl group attached to the nitrogen atom.

4) S. Yamada, H. Nishikawa and E. Yoshida, Proceedings 8. I. C. C. C. (International Conference on Co-ordination Chemistry), Vienna (1964), p. 373.

5) Bis(acetylacetonato)palladium(II) was prepared according to the method of A. A. Grinberg and L. K. Simonova (*Zhur. Priklad. Khim.*, **26**, 880 (1953)).

6) The symbol *acac* denotes an acetylacetonate anion.

derived from acetylacetone and alkyl amines. The elemental analysis of the complexes, which agrees with the general formula of $Pd(Aca.R)_2$, definitely excludes the formation of the sexa-co-ordinate complexes of $Pd(acac)_2(RNH_2)_2$, as may also be inferred from the property of palladium(II) of being generally reluctant to take a co-ordination number exceeding four. This is borne out by the infrared spectra of the complexes, which show no absorption due to the CO-group of the acetylacetonate ion co-ordinated with the metal ion, but instead absorption peaks at about 1510—1520 and 1590—1600 $cm^{-1}$. These two peaks are most probably due to the β-ketoamines in the metal complexes[7]. Of the three possible forms for the β-ketoamines (Fig. 1), the structure B was considered to be most likely.[8] For the metal complexes of the β-ketoamines, however, the structures corresponding to the complexes of A and B may be surmized.[7] The

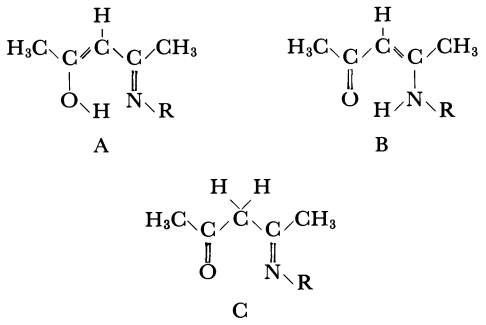

Fig. 1. Possible structures for the condensation products from acetylacetone and an amine, $RNH_2$: A, enolimine; B, ketoamine; c, ketoimine.

extent of the contribution of these forms in the metal complexes has not been determined in the present work.

It should be noted that the palladium(II) complexes, $Pd(Aca.R)_2$ (R being $n$-propyl and $n$-butyl), have been prepared as crystals, although the free ligands have never been isolated as pure substances. This is regarded as an example of the stabilization of the otherwise unstable ligands through co-ordination with a metal ion. No reaction of a similar type with nickel(II), which also has a $d^8$ configuration, was found to take place at all; that is, the color of the mixed solution did not show any sign of the reaction taking place. The difference in this respect between palladium(II) and nickel(II) seems to be in agreement with the current view that the palladium(II)-ligand bond is generally stronger than the nickel(II)-ligand bond.

It is most likely that the palladium(II) complexes prepared in the present work are square-planar in non-donor solvents as well as in the solid state, since it is known that the palladium(II) ion strongly demands the quadri-co-ordinate square-planar configuration. A recent X-ray study has revealed that $Pd(Aca.H)_2$ takes a trans-square-planar configuration.[9] However, it has not yet been definitely concluded whether the complexes reported here belong to a trans- or a cis-series.

For $Pd(Aca.CH_3)_2$, two kinds of crystals were obtained according to the method of the preparation, one being yellow and the other a brownish orange. The X-ray powder patterns of the two forms are difinitely different. Furthermore, the electronic spectrum of the one is quite different from the spectrum of the other in solution, the red form displaying an absorption band in a far lower frequency region than the yellow form (Fig. 2).

9) G. E. Gurr, *Inorg. Chem.*, **3**, 614 (1964).

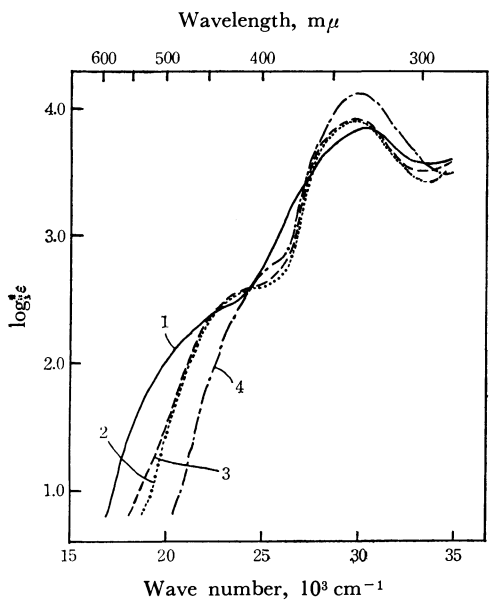

Fig. 2. Electronic spectra of ketoamine complexes of palladium(II) in chloroform: 1, Pd(Aca.-$CH_3$)$_2$, orange-red form (——); 2, Pd(Aca.-$CH_3$)$_2$, yellow form (----); 3, Pd(Aca.*n*-$C_4H_9$)$_2$ (— — —); 4, Pd(Aca.H)$_2$ (—·—·—).

Consequently, the difference in color between the two is not due to the difference in the mere effect of the packing of the molecules in the crystal, but to the difference in the molecular configuration. The two forms presumably correspond to cis- and trans-isomers. No definite conclusion has been reached in the present work about which is the cis- and which the trans-form.[10]

Judging from the similarity in the electronic spectrum (Fig. 2), the compounds prepared in the present work, which have the general formula of Pd(Aca.R)$_2$, R being ethyl, *n*-propyl and *n*-butyl, probably have the same geometrical configuration as the yellow form of Pd(Aca.$CH_3$)$_2$. The absorption band at about $24\times10^3$ cm$^{-1}$ is presumably due to an electronic transition between an orbital in the ligand and a d-orbital in the metal ion. The strong absorption band at about $30\times10^3$ cm$^{-1}$ may be due to an electronic transition within the ligand combined with the palladium(II) ion.

Many new complexes of palladium(II) β-ketoamines derived from acetylacetone and aryl amines have been prepared in the present work. As in the case of the corresponding alkyl complexes, the elemental analysis indicates that these palladium(II)-complexes are quadri-co-ordinate, with the formula of Pd(Aca.R)$_2$, while the infrared spectra show the formation of the ligands, Aca.R, combined with the metal ion.

10) A reaction similar to that employed in the preparation of the orange-red isomer does not yield the corresponding orange-red complex in the case of the aryl-substituents.

The free ligands can be isolated in the pure form with aryl group for R, while the isolation of the corresponding compounds in the pure form is possible only with methyl or ethyl for R throughout the alkyl series. The preparation of the metal complexes, therefore, is generally easier with the aryl than with the alkyl group for R.

As has been discussed in connection with the alkyl-derivatives, these palladium(II) complexes may also be considered square-planar. It is not certain at the present stage whether they should take a cis- or a trans-configuration. It might be argued that Pd(Aca.*o*,*o*'-xylidyl)$_2$ would take a configuration distorted from the square-plane due to the possible steric hindrance of the two methyl groups at the *o*- and *o*'-carbon atoms. However, this complex is also considered to be square-planar, since the formation of the corresponding nickel(II) complex with a square-planar configuration indicates that the probable steric hindrance of the two methyl groups is not so serious as to prohibit the square-planar configuration,[4] and since palladium(II) generally demands the square-planar configuration more strongly than nickel(II). This seems to be borne out by the electronic spectrum of this complex in non-donor solvents, (cf. Fig. 3); the spectrum is nearly superposable upon the spectra of Pd(Aca.tolyl)$_2$, which are all presumed to be square-planar since no steric hindrance is present in these complexes.

The capacity of nickel(II) in a square-planar

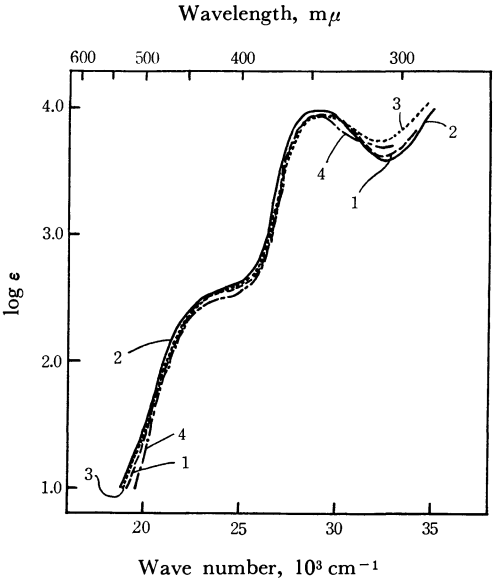

Fig. 3. Electronic spectra of ketoamine complexes of palladium(II): 1, Pd(Aca. *o*-tolyl)$_2$ in chloroform (----); 2, Pd(Aca. *m*-tolyl)$_2$ in chloroform (——); 3, Pd(Aca.*o*,*o*'-xylidyl)$_2$ in chloroform (----); 4, Pd(Aca.*o*,*o*'-xylidyl)$_2$ in pyridine (—·—·—).

complex to take the six-co-ordination by combining additional ligands was formerly examined, with pyridine used as the ligand.[4] In order to compare palladium(II) with nickel(II) in this respect, the electronic spectra were examined with the palladium(II) complexes prepared in the present work. The present measurements reveal that the spectra of these palladium(II) complexes in pyridine are almost superposable upon the spectra of the same compounds in non-donor solvents. This fact shows that these complexes keep the square-planar configuration, taking up no additional pyridine molecules at the fifth or the sixth site, even in pyridine. The corresponding nickel(II) complexes, $Ni(Aca.R)_2$ (R being aryl radicals), are found to form sexa-co-ordinated complexes by combining two pyridine molecules in the pyridine solution[4] (with the exception of Ni(Aca. *o*, *o'*-xylidyl)$_2$, which is square-planar in pyridine). It is found again that the palladium(II) has less of a tendency to form sexa-co-ordination than has nickel(II), as was also observed with other ligands.

No difference was observed in this property of the nickel(II) and palladium(II) complexes between the corresponding $\beta$-acetylacetoneamines and the salicylideneimines. A similar result was obtained with the corresponding complexes of salicylideneimines. The palladium(II) complexes of the $Pd(Sal.R)_2$ type (R being *o*, *o'*-xylidyl, *o*-, *m*- and *p*-tolyl, and phenyl) are all square-planar in pyridine as well as in non-donor solvents,[11] while the corresponding nickel(II) complexes, $Ni(Sal.R)_2$, are sexa-co-ordinated in pyridine (with the exception of Ni(Sal. *o*, *o'*-xylidyl)$_2$).[4]

11) S. Yamada and K. Fujita, unpublished.

## Summary

Numerous new palladium(II) complexes, $Pd(Aca.R)_2$, have been synthesized with $\beta$-ketoamines derived from acetylacetone and amines, where R represents methyl, ethyl, *n*-propyl, *n*-butyl, benzyl, phenyl, *o*-, *m*- and *p*-tolyl, and *o*, *o'*-xylidyl. It should be noted that when R denotes *n*-propyl or *n*-butyl, the palladium(II) complexes have been prepared successfully, although the free ligands can not be isolated in a pure form. This may be regarded as an example of the stabilization of a molecular configuration through co-ordination with a metal ion. The visible and ultraviolet spectra indicate that the palladium(II) complexes prepared in the present paper, which are considered to be square-planar in non-donor solvents as well as in the solid state, combine no additional pyridine molecules, even in pyridine. This is contrary to the previous observation that $Ni(Aca.R)_2$ complexes combine two molecules of pyridine to form a sexa-co-ordinated complex in pyridine.

The present authors wish to thank Professor Mitsue Koizumi and Dr. Shoichi Kume of the Institute of Geological Sciences of the College of General Education, Osaka University, for their X-ray diffraction diagrams. This investigation was supported in part by the Ministry of Education.

# The Selective Halogenation of Methylhydropolysiloxanes : Syntheses of Methylhalopolysiloxanes and Their Derivatives

By Minoru SAKIYAMA,† Yukinori NISHIZAWA and Rokuro OKAWARA

(Received June 18, 1965)

Toward nucleophilic reagents, the silicon-hydrogen bond is less reactive than Si–Cl, but more reactive than C–H. Thus, the hydrolysis of methylhydrochlorosilanes gives silicon-oxygen compounds with hydrogen still bonded to the silicon. Recently, we have reported on the synthesis of many organosiloxane polymers prepared by the co-hydrolysis of dimethylchlorosilane or methyldichlorosilane with other methylchlorosilanes.[1] The reaction of some of these compounds with cupric oxide has also been reported on.[2] In this

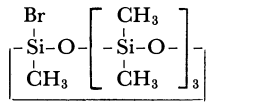
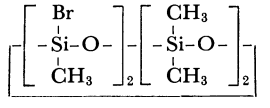
paper, we will report on the preparation of methylhalopolysiloxanes obtained by the halogenation of these polymers.

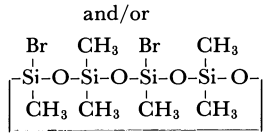
In these reactions, it is necessary to use a reagent which will halogenate the silanic hydrogen without reacting with the C–H and Si–O bonds. Photochlorination in a cooled carbon tetrachloride was applied successfully to $D'_n$ ($n$=4—7)* in order to chlorinate the silanic hydrogen.[3] However, this method brings about the chlorination of the methyl hydrogen when applied to the methylchlorosilanes, $M_2$ and $D_4$.[4] Moreover, in the case of $M_2$, the Si–O bond cleaved by hydrogen chloride. Elemental bromine readily reacts with alkylsilanes, for example, diethylsilane, to form alkylsilyl bromides.[5] However, bromine is unreactive toward hexamethyldisiloxane or alkylchlorosilanes not containing Si–H, except under forcing conditions.[6] Thus, bromine seemed a good choice as a reagent for the selective bromination of methylhydropolysiloxanes.

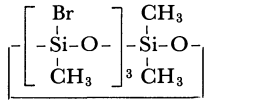
Photo-chlorination by chlorine gas by the method of Sokolov et al.[3] was first examined. $M'_2$ reacted with chlorine, but an aqueous layer soon separated, and much more chlorine was absorbed than had been calculated. It is evident that the carbon-hydrogen and silicon-oxygen bonds were attacked by, respectively, the chlorine and hydrogen chloride formed, in contrast to the case of $D'_n$. Bromine did not react with $M_2$ and $D_4$, even when refluxed, but did react violently with $M'_2$, the brown color disappearing soon after the addition. $D'_4$ also reacted with bromine, though less vigorously than $M'_2$. In both cases, however, the corresponding silicon-brominated compounds were obtained in only poor yields. A cleavage of the silicon-oxygen bond by hydrogen bromide probably takes place in these cases.

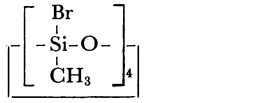
Pyridine forms crystalline adducts with bromine. The adducts are so unstable, however, that they decompose into bromine and pyridine when exposed to air.[7] Thus, pyridine may be expected to be utilized successfully in order to prevent the cleavage of the silicon-oxygen bond resulting from the attack of hydrogen bromide by forming pyridine hydrobromide. When bromine was added to a mixture of methylhydropolysiloxane and pyridine dissolved in carbon tetrachloride, the reaction took place smoothly and the corresponding bromo - compounds were obtained. The reaction scheme is as follows:

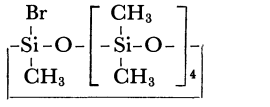












$$HBr + C_5H_5N \rightarrow C_5H_5NH^+Br^-$$

By this method the bromine-substituted methylpolysiloxanes given in Table I were synthesized. Iodine and iodine chloride were found to react neither with $M'_2$ nor with $D'_4$.

In the preceding paper, the isolation of methylhydrocyclotetrasiloxanes, $D_3D'$, $D_2D'_2$, $DD'_3$ as well as $D'_4$, was reported from the co-hydrolysis of methyldichlorosilane and dimethyldichlorosilane.[1b] In the present experiments, the isolation of methylhydrocyclopentasiloxanes was attempted, and $D_4D'$, $D_3D'_2$, and $D_2D'_3$ were obtained. Details of the reaction and the properties of these polysiloxanes are presented on Tables II and III. Fractions of the above-mentioned co-hydrolyzate, fractions which are composed mainly of $D'_4$, $DD'_3$, $D_2D'_2$, $D_3D'$, and $D_4D'$ respectively, were perfectly brominated in the presence of pyridine. Details of the reactions and properties of the methylbromopolysiloxanes thus obtained are given in Tables IV and V.

TABLE V. CYCLIC METHYLBROMOPOLYSILOXANES

| Compound | B. p. °C/mmHg | M. p. °C | %Br(-Si) Found (Calcd.) |
|---|---|---|---|
|  | 68/18 | — | 21.2 (22.1) |
|  and/or  | 107/20 | 49 | 37.2 (37.5) |
|  | 92/55 | 58—59 | 47.4 (48.8) |
|  | 112/ 4 | 97—98 | 56.8 (57.5) |
|  | 90/ 4 | — | 18.2 (18.4) |

Mono-bromine- or -chlorine-substituted methylpolysiloxanes synthesized as described above, or by the analogous method of Sokolov et al.,[3] were hydrolyzed or co-hydrolyzed with trimethylchlorosilane and dimethylchlorosilane in a large amount of water. Details of the experiments are given in Table VI. In the co-hydrolysis experiments,

* In order to show the structural units of methylpolysiloxanes, short-hand notations, which have been used frequently, will be used in this paper as follows:
$(CH_3)_3SiO_{1/2}$: M, $O_{1/2}Si(CH_3)_2O_{1/2}$: D,
$H(CH_3)_2SiO_{1/2}$: M', $HSi(CH_3)O_{2/2}$: D'.

hydroxy-substituted methylcyclotetrasiloxanes were also formed. The properties of the siloxanols thus obtained are given in Table VII.

## Experimental

**Starting Materials.**—The preparation of the methylhydropolysiloxanes used in these experiments has already been reported on.[1]

**Bromination.**—Into a mixture of methylhydropolysiloxane and pyridine, dissolved in carbon tetrachloride and placed in a three-necked flask equipped with an efficient stirrer, a reflux condenser and a dropping funnel, bromine, diluted with carbon tetrachloride was stirred. After the addition, the mixture was refluxed for 30 to 60 min. in order to complete the reaction. Pyridine hydrobromide was then filtered off, and the filtrate was fractionally distilled. Hydrolyzable bromine was analyzed by neutralizing the hydrogen bromide formed from the hydrolysis of the methylbromopolysiloxanes.

**Co-hydrolysis.** — Methylhalogenopolysiloxanes or mixtures of them with methylchlorosilanes, diluted with dry ether, was added to cooled water. In the case of siloxanol formation, a buffer solution was used, and the mixture was neutralized by a dilute alkaline solution in the course of the reaction. The ethereal layer was separated, and, after the ether had been distilled off, the residue was fractionated by the column described in the previous papers. The hydroxyl content was determined with a Karl Fischer reagent.

## Summary

Bromine was utilized in the presence of stoichiometric amount of pyridine to brominate silanic hydrogen of methylhydropolysiloxanes. Methylbromopolysiloxanes thus obtained and methylchloropolysiloxanes prepared from photo-chlorination of methylhydropolysiloxanes were hydrolyzed with or without methylchlorosilanes to yield new methylhydroxypolysiloxanes and branched methylpolysiloxanes. Preparation of methylhydrocyclopentasiloxanes was also reported.

# NOTES

## An Iodometric Assay of Some Derivatives of 7-Aminocephalosporanic Acid

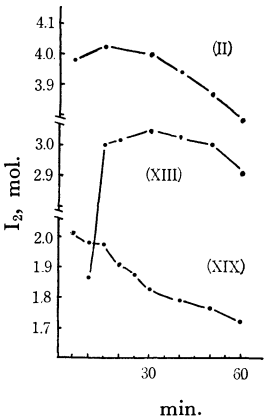
By Sachiko OKADA, Kiyoshi HATTORI and Tadayoshi TAKANO

(Received February 20, 1965)

The hydroxylamine method[1] and the iodometric assay are widely used for the determination of the purity of penicillins. Cephalosporin-C (II) is an antibiotic with a structure similar to penicillin; Alicino has reported an iodometric assay of this substances.[2]

An iodometric assay for some derivatives of 7-aminocephalosporanic acid (I) has now been studied. As the $\beta$-lactum ring of these derivatives is generally more stable than that of penicillins upon acidic and basic hydrolyses, only the conditions of the basic hydrolysis have been changed in the iodometric assay.

In Fig. 1, the time of hydrolysis is shown against the consumption of iodine. The experimental method has been standardized as follows: a sample



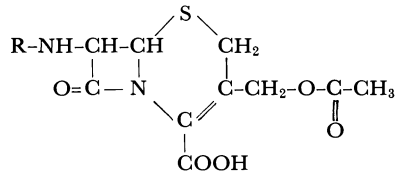


Fig. 1. The relation between $I_2$ consumption and time of basic hydrolysis; the number of derivative indicated in Table I.

1) J. H. Ford, *Ind. Eng. Chem., Anal. Ed.*, **19**, 1004 (1947).
2) J. F. Alicino, *Anal. Chem.*, **33**, 648 (1961).

(3—5 mg.) is dissolved in 5 ml. of a phosphate buffer (pH 6.0). To this solution is then added the same volume of N sodium hydroxide, and the mixture is kept at 23—25°C for fifteen minutes. Five milliliters of 1.2 N hydrochloric acid and 10 ml. of a 0.01N iodine solution are then added in order. Fifteen minutes later the residual iodine is titrated with 0.01 N sodium thiosulfate.

TABLE I. IODINE COMSUMPTION OF 7-AMINOCEPHALOSPORANIC ACID DERIVATIVES

| No. (derivatives) | R- (substituents) | Iodine consumption mol. |
|---|---|---|
| I | Hydrogen | 2.90 |
| II | δ-Aminoadipoyl | 4.01 |
| III | 10-Undecenoyl | 3.62 |
| IV | α-Chlorobutyroyl | 3.59 |
| V | Phenylacetyl | 4.18 |
| VI | *p*-Tolylacetyl | 3.98 |
| VII | *p*-Anisylacetyl | 4.76 |
| VIII | α-Thienylacetyl | 3.95 |
| IX | *p*-Chlorophenoxyacetyl | 4.15 |
| X | *o*-Nitrophenoxyacetyl | 3.68 |
| XI | Cinnamoyl | 3.88 |
| XII | β-(5-Nitro-2-furyl)acryloyl | 4.10 |
| XIII | α, β-Dichloro-β-phenylpropionoyl | 3.10 |
| XIV | α-Phenyl-β-(*p*-anisyl)propionoyl | 4.54 |
| XV | *N*-Benzyloxycarbonyl-*C*-phenylglycyl | 4.63 |
| XVI | Ethoxycarbonyl | 4.01 |
| XVII | Phenoxycarbonyl | 4.63 |
| XVIII | Phenylcarbamoyl | 3.86 |
| XIX | α-Naphthylcarbamoyl | 1.97 |

The results are listed in Table I.

The *N*-acylation of the 7-amino group gives evidence of an iodine consumption differing from that of the original 7-aminocephalosporanic acid (I); this behavior is similar to that between penicillin and 6-aminopenicillanic acid. Under these conditions, iodine consumption is not observed for the substituent parts—i. e., cinnamic acid, β-(5-nitro-1-furyl)acrylic acid, phenylacetic acid, *p*-chlorophenoxyacetic acid and 10-undecenoic acid.

Even when the substituents are sturcturally classified, there is no regular relationship between the iodine consumption and any of the groups. However, the reproducibility of the iodine consumption in this assay is high with respect to each of the derivatives. Hence, this assay might be useful for the inspection of the purity of each compound. The decreasing curves of iodine consumption in Fig.1 indicate that some destruction of the active structure or some formation of a reductive substance might occur during a long basic hydrolysis. The nature of the active structure in this assay remains to be studied, however.

# The Stereochemistry of Isoflavan-4-ols

By Shozo YAMAGUCHI, Shoei ITO, Asao NAKAMURA* and Naoto INOUE

(Received March 16, 1965)

One of the present authors, Inoue, obtained isoflavan-4-ol (I), 7-methoxyisoflavan-4$\alpha$-ol (II), 7-methoxyisoflavan-4$\beta$-ol (III) and 7, 4'-di methoxyisoflavan-4-ol (IV) by the reduction of the corresponding isoflavanones; he tentatively assigned a trans configuration to II and cis configurations to I, III and IV, mainly on the basis of the mechanism of the reduction and on that of the reactions of those compounds.[1]

(I): $R_1=R_2=H$
(II), (III): $R_1=OMe$, $R_2=H$
(IV): $R_1=R_2=OMe$

The NMR spectra of hydroxyflavans have been measured by Clark-Lewis and Jackman[2] and by other authors[3], who have reported that spin-spin

*1 Long range coupling ($J_{2,4}=1.0$ c. p. s.) was observed.
*2 Long range coupling ($J_{2,4}=1.2$ c. p. s.) was observed.
*3 The following values were calculated from the ABX pattern[7]:
$J_{AB}=10.4$ c. p. s., $J_{AX}=11.9$ c. p. s., $J_{BX}=3.0$ c. p. s., $\delta_{AB}=16.7$ c. p. s.
*4 These compounds[1] were also prepared from the corresponding isoflavones by reduction with sodium borohydride at room temperature.[8]

coupling constants between the 2- and 3-, and the 3- and 4- protons define the stereochemistry and conformation of the heterocyclic ring.

On the other hand, the NMR spectrum of only one 4-hydroxyisoflavan, 2-methyl-4-hydroxy-7, 4'-diacetoxyisoflavan, has been reported[4]; the spectra of pterocarpin and similar compounds have also been discussed,[5] but the simple 4-hydroxyisoflavans have not been investigated.

With this in mind, the NMR spectra of I, II, III, IV and their derivatives were measured out in order to determine their configurations and to decide whether relationships similar to those found in the case of the hydroxyflavans exist between the coupling constants and the configurations of the isoflavan-4-ols.

The experimental results are summarized in Table I.

A consideration of the dependence of the proton vicinal coupling constants on the dihedral angle, as in the Karplus equation,[9] leads unambiguoulsy to the assignment of the same configuration as was proposed in the preceding paper. The relationship between the 3, 4-coupling constants and the configurations which was observed with hydroxyisoflavans is the same as that seen in the case of the hydroxyflavans.[2,3] Therefore, it may be concluded that the configuration of a 4-hydroxyisoflavan can be determined from the coupling constant of the 3- and 4-protons.

Furthermore, the *S*-methylxanthates of II and III were submitted to thermal elimination in order to confirm the stereochemical relations obtained by NMR measurements. The *S*-methylxanthates

of II and III were prepared by Corey's method[10] and were subjected to elimination reactions at 180°C. The rate of the formation of the corresponding isoflavene was determined by measuring the extinction of the product at 332.5 mμ (Table II).

From the results summarized in Table II, it is apparent that the xanthate of II decomposes faster than that of III, consequently, II has the cis, and III has the trans, configuration.

## Experimental

The NMR spectra were determined with a Varian A-60 spectrometer, at 60 Mc., using deuterochloroform as the solvent and tetramethylsilane as the internal reference.

**Isoflavan-4-ol (I) and 7,4'-Dimethoxyisoflavan-4-ol (IV).** — A solution of isoflavone (0.7 g.) and sodium borohydride (0.3 g.) in methanol (130 ml.) was stirred for 2 days at room temperature. The methanol was then distilled off under reduced pressure, and the residue was decomposed with 70% acetic acid. The resulting solution was diluted with water and extracted with ether. The ether layer was washed once with a sodium bicarbonate solution and twice with water, then dried over anhydrous sodium sulfate and evaporated. The residue crystallized from petroleum ether as prisms (0.4 g.); m. p. 75°C.

7,4'-Dimethoxyisoflavan-4-ol (37%) m.p. 143—144°C was similarly prepared from the corresponding isoflavone.

***S*-Methylxanthates of II (V) and III (VI).**—A dimethyl sulfoxide solution (10 ml.) of sodium methylsulfinylcarbanion (prepared from 0.3 g. of sodium hydride and 20 ml. of dimethyl sulfoxide) was added to a stirred solution of II (0.25 g.) in dimethyl sulfoxide (5 ml.); the mixture was then stirred for 30 min. Then carbon disulfide (0.16 g.) was added and, after 30 min., 0.29 g. of methyl iodide, after which stirring was continued for 2.5 hr. All of these operations were carried out at room temperature under an atmosphere of nitrogen. Finally, the resulting solution was diluted with water and extracted with ether. The evaporation of the ether gave pale yellow crystals, which were treated with 5 ml. of methanol. The insoluble solid was collected and recrystallized from ethanol - ethyl acetate to give the *S*-methylxanthate of II (0.15 g.), m. p. 136—137.5°C.

Found: C, 62.17; H, 5.14. Calcd. for $C_{18}H_{18}O_3S_2$: C, 62.42; H, 5.24%.

*S*-Methylxanthate of III, m. p. 93—95°C (after recrystallization from ethanol - ethyl acetate), was similarly prepared from the corresponding isoflavan-4-ol.

Found: C, 62.31; H, 5.08. Calcd. for $C_{18}H_{18}O_3S_2$: C, 62.42; H, 5.24%.

**The Decomposition of the Xanthates.**—The weighed xanthates (ca. 0.1 mg.) described above were placed in separate glass tubes (4×150 mm.) under a nitrogen atmosphere; the tubes were then clamped vertically in an oil bath at 180°C. At the end of a given time, the tubes were removed from the bath, the reaction product was dissolved in methanol, and the extinction at 332.5 mμ for each solution was measured in order to determine the yield of isoflavene by reference to a previously-prepared calibration curve.

The authors wish to express their gratitude to Assistant Professor Ichiro Murata of Tohoku University for his valuable advice.

# The Isomerization and Pyrolysis of Cyclopropane in a Single-Pulse Shock Tube*

By Hajime MIYAMA and Tetsu TAKEYAMA

(Received April 22, 1965)

The isomerization of cyclopropane has been studied by several researchers.[1,2] However, no data at high temperatures (above 900°K) have been reported so far. Therefore, we have studied the isomerization and pyrolysis of cyclopropane over the temperature range from 1020 to 1660°K by using a single-pulse shock tube developed at Cornell University.[3]

The shock tube was fabricated from stainless steel tubing of 2.5 cm. i. d. The length of the driver section could be varied from 50 to 200 cm. by a piston mounted on a screw. A quick valve, placed at a distance of 22 cm. from the end-plate, was used to prevent the mixing and diffusion

of gases in the cold and hot regions. Five piezogauges were placed in a line over 90 cm. upstream of the endplate in order to measure incident shock velocities, and an additional piezogauge on the endplate, to record the reaction times. Matheson cyclopropane (99.5% pure), Takachiho propylene (99.90% pure) Nippon Sanso argon (99.999% pure), and Takachiho neon (99.9% pure) were used without further purification.

After each run, a 5 cc. sample was taken from the end section and analyzed by a gas chromatograph (Yanagimoto GCG-2) at 55°C by using columns of silica gel (1 m.) and β, β'-oxydipropionitrile (2 m.) for the analysis of $C_2$ and $C_3$ hydrocarbons and a column of molecular sieve 5A (1 m.) for the analysis of methane, with helium as the carrier. The other details of the experiment and calculation were almost the same as those described in Ref. 3, except that the incident shock velocities were used for the calculation of shock parameters.

The experimental conditions and results are shown in Tables I and II, where $T$, $P$, $t$ and $k$

are the reaction temperature, the pressure, the time, and the first-order rate constant respectively.

The first-order rate constant was calculated by the following equation:

$$k=\ln (C_0/C_f)/t$$

Here $C_0$ and $C_f$ are the initial and final concentrations of cyclopropane. An Arrhenius plot of the rate constants is shown in Fig. 1; it may be compared with the dashed-line extrapolated from the results obtained at lower temperatures.[2] There is apparently a bend at about 1200°K. The points of the low-temperature region fall somewhat above the extrapolated line; this seems due to the experimental difference between the shock-tube and conventional techniques.[4] Those of the high-temperature region fall below it and present a straight line with an apparent activation energy of 9.2 kcal./mol.

A comparison of Tables I and II with Fig. 1 would suggest that the production of methane and $C_2$ hydrocarbons affects the bend of $k$ values at 1200°K, although the materials recovered after each run are deficient; this deficiency can not be explained by the present study, because not all species in the reaction products could be analyzed in terms of the columns described above. A pyrolysis experiment with propylene under the same conditions as in the present study gave almost the same dependence of the composition of the reaction products upon the temperature, as is shown in Tables III and IV.

Therefore, it may be concluded that, at higher temperatures, the isomerization of cyclopropane occurs first, followed by pyrolysis, and that some of reaction products inhibit the isomerization. However, further experimentation will be necessary in order to establish a more detailed mechanism.

We are grateful to Messrs Akio Sawa and Kazutoshi Sugiyama for their help in the experiments.

# Diffusion Coefficients for Aqueous Solutions of Benzene and α-Naphthalene Sulfonates at 25°C*

By Hatsuho UEDAIRA and Hisashi UEDAIRA

(Received April 26, 1965)

Aromatic sulfonate ions consist of two distinct parts, a hydrophilic part (sulfonic group) and a hydrophobic part (aromatic ring). These two parts interact differently with water. The effect of these interactions on the limiting conductance of four kinds of sulfonates has been reported on previously.[1]

It now seems to be important to investigate the effect of these interactions on the other physicochemical properties of aromatic sulfonates. In this paper, the diffusion coefficients of sodium benzenesulfonate (BSNa) and sodium α-naphtalenesulfonate (NSNa) in water at 25°C were measured by the magnetically-stirred porous diaphragm method, and their apparent molar volumes were obtained by a density method. From the measured cell integral diffusion coefficients, the integral and differential diffusion coefficients were calculated by Stokes method.[2]

## Experimental

**Materials.**—The BSNa and NSNa were purified as before.[1] The potassium chloride was of an analytical grade (Merck) and was used without further purification. The conductance water was boiled before use in order to make it air-free. Its specific conductance was less than $1\times10^{-6}\,\mathrm{cm^{-1}\,\Omega^{-1}}$.

**Diffusion Cell.**—The diaphragm-cell was the same type as has been described by Stokes.[3] Modifications were, however, made in the lower stopper and in the magnet. In order to avoid disturbing the liquid in the diaphragm upon withdrawing or inserting the lower stopper, grooves were cut in both the stopper and the neck of the lower compartment, as is shown in the figure. The lower compartment was completely closed by rotating the stopper. When the cell was dipped in the thermostat water, the lower stopper was sealed by air.

A ring ferrite magnet was used instead of a horseshoe magnet. This magnet is so strong and light that it can be rotated smoothly by a small induction motor (Yokogawa SM-Q; output 2W) at a rate of 30 or 50 r.p.m.

**The Calibration of Cell and Measurements of the Diffusion Coefficient and Density.**—The cell

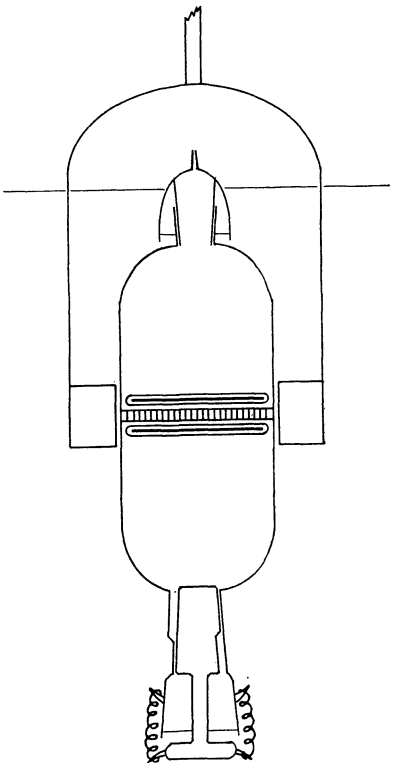

Fig. 1. The diaphragm cell.

integral diffusion coefficient, $\overline{D}$, is given by:

$$\overline{D}=\frac{1}{\beta t}\ln\frac{c_1-c_2}{c_3-c_4} \qquad (1)$$

where $\beta$ is the cell constant and $t$ is the duration of the experiment (sec.). $c_2$ (invariably zero, as recommended by Stokes[2]) and $c_4$ are the initial and the final molar concentrations in the upper compartment respectively, while $c_3$ is the final concentration in the lower compartment. The initial lower concentration, $c_1$ (mol./l.), is obtained by the Stokes method.[4]

The cell constant, $\beta$, was determined by the measurement of the diffusion of 0.08—0.1 N potassium chloride in water and by comparing the results with the data of Stokes.[2,4] The concentrations of potassium chloride were determined by measuring the conductances of the solutions, using the conductance data

obtained by Shedlovsky[5] and Stokes[6].

The time necessary for the concentration gradient in the diaphram to attain a steady state was estimated by Gordon's equation.[7]

The molar concentrations of BSNa and NSNa were determined by measuring the conductance of the solution. The conductance-concentration relation had been measured peviously.

The apparent molar volume, $\phi_v$, was calculated from the density, which was determined with a springel pycnometer 30 ml. in capacity. $\phi_v$ is expressed in the dilute solution by the following Masson relation:[8]

$$\phi_v = \phi_v^\circ + S_v c^{1/2} \quad (2)$$

where $\phi_v^\circ$ is the $\phi_v$ at an infinite dilution and $S_v$ is the limiting slope.

## Results and Discussion

The experimental equation of the density for a BSNa solution calculated by the method of least squares at 25°C is ($c < 1.0$ mol./l.):

$$d = 0.99707 + (0.0837 \pm 0.0013)c - (0.0106 \pm 0.0015)c^{3/2} \quad (3)$$

while the equation for NSNa is: ($c < 0.25$ mol./l.)**

$$d = 0.99707 + (0.09443 \pm 0.00056)c - (0.0076 \pm 0.0013)c^{3/2} \quad (4)$$

Thus, from Eqs. 2, 3 and 4, the apparent molar volumes for BSNa and NSNa solutions can be given by the following equations:

$$\phi_v = 96.70 + 10.61c^{1/2} \quad (5)$$

$$\phi_v = 136.2 + 7.620c^{1/2} \quad (6)$$

The cell integral diffusion coefficients, $\overline{D}$, for BSNa and NSNa solutions are shown in Tables I and II. The limiting diffusion coefficients at the infinite dilution, $D^\circ$, as calculated by Nernst's limiting law are $10.97 \times 10^{-6}$ and $9.840 \times 10^{-6}$ ($cm^2 sec^{-1}$) for BSNa and NSNa respectively, where the limiting equivalent conductances of sodium, $BS^-$ and $NS^-$ ions were 50.10,[4] 34.99[9] and 29.31[1] ($cm^2 \Omega^{-1}$ equiv$^{-1}$) respectively. The integral diffusion coefficients, $\overline{D}^\circ$, at the concentration $c_m$, where $c_m = (c_1 + c_3)/2$, could then be calculated from Stokes' equation[4]; they are shown in Tables I and II.

The differential diffusion coefficient, $D$, is calculated from $\overline{D}^\circ$ by Stokes' equation. The equations obtained for the $D$ of BSNa and NSNa solutions are as follows:

Table I. Diffusion coefficients for BSNa

| | | | | |
|---|---|---|---|---|
| $c_1$, mol./l. | 0.16223 | 0.23577 | 0.33732 | 0.49813 |
| $c_1^{1/2}$ | 0.4027 | 0.4856 | 0.5808 | 0.7058 |
| $c_m^{1/2}$ | 0.3917 | 0.4704 | 0.5627 | 0.6845 |
| $\overline{D} \times 10^6$ $cm^2 sec^{-1}$ | $10.5_4$ | $10.5_1$ | $10.3_9$ | $10.2_9$ |
| $\overline{D}^\circ(c_m) \times 10^6$ $cm^2 sec^{-1}$ | $10.5_6$ | $10.5_4$ | $10.4_2$ | $10.3_2$ |

Table II. Diffusion coefficients for NSNa

| | | | |
|---|---|---|---|
| $c_1$, mol./l. | 0.086599 | 0.15603 | 0.20588 |
| $c_1^{1/2}$ | 0.2943 | 0.3950 | 0.4537 |
| $c_m^{1/2}$ | 0.2859 | 0.3850 | 0.4406 |
| $\overline{D} \times 10^6$ $cm^2 sec^{-1}$ | $9.70_5$ | $9.60_4$ | $9.57_5$ |
| $\overline{D}^\circ(c_m) \times 10^6$ $cm^2 sec^{-1}$ | $9.71_1$ | $9.61_4$ | $9.58_2$ |

$$D \times 10^6 = 10.96 - 0.476c^{1/2} \quad (7)$$

$$D \times 10^6 = 9.840 - 0.280c^{1/2} \quad (8)$$

The integral and differential diffusion coefficients for BSNa and NSNa solutions decrease linearly with the square root of the concentration, whereas for most aqueous inorganic electrolyte systems, $D$ initially decreases rapidly with the concentration passes through a broad minimum at $c \approx 0.2-0.5$ mol./l., and thereafter increases slowly.

The concentration dependence of the diffusion coefficient and the apparent molar volume for NSNa are smaller than those for BSNa. The limiting slopes of the equivalent conductances for BSNa and NSNa solutions show a similar tendency.[10]

The experimentally-found values of the slopes for $D$ versus $c^{1/2}$ curves do not agree exactly with that predicted by the Harned theory;[11] nevertheless, the agreement is good with regard to the sign and the order of magnitude. The discrepancy for NSNa is larger.[12]

In a previous paper,[1] it was shown that the effect of the hydrophobic part-water interaction on the mobilities of aromatic sulfonate ions was larger for the $NS^-$ ion. Wen and Saito[13] showed that, in the case of the aqueous solutions of tetraalkylammonium salts, the value of $S_v$ for the more hydrophobic ion was smaller. The parallel relation between the conductances and the diffusion coefficients for BSNa and NSNa may be caused by the water interaction.

# Two Types of Water Contained in Transient Aluminas

By Hiroaki YANAGIDA, Goro YAMAGUCHI and Joe KUBOTA

(Received April 30, 1965)

All the polymorphs of alumina except the well-crystallized alpha modification have only a little water. The behavior of the water has, however, hardly been clarified at all. The water remaining after being heated at temperatures of 100—120°C has been simply explained as being combined with the oxygen atoms on the surface or in the lattice of alumina. The amount of the water depends either on the type of alumina[1] or on the forming conditions. For example, in gamma alumina the amount of water and the degree of the splitting of the 400-reflection in the powder pattern vary in accordance with the conditions of preparation.

Through an investigation into thermal effects on the lattices of gamma and eta alumina, the present authors have previously pointed out there should exist a certain type of water within only the former, one which causes a change in the lattice dimensions.[2]

For the present work, the behavior of the water within transient aluminas was investigated quantitatively with the help of a precise thermobalance.

Gamma alumina was prepared from the dehydration of well-crystallized boehmite in air at 750°C, and the delta, from the dehydration of the same boehmite under a water vapor of 1 atm. at

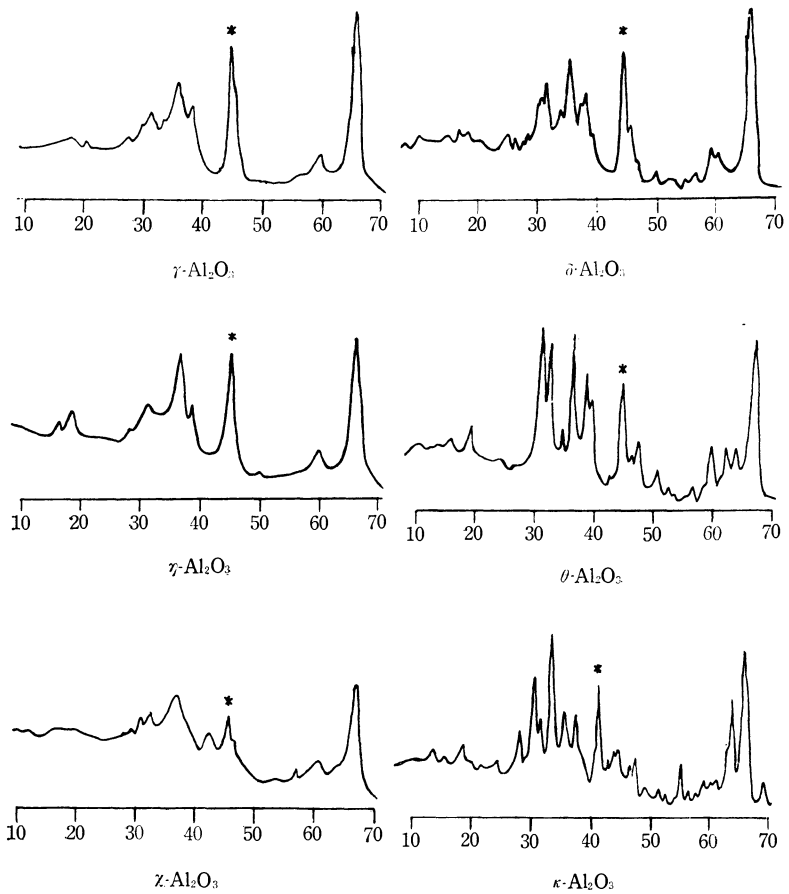

Fig. 1. X-Ray powder diffraction pattern of six transient aluminas using Cu$K\alpha$ radiation.

1) B. C. Lippens, Thesis, "Structure and Texture of Aluminas."

2) H. Yanagida and G. Yamaguchi, This Bulletin, **37**, 1229 (1964).

950°C. Eta and theta forms were obtained from the dehydration of bayerite in air, at 750°C and at 1100°C respectively. Chi and kappa forms were prepared from the dehydration of micro-crystalline gibbsite in air, at 750°C and at 1100°C respectively. The X-ray powder diagrams of these six aluminas are shown in Fig. 1.

The total amount of water (except that physisorbed ($W_0$ mg./g. $Al_2O_3$)) and the amount of water remaining in or on an alumina denoted as $W_t$ (mg./g. $Al_2O_3$) at a temperature were determined as follows; after being heated at 120°C for 24 hr. in air in order to remove the physisorbed water, each alumina was held at each given temperature in air or under a water vapor pressure of 1 atm. until the loss in weight could no longer be observed at that temperature in determining an ignition loss under the quasi-equilibriumic conditions. The weighings were made with a model LB-Shimazu direct vision balance (sensitivity; 0.1 mg.).

The typical d-spacings of each alumina, marked in Fig. 1. by an asterisk are measured by the Cu-$K\alpha$ irradiation X-ray powder diffraction method, after heat treatments at 120°C, 400°C, and 600°C.

The total amount of water, $W_0$, on transient aluminas and their specific surface areas as measured by the nitrogen adsorption method are summarized in Table I. They seem considerably different from each other. However, after plotting the ratio of $W_t$ to $W_0$, the present authors found the following rules.

Table I. The total amount of water except that physisorbed and specific surface area

| Transient alumina | Water content $W_0$ mg./g. $Al_2O_3$ | Specific surface area $m^2/g.$ |
|---|---|---|
| $\gamma$-$Al_2O_3$ | 11.0 | 44.8 |
| $\delta$-$Al_2O_3$ | 5.6 | 32.7 |
| $\eta$-$Al_2O_3$ | 34.0 | 183.7 |
| $\theta$-$Al_2O_3$ | 17.3 | 119.7 |
| $\chi$-$Al_2O_3$ | 25.2 | 126.3 |
| $\kappa$-$Al_2O_3$ | 6.7 | 74.6 |

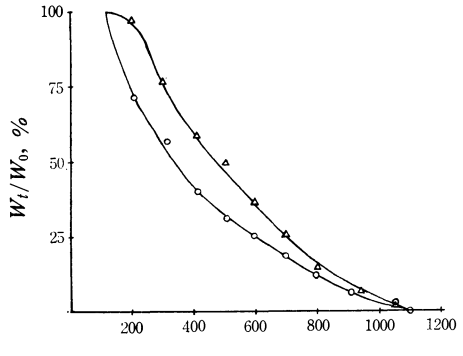

Fig. 2. Relation between heating temperature and ratio of remaining water to the total amount of water ($W_t/W_0$) on eta, ○; in air, △; in a water vapor of 1 atm.

Figure 2 shows the $W_t/W_0$ curve vs. the temperature for eta alumina in air and under a water vapor pressure of 1 atm. Theta, chi and kappa aluminas show curves approximately identical with that of eta when the $W_t/W_0$ ratios are plotted. As is shown in Table II, the typical d-spacings of these four aluminas are hardly changed at all by the thermal treatments. The present authors classify this type of water as the water not affecting the lattice dimensions and name it "non-lattice water."

Figure 3 shows the $W_t/W_0$ curve vs. the temperature for gamma alumina in air and under a water vapor pressure of 1 atm. Here the curve becomes quite different if the vapor pressure of the water is changed. The curve for delta alumina is identical with that for gamma. Table II shows that the removal of this type of water causes a change in the d-spacings. The present authors classify this as the water affecting the lattice dimensions and name it "lattice water."

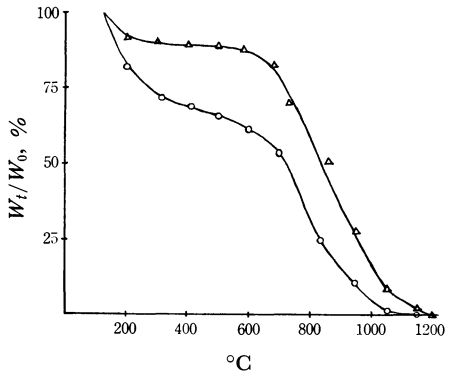

Fig. 3. Relation between heating temperature and ratio of remaining water to the total amount of water ($W_t/W_0$) on gamma, ○; in air, △; in a water vapor of 1 atm.

Table II. The change of the typical d-spacing of transient aluminas by thermal treatments measured at 25°C

| Transient alumina | Heating temperature 120°C | 400°C | 600°C | $d_{120}-d_{600}$ |
|---|---|---|---|---|
| $\gamma$-$Al_2O_3$ | 1.9867 Å | 1.9835 Å | 1.9810 Å | 0.0057 Å |
| $\delta$-$Al_2O_3$ | 1.9899 | 1.9879 | 1.9867 | 0.0032 |
| $\eta$-$Al_2O_3$ | 1.9790 | 1.9787 | 1.9787 | 0.0003 |
| $\theta$-$Al_2O_3$ | 2.0183 | 2.0186 | 2.0183 | 0.0000 |
| $\chi$-$Al_2O_3$ | 1.9909 | 1.9909 | 1.9909 | 0.0000 |
| $\kappa$-$Al_2O_3$ | 2.1195 | 2.1186 | 2.1186 | 0.0009 |

With the infrared absorption method, Peri showed that there are several types of water on the surface but not within the lattice of gamma-type

alumina.[3] The present results, however, show a certain type of water exists in the lattice of gamma and delta aluminas.

The present authors will report the results of further investigation into these types of water and the effects on the thermal conversions of transient aluminas in a later paper.

# The Effect of Ionizing Radiations on the Adsorption Rate of Hydrogen on Manganese Dioxide

By Toshizo TITANI and Tadamitsu KIYOURA

(Received May 25, 1965)

Kolarov and Kirilov[1] determined the temperature at which the reduction of differently-treated samples of manganese dioxide in a stream of hydrogen started; they found that this temperature was 234°C for the original manganese dioxide, whereas it was 217°C after the oxide had been ground for half an hour and 239°C after the irradiation of the oxide with ultraviolet light for half an hour. From these experimental results, they concluded that the grinding caused an activation, whereas the ultraviolet light caused an aging, of the oxide. We found a similar inactivation of manganese dioxide caused by the irradiation of ionizing radiations; the rate of hydrogen adsorption decreased for the oxide previously irradiated with radiations from a reactor or with $^{60}$Co $\gamma$-rays.

The manganese dioxide was prepared by the thermal decomposition of manganous nitrate, and the surface area of the oxide was measured by the B. E. T. method and found to be 10 $m^2/g$. The pile-irradiation of the oxide was carried out in the experimental hole of a swimming pool reactor of the Tokyo Atomic Industrial Research Laboratory. The flux of thermal and fast neutrons in the experimental hole was $1.7\times10^{12}$n/cm$^2$ sec. and $0.7\times10^{12}$n/cm$^2$ sec. respectively, and the dose rate of $\gamma$-rays was $1.1\times10^6$ r./hr. The oxide was irradiated in the hole for 15 hr. in the presence of air. The irradiation of the oxide by $^{60}$Co $\gamma$-rays was carried out in the hot cell of the Tokyo Metropolitan Isotope Research Center, under conditions similar to those of the pile-irradiation; the oxide was irradiated for 15 hr. in the presence of air, and the dose rate of $\gamma$-rays was $1.0\times10^6$ r./hr.

The oxide (400 mg.) was placed in the adsorption apparatus; after it had been evacuated at 100°C for 1 hr. the temperature of the apparatus was raised and kept costant at 175, 200, or 250°C respectively, and 1.6 ml. (N. T. P.) of the hydrogen gas was introduced. Then the pressure of the hydrogen in the apparatus was measured from time to time by a mercury manometer attached to the apparatus through a liquid nitrogen trap.

An example of the experimental results is graphically shown in Fig. 1, where the ordinate represents the logarithm of the manometric reading of the hydrogen pressure. As will be seen from Fig. 1, a rapid stage in the decrease of hydrogen pressure, shown by dotted lines, is followed by a slow stage of pressure decrease, shown by full lines in the figure. The slow stage proceeds as a first-order reaction rather than as a Zeldowitch[2] form. From the slope of the straight line, the rate

TABLE I. ADSORPTION RATE CONSTANTS UNDER VARIOUS CONDITIONS

| Samples of $MnO_2$ | Adsorption temp., °C: Rate const., $min^{-1}$ 175 | 200 | 250 | Activation energy, kcal./mol. |
|---|---|---|---|---|
| Original | 0.16 | 0.34 | | 12.5±0.5 |
| Irradiated in a reactor | | 0.033 | 0.12 | 12.8±0.5 |
| Irradiated by $^{60}Co$ $\gamma$-rays | 0.092 | 0.19 | | 12.0±0.5 |

constant can be obtained. The adsorption rate constants thus obtained under various conditions are tabulated in Table I, where the activation energy in the last column was calculated from the rate constants obtained at two different temperatures.

From Fig. 1 and Table I we can see that the adsorption rate of hydrogen on manganese dioxide is decreased by the preirradiation of the oxide with ionizing radiations. The decrease is especially significant in the case of the pile-irradiation, where the rate constant for the adsorption decreases to about one-tenth of the original one. If this decrease in the activity of the oxide is wholly due to the increase in the activation energy, the activation energy of the irradiated oxide must be about 2 kcal./mol. higher than that of the original one. However, as will be seen from Table I, the activation energy of the original and the irradiated oxide agree with each other within the limits of experimental error (±0.5 kcal./mol.). Therefore, it must be concluded that the decrease in the adsorption rate on the pile-irradiated manganese dioxide is solely due to the decrease in the number of active sites on the surface of the oxide. A part of the active sites on the surface of the manganese dioxide may be sintered by the irradiation with ionizing radiations. This sintering effect of the ionizing radiations from a reactor, if any, must be mainly due to the neutrons, because the decrease in the adsorption rate on the oxide irradiated with $^{60}Co$ $\gamma$-rays is far smaller than that on the oxide irradiated in a reactor, as may be seen from Fig. 1 and Table I, in spite of the fact that the dose rate of $\gamma$-rays was almost the same in both cases.

# A Microcell for NMR Spectral Measurements

By Shô Itô and Iwao Miura

(Received May 10, 1965)

The necessity of handling the minute amounts of substances encountered by many chemsits has lead to the invention of a few micro- and semimicro-cells.[1] Some of them, however, can not be used at an elevated temperature, and they are usually expensive. We have been using a convenient and simple microcell made from a glass-capillary for measurements with a Varian A-60 spectrometer.

The sample tube consists of a capillary, 1 to 2 mm. in outside diameter and about 19 cm. long (similar to a normal melting point tube), which is fixed inside a standard-size NMR tube by means of two cylindrical plugs.[2] These plugs have concentric holes with a diameter slightly larger than that of the capillary. The sample solution, usually prepared from about 3 mg. of the substance and about 30 $\mu$l. of a solvent containing a trace of the internal reference, is introduced into the capillary tube (one end sealed) either by a process of warming and cooling or with the aid of a micro-syringe. The open end is then sealed. One of the plugs is placed at the bottom, and the other, about 50 mm. from the bottom of the NMR tube; the capillary is inserted into the tube and through the hole in each plug. The upper end of the capillary tube is stabilized by inserting it through a hole bored in the center of a plastic cap, which is then fitted over the mouth of the NMR tube. The

1) As far as we know, three types of these cells are commercially available, those made by Varian Associates, U. S. A., Nuclear Magnetic Specialities Inc., Canada, and Japan Electron Optics Laboratory Co., Japan.

2) For the sake of convenience, we have been using sections of the nylon upper-plug of a Varian microcell or the insulating cover of electric wire for measurements at room temperature, and sections of Teflon tubing at elevated temperatures (up to 130°C).

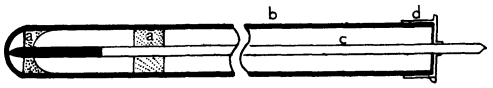

Fig. 1. Cross-section of the micro-cell.

d Plastic cap

completely-assembled micro-cell is illustrated in Fig. 1.

The measurement of the NMR spectra is carried out in the normal way. The spectra obtained with the use of this cell are usually as good as those obtained with 5 to 10 times the amount of sample in an ordinary 5-mm. cell. Examples of spectra obtained with the use of this microcell and of those with the use of a standard cell are shown in Figs.

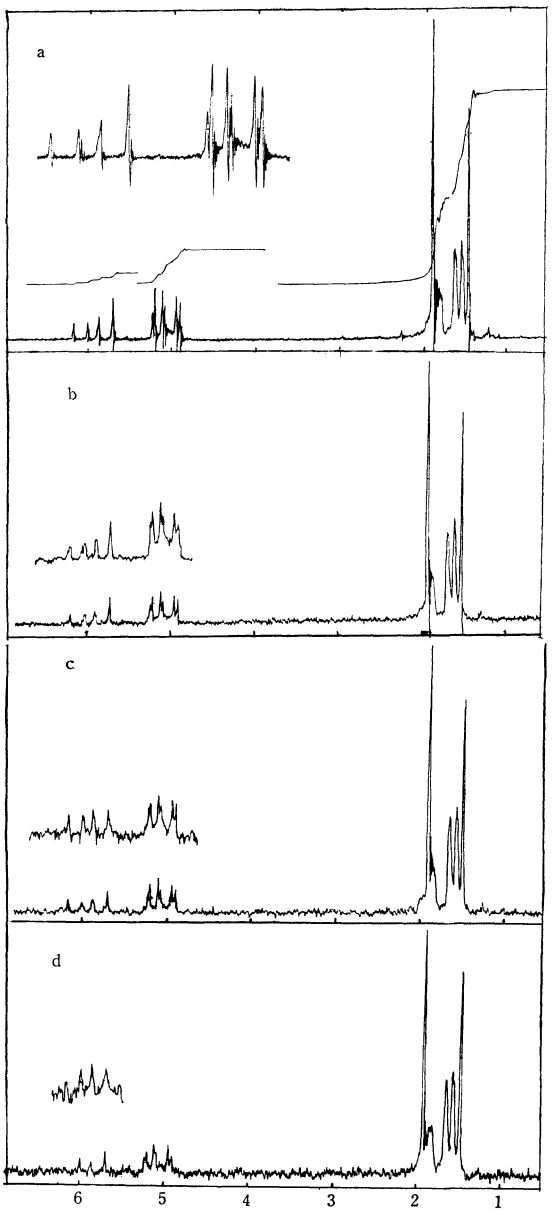

Fig. 2. NMR spectra of linalool in carbon tetrachloride

a 30 mg. in standard cell
b 8 mg. in microcell
c 5 mg. in microcell
d 3 mg. in microcell

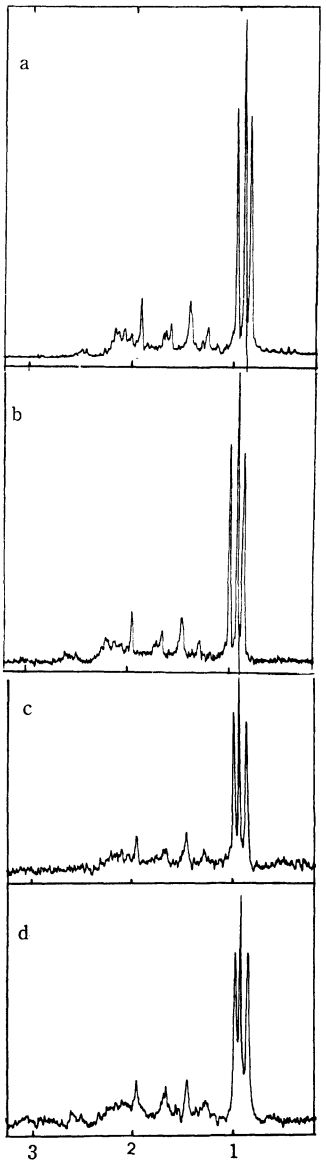

Fig. 3. NMR spectra of camphor in carbon tetrachloride.

a 30 mol.% in standard cell
b 30 mol.% in the microcell
c 10 mol.% in the microcell
d 3.2 mol.% in the microcell

2 and 3 in order to illustrate the limitations of this micro-cell.

In the case of linalool, the one proton quartet, due to the X part of the ABX system, is visible with 3 mg. of sample in about a 8 mol.% solution, whereas in the case of the methyl protons of camphor, the signal can be clearly recognized when 1.1 mg. of the sample (ca. 3.2 mol.% solution), or even as little as 0.35 mg. of the sample (1 mol.% solution), is used.

Although a certain degree of sensitivity is sacrificed because of the large diameter of the receiver coil, which has been designed for use with the larger standard NMR tubes, this cheap and simple micro-cell is very useful when only small quantities of sample are available.

# Intramolecular Hydrogen Bonds. VI.[1] The Characteristic Infrared OH Spectra of Isomeric Ethyl $\alpha$, $\beta$-Dihydroxy-carboxylates and Their Geometries

By Nobuo MORI, Satoshi ŌMURA* and Yojiro TSUZUKI

(Received May 24, 1965)

The threo and the erythro isomers of any compound of the RCH(OH)CH(A)R′ series, wherein R and R′ are alkyl groups and A is a proton-accepting group, show characteristic infrared OH spectra in a dilute carbon tetrachloride solution; the apparent relative intensities of the bonded and the free OH bands[2] and, in some cases, also the separations between the two bands $(\Delta\nu)$[3,4] are useful as important criteria for the configurational assignment. Such characteristic features, however, are not observed in ethyl dextro- and meso-tartrates, in which the apparent OH spectra are almost identical.[5]

In this investigation, we have found that isomeric $\alpha$, $\beta$-dihydroxy-carboxylates of the $CH_3(CH_2)_n$-CH(OH)CH(OH)COOEt series, wherein $n$ is an integer of 0, 1 and 2, exhibit some characteristic features which differ from the above statement in their OH spectra. The spectra were measured at 25°C according to a method previously[1] described. The concentrations were ca. 0.004 mol./l. in carbon tetrachloride, at which point intermolecular hydrogen bonding was absent. The erythro esters show identical OH spectra, composed of two peaks with nearly the same intensities, the higher frequency band being broadened on the higher frequency side. The threo isomers show a partially-resolved doublet with an additional shoulder at ca. 3625 $cm^{-1}$. In addition to these bands, both the isomers show a very weak band at ca. 3445 $cm^{-1}$ due to the overtone of a carbonyl group.[6] Typical spectra are shown in Fig. 1, while the data on the apparent OH bands are summarized in Table I.

As is shown in the table, the lowest frequencies

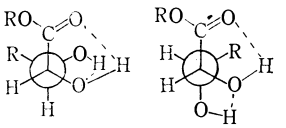
*1 $D=\log I_0/I$ for the apparent bands.
*2 These are of the shoulder of band.
*3 Presumed from the broadening on the higher frequency side of band II.



(ca. 3521 and 3532 cm$^{-1}$ (band I)) and the separations between the strong peaks (ca. 61 and 56 cm$^{-1}$) are characteristic of the threo and the erythro esters respectively, but their relative intensities are indiscriminate. The additional OH absorption on the higher frequency side is, in both cases, very weak, yet it can serve as another indicator for a configurational assignment.

The α-OH group and the β-OH group can form hydrogen-bonds with one another and with the carbonyl- and the ether-oxygen atom of the ester group. According to the findings on intramolecular hydrogen bonding in α- and β-hydroxycarboxylates previously[1] reported, the hydrogen bond with the carbonyl-oxygen atom is stronger in the α-series than in the β-series; the extent of this hydrogen-bonding is very high compared with that of the hydrogen-bonding with the ether-oxygen atom in both series. Evidence for the type of hydrogen-bonding between the OH groups has already been given for ethylene-glycols.[3] On the basis of this, band I may almost exclusively be due to the α-OH group bonded to the carbonyl-oxygen, and band II may be due to the β-OH group bonded to the oxygen atom of the above bonded α-OH group, since the free OH band IV does not appear or is only slightly present. In the erythro esters, the broadening on the higher frequency side of band II may be caused by an additional weak absorption of OH groups bonded to the ether-oxygen atom. Accordingly the OH groups assigned to bands I and II must be skew to one another in respect to the $C_\alpha$–$C_\beta$ bond, as is shown in geometries I—IV:

I II

Threo form

III IV

Erythro form

In the NMR spectra* of the threo and the erythro ester with $n=1$ in solutions of 5 v.% in carbon tetrachloride, the resonance line of the α-methine proton appears at −3.98 p.p.m. from TMS as a doublet ($J_{\alpha\beta}=2.3$ c.p.s.) for the threo ester and at −4.09 p. p. m. as a doublet ($J_{\alpha\beta}=3.8$ c. p. s.) for the erythro isomer. The $J$ values indicate in each case that the two methine-hydrogens are skew to one another in respect to the $C_\alpha$–$C_\beta$ bond.[7] Since such an orientation of the hydrogens is considered to be probable also in a concentration

* The spectra were measured at ca. 25°C in the concentration range from 5 to 20 v.% in carbon tetrachloride, using a Varian A-60 spectrometer on pre-calibrated chart paper; TMS was used as the internal standard. The $\delta$ values of the α-methine protons in both the esters were somewhat dependent on the concentrations, but the $J$ values were not.

7) K. Karplus, *J. Chem. Phys.*, **30**, 11 (1959); *J. Phys. Chem.*, **64**, 1793 (1960).

as low as 0.004 mol./l., form I seems to be most favorable for the threo esters in a dilute carbon tetrachloride solution, and form III and/or form IV for the erythro isomers.

## Experimental

The threo and the erythro esters were prepared by Fischer's method of esterification from the respective $\alpha$, $\beta$-dihydroxy-carboxylic acids,[8] which had been obtained by the oxidation of the corresponding *trans*-olefinic acids[9] with silver chlorate in the presence of osmium tetroxide and with perbenzoic acid respectively. The threo forms of the free dihydroxy-acids with $n=$ 0, 1 and 2 melted at 74, 75 and 107°C respectively, and the erythro isomers, at 80, 105 and 98°C. The boiling points of the ethyl esters are shown in Table I.

# The Electrical Conductivities of Aromatic Diamine-Chloranil and -Tetracyanoethylene Charge-Transfer Complexes*

By Hideaki KUSAKAWA and Shun-ichiro NISHIZAKI

(Received June 22, 1965)

We have reported in previous papers[1,2] on the electrical conductivities of the iodine complexes of several kinds of aromatic diamines. Since then we have obtained aromatic diamine, *p*-, *m*-, and *o*-phenylenediamine (*p*-, *m*-, *o*-PDA), 1,5-naphthylenediamine (NDA), benzidine (BEN), *o*-tolidine (TOL) and *p*, *p'*-diaminodiphenylmethane (APM) complexes, in which chloral (CHL) or tetracyanoethylene (TCNE) was used as the electron acceptor. In this report we will present the results obtained from a comparison of the electrical conductivities of CHL and TCNE complexes with those of iodine complexes.

These CHL and TCNE specimens were prepared by mixing the equivalent donor and acceptor solutions. The complex crystals precipitated rapidly by cooling or from a highly concentrated solution were not suited to the observation of their electrical properties.

The chemical analysis for these CHL and TCNE complexes indicated that TCNE specimens scarcely include the solvent at all, but that CHL specimens contain a respectable amount of the solvent; the ratio between the donor and the acceptor in these complexes was 1 : 1. These CHL and TCNE complexes showed the absorption bands arising from the NH stretching vibration in the wave number region between 3455 $cm^{-1}$ and 3140 $cm^{-1}$, and the signals of the electron-spin resonance at room temperature.

The magnitude and the temperature dependence of the resistivities and energies of the charge-transfer transitions obtained by previous methods[1,3] are summarized in Table I for CHL complexes and in Table II for TCNE complexes. Some of these crystals were given needle-shaped forms (about $3 \times 0.05 \times 0.01$ mm.). Therefore, the lattice constants along the crystal growth axis could be found for such crystals by applying an oscillation method. These results are listed in the last column in both tables.

The following results are obtained from the data shown in Tables I and II:

1) The energy of the charge-transfer transition is more than twice the activation energy of the resistivity for the aromatic-diamine-complex specimens.

2) In the case of CHL complexes, the order of resistivity, *p*-PDA:CHL, TOL:CHL and NDA:CHL, agrees with that of the lattice constant along the crystal growth axis. On the other hand, the resistivity of BEN:TCNE, the lattice constant of which is smaller than that of NDA:TCNE, is not as low as the resistivity of NDA:TCNE.

3) The donor character of an aromatic diamine is dependent on what the acceptor molecule is; e. g., BEN is the strongest donor for an iodine acceptor, *p*-PDA is for CHL, and NDA is for TCNE.

* This paper was presented in part at the 18th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1965.

1) S. Nishizaki and H. Kusakawa, This Bulletin, **36**, 1681 (1963).

2) H. Kusakawa and S. Nishizaki, ibid., **38**, 313 (1965).

3) H. Kusakawa and S. Nishizaki, ibid., **38**, 783 (1965).

Table I. Physical properties of aromatic diamine-chloranil complexes

| Donor | Resistivity at 20°C | Activation energy | Energy of c. t. transition | Lattice constant along crystal growth axis |
|---|---|---|---|---|
| | Ω cm. | eV. | eV. | *A* |
| *p*-PDA | $1.5\times10^{7}$ | 0.46 | 1.42 | 6.36 |
| *m*-PDA | Complex in solution only | | | |
| *o*-PDA | Complex in solution only | | | |
| NDA | $1.2\times10^{11}$ | 0.58 | 1.46 | 7.63 |
| BEN | Nonstoichiometrical composition | | | |
| TOL | $3.8\times10^{9}$ | 0.53 | 1.23 | 7.35 |
| APM | Complex in solution only | | | |

Table II. The phisical properties of aromatic diamine-tetracyanoethylene complexes

| Donor | Resistivity at 20°C | Activation energy | Energy of c. t. transition | Lattice constant along crystal growth axis |
|---|---|---|---|---|
| | Ω cm. | eV. | eV. | *A* |
| *p*-PDA | $2\times10^{15}$ | 0.78 | 2.26 | 8.73 |
| *m*-PDA | $6\times10^{14}$ | 0.93 | 2.11 | |
| *o*-PDA | $10^{16}$ | | 2.22 | |
| NDA | $1.0\times10^{7}$ | 0.40 | 1.14 | 6.75 |
| BEN | $1\times10^{14}$ | 0.71 | | 6.11 |
| TOL | $10^{16}$ | | | |
| APM | $>10^{16}$ | | | |

4) Among the three isomers of phenylenediamine (PDA), the para substituent is the best donor; for instance, *m*-PDA and *o*-PDA do not form complex crystals with CHL, and the resistivity of the *p*-PDA-iodine system is $10^{5}$ Ωcm., while those of *m*-PDA-isodine and *o*-PDA-iodine are $10^{7}$ Ωcm. and $10^{9}$ Ωcm.[4] respectively.

5) It cannot be expected that the charge-transfer complex the donor of which is nonconjugated aromatic amine, APM, will have a conductivity as good as that of conjugated amine complexes.

photochromism, thermochromism or piezochromism are due to the triarylimidazolyl radicals produced by the dissociation of the dimers by irradiation, heating or grinding respectively.[3]

The infrared absorption spectra of the compounds mentioned above and of the photochromic and piezochromic systems (KBr pellet) have now been observed with a Perkin-Elmer 521 grating infrared spectrophotometer.

The absorption bands of the dimers of triarylimidazolyls in the 1620—1480$cm^{-1}$ region are shown in Table I.

As was to be expected from the mechanism,[3] the spectra of the photochromic systems of these compounds were similar to those of the respective piezochromic systems. One or several new weak bands were observed in the spectra of the photochromically- and piezochromically-colored systems, as is shown in Table II.

Recently, White and Sonnenberg[4] showed that, in the 1620—1480 $cm^{-1}$ region, aryl-2*H*-imdazoles exhibit the characteristic bands at approximately 1615(w) and 1550 $cm^{-1}$(m-s), while arylimidazoles do not exhibit such bands and tetraphenyl-4*H*-imidazole exhibits strong bands at 1594 and 1563 $cm^{-1}$, along with the 1616 $cm^{-1}$ band. Since in the 1620—1480 $cm^{-1}$ region the absorption bands of the dimers of triarylimidazolyls were very similar to the characteristic bands of the aryl-2*H*-imidazoles, as is shown in Table I, the results may suggest that the structures of the dimers of triarylimidazolyls are not the hexaaryl-*N*, *N'*-biimidazolyls which were previously reported,[3] but rather hexaaryl-2, 2'-bi-2*H*-imidazolyls produced by the dimerization of the 2, 4, 5-triarylimidazolyl radicals at the 2-position, and that the homolytic dissociation of the C–C bond of hexaaryl-2, 2'-bi-2*H*-imidazolyls into 2, 4, 5-triarylimidazolyl radicals is the more probable mechanism of the photochromism, thermochromism and piezochromism of the dimers of triarylimidazolyls than the dissociation of the N–N bond of hexaaryl-*N*, *N'*-biimidazolyls. In order to determine more exactly the constitution of the dimers and the mechanism of the photochromism, thermochromism and piezochromism, further investigations are now being carried out.

# A New Method for the Determination of Nitrate Ions by Atomic Absorption Spectrophotometry

By Takahiro KUMAMARU, Eiji TAO, Nobuko OKAMOTO and Yuroku YAMAMOTO

(Received August 24, 1965)

In the course of our studies of the solvent extraction of anions with metal chelate cations,[1] it was found that a small amount of nitrate could be extracted into methyl isobutyl ketone (MIBK) when neo-cuproine* was contained in the organic phase and when copper(I) ions were present in the aqueous phase. This paper is concerned with the determination of nitrate ions by atomic absorption spectrophotometry. Figure 1 shows the

Reference: MIBK

absorption spectra in the organic phase. It may be observed that the presence of nitrate leads to a considerable increase in the extraction. The absorbance maximum of the extracted species is at 456 mμ. The chemical formula of the extracted species was determined to be $[Cu(Neocup.*)_2NO_3]$. It was also found that there is a linear relationship between the concentration of nitrate in the aqueous solution and the absorbance at 456 mμ of the organic phase. These facts suggest that it may be possible to determine the nitrate ions by spraying the extracted MIBK solution into the flame of an atomic absorption spectrophotometer using a copper hollow-cathode lamp (3247Å). The recommended procedure for the calibration curve is given below.

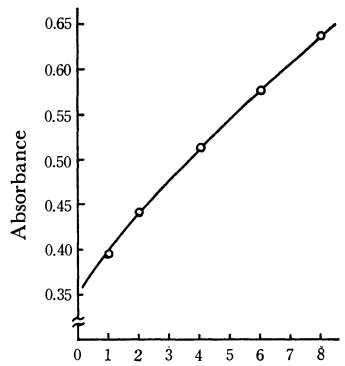

Fig. 2. Calibration curve (Reference: MIBK).

Two milliliters of the cupric sulfate solution ($1\times10^{-2}$ M), 2 ml. of the hydroxylamine sulfate solution (5%), 5 ml. of the buffer solution (0.25 M phosphate), and varying amounts of the standard nitrate solution ($2\times10^{-4}$ M, 1—8 ml.) were mixed. After the solution had been diluted with water to 25 ml., it was shaken for 2 min. with 10.0 ml. of a MIBK solution containing neo-cuproine ($2\times10^{-3}$ M). The atomic absorption measurements of the organic phase were made by using a Hitachi model 139—0420 atomic absorption spectrophotometer equipped with a copper hollow-cathode source. In atomic absorption spectrophotometry, it has generally been considered that the special spectral line issuing from the same metal as the element to be determined should be used. This has been a fairly great disadvantage in some cases because of the necessity of a special light source. Moreover, it has not been possible to apply the atomic absorption method to most non-metals. In this paper, we have suggested the possibility of determining some anions such as nitrate by solvent extraction with a metal chelate cation using a proper solvent and an appropriate hollow-cathode source.

# The Zeeman Effect of $^{35}Cl$ Nuclear Quadrupole Resonance Spectra in *p*-Chlorophenol

By Masahiko SUHARA, Tadashi YONEMITSU and Tokuzo TONOMURA

(Received August 27, 1965)

The Zeeman effect of the $^{35}Cl$ nuclear quadrupole resonance spectrum was studied on a single crystal of *p*-chlorophenol in order to obtain information about the crystal and molecular structures in the solid state and in order to explain the doublet separation of the spectrum.[1]

A commercial product was distilled and then purified by zone-melting before use; the single crystal was prepared by Bridgeman's method. The Zeeman effect was observed at room temperature by means of a superregenerative spectrometer and a goniometer equipped with a Helmholtz coil.

Two zero-splitting loci, for each element of the doublet, $\nu_1$ and $\nu_2$, were obtained. This suggests that the unit cell is composed of four molecules.

The asymmetry parameters obtained are listed in Table I. Asymmetry parameters in several chlorobenzene derivatives have been obtained by the studies of the Zeeman effect: for example, 0.08 in *p*-dichlorobenzene,[2] 0.06 in *p*-chloroaniline,[3] and 0.08 in *p*-chlorobenzoic acid.[4] In comparison with these values, the $\eta_1$ value of the present molecule is considerably larger. This indicates that two of the four chlorine nuclei in the unit cell are placed in an unusual intermolecular interaction, such as hydrogen bonding.

The double-bond character, the ionic-bond character, and the single-bond character of the C–Cl bond in *p*-chlorophenol were evaluated by the method proposed by Townes and Dailey[5] and developed by Bersohn,[6] from the asymmetry parameter, $\eta_2$, and the resonance frequency, $\nu_2$, extrapolated to 0°K. In this calculation, we used the values of 0.15[5] for the *s*-characters of the $\sigma$ and $\pi$ bonds, and of 0.15[7] for the screening correction for a positive formal charge at the chlorine atom. The results are shown in Table I.

The double-bond character thus evaluated is plotted against Hammett's $\sigma$-value in Fig. 1, together with the findings for other chlorobenzene derivatives without an ortho substituent. It may be concluded from the linear correlation in the figure that the double-bond character becomes larger as the substituent is more electron-attractive. A future study of the electronic structure of chlorobenzene derivatives with reference to this correlation seems of interest. A similar correlation has already been obtained for iodobenzene derivatives.[8]

# Copper and Nickel Chelates of Pyridine-2-carboxamide*

By Kazuo YAMASAKI and Masao SEKIZAKI

(Received September 2, 1965)

The metal chelates of pyridine-2-carboxamide, picolinic acid amide, have scarcely been studied at all; only a copper chelate containing two moles of the ligand was known.[1] Recently another chelate of copper with 1 mol. of the same ligand was reported.[2] The present communication deals with the syntheses of copper and nickel chelates of this ligand and with studies of their properties. In the following the ligand, pyridine-2-carboxamide, $C_5H_4NCONH_2$, will be abbreviated as "piaH."

The chelates prepared were: (1), $Cu(pia)_2 \cdot 5H_2O$; (2), $Cu(piaH)_2Cl_2 \cdot 2H_2O$; (3), $Ni(pia)_2 \cdot 2H_2O$ and (4), $Ni(piaH)_2Cl_2 \cdot 2H_2O$.

1) $Cu(pia)_2 \cdot 5H_2O$. This chelate was prepared after the method of Emmert and Brandl[1] by adding 1 g. of the ligand to a solution containing 2 g. of tetramminecopper(II) sulfate. Reddish-violet crystals were produced; they were soluble in cold water and chloroform only with difficulty. Emmert and Brandl reported the anhydrous compound, but the chelate prepared by the present authors had the formula, $C_{12}H_{10}O_2N_4Cu \cdot 5H_2O$.

Found: Cu, 16.06; N, 13.76; $H_2O$ 23.13%, Calcd. for $C_{12}H_{10}O_2N_4Cu \cdot 5H_2O$: Cu, 16.05; N, 14.15; $H_2O$, 22.76%.

2) $Cu(piaH)_2Cl_2 \cdot 2H_2O$. If 0.7 g. of copper(II) chloride was used instead of tetramminecopper(II) sulfate in the above preparation and if the mixed solution was concentrated on a water-bath, fine blue crystals of this chelate were crystallized.

Found: Cu, 15.34; N, 13.81; $H_2O$, 8.97%. Calcd. for $C_{12}H_{12}O_2N_4CuCl_2 \cdot 2H_2O$: Cu, 15.32; N, 13.51; $H_2O$, 8.69%.

3) $Ni(pia)_2 \cdot 2H_2O$. To an aqueous solution containing 2 g. of the ligand, 0.75 g. of sodium hydroxide dissolved in a small amount of water and then 2 g. of nickel chloride dissolved in 20 ml. of water were added. Fine orange-red crystals were precipitated; they were soluble in chloroform and ethanol only with difficulty and were insoluble in water.

Found: Ni, 17.44; N, 16.88; $H_2O$, 10.43%. Calcd. for $C_{12}H_{10}O_2N_4Ni \cdot 2H_2O$: Ni, 17.32; N, 16.63; $H_2O$, 10.63%.

4) $Ni(piaH)_2Cl_2 \cdot 2H_2O$. Prepared in a way similar to that used for 2). Blue crystals.

Found: Ni, 14.20; N, 14.01; $H_2O$ 9.10%. Calcd. for $C_{12}H_{12}O_2N_4NiCl_2 \cdot 2H_2O$: Ni, 14.32; N, 13.67; $H_2O$, 8.79%.

In the solution of pH 8.2 of $Ni(piaH)_2^{2+}$ the bands are at 602 and 995 m$\mu$, and while in a more alkaline solution they shift to a shorter wavelength, with the precipitation of insoluble $Ni(pia)_2$. In an acid solution of pH 0.9, the bands are at 645 and $>1050$ m$\mu$, rather close to those of the nickel aquo ion.[3] These facts suggest that, in a strongly acid solution, the nickel chelate (4) dissociates into the nickel aquo ion and the ligand, while in an alkaline solution the chelate (3) is formed. The copper chelates show a similar change in absorption spectra.

The infrared absorption bands of these chelates are listed in Table I, together with the tentative assignments.

TABLE I

| Chelate | C=O Str. vibr. | C-N Str. vibr. | M-N Str. vibr. | Magnetic moment |
|---|---|---|---|---|
| | | | $-(cm^{-1})$ | |
| piaH | 1659 | 1390 | | — |
| $Cu(pia)_2 \cdot 5H_2O$ | 1624 | 1395 | 567 | 1.87 (B.M.) |
| $Cu(piaH)_2Cl_2 \cdot 2H_2O$ | 1667 | 1440 | 510 | 1.90 |
| $Ni(pia)_2 \cdot 2H_2O$ | 1640 | 1400 | 592 | diamagnetic |
| $Ni(piaH)_2Cl_2 \cdot 2H_2O$ | 1660 | 1433 | 518 | 3.25 |

The ligand molecule in these chelates seems to be coordinated to the metal by nitrogen atoms, acting as a bidentate ligand.[4] Of these four chelates chelate (3) is diamagnetic, while the other three are paramagnetic; the magnetic moments are as shown in Table I. It is well known that nickel often forms, with the same ligand, paramagnetic and diamagnetic chelates of different colors. The present chelates add another example of this class of compounds.

# The Bromination of Tris(3-phenyl-2, 4-pentanediono)chromium(III)*

By Yukito MURAKAMI and Teruomi WAKABAYASHI

(Received September 13, 1965)

In connection with the quasiaromatic nature of a chelate ring in the metal acetylacetonates, the electrophilic substitution reactions of these complexes have been systematically investigated.[1] In order to understand further the characteristic properties of a metal-chelate ring formed with $\beta$-diketones, the chromium(III) chelate of 3-phenyl-2, 4-pentanedione was prepared in this study.

Into a mixture of tris(3-phenyl-2,4-pentanediono)-chromium(III) and pyridine in carbon tetrachloride, there was added bromine dissolved in the same solvent at around 0°C over a period of 20—25 min. The bromination product was then fractionated into five components by means of liquid-chromatography with a combination of silica gel (60—80 mesh) and benzene. The fraction which came off first from a column was re-crystallized from ligroin as green crystals; m. p. 237—239°C (decomp.).

Found: C, 39.16; H, 3.11; Br, 43.94; Cr, 5.0%. An infrared spectrum of this product is illustrated in Fig. 1, together with that of the starting material.

The absorption peaks characteristic of the starting chromium(III) chelate, i. e., 1452, 1357, 1343, and 928 $cm^{-1}$, disappeared in the brominated material, while new bands were observed in the latter at 1388 and 1240 $cm^{-1}$. In addition, absorption bands at 771 and 764 $cm^{-1}$ in the unbrominated chelate spread further to 785 and 758 $cm^{-1}$ in the product. Among these infrared absorption peaks, the 1240 $cm^{-1}$ band in the brominated chelate may be assigned to $CH_2$ wagging vibration in the $CH_2Br$ group;[2] while the 928 $cm^{-1}$ band in the unsubstituted chelate may be attributed to the coupled stretching vibration of C–$CH_3$ and CO.[3] Therefore, the infrared spectrum of the brominated chelate provides evidence for a substitution reaction through which all the methyl groups in tris(3-phenyl-2, 4-pentanediono)chromium(III) were brominated to the monobromomethyl ($CH_2Br$).

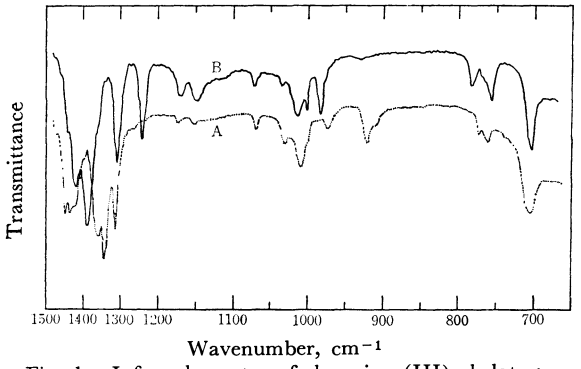

Fig. 1. Infrared spectra of chromium(III) chelates: A, tris(3-phenyl-2, 4-pentanediono)chromium(III); B, a bromination product of tris(3-phenyl-2, 4-pentanediono)chromium(III). (KBr disk method).

Calcd. for $C_{33}H_{27}O_6Br_6Cr$ (hexabromochelate): C, 37.71; H, 2.59; Br, 45.62; Cr, 4.95; and for $C_{33}H_{28}O_6Br_5Cr$ (pentabromochelate): C, 40.77; H, 2.90; Br, 41.17; Cr, 5.35%.

Thus, the possibility of the coexistence of pentabrominated chelate in the first fraction from the column may not be excluded, as its elemental analysis has indicated.

The later fractions from the chromatographic column were identified as less-brominated and unreacted chelates.

An attempt has been made to brominate 3-phenyl-2, 4-pentanedione under similar conditions in the absence of pyridine, but this attempt failed to afford the corresponding bromination product. Thus, the occurrence of the present reaction with the chromium chelate may be said to be due primarily to the chelate ring.

Since the bromination of tris(2, 4-pentanediono)-chromium(III) resulted only in the substitution of the $\gamma$-hydrogen,[1,4] the $\pi$-electronic interaction of a phenyl ring with the chelate ring in the present chromium chelate[5] seems to activate the methyl groups in the reaction process.

# The Transient Absorption of Irradiated α-Methylstyrene

By Meiseki KATAYAMA

(Received September 15, 1965)

A new transient absorption was observed at 5461Å in extremely dried α-methylstyrene by means of pulse radiolysis.

We have proposed previously[1,2] that the important intermediate in the radiation-induced polymerization of α-methylstyrene was the anion radical, which exhibited an absorption maximum at about 3500Å which was observed by a photographic method of pulse radiolysis.

It has been reported[3] that an absorption at 5100Å, as well as one at 3275Å, usually assigned to the anion radical, appeared when α-methylstyrene was brought into contact with alkalimetals. Therefore, irradiated α-methylstyrene may be expected to show an absorption maximum anywhere between 5000 to 6000 Å, in addition to that at 3500Å, if our proposal is correct.

The experimental details may be briefly explained as follows: An electron linear accelerator was used as the source of radiation. It provided a 1.6 μsec. pulse. A mercury lamp was used as the source of analytical light for spectroscopy. For recording the absorption, the photoelectric method was employed. The monomer was eventually dried by using a mirror of alkali metal. All the measurements were conducted at 15°C.

A typical synchroscope trace for the decay of absorption in dried α-methylstyrene is shown in Fig. 1. The arrow in the figure indicates the time of the irradiation of the sample with a pulse. The rate of the decay of the intermediate obeyed

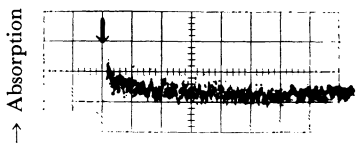

Fig. 1. Decay of absorption in extremely dried α-methylstyrene at 5461 Å (mean dose of 3 k. rads). Absorption: 1.6% per large division Sweep speed: 50 μ sec. per large division

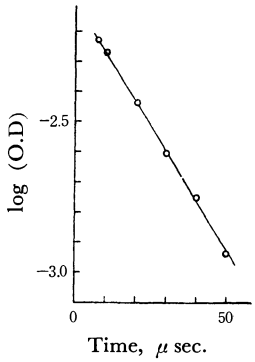

Fig. 2. The first-order plot of the decay of the absorption at 5461 Å (mean dose of 3 k. rads).

the first-order reaction kinetics (Fig. 2.) and had a half-life of about 25 μsec.

The transient absorption observed here at 5461Å behaves exactly like the one at 3500Å previously reported.[1] Thus, the addition of water or DPPH in a minute amount caused the intermediate to decay at a much faster rate. The decays with the additives were, actually, both too fast to be measured* with the same time scale as in Fig. 1. This is in conformity with the fact[2] that the polymerization is practically inhibited by the addition of these compounds. The first-order decay of the intermediate strongly suggests that it is reacting with the monomer molecules:

$$(\alpha\text{-MS})^{\ominus} + \alpha\text{-MS} \rightarrow \text{Polymerization}$$

It should be mentioned that the rate of the decay observed at 5461Å in the dried monomer quantitatively agreed with that at 3500Å.[4]

In conclusion, further support for the proposed anion radical mechanism in the radiation-induced polymerization of α-methylstyrene has been obtained by the present investigation.

# The Electron Spin Resonance of the Anion Radicals Formed on Metal Oxides*

By Kozo HIROTA, Keiji KUWATA and Yasaburo AKAGI

(Received September 20, 1965)

The formation of cationic species adsorbed on surfaces has been established by studies[1-3] of the adsorption of hydrocarbons on silica-alumina catalysts. It is also probable that an anionic species will be formed on an adsorbent of an electron donor if a strong electron acceptor is used as the adsorbate.[4]

The present authors will here report on the formation of such anionic species in the cases of tetracyanoethylene and benzophenone adsorbed on zinc oxide or alumina.

Tetracyanoethylene[5] and benzophenone, which are known to be strong electron acceptors and which can easily form stable anion radicals,[6,7] were adsorbed on zinc oxide or alumina in vacuo.

All the samples gave ESR signals which were stable for a week or more. The signals quickly dissappeared, however, upon the introduction of air.

A fairly well-resolved hyperfine structure of the ESR spectrum of tetracyanoethylene was observed when tetracyanoethylene was adsorbed on alumina from a benzene solution with a $10^{-1}$ mol. concentration and evacuated under a high vacuum (Fig. 1.)

The spectrum is the same as that for the anion of a solid state, and shows the characteristic feature of a nine-line hyperfine structrue for the solution of the anion.[4]

In the case of benzophenone, the hyperfine structure was not resolved so well and so was not

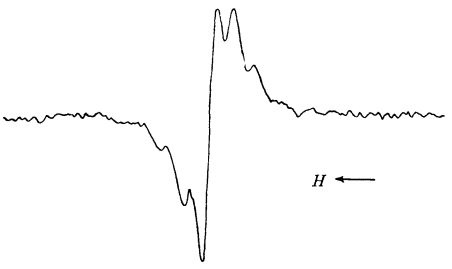

Fig. 1. ESR spectrum of tetracyanoethylene adsorbed on alumina.

confirmative evidence for the formation of aion radicals; however, the most probable paramagnetic species formed from benzophenone is its anion radical.

In an attempt to accelerate the electron transfer from donor to acceptor, the samples were exposed for several tens of minutes to a strong illumination of ultraviolet light from a high pressure mercury lamp. An increase in the signal intensity was observed in both cases upon irradiation.

A transfer of the trapped electrons from oxides to adsorbates will decrease the paramagnetic centers in the oxides; experimental evidence of this was, however, obtained only in the case of zinc oxide by the decrease of the signal at $g=1.96$.

It is interesting to observe the anion radical of tetracyanoethylene on alumina in contrast to the fact that aromatic hydrocarbons are easily oxidized into cation radicals on silica-alumina.[1-3] The milder treatment of the alumina samples in this experiment (evacuation for 3 hr. at 350°C) may be a reason for its poor oxidative tendency.

# On the Isothermal Decay of Trapped Electrons Formed in a Rigid $\gamma$-Irradiated Medium

By Hideo TSUJIKAWA, Kenji FUEKI and Zenichiro KURI

(Received September 29, 1965)

The study of trapped electrons formed by the $\gamma$-irradiation of organic glasses is of great significance in the elucidation of the primary processes in radiation chemistry. The isothermal decay of trapped electrons in 2-methyltetrahydrofuran (MTHF)[1] and in 3-methylpentane[2] at low temperatures has recently been observed by spectroscopic methods. It does not appear, however, that the mechanism for the isothermal decay of trapped electrons has been established.

As a theoretical approach to this problem, we have made a calculation of the tunneling of an electron from an electron-trapping center to a positive hole in MTHF. In the calculation the following formula has been used; it is similar to that used in the calculation of the tunneling of F-center electrons in alkali halides[3]:

$$\lambda(R)=-\frac{E_0}{\boldsymbol{h}}\exp\left[-\frac{4\pi}{\boldsymbol{h}}\int_{r_0}^{r^*}\sqrt{2\boldsymbol{m}\{U(r)-E_0\}}\,dr\right]$$

where $\lambda$ is the decay constant; $R$, the distance between a trapping center and a positive hole; $E_0$, the ground-state energy of the trapped electron; $\boldsymbol{m}$, the electron mass, and $\boldsymbol{h}$, the Planck constant. $U(r)$, the potential function, is given by;

$$U(r)=-\frac{\boldsymbol{e}^2}{\varepsilon(R-r)}, \qquad R>r\geq r_0$$

where $r$ is the distance from the trapping center; $r_0$, the radius of the trapping center[4]; $r^*$, the distance at which the kinetic energy of the trapped electron becomes negative and equal to $R-(\boldsymbol{e}^2/\varepsilon E_0)$, and $\varepsilon$, the dielectric constant of the medium. In the numerical computation we have used the values of $E_0=-1$ eV.[5] and $\varepsilon=4.6$ for MTHF.

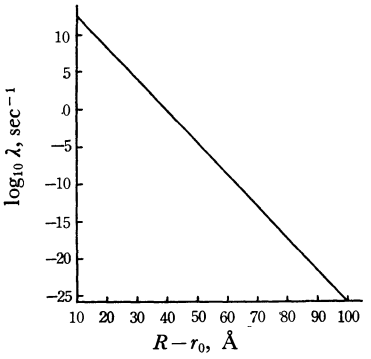

Fig. 1. Decay constant of trapped electrons in MTHF as a function of the ion-pair separation distance.

Figure 1 shows the decay constant of trapped electrons in MTHF, calculated as a function of the ion-pair separation distance. The decay constants of trapped electrons measured by Smith and Pieroni[1] are of the order of $10^{-4}$—$10^{-5}$ sec$^{-1}$ in this system. From Fig. 1 the corresponding ion-pair separation distance is obtained as $\sim$50 Å, in good agreement with the average distance ascertained experimentally.[1] Thus the tunneling of electrons is a possible mechanism for the isothermal decay of trapped electrons formed in rigid $\gamma$-irradiated media.

3) D. L. Dexter, *Phys. Rev.*, **93**, 985 (1954).
4) The radius of the trapping center, $r_0$, would be about 3 Å. It should be noted that the value of $r_0$ is not explicitly required for the present purpose.
5) This value corresponds to the electronic transition energy at the absorption maximum, which is believed to be close to the binding energy of the trapped electron in the ground state. W. H. Hamill, J. P. Guarino, M. R. Ronayne and J. A. Ward, *Discussions Faraday Soc.*, **36**, 169 (1963).

# The Dielectric Constant of Triethanolamine Borate

By Seiichi KONDO

(Received October 5, 1965)

The nearly spherical triptich or cage-type structure proposed for triethanolamine borate by Brown and Fletcher[1] suggested the possibility of molecular rotation in the crystalline state. Although Westrum[2] concluded, from his thermal measurements, that such rotation was unlikely, this paper will present a study of the dielectric properties in the crystalline state in an endeavor to shed further light on the nature of this transition.

The raw material synthesized from triethanolamine and boric acid was provided by the courtesy of the U. S. Borax Co.*; it was vacuum-sublimed four successive times at 180°C and $10^{-3}$ mmHg. The melting point of the purified sample was 513°K, in good accord with the literature values of 508°K[1] and 512°K[2]. The sample was put into the measuring electrode under streaming nitrogen gas. A bridge with a frequency range from $3\times10^2$ to $3\times10^4$ c. p. s., as described elsewhere,[3] was used. Temperatures over the range from 10°C to 238°C were determined with a copper-constantan thermocouple attached firmly to the electrode cell. The dielectric constant versus temperature curves obtained are shown in Fig. 1.

No frequency dependency of the dielectric constant was noted over the available range studied. At lower temperatures the dielectric loss is approximately $10^{-2}$ to $10^{-3}$. However, the resistance of the sample decreased very rapidly to $10^5$ ohm or less as the melting point was approached; hence, it was beyond the range of the bridge. Only a large and abrupt increase in the dielectric constant at the melting point could be observed; the dielectric constant of the liquid state was not obtained.

As is shown in Fig. 1, a small change in the dielectric constant may be noted at 474°K. The dielectric transition point presumably corresponds to the phase transition point, 466.54°K, found by Westrum.[2] Since both the increment in the dielectric constant and the entropy of transition are relatively small, the change in chemical bonding from a triptich to a cage-type structure is probably not involved in the mechanism of the phase transition. Moreover, there is no evidence of a rotational transition of the molecular dipole at this temperature; presumably dipolar rotation commences only at the melting temperature.

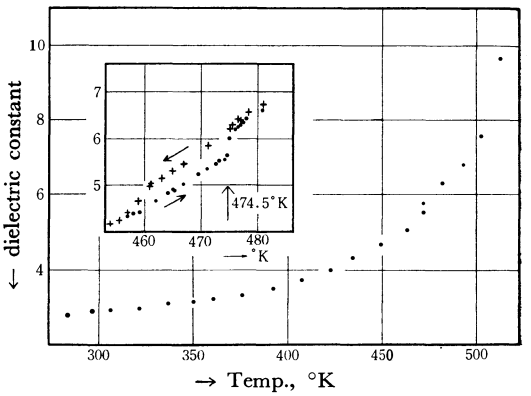

Fig. 1. The dielectric constant versus temperature curves of triethanolamine borate. The dotted and crossed points of the upper figure show the measured values in increasing and decreasing temperatures, respectively, near the phase transition.

These results thus confirm the conclusion by Westrum that this material is not plastically crystalline.

# Novel Dialkyl Cobalt Derivatives

By Hiroshi YAMAZAKI and Nobue HAGIHARA

(Received October 7, 1965)

Previously, we have reported[1] some stable alkyl nickel derivatives, with a formula of $\pi$-$C_5H_5Ni(PPh_3)R$, in which nickel metal attained the electronic configuration of krypton. The surprising stabilities of these compounds have now prompted us to prepare isoelectronic compounds of cobalt. Here we wish to report the preparation of the some dialkyl cobalt derivatives.

The treatment of a slurry of triphenylphosphine-$\pi$-cyclopentadienylcobalt diiodide[2,3] in benzene with a solution of methyl magnesium iodide in ether at room temperature gave an orange-red solution.* After the hydrolysis and evaporation of the solvent, the residue was separated on an alumina column, using benzene as the eluant. From the first red fraction, air-stable orange-red crystals of triphenylphosphine-$\pi$-cyclopentadienyl dimethylcobalt (I) ($\pi$-$C_5H_5Co(PPh_3)(CH_3)_2$) were obtained. (Yield, 54%. M. p. 142—143°C (decomp.). PMR (in $CS_2$)**: 2.65 $\tau$ ($C_6\underline{H}_5$), doublet ($J$=5 c. p. s.); 5.67 $\tau$ ($C_5\underline{H}_5$), sharp singlet; 10.02 $\tau$ ($C\underline{H}_3$), doublet ($J_{PH}$=6 c. p. s.).

Found: C, 71.80; H, 6.42. Calcd. for $C_{25}H_{26}PCo$: C, 72.11; H, 6.30%.) I is very stable in air, especially in the solid state, and it is soluble in most organic solvents.

From the second brown fraction, fine dark brown crystals of triphenylphosphine-$\pi$-cyclopentadienylmethylcobalt iodide (II) ($\pi$-$C_5H_5Co(PPh_3)(CH_3)I$) were obtained. (Yield, 1.3%. M. p. 112°C (decomp. without melting). Found: C, 54.35; H, 4.41. Calcd. for $C_{24}H_{23}IPCo$: C, 54.57; H, 4.39%.) Another experiment which was carried out employing an amount of methyl magnesium iodide equivalent to the diiodide and by the reverse addition method gave I in a 8% yield and II in a 13% yield.

According to the results of a similar procedure using benzyl magnesium chloride, dark red crystals of triphenylphosphine-$\pi$-cyclopentadienyldibenzylcobalt (III) ($\pi$-$C_5H_5Co(PPh_3)(CH_2Ph)_2$) were obtained. (Yield, 68%. M. p. 102°C (decomp.). PMR (in $C_6D_6$)***: 2.7 $\tau$ (P-$C_6\underline{H}_5$); 2.9 $\tau$ ($CH_2$-$C_6\underline{H}_5$); 5.67 $\tau$ ($C_5\underline{H}_5$); 6.85 and 7.15 $\tau$ (-$C\underline{H}_2$-), broad. Found: C, 77.96; H, 6.03. Calcd. for $C_{37}H_{34}PCo$: C, 78.16; H, 6.03%.)

The reaction of II with benzyl magnesium chloride resulted in the formation of triphenylphosphine - $\pi$ - cyclopentadienylmethylbenzylcobalt (IV) ($\pi$-$C_5H_5Co(PPh_3)(CH_3)(CH_2Ph)$) as red crystals. (Yield, 51%. M. p. 112—113°C (decomp.). PMR (in $C_6D_6$)***: 2.5 $\tau$ (P-$C_6\underline{H}_5$); 2.95 $\tau$ ($CH_2$-$C_6\underline{H}_5$); 5.72 $\tau$ ($C_5\underline{H}_5$); 6.75 and 8.30 $\tau$ (-$C\underline{H}_2$-), broad; 9.17 $\tau$ ($CH_3$), doublet ($J_{PH}$= 6 c. p. s.). Found: C, 76.07; H, 6.13. Calcd. for $C_{31}H_{30}PCo$: C, 75.60; 6.14%.) This is the first example of a compound with two different alkyl groups bonded to a cobalt metal. The air sensitivities of I, IV and III increase in this order.

The proton magnetic resonance spectra of III and IV show that the methylenic protons of the benzyl group are not equivalent, suggesting the inhibition of the free rotation of the benzyl group. Attempts to isolate other dialkyl and diaryl derivatives were unsuccessful. The steric factor is essential for their stabilities.

# Organic Syntheses by Means of Noble Metal Compounds. XIX. The Hydroformylation Reaction Catalyzed by Metallic Palladium.[1]

By Jiro Tsuji, Nobuo Iwamoto and Masanobu Morikawa

(Received October 19, 1965)

It is known that the syntheses of aldehydes from olefins, carbon monoxide and hydrogen (Oxo reaction) are catalyzed by cobalt carbonyl. In addition, some other metal carbonyls, such as rhodium and ruthenium carbonyls, are known to be active in the reaction.

In the course of our studies of the catalytic action of metallic palladium on the carbonylation of various olefins thus, forming saturated and unsaturated carboxylic esters,[2,3] we have found that palladium chloride or metallic palladium is also active in the hydroformylation of olefins.

A typical example will be described below. In order to avoid the effect of the metal surface of an autoclave, the reaction was carried out in a glass vessel equipped with a gas-inlet capillary. Benzene (15 ml.), toluene (for the gas chromatographic determination, 2 ml.) and palladium chloride (2 g.) were mixed in the glass vessel, which was then placed in a 100-ml. autoclave. Ethylene and synthesis gas were introduced (50 and 100 kg./cm$^2$ respectively), and the autoclave was shaken at 100°C for 15 hr.; a 55 kg./cm$^2$ pressure drop was observed during this period. The amount of propionaldehyde formed was gas chromatographically determined to be 1.2 g. The conversion was not very high in general. It was confirmed that a considerable amount of ethylene was consumed by hydrogenation, thus forming ethane. Such a metallic palladium as palladium black was equally active; it seems likely, therefore, that metallic palladium is the true catalyst. The recovered palladium could be used repeatedly. The reaction procedure is simple, because metallic palladium can be used and then recovered quantitatively. The application of the method to other olefins and the reaction mechanism will be reported in a forthcoming paper.

# The Catalytic Action of Binary Metal-Polyphthalocyanine Complexes on the Oxidation of Acetaldehyde Ethylene Acetal

By Hiroo INOUE, Yasuji KIDA and Eiji IMOTO

(Received October 28, 1965)

We wish to report in this communication our recent findings that acetaldehyde ethylene acetal is effectively oxidized with oxygen to ethylene glycol monoacetate in the presence of some metal-phthalocyanine complexes, which may act as catalysts. The catalytic activities of the phthalocyanine complexes are remarkably dependent on the type of complex involved. The acetal is not oxidized with oxygen at 30°C by copper- or iron-phthalocyanine, nor by copper- or iron-polyphthalocyanine. However, the acetal is quickly oxidized with oxygen at 30°C by binary copper-iron-polyphthalocyanine, although the acetal is not oxidized in the presence of the mixture of copper- and iron-polyphthalocyanines.

Similar phenomena have also been observed in the case of iron- and molybdenum-phthalocyanine complexes. The binary complex which contains iron and molybdenum ions together in polyphthalocyanine was active in the oxidation of the acetal with oxygen, but the mixture of iron- and molybdenum-polyphthalocyanines was not active. The meaning of the need for two kinds of metal ions in the complexes is not clearly understood. However, one could speculate that two kinds of metal ions may play different roles in the catalytic oxidation. For example, one kind of metal ion serves to produce the hydroperoxide of the acetal, and the other, to decompose it, while the conjugated system in the complexes would contribute to the electron transfer between two kinds of metal ions.

All of the metal-phthalocyanines used in this investigation were synthesized by a modification of the methods described by Epstein and Wildi,[1] and Drinkard and Bailar.[2] Acetaldehyde ethylene acetal was purified by repeated distillation over sodium. The oxidation of the acetal was carried out by stirring 0.05 g. of the catalyst in 5 ml. of the acetal under an atmosphere of oxygen at 30°C.

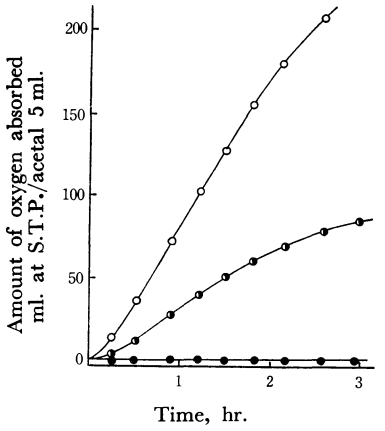

Fig. 1. Effects of metal-polyphthalocyanine complexes on the rate of the oxygen absorption: ◑ Cu-Fe-, ○ Mo-Fe-polyphthalocyanines, and ● Cu-, Fe-, Mo-, Cu- and Fe-, Mo- and Fe-polyphthalocyanines.

The amounts of oxygen absorbed and the reaction times were measured by using the equipment described in a previous paper.[3] The results are shown in Fig. 1. As the reaction products, ethylene glycol monoacetate and diacetate were identified and were determined by gas chromatography. In the case of binary iron-molybdenum-polyphthalocyanine, the yields of ethylene glycol monoacetate and diacetate, based on the amount of acetaldehyde ethylene acetal, were 41.2% and 1.3% respectively at the reaction time of 3.5 hr.; 58.5% of the acetal was recovered. A detailed report of this experiment will be published later.
