# The Reactions of Methyl β-(Substituted-2-pyrrolyl)-propionate and Ethyl β, β-Bis(substituted-2-pyrrolyl)-propionate with Some Formylating Reagents*

By Hiroyuki SHINOHARA, Masato SAWADA and Eiji IMOTO

(Received January 6, 1964)

In a preceding paper[1] we reported on an attempt to obtain cyclopenteno(b)pyrrole derivatives, the skeletal structure of which is present in chlorophyll-a and -b. The Friedel-Crafts cyclization of β-(3-ethoxycarbonyl-2-methyl-5-pyrrolyl)-propionyl chloride (Ia) failed to yield 3-ethoxycarbonyl-2-methyl-1, 4, 5, 6-tetrahydrocyclopenta(b)pyrrol-4-one (IIa) and this reaction gave an undesired product III, though in it β-(1, 2-dimethyl-3-ethoxycarbonyl-5-pyrrolyl)-propionyl chloride (Ib) afforded 1, 2-dimethyl-3-ethoxycarbonyl-4, 5, 6-trihydrocyclopenta(b)pyrrol-4-one (IIb).

(III)

As an alternative method of synthesizing a compound with a cyclopenteno(b)pyrrole ring, we propose to condense the active α-methylene group of the side chain of VIII or XII with a formyl group at the neighboring β-position of the pyrrole ring. The formylation of α, α', β'-trisubstituted pyrroles with such formylating reagents as (a) dimethylformamide and phosphorus oxychloride, (b) dichloromethyl ethyl ether and stannic chloride, or (c) dichloromethyl ethyl ether and boron trifluoride-etherate, is reported in this paper. As is shown in Fig. 1, these formylating reagents gave incoherent results. The formylating reagents a and b gave the normally formylated products V or VII respectively as the result of the reaction with ethyl 2, 5-dimethyl-3-pyrrolecarboxylate (IV)[2] or methyl β-(1, 2-dimethyl-3-ethoxycarbonyl-5-pyrrolyl)-propionate (VI),[1] but the reactions of these compounds with c resulted in the recovery of the starting materials. From methyl β-(3-ethoxycarbonyl-2-methyl-5-pyrrolyl)-propionate (VIII),[3] two different products were obtained. One is the normally formylated product IX, resulting from the reaction with a or b; the other is bis(4-ethoxy carbonyl-2-methoxycarbonylethyl-5-methyl-3-pyrrolyl)-carbinol (X), resulting from the reaction with c. From ethyl β, β-bis(4-ethoxycarbonyl-5-methyl-2-pyrrolyl)-propionate (XII)[4] two kinds of products were also derived; one is the normally formylated product XIII, resulting from the reaction with a, while the other is a compound, $C_{22}H_{28}N_2O_7$, the product of the reaction with a or b. The structures of all the normally formylated products, V, VII, IX and XIII, have been concluded to be as shown in Fig. 1 on the basis of the results of their elementary analyses, infrared spectra, the formation of 2, 4-dinitrophenylhydrazones, and elementary analyses of the 2, 4-dinitrophenylhydrazones. Moreover, the structure of the carbinol X has been assumed to be as given in the formula on the basis of the results of elementary analysis, the measurement of the molecular weight, and the infrared spectrum. Furthermore, the carbinol X gave a 2, 4-dinitrophenylhydrazone as the result of the reaction with 2, 4-dinitrophenylhydrazine in an acidic medium; this 2, 4-dinitrophenylhydrazone

TABLE I.

| Starting compound | Method* | Reaction temp., °C | Reaction time, min. | Resulting compound | Yield % |
|---|---|---|---|---|---|
| IV[2] | a | 50—55 | 30 | V | 84** |
| IV[2] | b | 0 | 15 | V | 40 |
| VI[1] | a | Room temp. | 30 | VII | 90 |
| VI[1] | b | 0 | 10 | VII | 14 |
| VIII[3] | a | 30 | 30 | IX | 56 |
| VIII[3] | b | 0 | 10 | IX | 4.5 |

* The procedures are shown in the synthesis of XIII and compound $C_{22}H_{28}N_2O_7$.
** This compound has been prepared by Fischer et al.[6] by the Gattermann formylation of IV with hydrogen cyanide and hydrogen chloride in yield of 75%.

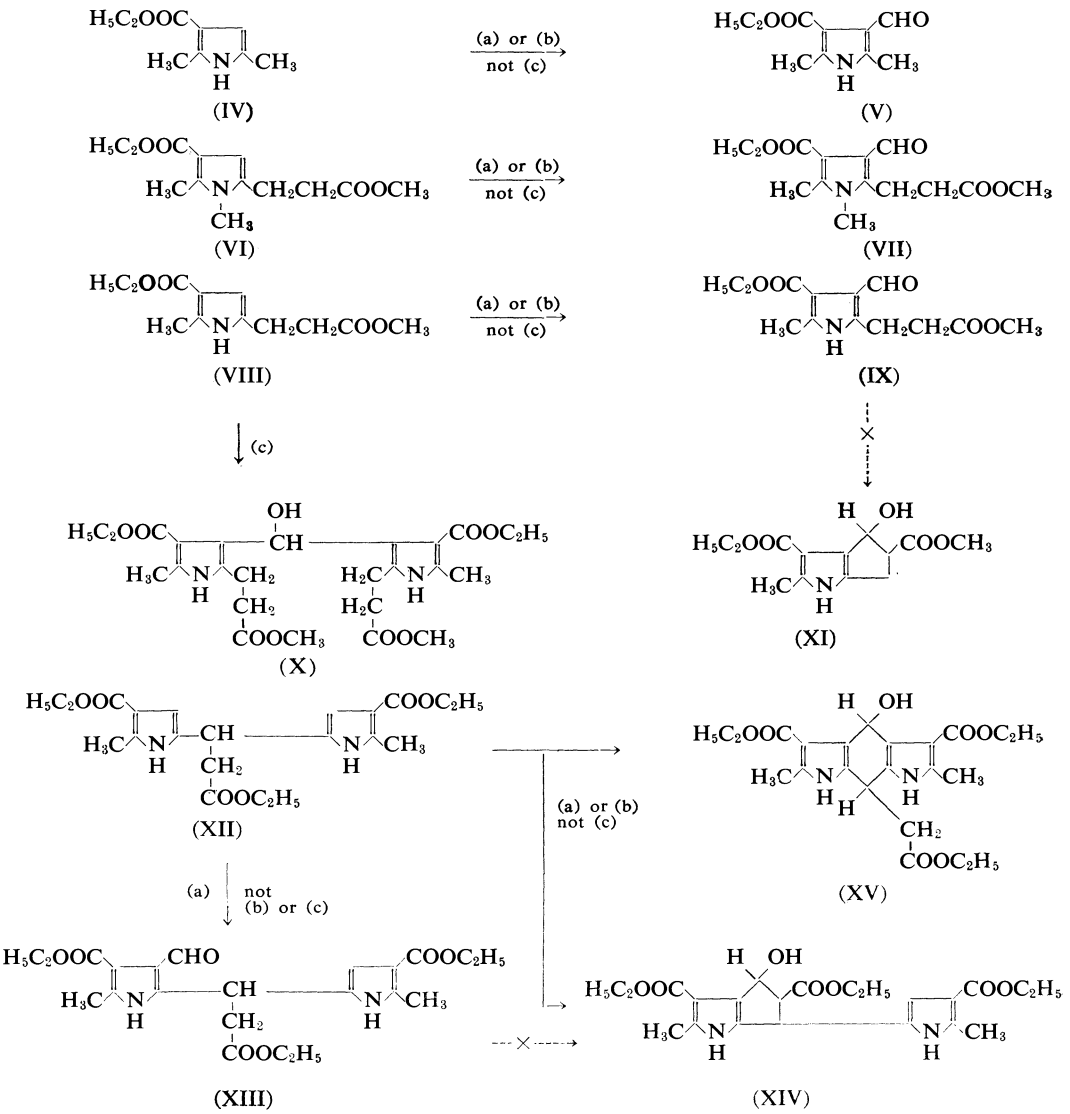

Fig. 1.

was identical with that derived from IX. This fact is also an evidence of the structure of X.

The compound $C_{22}H_{28}N_2O_7$ is an isomer of XIII, but it has no formyl group attached to the carbon atom or to the nitrogen atom of the pyrrole ring. Therefore, the structure of the compound $C_{22}H_{28}N_2O_7$ may be either XIV or XV.

The infrared spectrum definitely shows the presence of a hydroxyl group at 3500 $cm^{-1}$ and the compound $C_{22}H_{28}N_2O_7$ has a band at 3000 $cm^{-1}$ which should be assigned[5] to a stretching vibration of the C–H bond in the pyrrole ring. The compound $C_{22}H_{28}N_2O_7$ seems to have the structure formulated as XIV, because in the structure XV there is no hydrogen atom attached to the pyrrole nucleus. However, the NMR spectra of the compound $C_{22}H_{28}N_2O_7$ do not show a signal due to protons of the pyrrole ring. Attempts to derive XV from XIII in the presence of an acid as a catalyzer have also been unsuccessful, as have attempts to derive XIV from XIII in the presence of sodium methoxide as a catalyzer. From the results previously obtained, it is impossible to determine which structure should be assigned to the compound $C_{22}H_{28}N_2O_7$.

TABLE II.

| Compound | | M. p. °C | Analyses % Nitrogen Calcd. | Found |
|---|---|---|---|---|
| $C_{10}H_{13}NO_3$ | (V) | 149—151 | 7.74 | 7.76 |
| $C_{14}H_{19}NO_5$ | (VII) | 86—87 | 4.98 | 5.03 |
| $C_{13}H_{17}NO_5$ | (IX) | 113.5—114.5 | 5.24 | 5.38 |

2, 4-Dinitrophenylhydrazone of IX was prepared by the usual method. M. p. 202—205°C (decomp.)
Found: N, 15.68. Calcd. for $C_{19}H_{21}N_5O_8$: N, 15.44%.

## Experimental

**Bis(4-ethoxycarbonyl-2-methoxycarbonylethyl-5-methyl-3-pyrrolyl)-carbinol (X).**—To a cold mixture of 1 g. of VIII[3] and 4 g. of dichloromethyl ethyl ether, there was added 3 ml. of borontrifluoride-etherate under ice cooling. The reaction mixture was warmed to 49—50°C and stirred at this temperatue for 30 min., diluted with iced water, and neutralized to Congo red with a saturated solution of sodium acetate in order to precipitate crystals. These crystals were collected by filtration, washed with cold water, and recrystallized from aqueous ethanol repeatedly to give colorless needles with a m. p. of 150—151.5°C in a yield of 350 mg. (33%).
Found: C, 59.29; H, 6.66; mol. wt. (Rast), 508. Calcd. for $C_{25}H_{34}N_2O_9$: C, 59.30; H, 6.72%; mol. wt., 506.

**Reaction with 2, 4-Dinitrophenylhydrazine.** — A solution of 100 mg. of X was mixed with an acidic solution of 2, 4-dinitrophenylhydrazine, warmed for a short time, and allowed to stand in order to precipitate crystals, which were then recrystallized from ethanol. The m. p., 202—204°C (decomp.), was undepressed on admixture with 2, 4-dinitrophenylhydrazone of IX.

Found: N, 15.71. Calcd. for $C_{19}H_{21}N_5O_8$: N, 15.44%.

**Ethyl β-(4-Ethoxycarbonyl-3-formyl-5-methyl-2-pyrrolyl)-β-(4-ethoxycarbonyl-5-methyl-2-pyrrolyl)-propionate (XIII).** — To a cold solution of 3 g. of XII[4] in 3.1 g. of dimethylformamide, 2.3 g. of phosphorus oxychloride was added drop by drop at room temperature. The reaction mixture was stirred for 60 hr. at room temperature in order to precipitate a solid material stained by a resinous material, diluted with 70 ml. of a saturated solution of sodium acetate, and stirred for a further two days. After the aqueous layer of the reaction mixture had been removed by decantation, the solid material was repeatedly washed with water and then with a small amount of ethanol to remove the resinous material; then the material was collected by filtration, washed with water, and treated with boiling benzene. The insoluble part in benzene was recrystallized from ethanol to obtain the desired product, XIII, in a yield of 200 mg. (6.3%), m. p. 186—188°C (decomp.).
Found: C, 61.14; H, 6.57; N, 6.62. Calcd. for $C_{22}H_{28}N_2O_7$: C, 61.11; H, 6.49; N, 6.49%. 2, 4-Dinitrophenylhydrazone of XIII, m. p. 187~188°C.
Found: N, 13.78. Calcd. for $C_{28}H_{31}N_6O_{10}$: N, 13.67%.

**The Compound $C_{22}H_{28}N_2O_7$ XIV or XV.**—a) In to a mixture of 4 g. of XII[4] and 1.5 g. of dimethyl formamide, 1.53 g. of phosphorus oxychloride was gradually stirred at 40°C. After the addition, the reaction mixture was warmed to 60°C, kept at this temperature for 15 min., mixed with iced water, and then neutralized to Congo red with a saturated solution of sodium acetate. The precipitate thereby yielded was collected by filtration, washed with cold water, and recrystallized from aqueous ethanol. Yield, 1.2 g. Pale yellow crystals, m. p. 217—219°C (decomp.).

b) To a cold mixture of 1 g. of XII and 16 g. of dichloromethyl ethyl ether, 2 ml. of stannic chloride was added at once under ice cooling. After having been stirred for 10 min., the reaction mixture was poured into iced hydrochloric acid. Since the oily product which separated solidified slowly, it was collected by filtration, washed with cold water, and dissolved in warm ethanol. After the ethanolic solution had been treated with norite, it was diluted with water to reprecipitate the product. The product was then washed with a few drops of ethanol and repeatedly recrystallized from aqueous ethanol to obtain pale yellow crystals of the compound $C_{22}H_{28}N_2O_7$. M. p. 215—217°C (decomp.), undepressed with the sample obtained above at a) on admixture. Yield, 50 mg.
Found: C, 60.94; H, 6.50; N, 6.56. Calcd. for $C_{22}H_{28}N_2O_7$: C, 61.11; H, 6.49; N, 6.49%.

**An Attempt to Cyclize Methyl β-(4-Ethoxycarbonyl-3-formyl-5-methyl-2-pyrrolyl)-propionate (VII) into 3-Ethoxycarbonyl-5-methoxycarbonyl-2-methyl-1, 4, 5, 6-tetrahydrocyclopenta(b)pyrrol-4-ol (XI).**—a) To 100 ml. of an ethereal solution of sodium ethoxide prepared from 50 mg. of sodium 500 mg. of VII was added; the mixture was then refluxed for 5 hr. After the ether had been evaporated, the residue was dissolved in water and filtered.

5) A. R. Katrifzky, *Quart. Rev.*, **13**, 353 (1959).
6) H. Fischer and W. Zerweck, *Ber.*, **55**, 1942 (1922).

The filtrate was acidified to obtain a solid material. The solid material was washed with iced water and recrystallized from aqueous ethanol to obtain 180 mg. of β-(3-ethoxycarbonyl-4-formyl-2-methyl-5-pyrrolyl)-propionic acid, m. p. 166—167°C, which is soluble in an aqueous solution of sodium bicarbonate.

Found: N, 5.40. Calcd. for $C_{12}H_{15}NO_5$: N, 5.54%.

b) A mixture of 500 mg. of VII, 0.5 ml. of triethylamine, and 10 ml. of absolute ethanol was refluxed for 3 hr. and then poured into iced water to precipitate crystals. The crystals were collected by filtration, washed with water, and recrystallized from water to recover the starting material (about 500 mg.) with a m. p. of 113—114°C. Similarly, the reaction of VII with dispersed sodium in benzene at the refluxing temperature or with hydrogen chloride in absolute ethanol under reflux also resulted in the recovery of the starting material.

**Attempts to Cyclize XIII into XIV.**—a) To 80 ml. of an ethereal solution of sodium ethoxide prepared from 50 mg. of sodium, 300 mg. of XIII was added; the mixture was then refluxed for 3 hr. After it had evaporated, the residue was treated with iced hydrochloric acid and filtered. The solid material was washed with iced water and recrystallized from ethanol to recover the starting material.

b) The reaction of XIII with hydrogen chloride in absolute ethanol at reflux also resulted in the recover of the starting material.

*Infrared Spectra.* — These were recorded with a Hitachi EPI-2 spectrophotometer; the measurements were made on pressed disks of potassium bromide.

The authors wish to thank Dr. Naohiro Hayakawa of the Japan Atomic Energy Research Institute for his measurements and for invaluable advice on the assignment of NMR spectra.

# Poly-L-histidine and the Copolymer of L-Histidine with L-Glutamic Acid. Their Synthesis and Catalytic Activity on the Hydrolysis of *p*-Nitrophenyl Acetate*1

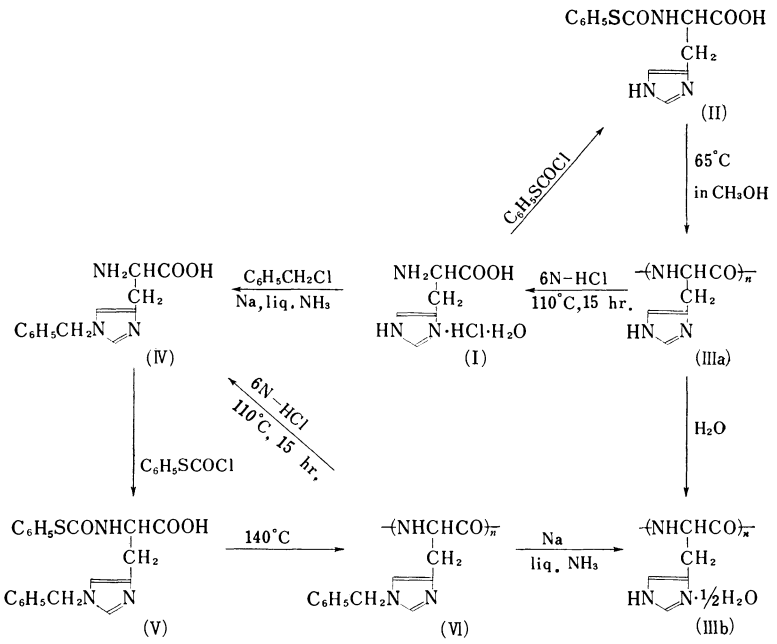
By Tomoo SAITO

(Received April 9, 1964)

It has previously been established that the histidine residue plays an important role in certain proteolytic enzymes. Poly-L-histidine is, therefore, an interesting material to use as a model compound in order to study the catalytic behavior of the histidine residue.

Poly-L-histidine has been prepared by Patchornik et al.[1] However, better results have been achieved in the present experiments, where the synthesis of homo- and co-polymers of L-histidine by the carbothiophenyl method[2] will be described. An attempt to polymerize 1-benzyl-$\alpha$, *N*-carbothiophenyl-L-histidine with $\gamma$-benzyl-L-glutamate *N*-carboxy anhydride (NCA) and their catalytic activities will also be described.

**The Synthesis and Properties of Poly-L-histidine.**—Two series of reactions are outlined in scheme A. In one process, the free imidazole group was used, and in the other, the imidazole imino group, which was protected by a benzyl group.



L-Histidine hydrochloride (I) was treated with sodium methylate to give free L-histidine, from which $\alpha$, *N*-carbothiophenyl-L-histidine (II) was obtained in a 43% yield by the action of carbothiophenyl chloride. II was polymerized in methanol at 65°C for 3 weeks to yield poly-L-histidine (mol. wt.$\fallingdotseq$2040, $n\fallingdotseq$15)*2 (IIIa). 1-Benzyl-$\alpha$, *N*-carbothiophenyl-L-histidine (V) was obtained from 1-benzyl-L-histidine (IV) in a 81% yield by a reaction with carbothiophenyl chloride in an anhydrous basic medium. In order to obtaine poly-1-benzyl-L-histidine (mol. wt.$\fallingdotseq$2830, $n\fallingdotseq$12.5)*2 (VI), V was polymerized at 140°C in vacuo for ten hours. The reduction of VI with metallic sodium in liquid ammonia gave poly-L-histidine (IIIb). Since the average degree of the polymerization of IIIb was shown to be ca. 13.3 (mol. wt.$\fallingdotseq$1940),*2 it was concluded that the average chain length of VI was unaffected by the reduction. The insolubility of

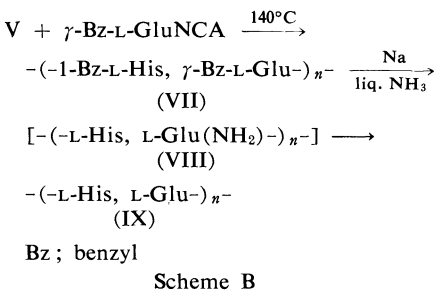
2) J. Noguchi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **74**, 961 (1953).

*2 The molecular weight was determined by a terminal end group titration with anhydrous sodium methylate.



Scheme A

VI in an alkaline solution can perhaps be explained by the absence of any free imidazole group in VI, and the solubilities of IIIa and IIIb in a dilute acid and in a strongly alkaline solution (above 3 N) showed that they behaved as polyampholytes. IIIb contained half a molecule of crystalline water per histidine residue; this could not be removed by drying at 100°C for 5 hr. in vacuo on phosphorus pentoxide.[1] However, neither water nor methanol was contained in IIIa. When IIIa, ($[\alpha]_D = -19.5°$),[1] was hydrolyzed with acid, L-histidine hydrochloride monohydrate resulted; this was proved to be optically pure ($[\alpha]_D = +13.0°$).[3] The configuration of the histidine residue in IIIa was, therefore, unaffected in the process of the synthesis.

The ultraviolet absorption spectra of IIIa showed the absorption maximum at 294 mμ ($\varepsilon = 29.8$) in 1 N sodium hydroxide, and at 275 mμ ($\varepsilon = 12.8$) in 1 N hydrochloric acid respectively. The former absorption band may be attributed to the imidazolium ion  and the latter, to the imino group 

**The Synthesis of the Copolymer of L-Histidine with L-Glutamic Acid.**—The synthetic process of the copolymer is shown in scheme B.

Scheme B

The bulk copolymerization of the equi-molar V and γ-benzyl-L-glutamate NCA gave the copoly(1-benzyl-L-histidine, γ-benzyl-L-glutamate)$_n$ (1 : 1) (VII) with an average degree of polymerization of ca. 25 (mol. wt.≒11300)*2 and in a 86% yield. Copoly(L-histidine, L-glutamic acid)$_n$ (1 : 1) (IX) was obtained from VII by reduction with metallic sodium in liquid ammonia in order to remove the protected groups. Van Slyke terminal nitrogen analysis for IX indicated that neither a remarkable decrease in its chain length nor the cyclization of the *N*-terminal residue had taken place and that the average degree of the polymerization of IX was ca. 20 (mol. wt.≒5320). Poly-β-benzyl-L-aspartate was converted to the β-amide of the polymer (polyasparagine) by treatment with liquid ammonia,[4] analogously,

3) L-Histidine HCl $H_2O$: $[\alpha]_D^{24} = +13.15°$ (in 6 N hydrochloric acid), S. Akabori and S. Mizushima, "Protein Chemistry" (Tanpakushitu Kagaku), Vol. 1, Kyoritsu Shuppan K. K., Tokyo (1952), p. 112.

4) J. Noguchi, T. Saito and M. Asai, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **81**, 620 (1960).

poly-γ-methyl-L-glutamate was converted to the γ-hydrazide of the polymer by treatment with hydrazine.[5] The elementary analysis for IX, however, proved that the glutamate residues were reduced to free glutamic acid residues. The discrepancy mentioned above might be due to the fact that a possible intermediate, VIII, was hydrolyzed to give IX in an alkaline treatment during the isolation of IX.

**Catalytic Activity on the Hydrolysis of *p*-Nitrophenyl Acetate.** — In a previous work,[6] catalytic activity on the hydrolysis of *p*-nitrophenyl acetate was examined in many histidine-containing oligopeptides and some polypeptides, and it was found that amino acids which were adjacent to the *N*- or the *C*-terminal of histidine through the peptide linkage increased the activity of histidine. However, the activity was not increased by the polymerization of these oligomers. For example, the activity of carnosine (β-alanyl-L-histidine) was 2.40 times that of histidine, while that of ε-aminocaproylhistidine was much the same as that of histidine. Each of the polymers prepared from carnosine and ε-aminocaproylhistidine (i. e., polycarnosine (poly-β-alanyl-L-histidine) and poly ε-aminocaproylhistidine), had the same activity as its monomer.

The activities of IIIa and IX on the hydrolysis of *p*-nitrophenyl acetate were determined by on the basis of the rate of appearance of *p*-nitrophenylate ions. It was observed that the catalytic activities of IIIa and IX were, respectively, 1.43 and 1.45 times that of L-histidine. The ratio, 1.43 of IIIa which has an average degree of polymerization ($n \fallingdotseq 15$), agreed with that (1.40) of the low molecular weight preparation ($n \fallingdotseq 3.3$).[6],*3 The ratio of IX, 1.45, agreed approximately with the average of the ratios, 1.64 in L-glutamyl-L-histidine and 1.12 in L-histidyl-L-glutamic acid. The activation of the hydrolytic effect for the substrate was, therefore, not affected by the increase in the degree of polymerization. The results concerning IX, however, seemed to suggest that L-histidine and L-glutamic acid were arranged irregularly in the copolymer chain.

## Experimental

All melting points are uncorrected.

**α, *N*-Carbothiophenyl-L-histidine (II).** — L-Histidine hydrochloride monohydrate (10 g.) was added to 2 N sodium methylate in methanol (47.8 ml.) at 0—5°C, and then carbothiophenyl chloride (9.0 g.) was vigorously stirred into the solution at −5°C. The resulting precipitates were filtered, and from the filtrate, II (m. p. 165—167°C (decomp.)) was obtained in a 48% (6.0 g.) yield.

Found: C, 53.5; H, 4.50; N, 14.4; S, 11.3; equiv. wt. 286 and 149 (determined by anhydrous perchloric acid and sodium methylate titration respectively). Calcd. for $C_{13}H_{13}O_3N_3S$: C, 53.6; H, 4.48; N, 14.4; S, 11.0%; equiv. wt. 291.3, 145.6.

**Poly-L-histidine (IIIa).** — II (1.0 g.) was dissolved in anhydrous methanol (15 ml.), and the atmosphere was replaced with carbon dioxide. The polymerization was carried out in a sealed tube at 65°C for 3 weeks. The resulting precipitate was collected by centrifugation, washed with methanol, and dried to yield 0.3 g. (64%) of IIIa, which gave positive biuret and Pauli reactions, $[\alpha]_D^{32} = -19.5°$ (*c* 0.77, glacial acetic acid). IIIa was soluble in glacial acetic acid and dichloroacetic acid, but insoluble in alcohol, acetone, and ether. It also dissolved in dilute hydrochloric acid and 3 N sodium hydroxide, but it was insoluble in water.

Found: C, 52.1; H, 5.17; N, 30.2; equiv. wt. 135 (determined by perchloric acid titration). Calcd. for $C_6H_7ON_3$: C, 52.5; H, 5.15; N, 30.6%; equiv. wt. 137.

**1-Benzyl-α, *N*-carbothiophenyl-L-histidine (V).** — 1-Benzyl-L-histidine[7] (10 g.) was treated with carbothiophenyl chloride (7.7 g.) in the presence of 2 N sodium methylate in methanol (20.4 ml.) at −5°C. The precipitate was collected by filtration, washed with warm water and then with distilled water, and dried to yield 12.5 g. (81%) of V (m. p. 143°C).

Found: C, 62.5; H, 5.01; N, 11.1; S, 8.42; equiv. wt. 378 and 189 (determined by perchloric acid and sodium methylate titration respectively). Calcd. for $C_{20}H_{19}O_3N_3S$: C, 63.0; H, 4.99; N, 11.0; S, 8.40%; equiv. wt. 381.5, 190.7.

**Poly-1-benzyl-L-histidine (VI).** — V (2 g.) was added to dioxane (2 ml.), and the atmosphere was replaced with nitrogen. Polymerization was carried out at 140°C for 30 min., and then it was continued in vacuo at the same temperature for 10 hr. The solidified reaction mixture was triturated with acetone and ether. The precipitate was contrifugated, washed with ether, and dried to yield 1.1 g. (93%) of VI, which gave a negative Pauli reaction, $[\alpha]_D^{32} = +43.5°$ (*c* 1.86, benzyl alcohol), $[\alpha]_D^{25} = -20.3°$C (*c* 0.94, glacial acetic acid). VI was soluble in chloroform, *N*, *N*-dimethylformamide, benzyl alcohol, glacial acetic acid, and dichloroacetic acid. VI was dissolved in 0.1 N hydrochloric acid and precipitated from this solution by neutralization with alkali, but it was insoluble in concentrated hydrochloric acid and caustic alkali.

Found: C, 68.3; H, 5.83; N, 18.4; equiv. wt. 230 (determined by perchloric acid titration). Calcd. for $C_{13}H_{13}ON_3$: C, 68.7; H, 5.77; N, 18.5%; equiv. wt. 227.3.

**Poly-L-histidine Hemi-hydrate (IIIb).** — VI ($n \fallingdotseq 12.5$) (1.0 g.) was suspended in anhydrous liquid

ammonia (50 ml.); finely divided metallic sodium (ca. 2 g.) was added to the mixture over a period of 15 min. until a blue color persisted for at least 5 min. The excess sodium was then discharged with ammonium chloride, and the ammonia was allowed to evaporate spontaneously. The residue was dissolved in 1 N hydrochloric acid (10 ml.). After the solution had been extracted with 20 ml. of ether, the aqueous layer was filtered and neutralized with 1 N sodium hydroxide. The precipitates were collected by centrifugation and washed with water. The product was dried in vacuo on phosphorus pentoxide at 100°C for 5 hr. to yield 0.5 g. (83%) of IIIb. which gave positive biuret and Pauli reactions, $[\alpha]_D^{32} = -13.3°$ (*c* 1.24, glacial acetic acid). The solubilities of IIIb were the same as those of IIIa.

Found: C, 48.8; H, 5.59; N, 28.9. Calcd. for $C_6H_7ON_3\,1/2\,H_2O$: C, 49.3; H, 5.50; N, 28.8%.

**The Hydrolysis of Poly-1-benzyl-L-histidine.**—A suspension of VI (0.1 g.) in 6 N hydrochloric acid (2.0 ml.) was heated at 110°C for 15 hr. in a sealed tube. From the hydrolysate, 0.08 g. of 1-benzyl-L-histidine melting at 241°C was obtained by neutralization with 6 N sodium hydroxide and recrystallization from water.

Found: Equiv. wt. 240 and 119 (determined by sodium methylate and perchloric acid titration respectively). Calcd. for $C_{13}H_{15}O_2N_3$: Equiv. wt. 245, 122.5.

**The Hydrolysis of Poly-L-histidine.**—IIIa (0.1 g.) was hydrolyzed under the same conditions as VI. When the hydrolysate was worked up in the usual manner, it gave L-histidine hydrochloride monohydrate (0.07 g., m. p. 160°C, $[\alpha]_D^{25} = +13.0°$ (*c* 1.15, 6 N hydrochloric acid)).

**Poly-L-histidine Hemi-hydrate (IIIb) from Poly-L-histidine (IIIa).**—IIIa (0.3 g.) was dissolved in 1 N hydrochloric acid (2.0 ml.) and the solution was filtered, then 1 N sodium hydroxide (2.0 ml.) was added to the filtrate. The precipitates were collected by centrifugation and washed with cold water. The analytical sample was dried on phosphorus pentoxide in vacuo at 100°C for 5 hr.

Found: C, 48.9; H, 5.54; N, 28.3; equiv. wt. 143 (determined by perchloric acid titration). Calcd. for $C_6H_7ON_3\,1/2\,H_2O$: C, 49.3; H, 5.50%; N, 28.8%; equiv. wt. 146.

**Copoly(1-Benzyl-L-histidine, γ-Benzyl-L-glutamate)$_n$ (1:1) (VII).**—A mixture of V (1.00 g.), γ-benzyl-L-glutamate NCA[8] (0.69 g.), and 2.0 ml. of dioxane was heated under a nitrogen atmosphere at 140°C for 24 hr. The product was triturated with acetone and ether, and collected by centrifugation to yield 1.0 g. (86%) of VII.

Found: C, 67.0; H, 5.93; N, 12.3; equiv. wt. 427 (determined by perchloric acid titration). Calcd. for $C_{25}H_{26}O_4N_4$: C, 67.3; H, 5.87; N, 12.6%; equiv. wt. 446.5.

**Copoly(L-Histidine, L-Glutamic Acid)$_n$ (1:1) (IX).**—To a suspension of VII (0.9 g.) in liquid ammonia (ca. 50 ml.), finely divided metallic sodium was added over a period of 15 min. until a blue color persisted for at least 5 min. The excess sodium was discharged with ammonium chloride, and the ammonia was allowed to evaporate spontaneously. The residue was then dissolved in water (20 ml.) and extracted twice with 20 ml. portions of ether. The aqueous layer was filtered and neutralized with 6 N hydrochloric acid to pH 6 and concentrated to dryness in vacuo. The residue was redissolved in water (20 ml.) and dialyzed. Then the solution was lyophilized to yield 0.4 g. (67%) of IX.

Found: C, 47.7; H, 5.51; N, 20.6; equiv. wt. 267 and 260 (determined by perchloric acid and sodium methylate titration respectively). Calcd. for $C_{11}H_{14}O_4N_4\,1/2\,H_2O$: C, 48.0; H, 5.45; N, 20.4%; equiv. wt. 275.3.

**The Determination of the Amino Acid Contents of IX.**—The histidine content of IX was determined by the reaction of the histidine residue with diazotized sulfanilic acid, followed by colorimetric analysis. After the hydrolysis of IX with 6 N hydrochloric acid at 110°C for 10 hr., both histidine and glutamic acid were assayed by the colorimetric determination of paper chromatography, using ninhydrine as a developer. It was demonstrated that they were in the ratio of ca. 1:1.

**The Determination of Catalytic Activity.**—The catalyst, IIIa or IX, in the concentration of 100 mg./l. and the substrate, *p*-nitrophenyl acetate, in the concentration of 3.311 mmol./l. were incubated for 30 min. at 25°C in a 1/30 mol. phosphate buffer solution of pH 6.4 containing 10% (V/V) acetone in order to dissolve the *p*-nitrophenyl acetate. The liberated *p*-nitrophenylate ions were determined by measuring the increases in optical density at 400 mμ using a Hitachi EPU type 2 spectrometer.

The author is very grateful to Professor Junzo Noguchi of the University of Hokkaido for his kind help.

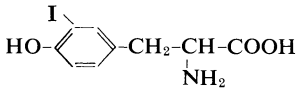
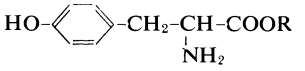
# The Ionization Constants of Organic Compounds. I. The Microscopic Ionization Constants of Tyrosine and Related Compounds*

By Futaba YAMAZAKI, Kiyoko FUJIKI and Yasue MURATA

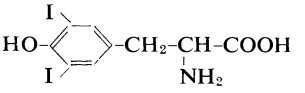
(Received April 10, 1964)

The object of this paper is to describe a method for evaluating microscopic ionization constants. Tyrosine (I), tyramine (II), 3-iodotyrosine (III), tyrosine methyl ester (IV), tyrosine ethyl ester (V), 3, 5-diiodotyrosine (VI), and 3, 5-dibromotyrosine (VII) will be investigated in the present work. The ionization of two protons from the phenolic and amino groups in these compounds may be represented by the following scheme:

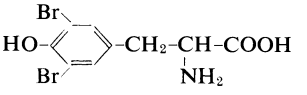




(I)

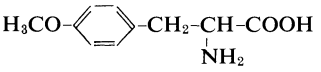


(II)



(III)

R=$CH_3$ (IV)
R=$C_2H_5$ (V)



(VI)

(VII)

* Read in part at the Autumn Meeting of the Chemical Society of Japan, Tokyo, November, 1963, and at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

** $K_2$ and $K_3$ should be properly replaced by $K_1$ and $K_2$ respectively for II, IV, and V.

(VIII)

The four compounds, I, III, VI, and VII, have a carboxyl group which corresponds to $pK_1$ as another ionizable group. However, as the $pK$ values of the carboxyl groups in these compounds are around 2, if we consider only the ionization which occurs at pH values above 4, it is safe to assume that the carboxyl group carries a negative charge in all the species under consideration.

The scheme is composed of two macroscopic constants, $K_2$ and $K_3$, and four microscopic constants, $k_a$, $k_b$, $k_c$ and $k_d$. Moreover, these constants are interrelated as follows:

$$K_2 = k_a + k_b \quad (1)$$

$$1/K_3 = 1/k_c + 1/k_d \quad (2)$$

$$K_2K_3 = k_ak_c = k_bk_d \quad (3)$$

The macroscopic constants of some of these compounds have been reported in the literature, but no discussion has been undertaken of the microscopic constants, except on I.[1]

We have reinvestigated the ultraviolet spectrum of I and confirmed that the maximum in the absorption spectrum shifts from 274 mμ to 294 mμ with an increase in the pH value of the solution (Fig. 1). On the other hand, *O*-methyltyrosine (VIII) displayed practically the same absorption at pH 6.10 and at pH 12.50 (see Experimental section). This behavior demonstrates that the ionization of the amino group does not affect the absorption spectra accordingly, it may be assumed that the molar extinction coefficient of the $NH_3^+$-R-$O^-$ form is identical with that of the $NH_2$-R-$O^-$ form. Furthermore, the molar extinction coefficients at 295 mμ and 300 mμ are practically zero for acidic media, where the OH group is un-ionized, whereas they are large in the alkaline media, where the OH group has been converted to $O^-$ ions. Therefore, the absorption at these wavelengths may be completely ascribed to $O^-$ species. The

1) J. T. Edsall, R. B. Martin and B. R. Hollingworth, *Proc. Natl. Acad. Sci.*, **44**, 505 (1958).

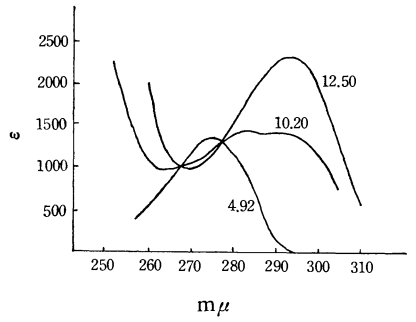


Fig. 1. Ultraviolet spectra of tyrosine at various pH (numbers besides curves).

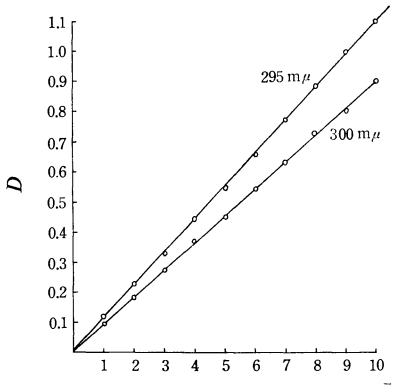

Fig. 2. Ultraviolet absorption of tyrosine at 295 mμ and 300 mμ in various dilution of 105 mg./l. solution at pH 12.50.

molar extinction coefficients of I in the completely ionized form (pH 12.50) were found to be independent of the concentration over the range less than 0.0005 M at these wavelengths (Fig. 2). Therefore, the fraction of all $O^-$ species in the solution at each pH can be determined from the extinction coefficient at 295 mμ and 300 mμ by dividing the maximum extinction coefficient at the same wavelength for the completely dissociated state (pH 12.50):

$$\alpha_{OH} = \varepsilon/\varepsilon_{max} \qquad (4)$$

where $\varepsilon$ and $\varepsilon_{max}$ represent the molar extinction coefficient at each pH and that at pH 12.50 respectively.

On the other hand, the fraction $\alpha_{OH}$ can be expressed as follows by making use of Eqs. 1—3:

$$\alpha_{OH} = \frac{(NH_3^+\text{-R-}O^-) + (NH_2\text{-R-}O^-)}{(NH_3^+\text{-R-OH}) + (NH_3^+\text{-R-}O^-) + (NH_2\text{-R-OH}) + (NH_2\text{-R-}O^-)} = \frac{k_a/(H^+) + K_2K_3/(H^+)^2}{1 + K_2/(H^+) + K_2K_3/(H^+)^2} \qquad (5)$$

Once macroscopic constants have been determined by independent titration, each value of $(H^+)$ with an associated value of $\alpha_{OH}$ from the ultraviolet absorption should fix the value of $k_a$ from Eq. 6, which is a modification of Eq. 5;

$$k_a = \alpha_{OH}[(H^+) + K_2] - (1-\alpha_{OH})K_2K_3/(H^+) \qquad (6)$$

A series of such $k_a$ values may be obtained and suitably averaged to obtain the most probable value of $k_a$. From this, the other microscopic constants may readily be determined from Eqs. 1—3. This method has been suggested by Edsall,[2] but no results have been reported. For the present work, the microscopic constants were studied by this procedure.

## Experimental and Calculations

**Materials.**—I, II, III, V, VI and VII were obtained from the Tokyo Kasei Co. and were recrystallized before use. IV was preared according to Fischer[3] from I. VIII was also prepared from I according to Beer[4] (monosulfate, $\lambda_{max}$: 274 mμ, log $\varepsilon$: 3.14 at pH 6.10, 3.16 at pH 12.50).

**Spectral Measurement.** — Spectral measurements were made with a Shimadzu QR-50 spectrophotometer and a Beckman DU spectrophotometer at 25±0.5°. For the measurement, 10 ml. of a 0.001 M solution of a compound were added to 10 ml. of buffer solution with an ionic strength of 0.01. The following buffers were used for the pH indicated: 6.10, 6.56, 7.13, 7.49, $Na_2HPO_4+NaH_2PO_4$; 8.10, $Na_2HPO_4+KH_2PO_4$; 8.60, $H_3BO_4+Na_2CO_3$; 9.15, 10.18, 10.60, 11.53, $Na_2CO_3+NaHCO_3$; 12.50, glycine + NaOH.—The absorption was determined immediately after mixing, the corresponding buffer being used as the blank.

**The Measurement of the pH.** — All pH measurements were carried out with a Horiba-Hitachi Model-P pH meter, equipped with a glass electrode and a double-junction sleeve-type caromel elctrode. The meter was calibrated with standard Horiba buffer solutions of pH 6.86 and 4.01 at 25°C.

**The Measurement of Macroscopic Constants.** — About a 0.001 M solution was titrated with 0.5 N sodium hydroxide. The titration solvent was a 0.05 M potassium nitrate solution in order to keep the ionic strength at 0.05. The vessel was maintained at 25±0.5°C in a water jacket with a stream from a thermo-circulator. The macroscopic constants were obtained from the titration curves, with reference to Albert.[5] The error is not greater than ±0.03 p$K$ units.

For the compounds other than I, it has also been assumed that the molar extinction coefficient of the $NH_3^+$-R-$O^-$ form is identical with that of the $NH_2$-R-$O^-$ form. The residual absorptions in acidic solutions, where the OH group is un-ionized, at a chosen wavelength were substantial in VI

5) A. Albert, "Ionization Constants of Acid and Bases" Methuen & Co. (1962), Chap. II.

and VII. Therefore, the following formula was used instead of Eq. 4 to obtain $\alpha_{OH}$ in VI and VII:

$$\alpha_{OH} = (\varepsilon - \varepsilon_O)/(\varepsilon_{max} - \varepsilon_O)$$

Where $\varepsilon_O$ stands for the extinction coefficient in acidic media.

The values of $k_a$ were calculated in the region where $\alpha_{OH}$ is more than 0.1 and less than 0.9.

## Results and Discussion

**Tyrosine (I).**—The values of $\alpha_{OH}$ obtained at 295 m$\mu$ and 300 m$\mu$ appeared to be almost identical, supporting the validity of such an evaluation of $\alpha_{OH}$. The macroscopic and microscopic constants (Table I) agree with those of Edsall[1] when account is taken of the difference in the ionic strengths in the experiments. The values of $k_a$, $K_2$ and $K_3$ were used to construct a theoretical curve, which closely follows the experimental points (Fig. 3.) The ratio of $NH_3^+$–R–$O^-$ species to $NH_2$–R–OH species, $K_z$, becomes:

$$K_z = k_a/k_b \cong 1.1$$

This value shows that, in the course of the titration, comparable amounts of the two species are in equilibrium. Therefore, it is safe to say that $K_2$ and $K_3$ are almost completely hybridized and that, accordingly, a single assignment to the ionization of either the amino or the phenolic group is incorrect.

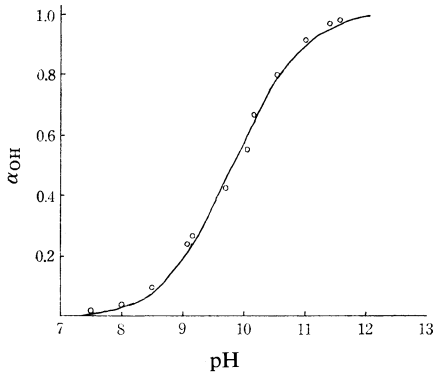

Fig. 3. Spectroscopic titration curve of tyrosine. The points are experimental, the line is calculated from the ionization constants.

The hydrogen ion concentration at $\alpha_{OH}=0.5$ is represented as follows from Eq. 5:

$$(H^+)_{\alpha=0.5} = \frac{2k_a - K_2 + [(K_2 - 2k_a)^2 + 4K_2K_3]^{1/2}}{2} \qquad (7)$$

This formula shows that, when a complete hybridization occurs in the ionization, i. e., $K_2 = 2k_a$, the value of pH at $\alpha_{OH}=0.5$ equals ($pK_2 + pK_3$)/2. The observed pH at $\alpha_{OH}=0.5$ for I was 9.82, which is approximately equal to ($pK_2 + pK_3$)/2. In the literature on I, the ultraviolet spectrometric $pK_{OH}$[6-8] values are significantly lower than the titrimetric $pK_3$ values.[9,10] Apparently the former is a composite value of $pK_2$ and $pK_3$, since in the procedure $pK_{OH}$ is determined as the pH value at $\alpha=0.5$.

Also in support of the present method, it was attempted to prove that the $K_2$ for *O*-methyltyrosine (VIII) should be nearly equal to the $k_b$ for I. The ionization constants of *O*-methyl derivatives of fatty acids and amino acids with hydroxyl groups appeared essentially to confirm the above statement.[11] The $pK_2$ for VIII was determined as 9.50 at an ionic strength of 0.05, which agrees with the $pk_b$ for I within the range of experimental error.

Benesch[12] was remarkably successful in solving Eq. 5 for $k_a$, $k_b$, and $k_d$ for cysteine by the substitution of the ultraviolet spectral $\alpha_{SH}$ and ($H^+$) values into three simultaneous equations. However, we have observed that in the case of I the ionization of the OH group was confined within a rather small pH range, and that the calculation error by his method became considerable.

**Tyramine (II).**—The values of $pK_1$ and $pK_2$ agree approximately with those obtained by Lewis[13] and by Ogston.[14] The microscopic constants are higher than the corresponding value for I by about 0.3 and 0.5 pH units respectively, as is to be expected from the elimination of the carboxyl group from I. From the results shown in Table I, the assignment of a single $pK_{OH}$ and a single $pK_{NH_3^+}$ is apparently unreasonable, as in the case of I, so each proton has an approximately equal chance to be ionized from either group.

**3-Iodotyrosine (III).** — The value of $K_z$, 5.0, shows that the hybridization in the ionization of the OH group and the $NH_3^+$ group is considerably less than those in I and II, and that the ionization of the OH group is mainly involved in $pK_2$. Herriot[15] has reported $pK'_{OH}$ as 8.20; he based his calculations on the ultraviolet absorption. The value is between $pK_2$ and $pK_3$, and it is obviously the composite constant of $pK_2$ and $pK_3$, Considerably lower values of $pK$ and $pk$, compared with those for I and II, apparently follow from the inductive effect of the iodine atom.

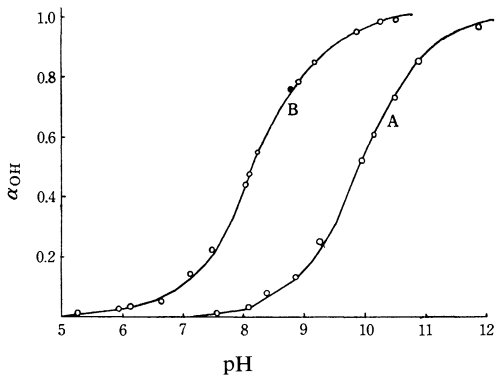

Fig. 4. Spectrophotometric titration curves of tyramine (A) and 3-iodotyrosine (B). The points are experimental, the lines are calculated from the constants given in Table I.

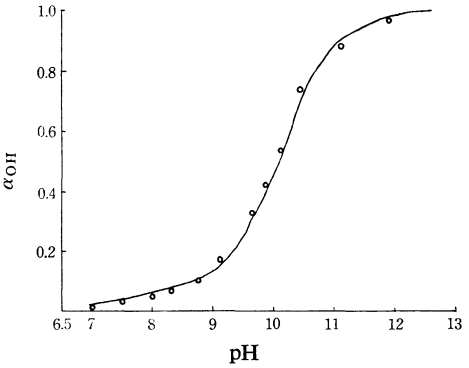

Fig. 5. Spectrophotometric titration curve of tyrosine methyl ester.

**Tyrosine Methyl Ester (IV) and Tyrosine Ethyl Ester (V).**—The ultraviolet spectra and ionization constants are identical within the range of experimental error in IV and V, as is to be expected from the nearly equal inductive effect of the methoxycarbonyl and ethoxycarbonyl groups. In these substances, $k_a \ll k_b$ and $k_b$ corresponds with $K_1$ within the range of experimental error. The Edsall method[15] is unsuitable for the cases where $k_a \ll k_b$ or where, conversely, $k_a \ll k_b$, but it is revealed that the present approach may be applied even in the former cases. In these compounds, p$K_1$ is reasonably shifted by nearly 2 pH units, compared with p$K_2$ of I, as a result of the removal of a negative charge on the carboxylate group. In conclusion, it is safe to say that $K_1$ and $K_2$ are mainly associated with the amino and the phenolic groups respectively in these compounds.

**3, 5-Diiodotyrosine (VI) and 3, 5-Dibromotyrosine (VII).**—In these compounds $k_a$ equals $K_2$ and corresponds to the pH value at which $\alpha_{OH}$ is exactly 0.5. It follows that the dissociation of the first proton is confined entirely to the OH group, and that $K_2$ and $K_3$ may be assigned exclusively to the ionization of the amino and phenolic groups respectively. It is revealed that when $k_a$ nearly equals $K_2$, $k_b$ and $k_d$ can not be estimated by the present method. The values of p$K_2$ are found to be lower than that of III, a natural result of the inductive effect of the second halogen atoms. Schmidt et al. determined the macroscopic constants from the solubility as p$K_2$=6.86, p$K_3$=7.82 for VI,[16] and p$K_2$=6.44, p$K_3$=7.58 for VII.[17] There is a significant discrepancy, especially in p$K_3$, between his values and those in Table I. However, the halogen atoms appear to be too separated from amino groups to exert such a large inductive effect as is shown by Schmidt's p$K_3$. It may be considered that the values of p$K_3$ in the present work are more reasonable.

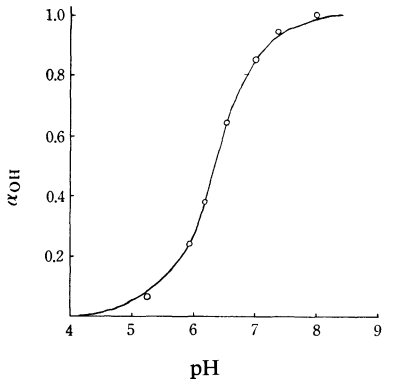

Fig. 6. Spectrophotometric titration curve of 3,5-dibromotyrosine

## Summary

A method has been formulated for the estimation of the microscopic ionization constants from spectroscopic data which measure the fractional ionization of one of the groups as a function of the pH value. This method has been applied at the ionic strength of 0.05 to the ionization of tyrosine (I), tyramine (II), 3-iodotyrosine (III), tyrosine methyl ester (IV), tyrosine ethyl ester (V), 3,5-diiodotyrosine (VI), and 3,5-dibromotyrosine (VII). The microscopic constants obtained are 9.55, 9.57, 10.08, 10.06 for I; 9.70, 10.09, 10.72, and 10.33 for II; 8.00, 8.70, 9.52 and 8.82 for III; 8.41, 7.27, 8.99 and 10.13 for IV, and 8.43, 7.31, 8.97 and 10.09 for V, in the order of p$k_a$, p$k_b$, p$k_c$, and p$k_d$. For VI and VII, the p$k_a$ values are 6.44 and 6.29, and the p$k_b$ values are 9.36 and 9.22, respectively. It has been illustrated that the method may be applied even in cases where $k_a \ll k_b$. This approach can probably be extended to other systems containing two dissociable protons, one of which affects the ultraviolet absorption and the other does not.

The authors wish to thank Miss Hisako Kimoto for her help in the experiments.

# The Oxidation of Iodide to Iodite and the Reduction of Iodate to Iodite in Iodine Solutions of Permanganate and Some of the Carboxylic Acids

By Yugul Kishore GUPTA and Anand Prakash BHARGAVA

(Received April 21, 1964)

The oxidation of iodide at low concentrations has been the subject of much recent interest. A number of oxidation products are possible, but some of which might be unstable. Such a possibility has already been indicated by Kahn and Wahl[1] and by Eiland and Kahn[2] in the oxidation of iodine by dichromate and cerium(IV). A number of the oxidation products of iodine from +1 to +5 states are possible if the oxidation is suitably carried out. However, iodate seems to be one of the most important products in all the oxidations reported by the above authors, and also in those reported by Musakin and Puchkov[3] and by one of the present authors[4] in permanganate oxidations.

During a kinetic study of the reduction of permanganate by citric and malonic acids in the presence of low concentrations of iodide, it has been reported by Misra and Gupta[5] that the reaction mixtures, even after becoming colourless, have some oxidant which could be determined iodometrically. This was suspected to be iodite. This observation necessitated a systematic attempt to identify this oxidant and to ascertain the mechanism by which it is produced. Similar observations have been reported by a number of workers[6-10] in the oxidation of oxalic acid by permanganate in

the absence of iodine, wherein hydrogen peroxide has been said to be formed.

Not much is known about iodite. Landolt[11] suspected the intermediate formation of iodite during the reduction of iodate. Lievin[12] and Guiseppe[13], from a study of the order of the conversion of hypoiodites into iodates, suspected the intermediate formation of iodite. Josien[14] found the existence of iodite in silver nitrate-iodine solutions by an analytical method. Kireev[15] reported the existence of silver iodite. The compound has not been isolated so far. Attempts have been made to discover a qualitative test to distinguish it from iodate or periodate, but no definite conclusions could be arrived at for want of this compound in the pure state.

It will be suggested in the present paper that, when permanganate is added to small amounts of iodide in aqueous solutions of citric or malonic acid, iodate is first formed and that this is subsequently reduced to iodite by the intermediate oxidation products of the acid. It will further be shown that iodate also is reduced to iodite in such solutions by the oxidation products of the acids.

## Experimental

All the chemicals were of B.D.H.A.R. quality; the malonic acid made by Riedel. Distilled water was freshly boiled and cooled for preparing stock solutions and reaction mixtures.

Requisite quantities of the citric or malonic acid and potassium iodide were mixed, a permanganate solution was added, and the mixture was thoroughly shaken. The reaction mixtures were preferably kept overnight, whereupon they became colourless. The oxidising capacity of the mixtures was determined iodometrically by titrating 10 ml. of the mixture against N/100 thiosulphate using a 10—15% solution of iodide and 2 N sulphuric acid. The temperature varied between 15—20°C.

In the case of citric acid and higher concentrations of iodide, when a precipitate was obtained the mixture was filtered and the oxidising capacities of the filtrate and of the precipitate were determined separately.

For reactions with iodate, permanganate and the organic acid were mixed and allowed to become colourless, and then a requisite quantity of iodate was added. Ten or twenty-five milliliters aliquots were determined for the oxidant iodometrically using 10% potassium iodide. The determinations were repeated after 8, 24 and 48 hr. Analytical measurements were also made in cases when iodate was added before the permanganate.

In the case of malonic acid, a few experiments were carried out by adding iodate to the reaction mixture when the permanganate colour had just disappeared and there remained a reddish orange colour.

When iodide is oxidised to iodite or iodate, iodine is the intermediate product; it may react with the organic acid or with its oxidation products (by permanganate). The substitution products may remain in the solution or may be thrown out of the solution, but all of them give back iodine in acidified solutions of potassium iodide and hence can be determined iodometrically. A few qualitative experiments were made to ascertain this, as Table I shows. Tests for iodate or iodide and iodometric measurements were made only in colourless solutions. In columns 4, 5 and 6 the permanganate and the acid were allowed to react in the presence of iodate or iodide or aqueous iodine, and then the tests were made. In the experiments of column 7, aqueous iodine was added after the permanganate-acid mixture had become colourless. The concentrations of the reactants used were as will be shown in subsequent tables.

It was found that malonic and pyruvic acids could immediately react with the aqueous iodine and give back the latter when acidified potassium iodide was added. The reaction of iodine with other acids is slow and photochemical. Such an oxidation of citric acid by iodine has been reported by a number of workers,[16-21] but little has been said about the reaction between iodine and the oxidation products of citric acid. Mecmohan and Srivastava[22] and Bakore and Bharadwaj[23] have mentioned the formation of tetraiodoacetone and hexaiodoacetone. Similarly, a number of workers[24-30] have studied the reaction between iodine and malonic acid, but nothing has been said about the oxidation products of malonic acid. Kappanna and Talati[31] reported a slower reaction between malonate ion and iodine in the presence of hydrogen or iodide ions — a fact which indicates that the reaction is reversible and that, under appropriate conditions, iodine may not react with malonic acid

at all or that the reacted iodine may be set free from the substitution product.

Iodometric determinations in colourless mixtures are based on the above observations and on the fact that iodite, being an oxidising substance, will also liberate iodine from acidified iodine solution. However, a qualitative distinction between two such determinations can always be made. The organic acid is treated with the permanganate until the mixture becomes colourless. If iodine solution in water or dilute potassium iodide is then added, it reacts to give colourless solutions. These mixtures do not give back iodine when more potassium iodide is added, though the medium is acidic. Iodine is obtained only when dilute hydrochloric acid or dilute sulphuric and is added. On the other hand, colourless mixtures containing iodate liberate iodine instantaneously on the addition of potassium iodide. The two processes are quite different. In the latter there is an oxidant which liberates the iodine, whereas in the former it is a substitution product of the iodine which gives back iodine, probably by displacement.

## Results and Discussion

For low concentrations of iodide ($<10^{-3}$ N) the oxidant produced is always four times the original iodide. This points to the existence of iodite in these colourless solutions. These solutions do not respond to the test for iodide. Some mixtures show the presence of iodate, while others do not, but all of them respond to this test after a couple of days. Qualitative tests for iodite, though not yet known, are likely to be similar to those of iodate, and, hence, in all probability, a positive thiocyanate test[32] can be obtained in all cases. The test is not administered in some cases in the beginning because when citric or malonic acid is oxidised by permanganate, a number of stable and unstable products may be formed which may then exist in colourless solution. When the test is applied, liberated iodine reacts with one or more of these intermediate products, and the blue colour with the starch is not obtained or it appears for only a short time. Afterwards these unstable products decompose and disappear and iodate test produces a positive response.

The data for the reduction of iodate by the oxidation products of the organic acids is given in Tables III, IV and V. In almost all

cases, subject to the conditions of mixing and the concentration of the reactants, the oxidising capacity of the original iodate is reduced to 2/3 (oxidising capacity), a fact which points to the reduction of iodate to iodite.

Higher iodometric values than the expected 2/3 of the added iodate are obtained only in cases where the reducing intermediates (the oxidation products of the organic acid) are not present in sufficient concentration, i. e., when there is less permanganate or comparatively more original iodate. In a few cases (Tables IV and V) the reduction of iodate seems to have gone further than the stage of iodite and the iodometric values are less than the expected 2/3 of the original iodate. This obviously happens when there is less iodate and when the reducing intermediates are formed in sufficient concentration. The mixtures are colourless and do not respond to the tests

of iodide. Some of the iodate, therefore, appears to have been reduced to hypoiodite. A possibility of iodite disproportionating in a mixture of iodate and hypoiodite, with the same oxidising capacity as iodite, is ruled out because the reaction mixtures, even on heating, do not show any visible colour change or other reactions giving tests for iodide, a product which is well known to be formed by heating a solution of hypoiodite. An ammonia test[32] was negative.

The iodometric determinations were made 2, 8, 24 and 48 hr. after the addition of iodate. It was found that the reduction to iodite was not complete in two hours. It was, however, complete the next day. In the case of iodate experiments, difficulty was encountered in carrying out the iodometric titrations. The blue colour of the iodine-starch complex appeared again and again. However, no such difficulty was met with after 2 or 3 days nor in the case of malonic acid, even in the beginning. This difficulty is linked with the formation of the oxidation products of the organic acid. These products, existing in solution, react with the iodine liberated from the acidified potassium iodide for the purpose of titration; this iodine is retrieved only slowly. In the case of malonic acid, iodine is readily obtained even from the substituted products, and there is no difficulty during the titration. The oxidation products of citric acid disappear after 2 or 3 days, and once again there is no difficulty in titration.

The experiments with iodate were carried out by adding it after the permanganate-acid mixture had become colourless, and also by adding it to the acid before the addition of the permanganate. This was done in order to ascertain the degree of the stability of the oxidation products of the organic acid. It would appear from the results that the oxidation products of citric acid are more stable than those of the malonic acid. In the case of malonic acid, when iodate is added after the acid-permanganate mixture becomes colourless, a little iodate is reduced to iodite. Macmohan and Srivastava[16] have reported that acetone dicarboxylic acid — a product of oxidation of citric acid — is fairly stable, whereas the corresponding oxidation products of malonic acid are not stable.

Experiments were also carried out by adding iodate when the acid-permanganate mixtures had just lost the characteristic colour of the permanganate and become reddish orange, due probably to the formation of colloidal manganese dioxide[33] and tripositive manganese complexes.[34-38] The results were the expected 2/3 of the original iodate.

An interesting observation made in the case of malonic acid was the persistence of a light yellow colour when iodate was added in a sufficient concentration before the acid-permanganate mixture had become colourless. It was not due to iodine; probably manganese(III) complexes of malonic acid persisted in the solution. It, therefore, appears that the reduction of manganese(III) by malonic acid is very slow and that it is mainly brought about by its oxidation products. Irrespective of the nature of these products, whether they be radicals[37] or tartronic and glyoxalic acids,[39-41] they are all oxidised by iodate, and the colour of manganese(III) complexes tends to persist.

In the case of citric acid when higher concentrations ($>10^{-3}$ N) of iodide are employed, a light yellow precipitate is obtained, presumably a substitution product of citric acid with iodine, by a mechanism which will be given latter. This substance gives back its iodine in the presence of 15—20% potassium iodide and 1—2 N sulphuric acid, though not as quickly as the similar soluble product of malonic acid. The iodine in the yellow solid and the oxidising capacity of the filtrate are separately determined, and from this the total iodide is calculated. Table VI shows these results.

The fourth column gives the oxidant values of iodine in the +3 oxidation state (iodite), and column 6 gives those of iodine in its normal state (iodine-substituted oxidised species of the acid). The total of the iodine and iodide is obtained by dividing column 4 by four and adding it to column 6. The results show many deviations because of the crude method employed for the determination of iodine in the solid. The results of the individual columns are generally not reproducible, although those of the last column are fairly so in the 15—20°C temperature range (not at higher temperatures). Two or three iodine-substituted products are posssible in this case; if the concentration of such a soluble product is fairly comparable to that of the solid product, the present calculations would not give the expected results. However,

| | | 0.02 | 12.00 | 3.00 | 15.00 | 18.00 | −10.0 |

the regular increase or decrease in the values of this table does point to the correctness of the procedure adopted for the calculation.

It may thus be seen that, for low concentrations of iodide, the oxidant is always four times the equivalents of initial iodide, indicating the presence of the +3 state of iodine. The following reactions appear to take place:

$$MnO_4^- + \text{organic acid} \rightarrow Mn^{3+} \text{ (complex)} + \text{oxidation products of acid} \quad (1)$$

$$I^- + MnO_4^- \rightarrow I^0 + MnO_2 \quad (2)$$

$$I^0 + MnO_4^- \rightarrow IO_3^- + MnO_2 \quad (3)$$

$$I^0 + \text{organic acid} \rightarrow \text{substitution products} \quad (4)$$

$$I^0 + \text{oxidation product of acid} \rightarrow \text{substitution products} \quad (5)$$

$$IO_3^- + \text{oxidation products of acid} \rightarrow IO_2^- \quad (6)$$

$$MnO_2 \text{ or } Mn(III) + \text{acid or its products} \rightarrow Mn(II) + \text{products} \quad (7)$$

It would be reasonable to conclude, from the experiments on iodate (Tables III to V) and from the fact that permanganate is a strong oxidant, that iodate is first formed and that it is subsequently reduced to iodite. This could have been verified had it been possible to make a number of determinations of the oxidant (Table II) immediately after the addition of permanganate to the iodide-acid mixture. The iodometric determinations could be made, however, only when coloured manganese(III) complexes were reduced to colourless manganese(II) or its complexes. By the time this happens, iodate, even if formed earlier, has been reduced to iodite. The presence of iodate has been found[42] also when small amounts of iodide are oxidised by the permanganate in a sulphuric acid solution.

The first reaction of the above scheme has been reported[18,19,33,37,43-46] to be slow, but 2 is fairly fast.[4,5] The fate of iodine is now determined by reaction 3 on one hand, and by reactions 4 and 5 on the other. Ordinarily if the concentration of iodide is low, reaction 3 is predominant, which through 6 yields iodite; but if the concentration of malonic acid is also low, reactions 1, 4, 5, 6 and 7 would be insignificant and iodate will be the final product, giving oxidant values higher than the expected value of four times the original iodide. In some such cases manganese(IV) oxide was also precipitated.

If the concentration of iodide is increased, more iodine is produced and reactions 4 and 5 compete with 3. Part of the iodine gives substitution products with the acid and its oxidised species and, hence, is not raised to the +5 state by the permanganate. Consequently, the iodometric results are lower than expected for higher concentrations of iodide.

Citric acid seems to yield at least two oxidation products, one of which gives a soluble substituted product and the other, an insoluble one. These two products are obtained together if the temperature of the reaction is 25°C or higher, but at 20°C or lower, only a solid product can be obtained if the concentrations of iodide and citric acid are high. This yellow

product has properties similar to the tetraiodoacetone[47] reported to be formed under very similar conditions. The oxidation products of citric acid[48,49] are acetone, and acetonedicarboxylic, formic and oxalic acids. The solid product may be an iodine compound of one of these. Further work on this compound is in progress. In the case of malonic acid, the substitution product is soluble and is reported to be diiodomalonic acid.[29,43] Thus citric and malonic acids provide the products for the reduction of iodate to iodite and also prevent the accumulation of manganese dioxide, a product obtained from the reduction of permanganate. The organic acids react with it, giving soluble manganese(III) complexes.

Experiments with malic acid give somewhat similar results, but under limited conditions. The concentration ranges studied were:

| Malic acid | $KMnO_4$ | KI |
|---|---|---|
| $4—32\times10^{-2}$ M | $1—4\times10^{-2}$ N | $2—20\times10^{-4}$ N |

In most cases the oxidant was found to be 4 to 6 times the original concentration of iodide, which corresponds to the situation of iodite or iodate or a mixture of the two, depending on the relative concentrations of malic acid and the permanganate. Permanganate should be more than ten times the concentration of iodide; otherwise the iodide is not likely to be oxidised beyond the stage of iodine. Reactions with iodate show its oxidising capacity reduced to 2/3 iodometric values only when the concentrations of the permanganate and the acid are high. At other concentrations, reduction does invariably take place in all cases, but not always to the extent expected.

Experiments with lactic acid and iodate reveal that the latter is not reduced by the permanganate-oxidation products of the acid. Experiments with iodine show that it is partly oxidised to iodate and partly to iodite.

## Summary

Permanganate oxidises small amounts of iodide to iodite in the presence of malonic, citric or malic acid. The colourless reaction mixtures always have an oxidising capacity equivalent to four times the concentration of the iodide originally taken. In mixtures of permanganate and one of these acids, iodate is reduced to its 2/3 oxidising capacity, showing the formation of iodite. A mechanism for this has been suggested. Iodine is the product in the first stage of the oxidation of iodide, which is further oxidised to iodite or iodate or which may react with the oxidation products of the organic acids. Citric acid probably gives a number of such iodinated products, one of which is solid.

# The Base-catalyzed Condensation of *o*-Nitroacetophenone. III. The Structure of Compound A, a Condensation Product

By Takeo SAKAN, Kousuke KUSUDA[1] and Toshio MIWA

(Received May 28, 1964)

In a previous paper,[2] compound A,[3] $C_{17}H_{14}O_5N_2$, an orange-red product of the base-catalyzed condensation of *o*-nitroacetophenone, has been shown to contain *o*-nitrophenyl and *N*-hydroxyindoline moieties.

The reduction of compound A methyl ether, $C_{18}H_{16}O_5N_2$, with sodium borohydride gave a colorless product, dihydro-compound A methyl ether, $C_{18}H_{18}O_5N_2$. The infrared absorption spectrum of this compound indicated that the nitro group of the original compound had survived during the reduction. The dihydro-compound, on acetylation with acetic anhydridepyridine, gave a monoacetyl derivative, $C_{20}H_{20}O_6N_2$. The infrared absorption spectrum

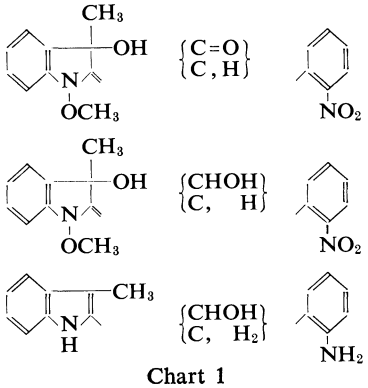
2) T. Sakan, K. Kusuda and T. Miwa, This Bulletin, 37, 1681 (1964).
3) T. Sakan, K. Kusuda and T. Miwa, ibid., 37, 1678 (1964).

of the latter has a peak at 3435 $cm^{-1}$, which should be assigned to a tertiary hydroxyl group of the indoline nucleus.[2] The formation of an acetylable hydroxyl group by the reduction seems to imply the presence of a carbonyl group in the original compound.

The catalytic hydrogenation of dihydro-compound A methyl ether in the presence of palladium-on-carbon gave an amine, $C_{17}H_{18}ON_2$. The ultraviolet absorption of the amine indicated the presence of an indole nucleus in it. The amine, on brief heating with acetic anhydride, was transformed into a monoacetyl derivative, whereas it was converted into an *O*, *N*-diacetyl derivative by treatment with acetic anhydride-pyridine. The latter derivative was obtained in the crystalline state with a molecule of benzene as a solvent of crystallization. The series of reductions will be represented by partial structures in Chart 1.



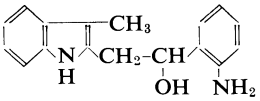


Chart 1

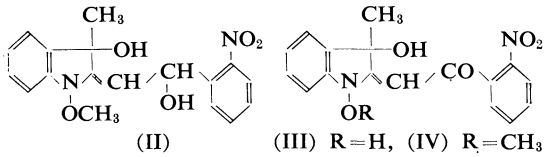
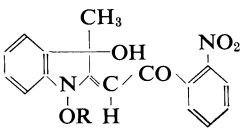


The fact that the catalytic hydrogenation of compound A methyl ether over Raney nickel at a high temperature and high pressure gave the same indole-amine confirmed that no skeletal change had occurred during the above reductions.

The indole-amine on alkali-fusion was cleaved to give 2, 3-dimethylindole and anthranilic acid in fairly good yields. The latter product was isolated as the *N*-acetyl derivative. Hence, structure I was assigned to the indole-amine.

(I)

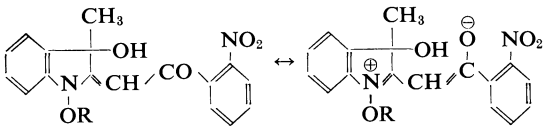


Consequently, dihydro-compound A methyl ether, compound A and its methyl ether possess structures, II, III and IV respectively.

(II) (III) R=H, (IV) R=$CH_3$

Loudon and Wellings[4] reported that the *O*-acetyl derivatives of cyclic hydroxamic acids exhibit an intense absorption near 1800 $cm^{-1}$. Interestingly, the acetyl derivative of compound A, a vinylog of hydroxamic acid, has a strong peak at 1796 $cm^{-1}$. The acetyl derivative decomposed gradually on being kept at room temperature for a long time.

The infrared spectra of compound A methyl ether and acetate give information on the stereochemistry around the double bond in these compounds. Both of the compounds in the solid state possess a very weak band near 3100 $cm^{-1}$ as a result of the tertiary hydroxyl group. The low wave number of the band is probably due to an intermolecular hydrogen bonding, for the band is shifted to about 3300 $cm^{-1}$ when the compounds are dissolved in carbon tetrachloride. The fact that this band of the methyl ether remains at 3300 $cm^{-1}$, even in a very dilute solution ($3.4\times10^{-4}$ M in carbon tetrachloride), suggests the presence of an intramolecular hydrogen bonding between the tertiary hydroxyl and the carbonyl of this compound, thus locating these groups on the same side of the double bond as shown in V. Compound A itself has the same configuration, for the mild conditions of the methylation should not change the stereochemistry around the double bond.



(V)

The carbonyl stretching absorption of compound A is quite obscure, as has been stated in a previous paper.[3] The infrared spectra of the methyl ether and the acetate also show quite unusual features in the region. Although they have a band of medium intensity at 1626 and 1632 $cm^{-1}$ respectively, it appears that these should be assigned to the double bond rather than to the carbonyl bond, the stretching band of the latter being considered to be shifted to about 1500 $cm^{-1}$ from the following reasons: (1) The bands at 1626 and 1632 $cm^{-1}$ are rather weak for the carbonyl bond; (2) the 1500 $cm^{-1}$ bands of these compounds are much broader than those of dihydro-compound A derivatives; (3) the 1500 $cm^{-1}$ bands show a shoulder near 1560 $cm^{-1}$ in a carbon tetrachloride solution. The unusual shift of the carbonyl absorption of compound A derivatives may be due to an intense interaction between

4) J. D. Loudon and I. Wellings, *J. Chem. Soc.*, **1960**, 3463.

the tertiary hydroxyl group and the carbonyl oxygen atom, which possesses a high electron density produced by the mesomerism VI ↔ VII.

(VI) (VII)

The characteristic ultraviolet spectra[3] of compound A and its alkyl ethers correspond to those of β-amino-α, β-unsaturated ketones.[5]

The base-catalyzed condensation of the homologous *o*-nitrophenyl ketones is currently being investigated. The mechanism for the formation of compound A will be discussed in a later paper.

## Experimental[6]

**The Sodium Borohydride Reduction of Compound A Methyl Ether. Dihydro-Compound A Methyl Ether (II).** — To a solution of 1.70 g. (5 mmol.) of compound A methyl ether[3] in 60 cc. of methanol 0.5 g. (13 mmol.) of sodium borohydride was added. The mixture was heated on a water bath for five minutes and diluted with 10 cc. of water, and the solvent was removed by distillation. The residue was then triturated with water, filtered, washed with water, and dried. The crude material weighed 1.25 g. (73%). A small portion of the material was recrystallized from aqueous methanol for analysis. A pure compound melts at 155°C. IR 3304, 3240 (OH), 1529, 1350, 855 ($NO_2$).

Found: C, 63.09; H, 5.83; N, 7.86. Calcd. for $C_{18}H_{18}O_5N_2$: C, 63.15; H, 5.30; N, 8.18%.

**Dihydro-Compound A Acetate.** — A mixture of 320 mg. (0.93 mmol.) of dihydro-compound A methyl ether, 1.5 cc. of acetic anhydride, and 7 drops of pyridine was shaken for three hours, left to stand overnight, and decomposed with water. The separated crystals were then filtered, washed with water, and dried. Crude acetate (m. p. 140.5—142°C) weighed 340 mg. (95%). Recrystallization from ethanol gave pure acetate melting at 145°C. IR 3435 (OH), 1718 (CO), 1522, 1355, 855 ($NO_2$).

Found: C, 62.33; H, 5.64; N, 7.34. Calcd. for $C_{20}H_{20}O_6N_2$: C, 62.49; H, 5.24; N, 7.29%.

**2-[2-(*o*-Aminophenyl)-2-hydroxyethyl]-3-methylindole (I).** — *The Catalytic Hydrogenation of Dihydro-Compound A Methyl Ether.* — Dihydro-compound A methyl ether (1.13 g., 3.3 mmol.) in 100 cc. of methanol was hydrogenated in the presence of 0.5 g. of 5% palladium-on-carbon. After the removal of the catalyst, the methanol was distilled and the residue dissolved in a small amount of hot benzene. On cooling, 0.63 g. (64%) of the indoleamine was obtained. The amine (m. p. 151—152°C) was found to be identical with the sample described below by an admixture test and by infrared spectroscopy.

*The High Pressure Hydrogenation of Compound A Methyl Ether.*—A solution of 1.0 g. (2.9 mmol.) of compound A methyl ether in 50 cc. of ethanol was hydrogenated over 1.0 g. of Raney nickel at a hydrogen pressure of 75 atm. and 125—145°C for three hours. The hydrogenation mixture was worked up as described above to give 0.2 g. of the amine melting at 146—148°C. The amine, after recrystallization from benzene, melted at 149.0—149.5°C. $\lambda_{max}$ 229—230 (4.61), 286 (4.02), 293 (3.99). IR 3390 (NH and OH).

Found: C, 76.60; H, 6.99; N, 10.30. Calcd. for $C_{17}H_{18}ON_2$: C, 76.66; H, 6.81; N, 10.52%.

***N*-Acetyl Derivative.**—A mixture of 0.46 g. (1.6 mmol.) of the amine and 0.8 cc. of acetic anhydride was heated to the boiling point, immediately cooled with water, and decomposed with 5 cc. of water. The separated solid was then filtered, washed with water, and dried. The acetate, after recrystallization from ethanol, melted at 154.5—155.5°C. IR 3400 (OH), 3210 (NH), 1645 (CO).

Found: N, 9.06. Calcd. for $C_{19}H_{20}O_2N_2$: N, 9.09%.

***O*, *N*-Diacetyl Derivative.**—To a solution of 240 mg. (0.8 mmol.) of the amine in 1 cc. of pyridine, 0.3 cc. of acetic anhydride was added at room temperature. The mixture was left to stand overnight and diluted with water, and the separated oil was triturated with 1 N hydrochloric acid until it became solid. The dried solid was recrystallized from benzene. The pure diacetyl derivative melts at 108°C. IR 3340 (NH), 1728, 1663 (C=O).

Found: C, 75.62; H, 6.64; N, 6.07. Calcd. for $C_{21}H_{22}O_3N_2$-$C_6H_6$: C, 75.67; H, 6.59; N, 6.54%.

**The Alkali-fusion of the Indole-amine I.** — A solution of 0.8 g. of the amine and 1.0 g. of potassium hydroxide in 3 cc. of methanol was heated under nitrogen to 180°C; at that temperature effervescence occurred. The mixture was kept at the temperature for a few minutes until the foaming subsided; then it was cooled and taken into water and ether. The aqueous layer was neutralized with 1 N hydrochloric acid until the solution had become slightly turbid, treated with two portions of 1 cc. of acetic anhydride each, acidified with hydrochloric acid to Congo red, and extracted with ether. The ether was then evaporated and the residue treated with benzene and petroleum ether to yield about 30 mg. of precipitates, which on recrystallization from water melted at 185.5°C. This material was identified with *N*-acetylanthranilic acid, m. p. 186—187°C, by the mixed melting point test with an authentic sample and by infrared spectroscopy. The original ethereal layer, on concentration, gave 180 mg. of crystals melting at 104—108°C. The crystals, after sublimation followed by recrystallization from petroleum benzine, melted at 107—108°C. This compound was identified as 2,3-dimethylindole, m. p. 106.5—107°C, by mixed melting point determination and by infrared spectral comparison.

**Compound A Acetate.**—An aqueous-alkaline solution of compound A was treated with acetic anhydride under ice-cooling. The precipitates formed

5) N. H. Cromwell and J. C. David, *J. Am. Chem. Soc.*, **82**, 2046 (1960).

6) All melting points are uncorrected. Unless otherwise noted, the ultraviolet spectra were taken in ethanol and the infrared spectra in Nujol mull; they are expressed in $\lambda_{max}$ mμ (log ε) and in IR $cm^{-1}$ respectively.

were dissolved in aqueous ethanol and the solution was condensed in a desiccator to give yellow crystals decompositing at 108—109°C. IR (in $CCl_4$) 3300 (OH), 1818 (C=O), 1525, 1346 850 ($NO_2$).

Found: C, 62.10; H, 4.57; N, 7.63. Calcd. for $C_{19}H_{16}O_6N_2$: C, 61.95; H, 4.38; N, 7.61%.

The authors are very much indebted to Dr. Hideo Kamio of the Research Laboratory of the Takeda Chemical Industries, Ltd., for his kind measurement of the infrared spectrum in high dilution, and also to Dr. Masao Yamaguchi of the Wakayama Prefectural Medical College for his valuable discussions about infrared spectroscopy. The present work was supported in part by a grant-in-aid from the Ministry of Education.

# An Electron Paramagnetic Resonance and Spectrophotometric Study of Titanium(III)-Chelate Compounds with Nitrilotricarboxylic Acid and Its Derivatives

By Maurice CODELL,* Shizuo FUJIWARA, Kozo NAGASHIMA and Tokuko SEKI

(Received June 9, 1964)

The EPR hyperfine structure of titanium(III) has recently been obtained with several chelating agents,[1] and the chemistry of mixed chelate compounds of titanium(III), EDTA and several complexing organic acids has recently been elucidated,[2] where titanium(III)-EDTA and oxalic, tartaric, citric, and lactic acids have been shown to form complexes which give EPR signals and can be spectrophotometrically identified. It has also been recently shown[3] that a complex formed between titanium(III), zinc and tartaric acid gives an EPR signal of two peaks.

The effect of varying numbers of carboxyl groups on chelating agents of a similar structure seemed of considerable interest, since experience with several chelating agents has shown that those agents with the largest numbers of coordinating groups are the most likely to give EPR signals showing the hyperfine structure of titanium(III). The chelating agents investigated were nitrilotriacetic acid (NTA) $N(CH_2COOH)_3$, hydroxyethyliminodiacetic acid (HEID) $N(CH_2COOH)_2CH_2CH_2OH$, Bishydroxyethyl glycine (BHEG) $N(CH_2OH)_2CH_2COOH$, and iminodiacetic acid (IDA) $HN(CH_2COOH)_2$. NTA gives the largest EPR signals, while IDA, which contains -H in place of $-CH_2CH_2OH$ in HEID, gives the smallest signals.

EPR spectra were obtained using capillary tubes containing solutions prepared by admixing the constituents and adjusting the pH. In the spectrophotometric establishment of the combining ratios of titanium(III) to NTA and HEID in an acid solution, the concentration range of the chelating agents was limited because of the slight solubility of the excessive agents.

**Apparatus and Reagents.**—The electron paramagnetic resonance spectrometer used was a model JES-118 manufactured by the Japan Electron Optics Company. The recording spectrophotometer used was a Cary Model 11. The spectrophotometers used were Hitachi, model EPU-2 and Hirama, model IIB, filter electrophotocolorimeters.

*Titanium(III) Chloride Solution.*—A pure grade of titanium sponge (courtesy of the Osaka Titanium Corporation, Amagasaki, Japan) was dissolved in hot 6 N hydrochloric acid. An excess of titanium sponge was added to the hydrochloric acid, and additional acid was added as the reaction progressed in order to prevent the acid concentration from falling to the point where hydrolysis could occur. The solution was decanted from the metal while the vigorous reaction was proceeding in order to prevent the formation of any appreciable quantity of titanium(IV). The solution was then maintained in an atmosphere of nitrogen. The final concentration of titanium(III) ions was determined volumetrically by titration with a ceric sulfate solution.

3) S. Fujiwara, K. Nagashima and M. Codell, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **85**, 305 (1964).

*Chelating Reagents.* — The NTA and IDA used were commercial first-grade reagents (Wako Junyaku Co., Tokyo). The HEID and BHEG were synthetized for this investigation (courtesy of Daiichi Seiyaku Co., Ltd., Tokyo).

**Titanium(III)-NTA Complexes.** — Nitrilotriacetic acid (NTA) forms a complex with titanium(III), which is quite stable and which gives the largest EPR signals of the group studied in this investigation (Fig. 1). A 0.1 M

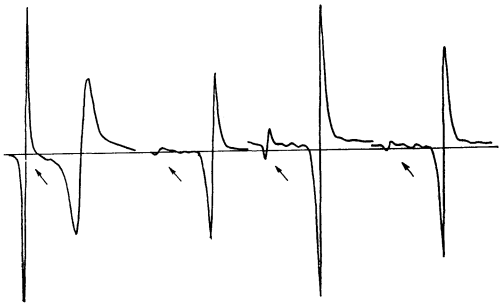

Fig. 1. EPR spectra for Ti(III)-NTA complexes. The concentration of Ti(III) is 0.2 M and the concentration of NTA is 0.4 M. The pH was adjusted with NaOH. Arrows designate DPPH.

titanium(III) solution of this complex gives signals at pH 1.7, although at pH 1.5 no signal was obtained. The signals become larger with increasing pH values up to approximately 4. Above pH 4, however, the signal intensity remains almost constant to a pH value of approximately 10.

Figure 2 shows a complex at pH 1 which gives a blue solution and exhibits a maximum absorbance at 600 m$\mu$, and another complex at pH 4.7 which gives a greenish yellow solution with a maximum absorbance at 710 m$\mu$.

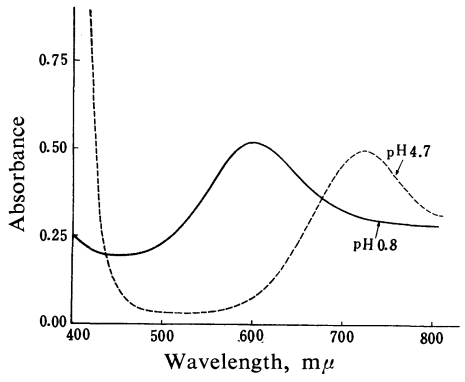

Fig. 2. Spectrophotometric curves of Ti(III)-NTA complexes in solution.

Figure 3 shows the change in the optical absorbance of each maximum with the changing pH value. The maximum, which occurs

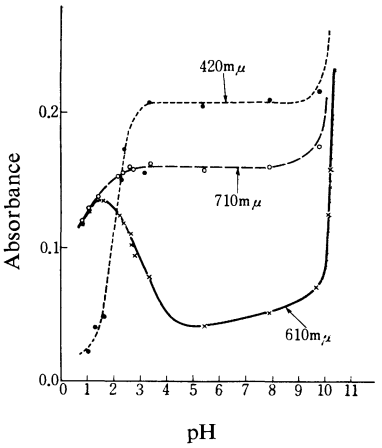

Fig. 3. Change of optical absorbance of Ti(III)-NTA solutions containing tartaric acid with change in pH values.

at 600 m$\mu$, increases with an increase in the pH value up to about pH 1.5, and then decreases from about pH 1.5 to about pH 4. A red filter whose absorbance curve reaches a peak at approximately 610 m$\mu$ was used to determine the above maximum. The points for pH values higher than 3.5 were extrapolated because of interference from the peak which shows a maximum absorbance at 710 m$\mu$. The maximum which occurs at 710 m$\mu$ increases with the increase in pH values. It attains the highest value at pH 3.5 and shows no further change with the increase in pH until a pH value of a little above 9 is attained, whereupon a rapid increase in absorbance occurs with the further increase in pH value.

The establishment of the ratios of titanium(III) to NTA are shown in Figs. 4a through

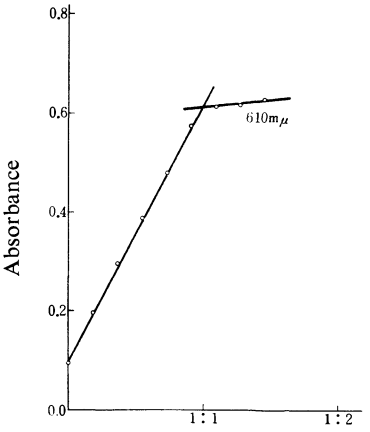

Fig. 4a. Establishment of the ratio of Ti(III) to NTA at pH 1.5 by the molar ratio method. Higher concentrations of NTA were not tested because of the limited solubility.

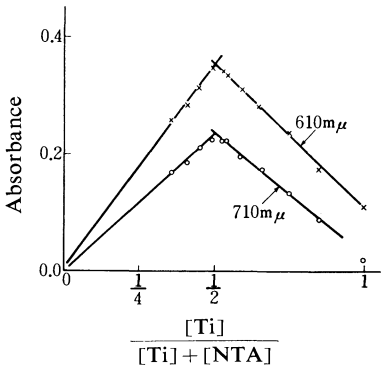

Fig. 4b. Establishment of the ratio of Ti(III) to NTA at pH 1.0 by the method of continuous variation.

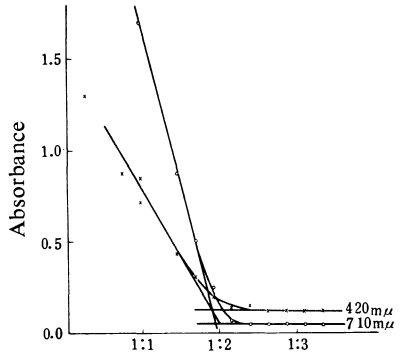

Fig. 4c. Establishment of the ratio of Ti(III) to NTA at pH 9.0 by the molar ratio method.

4c. Figure 4a shows the molar ratio method for determining the composition of the species which exists at pH 1.5 and which exhibits a maximum absorbance at 600 mμ. The red filter mentioned above was also used for this experiment. Figure 4b shows the method of continuous variation for establishing the ratio of the same species. The ratio is clearly shown to be 1 to 1 by both procedures. Figure 4c shows the molar ratio method for establishing the ratio of the species which appears at pH values between 3.5 and 9. Experiments were carried out at pH 9 in the presence of tartaric acid to prevent the hydrolysis of titanium(III). The strong blue color of the titanium(III)-tartrate compound becomes lighter upon the addition of increasing amounts of NTA. The absorbance curve changes abruptly at a ratio of 1 titanium(III) to 2 NTA, corresponding to the formation of the chelate. The species which exists in this solution shows a maximum absorbance at 710 mμ.

From the above discussion, the following complex species may be proposed;

| Formula | Optical absorbance at | Predominant at pH | g Value (EPR) |
|---|---|---|---|
| (1) $Ti(III)(NTA)_1$ | 600 mμ | 1.5 | unobservable |
| (2) $Ti(III)(NTA)_2$ | 710 mμ | 3.5—9 | $1.961 \pm 0.002$ |

**The Titanium(III)-HEID Complexes.**—Figure 5 shows the absorbance curves of a titanium(III)-HEID solution at different pH values. At pH 1.4 the solution is blue and the maximum absorbance is seen at 590 mμ. At pH 5.0 the solution is yellowish green and the maximum is shown at 720 mμ. At pH 9.2 the solution is purplish and the maximum appears at 540 mμ. Figure 6 shows the change in absorbance with the variation in pH values. It should be noted that the complex which shows a maximum absorbance at 590 mμ exhibits the highest intensity at pH 1.2 (traced with a 610 mμ filter). The complex which shows a maximum absorbance at 720 mμ shows a steady increase in intensity up to a pH value of about 3, and it remains constant to pH 5.5, after which an increase in intensity occurs until a pH of

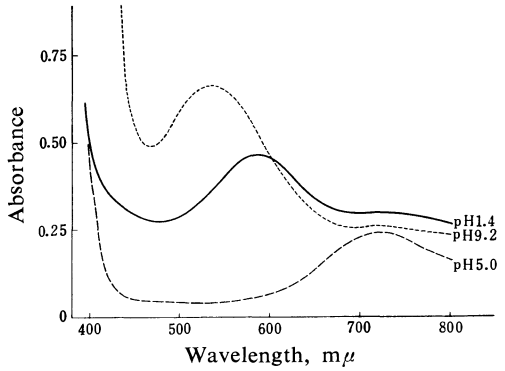

Fig. 5. Spectrophotometric curves of Ti(III)-HEID complexes in solution.

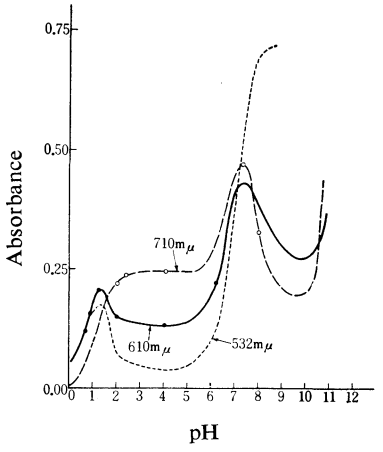

Fig. 6. Change of optical absorbance with pH of Ti(III)-HEID solutions.

about 7 is attained when a 710 mμ filter was used. At pH values above 7 a continual decrease is noted. The peculiar appearance of the curves at pH values above 8 is due to precipitation.

From Fig. 6 it may be seen that the complex which shows a maximum absorbance at 540 mμ (traced by using a 532 mμ filter) exhibits the highest intensity at pH 8, which indicates that this complex is the predominant species at higher pH values.

Figures 7a through 7c show the spectrophotometric determination of the ratios of titanium(III) to HEID. Filters which transmit the light of wavelengths close to the absorbance maxima of the complexes were used. The same procedures were applied for these determinations as for the titanium(III) to NTA ratios. Figure 7a shows that at pH 1.2 titanium(III) is combined with HEID in a 1 to 1 ratio. Two species were shown by the EPR spectra (Fig. 8) to exist at this pH, with one of the species being predominant.

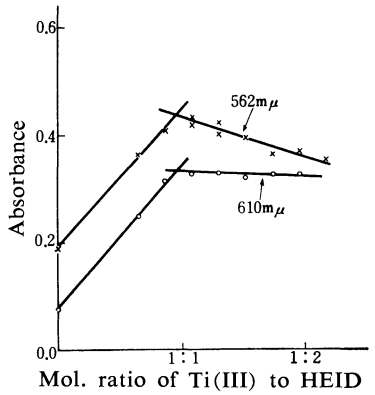

Fig. 7a. Establishment of the ratio of Ti(III) to HEID at pH 1.2 by the molar ratio method.

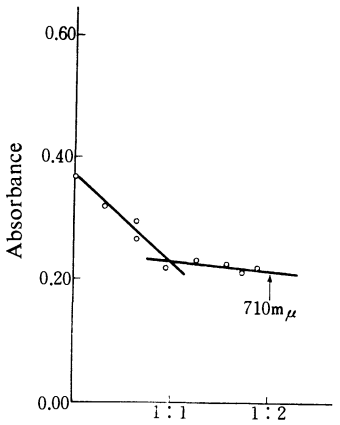

Fig. 7b. Establishment of the ratio of Ti(III) to HEID at pH 4.2 by the molar ratio method.

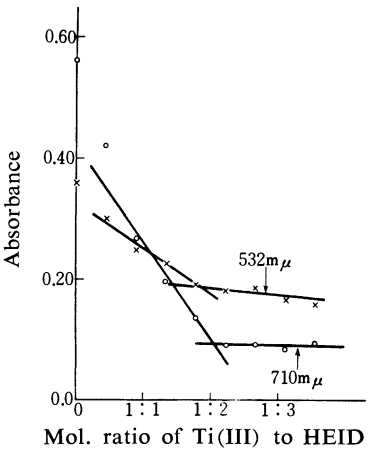

Fig. 7c. Establishment of the ratio of Ti(III) to HEID at pH 9.2 by the molar ratio method.

The minor species, which exhibits a maximum absorbance at 720 mμ and which is stable at higher pH values (pH 3—5.5) was shown, as is illustrated in Fig. 7b, to be in a 1 to 1 ratio. Thus, it must be concluded that the species which exhibits a maximum absorbance at 590 mμ and which is stable at the lower pH values (—pH 1.2) is composed of 1 to 1 proportions of titanium(III) and HEID. Figure 7b shows that at pH 4.2 a species composed of a 1 to 1 ratio is also predominant, while it may be seen in Fig. 7c that, at pH 9, a species composed of a 1 to 2 ratio predominates. The experiments illustrated in Fig. 7c were carried out in the presence of tartaric acid to prevent the hydrolysis of titanium(III). The strong blue color of the titanium(III)-tartrate compound becomes lighter upon the addition of increasing amounts of HEID. The absorbance curve changes abruptly at a ratio of 1 titanium(III) to 2 HEID.

Figures 7a through 7c show the decrease in the absorbances with an increase in the quantities of HEID. This is probably due to the

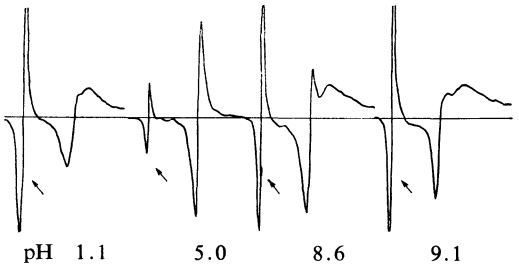

Fig. 8. EPR spectra for Ti(III)-HEID complexes. The concentration of $TiCl_3$ is 0.2 M and concentration of HEID is 0.4 M. The pH was adjusted with NaOH. Arrows designate DPPH.

oxidizing effect of some impurity in the reagent.

Figure 8 shows EPR spectra for the titanium(III)-HEID system. To obtain the EPR spectra at very low pH values a concentrated solution must be used, since the signal intensity is so low. At pH 1, two peaks are obtained. As the pH value is increased, however, only one peak is discernible. The signal intensity increases to pH 3.7, after which little change is noted until a pH of 7.5 is reached; a second peak then appears which is favored by higher pH values.

The following species may be proposed to represent the complexes which exist at the various pH values mentioned above.

| | Absorbance at | Predominant at pH | $g$ Value |
|---|---|---|---|
| (1) $Ti(III)_1$-$(HEID)_1$ | 590 m$\mu$ | 1.2 | 1.952± 0.002 |
| (2) $Ti(III)_1$-$(HEID)_1$ | 720 m$\mu$ | 3 to 5.5 | 1.952± 0.002 |
| (3) $Ti(III)_1$-$(HEID)_2$ | 540 m$\mu$ | >8 | 1.952± 0.002 |

Species 1 and 2 represent those species which are similar in composition but which are stable at different pH values and which exhibit different optical absorbances. Species 1 must be an acid complex in which the HEID is bidentate ($HEIDH^{-1}$) and one hydrogen of a carboxylic group remains unionized, and species 2, a complex in which HEID is tridentate and both hydrogens are ionized.

From Figs. 5 and 6 it may be seen that at pH 1 to 1.5 species 1 is predominant, but some absorbance at 720 m$\mu$ is observable. The EPR spectrum (spectrum at pH 1.1 of Fig. 8) shows a major species and a minor species which correspond to the species which were spectrophotometrically observed.

**Titanium(III)-BHEG, and -IDA Complexes.**— The absorbance curves obtained with the blue solutions of titanium(III) and BHEG are always very broad, with a considerable absorbance over the entire visible spectrum. This indicates some hydrolysis which precludes the establishment of formation ratios by the spectrophotometric technique. With titanium(III) and BHEG a very small EPR signal can be obtained at pH 5.2; the signal increases with an increase in pH values up to about 9, after which the signals decrease in size. Only one peak can be obtained, and no definite hyperfine structure is discernible.

Figure 9 shows that the signal obtained with a solution containing BHEG to titanium(III) in a ratio of 6 to 1 is definitely larger than that obtained with a 3 to 1 ratio. The presence of oxalic acid has no apparent effect on the signal size or shape.

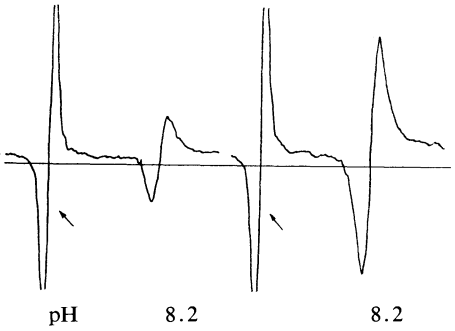

Fig. 9. EPR spectra for the Ti(III)-BHEG complex. The concentration of Ti(III) is 0.2 M and the concentration of BHEG is 0.6 M for the smaller spectrum and 1.2 molar for the larger spectrum. The pH was adjusted with NaOH. The chart speed for this figure is different than that used for Figs. 1 and 8. Arrows designate DPPH.

Solutions containing titanium(III) and IDA are blue and give EPR signals only over the narrow pH range of 7.5 to 9.0. Only one peak can be seen, and all the signals are very small. The presence of oxalic acid has a definite depressing effect on the signal intensity.

## Summary

Complexes formed by titanium(III) and agents which are similar in structure but varying in numbers of carboxyl groups have been studied by EPR and spectrophotometry. Among the reagents investigated, NTA, which posesses four coordinating groups, gives the largest EPR signals with a well-developed hyperfine structure. BHEG, which possesses two coordinating groups, gives much smaller signals, and even at the highest sensitivity setting of the instrument, no definite hyperfine structure can be detected. HEID, which posesses three coordinating groups, gives signals with two peaks, which indicates the simultaneous existance of two complexes in the solution. The ratios of the complexes of titanium(III) and NTA and HEID which exist in solution at various pH values have been spectrophotometrically determined.

The authors wish to express their thanks to Dr. Junzo Shinoda of the Daiichi Seiyaku Co., Ltd., Tokyo for his kindness in giving them reagents.

# Life-time of the Propagating Radicals in the Radiation-Induced Telomerization of Ethylene with Propanol-2*

By Motoyoshi HATADA and Kozo HIROTA

(Received June 10, 1964)

In previous reports[1,2] the telomerization of an ethylene - propanol-2 mixture was investigated by using $\gamma$-rays as the initiating agent, and it was concluded that the telomers are produced by the following elementary reaction:

$$(CH_3)_2CHOH \rightsquigarrow (CH_3)_2\dot{C}OH$$

$$(CH_3)_2\dot{C}OH + C_2H_4 \longrightarrow (CH_3)_2C(OH)-CH_2-CH_2\cdot$$

$$\longrightarrow (CH_3)_2C(OH)CH_2-CH_3$$

$$\text{or } (CH_3)_2C(OH)-CH_2-CH_2-CH_2-CH_2\cdot$$

In the present research, the telomerization of the same system will be investigated by the use of electron beams from a Van de Graaff accelerator instead of $\gamma$-rays, adopting both intermittent and steady irradiation methods in order to determine the life-time of the chain-carrying radicals. The results will be given and compared with those of the previous reports.

## Experimental

**Materials.**—Propanol-2 was dried over calcium hydride and was distilled before each use. Commercial ethylene (99.8%) was used without any purification.

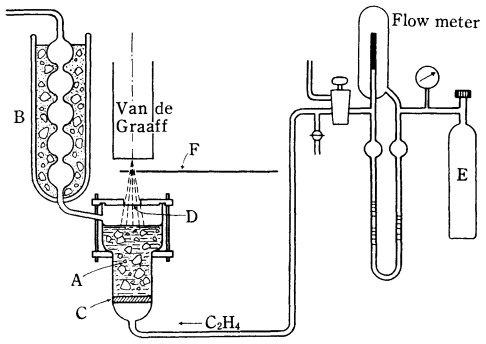

Fig. 1. Apparatus for electron beam irradiation.

**Irradiation Procedures.** — Figure 1 shows the apparatus for irradiation. Propanol-2 (80 ml.) was held in the irradiation vessel (A) (56 mm. $\phi$ in diameter) equipped with the condenser (B) kept at $-78°C$, a glass-filter (C) for bubbling ethylene into the vessel, and a window (D) made of aluminum film (0.1 mm. thick, 3.0 cm. in diameter), through which the electron beam penetrates into the irradiation vessel.

For the intermittent irradiation, the rotating sector method was used. A rotating aluminum disk (F) (4 mm. thick, 60 cm. in diameter) with two $\pi/6$ sector openings was placed between the irradiation windows of the Van de Graaff accelerator and the irradiation vessel. The ratio of the off-to-on time was kept constant at 5 throughout the experiments. The period of a whole cycle could be varied from 0.06 to 6.0 sec.

A spot electron beam (1.5 MeV, 100 $\mu$amp.) from the Van de Graaff accelerator (High Voltage Eng. Co.) was used for the irradiation. The dose rate was estimated to be $2.6\times10^{22}$ eV. $min^{-1}$ from the amount of oxalate ions produced by the irradiation of an aqueous solution of sodium formate, which was contained in a vessel with the same specifications as the irradiation vessel of propanol-2 and ethylene. This method was proposed and elaborately described by Hardwick and Guenter.[3]

**Analysis.**—After irradiation, samples were taken out and subjected to gas-chromatographic analysis. (Apparatus: Shimadzu GC1A)

## Results

In the sample irradiated, *t*-amyl alcohol could be identified by the use of a 3.0 m. column of dioctylphthalate. The higher telomers found in the previous reports were not identified in the present experiment. In Fig. 2, the amount of *t*-amyl alcohol produced is plotted against the irradiation time. Without any inhibitor, as is indicated by the open circles in the figure, the amount of telomer increases linearly with the irradiation time. By the addition of $3.66\times10^{-4}$ mol. of DPPH, some retardation was observed, as is indicated by the filled circles. The inclinations of the linear part of the two lines are equal, however.

By the use of a gas chromatograph equipped with a hydrogen flame ionization detector, several products other than *t*-amyl alcohol were

found to be produced. The details of the results will be published elsewhere.

In Fig. 3 the amount of the telomer produced after 30 min. of irradiation is plotted against the flow rate of ethylene. Up to the flow rate of 30 ml./min., the rate of telomer formation increases markedly with the flow rate of ethylene, but above this critical flow rate the rate of formation seems to increase linearly with the ethylene flow rate.

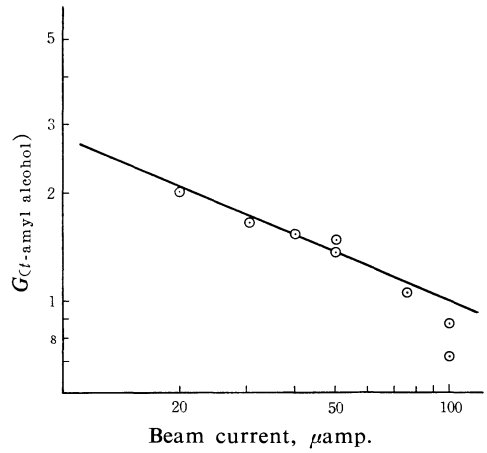

Fig. 4. $G_{(t\text{-amyl alcohol})}$ vs. electron beam current.
Ethylene flow rate : 128 ml./min.

In Fig. 4 the $G$ value for *t*-amyl alcohol formation is plotted against the electron beam current in logarithmic scales. Since the dose rate depends linearly on the beam current, the $G$ value for telomer formation is proportional to the $-1/2$ power of the dose rate.

The results of the sector experiment are shown in Fig. 5, in which the $R_0/R_s$ is plotted

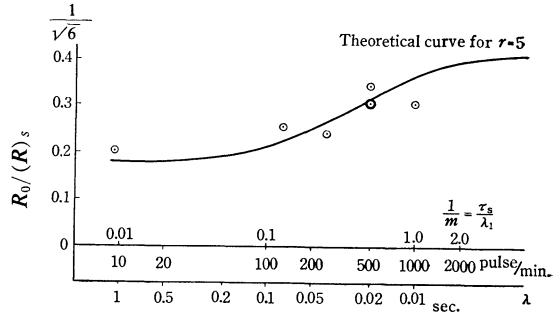

Fig. 5. Comparison of theoretical and experimental relative reaction rates.
Dose rate : $2.6\times10^{22}$ eV./min.
Ethylene flow rate : 128 ml./min.

against logarithms of the pulse frequency in pulses/min. as the abscissa, where $R_0$ and $R_s$ are the average radical concentration under intermittent and steady irradiations respectively and are assumed to be given by the amount of the telomer produced by irradiation. The theoretical curve shown in the same figure is plotted against $\lambda_1/\tau_s$ from the table by Burnett and Melville,[4] where $\lambda_1$ is the time when the beam is on, and $\tau_s$ is the mean life-time of the radicals.

## Discussion

As is shown in Fig. 2, the formation of *t*-amyl alcohol was not inhibited completely, but it was retarded by the addition of DPPH. This retardation may be caused by the fact that, because of the high concentration of radicals produced by the electron beams of a high dose rate, DPPH can not inhibit the telomer formation effectively.

On the other hand, this retardation might be considered to be a contribution of some reaction paths which are not affected by the presence of DPPH. However, in the present research, these paths were assumed to play little part in the telomer formation.

The rate of initiation, $v_i$, was estimated approximately to be of the order of $10^{-5}$ mol. $l^{-1}$ $sec^{-1}$ from the following equation:

$$v_i = -\frac{d[DPPH]}{dt} \simeq \frac{\Delta[DPPH]}{\Delta t}$$

Where [DPPH] is the initial concentration of diphenylpicrylhydrazyl in mol. $l^{-1}$ and $\Delta t$ is the induction period in sec. assumed to be given by the intercept of curve b.

From the $\lambda_1$ scale of Fig. 5, where $\lambda_1/\tau_s$ is unity, $\tau_s$ is estimated to be 0.01 sec. This value is a little smaller than that estimated by Clingman in a similar telomerization reaction between *n*-butylmercaptane and *n*-octene,[5] although the chain-carrying radicals and dose rates are different in the two cases.

However, there remain some ambiguities which may arise from the shape of the electron pulses. The electron pulses used in the present research were not exactly square in shape, but were rather complicated, because each pulse consisted of a number of trigonometrical waves of 400 c./sec., which might be induced by the rotating magnetic field (400 c./sec.) of the generator of the Van de Graaff accelerator. However, since the frequency of pulses was very low compared to 400 c./sec., the pulse shape can be regarded as square.

If the dissolving or diffusion rate, $k_s$, of ethylene into propanol-2 and the rate of reaction 2, $k$, in the following scheme:

$$(E)_g \overset{k_s}{\rightarrow} (E)_s \qquad (1)$$

$$(P\cdot) + (E)_s \overset{k}{\rightarrow} (PE\cdot) \qquad (2)$$

are assumed to have a significant role in the reaction, the plots in Fig. 5 might be explained in terms of $k_s$. However, since it has been reported that the diffusion rate did not affect the sector curve in the system of *n*-butylmercaptane and *n*-octene,[5] the diffusion rate was assumed to be negligible in the present research.

By the use of the data obtained, the average concentration of radicals, $R_s$, the kinetic chain length, $\nu$, and the rate constant of the termination reaction $k_t$, can be estimated to be of the order of $10^{-7}$ $mol^{-1}$, 10 and $10^9$ $mol^{-1}$ l. $sec^{-1}$ respectively from the following relations:

$$\tau_s = [R_s]/v_i, \quad [R_s] = (v_i/k_t)^{1/2} \text{ and } \nu = \frac{v_p}{v_i}$$

The $G$ value for telomer formation obtained in the present research is compared in Table I with that obtained in the $\gamma$-ray irradiation,

Table I. The effect of the dose rate on $G$(*t*-amyl alcohol)

| Radiation source | Electron beams from the Van de Graaff Accelerator | | $\gamma$-Rays from cobalt-60 |
|---|---|---|---|
| Dose rate, I (eV./min.) | $7.2\times10^{22}$ | $5\times10^{22}$ | $8\times10^{16}$ |
| $I_e/I\gamma$ | 960 | 780 | 1 |
| $G$(*t*-amyl alcohol) | 1.6$_7$ | 2.0 | 250 |

as has already been reported.[1] The $G$ value in the present paper is smaller than that in the former by a factor of $10^2$. This can be explained as being caused by a higher dose rate of the electron beam, considering that $G$ (telomer) depends on the $-1/2$ power of the dose rate. There are some ambiguities in this comparison, however, which come from the non-uniformity of the dose rate in the present system caused by the weaker penetrating power of the electron beams.

## Conclusion

It has been found that the 1 : 1 telomer, *t*-amyl alcohol, is produced by electron irradiation, and that it has a $G$ value smaller than that obtained by $\gamma$-irradiation. The average life-time of the radicals of the rate-determining step has been estimated to be 0.01 sec. by the rotating sector method.

The authors wish to thank Dr. Yohta Nakai for his operation of the Van de Graaff accelerator. Some of the expenses have been defrayed by a grant given by the ministry of Science and Technology, to which the authors' thanks are due.

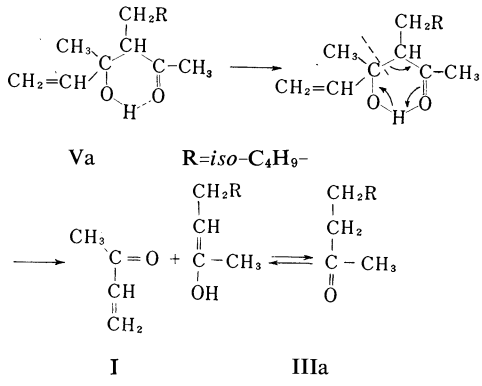
# The Reaction of Methyl Vinyl Ketone with Alkyl Grignard Reagents



By Yoshie KURIHARA, Tatsuo HIGA, Kikumasa SATO and Shigehiro ABE

(Received June 11, 1964)

The reaction of methyl vinyl ketone (I) with acetylenic Grignard reagents has been reported[1,2] to afford almost exclusively the 1,2-addition product, ethynylcarbinol. However, Smith and Sprung[3] could not obtain a simple product in the reaction between laurylmagnesium bromide and the ketone I because of the polymerization of I. Sarycheva et al.[4] obtained the 1, 2-addition product in the reaction between the Grignard reagent from 5-bromo-2, 3-dimethylpentene-2 and I, but its infrared spectrum seems to indicate that the product is a mixture of the 1, 4- and 1, 2-addition products.

In a previous study,[5] isophytol was synthesized from pseudoionone and propargyl alcohol, and it was found that the ketone I reacted with laurylmagnesium bromide to yield the 1, 4-addition product rather than the 1, 2-addition product. The reactions of I with isobutylmagnesium bromide IIa or ethylmagnesium bromide IIb will be studied in the present paper to see whether or not the previous findings concerning 1, 4-addition indicate a general tendency in the reaction between methyl vinyl ketone and alkyl Grignard reagents.

The reactions were carried out at low concentrations of the reactants and at low temperatures in order to suppress the polymerization of I. The reaction between I and IIa at $-50°C$ gave two products as colorless liquids. The lower boiling substance was found to be the 1, 4-addition product, methylheptanone (IIIa), and 3-isoamyl-2-vinyl-2-pentanol-4-one (Va) was assigned to the higher boiling product. The spectrum of Va indicated the presence of tertiary hydroxyl, non-conjugated carbonyl, and vinyl groups. When Va was treated with semicarbazide by an ordinary method,[6] no precipitate was formed. When the mixture with semicarbazide was warmed for thirty minutes or allowed to stand at room temperature for a long time, the semicarbazone of IIIa was obtained. In this reaction, IIIa was supposed to be derived by the decomposition of Va. Actually the compound, Va, decomposed readily when heated at 150°C to afford IIIa and I quatitatively. Such a decomposition supported the assignment of structure Va for the higher-boiling product, and the decomposition probably proceeds through a cyclic transitional state, as is illustrated below. This decomposition occurred also in the presence of sulfuric acid to give IIIa in a high yield.

Va R=*iso*-$C_4H_9$-

I IIIa

Thus, the reaction of I with IIa has been shown to yield a mixture of IIIa and Va. The formation of IIIa and Va can reasonably be explained by assuming the following reaction mechanism (Fig. 1). The Grignard reagent, IIa, condenses with I by the 1, 4-addition process to form an enolate III'a of methylheptanone in the first step. The enolate is converted into IIIa by hydrolysis. On the other hand, when the enolate is added to the carbon atom of the carbonyl group of another molecule of I, compound V'a is formed; this is finally hydrolyzed to Va. These courses of the reaction are shown by pathways A and B in Fig. 1 respectively.

The reaction mechanism of the Grignard

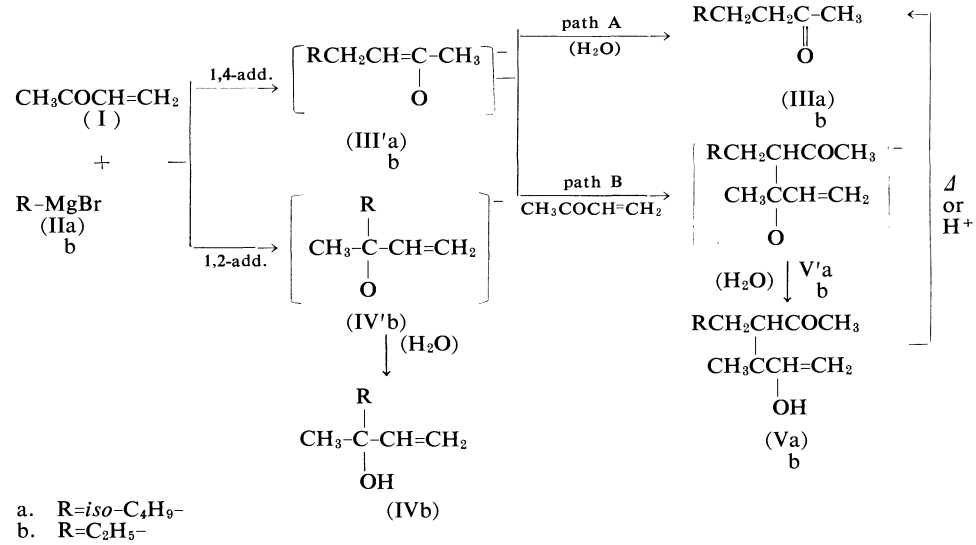

Fig. 1.

enolate ion with methyl vinyl ketone (pathway B) is supported by a number of investigations[7] of the condensation of ketones during the Grignard reaction. For example, Mosher and Lux[8] demonstrated that the interaction of methyl isopropyl ketone and *t*-butylmagnesium chloride led to the formation of not only the secondary alcohol to be expected from the reduction of the ketone but also of the ketol, 2, 3, 6-trimethyl-3-heptanol-5-one, which is a self-condensation product of methyl isopropyl ketone. According to the commonly accepted view,[7] the formation of this ketol may be explained as follows; the Grignard reagent causes the enolization of the ketone, as is already known, and the enolate thus formed is added to the carbon atom of the carbonyl group in a molecule of the corresponding keto form (Fig. 2).

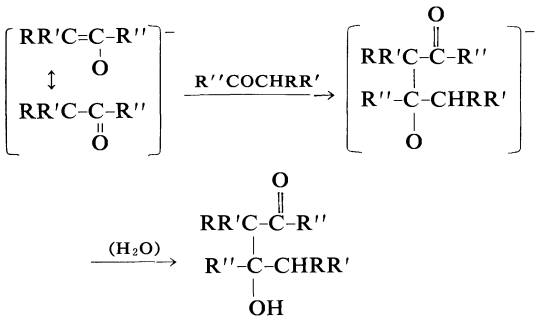

Fig. 2.

The yields of compound IIIa and compound Va were strongly influenced by the experimental conditions. The effect of varying the molar ratio of the reactants at −50°C was examined. When two moles of I per mole of IIa were used, the main product was Va, and only a trace of IIIa was obtained. When approximately equimolar amounts of I and IIa were used, both IIIa and Va were obtained in, respectively, 7.5% and 38% yields based on I. When half a mole of I was used, Va was again preferably obtained. Judging from these results, it seems likely that the reaction of the enolate, III'a, with I is faster than that of IIa with I. When the reaction temperature was raised to −15°C, only Va was obtained, even with equivalent moles of the reactants.

On the other hand, the reaction between equimolar amounts of I and ethylmagnesium bromide, IIb, at −50°C afforded 3-methyl-1-penten-3-ol (IVb, the 1, 2-addition product) contaminated with methyl *n*-butyl ketone (IIIa) and 3-propyl-2-vinyl-2-pentanol-4-one (Vb, the addition product between I and the 1, 4-addition product). The yields of IVb and Vb were, respectively, 6.6% and 17% based on I. The structure of IVb was established by infrared spectrum and by conversion into its 3, 5-dinitrobenzoate. The purification of IVb was unsuccessful, even by means of careful fractionation. Methyl *n*-butyl ketone as a contaminant was identified by gas chromatography using an authentic sample. The structure of Vb was established by means of elemental analysis and its infrared spectrum. Compound Vb may have been formed from III'b by a mechanism similar to that found in the formation of Va. It was decomposed into IIIb in

8) W. A. Mosher and A. R. Lux, *J. Am. Chem. Soc.*, **63**, 648 (1941).

the presence of sulfuric acid. Although the ratios of the reaction products were not studied under a variety of reaction conditions, it might be concluded from the above results that the reaction of I with IIb proceeds by both 1,2- and 1,4-addition, and that the 1,4-addition product III'b subsquently condenses with I to afford Vb. As has been described above, IIa gives only the 1,4-addition product. The reason for this difference in the reaction products has not been clariffied in the present study. It may, however, be worth noticing that, in the cases of both IIa and IIb, methyl vinyl ketone is added to their 1,4-addition products, whereas no further addition was previously observed in the case of laurylmagnesium bromide.

## Experimental[9]

**Materials.**—Methy vinyl ketone was prepared from γ-ketobutanol (78—80°C/18 mmHg, prepared from acetone and formalin) by dehydration with oxalic acid according to the method of Murata[10]; b. p. 80—82°C. Commercially available isobutyl bromide and ethyl bromide were used after purification (isobutyl bromide, b. p. 90—90.8°C; ethyl bromide, b. p. 38—39°C).

**The Reaction of Methyl Vinyl Ketone (I) with Isobutylmagnesium Bromide (IIa).—(a) At −50°C.**—*i) The Equimolar Ratio of I to IIa.*—The Grignard reagent was prepared from 54.8 g. of isobutyl bromide and 9.8 g. of magnesium in 300 ml. of anhydrous ether. To the solution, 22.4 g. of freshly-distilled methyl vinyl ketone in 150 ml. of anhydrous ether was added drop by drop at such a rate as to maintain the temperature at −50°C. After the reaction mixture had been continuously stirred for a further hour, it was decomposed with an ice-cooled saturated ammonium chloride solution and extracted with ether. The ether extract was washed with water and with a saturated sodium bicarbonate solution, dried, and evaporated. The residue was distilled fractionally; fraction I (5.5 g.) (b. p. 25—37.5°C/18 mmHg), fraction II (5 g.) (b. p. 27—50°C/4 mmHg), fraction III (14.5 g.) (b. p. 80—103°C/5 mmHg), and a residue (2.1 g.). By gas chromatographic analysis (column temp. 151°C; injection temp. 185°C; $N_2$ flow 12.8 ml./min.; silicon oil DC550, 2 m.), fraction I was found to be composed mostly of isobutyl alcohol (retention time 1.2 min.) contaminated with a small amount of methylheptanone (retention time 6 min.). These retention times were in good agreement with those for authentic samples. Fractions II and III were redistilled. Fraction II gave 3.0 g. (7.5% based on I) of methylheptanone, boiling at 30—31°C/4 mmHg, 166—167°C/760 mmHg, $n_D^{20}$ 1.4230 (lit.[11] $n_D^{19}$ 1.4144, b. p. 164—165°C/760 mmHg). The infrared spectrum indicated a band at 1715 $cm^{-1}$ (>C=O).

Found: C, 74.13; H, 12.71. Calcd. for $C_8H_{16}O$: C, 74.96; H, 12.58%.

The semicarbazone was recrystallized from $C_2H_5OH$ and $H_2O$ (1:1); m. p. 150.5—151°C (lit. m. p. 157°C,[11] m. p. 146°C[12]).

Found: C, 58.12; H, 10.45; N, 22.65. Calcd. for $C_9H_{19}ON_3$: C, 58.34; H, 10.34; N, 22.68%.

Fraction III gave 12.0 g. (38% based on I) of Va, boiling at 88—90°C/3 mmHg, $n_D^{20}$ 1.4602, $d_4^{20}$ 0.9223. The infrared spectrum of this substance showed bands at 1640, 1415, 990, 920 (-CH=$CH_2$), 3450, 1165 (tert. OH), and 1705 $cm^{-1}$ (C=O).

Found: C, 72.33; H, 10.97. Calcd. for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18%.

*ii) The Molar Ratio of I to IIa (2:1).*—To the Grignard reagent (prepared from 54.8 g. of isobutyl bromide, 9.8 g. of magnesium and 300 ml. of anhydrous ether), 44.8 g. of I in 400 ml. of anhydrous ether was added at −50—−55°C. The reaction mixture was then treated by the same procedure as that described in part i. Methylheptanone (1.8 g.), b. p. 31—33°C/3 mmHg, the ketol (22.3 g.), b. p. 88—90°C/3 mmHg, and the residue (9.0 g.) were obtained. These materials were proved to be identical with the samples described in the preceding paragraph by gas chromatography or the refractive index.

*iii) The Molar Ratio of I to IIa (1:2).*—The same procedure as that described in the part i was employed. 3.4 g. of Va, b. p. 81—85°C/4 mmHg, and 0.2 g. of IIIa, b. p. 38—40°C/4 mmHg were obtained from 25.5 g. of isobutyl bromide, 4.8 g. of magnesium and 5.6 g. of I.

**(b) At −15°C.**—To the Grignard solution prepared from 27.4 g. of isobutyl bromide, 5.0 g. of magnesium in 150 ml. of anhydrous ether, 12.6 g. of I in 160 ml. of anhydrous ether was added. The oily product isolated was 5.8 g. of Va (b. p. 87—92°C/3 mmHg, redistilled, b. p. 97—100°C/5 mmHg). The refractive index of this substance agreed with that of the preceding sample.

**The Decomposition of 3-Isoamyl-2-vinyl-2-pentanol-4-one (Va).**—*a) By Sulfuric Acid.*—Three grams of Va, 2 ml. of ethyl alcohol and ten drops of diluted sulfuric acid (1:1) were placed in a flask; then the mixture was heated to 100°C while being stirred for half an hour. After cooling, the reaction mixture was neutralized with a sodium bicarbonate solution and extracted with ether. After the ether had been removed, the residual liquid was distilled under atmospheric pressure; b. p. 165—169°C (1.6 g.). The product gave the semicarbazone with a m. p. of 152°C, which did not depress the melting point of an authentic sample of IIIa.

*b) By Heating.*—The pyrolysis was carried out with a gas chromatograph apparatus (column temp. 150°C; injection temp. 181°C; $N_2$ flow 10.7 ml./min.; silicon oil DC 550, 2 m.). The two peaks

9) The boiling points and melting points are uncorrected. The infrared spectra and gas chromatograms were recorded with a Hitachi Model EPI-S2 spectrophotometer and a Hitachi Model KGL-2 gas chromatograph.

10) J. Murata, "Synthetic Methods of Monomers," Vol. 9, Kyoritsu Shuppan Co., Tokyo (1957) p. 183.

11) O. Wallach, *Ann.*, **381**, 86 (1911).

12) M. Guerbert, *J. Pharm. Chim.*, (7), **6**, 49 (1912); *Chem. Zentr.*, **83**, 1099 (1912 II).

in the chromatogram were found by the use of authentic samples to be methyl vinyl ketone (retention time 4.5 min.) and methylheptanone (retention time 9.8 min.) respectively.

**The Reaction of I with Ethylmagnesium Bromide (IIb).**—A procedure similar to that described for the reaction of I and IIa was adopted. To a Grignard reagent solution (prepared from 43.6 g. of ethyl bromide, 9.7 g. of magnesium and 150 ml. of anhydrous ether), freshly-distilled methyl vinyl ketone (39.6 g.) in 500 ml. of anhydrous ether was added in such a manner as to maintain the reaction temperature at −50—−55°C. The products were fractionated. Fraction I (3.7 g.) boiled at 33—35°C/17 mmHg. On redistillation, the sample was obtained at 117—119°C/760 mmHg; $n_D^{20}$ 1.4310 (lit.[13] b. p. 116°C/760 mmHg). The infrared spectrum showed bands at 3400 and 1160 (tert. OH), 1850, 1650, 1415, 995 and 920 (CH=$CH_2$), and 1715 $cm^{-1}$ (C=O, very weak). Two peaks appeared in the gas chromatogram (column temp. 96°C; injection temp. 120°C; $N_2$ flow 2.4 ml./min.; silicon oil DC 550, 2 m.). The peak corresponding to the ketone was increased when methyl *n*-butyl ketone was added (retention time 2.5 min.). The ratio of 3-methyl-1-penten-3-ol to methyl *n*-butyl ketone was estimated to be about 5 to 1. The 3, 5-dinitrobenzoate obtained from fraction I was recrystallized from ethyl alcohol, m. p. 91—92°C.

Found: N, 9.68. Calcd. for $C_{13}H_{14}N_2O_6$: N, 9.52%.

Fraction II (13.7 g.) boiled at 50—77°C/5 mmHg, and the residue amounted to 1.8 g. The redistillation of fraction II afforded 8.5 g. (17% based on I) of Vb, b. p. 73.5—75°C/3.5 mmHg, $n_D^{20}$ 1.4589. The infrared spectrum showed bands at 1650, 1420, 995, 920 (CH=$CH_2$), 3500, 1170 (tert. OH), and 1705 $cm^{-1}$ (C=O).

Found: C, 70.57; H, 10.84. Calcd. for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

The semicarbazone, m. p. 124°C (lit.[14] m. p. 122°C), obtained from Vb by the action of sulfuric acid as described in the case of Va, did not depress the melting point of methyl *n*-butyl ketone semicarbazone. No attempt was made to determine the structure of the residue.

14) See Ref. 6, p. 262.

## Summary

The reactions of methyl vinyl ketone with isobutylmagnesium bromide and ethylmagnesium bromide have been studied. Methyl vinyl ketone reacts with isobutylmagnesium bromide to give methylheptanone and 3-isoamyl-2-vinyl-2-pentanol-4-one as a result of 1, 4-addition; the latter compound is formed from 2 mol. of ketone and one mole of the Grignard reagent. On the other hand, in the reaction of ethylmagnesium bromide with methyl vinyl ketone, both 1, 2- and 1, 4-addition take place, and 3-methyl-1-penten-3-ol and 3-propyl-2-vinyl-2-pentanol-4-one are obtained. These keto-alcohols have been decomposed to the corresponding ketones and methyl vinyl ketone by heating or by treatment with sulfuric acid.

The authors are grateful to Mr. Mohammad Raees for his help in carrying out the experiments.

# On the Competition of Homogeneous and Heterogeneous Chain Terminations in Heterogeneous Photooxidation Catalysis by Zinc Oxide

By Akiko IKEKAWA, Mamoru KAMIYA, Yuzaburo FUJITA and Takao KWAN

(Received June 12, 1964)

It has previously[1] been shown that the photoexcited adsorption or desorption of oxygen takes place on zinc oxide when lights of 3650—4350 Å are irradiated. In connection with this finding, the photooxidation of isopropyl alcohol has been investigated on zinc oxide in the presence of oxygen, the products being identified as acetone and hydrogen peroxide exclusively.[2] The same photooxidation was investigated also by Kriascose and Markham[3] on zinc oxide in pure isopropyl alcohol and aqueous suspensions. The ratio

of the oxygen uptake to the hydrogen peroxide formed was always greater than unity, especially when zinc oxide was suspended in pure liquid, suggesting that hydrogen peroxide is decomposing or participating in the oxidation of alcohol to a certain extent.

Despite the simple reaction, however, little is yet known about the photooxidation mechanism, probably because of the complex nature of the reactions occurring in the heterogeneous phase. In this paper we shall show some significant aspects of the photooxidation kinetics and then discuss them with respect to the competition of homogeneous and heterogeneous chain terminations.

## Experimental and Results

The photooxidation of isopropyl alcohol by zinc oxide in the presence of oxygen has been characterized by a certain induction period.[2] This can be eliminated, however, by stirring the zinc oxide - alcohol mixture in an oxygen atmosphere prior to photoirradiation. The initial steady-state rate for the consumption of oxygen was thus obtained within twenty minutes at the most. The apparatus and procedure for the measurements of the photooxidation catalysis were almost the same as those described previously.[2,4] The reaction was carried out at a constant oxygen pressure above 30 cmHg, where the rate of oxygen consumption was found to be independent of the oxygen pressure. The volume of oxygen consumed was determined by a conventional gas burette kept in a thermostat. Typical rate data, expressed by the volume of oxygen consumed upon irradiation, are shown in Fig. 1.

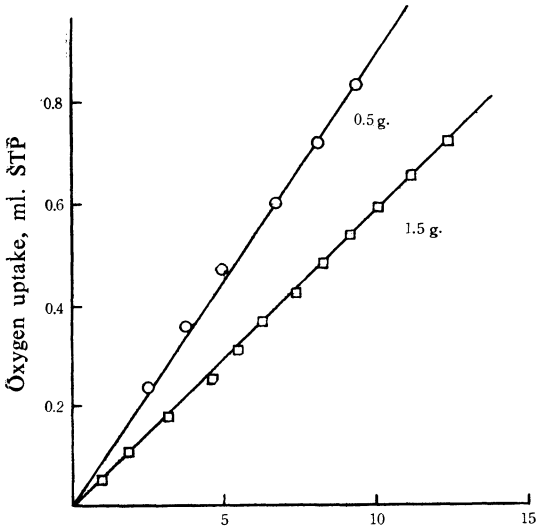

Fig. 1. Initial photooxidation rate of isopropyl alcohol on zinc oxide.
Isopropyl alcohol: 50 ml.
Partial pressure of oxygen: ca. 45 cmHg. Reaction temperature: 60°C.
Intensity of entering light $I_0$: $4.3^6\times10^{17}$ quanta/l. sec.

It was found in this way that the rate of oxygen uptake increases with the increase in the amount of zinc oxide added, suggesting that the light quanta absorbed increases with an increase in the concentration of photocatalysts. A further increase in the amount of zinc oxide, however, caused the rate of oxygen uptake to decrease gradually, hence giving rise to a maximum in the plot of the rate against the amount of zinc oxide present. Such a curve obtained at the reaction temperature of 60°C is illustrated in Fig. 2.

The quantum yield for the oxygen uptake is calculated in Table I at various amounts of zinc oxide.

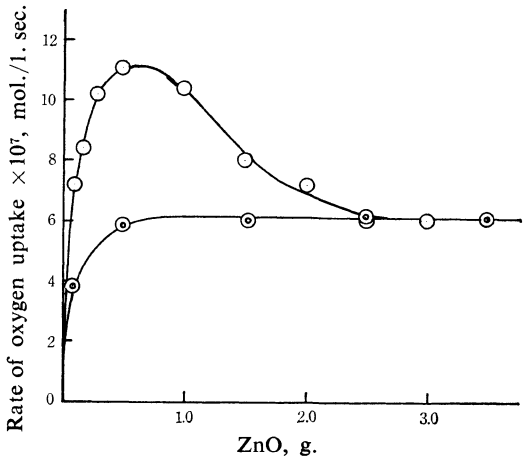

Fig. 2. The relationship between the rate of oxygen uptake and the amount of zinc oxide present.

## Discussion

It is generally accepted that the liquid phase oxidation of alcohol at high temperature is of a chain character. It has already been shown[4] that the anthraquinone-sensitized oxidation of isopropyl alcohol proceeds with a chain mechanism above 50°C. The quantum yield given in Table I, probably showing the lower limit due to the light scattering on the suspensions and also to the light penetration through the liquid phase at lower concentrations of zinc oxide, may be indicative of the chain reaction participating to some extent.

The following mechanism is, therefore, assumed to be the principal process for the photooxidation of isopropyl alcohol on zinc oxide. The primary process may be schematically represented by:

where $I_a$ is the intensity of light absorbed or the rate of the excitation of oxygen on zinc oxide, $k_0$ and $k_1$ are rate constants of the respective steps, and RH denotes the isopropyl alcohol molecule. No description will be made at the moment regarding the adsorbed state of oxygen and the mechanism of photoexcitation; detailed investigations will soon be reported in association with adsorption, conductivity and ESR measurements of zinc oxide and adsorbed oxygen.[5] The steady state rate of the primary process may readily be derived as:

$$R_i = \frac{k_1 I_a (\mathrm{RH})}{k_0 + k_1 (\mathrm{RH})} \qquad (1)$$

The secondary process may be thermal, and the following steps are expected to participate at least:

$$\mathrm{R} + \mathrm{O_2} \xrightarrow{k_2} \mathrm{RO_2}$$

$$\mathrm{RO_2} \xrightarrow{k_3} \mathrm{CH_3}\rangle\mathrm{CO} + \mathrm{HO_2}$$
$$\mathrm{CH_3}$$

$$\mathrm{RH} + \mathrm{HO_2} \xrightarrow{k_4} \mathrm{R} + \mathrm{H_2O_2}$$

$$\mathrm{HO_2} + \mathrm{HO_2} \xrightarrow{k_5} \mathrm{H_2O_2} + \mathrm{O_2}$$

$$\mathrm{HO_2} + \mathrm{HO_2} \xrightarrow[\mathrm{M}]{k_5'} \mathrm{H_2O_2} + \mathrm{O_2}$$

where the last step indicates the heterogeneous chain termination effected on the third body, M, or on the surface of zinc oxide competing with the homogeneous bimolecular chain termination given just above.

The steady state treatment of the overall reaction yields the expression:

$$-\frac{\mathrm{d(O_2)}}{\mathrm{d}t} = R_i + \frac{k_4}{\sqrt{k_5}}\sqrt{R_i}\,(\mathrm{RH}) \qquad (2)$$

for the homogeneous chain termination. The substitution of $k_5'$ (M) for the $k_5$ of Eq. 2 gives, of course, the rate equation for the heterogeneous chain termination:

$$-\frac{\mathrm{d(O_2)}}{\mathrm{d}t} = R_i + \frac{k_4}{\sqrt{k_5'(\mathrm{M})}}\sqrt{R_i}(\mathrm{RH}) \qquad (3)$$

It seems more likely that the heterogeneous chain termination on zinc oxide is monomolecular rather than a third-body collision involving M. The rate of oxygen uptake is, then, given by:

$$-\frac{\mathrm{d(O_2)}}{\mathrm{d}t} = R_i + \frac{k_4}{k_5''(\mathrm{M})} R_i(\mathrm{RH}) \qquad (4)$$

The $\mathrm{RH} + \mathrm{HO_2} \rightarrow \mathrm{R} + \mathrm{H_2O_2}$ step requires a definite energy of activation, so the chain can not propagate around room temperature.[4] In other words, the second term on the right of Eq. 2 will only be significant at elevated temperatures. This may be applicable not only in the homogeneous phase but also in the heterogeneous phase provided the concentration of zinc oxide is low enough.

On the other hand, the chain will not propagate, according to Eq. 3 or 4 even at elevated temperatures in the heterogeneous phase, if sufficient amounts of M or zinc oxide are present, leaving only the first term in the rate expression. Thus, the rate of oxygen uptake may be expected to decrease with an increasing M value and finally to approach a limiting value which may be identified to $R_i$. The decreasing curve of Fig. 2 observed at high concentrations of zinc oxide may probably be ascribed to such a predomination of the heterogeneous chain termination.

A low temperatures, where the chain propagation is suppressed, the rate may be expected to increase monotonously with an increase in the amount of zinc oxide, finally attaining $R_i$ without showing any maximum. The supposition was supported by experiments at the temperature of 40°C, where the chain reaction was almost negligible.[4] As is shown by the double circles of Fig. 2, the results were found to be strikingly consistent with the expectation.

Mashio,[6] who studied the benzoyl peroxide-initiated oxidation of isopropyl alcohol above 80°C, estimated the temperature coefficient of

5) Y. Fujita and T. Kwan, *Shokubai* (*Catalyst*), **5**, 206 (1963).

6) F. Mashio, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **63**, 699 (1960).

$k_4/\sqrt{k_5}$ to be 9.8 kcal./mole. Hence, the temperature coefficient of the rate of oxygen uptake should assume a more or less rapid increase with a rise in the temperature from room temperature to, say, 80°C, because the reaction around room temperature is photochemical, involving radical recombinations, and so the rate should be little dependent on the temperature.

In the presence of excess zinc oxide, the rate of oxygen uptake was found actually to agree with that of the primary process. The temperature coefficient of the rate is, then, expected to be very small, even beyond the temperature where the chain propagation actively participates. On the other hand, such would not be the case when the amount of zinc oxide is sufficiently small; the temperature coefficient of the rate is expected to increase with the increasing temperature, much as in the homogeneous phase.

In Fig. 3 the plot of $\log(-\mathrm{d}(O_2)/\mathrm{d}t)$ vs. $1/T$ with 0.1 g. zinc oxide added on the one hand and that with 2.5 g. zinc oxide on the other hand are compared.

As can be seen from Fig. 3, the temperature coefficient of the oxidation rate increases distinctly from near zero to about 10 kcal./mole. at around 45°C when the amount of zinc oxide present was small, whereas it was nearly constant at a very small value on excess zinc oxide over the same temperature range.

The decreasing curve of Fig. 2, already explained as being due to the heterogeneous chain termination of $HO_2$, might resemble the effect of the third gases in the photochemical dissociation of the bromine or iodine molecule worked out by Rabinowitch and Wood[7] many years ago, although the increase in the third gases, in the latter reaction, serves to accelerate the homogeneous recombination of dissociated atoms and, hence, to decrease the concentration of halogen atoms.

The effect of the electronic properties of zinc oxide on the photocatalytic activity will be discussed next. It has previously been shown[2] that the rate of oxygen uptake continues, even when the light is interrupted, when a sample of oxidized zinc oxide is subjected to photo-oxidation catalysis. No such memory was perceptible on a reduced zinc oxide sample. Investigations of these phenomena led to the conclusion that the dark oxidation of isopropyl alcohol on oxidized zinc oxide is due to the hydrogen peroxide-initiated oxidation of alcohol.

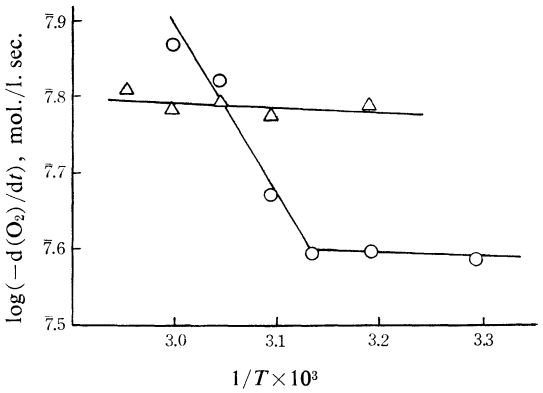

Fig. 3. The temperature coefficient of the photooxidation rate at low and high concentrations of zinc oxide.
○ ZnO 0.1 g. △ ZnO 2.5 g.

In view of the dual nature of the photoresponses for the oxygen adsorbed on reduced and oxidized zinc oxide samples on the one hand and on alumina-doped and lithia-doped zinc oxide samples on the other hand, it seemed of interest to find the difference in the activity in the photo-primary process using doped zinc oxide samples. Preliminary experiments have shown that the rate of oxygen uptake is much greater on lithia-doped zinc oxide than on an alumina-doped sample at the temperature of 60°C. The rate on the lithia-doped sample was autocatalytic, controlled even by the diffusion of oxygen into the liquid phase at the later stage of the reaction. It was considered that the thermal oxidation of isopropyl alcohol, initiated by the decomposition of hydrogen peroxide, occurs simultaneously on the surface of lithia-doped zinc oxide. At the initial stage of the photoreaction, the rate of oxygen uptake was greater on lithia-doped zinc oxide than on an alumina-doped sample; $ZnO(Li_2O) > ZnO(Al_2O_3)$.

It is interesting to note that the sequence of the activity is reversed at a lower temperature, i. e., at 30°C. The rate of oxygen uptake upon irradiation was the greatest on alumina-doped zinc oxide, as $ZnO(Al_2O_3) > ZnO > ZnO(Li_2O)$. Markham and Kuriacose did not investigate the effect of doping zinc oxide on the photocatalytic activity, but they noted that the addition of hydrogen peroxide to a zinc oxide suspension does not affect the rate of acetone formation at 25°C. If the decomposition of hydrogen peroxide to give oxygen and water is the only side reaction on zinc oxide samples around room temperature, then the activity sequence mentioned above may be quite natural, for Sedaka of this laboratory found that the decomposition of hydrogen

7) E. Rabinowitch and W. C. Wood, *J. Chem. Phys.*, **4**, 497 (1936). See also W. A. Noyes, Jr., and P. A. Leighton, "The Photochemistry of Gases," Reinhold Publishing Co., New York (1941), p. 195.

peroxide in an aqueous solution occurs more rapidly on lithia-doped zinc oxide than an alumina-doped sample. The decomposition of hydrogen peroxide on lithia-doped zinc oxide may compensate for the consumption of oxygen to some extent.

In this connection, reference may be made to the work by Bernas and Doo-Kingue.[8] Bernas reported that the photoirradiation of an aqueous suspension of zinc oxide produces hydrogen peroxide more efficiently on reduced zinc oxide than on an oxidized sample. The efficient production of hydrogen peroxide on zinc oxide of a reduced state, according to Bernas and Dook-Kingue, might be due to its inefficient activity in the thermal decomposition of hydrogen peroxide; this is in accordance with the finding by Sedaka.

In studying the photooxidation of carbon monoxide on zinc oxide, Stone[9] found that the relative catalytic activity is the sequence: $ZnO(Li_2O) > ZnO > ZnO(Cr_2O_3)$. A similar result was found concerning oxygen exchange catalysis on zinc oxide samples.[10] The activity of doped zinc oxide samples in the decomposition of hydrogen peroxide, as well as in the oxidation of isopropyl alcohol, may be correlated with the data available in the literature.

## Summary

The photooxidation catalysis of isopropyl alcohol on zinc oxide has been investigated with special reference to the chain termination mechanism. It has been proposed that homogeneous and heterogeneous chain terminations compete in this system. At a low concentration of zinc oxide, the homogeneous termination predominates, while at a high concentration the heterogeneous termination may come into play. As a result, a maximum may appear in the relation of the rate of oxygen uptake to the amount of zinc oxide present. With excess zinc oxide, chain reactions are suppressed, so no maximum may appear in the corresponding plot and the temperature coefficient should be very small. The experimental results have been found to be consistent with the expectations. The effect of doping zinc oxide on the photooxidation kinetics has been investigated and discussed, mainly on the basis of the data available on the formation and decomposition of hydrogen peroxide on doped zinc oxide samples.

It has been suggested that lithia-doped zinc oxide is more active than alumina-doped zinc oxide at higher temperatures because of the accompanying hydrogen peroxide-initiated oxidation of isopropyl alcohol on the former, while it is less active at lower temperatures because of the efficient decomposition of hydrogen peroxide, giving oxygen and water.

# Kinetics of Methane Oxidation in Shock Waves*

By Hajime MIYAMA and Tetsu TAKEYAMA

(Received June 12, 1964)

The oxidation of methane at comparatively low temperatures has been extensively studied and its mechanism has been well established by Semenov[1] and others[2]. Although there have also been several papers[3-6] about the methane oxidation at higher temperatures, satisfactory results were not obtained because of experimental difficulties. However, the recent development of the shock tube technique has made possible such high temperature studies; Skinner and Ruehrwein[7] measured induction periods of visible light emission in the range of conditions, $1150 \leq T \leq 1740$°K and $0.25 \leq [O_2]/[CH_4] \leq 0.67$; he suggested that the initiating reaction is $CH_4 + O_2 \rightarrow CH_3 + HO_2$. Kistiakowsky and Richards[8] observed the emission of vacuum ultraviolet radiation from the shock-heated gas mixtures in the range of conditions, $1800 \leq T \leq 2700$°K and $0.5 \leq [O_2]/[CH_4] \leq 4.5$ and suggested that the step $H + O_2 \rightarrow OH + O$ controls the reaction rate during the induction period. On the other hand, Asaba et al.[9] measured the ignition delay by a pressure transducer over the wide range of conditions and proposed that the reaction $CH_3 + O_2 \rightarrow CH_2O + OH$ is rate-determining for methane-lean mixtures and that the reaction $CH_4 + O_2 \rightarrow CH_3 + HO_2$ is rate-determining for the methane-rich mixtures.

In the present study, in order to clarify the mechanism of methane oxidation, the induction period of the OH absorption (3067 Å) and that of the pressure increase were measured simultaneously, and also the reaction products of certain cases were analyzed by gas chromatography.

## Experimental

**Materials.** — Takachiho methane (99.9% min.), Nippon Sanso oxygen (99.5% min.), and Nippon Sanso argon (99.999% min.) were used without further purification. The gas mixtures were prepared manometrically in a reservoir and allowed to stand for at least 24 hr. before being used. Helium was used as the driver gas in the shock tube at pressures up to 11 atm.

**Shock Tube and Instrumentation.**—A schematic diagram of the apparatus is shown in Fig. 1. A

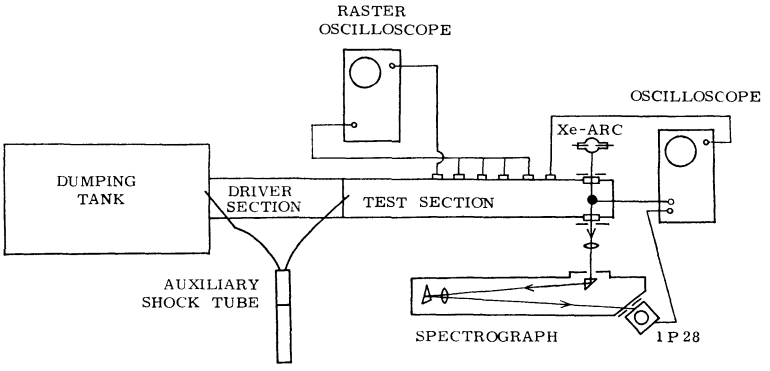

Fig. 1. Schematic diagram of apparatus.

single-pulse shock tube consisted of a 2.4 m.-long driver section and a 3.5 m. experimental section which were made of 7.6 cm. inside diameter precision-bore stainless steel tubing, and a dumping tank 90 cm. inside diameter and 3.6 m. long. One of six piezo gauges (Murata $BaTiO_3$ Ceramic Vibrator) was used to trigger the oscilloscopes, while the others were used to measure the shock velocities along the tube. The gauge signals were displayed on a raster-sweep oscilloscope (Iwasaki SS-5102), which permitted the measurement of the shock velocity in each gauge interval to a 0.5% accuracy. A quartz pressure transducer (Kistler Model 603) was installed 5.5 mm. from the end of the tube in order to measure the pressure change of the reacting system. Also, at the end of the tube, 5.5 mm. from the end plate, two quartz windows, each with a slit 2 mm. wide, were inserted to provide an optical path through the tube. The light source used was an Ushio 500 W. xenon arc lamp, the power for which was supplied by batteries. The other optics consisted of a Shimadzu QL-170 spectrograph with a $0.3\times8$ mm. entrance slit and a $0.5\times8$ mm. exit slit set a 3067 Å and an RCA 1P28 photomultiplier. The outputs of the pressure transducer and the photomultiplier were fed to a dual-beam oscilloscope (Iwasaki DS-5305) and recorded with a Polaroid camera. Before each run, the experimental section was evacuated to $10^{-3}$ mmHg and the lamp had been lit for at least 20 min. The measured leak rate of the shock tube was 3 $\mu$Hg per min.

**Gas Analysis.**—All the gas mixtures used and the produced gas mixtures, which were withdrawn through a valve near the end plate immediately after each run, were analyzed by gas chromatography. These analyses were performed with a Yanagimoto GCG-2 gas chromatograph at 50°C employing 1.5 m. columns of a molecular sieve 5A and silica gel, with helium as the carrier; the former column was used for the analysis of methane and carbon monoxide, and the latter, for ethane, ethylene, acetylene and carbon dioxide. The chromatograph was calibrated carefully for the peak area with pure gas specimens, using neon as an internal standard. The reproducibility of the analyses was maintained within an error of $\pm1\%$.

## Calculations

The temperatures, pressures and other parameters of the gas behind the reflected shock waves were calculated by means of the one-dimensional theory, assuming rotational and vibrational relaxations but no chemical relaxation. Numerical calculations were made by a USS 90 computor using Strehlow's method.[10]

Gas chromatographic analysis was applied to the reaction products of the methane-rich mixtures. For these mixtures, the second-order reaction was assumed by other researchers.[8,9] In order to evaluate the second-order rate constant from the analytical results of the reaction products, the following procedure was adopted, extending the method of Asaba et al.[11] The rate of the consumption of methane was considered to be given by Eq. 1:

$$dx/dt=k(a-x)(b-nx) \tag{1}$$

where $a$ and $b$ denote the initial concentrations of methane and oxygen respectively; $x$ and $nx$, the quantities of methane and oxygen respectively consumed during $t$, and $k$, the rate constant. In this equation, it is implicity assumed that, during the whole reaction time, methane reacts with $n$-fold oxygen; the value of $n$ can be determined by the material balance from the results of the analysis of the products. The integration of Eq. 1 gives:

$$x=\frac{ab\{1-\exp[(na-b)kt]\}}{b-na\exp[(na-b)kt]} \tag{2}$$

As is shown in Fig. 2, the dwell time of gas molecules exposed to a high temperature varies along the distance from the end plate; accordingly, the extents of reaction are not equal along all the distance. The quantity of methane decomposed at a distance of $l$ from the intersection of a reflected shock wave with a rarefaction wave may be expressed as follows by using Eq. 2:

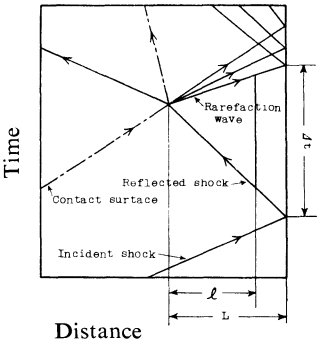

Fig. 2. Distance-time diagram.

$$x(l)=\frac{ab\left\{1-\exp\left[(na-b)k\frac{l\Delta t}{L}\right]\right\}}{b-na\exp\left[(na-b)k\frac{l\Delta t}{L}\right]} \tag{3}$$

Here, $\Delta t$ is the dwell time at the end plate and $L$, the distance from the intersection to the end of the tube. Thus, the average of $x(l)$ over the range $l=0$—$L$ is given by the equation:

10) R. A. Strehlow, Ballistic Research Laboratories Report No. 978, April, 1956, Aberdeen Proving Ground, Maryland, U. S. A.

11) T. Asaba, K. Yoneda and T. Hikita, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **64**, 1925 (1961).

$$\bar{x}=\frac{1}{L}\int_0^L x(l)\,\mathrm{d}l=a-\frac{1}{kn\Delta t}\times \ln\frac{b-na\exp[(na-b)k\Delta t]}{b-na} \quad (4)$$

Since $a$, $b$ and $\Delta t$ can be obtained from the experimental conditions combined with calculated shock parameters and $\bar{x}$ and $n$, from the analytical data of the reaction products, the rate constant, $k$, can be calculated from Eq. 4.

## Results

**The Methane-Lean Mixtures.**—A typical oscillogram, obtained for the mixture consisting of 70% argon, 9% methane and 21% oxygen, is shown in Fig. 3. The OH absorption appears

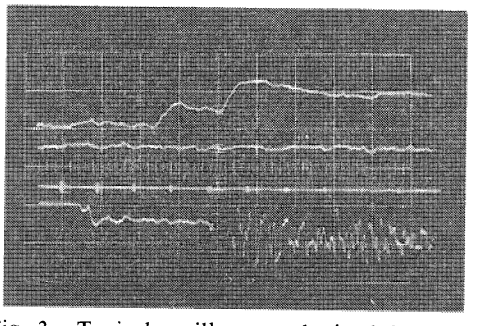

Fig. 3. Typical oscillogram obtained from the mixture of 70% Ar, 9% $CH_4$ and 21% $O_2$. The uppermost beam shows the change in the OH absorption, the second the noise level of Xe-lamp, the third timing markers and the lowest the pressure change. Sweep velocity is 100 $\mu$ sec./division.

after the induction time $\tau_1$. Its intensity increases exponentially to a limiting value, again increases as an explosive reaction starts, and decreases when the mixture is cooled by a rarefaction wave. On the other hand, the pressure increases suddenly after the induction time $\tau_2$ which is longer than $\tau_1$. The time of this pressure increase agrees with that of the second increase in OH absorption. From the data obtained in the range of conditions, $1050 \leq T \leq 2100$°K, $3 \leq p \leq 9$ atm. and $4.1\times10^{-3} \leq [O_2] \leq 1.5\times10^{-2}$ mol./l., it was found[12] that the logarithmic values of $\tau_1[O_2]$ and $\tau_2[O_2]$ are linearly proportional to $1/T$, but that other plots, such as $\log \tau_1[CH_4]$ or $\log \tau_1[CH_4][O_2]$, are not linearly proportional to $1/T$. Also, the apparent activation energies obtained from the slope of these straight lines are 21.5 and 33.8 kcal./mol. respectively.

A typical oscillogram obtained for the mixture of 30% methane and 70% oxygen without

12) H. Miyama and T. Takeyama, *J. Chem. Phys.*, **40**, 2049 (1964).

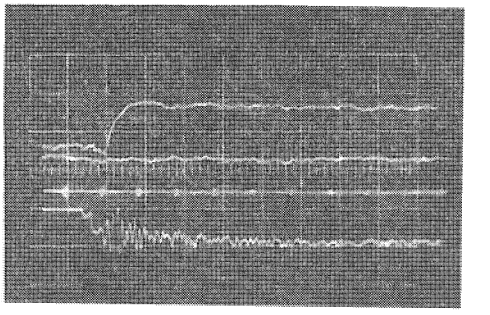

Fig. 4. Typical oscillogram obtained from the mixture of 30% $CH_4$ and 70% $O_2$. The four traces are the same as in Fig. 3.

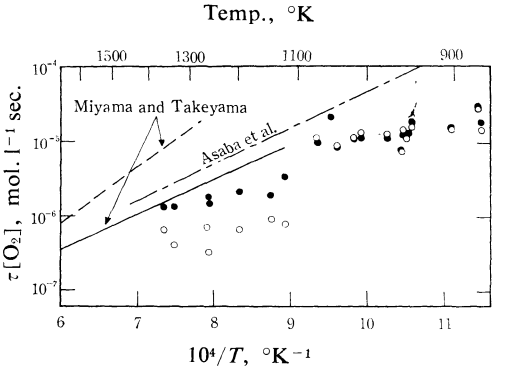

Fig. 5. Induction period vs. reciprocal temperature. Solid and open circles are from the pressure and OH-absorption measurements, respectively. Solid and dashed lines are obtained from the mixture with 70% Ar, measuring the OH-absorption and the pressure change, respectively.

argon is shown in Fig. 4. The OH absorption appears almost simultaneously with the pressure increase. Data obtained over the range of conditions, $870 \leq T \leq 1360$°K, $3.7 \leq p \leq 6.6$ atm. and $2.4\times10^{-2} \leq [O_2] \leq 6.0\times10^{-2}$ mol./l. are plotted in Fig. 5. Obviously, the data obtained for the mixtures without argon deviate markedly from those for the mixtures with a large amount of argon. Also, the data of Asaba et al.[9] obtained for the mixtures without argon are shown for purposes of comparison.

**The Intermediate Mixtures.**—The same measurements as have been described above were conducted for mixtures of 70% argon, 18% methane and 12% oxygen and those of 60% methane and 40% oxygen over the range of conditions $1420 \leq T \leq 2010$°K, $4.2 \leq p \leq 7.1$ atm. and $2.9\times10^{-3} \leq [O_2] \leq 2.2\times10^{-2}$ mol./l. The OH absorption and pressure change appeared at the same time in both mixtures. The induction periods measured are shown in Fig. 6 as a plot of $\log(\tau[CH_4][O_2])$ vs. $1/T$, which presents a fairly straight line in spite of the rather wide range of oxygen and methane concentrations, although the other

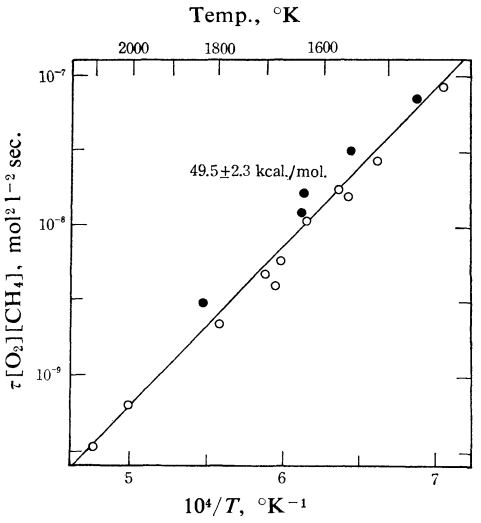

Fig. 6. Induction period vs. reciprocal temperature. Open and solid circles are obtained from mixture with and without argon, respectively. Solid line is a least-squares fit to these points.

plots, such as $\log(\tau[O_2])$ vs. $1/T$ and $\log(\tau[CH_4])$ vs. $1/T$, showed marked deviations of the measured points. The least-squares equation obtained for this line is:

$$\log \tau[CH_4][O_2] = -14.62\pm0.12+(10810\pm500)/T \quad (5)$$

From the slope of this line, the apparent activation energy is found to be 49.5±2.3 kcal./mol.

**The Methane-Rich Mixtures.** — Experiments were performed for mixtures of 86% argon, 12% methane and 2% oxygen and those of 86% methane and 14% oxygen. However, for the latter mixtures, it was very difficult to define the reaction temperature because the reflected shock wave interacted with the contact surface to produce a new shock wave and reheat the gas. Therefore, only the results obtained for the former mixtures will be reported. For the methane-rich mixtures, it was impossible to apply the above technique because the carbon precipitation obscured the OH absorption and the pressure increase was not appreciable. Therefore, the reaction products obtained by using a single pulse shock wave[13] were analyzed by gas chromatography.

The dwell time during which the reaction mixture was exposed to a high temperature was measured by a pressure transducer at the endplate and was adjusted to be about 1 msec. In Fig. 7, percentages of the products, based on the initial methane concentration, are plotted against the reaction temperatures. Using the analytical data shown in Fig. 7, the rate constants of methane oxidation were calculated on the assumptions[7,9] that the rate of consumption of methane is proportional to the product of methane and oxygen concentrations, and that the change in the concentration of various species during the cooling process in the rarefaction waves can be neglected.*

* The latter assumption is not justified for the reaction of a small activation energy. In the case of hydrazine decomposition,[14] the activation energy is 35 kcal./mol. and about 25% of the total reaction occurs in the cooling process. However, this assumption may be approximately applicable in the present case since the activation energy is 51 kcal./mol.

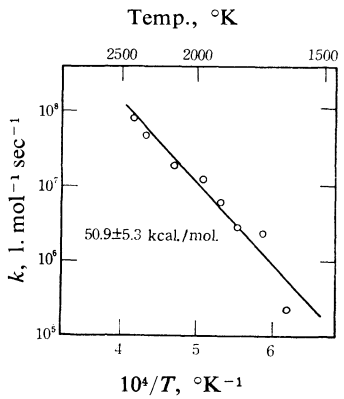

Fig. 8. Arrhenius plot of second-order rate constants. Solid line is a least-squares fit.

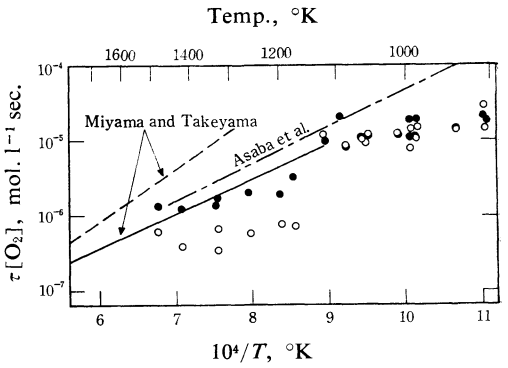

Fig. 9. Induction period vs. reciprocal temperature. The lines and symbols have the same significance as in Fig. 5. Temperatures were recalculated as described in the text.

Numerical calculations were conducted by using Eq. 4 combined with the values shown in Table I, where the calculated values of $k$ are also tabulated in the last column. Figure 8 shows an Arrhenius plot of these rate constants. The equation of the least-squares line is:

$$\log k = 12.56 \pm 0.21 + (-11070 \pm 1150)/T \quad (6)$$

The apparent activation energy obtained from the slope of this line is 50.9±5.3 kcal./mol. Further, the first-order rate constants were calculated in an analogous method, assuming that the rate of consumption of methane is proportional to the concentration of methane or oxygen. However, the Arrhenius plot did not show a straight line.

## Discussion

As is shown in Fig. 5, the data obtained for the methane-lean mixtures without argon deviate markedly from those for the mixtures with argon. At about 800°K, the vibrational relaxation time of oxygen molecule[15] is of almost the same order of magnitude as the induction periods described above, although that of methane is negligibly small.[16] Therefore, the temperatures and pressures of reflected shock waves were recalculated by assuming that the vibrational energy of the oxygen molecule is *frozen* but that the other relaxation conditions are the same as have been described above. The corrected data are plotted in Fig. 9. The agreement between the data for the mixtures with and without argon is thereby improved a little. However, there is still a large discrepancy. Other factors which possibly cause this discrepancy are considered to be as follows: when the mixture is not diluted with argon, the large concentrations of reactants release an appreciable amount of heat of reaction, even during the induction period; when the shock wave passes through the large concentration of polyatomic gases, bifurcation occurs as a result of the interaction between the reflected shock wave and the boundary layer;[17] and because of the high concentration of reactants, the abundance of reactive species such as radicals changes the reaction mechanism.

Since not enough data are available to explain the above-described discrepancies, however, the results obtained for the methane-lean mixtures without argon will not be discussed further.

According to Semenov,[1] the mechanism of methane oxidation at relatively lower temperatures may be considered to be as follows:

$$CH_4 + O_2 \rightarrow CH_3 + HO_2$$
(I) $E = 55$ kcal./mol.

$$CH_3 + O_2 \rightarrow CH_2O + OH$$
(II) $E = 20$ kcal./mol.

$$OH + CH_4 \rightarrow H_2O + CH_3$$
(III) $E = 8$ kcal./mol.

$$OH + CH_2O \rightarrow H_2O + HCO$$
(IV) $\Delta H = -38$ kcal./mol.

$$CH_2O + O_2 \rightarrow HCO + HO_2$$
(V) $E = 32$ kcal./mol.

$$HCO + O_2 \rightarrow CO + HO_2$$
(VI) $\Delta H = -20$ kcal./mol.

$$HO_2 + CH_4 \rightarrow H_2O_2 + CH_3$$
(VII) $E = 11$ kcal./mol.

17) R. A. Strehlow and A. Cohen, *J. Chem. Phys.*, **30**, 257 (1959).

$$HO_2 + CH_2O \rightarrow H_2O_2 + HCO$$
(VIII) $\Delta H = -12$ kcal./mol.

$$OH \xrightarrow{\text{wall}} \text{destruction}$$
(IX)

$$CH_2O \xrightarrow{\text{wall}} \text{destruction}$$
(X)

At higher temperatures in shock waves, Asaba et al.[9] proposed to adopt reactions I, II, III, V, VI and VII, and they concluded from the measurements of the ignition delay that the rate-determining step for a methane-rich mixture with a methane-oxygen ratio above unity is reaction I, while the rate-determining step for a methane-lean mixture with a methane-oxygen ratio below unity is reaction II.

The results described in the preceding section for the methane-rich mixtures and for the intermediate mixtures support their conclusion regarding rich mixtures; the consumption of methane is a second-order reaction with an activation energy of 50.9±5.3 kcal./mol., which is first order with regard to both methane and oxygen. However, in the case of methane-lean mixtures, it was found that the induction periods, $\tau_1$s and $\tau_2$s, were inversely proportional to the concentration of oxygen. In addition, apparent activation energies of 21.5±1.2 and 33.8±1.0 kcal./mol. were obtained from the plots of log ($\tau_1[O_2]$) vs. $1/T$ and log ($\tau_2[O_2]$) vs. $1/T$ respectively. In order to establish the actual meaning of these findings, it is assumed that, during the induction period $\tau_1$, OH, $HO_2$, HCO and $CH_2O$ are steady-state intermediates and that the principal chain carrier is the $CH_3$ radical. Therefore, the rate of increase of the $CH_3$ radical is expressed in Eq. 7:

$$\begin{aligned} d[CH_3]/dt &= k_1[CH_4][O_2] - k_2[CH_3][O_2] \\ &\quad + k_3[OH][CH_4] + k_7[HO_2][CH_4] \\ &= 2k_1[CH_4][O_2] + k_2[CH_3][O_2] \end{aligned} \quad (7)$$

The integration of Eq. 7 gives Eq. 8, assuming $[CH_4] = [CH_4]_0$ and $[O_2] = [O_2]_0$:

$$\frac{2k_1[CH_4][O_2] + k_2[CH_3][O_2]}{2k_1[CH_4][O_2] + k_2[CH_3]_0[O_2]} = \exp\{k_2[O_2](t - t_0)\} \quad (8)$$

Here, $t_0$ is any reference time following which Eqs. 7 and 8 are valid, and the subscript zero on a concentration denotes the value of that concentration at time $t_0$. Defining the origin of time as the time when the rate of reaction II becomes equal to that of initiation I, i. e., at $t=0$:

$$k_1[CH_4][O_2] = k_2[O_2][CH_3]_0 \quad (9)$$

Eq. 10 is obtained from Eq. 8.

$$[CH_3] = 3[CH_3]_0\{\exp(2k_2[O_2]t) - 2/3\} \quad (10)$$

The steady-state expression for [OH] in terms of $[CH_3]$ is:

$$[OH] = [CH_3](k_2[O_2]/k_3[CH_4]) \quad (11)$$

so [OH] also increases exponentially according to:

$$[OH] = 3[OH]_0\{\exp(2k_2[O_2]t) - 2/3\} \quad (12)$$

$[OH]_0$ is given by Eqs. 9 and 11.

Defining $[OH]_{\tau_1}$ and $[CH_3]_{\tau_1}$ as the concentrations of [OH] and $[CH_3]$ respectively at $t=\tau_1$, the following relations are obtained:

$$\begin{aligned} [CH_3]_{\tau_1}/[CH_3]_0 &= [OH]_{\tau}/[OH]_0 \\ &= 3\{\exp(2k_2[O_2]\tau_1 - 2/3\} \end{aligned} \quad (13)$$

It can be assumed, in analogy with the hydrogen-oxygen reaction,[18] that the ratio $[OH]_{\tau_1}/[OH]_0$ remains approximately constant over the temperature range studied. Therefore;

$$k_2[O_2]\tau_1 = \text{const.}$$

Thus, a plot of log ($\tau_1[O_2]$) vs. $1/T$ should give a straight line, the slope of which gives the activation energy of reaction II.

On the other hand, after the induction period $\tau_1$ formaldehyde can no longer be assumed to be a steady-state intermediate and its concentration accumulates, since reaction II is faster than reaction V. Hence, the rate of increase of $[CH_3]$ is:

$$d[CH_3]/dt = 2k_1[CH_4][O_2] + k_5[CH_2O][O_2] \quad (15)$$

Since the first term may be disregarded for the methane-lean mixtures,[9] Eq. 16 should approximately hold when Eq. 15 is integrated:

$$[CH_3]_{\tau_2} = k_5[O_2]\int_0^{\tau_2}[CH_2O]dt \quad (16)$$

Here, $[CH_3]_{\tau_2}$ is the concentration at the end of the induction periods $\tau_2$, and its value is considered to be approximately a constant which depends upon the detectability of the pressure transducer. Therefore, Eq. 17 may be obtained from Eq. 16:

$$[CH_3]_{\tau_2} = k_5[O_2]\tau_2[CH_2O]_{av} \quad (17)$$

where:

$$[CH_2O]_{av} = \frac{1}{\tau_2}\int_0^{\tau_2}[CH_2O]dt$$

If it is assumed that $[CH_2O]_{av}$ reaches a certain limiting value at the start of the explosive reaction, $\tau_2[O_2]$ is inversely proportional to $k_5$:

$$\tau_2[O_2] \propto 1/k_5 \quad (18)$$

Thus, a plot of log ($\tau_2[O_2]$) vs. $1/T$ should also give a straight line, the slope of which gives the activation energy of reaction V.

18) G. L. Schott and J. L. Kinsey, *J. Chem. Phys.*, **29**, 1177 (1958).

Therefore, the results presented in the previous paper[12] suggest that the rate-determining step for OH formation is reaction (II) and that that for the over-all reaction is reaction V. The discrepancy about the rate-determining step of the over-all reaction for the methane-lean mixtures between the present study and that of Asaba et al. might be explained by the difference in experimental conditions which was discussed at the beginning of this section. For the intermediate mixtures under the present experimental conditions, it may be considered from the value of the apparent activation energy and the distinct dependence of $\tau$s on the product of methane and oxygen concentrations that the over-all reaction is controlled also by the reaction $CH_4 + O_2 \rightarrow CH_3 + HO_2$.

According to the recent papers of Kistiakowsky and his coworkers,[19,20] the kinetics at lower partial pressures of reactants differ from those observed or proposed for reactions taking place at much higher partial pressures or at much lower temperatures; that is, ion molecules must be taken into account under the former conditions. In the present studies, the partial pressures of reactants ranged from 250 to 5000 mmHg and so are much higher than those chosen by them (a few mmHg). Thus, it may be reasonable to suppose that reactions I, II, III, V, VI and VII occur during the induction periods under the present experimental conditions, as has been proposed by Semenov as occurring at lower temperatures.

**Summary**

The mechanism of methane oxidation in reflected shock waves has been studied by measuring the induction period of the OH absorption and that of the pressure increase simultaneously, and also by using the single-pulse technique combined with gas chromatography.

As a result, it has been found under the present experimental conditions that the rate-determining step for the over-all reaction of the methane-rich mixtures with the ratio $[CH_4]/[O_2]=6$ is $CH_4 + O_2 \rightarrow CH_3 + HO_2$, and that the rate-determining step for the over-all reaction of the methane-lean mixtures with the ratio $[CH_4]/[O_2]=3/7$ is $CH_2O + O_2 \rightarrow HCO + HO_2$. Also, the rate-determining step for the OH formation of the lean mixtures has been found to be $CH_3 + O_2 \rightarrow CH_2O + OH$ under the present conditions. In the case of the intermediate mixtures with the ratio $[CH_4]/[O_2]=1.5$, the over-all reaction is considered to be controlled mainly by the reaction $CH_4 + O_2 \rightarrow CH_3 + HO_2$.

The authors wish to express their thanks to Mr. Akio Sawa for his help in the experiments and to Mr. Daisuke Miura and Mrs. Yukiko Takemura for their computations of shock parameters.

# The Oxidimetric Determination of Thioureas with Potassium Bromate

By Balwant SINGH, Balbir Chand VERMA and M. S. SARAN

(Received June 10, 1964)

Szebelledy and Madis[1] determined thiourea by titrating it with bromate in a hydrochloric acid medium at 40 to 50°C in the presence of potassium bromide and a little gold chloride. The end-point was marked by the appearance of a yellow colour which persisted only for 5 to 10 sec. On the other hand, Mahr[2] titrated thiourea with a standard bromate-bromide solution in a sulphuric acid medium at 35°C in the presence of potassium iodide and a little starch. The end-point was the appearance of a blue colour when thiourea was oxidised to formamidine disulphide. Rao and Neelakantam[3] found Mahr's method to be erratic and developed a method replacing

potassium bromate by potassium permanganate and using a lower concentration of sulphuric acid and double the amount of potassium iodide.

However, no systematic study has so far been made regarding the oxidimetric determination of thiourea and its organic derivatives. In the present work an attempt will be made to use potassium bromate as a redox reagent for the determination of thioureas in a sulphuric acid medium at room temperature. In the presence of potassium iodide, the thiourea and its organic derivatives will be oxidised to their corresponding disulphides with this oxidant.

## Experimental

A known weight (10 to 60 mg.) of each compound was taken in a titration flask. In the case of thiourea and its alkyl derivatives, sufficient water and enough sulphuric acid to keep the acid concentration at 2 N were added. Each aryl derivative of thiourea was dissolved in 18 N sulphuric acid (10 to 15 ml.), and sufficient water (50 to 90 ml.) was added to keep the acid concentration between 2.5 to 4.0 N. To the solution of each compound a 0.40 ml. portion of 10% potassium iodide solution was added except in the case of the *p*-tolyl-, *p*-methoxyphenyl- and *p*-ethoxyphenyl thioureas, to which 0.10 ml. portions of 10% potassium iodide solution were added. The solution in each case was cooled to room temperature and titrated with standard (N/20) potassium bromate. The end-point in each case was detected visually as well as potentiometrically. In visual titrations,

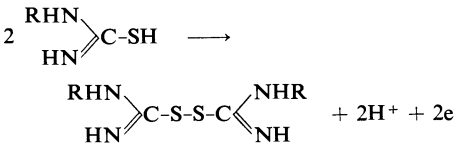
J Methyl thiourea

0.20 ml. of 1% amylose was used as an indicator, and the solution acquired a blue colour at the end-point. A series of potentiometric titrations was performed with different amounts of the compound in each case. The potentiometric titrations, one for each compound, are represented by curves A to J in Fig. 1.

From the volume of the standard (N/20) potassium bromate solution used corresponding to the end-point in each titration, the amount of each compound was calculated. Some typical results are given in Table I.

The results recorded in the table show that the listed compounds can be determined volumetrically by titrating them with standard (N/20) potassium bromate. Thiourea and its organic derivatives are oxidised by potassium bromate to their corresponding disulphides in the presence of potassium iodide in a sulphuric acid medium.



$$BrO_3^- + 6\,I^- + 6H^+ \longrightarrow Br^- + 3\,I_2 + 3\,H_2O$$

(R=hydrogen atom, alkyl or aryl group)

## Summary

Potassium bromate has been used as a redox reagent in the presence of potassium iodide for the visual and potentiometric determination of thiourea and its several alkyl and aryl derivatives in a sulphuric acid medium. In visual titrations, amylose, is used as a visual indicator, turning blue at the end-point. In the potentiometric method, a bright platinum wire is used as an oxidation-reduction electrode; this is coupled with a saturated calomel electrode. The thioureas are oxidised to their corresponding disulphides with a single electron-change:

(R=hydrogen atom, alkyl or aryl group)

This direct method is simple, accurate, instantaneous and widely applicable.

One of the present authors (B. C. V.) wishes to thank the Council of Scientific and Industrial Research, Rafi Marg, New Delhi, for the award of a Senior fellowship.

# Electron Paramagnetic Resonance Absorption of Chromium Ions Dispersed on Silica-alumina. I. The Influence of Chemical Constitution of the Supporting Materials on the Dispersed State

By Akira MATSUMOTO, Hazime TANAKA and Nobuhisa GOTO

(Received June 12, 1964)

The electron paramagnetic resonance (EPR) absorption of chromium ions dispersed on supporting materials, principally silica, silica-alumina and gamma alumina, has been examined by several investigators for the purpose of clarifying their catalytic active sites in some chemical reactions.[1-11] Three types of resonance absorption have been confirmed. The first of these appears in the vicinity of 1500 oe. in the X-band and has been referred to as the $\delta$-line. This absorption has been interpreted as due to $Cr^{3+}$ ions well dispersed and electronically isolated.[4] The second resonance,

referred to as the $\beta$-line, is broad and centered at about 3400 oe. in the X-band. MacIver et al.[5] distinguished two kinds of $\beta$-lines, using coprecipitated chromia-alumina, and attributed them to $Cr^{3+}$ in small clusters of chromia in the amorphous phase and in the solid solution phase. The last resonance, whose $g$ value is almost the same as that of the $\beta$-line but whose width is narrower, has been referred to as the $\gamma$-line. This absorption has been generally attributed to $Cr^{5+}$.

The character of these absorptions varies with the supporting materials and the oxidation-reduction conditions and, though the various general explanations of their origin agree with each other fairly well, some uncertainty remains about the configurational state of the ions. In the present investigation, we intend to examine the structural change of chromium ions with the variation in the chemical constitution of the supporting material under the heat treatment, pursuing principally the behavior of the $\gamma$-lines and comparing their shapes with those of some chromium compounds.

## Experimental

**Materials and Treatment.** — As supporting materials pure silica gel, silica-alumina and gamma alumina were prepared by the hydrolysis of ethyl-orthosilicate, aluminum isopropoxide and their mixtures in order to avoid their containing impurities of transition elements. Aluminum isopropoxide was made from highly pure metallic aluminum. After having been crushed down to 30 mesh pass, they were heat-treated at 500°C for 17 hr. in a stream of dry air. Figure 1 shows their thermal variation, while Table I indicates the chemical composition, the surface area, and the results of qualitative analysis by the emission spectroscopy of the materials heat-treated. In some cases a commercial silica-alumina cracking catalyst (Davison Co.) was employed; the official specifications are also shown in Table I.

The impregnation of chromia was carried out with an aqueous solution of chromic anhydride of a special grade (Kanto Kagaku Co.). The supporting materials were immersed in the solution and strirred at 50°C for 2 hr. The excess solution was then filtered out, and the impregnated materials were dried for 24 hr. in an air bath at 120°C. The quantity of chromium was controlled by changing the concentration of the solution and the ratio of the supporting material to the solution. Table II indicates the impregnated samples used in the experiment. The heat treatment of the impregnated materials was carried out in a stream of dry air for 4 hr. at definite temperatures.

Chromic anhydride was also heat-treated without supporting material. This compound melts at a relatively low temperature, i.e., at 196°C, and it is changed into alpha chromia at about 400°C through a few intermediates. Various intermediate chromium oxides between CrO and $CrO_3$ have been

reported; however, their crystal structures are unknown except in a few cases. For the present work the chemical formulas of the thermal decomposition products were determined from the X-ray powder patterns obtained by Schwartz et al.[12]

The alkaline peroxychromates ($K_3CrO_8$, $Na_3CrO_8$ and $(NH_4)_3CrO_8$) were prepared using the method of Riesenfeld.[13] In one case they were prepared in the presence of supporting material.

**The Measurement of EPR Spectra.** — The EPR measurements were performed with a superheterodyne-type spectrometer, constructed by the Applied Electric Laboratory Co., which operated in the K-band (24 kMc./s.) using two klystrons (24 VlO) and 45 Mc./s. as I. M. F. The first derivatives of resonance spectra were recorded on a chart, using modulation amplitudes from 2 to 50 oe. The peak-to-peak width and the position of the spectra were measured with a proton magnetic resonance recorded on the same chart and corrected by the spectra of DPPH.

The relative intensity of the spectra was determined by comparing it with a resonance absorption of a piece of synthetic ruby fixed in the cavity. The absolute number of unpaired electrons in the sample was estimated from a comparison of this standard resonance with that of DPPH.

Most of the measurements were made at room temperature and in open air. It has been recognized that the width of the resonance in the X-band was affected by the partial pressure of oxygen over the sample.[2] We could not observe this effect when the sample sealed off with nitrogen after the heat treatment was exposed to air. Samples were put into quartz tubes 3 mm. in o. d. directly after the treatment and measured.

**Chemical Analysis.** — The portion of the chromium which dissolved out into distilled water was determined with several samples. About 100 mg. of the sample was boiled in 50 cc. of distilled water for 10 min. and then filtered. The chromium in the filtrate was determined colorimetrically.

The total chromium content was measured after the heat treatment using flux agents to make them all water soluble. In the course of this analysis, it was recognized that potassium-sodium carbonate and potassium sulfate were sufficient as the flux in most cases, but the silica-alumina II indicated in Table I fixed chromium strongly and it became difficult to make all chromium water soluble with this flux. For these exceptional cases sodium peroxide was used as the flux.

The oxidation number was also determined in some cases. About 100 mg. of the sample was immersed in 60 cc. of distilled water; 10 cc. of 1 : 4 hydrochloric acid and 1 g. of potassium iodide were added, and then the mixtures were kept still for 1 hr., after which time iodometry was carried out.

## Results

**The $\gamma$-Absorption of Dispersed Samples.** — *The Variation in $\gamma$-Line Shape with the Supporting Materials.* — The general features of the spectra obtained in the experiment agree with the results given in the preceding reports. The factor which has the greatest effect on the spectral shape is the constitution of the supporting material. The spectra of chromium

ions on pure silica gel show typical asymmetric features; the three components of the $g$ tensor are distinct (Fig. 2). The addition of alumina to the base material makes the separation of the peak indistinct, and only the difference between $g_{//}$ and $g_{\perp}$ can be recognized. When the content of alumina reaches 50 mol.%, it becomes more difficult to see the separated peaks and the apparent symmetry of the spectra increases. Chromium ions on gamma alumina are similar. When the measurement is performed at the temperature of liquid nitrogen, the intensity of the absorption increases but the line shape hardly changes at all.

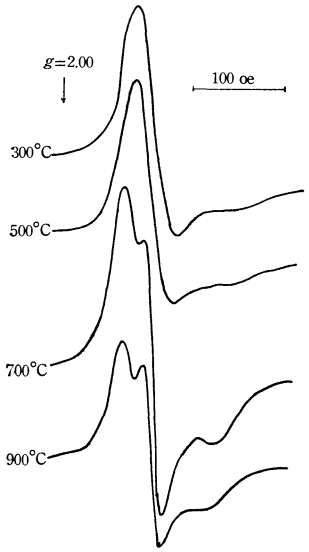

Fig. 4 (a). Variation of $\gamma$-absorption shape with heat treatment (Sample No. 5-2 in Table II).

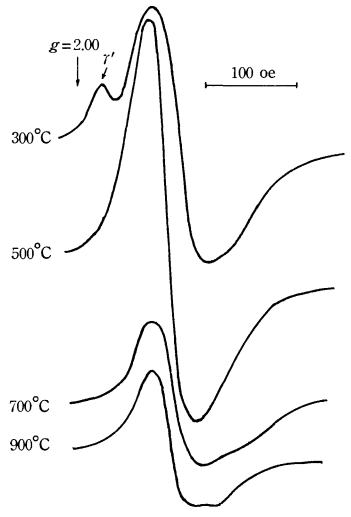

Fig. 4 (b). Variation of $\gamma$-absorption shape with heat treatment (Sample No. 5-1 in Table II).

The $g$ values and the width of the $\gamma$-line vary slightly with the temperature of the heat treatment (Fig. 3). The chromium content in the sample also affects the line shape (Fig. 4). When commercial silica-alumina is used as the supporting material and when the chromium concentration is low, a new resonance appears at a lower magnetic field, between 250 and 300°C, of the heat treatment. This resonance, indicated in Fig. 4b as the $\gamma'$-line, does not appear in other cases; here we will only note its appearance.

*The Variation in Intensity with Heat Treatment.*—The intensity of the $\gamma$-line varies with the temperature of heat treatment and shows a maximum value between 400 and 700°C (Figs. 5 and 6). If one compares the relative intensities of the different samples, two main inclinations may be recognized: first, the increase in chromium content decreases the portion of chromium which contributes to the $\gamma$-absorption (Fig. 6), and second, the chromium dispersed on the supporting material which contains more alumina makes many more sites of $\gamma$-absorption, though it remains difficult to compare the relative intensities of samples with different supporting materials because of the differences in spectral shape.

As is shown in Fig. 5, the sample of pure silica gel does not show a sharp maximum of intensity during the heat treatment, but it

make the total chromium soluble using the flux which is effective in other cases.

In order to make it clear whether it is the water-soluble part of chromium or the insoluble part which contains the sites which give the γ-absorption, EPR measurements were also carried out of the residues of filtration in the analysis of water-soluble chromium. The results shown in Fig. 9 indicate that silica-alumina, particularly silica-alumina II, retains more sites of the resonance per chromium; i. e., the chromium ions which give the γ-line exist mainly in the water-insoluble part in these supporting materials. However, there remains some uncertainty whether the sites of the γ-absorption regenerate or disappear in the course of dissolving and drying.

The variation in oxidation number is shown in Fig. 10. On the silica-alumina II, the oxidation number is already low in the original impregnated sample. It is noticiable that

gamma alumina gives rather a high oxidation number, though the water-soluble chromium is poorest on this material.

**The EPR of Some Chromium Compounds.** — For the purpose of comparison, EPR measurements were made of some chromium compounds. The results are shown in Fig. 11 and Table IV. Alkaline peroxychromates give

absorptions similar to the $\gamma$-line. These materials are unstable at room temperature, and $(NH_4)_3CrO_8$ shows a spectrum which is similar to a superposition of the $\beta$-line and the $\gamma$-line. These peroxychromates contain $Cr^{5+}$ ions; recently Swalen and Ibers[14] and McGarvey[15] discussed their electronic level scheme on the basis of the optical absorption and the EPR absorption. $Cr(OH)_3$ and $Cr_2(SO_4)_3$ dispersed on the supporting material give a resonance absorption like the $\beta$-line.

## Discussion

**An Analysis of the Line Shape.** — Cossee and VanReijen[1] first pointed out that the chemical composition of the supporting material affected the line shape of the $\gamma$-line. We intend here to consider the differences in the dispersed state of chromium ions on different supporting materials, working through a consideration of the variation in EPR spectral shape.

As is shown in Fig. 2, chromium ions on silica gel give an asymmetrical $\gamma$-line in which three peaks in the first derivative can be distinguished. The addition of alumina makes the separation of peaks obscure. On gamma alumina the ions give an apparently symmetrical $\gamma$-line, and the apparent width increases.

The origin of the $\gamma$-absorption has been ascribed to $Cr^{5+}$ ions, as has been cited. Indeed, alkaline peroxychromates containing $Cr^{5+}$ ions give a quite similar absorption line (Fig. 11). Garif'yanov,[16] however, using borosilica glass, observed a similar absorption which might contain dispersed $Cr^{5+}$ ions. The $g$ values of these lines agree well with each other.

The shoulder of the absorption in the low magnetic field in the case of silica gel had not previously been recognized. We think that the variation in the line shape, this shoulder, depends mainly on the $g$ anisotropy and the line width: the three principal values of $g$ tensor can be observed with $Cr^{5+}$ ions on silica gel, but the increase in the content of alumina in the supporting material makes it obscure and increases the apparent symmetry as a results of the increase in the width or the variation in $g$ anisotropy.

First, we will consider the variation in the line shape from this point of view, using a simple approximation. There have been several works[17-19] about the line shape, which must be given an assembly of crystallites randomly oriented but with a $g$ anisotropy. These works have used a $\delta$-function approximation or a Lorentzian line shape for the absorption of each crystallite. Here we employ the method of Kneubühl.[18] The assumptions in this calculation are as follows:

(a) Each chromium ion has an anisotropy of the $g$ tensor;

(b) The resonance absorption line of each crystallite is Lorentzian;

(c) The width is constant and independent of the orientation of the orientation of the crystallites;

(d) The orientations of the crystallites are at random;

(e) The spin Hamiltonian consists of the Zeeman, dipolar and exchange terms only.

The results of the calculation are shown in Fig. 12, where the parameter, $b$, is the half-width at the half-power of absorption which must be given by each individual crystallite. It must be noted that, as the three principal values of $g$ tensor, the values observed in the silica gel sample, which was heat-treated at 700°C, are used. Figure 13 shows how the half-width, maximum slope width and asymmetry, expressed by (half-width of low field side)/(half-width of high field side), change with $b$.

Figure 12 shows that the three components of the $g$ tensor are distinct until $b$ becomes 15 oe. When $b$ is over 20 oe., the existence of $g$ anisotropy can be recognized only from the asymmetric figures. From Fig. 12, it can also be seen that the position of the maximum of

the absorption line goes up to a higher magnetic field with the increase in $b$. This inclination contradicts the experimental results shown in Fig. 3. If samples with the same supporting material are compared, the apparent $g$ value slightly decreases or is constant when the temperature of the heat treatment rises and the apparent width of the maximum slope increases. However, if samples with different supporting materials are compared, it is noticed that gamma alumina gives lines with somewhat larger apparent $g$ values than the $g_2$ values of those with silica gel. In the above calculations the definite $g$ components given in the silica gel sample are used, but it is doubtful that the principal values of th $g$ tensor remain constant among the different supporting materials. It is rather more probable that $g$ anisotropy decreases with the increase in the alumina content of the supporting materials.

Keeping this precaution in mind, we will try a rough comparison of the observed results shown in Fig. 3 with those of Fig. 13. The $\gamma$-line of samples with silica gel gives spectra which show the three components of $g$ distinctly and which have a maximum slope width of 30 oe. This corresponds to the calculated curves with $b < 10$ oe. The samples with silica/alumina 4:1 give $\gamma$-lines with maximum slope widths of 40—60 oe., indicating a still considerable asymmetry; they corresponds to the calculated curves with $b$=15—20 oe. Silica-alumina II produces samples which give $\gamma$-lines corresponding to those of $b$=20 oe. When gamma alumina is used as the supporting material, the width is about 60 oe. when the temperature of the heat treatment is low, but if the temperature of the heat treatment is over 700°C, the width increases up to about 100 oe.; this corresponds to the curves calculated with $b$=50—60 oe.

**The Dispersed State of Chromium Ions on the Different Supporting Materials.** — As has been described, three kinds of absorption, $\delta$, $\beta$ and $\gamma$, are observed with chromia dispersed on silica-alumina; the $\delta$-absorption has been attributed to $Cr^{3+}$ ions well dispersed and isolated. Howard[11] indicated that this $\delta$-absorption was not observed with chromia dispersed on silica gel. This means that there are few isolated chromia on silica gel. On the other hand, the decrease in $\gamma$-absorption and the increase in $\beta$-absorption occur with the same inclination during heat treatment, though the quantitative correspondence does not exist. This indicates that the sites of both absorptions may be in the same region on the sample. Eischens and Selwood[20] concluded from their susceptibility measurements that chromic anhydride dispersed on gamma alumina is deposited mainly three oxide layers thick.

The chromia dispersed on silica gel is almost entirely water-soluble, and the solubility is not affected by the heat treatment of a higher temperature. On the contrary, gamma alumina and silica-alumina II make insoluble chromium which increases remarkably in amount with the heat treatment. As is well known, alumina easily makes a solid solution with chromia; also, alumina crystallizes from hydroxide at about 500°C. On the other hand, the

20) R. P. Eischens and P. W. Selwood, *J. Am. Chem. Soc.*, **69**, 1590, 2698 (1947).

silica gel used in the present experiment does not produce a solid solution with chromia, at least below 1000°C, and it does not crystallize before 1000°C, according to the X-ray diffraction analysis. Chromic anhydride changes into alpha chromia at about 400°C, as has been mentioned before.

From these facts it may be considered that on silica gel chromia exists mainly in the form of clusters, probably several atomic layers thick. If 5 wt.% of chromium are dispersed homogeneously on the material with a surface area of 500 $m^2/g$., the distance between chromium atoms becomes about 10 Å. This means that, though the dispersed chromia exists in the form of clusters, their thickness may be rather thin if the affinity of chromia to the supporting material does not greatly differ from the affinity between them.

On gamma alumina and on silica-alumina II, the isolated dispersion of chromium occurs simultaneously and the interaction between the base materials and chromium is stronger. It is not clear at present whether $Cr^{5+}$ ions isolate from other chromium ions, but at least the variation in the $\gamma$-line shape with the variation in supporting materials indicates that the base materials can influence the electronic condition of chromium ions. Dereń et al.[21] reported that chromia gel also gave a variation of the water-soluble part under heat treatment similar to the present results obtained by dispersed chromia. However, in their experiment pure chromia gel showed a maximum value of water-soluble chromia at a lower temperature of heat treatment. One can consider pure chromia gel to be chromia dispersed on chromia.

As is shown in Figs. 5 and 6, the concentration of $Cr^{5+}$ ions in the samples is at most several percent of the total chromium content, and in the case of silica gel this concentration is particularly low. From this fact, it is natural to consider that $Cr^{5+}$ ions are separated from each other. If chromia exists almost entirely in the form of small clusters on the silica gel, the mean distance among $Cr^{5+}$ ions becomes small and their coordination is decided principally by the superficial condition of chromia. As is well known, gamma alumina has a spinel-like structure and it contains many lattice defects of a symmetrical coordination. If these defects take part in the fixation of chromium ions or if chromium ions replace aluminum ions because of compatibility between their oxides, they bring about a more stable fixation of the chromium and give them a more symmetrical crystal field. This will cause a reduction of the $g$ anisotropy. If the coordination becomes perfectly octahedral or tetrahedral, it is difficult to observe the EPR absorption at room temperature, as will be described below.

**A Further Consideration of the Line Width.**— The apparent width of $\gamma$-lines obtained in the present work by using the K-band wave is somewhat larger than those in the X-band reported by others. O'Reilly also pointed out this fact[3] in the case of gamma alumina. It shows that one of the causes of the line width is probably $g$ anisotropy.

At the same time another cause of the increase in line width must be considered: spin-lattice relaxation. Many investigations have been made of the electronic structure of the ion which has a $3d^1$ electron in various crystal fields. When the symmetry of the field is high, the first excited level is so close to the ground level that it is generally impossible to observe the EPR absorption at room temperature. Concerning the $Cr^{5+}$ ion, Carrington et al.[22] and Van Reijen et al.[23] showed that EPR observation of $(CrO_4)^{3-}$ and $Ba_3(CrO_4)_2$ respectively was not possible at room temperature. However, when $Cr^{5+}$ ions are placed in a field of tetrahedrally-distorted octahedron, as in the case of $(NH_4)_2CrCl_5$,[23] or in a field of dodecahedron, as in the cases of the above-mentioned alkaline peroxychromates, a narrow absorption can be observed, even at room temperature.

In the peroxychromates, $Cr^{5+}$ ions are situated in a field with an axial symmetry: $g_1 = g_2$. Swalen and Ibers,[17] using 25 oe. as the half width, $b$, showed that the observed line agrees with the calculated curve. As compared with the value of $b$ which was estimated in the preceding section for the samples dispersed on silica gel, this value is fairly large. It may arise from the dipole interaction. Indeed, McGarvey[15] indicated that the dilution of peroxychromate with peroxyniobate markedly reduced the apparent line width. In connection with this width, it is necessary to consider the possibility of motional narrowing in the dispersed samples.

At present it is impossible to evaluate the relative contribution of these effects to the line width. It will be useful to examine the variation in optical absorption, electrical conductivity, etc. in these materials.

Concerning the variation in $\gamma$-line with dissolution, some uncertainty remains, as has been mentioned before. There have been

attempts to distinguish $Cr^{5+}$ from $Cr^{6+}$ by using the difference between them in the solubility in water, but when the base material changes, this method can not be applied, even for relative measurements. We will discuss the variation in $\gamma$-absorption sites under several chemical treatments in our next paper.

## Summary

Chromic anhydride has been dispersed on several supporting materials of silica-alumina of different compositions, and the so-called $\gamma$-line in the EPR of these samples has been observed. When the temperature of heat treatment rises, the intensity of this absorption becomes strong, but after reaching a maximum value it decreases again. The chemical composition of the base materials remarkably influences the behavior of the absorption. The variations in water soluble chromium and oxidation number show corresponding results. However, $\gamma$-absorption sites may be distributed in the water-insoluble part of chromium as well as in the water-soluble part. The ratio between them depends on the base materials.

Under the assumption of $g$ anisotropy, the observed absorption lines have been compared with the calculated curves and the half-width at the half power of the absorption with the crystallite in these samples. From these results and from the differences in behavior, the states of chromium ions in various samples have been compared. By comparing the present results with those of other investigators, it has been concluded that, on pure silica gel, chromia is dispersed mainly in the form of thin-layer clusters and that this dispersion gives the characteristic of this matter. On the contrary, an alumina-rich base produces a more dispersive state of chromium and the fixation of chromium rapidly becomes stronger with the heat treatment. The influence of the supporting material on dispersed chromium becomes great and the characteristics are affected by this fact. These differences may be caused principally by the differences among these materials in thermal stability and in the compatibility with chromia.

The authors wish to express their thanks to Professor Hidetaro Abe, The Institute for Solid State Physics, The University of Tokyo, for his kind advice. They also wish to thank Jiro Nishimura, Kunihiko Nakamura and Hiroshi Fukunaga for their help during the course of these experiments.

# Corundum $\alpha$-$Al_2O_3$ Formation from the Dehydration of Boehmite $\gamma$-AlOOH under Hydrothermal Conditions. II. The Reaction Rates and the Mechanism*

By Goro YAMAGUCHI, Hiroaki YANAGIDA and Takeshi FUJIMARU

(Received June 26, 1964)

Aluminum hydroxide are transformed into corundum under hydrothermal conditions near 400°C. In the previous paper,[2] the present authors investigated the factors determining the grain size of the corundum produced from the hydrothermal dehydration of boehmite and proposed a scheme for the reaction mechanism. It seems essential that there be in the reaction a process for forming hydrated polyaluminate ions with a structure related to the lattice of the product phase, corundum in the present case. In the present work, the reaction rates of corundum formation will be measured for the purpose of further discussion of the reaction mechanism.

## Experimental

**Procedure.** — 1.20 or 3.60 g. of boehmite is weighed and laid in a Morey-type reactor, the inner volume being 10 ml., with an appropriate amount

* Subtitled "Investigations into the Processes of Solid Phase Formation." No. 3. The first one is "On the Reaction Mechanism of Boehmite Formation from the Dehydration of Gibbsite,"[1] while the second is Part I of the present main title: "Factors Determining the Grain Size of Corundum and a Proposal for the Formation Mechanism."[2]

2) G. Yamaguchi and H. Yanagida, This Bulletin, **36**, 1155 (1963).

of the solvent, 0.1 or 1.0 N aqueous sodium hydroxide. The amount is calculated from Kennedy's table showing the relation among the P. V. T. values of water,[3] in order to produce a hydrothermal pressure of 1000 atm. at the reaction temperature. The reactor is heated up to the reaction temperature within 15 min. in an electric furnace and thereafter kept at that temperature for various periods; then it is quenched to room temperature within 5 min. The residues produced consist of grains of boehmite and/or corundum. The grains are washed with dilute hydrochloric acid and then with pure water, and dried at 110°C.

**The Determination of the Reaction Rates.**—The reaction rates of corundum formation are determined by measuring the ignition loss of the residues. The percentage of boehmite in a residue is calculated from the difference in weight before and after the residue has been heated at 1000°C for 1 hr. in air. In the present work, the ignition loss of boehmite treated at the temperature of 435—445°C under a hydrothermal pressure of 1000 atm. was found to be 16.18%, a value which corresponds to $Al_2O_3 : 1.08H_2O$. Boehmite is usually found in a non-stoichiometric form, $Al_2O_3 : (1+x)H_2O$.[4] The present authors will discuss the behavior of the non-stoichiometric water in a later paper.[5]

## Results

The results are shown in Figs. 1 to 5 and are summarized in Table I. The present authors determined the length of the induction period before the onset of the corundum formation by extrapolating the function $f(x, t) \equiv t_x - (t_{2x} - t_x)$ to $x=0$, where $t_x$ indicates the time (hours) required for the formation of corundum by $x$%.

**The Effect of the Initial Amount of Boehmite upon the Reaction Rates of Corundum Formation.**—The reaction rates were first measured under the following conditions: temperature 445°C; the solvent, 0.1 N sodium hydroxide; the pressure, 1000 atm. and the initial amount of boehmite, $B_0$, 1.20 or 3.60 g. without the addition of seed crystals of corundum. Figure 1 shows the results; here A-1 denotes the run of the initial amount of boehmite, $B_0$, 1.20 g., and A-3, that of 3.60 g. We can easily observe that the induction period of A-3 is shorter than that of A-1. The function $f(x, t)$ gives the induction period of the run A-1, 6.6 hr., and that of the run A-3, 2.8 hr. The induction period becomes shorter with the increase the initial amount of boehmite. The curves of the reaction rates after these induction periods are similar, except that a slight retardation of the reaction is noticeable in the curve A-3, especially in the last stage.

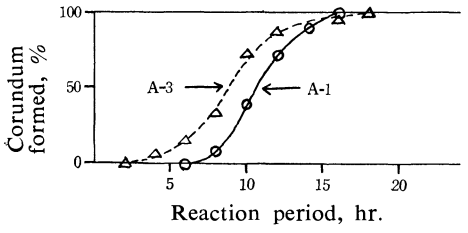

Fig. 1. The reaction rate of corundum formation; 445°C, 1000 atm., 0.1 N NaOH, A-1; $B_0$=1.20 g., A-3; $B_0$=3.60 g., No corundum seed added.

**The Effect of the Alkaline Concentration of the Solvent on the Reaction Rates.**—Next the reaction rates were measured under similar conditions to those of A-1 and A-3; that is, the temperature was 445°C, the pressure, 1000 atm., and the initial amount of boehmite, $B_0$, 1.20 or 3.60 g. without the addition of seed crystals of corundum, though in the present runs the alkaline concentration of the solvent was 1.0 N sodium hydroxide. The results are shown in Fig. 2, in which B-1 denotes the run of the initial amount of boehmite, $B_0$, 1.20 g., and B-3, that of 3.60 g. The induction period of B-3, 1.6 hr., is shorter than that of B-1, 3.6 hr. The induction period also becomes shorter with the increase in the initial amount of boehmite, as is true also in the A runs. The curves after both these induction periods are similar, as was also found in the A runs. Comparing the induction period of A-1 to that of B-1, and the length of A-3 to that of B-3, we find that the induction period becomes shorter with the increase in the alkaline concentration of the solvent.

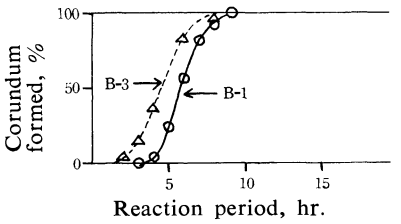

Fig. 2. The reaction rate of corundum formation; 445°C, 1000 atm., 1 N NaOH, B-1; $B_0$=1.20 g., B-3; $B_0$=3.60 g., No corundum seed added.

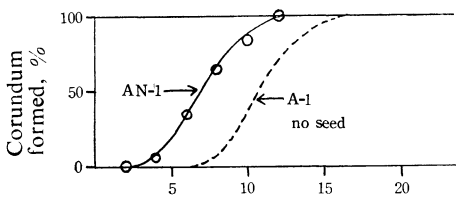

Fig. 3. The reaction rate of corundum formation; 445°C, 1000 atm., 0.1 N NaOH, AN-1 : $B_0$=1.20 g,, corundum seed 1.5 $cm^2$ added.

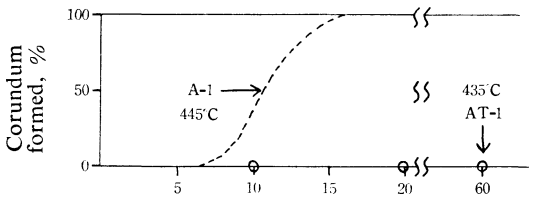

Fig. 4. The reaction rate of corundum formation; 435°C, 1000 atm., 0.1 N NaOH, AT-1 : $B_0$=1.20 g., No corundum seed added.

boehmite. The results are shown in Fig. 3, where they are denoted as AN-1; in this figure the run A-1 without any seeds is also shown as a reference. The seed crystals of corundum do shorten the induction period, 6.6 hr. for A-1 to 3.4 hr. for the present AN-1, but it does not have any remarkable effect upon the reaction rate after the induction period. Although the seed crystals grew by about 0.001 g./$cm^2$ hr. throughout the reaction, most of the grains of corundum were formed separately from the seeds.

**The Effect of the Reaction Temperature on the Reaction Rates without Seed Crystals.**—The residue of the run AT-1, obtained from the hydrothermal treatment of boehmite, initially 1.20 g. without any seed crystals of corundum, in 0.1 N sodium hydroxide under 1000 atm. at 435°C for up to 60 hr., was only boehmite grains. No crystals of corundum could be found with microscopic observation. Boehmite had been completely converted into corundum, however, with treatment similar to that of run A-1 at 445°C for less than 20 hr. The temperature difference, 10°C in the present case, had a remarkable effect on the initiation of corundum formation when no seed crystals of corundum had been added beforehand to the boehmite. The curves of the reaction rate of A-1 at 445°C and the present AT-1 at 435°C are shown in Fig. 4.

**The Effect of the Reaction Temperature on the Reaction Rates with the Addition of Seed Crystals of Corundum.**—The residues of the run ANT-1 obtained from the hydrothermal treatment of boehmite, initially 1.20 g. with addition of the seed crystals of corundum with a surface area of about 1.5 $cm^2$, in 0.1 N sodium hydroxide under 1000 atm. at 435°C and for various reaction periods have shown that the reaction of corundum formation takes place under the present conditions. The curve of the reaction rate of the run ANT-1 is shown in Fig. 5, where that of AN-1 at 445°C is also shown as a reference. The induction period of AN-1, 3.4 hr., has been lengthened to 8.1 hr.

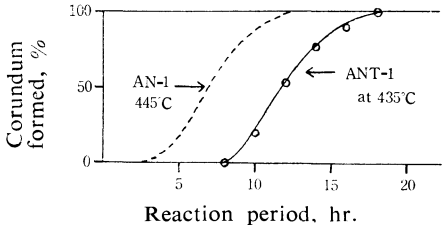

Fig. 5. The reaction rate of corundum formation; 435°C, 1000 atm, 0.1 N NaOH, ANT-1 : $B_0$=1.20 g., corundum seed 1.5 $cm^2$ added.

for the present ANT-1 by lowering the temperature by 10°C. The curve of the reaction rate of the run ANT-1 after the induction period is almost the same as that of the run AN-1. The temperature difference of 10°C had a noticeable effect on the initiation of the corundum formation, but it had no remarkable effect on the propagation of the reaction. The effects of the temperature, however, are different depending on whether or not the seed crystals have been added beforehand. At 435°C the initiation of corundum formation can take place in less than 10 hr. when the seed crystals of corundum have been added beforehand, as in the present ANT-1 run, but the reaction does not take place for up to 60 hr. when the seed crystals have not been added, as in the run AT-1.

## Discussion

With the measurements of the reaction rates of corundum formation under some hydrothermal conditions, we have established the following facts; 1) The induction period becomes shorter with an increase in the initial amount of boehmite (A-1 to A-3, B-1 to B-3). 2) The induction period becomes shorter with an increase in the alkaline concentration of the solvent (A-1 to B-1, A-3 to B-3). 3) The curves of the reaction rates after the induction periods are similar, independently of the initial amount of boehmite (A-1 and A-3, B-1 and B-3). 4) The addition of seed crystals of corundum shortens the induction period (A-1 to AN-1). 5) However, the reaction rates after the induction period are inifluenced by the addition of seed crystals (A-1 to AN-1). 6) When no seed crystals of corundum have been added beforehand, the induction period can be very remarkably lengthened by slightly lowering the reaction temperature. As in the present work without corundum seeds at 435°C, no corundum crystals can be formed from boehmite for up to 60 hr. At that temperature corundum phase is more stable than boehmite (A-1 to AT-1). 7) When seed crystals of corundum have been added beforehand, the induction period can be lengthened by lowering the reaction temperature (AN-1 to ANT-1). 8) The reaction rates after the induction periods are only slightly decreased by lowering the reaction temperature (AN-1 to ANT-1). 9) Although the seed crystals grow through the reaction, most of the grains are formed separately from the seed (AN-1 and ANT-1).

The present authors have proposed the reaction scheme for corundum formation which

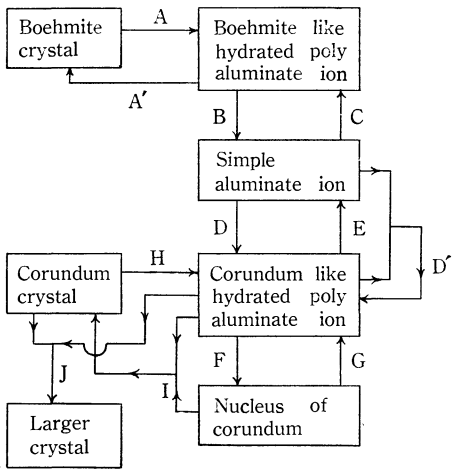

Fig. 6. The reaction scheme for corundum formation under hydrothermal condition.

is shown in Fig. 6, where a new process, D', is added to the previous scheme.[2] The present scheme, with the additional process, D', can explain the results of the reaction of the corundum formation better than the previous one[2] without the D'. The present results seem to support the mechanism.

Before the initiation of corundum formation, processes A, B, D and F should take place successively. The induction periods of the runs A-1, B-1, A-3, B-3 and AT-1, however, correspond to the time required for the onset of process D. The dissolution equation of aluminas under hydrothermal conditions[6] shows that processes A, A', B and C have been substantially in equilibrium when the boehmite grain in the reactor is heated up to the reaction temperatures. The grains of boehmite have a large enough specific surface area. Fact 1), therefore, shows that boehmite grains have a slight catalytic behavior in process D. On the basis of the dissolution equation, we can say that fact 2) is not due to the different times required for attaining the equilibrium in processes A, A', B and C. This may indicate that the concentration of simple aluminate ions in the liquid, not the relative concentration nor the supersaturation ratio, but the absolute one, determines the rate of process D. Fact 4) shows that the corundum grains added beforehand as seed crystals act as an effective catalyst for process D. The seed crystal supplies the corundum-like hydrated poly ions through process H. In the presence of the corundum-like hydrated poly ions in a solution, process D seems to take place easily. Note here that the corundum-like hydrated poly ion is characterized by a structure in which two adjacent aluminum ions are joined through

6) G. Yamaguchi, H. Yanagida and S. Soejima, This Bulletin, 35, 1789 (1962).

three oxygen atoms, as in the lattice of corundum. Interaction between the active sites of the poly ions and the simple aluminate ions may give new poly ions through process D' more easily than interaction among the simple ions themselves through process D. Fact 6) shows that a high reaction barrier exists against process D. Fact 7), on the other hand, shows that the barrier can be easily passed through another process, D', when the poly ions are supplied according to process H. Facts 6) and 7), therefore, may mean that the activation energy of process D is considerably higher than those of processes D', F, or H. In the runs when the seed crystals have been added beforehand, process D' or F may become the rate-determinant. Process F indicates a nucleation process through the further polymerization of the poly ions ; through it, the new crystal of corundum becomes precipitated separately from the seed. Process F, therefore, causes fact 9). After the induction periods, some of the runs show similar curves of the reaction rates, as can be seen in facts 3), 5) and 8), where corundum grain newly produced also becomes a new seed which supplies the poly ions through process H and process D is replaced by process D'. Fact 8) shows that the activation energy of the rate-determinant process after the induction periods is considerably lower than those before the onset of new corundum formation.

## Summary

The authors have measured the reaction rates of corundum formation from boehmite under some hydrothermal conditions for the purpose of discussing the reaction mechanism. They have proposed that, in such cases as the crystallization of corundum or boehmite, there exists the hydrated poly ion of the structure intimately related to the lattice of the product phase and that the formation process often becomes the rate-determinant if no seed crystals of the product phase have been added beforehand. The seed crystal supplies the poly ions which accelerate the simple ions to transform themselves into the poly ions. The mechanism has been illustrated schematically and discussed in detail.

# Rearrangements of Tertiary Amine Oxides. XIII.* The Reactions of *p*-Nitrobenzenesulfenyl Chloride with Pyridine- and $\alpha$-Picoline *N*-Oxides

By Shigeru OAE and Katuyata IKURA

(Received June 26, 1964)

Since it was discovered in Professor Ochiai's Laboratories that the reaction between pyridine *N*-oxides and acetic anhydride leads to the formation of 2-acetoxypyridine,[1] many investigations have been made of the reactions between heteroaromatic *N*-oxides and acylating agents.[2]

Recently, by the aid of the $^{18}O$ tracer technique, the mechanistic features of these reactions have gradually been uncovered and it has become quite clear that one cannot draw any single common mechanistic scheme which can explain all these apparently similar reactions. The nature of the reaction may differ with the variation in *N*-oxides and in acylating agents and also in other reaction conditions, such as the change in solvent. For example, 2-picoline *N*-oxide has been considered to react with acetic anhydride via a free radical cage process,[3] while its isomer, 4-picoline *N*-oxide, apparently undergoes a nucleophilic SN2'-type replacement with the same reagent.[4] The reaction between pyridine *N*-oxide and acetic anhydride has been presumed to proceed through the initial nucleophilic addition of acetate ion at the $\alpha$-position to give $\alpha$-acetoxypyridine.[5]

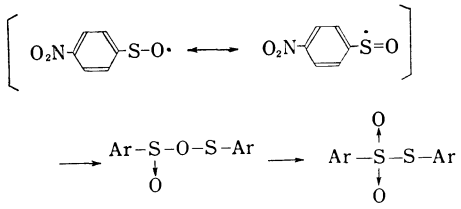
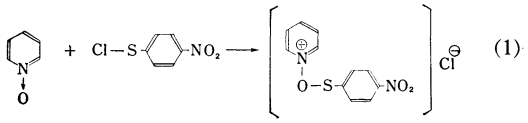
An especially interesing reaction is that of pyridine- or isoquinoline *N*-oxide with *p*-toluenesulfonyl chloride. Here, the mechanism, suggested as the result of $^{18}O$ tracer experiments, is very unusual and involves an intramolecular rearrangement via the $\alpha,\gamma$-intimate ion pair, as is shown below.[6]

The unique feature of this reaction may arise either in the intrinsic nature of sulfur-oxgen linkages or merely in the different bond strength of the acylated N–O bond. Thus, we have attempted to find some important information on the influence of the nature of sulfur-oxygen linkages on these reactions by reacting *N*-oxides of pyridine bases with arylsulfenyl and arylsulfinyl chlorides. This paper will deal with the reactions of *p*-nitrobenzenesulfenyl chloride with pyridine and α-picoline *N*-oxides.

## Results and Discussion



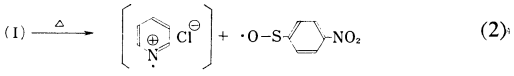
When equivalent amounts of pyridine *N*-oxide and *p*-nitrobenzenesulfenyl chloride were mixed in a benzene solution, colorless crystalline precipitates were formed immediately, with an evolution of heat. The crystals apparently has following structure (I); this structure is very hygroscopic, but it can readily be converted to its perchlorate, which has the correct analytical composition.



(I)

The salt I obtained after the thorough removal of the solvent benzene in a vacuum line was sealed in an ampoule; the ampoule was then heated at 150—160°C for five hours. It began to melt at around 80°C, at which point also color began to be formed, and at around 150°C the mixture became a dark, oily mass. Among the reaction products isolated were pyridine, *p*,*p*'-dinitrodiphenyl disulfide, *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate and *p*-nitrobenzenesulfonic acid; these ingredients constituted more than 85% of the product mixture. Neither a ring-substituted rearrangement product nor unreacted pyridine *N*-oxide was found among the products. The evolution of hydrogen chloride was not observed when the salt was heated in an open vessel, unlike as in the case of pyridine *N*-oxide with tosyl chloride or *p*-nitrobenzoyl chloride.[7]

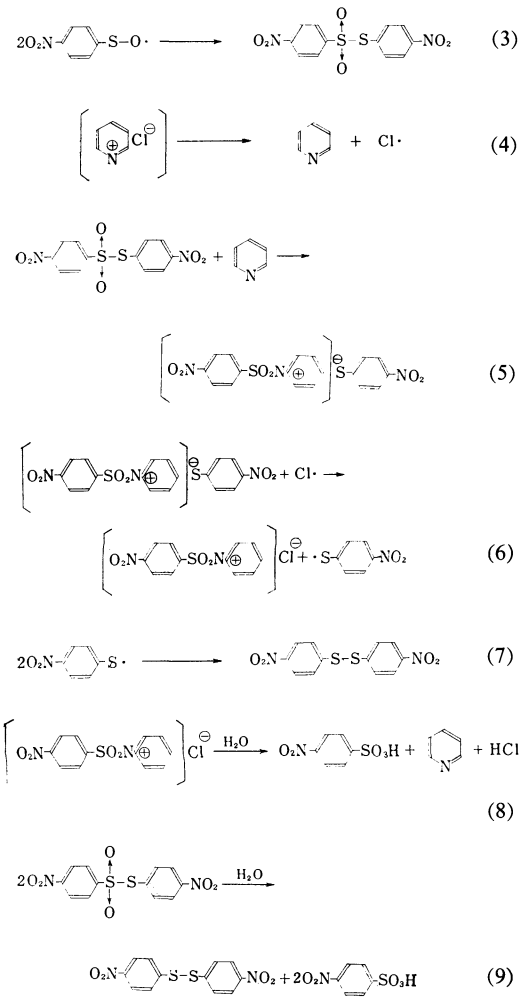
If the reaction followed a path similar to that of pyridine *N*-oxide with tosyl chloride, one would expect some pyridine ring-substituted compound among the products mixture, for the heterolytically-cleaved species, presumably nitrobenzenesulfinate ions, is considered to be more nucleophilic than tosylate and, hence, to react more readily with the other cleaved partner, 2-chloro-2-hydropyridinium cation, to give perhaps the sulfinyl product. On the other hand, if the N–O bond is assumed to cleave homolytically, the resulting radical, *p*-nitrosulfinyl, may not recombine with the other partner to give any pyridine ring-substituted compound, since the radical has been known to be quite stable, due to the electron-sharing 3d orbital resonance, as is shown below,[8] and to dimerize readily eventually yielding *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate.[9]



The lack of any heteroring-substituted product, together with the formation of *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate, seems to favor the homolytic cleavage of the N–O bond of the salt I. Thus, the over-all reaction scheme may be formulated as is shown below:

(1)

(I)



(2)

7) Our preliminary experiment suggests that *p*-nitrobenzoyl chloride reacts with pyridine *N*-oxide and similarly gives 3-acyloxypyridine as the main product.

(3)

(4)

(5)

(6)

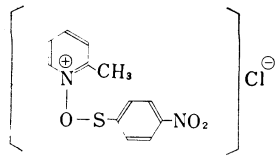
(7)

(8)

(9)

The clear-cut ESR signals seen[10] during and shortly after the reaction also appear to suport the free radical mechanism.

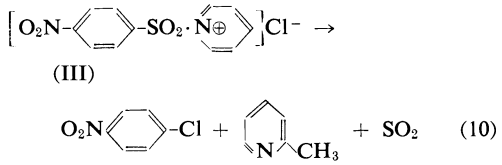
Previously it was shown that the *p*-nitrobenzenesulfinyl radical, once formed, readily dimerized to give stable *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate. However, the amount of this compound actually isolated was rather small as compared to those of the disulfide and *p*-nitrobenzenesulfonic acid. The latter two compounds were perhaps formed through steps 5—8.



When *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate was reacted with pyridine and the reaction mixture was quenched with water, both *p*-nitrobenzenesulfonic acid and *p*, *p'*-dinitrodiphenyl disulfide were actually obtained in substantial yields. Exactly the same compounds were also obtained when a mixture of the thiolsulfonate and pyridine hydrochloride was heated at 150°C and then quenched with water.

Some of the thiolsulfonate probably suffered hydrolysis during the treatment and was disproportionated to the disulfide and the sulfonic acid according to step 9.

Previously there was a case where the use of a solvent did change the reaction pathway. However, in this reaction of pyridine *N*-oxide with *p*-nitrobenzenesulfenyl chloride, the use of xylene as the solvent did not change the pattern of the reaction; it yielded essentially the same products.



The same reaction was applied to $\alpha$-picoline *N*-oxide to see if the presence of the $\alpha$-methyl group would change the nature of the reaction as with acetic anhydride.

In this case, too, as soon as equimolar amounts of $\alpha$-picoline *N*-oxide and *p*-nitrobenzenesulfenyl chloride was mixed in a benzene solution, white crystalline precipitates formed, with an evolution of heat. The hygroscopic crystals were changed to its perchlorate, which was found by analysis to have the correct composition as derived from the salt, II.

(II)

The reaction conditions were nearly the same as in the case of pyridine *N*-oxide. Here again no detectable amount of any heteroring-substituted product was obtained among the reaction products. There was only one difference; that is, the formation of *p*-nitrochlorobenzene was observed in this case. Otherwise, the pattern product distribution was almost the same. Therefore, reaction also seems to proceed via the homolytic cleavage of the N–O bond of the salt II and the overall reaction scheme is considered to be very similar to the one previously obtained with pyridine *N*-oxide.

(III)

(10)

The formation of *p*-nitrochlorobenzene may be explained when one considers that this compound was formed through step 10, involving the nucleophilic attack of the chloride anion on the complex III.

10) A detailed study along this line is now underway by the group headed by Professor W. F. Forbes.

Indeed, *p*-nitrochlorobenzene was actually obtained when the mixture of *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate and α-picoline hydrochloride was heated at around 150°C. The formation of *p*-nitrochlorobenzene in this case and not with pyridine *N*-oxide is fascinating; however, we have no way at present to explain it.

Apparently the overall pattern of the reaction was not much changed by the substitution of the α-methyl group. Even in alkaline conditions, where it was anticipated that the proton of the α-methyl group wolud be abstracted by base to form possibly an anhydrobase, there was no formation of any detectable amount of heteroring-substituted product. Thus, the reaction of the salt II in the presence of sodium ethoxide in ethanol was found to yield nearly the same compounds.

## Experimental

**Material.** — *Pyridine N-Oxide.* — Pyridine *N*-oxide was prepared by the oxidation of pyridine with hydrogen peroxide in glacial acetic acid, following the procedure used by Ochiai.[11]

B. p. 150—153°C (24 mmHg); lit.[11] 138—144°C (15 mmHg).

*Picoline N-Oxide.*—This *N*-oxide was also prepared by the same method.

B. p. 108—109°C (9 mmHg); lit.[12] 123—124°C (15 mmHg).

*p-Nitrosulfenyl Chloride.*—At first, *p, p'*-dinitrodiphenyl disulfide was prepared from sodium sulfide, sulfur,and *p*-nitrochlorobenzene,[13] m. p. 179~180°C (recrystallized from xylene) (lit.[13] 181°C).

Then this disulfide was chlorinated with dry chlorine gas in chloroform at room temperature until the solution turned yellow. The solvent was distilled off in a vacuum to obtain the chloride, m. p. 49—51°C (lit.[13] 52°C).

**The Reaction of Pyridine *N*-Oxide with *p*-Nitrobenzenesulfenyl Chloride.**—The benzene solutions of both pyridine *N*-oxide (1.00 g.) and *p*-nitrobenzenesulfenyl chloride (2.00 g.) were mixed at 10°C; then the solvent was distilled off and the crystalline residue was sealed in a vaccum line. This salt was heated at 150—160°C for five hours. It began to melt at around 80°C and turned dark red, while at around 150°C the reaction mixure became a dark, oily mass. After the reaction had been completed, dilute hydrochloric acid was added and the mixture was extracted with chloroform.

The removal of the solvent gave *p, p'*-dinitrodiphenyl disulfide (1.15 g.) and a mixture of *p, p'*-dinitrodiphenyl disulfide and *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate (0.30 g.), m. p. 178—179°C and 154—155°C respectively.

The presence of *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate was confirmed by the use of infrared spectra.

The aqueous layer was made neutral with sodium carbonate and extracted with chloroform. The removal of the solvent gave a colored liquid; then the residual liquid was converted into picrate. From its melting point and infrared spectrum, this picrate was confirmed to be the picrate of pyridine (0.67 g.), m. p. 164—165°C (lit.[14] 167°C).

Then, a 10% ethanol solution of benzylisothiourea hydrochloride salt was added to the aqueous mother solution from which pyridine had already been recovered, and the crystals thus precipitated was collected and recrystallized from a water-ethanol mixture. This was confirmed by elemental analysis, mixed melting point, and infrared spectra to be thiuronium salt of *p*-nitrosulfonic acid (0.21 g.), m. p. 205—206°C.

Found: N, 9.20. Calcd. for disulfide $C_{12}H_8N_2O_4S_2$: N, 8.92%.

Found: C, 45.71; H, 4.20; N, 11.78. Calcd. for thiuronium salt: C, 45.52; H, 4.09; N, 11.37%.

**The Isolation of 1-*p*-Nitrobenzenesulfinylpyridinium Perchlorate.** — In a separate experiment the hygroscopic crystalline precipitate obtained by reacting 0.5 g. of *p*-nitrobenzenesulfenyl chloride on 0.25 g. of pyridine *N*-oxide was treated with 0.43 g. of 60% perchloric acid at 0°C. The colorless crystals which precipitated immediately were washed well with water and dried; m. p. 160—170°C with decomposition.

Found: C, 40.09; H, 2.63; N, 8.04. Calcd. for $C_{11}H_9N_2O_7SCl$: C, 41.33; H, 2.58; N, 8.03%.

**The Reaction of α-Picoline *N*-Oxide with *p*-Nitrobenzenesulfenyl Chloride.**—α-Picoline *N*-oxide (1.00 g.) and *p*-nitrobenzenesulfenyl chloride (2.00 g.) were used. The reaction conditions and the treatment of the reaction products were exactly the same as in the case of pyridine *N*-oxide. The products from the chloroform layer were *p, p'*-dinitrodiphenyl disulfide (1.2 g.), *p*-nitrochlorobenzene (0.08 g.), and a mixture of *p, p'*-dinitrodiphenyl disulfide and *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate (0.08 g.); m. p. 165—169°C. From the aqueous layer, α-picoline (0.62 g.), (picrate m. p. 160—163°C; (lit.[15] 164°C)) and *p*-nitrosulfonic acid (0.20 g.) (m. p. 204—205°C (thiuronium salt)) were obtained.

**The Isolation of 1-*p*-Nitrobenzenesulfinyl-2-picolinium Perchlorate.** — In a separate experiment the hygroscopic crystalline precipitate obtained by reacting 0.5 g. of *p*-nitrobenzenesulfenyl chloride on 0.25 g. of α-picoline *N*-oxide was treated with 0.42 g. of 20% perchloric acid at 0°C. The colorless crystals which precipitated immediately were washed well with water and dried; m. p. 128—150°C with decomposition.

Found: N, 8.43. Calcd. for $C_{12}H_{11}N_2O_7SCl$: N, 7.76%.

The slight discrepancy in the elemental analysis for salt II may be due to the instability of the salt, which could not be purified by recrystallization.

**The Reaction of Pyridine *N*-Oxide with *p*-Nitrosulfenyl Chloride in Xylenen.** — The salt I (3 g.) was placed in dry xylene (10 ml.) and refluxed

11) E. Ochiai, *J. Org. Chem.*, **18**, 534 (1953).
12) V. Boekelheide and W. J. Linn, *J. Am. Chem. Soc.*, **76**, 1286 (1954).

15) Ibid., Vol. 16, Asakura, Tokyo (1959), p. 12.

for 5 hr. The reaction products were *p*, *p*'-dinitrodiphenyl disulfide (1.56 g.), *p*-nitrobenzenesulfonic acid (0.25 g.) and pyridine (0.61 g.).

**The Reaction of Salt II with Sodium Ethoxide in Ethanol.** — Sodium (0.26 g.) was added to anhydrous ethanol (10 ml.) and dissolved. Then the salt II (3 g.) was added at room temperature and warmed at 40°C for two hours. Finally the mixture was refluxed for three hours. The products isolated were *p*, *p*'-dinitrodiphenyl disulfide (0.91 g.), a mixture of *p*, *p*'-dinitrodiphenyl disulfide and *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate (0.65 g.), and α-picoline (0.61 g.).

All the compounds were identified by mixed melting point, infrared spectra, and elemental analyses.

**Summary**

In the reactions of both pyridine and α-picoline *N*-oxides with *p*-nitrobenzenesulfenyl chloride, the N–O bonds of the intermediate salts appear to cleave homolytically, and the *p*-nitrosulfinyl radical which arises from the homolytic cleavage of the N–O bond is considered to be so stable that only the secondary reaction products from the sulfinyl radical, and no heteroring-substituted products, were obtained.

# The Mechanism of the Base-Promoted Rearrangement of *N*, *N*-Dichlorodiphenylethylamine to Desylamine

By Shigeru OAE and Naomichi FURUKAWA

(Received June 26, 1964)

Some years ago, Baugarten and his coworkers showed that the treatment of *N*, *N*-dichlorodiphenylethylamine with sodium methoxide, followed by that with aqueous hydrochloric acid, gave desylamine hydrochloride in a substantial yield.[1] They then successfully extended this remarkable reaction to various *N*, *N*-dichloro-*s*-alkylamines.[2] A similar rearrangement of *N*, *N*-dichlorocyclohexylamine to 2-aminocyclohexanone hydrochloride has also recently been reported.[3]

The following mechanism has been suggested for this reaction (Fig. 1):

Although this mechanism appears to be valid and although it is essentially the same as that of Neber Rearrangement of the corresponding oxime tosylate which was proposed earlier by Cram and Hatch,[4,5] there is no unequivocal evidence to support it. Meanwhile, since *N*-chloro compounds are known to halogenate the benzylic methylene group very readily,[6] and since the resulting halogenated benzylic compound would undergo a facile hydrolysis,[7] one can postulate another possible mechanism, namely, one involving the initial *gem*-dichlorination of 2-methylene and the subsequent hydrolysis, thus giving product as is shown below (Fig. 2).

One noticeable difference between these two mechanisms is that the former involves the 1, 2-migration of the amino group, while in the later the amino group remains in the original position.

Recently, an *N*-chloroimine intermediate similar to II was actually isolated in the case of *N*, *N*-dichlorocyclohexylamine;[3] also, the formation of the azirine ring III was strongly supported by the successful isolation of *cis*-2, 3-diphenylethyleneimine in the reduction of the reaction mixture of *N*, *N*-dichloro-1, 2-diphenylethylamine with lithium aluminum hydride.[2]

These two pieces of evidence seem to support very strongly the former mechanism, involving the 1, 2-migration of the amino group via the formation of the azirine ring. However, in strong alkaline conditions such as sodium methoxide in the methanol used in this

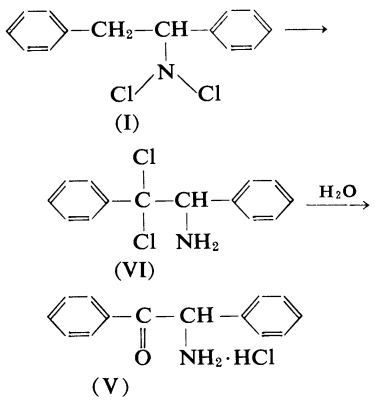

Fig. 2

reaction, one must also take into account the possibility of facile prototropy,[8] as is shown below (Fig. 3).

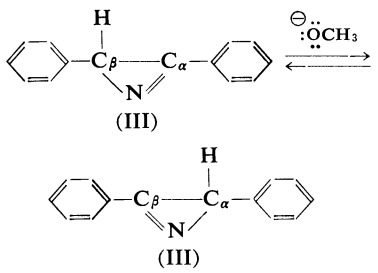

Fig. 3

If there were facile prototropy in III before the nucleophilic cleavage, the nucleophilic attack of the methoxy group could take place at both carbon atoms, $C_\alpha$ and $C_\beta$, with equal probability, yielding a fifty-fifty mixture of both 1,2-shifted and unshifted aminoketones.

All these unresolved problems can be readily answered by tracing the fate of a labeled carbon atom placed either at the $\alpha$ or the $\beta$-position of the original *N,N*-dichloro-1,2-diphenylethyl amine in the rearrangement.

Thus, *N,N*-dichloro-1,2-diphenylethylamine-1-$^{14}$C has been synthesized, and a series of succesive degradations has been carried out. This paper will present detailed accounts of the results and implications of these experiments.

The synthetic and degradative methods of $^{14}$C labeled desylamine may be shown as follows (Fig. 4).

## Experimental

**The Preparation of the *N,N*-Dichloro-1,2-diphenylethylamine-1-$^{14}$C.** — Phenylacetic acid-1-$^{14}$C[9] (VIII) was obtained by the carbonation of benzylmagnesium bromide which had been prepared from 1.3 g. of magnesium and 6.3 g. of benzylchloride with $^{14}CO_2$ which had been generated from 7.0 g. (1.0 mc.) of barium carbonate. The yield was 4.3 g. in 63%; m. p. 76°C.

Phenylacetic acid-1-$^{14}$C (4.3 g.) was converted to phenylacetyl chloride (IX) by treating it with 3 g. of phosphoroustrichloride; the phenylacetyl chloride thus prepared was then treated with 3.8 g. of aluminum chloride in a benzene solution. From the reaction mixture deoxybenzoin-1-$^{14}$C[10] (X) (4.3 g.) was obtained in a 75% yield; m. p. 56°C.

When deoxybenzoin-1-$^{14}$C (4.3 g.) was then allowed to react with a mixture of 6 g. of ammonium formate and 1 ml. of formic acid, 1,2-diphenylethylamine-$^{14}$C[11] (3.7 g.) was obtained in a 85% yield; b. p. 143°C/2.4 mmHg.

1,2-Diphenylethylamine-1-$^{14}$C (3.7 g.) was chlorinated with 5.5 g. of *t*-butylhypochlorite in dry benzene. The *N,N*-dichloro-1,2-diphenylethylamine-1-$^{14}$C[2] thus obtained was not isolated; the solution was used directly for the preparation of desylamine hydrochloride-*x*-$^{14}$C, as in the experiments of previous workers.[2]

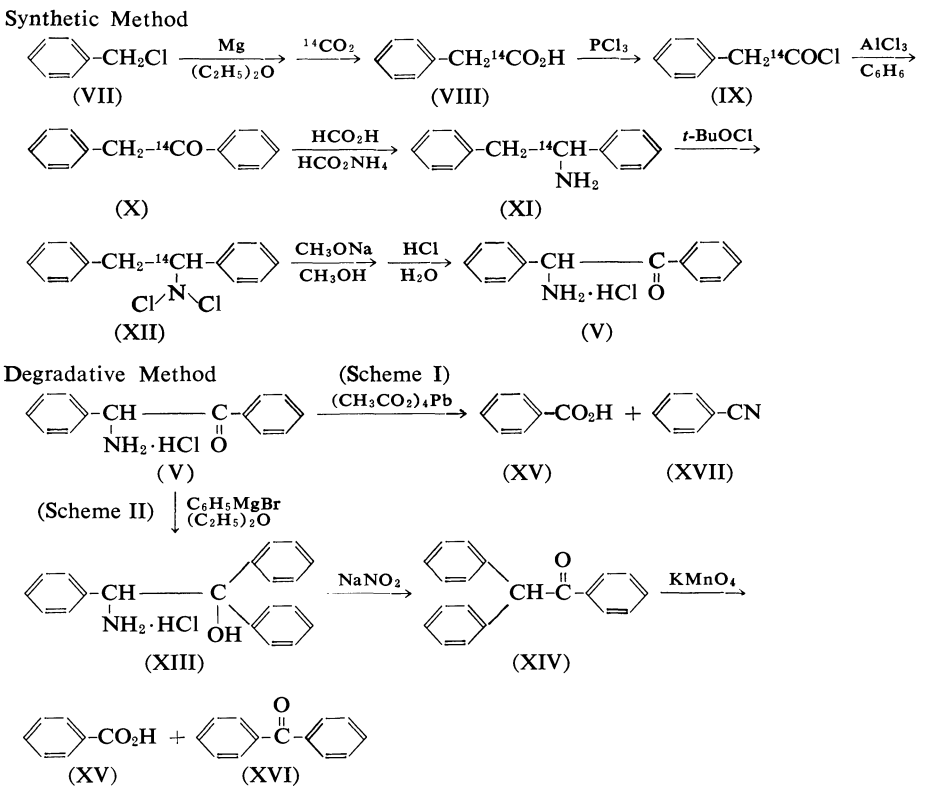

Fig. 4

**The Rearrangement of *N,N*-Dichloro-1,2-diphenylethylamine-1-$^{14}$C.** — The rearrangement of *N,N*-dichloro-1,2-diphenylethylamine-1-$^{14}$C was carried out following the procedure used previously.[2] Namely, the benzene solution of *N,N*-dichloro-1,2-diphenylethylamine-1-$^{14}$C prepared from 3.7 g. of 1,2-diphenylethylamine was treated in situ with 25 ml. of a methanol solution in which 2.5 g. of sodium had been dissolved. The yield was 1.7 g. (36%); m. p. 234°C.

**The Degradation of Desylamine-*x*-$^{14}$C.** — *Degradation Scheme I.* — In a 100 ml. three-necked flask equipped with a mechanical stirrer and a reflux condenser, 3.0 g. of desylamine hydrochloride-*x*-$^{14}$C was suspended in 50 ml. of dried benzene. To this mixture 10 g. of freshly prepared lead tetraacetate was added portion by portion, and then the mixture was heated for 2 hr. on a steam bath. After the mixture had cooled, the precipitated lead acetate was filtered off and washed with small portions of benzene. The combined benzene solution was extracted twice with 20 ml. of a 10% sodium carbonate solution. The aqueous extracts was acidified with concentrated hydrochloric acid. A white crystalline precipitate was thus obtained. Recrystallization from hot water gave hair-like crystals. These were identified as benzoic acid XV by a mixed melting point determination with authentic benzoic acid and by a study of the infrared spectrum. The yield was 1.0 g. (67.5%). The benzene solution was then evaporated and the residual oily substance (1.5 g.) distilled under reduced pressure to give benzonitrile XVI, which was identified by comparing its infrared spectrum with that of authentic benzonitrile. The yield was 0.3 g. (24%).

*Degradation Scheme II.*[12] — To a Grignard reagent prepared from 16 g. of bromobenzene and 2.4 g. of magnesium, 4.0 g. of powdered desylamine hydrochloride-*x*-$^{14}$C was added; 1,1,2-triphenyl-1-hydroxyethylamine hydrochloride-*x*-$^{14}$C was thus obtained in a 85% yield (4.5 g.).

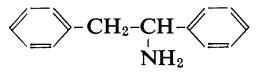
1,1,2-Triphenyl-1-hydroxy-ethylamine hydrochloride-*x*-$^{14}$C (XIII) (4.5 g.) was deaminated by diazotization with 2.0 g. of sodium nitrite, followed by the migration of the phenyl group. Phenyldeoxybenzoin-*x*-$^{14}$C (XIV) was thus obtained (1.1 g.) in a 26% yield; m. p. 130—131°C.

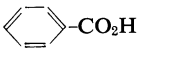
The deoxybenzoin-*x*-$^{14}$C (0.25 g.) thus obtained was oxidized with 1.0 g. of potassium permanganate at room temperature; thus 50 mg. of benzoic acid (45%) and 0.17 g. of benzophenone (51%) were obtained. The benzoic acid XV was identified by mixed melting point determination. The benzophenone XVI thus obtained was derived to its 2,4-dinitrophenylhydrazone (m. p. 239°C).

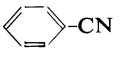
**The Measurement of the Activities.**—*Scheme I.*— The activities of the $^{14}$C which were distributed in the compounds were measured by using a Packard-liquid scintilation spectrometer model 500B, Tricarb. The purified 1,2-diphenylethylamine-1-$^{14}$C

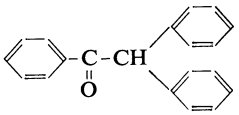
12) J. G. Burr, *J. Am. Chem. Soc.*, **75**, 1990 (1953); W. A. Bonner and C. J. Collins, ibid., **75**, 5372 (1953).

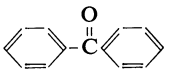
TABLE I. THE $^{14}C$ COUNTING OBTAINED IN SCHEME I











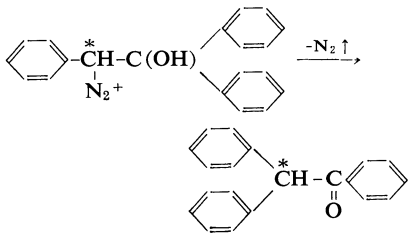
| |  |  |  |
|---|---|---|---|
| c. p. m./mmol. | $4.00\times10^5$ | $2.75\times10^5$ | $3.52\times10^3$ |
| % | (100%) | (68.8%) | (0.37%) |

TABLE II. THE $^{14}C$ COUNTING OBTAINED IN SCHEME II

| |  |  |  |
|---|---|---|---|
| c. p. m. | 1712 | 1663 | 19 |
| % | (100%) | (97.8%) | (1.1%) |
| c. p. m. | 1692 | 1656 | 15 |
| % | (100%) | (97.9%) | (0.90%) |

was chosen as a standard for the original total activity. The counting methods were as follows. Three samples, namely, 4.985 mg. of 1,2-diphenylethylamine-1-$^{14}C$, 3.176 mg. of benzoic acid, and 9.958 mg. of benzonitrile, were dissolved separately in 20 ml. each of toluene containing POP and POPOP as scintilators; then they were subjected to a Packard Tri-carb. The data obtained are shown in Table I.

*Scheme II.* — The measurements of the activities of the samples were carried out in this case by a JRC Aloka $2\pi$-gas flow proportional counter using Q-gas. Phenyl deoxybenzoin-*x*-$^{14}C$ was used as the standard sample of the total activity. A known amount of a sample was thoroughly oxidized by the Van-Slyke method, and all the carbon dioxide formed was converted to a barium carbonate pellet which was then subjected to $^{14}C$ counting. The respective pellets of barium carbonate obtained were, i. e., 158.1 mg. (98%) from phenyldeoxybenzoin (11.4 mg.), 120.5 mg. (96%) from benzoic acid (11.0 mg.), and 110 mg. (94%) from benzophenone-2,4-dinitrophenylhydrazone (11.4 mg). The counting data obtained are shown in Table II.



## Results and Discussion

The results of the degradations of the desylamine-*x*-$^{14}C$ obtained are shown in Tables I and II.

The first scheme of degradation involves the direct oxidation of desylamine hydrochloride with lead tetraacetate to yield benzoic acid and benzonitrile. The latter compound was obtained in rather a poor yield; however, it undoubtedly originated from the $\alpha$-amino benzylic portion of desylamine. It carries only a very small portion of the $^{14}C$ activity (0.87%) of the original activity of desylamine employed.

On the other hand benzoic acid was obtained in a substantial yield; it is the only compound isolated that carries a substantial amount of $^{14}C$ activity. However, its activity was somewhat reduced; e. g., in one experiment, it was 68.8% of that of the desylamine employed. This apparently diminished activity of the benzoic acid is assumed to be caused by the dilution of the $^{14}C$-active benzoic acid formed from the oxidation of the benzyl portion of desylamine with the non-active benzoic acid formed from the hydrolysis of benzonitrile during the treatment. Incidentally, this assumption seems to be quite valid in view of the results of the degradation by the second procedure. The very small amount of $^{14}C$ activity formed in the benzonitrile is quite significant, because it excludes both the $^{14}C$ scrambling that could be expected from the prototropy of the azirine ring III, and the *gem*-dichlorination hydrolysis mechanism. If the reaction were assumed to proceed according to the latter mechanism, all the $^{14}C$ activity would remain in the $\alpha$-amino benzylic carbon and, hence, the benzonitrile would carry the same amount of specific activity as the original amine. This was found not to be the case. Therefore, since it is considered that a portion of the benzoic acid originates in the hydrolysis of benzonitrile, the results of this degradation can serve as strong evidence in support of the mechanism proposed by Baumgarten.

The second degradation scheme is a beautiful product of Collins et al., who have demonstrated unequivocally through a $^{14}C$ tracer experiment that the deamination of 1,1,2-triphenyl-1-hydroxy-ethylamine by diazotization undergoes the following rearrangement:

Therefore, the only uncertainty, if any, is in the step of the reaction between desylamine and phenylmagnesium bromide to give 1, 1, 2-triphenyl-1-hydroxy-ethylaminehydrochloride, however, this step is a straightforward reaction involving the nucleophilic attack of the phenyl Grignard reagent on the carbonyl carbon. Thus, according to this degradative scheme, benzoic acid may be considered to originate from the benzoyl group and benzophenone, from the benzhydryl group. Here again the data indicates that the benzoic acid carries practically all the activity, while benzophenone is incorporated with almost no $^{14}C$ activity.

These data on $^{14}C$ distribution obtained by the second scheme are in accord with those obtained by the first scheme; they clearly exclude any mechanisms involving an initial *gem*-dihalogenation and subsequent hydrolysis, and also that one involving a rapid prototropic equilibrium of the azirine ring.

Therefore, the only remaining plausible mechanism is that suggested previously by Baumgarten et al.; this is essentially the same as that proposed originally by Cram and Hatch for the Neber rearrangement (Fig. 1).

**Summary**

*N*, *N*-Dichloro-1, 2-diphenylethylamine-1-$^{14}C$ has been treated with sodium methoxide in methanol and then with hydrochloric acid to yield $^{14}C$-labeled desylamine hydrochloride. Successive degradations have revealed that practically all the $^{14}C$ activity was found in the carbonyl carbon. From the $^{14}C$ distribution, it has been concluded that the reaction is essentially the same as that proposed for the Neber rearrangement, which involves the formation of the azirine ring intermediate.

# Studies of Mixed Cyano Cobalt(III) Complexes. I. The Cyano-Diamine Series

By Kuwako OHKAWA, Junnosuke FUJITA and Yoichi SHIMURA

(Received June 29, 1964)

Notwithstanding the strong tendency of cyanide to be coordinated to cobalt(III), a smaller number of mixed cyano cobalt(III) complexes have been known than of mixed ammine complexes. In particular, we know of extremely few cobalt(III) complexes which contain organic amines with cyanide.[1]

In the present paper, the preparation and the properties of mixed cyano complexes of a new type, $M[Co^{III}(CN)_4an]$ (an=en and tn),* which contains only one organic diamine molecule as a chelate ring, will be reported and discussed in comparison with those of the related bis(diamine) complexes, $[Co^{III}(CN)_2an_2]X$ (an=en, pn and tn).*

## Experimental

**Preparation.** — *Potassium Tetracyanoethylenediaminecobalt(III) Monohydrate: $K[Co(CN)_4en]\cdot H_2O$.*— Into a 200 ml. aqueous solution of 10 g. of *t*-$[CoCl_2(NH_3)_2en]Cl\cdot 1/2\,H_2O$,[2] 15 g. of potassium thiosulfate dissolved in 200 ml. of water was stirred. The greenish brown solution obtained was then warmed on a water bath until it gave a brownish red solution. Then 10 g. of potassium cyanide dissolved in 100 ml. of water was stirred drop by drop into this solution. An orange yellow solution evolving ammonia gas was obtained. After this had been warmed on a water bath for a while, it was filtered. The filtrate was concentrated to a volume of about 200 ml. on a water bath; then 18.2 g. of barium chloride dihydrate dissolved in 100 ml. of hot water was added to remove the thiosulfate ions as a precipitate of barium thiosulfate. This precipitate was filtered, and the filtrate was evaporated further to a volume of about 50 ml. and then cooled in ice. The crude orange crystals thus formed were filtered, washed with methanol, and dried in air.

The product of this was dissolved in a minimum amount of water, and about one-fourth the volume of methanol was added. After the mixture had cooled at 0°C for half an hour, the precipitate was removed by filtration. Methanol was added to the filtrate, and the mixture was cooled in ice. The pure

product obtained by repeating the procedure three times was orange-colored crystalline plates which were effloresced on exposure to the air. The crystals freshly dried were analyzed for water of crystallization. The analyses for the other components were performed by using samples dehydrated in vacuo at 80°C.

Found: C, 26.96; H, 3.28; N, 31.10. Calcd. for $C_6H_8N_6KCo=K[Co(CN)_4en]$: C, 27.48; H, 3.18; N, 32.05%.

Found: $H_2O$, 6.42. Calcd. for $K[Co(CN)_4en]\cdot H_2O$: $H_2O$, 6.42%.

*Sodium Tetracyanoethylenediaminecobalt(III) 3.5 Hydrate: $Na[Co(CN)_4en]\cdot 3.5H_2O$.* — This was obtained by almost the same method as the potassium salt described above, using sodium thiosulfate and sodium cyanide.

The recrystallized orange crystals were soluble in methanol; therefore, ethanol was used for precipitation from the aqueous solution after the impurities had been removed by adding methanol.

Found: C, 28.07; H, 3.47; N, 33.29. Calcd. for $C_6H_8N_6NaCo=Na[Co(CN)_4en]$: C, 29.28; H, 3.28; N, 34.15%.

Found: $H_2O$, 20.39. Calcd. for $Na[Co(CN)_4en]\cdot 3.5H_2O$: $H_2O$, 20.39%.

*Dicyanobis(propylenediamine)cobalt(III) Thiosulfate Monohydrate; $[Co(CN)_2pn_2]_2S_2O_3\cdot H_2O$.*—This complex was prepared by almost the same method as that given by Rây and Sarma[1] for the preparation of $[Co(CN)_2en_2]_2S_2O_8\cdot H_2O$.

Into 150 ml. of an aqueous solution of 12.6 g. of *t*-$[CoCl_2pn_2]ClO_4$,[3] 16.6 g. of $Na_2S_2O_3\cdot 5H_2O$ dissolved in 150 ml. of water was stirred. After the green color of the solution had turned to brownish-violet, a 1:2 mixture of methanol and ethanol was added. When the mixture had cooled about 9 g. of bright brownish-violet crystals were formed. These were filtered, washed with methanol, and dried in air. These crystals (perhaps $Na[Co(S_2O_3)_2pn_2]$) were then dissolved in 150 ml. of water, and into the solution 13.2 g. of potassium cyanide dissolved in 150 ml. of water was stirred. The brownish yellow solution obtained was evaporated on a water bath until yellow crystals appeared. These crystals were filtered and recrystallized from hot water or from the aqueous solution by adding methanol.

Found: C, 30.19; H, 6.56; N, 26.21. Calcd. for $C_{16}H_{40}N_{12}O_3S_2Co_2=[Co(CN)_2pn_2]_2S_2O_3$: C, 30.47; H, 6.39; N, 26.66%.

Found: $H_2O$, 3.41. Calcd. for $[Co(CN)_2pn_2]_2S_2O_3\cdot H_2O$: $H_2O$, 3.39%.

*Dicyanobis(trimethylenediamine)cobalt(III) Thiosulfate: $[Co(CN)_2tn_2]_2S_2O_3$.*—To 100 ml. of an aqueous solution of 3.2 g. of *t*-$[CoCl_2tn_2]Cl$,[4] 5 g. of $Na_2S_2O_3\cdot 5H_2O$ dissolved in 50 ml. of water was added with continuous stirring, and then after ten minutes 50 ml. of an aqueous solution of 1 g. of potassium cyanide was added. The solution was concentrated on a water bath until crude dark yellow crystals began to appear. The crystals recrystallized from hot water were yellow and anhydrous.

Found: C, 30.15; H, 6.41; N, 26.99. Calcd. for $C_{16}H_{40}N_{12}O_3S_2Co_2=[Co(CN)_2tn_2]_2S_2O_3$: C, 30.47; H, 6.39; N, 26.66%.

*Trinitroamminetrimethylenediaminecobalt(III): $[Co(NO_2)_3(NH_3)tn]$.*—A mixture containing 10 g. of *m*-$[Co(NO_2)_3(NH_3)_3]$ and 30 ml. of a 10% aqueous solution of trimethylenediamine was heated gently on a free flame. After the evolution of ammonia gas had ended, the unreacted materials were separated by filtration. The filtrate was concentrated on a water bath until brownish-red needle crystals were formed. The crude crystals were then recrystallized from hot water containing a few drops of acetic acid.

Found: C, 12.73; H, 4.70; N, 30.83. Calcd. for $C_3H_{13}N_6O_6Co=[Co(NO_2)_3(NH_3)tn]$: C, 12.51; H, 4.55; N, 29.17%.

*Dichloroaquoamminetrimethylenediaminecobalt(III) Chloride Monohydrate: $[CoCl_2(OH_2)(NH_3)tn]Cl\cdot H_2O$.* Finely powdered $[Co(NO_2)_3(NH_3)tn]$ was dissolved in concentrated hydrochloric acid by warming it on a water bath. After the evolution of gas had ceased, a dark green solution was obtained; this was then cooled in ice. The dark green crystals thus obtained were filtered, washed with alcohol, and dried in air.

Found: C, 12.61; H, 6.19; N, 13.98. Calcd. for $C_3H_{15}N_3OCl_3Co\cdot H_2O=[CoCl_2(OH_2)(NH_3)tn]Cl\cdot H_2O$: C, 12.32; H, 5.86; N, 14.37%.

*Barium Tetracyanotrimethylenediaminecobalt(III) Tetrahydrate: $Ba[Co(CN)_4tn]_2\cdot 4H_2O$.*—To 200 ml. of an aqueous solution of 10 g. of $[CoCl_2(OH_2)(NH_3)tn]Cl\cdot H_2O$, 18.1 g. of $Na_2S_2O_3\cdot 5H_2O$ dissolved in 100 ml. of water was added, and then 7.2 g. of sodium cyanide in 150 ml. of water was stirred in drop by drop. The brownish yellow solution thus obtained was evaporated on a water bath to a volume of about 100 ml., and then 15 g. of $BaCl_2\cdot 2H_2O$ dissolved in 150 ml. of water was added and the mixture was cooled. After the filtration of barium thiosulfate, the mother liquor was concentrated further until crystals began to appear. These orange yellow crystals were then filtered and recrystallized from hot water.

In this preparation, an excess of barium chloride was used in order to convert potassium salt into the less soluble barium salt. The potassium salt which was prepared by the same method as the ethylenediamine complex was much contaminated by the barium salt.

Found: C, 24.43; H, 4.26; N, 24.91; $H_2O$, 10.32. Calcd. for $C_{14}H_{20}N_{12}BaCo_2\cdot 4H_2O=Ba[Co(CN)_4tn]_2\cdot 4H_2O$: C, 24.60; H, 4.13; N, 24.59; $H_2O$, 10.54%.

**Absorption Measurements.**—A Beckman DU and a Shimadzu QR-50 spectrophotometer were used to obtain visible and ultraviolet absorption spectra in the range from 30 to $150\times10^{13}$ $sec^{-1}$. All the complexes obeyed Beer's law in aqueous solutions in the $1-10^{-5}$ mol./l. range at room temperature. A Hitachi EPI-2G infrared spectrophotometer equipped with a potassium bromide foreprism and a grating double monochrometer was used to obtain infrared spectra in both the Nujol mull and the KBr disk methods.

## Results and Discussion

**The Method of Preparation.**—In general, it has been recognized that the cobalt(III) complexes which coordinate one ethylenediamine molecule besides four unidentate ligands are rather difficult to prepare. The sulfitocomplex ion, $[Co(SO_3)_2(NH_3)_2en]^-$,[2] which is prepared[5] from $[Co(SO_3)_2(NH_3)_4]^-$ and ethylenediamine, is known as a starting material for the preparation of the complexes of this type.[6] The trans isomer of $[CoCl_2(NH_3)_2en]Cl$[2] which was used for the present preparation of tetracyanoethylenediaminecobalt(III) complex was prepared by warming this sulfito complex with hydrochloric acid, but the yield was rather low. The direct reaction of $[CoCl_2(NH_3)_2en]^+$ with cyanide gave no desired complex unless the chloro complex was transformed to the thiosulfato complex $[Co(S_2O_3)_2(NH_3)_2en]^-$. In the present work, the latter complex was not separated. Rây and Sarma[1] have prepared the dicyano complex $[Co(CN)_2en_2]^+$ from the bis(thiosulfato)complex $[Co(S_2O_3)_2en_2]^-$,[7] while Chan et al.[8] have reported that no mixed cyano complex was produced by the direct reaction of $[CoCl_2en_2]^+$ with cyanide in an aqueous solution.

An attempt to isolate a pure tetracyanopropylenediamine complex failed because of

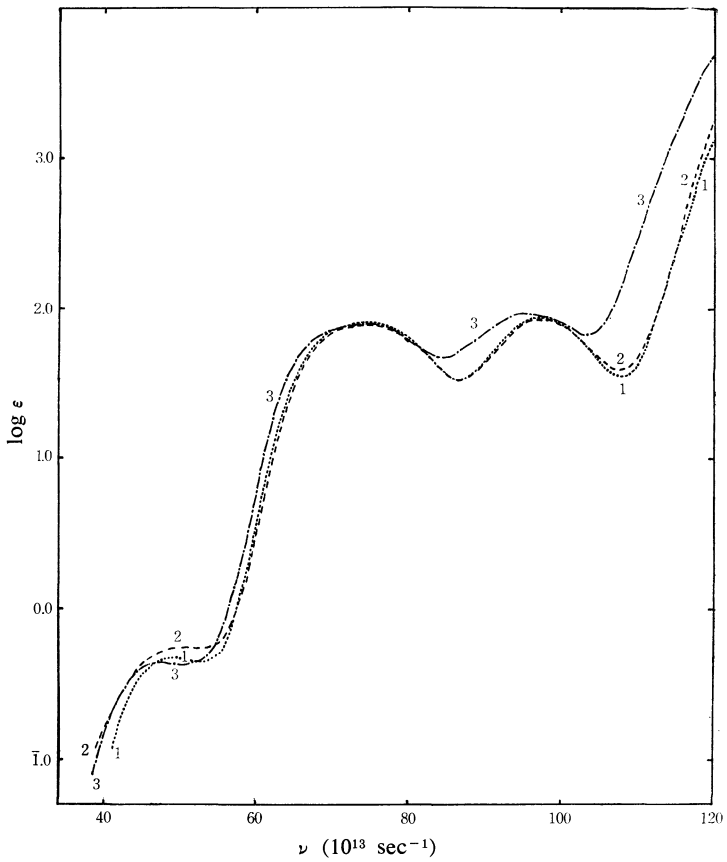

Fig. 3. Absorption curves of *cis*-$[Co(CN)_2an_2]^+$ complexes(thiosulfate).
1 : $[Co(CN)_2en_2]^+$ 2 : $[Co(CN)_2pn_2]^+$ 3 : $[Co(CN)_2tn_2]^+$

the extreme solubility of the complex.

For the preparation of the tetracyanotrimethylenediamine complex, a dark green complex, $[CoCl_2(OH_2)(NH_3)tn]^+$, was employed instead of $[CoCl_2(NH_3)_2tn]^+$, since the purification of the latter was hard.

The method for the preparation of dicyanobis(trimethylenediamine) and dicyanobis(propylenediamine) complexes was a modification of the method of Rây and Sarma described above for the corresponding ethylenediamine complex.

**Visible and Ultraviolet Absorption Spectra.**— Table I lists the numerical data of the absorption maxima of the complexes measured. In the table, the first four absorption bands are assigned to ligand field bands. The last strong band could be attributed to a characteristic absorption caused by the ligands, cyanides and diamines.

In a previous paper,[9] we have discussed the experimental relationships between the ligand field bands of cobalt(III) complexes, which also fit the complexes measured in the present work.

Figure 1 shows that the absorption frequencies of the first and second spin-allowed bands of the cyano-ethylenediamine series shift to shorter wavelengths in proportion to the number of ligand cyanides, as has been observed in the oxalato-ammine series.[10] The same relation is seen in the cyano-trimethylenediamine series. The absorption intensities of these cyano complexes, on the other hand, exhibit no such regular relation. The A bands of the weak spin-forbidden absorptions are observed on the longer wavelength side of the first spin-allowed bands. All the B bands of cyano complexes are hidden by the feet of the strong first bands.

Theoretically, two geometrical isomers, cis and trans, exist in the dicyanobis(ethylenediamine)cobalt(III) ion, but so far only one species has been obtained. Chan et al.[8] determined through the optical resolution that

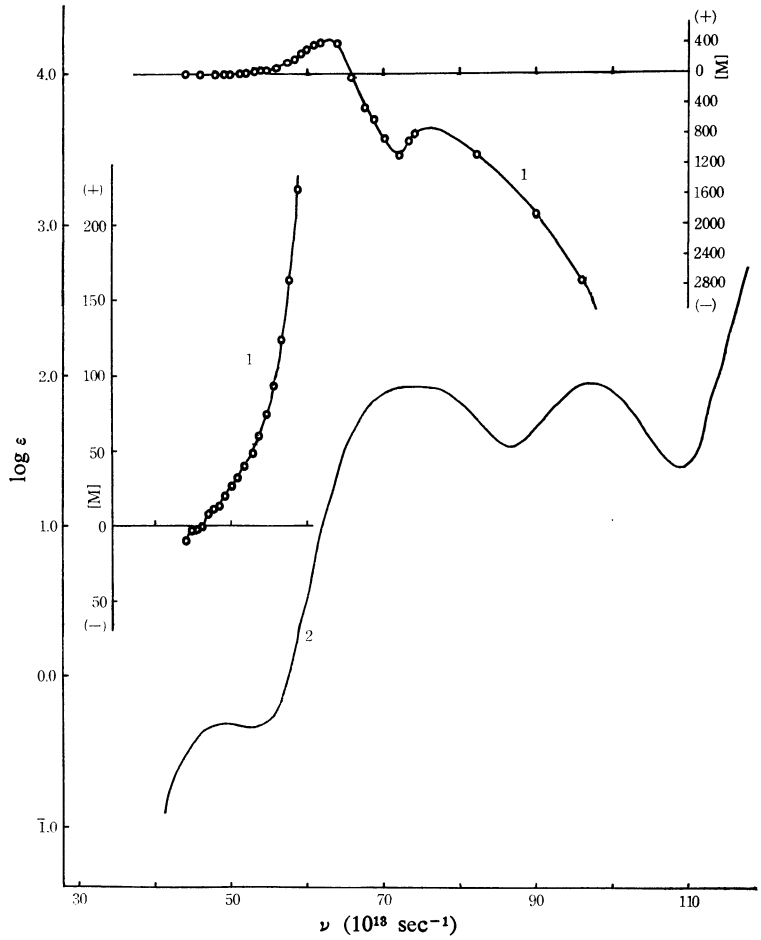

Fig. 4. Rotatory dispersion and absorption curves of $(+)_{546}$-*cis*-$[Co(CN)_2en_2]^+$.
1 Rotatory dispersion curves 2 Absorption curve

this complex takes the cis configuration. The absorption spectra of the dicyanobis(propylenediamine) and dicyanobis(trimethylenediamine) complexes closely resemble the ethylenediamine complex with the cis configuration. It may be concluded, therefore, that all three of the dicyano complexes prepared in this work correspond to the cis isomers.

**The Rotatory Dispersion of** $[Co(CN)_2en_2]^+$. —As has been described above, Chan et al.[8] have resolved the dicyanobis(ethylenediamine) cobalt(III) complex into its optically-active forms through its α-bromocamphor-π-sulfonate. In the present study, we have determined the rotatory dispersion of the $(+)_{546}$-isomer (Fig. 4). It exhibits a positive Cotton effect in the region of the first spin-allowed absorption band. The amplitude of this partial dispersion is as large as those of the same type of cobalt(III) complexes, such as $[CoCl_2en_2]^+$,[11] and $[Co(NO_2)_2en_2]^+$.[12]

It is interesting to note that no remarkable Cotton effect is shown in the region of the A spin-forbidden band of the complex. This might be because the Cotton effects are too weak to be measured, or because this small partial dispersion is hidden by the foot of the dispersion of the first spin-allowed absorption band. Mason[13] reported a very weak circular dichroism band ($\varepsilon_l - \varepsilon_r = +0.008$) in the region of the A spin-forbidden band of the $(+)_D$-$[Co\,en_3]^{3+}$ ion. Kling and Woldbye[14] have found several weak Cotton effects in the spin-forbidden bands of the tris(ethylenediamine) chromium (III) and related complexes.

**Infrared Spectra.**—Figure 5 shows the infrared absorption spectra of the C≡N stretching region for the cyano-diamine complexes. The

8 : *cis*-$[Co(CN)_2tn_2]_2S_2O_3$

complex ion $[Co(CN)_6]^{3-}$ which has an $O_h$ symmetry exhibits only one triply-degenerate C≡N stretching band,[15] while the mixed-diamine complex shows a group of C≡N stretching bands split by the lowering of the symmetry. The complex ion $[Co(CN)_4en]^-$ exhibits three C≡N stretching bands, although the theoretical number of this stretching band is four. The complex ion $[Co(CN)_4tn]^-$ distinctly shows four peaks. The optically-active dicyanobis(ethylenediamine) and racemic dicyanobis(trimethylenediamine) complexes, whose approximate symmetries are $C_{2v}$, exhibit two peaks, while the racemic dicyanobis(ethylenediamine) and dicyanobis(propylenediamine) complexes show no splitting. It is curious that there is a marked difference in the C≡N stretching band between the resolved and the racemic bis(ethylenediamine) complexes.

It is interesting to note that the magnitude of the splitting of the C≡N stretching bands in these cyanodiamine complexes is 1/10 those of the C=O stretching bands in several carbonyl complexes.[16] This suggests that the character of the bonding between the cyanide and the cobalt(III) ion in the former complexes would be considerably weak compared with that between the carbon monoxide and the metal atom in the latter ones.

## Summary

Several new mixed cyano-diamine complexes, $M[Co(CN)_4en]\cdot xH_2O$ ($M=K$, $x=1$; $M=Na$, $x=3.5$), $Ba[Co(CN)_4tn]_2\cdot 4H_2O$, $[Co(CN)_2pn_2]_2S_2O_3\cdot H_2O$ and $[Co(CN)_2tn_2]_2S_2O_3$, have been prepared, and their infrared, visible and ultraviolet absorption spectra have been determined. From these spectral results, it has been concluded that the two dicyano complexes are cis isomers.

No remarkable Cotton effect has been observed in the region of the spin-forbidden band of the *cis*-$[Co(CN)_2en_2]^+$.

# The Reaction of Tropoids and Quinone Derivatives. VI. On the Structures of the Reaction Products of *p*-Benzoquinonedibenzenesulfonimide with Phenol or Tropolone

By Yukio NISHIYAMA, Yusaku IKEGAMI and Shuichi SETO

(Received July 1, 1964)

Adams and Blomstrom[1] reported that the reaction of *p*-benzoquinonedibenzenesulfonimide (I) with phenols in the presence of triethylamine yielded the products exemplified by formula II.[2] The present authors[5] then applied this reaction to tropolone and reported that the product thereby obtained, which corresponded to an adduct of one molecule of I and one molecule of tropolone, would have structure III, as determined by analogy to the case of phenol.[1] Thereafter, as an extension of this reaction, the reaction of *o*-benzoquinonedibenzimide (IV) with phenol[6,7] or tropolone[8] was carried out, giving an adduct of one molecule of IV and one molecule of phenol or tropolone. The investigation of the structures of these adducts revealed that they were the *N*-(4-hydroxyphenyl)- and *N*-(tropolon-5-yl)-*o*-phenylenediamine derivatives V and VI respectively. Since this fact threw doubt upon the structures of the reaction products of I with phenol and tropolone, which had been previously assumed to be II and III respectively, the present authors attempted to reexamine these structures. This paper will present evidence showing that the structures previously assumed are erroneous and should be revised to the *N*-substituted derivatives VII and VIII.

The reaction of I with phenol in the presence of a catalytic amount of triethylamine gives colorless crystal (A), m. p. 227—228°C (decomp.). Adams et al. reported the melting points of 228.5—229.5°C (decomp.)[1] or 227—228°C (decomp.).[3] The methylation of A with diazomethane affords a methyl derivative (A), m. p. 136°C, which does not exhibit any absorption band due to the OH and NH groups in its infrared spectrum. In the NMR spectrum of B,[9] the signals for the protons of $NCH_3$ and $OCH_3$ groups appear at 6.85 and 6.21 $\tau$, respectively and have almost equal intensities. These facts show that B is not IX, but X. *N*-Methyl-*N'*-(4-methoxyphenyl)-*N*, *N'*-dibenzenesulfonyl-*p*-phenylenediamine (X) was then synthesized for purposes of comparison by an unequivocal route; the diamine obtained by the catalytic reduction of known 4-nitro-4'-methoxydiphenylamine[10] gives X on benzenesulfonylation followed by methylation. The compound X synthesized thus was found to be identical with the methyl derivative (B) through a mixed fusion test and by a comparison of the ultraviolet and infrared spectra. This evidence firmly establishes that, on the reaction of *p*-benzoquinonedibenzenesulfonimide (I) with phenol, the bond formation between the nitrogen atom of I and the carbon atom at the 4-position of phenol occurs, as in the case of the reaction with the *o*-benzoquinone derivative IV,[6] and that, consequently, the product is not 2-(4'-hydroxyphenyl)-*N*, *N'*-dibenzenesulfonyl-*p*-phenylenediamine (II), as was reported by Adams et al.,[1,3] but *N*-(4-hydroxyphenyl)-*N*, *N'*-dibenzenesulfonyl-*p*-phenylenediamine (VII). Adams and Braun[11] reported an example of such C–N bond formation by the reaction of the quinoneimide derivatives; the reaction of 2, 3, 5, 6-tetrachloro-*p*-benzoquinonedibenzenesulfonimide (XI) with aromatic amines, e. g., aniline and *N*-dimethylaniline, gave as products XII and XIII without a catalyst. The present authors carried out the reaction of XI with phenol in the presence of triethylamine and obtained a products XIV analogous to XII. On methylation with diazomethane, XIV affords a methyl derivative

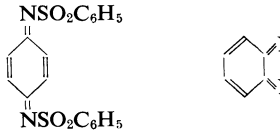
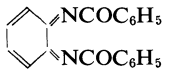
(XV) whose NMR spectrum exhibits the signal at 6.78 and 6.20 $\tau$, due to the protons of the $NCH_3$ and $OCH_3$ groups respectively, with almost equal intensities.



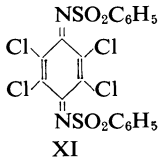
The reaction product (C)[12] of I with *o*-cresol was also methylated to a methyl derivative (D). The NMR spectrum of D shows the signals for the protons of $NCH_3$, $OCH_3$ and $CH_3$ at the position at 6.87, 6.21 and 7.84 $\tau$ respectively; their intensities are almost the same. These facts indicate that compounds C and D are XVI and XVII respectively, analogous to the case of the reaction product of I with phenol.

In the case of the reaction product (E)[5] of I with tropolone, the situation is very similar to that with phenols. The methylation of E with diazomethane gives a methyl derivative (F)[13], m. p. 190—191°C, whose infrared spectrum does not show any absorption band due to the OH or NH groups. To compound E, the introduction of two or three methyl groups may be expected, but the analytical figures do not permit the selection of the number of methyl groups in the case of a compound with a large molecular weight, such as F. Hence, the benzylation of E was undertaken; a monobenzyl derivative (XVIIIa) was thereby obtained. Its infrared spectrum shows the band due to the OH group, but it lacks that due to the NH group. The NMR spectrum of F shows the signals for the protons of $NCH_3$ and $OCH_3$ attached to the tropone nucleus at 6.84 and 6.04 $\tau$ respectively;[14] they have almost equal intensities. These facts suggest that product E is not III, but VIII.



In order to confirm the structure further, the rearrangement of the tropolone ring in F into benzoic acid was attempted. The heating of F with sodium ethoxide in absolute ethanol, followed by hydrolysis, gave a benzoic acid derivative which was then converted into a methyl ester (G) by treatment with diazomethane. If product E is VIII and, consequently, F is XVIII, methyl ester G should be XIX. Therefore, the synthesis of XIX by an unequivocal route was carried out.

The treatment of known 4-amino-4'-methyldiphenylamine[15] with benzenesulfonyl chloride in pyridine gave XX, whose oxidation with potassium permanganate, followed by methylation with diazomethane, gave XIX. Methyl ester G showed no depression of its melting point on admixture with XIX, and the ultraviolet and infrared spectra of these two substances were in good agreement. Consequently, product E must be *N*-(tropolon-5-yl)-*N*, *N*'-dibenzenesulfonyl-*p*-phenylenediamine (VIII).



The reaction of XI with tropolone gave the tetrachloro-derivative XXI. The NMR spectrum of the methyl derivative of XXI shows the

signals for the protons of the $NCH_3$ and $OCH_3$ groups at 6.83 and 6.08 $\tau$ respectively, and they have almost equal intensities all indicating that the methyl derivative is XXII.

## Experimental[16]

***N*-(4-Hydroxyphenyl)-*N*, *N'*-dibenzenesulfonyl-*p*-phenylenediamine (VII).** — a) VII was prepared in the manner reported by Adams and Blomstrom,[1] using 1 g. of I and 600 mg. of phenol. Colorless crystals m. p. 227—228°C (decomp.) were obtained. Yield, 780 mg.

b) To a solution of 0.5 g. of I in 20 ml. of chloroform, a solution of 0.3 g. of phenol in 3 ml. of chloroform was added. The addition of 3 drops of boron trifluoride etherate changed the color of the solution temporarily to dark violet, but colorless crystals began to separate after a few minutes. The mixture was allowed to stand for 1 hr., and then the crystals were collected to give 530 mg. of VII. This compound was found to be identical with that prepared by method a) through a mixed fusion test and by a comparison of the ultraviolet and infrared spectra.

***N*-(4-Methoxyphenyl)-*N'*-methyl-*N*, *N'*-dibenzenesulfonyl-*p*-phenylenediamine (X).** — a) An ether solution of diazomethane was added to 100 mg. of VII suspended in 4 ml. of methanol; thereby, with the evolution of nitrogen the crystals dissolved once, and after a few minutes new colorless crystals began to separate out. After the mixture had been allowed to stand overnight, the crystals were collected and recrystallized from a mixture of methanol and chloroform to afford 65 mg. of X, m. p. 163—164°C.

Found: C, 61.19; H, 4.85; N, 5.54. Calcd. for $C_{26}H_{24}O_5N_2S_2$: C, 61.43; H, 4.72; N, 5.51%.

b) A suspension of 500 mg. of 4-nitro-4'-methoxydiphenylamine[10] in 40 ml. of ethanol, with 300 mg. of 5% palladium-carbon added, was shaken in a hydrogen atmosphere at an ordinary temperature. After the absorption of hydrogen had ended, a small amount of sodium dithionite was added to the mixture and the catalyst was removed by filtration. The filtrate was then evaporated to dryness under reduced pressure. The solid which formed on the addition of a small amount of water to the residue was collected to afford 400 mg. of 4-amino-4'-methoxydiphenylamine m. p. 98°C. To a solution of 200 mg. of this compound in 1 ml. of pyridine, 300 mg. of benzenesulfonyl chloride was added drop by drop. The color of the mixture changed to dark red and then to dark violet. After heating on a water bath for 3 hr., pyridine was evaporated under reduced pressure. The addition of ice water to the residue gave a solid which was recrystallized from ethanol to give 410 mg. of *N*-(4-methoxyphenyl)-*N*, *N'*-dibenzenesulfonyl-*p*-phenylenediamine, m. p. 187—188°C.

Found: C, 60.90; H, 4.44; N, 5.91. Calcd. for $C_{25}H_{22}O_5N_2S_2$: C, 60.74; H, 4.45; N, 5.66%.

To a suspension of 100 mg. of the *p*-phenylenediamine derivative obtained above in 5 ml. of ethanol, an ether solution of dizomethane was added. After the mixture had been allowed to stand overnight, the crystals were collected and recrystallized from methanol to give 95 mg. of colorless crystals, m. p. 163—164°C. The crystals thereby obtained did not show any depression of melting point on admixture with the compound obtained by method a), and the infrared spectra of the two were in good agreement.

***N*-(4'-Hydroxyphenyl)-*N*, *N'*-dibenzenesulfonyl-2, 3, 5, 6-tetrachloro-*p*-phenylenediamine (XIV).** — To 200 mg. of 2,3,5,6-tetrachloro-*p*-quinonedibenzenesulfonimide (XI) suspended in 4 ml. of chloroform, a solution of 130 mg. of phenol in 2 ml. of chloroform was added. On the addition of 2 drops of triethylamine to the mixture, the crystals of XI dissolved immediately, and then colorless crystals separated out. After the mixture had been allowed to stand overnight, the crystals were collected and recrystallized from chloroform to give 200 mg. of XIV as colorless crystals, m. p. 232—233°C.

Found: C, 46.72; H, 2.48; N, 4.70. Calcd. for $C_{24}H_{16}O_5N_2S_2Cl_4$: C, 46.64; H, 2.56; N, 4.53%.

**Dimethyl Derivative (XV) of XIV.** — An ether solution of diazomethane was added to 100 mg. of XIV suspended in 1 ml. of methanol. After the mixture had been allowed to stand for 1 hr., the crystals that separated out were collected and its solution in ethyl acetate was purified through an alumina column to give 30 mg. of XV, m. p. 228°C.

Found: C, 48.36; H, 2.78; N, 4.62. Calcd. for $C_{26}H_{20}O_5N_2S_2Cl_4$: C, 48.33; H, 3.09; N, 4.33%.

***N*-(4-Methoxy-3-methylphenyl)-*N'*-methyl-*N*, *N'*-dibenzenesulfonyl-*p*-phenylenediamine (XVII).** — To 150 mg. of XIV (the reaction product[1] of I with *o*-cresol) suspended in 5 ml. of methanol, an ether solution of diazomethane was added. After 24 hr. the solvent was evaporated and the residue was recrystallized from methanol to afford 135 mg. of colorless crystals (XVII), m. p. 158—160°C. The infrared spectrum of this compound did not show

16) All melting points are uncorrected. Microanalyses were carried out by the Misses Yoko Endo and Yukiko Endo in this Institute. Measurements of ultraviolet and infrared spectra were made, respectively, with a Hitachi EPU-2A type spectrophotometer and with a Perkin-Elmer 21 infrared spectrophotometer using a potassium bromide disk.

any absorption band due to the OH and NH groups.

Found: C, 62.31; H, 5.02; N, 5.51. Calcd. for $C_{27}H_{26}O_5N_2S_2$: C, 62.09; H, 4.98; N, 5.36%.

***N*-(2-Methoxytropon-5-yl)-*N'*-methyl-*N*, *N'*-dibenzenesulfonyl-*p*-phenylenediamine (XVIII).**—To 1 g. of VIII (the reaction product[5] of I with tropolone) suspended in 10 ml. of methanol, an ether solution of diazomethane was added. After the mixture had been allowed to stand overnight, the crystals that separated out were collected and recrystallized from a mixture of methanol and chloroform to give 950 mg. of XVIII, m. p. 190—191°C.

Found: C, 60.44; H, 4.35; N, 5.18. Calcd. for $C_{27}H_{24}O_6N_2S_2$: C, 60.46; H, 4.47; N, 5.22%.

**The Rearrangement Reaction of XVIII with Sodium Ethoxide.**—A mixture of 150 mg. of XVIII and sodium ethoxide prepared from 100 mg. of sodium and 2.5 ml. of absolute ethanol was heated at 120°C; thereby the crystals of XVIII once dissolved once, and after a while a solid separated out. After being heated for 1 hr., the mixture was cooled. The solid was collected by filtration and washed with ethanol. The solid (50 mg.) was heated in 2 ml. of 6 N hydrochloric acid on a water bath for 1 hr. After being cooled, the solid was collected, suspended in 2 ml. of methanol, and treated with an ether solution of diazomethane. After standing overnight, the solvent was evaporated. The residue was chromatographed on an alumina column, and elution with ethyl acetate afforded 20 mg. of colorless needles (XIX), m. p. 182—183°C.

Found: C, 60.69; H, 4.64; N, 5.51. Calcd. for $C_{27}H_{24}O_6N_2S_2$: C, 60.46; H, 4.47; N, 5.22%.

***N*-(4-Methoxycarbonylphenyl)-*N'*-methyl-*N*, *N'*-dibenzenesulfonyl-*p*-phenylenediamine (XIX).**—To a solution of 250 mg. of 4-amino-4'-methyldiphenylamine[14] in 2 ml. of pyridine, 390 mg. of benzenesulfonyl chloride was added drop by drop in a nitrogen atmosphere; the color of the mixture thereupon changed to a red dish purple and then, after 5 min., faded. The mixture was heated on a water bath for 30 min., and pyridine was removed under reduced pressure. The residue solidified on the addition of water. The solid thereby formed was collected and recrystallized from ethanol to give 400 mg. of *N*-(4-methylphenyl)-*N*,*N'*-dibenzenesulfonyl-*p*-phenylenediamine (XX) as colorless crystals, m. p. 175°C.

Found: C, 62.73; H, 4.27; N, 5.93. Calcd. for $C_{25}H_{22}O_4N_2S_2$: C, 62.77; H, 4.59; N, 5.85%.

To 50 mg. of XX suspended in a solution of 100 mg. of potassium hydroxide in 10 ml. of water, a solution of 50 mg. of potassium permanganate in 10 ml. of water was added. The mixture was then heated at 100°C for 1.5 hr. After the remaining potassium permanganate had been decomposed by the addition of methanol, the mixture was filtered to remove any manganese dioxide. The filtrate was then acidified, and the precipitate thereby formed was collected. The precipitate was added to an aqueous solution of sodium carbonate (30 mg. in 5 ml. of water), and an insoluble substance was removed by filtration. When the filtrate was acidified again, 35 mg. of the precipitate was collected. A solution of this precipitate in methaol was treated with an ether solution of diazomethane. The evaporation of the solvent gave 20 mg. of colorless needles, m. p. 183°C. This substance was identical with the compound (XIX) derived from the rearrangement reaction mentioned above.

Found: C, 60.61; H, 4.34; N, 5.04%.

***N*-(Tropolon-5'-yl)-*N*, *N'*-dibenzenesulfonyl-2, 3, 5, 6-tetrachloro-*p*-phenylenediamine (XXI).**—To 200 mg. of XI suspended in 4 ml. of chloroform, a solution of 100 mg. of tropolone in 2 ml. of chloroform was added. On the addition of one drop of triethylamine to the mixture, the orange crystals of XI dissolved immediately and colorless crystals separated out. After they had stood for 3 hr., the crystals (200 mg.) were collected. Recrystallization from a mixture of ethanol and chloroform gave 190 mg. of XXI as colorless crystals, m. p. 208—210°C (decomp.).

Found: C, 45.97; H, 2.73; N, 4.49. Calcd. for $C_{25}H_{16}O_6N_2S_2Cl_4$: C, 46.47; H, 2.48; N, 4.33%.

***N*-(2'-Methoxytropon-5'-yl)-*N'*-methyl-*N*, *N'*-dibenzenesufonyl-2, 3, 5, 6-tetrachloro-*p*-phenylenediamine (XXII).**—This compound was prepared by the treatment of 100 mg. of XXI with an ether solution of diazomethane in the same manner as in the case of XV. Colorless crystals; m. p. 228°C (decomp.).

Found: C, 47.96; H, 3.14; N, 4.21. Calcd. for $C_{27}H_{20}O_6N_2S_2Cl_4$: C, 48.10; H, 2.97; N, 4.15%.

***N*-(Tropolon-5-yl)-*N'*-benzyl-*N*, *N'*-dibenzenesulfonyl-*p*-phenylenediamine (XVIIIa).**—Into a solution of 300 mg. of VIII in aqueous potassium hydroxide (400 mg. in 12 ml. of water), 265 mg. of benzyl chloride was stirred at 30—40°C. After the treatment had been continued for 6 hr., the solid thereby formed was collected by filtration, suspended in a small amount of water, and acidified with dilute sulfuric acid. After the mixture had been stirred for a while, 160 mg. of the solid was collected; the recrystallization of this from a mixture of ethyl acetate and ethanol gave 120 mg. of the desired compound as colorless crystals, m. p. 220—222°C (decomp.). This compound showed a positive color reaction with ferric chloride.

Found: C, 64.78; H, 4.67; N, 4.82. Calcd. for $C_{32}H_{26}O_6N_2S_2$: C, 64.23; H, 4.35; N, 4.68%.

***N*-(2-Methoxytropon-5-yl)-*N'*-benzyl-*N*, *N'*-dibenzenesulfonyl-*p*-phenylenediamine (XVIIIb).**—The treatment of 50 mg. of the benzyl derivative prepared above with an ether solution of diazomethane gave 39 mg. of the methyl derivative; colorless needles, m. p. 204—205°C.

Found: C, 64.97; H, 4.65; N, 4.53. Calcd. for $C_{33}H_{28}O_6N_2S_2$: C, 64.72; H, 4.57; N, 4.57%.

***N*,*N'*-Dimethyl-*N*,*N'*-dibenzenesulfonyl-*p*-phenylenediamine.**—To 300 mg. of *p*-phenylenedibenzenesulfonamide suspended in 5 ml. of methanol, an ether solution of diazomethane was added. After the mixture had been allowed to stand overnight, the solvent was removed by evaporation. The residue was recrystallized from a mixture of chloroform and ethanol to afford 220 mg. of colorless crystals, m. p. 193—195°C.

Found: C, 58.43; H, 4.95; N, 6.84. Calcd. for $C_{20}H_{20}O_4N_2S_2$: C, 57.70; H, 4.80; N, 6.74%.

In its NMR spectrum, a singnal for the protons of $NCH_3$ appears at 6.84 $\tau$.

# The Chemiluminescence, Fluorescence and Absorption Spectra of 2, 4, 5-Triphenylimidazole

By Koko MAEDA, Heijiro OJIMA and Taro HAYASHI

(Received July 2, 1964)

In 1877 Radziszewski[1] found that 2, 4, 5-triphenylimidazole (lophine) exhibits chemiluminescence in ethanolic potassium hydroxide with oxygen at room temperature, yielding benzoic acid and ammonia. Trautz[2] later reported that lophine exhibited a brighter chemiluminescence with such ordinary oxidizing agents as aqueous solutions of hydrogen peroxide, chlorine, bromine and potassium ferricyanide. Cottman, Moffet and Moffet[3] and Cook and Jones[4] investigated the chemiluminescence of several substituted derivatives of lophine. However the mechanism of the chemiluminescence of lophine has never been studied. We have, therefore, studied the mechanism of the chemiluminescence of lophine for several years and have published[5] a mechanism involving the triphenylimidazolyl radical. molecular oxygen and peroxide. The details of our study of the mechanism of the chemiluminescence of lophine will be reported in the following papers.

Cottman and his collaborators[3] measured the chemiluminescence spectra of lophine and several of its substituted compounds with a photographic method and reported that those spectra were spread over 480—600 m$\mu$, with a single maximum near 530 m$\mu$. No details of the spectra, however, were shown. We measured the chemiluminescence spectra of lophine and several of its substituted compounds with a recording spectrophotometer and also measured the spectra of fluorescence and absorption. The present paper deals with the results obtained on those spectra of lophine.

## Experimental

Lophine was prepared by the method of Davidson, Weiss and Jelling.[6] It was recrystallized from ethanol as colorless fine needles, m. p. 271—272°C.

**The Chemiluminescence Spectrum.** — The chemiluminescence spectrum of lophine in 1 N ethanolic potassium hydroxide and oxygen was measured with the Hitachi recording spectrophotometer, EPS 2 type, equipped with an apparatus for measuring the chemiluminescence spectrum of a solution. The equipment and the procedure for measuring the chemiluminescence spectrum are as follows: lophine (0.5 g.) was added to 12 ml. of 1 N ethanolic potassium hydroxide in a quartz tube 1.5 cm. inner diameter and 25 cm. long. A cork at the upper end of the tube was provided with a small reflux condenser, a thermometer and a narrow glass tube for streaming gas into the solution in the tube. When the mixture in the tube was stirred by a nitrogen stream for a while, a pale yellow solution of lophine ($C=2.81\times10^{-1}$ mol./l.) was obtained. Then the tube containing the solution was put in a metallic tube, about 2 cm. in inner diameter, fixed in the center of a small metallic cylindrical thermostat which had been set in place of a light source. Hot water was circulated throughout this thermostat from another one in order to heat the solution in the tube at 70°C. Small windows both on an outer wall of the cylindrical thermostat and on a wall of the metallic tube containing the quartz tube which contained a solution of lophine, were connected with a narrow horizontal metallic tube, through which a light of chemiluminescence was introduced into the spectrophotometer. When the temperature of the solution of lophine became 70°C, a gentle stream of heated oxygen was passed into the solution. A chemiluminescence was exhibited at once; the spectrum was immediately measured by the recording spectrophotometer.

**The Fluorescence Spectra.** — The fluorescence spectra of lophine were measured with the spectrophotometer equipped with an apparatus for measuring fluorescence spectra. The 365 m$\mu$ line of a high

6) D. Davidson, M. Weiss and M. Jelling, *J. Org. Chem.*, **2**, 319 (1937).

pressure mercury lamp was used for the excitation.

**The Absorption Spectra.**—The absorption spectra of lophine were measured with the spectrophotometer.

## Results and Discussion

**The Chemiluminescence Spectra of Lophine.**—An ethanolic potassium hydroxide solution of lophine was used for measuring the chemiluminescence spectrum, since lophine was not dissolved in water. Like luminol and lucigenin, lophine exhibited chemiluminescence only in an alkaline medium. The light of the chemiluminescence of lophine with oxygen or with an aqueous solution of hydrogen peroxide was greenish blue, and the light could be detected even at the concentration of $10^{-5}$ mol./l. However, the intensity of chemiluminescence at room temperature was so weak that the chemiluminescence spectrum could not be measured by the recording spectrophotometer.

The intensity of the chemiluminescence with oxygen increased with a rise in the temperature. For example, a 2 N ethanolic potassium hydroxide solution of lophine ($C=1.6\times10^{-2}$ mol./l.) did not emit luminescence at $-15$°C. It did, however, emit a very weak luminescence at 0°C; the intensity increased with a rise in the temperature to about 80°C, at which point the solution began to boil, resulting in a rapid decrease in the intensity of the luminescence. Since the intensity was recovered by passing oxygen into the boiling solution, the rapid decrease in luminescence by boiling was obviously due to the loss of oxygen from the solution. These results indicated that the optimum temperature for measuring the chemiluminescence spectrum of lophine was 70—75°C.

In the chemiluminescence of lophine (concentration $10^{-1}$—$10^{-2}$ mol./l.) in 1—2 N ethanolic potassium hydroxide at room temperature, with oxygen which had previously been saturated, it was found that the logarithum of the total intensity of the chemiluminescence on an arbitrary scale linearly decreased with time for about ten minutes, that is at a rate probably of the first order with respect to the concentration of oxygen, whereas in the chemiluminescence with oxygen continuously passed into the solution, it was found that the total intensity hardly decreased at all for several minutes.

In view of these results, the chemiluminescence spectrum was measured by passing oxygen into a solution ($C=2.81\times10^{-1}$ mol./l.) in 1 N ethanolic potassium hydroxide at 70°C. The spectrum is shown in Fig. 1. It spreads over only a visible region, about 465—660 mμ, with a maximum at about 545 mμ. The time of the sweeping of the recorder from 450 to 680 mμ was 24 sec. Although it was found that the intensities of chemiluminescence just before and after measurement hardly decreased, resulting in no shift in the maximum, a part of the spectrum between about 520—590 mμ, centering about the maximum, was repeatedly measured with a sweeping time of 7 sec.; thus it was ascertained that the maximum was at 545 mμ.

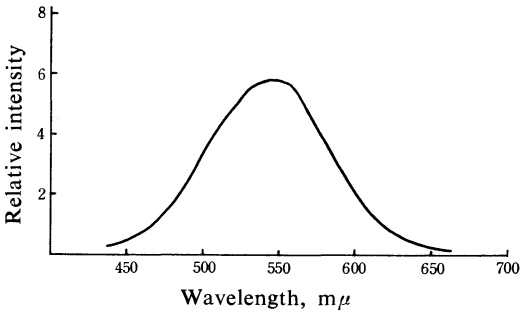

Fig. 1. The chemiluminescence spectrum of lophine in 1 N ethanolic potassium hydroxide ($C=2.81\times10^{-1}$ mol./l.) exhibited by passing oxygen through at 70°C.

The maximum wavelength, 545 mμ, in the chemiluminescence spectrum is more than 100 mμ longer the maximum wavelength, 441mμ, in the fluorescence spectrum of lophine and that, 440 mμ, of the fluorescence spectrum of benzoic acid, which is a product of the chemiluminescence of lophine. Therefore, the chemiluminescence of lophine is neither the fluorescence of lophine nor the fluorescence of benzoic acid. It is most likely a radiation emitted from some substance in an excited state which is probably produced by reactions involving the 2,4,5-triphenylimidazolyl radical produced from lophine and molecular oxygen. We now study the constitution of the intermediate compound emitting luminescence.

When a 1 N ethanolic potassium hydroxide solution of lophine was heated at 70°C on a water bath while being stirred by a stream of oxygen in the light, fine colorless crystals gradually appeared in the solution and ammonia was detected with a Nessler reagent in 0.1 N sulfuric acid by which the oxygen which had passed through the solution of lophine was washed. The fine crystals which separated were identified as potassium benzoate. In addition to benzoate and ammonia, sometimes a small quantity of fine colorless needles was isolated and then recrystallized from ethanol as fine needles, m. p. 231—232°C. This compound was identified as 2,4,6-triphenyl-1,3,5-triazine (cyaphenine). It was also obtained when chemiluminescence was exhibited with

ethanolic solution of bromine, its yield increasing when the solution of lophine was saturated with ammonia before the addition of bromine. These facts, and the formation of lophine by the reduction of cyaphenine with zinc dust in acetic acid,[4] suggest the formation of cyaphenine on the chemiluminescence is likely to be due to a reaction involving lophine and ammonia produced by the oxidation of lophine on the cheminescence.

The chemiluminescence spectrum with a 3% aqueous solution of hydrogen peroxide at 70°C was also measured with the recording spectrophotometer. Two milliliters of hydrogen peroxide heated at 70°C was quickly stirred into a solution of 0.72 g. of lophine in 12 ml. of 1 N ethanolic potassium hydroxide ($C=2.04\times10^{-1}$ mol./l.) heated at 70°C in the tube used for the measurement of the spectrum with oxygen; the spectrum was then immediately recorded. It spreads over 480—650 m$\mu$, with a maximum at 555 m$\mu$. When a 1 N ethanolic potassium hydroxide solution containing 0.5 g. lophine was heated at 70°C with 3% hydrogen peroxide for about 30 min. in another experiment, benzoic acid (0.3 g.) and ammonia were produced.

The measurement of the chemiluminescence spectrum with bromine was unsuccessful because of coloration by bromine. However, an important clue to the mechanism of chemiluminescence of lophine was obtained. When an ethanolic solution of bromine was added very slowly, drop by drop, to a hot solution of lophine in ethanolic potassium hydroxide without stirring, a reddish-purple color at once appeared around the part where a drop of a bromine solution was added; this color rapidly disappeared however, with the formation of a white precipitate, which was identified as potassium bromide. When a similar experiment was carried out in a dark room, chemiluminescence was observed around the part where a drop of a solution of bromine was added. The part where chemiluminescence was observed obviously corresponded to that where a reddish-purple color had appeared. In the chemiluminescence of lophine with a 2% aqueous solution of potassium ferricyanide, a reddish-purple color also appeared. When the dissolved oxygen in the solutions was removed, no chemiluminescence was observed, although the reddish-purple color appeared with the addition of bromine or potassium ferricyanide. Therefore, molecular oxygen was necessary for the chemiluminescence with bromine or potassium ferricyanide. From these facts and some other investigations concerning this coloration,[7] it was established that the reddish-purple color was due to the 2, 4, 5-triphenylimidazolyl radical produced by the oxidation of the lophine anion with bromine or potassium ferricyanide, and that the disapperance of the color was due to the combination of the free radical with oxygen in the solution to form an adduct which was probably in the following illuminating stage. The 2, 4, 5-triphenylimidazolyl radical was reasonably considered to be the intermediate also in the chemiluminescence with oxygen or hydrogen peroxide, although no reddish-purple color was observed in these cases.

**The Fluorescence Spectra of Lophine.** — The fluorescence spectra of lophine were measured at 20°C in ethanolic potassium hydroxide, in ethanol, and in ethanol containing acetic acid. In order to exclude a shift of the maximum of a spectrum by the oxidation of lophine, the dissolved oxygen in the solution was removed by a stream of nitrogen previously. The fluorescence spectra of lophine are shown in Fig. 2.

*C*: the concn. of lophine in a solution of 0.4 N ethanolic potassium hydroxide

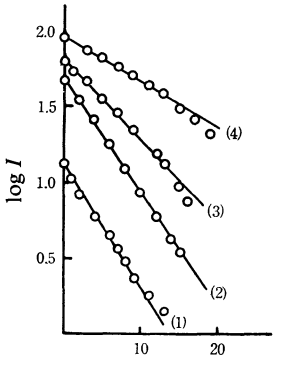

Fig. 4. The decrease with time in relative intensity at 440 mμ of the fluorescence spectrum of lophine in 0.4 N ethanolic potassium hydroxide at 25°C.
*I*: relative intensity of fluorescence at 440 mμ
Concn. of lophine:
(1) $5.05\times10^{-6}$ mol./l. (3) $1.01\times10^{-4}$ mol./l.
(2) $5.05\times10^{-5}$ mol./l. (4) $3.40\times10^{-4}$ mol./l.

maximum intensity at 440 mμ linearly decreased with the time of irradiation, as is shown in Fig. 4. When the dissolved oxygen in the solution was removed by a stream of nitrogen, no decrease in the intensity of fluorescence was observed, but when a stream of oxygen was passed into the solution, the rate of the decrease of fluorescence increased. Hence, the decrease of fluorescence is obviously involved with the oxidation with oxygen, and the rate of decrease is first order with respect to the concentration of oxygen in the solution.

The rate of the decrease of fluorescence was increased when the quantity of light illuminated was augmented by an increase in the area of a window on the wall of a cell containing the solution, but it was hardly affected by a rise in the temperature from 10 to 30°C. Therefore, the oxidation of the lophine responsible for the decrease in fluorescence was likely to be photochemical.

The tendency for the rate of the decrease of fluorescence to decrease with an increasing concentration of lopine, as shown in Fig. 4, can be understood from the relation between the relative intensity of fluorescence and the concentration of lophine which is shown in Fig. 3.

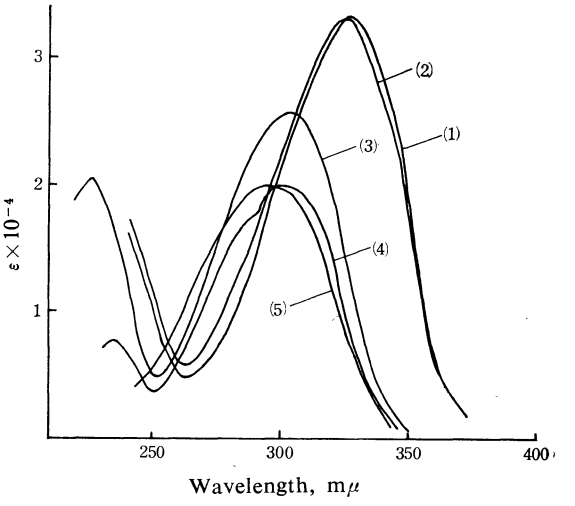

Fig. 5. The absorption spectra of lophine in ethanolic potassium hydroxide, and in ethanolic solutions of acetic acid at 20°C.
Concn. of lophine:
(1) $4.08\times10^{-5}$ mol./l. in 1 N KOH-$C_2H_5OH$
(2) $4.18\times10^{-5}$ mol./l. in 0.1 N KOH-$C_2H_5OH$
(3) $3.91\times10^{-5}$ mol./l. in ethanol
(4) $4.12\times10^{-5}$ mol./l. in 0.1 N $CH_3COOH$-$C_2H_5OH$
(5) $4.13\times10^{-5}$ mol./l. in 1 N $CH_3COOH$-$C_2H_5OH$

When the fluorescence of lophine in such a dilute ethanolic potassium hydroxide as 0.5 N was exhibited with or without a gentle stream of oxygen at room temperature, a small quantity of cyaphenine was isolated from a solution in which fluorescence had nearly ended. When fluorescence was exhibited in a rather concentrated ethanolic potassium hydroxide such as 1.8 N with a stream of oxygen at room temperature, a small quantity of benzoic acid was isolated and ammonia was detected. Cyaphenine was probably formed from lophine and ammonia which had been formed by the oxidation of lophine. Considering the facts that cyaphenine was very weakly fluorescent in the solution and that benzoic acid was also

weakly fluorescent, the decrease in the intensity of the fluorescence of lophine with time may be attributed to the photochemical oxidation of lophine with oxygen to give benzoic acid and ammonia.

**The Absorption Spectra of Lophine.** — The absorption spectra of lophine were measured in ethanol, in ethanolic potassium hydroxide, and in ethanolic solution of acetic acid at 20°C. The spectra are shown in Fig. 5.

The absorption maximum, $\lambda_{max}$ 303 m$\mu$ ($\varepsilon = 2.56\times10^4$), in ethanol was shifted to 326 m$\mu$ ($\varepsilon = 3.33\times10^4$) in 1 N ethanolic potassium hydroxide; conversely, 303 m$\mu$ was shifted to 295 m$\mu$ ($\varepsilon = 2.03\times10^4$) in a 1 N ethanolic solution of acetic acid. The shift in ethanolic potassium hydroxide is probably due to the dissociation of the NH of an imidazole ring.

## Summary

The chemiluminescence spectra of 2, 4, 5-triphenylimidazole (lophine) in 1 N ethanolic potassium hydroxide exhibited with oxygen and with hydrogen peroxide at 70°C have been measured. Both spectra spread over about 470—660 m$\mu$; the maximum wavelengths are 545 m$\mu$ and 555 m$\mu$ respectively.

The fluorescence spectra of solutions of lophine have been measured at 70°C. The maximum wavelengths are as follows: 371 m$\mu$, 388 m$\mu$ (ethanol), 441 m$\mu$ (1 N KOH–$C_2H_5OH$) and 391 m$\mu$ (1 N $CH_3COOH$–$C_2H_5OH$).

The absorption spectra of lophine have also been measured: $\lambda_{max}$ 303 m$\mu$ ($\varepsilon = 2.56\times10^4$) in ethanol: $\lambda_{max}$ 326 m$\mu$ ($\varepsilon = 3.33\times10^4$) in 1 N ethanolic potassium hydroxide, and $\lambda_{max}$ 295 m$\mu$ ($\varepsilon = 2.03\times10^4$) in a 1 N solution of acetic acid in ethanol.

The authors wish to express their hearty thanks to Dr. Hiroshi Midorikawa of the Institute of Physical and Chemical Research and Professor Ryojiro Iwaki of Aichi Gakugei University for their kind help, and to the Ministry of Education for the Scientific Research Expenditure Grant given to Mr. Hayashi.

# The Effect of Sodium Triphosphate on the Nucleation of Strontium Sulfate

By Hiromitu NAONO and Masaji MIURA

(Received July 7, 1964)

Since the patent of Rosenstein[1] was first presented, several investigators[2] have considered the inhibiting action of condensed phosphates on the crystallization of several sparingly soluble inorganic salts from their supersaturated solutions. In our previous papers[3] it has been reported that a supersaturated solution of strontium sulfate is perfectly stabilized for an extended period in the presence of a minute amount of sodium triphosphate. The concentration of the coexisting triphosphate is several hundred times less than that of strontium sulfate, and so the decrease in the concentration of free strontium ions by forming a complex with triphosphate may be regarded as negligibly small, despite the fact that the triphosphate is known to form a stable and soluble complex with strontium ion.[4] Under such conditions, it can not be expected that the concentration of strontium sulfate solution will be so reduced by the addition of triphosphate as to be unable to form nuclei.

In order to explain such observations, it has been proposed by some authors[2] that the phosphate ions are adsorbed on the surface of crystal nuclei born in the solution and that

they prevent the further growth of nuclei. Our previous investigation[3] has shown that the surface of strontium sulfate particles is completely covered by a monomolecular layer of adsorbed triphosphate in the vicinity of the concentration where the triphosphate exhibits the inhibiting action. This finding seems to indicate that the adsorption plays a predominant role in the action.

According to the above assumption, the number of nuclei should increase rapidly and, after an extended period, a large number of the nuclei should be accumulated in the supersaturated solution, while the growth of nuclei is prevented by the triphosphate adsorbed on them. Contrary to these expectations, however, a small number of large, distorted crystals of strontium sulfate were found to be deposited by the supersaturated solution when the concentration of triphosphate is slightly lower than that which makes the supersaturated solution stable. Therefore, there still remain some problems to be solved concerning the major effect of triphosphate on the nucleation of some inorganic salts.

In this paper, two physico-chemical methods are employed to investigate and clarify the problems described above: (1) a light-scattering study of the supersaturated solution of strontium sulfate stabilized in the presence of triphosphate, and (2) a study of the nucleation rate of strontium sulfate from its supersaturated solutions containing various amounts of triphosphate.

## Experimental

**Materials.**—The special grade reagents of strontium chloride and potassium sulfate were further purified by recrystallizing them from aqueous solutions. The method of the preparation and purification of sodium triphosphate has been described previously.[5]

**Light Scattering.**—The light-scattering measurements were performed at 25°C using a Shimadzu light-scattering photometer. All the solutions used in this work were filtered by a Cerafilter (its average pore diameter was 100—200 m$\mu$). The values of the turbidity and of the dissymmetry coefficient of water were $5.4\times10^{-5}$ cm$^{-1}$ and $1.00\pm0.01$ respectively at 436 m$\mu$. White light was used in place of monochromatic light in order to increase the intensity of the scattered light. Measurements were carried out in a semioctagonal cell for four samples: (1) 0.04 M $SrCl_2$; (2) 0.04 M $K_2SO_4$ containing $6\times10^{-5}$ M $Na_5P_3O_{10}$; (3) a mixed solution containing equal volumes of solutions (1) and (2), and (4) 0.02 M $SrCl_2$ containing $3\times10^{-5}$ M $Na_5P_3O_{10}$.

**Nucleation Kinetics.**—The rate of nucleation was measured by counting the number of crystals deposited from supersaturated solutions of strontium sulfate containing various amounts of sodium triphosphate. All the solutions used in this experiment were filtered according to the procedure used in the light-scattering measurements.

The supersaturated solution of strontium sulfate was prepared by adding 2.5 ml. of a 0.04 M strontium chloride solution to an equal volume of a 0.04 M potassium sulfate solution which also contained sodium triphosphate, the concentration of which varied from 0 to $3\times10^{-5}$ M. The solution thus obtained was allowed to form nuclei for an appropriate period (nucleation time), during which time the degree of supersaturation remained nearly constant.

Preliminary experiments showed that, in the strontium sulfate solution of the above-described concentration, containing $3\times10^{-5}$ M triphosphate, no crystals were formed for 1500 min., but the crystals placed in the solution grew slowly, although the number of crystals remained constant over the growth period. A solution of the same composition was used in this experiment as a growth medium. After the nucleation was over, the nuclei were transferred into a growth medium of a large volume and left to grow to crystals of a size large enough to be detected under a microscope (the growth time was about 1000 min.). The number of crystals thus grown was counted under a microscope using a Bürker counting room. In order to reduce the counting error, the average value of twenty-five runs was used to calculate the total number of crystals formed during nucleation.

## Results and Discussion

The results of the light-scattering measurements are shown in Tables I, II and III, where $i_\theta$ is the scattering intensity in the $\theta$ direction and $z_{45}$, the ratio of $i_{45}$ to $i_{135}$. As may be seen in Tables I and II, the value of $i_{90}$ for the supersaturated solution stabilized with triphosphate show no appreciable increase with the lapse of time and takes, within the range of experimental error, the same value as that for each solution from which the supersaturated solution is prepared. The nucleation of the solution may, therefore, be almost completely prevented by the presence of triphosphate. In contrast to $i_{90}$, the value of $z_{45}$ for the supersaturated solution changes with time. The two figures in the $z_{45}$ column in Table II indicate the maximum and minimum values for one minute. The fluctuation of the values of $z_{45}$ is mainly due to those of $i_{45}$. Even with the naked eye a small number of particles were observed to move at random by Brownian movement in the path of the incident beam. Scrupulous care was used to eliminate the traces of dusts in the solution, but the fluctuation in the values of $i_{45}$ did not disappear. As is shown in Table III, this phenomenon was not observed in the system containing

both sodium triphosphate and strontium chloride. From these observation it has been concluded that the fluctuation is caused by a small number of crystallites of strontium sulfate formed in the supersaturated solution.

The effect of triphosphate upon the nucleation rate of strontium sulfate is shown in Table IV, where the nucleation rate, $J$, is defined as the rate of nuclei formation per unit volume (ml.) per unit time (sec.). In Fig. 1 the nucleation rate is plotted against the concentration of triphosphate in a log-log scale. The explosive formation of nuclei occurs in the absence of triphosphate, but the nucleation rate is markedly reduced by an increasing concentration of triphosphate. Within the concentrations of triphosphate ranging from $0.2\times10^{-5}$ M to $1.5\times10^{-5}$ M, the curve in Fig. 1 obeys the equation:

$$J=Kc^{-9.5}$$

where $K$ is a constant and $c$, the molar concentration of triphosphate. The equation shows that a tenfold increase in the concentration of triphosphate reduces the nucleation rate to approximately one-several thousand millionth.

TABLE IV. INFLUENCE OF TRIPHOSPHATE ON THE NUCLEATION RATE OF STRONTIUM SULFATE

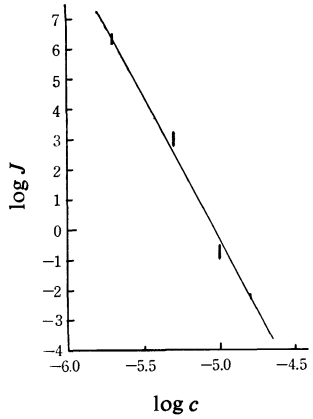

Fig. 1. Relation between the nucleation of strontium sulfate and the concentration of triphosphate.

It is now clear from these results that the minute amount of triphosphate greatly supresses the nucleation of strontium sulfate. In the previous papers of our laboratory[3,5] it was reported that the inhibiting action of condensed phosphates was closely related to the adsorption of phosphates onto the crystal surface in the cases of strontium sulfate and calcium carbonate.

By combining the finding concerning light scattering and the nucleation rate with those of adsorption, we may consider that the clusters of strontium sulfate with the embryonic dimension which are generated in the supersaturated solution may be broken into separated ions by the adsorption of triphosphate and that such a probability increases with the increase in the concentration of triphosphate.

## Summary

The nucleation from supersaturated solutions of strontium sulfate containing various amounts of triphosphate has been investigated by means of light scattering and nucleation kinetics. The nucleation rate is remarkably reduced by the increase in the concentration of triphosphate and may be represented by an empirical expression, $J=Kc^{-9.5}$. Light-scattering measurements have confirmed that practically no

nucleation occurs in the supersaturated solution stabilized in the presence of triphosphate.

The authors wish to express their thanks to Dr. Otani for his helpful discussions.

# On the Parameterization in the Semi-Empirical LCAO MO Method

By Takeshi NAKAJIMA

(Received July 10, 1964)

Although in the last decade Pariser and Parr's semi-empirical LCAO MO method[1] has been extensively and successfully used for the prediction of the electronic spectra of unsaturated molecules,[2] its applicability to the description of the ground-state electronic properties has not yet been clearly established. In fact, as will be shown in this paper, Pariser and Parr's approximation, with its original parameterization, if applied to benzene, gives the unexpected result that a skew structure ($D_{3h}$) is energetically favored as compared with the symmetric one ($D_{6h}$). In this paper we will, then, point out the origin of such an absurd result and propose a new parameterization applicable to the calculation of ground-state electronic properties as well as to the spectral calculation.

## The SCF-MO's of Benzene

The Pariser and Parr approximation, with its original parameterization, is applied to benzene in conjunction with the self-consistent field technique of Roothaan.[3] In computing interaction terms for adjacent atoms, the internuclear distances were predicted at each step of the iterative process from the $\pi$-bond orders, $p$, using the formula:[4]

$$r\,(\text{in Å}) = 1.520 - ap \tag{1}$$

with

$$a = 0.186 \tag{2}$$

However, nonneighbor internuclear distances were calculated by assuming the ring to be regular, with all bonds of an equal length (1.397Å). The Coulomb repulsion integrals $(pp/qq)$ were evaluated using the procedure of Pariser and Parr, and the core resonance integrals, $\beta$, for various distances were obtained from the Pariser and Parr curve;

$$\beta(r) = \beta_0 \exp[b(1.39 - r)] \tag{3}$$

with

$$\beta_0 = -2.39\ \text{eV. and}\ b = 5.6864\ \text{Å}^{-1} \tag{4}$$

The starting molecular orbitals used were of the Hückel type.

For the symmetric benzene ($D_{6h}$), the SCF-MO's are given directly by the Hückel type orbitals and are independent of parameterization. It is particularly noteworthy that the use of the above parameterization results also in the achievement of a self-consistency of molecular orbitals for an asymmetric benzene with the $D_{3h}$ molecular symmetry. The obtained self-consistent bond orders for the skew benzene indicate that the bond lengths vary considerably, the length of the shorter bonds being 1.347Å and that of the longer bonds 1.465Å. The refinement of the values of the Coulomb repulsion integrals (vide infra) leads to a further increase in skewness.

Now let us enquire which of the symmetric and asymmetric structures is more favorable in energy. It has been recognized[5,6] that a conclusion regarding the stability or the equilibrium configuration of a conjugated molecule cannot be based on $\pi$-electron calculations only; allowance for the effects of the $\sigma$-bond compression must also be made. Unfortunately, there is at present no theoretical method of estimating the $\sigma$-bond compression energy in the same degree of approximation as Pariser-Parr's. Longuet-Higgins and Salem's modification[5] of the Hückel MO theory is adopted here to obtain an estimate of the desired difference in energy between the two structures. According to Longuet-Higgins and Salem, the total binding energy of a conjugated molecule,

1) R. Pariser and R. G. Parr, *J. Chem. Phys.*, **21**, 446, 767 (1953).
2) R. G. Parr, "The Quantum Theory of Molecular Electronic Structure," W. A. Benjamin, New York (1963).
3) C. C. J. Roothaan, *Rev. Mod. Phys.*, **23**, 69 (1951).
4) T. Nakajima and S. Katagiri, *Mol. Phys.*, **7**, 149 (1963).

6) C. A. Coulson, *Tetrahedron*, **12**, 193 (1961); C. A. Coulson and A. Golebiewski, *Mol. Phys.*, **5**, 71 (1962).

taken to be the sum of the $\pi$-bond energy and the $\sigma$-bond energy, is given by:

$$V=E_\pi+E_\sigma=\sum_{p<q}2\int(\mathrm{d}p_{pq}/\mathrm{d}r)\bar{\beta}_{pq}(r)\mathrm{d}r \qquad (5)$$

where $\bar{\beta}(r)$, the resonance integral parameter in the Hückel MO theory, is interpreted as an "effective resonance integral" which includes an electron interaction term; it is assumed to be given as:*

$$\bar{\beta}_{pq}(r)=[2\beta_{pq}(r)-(p_{pq}/2)(pp/qq)]/2 \qquad (6)$$

Then, using Eqs. 1—4 and the Pariser and Parr quadratic formula:

$$(pp/qq)=0.2157r^2-2.625r+10.53 \qquad (7)$$

and integrating Eq. 5, we obtain:

$$V=\sum_{p<q}[1.8909\beta_{pq}(r)-0.7794r^4+14.2252r^3-104.9285r^2+231.3215r]+\text{const.} \qquad (8)$$

where the last term is the constant of integration, which is canceled in estimating the desired difference in $V$.

The total energy values thus calculated for the two structures indicate that the skew structure is more favorable in energy than the symmetric one, the deformation energy which favors the skew structure being 0.29 eV.—about 7 kcal./mol.—an appreciable amount.

## Stable Configurations in the $(4n+2)$ Cyclic Polyenes

In order to investigate the cause of the unreasonable results above, let us now examine the equilibrium configurations with respect to bond length distortion in cyclic polyenes generally having $(4n+2)$ carbon atoms. The Longuet-Higgins and Salems modification of the Hückel MO theory is again adopted to estimate the change in energy caused by the distortion.

At the outset, we define the bond alternation parameter, $k$, as

$$k=\bar{\beta}_\mathrm{s}/\bar{\beta}_\mathrm{d} \qquad (9)$$

where the subscripts s and d indicate the single and double bonds in an unexcited Kekulé structure respectively. As was taken in Longuet-Higgins and Salem's original theory, $\bar{\beta}(r)$ is now assumed to vary exponentially with $r$:

$$\bar{\beta}(r)=\bar{\beta}_0\exp[\bar{b}(1.39-r)] \qquad (10)$$

The total electronic energy, taken to be the sum of the $\pi$-bond energy and the $\sigma$-bond energy, is then given by:

$$V=(2/a\bar{b})\sum_{p<q}\bar{\beta}_{pq}(r)+\text{const.} \qquad (11)$$

For a given molecule, using Eqs. 1, 10 and 11, we can calculate the total electronic energies for various $k$ values (0—1), and the $V$-$k$ curve can be obtained.

The static equilibrium configurations of a given molecule are then given by the points of the $V$-$k$ curve where $\partial V/\partial k=0$; namely,

$$\exp[a\bar{b}(p_\mathrm{s}-p_\mathrm{d})]=k \qquad (12)$$

where

$$p_\mathrm{s}-p_\mathrm{d}=\sum_{l=-n}^{n}(k-1)\left(1-\cos\frac{2\pi l}{2n+1}\right)\Big/(2n+1)\left(1+2k\cos\frac{2\pi l}{2n+1}+k^2\right)^{1/2} \qquad (13)$$

It should be noted that Eq. 12 is nothing but the condition for the self-consistency of MO's with respect to $k$.

From Eq. 13 it follows at once that Eq. 12 is always satisfied by the point $k=1$, regardless of the value of $n$. It may be shown further that the sign of $(\partial^2V/\partial k^2)_{k\to1}$ coincides with that of the quantity:

$$A=1-a\bar{b}[\partial(p_\mathrm{s}-p_\mathrm{d})/\partial k]_{k\to1} \qquad (14)$$

where

$$[\partial(p_\mathrm{s}-p_\mathrm{d})/\partial k]_{k\to1}=\left(\frac{1}{2n+1}\right)\sum_{l=-n}^{n}\left|\sin\frac{\pi l}{2n+1}\tan\frac{\pi l}{2n+1}\right| \qquad (15)$$

Thus, if $A\geqq0$, the configuration $k=1$ is one of stable equilibrium, but if $A>0$, though it is one of static equilibrium, the configuration $k=1$ is one of unstable equilibrium. In the latter case a stable equilibrium is given by a point $k<1$, one in which $\partial V/\partial k=0$ and $\partial^2V/\partial k^2>0$.

For benzene the symmetric configuration with $k=1$ should, of course, be one of stable equilibrium. This yields

$$a\bar{b}\leqq1 \qquad (16)$$

This condition severely restricts our choice of $\bar{b}$ value, the value of $a$ being fairly narrowly determined empirically.

As was pointed out in the preceding section, the Pariser and Parr approximation, if applied to benzene, brings about the conclusions that the SCF MO's are achieved for the two symmetry types and that a skew structure is energetically favored as compared with the symmetric one. It is now clear that this absurd result is due to too large a value of $b$

* The resonance integral parameter, $\bar{\beta}_{pq}$, in the simple Hückel MO theory should explicitly be considered to be the arithmetic mean of the core resonance integral, $\beta_{pq}$, and the corresponding Fock matrix element, $\beta^\mathrm{F}_{pq}$ $(=\beta_{pq}-(p_{pq}/2)(pp/qq))$. If $\bar{\beta}_{pq}$ is interpreted merely as $\beta^\mathrm{F}_{pq}$, electron interactions are included twice in the total $\pi$-electronic energy.[7]

7) R. Daudel, R. Lefebvre and C. Moser, "Quantum Chemistry," Interscience, New York (1963), p. 303.

having being assigned by Pariser and Parr in their original parameterization. In fact, if we rewrite Eq. 6 in an approximately exponential form like Eq. 10, using the Pariser and Parr parameterization, the value of $\bar{b}$ turns out to be about $7\text{Å}^{-1}$,* which does not satisfy Eq. 16 when multiplied by $a=0.186$.

## A Refined Parameterization

Pariser and Parr's $b$ value was determined from $\beta$ values so adjusted as to reproduce the observed excitation energies of ethylene and benzene. Actually, at the time of the original development of the Pariser and Parr method the bond lengths of these molecules were not accurately known. In order to improve the $b$ value, we follow Pariser and Parr's procedure but use the recently observed bond lengths, 1.333 Å for ethylene[8] and 1.397 Å for benzene.[9] Moreover, the one-center electronic repulsion integral, given in the Pariser and Parr theory as $I_c-A_c$ is taken to be $11.54-0.46=11.08$ eV.[10] The two-center repulsion integrals were determined by the normal extrapolation procedure of Pariser and Parr.

Thus, adjusting the $\beta$ values of ethylene and benzene to fit the observed spectra, we obtain:

$$\beta(1.333\text{Å})=-2.80\text{ eV}. \quad (17)$$

and

$$\beta(1.397\text{Å})=-2.38\text{ eV}. \quad (18)$$

From these, we obtain $b=2.5801\text{Å}^{-1}$.* This value of $b$ is considerably smaller than Pariser and Parr's original value, and for benzene for use of this $b$ value results in the achievement of self-consistency only for the symmetric configuration. Furthermore, for butadiene the SCF MO's obtained by using the new parameterization lead to a good reproduction of experimental bond lengths and spectral data; the bond lengths for the double and single bonds are predicted to be 1.34 and 1.47 Å respectively, and the lowest singlet excitation energy is calculated to be 6.0 eV. If we rewrite Eq. 6 in an exponential form like Eq. 10, using the $b$ value obtained above, the value of $\bar{b}$ turns out to be about $4.5\text{Å}^{-1}$, which satisfies Eq. 16, and which is in good agreement with the value $4.5988\text{Å}^{-1}$,[4] which was determined by reference to the observed bond length alternation in butadiene. The latter $\bar{b}$ value has been successfully used in accounting for the ground-state electronic properties and electronic spectra of fundamental nonbenzenoid aromatic hydrocarbons.[12-14],**

*Department of Chemistry*
*Ibaraki University*
*Watari-cho, Mito*

* The SCF MO's obtained above for the skew benzene correspond to the MO's calculated by the simple Hückel method with $k=0.45$. To the degree of approximation, self-consistency is achieved for configurations with a static equilibrium, and for the skew benzene the $V$-$k$ curve should have a minimum at the point $k=0.45$. We obtain such a curve if we set $\bar{b}=6.7712\text{Å}^{-1}$, using $a=0.186$.

# The Electronic Spectra of Pyrene, Chrysene, Azulene, Coronene and Tetracene Crystals

By Jiro TANAKA

(Received July 14, 1964)

The theory of molecular exciton developed by Davydov and others has been widely used for the interpretation of the crystal spectrum, and a lot of results have been published which confirm a validity of the theory in general.[1] However, when a molecule has many excited levels, a mixing of excited states may occur between weak, medium and strong intensity bands and a spectrum may became so complicated that a simple correlation cannot be made between molecular and crystalline absorption bands.

In the present paper the electronic absorption spectra of single crystals of pyrene, chrysene, azulene, coronene and tetracene are reported in an attempt to affirm the theory; a particular effort will be made to find the mechanism of the intermolecular electronic interaction of the excited states in crystals.

The hydrocarbons cited above are characterized by having many strong absorptions in the near ultraviolet and relatively lower ionization potentials. The dipolar interaction between the excited levels might be very strong in such crystals, and the charge transferred level will be located at a relatively low energy region. The band splittings and intensities are calculated by including the configuration interaction between several excited states, and the results are compared with observed absorption bands.

Although the general features of the spectra can be explained very well, a discrepancy is noticed with some crystals, particularly in the intensities of very strong and very weak bands. The strong band is weakened and the weak band is strengthened more than would be expected from the dipole-dipole interaction scheme. The hypochromism of the stronger band may arise from the interaction with the ionization continuum level, and the hyperchromism of the weaker band may occur as a result of the higher order interaction with allowed transitions. Also the calculated splitting of some crystals does not agree completely

Oppenheimer, Jr.), McGraw-Hill, New York (1962); D. P. Draig and S. H. Walmsley, "Physics and Chemistry of the Organic Solid State," Vol. I, Ed. by Fox, Labes and Weissberger, Interscience Publishers, New York (1963), p. 586.

with the experimental results; this may suggest a need for more elaborate calculations, including that of the electron overlap effect.

## Experimental

The ultraviolet and visible spectra of *n*-heptane solutions were measured by a Cary recording spectrophotometer, model 14. The crystal spectra were measured by an ultraviolet microspectrophotometer described in a previous paper.[2] All the samples were purified by recrystallization or chromatography, followed by sublimation. The thin crystals suitable for spectral measurement were prepared by sublimation. The thicknesses of these crystals were roughly estimated by means of the interference color as seen under a polarization microscope.

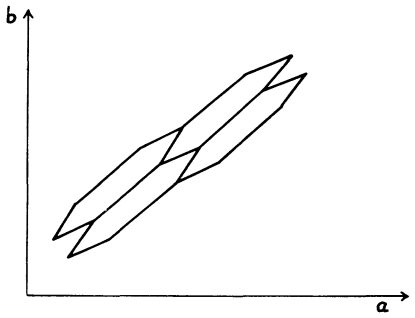

Fig. 2 (a). Projection of pyrene molecule onto the (001) plane.

## Pyrene

Five absorption bands have been observed in a *n*-heptane solution, as Fig. 1 and Table I show. Ham and Rudenberg[3] predicted that transitions to the $^1L_b$ and $^1B_a$ states are possible along the short-axis (M-axis) of the molecule, while the $^1L_a$ and $^1B_b$ transitions are active along the long-axis (L-axis). The crystalline spectrum (Fig. 2 (b)) has been recorded using a crystal about 0.4 $\mu$ thick* through the (001) plane and with a light polarized along the a- and b-axes. The projection of the molecules onto the (001) plane, based on the X-ray crystal analysis results of Robertson and White,[4] is shown in Fig. 2 (a). The wave functions of the crystalline exciton state are given by the following formula for each excited state:

** Those bands are regarded as the charge-transfer transitions.

$$\left.\begin{aligned}\Psi^{\alpha} &= \frac{1}{\sqrt{4N}}\Big(\sum_{i=1}^{N}\phi_{1i}' - \sum_{j=1}^{N}\phi_{2j}' \\ &\quad - \sum_{k=1}^{N}\phi_{3k}' + \sum_{l=1}^{N}\phi_{4l}'\Big); \quad B_u \\ \Psi^{\beta} &= \frac{1}{\sqrt{4N}}\Big(\sum_{i=1}^{N}\phi_{1i}' - \sum_{j=1}^{N}\phi_{2j}' \\ &\quad + \sum_{k=1}^{N}\phi_{3k}' - \sum_{l=1}^{N}\phi_{4l}'\Big); \quad A_u\end{aligned}\right\} \quad (1)$$

where $\phi_{1i}'$ denotes the excited state in which the 1st site molecule in the $i$-th cell is excited while the others are in the ground state. The coordinate of the molecule on each site is chosen following the notation of the International Table,[5] namely, 1 $(x, y, z)$, 2 $(\bar{x}, \bar{y}, \bar{z})$, 3 $(1/2-x, 1/2+y, \bar{z})$ and 4 $(1/2+x, 1/2-y, z)$. The first-order energy levels are given by Eq. 2 for each excited state:

$$\left.\begin{aligned}&E^{\alpha} = E_0 + V_{11} - 1/2V_{12} - 1/2V_{13} + 1/2V_{14} \\ &E^{\beta} = E_0 + V_{11} - 1/2V_{12} + 1/2V_{13} - 1/2V_{14} \\ &V_{kl} = \\ &\sum_{i=1}^{N}\int \phi_k^{*\prime}(1)\phi_{li}^{*}(2)\, V\phi_k(1)\phi_{li}'(2)\mathrm{d}\tau_1\mathrm{d}\tau_2\end{aligned}\right\} \quad (2)$$

where $E_0$ indicates the energy of the molecular excited state, including a small shift due to interaction between the excited state and the ground state. $V$ is the intermolecular potential, $\phi_k$ and $\phi_k'$ represent the ground- and the excited-state wave function of the $k$-th site molecule, and $\phi_l$ and $\phi_l'$ are those of $l$-th site molecule.

Actually, we have taken only the dipole-dipole interaction term, and the calculations have been carried out by the method of direct summation over molecules inside the restricted radius sphere. The ISSP Facom 202 computer has been used; the results are shown in Appendix I. It may be seen that the value obtained by the summation over a 30Å radius sphere is very close to the value of a 50Å radius sphere. Craig and Walmsley[1] published the results of similar calculations by the Ewald-Kornfeld's method; it is very interesting that the present results are in good agreement with their values in spite of the different computational procedures. The convergence of a direct summation seems to be sufficient if we take the summation within a 50Å radius sphere.

Since we are considering four excited levels in the present case, it might be necessary to calculate the second order interaction between those levels. The secular equation is given by:

$$\left.\begin{aligned}&\mathrm{Det}\,|H_{rs} - E\delta_{rs}| = 0 \\ &H_{rs} = \int \Psi_r{}^{\alpha} H \Psi_s{}^{\alpha}\,\mathrm{d}\tau, \\ \text{or}\quad &H_{rs} = \int \Psi_r{}^{\beta} H \Psi_s{}^{\beta}\,\mathrm{d}\tau \\ &H = H_0 + V,\ \delta_{rs} = 1 \text{ when } r = s, \\ &\delta_{rs} = 0 \text{ when } r \neq s\end{aligned}\right\} \quad (3)$$

where $H$ indicates the total Hamiltonian of the system, and $\Psi_r$ and $\Psi_s$ represent the $r$-th and $s$-th excited levels ($^1L_b$, $^1L_a$, $^1B_a$ or $^1B_b$ states). The interaction between $B_u$ and $A_u$-type functions vanishes for symmetry reasons. The diagonal element is taken as a first-order

5) "International Tables for X-ray Crystallography," Vol. I, Kynoch Press, Birmingham (1959).

exciton energy calculated by Eq. 2, while the off-diagonal term is calculated by a similar equation using the dipole approximation. For the $^1L_a$ band we have considered three vibrational levels separately; this implies a weak coupling between the $^1L_a$ state and other states. The secular equation is shown in Appendix II. Solving this equation, the wave function for the $L$-th crystal excited state is obtained as a linear combination of excited states $\Psi_r$:

$$\Psi_L{}^\alpha = \sum a_r \Psi_r{}^\alpha, \qquad \Psi_L{}^\beta = \sum b_r \Psi_r{}^\beta \tag{4}$$

and the transition moment, say, to the $\alpha$ state is given by a sum of the composite transition moments projected along the particular crystalline axis:

$$M_{OL}{}^\alpha = \int \Psi_0{}^* \boldsymbol{r} (\sum a_r \Psi_r{}^\alpha) \mathrm{d}r = \sum a_r M_{or} \cos\theta_{ar} \tag{5}$$

where $M_{or}$ is the magnitude of the transition moment to the $r$-th state, and $\theta_{ar}$ is the angle between the transition moment and the a-axis. The oscillator strength of the crystalline absorption band is calculated by Eq. 6:

$$f_{OL} = 3.25 \times 10^{-5} \times \nu \times (M_{OL}{}^\alpha)^2 \tag{6}$$

The second-order perturbation effect for the ground state (van der Waals force) has been disregarded. The results of the calculation are given in Table I and Fig. 3.

At room temperature the observation of the band splitting is not very feasible, but it may be clearly seen in Fig. 2(b) that both the $^1L_a$ and $^1B_a$ bands show appreciable splittings. By comparing the calculated intensity ratio with the observed spectrum, it is easy to prove the theoretical results of Ham and Rudenberg concerning the polarization of the bands. The first $^1L_b$ band, the weakest of all, might be influenced by the nearby stronger transition, and it shows the dichroic ratio $D_a : D_b = 1.7 : 1.0$, while the second-order calculation value is 1.35 : 1.0. The oriented gas value (the zeroth and first-order approximation) of 1.0 : 1.0 is improved by the second-order calculation, and it is almost certain that the $^1L_b$ state is short-axis polarized. The conclusion is in agreement with the earlier findings of Ferguson.[6]

The $^1L_a$ band shows four or more vibrational structures in the crystalline spectrum, the first and the second peaks being split about 240 $cm^{-1}$ and 130 $cm^{-1}$. The calculated values, 249 $cm^{-1}$ and 243 $cm^{-1}$ respectively, are in excellent agreement with the observed values. The splittings of the third and fourth peaks are reversed in sign; therefore, it might be possible that those peaks have a different origin. The charge-transfer transition might be very probable in such a crystal as pyrene, where molecules are placed in pairs, and it has been observed in the case of perylene.[7] The fluorescence of pyrene crystal has been established to originate from an excited dimeric state,[6] and the corresponding absorption should exist at a higher energy region. Following the recent theory of Murrell and Tanaka[8] on the spectra of the pyrene dimer, it is expected that the intermolecular charge-transfer band will appear in the 30000 $cm^{-1}$ spectral region when molecular planes are separated by about 3.5 Å. Therefore, the band near the 31000 $cm^{-1}$ region is regarded as charge-transfer band overlapped with the progression of the $^1L_a$ band. The polarization of the $^1L_a$ band is deduced from the dichroic intensity ratio to be long-axis, because the observed value of 4.2 : 1.0 is close to the calculated value of 7.4 : 1.0 (that of the zeroth and first-order value is 5 : 1), while the short-axis assignment will give a value of about 1.0 : 1.0.

The band system at about 35000 $cm^{-1}$ is clearly demonstrated by the intensity relations to be the short-axis polarized band. It shows splittings of 562, 470 and 563 $cm^{-1}$ for each vibrational progression; these values should be compared with the calculated value of 110 $cm^{-1}$ (strong coupling model). The first-order splitting was $-37$ $cm^{-1}$; therefore, the second-order calculation gives the right sign and the correct order of magnitude. The calculated intensity ratio, $D_a : D_b = 1.31 : 1.0$, is in good agreement with the observed value. The $^1B_b$ band is predicted to be at about 40000 $cm^{-1}$, but we see rather weaker absorptions in this region. Presumably the $^1B_b$ band is merged with the transitions to the ionization continuum state, and the original intensity is shared with the

band at higher frequencies. The mechanism of this sort of interaction requires further investigation.

The thickness of the crystal could not be determined accurately enough to discuss the accurate value of the intensity of the crystal absorption; however, it seems certain that a hypochromism occurs in the $^1L_a$, $^1B_a$ and $^1B_b$ bands. Contrary to this the $^1L_b$ band intensity is nearly in agreement with the value of the second-order theory. Therefore, the deviations of the absorption intensities of the stronger band should be ascribed to a mechanism which has not been considered in the above treatment.

### Chrysene

Five absorption bands have been found in a *n*-heptane solution (Fig. 4); the band positions are tabulated in Table II, together with the theoretical assignment of Ham and Rudenberg.[3] The crystal structure analysis of chrysene was made by Iball;[9] the projection of molecules onto the (001) plane is pictured Fig. 5(a). The crystalline spectrum has been measured through the (001) plane by a polarized light (Fig. 4(b)). The thickness of the crystal has been estimated to be 0.25 $\mu$ by the use of optical data on the birefringence of Krc.[10] Since we are using a convergent light of a microscope lens, the absolute intensity of a band whose transition moment is vertical to the developed plane might not be accurate enough to discuss the direction of the transition moment on the basis of the dichroic intensity ratio. In the crystal spectrum the intensity is weaker with the light polarized along the a-axis than with that polarized along the b-axis for all absorption bands. Theoretical calculation[3] showed that the strongest $^1B_b$ band is polarized along the long-axis of the molecule and that the long-axis is nearly perpendicular to the b-axis; therefore, it seems to be unreasonable that the $^1B_b$ band is weaker along the a-axis than along the b-axis. This anomaly of intensity relation is clarified by the second-order calculations including interactions between $^1L_b$, $^1L_a$, $^1B_b$ and $^1B_a$ states. The crystal excited-state wave functions which are active along the a- and b-axes are:

$$\left.\begin{aligned}\Psi^{\alpha} &= \frac{1}{\sqrt{4N}}\left(\sum_{i=1}^{N}\psi_{1i}' + \sum_{j=1}^{N}\psi_{2j}' - \sum_{k=1}^{N}\psi_{3k}' - \sum_{l=1}^{N}\psi_{4l}'\right)\\ \Psi^{\beta} &= \frac{1}{\sqrt{4N}}\left(\sum_{i=1}^{N}\psi_{1i}' + \sum_{j=1}^{N}\psi_{2j}' + \sum_{k=1}^{N}\psi_{3k}' + \sum_{l=1}^{N}\psi_{4l}'\right)\end{aligned}\right\} \quad (7)$$

where $\psi_{1i}'$, $\psi_{2j}'$, $\psi_{3k}'$ and $\psi_{4l}'$ represent the excited state in which a molecule at the 1$i$-th, 2$j$-th, 3$k$-th or 4$l$-th site, respectively, is excited while the others are in their ground state. The coordinates of molecules are chosen following the space group notation of $C_{2h}^6$ I (2/C) : 1($x$, $y$, $z$), 2($1/2+x$, $1/2+y$, $1/2+z$), 3($1/2-x$, $1/2+y$, $z$) and 4($\bar{x}$, $y$, $1/2-z$). The diagonal and the off-diagonal elements of the energy matrix are give for $\alpha$ and $\beta$ states by:

$$\left.\begin{aligned}
&\int \Psi_m{}^{\alpha} H \Psi_m{}^{\alpha} d\tau = \\
&E_m + <m|V_{11} + 1/2 V_{12} - 1/2 V_{13} \\
&- 1/2\ V_{14}|m> \\
&\int \Psi_m{}^{\alpha} H \Psi_n{}^{\alpha} d\tau = \\
&<m|V_{11} + 1/2 V_{12} - 1/2 V_{13} \\
&- 1/2 V_{14}|n> \\
&\int \Psi_m{}^{\beta} H \Psi_m{}^{\beta} d\tau = \\
&E_m + <m|V_{11} + 1/2 V_{12} + 1/2 V_{13} \\
&+ 1/2\ V_{14}|m> \\
&\int \Psi_m{}^{\beta} H \Psi_n{}^{\beta} d\tau = \\
&<m|\ V_{11} + 1/2 V_{12} + 1/2 V_{13} \\
&+ 1/2 V_{14}|n>
\end{aligned}\right\} \quad (8)$$

where $\Psi_m{}^{\alpha}$ and $\Psi_n{}^{\alpha}$ denote the $m$-th and $n$-th excited states of the $\alpha$-type wave function (a-active), and $\Psi_m{}^{\beta}$ and $\Psi_n{}^{\beta}$ denote those of the $\beta$-type wave function (b-active). The intermolecular interaction terms, $V_{ij}$, have a similar meaning in Eq. 2; they have been evaluated using the direction of the transition moments predicted by Ham and Rudenberg ($l$, $m$, $n$ and $o$ for the $^1B_b$, $^1B_a$, $^1L_a$ and $^1L_b$ states respectively). The results of the calculation are shown in Appendix I; the terms $V_{ij}$ have been determined by the use of experimental values of the transition moment. We considered four vibrational sub-levels for the $^1L_a$ state; the resultant secular equation of the seventh degree is shown in Appendix II. The final result is compared with the observed values in Table II and Fig. 6.

For the first $^1L_b$ band the calculated small splitting is in accord with the observed value of nearly zero, but the crystalline band as a whole shifts to red about 400 $cm^{-1}$ from the calculated value. The observed intensity is larger than the calculated value by a factor of about 10 for both a- and b-axes.

The second $^1L_a$ band shows the vibrational structure in crystal, but the band splitting is unusual. The first 0-0 band shows a splitting of 490 $cm^{-1}$ (the a-axis is higher than the b-axis), while the second 0-1 band shows almost no splitting and the third 0-2 band shows a splitting of the reversed sign −100 $cm^{-1}$ (the a-axis is lower than the b-axis). Such results can not be explained by the first-order exciton theory, since the splitting should be proportional to the intensity of each vibrational level. Second-order calculations, including interaction with a higher state, give a better explanation for those splittings since the calculated value is reversed in sign for higher vibrational progressions. However, the magnitude of the calculated value for the 0-0 band is smaller than the observed value (217 $cm^{-1}$ compared with 490 $cm^{-1}$), while the first-order splitting is 530 $cm^{-1}$.

Another way of interpreting small splittings for higher vibrational levels might be to consider a strong coupling of the vibronic excited state with the internal vibration of the molecule, and to think that the vibrational relaxation precedes the excitation transfer. However,

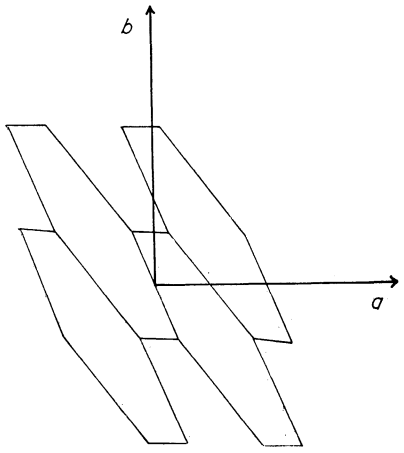

Fig. 5(a) Projection of chrysene molecule onto the (001) plane.

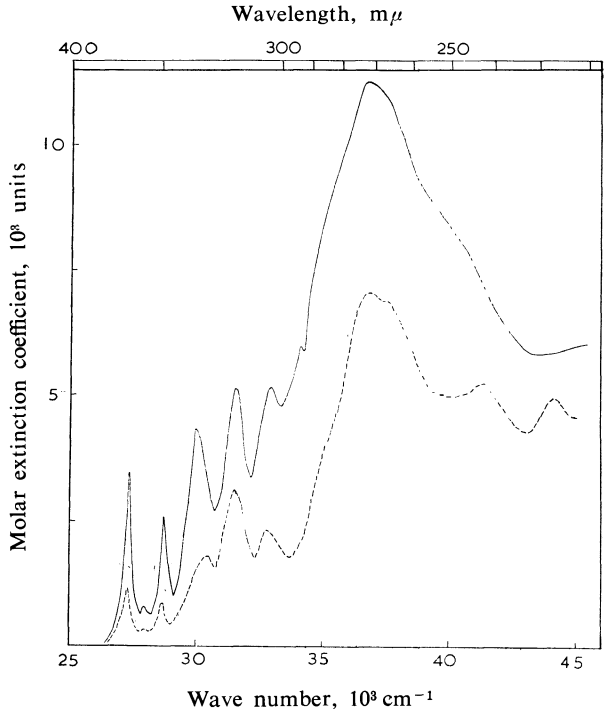

Fig. 5(b) Polarized absorption spectrum of chrysene crystal.

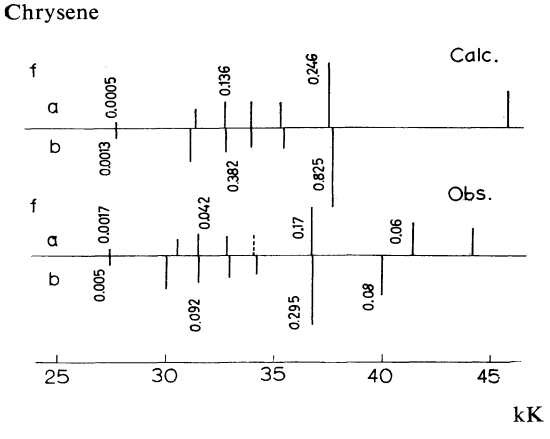

Fig. 6. Calculated and observed band positions of chrysene.

the change in the sign of the splitting can not be explained in this way.

The third $^1B_b$ band, which is the strongest of all the observed bands in solution, was predicted to be long-axis polarized and should be stronger along the a-axis than along the b-axis. However, both the first- and the second-order calculations show that the $^1B_b$ band will move to a higher frequency along tha a-axis, and that along the b-axis the $^1B_b$ and $^1B_a$ states will appear close together. Therefore, the interpretation of the spectrum in the 37000 $cm^{-1}$ region is that along the a-axis the $^1B_a$ band appears at a lower frequency than the $^1B_b$ band, and that the apparent intensity is weakened, since the $^1B_b$ band moves to a higher frequency. The intensity along the b-axis will be larger than along the a-axis since both $^1B_a$ and $^1B_b$ bands are expected to appear in the same region. The second-order calculations demonstrate that the b-axis intensity is stronger than the a-axis in this region and that two bands will be observed along the a-axis while one strong band will appear along b-axis. The observed crystalline spectrum is in fair agreement with this prediction (Fig. 6).

The confirmation of the theory of Ham and Rudenberg[3] concerning the direction of the transition moment is difficult for such an unsymmetrical molecule, because the second-order effect modifies the intensities and positions of each band. However, their theory seems to be correct, since the present calculations, based on their polarization direction, give a satisfactory explanation of the crystalline spectrum.

## Azulene

The ultraviolet and visible spectrum of azulene has been measured in a *n*-heptane solution (Fig. 7 (a), (b) and Table III). A theoretical assignment was made by Pariser;[11]

11) R. Pariser, *J. Chem. Phys.*, **25**, 1112 (1956).

his results are also included in Table III. The crystal structure of azulene was determined by Robertson, Shearer, Sim and Watson,[12] who established that the structure is disordered in such a way that successive azulene molecules are subject to a random reversal of direction. Such disorder in the crystal must be taken into account in the calculation of exciton-type interaction. However, it is verified that it is not necessary to change the usual treatment, since the allowed transition will occur when the molecular transition moments are taken in phase for the specified crystal directions. In Fig. 8 this situation is illustrated for the two molecules in an unit cell. The arrows in the figure indicate the direction of the transition moment reversed in the direction of the molecule B from Fig. 8(a) to Fig. 8(b). The allowed combination in Fig. 8 (a) is $\phi_A'\phi_B-\phi_A\phi_B'$ for the a-axis and $\phi_A'\phi_B+\phi_A\phi_B'$ for the b-axis, while in Fig. 8(b) it is $\phi_A'\phi_B+\phi_A\phi_B'$ for the a-axis and $\phi_A'\phi_B-\phi_A\phi_B'$ for the b-axis, where $\phi_A$ and $\phi_A'$ indicate the wave function of the A molecule in the ground and the excited states and $\phi_B$ and $\phi_B'$ are those for the B molecule. The sign of the dipolar interaction energy is reversed in Fig. 8(b) from Fig. 8(a); it follows that the splitting of the band is not changed by the reversal of the direction of the molecule. This relation can be extended for an infinite number of molecules in the crystal. The second-order calculation of band splitting is performed with a method similar to that described in the previous paragraphs. The calculated dipole-dipole interaction energy is shown in Appendix I, and the secular equation is given in Appendix II. The calculated rerults are compared with the experimental results in Fig. 9 and Table III.

For the first and the second bands, Sidman and McClure[13] had previously measured the polarization in the mixed crystal of azulene in naphthalene. Hunt and Ross[14] published a

pure crystal spectrum for the longer wavelength region; both pairs of authors concluded that the first band is polarized along the short-axis of the molecule. In the present study the pure crystal spectrum has been measured through the (001) plane by a polarized light, as is shown in Fig. 10(b). The projection of molecules according to X-ray results is pictured in Fig. 10(a). The band positions of the visible band are in good agreement with

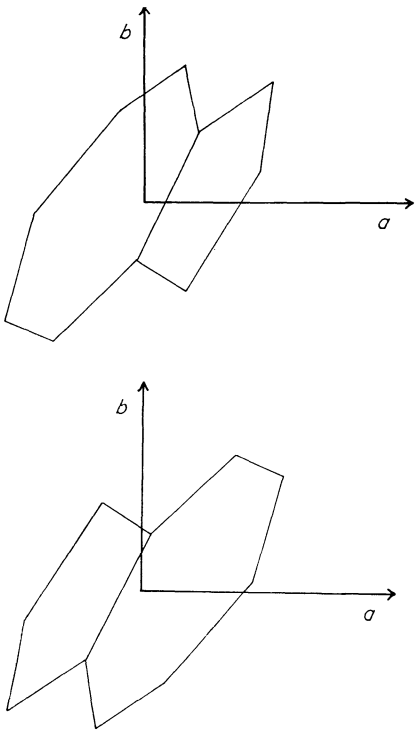

Fig. 10 (a). Projection of the azulene molecule onto the (001) plane.

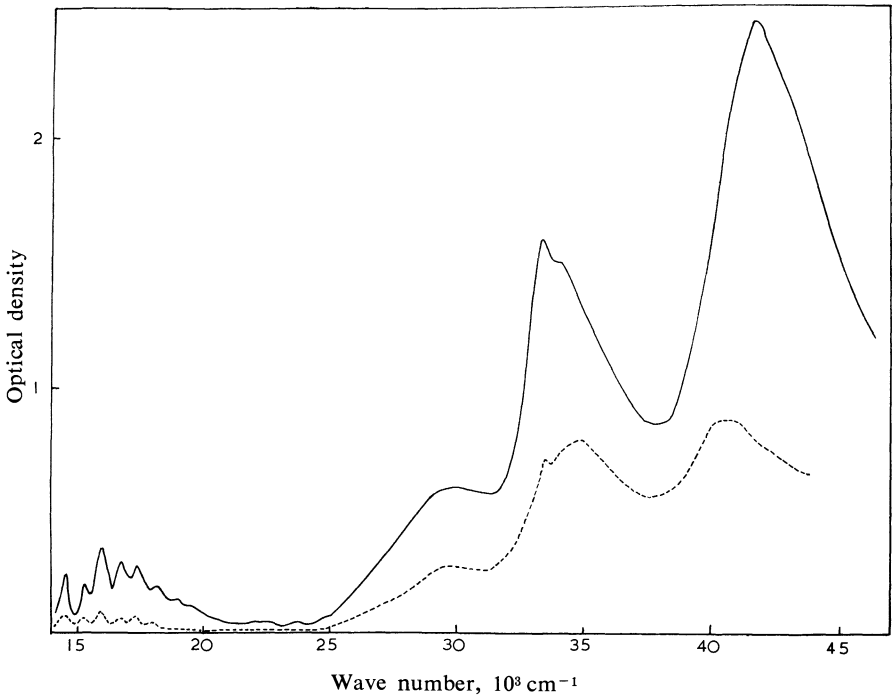

Fig. 10 (b). Polarized absorption spectrum of azulene crystal.

the results of Hunt and Ross within a range of experimental error of $\pm 50\,cm^{-1}$. The dichroic ratio is $D_b : D_a = 5 : 1$; this is in good agreement with the oriented gas value of the short-axis polarization ($D_b : D_a = 4.8 : 1.0$). Since the visible band is situated far from the stronger transitions at higher frequencies, it is possible to treat this band separately from the other transitions. The observed dichroic ratio is in good agreement with the short-axis polarization ratio, so the band may be deduced to be a B-type.

For the second band, Sidman and McClure[13] confirmed the polarization to be long-axis by mixed crystal measurement. Both the present results and the earlier results by Wolf[15] have shown that the absorption is stronger along the b-axis than along the a-axis. If we compare the intensity ratio obtained by the simple oriented gas model with our present results, the dichroic ratio is not in conformity with the long-axis polarization. By the second-order interaction calculation the calculated intensity is still stronger along the a-axis than along the b-axis, but the dichroic ratio is certainly improved. This is mainly due to the interaction with the strongest allowed transition (long-axis polarized), which increases the b-axis intensity and decreases the a-axis intensity. The observed intensity relation might be explained in this way; however, the calculated splitting of $980\,cm^{-1}$ is not clearly observed in the crystal spectrum.

The third band, which has been observed in solution as a shoulder on the tail of a very strong fourth band, is assigned by Pariser to a short-axis polarized B-type band. By a second-order calculation this band is calculated to appear at about $33800\,cm^{-1}$ in both the a- and b-axes, the latter being stronger than the former. In the observed crystal spectrum, the dichroic ratio is in good agreement with these predictions that the b-axis band is stronger than the a-axis and that they will appear at about $33500\,cm^{-1}$.

The fourth absorption band, which is the strongest of all, was shown by Pariser to be a long-axis polarized A-type band. The first order exciton splitting calculation shows that the band should be split very greatly and that the b-axis absorption should be lower in frequency than the a-axis. The second-order calculation shows that it will appear along the b-axis at about $32600\,cm^{-1}$ and along the a-axis at about $41030\,cm^{-1}$. Therefore, the spectrum of the crystal is explained in such a way that the b-axis band is overlapped with the third band and the a-axis band is removed to a higher frequency, at about $40500\,cm^{-1}$.

The fifth band, which was predicted to be of the short-axis polarized B-type, is expected to appear along the b-axis at about $41850\,cm^{-1}$

15) H. C. Wolf, *Solid State Physics*, **9**, 1 (1959).

with the largest intensity and along the a-axis at 43715 $cm^{-1}$ with a smaller intensity. The observed band at 41700 $cm^{-1}$ along the b-axis is assigned to this origin, but along the a-axis the band is not clearly seen because the shifted fourth band overlaps it in this region.

In this way, all the crystalline absorption bands are correlated with the calculated energy levels, but the changes from molecular levels to crystalline states are so complicated that it is difficult to give an explanation of the nature of the crystalline transition by a one-to-one correspondence with each molecular absorption band. The second-order calculation based on Pariser's assignment is shown to be satisfactory in explaining the whole pattern of the crystalline spectrum, but still there remain some discrepancies between the observed and the calculated splittings and intensities. The calculated intensities show a big difference between the

* The oscillator strength of crystal is tentatively determined by assuming the value of birefringence of 0.1 between the b- and a-axes.

strong and weak bands, but the observed spectrum shows a rather stronger mixing, so that there must be unknown mechanism which changes the intensity of the crystalline band.

## Coronene

The ultraviolet absorption spectrum of coronene has been measured in an ethanol solution; three strong absorption bands were observed, as Fig. 11 and Table IV show. In a benzene solution another weaker band is observed in the region of 23400 $cm^{-1}$. The crystal spectrum has been recorded through the (001) plane; it is shown in Fig. 12(b). The crystal structure was determined by Robertson and White,[16] and the projection of molecules onto the (001) plane is pictured in Fig. 12(a). The characteristics of the spectrum resemble these of benzene since coronene has a symmetry like that of $D_{6h}$. The first weak band at 23400 $cm^{-1}$ may correspond to the 2600 Å band of benzene ($^1B_{2u}$); the band in the 29000 $cm^{-1}$ region, to the 2000 Å band of benzene ($^1B_{1u}$), and the strongest band at 33000 $cm^{-1}$, to the 1800 Å band ($^1E_{1u}$).

In the free coronene molecule the transition to the $^1B_{1u}$ state is possible along the three two-fold symmetry axes passing through carbon atoms (three axes like m in Fig. 13), and the transition to the $^1B_{2u}$ state is possible along the other three two-fold axes (three axes like l in Fig. 13). Davydov[1] has discussed the relation between the symmetry of the molecular excited state and that of the crystalline state, but his argument may be justified only when the molecular symmetry axis coincides with the crystalline symmetry axis. In crystal coronene one of the m-axis (with the direction cosines of $m_a=0.7174$, $m_b=0.6865$ and $m_{c'}=-0.1188$) is nearly perpendicular to the c'-axis. Therefore, we will assume that this axis is the pseudo-two-fold unique symmetry axis of coronene in crystal. Namely, the crystal symmetry operation, $C_2^b$, may correspond to the transposition of the molecule

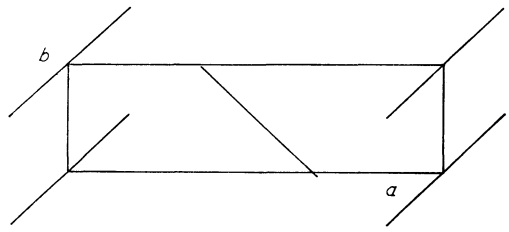

Fig. 12 (a). Projection of coronene molecule onto the (001) plane.

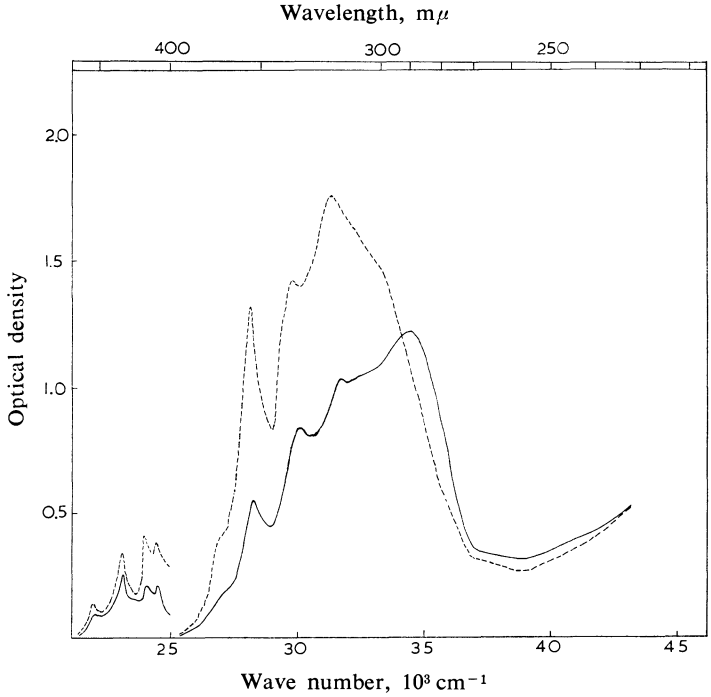

Fig. 12 (b). Polarized absorption spectrum of coronene crystal. (The retardation in the thin crystal (right curve) is about 25 mμ and that in the thick crystal (left curve) is 190 mμ.)

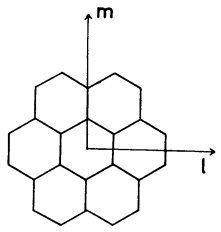

Fig. 13. Coronene.

at the origin to the (1/2, 1/2, 0) position, followed by a rotation of 180° around the m-axis and a rotation of about 90° around the l-axis. In this situation the degeneracy of the electronic transitions might be removed so that the m-axis may be taken as an axis along which the transition to the $^1B_{1u}$ state is possible. From the intensity relations observed in the crystal spectrum, it seems certainly correct to choose the m-axis as an unique two-fold symmetry axis, since the 29000 $cm^{-1}$ band is observed strongly in crystal, while the 22000 $cm^{-1}$ band is very weak. The 22000 $cm^{-1}$ band is supposed to be strengthened in intensity in crystal by mixing with stronger transitions, but in reality the band is observed very weakly in crystal; therefore, the direction of the transition moment is considered to be on the l-axis, which is nearly vertical to the (001) plane.

Lyons and Walsh[17] have calculated the first-order splitting of the $^1E_{1u}$ level, but they did not pay any particular attention to the interaction with the $^1B_{1u}$ state. Actually the observed band shows a mixing of the $^1B_{1u}$ state with the $^1E_{1u}$ state; namely, the intensity of the absorption band at 29000 $cm^{-1}$ is far less than that of the 33000 $cm^{-1}$ band in solution, while it becomes comparable in crystal. Therefore, it might be necessary to include the interaction between the $^1B_{1u}$ state and two $^1E_{1u}$ states. The first-order wave function for each excited states may be given by the following formulae:

$$\left.\begin{aligned}\Psi^{\alpha} &= \frac{1}{\sqrt{2N}}\left(\sum_{i=1}^{N}\phi_{1i}' - \sum_{j=1}^{N}\phi_{2j}'\right)\\ \Psi^{\beta} &= \frac{1}{\sqrt{2N}}\left(\sum_{i=1}^{N}\phi_{1i}' + \sum_{j=1}^{N}\phi_{2j}'\right)\end{aligned}\right\} \quad (9)$$

where $\Psi^{\alpha}$ and $\Psi^{\beta}$ represent the wave functions which are active along the a- and b-axes respectively. The functions $\phi_{1i}'$ and $\phi_{2j}'$ indicate that a molecule at the $1i$-th or $2j$-th site is excited and that the others are in their ground state. The dipole-dipole interaction energies have been calculated over molecules within 20 Å and 40 Å radius spheres; they are shown in Appendix I. The figures for the 40 Å radius summation are in excellent agreement with the values of Lyons and Walsh who employed the Ewald-Kornfeld method for infinite summation, so that the convergence of the summation seems to be sufficient by 40 Å for such a large molecule.

The assignment of the crystalline absorption bands is very much complicated by the presence of the vibrational structures. We have tentatively decided on the assignments shown in Table IV, taking the 31300 $cm^{-1}$ band along the a-axis and the 34500 $cm^{-1}$ band along the b-axis as the split $^1E_{1u}$ components. The other peaks around 28000—32000 $cm^{-1}$ are ascribed to the vibrational progressions of the $^1B_{1u}$ band. The first-order band splitting of the $^1E_{1u}$ level, considering the degeneracy of the band, is 3110 $cm^{-1}$, while the observed value will be 3200 $cm^{-1}$ if we follow the assignment mentioned above. The value suggested by Lyons and Walsh was 3615 $cm^{-1}$; their value might be larger than ours because they used a larger transition dipole moment.

As has been mentioned previously, a characteristic feature of the crystalline spectrum is the mixing of the $^1B_{1u}$ state with the $^1E_{1u}$ state; therefore, the second-order calculations have been made with the first $^1B_{1u}$ state and two degenerate $^1E_{1u}$ levels. The higher $^1B_{1u}$ progressions are disregarded since they are situated close to the $^1E_{1u}$ state. The first trial using the solution's intensity data gave too strong a coupling between the $^1B_{1u}$ and $^1E_{1u}$ states, so we have reduced the magnitude of the transition dipole for the $^1B_{1u}$ state to half of the observed value. The calculated results are compared with the experimental results in Fig. 14 and Tabe IV. It is found that the general pattern of the spectrum is

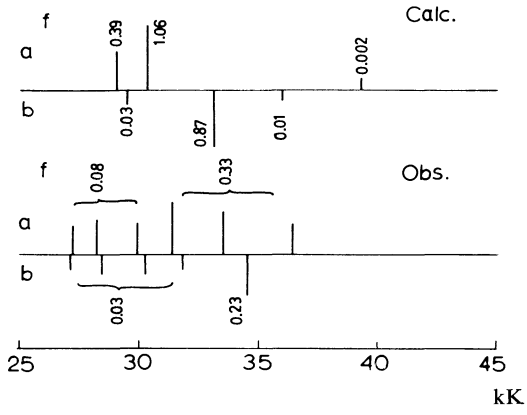

Fig. 14. Calculated and observed band positions of coronene.

17) L. E. Lyons and J. R. Walsh, ibid., 1959, 3447.

rather well reproduced in the calculations, particularly in intensity relations between the $^1B_{1u}$ and $^1E_{1u}$ states, but the splittings are slightly smaller than the observed values. Presumably a more complicated interaction will occur between the $^1B_{1u}$ and $^1E_{1u}$ states in crystal by the electron exchange or another effect, because the electron overlap along the b-axis is expected to be large.

The use of a smaller transition moment for the $^1B_{1u}$ state is possible if we think that the band is originally forbidden in character but appears through the vibrational coupling.

The absorption tail at about 38000 $cm^{-1}$, which continues to the shorter ultraviolet region, may involve a transition to the Rydberg series or to the continuous band.

## Tetracene

The electronic absorption spectrum of tetracence in ethanol and in a crystal has been measured as is shown in Figs. 15 and 16(b). Pariser[18] calculated the energy levels of the molecule; the bands at 21000 $cm^{-1}$ and 34000 $cm^{-1}$ were shown to be short-axis (M-axis) polarized, while the 36400 $cm^{-1}$ band is long-axis (L-axis) polarized. Another transition at about 60000 $cm^{-1}$ was also predicted to be an M-axis polarized band.

The crystal spectrum was measured by Bree and Lyons,[19] but they did not discuss the results with reference to the crystal structure. The present results are nearly in agreement with theirs; in addition, the shape of the 46000 $cm^{-1}$ band is confirmed to be at a shorter

ultraviolet region. The crystal structure has been determined recently by Robertson, Sinclair and Trotter;[20] they have found that the crystal is triclinic with the space group of $P\bar{1}$ (cf. Fig. 16(a)). For this crystal symmetry the selection rule which is strict for the crystal of a higher symmetry does not hold, and possible transitions are observed in all directions of the crystal. The excited state wave functions are:

$$\Psi^{\alpha} = \frac{1}{\sqrt{2N}} \left( \sum_{i=1}^{N} \phi_{1i}' + \sum_{j=1}^{N} \phi_{2j}' \right)$$

$$\Psi^{\beta} = \frac{1}{\sqrt{2N}} \left( \sum_{i=1}^{N} \phi_{1i}' - \sum_{j=1}^{N} \phi_{2j}' \right)$$

where $\phi_{1i}'$ represents the state in which the molecule on the $1i$-th site is excited and the others are in their ground state. These two types of excited-state wave functions will behave differently in intensity relations. Following the crystal structure data, it is found that the M-axis polarized band is stronger for the $\Psi^{\alpha}$ state along the b-axis than along the a-axis, while for the $\Psi^{\beta}$ state the situation is reversed. The L-axis polarized band will appear only for the $\Psi^{\alpha}$ state in both a- and b-axes directions, and the band for the $\Psi^{\beta}$ state will be very weak. The dipole interaction energies have been calculated for every combination of directions of the transition moment on 1st-site and 2nd-site molecules, as Appendix I shows.

The band observed near 20000 $cm^{-1}$ is assigned to the M-axis polarized band on the basis of the dichroic intensity ratio. The b-axis polarized band is considered to be the transition to the $\Psi^{\alpha}$ state, while the a-axis band is regarded as arising from the $\Psi^{\beta}$ state. The first-order dichroic ratio is;

$$D_b : D_a = (\cos m_b(\mathrm{I}) + \cos m_b(\mathrm{II}))^2 / (\cos m_b(\mathrm{I}) - \cos m_b(\mathrm{II}))^2 = 5.1 : 1.0$$

where $m_b(\mathrm{I})$ indicates the angle between the b-axis and the M-axis of the 1st site molecule. The observed dichroic ratio is 2.8 : 1.0. The results of the calculation of splitting between the $\Psi^{\alpha}$ and $\Psi^{\beta}$ states are shown in Table V, where it is shown that the calculated value is less than 30 $cm^{-1}$ according to a weak coupling model. The observed value is as large as 630 $cm^{-1}$; even when a strong coupling model is employed, the calculated value does not exceed 130 $cm^{-1}$. Presumably the interaction involving electron exchange and the charge transfer effect might be important in explaining this splitting. Near the 37000 $cm^{-1}$ region in the crystal another band is observed which is regarded as the M-axis polarized band observed in solution at 34000 $cm^{-1}$.

The strongest L-axis polarized band, situated at 36000 $cm^{-1}$ in solution, is expected to split into $\Psi^{\alpha}$ and $\Psi^{\beta}$ states in the crystal. The first-order band shift is calculated to be about 14000 $cm^{-1}$ for the $\Psi^{\alpha}$ stated and $-6000$ $cm^{-1}$ for the $\Psi^{\beta}$ state. Actually, the $\Psi^{\alpha}$ state is shifted about 8000 $cm^{-1}$ to a higher frequency and the $\Psi^{\beta}$ state, although it can not be clearly seen, seems to be unchanged in position and to overlap with the M-axis polarized band. The $\Psi^{\beta}$ state is calculated to appear more strongly along the b-axis than along the a-axis, so that the extra band along the b-axis near 34000 $cm^{-1}$ might be explained by this origin. The observed smaller shift of the $\Psi^{\alpha}$ state can be explained if we use a smaller value of the transition dipole in crystal; the second-order calculation value using $1/\sqrt{2}$ of the solution's $f$-value is shown in Table V. The $\Psi^{\alpha}$ state shows a splitting of 800 $cm^{-1}$ between the b- and a-axes; such a result cannot be explained by the present calculations. A possible mechanism for this shift is interaction with the higher ionized state in the crystal.

With regard to the band position of the first $^1B_{2u}$ band, the present results are in good agreement with the earlier results of Bree and Lyons, but the present intensity is not in

20) J. M. Robertson, V. C. Sinclair and J. Trotter, *Acta Cryst.*, **14**, 697 (1961).

accordance with theirs. The prsent measuerement of the thickness of the crystal is not as accurate because we have determined the thickness by a retardation of the crystal as measured by a compensator, which might be in error by as much as 20%. The molar extinction coefficient of the first peak is estimated to be $\varepsilon_b = 6300$; this is a half of the value of Bree and Lyons. However, our oscillator strength is larger than theirs, since we have used the usual formula for the oscillator strength instead of that for the reduced oscillator strength. The theoretical intensities are compared with the experimental values in Table V; it is remarkable that the second calculation using the smaller transition dipole for the $^1B_{3u}$ state gives nearly the correct size of the oscillator strength in the crystal. The intensity of the first $^1B_{2u}$ state is smaller than the calculated value; therefore, it seems certain that a general hypochromism occurs in the crystal of tetracene.

## Discussion

When the observed band splittings and intensities are compared with the calculated values, the second-order theory, which includes interactions between several excited levels, is shown to be better than the first-order calculation. In crystals such as azulene and chrysene, the first-order intensity relations are so greatly changed that the direction of the transition moment can not be simply determined from the dichroic intensity ratio for each band. This is quite contrary to the case of substituted benzenes,[2] where the direction of the transition moment has been nicely determined from the intensity relations. When these two cases are examined in the off-diagonal ($H_{ij}$) and the diagonal matrix element ($H_{ii}$, $H_{jj}$) in the second-order secular equation, it is found that a big deviation occurs when the term

$$H_{ij}/H_{ii}-H_{jj}$$

becomes large enough to make for an efficient mixing of several excited states. In cases of substituted benzenes, the separation of each band, $H_{ii}-H_{jj}$, is relatively large, and the off-diagonal term is smaller because of the small magnitude of the transition moment; hence, the simple oriented gas model holds rather well. In the aromatic hydrocarbons described in the present paper, an efficient mixing of excited levels occurs under favorable conditions of large interaction terms and a narrow spacing of excited states. In this way the larger deviation of the intensity relation from the simple oriented gas rule in azulene and chrysene crystals can be explained.

However, there still remains some question unexplained by the dipolar interaction theory. Namely, in coronene and tetracene crystals the calculated splittings do not agree with the observed values. One possible reason for these difficulties might be our ignorance of electron overlap and charge transfer effects, which are certainly important in such crystals as pyrene and perylene.[7] The matrix element, including the electron overlap effect, has been disregarded in the present calculations; however, it would be significant if we consider the interaction between the exciton state and the charge transfer state.[8] Because of the small ionization potential and the large electron affinity of aromatic hydrocarbon molecules, the diagonal element of the charge-transfer state would be comparable in energy to some exciton state, and the off-diagonal term includes the energy which is first-order with the electron overlap. In recent notes[21] some authors have stressed the importance of electron exchange effect in triplet exciton, the magnitude of which has been estimated to be about 5 to 10 $cm^{-1}$, but the effect might be second-order to the electron overlap, which should be one to two orders of magnitude smaller than the present consideration of interaction energy. Therefore, the charge-transfer electron overlap effect may be important in the calculation of splitting, since its magnitude may reasonably be guessed to amount to several hundred reciprocal centimeters under favorable conditions. This point will be explored in a further study.

## Summary

The electronic absorption spectra of single crystals of pyrene, chrysene, azulene, coronene and tetracene have been measured by a polarized light. Some crystal absorption bands exhibit appreciable splittings and changes in intensity relations according to the simple exciton theory. Those results are explained by the use of the second-order exciton calculation without the inclusion of the electron overlap effect. The theoretical results give a fairly reasonable explanation of crystal spectra, and it has been shown that the second-order mixing of excited states plays an essential role in modifying the crystal spectra from the pattern of the free molecule.

The directions of the transition dipoles are referred to the long (l), short (m) and normal (n) axes of the molecule for pyrene, azulene, coronene and teracene. The directions for chrysene are shown below. N. S. means the number of molecules summed.

* Numbers without bracket are for 50Å-radius summation and those in bracket are for 30Å-radius summation.

** Numbers without brackets are for 40Å-radius summation and those in brackets are 20Å-radius summation.

*** The summation was taken for a 30Å-radius sphere only.

# Mean-Square Amplitudes and Force Constants of Tetrahedral Molecules. II. Silicon Tetrachloride*

By Yonezo MORINO and Yoshitada MURATA

(Received July 15, 1964)

In a preceding paper,[1] we have proposed a new method for determining the force field of molecules by the use of the mean-square amplitudes in addition to the vibrational frequencies, and have shown that the application of the method to germanium tetrachloride and carbon tetrachloride molecules provides reasonable sets of the force constants. In the present report, the results of the application of the same method to silicon tetrachloride will be shown, with a special emphasis on the estimation of the uncertainties of the results by a statistical consideration.

In order to use the mean-square amplitudes for the determination of the force field, it is essential to ascertain the precise experimental values of the amplitudes, with their uncertainties. Accordingly, possible sources of experimental errors are discussed in this paper.

The failure of the first Born approximation is often regarded as a serious error for an atom pair with very different atomic numbers. Fortunately, however, silicon tetrachloride has the advantage that the error caused by the Born approximation is negligibly small; the correction is only 1% for the Si–Cl pair, in contrast to about 20% for the Ge–Cl pair in germanium tetrachloride, or 10% for the C–Cl pair in carbon tetrachloride.[2] The finite sample size is another source of the error,[3,4] and presumably the largest one for this molecule. It is assumed in the theory of gas diffraction that the scattering occurs at an infinitesimal point, but in a practical experiment the diffracted beams come from a finite cross-section of the primary beam in the gas stream. A needle-type nozzle is, therefore, employed in this study in order to reduce the sample delocalization, and at the same time, the correction for the finite sample size was estimated on the basis of the distribution of the gas molecules along the primary beam, which was measured with a special device which will be described in detail in a following paper.[5]

The atomic distances in the silicon tetrachloride molecule have been determined by the visual method by Wierl,[6] Brockway and Wall,[7] Pauling and Brockway,[8] and Iwasaki et al.[9] The Si-Cl distances obtained are 2.02Å, 2.02Å, 2.00±0.02Å and 2.01±0.02Å respectively and the tetrahedral structure has been established, although the mean-square amplitudes have not been reported any of the above papers.

## Experimental

The apparatus used for the electron diffraction measurement is the same as that reported in a previous paper,[1] except for a few improvements. Diffraction photographs were obtained on Fuji Process Hard plates through an $r^3$-sector, with camera lengths of 11.8 cm. and 27.9 cm. The accelerating voltage was about 45—47 kV., and its fluctuation and drift were regulated to within 0.1%. The sample of silicon tetrachloride was kindly provided by the Shin-Etsu Chemical Industrial Co., Ltd. The gaseous sample was held in a glass flask of about 1 l. at a pressure of about 30 mmHg, and the gas flow was controlled by a needle valve at the rate of decrease in the gas pressure in the flask of about 1 mmHg/min. The exposure time was varied from 2 to 5 min. Two kinds of nozzles were used. One was of a drum-type, the same as that reported by Kuchitsu;[4] it is shown in Fig. 1. The other, a needle-type nozzle, was made of a straight tube of stainless steel with an inner diameter of 0.55 mm. The drum-type nozzle gives a wider spread of the gas distribution at the diffraction center, and it presumably leads to an apparent increase in the mean-square amplitudes. Therefore, the needle-type nozzle is more suitable for obtaining the precise values of the mean-square amplitudes. The drum-type nozzle was, then, used as an auxiliary nozzle for calibrating the scale factor of the needle-type nozzle, because the needle-type nozzle had no space

* A preliminary report on this work was presented at the International Conference on Magnetism and Crystallography, Kyoto, 1961.

on which to attach a reference gold-foil without disturbing the gas flow near the nozzle.

The beam current was about 0.02 $\mu$amp. for the short camera length and about 0.005 $\mu$amp. for the long camera length when the drum-type nozzle was used. In the case of the needle-type nozzle, it was necessary to increase the beam current by five times. The photographs were developed at 20°C for 5 min. with an FD-131 developer diluted twice. The photographs were scanned with a Rigaku-Denki MP-3 microphotometer. The optical densites of the plates were regulated to be less than 0.6. It has been confirmed by Morino and Iijima[10] that the intensity is directly proportional to the photographic density in the range of density less than 0.6.

The wavelength of the electron beam was calibrated with reference to the diffraction pattern of the gold-foil on the assumption that the camera length for the gas pattern was equal to that for the gold-foil pattern. After a gas pattern had been taken, the gas nozzle was replaced by the gold-foil and the scattering pattern of the reference was taken on the same photographic plate, beside the gas pattern, by sliding the plate holder. In order to make a precise calibration, it was thought important to make sure that the reference gold-foil was placed in exactly the position of the gas diffraction center, and that the photographic plate was set in exactly the same position when the photographic plate was moved for the reference pattern to be taken; the latter test was necessary because the plate may not be exactly perpendicular to the beam axis due to a mechanical imperfection in the construction of our plate-holder.

For the former test, the gas pattern was taken at a reversed orientation where the nozzle, together with the gold-foil, was rotated around the axis by 180°, keeping their relative positions fixed (see Fig. 1.). The difference in the camera lengths, if there is any, should have a reverse effect by the same amount on the diffraction pattern at the reversed orientation. In fact, about a 0.22% increase in the atomic distance was observed after this reversal of the nozzle, as is shown in Table I. For the latter test, the difference in the camera length was measured by taking gold-foil patterns at the center of the photographic plate, where, in our normal operation, the gas pattern was taken, and also at the place where the reference pattern was normally taken; the difference in the camera length thus found was corrected for each gas pattern.

A slight blackening by an extraneous scattering was observed by a blank experiment near the outer periphery of the pattern. The density of the blank photograph was subtracted from each photograph in order to correct for the extraneous scattering.

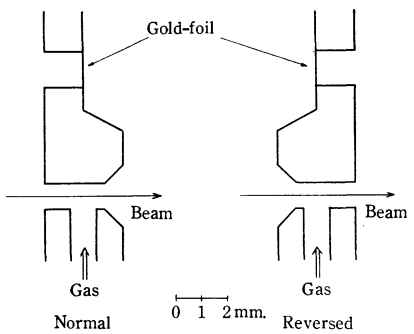

Fig. 1. Normal and reversed orientations of the drum-type nozzle.

## Analysis

A small fluctuation from the defined opening, $\theta = cr^3$, was observed in the $r^3$-sector used in this experiment. The variations in the parameters caused by the correction for this sector deficiency were $-0.0013$Å and $+0.0009$Å for the Si–Cl and the Cl–Cl distances respectively, and $-0.0021$Å and $+0.0017$Å for the mean amplitudes of Si–Cl and Cl–Cl respectively. These corrections were especially important for the mean amplitudes in comparison with their total errors, even though the defects in the sector were less than 1%.

In order to calculate the molecular intensities, a correction for the so-called non-nuclear scattering was made by Bartell's method.[11] For the atomic scattering factors of the silicon and chlorine atoms, appropriate averages of the factors given by Viervoll and Ögrim[12] and those by Tomiie and Stam[13] were used. The values of the inelastic scattering factors were taken from the table given by Bewilogua,[14] and the values of $\Delta\eta(\theta)$, from the table of Ibers and Hoerni.[15]

The reduced molecular intensity curves thus obtained were compared with the theoretical expression:

$$qM(q) = \frac{10}{\pi} \sum_i \sum_j{}' k_{ij} \frac{1}{r'_{aij}} \frac{Z_i Z_j}{\sum_k (Z^2_k + Z_k)} \times \mu_{ij} \cos \Delta\eta_{ij} \exp\left(-\frac{1}{2}(l'_{aij})^2 s^2\right) \times \sin\left(sr'_{aij} - s^3\kappa_{ij}\right) \quad (1)$$

by a procedure essentially the same as that used in a previous paper:[1] the parameters to be determined by the least-squares calculation were the atomic distances, $r'_a$(Si–Cl) and $r'_a$(Cl–Cl), the mean amplitudes, $l'_a$(Si–Cl) and $l'_a$(Cl–Cl), and the indices of resolution, $k$(Si–Cl) and $k$(Cl–Cl). As was described in

a previous paper,[16] the indices of resolution varied independently for each atomic pair. The $r'_a$ and $l'_a$ constants are not equal to the molecular constants, $r_a$ and $l_a$ respectively, since the effect of gas distribution at the diffraction center is involved in the former. The anharmonicity constants, $\kappa$(Si–Cl) and $\kappa$(Cl–Cl), were fixed at approximate values (perhaps a very crude one for $\kappa$(Cl–Cl)) as follows.

If a potential funtion of the Morse-type is assumed for the bonded Si–Cl pair,[17] the anharmonicity parameter, $\kappa$, and the so-called anharmonic term of the internuclear distance, $\langle \Delta z \rangle$, may be approximately represented by:[18]

$$\kappa = \frac{a}{6} l^4 \tag{2}$$

and

$$\langle \Delta z \rangle = \frac{3}{2} a l^2 \tag{3}$$

where $a$ is the asymmetry constant of the Morse function and may be obtained on the basis of the parameters given by Lippincott and Schroeder.[19] The parameter $\kappa$(Si–Cl) is thus found to be $1.21 \times 10^{-6}$ Å$^3$.

The anharmonicity parameter $\kappa$ for the non-bonded Cl–Cl pair may be obtained if the actual motion of the two chlorine atoms along the line connecting their equilibrium positions is approximated by a motion under a Morse potential. In such a case, the following relation is derived from relations 2 and 3:

$$\kappa = \frac{1}{9} l^2 \langle \Delta z \rangle \tag{4}$$

where $l$ is the mean amplitude of the atom pair and can be obtained by measurements. On the other hand, the $\langle \Delta z \rangle$ value for the pair is given by:

$$\langle \Delta z \rangle (\text{Cl–Cl}) = 2\sqrt{\frac{2}{3}} \langle \Delta z \rangle (\text{Si–Cl}) \tag{5}$$

since there is no totally symmetric deformation vibration for a tetrahedral molecule.[20] The parameter $\kappa$(Cl–Cl) thus obtained is $7.11 \times 10^{-6}$ Å$^3$.*

As will be mentioned in the next section, it is reasonable to assume that the weight matrix is given by a diagonal form when the observations are made in the interval of $\Delta q = 1$. Thus, the statistical weight given in Fig. 1(c) of Ref. 16 was used in the present analysis.

As is shown in Table I; the least-squares fit was carried out on several observed molecular intensity curves for each of the three kinds of nozzles; for the drum-type nozzle in the normal and reversed positions and for the needle-type nozzle. Ten sets of parameters with their standard deviations were obtained by making the respective least-squares outputs converge.[21] Table I shows the average values for each nozzle with the estimated standard deviations $\sigma_1$ and $\sigma_2$; $\sigma_1$ denotes the standard deviation for the average value of the atomic distances obtained by the least-squares fit, and $\sigma_2$, the standard deviation obtained from the deviations of the several observed values from the average value.[16] The calculation was carried out by means of two digital computers, PC-1 and PC-2, in the University of Tokyo.

It has already been mentioned that the atomic distances obtained by the reversed orientation of the nozzle were larger than those obtained by the normal orientation.** Because there are four observations corresponding to the normal position and two to the reversed position, the most probable values of the observed atomic distances may be given according to an ordinary statistical theory, by means of the arithmetic means of each averaged value, with their standard deviations $(\sqrt{3}/4\sqrt{2})(6\sigma_-^2 + \sigma_+^2)^{1/2}$, where $\sigma_-$ and $\sigma_+$ denote their standard deviations. However, the values of $\sigma_+$ obtained in this experiment is not considered to be reliable, because it was obtained

* In the analysis mentioned above, the anharmonicity constants were fixed as the estimated values. However, when they were taken as variable parameters in the least-squares analysis, the following values were obtained for the most probable values and their standard deviations (in $10^{-6}$ Å$^3$ units):

| | | Average | $\sigma_1$ | $\sigma_2$ |
|---|---|---|---|---|
| Needle-type nozzle: | $\kappa$(Si-Cl) | 2.2 | 1.3 | 0.3 |
| | $\kappa$(Cl-Cl) | 11.3 | 4.1 | 3.3 |
| Drum-type nozzle: | $\kappa$(Si-Cl) | −2.1 | 1.7 | 1.7 |
| | $\kappa$(Cl-Cl) | −1.1 | 5.9 | 6.3 |

The negative values of $\kappa$ obtained for the drum-type nozzle may be caused by the effect of finite sample distribution. When this nozzle is used, some of the scattered electrons are screened by the edge of the nozzle because of the finite spread of the gas molecules, and they do not reach the photographic plate at larger scattering angles. Therefore, the center of gravity of the distribution of gas molecules, by which electrons are scattered to a given point on the photographic plate, changes with the scattering angle; the change makes the effective $\kappa$ values significantly different from the ideal values. By using the distribution function of the gas molecule obtained for the drum-type nozzle,[5] the shift, $\kappa$, caused by the above shielding effect was approximately determined by a numerical calculation to be $-1 \times 10^{-5}$ Å$^3$ and $-2 \times 10^{-5}$ Å$^3$ for Si–Cl and Cl–Cl respectively. The deviations in atomic distances obtained in this analysis were taken into account in estimating the systematic errors caused by uncertainties in the assumed $\kappa$ values.

** This discrepancy may be explained by an asymmetric distribution of the gaseous sample, as will be described in a following paper.[5]

Four observed curves were used.
$r'_a$ and $l'_a$: See text.

from only two observations. On the other hand, $\sigma_-$ is somewhat more reliable since it was obtained from four observations. Therefore, it seems more reasonable in this case to assume $\sigma_+^2 \sim 2\sigma_-^2$ since both experimental procedures are essentially the same, and the standard deviation for the most probable values is taken to be $(\sqrt{3}/2)\sigma_-$.

After the series of corrections mentioned above, the final results for the observed atomic distances and their standard deviations shown in Table II have been obtained. As has been mentioned above, the values obtained by using the needle-type nozzle are suitable for determining the mean amplitudes, while the average of all the observed values were used for the indices of resolution, because the latter are not influenced by the sample delocalization around the nozzle.[5]

The scale factor for the needle-type nozzle was adjusted to give the atomic distances consistent with those obtained with the drum-type nozzle. Fortunately, the apparent increment or decrement of the atomic distances in the drum-type nozzle, $\Delta r$, was in almost the same ratio for Si-Cl and Cl-Cl; the Cl-Cl distance obtained by the needle-type nozzle

TABLE II. FINAL RESULTS OF THE LEAST-SQUARES ANALYSIS
($r$ and $l$ in Å units)

| Parameter | Most probable value | $\sigma_1$ | $\sigma_2$ |
|---|---|---|---|
| $r_a$(Si-Cl) | 2.0182 | 0.0003 | 0.0010 |
| $r_a$(Cl-Cl) | 3.2928 | 0.0006 | 0.0018 |
| $l'_a$(Si-Cl) | 0.0479 | 0.0005 | 0.0006 |
| $l'_a$(Cl-Cl) | 0.0905 | 0.0007 | 0.0009 |
| $k$(Si-Cl) | 1.020 | 0.005 | 0.019 |
| $k$(Cl-Cl) | 1.015 | 0.009 | 0.017 |

was longer by 0.0007 Å than that obtained by the other nozzle, but this discrepancy is smaller than the uncertainty of the Cl-Cl distance.

The photographs taken with the long camera distance ($q=8-36$) were analyzed separately because their index of resolution was much larger than that derived from the photographs taken with the short camera distance. These results will be described in the Appendix.

## The Estimation of the Uncertainties of the Molecular Constants

**Atomic Distances.**—Let us first consider the uncertainties of the observed atomic distances. The standard deviation of each least-squares fit, $\sigma_1$, was found to be about 0.0003 Å and 0.0006 Å for the Si-Cl and the Cl-Cl pairs respectively (Table II), whereas the $\sigma$ values of the fluctuations among the mean values of the atomic distances obtained by the respective least-squares fit, $\sigma_2$, were 0.0010 Å and 0.0018 Å respectively. If the experimental conditions were kept strictly the same for all photographs, the latter should have been equal to the former. The difference between $\sigma_1$ and $\sigma_2$ may be attributed mainly to the difference between the accelerating voltages when the photographs of the sample and those of the gold-foil reference were taken, to the failure in locating the center of the halos when the plates were photometered, to the difference in the gas spread among different exposures, to the difference in the conditions of developing the photographic plates, and to random errors in the determination of the camera lengths for the sample and for the reference. In our present experiment, none of these sources of difference can be corrected for by the measurement of the deviations. All of them can occur randomly and, hence, they must be included in the random errors, $\sigma_2$, described above.

The systematic errors consist of all the uncertainties which do not occur at random and which can, in principle, be estimated. Uncertainties of various corrections made of the

observed values should also be included in these errors. For instance, the true lattice constant of the gold-foil used in this experiment may have been different from the assumed value, 4.070Å; this difference should give an uncertainty to the scale factor. It was reported by Morino and Iijima that the error of this origin may be 0.05%.[10] A gradual drift of the accelerating potential during the measurement may be another source of the uncertainty: it was found to be within 0.1%, corresponding to 0.05% in $\lambda$.

The inclination of the plates has been corrected for by the procedure described in the Experimental Section. The $\sigma$ in the measurement of the correction gives an uncertainty of 0.03% to the final result concerning the atomic distance.

Another error may originate from the difference in the camera lengths between the sample and the reference, as has been pointed out in the preceding section.

The failure in estimating the correct anharmonicity constants may possibly lead to some uncertainty in the final results, because the anharmonicity constant has an intensive correlation with the interatomic distance. In order to estimate these uncertainties, the parameters $\kappa$ were either taken as variable parameters or were fixed as constants of various estimated values. The uncertainties thus estimated are 0.0010Å and 0.0025Å for the Si–Cl and Cl–Cl distances respectively.

If the accuracy of the measurement be expressed by the limit of errors, two-and-a-half times the standard deviation plus the systematic errors, it corresponds to taking a 99% confidence interval. Because the individual errors are considered to be all mutually independent, the square roots of their squared sums, 0.0034Å and 0.0062Å (as is shown in Table III), are taken as the limit of errors of the Si–Cl and Cl–Cl pairs respectively.

TABLE III. ERRORS OF THE ATOMIC DISTANCES (in Å units)

| Source of error | $r$(Si–Cl) | $r$(Cl–Cl) |
|---|---|---|
| Random error ($2.5\sigma$) | 0.0025 | 0.0045 |
| Drift of voltage | 0.0010 | 0.0017 |
| Lattice constant | 0.0010 | 0.0017 |
| Inclination of plate | 0.0015 | 0.0025 |
| Effect of $\kappa$ | 0.0010 | 0.0025 |
| Total error | 0.0034 | 0.0062 |

**Mean-Square Amplitudes.** — The errors in the mean amplitudes are estimated in the following way. The standard deviations obtained by the least-squares method for each of the four molecular intensities, $\sigma_1$, were 0.0005Å and 0.0007Å for Si–Cl and Cl–Cl respectively, while those of the fluctuations from the mean values, $\sigma_2$, were found to be 0.0006Å and 0.0009Å respectively. As the standard deviations, $\sigma_1$ and $\sigma_2$, are almost equal in magnitude, either of them can be taken as a measure of the random error of the mean amplitude.

It should be mentioned in this connection that an appropriate interval of the observations, $\Delta q$, should be taken if a diagonal weight matrix is used in the least-squares analysis. It appears plausible to take the interval $\Delta q$ as unity in our experiment because of the following consideration.

(1) If the interval $\Delta q$ decreases, the standard deviation, $\sigma_1$, decreases while $\sigma_2$ is expected to remain almost invariant. Since the observations made at an unreasonably small interval can not be regarded as mutually independent, such a $\sigma_1$ value is of little statistical significance; for a proper treatment, a weight matrix with off-diagonal elements must be used in such a case.[22] In other words, only for the range of $\Delta q$ for which $\sigma_1$ is not smaller than $\sigma_2$ may the weight matrix be approximated by a diagonal form. (2) The standard deviations, $\sigma_1$, obtained by the least-squares analysis of $f(r)$ by using diagonal matrices are of almost the same magnitude as those shown in Table I(b) of Ref. 16, where the number of the observations was the same as in the case of the analysis of $qM(q)$, where the interval was taken to be $\Delta q=1$. It, therefore, seems likely that the observations are mutually independent if the interval is taken to be as small as unity.

The above arguments are based on somewhat indirect reasoning. It may, nevertheless, be a plausible approximation for the weight matrix in a diagonal form corresponding to $\Delta q=1$ to be taken in our experiment. The random errors obtained by taking two-and-a-half times the present standard deviations, 0.0015Å and 0.0023Å for Si–Cl and Cl–Cl respectively, will, therefore, be statistically adequate.

Of the uncertainties which belong to the systematic errors, those from the drift of the accelerating voltage and from the lattice constant are both about 0.05%, while that from the fluctuation of the camera length is 0.08%, as has already been described. The contribution from the multiple sacttering may not be important, because the indices of resolution were found to be roughly unity. Even if the multiple scattering were present, it would have a significant effect only on the effective damping factor in the range $q \lesssim 10$.[23] Since the

22) Y. Murata and Y. Morino, *Acta. Cryst.*, to be published.

23) J. A. Hoerni, *Phys. Rev.*, **102**, 1530 (1956).

mean amplitudes were determined in the range $q=18-100$, the effect of the multiple scattering on the mean amplitude may be ignored. The effect of the finite sample size has been corrected for by estimating the distribution of the gas molecules.[5] The uncertainty in the theoretical approximation for this procedure was estimated to be about 10%, as will be described in a following paper.[5] The uncertainty caused by the experimental error in the intensity measurement cannot be estimated in a reliable way. However, even if it were assumed to be 50%, which is certainly an overestimate, it would have no appreciable influence on the final results. The failure of the Born approximation, and the imperfection in the assumption of a linear relationship between the photographic darkness and the electron intensity, is so slight that the errors in their corrections are negligible. The error caused by the correction for the extraneous scattering is probably included in $\sigma_2$. The final values of the limit of errors are 0.0016 Å for Si–Cl and 0.0024 Å for Cl–Cl, as is shown in Table IV.

TABLE IV. ERRORS OF THE MEAN AMPLITUDES* (in Å units)

| Source of error | $l$(Si-Cl) | $l$(Cl-Cl) |
|---|---|---|
| Random error ($2.5\sigma$) | 0.0015 | 0.0023 |
| Sample size | 0.0005 | 0.0007 |
| Total error | 0.0016 | 0.0024 |

* Errors of negligible magnitude are excluded from the table.

The uncertainties in the indices of resolution are considered to arise from the same origins as those in the mean amplitudes, except for the finite sample size, which makes no appreciable contribution to the uncertainties in the former. The standard deviations obtained from the ten plates, $\sigma_2$, were 0.019 and 0.017, and the $\sigma_1$ values for each least-squares fit were 0.005 and 0.009 for $k$(Si–Cl) and $k$(Cl-Cl) respectively. The limit of errors in the indices of resolution are, therefore, taken to be 0.05 and 0.04.

## Results

**Atomic Distances and Mean-Square Amplitudes.** — The atomic distance obtained by the least-squares fit of the observed curve to the molecular intensity function, $qM(q)$, is neither the equilibrium distance, $r_e$, nor the mean value of the internuclear probability distribution function, $r_g$. When $r'_a$ is corrected to $r_a$ to compensate for the difference in the camera lengths, the observed distance, $r_a$, is approximately equal to the mean value with respect to the radial distribution function; it is related to $r_g$ as follows;[1]

$$r_g = r_a + l^2/r_a \tag{6}$$

The observed mean amplitude, $l_a$, for which the effect of the sample size is corrected, is approximately equal to $l_g$, the mean amplitude referred to $r_g$ as will be shown below. It is assumed that the internuclear probability distribution function is represented by:

$$P(r) = [1+\beta_1(r-r_e)+\beta_2(r-r_e)^2 + \beta_3(r-r_e)^3]\,P_h(r) \tag{7}$$

where $P_h(r)$ is a probability distribution function corrected to the harmonic oscillator. The observed mean-square amplitude, $l_a^2$, is represented by:

$$\begin{aligned} l_a^2 = l_\alpha^2 + l_\alpha^4\{&2(\beta_2+\gamma\beta_1)-(\beta_1+\gamma)^2 \\ &-6l_\alpha^2(\beta_3+r\beta_2)(\beta_1+\gamma) \\ &-9l_\alpha^4(\beta_3+\gamma\beta_2)^2\} + l_\alpha^4\{(1/r_e^2) \\ &+6l_\alpha^2(\beta_3+\gamma\beta_2)/r_e\} \end{aligned} \tag{8}$$

and $l_g^2$ is represented by:

$$\begin{aligned} l_g^2 = l_\alpha^2 + l_\alpha^4\{&2(\beta_2+\gamma\beta_1)-(\beta_1+\gamma)^2 \\ &-6l_\alpha^2(\beta_3+\gamma\beta_2)(\beta_1+\gamma) \\ &-9l_\alpha^4(\beta_3+\gamma\beta_2)^2\} \end{aligned} \tag{9}$$

where $\gamma = (\langle\Delta x^2\rangle + \langle\Delta y^2\rangle)/2\langle\Delta z^2\rangle r_e$ and $l_\alpha$ is the mean amplitude referred to the harmonic oscillator. The last term in Eq. 8 is of the order of $(l/r)^2$. Therefore, $l_a$ is approximately equal to $l_g$.[17] It may easily be shown that almost the same result can be obtained if the Morse potential is assumed, in which case the term of $(r-r_e)^6$ is significant.

It should also be noted that the difference in the observed mean amplitudes, $l_g$, from the amplitudes, $l_\alpha$, which refer to the harmonic oscillators, is negligibly small when it is compared with their experimental errors; accordingly, $l_g$ may be used directly for the computation of the force constants.

We have recently proposed an internuclear distance parameter, $r_\alpha$:[24]

$$r_\alpha = r_g - (\langle\Delta x^2\rangle + \langle\Delta y^2\rangle)/2r_e - \delta r \tag{10}$$

where $\delta r$ is the correction for the centrifugal distortion; it is negligibly small for this molecule. For a tetrahedral molecule, $XY_4$, the perpendicular amplitudes, $\langle\Delta x^2\rangle$ and $\langle\Delta y^2\rangle$, are given by,

for the X-Y pair:

$$\langle\Delta x_1^2\rangle = \langle\Delta y_1^2\rangle = \frac{\mu_Y}{4}\langle Q_2^2\rangle + \left\{\frac{2}{\sqrt{3}}\mu_X L^{-1}{}_{33} - \left(\frac{4}{\sqrt{3}}\mu_X + \frac{\sqrt{3}}{2}\mu_Y\right)L^{-1}{}_{34}\right\}^2\langle Q_3^2\rangle$$

24) Y. Morino, K. Kuchitsu and T. Oka, *J. Chem. Phys.*, 36, 1108 (1962).

$$+\left\{\frac{2}{\sqrt{3}}\mu_X L^{-1}{}_{43} - \left(\frac{4}{\sqrt{3}}\mu_X + \frac{\sqrt{3}}{2}\mu_Y\right)L^{-1}{}_{44}\right\}^2\langle Q_4^2\rangle \quad (11)$$

and for the Y–Y pair:

$$\langle \Delta x_2^2\rangle = \frac{2}{3}\mu_Y^2(L^{-1}{}_{33}+L^{-1}{}_{34})^2\langle Q_3^2\rangle + \frac{2}{3}\mu_Y^2(L^{-1}{}_{43}+L^{-1}{}_{44})^2\langle Q_4^2\rangle \quad (12)$$

$$\langle \Delta y_2^2\rangle = \mu_Y\langle Q_2^2\rangle, \quad (14)$$

where $\mu_i$ denotes the reciprocal mass and $L^{-1}{}_{ij}$ the $i$, $j$ element of the $\boldsymbol{L}^{-1}$ matrix. The x and y axes are taken to be as shown in Fig. 2. The values of $r_\alpha$ obtained in this way are shown in Table V. The uncertainties listed in Table V are the 99% confidence limit of errors, including the systematic errors, as has been discussed above.

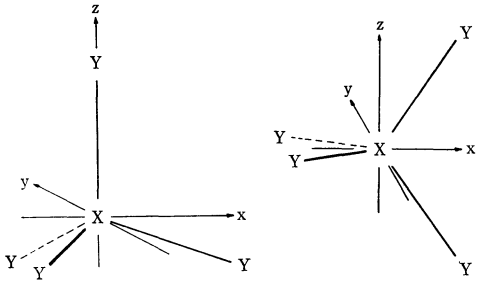

Fig. 2. Cartesian coordinates. The $z_i$ axes ($i$=1 or 2) are taken in the direction of the atomic pair at their equilibrium positions, the $x_i$ axes are taken on the plane Y-X-Y and perpendicular to $z_i$, and $y_i$ are perpendicular to $x_i$ and $z_i$.

TABLE V. FINAL RESULTS OF THE MOLECULAR CONSTANTS ($r$, $l$ and $\delta$ in Å units)

| | | |
|---|---|---|
| $r_g$ | 2.0193±0.0034 | 3.2953±0.0062 |
| $r_\alpha$ | 2.016 ±0.004 | 3.293 ±0.007 |
| $l_g$ | 0.0470±0.0016 | 0.0892±0.0024 |
| $k$ | 1.020 ±0.048 | 1.015 ±0.043 |
| $\delta_g$ | 0.0022±0.0032 | |

In this type of molecule, there is no totally-symmetric deformation mode; hence, the shrinkage of the Y–Y distance can be evaluated only by means of quadratic potential constants, just as in the case of linear molecules.[20] It is shown to be 0.0036Å for Cl–Cl. The observed shrinkage, $\delta_g$, on the other hand, is 0.0022±0.0032Å. It should be noted here that the shrinkage is not influenced by the uncertainty in the scale factor; it is given by the difference between two large quantities, both of which vary in the same ratio, when the scale factor changes.

The distance $r_\alpha$ does not show any shrinkage effect, because by definition it does not include the perpendicular vibration. The experimental result satisfies this requirement, although the uncertainty in the measurement does not give any clear evidence for the presence of the shrinkage effect in $r_g$ or for its absence in $r_\alpha$.

**Force Constants.**—It has already been pointed out that, in the tetrahedral molecules, all of the force constants in the general quadratic form cannot uniquely be determined from the vibrational frequencies alone. Accordingly, mean-square amplitudes cannot be calculated simply by using the frequencies. Since there are four frequencies in contrast to five constants, one degree of freedom is left undetermined. The two mean-square amplitudes which are compatible with the four vibrational frequencies, if taken as a set of coordinates, are given by a point on a closed curve given by the following set of relations:

$$l^2(\text{Si–Cl}) = \frac{1}{4}G_{11}\langle Q_1^2\rangle + \frac{3}{4}G_{33}\langle Q_3^2\rangle - \frac{3}{4}L_{34}^2(\langle Q_3^2\rangle - \langle Q_4^2\rangle) \quad (14)$$

$$l^2(\text{Cl–Cl}) = \frac{2}{3}G_{11}\langle Q_1^2\rangle + \frac{1}{9}G_{22}\langle Q_2^2\rangle + \frac{1}{6}(4G_{33}+4G_{34}+G_{44})\langle Q_3^2\rangle - \frac{1}{6}(2L_{34}+L_{44})^2(\langle Q_3^2\rangle - \langle Q_4^2\rangle) \quad (15)$$

$$(G_{33}-L_{34}^2)(G_{44}-L_{44}^2) = (G_{34}-L_{34}L_{44})^2 \quad (16)$$

where the $G_{ij}$'s are the elements of the $\boldsymbol{G}$-matrix, and the $\langle Q_i^2\rangle$'s are the squared mean

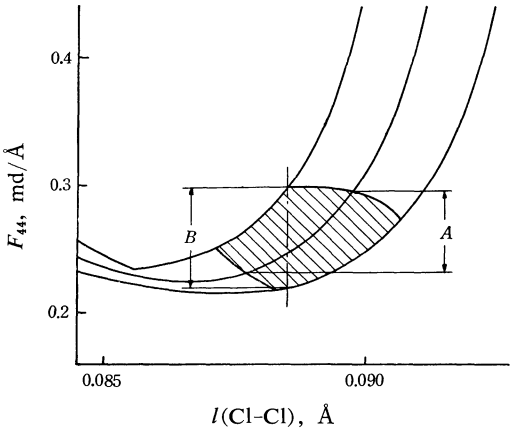
values of the displacements of the normal coordinates. The curve is shown in Fig. 3.



For the tetrahedral molecules, all fundamentals are Raman active, while only two frequencies of the symmetry $F_2$ are active in the infrared; for silicon tetrachloride one of them has a frequency too small to be observed by an ordinary infrared spectrometer. For the calculation of the force constants, we must use the normal frequencies of the molecule in the gaseous state. Since no observations of the Raman spectrum of this molecule in the vapor state had been reported, the measurement of the gaseous Raman spectrum was undertaken. The details of the experiment have beed reported elsewhere.[25] The vibrational frequencies obtained in this measurement are used in the calculations except for $\nu_3$, for which the fundamental frequency obtained by the infrared spectrum in the gaseous state[25] was used.

It is not practicable to make the correction of fundamental frequencies to the normal frequencies, because we have no exact knowledge on the anharmonicity factors of the potential function as a basis for calculating the correction. A tentative assumption regarding the potential function shows that the correction may be of the same order of magnitude as the uncertainties of the frequencies. The uncertainties in the frequencies cause the spread of the position and the size of the curve shown in Fig. 3. On the other hand, the mean amplitudes obtained by the electron diffraction experiment are expressed by an area enclosed by a circle which represents the limit of errors around the observed values. Thus, any point included in the overlapping area, the shaded portion in Fig. 3, is compatible with both the observed mean amplitudes and the observed vibrational frequencies within the limit of errors. As is clearly indicated in Figs. 4a and 4b, the uncertainties of the force constants originate from the mean amplitudes by the same order of magnitude as from the vibrational frequencies.

Table VI gives the force constants of the potential function in the general quadratic form in terms of the symmetry coordinates and of the internal coordinates. The force constants of the Urey-Bradley force field, with the additional assumption proposed by Shimanouchi that $F' = -(1/10)F$,[26] were computed by using the observed vibrational frequencies; the results are shown in Table VII. The possible range of the mean amplitudes

assumption of the Urey-Bradley type with $F' = -(1/10)F$ is approximately permissible in the case of silicon tetrachloride.

## Summary

The atomic distances and the mean-square amplitudes of silicon tetrachloride have been determined by the sector-microphotometer method. The possible sources of experimental errors have been thoroughly examined. The quadratic force constants of the potential function have been determined by the use of the mean-square amplitudes thus obtained, by combining them with the vibrational frequencies obtained from the Raman spectrum in the gaseous state. It has been shown that the errors of the force constants originate from those of the mean-square amplitudes by the same order of magnitude as from those of the frequencies.

The authors wish to express their gratitude to the Shin-Etsu Chemical Industrial Co., Ltd., for the supply of silicon tetrachloride, and to Professor Hidetoshi Takahashi of the Physics Department of the University of Tokyo for the use of the digital computer, PC-1. The expenses of the work were defrayed by the Ministry of Education, to which their thanks are also due.

## Appendix

**The Analysis of Small-Angle Intensities.**—As has been described in this text, the atomic distances and the mean-square amplitudes of silicon tetrachloride have been determined precisely by the analysis of the electron diffraction halos taken by the short camera length, 11.8 cm. ($q$=18—97). On the other hand, the errors of the atomic distances and mean amplitudes are inversely proportional to $s$ and $s^2$ respectively, and the error caused by the uncertainty in the $\mu$-factor increases in the range of small $q$-values. It would be of interest to see what results can be obtained by the analysis of the photographs of silicon tetrachloride taken by the long camera distance at smaller scattering angles ($q$=8—36).

Since there are four humps in this range, as is shown in Fig. 5, reasonable background curves were obtained by Karle's method.[27] An analysis was made by the same procedure as that used in the analysis for the short camera distance except for the few points given below. In view of the limited number of observations (less than 30 for $\Delta q$=1), it was thought advantageous to make the number of variables for the analysis as small as possible. Therefore, by assuming that the Si-Cl and Cl-Cl distances have equal indices of resolution, the index was taken as one of the parameters instead of having both indices varied. A conventional weight function was used, since the use of other weight functions caused little change in this case. Four photographs were used for the analysis.

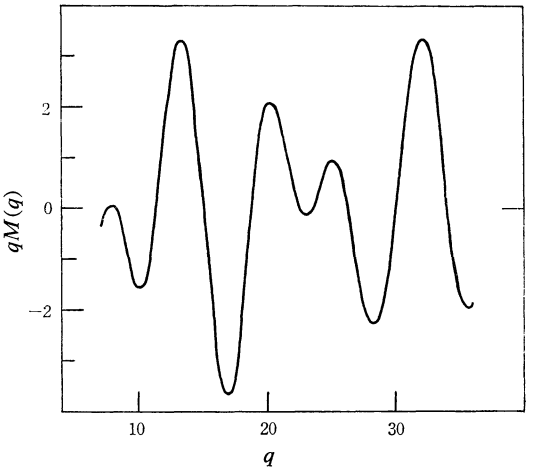

Fig. 5. Molecular intensity curve of $SiCl_4$ obtained by the long camera distance.

In the small-angle scattering ($s \lesssim 10$), the theoretical atomic form factor is strongly dependent on the original wave function used in the calculation. Therefore, the analysis of the intensity taken by the long camera distance, as separated from that taken by the short camera distance, was useful as a test of the effect of the atomic form factors on our analysis by using the various values listed below. The atomic form factors for silicon and chlorine have been obtained by Viervoll and Ögrim[12] on the basis of Hartree's wave function; by Ibers and Hoerni,[15] who reported $|f|$ based on the Thomas-Fermi model, and by Tomiie and Stam,[13] whose calculation was based on Slater's wave function. Three kinds of atomic form factor, were, threfore, used in the present analysis; (the first obtained by Viervoll and Ögrim, the second given by Tomiie and Stam for the silicon and chlorine atoms, and the third obtained by the

27) I. L. Karle and J. Karle, *J. Chem. Phys.*, **18**, 565 (1950).

arithmetic mean values of $f(Si^{4+})$ and $f(Si)$, and $f(Cl^-)$ and $f(Cl)$, for silicon and chlorine respectively, and given by Tomiie and Stam) since the Si-Cl bond in the silicon tetrachloride molecule is likely to have about a 50% ionic character at the chlorine atom, as estimated from the pure quadrupole resonance frequency[28] of $^{35}Cl$. Two kinds of the inelastic scattering factors which were obtained by Bewilogua[14] and Freeman[29] were used for calculating the $\mu$-factors. Unfortunately, however, the inelastic scattering factor for the chlorine atom was not calculated by Freeman; hence, an approximate value was estimated for our use.

Four sets of $\mu$-factors were obtained for Si-Cl and Cl-Cl, as is shown in Fig. 6; by using these

| B | 0.0520 | 0.0032 | 0.0018 | 0.0949 | 0.0021 | 0.0017 |
| C | 0.0520 | 0.0036 | 0.0017 | 0.0943 | 0.0024 | 0.0016 |
| D | 0.0467 | 0.0041 | 0.0019 | 0.0918 | 0.0025 | 0.0017 |
| | $k$ | $\sigma_1$ | $\sigma_2$ | | | |
| A | 1.098 | 0.011 | 0.018 | | | |
| B | 1.098 | 0.011 | 0.018 | | | |
| C | 1.096 | 0.012 | 0.019 | | | |
| D | 1.065 | 0.012 | 0.018 | | | |

a) The atomic form factors and the inelastic scattering factors used for calculating the $\mu$-factors were taken in the following combinations: A(a, d); B(b, d); C(c, d); and D(c, e).
a: The atomic form factor given by Viervoll and Ögrim.
b: The atomic form factor given by Tomiie and Stam.
c: The atomic form factor given by Tomiie and Stam in which the 50% ionic character was taken into account.
d: The inelastic scattering factor obtained by Bewilogua.
e: The inelastic scattering factor obtained by Freeman.

$\mu$-factors and each of the four observed intensity curves, the corresponding average values and the standard deviations of the parameters were obtained by the method of the least squares,[21] as is shown in Table VIII. It was found that the most probable values of the parameters in the first three sets were almost equal to one another, but that they are significantly different from the values obtained with the short camera distance, especially for the mean amplitudes. The last set agreed with the values obtained by the short camera distance. The $\mu$-factor is little affected by the change in the atomic form factor, since the change of the numerator is seemingly cancelled by that of the denominator. The inelastic scattering factor, on the other hand, is included only in the denominator of the $\mu$-factor, since, on the basis of the basic assumption, the inelastic scattering makes no contribution to the molecular term. The change in the inelastic scattering factor, therefore, has an appreciable effect on the molecular intensity in the small-angle region.

# The Distribution of Gas Molecules at the Diffraction Center in the Electron Diffraction Experiment*

By Yonezo MORINO and Yoshitada MURATA

(Received July 15, 1964)

The mean square amplitude determined by electron diffraction provides us with valuable information regarding the dynamical properties of molecules. Since, however, the values of the mean square amplitudes directly obtained from our measurements are strongly influenced by the delocalization of the sample, physically significant values cannot be obtained unless the correction for this effect is properly made. Moreover, the distribution of gas molecules depends on the shape of the nozzle, and sometimes a systematic error from this origin is introduced into the observed atomic distances.

The effect of a finite sample size has been discussed by Karle and Karle,[1] Harvey et al.,[2] and Kuchitsu.[3] Kuchitsu evaluated the distribution of gas molecules from a gradual decrease in the background curve at more than 80 in the $q$-scale. His basic idea was that the decrease was produced by the shielding of electron beams by the edge of the nozzle. The principle has been extended in the present experiment for a nozzle with an artificial diaphragm especially designed for the measurement of the distribution of gas molecules.

## The Measurement of the Distribution of Gas Molecules at the Diffraction Center

A diaphragm with a circular aperture at its center is attached immediately behind the nozzle. The main electron beam is adjusted to pass through the center of the aperture at a right angle to the plane of the diaphragm, as is shown in Fig. 1. If diffraction occurs in an infinitesimally small region at O, as assumed in the theoretical calculation, the diffraction intensity on the plate should be cut off sharply at point P, with no blackening beyond that point. However, as the gas stream has a finite width, some electrons diffracted at points nearer to the plate than O arrive at points farther away than P, resulting in a gradual

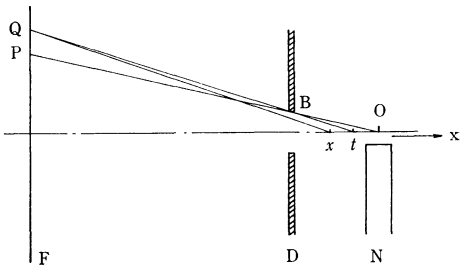

Fig. 1. Schematic representation of the arrangement for measurement of the gas distribution.
N: Nozzle D: Circular diaphragm
F: Photographic plate

change in the intensity. From the measurement of the change in the intensity near point P on the photograph, information is obtained regarding the distribution function, $f(x)$.

If multiple scattering is ignored, the scattered intensities with and without the diaphragm, $I_T{}^a$ and $I_T{}^b$ respectively, are given by the following expressions:

$$P(t)=\frac{I_T{}^a(s_0)}{I_T{}^b(s_0)}=\frac{\int_{-\infty}^{t} I_T(x, s_0)f(x)\mathrm{d}x}{\int_{-\infty}^{\infty} I_T(x, s_0)f(x)\mathrm{d}x} \qquad (1)$$

where $I_T(x, s_0)$ denotes the total intensity scattered at point $x$ along the main beam toward point Q, which corresponds to the direction, $s_0$, from the origin. The origin of the x axis is taken at a point above the center of the nozzle, while the negative direction of the x axis is taken from the nozzle towards the photographic plate. The function $f(x)$ denotes the linear density of gas molecules along the path of the primary electron beam. The upper limit of Eq. 1, $t$, designates the point at which line QB intersects the x axis, B being the edge of the diaphragm. The electrons diffracted before reaching point $t$ hit the diaphragm and do not arrive at the photographic plate.

When the main portion of the gaseous sample is localized in a small region near point O, $f(x)$ decreases steeply as $x$ increases. In such a case, $I(x, s_0)$ is supposed to be nearly constant in the range where $f(x)$ is of a significant magnitude, and Eq. 1 is simply

* Some preliminary results of this work were presented at the International Conference on Magnetism and Crystallography, Kyoto, 1961.

approximated by:

$$P(t)=\int_{-\infty}^{t} f(x)\mathrm{d}x \qquad (2)$$

when $f(x)$ is normalized as:

$$\int_{-\infty}^{\infty} f(x)\mathrm{d}x=1 \qquad (3)$$

The accuracy of such an approximation will be considered in Appendix II.

A diaphragm with an aperture 2.38 mm. in diameter was attached to the nozzle at a distance of 4.51 mm. The primary beam passed 0.41 mm. above the top of the nozzle. The surface of the diaphragm was coated with colloidal graphite powder in order to decrease the extraneous scattering.

A set of three photographs was taken by using silicon tetrachloride. The first photograph was taken for a blank test to make a correction for the extraneous scattering. The second was taken with the diaphragm, and the third, without it. The experimental conditions were the same as those in the case of the needle-type nozzle described in a previous paper.[4] The microphotometer tracings shown in Fig. 2 clearly indicate the decrease in

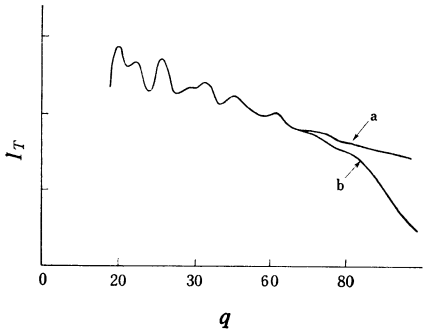

Fig. 2. Photometer curves of $SiCl_4$ with and without the diaphragm. The ordinate scale is in arbitrary units.
a: Without the diaphragm
b: With the diaphragm

intensity when the diaphragm was used. By the use of the dimension of the diaphragm and the observed ratio of the diffraction intensities at $s_0$, the function of $t$, $P(t)$, in Eq. 2 was derived. The $P(t)$ curve is shown in Fig. 3. The fact that the $P(t)$ curve was 1/2 at $t=0$ is consistent with the expectation derived from the assumption that the distribution of gas molecules is symmetric across the origin. It also indicates that the experimental arrangement conformed to our original plan. The plot of $\log(1-P(t))$ against $t$ was found to be closely approximated by two straight lines, as is shown in Fig. 4. It was

4) Y. Morino and Y. Murata, This Bulletin, 38, 105 (1965).

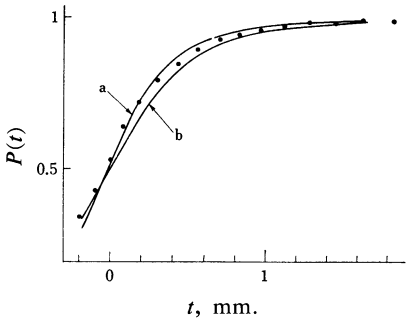

Fig. 3. Observed and calculated $P(t)$ curves. Observed values are shown in dots.
a: Calculated curve obtained by Eq. 9
b: Calculated curve obtained by Eq. 10

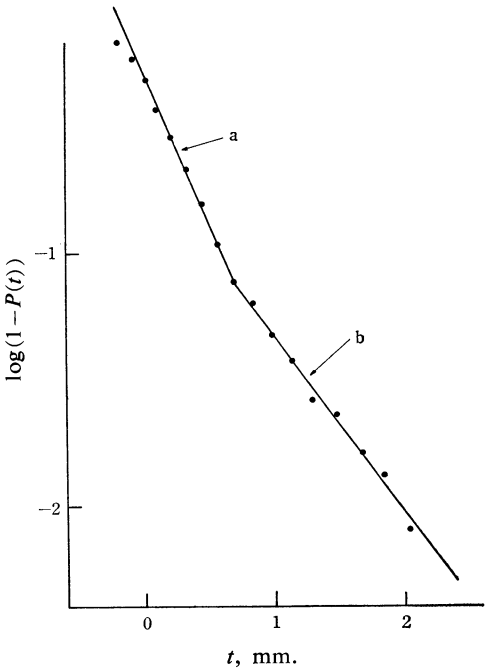

Fig. 4. Plots of $\log(1-P(t))$ vs. $t$; observed values are shown in dots. The straight lines a and b are represented by Eqs. 4a and 4b respectively. A break at $t=0.7$ is of little significance, since the lines a and b are only approximate representations of the original curve, which may lie on a smooth line. See descriptions in the text.

found that:

for

$$0.7 \geqq t \geqq 0, \quad P(t)=1-\frac{1}{2}\exp(-2.74t) \qquad (4a)$$

and for

$$t \geqq 0.7, \quad P(t)=1-0.224\exp(-1.59t) \qquad (4b)$$

when $t$ was measured in millimeter. By differentiating the above equations by $t$, the distribution function on the beam is represented

by:

for $0.7 \geqq x \geqq 0$,

$$f(x) = (2.74/2)\exp(-2.74x) \quad (5a)$$

and for $x \geqq 0.7$,

$$f(x) = 0.356\exp(-1.59x) \quad (5b)$$

where $x$ is also measured in millimeter. It may be possible to assume the same distribution function on the negative side of the x axis, because the value of $P(t)$ at $t=0$ was compatible with the assumption of the symmetric distribution around the origin. It seems strange that the density functions obtained above, 5a and 5b, are discontinuous at the intersection $x=0.7$. The sharp break results from the approximation that $\log(1-P(t))$ may be expressed by two straight lines.

As will be shown in Appendix I, the atomic distances and the index of resolution are little affected by the finite spread of gas molecules at the diffraction center, whereas the apparent increment in the root-mean-square amplitude, $\Delta l$, is given by:

$$\Delta l_{ij} = r_{ij}^2/l_{ij}\rho^2 L_0^2 \quad (6)$$

if the distribution function $f(x) = (\rho/2)\times \exp(-\rho|x|)$, with $\rho = 2.74\,\mathrm{mm}^{-1}$, is used through the whole range. The calculated values are listed in column a in Table I. In the range of $|x| \geqq 0.7$, the real distribution is slightly different from this function; it is expressed by another exponential function, 5b, which results in a 10% increase in the increment. The values of $\Delta l$ derived with this function are shown in column b of Table I.

TABLE I. CORRECTION FOR THE MEAN AMPLITUDES DUE TO THE FINITE SPREAD OF GAS MOLECULES (in Å units)

| | $l_a$(obs) | $\Delta l(a)$ | $\Delta l(b)$ |
|---|---|---|---|
| Si-Cl | 0.0479 | 0.0008 | 0.0009 |
| Cl-Cl | 0.0905 | 0.0012 | 0.0013 |

$\Delta l(a)$: Calculated by Eq. 6, on the assumption that the gas distritution is expressed by a simple distribution function 5a.
$\Delta l(b)$: Calculated by taking both functions 5a and 5b into account.

In the calculations described above, several approximations and assumptions were made. We will consider the validity of these approximations and assumptions below.

First, the assumption that the main portion of the gaseous molecules is confined to the range $|x/L_0| \ll 1$ is satisfied, because the value of $f(x)$ at $L_0 = 118$ mm. is very small, as is evident from Eq. 5. Next, the multiple scattering[5] can be disregarded in this experiment, because the indices of resolution were found to be unity or at least very close to unity.[4] This means that no "delocalization" of the gas molecules in the camera box[6] was recognized.

It will be shown in Appendix II that the approximation made in Eq. 2 is valid within 5% if we consider that $t$ is less than 2 mm. and $L_0 = 118$ mm.

## The Flow of Gas Molecules Emitted from the Nozzle

It is interesting to see what kind of gas flow is responsible for the distribution of gas molecules obtained above. The model to be considered first is the simplest one, in which the gas molecules are emitted from the center of the nozzle with an equal probability in all directions. The solid angle, $d\omega$, which corresponds to a rectangular area enclosed by the width, $d$, and the length of $dx$ on the beam is given by:

$$d\omega = ad\,dx/(x^2+a^2)^{3/2} \quad (7)$$

where $a$ is the distance from the top of the nozzle to the main beam ($a = 0.41$ mm.). Therefore, the normalized distribution function is represented by:

$$f(x) = a^2/2(x^2+a^2)^{3/2} \quad (8)$$

It follows that:

$$P(t) = (1/2)\,(1+t/(a^2+t^2)^{1/2}) \quad (9)$$

This formula, which denotes the integrated distribution of the gas molecules, contains only a measurable parameter, $a$. In Fig. 3, curve a shows the $P(t)$ which was obtained by inserting the actual dimension of $a = 0.41$ mm. into Eq. 9.

In the model described above, the drastic assumption was made that the flow of the molecules comes from a single point, i. e., from the center of the top of the nozzle. In the actual experiment, however, the molecules come out from the whole area of the nozzle exit. It is, accordingly, likely that the gas distribution near the nozzle is quite different from that derived above. Thus another model must be considered, one in which gas molecules are emitted from the entire opening of the nozzle with an equal probability in every direction. It is easy to show that, when the radius of the nozzle is $b$, the distribution function on the main beam is given by:

$$f(x) = \int_0^b \int_0^{2\pi} \frac{Aar\,dr\,d\theta}{(x^2+a^2+r^2-2xr\cos\theta)^{3/2}} \quad (10)$$

5) J. A. Hoerni, *Phys. Rev.*, **102**, 1530 (1956).

6) L. S. Bartell, *J. Appl. Phys.*, **31**, 252 (1960).

where $A$ is a normalization constant.

An approximate calculation was carried out by the use of a series expansion, instead of exact integration using the elliptic function of the second kind. The results are shown by curve b in Fig. 3. Both of the calculated $P(t)$ functions, a and b, are consistent with the observed $P(t)$, but a detailed comparison reveals that the first model is slightly better than the second. It may be considered from this finding that the gas flows faster in the central part than in the outer part of the nozzle; in other words, the flow is more or less viscous within the tube, even though the stream of gas molecules behaves as a molecular flow after leaving the nozzle. In fact, the mean free path in the nozzle is estimated to be 0.03 mm., much smaller than the diameter of the nozzle, 0.55 mm.

### The Effect of Asymmetric Distribution at the Nozzle

It was shown in the previous section that, in the case of the needle-type nozzle, the gas distribution has its center exactly over the nozzle and fades away symmetrically from the center in both directions. However, in the case of the drum-type nozzle, as is shown in Fig. 8 of Ref. 3, the distribution may be asymmetric with respect to the center of the nozzle, because the front edge of the nozzle was cut off in a cone-shape in order to secure a wide angle for the diffracted electrons. Hence, it is worthwhile measuring the difference in the distribution on both sides and estimating its influence on the observed molecular parameters.

For the needle-type nozzle, it was found in this study that the distribution may be represented by an exponential function, $C\exp(-\rho|x|)$. However, in the case of the drum-type nozzle, a Gaussian function is more suitable for the distribution. This is because the emitted gas molecules hit the upper wall of the nozzle and recoil to give an increased gas density near the center of the nozzle and an increased spread of the gas distribution. Accordingly, for a drum-type nozzle, the distribution may be fitted by two Gaussian functions with different parameters in the exponents, one for the positive side and the other for the negative side. It may be reasonable to take the maximum at $x=0$. Thus the distribution function in the regular orientation is assumed to be

$$f(x)=C_1\exp(-ax^2), \quad \text{for} \quad x>0 \tag{11a}$$

and

$$f(x)=C_2\exp(-bx^2), \quad \text{for} \quad x<0 \tag{11b}$$

If the functions are taken to be continuous at $x=0$ and are normalized to unity, then the coefficient is given by:

$$C_1=C_2=2(a/\pi)^{1/2}/(1+K) \tag{12}$$

where $K=(a/b)^{1/2}$ denotes the ratio of the half-widths. In order to estimate parameters $a$ and $b$, two photographs were taken, one at the regular orientation to obtain the constant $b$, and the other at the reversed orientation of the nozzle, i. e., by turning the other face of the nozzle to the plate, to obtain the constant $a$. Silicon tetrachloride was taken as a sample, and experimental conditions were chosen to be almost the same as in the case of the drum-type nozzle described in the previous paper.[4] For both regular and reversed orientations of the nozzle, the experimental background curves were compared with the theoretical curve.[3]

The observed $P(t)$ curve should fit with

$$P(t)=\frac{K}{1+K}+\frac{1}{1+K}\,\mathrm{Erf}(\sqrt{a}\,t) \tag{13a}$$

for the regular position, and

$$P(t)=\frac{1}{1+K}+\frac{K}{1+K}\,\mathrm{Erf}(\sqrt{b}\,t) \tag{13b}$$

for the reversed orientation. Parameters $a$ and $b$ cannot be determined separately, because both Eqs. 13a and 13b contain $K$, in addition to a single parameter, $a$ or $b$. Hence, by considering both curves simultaneously, the values of $a$ and $b$ were obtained to be $a=0.42\,\mathrm{mm}^{-2}$ and $b=0.67\,\mathrm{mm}^{-2}$, while $K=0.79$. It is interesting to notice that 0.79 is much larger than the value presumed from the geometrical dimension of the nozzle; if we assume that the half-width of each side of the distribution is proportional to the width of the nozzle wall, $K$ should be 0.53. The result indicates that the asymmetry of the gas distribution is smaller than the geometrical asymmetry of the nozzle.

As will be shown in Appendix I, the apparent increases in the atomic distances and in the root-mean-square amplitudes are given by:

$$\frac{\Delta r}{r}=-\frac{1-K}{\sqrt{\pi a}\,L_0} \tag{14}$$

and:

$$\frac{\Delta l}{l}=\frac{(1-K+K^2)}{4aL_0^2}\left(\frac{r}{l}\right)^2 \tag{15}$$

The values of $a$ and $b$ determined above lead to the result that $\Delta r$'s are $-0.0032$ Å and $-0.0052$ Å, while $\Delta l$'s are 0.0031 Å and 0.0045 Å for Si–Cl and Cl–Cl respectively.

On the other hand, a small discrepancy in the atomic distance was observed by reversing the orientation of the nozzle, as has been described in a previous paper.[4] Since the observed differences in the atomic distances, shown in Table I of Ref. 4, correspond to $2\Delta r$, the apparent increases, $\Delta r$ caused by the asymmetric distribution are shown to be $-0.0022$ Å

for Si–Cl and −0.0035 Å for Cl–Cl; they are in good agreement with the values obtained above by estimating the gas distribution.

It should be noted that the apparent increase in the mean amplitudes is much larger in the case of the drum-type nozzle than in the case of the needle-type nozzle. The mean amplitudes obtained by the drum-type nozzle, when corrected for the gas distribution given above, agree well with the values obtained by the needle-type nozzle, as Table II shows.

TABLE II. MEAN AMPLITUDES OBTAINED BY TWO TYPES OF NOZZLES (in Å units)

| | | $l$(Si–Cl) | $l$(Cl–Cl) |
|---|---|---|---|
| Needle-type | (a) | 0.0479 | 0.0905 |
| | (b) | 0.0470±0.0016 | 0.0892±0.0024 |
| Drum-type (regular orientation) | (a) | 0.0495 | 0.0943 |
| | (b) | 0.0464±0.0045 | 0.0898±0.0053 |

(a): Most probable values obtained by the method of least squares to each of four photographs.
(b): Final values. The errors associated with the drum-type nozzle caused by the estimation of the finite sample size were assumed to be 100% of the corrections.

## Summary

A method has been proposed for estimating the distribution of gas molecules at the diffraction center in order to evaluate the correction for finite sample size in gas electron diffraction. The distribution measured in this way has been interpreted by a simple model regarding the motion of the gas molecules in the vicinity of the nozzle. A slight asymmetry of the nozzle construction produces in the atomic distances a deviation which cannot be disregarded if an accurate measurement is desired.

The expenses of the work were defrayed by a grant from the Ministry of Education, to which the authors' thanks are due.

## Appendix I

Let us consider the influence of the finite distribution of gas molecules at the diffraction center upon the atomic distances, mean square amplitudes, and index of resolution.

If the gas distribution is given by $f(x)$, the observed total intensity is expressed by:

$$I_T(s_0)=\int_{-\infty}^{\infty} I_T(x,s_0)f(x)\,dx \tag{A1}$$

and the observed molecular intensity function is given by:

$$M(s_0)=\int_{-\infty}^{\infty} I_M(x,s_0)f(x)\,dx \Big/ \int_{-\infty}^{\infty} I_B(x,s_0)f(x)\,dx \tag{A2}$$

where $I_M(x,s_0)$ and $I_B(x,s_0)$ are the functions of $x$ through $s$ and $L$:

$$I_M(x,s_0)=\sum_{ij} C_{ij}\frac{L}{(L^2+R^2)^{3/2}s^4}\frac{\sin sr_{ij}}{sr_{ij}} \times\exp(-\alpha_{ij}s^2) \tag{A3}$$

and

$$I_B(x,s_0)=\sum_{ij} C'_{ij}\frac{L}{(L^2+R^2)^{3/2}s^4} \tag{A4}$$

To the second order of approximation with regard to $z=x/L_0$ and $a^2=(R/L_0)^2$ ($L_0$ being the camera length from the origin of the x axis, and $R$, the radius of point P on the photographic plate), $s$ is given by:

$$s=s_0(1-\gamma z+\delta z^2) \tag{A5}$$

where

$$\gamma=1-\frac{3}{4}bs_0^2+\frac{1}{8}b^2s_0^4 \tag{A6}$$

$$\delta=1-\frac{15}{8}bs_0^2+\frac{41}{32}b^2s_0^4 \tag{A7}$$

and

$$L=L_0+x \tag{A8}$$

$$a^2=bs_0^2\left(1+\frac{3}{4}bs_0^2\right) \tag{A9}$$

Here $s_0$ denotes the $s$-value for the diffraction at the origin to point P and $b=\lambda^2/4\pi^2$. Expanding Eqs. A3 and A4 in terms of $x$ and $a^2$, and disregarding coefficients smaller than 1% of the largest one, it can be shown that:

$$\begin{aligned}M(s)=&\sum I_M(0,s_0)\Big[(1+\langle z\rangle+2\langle z^2\rangle-2\langle z\rangle^2)\\&+\Big(2\alpha\langle z\rangle-\frac{1}{2}r^2\langle z^2\rangle\Big)s_0^2\\&+\Big\{-\frac{3}{2}\alpha b\langle z\rangle+\Big(\frac{3}{4}br^2+2\alpha^2\Big)\langle z^2\rangle\Big\}s_0^4\Big]\\&+\sum I_M(0,s_0)\frac{\cos s_0r}{\sin s_0r}rs_0\Big[(-\langle z\rangle-2\langle z^2\rangle+2\langle z\rangle^2)\\&+\Big(\frac{3}{4}b\langle z\rangle-2\alpha\langle z^2\rangle\Big)s_0^2\\&+\Big(-\frac{1}{8}b^2\langle z\rangle+3\alpha b\langle z^2\rangle\Big)s_0^4\Big]\end{aligned} \tag{A10}$$

where

$$\langle z\rangle=\int_{-\infty}^{\infty} zf(x)\,dx \tag{A11}$$

On the other hand, if it is assumed that the diffraction intensity can be expressed by the usual diffraction formula with slightly modified molecular parameters:

$$M(s)=\sum kC\exp(-(\alpha+\Delta\alpha)s_0^2)\sin(s_0r+s_0\Delta r)/ s_0(r+\Delta r) \tag{A12}$$

a formula corresponding to Eq. A10 is obtained by expanding Eq. A12 with regard to the small quantities. Comparing the corresponding terms in $s_0$, the following relations are obtained:

$$1+\langle z\rangle+2\langle z^2\rangle-2\langle z\rangle^2=k(1-\Delta r/r) \tag{A13}$$

$$2\alpha\langle z\rangle-\frac{1}{2}r^2\langle z^2\rangle=-k(1-\Delta r/r)(\Delta\alpha+\Delta r^2/2) \quad \text{(A14)}$$

$$(3b/4)(-2\alpha\langle z\rangle+r^2\langle z^2\rangle)=k(1-\Delta r/r)\times(\Delta\alpha\Delta r^2/2+\Delta\alpha^2/2+\Delta r^4/4!) \quad \text{(A15)}$$

$$-r(\langle z\rangle+2\langle z^2\rangle-2\langle z\rangle^2)=k(1-\Delta r/r)\Delta r \quad \text{(A16)}$$

$$-r(2\alpha\langle z^2\rangle-\frac{3}{4}b\langle z\rangle)=-k(\Delta\alpha+\Delta r^2/6)(1-\Delta r/r)\Delta r \quad \text{(A17)}$$

and

$$r(3\alpha b\langle z^2\rangle-\frac{1}{8}b^2\langle z\rangle)=k(1-\Delta r/r)\Delta r\times(\Delta\alpha\Delta r^2/6+\Delta\alpha^2/2+\Delta r^4/5!) \quad \text{(A18)}$$

From Eqs. A13 and A16 we obtain:

$$\Delta r/r=-(\langle z\rangle+2\langle z^2\rangle-3\langle z\rangle^2) \quad \text{(A19)}$$

By inserting the result in Eq. A13, it is shown that:

$$k=1 \quad \text{(A20)}$$

and also in Eq. A14:

$$\Delta\alpha=\frac{1}{2}r^2\langle z^2\rangle-2\alpha\langle z\rangle-\frac{1}{2}r^2\langle z\rangle^2+2\alpha\langle z\rangle^2 \quad \text{(A21)}$$

**(I) The Case of a Symmetric Distribution.**—It was found that the distribution of gas molecules for the needle-type nozzle was symmetrical with respect to the origin $x=0$. In this case, $\langle z\rangle=0$, and Eqs. A19 and A21 are simplified as follows:

$$\Delta r/r=-2\langle z^2\rangle \quad \text{(A22)}$$

and

$$\Delta\alpha=\frac{1}{2}r^2\langle z^2\rangle \quad \text{(A23)}$$

Now, if the distribution function obtained above, $f(x)=(\rho/2)\exp(-\rho|x|)$, with $\rho=2.74\,\mathrm{mm}^{-1}$, is used over the whole range, the mean value of $z^2$ is given by:

$$\langle z^2\rangle=2/\rho^2L_0^2 \quad \text{(A24)}$$

and: $$\Delta r/r=-4/\rho^2L_0^2 \quad \text{(A25)}$$

The apparent increase in the mean amplitude is thus obtained by:

$$\Delta l=\Delta\alpha/l=r^2/l\rho^2L_0^2 \quad \text{(A26)}$$

**(II) The Case of Asymmetric Distribution.**—For the drum-type nozzle, we have evidence that the distribution of gas molecules is not symmetrical with respect to the origin. Therefore, correction must be made in such a case.

If the distribution function in the regular orientation is expressed by the following formulas:

$$f(x)=C\exp(-ax^2) \quad \text{for } x>0 \quad \text{(A27)}$$

and $$f(x)=C\exp(-bx^2) \quad \text{for } x<0 \quad \text{(A28)}$$

where $$C=2\sqrt{a}/\sqrt{\pi}\,(1+K) \quad \text{(A29)}$$

and $$K^2=a/b \quad \text{(A30)}$$

the means of $z$ and $z^2$ are expressed by:

$$\langle z\rangle=(1-K)/\sqrt{\pi a}\,L_0 \quad \text{(A31)}$$

and $$\langle z^2\rangle=(1-K+K^2)/2aL_0^2 \quad \text{(A32)}$$

The observed values of $a=0.418$, $K=0.787$ and $L_0=118$ lead to the results $\langle z\rangle=1.57\times10^{-3}$, and $\langle z^2\rangle=7.15\times10^{-5}$. Therefore, disregarding smaller terms, Eqs. A19 and A21 reduce to:

$$\Delta r/r=(K-1)/\sqrt{\pi a}\,L_0 \quad \text{(A33)}$$

and $$\Delta\alpha=(1-K+K^2)r^2/4aL_0^2 \quad \text{(A34)}$$

and $$\Delta l/l=(1-K+K^2)r^2/4l^2aL_0^2 \quad \text{(A35)}$$

Equations A15, A17 and A18 give further relations among $\Delta r$, $\Delta\alpha$ and $k$, but they are not always reasonable, because the basic assumption A12 does not hold exactly for such higher terms.

## Appendix II

It will be worthwhile to consider the uncertainty of the approximation used in Eq. 2; that is:

$$P(t)=\frac{\int_{-\infty}^{t}I_Tf(x)\mathrm{d}x}{\int_{-\infty}^{\infty}I_Tf(x)\mathrm{d}x}=\int_{-\infty}^{t}f(x)\mathrm{d}x \quad \text{(A36)}$$

Now the total scattering intensity is given by:

$$I_T=I_B(1+M) \quad \text{(A37)}$$

By expanding it in terms of $z$,

$$I_T\cong I_T^0(1+2z+z^2)+I_B^0\times\left[\left(\frac{dM}{dz}\right)_0z+2\left(\frac{dM}{dz}\right)_0z^2+\frac{1}{2}\left(\frac{d^2M}{dz^2}\right)_0z^2\right] \quad \text{(A38)}$$

while by assuming the symmetric distribution $f(x)=(\rho/2)\exp(-\rho|x|)$, the $P(t)$ function is shown to be as follows:

$$P(t)=\int_{-\infty}^{t}f(x)\mathrm{d}x(1+\Delta) \quad \text{(A39)}$$

where

$$\Delta=\frac{1}{L_0}\left(t-\frac{1}{\rho}\right)\left[2I_T^0+I_B^0\left(\frac{dM}{dz}\right)_0\right]\Big/\int_{-\infty}^{\infty}I_Tf(x)\mathrm{d}x \quad \text{(A40)}$$

By considering the fact that:

$$2/\rho^2L_0^2=2\times10^{-5}\ll1$$

$$I_B^0\cong I_T^0$$

$$\left|\left(\frac{dM}{dz}\right)_0\right|\cong1$$

$$\left|I_B^0\left(\frac{dM}{dz}\right)_0\frac{1}{\rho^2L_0^2}\right|\ll I_T^0$$

$$\left|\left(\frac{d^2M}{dz^2}\right)_0\right|<(rs_0+4\alpha s_0^2)$$

$$\left|I_B^0\left(\frac{d^2M}{dz^2}\right)_0\frac{1}{\rho^2L_0^2}\right|<\frac{1}{100}I_T^0$$

and that, therefore:

$$\int_{-\infty}^{\infty}I_Tf(x)\mathrm{d}x\cong I_T^0$$

Eq. A40 may be roughly evaluated as follows:

$$|\Delta|\cong\frac{2}{L_0}\left(t-\frac{1}{\rho}\right)\left(1+\frac{1}{2}\right)=\frac{3}{L_0}\left(t-\frac{1}{\rho}\right)\cong5\% \quad \text{(A41)}$$

In conclusion, the approximation made in Eq. 2 is satisfied within an uncertainty of 5%.

# A Synthesis of Oxytocin

By Shumpei SAKAKIBARA, Yoshibumi NOBUHARA,*
Yasutsugu SHIMONISHI and Reiko KIYOI

(Received July 27, 1964)

Oxytocin, which is well known as a hormone of the posterior pituitary gland, has been synthesized by many workers[1-6] in different ways since the first brilliant synthesis of the hormone by du Vigneaud et al. in 1953—1954[7]. In all cases, two protecting groups, *S*-benzyl for the cysteinyl residue and carbobenzoxy for the amino nitrogen, have been employed during the syntheses for the following reasons: (1) The *S*-benzyl group is comparatively stable during the peptide synthesis. (2) The carbobenzoxy group is, generally, the most convenient *N*-protecting group for peptide synthesis, and the selective removal of the *N*-protecting group from an *N*-carbobenzoxy-peptide derivative containing *S*-benzyl cysteine can be accomplished by using anhydrous hydrogen bromide without any complications in other parts of the peptide. (3) Both protecting groups can be removed simultaneously using sodium in liquid ammonia.

The sodium treatment of the protected peptide in liquid ammonia, however, is rather drastic, and some side-reactions may occur during the process. Moreover, it must be remembered that the removal of a protecting group from a larger peptide is, in general, more difficult than the removal of one from a smaller peptide. Actually, du Vigneaud et al. reported that the protected pre-oxytocic nona-peptide had been reduced in boiling liquid ammonia.[7] Nevertheless, the yield of active oxytocin from a large-scale sample (1.3 g.) of the protected nona-peptide was less than that from a small-scale sample (50 mg.) of the same intermediate.[5] This must be because it is difficult to remove the *S*-benzyl group with sodium in liquid ammonia. Therefore, an *S*-protecting group which is easier to remove has long been required in the preparation of such a complicated cysteine-peptide.

Only one different route to oxytocin has been reported, the method of Velluz.[3] In this the *S*-trityl group is used for the protection of the sulfhydryl group. Since, however, the *S*-trityl group is quite unstable against anhydrous hydrogen bromide, the use of the carbobenzoxy group for the protection of amino nitrogen during peptide synthesis is impossible, and the more labile *N*-trityl group is used. This limitation is fatal to the practical synthesis of the hormone, because the synthesis of *N*-trityl amino acids or peptides is, in general, much more complicated than that of carbobenzoxy derivatives.[8]

Recently, it was found by the present authors[9] that the *p*-methoxybenzyl (anisyl) group was valuable in protecting the thiol of cysteinyl residues; that is, the protecting group was stable against hydrogen bromide at room temperature, and it was easily cleaved from the final product by treatment with either sodium in liquid ammonia, or boiling trifluoroacetic acid. Moreover, it was found that the synthesis of *S*-*p*-methoxybenzyl cysteine was as easy as that of the *S*-benzyl derivative.

In the present paper, the synthesis of oxytocin using the *p*-methoxybenzyl group for the protection of cysteinyl residues will be described. For the synthesis of the hormone, the step-wise elongation method using carbobenzoxyamino acid *p*-nitrophenylesters was employed. *N*-Carbobenzoxy-*S*-*p*-methoxybenzyl-L-cysteine *p*-nitrophenylester (III) was synthesized by the dicyclohexylcarbodiimide method. Compound III was coupled with L-prolyl-L-leucylglycinamide,[10] and then the carbobenzoxy group was removed from the

product, *N*-carbobenzoxy-*S*-*p*-methoxybenzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (IV), by treatment with hydrogen bromide in the normal way. A series of carbobenzoxyamino acid *p*-nitrophenylesters were then coupled one by one with the respective peptide amides after treatment with hydrogen bromide. No complications occurred with *S*-methoxybenzyl cysteine residues during the synthesis, and the final protected nona-peptide amide (IX) was obtained in a good yield.

First, the protected nona-peptide (IX) was treated with boiling trifluoroacetic acid for two hours; it was confirmed that a total oxytocic activity of about 3300 units is obtained from 100 mg. of substance IX after the usual aeration procedure. Some hydrolysis of amide-bonds probably occurs during the process, and this is the main reason why the recovery of the active oxytocin is low. The trifluoroacetic acid procedure is now being improved in the laboratory. The usual procedure of sodium reduction in liquid ammonia, followed by aeration at pH 6.5, gave a high oxytocic activity, regardless of the quantity of material IX fed into the reaction (170000 units from 1 g. of substance IX, or 24000 units from 100 mg. of the same substance). This was surprising in view of the results of Bodanszky et al.,[5] who reported that 12500—15000 units were obtained from 50 mg. of a protected nona-peptide containing *S*-benzyl-cysteinyl residues, whereas 168000 units were obtained from 1.3 g. of the same material.

## Experimental*

***S*-*p*-Methoxybenzyl-L-Cysteine (I).** — This compound was prepared from L-cystine (50.0 g., 0.21 mol.) and *p*-methoxybenzyl chloride (72.0 g., 0.46 mol.) according to the procedure of du Vigneaud et al. for the synthesis of *S*-benzyl derivatives. The recrystallization of the crude product (107 g.) from water gave colorless plates; wt. 78.0 g. (78%), m. p. 198—199°C (decomp.), $[\alpha]_D^{25}$ +22.6° (*c* 1.02, N NaOH).

Found: C, 54.50; H, 6.33; N, 5.89; S, 13.05. Calcd. for $C_{11}H_{15}O_3NS$: C, 54.75; H, 6.26; N, 5.81; S, 13.29%.

***N*-Carbobenzoxy-*S*-*p*-methoxybenzyl-L-cysteine (II).**—A solution of I (12.1 g., 0.05 mol.) in a cold N sodium hydroxide solution (50 ml.) was treated with carbobenzoxy chloride (10.3 g., 0.06 mol.) and 2 N sodium hydroxide (30 ml.) alternately under vigorous stirring below 0°C. The stirring was continued for an additional hour without external cooling. When usual extraction procedures were then followed, an oily material was obtained which was solidified by adding petroleum ether (60—80°C). The crude material was recrystallizable from toluene; wt. 14.2 g. (76%), m. p. 62—65°C, $[\alpha]_D^{23}$ −45.5° (*c* 1.98, acetone).

Found: C, 61.11; H, 5.81; N, 3.68; S. 8.46. Calcd. for $C_{19}H_{21}O_5NS$: C, 60.78; H, 5.64; N, 3.73; S, 8.54%.

***N*-Carbobenzoxy-*S*-*p*-methoxybenzyl-L-cysteine *p*-nitrophenylester (III).**—A solution of II (109 g., 0.29 mol.) and *p*-nitrophenol (48.4 g., 0.348 mol.) in ethyl acetate (250 ml.) was cooled to −10°C, and dicyclohexylcarbodiimide (59.7 g., 0.29 mol.) in ethyl acetate (100 ml.) was stirred in. The mixture was allowed to react for an hour at −10°C, and then for two hours more at room temperature. The precipitated materials were filtered off and washed with a small amount of ethyl acetate. The filtrate and washings were combined and concentrated to dryness in vacuo. Crude material III was collected by using a mixture of ethanol and petroleum ether (60—80°C); wt. 18.5 g., m. p. 92—97°C. Recrystallization from ethanol gave colorless fine needles; wt. 110 g. (76%), m. p. 94—97°C, $[\alpha]_D^{21}$ −39.8° (*c* 2.06, dimethylformamide).

Found: C, 60.71; H, 4.80; N, 5.78; S, 6.68. Calcd. for $C_{25}H_{24}O_7N_2S$: C, 60.48; H, 4.87; N, 5.64; S, 6.46%.

***N*-Carbobenzoxy-*S*-methoxybenzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (IV).** — A solution of III (19.8 g., 0.04 mol.) and L-prolyl-L-leucylglycinamide[10] (11.4 g., 0.04 mol.) in dimethylformamide (20 ml.) was allowed to react overnight at room

* All melting points given are uncorrected. All samples for analyses were first dried in vacuo at 110°C for 2 hr.

temperature. Ethyl acetate (60 ml.) was then added to the reaction mixture to precipitate the product as crystals, which were collected by filtration. The crude product was recrystallized from hot methanol (300 ml.) and water (300 ml.); wt. 19.8 g. (77%), m. p. 165—167°C, $[\alpha]_D^{21}$ −55.4° (*c* 2, dimethylformamide).

Found: C, 59.90; H, 6.81; N, 10.59; S, 4.91. Calcd. for $C_{32}H_{43}O_7N_5S$: C, 59.88; H, 6.75; N, 10.91; S, 5.00%.

***N*-Carbobenzoxy-L-asparaginyl-*S*-*p*-methoxybenzyl-L-cysteinyl-L-prolyl-L-leucyl-glycinamide (V).**—A suspension of IV (15.09 g., 0.024 mol.) in acetic acid (25 ml.) was treated with 29% hydrogen bromide in acetic acid (120 g.). After one hour at room temperature, dry ether (1000 ml.) was added to the reaction mixture. The precipitated mass was separated by filtration, washed well with ether three times, and dried over sodium hydroxide. The dried material was dissolved in methanol (150 ml.), and ion exchange resin IRA-400 (in an OH cycle) was added until the bromine ions disappeared. Then the resin was filtered off and washed throughly with methanol. The filtrate and washings were combined and evaporated to dryness. The residue and *N*-carbobenzoxy-L-asparagine *p*-nitrophenyl-ester[5] (9.09 g., 0.024 mol.) were dissolved in dimethylformamide (30 ml.), and the mixture was allowed to react at room temperature for two days. The product was then precipitated by adding ethyl acetate (100 ml.), collected by filtration, washed with ethyl acetate and with ethanol, and dried; wt. 15.4 g. (87%), m. p. 211—212°C, $[\alpha]_D^{20}$ −50.5° (*c* 1, dimethylformamide). For analysis, a part of the product was recrystallized from 80% methanol; m. p. 213—214°C, $[\alpha]_D^{21}$ −51.9° (*c* 1, dimethylformamide).

Found: C, 57.14; H, 6.47; N, 12.68; S, 4.12. Calcd. for $C_{36}H_{49}O_7N_9S$: C, 57.20; H, 6.54; N, 12.97; S, 4.24%.

***N*-Carbobenzoxy-L-glutaminyl-L-asparaginyl-*S*-*p*-methoxybenzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (VI).**—A suspension of V (15.12 g., 0.02 mol.) in acetic acid (20 ml.) was treated with 29% hydrogen bromide in acetic acid (150 g.) for one hour at room temperature. Dry ether (1000 ml.) was added to the reaction mixture to precipitate the product, which was then separated and washed with ether three times and dried over sodium hydroxide. Then the dried mass was dissolved in methanol (200 ml.), and the bromine ions in the solution were removed by adding ion exchange resin IRA-400 (in an OH cycle). The bromine-free solution was concentrated to dryness in vacuo, and the residue was dissolved in dimethylformamide (30 ml.). *N*-Carbobenzoxy-L-glutamine *p*-nitrophenylester[5] (8.42 g., 0.021 mol.) was added to the solution, and the mixture was kept for two days at room temperature. Then the product was precipitated by adding ethyl acetate, which was collected by filtration and washed with ethyl acetate and ethanol. The yield was 13.51 g. (76%); m. p. 207—208°C, $[\alpha]_D^{21}$ −42.6° (*c* 1, dimethylformamide). For analysis, a part of the product was recrystallized from 80% methanol; m. p. 208—210°C, $[\alpha]_D^{21}$ −51.3° (*c* 1, dimethylformamide).

Found: C, 55.93; H, 6.79; N, 14.51; S, 3.43. Calcd. for $C_{41}H_{57}O_{11}N_9S$: C, 55.70; H, 6.50; N, 14.26; S, 3.63%.

***N*-Carbobenzoxy-L-isoleucyl-L-glutaminyl-L-asparaginyl-*S*-*p*-methoxybenzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (VII).**—A suspension of VI (9.72 g., 0.011 mol.) in 20 ml. of acetic acid was treated with 29% hydrogen bromide in acetic acid (80 g.) for one hour. The product was precipitated by adding dry ether (600 ml.), and the precipitate was washed three times with dry ether and dried. The dried product was dissolved in methanol (300 ml.), and the solution was treated with ion exchange resin IRA-400 (in an OH cycle) until bromine ions disappeared. The resin was filtered and washed well with methanol. The filtrate and washings were combined and concentrated to dryness in vacuo. The residue was dissolved in 25 ml. of dimethylformamide, and to the solution was added *N*-carbobenzoxy-L-isoleucine *p*-nitrophenyl-ester[5] (4.63 g., 0.012 mol.). The mixture was allowed to react for two days at room temperature. Ethyl acetate (200 ml.) was added to the reaction mixture, and the precipitates were collected by filtration and washed with ethyl acetate and then with ethanol. The yield was 8.56 g. (78%); m. p. 216—217°C, $[\alpha]_D^{20}$ −43.6° (*c* 1, dimethylformamide). The product was recrystallized from 80% methanol (500 ml.); wt. 6.93 g., m. p. 217—218°C, $[\alpha]_D^{18}$ −44.2° (*c* 1, dimethylformamide).

Found: C, 56.55; H, 7.07; N, 13.89; S, 3.10. Calcd. for $C_{47}H_{68}O_{12}N_{10}S$: C, 56.61; H, 6.87; N, 14.05; S, 3.22%.

***N*-Carbobenzoxy-*O*-benzyl-L-tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-*S*-*p*-methoxybenzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (VIII).**—A suspension of VII (4.99 g., 0.005 mol.) in acetic acid (10 ml.) was treated with 29% hydrogen bromide in acetic acid (25 g.) for one hour. Dry ether (250 ml.) was added to the reaction mixture to precipitate the product, which was collected by filtration, washed with ether three times, and dried. The dried material was dissolved in methanol (500 ml.). Ion exchange resin IRA-400 (in an OH cycle) was added to the solution until bromine ions disappeared, and then the resin was filtered off. The filtrate was evaporated to dryness. The residue was dissolved in dimethylformamide (60 ml.), and *N*-carbobenzoxy-*O*-benzyl-L-tyrosine *p*-nitrophenyl ester[5] (2.63 g., 0.005 mol.) was added to the solution. After two days, ethyl acetate (300 ml.) was added to the reaction mixture to precipitate the product, which was then filtered off, washed with ethyl acetate and then with ethanol, and dried; wt. 5.33 g. (85%), m. p. 221—222°C, $[\alpha]_D^{18}$ −33.1° (*c* 1, dimethylformamide). For analysis, a part of the product was recrystallized from 80% methanol; m. p. 223—224°C, $[\alpha]_D^{18}$ −35.7° (*c* 1, dimethylformamide).

Found: C, 60.31; H, 6.54; N, 12.42; S, 2.63. Calcd. for $C_{63}H_{83}O_{14}N_{11}S$: C, 60.51; H, 6.69; N, 12.32; S, 2.57%.

***N*-Carbobenzoxy-*S*-*p*-methoxybenzyl-L-cysteinyl-L-tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-*S*-*p*-methoxybenzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (IX).**—A suspension of VIII (5.00 g.,

0.004 mol.) in acetic acid (20 ml.) was treated with 29% hydrogen bromide in acetic acid (40 g.). After one hour, dry ether (400 ml.) was added to precipitate the product, which was then separated, washed with ether, and dried. The dried mass was dissolved in dimethylformamide (40 ml.) and triethylamine (6 ml.) was carefully added to the solution. Triethylamine hydrobromide which formed was filtered off, and III (2.38 g., 0.0048 mol.) was added to the filtrate. After three days, ethyl acetate (200 ml.) was added to the reaction mixture and the precipitate which formed was collected by filtration and washed with ethyl acetate and then with ethanol. The yield was 5.16 g. (93%); m. p. 218—220°C, $[\alpha]_D^{20}$ −41.1° (*c* 1, dimethylformamide). For analysis, a part of the product was recrystallized from 80% methanol; m. p. 223—224°C, $[\alpha]_D^{18}$ −43.7° (*c* 1, dimethylformamide).

Found: C, 58.19; H, 6.68; N, 12.29; S, 4.56. Calcd. for $C_{67}H_{90}O_{16}N_{12}S_2$: C, 58.15; H, 6.56; N, 12.15; S, 4.63%.

**Oxytocin.**—a) A solution of IX (100 mg.) and anisole (50 mg.) in trifluoroacetic acid (30 ml.) was gently refluxed for two hr. Then the solvent was evaporated off in vacuo, and the residue was dissolved in water (100 ml.). The pH was adjusted to 6.5 with diluted aqueous ammonia, and carbon dioxide free air was bubbled through the solution until the nitroprusside-test became negative. Then the solution was acidified to pH 4 with acetic acid, and the small amount of insoluble material was filtered out. The final solution showed a total oxytocic activity of 3300 units as determined by rat-uterine contractive activity.

b) Product IX was reduced with sodium in liquid ammonia, as described by Bodanszky and du Vigneaud,[4] and the final reduced material was aerated to oxytocin as has been described before. The total oxytocic activity obtained from 100 mg. of IX was 24500 units, while that from 1 g. IX was 180000 units.

## Summary

*N*-Carbobenzoxy-*S*-methoxybenzyl-L-cysteinyl-L-tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-*S*-*p*-methoxybenzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (IX) was synthesized by the step-wise elongation method, and highly potent oxytocin was obtained from IX by treatment not only with sodium in liquid ammonia, but also with boiling trifluoroacetic acid, followed by the usual aeration procedure. It was demonstrated during the reactions that the newly introduced *S*-*p*-methoxybenzyl group could be cleaved more easily than the usual *S*-benzyl group, and that the new *S*-protecting group was useful in the preparation of complicated cysteinyl peptides.

The authors wish to express their thanks to Professor Shiro Akabori for his encouragement and valuable advice, and to Professor Shigeru Aonuma and to Dr. Keiji Nakamura of the Dainippon Pharmaceutical Co., Ltd. for determining the oxytocic activities of the synthetic materials.

# The Preparations and the Electronic Spectra of Sexa-co-ordinate Molybdenum(III) Complexes

By Takashi KOMORITA, Seiko MIKI and Shoichiro YAMADA

(Received August 1, 1964)

It is interesting to compare the electronic spectra of the corresponding coordination compounds of molybdenum(III) and of chromium(III), both of which have a $d^3$-electronic configuration.

There have been a number of systematic studies of the spectra of chromium(III) complexes, and the band assignments have been well established,[1] as is schematically shown in Fig. 1, where quartet-quartet transitions are denoted with Roman numerals and quartet-doublet transitions, with letters of the alphabet.

In contrast with the case of chromium(III) complexes, however, such investigations of molybdenum(III) complexes have been so rare that only the hexachloro- and the pentachloroaquo-molybdate(III) ions appear to have been well investigated with regard to the inner d-shell bands. The absorption curves and the band assignments were reported by Jørgensen for these complexes.[1] According to these assignments and to the concept of

1) C. K. Jørgensen, "Absorption Spectra and Chemical Bonding in Complexes," Pergamon Press, Oxford (1962).

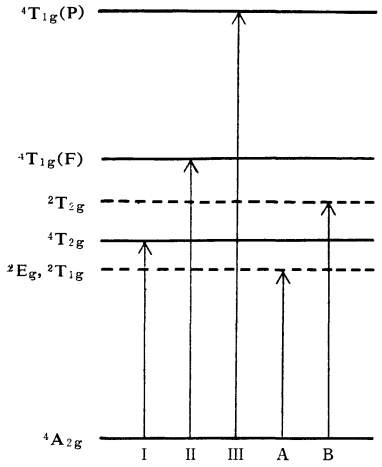

Fig. 1. Observed electronic transitions in $d^3$-system ($Cr^{3+}$) in octahedral field.

the spectrochemical series, the absorption spectra and band assignments by other authors for trichlorotripyridine- and "hexaquo-" molybdenum(III) complexes are doubtful.[2,3] Thus no systematic discussion of the electronic spectra of molybdenum(III) complexes has so far been presented because of a lack of available data.

The present paper is concerned with the preparation of and the electronic absorption spectra of several sexa-co-ordinate molybdenum(III) complexes, including three new compounds. Experimental results will be discussed, together with the available data on the corresponding chromium(III) complexes.

## Experimental

**Materials.**—The following molybdenum(III) compounds were prepared: $K_3[MoCl_6]$, $(NH_4)_2[MoX_5(H_2O)]$, $[MoX_3(urea)_3]$, $[Mo(urea)_6]Br_3$, $[MoX_3(dmf)_3]$, $[MoCl_3(tu)_3]$ and $[MoX_3(py)_3]$ (where dmf=*N*, *N*-dimethylformamide, tu=thiourea, py=pyridine and X=Cl and Br). Among these compounds, $[MoBr_3(urea)_3]$, $[MoCl_3(dmf)_3]$ and $[MoBr_3(dmf)_3]$ are new compounds, while $[MoCl_3(urea)_3]$, $[Mo(urea)_6]Br_3$* and $[MoCl_3(tu)_3]$ have been briefly reported on by Russian authors.[4] No description, however, has yet been given of their preparation methods.

*Trichlorotriureamolybdenum(III), $[MoCl_3(urea)_3]$.*—Five grams of $(NH_4)_2[MoCl_5(H_2O)]$ and five grams of urea, ground together in a mortar, were added to 30 ml. of ethanol in a nitrogen atmosphere; the reaction mixture was then stirred continuously at 50—55°C. As the reaction proceeded, the color of the precipitate gradually changed from orange to yellow. After 3.5 hr. the product was filtered in air, washed with water until the filtrate became colorless and then with ethanol, and dried at 60°C. A yellow powder was obtained. Yield, 2.5 g. (43%).

This crude product was recrystallized with a concentrated aqueous solution of urea to give as a pure product yellow, tetragonal plates. The yield of the recrystallization was rather poor (less than 20%) because of the predominant decomposition,

Found: C, 9.42; H, 3.26; N, 21.77. Calcd. for $[MoCl_3(urea)_3]$: C, 9.42; H, 3.16; N, 21.97%.

Preparation in an aqueous medium was also possible.

*Tribromotriureamolybdenum(III), $[MoBr_3(urea)_3]$.*—A saturated aqueous solution of urea was prepared at room temperature. Five grams of $(NH_4)_2[MoBr_5(H_2O)]$ and three grams of urea were dissolved in as small an amount as possible of the urea solution in a nitrogen atmosphere, and then the mixture was stirred continuously at 48—50°C. After about 15 min. a crystalline precipitate began to separate. For an additional 30 min. the stirring was continued; then the mixture was cooled to room temperature, poured into about 50 ml. of water in air, and stirred for about 15 min. The precipitate was filtered, washed with water and with ethanol, and dried at 60°C. Yield, 1.3 g. (28%).

Found: C, 7.02; H, 2.24; N, 16.78. Calcd. for $[MoBr_3(urea)_3]$: C, 6.99; H, 2.34; N, 16.29%.

This compound, which consists of fine, orange microcrystals, is soluble in a warm aqueous solution of urea with decomposition, but insoluble in cold water and in common organic solvents.

*Hexaureamolybdenum(III) Bromide, $[Mo(urea)_6]Br_3$.*—The initial procedure was the same as that described for $[MoBr_3(urea)_3]$. When the orange precipitate of $[MoBr_3(urea)_3]$ had separated out, the temperature of the reaction mixture was raised to 70°C. Soon the precipitate was dissolved, and about 10—20 min. after the dissolution a pale-colored crystalline precipitate separated slowly from the dark brown solution. When the amount of the precipitate no longer increased, the stirring was stopped and the mixture was allowed to cool at room temperature. The crystals, which separated abundantly, were filtered in air, washed with ethanol, and dried at 60°C. Yield, 2.2 g. (35%).

For the elemental analyses the crude crystals were added to a large amount of ethanol at 40°C and stirred continuously for 20 min., filtered, washed with cold ethanol, and dried at 30°C under reduced pressure over phosphorus pentoxide for half a day.

Found: C, 10.48; H, 3.75; N, 23.83. Calcd. for $[Mo(urea)_6]Br_3$; C, 10.35; H, 3.48; N, 24.15%.

The pale greenish yellow pillar-shaped crystals thus obtained were soluble in water with decomposition but insoluble in common organic solvents.

*Trichlorotris(N, N-dimethylformamide)molybdenum(III), $[MoCl_3(dmf)_3]$.*—To 50 ml. of a purified *N*, *N*-dimethylformamide[5] 15 g. of $(NH_4)_2[MoCl_5(HO_2)]$

3) H. Hartmann and H.-J. Schmidt, *Z. phys. Chem., N. F.*, **11**, 234 (1957).

* In the Russian paper it is described as a dihydrate, $[Mo(urea)_6]Br_3 \cdot 2H_2O$.

4) V. B. Evdokimov, V. V. Zelentsov, I. D. Kolli, Wen-Hsia T'ang and V. I. Spitsyn, *Dokl. Akad. Nauk S. S. S. R.*, **145**, 1282 (1962).

5) D. W. Meek, R. S. Drago and T. S. Piper, *Inorg. Chem.*, **1**, 285 (1962).

were added. The mixture was then stirred continuously for 12 hr. at 30—35°C in a nitrogen atmosphere. The insoluble red precipitate of the starting molybdate salt was slowly displaced by a white precipitate of ammonium chloride until the red color disappeared in the precipitate at the end of the reaction. This was separated with a glass filter, and the dark-brown filtrate was concentrated to a thick paste under reduced pressure below 35°C and preserved in an ice-box for several days. When the crystallization of the paste did not occur spontaneously, one of the following procedures was taken: (1) scratching by means of a magnetic stirrer, (2) dissolving the paste in ethanol at 50°C, followed by cooling the solution with an ice-bath as soon as possible and scratching,* or (3) dissolving the paste in ethanol or in acetone at room temperature and then preserving it in an ice-box for a few weeks. The yellow product separated was filtered and washed with ethanol. Yield of the crude product was about 60%. As the crude product was often contaminated with ammonium chloride, purification was performed by procedure 2 for the elemental analyses. The yellow powder produced was filtered, washed with ethanol several times, and dried at 35°C under reduced pressure over phosphorus pentoxide for 100 min. All the procedures were carried out in an oxygen-free atmosphere so far as possible.

Found: C, 26.13; H, 5.21; N, 10.36. Calcd. for $[MoCl_3(dmf)_3]$: C, 25.64; H, 5.02; N, 9.97%.

This compound is soluble with decomposition in water, ethanol, acetone, pyridine and chloroform, but insoluble in benzene; the color changes after a few days in moist air.

*Tribromotris(N, N-dimethylformamide)molybdenum(III), $[MoBr_3(dmf)_3]$*—Five grams of $(NH_4)_2[MoBr_5(H_2O)]$ were dissolved in 17 ml. of purified *N, N*-dimethylformamide; the mixture was then stirred continuously at 29—31°C for 6 hr. in a nitrogen atmosphere. After about 15 min. the color of the solution became blood-red. Near the end of the reaction, the white precipitate of ammonium bromide separated. This was filtered rapidly in air, and the filtrate was concentrated at 30°C under reduced pressure in an atmosphere of carbon dioxide until just enough of the solvent remained to moisten the crystalline product. All the contents were then poured into about 50 ml. of water, and the suspension was stirred for 20 min. at room temperature. The orange crystalline substance was filtered, washed with water and with methanol, and dried at about 30°C under reduced pressure over calcium chloride. Yield, 1.4 g. (28%).

Found: C, 19.55; H, 3.79; N, 7.97. Calcd. for $[MoBr_3(dmf)_3]$: C, 19.48; H, 3.81; N, 7.57%.

The orange-red hexagonal microcrystalline plates of the compound are soluble in chloroform, where they rapidly decompose; soluble in water and in acetone only with difficulty, and insoluble in ethanol and in ether. The color of the compound changes when it is left in moist air for several days.

*Trichlorotrithioureamolybdenum(III), $[MoCl_3(tu)_3]$.*—Fifteen grams of $(NH_4)_2[MoCl_5(H_2O)]$ and ten grams of thiourea were ground together in a mortar, added to about 200 ml. of ethanol, and the mixture was stirred continuously at 50°C for 20 hr. in a nitrogen atmosphere. The color of the solution gradually became dark brown. Then the reaction mixture was left at room temperature for 10 hr., and filtered. The crude precipitate was washed with cold and warm water until the reddish color faded from the filtrate; it was then washed with ethanol and dried at 60°C for several minutes. Yield, 8.5 g. (43%).

Found: C, 8.58; H, 2.84; N, 19.30. Calcd. for $[MoCl_3(tu)_3]$: C, 8.38; H, 2.81; N, 19.54%.

This compound, obtained as an orange-yellow microcrystalline powder, is soluble in *N, N*-dimethylformamide with decomposition, slightly soluble in water and in pyridine, and insoluble in common organic solvents. The compound is stable in air, at least for several days.

*Other Compounds.* — $K_3[MoCl_6]$, $(NH_4)_2[MoCl_5(H_2O)]$ and $(NH_4)_2[MoBr_5(H_2O)]$ were prepared according to the method of Hartmann and Schmidt[3] with slight modifications.

$[MoCl_3(py)_3]$ was prepared according to the method described in the literature.[6]

Found: C, 40.93; H, 3.35; N, 9.56. Calcd. for $[MoCl_3(py)_3]$: C, 40.98; H, 3.44; N, 9.56%.

$[MoBr_3(py)_3]$ was obtained by almost the same method as that used for $[MoCl_3(py)_3]$.

Found: C, 32.23; H, 2.34; N, 7.54. Calcd. for $[MoBr_3(py)_3]$: C, 31.44; H, 2.64; N, 7.33%.

**Measurements.**—Electronic absorption spectra in the solid state were measured with a Hitachi EPU-2A spectrophotometer equipped with a diffuse reflectance attachment, and the spectra in solution, with a Beckman DU spectrophotometer. A Hitachi EPS-2 self-recording spectrophotometer was employed for the measurement of $[Mo(urea)_6]Br_3$ in solution.

The infrared absorption spectra measurements of the three molybdenum(III) compounds containing urea and of hexaureachromium(III) chloride were made in the rock salt region by the KBr disk technique.

All the measurements of the ultraviolet and infrared spectra were carried out at room temperature.

## Results and Discussion

**The Ultraviolet Spectra and the Structures of the Molybdenum(III) Complexes.** — The main results of the ultraviolet measurements are given in Figs. 2—4 and in Table I. There are common features through all these absorption spectra: each spectrum has two sharp bands of a lower intensity near 9000 $cm^{-1}$ and 15000 $cm^{-1}$ and two more intense broad bands of a similar type in the higher wave number region, though these bands are partly embedded under

* This complex is rapidly decomposed in ethanol at 50°C.

6) H. B. Jonassen and L. J. Bailin, *Inorg. Syn.*, 7, 140 (1963).

much more intense bands in some spectra. This observation gives support to Jørgensen's band assignments, which are shown in Figs. 1—2,[1] and to the octahedral configuration in all these complexes. The corresponding bands of the molybdenum(III) compounds have been similarly assigned.

The absorption spectra of ammonium pentabromoaquomolybdate(III) were measured in the solid state, in 3 N hydrobromic acid and in 12 N hydrobromic acid (Fig. 2). The I- and II-bands in the 12 N hydrobromic acid solution are shifted by about 1000 $cm^{-1}$ to a lower wave number compared with those in the solid state, and they show almost no change during

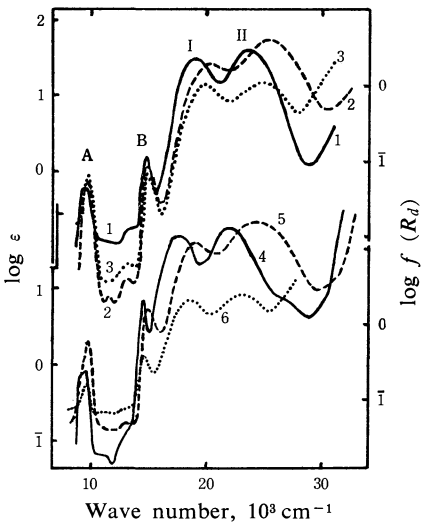

Fig. 2. Absorption spectra of: 1, $K_3[MoCl_6]$ in 12 N HCl; 2, in 3 N HCl; 3, $(NH_4)_2[MoCl_5(H_2O)]$ in solid state; 4, $(NH_4)_2[MoBr_5(H_2O)]$ in 12 N HBr; 5, in 3 N HBr; 6, in solid state.

the measurement. On the other hand, the corresponding bands in the 3 N hydrobromic acid solution are shifted to a higher wave number and show a considerable time dependency. The same behavior was observed among the spectra of the corresponding chlorocomplexes, such as $(NH_4)_2[MoCl_5(H_2O)]$ and $K_3[MoCl_6]$ (Fig. 2). Table I summarizes the corresponding band maxima in these spectra. From these observations it may be concluded that the spectra of $(NH_4)_2[MoBr_5(H_2O)]$ in 12 N hydrobromic acid and of $K_3[MoCl_6]$ in 12 N hydrochloric acid are due to the $[MoBr_6]^{3-}$ ion and to the $[MoCl_6]^{3-}$ ion respectively, and that considerable decomposition takes place in the 3 N hydrobromic acid solution of the bromomolybdate complex.

Since $[Mo(urea)_6]Br_3$ is rapidly decomposed, even in a concentrated aqueous solution of

TABLE I. SPIN-ALLOWED BANDS OF SOME MOLYBDENUM(III) COMPLEXES

wave number, $10^3$ $cm^{-1}$

urea (about 4 mol. urea), the spectrum was obtained within 15 min. after dissolution. Both the I- and II-bands are considerably (about 1000 $cm^{-1}$) shifted to a lower wave number compared with those of the solid state. Therefore, any structure in which the bromide ion is directly attached to the molybdenum ion is improbable for the compound in the solid state. Moreover, the pronounced intensity of the B-band common to the other bromide-containing complexes is not obvious in the spectra of the hexaurea compound. It is, therefore most likely that this contains the $[Mo(urea)_6]^{3+}$ ions.

It may obviously be concluded, on the basis of absorption spectra and chemical properties, that the two trihalotriurea complexes are not $[MoX_6]$ $[Mo(urea)_6]$ but $[MoX_3(urea)_3]$ (Figs. 2 and 3). The infrared absorption spectra of these three urea-containing compounds and of $[Cr(urea)_6]Cl_3$ were, therefore, measured in order to obtain further information on their molecular structure. The results are summarized in Table II.

Penland et al.[7] have studied the infrared spectra of many transition metal-urea complexes and found a method to determine the species of atom by which the central metal ion is coordinated in each of the complexes. This consists mainly of comparisons of NH-stretching frequencies and of CO-stretching frequencies coupled with $NH_2$ bending. According to this method, it may be concluded from Table II that urea is coordinated through the oxygen atom to the metal atom in the molybdenum complexes as well as in the chromium complex.

The trichloro- and tribromo-triureamolybdenum(III) have almost the same infrared patterns, while the pattern of hexaureamolybdenum(III) bromide is quite similar to that of hexaureachromium(III) chloride. The main differences between the spectra of these two

* Our measurement virtually reproduced the Penland's data for this compound (Cf. Ref. 7).

couples are found in the bands near 3200 cm$^{-1}$ and near 1150 cm$^{-1}$. The former band is found only in the spectra of the hexaurea complexes; a corresponding band has also been found in hexaureairon(III) chloride.[7] On the other hand, both the frequency and the shape of the latter $NH_2$ rocking band are the same within each of the two pairs of compounds, but they are differentiated between the two pairs. These observations also support the presence of the $[Mo(urea)_6]^{3+}$ species in the hexaureamolybdenum(III) bromide.

Although the electronic absorption spectrum of the trichlorotris(*N*, *N*-dimethylformamide)-molybdenum(III) has some ambiguous features, which may be related to the difficulty of preparation (Fig. 3), the wave numbers of both the I- and II-bands of the two *N*, *N*-dimethylformamide complexes are not essentially different from those of the two corresponding triurea complexes, so the former two complexes, as well as the latter two, may be regarded as having the configuration $[MoX_3O_3]$.

The spectrum of trichlorotrithioureamolybdenum(III) appears to show at least four bands in the near infrared and visible region. These bands may be assigned to the A, B and I transitions, as is shown in Fig. 3. According to this assignment and to the spectrochemical series, this complex may be concluded to be of the $[MoCl_3S_3]$ type.

The spectra of trichlorotripyridinemolybdenum(III) have already been investigated by König and Schläfer[2]; one of them is shown in Fig. 4. However, our measurements for this compound gave slightly different absorption curves (Fig. 4), which show the spectral features common to the other sexa-co-ordinate molybdenum(III) complexes. The I- and the II-bands are most probably embedded under the much more intense charge transfer bands, because a part of the I-band appears on the lower wave number side of the charge transfer band in the spectra of the tribromotripyridinemolybdenum(III) (Fig. 4). A considerable splitting of the B-band was observed in the spectra of the two complexes, both in solution and in the solid state. On the contrary, a broad band at 12500 cm$^{-1}$ in the spectra of the trichlorotripyridine complex has an enhanced

intensity only in the solid state. More detailed investigations will be necessary to explain these phenomena.

**Spectrochemical Series and Nephelauxetic Series.**—From our spectral data the spectrochemical series for molybdenum(III) complexes was obtained as:

$$py \gtrsim (urea, dmf, and\ tu) > Cl^- > Br^-$$

This agrees with the series for complexes of other transition metal ions.

Using the wave numbers of the I- and II-bands, the Racah's parameter *B*'s of interelectronic repulsion were calculated for the three octahedral molybdenum(III) complexes. From these values nephelauxetic ratios $\beta$' were then obtained by assuming $B=0.61\,(10^3\,cm^{-1})$ for free molybdenum(III) ions, in accordance with the findings of Jrgøensen.[1] The results are tabulated in Table III. For the purpose of comparing these parameters for $3d^3$- and $4d^3$-complexes, the corresponding values for three octahedral chromium(III) complexes are also given in Table III.[1,8,9] The following nephelauxetic series were obtained:

$Br^- > Cl^- >$ urea for molybdenum(III) complexes, and Cr(III) > Mo(III) for the same ligands.

These series are in good agreement with those for the chromium(III) and other transition metal complexes.[1]

Approximating the transition energies for the first and the second spin-forbidden bands as $9B+3C$ and $15B+5C$ respectively, Racah's parameters *C*' were calculated for the three molybdenum(III) complexes. These give ratios $C/B$ between 4 and 5.

Hartmann and Schmidt[3] regarded the spectra of the green solutions obtained by the electrolytic reduction of diluted solutions of molybdenum oxide in various mineral acids as due to the "hexaquomolybdenum(III) ion"; a typical spectrum is shown in Fig. 3. This is apparently not a spectrum of the genuine hexaquomolybdenum(III) ion, in the light of the present investigation.

## Summary

Several sexa-co-ordinate molybdenum(III) compounds containing some of chloride ions, bromide ions, urea, thiourea *N*, *N*-dimethylformamide and pyridine as ligands have been

8) W. E. Hatfield, R. C. Fay, C. E. Pfluger and T. S. Piper, *J. Am. Chem. Soc.*, **85**, 265 (1963).

9) M. Nakahara, private communication.

10) Y. Tanabe and S. Sugano, *J. Phys. Soc. Japan*, **9**, 753 (1954).

prepared, and their electronic absorption spectra determined.

It has been shown that the spectrum of the sexa-co-ordinate molybdenum(III) compound generally has two spin-forbidden and two spin-allowed bands. The ligand field parameters of the octahedral molybdenum(III) complexes have been calculated and compared with those of the corresponding chromium(III) complexes.

We wish to express our sincere thanks to Dr. Masayoshi Nakahara of Rikkyo St. Paul's University for his valuable information on the spectrum of the hexachlorochromium(III) complex.

# Band Structure of Circumanthracene

By Yoshiya HARADA, Yusei MARUYAMA, Hiroo INOKUCHI and Noriko MATSUBARA

(Received August 14, 1964)

Considerable interest has developed in recent years in the theoretical interpretation of the electrical transport properties of organic molecular crystals. The characteristic nature of the crystals is their small mobilities. In fact, values of the order of $10^{-1}$—$10^{0}$ $cm^2/V.sec.$ were observed for both electrons and holes at room temperature.[1-3] In order to account for the electron and the hole mobilities, two mechanisms have so far been considered; the usual band model (the Bloch theory), and the hopping one (the Heitler-London approach).[4] When the mobility is much larger than 1 $cm^2/V.sec.$, the band model is applicable, while the hopping model may be better when the mobility is much smaller than 1 $cm^2/V.sec.$[4b] Since mobilities of the order of unity are on the borderline region between the two mechanisms, neither approach seems to be accurate enough.

The temperature dependence of the mobility also offers a condition under which one of the two models can be selected. In the usual band model the mobility should decrease with an increase in the temperature. On the other hand, the hopping model should lead to a mobility which increases exponentially with a rise in the temperature, because the thermally-activated charge carrier wanders through the crystal by jumping from one lattice site to another.* Although the mobility of anthracene decreases as the temperature increases, the situation is not favourable to the band model, because the decrement of the mobility due to the thermal expansion of the crystal has a comparable effect.[1b]

Recently, Toyozawa[5] has proposed an alternate model which is applicable to an intermediate between the above two mechanisms. He treated the carrier transport of the organic semiconductor by a localized picture and obtained, below room temperature, a mobility which is almost independent of the temperature.**

* In the case of the hopping model, the self-trapping due to the interaction of the carrier with the lattice may be necessary. Friedman (Ref. 4) suggested the absence of the self-trapping, judging from the estimation that the bandwidths are not small compared to the binding energy of the excess carrier on the mononegative anthracene ion due to the associated lattice deformation.

5) Y. Toyozawa, Private communication.

** His basic idea is as follows: The characteristic nature of organic semiconductors which can be clearly distinguished from inorganic ones is the existence of a large number of intramolecular vibrations. Since numerous vibronic levels resulting from these vibrational modes and their various combinations spread almost continuously over a pure electronic state (a state used for the construction of the band), and also since the distribution width of the vibronic energy states is larger than the values of the intermolecular resonance integrals, a non-localized treatment (band picture) may be a poor approach. On the other hand, since the interaction of the carrier with the lattice is relatively small (cf. preceding note), only a little activation energy may be required for the resonance transfer of the excess carrier between adjacent molecules (this is a difference from the hopping motion).

The intermolecular overlap integrals in the anthracene crystal were first calculated by Murrell.[6] Later calculations of this type were reported by Ohki et al.[2b] for pyrene. In these calculations the anisotropy of the mobility may be explained on the assumption that the overlap integrals are roughly proportional to the resonance integrals.

The tight-binding band approximation for the anthracene crystal was first calculated by LeBlanc[7] in order to describe the motion of excess charge carriers. The calculated mobility anisotropy agreed qualitatively with those experimentally observed, and the bandwidth was found to be approximately $0.56\,kT$ at room temperature.* Subsequently, Thaxton et al.[8] extended LeBlanc's method to homologs of anthracene: naphthalene, anthracene, tetracene and pentacene. Katz et al.[9] also calculated the band structure of naphthalene, anthracene, and several polyphenyls in the tight-binding band approximation. In the calculation of intermolecular resonance integrals they used the SCF carbon atomic orbital, represented in the form of a linear combination of four Slater wave functions.[10],* The bandwidths calculated by their method were about five times larger than those found by LeBlanc. Recently, Friedman[11] calculated the electrical and thermal transport properties of organic crystals from a Boltzmann equation treatment based on the tight-binding band structure. For anthracene the calculated mobility anisotropies in the ab plane were the same as those obtained by LeBlanc, but in the $c'$ direction a better agreement with the experiments was found.

We have already examined in a previous paper[12] the band structure of the anthracene crystal at atmospheric pressure and also at 160 kilobars. It was found that the increase in the mobility due to the decrease in the lattice constants was found to be several tens of times at 160 kilobars. In the case of a larger hydrocarbon, the distances between molecules in the crystal, are also expected to be shorter, in addition to the change in the distribution of the carriers in the molecule.

In this report, we will attempt to calculate the band structure of circumanthracene, $C_{40}H_{16}$ (Fig. 2), by the method used by LeBlanc. Since circumanthracene is a largest hydrocarbon in the polycyclic aromatics, the electrical properties of which have been experimentally investigated,[13] it may be worth-while to compare the band structure and the mobility properties of the compound with those of anthracene.

## Crystal Structure

The first step in the calculation of the band structure of the circumanthracene crystal is to estimate the coordinates of atoms in the crystal. Although the lattice constants of the crystal have been set up,[14] the orientation of the molecule in the crystal has not yet been determined. Hence, we will try to estimate the latter from the crystal structure of coronene.[15] A method of estimation is described in the Appendix. The crystal data of these two compounds, in addition to those of anthracene, are compared in Table I. The estimated orientation of the molecule in the

crystal is given in Table II,* where $\chi_L$, $\phi_L$, $\omega_L$; $\chi_M$, $\varphi_M$, $\omega_M$; $\chi_N$, $\psi_N$, $\omega_N$ are the angles which the molecular long (L) and short (M) axes and their perpendicular (N) make with the a and b crystal axes and with their perpendicular, c'. Furthermore, all the hexagons in circumanthracene were assumed to be regular ones with a radius of 1.39Å. Thus, the coordinates of atoms referred to orthogonal axes a, b and c' were estimated.** Although the above estimate of the coordinates of atoms lacks confirmation, it may be adequate for the calculation of the band structure, considerering the rather rough nature of the present theoretical treatment.

## Method of Calculation

The band structure and mobility tensors for circumanthracene are calculated by the method introduced by LeBlanc.[7]

Disregarding the interaction between carriers (electrons or holes), the Hamiltonian operator appropriate to an electron or a hole is expressed in the form:

$$\boldsymbol{H}=(-\hbar^2/2m)\nabla^2+\sum_n V_n(\boldsymbol{r}-\boldsymbol{r}_n) \tag{1}$$

where $V_n$ is the Hartree potential of an isolated molecule. Since the circumanthracene crystal has two molecules per unit cell, the wave function in the tight-binding band approximation is expressed by:

$$\Psi=C_1\psi_1+C_2\psi_2 \tag{2}$$

where

$$\begin{aligned}\psi_1&=\textstyle\sum_A \exp[i\boldsymbol{k}\cdot\boldsymbol{r}_A]\,\phi(\boldsymbol{r}-\boldsymbol{r}_A)\\ \psi_2&=\textstyle\sum_B \exp[i\boldsymbol{k}\cdot\boldsymbol{r}_B]\,\phi(\boldsymbol{r}-\boldsymbol{r}_B)\end{aligned} \tag{3}$$

in which $\phi(\boldsymbol{r})$ denotes the molecular wave function. In Eq. 3, the first sum is taken over the centre of the standard molecule and all the lattice points generated from it by primitive lattice translations; the second sum is similarly taken over the points generated from the centre of the reflected molecule at $(\boldsymbol{a}/2, \boldsymbol{b}/2)$. On the basis of variational principles, the band energy can be determined by the solution of a secular equation:

$$\begin{vmatrix} H_{11}-ES & H_{12} \\ H_{21} & H_{22}-ES \end{vmatrix}=0 \tag{4}$$

where

$$\begin{aligned}H_{11}&=H_{22}=\int \phi_1^* H\phi_1 d\tau\\ H_{12}&=H_{21}^*=\int \phi_1^* H\phi_2 d\tau\end{aligned} \tag{5}$$

Therefore, by disregarding overlap integrals, the solution of Eq. 4 becomes:

$$E=H_{11}\pm|H_{12}| \tag{6}$$

By disregarding three-centre integrals and overlap integrals, the substitution of Eq. 3 into 6 leads to:

$$\begin{aligned}E(\boldsymbol{k})=E_0+\sum_{n\,(r_n\neq 0)} E_n^\alpha+\sum_{l\,(r_l\neq 0)} E_l^\gamma \exp[-i\boldsymbol{k}\cdot\boldsymbol{r}_l]\\ \pm\Big|\sum_l E_{l+AB}^\gamma \exp[-i\boldsymbol{k}(\boldsymbol{r}_l+\boldsymbol{r}_{AB})]\Big|\end{aligned} \tag{7}$$

where

$$\left.\begin{aligned}E_0&=\int \phi^*(\boldsymbol{r}-\boldsymbol{r}_n)\,[(-\hbar^2/2m)\nabla^2+V_n]\\ &\quad\times\phi(\boldsymbol{r}-\boldsymbol{r}_n)d\tau\\ E_n^\alpha&=\int \phi^*(\boldsymbol{r})\,V_n(\boldsymbol{r}-\boldsymbol{r}_n)\,\phi(\boldsymbol{r})d\tau\\ E_l^\gamma&=\int \phi^*(\boldsymbol{r}-\boldsymbol{r}_l)\,V_l(\boldsymbol{r}-\boldsymbol{r}_l)\,\phi(\boldsymbol{r})d\tau\\ E_{l+AB}^\gamma&=\int \phi^*(\boldsymbol{r}-\boldsymbol{r}_l-\boldsymbol{r}_{AB})\\ &\quad\times V_{l+AB}(\boldsymbol{r}-\boldsymbol{r}_l-\boldsymbol{r}_{AB})\,\phi(\boldsymbol{r})d\tau\end{aligned}\right\} \tag{8}$$

in which $E^\alpha$ and $E^\gamma$ denote the coulomb and the intermolecular resonance integrals respectively. In Eq. 7, while the sum, $\sum_n$ is taken over all molecules except the one with a centre located at the origin, the sum, $\sum_l$, is carried out over the primitive lattice translations.

In the actual calculation of the circumanthracene crystal, $E^\gamma$'s with values of less than $10^{-16}$ erg were disregarded (cf. Table III). Therefore, Eq. 7 becomes

$$\begin{aligned}E(\boldsymbol{k})=&\text{const.}+2E_b\cos\boldsymbol{k}\boldsymbol{b}+2E_c\cos\boldsymbol{k}\boldsymbol{c}\\ &+2E_{b\bar{c}}\cos\boldsymbol{k}(\boldsymbol{b}-\boldsymbol{c})\\ &\pm|2E_{a/2\,b/2}[\cos\boldsymbol{k}(\boldsymbol{a}/2+\boldsymbol{b}/2)\\ &+\cos\boldsymbol{k}(\boldsymbol{a}/2-\boldsymbol{b}/2)]|\end{aligned} \tag{9}$$

which shows the interaction of the centre molecule with ten neighbouring ones (Fig.

---

* The inclination of molecules to the ac face and also the perpendicular distances between the planes of molecules overlying each other in the b axial direction are collected in the following table. Since ovalene, $C_{32}H_{14}$, has a molecular structure intermediate between those of coronene and circumanthracene, and also since its crystal structure is similar to that of coronene, the estimated data for circumanthracene may be regarded as appropriate.

| | Coronene[a] | Ovalene[b] | Circumanthracene[c] |
|---|---|---|---|
| Inclination of molecule | 43.7° | 42.7° | 38.7° |
| Distance between the molecular planes | 3.40 Å | 3.45 Å | 3.58 Å |

a) Ref. 15.
b) D. M. Donaldson and J. M. Robertson, *Proc. Roy. Soc.*, A220, 157 (1953).
c) Calculated from Table II.

** While, in the case of coronene, the shortest distance between carbon atoms of the standard molecule and those of the reflected molecule at $(\boldsymbol{a}/2, \boldsymbol{b}/2)$ is 3.77 Å, the corresponding distance of circumanthracene is found to be 3.90 Å, showing the estimated coordinates of atoms to be appropriate.

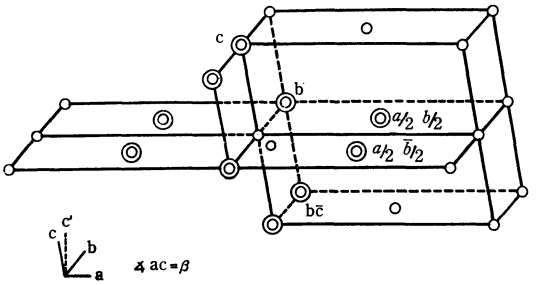

Fig. 1. The unit cell of the circumanthracene crystal. The interaction of the centre molecule (O) with molecules marked with double circles was considered.

1). The constant in Eq. 7 is immaterial to the determination of bandwidths and mobilities.

The molecular wave functions, $\phi$, are linear combinations of Slater-type $2p_z$ atomic orbitals:

$$\phi=\sum_i a_i\chi_i \tag{10}$$

with

$$\chi_i=(\alpha^5/\pi)^{1/2}r_i\cos\xi_i\exp(-\alpha r_i) \tag{11}$$

and

$$\alpha=1.64\text{ a. u.}=3.08\times10^8\text{ cm}^{-1}$$

The coefficients, $a_i$, are determined using the approximation of Hückel. Although the orbital energies and the bond orders of the circumanthracene molecule had already been investigated by Baudet and Pullman,[16] we recalculated the orbital coefficients (cf. Fig. 2), because the latter were not shown in their paper. In cases of multiple signs the upper signs are associated with the lowest antibonding orbital (for the electron) and the lower signs with the highest bonding orbital (for the hole).

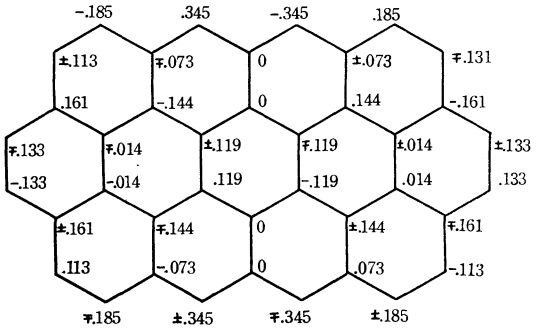

Fig. 2. Values of the coefficients for the Hückel wave functions. The magnitudes of these coefficients are the same for holes and electrons; when they differ in phase, the upper sign is for the electron and the lower for the hole.

16) J. Baudet and B. Pullman, *Compt. rend.*, **244**, 777 (1957).

The intermolecular resonance integrals, $E_b$, $E_c$, etc., were calculated by the method used by LeBlanc except that all of the two-centre interatomic integrals were considered for the evaluation of each intermolecular resonance integrals.

If we assume that the carrier-scattering can be described by the constant mean free time, $\tau(\boldsymbol{k})=\tau_0$, the mobility components are given by:

$$\mu_{ij}=e\tau_0\langle v_iv_j\rangle/\boldsymbol{kT} \tag{12}$$

where $v_i$ is the $i$th component of the carrier velocity, and is given by:

$$v=(1/h)\partial E(\boldsymbol{k})/\partial\boldsymbol{k} \tag{13}$$

The quantity $\langle v_iv_j\rangle$ is a statistical average over the band.

## Results of Calculation

The intermolecular resonance integrals of the circumanthracene crystal are given in Table III in comparison with those of anthracene.*

Table III. Intermolecular resonance integrals ($10^{-16}$ erg)

| | Circumanthracene* | | Anthracene | |
|---|---|---|---|---|
| | Electron | Hole | Electron | Hole |
| $E_b$ | −86.0 | −89.7 | 25.2 | −33.5 |
| $E_c$ | −34.0 | 34.8 | 0.802 | 0.167 |
| $E_{b\bar{c}}$ | 1.91 | −2.10 | −0.000100 | 0.000291 |
| $E_{a/2\ b/2}$ | −1.23 | −1.20 | −39.7 | −29.0 |
| $E_{a/2\ b/2\ c}$ | 0.207 | −0.282 | 1.02 | 6.64 |

* The values of some of other resonance integrals are in unit of erg; $E_a=0.494\times10^{-32}$, $E_{bc}=0.748\times10^{-16}$, $E_{a/2\ b/2\ \bar{c}}=-0.750\times10^{-23}$ for the electron; $E_a=-1.30\times10^{-31}$, $E_{bc}=-0.916\times10^{-16}$, $E_{a/2\ b/2\ \bar{c}}=0.571\times10^{-23}$ for the hole.

In the reduced zone scheme given by $-\pi<\boldsymbol{ka}, \boldsymbol{kb}, \boldsymbol{kc}<\pi$, the electron and hole band structures of circumanthracene in the reciprocal crystal axis direction are shown in Figs. 3 and 4. The origins of the energy scales are arbitrarily taken in both figures. The band structures of the anthracene crystal are also given in Figs. 5 and 6.

In Table IV we present the values of the bandwidths in the $\boldsymbol{a}^{-1}$, $\boldsymbol{b}^{-1}$, and $\boldsymbol{c}^{-1}$ directions,

* The band structure of the anthracene crystal was calculated by the same method. For the evaluation of the band energy, the interaction of the centre molecule with twelve neighbouring ones was considered (cf. Ref. 12):

$$E(\boldsymbol{k})=\text{const.}+2E_b\cos\boldsymbol{kb}+2E_c\cos\boldsymbol{kc}\pm[2E_{a/2\ b/2}[\cos\boldsymbol{k}(\boldsymbol{a}/2+\boldsymbol{b}/2)+\cos\boldsymbol{k}(\boldsymbol{a}/2-\boldsymbol{b}/2)]+2E_{a/2\ b/2\ c}[\cos\boldsymbol{k}(\boldsymbol{a}/2+\boldsymbol{b}/2)+\boldsymbol{c})+\cos(\boldsymbol{a}/2-\boldsymbol{b}/2+\boldsymbol{c})]]$$

and also the splittings in the $c^{-1}$ direction. Since there are two branches in each band, the lower and the upper branches are shown by $-$ and $+$ suffices respectively.

The velocity components and the mean square velocities of circumanthracene are given in Table V, in addition to those of the anthracene crystal.

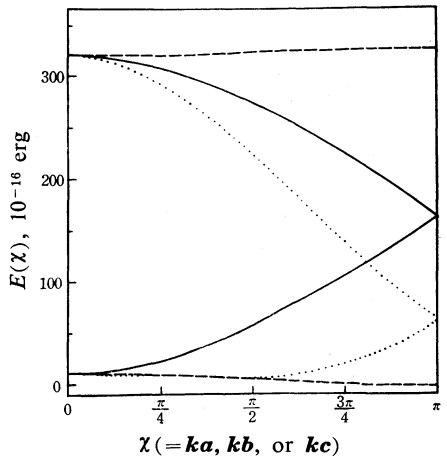

Fig. 5. Electron band structure of anthracene in the $a^{-1}$ (solid line), $b^{-1}$ (dotted line), and $c^{-1}$ (dashed line) directions.

## Discussion

**Band Structure.**—As is shown in Figs. 3—6, and also in Table IV, while the bandwidths of both the electrons and holes of circumanthracene are largest in the $b^{-1}$ direction (ca. $2\times10^{-2}$ eV.), the widths in the $a^{-1}$ direction are only $3\times10^{-4}$ eV. In the case of anthracene, the direction of the smallest bandwidth is that of $c^{-1}$. Moreover, the splittings between the upper lying bands and the lower ones of circumanthracene are smaller by a factor of 30 than those of the anthracene crystal. These relations may be due to the differences in molecular and crystal structure between these two hydrocarbons. In spite of a larger size of the molecular long axis, however, the c axis of the circumanthracene crystal is shorter than that of anthracene. This leads to far larger $E_c$ values of circumanthracene (Table III) and, accordingly, larger bandwidths in the $c^{-1}$ direction. On the

b) H. Inokuchi, unpublished.

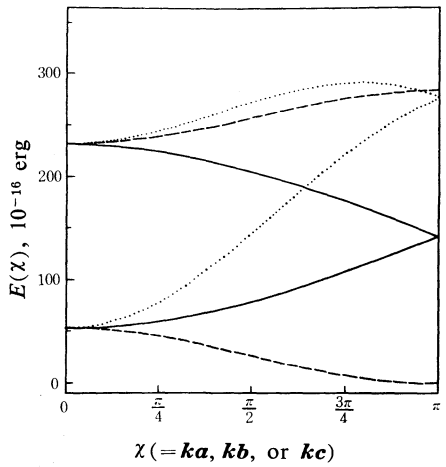

Fig. 6. Hole band structure of anthracene in the $a^{-1}$ (solid line), $b^{-1}$ (dotted line), and $c^{-1}$ (dashed line) directions.

other hand, the much longer a axis of circumanthracene brings about smaller $E_{a/2\,b/2}$ values, with the consequence that the bandwidths in the $a^{-1}$ direction and also the splittings between the upper and lower branches become very small (cf. Eq. 9). The large bandwidths in the $b^{-1}$ direction of circumanthracene may be due to the remarkably short b axis.

As is shown in Figs. 3—6, the total bandwidths are slightly larger for circumanthracene. The total widths of the electron and the hole band of circumanthracene are 0.021 eV. (0.82 $kT$) and 0.031 eV. (1.22 $kT$); the corresponding widths of anthracene are 0.020 eV. (0.79 $kT$) and 0.018 eV. (0.70 $kT$) respectively.

**Mobility Tensors.**—It can be noted from Table V that the anisotropy properties of the band structure also appear in the mobility anisotropy. In the case of circumanthracene, the largest mobilities of both electrons and holes are found in the $b$ direction, corresponding to the widest bands in the $b^{-1}$ direction. Moreover, the mobilities in the $a$ direction are found to be much smaller than those in the other directions, a corollary of the small bandwidths in the $a^{-1}$ direction. On the other hand, the mobilities of anthracene are fairly isotropic on the ab plane and smaller perpendicular to it, reproducing the anisotropy properties of the bandwidths in the reciprocal lattice directions. We may, therefore, conclude that the significant differences between the mobility anisotropies of the two compounds may also be due to the differences in their crystal geometry and molecular structure.

If we assume that the values of $\tau_0$ are comparable for these hydrocarbons, it can be seen, by comparing the values of their mean square velocities, that the mobility of circumanthracene is, on the whole, 2 or 3 times larger than that of anthracene. In general, as the resonance structure of aromatic compounds becomes larger, the electron and the hole densities at a carbon atom are smaller one side, while the distances between molecules in the crystal become shorter on the other side. The former effect may decrease the mobilities of the carriers, since it may reduce the electron and the hole densities at positions favourable to making the resonance integrals large. On the other hand, the latter effect may clearly lead to a larger mobility. Since the change in the molecular distances has a greater influence on the mobilities,* the latter effect may decide the variation in the mobility, as is found in the cases of circumanthracene and anthracene.

**A Comparison with Experimental Results.**—The experimental results for the electrical conductivity of circumanthracene and anthracene are summarized in Table VI. The

* In the case of anthracene, the one percent change of the lattice distances (corresponding to the application of a pressure of 3000 atm.) leads to an increase in the mobility by a factor of 1.1—1.4 (cf. Refs. 1b, 9 and 12).

conductivity of the former was measured in the direction parallel to the b axis of a single crystal. However, in the case of anthracene, the values of a powder specimen were used.* In Table VI the ratios of the number of carrier concentrations, $n_{\text{circum}}/n_{\text{anth}}$, and of the mobilities, $\mu_{\text{circum}}/\mu_{\text{anth}}$, are estimated from two relations, $n \propto \exp(-\Delta\varepsilon/2kT)$ and $\sigma \propto n\mu$. In Table V it is found that, assuming that the values of $\tau_0$ are comparable for both compounds, the mobilities of both the electrons and the holes of circumanthracene are three times larger than those of anthracene in the ***b*** direction, and also two or three times larger in the mean (corresponding to the mean square velocity). Thus, the calculated mobility ratio is roughly in agreement with the experimentally estimated one (Table VI), the values of the mobility of circumanthracene perhaps being several $cm^2/V.sec$. It is also pointed out from Table VI that, in the case of circumanthracene, while the increment of the conductivity due to the increase in the mobility is relatively small, the great increase in charge carriers due to the lowering of the energy gap value causes a sharp drop in the resistivity. When the organic crystal is compressed under high pressure, it behaves similarly.[12] The increase in the conductivity, which amounts to a factor of $10^4$—$10^6$ at high pressure, is also due mostly to the increase in the concentrations of carriers, $10^3$—$10^4$ times.

As for the mobility anisotrotropy of circumanthracene, although interesting properties are expected theoretically, no experimental confirmation has been obtained.**

Finally, it can be noted that, judging from the estimated magnitude of the mobility, the band model may be not satisfactory enough for us to understand the conduction in the circumanthracene crystal, as has been discussed in the introduction to the present paper. Although the substance is among the largest polycyclic aromatics, its conduction mechanism may still be distinguished from that of graphite, the electrical-transport properties of which can be satisfactorily explained by the band model.[17]

## Summary

The band structure and mobility tensors of circumanthracene have been calculated by the tight-binding band approximation.

The total bandwidths of the compound have been found to be slightly larger than those of anthracene; the total widths of the electron and the hole band being $0.82\,kT$ and $1.22\,kT$ room temperature.

The values of the calculated mobilities for the electron and the hole are comparable in the ***b*** and the ***c'*** directions, but the corresponding values in the ***a*** direction are smaller by a factor of about 30~40, reproducing the anisotropy properties of the bandwidths in the reciprocal lattice directions. Thus, the anisotropy of the band structure of the compound is considerably different from that of anthracene. This behaviour may be associated with the differences in their crystal geometry and molecular structure.

The magnitude of the mobility is three times larger than that of anthracene in the ***b*** direction, and two or three times larger in the mean, the calculated ratio being roughly in agreement with the experimentally-estimated one. Hence, it has been concluded the sharp drop in the resistivity in going from anthracene to circumanthracene is due mostly to the great increase in the concentrations of charge carriers, $10^7$ times, as a result of the lowering of the energy gap value.

Finally, it has been pointed out that, although circumanthracene is among the largest polycyclic aromatics, judging from the estimated magnitude of the mobility (several $cm^2/V.sec$), the band model may be not satisfactory enough for us to understand the conduction in the crystal.

We would like to thank Professor Yoshihiko Saito and Professor Yutaka Toyozawa for their helpful discussions.

## Appendix

Both coronene and circumanthracene have a monoclinic unit cell containing two molecules, one at the corner and the other in the centre of the ab face. The very short b axis is a striking feature of the circumanthracene crystal structure. This periodicity and that of the c axis are almost identical with the corresponding axial lengths in coronene. On the other hand, the length of the a

* We adopted the values of anthracene given in Table VI for the following two reasons. Firstly, although various data for single crystals and powder specimens are found in the literature, few of them are reliable. Secondly, since the value of the conductivity of a powder specimen may be close to that on the ab plane of a single crystal, and also since the conductivity is almost isotropic on the plane, the values in Table VI may be taken as those in the b direction. In fact, Nakada's values, recently obtained on the ab plane of a single crystal, are near above-mentioned values.

** Since the single crystal used by Matsubara et al. was a fine needle developed in the b axial direction (0.2 ×0.2×5 mm.), the conductivity in other directions could not be observed.

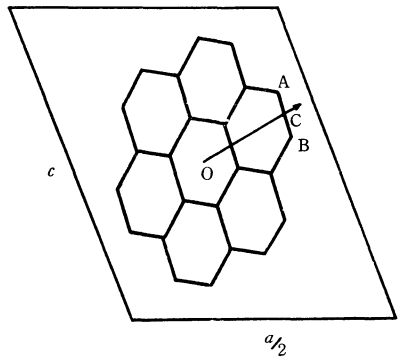

Fig. A1. Projection of the coronene structure on (010). C is the middle point of AB.

axis of circumanthracene is considerably longer that of coronene. These relations suggest that the orientations of molecules are similar in the two cases, and also that the long axis of the molecule is in the direction of the monoclinic a axis. The projection of the coronene structure on the ac face is shown in Fig. A1. In the estimation of the molecular orientation of circumanthracene, the molecule was first arranged in the same orientation as the coronene molecule, the molecular long axis being directed toward the OC axis of coronene, as is shown in Fig. A1. Then, since the circumanthracene crystal has a slightly shorter b axis, the molecule was rotated by 5° about the intersection of the molecular plane and the ac face, so as to reduce the inclination of the molecular planes to (010).

NOTES

# The Influence of pH on Mercuric Chloride Reduction under Ionising Radiations

By P. Srinivasa RAO*

(Received November 9, 1963)

The post-irradiation effects in the mercuric chloride - sodium oxalate reduction system under X, $\beta$, $\gamma$- and ultraviolet radiations have been shown earlier by the present author.[1] The present study will report data on the influence of pH on the radiation-induced reduction of the above system in the presence and in the absence of oxygen.

The aerated and $H_2$-saturated Eder's solutions (mercuric chloride - sodium oxalate) were prepared as described earlier.[1] The pH values were altered by the addition of pure concentrated hydrochloric acid and were determined by a Beckmann pH meter. These solutions of different pH values were then exposed to radiations from (1) an ultraviolet source (a quartz Hg vapour lamp run at 220 V. 0.12 amp. from a distance of 10 cm.), (2) 112 pkV. $-X$ rays ($5\times10^5$ r/hr.), and (3) 1 MeV. electrons ($2\times10^7$ r/hr.), for 20 min. at 30.5°C; the amount of mercurous chloride formed was calculated by titrating it against standard potassium iodate (using Jamieson's[2] procedure).

It may be seen from the figure that, in aerated solutions, the yields of mercurous chloride diminish with decreasing pH values and that at pH$\leqslant$1.9 the reduction is completely inhibited under ultraviolet, at pH$\leqslant$1.78, under X-rays, and at pH$\leqslant$1.62, with 1 MeV. electrons. It is significant that, in the presence of molecular $H_2$, the reduction is not completely inhibited.

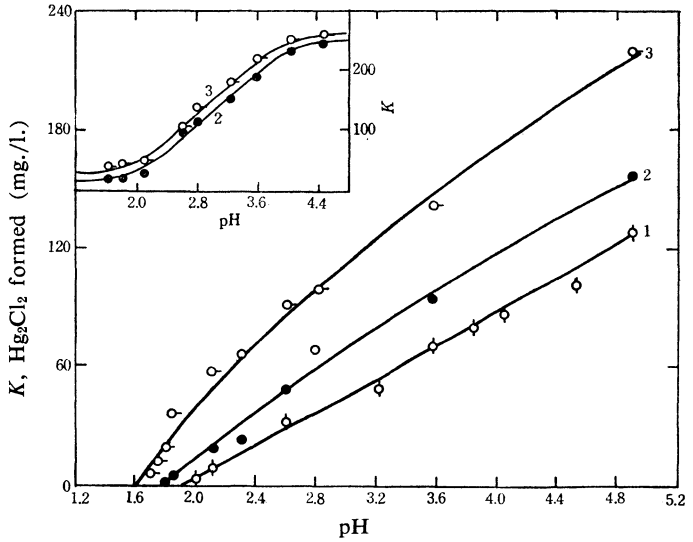

Fig. 1. Plots of $K$ vs. pH in the presence of $O_2$ and saturated with $H_2$ (inset).
1, UV 2, X-rays 3, 1 MeV. electrons

* Present Address: Radiation and Nuclear Chemistry Section, National Chemical Laboratory, Poona-8, India.

2) A. I. Vogel, "A Text Book of Quantitative Inorganic Chemistry" (1961), p. 377.

The rate law[3] can be written as:

$$\frac{K_1[Hg_2Cl_2(C_2O_4)^{2-}]I}{P_1[1/pH]}$$

where $K_1$ is the rate of formation of $Hg_2Cl_2(K)$ in the absence of acid (in this system, at pH 4.9); $I$ is the intensity of the ionising radiation, and $P_1$ is the critical value of pH when $K=0$. The near linearity of the $K$ vs. reciprocal acidity (pH) plots and the diminution of $p$, with $I$ follows from the above relationship.

It is well known[4] that the complex $Hg_2Cl_2(C_2O_4)^{2-}$ formed by mercuric chloride and oxalate decomposes to mercurous chloride under both ultraviolet and ionising radiations as follows: $2Hg_2Cl_2(C_2O_4)^{2-}+h\nu \rightarrow 2HgCl+2Cl+2(C_2O_4)^{-}$ with $C_2O_4^-$ and probably $Hg^+$ acting as chain carriers. At high acid concentrations and under ultraviolet, it can be assumed that the chain carrier $C_2O_4^-$ is destroyed:

$$H^+ + C_2O_4^- \rightarrow HC_2O_4$$

Under ionising radiations, H atoms are produced by the disruption of $H_2O$ molecules:[5]

$$H_2O \rightsquigarrow H+OH$$

These can be removed in the presence of $O_2$ or by the $O_2$ formed by the interaction of OH radicals.

$$2OH \rightarrow H_2O+O$$

and

$$2O \rightarrow O_2$$

Thus, at high acid concentrations,

$$H+O_2 \rightarrow HO_2$$

$$HO_2+Hg^+ \rightarrow Hg^{2+}+HO_2^-$$

which might result in an inhibition of the reaction.

In the presence of molecular $H_2$, the possibility of H atoms exerting an oxidising effect on the present system can be shown if one assumes the formation of hydrated hydrogen molecular ions in the solution.[6]

$$H+H^+(\text{hydra.}) \leftrightharpoons H_2^+(\text{hydra.})$$

The $H_2^+$ ion has been shown to have an oxidising effect in the $FeSO_4$ system.[7]

Thus, the back reaction,

$$Hg^+ + H_2^+(\text{hydra.}) \rightarrow Hg^{2+}+H_2$$

might account for the observed inhibition of the reduction.

The author wishes to thank Professor F. H. Barlow of the Agricultural Engineering College, Michigan State University, for loaning 1 MeV.-electron irradiation facilities and Miss R. V. Gowramma of N. C. L., Poona, for her assistance.

# Three Crystalline Forms of Iminodiacetic Acid*

By Yuko TOMITA, Takeshi ANDO and Keihei UENO

(Received May 16, 1964)

There have been reports on the polymorphism of such amino acids as glycine[1,2] and ethylenediaminetetraacetic acid (EDTA),[3] however, no mention has been made of the polymorphism of iminodiacetic acid (IDA).

During the course of our investigation of the infrared spectra of aminopolycarboxylic acid metal chelates, we have found new forms of IDA which do not match the standard spectrum of IDA. Chemical analyses have proved the compounds to be IDA with different spectra and X-ray diffraction patterns.

Further work has then been undertaken to substantiate these three crytsal forms of IDA.

## Experimental

When IDA is dissolved into hot water and the solution is allowed to cool to room temperature, the stable form of IDA ($\alpha$) is obtained. When the hot solution is rapidly chilled to 0°C, a metastable form ($\gamma$) is obtained. Another metastable form ($\beta$) is obtained by adding ethanol to an aqueous solution of IDA at room temperature. The results

3) R. B. LeBlanc and H. L. Spell, *J. Phys. Chem.*, **64**, 949 (1960).

of elementary analyses show the chemical identity of three forms:

| | Anal. Calcd. for IDA | Found for $\alpha$ | Found for $\beta$ | Found for $\gamma$ |
|---|---|---|---|---|
| C | 36.09% | 36.04% | 36.03% | 36.03% |
| H | 5.30% | 5.32% | 5.27% | 5.32% |

The melting point (232°C with decomposition) is also the same for the three forms.

The main differences between the three forms are observed in their infrared absorption spectra and X-ray diffraction patterns. The infrared absorption curves of the three forms in KBr disks are reproduced in Fig. 1, which indicates that the $\alpha$-, $\beta$-, and $\gamma$-forms of IDA have different crystalline structures. However, when their spectra were taken in a $D_2O$ solution using a cell with calcium fluoride windows, they gave an identical curve in 5000—1200 $cm^{-1}$ region, the only transparent region for a $D_2O$ solution.

| | | 2.23 | ( 20) | | |

* The diffractions data were obtained with a Norelco X-ray diffractometer by using the copper $K\alpha$ radiation.

The data of X-ray diffraction which were taken on the powdered sample are shown in Table I; they also support the polymorphism of IDA.

Metastable $\beta$- and $\gamma$-forms can be converted to the stable $\alpha$-form by simple heating; their transitions are observed around 184°C under a polarized microscope. The transitions can also be observed by a differential thermal analysis, in which a broad weak peak can be noticed at around 180°C. The conversions from $\beta$- and $\gamma$-forms to the $\alpha$-form were confirmed by comparing the infrared spectra and X-ray diffraction patterns of the samples before and after heating. After heating, the samples gave spectral and X-ray diffraction patterns completely identical with those of the $\alpha$-form.

## Discussion

No difference in chemical properties was observed for the three forms of IDA, nor was any difference observed in the physical properties in a solution. In the case of glycine, three modifications are known to give different spectra; their differences can be attributed to the differences in the crystalline structures. By analogy, it seems reasonable to assume that the differences in the infrared spectra and X-ray diffraction patterns of IDA are caused by the differences in the crystalline structures. However, the change in the infrared spectra of the $\gamma$-form is so drastic compared with the other two forms that it seems also probable that the $\gamma$-form has a different molecular configuration rather than a different crystalline structure. As we have not been successful so far in obtaining single crystals which are large enough to give diffraction data for the crystalline structure analysis, no conclusive structure can be given for any of the forms.

Some of the expenses of the work reported on in this paper were supported by a research grant provided by the Ministry of Education, to whom the author's thanks are due.

# A Convenient Method of Determining the Stability of a 1:1 Complex in Solution by the Refractometric Method

By Zen-ichi YOSHIDA and Eiji ŌSAWA

(Received May 20, 1964)

Giles' method[1] of detecting complex formation in solution by the refractive index measurement is a well-established, simple and sensitive one, especially for detecting intermolecular hydrogen-bonding pairs, including the X–H$\cdots\pi$ electron type (X=O and N).[2] In this communication the possibility of estimating the equilibrium constant, $K$, of a 1:1 complex formation ($X+Y \leftrightarrows XY$) by this method will be described.

In the Giles method, a physical property (the square of the refractive index) of the solution of X and Y is plotted against the solute molar ratio, while the total concentration (X+Y) is kept constant. The deviation from the "additivity" line PQ (see Fig. 1) is

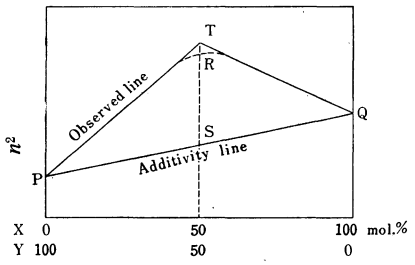

Fig. 1. Schematic representation of $n^2$ vs. molar ratio plot where 1:1 complex is formed between X and Y.

proportional to the concentration of the complex XY.[3] For an equimolar mixture of X and Y, where the deviation is the maximum value, $RS$[4], we can write:

$$RS=\alpha Z \tag{1}$$

where $Z$ is the maximum concentration of XY, and $\alpha$ is constant for the three substances X, Y and XY. When the total concentration, $C$, is changed to $C'$ and the same procedure repeated, we can obtain the similar relation:

$$R'S'=\alpha Z' \tag{2}$$

From Eqs. 1 and 2 we obtain:

$$RS/R'S'=Z/Z'=k \tag{3}$$

The equilibrium constant, $K$, is given by:

$$K=Z/(C/2-Z)^2=Z'/(C'/2-Z')^2 \tag{4}$$

From Eqs. 3 and 4,

$$K=2\sqrt{k}\{\sqrt{k}(C+C')-(C+kC')\}/(C-kC')^2 \tag{5}$$

Thus K can be calculated from Eq. 5.

A preliminary test of the utility of this equation was carried out using an Abbe refractometer. The results are summarized in Table I.

Because of the limited accuracy of the Abbe refractometer ($\pm 0.0002$), it was necessary to raise the concentration of the solute to $10^{-1}$ mol./l. in order to make the $k$ term large enough to fit Eq. 5. At these large concentrations, howerver, the data obtained are less reliable because of the self-association of the solutes (over 30%). Nevertheless, the orders of $K$ obtained are in agreement with the literature values: phenol-methyl acetate, $K_{20°}$ 13.4,[5] phenol-naphthalene $K_{27°}$ 4.6.[6] It will be possible to obtain reliable thermodynamic data on 1:1 association in solution by utilizing a differential refractometer of a higher precision.[7]

TABLE I. THE ESTIMATION OF THE $K$ VALUE BY REFRACTIVE INDEX MEASUREMENT

| X | Y | $C$, mol./l. | Temp., °C | $K$, l./mol. |
|---|---|---|---|---|
| Phenol | Methyl acetate | 0.20—0.15 | 19 | ca. 10 |
| Phenol | Naphthalene | 0.10—0.16 | 27 | ca. 5 |
| Ethanol | Naphthalene | 0.30—0.40 | 28 | ca. 5 |

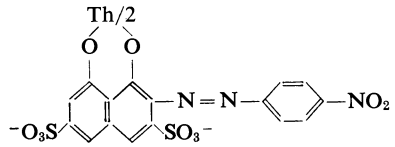
# *p*-Nitrobenzene Azochromotropic Acid (Chromotrope 2B) as a Colorimetric Reagent for Thorium



By Satendra P. SANGAL

(Received June 22, 1964)

Metal chelates of *p*-nitrobenzene azochromotropic acid (disodium salt), (Chromotrope 2 B, abbreviated as CTB) with copper,[1] thorium,[2] lanthanum[3] and rare earths have been extensively studied in these laboratories. Chromotrope 2 B has also been recommended as a metalochromic indicator in the EDTA titration of thorium.[4] The structure of the reagent is as follows:

The possibility of chelation with metals in the ligand is at 1 : 8 hydroxy groups; hence, the structure of the metal chelate of Chromotrope 2 B may be assigned as:

The composition of the thorium - Chromotrope 2 B chelate ($\lambda_{max}$ 550 m$\mu$), as reported by Banerji and Dey,[2] is 1 : 2. This communication report the results of the spectrophotometric determination of thorium using Chromotrope 2 B as a chromogenic reagent.

## Experimental

**Instruments.**—A Unicam SP 500 spectrophotometer operated by a Doran mains unit was employed for the absorbance measurements. The measuring glass cells, 1 cm. thick, were those supplied with the instrument.

A Leeds and Northrup direct reading pH indicator was employed for the adjustment of the hydrogen ion concentration.

**Reagents.**—Stock solutions of thorium chloride (B. D. H. AnalaR) and *p*-nitrobenzene azochromotropic acid (disodium salt) were prepared in distilled water and standardised by the usual methods. Solutions of various concentrations were obtained by suitable dilution. The other reagents used were also of the AnalaR grade.

## Results and Discussion

**The Rate of Colour Formation.**—The colour formation is almost immediate; it takes less than five minutes to assume the full colour intensity.

**The Influence of pH Value.**—Full coloration is obtained between pH 3.0 and 6.5 (Fig. 1).

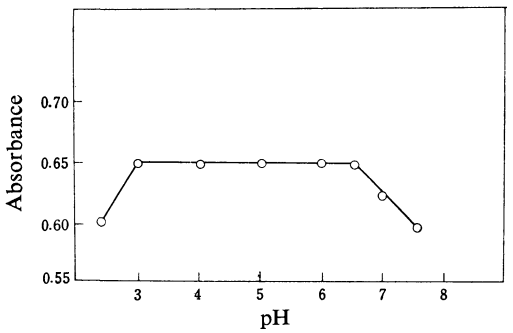


Fig. 1. The Effect of pH on the intensity of the colour.
CTB $2.0 \cdot 10^{-4}$ M
Thorium chloride $4.0 \times 10^{-5}$ M, 580 m$\mu$

**The Effect of the Temperature.**—The absorbance value of a mixture containing ($2.0 \times 10^{-4}$ M) Chromotrope 2 B and ($8.0 \times 10^{-5}$ M) thorium chloride was found to be constant, i. e., 0.820 at 580 m$\mu$, at temperatures from 5 to 95°C.

**Beer's Law.**—Varying quantities (1 ,2, 3, ....., 8, 9 ml.) of thorium chloride were added to an excess of the reagent and the volume was raised to 25 ml. after the pH had been adjusted to 3.5. The colour instensity was measured with a Unicam SP 500 spectrophotometer at 580 m$\mu$. It was found that the system adheres to Beer's law in the range from 0.74 p. p. m. to 16.6 p. p. m. of thorium (Fig. 2).

**Sensitivity.**—The sensitivity as defined by Sandell[5] was found to be 0.232 $\gamma$/cm$^2$. The practical sensitivity based upon an absorbance

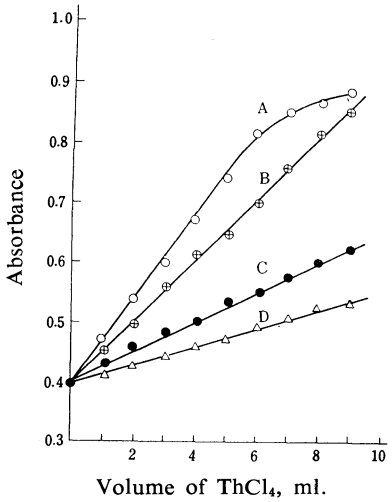

Fig. 2. Adherence to Beer's law.
(Total volume 25 ml.), pH 3~5, 580 mμ
Curve A 5 ml. ($1.0\times10^{-3}$ M) CTB + $x$ ml. ($4.0\times10^{-4}$ M) $ThCl_4$ + $(20-x)$ml. $H_2O$
Curve B 5 ml. ($1.0\times10^{-3}$ M) CTB + $x$ ml. ($2.0\times10^{-4}$ M) $ThCl_4$ + $(20-x)$ml. $H_2O$
Curve C 5 ml. ($1.0\times10^{-3}$ M) CTB + $x$ ml. ($1.0\times10^{-4}$ M) $ThCl_4$ + $(20-x)$ml. $H_2O$
Curve D 5 ml. ($1.0\times10^{-3}$ M) CTB + $x$ ml. ($8.0\times10^{-5}$ M) $ThCl_4$ + $(20-x)$ ml. $H_2O$

of 0.01 unit was found to be 2.32 $\gamma/cm^2$ at 580 mμ.

**Interference Due to Foreign Ions.**—The effect of various cations and anions was studied; it was found that silver, copper, beryllium, cadmium, titanium, zirconium, hafnium, tungsten, scandium, yttrium, lanthanum and rare earths, uranium, tartrate, oxalate, citrate, acetate and fluoride interfere.

**Recommended Procedure.**—For the determination of thorium from this method, the interfering substances must be removed. The pure solution of thorium chloride should then be added to an excess of the reagent and the pH adjusted to 3.5. The colour intensity is then measured by a spectrophotometer at 580 mμ.

## Summary

A method for the colorimetric determination of thorium with Chromotrope 2 B has been described. The composition of the coloured chelate ($\lambda_{max}$ 550 mμ) is $Th(Ke)_2$. The system adheres to Beer's law from 074 p. p. m. to 16.6 p. p. m. of thorium between pH 3.0 and 6.5 at all temperatures from 5 to 95°C. The sensitivities are 0.232 $\gamma/cm^2$ (Sandell) and 2.32 $\gamma/cm^2$ (practical) based on an absorbance of 0.01 unit at 580 mμ. The interference of some cations and anions has also been reported.

The author is thankful to Dr. A. K. Dey for his suggestions and to The Council of Scientific and Industrial Research for its financial aid.

# Photolysis of Butene-1 at 1849Å

By Noriho HARUMIYA, Shoji SHIDA and Shigeyoshi ARAI

(Received June 26, 1964)

The photolysis of gaseous olefins has been studied on ethylene[1,2] and propylene[3], but the study of the photolysis of butene-1 seems not to have been made. The mercury photosensitized decomposition of butene-1, however, has been studied by several workers. Gunning and Steacie[4] showed, from the pressure dependence of the reaction, that in the primary step an excited molecule of butene-1 is produced which either decomposes or is collisionally deactivated. Lossing et al.[5] and recently Cvetanović and Doyle[6] showed that there are two modes of primary dissociation involving the splittings of C–C and C–H bonds, the ratio being estimated to be 1.3—1.6. For the present work we have studied the photolysis of butene-1 with the light of 1849 Å and

TABLE I. RELATIVE AMOUNTS OF PRODUCTS FORMED BY PHOTOLYSIS OF BUTENE-1 AT 1849Å, WITH REFERENCE TO $C_2H_6=10.0$

Time of irradiation: 2 min. Pressure range: 1.7—125 mmHg. The listed values are pressure-independent unless otherwise stated.

| | | | |
|---|---|---|---|
| $H_2$ | 1.7 | *iso*-$C_5H_{12}$ | 1.8 |
| $CH_4$ | 0.4 | 3-Methylbutene-1 | 0.8 |
| $C_2H_6$ | (10.0) | 2-$C_5H_{10}$ | 1.6 |
| $C_2H_2$ | 0.5 | 1-$C_5H_{10}$ | 1.1(1.7 mmHg) |
| $C_3H_8$ | 0.6 | | 1.0(125 mmHg) |
| $C_3H_6$ | 3.5(1.7 mmHg) | 1,5-Hexadiene | 5.8(1.7 mmHg) |
| | 1.1(20—125 mmHg) | | 6.8(30—125 mmHg) |
| $C_4H_{10}$ | 0.3 | 4-Methylhexene-1 | 2.8 |
| *trans*-$C_4H_8$-2 | 0.2 | 3-Methyl-1,5-hexadiene | 3.1 |
| *cis*-$C_4H_8$-2 | trace | 1,5-Heptadiene | |
| Methylcyclopropane | 0.0 | $C_8$ | trace |
| 1,3-Butadiene | 0.6 | | |

have compared the results with those obtained in the previous works on the mercury-photosensitized reaction. Only the main features of the reaction will be reported on here.

Butene-1 of a pure grade, supplied by the Takachiho-Shoji Co., was purified from mercury using gold foil and was then distilled several times in vacuo. The remaining impurities were 1,3-butadiene (0.09%) and *cis*-butene-2 (<0.05%). A quartz cell, 47 mm. in diameter and 13 mm. thick, was connected to a mercury-free vacuum line. All runs were made statically at room temperature, 22±2°C. An ordinary mercury resonance lamp was used as the light source. The absence of mercury in the system was confirmed by making runs using the light source with a filter which transmitted 2537Å but not 1849Å. A 20 m. DMS column was used for the gas chromatographic analysis of light hydrocarbon products ($C_2$—$C_5$) and a 10 m. DNP column for heavier ones. Hydrogen and methane were analyzed volumetrically as usual.

Some twenty products, shown in Table I, were analyzed. The amounts of major products were measured with varying irradiation times at a 20 mmHg pressure. Until 4 min. every product increased linearly with time, showing no measurable secondary reaction of the product at this stage of reaction, although the rates of the formation of some products gradually decreased with time after 4 min. The variation in the light intensity by the factor of ten had no effect on the relative amounts of products. The effect of pressure was examined in the range of 1.7 to 125 mmHg. The rates of the formation of all the products except 1,5-hexadiene and propylene were practically constant, irrespective of the pressure (Table I). This is remarkably different from the results in the photosensitized decomposition and suggests that different kinds of excited states are involved. Methylcyclopropane was not found in any appreciable amount,* and $C_8$ products were found only in a trace; both of these are products in the mercury photosensitization. The polymer formation was not measured, but it may be assumed to be of minor importance on the basis of several pieces of indirect evidence, such as the practical absence of $C_8$ products (dimer), no visible deposit on the cell wall, and the linearity of the product formation with the irradiation time. The addition of nitric oxide (0—15%) to butene-1 at 20 mm. did not change the amount of propylene, but in the low pressure region below 20 mmHg reduced it to the high pressure value, i.e., 1.1 in Table I. This result seems to indicate that a fraction of propylene is produced molecularly in the primary process.

To explain the above results we may assume the following two primary processes:

$$C_4H_8\text{-}1 + h\nu \rightarrow CH_3 + C_3H_5 \quad \text{(A)}$$

$$\searrow H + CH_2=CH-CH-CH_3 \quad \text{(or } CH_2-CH=CH-CH_3\text{)} \quad \text{(B)}$$

The hydrogen atoms thus formed are scavenged by butene-1 to give butyl radicals, $C_4H_9$. Conforming to Cvetanović's procedure, we assume only the recombination reactions of the free radicals thus produced; disproportionations are assumed to be of minor importance. $CH_3 + CH_3 \rightarrow C_2H_6$, $CH_3 + C_3H_5 \rightarrow C_4H_8$-1, $CH_3 + C_4H_7 \rightarrow$ 2-pentene or 3-methylbutene-1, $CH_3 + C_4H_9 \rightarrow$ isopentane, $C_3H_5 + C_3H_5 \rightarrow$ 1,5-hexadiene, $C_3H_5 + C_4H_7 \rightarrow$ 3-methyl-1,5-hexadiene or 1,5-heptadiene, $C_3H_5 + C_4H_9 \rightarrow$ 4-methylhexene-1. Then,

* In an experiment in which butene-1 was photolyzed by mercury photosensitization, methylcyclopropane was actually detected by gas chromatography. In this case the peak of methylcyclopropane was superposed on those of *trans*-butene-2 and isopentane using a DMS column, but it could be separated from the others using a benzylether column.

from the measured yields of products, we obtain the relative yields of radicals as follows: $CH_3$ 39.4, $C_3H_5$ 37.3 (mean value 38.3), $C_4H_7$ 5.5, and $C_4H_9$ 4.6, all with reference to $C_2H_6=10.0$. Judging from these results the relative importance of the two primary processes, A and B, are about 7 : 1. Thus, the C–C bond rupture is far more important in the direct photolysis at 1849Å than in the mercury-photosensitized decomposition. A similar trend has also been found in the photolysis of propylene at 1849Å.[3)]

The formation of propylene can not be explained uniquely in the present stage of study. Possible reactions are $C_4H_8\text{-}1+h\nu \rightarrow C_3H_6+CH_2$ and, in the low pressure region:

$$H+C_4H_8\text{-}1 \rightarrow C_4H_9' \xrightarrow{+M} C_4H_9$$
$$\searrow C_3H_6+CH_3$$

# Alkali Metal Hyperfine Splittings of *o*-Substituted Benzophenone Ketyls

By Rikuhei TANIKAGA, Kazuhiro MARUYAMA and Ryozo GOTO

(Received June 27, 1964)

Aromatic ketyls formed by the reaction of alkali and alkali earth metals with aromatic ketones exist as a contact ion-pair in ethers.[1,2] Their ESR spectra, therefore, show the lines due to splitting by metals as well as by protons. The metal hyperfine splitting of the ketyl generally decreases with an increasing dielectric constant of the solvent, as with other anion-radicals.[3] On the other hand, in a very polar solvent such as *N*, *N*-dimethylformamide, no metal splitting at all has been observed. This variation in the metal splitting can be attributed to charge separation in an ion-pair through solvation.

In the electronic spectrum of the ketyl, the wave number of the maximum absorption peak due to a $\pi \rightarrow \pi^*$ transition shifts towards the red as the radius of the metal cation and the dielectric constant of the solvent increase.[4,5] This spectral shift can be interpreted as a decrease in the cationic effect of a metal on a ketyl anion.[6] Consequently, we expected to find a relationship between the metal splitting, $a_M$, of the ESR spectra and the wave number, $\bar{\nu}_m$, of the maximum absorption peak of the electronic spectra. Indeed, a close relationship between them was observed; that is, $a_M$ increased with $\bar{\nu}_m$.

In the course of an investigation of the ion-pair structure, we have measured the ESR spectra and the electronic spectra of *o*- and *p*-substituted benzophenone ketyls, such as

TABLE I. METAL HYPERFINE SPLITTING CONSTANTS $a_M$ (GAUSS) AND WAVE NUMBERS $\bar{\nu}_m$ OF MAXIMUM ABSORPTION ($\times 10^3\,cm^{-1}$) OF KETYLS IN THF AT 18°C

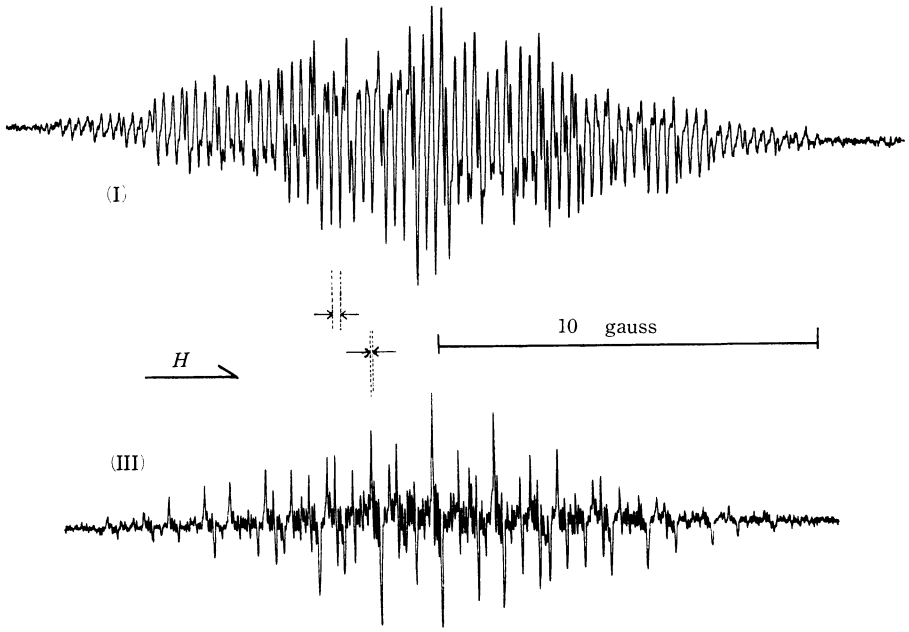

Fig. 1. Potassium splittings of benzophenone (I) and 2,6,2′,6′-tetramethylbenzophenone (III) ketyls in THF at 18°C.

benzophenone (I), 4,4′-dimethylbenzophenone (II), 2,6,2′,6′-tetramethylbenzophenone (III) and 2,6,2′,6′-tetraethylbenzophenone (IV). The preparation of metal ketyls and the method of ESR measurement were described in a previous paper.[7] The metal hyperfine splittings of ketyls in tetrahydrofuran (THF) are summarized in Table I, while representative spectra are shown in Fig. 1.

In the ketyl ion-pair the cation is mainly localized near the oxygen atom,[6,8] so that the decrease in the metal splitting shown in Table I can only be attributed to the steric effect of the *o*-substituents on the metal cation. Although in the case of the metal ketyl of IV the existence of a contact ion-pair is shown by the fact that the $\bar{\nu}_m$ value shifts regularly with the radius of a metal, no metal splitting is observed in its ESR spectrum. These facts indicate that the magnetic effect of a cation attached to an aromatic negative anion is only effective in rather close contact.

The proton hyperfine splittings of benzophenone ketyls will be discussed in subsequent publications.

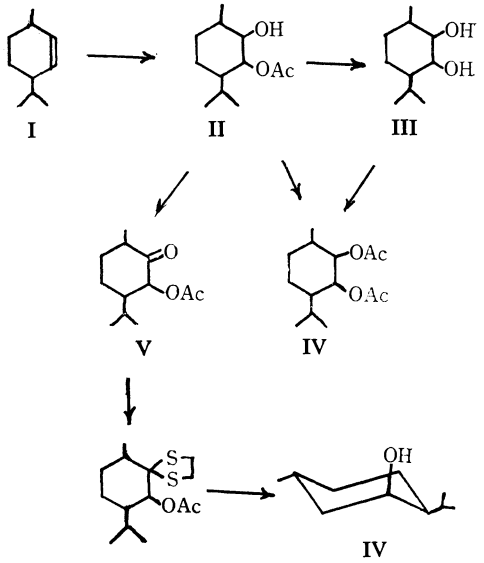
# The Conformation of *p*-Menthane-2, 3-diol*



By Shin-ichi SASAKI and Shoei ITO

(Received July 10, 1964)

The hydroxylation of (+)-*p*-menth-2-ene (I) with an organic peracid, or the hydrolysis of its epoxide, affords *p*-menthane-2, 3-diol (II), which has its hydroxyls in the trans configuration. Infrared studies[1] have indicated that the diol adopts a conformation in which both the hydroxyls are axial; its spectrum exhibits the absorption (at 3635 $cm^{-1}$) due to free (non-bonded) hydroxyls only. We have arrived at the same conclusion in the investigation reported here.

(+)-*p*-Menth-2-ene (I), derived from (−)-menthol, after treatment with peracetic acid afforded a viscous liquid b. p. 120—128°C/3mmHg, which deposited crystals of 2-hydroxy-3-acetoxy-*p*-menthane (III), m. p. 114—116°C, $[\alpha]_D = +16.8°$ (methanol), after standing for several days at room temperature. The oily mother liquor, which is apparently a mixture of the diol and its partial acetate, was not separated but was treated with alkali, whereupon it afforded pure *p*-menthane-2, 3-diol (II) b. p. 98—100°C/0.1 mmHg, $[\alpha]_D = +66.4°$ (benzene), identical with that obtained by the hydrolysis of compound III. The diol II and its monoacetate III afforded the same diacetate, m. p. 48—50°C on acetylation. The monoacetate III, which is considered to be an intermediate in the formation of the diol, was used in the following conformational study.

The chromic acid oxidation of the monoacetate III yielded the acetoxy ketone V, m. p. 46—47°C, $[\alpha]_D = +37.1°$ (methanol). The thioketal derived from the ketone V, on desulfurization with Raney nickel, afforded an oil which was identified as (+)-neomenthol by a comparison of their *p*-nitrobenzoates (infrared spectrum and mixed melting point). (+)-Neomenthol has been shown to have the absolute configuration and conformation shown in VI[2]. The acetoxy ketone V is, therefore, 3-acetoxycarvomenthone, which has an axial acetoxyl group, and the conformation of the two oxygenated functions in III and II must be transdiaxial. This finding is in agreement with the ultraviolet spectrum of the monoacetate V, which shows a bathochromic shift of 9 mμ with respect to carvomenthone (see Table I), thus indicating[3] the presence of an axial acetoxyl group at the α-position in V. Consequently, III has axial hydroxyl and acetoxyl groups, and in II both hydroxyls are axial.

The ORD curve of V shows a strong positive Cotton effect in both methanol and in isooctane (see Fig. 1). It has been observed[4] that an α-acetoxyl group makes an irregular contribution to the Cotton effect. In our case the axial acetoxyl group probably does not make much contribution to the effect in both solvents, and the conformational mobility normally

dependent on the polarity of the solvents was not observed.

## Experimental

**The Hydroxylation of *trans-p*-Menth-2-ene (I) with Peracetic Acid.** — *trans-p*-Menth-2-ene (I), b. p. 55—56°C/15 mmHg, $d_4^{15}=0.8160$, $[\alpha]_D=+120.46$ (neat), was prepared from 1-menthyl tosylate.

I (15 g.) was added drop by drop over a half-hour period to a solution of 30% hydrogen peroxide (25 ml.) in acetic acid (120 ml.) containing a few drops of concentrated sulfuric acid and warmed at 50°C. After the addition of I, the reaction mixture was stirred for another hour. The acetic acid was then removed in vacuo. The residue was dissolved in ether, washed with saturated sodium bisulfite to destroy the excess peracid, and then washed with aqueous sodium carbonate. The evaporation of the dried (sodium sulfate) ether solution yielded a viscous liquid (14.5 g.), b. p. 120—128°C/3 mmHg. On standing at room temperature the liquid gradually deposited crystals of 2-hydroxy-3-acetoxymenthane (III) (1.5 g.) ; after recrystallization from ligroin, it had an m. p. of 114—116°C, $[\alpha]_D=+16.8°$ (*c* 2.10, methanol) (Found : C, 66.82; H, 10.52. $C_{12}H_{22}O_3$ requires C, 67.25 ; H, 10.35%). The acetylation of III with acetic anhydride and sodium acetate gave the diacetate IV, m. p. 48—50°C (Found : C, 65.82 ; H, 9.41. $C_{14}H_{24}O_4$ requires C, 65.59 ; H, 9.44%).

The filtrate (10 g.) was heated in 20% alcoholic potash (100 ml.) under reflux for an hour. After acidification with hydrochloric acid, the product was isolated by ether extraction to yield *p*-menthane-2,3-diol (II) (8 g.) b. p. 98—100°C/0.1 mmHg, $[\alpha]_D=+66.4°$ (*c* 2.12, benzene)). Diacetate : m. p. and mixed m. p. with acetate IV of III 48—50°C. Di-*p*-nitrobenzoate : m. p. 179—180°C (Found : N, 5.86. $C_{24}H_{26}O_8N_2$ requires N, 5.96%).

**The Chromic Acid Oxidation of 2-Hydroxy-3-acetoxymenthane (III).**—A solution of 2-hydroxy-3-acetoxymenthane (III) (3 g.) in pyridine (20 ml.) was added drop by drop to a suspension of chromic anhydride (4.5 g.) in pyridine (45 ml.). After the addition of III, the reaction mixture was stirred for five days at room temperature. After acidification with dilute sulfuric acid, the product was isolated by continuous extraction with ether (five days). The evaporation of the ether gave crude 3-acetoxycarvomenthone (V), which, after purification by vacuum sublimation (120°C (bath), 0.03 mmHg), had an m. p. of 46—47°C ; yield 2.1 g. (Found : C, 68.04 ; H, 9.85. $C_{12}H_{20}O_3$ requires C, 67.89; H, 9.50%). 2,4-Dinitrophenylhydrazone : m. p. 157°C (from alcohol) (Found : N, 14.16. $C_{18}H_{24}O_6N_4$ requires N, 14.28%).

The ORD curves were measured in methanol and in isooctane.

In methanol (*c* 0.1025) :
$[\alpha]_{318}=+975.6°$ (peak)
$[\alpha]_{280}=-1326.8°$ (trough)

In isooctane (*c* 0.1035) :
$[\alpha]_{322}=+1078.4°$ (peak)
$[\alpha]_{308}=-850.3°$ (trough)

**The Reduction of 3-Acetoxycarvomenthone (V).** —A mixture of 3-acetoxycarvomenthone (V) (2 g.), ethane dithiol (6.5 ml.) and boron trifluoride etherate (6.5 ml.) was allowed to stand for four hours at room temperature. After the addition of water, the product was extracted with ether. The ethereal solution was washed with dilute sodium hydroxide and dried over sodium sulfate. The evaporation of the ether yielded the thioketal of V. Without further purification the thioketal was heated with Raney nickel (from 30 g. of Raney alloy) in dioxane for five hours. After filtration and the removal of the solvent, the residue was treated with *p*-nitrobenzoyl chloride in pyridine at room temperature. The *p*-nitrobenzoate after recrystallization from alcohol showed an m. p. and mixed m. p. with *p*-nitrobenzoate of *d*-neomenthol of 96—99°C. The two *p*-nitrobenzoates showed identical infrared spectra.

# Absorption Spectra of Quinoline Adsorbed on Nickel Plates in an Aqueous Solution

By Wataru SUËTAKA*

(Received July 6, 1964)

In a previous paper,[1] a remarkable decrease in the intensity of the absorption bands of thiourea and potassium iodide caused by the presence of nickel plates in aqueous solutions was observed and strong adsorptions on the metal was deduced. In the present investigation, the absorption spectrum of quinoline adsorbed on nickel plates was observed by means of the technique already reported.[1]

The absorption spectra of a solution of quinoline (b. p. 83.5—84.0°C/3 mmHg) in purified water, as measured with a reflection cell and a transmission cell, are shown in Fig. 1.

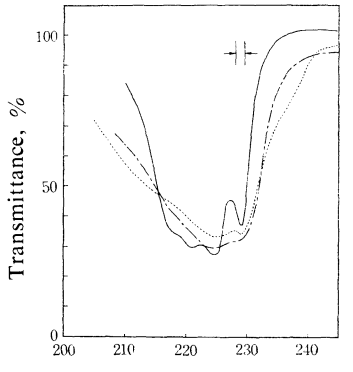

Fig. 1. Absorption spectra of quinoline in purified water measured with the reflection and transmission methods.
-·-·- : reflection (concentration of quinoline : $1.70\times10^{-5}$ mol./1.)
···· : transmission (concentration of quinoline : $1.70\times10^{-1}$ mol./1.)
—— : in isooctane (concentration : $2.09\times10^{-5}$ mol./1.)

In this figure, the absorption spectrum of an isooctane solution is also shown for purposes of comparison. The relative intensities of a peak at 220 mμ and shoulders at 233 mμ and 212 mμ evidently decreased the reflection measurements.

The nickel plates were probably covered with oxide or hydroxide, which could dissolve in the aqueous solution because the water contained carbonic acid. In consequence, the concentration of hydrogen ions in the solution probably diminished as a result of the immersion of the nickel plates, and the decrease in the hydrogen ion concentration might produce an intensity reduction of some absorption bands.

The spectra of quinoline in aqueous solutions containing hydrogen ions at various concentrations were observed (Fig. 2). The shoulder at

233 mμ, decreased in relative intensity with the decrease in the hydrogen ion concentration and can be assigned to quinolinium ions. Furthermore, the absorption spectrum of aqueous solution of quinoline was measured after the withdrawal of nickel plates which had been dipped in the solution for about twenty minutes a relative intensity reduction of the shoulder at 233 mμ was found.

On the basis of the results mentioned above, the intensity reduction of the shoulder at 233 mμ observed in the reflection measurement can be concluded to be due to the reduction of the quinolinium ion concentration in the solution as a result of the dissolution of nickel

* Present adress : Department of Chemistry, University of Virginia, Charlottesville, Va., U. S. A.
1) W. Suëtaka, This Bulletin, 37, 1121 (1964).

oxide or hydroxide, accompanied by a decrease in the hydrogen ion concentration.

The experimental results reported in the preceding paragraphs indicate that the decrease in the relative intensity of the peak at 229 mμ and more particularly that in the intensity of the shoulder at 212 mμ observed in the reflection measurements cannot be explained on the basis of the decrease in the hydrogen ion concentration in the solution. Since the complex formation of quinoline with nickel salts has been reported,[2] it may be considered that the spectral change in question arises from the complex formation in the solution. The spectrum of quinoline in an aqueous solution containing nickel sulfate of a relatively high concentration (1.0 mol./l.)* has shown, however, only a slight increase in the relative intensity of the shoulder at 212 mμ. It must be added that the shape of the absorption band due to quinoline in water did not change with the dipping of nickel plates in the solution, except for the minor variation produced by the decrease in quinolinium ion concentration. The change in the spectrum observed in the reflection measurements, therefore, cannot be the result of the formation of a quinoline-nickel salt complex in the solution.

As a result of the investigation described above, the change in the shape of absorption band in question can be attributed to the overlapping of an absorption band of adsorbed quinoline and a band of the same compound in solution. The absorption band of adsorbed quinoline is assumed to have the shape shown in Fig. 3. In drawing the assumed band, the shape of the band due to quinoline in solution is supposed to be the same as that observed for the aqueous solution of quinoline after the withdrawal of the dipped nickel plates. The similarity in the band shape between the hypothetical absorption band of adsorbed quinoline and that of quinolinium ions is very interesting, because it suggests that the adsorption might occur at the acid center of the surface oxide on the nickel plates.

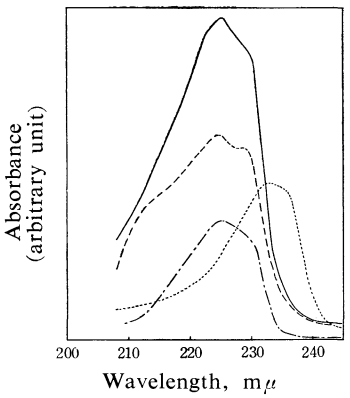

Fig. 3. Assumed absorption band of adsorbed quinoline.

# Temperature Effect in a Radiolytic System under Steady Irradiation

By Kenji FUEKI and John L. MAGEE

(Received July 23, 1964)

There are two types of temperature effects in a system under irradiation by high-energy radiation; one is a local temperature effect on a microscopic scale, and the other is a gross or macroscopic temperature effect. The former is initially confined to a small region of the system (spur) which cools rapidly.[1] No significant contribution from such effect can be expected in the case of low LET radiations. The latter effect is the temperature rise in the system when a thermally steady state is reached under irradiation; its magnitude depends upon dose rate, properties of the system, and chemical reactions involved. In this note we will describe the gross temperature effect and estimate average temperature rise, the time constant for approach to steady condition, and an effective rate constant in an irradiated system. This consideration is of interest in connection with the conditions under which irradiations can be taken to be isothermal.

Let us consider a spherical system with radius $r_m$ in a thermostat at a constant temperature, $T_0$.

The temperature of the system as a function of the space ($r$) and the time ($t$) is given by:

$$\frac{\partial T(r,t)}{\partial t}=\frac{\kappa}{\rho c_v}\nabla^2 T(r,t)+\frac{1}{\rho c_v}\left(qI+\frac{\partial(\Delta H)}{\partial t}\right) \tag{1}$$

where $T$, $\kappa$, $c_v$ and $\rho$ are the absolute temperature, the heat conductivity, the specific heat and the density, and $qI$ and $\Delta H$ are the dose rate and the heat of reaction per unit volume, respectively.

We put:

$$\frac{\partial(\Delta H)}{\partial t}=h,\quad \theta=\frac{T-T_0}{T_0},$$
$$\tau=\left(\frac{\kappa}{r_m^2\rho c_v}\right)t,\quad x=\frac{r}{r_m} \tag{2}$$

We can then solve Eq. 1 by using the boundary condition $T=T_0$ at $r=r_m$. The solution is given by:

$$\theta(x,\tau)=\frac{T(x,\tau)-T_0}{T_0}$$
$$=\frac{\lambda}{6}\left[1-x^2+\frac{12}{\pi^3 x}\sum_{n=1}^{\infty}\frac{(-1)^n}{n^3}(\sin\pi nx)\times\exp\left(-n^2\pi^2\tau\right)\right] \tag{3}$$

where $\lambda=-\dfrac{(qI+h)r_m^2}{\kappa T_0}$

Since the temperature at a steady state can be defined as that when $t$ approaches to infinity, we get:

$$\theta(x,\infty)=\frac{T(x,\infty)-T_0}{T_0}=\frac{\lambda}{6}(1-x^2) \tag{4}$$

Taking an average over space, we get:

$$\bar{\theta}=<\theta(x,\infty)>_{av}=-\frac{\lambda}{15} \tag{5}$$

where $\bar{\theta}$ represents the relative temperature rise of the system at a steady state.

In the case where $qI\gg h$, as is the case with most systems in radiation chemistry, $\bar{\theta}$ is given by:

$$\bar{\theta}\simeq\frac{qIr_m^2}{15\kappa T_0} \tag{6}$$

As an example, we have estimated $\bar{\theta}$ for liquid hydrocarbons as a function of the dose rate and the sample size. The results are shown in Fig. 1.

As we can see from Eq. 6, the relative temperature rise is proportional to $I$ and $r_m^2$ and inversely proportional to $T_0$ in the temperature

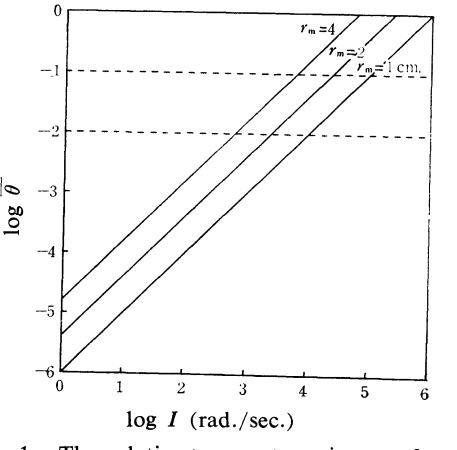

Fig. 1. The relative temperature rise as a function of dose rate and sample size.
$\kappa=4\times10^{-4}$ cal./cm. sec.°C; $\rho=0.8$ g./cm$^3$
$T_0=300$°K

range in which the physical constants do not change very much. Consequently, a smaller sample at a higher temperature is more favorable for maintaining isothermal conditions in an irradiated system, provided that the system is irradiated uniformly.

The time constant for approach to this steady state is given by the condition that the first term in the series in Eq. 3 falls to 1/e of its initial value:

$$\tau_c=\frac{1}{\pi^2}, \quad \text{or} \quad t_c=\frac{r_m^2\rho c_v}{\pi^2\kappa} \tag{7}$$

Putting numerical values into Eq. 7, we get:

$$t_c\simeq 100\ r_m^2\ \text{(sec.)}$$

where $r_m$ is in unit of cm. and $c_v$ is taken to be 0.5 cal./g.°C.

Let us consider the case where a rate constant is expressed by the Arrhenius equation. We define an effective rate constant as the rate constant averaged over space, since temperature is a function of space. Then, the ratio of the effective rate constant to the rate constant at the temperature $T_0$ is given by:

$$\frac{k_{eff}}{k_{T_0}}=3\ \exp\left(\frac{E}{RT_0}\right)\int_0^1 X^2 \times \exp\left[-\frac{E}{FT_0\{1+qIr_m^2(1-x^2)/6\kappa T_0\}}\right]dx \tag{8}$$

where $E$ is an activation energy and $R$ is the gas constant.

The ratio $k_{eff}/k_{T_0}$ calculated using Eq. 8 is shown in Fig. 2. At high dose rates the ratio deviates considerably from unity.

Thus care must be taken in application of simple kinetic techniques to systems irradiated at such high dose rates.

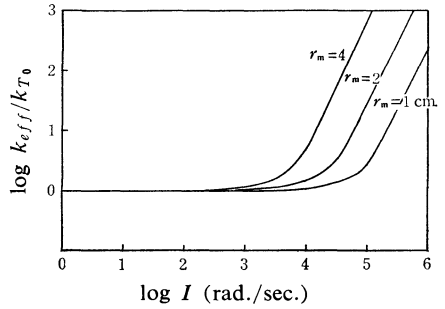

Fig. 2. The effective rate constant as a function of dose rate and sample size.
$E$=6 kcal./mol.; $T_0$=300°K

## SHORT COMMUNICATIONS

# Neutron Diffraction Study of Deuterated Oxalic Acid Dihydrate, $(COOD)_2 \cdot 2D_2O$

By Fujiko FUKUSHIMA, Hitoshi IWASAKI, Yoshihiko SAITO, Shoichi SATO and Sadao HOSHINO

(Received October 27, 1964)

Crystals of deuterated oxalic acid dihydrate, $(COOD)_2 \cdot 2D_2O$, have been found not to be isomorphous[1,2] with those of $(COOH)_2 \cdot 2H_2O$.[3] The crystal structure of the former was determined by X-ray study.[1]

This isotope effect is expected to be closely related to the nature of the hydrogen bonds. A neutron diffraction study has thus been undertaken in order to determine the deuteron positions and to investigate the difference between the hydrogen bonds in the two structures.

Anhydrous oxalic acid was dissolved in $D_2O$

1) F. Fukushima, H. Iwasaki and Y. Saito, *Acta Cryst.*, in press; This Bulletin, to be published.

with warming, and the water was evaporated in vacuo. This procedure was repeated three times, then the rhomboidal crystals of $(COOD)_2 \cdot 2D_2O$ were obtained. A high concentration of $D_2O$ was necessary to the formation of these crystals.[2]

The crystal data obtained with X-rays (Cu$K\alpha$, $\lambda = 1.542$ Å) are listed in Table I.

TABLE I. CRYSTAL DATA

| | $(COOD)_2 \cdot 2D_2O$ | $(COOH)_2 \cdot 2H_2O$ |
|---|---|---|
| Crystal system | Monoclinic | Monoclinic |
| Space group | $P2_1/a$ | $P2_1/a$ |

| $Z$ | 2 | 2 |

For the neutron diffraction work, crystals approximately $5 \times 5 \times 2$ mm$^3$ in dimensions were grown slowly from a supersaturated solution. They are colorless and unstable when exposed to air. The specimens were coated with a glyptal film and enclosed in glass tubes with a drop of mother liquor. The integrated intensities were measured at the JRR-2 reactor, Japan Atomic Energy Research Institute, Tokai, using the apparatus described by Miyake et al.[4] A neutron wavelength of 1.057 Å was obtained by means of a lead monochromator. The 27 reflections $0kl$ and the 26 reflections $h0l$ were observed in each zone for which $2\theta < 65°$.

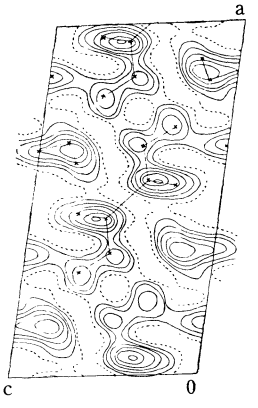

Fig. 1. Fourier projection along the b axis.

The approximate deuteron positions were found by the Fourier method, assuming the carbon and oxygen parameters derived from the X-ray analysis. Then $(F_o - F_{C,O})$ synthesis was carried out, where $F_{C,O}$ was the calculated contribution to the structure factor of all the atoms except deuteron. Figures 1 and 2 show

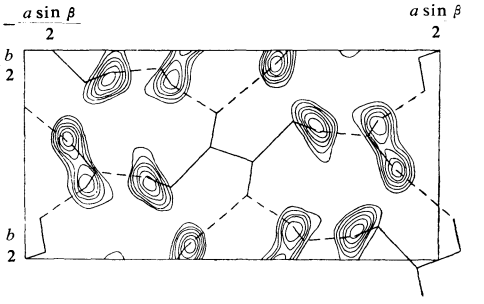

Fig. 2. $(F_o - F_{C,O})$ synthesis projected along the c axis.

the Fourier projection along the b axis and the $(F_o - F_{C,O})$ synthesis projected along the c axis respectively. The atomic co-ordinates are listed in Table II. They give the reliability index, $R = \sum ||F_o| - |F_c|| / \sum |F_o|$, of 0.19. These deuteron parameters agree with those obtained from the difference synthesis of X-ray data[1] and with the O–D directions suggested from the nuclear magnetic resonance study.[2]

TABLE II. ATOMIC CO-ORDINATES

# Radical Formation from the Intermediates of $S_N1$ Reacions. A One-Electron Transfer Reaction between a Carbonium-ion Type Intermediate and Nucleophiles

By Kunio OKAMOTO, Yoshihisa MATSUI and Haruo SHINGU

(Received November 5, 1964)

The recent work of Kerber et al.[1] on the transient formation of a radical anion, probably of E. Weitz's molecular-complex type,[2] during the course of the reaction of *p*-nitrobenzyl halides with a salt of 2-nitropropane prompts us to report on some of our previous work.[3] It has been found that reactions of benzhydryl halides with hindered nucleophiles, e. g., potassium 2, 6-di-*t*-butyl-4-methylphenoxide (I) and tri-*n*-butylamine, afford not the products anticipated for nucleophilic substitution, but rather products derived from benzhydryl radicals, i. e., *sym*-tetraphenylethane, diphenylmethane, and 1-(3′, 5′-di-*t*-butyl-4′-hydroxyphenyl)-2, 2-diphenylethane (II). The results are illustrated in Table I.

The structure of II, m. p. 113.0—115.0°C, was assigned on the basis of its elementary composition and spectral data (Found: C, 87.07; H, 8.76; mol. wt., 386 (cryoscopic measurements in benzene). Calcd. for $C_{28}H_{34}O$: C, 86.99; H, 8.87%; mol. wt., 386.6). Spectral peaks appeared at: infrared spectrum $\lambda_{max}$ (KBr pellet) 2.70 $\mu$ (OH, monomeric), no polymeric OH; 60 Mc. NMR (carbon tetrachloride) :[4] 1.28 p.p.m. (18-proton singlet, *t*-butyl methyls), 3.20 p.p.m. (2-proton doublet, methylene, $J$=7.7 c.p.s.), 3.93 p.p.m. (1-proton triplet, methine, $J$=7.7 c.p.s.), 4.78 p.p.m. (1-proton singlet, hydroxyl), 6.52 p.p.m. (2-proton singlet, tetra-substituted phenyl) and 7.10 p.p.m. (10-proton, mono-substituted phenyl).

For purposes of comparison the results of the reaction of benzhydryl chloride and potassium phenoxide in acetonitrile are also presented in Table I.

Despite their second-order kinetics (Table I), the $S_N1$ ionization character of the initiation of these reactions of hindered nucleophiles is supported by the following facts and considerations: (1) The reaction of unhindered potassium phenoxide displays characteristics typical of an $S_N1$ reaction with respect to the reaction-order and the products (Table I). Consequently, there would exist an $S_N1$ intermediate produced from a benzhydryl halide in acetonitrile in all reactions with hindered nucleophiles. (2) The nature of the reaction products can not be explained by the $S_N2$ mechanism. (3) The rates of these second-order reactions are sensitive to the natures of the solvents and of the leaving groups. The reaction of benzhydryl chloride and tri-*n*-butylamine proceeds more than 68% at about 150°C for 6.5 hr. (Table I), whereas the same reaction in decalin yields chloride ions less than 4% of the starting chloride under identical reaction conditions. Furthermore, it is estimated that bromide is about 5—30 times as reactive as the chloride (Table I) (4) These second-order reactions of benzhydryl chloride proceed with rates which do not exceed the rate of a typical $S_N1$ reaction of the chloride and potassium phenoxide (Table I).

On the basis of the above facts, (1)—(4), these reactions can be explained as a limiting case of an $S_N1$ reaction where the condition, $k_{-1} \gg k_2[Y]$, is satisfied in the following rate expression, which correspondes to the general reaction scheme of the $S_N1$ reaction:

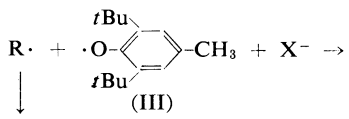
$$RX \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} (R^{\delta+} \cdots X^{\delta-}) \xrightarrow{k_2[Y]} RY$$

$$\text{Rate} = \frac{k_1 k_2 [RX][Y]}{k_{-1} + k_2[Y]}$$

Namely, for hindered nucleophiles,

$$\text{Rate} = \frac{k_1 k_2}{k_{-1}} [RX][Y].$$

Therefore, we propose a bimolecular one-electron transfer mechanism for the transient formation of benzhydryl radicals in the reaction of the $S_N1$ intermediate and hindered nucleophiles. This is illustrated in the following scheme:



1) R. C. Kerber, G. W. Urry and N. Kornblum, *J. Am. Chem. Soc.*, **86**, 3904 (1964).
2) E. Weitz, *Angew. Chem.*, **66**, 658 (1954).
3) K. Okamoto, Y. Matsui and H. Shingu, Abstracts of the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964, p. 128.
4) We are indebted to Professor Kenichi Fukui and Mr. Isao Morishima for their assistance with the measurement of the NMR spectrum. The spectrum was taken with tetramethylsilane as an internal standard on a Varian Associates Model A-60 spectrometer.

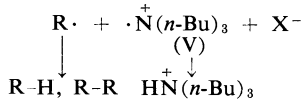
$$RX \underset{\text{in } CH_3CN}{\rightleftharpoons} (R^{\delta+}\cdots X^{\delta-}) \xrightarrow{+(I)}$$



(III)

(IV)

(II)

$$RX \underset{\text{in } CH_3CN}{\rightleftharpoons} (R^{\delta+}\cdots X^{\delta-}) \xrightarrow{+(n\text{-}Bu)_3N}$$

(R=Benzhydryl)

It is known[5] that I easily undergoes oxidation to give the 2,6-di-*t*-butyl-4-methylphenoxy radical (III) and that III isomerizes rapidly to the 3,5-di-*t*-butyl-4-hydroxybenzyl radical (IV). In our experiments, a coupling product II between a benzhydryl radical and a radical IV has been isolated. It is also known that aliphatic tertiary amines, e.g., triethylamine, lose one electron to yield a charge-transfer complex with tetracyanoethylene[6a] and 7,7,8,8-tetracyanoquinodimethane.[6b] A part of the amminium ion radical (V) seems to be stabilized by forming tri-*n*-butylammonium ions, which have been isolated in our experiments as the halide with a yield of 50—60%. The source of the hydrogen atoms has not been established.

# The Optical Rotatory Dispersion of Triptycene Derivatives. The Direction of Electronic Polarization as a Determining Factor of the Sign of the RD Curve

By Fumio OGURA and Masazumi NAKAGAWA

(Received November 9, 1964)

In a previous paper,[1] the present authors have reported the synthesis and optical resolution of 7-carboxy-2,5-diacetoxy-triptycene (I). The acetyl groups at 2,5-positions could be replaced by different groups.[2] Various kinds of optically-active triptycenes thus prepared (II–X)* have the same configuration as that of the parent triptycene (I), as the rigid cage structure of triptycene excludes the occurrence of any racemization or Walden inversion during the course of the transformation. In view of their rigid structure, the series of optically-active triptycenes bearing different substituents seems to offer the best tool for studying the effect of substituents on the rotatory properties.

I: $R_1=R_2=CH_3CO$, $R_3=H$, m. p. 269~270°C
II: $R_1=R_2=CH_3CO$, $R_3=CH_3$, m. p. 200~202°C
III: $R_1=R_2=H$, $R_3=CH_3$, m. p. 294~297°C (decomp.)
IV: $R_1=H$, $R_2=R_3=CH_3$, m. p. 250~251°C
V: $R_1=R_3=CH_3$, $R_2=H$, m. p. 256~258°C
VI: $R_1=R_2=R_3=CH_3$, m. p. 261.5~262.5°C
VII: $R_1=CH_3CO$, $R_2=R_3=CH_3$, m. p. 270~271°C
VIII: $R_1=R_3=CH_3$, $R_2=CH_3CO$, m. p. 278~279°C
IX: $R_1=CF_3CO$, $R_2=R_3=CH_3$, m. p. 262~263.5°C
X: $R_1=R_3=CH_3$, $R_2=CF_3CO$, m. p. 241~243°C

The compounds II, III, VI, VII, VIII, IX and X used in the measurements of the rotatory dispersion were derived from the *d*-isomer of I, while IV and V were derived from its *l*-isomer. The compounds I, II, III, IV, V, and VI exhibit plain curves of the same sign in so far as they have identical configurations. In sharp contrast to this fact, the sign of the plain curves of VII and IX are positive, whereas VIII and X show negative plain curves in spite of having the same configuration as VII and IX. Some representative RD curves are given in Fig. 1. The electronic spectra of VII, VIII, IX and X were found to be almost superimposable over a wide range of wavelengths. The only difference between VII and VIII and between IX and X are the relative positions of the electron-donating methoxyl groups and electron-attracting acyloxy groups in the *p*-disubstituted benzene ring in the triptycene molecules.

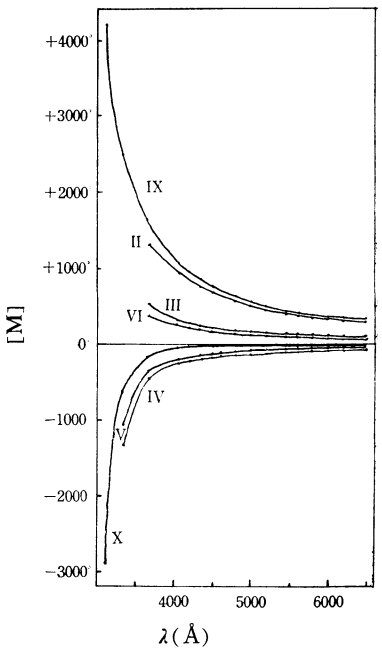

Fig. 1. The RD curves of the triptycenes.

These experimental results clearly indicate that the direction of electronic polarization is a determining factor in the sign of the RD curve. It seems evident that the inversion of the direction of electronic polarization exerts an inverse effect on the electric transition moment of the optically-active absorption band. However, the more extensive influence of the inversion of the direction of polarization is reflected in the fact that the RD curves of

2) F. Ogura, Y. Toshiyasu. K. Kimura, R. Fujishiro and M. Nakagawa, ibid., 37, 757 (1964).
* All compounds described in this paper gave satisfactory IR spectra and elemental analyses.

II, III, IV, V, VI, VII and IX can be expressed by a one-term Drude equation, whereas in the cases of VIII and X the plots of $1/[M]$ versus $\lambda^2$ give no straight lines.

In order to obtain more precise information, the authors are now preparing to measure the optical rotatory dispersion at a shorter wavelength region and to measure the circular dichroism of the triptycene derivatives.

# The Rearrangement Polymerization of Propenylbenzene: A Reinvestigation

By Shunsuke MURAHASHI, Shun'ichi NOZAKURA, Kazuhiko TSUBOSHIMA and Yahide KOTAKE

(Received November 20, 1964)

In a previous paper[1] the present authors studied the rearrangement polymerization of propenylbenzene, which had been proposed by Staudinger,[2] and reported a set of confirmative data. However, further study has revealed that the propenylbenzene used, which had been prepared by thermal cracking of ethylbenzyl acetate at 500°C,[3] contained a small impurity (ca. 5%), and that this impurity even in a minute quantity deeply influences the course of polymerization.

The impurity was, therefore, concentrated by preparative gas chromatography and identified with indene by a comparison of its infrared spectrum with that of an authentic sample.

Since indene is a monomer with a high cationic polymerizability, the presence of indene in propenylbenzene of a low activity influences the polymerization of propenylbenzene a great deal. Thus, i) the residual monomer, which was recovered after the initial polymerization (about 20% conversion) with a mild catalyst, $BF_3Et_2O$, is found to contain no indene. This means that indene has been consumed at an early stage of polymerization. ii) The initial rate of polymerization became larger upon the addition of a small amount of indene to pure propenylbenzene. iii) The initial polymer obtained with a $BF_3Et_2O$ catalyst using an indene-containing propenylbenzene yielded a methanol-insoluble polymer of a comparatively high molecular weight, as was reported in the previous paper. On the other hand, pure propenylbenzene yielded only a methanol-soluble polymer of a low molecular weight. Many differences are observed between the two polymers in infrared and NMR spectra. While the former shows a very weak $CH_3$ band at 2960 $cm^{-1}$ and a strong $CH_2$ band at 2925 $cm^{-1}$, and the ratio of the number of methyl protons to that of aromatic protons is found to be 0.26, the latter has a strong $CH_3$ band and a comparatively weak $CH_2$ band, and the ratio of methyl protons to aromatic protons is nearly 0.6, which corresponds to the theoretical value for polypropenylbenzene polymerized by a 1,2-opening. When a strong cationic initiator, such as $BF_3$, is used, the effect of the presence of a small amount of indene is masked by the rapid production of a large amount of polypropenylbenzene.

Table I shows a gas chromatographic analysis of relative amounts of impurities contained in samples of propenylbenzene prepared by three different methods.

In order to examine the existence of rearrangement polymerization in more detail, the polymerization was carried out under various conditions, including Staudinger's system. When toluene was used as a solvent, as in the case of Staudinger's original work, the resulting viscous polymer appeared to contain toluene residues ($\tau = 7.7$). This complicated the NMR analysis and made the apparent ratio of methyl protons ($\tau \sim 9.2$) to aromatic protons considerably lower than the theoretical value (0.4—0.5). When *n*-heptane or methylene chloride was used as the solvent and boron fluoride or titanium(IV) chloride as the initiator, the resulting polymers showed a ratio of methyl to aromatic protons of about 0.6, indicating

# The Crystal Structure of Hexachlorocyclopropane $C_3Cl_6$

By Tsunehiro TAKANO, Tohru CHIBA, Yoshio SASADA, Masao KAKUDO, Shun'ichi NOZAKURA and Shunske MURAHAHI

(Received November 26, 1964)

The crystal structure of the hexachlorocyclopropane synthesized at the laboratory of two of the authors was determined by X-ray analysis. Equi-inclination photographs around the b axis were taken with Mo-$K\alpha$ radiation ($k=0, \cdots\cdots, 5$).

The unit cell dimensions obtained are:

$a=12.60$, $b=6.13$, $c=10.94$ Å, $\beta=112.0°$.

The space group is $C_{2h}^5-P2_1/a$, and $Z=4$.

Intensities were measured by a visual comparison with an intensity scale and corrected for Lorentz and polarization factors. However, no correction for absorption was made. The Weissenberg photographs showed a characteristic distribution of intensities; the reflections were very weak for $h+k+l=2n+1$. This suggested that the arrangement of the molecules is approximately body-centered.

Two-dimensional Patterson synthesis projected along [010] and [001] were also computed. The crystal structure was derived uniquely from the Patterson maps and from the requirement of a psuedo-body-centered arrangement of the molecules.

The refinement of the structure projected on the (010) plane was carried out by the least-squares method. After several cycles, the discrepancy index, $R=\sum||F_o|-|F_c||/\sum|F_o|$, became 0.14.

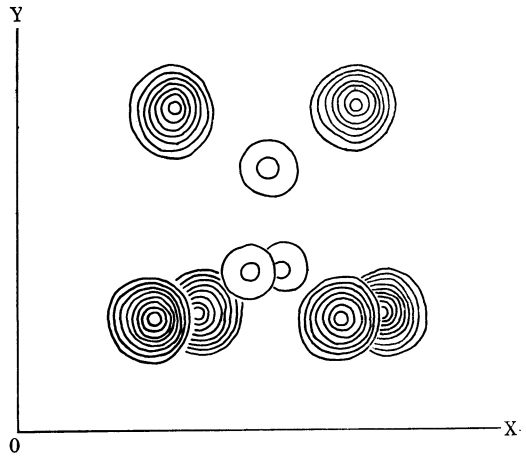

Fig. 1. Composite Fourier diagram of sections parallel to (001).

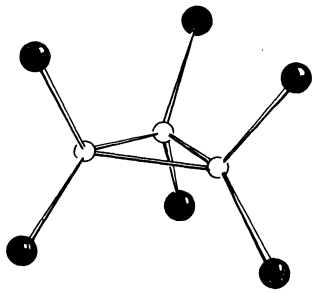

Fig. 2. The molecular configuration of hexachlorocyclopropane.

The three-dimensional Fourier synthesis is shown in Fig. 1. According to the Fourier map, the molecular configuration may be as is shown in Fig. 2.

Intermolecular contacts consist of the ordinary van der Waals distance between chlorine atoms.

The accuracy of the analysis at this stage of refinement is not sufficient to evaluate the bond lengths and bond angles. In order to obtain the details of the structure, a three-dimensional refinement of the atomic parameters is in progress by the least-squares method.

A fullpaper will be published soon.

# The Cation Exchange Adsorption of Calcium and Strontium from an Ammonium Formate or Ammonium Acetate Solution in Mixtures of Organic Solvents and Water*

By Hiroyuki TSUBOTA

(Received March 20, 1963)

Several methods for separating calcium and strontium by cation exchange resin have been reported.[1-5] Most of them, however, have difficulty in handling a large sample. Although EDTA has been used for separating strontium from a large quantity of calcium,[6] it is not suitable for usual purposes because of the difficulty of the after-treatment of the effluent.

There are other possibilities for overcoming these difficulties, for example, the use of non-aqueous or mixed solvents as elutriants.[7-15] The results of studies of the anion exchange adsorption of anionic metal complexes have shown that the addition of an organic solvent to the system has a large effect on the exchange equilibrium when an ion exchange reaction is accompanied by a complex formation.[10-14] For a cation exchange system, Ionescou et al.[15] measured the distribution coefficients of some transition metals between a phenol - sulfonic acid - type cation exchange resin and an acetone-hydrochloric acid mixture, and used the results for the separation of these metals. Thus, a study of cation exchange equilibria when an organic solvent is added to a calcium or strontium solution containing a complexing agent would be of interest and would be useful for the separation of these metals. In this report, the selectivity coefficients of calcium-ammonium and strontium-ammonium exchange reactions have been measured in methanol-water, acetone-water and dioxane-water mixtures containing formate or acetate as a complexing agent. In addition, by using these complexing agents, the treatment of effluents is greatly simplified. Experiments by column operation have been also carried out to learn whether the expectation from the selectivity coefficient measurements can be actually applied to the separation of calcium and strontium.

## Experimental

**Chemicals.**—Air-dried Amberlite IR-120 (a sulfonated polystylene divinylbenzene cation exchange resin, 100—120 mesh) in ammonium form was used for batch measurement after thorough conditioning. The exchange capacity was 3.5 meq. for 1 g. of the air-dried resin. The organic solvents were used after purification, and calcium and strontium salts were purified by the ion exchange method.

A column of cation exchange resin, Amberlite IR-120, 100—200 mesh in hydrogen form, 10 cm. long and 1.1 cm. in diameter, was used for the column operation.

**Measurements.**—The adsorption of metal ions by the resin was measured by the equilibrium method, and the results were described in terms of the selectivity coefficients of the ion against the ammonium ion, $K^{M}_{NH_4}$, as defined by the following equation:

$$K^{M}_{NH_4} = \frac{[M^{2+}]_r[NH_4^+]_s}{[M^{2+}]_s[NH_4^+]_r}$$

where parentheses denote molarities, the suffixes r and s denote the resin phase and the outer solution phase respectively, and $M^{2+}$ denotes calcium or strontium ions, including their cationic complex ions.

Solutions with the following composition were prepared:

| | |
|---|---|
| $NH_4A$: | $(1-2a)$ mol./l. |
| $MA_2$: | $a$ mol./l. |
| Organic liquid: | $b$ % (v/v) |

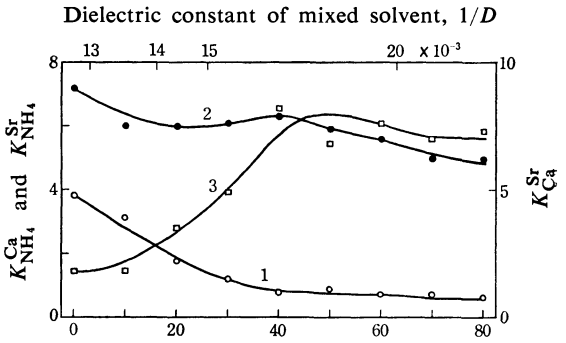
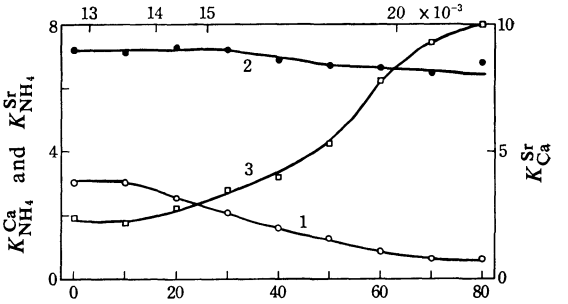
where A denotes a formate or acetate ion. The value of $a$ ranged from $1\times10^{-3}$ to $40\times10^{-3}$, but it was kept constant in each series of experiments. The percentage of the organic solvent, $b$, was in the 0—80 range for methanol and the 0—60 range for acetone and dioxane. Fifty milliliters of the calcium solution was shaken with 1.000 g. of the dried resin for 24 hr. in a constant temperature bath at 25°C. After an exchange equilibrium had been reached, the outer solution was rapidly separated from the resin with a glass filter, and the calcium concentration in the solution was measured by EDTA titration, using Eriochrome Black T as an indicator. The ammonium ion concentration in the outer solution was determined from the difference between the total concentration and the calcium concentration measured above, the former being measured by alkalimetry after the solution had been converted to acid with a hydrogen-form cation exchange column. The quantities of calcium and ammonium ions in the outer solution and the quantities of the ions in the resin phase were then calculated, with a correction for the swelling of the ion exchanger. The relative volume decrease in the solution caused by the swelling was determined by the quotient between the initial and the equilibrium total ion concentrations of the outer solution.



Since the selectivity coefficients will vary with the fraction of exchangeable sites occupied by calcium ions, they were measured at various loading-values, and the selectivity coefficients were normalized at a certain loading-value by interpolation or extrapolation. The selectivity coefficient of strontium was obtained in the same manner as calcium.

In the column operation, the calcium and strontium adsorbed on the column were eluted with various elutriants. The concentration of ammonium ions in the elutriants was kept at 1 mol./l. throughout the experiments. The effluents from the column were divided into 5 ml. fractions and the amount of calcium or strontium in each fraction was determined by EDTA titration.

## Results and Discussion



**The Selectivity Coefficients of Calcium and Strontium.**—In Figs. 1—6, the selectivity coefficients in an acetate solution containing methanol, acetone or dioxane are plotted against the percent concentration (v/v) of the organic solvent. Curves 1 and 2 in each figure show the selectivity coefficients of calcium and strontium against ammonium, $K^{Ca}_{NH_4}$ and $K^{Sr}_{NH_4}$, respectively, while curve 3 shows the ratio of the two coefficients, i. e., the selectivity coefficients of strontium against calcium, $K^{Sr}_{Ca}$, or the separation factor of these two ions.

In Figs. 7—10, the selectivity coefficients in a formate solution containing acetone or dioxane are plotted. The results are not shown for the solution containing methanol,

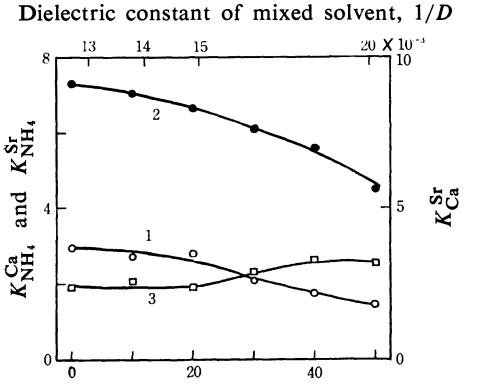
because methyl formate was formed during 24 hr. shaking in the presence of the resin.*

The same tendencies are found in all figures, irrespective of the loading values and of the organic solvents. The selectivity coefficients of both calcium and strontium against ammonium decrease with an increasing concentration of the organic solvent. The decrease is greater for calcium than for strontium, and the separation factor between strontium and calcium increases with an increasing concentration of the organic solvent.



The causes for the variation in the selectivity coefficients with the concentration of organic

solvents can not be explained clearly. We can, however, say that the change in the selectivity coefficients in these systems depends on the following three factors: 1) *The variation in the formation constant of complex ions with the dielectric constant of the outer solution.* It is known that ion association generally increases with a decrease in the dielectric constant of the solution caused by the addition of an organic solvent. 2) *The variation in the affinities of metal and complex ions for the resin with the dielectric constants of the outer solution phase and the resin phase.* It is known that the distribution coefficients for a 1-1 exchange in a mixed solvent varies with the $1/D$ ($D$: dielectric constant) of the solution phase.[8,11] In the present work, however, we can not discover any clear relationship between $K^{Ca}_{NH_4}$ or $K^{Sr}_{NH_4}$ and $1/D$, and the correlation between $K^{Sr}_{Ca}$ and $1/D$[16] is rather uncertain, as is shown in Figs. 1—10. Ohtaki and his coworkers[17] explained their experimental results concerning the distribution coefficients for a 1-1 exchange in mixed solvents, in which an electrolyte existed, on the basis of the

calculated dielectric constants of the solution phase ($D_s$) and that of the resin phase ($D_r$). However, the method cannot be applied to such complicated cases as are discussed here, because $D_s$ and $D_r$, the formation constants of the complex ions, and the affinities of complex and metal ions to the exchanger are not yet known for the systems studied. 3) *The specific solvation effect on the metal and complex ions.* The variation in the selectivity coefficients with an organic solvent may be caused also by the solvation effect. The finding that dioxane, unlike cellosolves,[18] is not effective in separating calcium and strontium seems to correspond to the fact that dioxane shows no evident solvation effects[19] on these ions. When the cellosolves are used in the column operation, the separation of calcium and strontium is as excellent as can be expected, as is shown in Fig. 11. Thus, the solvation effect may be considered to be one of the factors strongly affecting the selectivity coefficients.

From these results, it may be expected that strontium can be easily separated from calcium by the column operation when an elutriant with a high separation factor, and, at the same time, a low selectivity coefficient

K: Ammonium formate - 50% methanol cellosolve
L: Ammonium formate - 25% ethyl cellosolve

of calcium against ammonium is used. A 1 M acetate solution containing over 40% methanol and a 1 M ammonium formate solution containing about 60% acetone will meet this purpose. It is, however, very difficult to ascertain the most suitable concentration of the organic solvent, because the variation in selectivity coefficients with the percentage of organic solvents is different for different loading-values. The best can be found only by experiments in the future.

**The Separation of Calcium and Strontium.**— Figure 11 shows the elution curves of calcium and strontium (10 mg. each) with various elutriants, using a 10 cm. column of Amberlite IR-120. The most suitable elutriant is a 1 M ammonium formate solution containing 50% acetone, as is shown by curve I in the figure; the next was a 1 M ammonium acetate solution containing 50% methanol, shown by curve D, as has been expected from the results of the batch operation.

The elution curves by the same column with various amounts of calcium and strontium are shown in Fig. 12. A 1:1 mixture of a 2 M ammonium formate aqueous solution and acetone and a 1:1 mixture of a 2 M ammonium acetate aqueous solution and methanol were used as elutriants.* When the strontium and calcium added to the column were less than 25 mg. and 50 mg. respectively, the elution front of strontium remained unchanged and well separated from the calcium fraction.

* The results with these elutriants were essentially the same as those with the elutriants used for batch operation.

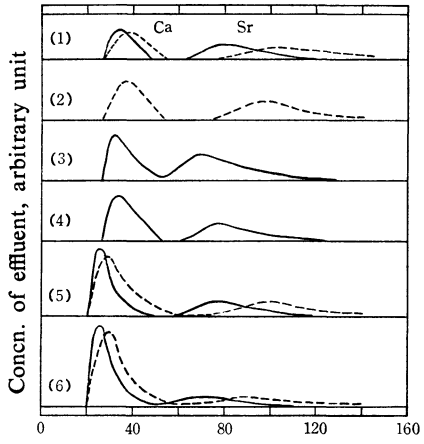

Fig. 12. Elution curves of various amounts of calcium and strontium.
Column : Amberlite IR-120, 1.1$\phi \times$10 cm.
Elutriants :
——: mixture of 2 M ammonium formate aqueous solution and acetone in equal volume
----: mixture of 2 M ammonium acetate aqueous solution and methanol in equal volume
(1) Ca 9.7 mg., Sr 10.0 mg.
(2) Ca 19.4 mg., Sr 20.0 mg.
(3) Ca 19.4 mg., Sr 50.0 mg.
(4) Ca 19.4 mg., Sr 25.0 mg.
(5) Ca 48.5 mg., Sr 25.0 mg.
(6) Ca 67.8 mg., Sr 25.0 mg.

When the amounts of calcium and of strontium increased further, however, strontium came to be soon eluted from the column, and the elution curves of calcium and of strontium overlapped to some extent.

The column dimensions and the volume of the elutriants necessary to treat various amounts of calcium and strontium were determined; they are shown in Table I. Allowance was made for small changes in column dimensions and in the concentration of elutriants. When a large quantity of calcium existed and an ammonium formate solution in acetone-water was used, a white precipitate was formed in the column, preventing the downward flow of the solution and the clear-cut separation of the two cations. The elution curves of strontium show a considerable tailing when the elutriant used to elute calcium is used, as is shown by the dotted curves in Fig. 13. Strontium can be completely eluted with a 2 M ammonium acetate or formate aqueous solution (without organic solvents). The volume of the elutriant necessary to elute strontium is shown in the same table, while the elution curves are shown in Fig. 13 by solid curves.

Dotted lines show the elution curves of strontium using elutriant-1.

## Summary

Ion exchange equilibria of calcium- and strontium-ammonium exchange systems have been studied in methanol-water, acetone-water and dioxane-water mixtures in which acetate or formate ions co-exist as a complexing anion. The selectivity coefficients of calcium against ammonium and those of strontium against ammonium decrease, while the separation factor between strontium and calcium increases, with an increase in the organic solvent concentration. Therefore, by the column operation, calcium can easily be eluted from the column, and strontium can be well separated from calcium when a suitable elutriant with a high separation factor between strontium and calcium and with a low selectivity coefficient of calcium against ammonium is selected. A 1 : 1 mixture of a 2 M ammonium formate aqueous solution and acetone or a 1 : 1 mixture of a 2 M ammonium acetate aqueous solution and methanol is recommended. When strontium in a large amount of calcium is to be analyzed, the latter elutriant is the most suitable.

The author wishes to thank Professor Hidetake Kakihana of the Tokyo Institute of Technology, Professor Hideo Yamatera of Rikkyo (St. Paul's) University, and Dr. Masami

Izawa of the National Institute of Radiological Sciences for their helpful discussions and advice.

# The Cation Exchange Investigation of Scandium Acetate and Sulfate Systems

By Akira TATEDA

(Received July 9, 1963)

Previously the present author[1] has reported on the adsorption of scandium ions on several adsorbents, showing that the concentrations and kinds of salts contained in the solution have an influence on the ratios of scandium adsorption. The aim of the present investigation is to make quantitative studies of the formation equilibria of the complexes in the scandium acetate and sulfate systems, in order to get some clue as to the mechanism of the influence described above.

A work[2] has recently reported on the scandium acetate system, in which, by the cation exchange method, scandium was separated from rare earth elements, using a 0.5 M ammonium acetate - acetic acid solution (pH 4.5) as an eluent. However, there has been no study of the composition of the eluted species.

In the present study, the compositions of the scandium acetate and sulfate complexes will be determined by the cation exchange method according to the procedures of Fronaeus,[3] with some simplification to be described below. Judging from the data obtained, species with scandium to ligand ratios of 1 : 1, 1 : 2 and 1 : 3 seem to be formed both in acetate solutions and in sulfate solutions at a constant ionic strength of $\mu=0.5$ and at 25°C. Then overall formation constants of the various complexes will be determined.

## Derivation of Equations

An equation for determining the compositions and the formation constants of metal complex species using cation exchange resin has been derived by Schubert.[4] Fronaeus[3] has applied the cation exchange method to the step to step equilibria between a divalent cation and a univalent complexing anion. In this investigation, an equation was derived for the complex systems of the $M^{3+}-A^{-}$ and $M^{3+}-B^{2-}$ types, and a graphical method developed by Banerjea and Tripathi[5] was used in evaluating the formation constants. According to the data of Biedermann[6] concerning the hydrolysis of scandium ions, the mononuclear complexes exist in an acid solution which contains a low concentration of scandium. As a small amount of radioactive scandium was used in these experiments, the formation of only the mononuclear complexes need to be considered.

The following equilibrium is obtained between a cation exchanger in the sodium form and a solution containing scandium ions, $Sc^{3+}$, and complex ions, $ScA_j^{3-j}$:

$$(3-j)\,Na_R^{+}+ScA_j^{3-j} = (3-j)\,Na^{+}+ScA_{jR}^{3-j};\ (j=0,\ 1,\ 2)$$

If the law of mass action is applied to this exchange equilibrium,

$$[ScA_j^{3-j}]_R/[ScA_j^{3-j}] = k_j[Na^{+}]_R^{3-j}/[Na^{+}]^{3-j}=l_j;\ (j=0,\ 1,\ 2) \quad (1)$$

where [ ] indicates the molar concentration and the subscript R indicates the resin phase.

In this experiment, the total concentration of the scandium ions is very low and the load of metal ions in the resin phase is very low compared with the total exchange capacity. Moreover, the ionic strengths of both the resin and the aqueous phase have been nearly constant. Under these conditions, $k_j$ and $l_j$ in Eq. 1 may be considered to be constant. The total concentration of scandium ions in the

resin phase, $C_{MR}$, and in solution, $C_M$, are considered to be as follows:

$$C_{MR}=[Sc^{3+}]_R+[ScA^{2+}]_R+[ScA_2^{+}]_R \quad (2)$$

and

$$C_M=[Sc^{3+}]+[ScA^{2+}]+\cdots\cdots+[ScA_N^{3-N}]$$
$$=[Sc^{3+}](1+\sum_{j=1}^{N}\beta_j[A^-]^j) \quad (3)$$

where a $N$ indicates a maximum ligand number bound to a scandium ion, and $\beta_j$ is the overall formation constant of $j$th complex, $ScA_j^{3-j}$, i. e. $\beta_j=[ScA_j^{3-j}]/[Sc^{3+}][A^-]^j$.

From Eqs. 1, 2 and 3, putting $l_1\beta_1/l_0=L_1$ and $l_2\beta_2/l_0=L_2$, the distribution coefficients of the scandium between the resin and the solution, $K_d$, can be represented by:

$$K_d=C_{MR}/C_M=l_0(1+L_1[A^-]+L_2[A^-]^2)/X \quad (4)$$

where

$$X=1+\sum_{j=1}^{N}\beta_j[A^-]^j$$

For determining the value of $L_1$, the following function, $f_1$, is introduced:

$$f_1=(K_d^{-1}-l_0^{-1})/[A^-] \quad (5)$$

The relation, Eq. 6, is derived by introducing the expression of $K_d$ from Eq. 4 into Eq. 5 and by extrapolating it to $[A^-]=0$;

$$\lim_{[A]\to 0} f_1=f_1^0=(\beta_1-L_1)/l_0 \quad (6)$$

When the ligand concentration, $[A^-]$ in Eq. 4, is very small, it may be assumed that the $L_1$ and $L_2$ terms can be disregarded. Then an approximate value of $\beta_1$ can be determined graphically by extrapolation to $[A^-]=0$, according to the following equation:

$$(l_0/K_d-1)/[A^-]=\beta_1+\beta_2[A^-]+\cdots\cdots$$
$$+\beta_N[A^-]^{N-1} \quad (7)$$

As $l_0$ is measurable or calculable, $L_1$ can be estimated from Eq. 6. $L_2$ can be determined in the same way. Another function, $f_2$, is also introduced as follows:

$$f_2=[f_1-(\beta_1-L_1)l_0]/[A^-] \quad (8)$$

Now the values of $f_1^0$, $L_1$ and $l_0$ and an approximate value of $\beta_2$ being known or calculated, the value of $L_2$ can be calculated from Eq. 9, obtained by extrapolating the $f_2$ function to $[A^-]=0$:

$$\lim_{[A^-]\to 0} f_2=f_2^0=[(\beta_2-L_2)-f_1^0l_0L_1]/l_0 \quad (9)$$

When $L_1$ and $L_2$ have been determined in this way, the function $X$ in Eq. 4 can be calculated, and from the corresponding values of $X_j$ and $[A^-]$ the formation constant can be computed from the relations:

$$X_1=(X-1)/[A^-]=\beta_1+\beta_2[A^-]$$
$$+\beta_3[A^-]^2+\cdots\cdots+\beta_N[A^-]^{N-1} \quad (10)$$
$$X_2=(X_1-\beta_1)/[A^-]=\beta_2+\beta_3[A^-]$$
$$+\beta_4[A^-]^2+\cdots\cdots+\beta_N[A^-]^{N-2} \quad (11)$$

This process is continued till the $X_N$ function independent of $[A^-]$ is obtained, where:

$$X_N=\beta_N$$

Hence a plot of $X_N$ versus $[A^-]$ will be a straight line parallel to the $[A^-]$ axis, indicating that the highest complex formed in the system is $ScA_N^{3-N}$.

In the case of a divalent complexing anion $B^{2-}$ such as the sulfate ion, it has only to be considered that the complex ions in the resin phase are $Sc^{3+}$ and $ScB^+$. Therefore, Eq. 4 can be rewritten as:

$$K_d=l_0(1+L_1[B^{2-}])/X \quad (12)$$

Since $L_1$ can be determined as has been described above, the function $X$ can be calculated and $\beta_j$ can be estimated.

## Experimental

**Reagents.** — Radioactive $^{46}Sc$ ($T_{1/2}$=85 days) in dilute hydrochloric acid, obtained from N. V. Philip-Duphar (Holland), was employed as a stock solution of scandium ($\sim 5\times10^{-4}$ M). In these experiments, a portion of the above solution was dried in a glass dish and then dissolved in dilute perchloric acid. When the solution was converted into a 0.5 M sodium perchlorate solution, the radioactivity corresponded to about one microcurie per ml. of solution.

The resin used in all the experiments was the sodium form of the cation exchanger, Amberlite IR-120, with a particle size of 60 to 100 mesh and with a capacity of 3.69 meq. per g. in hydrogen form.

The sodium acetate solution and the sodium sulfate solution used as sources of complexing anions were prepared from guaranteed reagents.

**Procedure.** — The adsorbability of the scandium ions was measured by a batch method as follows; To the solution which contained a known quantity of a 0.5 M ligand solution and 1.0 ml. of the scandium solution, 0.5 M sodium perchlorate solution was added until the volume of the solution reached 10 ml. in a small stoppered glass vessel. The ionic strength of the resultant solution was then made up to 0.5. Since a 0.5 M acetic acid-sodium acetate buffer solution (pH 4.5) was used as the ligand solution in the case of the acetate system, pH of the solution prepared above could be adjusted easily. In the case of the sulfate system, the pH of the solution was adjusted with a dilute perchloric acid. Each of these solutions was shaken with 0.2 g. of the resin for 24 hr. at 25°C. A portion of the supernatant solution was then taken with a pipet and dried in a glass dish. The radioactivity of the residue was measured, and the distribution coefficient was calculated from the difference in the scandium activity before and

after the achievement of equilibrium. The measurements of the radioactivity were carried out with a Toshiba Scintillation Detector, DDS-14301 type (NaI: $1''\phi \times 1''l$), attached to a Flow Counter Scaler, UDS-24204 type.

## Results and Discussion

**On the Formation of Scandium Acetate and Sulfate Complexes.**—In Fig. 1 the distribution coefficients, $K_d$, are plotted against pH values of scandium-perchlorate, -acetate and -sulfate solutions. The ionic strength of each solution was kept constant at 0.5 and, since the radioactive scandium used in this experiment was considered to form radiocollid or to precipitate hydroxide in an alkaline solution,[7,8] these experiments were carried out over the range of pH values from 1.0 to 7.0.

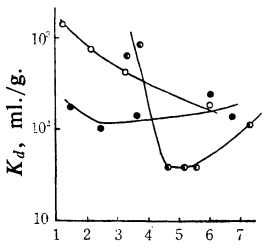

Fig. 1. Relation between the distribution coefficient and pH of the solutions.
Ionic strength: 0.5, Temp.: 25°C
—○— $NaClO_4$
—◐— $CH_3COONa + CH_3COOH$
—●— $Na_2SO_4$

It may be observed from Fig. 1 that $K_d$ values in the acetate solution in the pH range from 4.5 to 6.0 are smaller than that in the perchlorate solution and that $K_d$ values in the sulfate solution are also smaller than that in the perchlorate solution over a broad range of the acidic side of pH values. In the curve obtained with a perchlorate solution, $K_d$ decreases with an increase in the pH values. This phenomenon may be considered to be due to the hydrolysis of scandium ions. Since the concentrations of scandium ion used in these experiments are below $10^{-5}$ mol./l., there is little or no tendency to precipitate scandium hydroxide below pH 5, according to the data of the solubility product.[8] $K_{so}=[Sc^{3+}][OH^-]^3 = 10^{-27-30.1}$.

Moreover, the formation of the hydroxo complex ions, $Sc(OH)^{2+}$, $Sc(OH)_2^+$ and $Sc_2(OH)_2^{4+}$, were considered. From the values of the formation constants of these complex ions obtained by Biedermann et at.,*,[6] it has been found that only the scandium ion, $Sc^{3+}$, is a predominant species in the sulfate solution with pH=2.7 and that the hydroxo complex ions, $Sc(OH)^{2+}$ and $Sc(OH)_2^+$, form 26% and 7% of the total scandium concentration respectively in the acetate solution with pH=4.5. The polymerization of scandium ions is negligibly small in both cases.

On the other hand, the $K_d$ value without a ligand obtained by the graphical extrapolation of the relation between $1/K_d$ and $[A]^2$ to $[A]=0$ in the acetate or the sulfate system, agreed with the value $K_d$ obtained experimentally in the perchlorate solution with the same pH. In the case of acetate system, the numerical values of 204 ml./g. and 225 ml./g. respectively were obtained for the extrapolated and the experimental values at pH=4.5, while as regards the sulfate system, 545 ml./g. and 520 ml./g. respectively were obtained. Therefore, it has been proved, as has been shown by Feldman et al.,[9] that the species of the metal ion in the complexes are the same as that in the uncomplexed metal.

On the basis of these facts, it seems reasonable to assume that the decrease in the $K_d$ value in both the acetate and sulfate solutions as compared with the $K_d$ value of the perchlorate solution shows the occurrence of a considerable complex formation, since, although the resin adsorbs not only $Sc^{3+}$ ions but also the cationic complexes, the adsorption of the latter for the resin is small because of the lower charge on the cationic complex and its low concentration in each system.

**On the Composition and Formation Constants of Scandium Acetate Complexes.**—In the formation reaction between the scandium ion and the acetate ion, it must be taken into consideration that the scandium ion has been hydrolyzed in the solution with pH=4.5, as has been described above. Therefore, the following equilibria are considered in solution, assuming that: 1) the species of the scandium ions reacting with the acetate ion, $A^-$, are $Sc^{3+}$ and $Sc(OH)^{2+}$; 2) since only a few dihydroxo complex ions, $Sc(OH)_2^+$, are present in the solution under the experimental conditions, they can be disregarded as central metal ions; 3) the monohydroxo complex ion, $Sc(OH)^{2+}$, forms complexes with acetate ions. The formation of the hydroxo acetato complex ion, $Sc(OH)A_n^{2-n}$,

7) J. D. Gile, W. M. Garrison and J. G. Hamilton, *J. Chem. Phys.*, **18**, 1685 (1950).
8) J. Bjerrum, G. Schwarzenbach and L. G. Sillén, "Stability Constants of Metal-ion Complexes, Part II: Inorganic Ligands," The Chemical Society, London (1958).

* These values are used: $*K_1=[Sc(OH)^{2+}][H^+]/[Sc^{3+}] = 10^{-4.90}$, $*K_2=[Sc(OH_2)^+][H^+]/[Sc(OH)^{2+}]=10^{-5.1}$ and $\beta_{22}=[Sc_2(OH_2)^{4+}][H^+]^2/[Sc^{3+}]^2=10^{-5.9}$ (cf. Biedermann et al.[6]).
9) L. Feldman, T. V. Toribara, J. R. Havill and W. F. Neuman, *J. Am. Chem. Soc.*, **77**, 878 (1955).

may be supported by the finding[10] that Sc(OH)$A_2$ was precipitated from a hot and concentrated solution with pH=4.76 and 4.93.

$$Sc^{3+}+jA^-=ScA_j^{3-j}$$
$$\beta_j=[ScA_j^{3-j}]/[Sc^{3+}][A^-]^j$$
$$Sc^{3+}+H_2O=Sc(OH)^{2+}+H^+$$
$$*K_1=[Sc(OH)^{2+}][H^+]/[Sc^{3+}]$$
$$Sc(OH)^{2+}+nA^-=Sc(OH)A_n^{2-n}$$
$$\beta_n'=[Sc(OH)A_n^{2-n}]/[Sc(OH)^{2+}][A^-]^n$$

The exchange equilibrium in the resin phase is considered, along with that of Eq. 1, as follows:

$$(2-n)Na_R^+ + Sc(OH)A_n^{2-n} = (2-n)Na^+ + Sc(OH)A_{nR}^{2-n}$$
$$[Sc(OH)A_n^{2-n}]_R/[Sc(OH)A_n^{2-n}] = k_n'[Na^+]_R^{2-n}/[Na^+]^{2-n}=l_n' ;\ (n=0, 1) \quad (13)$$

From these equations, $K_d$ is represented as follows, by the same treatment from Eq. 1 to Eq. 4:

$$K_d=\frac{\left(\begin{array}{l} l_0+l_0'*K_1[H^+]^{-1}+l_1\beta_1[A^-]+ \\ l_1'\beta_1'*K_1[H^+]^{-1}[A^-]+l_2\beta_2[A^-]^2 \end{array}\right)}{\left(\begin{array}{c} (1+\sum_{j=1}^{N}\beta_j[A^-]^j)+ \\ *K_1[H^+]^{-1}(1+\sum_{n=1}^{M}\beta_n'[A^-]^n) \end{array}\right)}$$

$[H^+]$ is determined by the pH value in solution and a constant value in this experiment, while $*K_1$ is a known value.* Putting $l_0+l_0'*K_1[H^+]^{-1}=K_{d_0}$, $l_1\beta_1/*K_{d_0}=L_1$, $l_1'\beta_1'*K_1\cdot[H^+]^{-1}/*K_{d_0}=L_1'$ and $l_2\beta_2/*K_{d_0}=L_2$, $K_d$ can be represented by:

$$K_d=*K_{d_0}[1+(L_1+L_1')[A^-]+L_2[A^-]^2]/X'$$
$$X'=1+*K_1[H^+]^{-1}+B_1[A^-]+B_2[A^-]^2+\cdots\cdots \quad (14)$$

where $B$ represents $\beta_j+\beta_j'*K_1[H^+]^{-1}$ and gives a constant value when $[H^+]$ is kept constant. Since the distribution coefficients of $Sc^{3+}$ and $Sc(OH)^{2+}$ ions in the absence of an acetate ion, $K_{d_0}$, are obtained by the graphical extrapolation of $K_d$ to $[A^-]=0$, $*K_{d_0}$ can be calculated from the following equation:

$$K_{d_0}=*K_{d_0}/(1+*K_1[H^+]^{-1})$$
or $$*K_{d_0}=K_{d_0}(1+*K_1[H^+]^{-1}) \quad (15)$$

Equation 14 can be made analogous to Eq. 4 by substituting $L_1$ and $\beta_j$ for $(L_1+L_1')$ and $B_j$ respectively. Similarly, the following equations are obtained instead of Eqs. 5, 6, 7, 8 and 9 respectively:

$$f_1=(K_d^{-1}-K_{d_0}^{-1})/[A^-] \quad (16)$$
$$\lim_{[A]\to 0} f_1=f_1^0=[B_1-(L_1+L_1')\times(1+*K_1[H^+]^{-1})]/*K_{d_0} \quad (17)$$
$$[*K_{d_0}/K_d-(1+*K_1[H^+]^{-1})]/[A^-] = B_1+B_2[A^-]+\cdots\cdots \quad (18)$$
$$f_2=(f_1-f_1^0)/[A^-] \quad (19)$$
$$\lim_{[A]\to 0} f_2=f_2^0 = [B_2-L_2-(L_1+L_1')f_1^0*K_{d_0}]/*K_{d_0} \quad (20)$$

In the case of an acetate system, the ratios of ligands to scandium can be determined, but the chemical formulae and the formation constants for the corresponding complex ions can not be estimated unless either $\beta_j$ or $\beta_j'$ are estimated.

—◐— $C_M'=2.9\times10^{-5}$ mol./l.
Broken line curve: Total concentration of Sc(III) in resin phase, $C_{MR}=1\times10^{-4}$ mol./l.

Figure 2 shows the dependence of $K_d$ on the acetate ion concentrations and the scandium concentrations, when the ionic strength is kept constant at 0.5 in a sodium perchlorate solution and at pH 4.5. The acetate ion concentration of the solution was calculated from the added acetate concentration, the pH of the solution and the dissociation constant of acetic acid.** In all of the above equations, $[A^-]$ represents the concentration of free acetate ions. However, since the total acetate ion concentration is very much larger than the total scandium

ion concentration, $[A^-]$ can be substituted for the total acetate ion concentration, $[Ac^-]$.

The scandium concentration in the resin phase was selected as $1\times10^{-4}$ mmol./g. resin, so that the total concentration in the resin phase might be kept constant. The relation between $K_d$ and the scandium concentration in the resin phase at a constant value of $[Ac^-]$ is presumed to be practically linear when graphically represented. Therefore, it is easy to determine the values of $K_d$ corresponding to a constant and low value of $C_{MR}$ by graphical interpolation. The resultant value of $K_d$ is shown as a broken-line curve in Fig. 2 and in the second column of Table I.

The value of $K_{d_0}$ was determined by graphical extrapolation. Since $1/K_d$ plotted against $[Ac^-]^2$ was shown to be a straight line at a low concentration of $[Ac^-]$, by extrapolation to $[Ac^-]=0$ the value of $K_{d_0}$ was found to be 204 ml./g. Therefore, $^*K_{d_0}$ was calculated from Eq. 15 to be 286 ml./g.

In order to get the values of $(L_1+L_1')$ and $L_2$, an approximate value of $B_1$ was calculated according to Eq. 18. The calculated values of approx. $X_1'=[^*K_{d_0}/K_d-(1+{}^*K_1[H^+]^{-1})]/[Ac^-]$ are plotted as a function of $[Ac^-]$ in curve 1 of Fig. 4; by graphical extrapolation to $[Ac^-]=0$, $B_1$ was found to be $22\pm10$ $mol^{-1}$ l. On the other hand, as is shown in Fig. 3, the relation between $f_1$ and $[Ac^-]$ is practically linear at $[Ac^-]\leq9.07\times10^{-2}$ mol./l., and $f_1^0$ was found to be $(30\pm6)\times10^{-3}$ g. $ml^{-1}$ $mol^{-1}$ l. Accordingly, the value of $(L_1+L_1')=9\pm2$ $mol^{-1}$ l. was obtained from Eq. 17.

Therefore, on substituting numerical value for the $L_1+L_1'$ quantity into Eq. 14 the $X'$ function may be shown as:

$$X'={}^*K_{d_0}(1+9[Ac^-])/K_d \qquad (21)$$

The values of $f_2$ calculated from Eq. 19 are plotted as a function of $[Ac^-]$ in Fig. 3. The $f_2^0$ value obtained by the extrapolation of $f_2$ to $[Ac^-]=0$ was $4.93\pm0.04$ g. $ml^{-1}$ $mol^{-2}$ $l^2$. On the other hand, the approximate value of $B_2$ at $[Ac^-]\leq9.07\times10^{-2}$ mol./l. was found to be $(15\pm7)\pm10^2$ $mol^{-2}$ $l^2$ by the extraporation of curve 4 in Fig. 4 plotted from the relation between $X_2'=(X_1'-22)/[Ac^-]$ and $[Ac^-]$. Then the value of $L_2$ was given as almost zero by calculating from Eq. 20.

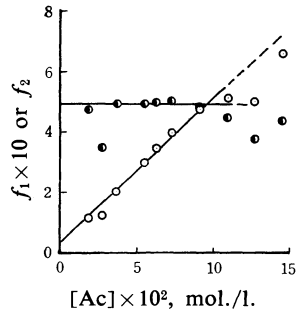

Fig. 3. $f_1$ and $f_2$ as a function of acetate ion concentration.
—○— $f_1$ —◐— $f_2$

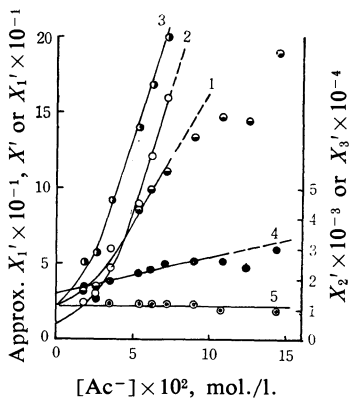

Fig. 4. Approximate $X_1'$ and $X_j'$ as a function of acetate ion concentration.
1: Approx. $X_1'$, 2: $X'$, 3: $X_1'$, 4: $X_2'$, 5: $X_3'$.

The functions $X'$ calculated are shown in Fig. 4 and in Table I. By the extrapolation of $X_1'$ and $X_2'$ to $[Ac^-]=0$, $B_1$ and $B_2$ agreed, of course, with the values of the first approximation. The function $X_3'$ in curve 5 of Fig. 4 and in the sixth column of Table I has been calculated for such $[Ac^-]$ values in which the difference $X_2'-B_2$ is not small compared with $B_2$. By the extraporation of $X_3'$ to $[Ac^-]=0$, $B_3$ was determined to be $(11\pm3)\times10^3$ mol.$^{-3}$ l$^3$. No value of $B_4$ can be obtained from this experiment.

From the results obtained it appears that the species with scandium to ligand ratios of 1 : 1, 1 : 2 and 1 : 3 are formed in an acetate solution with pH=4.5, while the species with the ratio of 1 : 2, $Sc(Ac)_2^+$ or $Sc(OH)(Ac)_2$ or both $Sc(Ac)_2^+$ and $Sc(OH)(Ac)_2$, appear to the predominant species in the acetate system under the experimental conditions, judging from the determined values of the formation constants.

**On the Compositions and Formation Constants of Scandium Sulfate Complexes.** — Figure 5 presents a plot of the $K_d$ value versus the sulfate ion concentration. The experiment was carried out at a constant ionic strength of $\mu=0.5$ and at pH 2.7. The values of $f_1$ calculated according to Eq. 5 are plotted as a function of $[SO_4^{2-}]$ in Fig. 6; the extrapolated value of $f_1$ was found to be $(6.8\pm0.1)\times10^{-2}$ g. ml$^{-1}$ mol$^{-1}$ l. The values of approx. $X_1=(l_0/K_d-1)/[SO_4^{2-}]$ versus $[SO_4^{2-}]$ are shown in Fig. 6. The approximate formation constant, $\beta_1=39.2\pm0.3$ mol$^{-1}$ l., was easily found by extrapolating the approx. $X_1$ to $[SO_4^{2-}]=0$ at $[SO_4^{2-}]\leq2.79\times10^{-2}$ mol./l. Then the value $L_1=3\pm1$ mol$^{-1}$ l. was calculated from Eq. 6.

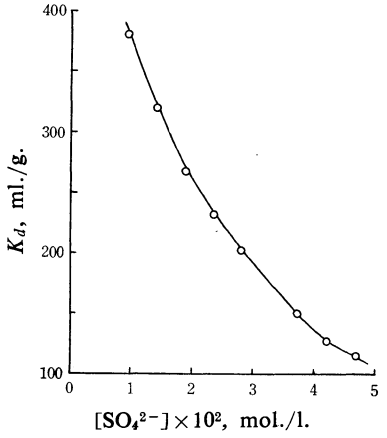

Fig. 5. $K_d$ as a function of sulfate ion concentration.

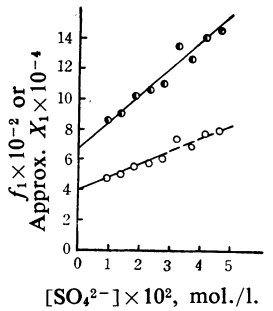

Fig. 6. $f_1$ and approximate $X_1$ as a function of sulfate ion concentration.
◐ $f_1$ ○ Approx. $X_1$

On substituting the value $L_1$ into Eq. 12, the function $X$ can be calculated; by the extrapolation of $X_1$ to $[SO_4^{2-}]=0$, the more accurate value of $\beta_1$ was found, $46\pm5$ mol$^{-1}$ l. Then the value $L_1=8\pm1$ mol$^{-1}$ l. was estimated. For the next approximation, the same procedure was repeated; the $\beta_1$ value obtained was practically the constant value. The function $X$ may, then, be shown as follows:

$$X=l_0(1+8[SO_4^{2-}])/K_d \qquad (22)$$

The functions $X$ calculated from Eq. 22 are shown in Table II and in Fig. 7. The $\beta_1$, $\beta_2$ and $\beta_3$ formation constants were found to be $46\pm5$ mol$^{-1}$ l., $(11\pm6)\times10^2$ mol$^{-2}$ l$^2$ and $(10\pm7)\times10^3$ mol$^{-3}$ l$^3$ respectively.

## Summary

Ion exchange equilibria between the cation exchange resin, Amberlite IR-120, and an aqueous solution containing a small concentration of scandium ions and a relatively large concentration of acetate or sulfate ions have been measured at a constant ionic strength of $\mu=0.5$ and at 25°C. The values of the formation constants of the complexes in solution have been calculated by the application of the Fronaeus method[3] and by the graphical method.[5]

In the case of the acetate system, at an acetate ion concentration $[Ac]\leq14.5\times10^{-2}$ mol./l. and pH 4.5, species with scandium to ligand ratios of 1:1, 1:2 and 1:3 seem to be formed. However, since scandium exists mainly in two ionic species, $Sc^{3+}$ and $Sc(OH)^{2+}$, in the solution, the chemical formulae can not be determined; therefore, the formation constants have been estimated for the addition of each formation constant of two complexes with the same ligand ratio, $Sc(Ac)_j^{3-j}$ and $Sc(OH)(Ac)_j^{2-j}$. The values of $B_j=(\beta_j+\beta_j'{}^*K_1[H^+]^{-1})$ were $B_1=22\pm10$ mol$^{-1}$ l., $B_2=(15\pm7)\times10^2$ mol$^{-2}$ l$^2$ and $B_3=(11\pm3)\times10^3$ mol$^{-3}$ l$^3$ at pH 4.5. In the case of the sulfate system, three complex ions were formed at a sulfate ion concentration of $[SO_4^{2-}]\leq4.65\times10^{-2}$ mol./l. and pH 2.7: $Sc(SO_4^{2-})^+$, $Sc(SO_4^{2-})_2^-$ and $Sc(SO_4^{2-})_3^{3-}$. The formation constants were $\beta_1=46\pm5$ mol$^{-1}$ l., $\beta_2=(11\pm6)\times10^2$ mol$^{-2}$ l$^2$ and $\beta_3=(10\pm7)\times10^3$ mol$^{-3}$ l$^3$.

The author is grateful to Professor Jun Yoshimura, of Kyushu University, for his suggestions and encouragement; he also wishes to thank Mr. Tokio Aihara, Kurita Chemical Industry Co., Ltd., for his valuable assistance during the measurements.

# Studies of Thio Acids. III.[1] The Ultraviolet Absorption Spectra of Thiostearic Acid and Related Compounds*1

By Yoshio HIRABAYASHI and Tetsuro MAZUME*2

(Received December 26, 1963)

The ultraviolet absorption spectrum of thioacetic acid has been studied by Hantzsch,[2] Cunneen[3] and Koch.[4] However, no studies of the ultraviolet absorption spectra of higher aliphatic thio acids have yet been published.

The present authors have, therefore, investigated the ultraviolet absorption spectra of thiostearic acid,[5] its derivatives, and thioacetic acid. An absorption maximum of thiostearic acid appears at 221 mμ in a cyclohexane solution, while a low-intensity absorption appears at 260—290 mμ. The latter is assumed to be an R-band due to the C=O group. Similar phenomena have been observed with thioacetic acid and methyl thiostearate. An absorption maximum of thiostearic acid appears at 223 mμ in an ethanol solution, and in lower concentrations another absorption maximum

appears at 250 mμ, which is probably due to the mesomeric anion produced by the dissociation. Similar phenomena have been observed with thioacetic acid and potassium thiostearate in ethanol.

## Results and Discussion

**The Spectra of the Solution in Cyclohexane.** —*Thiostearic Acid and Thioacetic Acid.*—The ultraviolet absorption spectrum of thiostearic acid in cyclohexane shows a band with its maximum at 221 mμ (ε, 1800).[5] The shape of the absorption curve is in good accord with that of thioacetic acid measured in cyclohexane by Cunneen.[3] However, at higher concentrations, an inflection was observed in the region 260—290 mμ (see Fig. 1). The ε value at 275 mμ is nearly 40. This low-intensity absorption band in the region 260—290 mμ is not due to impurities, as is proved by the following observations. The thiostearic acid used for the measurement has a purity of more than 99%; the impurities which could not be separated by recrystallization are stearic acid and distearoyl disulfide.[5] Distearoyl disulfide has an absorption in the region 260—290 mμ; $\lambda_{max}$=224 mμ, ε=4260 in cyclohexane (cf. Fig. 2). Distearoyl disulfide (10%) was added to the sample of thiostearic acid, and the ultraviolet absorption spectrum of the mixture in cyclohexane was measured (Fig. 1). The absorption band slightly shifts toward a longer wavelength and is intensified, but the inflection in the region 260—290 mμ is not intensified.

The ultraviolet absorption spectrum of thioacetic acid reported by Cunneen[3] indicated no absorption at 260—290 mμ. However, according to the present authors' measurements, in the ultraviolet absorption spectrum of thioacetic acid in cyclohexane as well (Fig. 2, $\lambda_{max}$=220 mμ, ε=1660), an inflection was observed in the region 260—290 mμ at higher concentrations (ε=24 at 270 mμ).

Koch[4] explained that the absorption band at 220 mμ is undoubtedly associated with the sulfur-carbonyl conjugation (between the non-bonding ($3p^2$) electron pair of the sulfur atom and the π electrons of the carbonyl group), involving contributions from the polar canonical structure*3 I in the excited state. As to the assignment of this band, the authors agree with Koch's opinion. However, the low-intensity absorption (inflection) at a longer wavelength measured by the present authors has never been discussed. The authors suppose that this absorption is an R-band due to the C=O group.

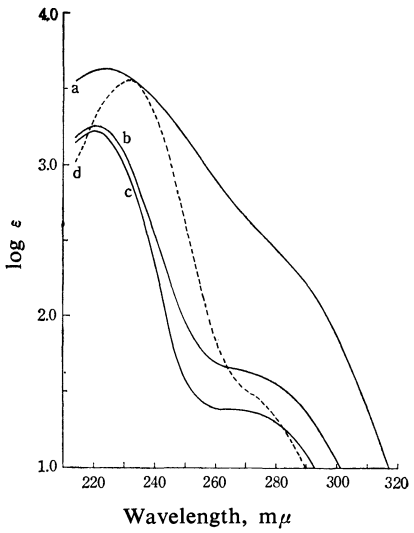
Thiostearic acid (- - -): a, 1.0; b, 2.0 g./l. solution.
Thiostearic acid containing distearoyl disulfide (10%) (——): c, 1.0; d, 2.0 g./l. solution



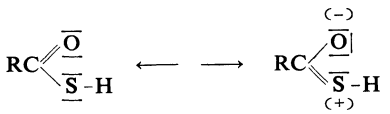


Fig. 2. Ultraviolet absorption spectra in cyclohexane.
a : Distearoyl disulfide
b : Thiostearic acid
c : Thioacetic acid
d : Methyl thiostearate

*3 Electron-diffraction bond-length measurements by Gordy suggest that I makes only a very slight contribution to the ground state of thioacetic acid (W. Gordy, *J. Chem. Phys.*, **14**, 560 (1946)).

*Methyl Thiostearate.*—The ultraviolet absorption spectrum of methyl thiostearate in cyclohexane is shown in Fig. 2 ($\lambda_{max}$=231 m$\mu$, $\varepsilon$=3560). The absorption band at 231 m$\mu$ is undoubtedly associated with the sulfur-carbonyl conjugation. Probably the low-intensity absorption (inflection) at 265—290 m$\mu$ is an R-band due to the C=O group.

**The Spectra of the Solution in Ethanol.**—*Thiostearic Acid and Thioacetic Acid.* — The ultraviolet absorption spectrum of thiostearic acid in ethanol (98 wt.%) is shown in Fig. 3. At lower concentrations, the position and intensity of the absorption band at 223 m$\mu$ remain almost unchanged and a large inflection appears near 250 m$\mu$. In further dilutions, the second absorption maximum (248 m$\mu$) appears; its intensity varies, depending on the concentration (see Table I).

These phenomena were found not only in such higher thio acids as thiostearic acid, but also in thioacetic acid. The ultraviolet absorption spectrum of thioacetic acid in ethanol is shown in Fig. 4. Absorption maxima appear in the regions 218—222 and 248—249 m$\mu$ as is shown in Table I.

| 1.64 | 221 | 2830 | 248 | 3140 |
| 0.82 | 218 | 2820 | 249 | 4560 |

*Potassium Thiostearate.* — The ultraviolet absorption spectrum of potassium thiostearate in ethanol is shown in Fig. 5. At lower concentrations, only one absorption maximum appears, at 251 m$\mu$ ($c=9.30\times10^{-5}$ mol./l., $\varepsilon$=7610). At higher concentrations, another maximum appears in the region 290—350 m$\mu$.

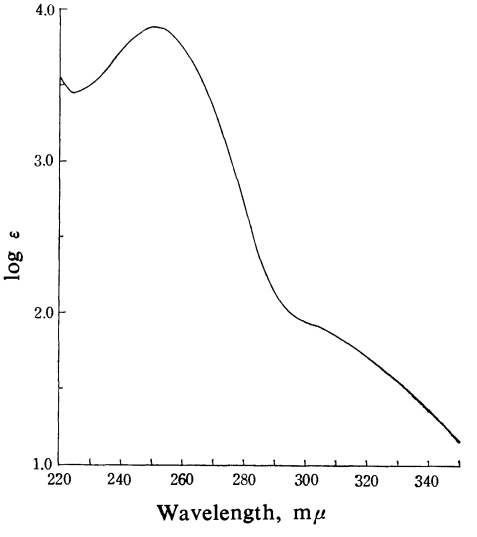

Fig. 5. Ultraviolet absorption spectrum of potassium thiostearate in ethanol.
Concn.: 220—280 m$\mu$, $9.30\times10^{-5}$ mol./l.
280—350 m$\mu$, $3.72\times10^{-3}$ mol./l.

The results obtained above show that in the spectra of thio acids or its salts, which are dissociable to $RC\overset{O}{\underset{S}{<}}(-)$ and $H^+$ or $K^+$, an absorption maximum appears at 250 mμ in ethanol. Furthermore, in the spectra of thiostearic acid and thioacetic acid, the absorption at 250 mμ does not obey Beer's law, but increases in intensity in higher dilutions. In view of thess facts, it may be concluded that, in ethanol, thio acids are partly dissociated to produce the mesomeric anion III, which in turn causes the absorption at 250 mμ. The water content in ethanol probably has a great effect on the dissociation. On the other hand, the absorption at 223 mμ due to undissociated acid (II) obeys Beer's law approximately within the range of measuring concentrations. This behavior of the absorption at 223 mμ would appear to be apparently inconsistent with the above conclusion. This apparent discrepancy can be satisfactorily explained by considering the following two reasons together: first, the degree of the disociation of thio acid in ethanol is very low, so that the decrease in undissociated acid caused by the increasing dilution is very small; secondly, the absorption band at 223 mμ is partially superposed by that of the mesomeric anion, which has a high-intensity absorption at 250 mμ.

Potassium thiostearate is more ionized in ethanol. The anomaly at 290—300 mμ in a higher concentration observed in the spectrum of potassium thiostearate is probably related to the thionic acid form reported by Hantzsch.[2] This problem will be discussed in the future.

(III)

## Experimental

**Ultraviolet Absorption Spectra.** — A Shimadzu quartz spectrophotometer, model QB-50, and a silica cell (1 cm.) were used (measuring temperature 26±1°C).

**Methyl Thiostearate.** — Thiostearic acid (3.5 g.) in absolute ethanol (350 ml.) was neutralized with ethanolic potassium hydroxide. Methyl iodide (15 g.) was added to the above solution, and the mixture was refluxed for 6 hr. and extracted with ether after the ethanol had been distilled off. The ether layer was washed with a diluted potassium carbonate solution and water succesively and dried over anhydrous sodium sulfate, and the ether was distilled off. The residue (yield 3.2 g.) was recrystallized from methanol to give colorless needles (m. p. 50.3—50.8°C) (yield 1.5 g.), which corresponded with the product obtained by Ralston in another way.[6]
(Found: S, 10.14. Calcd. for $C_{19}H_{38}OS$: S, 10.19%).

**Thioacetic Acid.** — Prepared from phosphorus pentasulfide and glacial acetic acid and purified by Kitamura's[7] method (b. p. 88.0—88.5°C).
(Found: S, 41.80 (Kitamura's method). Calcd. for $C_2H_4OS$: S, 42.13%).

# Studies of Thio Acids. IV.[1] Dipole Moments of Methyl Thiostearate, Thiostearic Acid and Thioacetic Acid*1

By Yoshio HIRABAYASHI

(Received May 22, 1964)

The acyl-thiol structure, RCO·SH, of aliphatic thio acids previously studied, e.g., thioacetic acid[2,3] and thiostearic acid,[4] has been confirmed by infrared absorption and other physical data. Furthermore, their molecular structures have been elucidated by the bond-length measurements[5] of electron diffraction. However, no study of the dipole moments of thio acids and their esters has yet been reported.

In this paper, the dipole moments of thiostearic acid, methyl thiostearate, and thioacetic acid (each of which has the thiol form) are measured, and some discussion on their molecular structures will be presented.

## Experimental*2 and Results

**Materials.**—The samples used in the present investigation were prepared according to the procedure previously described and were carefully purified. They are:

Thiostearic acid:[4] m. p. 39.8—40.3°C; neutralisation value 186.0; S, 10.60%.

Methyl thiostearate:[1] m. p. 50.3—50.8°C; S, 10.14%.

Thioacetic acid[1]: b. p. 88.0—88.5°C; S, 41.80%.

All the solvents, *n*-hexane, benzene, and dioxane, used for the measurement of dipole moments were purified according to the methods given in "Organic Solvents."[6]

**Measurement.**—The densities, $d$, and the dielectric constants, $\varepsilon$, of solutions of various concentrations were measured with a picnometer and an apparatus which consists of a fixed-frequency (3 Mc.) crystal oscillator and a variable-frequency oscillator with a cell (ca. 45 pF in capacity) for the measurement of the dielectric constant. The tuning points of the variable-frequency oscillator with the fixed-frequency oscillator were determined by a Lissajous' figure on a cathode-ray oscilloscope. The frequency used for the measurements was 1 Mc., and all measurements were made at 30.0°C.

The specific solute polarization, $p_{2\infty}$, (at an infinite dilution) was calculated by the following

TABLE I. DIPOLE MOMENTS OF METHYL THIOSTEARATE, THIOSTEARIC ACID AND THIOACETIC ACID

| Solvent | $\varepsilon_\infty$ | $d_\infty$ (g./cc.) | $a$ | $b$ (g./cc.) | $p_{2\infty}$ (cc./g.) | $P_{2\infty}$ (cc.) | $\mu$ (D) |

formula, derived from Halverstadt-Kumler's method:[7]

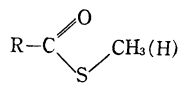
$$p_{2\infty}=\frac{\varepsilon_\infty-1}{\varepsilon_\infty+2}\cdot\frac{1}{d_\infty}\left[1+\frac{3a}{(\varepsilon_\infty-1)(\varepsilon_\infty+2)}-\frac{b}{d_\infty}\right]$$
$$\varepsilon=\varepsilon_\infty+aw,\quad d=d_\infty+bw$$

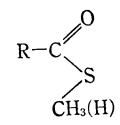
where $\varepsilon_\infty$ and $d_\infty$ are extrapolated values, at the concentration of 0, for $\varepsilon$ and $d$ respectively. The values of $a$ and $b$ are the coefficients of the linear expansion of the dielectric constant and the density of the solution with respect to the weight fraction of the solute, $w$, respectively.

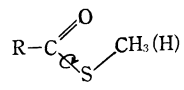
The dipole moment, $\mu$, is then given by the following equation:

$$\mu=0.0128\ [(P_{2\infty}-R'_D)\cdot T]^{1/2}$$

where $P_{2\infty}=M_2\cdot p_{2\infty}$ is the solute molar polarization at an infinite dilution, $M_2$ is the molecular weight of the solute, and $T$ is the absolute temperature. The sum of the electronic ($P_E$) and atomic ($P_A$) polarization was assumed to be equal to the molar refraction, $R'_D$, for the sodium D line calculated by adding the bond refractions[8] of the constituent atoms and bonds.







The results are shown in Table I.

## Discussion

The molecular structures of methyl thiostearate, thiostearic acid, and thioacetic acid may now be discussed on the basis of the dipole moments obtained by the above measurements.

Three models for the spacial configurations of thio acids and their methyl esters have been selected and are shown as I, II, and III of Table II. In configurations I and II, the

TABLE II. RESULTANT MOMENTS OF THIO ACID AND ITS ESTER

| Configuration | Resultant moment: Ester | Acid |
|---|---|---|
| I  | $1.1_8$ | $1.6_4$ |
| II  | $3.5_8$ | $2.9_5$ |
| III  | $2.3_4$ | $2.2_9$ |

C–C, C=O, C–S, and S–$C_{CH_3}$ or S–H bonds are all coplanar, and the S–$C_{CH_3}$ or S–H bond is fixed on the same side as the C=O bond in configuration I, while it is on the opposite side in configuration II. Configuration III corresponds to the case of free rotation about the C–S bond (the C–C(=O)–S group being assumed to be coplanar). The moments calculated by using the bond moments derived from the textbook of Smyth[9] and from the following valence angles are given in Table II for each configuration: H–C, 0.4; H–S, 0.68; C–S, 0.9; C=O, 2.3 D; the moment of $C_{17}H_{35}$–C or $CH_3$–C is assumed to be 0.4 D. The valence angles, ∠C–C=O (=125°), ∠C–C–S (=110°), and ∠O=C–S(=125°), are assumed to be the same as those of $CH_3COSH$,[10] and the valence angles, ∠C–S–$C_{CH_3}$(=105°) and ∠C–S–H(=100°), are set equal to the values of R–S–R[11] and R–SH[12] respectively.

**Methyl Thiostearate.**—The dipole moments ($\mu$) measured in the solvents were 1.30 D(H), 1.37 D(B), and 1.37 D(D). The orientation polarization is not very large; the observed values, therefore, depend relatively upon the assumed values of the $P_E+P_A$. When the sum of the $P_E$ and $P_A$ is assumed to be equal to the 1.05 $R'_D$ or 1.10 $R'_D$, the observed values become as follows:

$\mu'$(for 1.05 $R'_D$): 1.21 D(H); 1.28 D(B); 1.28 D(D)

$\mu''$(for 1.10 $R'_D$): 1.10 D(H); 1.18 D(B); 1.18 D(D)

Although these data are still insufficient to enable us to discriminate whether the solvent effect is positive or negative, the order of this effect may be estimated by the following values, which are obtained when a plot of $\mu$, $\mu'$, or $\mu''$ versus $(\varepsilon_\infty-1)^2$, or $(\varepsilon_\infty-1)/(\varepsilon_\infty+2)$ is extrapolated to $\varepsilon_\infty=1$:

For $(\varepsilon_\infty-1)^2$: $\mu_e=1.22$ D, $\mu'_e=1.13$ D, $\mu''_e=1.02$ D

For $(\varepsilon_\infty-1)/(\varepsilon_\infty+2)$: $\mu_{e'}=1.06$ D, $\mu'_{e'}=0.95$ D, $\mu''_{e'}=0.83$ D

As a result, the dipole moment of this molecule is found to be 1.1±0.3 D.

On the other hand, since the induction effect is left out of consideration for the calculated values given in Table II, the moments induced at each bond by the C=O dipole should, of course, be taken into consideration. While

the quantitative values of these induced moments are not known at present, the calculated values given in Table II may not be grossly in error (possibly to within 20%) for the moments corresponding to configuration I since an intramolecular compensation of this effect seems to occur; the values for configurations II and III, on the other hand, will become somewhat larger than the values given in Table II, since no intramolecular compensation of this effect seems to occur with them.

On the basis of the above consideration of the observed and the calculated values, configuration I seems to be the most probable of the three possible configurations for methyl thiostearate. Furthermore, though it is still unknown whether or not the S–$C_{CH_3}$ bond is fixed in the  plane in configuration I, it seems reasonable, from a consideration of its resonance structures and of its electrostatic potential, to assume that the S–$C_{CH_3}$ bond is fixed in the  plane as in configuration I.

**Thiostearic Acid and Thioacetic Acid.**—Thiostearic acid is considerably stable and remains almost unchanged in solvents at room temperature. On the other hand, an authentic sample of thioacetic acid is rapidly changed with a decrease in its sulfur content. Even when much care was taken in the treatment of the latter, some change in the quality was inevitable.

The dipole moments measured were 2.06D(H), 2.14 D(B), and 2.21 D(D) for thiostearic acid, and 2.12 D(H), 2.16 D(B), and 2.36 D(D) for thioacetic acid. In carboxylic acids, the dipole moments measured in benzene or hexane have sometimes been different from those in dioxane, and it is known that two molecules of carboxylic acids associate in benzene or hexane by hydrogen bonds.[13] For thio acids, however, the presence of only a slight solvent effect in the observed dipole moments suggests that such association by hydrogen bonds does not take place to any appreciable extent.

In the case of thio acids, for which the orientation polarizations are large, the decreases in the observed values are only 0.1 D for thiostearic acid, and about 0.02 D for thioacetic acid, when the sum of $P_E$ and $P_A$ is assumed to be equal to $1.10\,R'_D$. Furthermore, by a treatment similar to that used in the case of methyl thiostearate, the following values are obtained:

For thiostearic acid: $\mu_e=1.95$ D; $\mu_{e'}=1.82$ D

For thioacetic acid: $\mu_e=1.96$ D; $\mu_{e'}=1.82$ D

The dipole moments are thus found to be $1.9\pm0.2$ D for both molecules.

The obtained values are somewhat too large and too small respectively for the  group to be planar with configurations I and II.

As for the structures of thio acids, either of the following four cases appears reasonable judging from their observed values: A. configuration I; B. a configuration in which the S–H bond is located at a certain angle to the  plane from configuration I;*3 C. the coexistence of configurations I and II; D. configuration III. However, the free rotation (D) is not probable in view of its electrostatic potential and in view of the fact that its resonance structures are similar to those of the ester. The other three structures (A, B, C) may be suitable; it seems difficult at present to determine which of the three is the most reasonable.

## Summary

The dipole moments of methyl thiostearate, thiostearic acid, and thioacetic acid have been measured in *n*-hexane, benzene, and dioxane solutions at 30°C. The values obtained are; methyl thiostearate, $1.3_0$ D (*n*-hexane), $1.3_7$ D (benzene), $1.3_7$ D (dioxane); thiostearic acid, $2.0_6$ D (*n*-hexane), $2.1_4$ D (benzene), $2.2_1$D (dioxane); thioacetic acid, $2.1_2$ D (*n*-hexane), $2.1_6$ D (benzene), $2.3_6$ D (dioxane). On the basis of the above results, a planar configuration similar to the cis configuration of carboxylic ester is considered to be the most probable structure of methyl thiostearate; three probable alternative configurations have been suggested for the structure of thio acid.

The author wishes to express his sincere appreciation to Mr. Kotobuki Watanabe and Mr. Hideo Uchihiro for their assistance in carrying out the experiments. He is also indebted to Dr. Tetsuro Mazume for his invaluable guidance and encouragement.

*3 For the configuration in which the S-H bond is fixed on the plane perpendicular to the  plane, the resultant moment should be $2.3_9$D.

# The Near-infrared Absorption Spectra of Lanthanide Chlorides Dissolved in Molten LiCl-NaCl-KCl Eutectic

By Masato MAMIYA

(Received February 26, 1964)

The observation of the absorption spectra of fused metal salt with[1-12] or without[13-15] the addition of a diluent has recently become a powerful means for analyzing or identifying the metallic constituents of the salts.

This investigation is concerned with the determination of molar absorptivities for significant absorption bands from the near-infrared absorption spectra of lanthanide chlorides dissolved in molten alkali chloride eutectic solvents.

A previous report on the spectra of several lanthanide chlorides in a fused LiCl-KCl eutectic solution was limited to the visible and ultraviolet regions.[7] Similar studies in the visible region have been carried out in molten LiF-KF[5,6] and in $LiNO_3$-$KNO_3$ eutectics.[2] Recently, the near-infrared absorption spectra of lanthanides in molten $LiNO_3$-$KNO_3$ eutectic and in a deuterium perchloric acid solution have been observed by Carnall and his associates.[9]

There are, of course, many different fused salt systems in which a spectrophotometric study could be made; most of the work has thus far been done in alkali fluorides, chlorides, nitrates and sulfates. In this paper, the fused LiCl-NaCl-KCl eutectic was used because of the advantage of its optical transparency in the near-infrared region and its relatively low melting point (about 333°C).

Several characteristic absorption bands of praseodymium, neodymium, samarium, dysprosium holmium, erbium, thulium and ytterbium in this medium were observed in the region from 0.8 to 2.6 $\mu$. These near-infrared data will be compared with similar results which have been obtained in molten nitrate[9] and deuterium oxide solutions.[16]

## Experimental

**Apparatus.** — The spectral measurements were made using a Cary recording spectrophotometer, Model 14M, equipped with the high-temperature cell assembly described in a previous report by the present author.[12] The furnace was designed for high temperature investigation in the near-infrared region. Temperature control to ±2°C at 400°C was achieved with an electronic thermocouple control unit on a Chino automatic thermometer, Modell 600, and temperatures were measured with a platinum-platinum rhodium thermocouple (0°C cold junction) placed near the sample. The optical absorption cells used were fused quartz cells with 10.0 and 2.0 mm. light paths.

**Alkali Chlorides Eutectic.** — In most of the reported spectrophotometric studies of solutions of several chloride salts, a LiCl-KCl mixture with a composition close to that of eutectic (about 59 mol.% LiCl m. p. 350°C) has been used. The solvent used in this study was a eutectic mixture of LiCl-NaCl-KCl (49.0 - 17.3 - 33.7 mol.%, m. p. 333°C) which melts at a lower temperature than the above binary mixture.

In order to obtain clear sample solutions, free of oxidation and precipitation products, the eutectic had to be anhydrous. Since water has an appreciable solubility in the eutectic, even at 500°C, it is very difficult to achieve complete dehydration by vacuum fusion alone. Various techniques have been described for preparing anhydrous melts, techniques which involve treatment while dry hydrogen chloride gas is blown in to the molten salts.[3,17] The pure alkali chlorides eutectic pellets were dehydrated and purified by the bubbling method proposed by Gruen and McBeth.[2]

**Sample Preparation.**—The lanthanides used were obtained commercially in the form of oxides with a stated purity higher than 99.0%. The dried

lanthanide oxides were weighed and then dissolved in a minimum of hydrochloric acid. These solutions were evaporated to dryness by heating them at 200°C for two hours under an atmosphere of flowing nitrogen gas. A weighed amount of the appropriate lanthanide chloride was placed in the spectrophotometer cell with the desired amount of the purified eutectic pellets, and the cell was heated to 400°C under the above conditions.

The lanthanide dissolved when the molten eutectic solution was stirred with bubbles of dry nitrogen gas from a tube inserted in the cell. If water and oxygen remain in the eutectic solvent, lanthanide chloride reacts with these, water, and oxygen to form lanthanide oxychloride, which is not soluble in the molten salt solution. This insoluble matter may, however, be brought into the solution by the addition of a few grams of ammonium chloride. This salt acts as an acid in the chloride melt and dissolves the insoluble lanthanide compound when nitrogen is bubbled at 450°C for 1 to 2 hr.

Figure 1 shows the absorption characteristics of

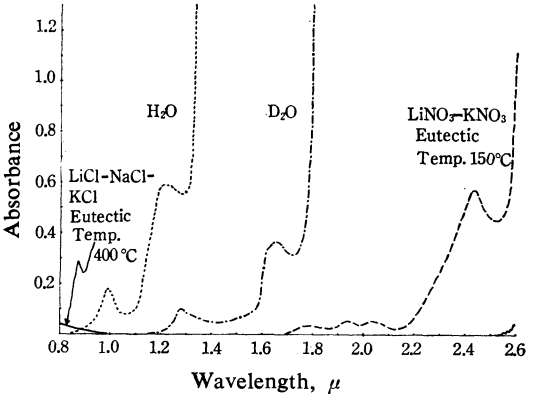

Fig. 1. Absorption characteristics of water, deuterium oxide, $LiNO_3$-$KNO_3$ and LiCl-NaCl-KCl in the near infrared region using quartz cell with 10.0 mm. path length.

the pure LiCl-NaCl-KCl eutectic melt in a 10.0 mm. fused quartz cell for the range between 0.8 and 2.6 $\mu$ at 350°C, together with the absorption characteristics of water, deuterium oxide, and $LiNO_3$-$KNO_3$ eutectic in this range. The pure alkali chloride eutectic mixture has no absorption band, and other solvents absorb strongly in the near-infrared region, but the deuterium oxide and molten alkali nitrate solvents were seen to have a wide range of transparency. The absorption increase in alkali chloride eutectic (shown in Fig. 2) at wavelengths shorter than 1.0 $\mu$ arises from the optical cell etching caused by the impurity in the eutectic salts at temperatures above 600°C, but below 550°C the polished quartz cell was not etched, even after repeated measurements. The effect of temperature on a blank run is not observed at temperatures below 500°C, but at high temperatures, above 550°C the polychromatic radiation from an emitting eutectic medium and furnace is accepted by the signal amplifier, resulting in increased transmittance signals.

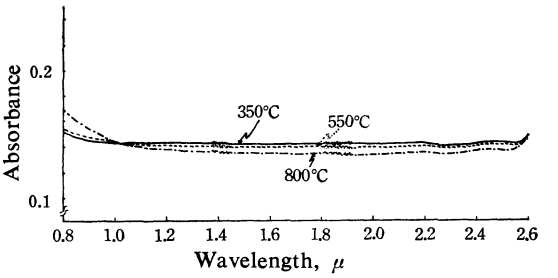

Fig. 2. Absorption base lines of LiCl-NaCl-KCl eutectic at several temperatures.

A correction for emission becomes necessary for wavelengths above approximately 1.0 $\mu$.

The ratio of the energy emitted by the furnace and the sample to that emitted by the light source is given in Plank's equation:

$$E_{\lambda T_1}/E_{\lambda T_2}=(e^{1.43/\lambda T_2}-1)/(e^{1.43/\lambda T_1}-1)$$

where $\lambda$ is the wavelength, $T_1$ the temperature of the light source, and $T_2$ the temperature of the furnace and the sample. This calculated value is not the same as the experimentally determined value.[8] The discrepancy undoubtedly is due to the fact that the assumption of equal emitting values made in Plank's equation is inadequate for this particular experiment.

The correction for radiation from the molten salts solution, cell and furnace at a high temperature was made by the base line method.[2]

The experimental results are plotted in terms of molar absorptivity, $\varepsilon=\log(I_0/I)cd$, where $I_0/I$ is the intensity ratio of the incident to the transmitted light beam, $c$ the molar concentration, and $d$ the light path length. Molar concentrations were calculated from density values of Van Artsdalen and Yaffe who have determined the values for the LiCl, NaCl, KCl and LiCl-KCl eutectics. Their value of 1.69 g. per cubic centimeter at 400°C was used in calculating the molarity of each molten LiCl-NaCl-KCl eutectic.

In each case, the absorption bands of lanthanide in the alkali chloride eutectic was determined by a comparison of the spectra of the sample and of the solvent. Thus, the blank run was measured by recording first the characteristic spectrum of a cell containing the pure eutectic solution vs. air as the reference, and then sample spectra were measured by running the same cell containing the desired concentration of the lanthanide vs. air. All the absorption bands were scanned at speeds commensurate with their sharpness to obtain a reliable value at the position of the absorbance maximum.

## Results and Discussion

The absorption spectra of fourteen lanthanide chlorides, from lanthanum to lutetium (except. promethium), in the molten LiCl-NaCl-KCl eutectic media have been measured at temperatures 400±2°C in the range from 0.8 to 2.6 $\mu$.

Of these, it was found that praseodymium, neodymium, samarium, dysprosium, holmium, thulium and ytterbium each have a characteristic absorption band, as is shown in Figs. 3 to 5. Near-infrared absorption bands of lanthanide ions arise from electronic transitions within the inner shell 4f-configurations, as is the case with their visible and ultraviolet absorption bands, with few exceptions.

Lanthanum and lutetium lie at the extremes of the lanthanide group, the former with no 4f-electrons and the latter with a completed 4f-electron shell. Trivalent ions of neither element showed any characteristic absorption band in the 0.8 to 2.6 $\mu$ range.

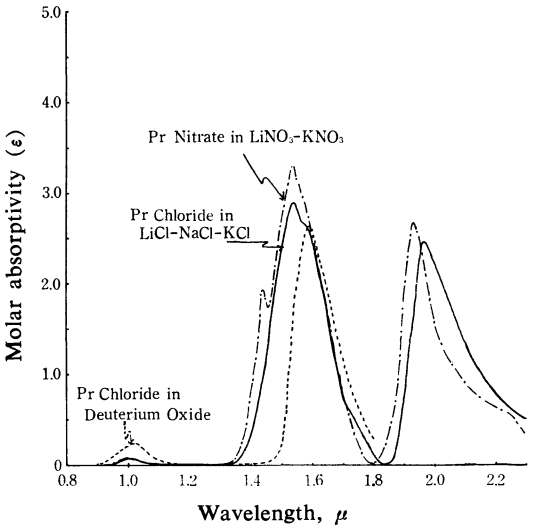

Fig. 3. Absorption spectra of praseodymium in the near-infrared region.

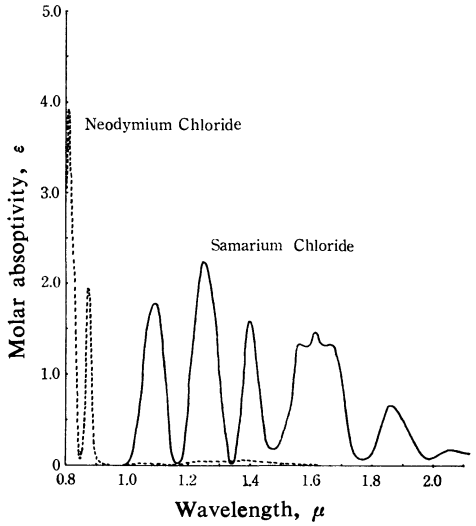

Fig. 4. Absorption spectra of neodymium and samarium chlorides in LiCl-NaCl-KCl eutectic.

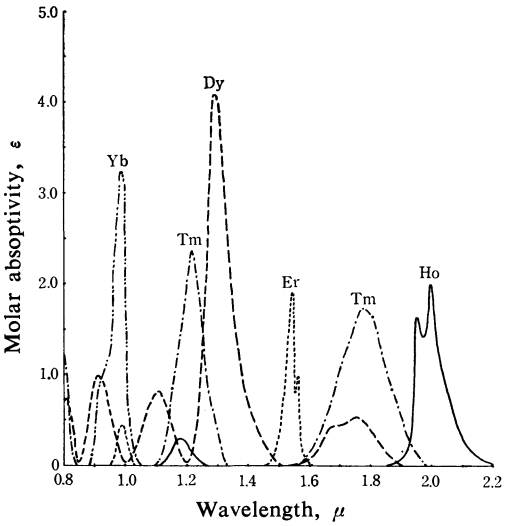

Fig. 5. Absorption spectra of dysprosium, holmium, erbium, thulium and ytterbium in LiCl-NaCl-KCl eutectic.

Trivalent cerium and gadolinium, whose absorption bands are observed only in the ultraviolet[7] and/or infrared regions,[19] have no bands in the wavelength range investigated in this study.

Promethium was excepted from the present experiment because this element is non-existent in natural lanthanide, and the absence of an absorption band in the near-infrared region in molten nitrate and deuterium oxide solutions has been indicated by Carnall[9] and Gruber.[20]

**Praseodymium Chloride.** — The absorption spectra in the near-infrared region of praseodymium chloride in fused LiCl-NaCl-KCl eutectic and of praseodymium ions at 400°C in the alkali chloride eutectic solution resemble the spectra at 150°C in molten nitrate media, in spite of the large differences in temperature and solvent effects. An absorption peak occurring at 1.445 $\mu$ in fused nitrate eutectic has been reported. This peak, however, has not been observed in alkali chloride eutectic and in a deuterium oxide solution. On the basis of these data, it seemed reasonable to assume that this absorption band is the O–H overtone of the water remaining in molten nitrate media as a result of incomplete dehydration.

**Neodymium Chloride.** — The trivalent neodymium ion in the LiCl-NaCl-KCl eutectic has only two absorption maxima, at 0.810 and 0.876 $\mu$, in the near-infrared region. These absorption maxima are quite comparable to

19) R. J. Lang, *Can. J. Res.*, **14**, 127 (1936).
20) J. B. Gruber and J. G. Conway, *J. Inorg. & Nucl. Chem.*, **14**, 303 (1960).

the absorption maxima of neodymium in LiCl-KCl eutectic, at 0.810 and 0.885 $\mu$, which have been reported by Sundheim and Harrington.[21] The effect of different solvents on these absorption bands is small; namely, the similar spectra are obtained in molten nitrate media[9] and in other solvents.[5]

**Samarium Chloride.** — The spectrum of samarium chloride in fused LiCl-NaCl-KCl eutectic is presented in Fig. 4. The wavelengths of the absorption bands below the 1.4 $\mu$ range obtained by the author in aqueous solution are almost the same as those reported by Carnall[9] in alkali nitrates eutectic. The absorption maxima beyond the 1.40 $\mu$ range were found to be located at different wavelengths due to the solvent effect. These absorption bands showed the formation of different species of the complex in each solvent.

**Europium Chloride.**—The europium chloride in molten LiCl-NaCl-KCl eutectic has no absorption peaks in the near-infrared range, and also no absorption band structure is reported in the visible range for europium chloride in fused LiCl-KCl eutectic.[7] However, the characteristic absorption bands of europium in molten nitrate media have been reported; the maximum absorbance was observed at 0.395, 0.465, 2.05 and 2.165 $\mu$ in the visible and near-infrared ranges by Carnall.[9]

In the visible range, the spectra of europium chloride in molten alkali chloride eutectic are similar to the spectra of $Eu^{2+}$ in an aqueous solution.[22] It is reported that $EuCl_2$ can be formed from $EuCl_3$ at about 270°C under an atmosphere of flowing hydrogen gas,[23] since the absorption spectrum obtained in the LiCl-NaCl-KCl eutectic melt may be due at least in part to $EuCl_2$ formed by the practical thermal decomposition of $EuCl_3$ or by reducing matter in the eutectic media. The difference between near-infrared absorption spectra in molten chloride and nitrate solutions is due to the existence of different valency ions and complex species in each solution.

**Terbium Chloride.**—The terbium chloride in fused LiCl-NaCl-KCl eutectic media has no absorption band in the range from 0.8 to 2.6 $\mu$. However, the characteristic absorption bands of terbium in molten nitrate media have been reported; maximum absorbance was observed at 1.837, 1.938 and 2.275 $\mu$ in the near-infrared region by Carnall.[9] The difference between the absorption spectra in the two molten salts solutions is due to the presence of different complex species in each solvent.

**Holmium Chloride.** — The near-infrared absorption spectrum of holmium chloride in the molten alkali chloride eutectic is presented in Fig. 5. The absorption band at 1.18 $\mu$ is identified in various fused salt media and in an aqueous solution. However, the absorption band at about 1.95 $\mu$ was found to be different in molten nitrate and chloride eutectic solvents; thus, the absorption bands have been determined to be located at 1.922 $\mu$ in $LiNO_3$-$KNO_3$ eutectic,[9] whereas, for holmium in LiCl-NaCl-KCl eutectic media, its two absorption peaks occur at 1.959 and 1.996 $\mu$. This discrepancy is due to the different species of complexes in the different molten salts solutions.

**Other Lanthanide Chlorides.**—The near-infrared absorption spectra of dysprosium, erbium, thulium and ytterbium chlorides in fused LiCl-NaCl-KCl eutectic media are presented in Fig. 5. The wavelengths of the maximum absorbances of these lanthanide chlorides in molten alkali chloride eutectic media at 400°C, in fused nitrate media at 150°C and in deuterium oxide solution[16] are substantialy comparable, considering the great differences in measurement conditions.

**Solvent Effect.** — A number of studies have been made concerning chlorocomplexes of metal ions in nitrate melts to which excess chloride ions have been added.[4] This method was here applied to lanthanide, that is, lithium chloride was added to the fused $LiNO_3$-$KNO_3$ eutectic lanthanide nitrates solution until the solution was saturated with the chloride ions. As a result, the author observed only an absorbance decrease on the characteristic absorption band of lanthanide nitrate in the wavelength range investigated. Most of the lanthanide complexes in fused nitrate media react with the chloride ions and water in

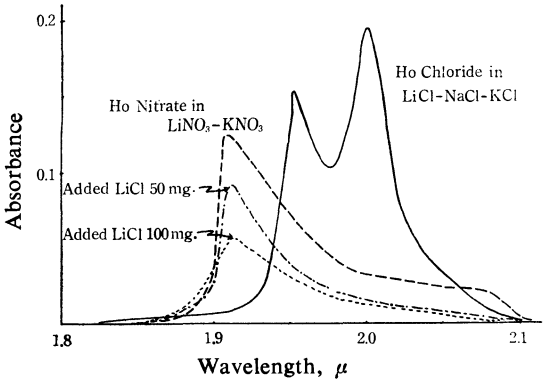

Fig. 6. The change of absorption spectra of holmium ion in $LiNO_3$-$KNO_3$ eutectic at 160°C by addition of several amounts of lithium chloride.

solvent to form insoluble compounds, oxychlorides. Thus, the absorbance on characteristic bands of lanthanide nitrate is decreased.

For example, the change in the absorption bands of holmium nitrate in fused $LiNO_3$-$KNO_3$ eutectic media upon the addition of lithium chloride is presented in Fig. 6. Thus, the chlorocomplex of lanthanides in molten nitrate media was not observed by this method. However, several different absorption bands have been observed in various solvents, such as molten nitrate, chloride and deuterium oxide solutions. These solvent effects could be attributed to the presence of different complex species in the various solvents, for the ligand field affects the 4f-electronic energy levels of the lanthanide elements.

**Temperature Effect.** — Most of the peaks of the near-infrared absorption bands of lanthanide chloride in fused LiCl-NaCl-KCl eutectic are slightly shifted to longer wavelengths when the temperature is increased from 400 to 800°C, and at the same time their absorbances decrease. For example, the temperature effect of the absorption bands of holmium chloride in molten alkali chloride media is shown in Fig. 7.

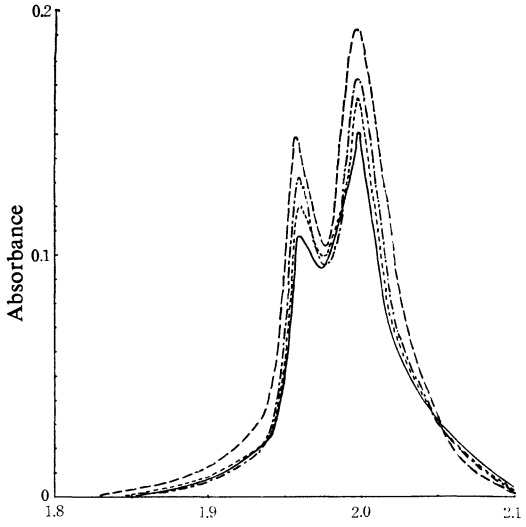

Fig. 7. Absorption spectra of holmium chloride in LiCl-NaCl-KCl eutectic at various temperatures.

| | Temp. | | Temp. |
|---|---|---|---|
| ------ | 400°C | ..... | 660°C |
| —·—· | 530°C | ——— | 800°C |

This observation is not comparable with the fact that in the study of the molten salt spectra absorption peaks have been observed to change with the chang of temperature.[3,12,24]

24) J. R. Morrey, *J. Chem. Phys.*, **66**, 2169 (1962).

Because the shifts of the absorption peaks are too small for the absorption species to be distinguished, the concentration of the lanthanide ions changes as the fluid expands and contracts, and also the absorption bands are broadened at high temperatures. Thus, the temperature effect of lanthanide absorption bands is due to a single absorbing species, the concentration and peak intensity of which change as a function of the temperature. However, in the narrow temperature range of 400±2°C, the temperature effect on the characteristic lanthanide absorption band is negligibly small.

**Analytically Principal Lanthanide Absorption Bands.**—As can be seen from the spectra and

molar absorptivities, it would be practical to determine the concentrations of most of lanthanides dissolved in fused salts media by the use of the spectrophotometric technique. The wavelengths and molar absorptivities of the main absorption bands found in the spectra of eight of the lanthanide chlorides in fused LiCl-NaCl-KCl at 400±2°C are presented in Table I, along with the absorbance peaks which have been reported in a deuterium oxide solution and the lanthanide nitrates reported in molten $LiNO_3$-$KNO_3$ media. The reproducibility of all the absorption spectra of these lanthanide chlorides was good, with standard deviations below 3.0% (Table II), and the absorbances of these spectra obeyed Beer's law, indicating that these absorption bands could be used for the quantitative analysis of each lanthanide.

## Summary

Using a high temperature cell for molten salts, a spectrophotometric investigation in the near-infrared region from 0.8 to 2.6 $\mu$ and at temperatures from 400 to 800°C has been carried out with fourteen lanthanide chlorides dissolved in a LiCl-NaCl-KCl mixture of eutectic composition (49.0 - 17.3 - 33.7 mol.%, m. p. 333°C). Praseodymium, neodymium, samarium, dysprosium, holmium, erbium, thulium and ytterbium have characteristic absorption bands in this region. Most of the near-infrared absorption bands of lanthanide chlorocomplexes have been compared to similar spectra obtained in molten nitrate media. However, the several absorption bands have been found to be different in molten nitrate and chloride eutectics. Thus, the absorption bands of europium and terbium have been observed in nitrate, wheras their bands have not been found in chloride, and the absorption bands of praseodymium, samarium and holmium beyond the 1.4 $\mu$ range have been found to be located at different wavelengths. These solvent effects can be attributed to the existence of a different lanthanide complex in each solvent, for the ligand field affects the 4f-electronic energy levels of the above elements.

The absorption peaks of lanthanide ions decrease as the temperature increases, partly due to the change in the concentration of the ions associated with the volume change. However, all the characteristic absorption bands of lanthanide in the near-infrared region have stable molar absorptivities at a constant temperature. These absorption bands can be used for the investigation of chemical constitution and electronic structure, for analysis and for other purposes.

The author wishes to thank Mr. Hiroshi Fukuda for his kind cooperation in this research.

# Studies of Diarylalkanes. III.*[1] The Cleavage of Diarylmethanes under the Influence of Aluminum Chloride

By Otohiko TSUGE and Masashi TASHIRO

(Received March 13, 1964)

In the course of the study of the reaction of diarylalkanes with Friedel-Crafts catalysts, an investigation was carried out in order to find how various diarylmethanes cause cleavage under the catalytic influence of aluminum chloride.

It was reported in the preceding paper[1] that, under the influence of aluminum chloride, while diphenylmethane gives benzene, toluene, methyldiphenylmethane, dimethyldiphenylmethanes and anthracene, methyl-substituted diphenylmethanes give trimethylbenzene and dimethylanthracene beside the above products. It was also found that, in the case of methyldiphenylmethanes (I), the bond a is more easily cleft than the bond b and that the facility of the cleavage of the former is increased by increasing the number of methyl groups at the benzene ring, if the facility of the bond cleavage is estimated by the molar ratio of methylbenzene to the benzene which is formed by the cleavage. In other words, the higher the relative basicity of the methyl-substituted benzene ring in I, the more easily the bond a is cleft.

$n=1,2,3$

(I)

In the present work, the reaction of various diarylmethanes with aluminum chloride was studied in the absence of a solvent or by using excess aromatics as a solvent so that clearer information concerning the effect of the substituent could be obtained on the bond cleavage.

## Results and Discussion

Diphenylmethane (II), 4-methyl- (III), 4-ethyl- (IV), 4-isopropyl- (V), 4-hydroxy- (VI), 2-hydroxy- (VII), 4-methoxy- (VIII), 2-methoxy- (IX), 4-chloro- (X), 4-phenyldiphenylmethane (XI) and 1-benzylnaphthalene (XII) were treated with aluminum chloride under various

conditions and the products were analyzed by a quantitative gas-liquid chromatographic method.

**The Reaction in the Absence of a Solvent.**— The reaction of IV, V and X with aluminum chloride was carried out under conditions similar to those described previously.[1] The results are shown in Table I.

As Table I shows, various unidentified products were obtained from IV or V; hence, it is difficult to give the relative facility of the bond cleavage. The data for nine diarylmethanes (IV—XII) which may imply the approximate relative facility are shown in Table II.

The relative reactivities of the aromatic compounds which showed good agreement with the known order of the relative stabilities of aromatic $\pi$-complexes, toluene>ethylbenzene >propylbenzene,[2] are also listed in Table II. The relative facility of the bond cleavage in I and IV is in accordance with the relative basicities of the two aromatic rings.

In the case of V, however, the bond in the side of benzene exhibited a higher reactivity for the cleavage than the other; this is inconsistent with the relative basicities of benzene and propylbenzene. This discrepancy may be attributed chiefly to the secondary formation of benzene by the dispropotionation of the products, in addition to the formation of unidentified substances.

In the cases of VI, VII, VIII and IX (runs 6—11), the corresponding aromatic compound (phenol or anisole) was formed more than benzene in the corresponding case. The amount of the aromatic compound in the cases of VIII and IX, however, is given as the total mol. % of anisole, phenol and cresols, since the reaction of anisole with aluminum chloride under the same conditions was found to afford anisole, phenol and cresols in 28.0, 56.8 and 15.2 mol. % yields respectively.

As is shown in runs 7 and 9, the more severely the reaction condition was used, the larger the amount of lower boiling compounds formed and the smaller the amount of resinous material. This suggests that the resinous material consisting of a mixture of polybenzyls is partially decomposed to regenerate the corresponding aromatics. This seems to conform with the fact that diphenylmethane is regenerated by heating the mixture of polybenzyl and benzene with a large amount of aluminum chloride.[3]

In spite of the lower basicity of chlorobenzene than benzene, more chlorobenzene than benzene was obtained in the cleavage X, as is shown in runs 3 and 12. Moreover, the amount of unidentified substances was smaller than that in the cases of the alkyl derivatives mentioned above. This seems to be due to the stability of the chlorobenzene formed by the cleavage. When an equimolar

amount of chlorobenzene and aluminum chloride was heated at 100°C for 1 hr. only unchanged chlorobenzene was recovered; this finding is also endorsed by Olah and his co-workers,[4] who reported that chlorobenzene was not disproportionated by water-promoted aluminum chloride.

In the cases of XI and XII (runs 13 and 14), less biphenyl and naphthalene, respectively which exhibit a higher basicity than benzene, were formed than benzene.

On the basis of the data mentioned above, it may be considered that the diarylmethanes are divided into two groups which exhibit different tendencies of the bond cleavage.

**The Reaction in the Presence of Excess Aromatic.**—As it may be considered that the resinous material is composed of polybenzyls, it is anticipated that the reaction in the excess benzene derivative will cause a decrease in its formation.

The data for some diarylmethanes which have been treated in excess benzene or chlorobenzene are shown in Table III. As expected, the amount of resinous material decreased definitely in comparison with the data in Table II.

In the reaction of II in excess chlorobenzene (run 15), the II was almost all consumed, and chloro-, dichlorodiphenylmethanes[5] and anthracene were obtained. It was also observed that the amount of benzene increased and that of chlorobenzene decreased. In the similar reactions of X and XII in excess benzene (runs 16 and 17), similar phenomena were observed, where X and XII were consumed and diphenylmethane was formed in yields of 66.8 and 60.8 mol.% respectively.

On the basis of these data, it may be considered that benzyl cation entities were formed as the intermediates in the cleavage process.[6] In run 15, furthermore, more anthracene was formed than in run 16 or 17. This fact may be interpreted as follows. The self-condensation of the benzyl cation to dihydroanthracene, which easily converts to anthracene,[7] can take place to some extent in chlorobenzene, since the attack of the benzyl cation on chlorobenzene is relatively slow as a result of the low basicity of chlorobenzene.

On the other hand, the attack of the benzyl cation on benzene is more predominant than the self-condensation in runs 16 and 17, because the basicity of benzene is higher than that of chlorobenzene.

From the data in runs 15 and 16, also, it seems reasonable to say that a reaction of this kind is reversible.

When 0.1 mol. of aluminum chloride and 20 mol. of benzene derivative were used with the diphenylmethanes, it was also observed that the bond cleavage took place and that only a small percentage of the resinous material was formed.[8] The results in the reactions of III, X, XI and XII in 20 mol. of benzene are shown in Fig. 1.

As is shown in Fig. 1, an incubation which had been reported in the Friedel-Crafts alkylation of aromatics at a low temperature[9,10] was observed, and toluene, chlorobenzene, biphenyl and naphthalene were formed in a ratio of about 5 mol. % to the benzene, respectively. It was also observed that diphenylmethane was invariably formed in a ratio of about 5 mol. % to the benzene in all cases.

4) G. A. Olah, W. S. Tolgyesi and R. E. A. Dear, *J. Org. Chem.*, **27**, 3441 (1962).
5) Dichlorodiphenylmethanes are considered to be a mixture of bis(chlorophenyl)methanes.
6) H. C. Brown and M. Grayson (*J. Am. Chem. Soc.*, **75**, 6285 (1953)) reported that a benzyl cation entity in the Friedel-Crafts benzylation is not an ionized form, such as $C_6H_5\overset{\oplus}{C}H_2$, but a polarized form, $C_6H_5\overset{\oplus}{C}H_2\cdots\overset{\ominus}{A}lCl_4$.
7) R. Scholl and C. Seer, *Ber.*, **54**, 330 (1922).
8) In order to obtain the reproducibiliy of data, a 0.025 molar ratio of water was added to aluminum chloride.

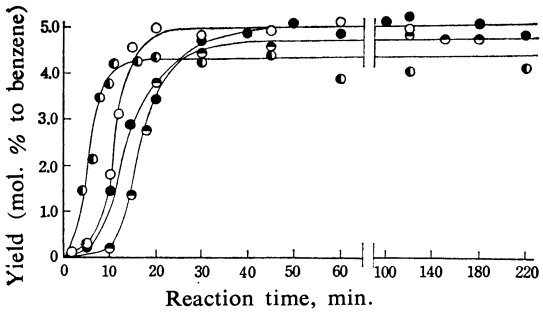

Fig. 1. Formation of the corresponding aromatic compounds by reactions of III, X, XI or XII (1.0 mol. respectively) with aluminum chloride (0.1 mol.) in the presence of benzene (20 mol.) at 50°C.
○ Toluene
● Chlorobenzene
◔ Biphenyl
◐ Naphthalene

On the basis of the apparent formation rates of the corresponding aromatics at the initial stage, the formation rate of chlorobenzene was considerably slower than those of naphthalene, toluene and biphenyl. This order is roughly in agreement with that of the relative basicity of the corresponding aromatic compounds.

In order to evaluate concurrently the effect of the two aromatic rings on the cleavage of the diarylmethane, the reactions of X in excess toluene and of III in excess chlorobenzene were carried out. The results are shown in Fig. 2.

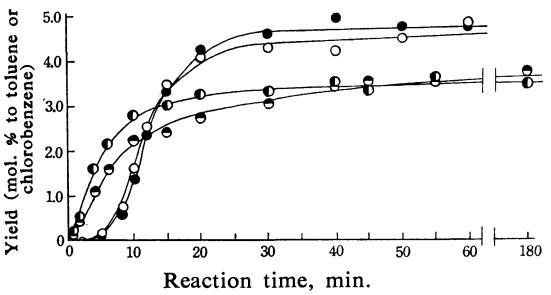

Fig. 2. Reactions of X (1.0 mol.) in toluene (20 mol.) and of III (1.0 mol.) in chlorobenzene (20 mol.) with aluminum chloride (0.1 mol.) at 50°C.
○ Benzene
● Chlorobenzene } in the reaction of X
◔ Benzene
◐ Toluene } in the reaction of III

Contrary to expectation, benzene and chlorobenzene were formed at nearly equal rates, as is shown in Fig. 2. However, the formation rate of toluene at the initial stage was faster than that of benzene. It may be considered that the contrast is due to the different strengths of the basicities of the chlorobenzene and toluene used as solvents.

Consequently, it is considered that the bond cleavage is affected by the basic strength of the benzene derivative which is present in the reaction system as well as by the relative basicities of the two aromatic rings in the diarylmethane.

Further investigation of the point in dispute is in progress; details will be published in the near future.

**Resinous Material.**—As has been mentioned above, the resinous material is composed of a mixture of polybenzyls. The resinous material in several runs was divided into three main fractions: the benzene-insoluble fraction ($F_1$), the benzene-soluble and petroleum ether-insoluble fraction ($F_2$) and the petroleum ether-soluble fraction ($F_3$). In general, $F_1$ was a higher melting black solid (m. p. above 200°C), $F_2$ was an orange-to-reddish brown powder (m. p. 60—100°C) and $F_3$ was an oily brown substance. As no suitable solvent of $F_1$ could be found, its molecular weight was not determined. The degree of the polymerization of $F_2$ and $F_3$ was about 5 to 8, like the polybenzyls, as judged by measuring their molecular weights by the Rast method.

## Experimental

**Materials.**—The diarylmethanes were prepared by the reported method and were purified by fractional distillation and/or recrystallization. Diphenylmethane:[3] b. p. 140—141°C/5 mmHg, m. p. 25°C, retention time (hereafter referred to as R.T.[11]), 4.6 min.

4-Ethyldiphenylmethane:[12] b. p. 121—123°C/2 mmHg, $n_D^{20}$ 1.5707, R.T., 7.0 min. 4-Isopropyldiphenylmethane:[13] b. p. 143—145°C/3 mmHg, $n_D^{20}$ 1.5650, R.T., 9.5 min., 2-Hydroxydiphenylmethane:[14] b. p. 156—159°C/6 mmHg, m. p. 53—54°C, R.T., 8.5 min. 4-Hydroxydiphenylmethane:[15] b. p. 141—143°C/4 mmHg, m. p. 84°C, R. T., 10.5 min. 2-Methoxydiphenylmethane:[14] b. p. 148—152°C/9 mmHg, m. p. 31°C, R.T., 7.6 min. 4-Methoxydiphenylmethane:[15] b. p. 155°C/4 mmHg, $n_D^{20}$ 1.5775, R.T., 9.1 min. 4-Chlorodiphenylmethane:[16] b. p. 130—135°C/3 mmHg, $n_D^{20}$ 1.5885, R.T., 7.9 min. 4-Phenyldiphenylmethane:[17] b. p. 180—188°C/2 mmHg, m. p. 83—84°C, R.T., 43.1 min. 1-Benzylnaphthalene:[17] b. p. 175—179°C/5 mmHg, m. p. 57—58°C, R.T., 22.0 min.

11) Column: 30% High vacuum silicon grease; Column temperature: 235°C; Carrier gas: $H_2$, 22 ml./min.
12) C. Söllscher, *Ber.*, **15**, 1680 (1882).
13) K. Allendorff, ibid., **31**, 1000 (1899).

Aluminum chloride (reagent grade, of the Wako Pure Chemical Industries, Ltd.) was purified by sublimation.

**Procedure.**—The experiments were carried out in an apparatus similar to one described previously.[1] Aluminum chloride was stirred into the diarylmethane at a constant temperature. After the specified reaction time, the reaction was quenched with dilute hydrochloric acid under ice-cooling.

The quenched product was treated by the following methods according to the individual case.

*Method A.*—When the product was contaminated with a fairly large amount of a resinous material (runs 1 to 14), this method was used. After the quenched product was subjected to steam distillation, the distillate $f_1$ was extracted with ether. The ether solution was washed well with water, dried over sodium sulfate, and analyzed by gas chromatography. The ether-insoluble residue was separated by a distillation into three fractions, the fraction $f_2$ distilling below 150°C (bath temperature), the higher boiling fraction $f_3$ distilling below 240°C (bath temperature)/1—2 mmHg, and the residual fraction. The fractions $f_2$ and $f_3$ were analyzed by gas chromatography.

*Method. B.*—When the amount of a resinous material was relatively small (runs 15 to 17), this method was applied. After being quenched, the reaction mixture was extracted with ether. The ether solution was washed with water to remove traces of acid and dried over sodium sulfate. The solution was divided by a distillation into three fractions, the lower boiling fraction $f_1$, the higher boiling fraction $f_2$, and residual fraction, as above. The distillates $f_1$ and $f_2$ were analyzed by gas chromatography.

*Method C.*—This method was used in the case of a reaction mixture in which a little resinous material was contained (Figs. 1 to 2). After the quenched product had been extracted with ether, the ether solution was washed well with water, dried over sodium sulfate, and immediately analyzed by gas chromatography.

**Analytical Procedure.**—The analyses were carried out by gas-liquid chromatography. The conditions for the gas chromatographic analyses were as follows. For the lower boiling fraction: column, 30% high vacuum silicon grease (HVSG) 2 m., temperature, 150°C, carrier gas, hydrogen, 30 ml./min. For the higher boiling fraction: column, 30% HVSG, 2 m., temperature, 235°C, carrier gas, hydrogen, 22 ml./min.

From the areas of individual peaks, mol. % figures were calculated for each product after determining the relative response data by the internal standard method. Individual peaks were identified by means of the retention times of pure samples.

**The Measurement of Relative Basicity.**—The relative basicities of phenol, anisole, chlorobenzene, biphenyl and naphthalene to benzene were measured by a modification of Olah's method.[2]

Aluminum chloride (0.5 g.) dissolved in 20 ml. of nitrobenzene was vigorously stirred drop by drop into a mixture of benzyl chloride (8.7 mmol.), benzene (113 mmol.) and the corresponding aromatic compound (110 mmol.). After the addition of the aluminum chloride solution, the mixture was stirred at 30°C for another 30 min., and then it was quenched by the usual method. The quenched product was extracted with benzene, and the organic layer was washed well with water, dried over sodium sulfate, and analyzed by gas chromatography. The relative basicities of the corresponding aromatics were calculated by means of the molar ratio of the diarylmethane to diphenylmethane in each individual case.

## Summary

The reaction of several diarylmethanes (III—XII) with aluminum chloride under various conditions has been carried out in order to elucidate the effect of the substituent on the cleavage of diarylmethanes. It has been established that the bond between the aromatic ring and the methylene group is cleft and that the cleavage is affected by the relative basicities of the two aromatic rings in the diarylmethane as well as by the basic strength of the benzene derivative which is present in the reaction system.

# The Reactivity of Hydrogen Atoms of Unsaturated Hydrocarbons in Metathetical Reactions

By Hiroshi KATO, Kenichi FUKUI and Teijiro YONEZAWA

(Received April 28, 1964)

In order to discuss quantum-mechanically the reactivity of the hydrogen atoms of unsaturated compounds in abstraction reactions, the stabilization energy due to $\pi$ conjugation occurring in the structure of the final product, which is calculated by the molecular orbital method, has been employed as a measure of the reactivity.[1] However, no attention has been paid to the behavior of the $\sigma$ electrons of the unsaturated compounds which must play the main part in these reactions. The present authors have previously proposed a new reactivity index—delocalizability, $D_r$—which has proved to be a satisfactory one for metathetical reactions of saturated hydrocarbons.[2] In the present paper, we will treat the $\sigma$ electronic system in various unsaturated hydrocarbons, such as olefins, alkylbenzenes and acetylenes, by the same method as that used in our previous paper[3] in order to show the calculated values of $D_r^{(R)}$ (delocalizability for radical reaction) at each hydrogen atom in these compounds. The results display a good correlation with experience and generally explain the high reactivity of $\alpha$ hydrogen atoms in unsaturated hydrocarbons.

## Theoretical

As has already been shown, the $\sigma$ electronic structure in unsaturated compounds is investigated by the LCAO MO method, taking only $\sigma$-electrons explicitly into consideration. Accordingly, the molecular orbitals in these molecules are represented by a linear combination of hydrogen 1s orbitals and carbon hybridized orbitals.

The values of the parameters used in the present paper are summarized as follows:

Coulomb integrals

$C(sp^3)$ : $\alpha$ $C(sp^2)$ : $\alpha+0.1\beta$

$C(sp)$ : $\alpha+0.2\beta$ H: $\alpha-0.2\beta$

resonance integrals

a) between adjacent carbon atoms:

$C(sp^3)$–$C(sp^3)$ : $\beta$ $C(sp^2)$–$C(sp^2)$ : $1.2\beta$

$C(sp)$–$C(sp)$ : $1.3\beta$ $C(sp^3)$–$C(sp^2)$ : $\beta$

$C(sp^3)$–$C(sp)$ : $1.1\beta$

b) between carbon and hydrogen atoms:

$C(sp^3)$–H: $1.1\beta$ $C(sp^2)$–H: $1.1\beta$

$C(sp)$–H: $1.2\beta$

c) between two orbitals in the same carbon atom:

$C(sp^3)$–$C(sp^3)$ : $0.34\beta$ $C(sp^2)$–$C(sp^2)$ : $0.40\beta$

$C(sp)$–$C(sp)$ : $0.70\beta$

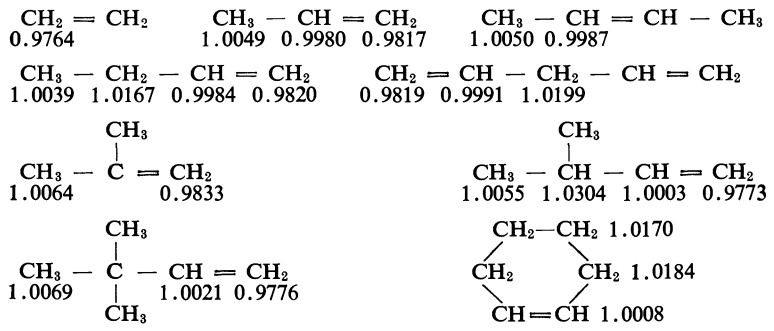
where $\alpha$ and $\beta$ denote the Coulomb integral of an $sp^3$ carbon atom and the resonance integral between two $sp^3$ hybridized orbitals at the C–C $\sigma$ bond respectively.* This parameter system is convenient for comparing the value of the $D_r^{(R)}$ of unsaturated compounds with those of saturated compounds which have already been calculated.[2]

The reactivity index referred to as the delocalizability for the radical reaction, $D_r^{(R)}$, may then be given as:

$$D_r^{(R)}=\sum_i^{occ}\frac{(C_r^i)^2}{\lambda_i}+\sum_j^{unocc}\frac{(C_r^j)^2}{-\lambda_j}$$

where $C_r^i$ is the coefficient of the $r$th $\sigma$ orbital in the $i$th MO and $\lambda_i$ is given by $\varepsilon_i=\alpha+\lambda_i\beta$, in which $\varepsilon_i$ is the energy of $i$th MO.

## Results and Discussion



The calculated $D_r^{(R)}$ values of the hydrogen atoms in various unsaturated hydrocarbons are given in Figs. 1a, b, c and d. In Fig. 2 the calculated $D_r^{(R)}$ values of hydrogen atoms are plotted according to their grouping. A detailed discussion with regard to the variation in the $D_r^{(R)}$ in each group will be given in the following sections. As a general trend, it can be pointed out that the reactivity of a hydrogen atom bonded to an $sp^3$ carbon atom will be larger than that of hydrogen atoms attached to an $sp^2$ or sp carbon atom, and also larger than that of the same kind

(that is, primary, secondary or tertiary) in saturated hydrocarbons.

In particular, the large reactivity of hydrogen atoms in the $\alpha$-methylenic group is interpreted by $D_r^{(R)}$ values, for instance, in cyclohexenene and indane molecules.

**Olefins.**—The calculated $D_r^{(R)}$ values of hydrogen atoms in several olefinic compounds are summarized in Fig. 1a. The value of $D_r^{(R)}$ falls in a definite range for each type of hydrogen atom; the average $D_r^{(R)}$ value of hydrogen atoms of the same type, that is, of each primary, secondary and tertiary hydrogens, is compared in Table I with the rate

* These values correspond to the average of the hydrogen atom with similar circumstances.
a) The attacking reagent is the $CH_3$ radical in Ref. 4 and olefinic peroxy radicals in Ref. 5.

constants characteristic of various types of hydrogen atoms in metathetical reaction by means of the methyl radical.[4] A parallelism is observed between these two and the calculated values of olefins are on an average larger than those of corresponding paraffins, although the differences between them are rather smaller than expected and the calculated orders of reactivity between the different types of hydrogen atoms in unsaturated and saturated hydrocarbons are inconsistent with the observed values. These discrepancies may result from the neglect of $\pi$ conjugation energies.

In Fig. 1a, the $D_r^{(R)}$ values of $\alpha$ methylenes in 1-butene, 1,4-pentadiene and cyclohexene are large, obviously corresponding to the large reactivities. That is, in cyclohexene the $D_r^{(R)}$

4) A. F. Trotman-Dickenson, *Quart. Revs.*, **7**, 198 (1953); A. F. Trotman-Dickenson and E. W. R. Steacie, *J. Chem. Phys.*, **19**, 329 (1951).

of the $\alpha$-hydrogen atom is 1.0184, while at the $\beta$-hydrogen atom it is 1.0170. In 1, 4-pentadiene, the hydrogen atom of the methylene has a value of 1.0199, which is larger than that of the average of methylenes in paraffins (ca. 1.016).

These $D_r^{(R)}$ values of hydrogen atoms on $\alpha$ carbon atoms in several olefinic molecules are listed in Table II, together with the observed activation energies[4,5] and experimental reactivities[4] in hydrogen abstraction reactions. (In Ref. 4, the values were obtained in the reactions with the methyl radical, and in Ref. 5, the values in the autoxidation reactions with benzoyl peroxide as an initiator were estimated by assuming frequency factors to be constant for all reactants). We can remark with a certain reservation that there is an apparent parallelism between calculated and observed values, since Trotman-Dickenson has pointed out that the rate in these type reactions does not depend on the magnitudes of the activation energy, but on that of frequency factor.[4] This point should be reinvestigated by future calculations and experiments.

**Alkyl Ions and Radicals.**—For the sake of comparison, calculated values of $D_r^{(R)}$ in some alkyl ion or radicals* are indicated in Fig. 1b. It is of interest to see that the reactivity of hydrogen atoms bonded to an $sp^3$ carbon atom is larger than that of the hydrogen atoms of an $sp^2$ carbon atom which had the same circumstances in a parent molecule. In this way, the change in the hybridization of a carbon atom from $sp^3$ to $sp^2$ causes a deactivation of the hydrogen atoms attached to this carbon atom and a simultaneous slight activation of the hydrogen atoms in other parts of the molecule.

**Alkylbenzenes.**—The calculation with respect to several alkylbenzenes was also made; the results are shown in Fig. 1c. The reactivity of $\alpha$ hydrogen atoms may be clearly recognized. For instance, in the indane molecule, the $D_r^{(R)}$ value of the $\alpha$ hydrogen atom is 1.0186 and that of the $\beta$ hydrogen atom is 1.0162, while it is about 0.99 at the hydrogen atoms on the benzene ring. Similarly, in ethylbenzene the value at the methylene group is 1.0184. These values correspond to the largest one among those of different positions in each hydrocarbon of this sort; such an order of magnitude is larger than that of the hydrogen atoms of the corresponding class (that is, primary, secondary or tertiary) in saturated hydrocarbons.

5) a) L. Bateman, *Quart. Revs.*, **8**, 147 (1954); b) J. L. Bolland, ibid., **3**, 1 (1948).

* If we neglect the behavior of $\pi$ electrons, the $\sigma$ electronic states of the ion and the radical are identical for the first approximation.

TABLE III. THE VALUES OF $D_r^{(R)}$ AND THE EXPERIMENTAL REACTIVITY OF $\alpha$-HYDROGEN TOWARD THE $CCl_3$ RADICAL IN VARIOUS ALKYLBENZENES

| Compound | Type of H atom | $D_r^{(R)}$ | Relative[6] rate per $\alpha$-hydrogen atom $k$ |
|---|---|---|---|
| Benzene | — | 0.9862 | — |
| Toluene | prim. | 1.0060 | 0.080 |
| *p*-Xylene | prim. | 1.0061 | 0.090 |
| Ethylbenzene | sec. | 1.0184 | 0.37 |
| Indan | sec. | 1.0186 | 0.57 |
| Diphenylmethane | sec. | 1.0231 | 0.958 |
| Isopropylbenzene | tert. | 1.0319 | 1.00 |
| Triphenylmethane | tert. | 1.0450 | 4.00 |

In Table III the $D_r^{(R)}$ values of $\alpha$ hydrogen atoms in these compounds are listed, together with the relative rates per hydrogen atom as summarized by Russell[6] in the hydrogen abstraction reaction. The parallelism between the calculated theoretical indices, $D_r^{(R)}$, and the experimental indices is almost sufficient. However, Russell and Desmond[7] recently pointed out that diphenylmethane is less reactive than ethylbenzene in reaction with the chlorine atom and with the bromine atom. This result seems to be inconsistent with the result indicated in Table III. This discrepancy will be discussed in the last part of the present paper.

**Acetylenic Compounds.**—Figure 1d illustrates some acetylenic compounds with their $D_r^{(R)}$. The acetylene hydrogen atom is the least reactive of the common hydrocarbon molecules. The hydrogen atoms in the methyl and methylene groups of alkyl derivatives of acetylene are in general more reactive than the corresponding atoms in saturated hydrocarbons, according to our calculation. The $D_r^{(R)}$ values of $\alpha$ hydrogen atoms in alkyl acetylenes are given in Table IV, together with the observed activation energies and reactivities obtained by Trotman-Dickenson.[4] The calculated reactivity is not parallel with the observed activation energy with respect to ethylacetylene and

TABLE IV. THE VALUE OF $D_r^{(R)}$ AND OBSERVED ACTIVATION ENERGY AND REACTIVITY OF $\alpha$-HYDROGEN ATOM IN SOME ALKYL ACETYLENES

| Compound | $D_r^{(R)}$ | Activation[4] energy kcal./mol. | Reactivity[4] toward $CH_3$ radical |
|---|---|---|---|
| $CH{\equiv}CH$ | 0.9307 | — | — |
| $CH_3C{\equiv}CCH_3$ | 1.0054 | 8.6 | 11 |
| $CH_3CH_2C{\equiv}CH$ | 1.0172 | 9.1 | 33 |

6) G. A. Russell, *J. Am. Chem. Soc.*, **78**, 1047 (1956).

7) G. A. Russell and K. M. Desmond, ibid., **85**, 365 (1963).

dimethylacetylene. However, it agrees with the observed reactivity as defined by Trotman-Dickenson.[4]

As has been described in preceding sections, a good parallelism is observed, with some exceptions, between the calculated magnitude of $D_r^{(R)}$ and the experimental reactivity in hydrogen abstraction reactions. However, we should not neglect the following problems, which have to be taken into account before accepting the theoretical results mentioned above as being of significance. One of these problems is: which is the more essential index in this type of reaction, the delocalizability, derived by considering the $\sigma$ type transition state, or the $\pi$ conjugation energy in the radical species formed as the result of a hydrogen abstraction.

The answer of this question may be dependent upon the model for the transition state. That is, in the scheme:

$$\mathrm{R:H} + \mathrm{X}\cdot \rightarrow \mathrm{R:H\cdot X} \rightarrow$$
(I)
$$\mathrm{R\cdot H:X} \rightarrow \mathrm{R}\cdot + \mathrm{H:X}$$
(II)

if model I happens to correspond to the actual transition state, the reactivity will be represented by $D_r^{(R)}$, whereas, for the transition state represented by model II, the $\pi$ conjugation energy will become a better index. Fortunately, the orders of reactivity predicted by these two indecies are almost parallel with each other in simple unsaturated hydrocarbons.[1]

The next problem is that an attacking radical which will bring about a large polarization to hydrocarbon molecules in its approach may yield a different order of reactivity from such a nonpolar radical as an alkyl radical.[6-8] This polar effect is explained by the procedure mentioned in our previous paper.[9] In deriving the index, $D_r^{(R)}$, the Coulomb energy of the orbital of an attacking reagent was assumed to be equal to that of the $sp^3$ hybridized orbital of the carbon atom. However, for polarizing radicals like chlorine and bromine this assumption has to be changed. We remember that in our previous paper[2] the Coulomb energies of chlorine and bromine atoms were taken as $\alpha+0.5\beta$ and $\alpha+0.45\beta$ respectively. We use these values, so that $D_r^{(R)}$ is given by the following equation:

$$D_r^{(R)}(\lambda_a) = \sum_i^{\mathrm{occ}} \frac{(C_r^i)^2}{\lambda_i-\lambda_a} + \sum_j^{\mathrm{unocc}} \frac{(C_r^j)^2}{-\lambda_j+\lambda_a}$$
$$= \frac{1}{2} D_r^{(E)}(\lambda_a) + \frac{1}{2} D_r^{(N)}(\lambda_a)$$

in which $\lambda_a$ is the coefficient in the Coulomb energy of the attacking reagent orbital, $\alpha+\lambda_a$, and $D_r^{(E)}$ and $D_r^{(N)}$ denote the delocalizability for the electrophilic attack and for the nucleophilic attack, respectively. For an electronegative reagent, the sign of $\lambda_a$ will be positive. In this way, with the electronegative reagent orbital, the magnitude of $D_r^{(E)}$ increases and at the same time that of $D_r^{(N)}$ decreases. That is, an electronegative reagent shows a more electrophilic character than otherwise in the reaction, thus changing the reactivity. For instance, the $D_r^{(E)}$, $D_r^{(N)}$ and $D_r^{(R)}$ values of the $\alpha$ hydrogen atom are 1.0288, 1.0080 and 1.0184 respectively in ethylbenzene, and 1.0178, 1.0284 and 1.0231 respectively in diphenylmethane. Hence, if the electrophilic character of the reaction is larger, the reactivity may be in the order; ethylbenzene>diphenylmethane, which was observed in the experiment of Russell and Desmond.[7],*

The numerical calculation has been carried out on the digital computer, KDC-I, of Kyoto University.

* The orders of magnitude of $D_r^{(N)}$ and $D_r^{(E)}$ are parallel with that of $D_r^{(R)}$ in olefinic compounds, and so the reactivity orders obtained by the above treatment do not vary from the order given in Table II.

# The Kinetics of the Phosphate-catalyzed Epoxidation of Styrenes with a Mixture of Nitrile and Hydrogen Peroxide*

By Yoshiro OGATA and Yasuhiko SAWAKI

(Received April 30, 1964)

The reaction of benzonitrile with alkaline hydrogen peroxide has been found to proceed by way of peroxycarboimidic acid (I) :[1]

$$RCN+OOH^- \xrightarrow[\text{slow}]{} R\text{-}\underset{\underset{OOH}{|}}{C}=N^-$$

$$\xrightarrow[\text{fast}]{H_2O} \underset{\underset{OOH}{|}}{RC}=NH+OH^- \qquad (1)$$

(I)

$$(I)+H_2O_2 \xrightarrow[\text{fast}]{} RCONH_2+O_2+H_2O \qquad (2)$$

Peroxycarboimidic acid can oxidize such other substrates as olefins,[2] and it is a favorable oxidant which acts under milder and alkaline conditions and avoids the Baeyer-Villiger reaction,[3] although the oxidation must be done under the controlled pH value (ca. 8).

The present authors have discovered that an aqueous methanolic mixture of nitriles and hydrogen peroxide can oxidize styrene in the presence of alkaline phosphate, giving a high yield (above 95%) of epoxide according to this stoichiometric equation[4]:

$$RCN+H_2O_2+C_6H_5CH=CH_2$$

$$\xrightarrow{HPO_4^{2-}} RCONH_2+C_6H_5\underset{\underset{O}{\diagdown\diagup}}{CH}\text{-}CH_2 \qquad (3)$$

The present paper summarizes the kinetic data which treats the effect of basicity of the reaction media and of substituent effects in benzonitrile and styrene. A probable mechanism is postulated from these data. The reaction of nitriles with hydrogen peroxide in the presence of borate was also studied to compare with the case of phosphate.

## Experimental

**Materials.**—Commercial benzonitrile, acetonitrile and styrene were purified by fractional distillations, b. p. 190°C, 83°C and 58°C (35 mmHg), respectively. Substituted benzonitriles were synthesized from the corresponding anilines:[5] *p*-tolunitrile, b. p. 107—110°C (23 mmHg); *p*-anisnitrile was recrystallized from ethanol, m. p. 60°C; *p*-chloro- and *p*-nitrobenzonitrile were purified by recrystallization from ethanol, m. p. 93°C and 140°C, respectively. Substituted styrenes were prepared by the dehydration of phenylmethylcarbinols[6] obtained from the corresponding acetophenones[7]: *p*-chlorostyrene, b. p. 54—55°C (3 mmHg); *p*-methylstyrene, b. p. 43—44 (5 mmHg); *m*-nitrostyrene, b. p. 100—103°C (5 mmHg).

Hydrogen peroxide, phosphate and other inorganic reagents were all of guaranteed grade. Commercial methanol was used without further purification, since no appreciable difference in the rates was found between purified methanol and the commercial one.

**The Analytical Method.**—Hydrogen peroxide was analyzed iodometrically, 10 ml. of a reaction mixture was added to 30 ml. of ca. 0.1 N aqueous sulfuric acid containing 0.2—0.3 g. of potassium iodide, and the mixture was titrated with 0.1 N aqueous sodium thiosulfate immediately after the addition of three drops of a 1% sodium molybdate solution, thus avoiding the reaction of iodine with styrene. Neither nitriles nor styrenes interfered with the analysis.

The concentration of styrene oxide produced was determined by adding a 10 ml. aliquot to aqueous saturated sodium chloride (40 ml.) in a separatory funnel, extracting it with three 10 ml. portions of chloroform. The organic layer was washed three times with water and dried with anhydrous sodium sulfate. Then the oxirane oxygen content was determined by the pyridinium chloride-chloroform method.[8] This method gave 90.0±1.0% of the recovery of styrene oxide and was not interfered with the presence of nitriles and styrene. The estimation of styrene oxide was corrected by the above value.

**A Typical Procedure for Rate Measurement.**—A 75% (v/v) methanolic solution containing nitrile and styrene of a known concentration was buffered by the addition of potassium dihydrogen phosphate-sodium hydroxide and then thermostated in a brown flask. The epoxidation was started by adding a thermostated solution of hydrogen peroxide of the desired concentration. Aliquots were taken out at appropriate intervals, and the remaining

hydrogen peroxide was estimated as has been described above. The oxirane content was also determined, if it was necessary. Most reactions were carried out to 40—50% conversion, and the constancy of rate constants was confirmed up to 80% conversion.

The decomposition of hydrogen peroxide itself was not appreciable, and its consumption in the presence of nitrile alone was so small that it was negligible in the calculation of the rate constants.

## Results

**Rate Law.**—The rate of the epoxidation of styrene with nitrile and alkaline hydrogen peroxide catalyzed by phosphate in 75% methanol were determined by estimating the disappearence of hydrogen peroxide. The results of a typical kinetic run shown in Table I clearly indicate that the reaction is of third-order:

$$v=k_4[RCN][H_2O_2][C_6H_5CH=CH_2] \quad (4)$$

These third-order kinetics are satisfactory with various initial concentrations of reactants or phosphate (Table II-A). The slight decrease in the rate with increasing concentration of styrene may be attributed to the decrease in the polarity of the reaction mixture, as will be described below.

**The Effect of pH.**—The effect of pH on the rate was examined by changing the composition of the phosphate buffer (Table II-B). The rate of epoxidation increased only a little with the increasing pH except at pH values below 10, which is rather surprising if it is remembered that $\log k$ linearly increased with the pH value in the reaction of benzonitrile with hydrogen peroxide.[1] Although a small amount of hydrogen peroxide was consumed in the absence of styrene, the yields of styrene oxide based on the peroxide consumed were essentially the same (93—96%) in each pH examined.

**The Effect of the Polarity of Solvent.**—The rate of epoxidation was affected by the composition of the solvent (Table II-C). The higher water content in the reaction mixture tended to increase the rate. Compare methanolic solvents with 15% and 35% water. Hence, the slight decrease of rate with increasing initial concentration of styrene may be attributed to the decrease in the polarity of the reaction mixture. The addition of toluene also resulted in the same decrease in the rate.

**Substituent Effect.**—Substituent effects are shown in Table III-A and Fig. 1. The introduction of electron-attracting groups in benzonitrile increases the rate, the Hammett's $\rho$-value being 0.57, while substituents in styrene exhibit the reverse effect, giving a $\rho$-value of $-0.51$. These results suggest an electrophilic attack of the peroxycarboimidic acid intermediate.

For purposes of comparison, the reaction of substituted benzonitrile with alkaline hydrogen peroxide was also studied in the presence of borate (Table III-B and Fig. 1); the resulting $\rho$-value of 1.14 in 75% methanol is somewhat smaller than that obtained in 50% acetone.[9] This $\rho$-value is about two times greater than that in the phosphate-catalyzed epoxidation of

styrene with a mixture of substituted benzonitriles and alkaline hydrogen peroxide. The energies and entropies of activation also substantially differ between these two reactions, 1 and 3.

## Discussion

The reaction of nitrile with alkaline hydrogen peroxide[10] ($RCN + 2H_2O_2 \rightarrow RCONH_2 + O_2 + H_2O$, Radziszewski's reaction) is suppressed by the presence of phosphate, yielding styrene oxide almost quantitatively on addition of styrene.[4] Our results may be summarized as follows: (1) The phosphate-catalyzed epoxidation of styrene with nitrile and alkaline hydrogen peroxide follows third-order kinetics, being first-order in each reactant. (2) The rate of epoxidation is essentially constant at various pH's, while the rate increases with the increasing polarity of the reaction mixture. (3) Electron-attracting substituents on the

benzonitrile accelerate the rate of epoxidation to give a Hammett's $\rho$-value of 0.57, while the Radziszewski's reaction results in the $\rho$-value of 1.14. (4) Electron-releasing groups in the styrene accelerate the rate, exhibiting a negative $\rho$-value of −0.51. (5) The energy of activation is low and the entropy of activation is highly negative, while with the Radziszewski's reaction the former is higher and the latter is less negative.

**Reaction Scheme.**—The kinetic data show that nitrile, hydrogen peroxide and styrene are involved in the transition state, while the phosphate catalysis suggests that the oxidizing intermediate stabilized by phosphate dianion is effective for an electrophilic attack on olefin. These results agree with the following mechanism:

$$H_2O_2+OH^- \overset{K_5}{\rightleftharpoons} HO_2^-+H_2O \qquad (5)$$

$$RCN+HO_2^- \overset{K_6}{\rightleftharpoons} \underset{\underset{\text{(II)}}{\overset{|}{OOH}}}{R-C=N^-} \qquad (6)$$

$$\text{(II)}+H_2O \overset{K_7}{\rightleftharpoons} \underset{\underset{\text{(I)}}{\overset{|}{OOH}}}{R-C=NH}+OH^- \qquad (7)$$

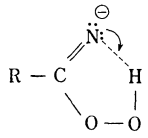
$$\text{(I)}^+ + \begin{matrix} {}^{-}O \\ {}^{-}O \end{matrix}\!\!>\!P\!<\!\begin{matrix} O \\ OH \end{matrix} \overset{K_8}{\rightleftharpoons} \underset{\underset{\text{(III)}}{}}{\begin{matrix} R-C=N\cdots H\cdots{}^{(-)}O \\ | \\ O-O\cdots H\cdots{}^{(-)}O \end{matrix}\!\!>\!P\!<\!\begin{matrix} O \\ OH \end{matrix}} \qquad (8)$$

$$\text{(III)}+PhCH=CH_2 \underset{\text{slow}}{\overset{K_9}{\longrightarrow}} PhCH\underset{O}{\overset{\diagup\diagdown}{-}}CH_2 + RCONH_2+HPO_4^{2-} \qquad (9)$$

Assuming that the concentrations of I and II are both very low and that equilibrium 8 is mobile and very favorable to the right side, the concentration of III may be expressed as:

$$[III]\cong\frac{K_7[II][H_2O]}{[OH^-]} \cong\frac{K_6K_7[H_2O][RCN]_s[HO_2^-]}{[OH^-]} \cong K_5K_6K_7[RCN]_s[H_2O_2]_s$$

Here, $k$ and $K$ are the rate and equilibrium constants of the subscripted steps, respectively, and [ ]$_s$ represents its stoichiometric concentration. Hence, the rate equation is:



$$v=k_9[III][PhCH=CH_2] =k_9K_5K_6K_7[RCN]_s[H_2O_2]_s[PhCH=CH_2]_s \qquad (10)$$

Rate Eq. 10 is consistent with the observed third-order kinetics and also with the independence of the rate on the hydroxide ion concentration (pH).

The mechanism assumes that II is not so active as to epoxidize styrene and that I is rapidly stabilized by phosphate to prohibit the reaction with hydrogen peroxide.

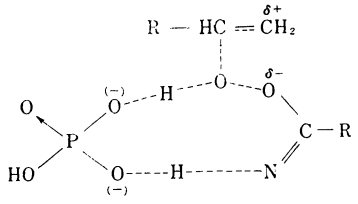
**Active Epoxidizing Species.**—Phosphoric acid should exist exclusively in the form of

dianion, $HPO_4^{2-}$, in these pH's in view of the dissociation constant. The interaction of the dianion with the intermediate anion II is less probable because of the electrostatic repulsion. While the intermediate I may easily form with the nucleophilic phosphate dianion, the intermediate III is so deactivated as to fail to oxidize hydrogen peroxide. The epoxidizing species is thought to be stabilized by the electron-releasing interaction of the phosphate dianion.

(II')

The intermediate anion, II, presumably has a chelate structure II', resembling that of peroxyacid,[11-13] where the electrophilicity of the oxygen atom is increased by internal hydrogen bonding. However, the electophilicity of peroxide oxygen should be greatly decreased with the anion II' by the presence of a negative charge. Although the intramolecular activation of II' by hydrogen bonding may actually exist, this effect would not surpass the electron-releasing power of the imide anion, since hydrogen bonding may contribute much less than does the inductive effect.

When boric acid was added to the phosphate buffer, the Radziszewski's reaction[10] occurred in spite of the presence of an exess of phosphate and the rate increased with increasing amount of the added acid, although the pH's of the reaction mixture decreased.[4] This promotion of the Radziszewski's reaction by boric acid is probably due to the ability of the acid to combine with the unshared electron pair of the nitrogen atom, decreasing the electron density on the peroxide oxygen atom.



**Substituent Effects.**—The substituent effects on both benzonitrile and styrene imply an electrophilic attack of III on the doubly-bound carbon atoms. The same effects have been observed with the peroxybenzoic acid epoxidation of olefins.[14] The Hammett's $\rho$-value for the epoxidation with substituted benzonitriles is about one-half of that for the Radziszewski's reaction, indicating a lower sensitivity to the polar effect. This lower value of $\rho$ can be well understood by considering the effect on equilibrium 7 reverse to that on equilibrium 6, thus leading to the decrease in total $\rho$-value.

The Hammett's plot for epoxidation with substituted benzonitriles in Fig. 1 shows a little departure from linearity especially for the *p*-methoxy group, while the plot for the Radziszewski's reaction is more satisfactory. The deviation of the former plot may be attributed to the overestimation of the resonance effect, since II should be less resonance-stabilized than the benzoate anion; hence, the above deviation is conceivable.

As for the epoxidation of substituted styrenes, the Hammett's plot is much more satisfactory, but it has a slight deviation as to *p*-substituents. According to the correction for $\sigma$-value using the $\gamma$ parameter,[15] $\sigma = \sigma + \gamma \times \Delta_{\sigma R}$, the value for $\rho$(meta) is calculated to be $-0.48$ from the rates for unsubstituted and *m*-nitrostyrene and the $\gamma$'s are 0.62 for *p*-methyl- and 0.59 for *p*-chlorostyrene. The $\gamma$-value of 0.61 (average) is similar to 0.48 for the perbenzoic acid epoxidation of styrenes,[7] suggesting a similar resonance effect in the transition state.

**The Approach of the Reagent to Substrate.**—The rate of epoxidation increased in solvents with higher dielectric constants, which seems to mean that an increase of polarity may increase the degree of dissociation of III, resulting in the regeneration of the stronger oxidant (I). This was confirmed by the fact that the reaction rate of benzonitrile with hydrogen peroxide alone increased with the increasing water content of methanol.[4]

Considering the above discussion, the transition state may be expressed as IV:

(IV)

As is to be expected, IV, a highly-crowded transition state, would require a highly negative entropy of activation, reflecting the hindered motion of each reactant. Thus, the present reaction is considered to be slowed down by the highly negative entropy of activation in spite of the low energy of activation. The less negative entropy of activation for the Radziszewski's reaction can be well explained by the less crowded transition state containing

only two species, e. g., nitrile and hydroperoxide ion.

## Summary

The phosphate-catalyzed epoxidation of styrenes with a mixture of nitriles and alkaline hydrogen peroxide have been studied kinetically in 75% methanol. The reactions satisfy third-order kinetics, being first-order in nitrile, hydrogen peroxide and styrene. The rate is essentially constant at various pH's, while it increases with the increasing polarity of the reaction medium. The energy of activation is low (6—8 kcal. $mol^{-1}$), and the entropy of activation is highly negative (−50 e. u.). The effect of substituent in benzonitrile is to give a Hammett's $\rho$-value of 0.57, while that in styrene resulted in a negative $\rho$-value of −0.51. It is probable that the peroxycarbimidic acid (I), produced by mobile equilibria from nitrile and hydroperoxide ion, is stabilized by an intermolecular hydrogen bonding with the phosphate dianion, and that this species contributes mostly to the epoxidation of styrene in the following, rate-determining step.

# Application of Electrostatic Models to the Colloidal Behavior of Plate-shaped Particles

By E. St. A. JORDINE, B. J. STEEL and J. D. WOLFE

(Received June 4, 1964)

The approach to many colloidal problems has usually been based on the equilibrium assumption, that is, of a Boltzmann distribution of ions around the macromolecular surface in question. It would appear however, that certain electrostatic models may give only an approximate but yet more useful description of systems which possess some symmetry. The two methods are in a way analogous to the equilibrium and orbit theories of plasma physics.

While the use of electrostatic models seems to be valid only for perticle-particle separations which are no greater than 20 to 30 Å, it is precisely in this region that the equilibrium approach fails catastrophically.

The idea of specific attractive forces between the counter ions and charged macromolecules was first proposed by Langmuir.[1] He first considered the colloid system as a whole instead of the two interacting particles. This approach has been severely criticised by Verwey and Overbeek (Ref. 2, p. 195). Actually, as will be seen in the present work, where two particles are considered with the aid of an electrostatic model, fairly good results are obtained.

Langmuir[1] believed that unipolar coacervation was due to Coulomb forces and suggested that a repulsive force, possibly hydration, was needed in order to counter-balance the tendency of the colloid system as a whole to contract under the influence of attractive Coulomb forces. This casts serious doubt on the exact role of the long-range London-van der Waals attractive force.

That this repulsive force has eluded most investigators has been due mainly to two factors: The belief that the Boltzmann distribution of ions always exists, and the gross simplification of treating the macromolecule either as a conductor or as a point charge. It is well known that, even for fairly ideal systems, such as are found in the gas phase, the first assumption has been found to fail. Now, to regard the macromolecule as a point charge means to ignore the important surface and dipole effects, while the assumption that it is a conductor is equivalent to assigning a value of infinity to the dielectric constant. This last factor will be shown to be of considerable importance.

As has been pointed out by McEwan[3] and Norrish[4], for small separations of two large plate-shaped particles the counter ions may be

1) I. Langmuir, *J. Chem. Phys.*, **6**, 873 (1938).

regarded as being ordered between the particles. The counter ions may, therefore, be considered to a first approximation as having specific areas of interaction with additive effects, quite analogous to the specific orbits describing the interactions in plasma physics. Derjaguin[5] makes a similar assumption concerning the volume elements of polarization which he justifies for small particle-particle separations. The main requirement for this model to hold is that the macromolecules should have relatively large surface areas per counter ion. While edge effects are important, montmorillonite or vermiculite platelets with surface areas of the order of millions of square angstroms[6] should be very suitable systems for treatment in the crystalline region of swelling.

Recently Jordine, Bodman and Gold[6] and Jordine[7] have applied the method of the electrostatic images of an infinite dielectric slab to montmorillonite systems. Only an approximate solution was obtained, however, since several terms were ignored. A rigorous solution of a point charge located between two charged slabs of dielectric will now be given. It will be seen that a repulsive image force arises quite naturally, and in such a way as to contribute to a minimum in the potential energy curve. A major problem, however, is that of assigning the correct effective dielectric constant to the intervening solvent medium. Nevertheless, as in Ref. 6 and Ref. 7, dielectric saturation has been taken into account.

The problem will be solved for the midway position*[1] of the charge between the dielectric slabs. It will also be outlined how a generalised crystal lattice theory of images can be developed to treat the system as a whole without making any assumptions concerning specific areas of interaction by the interlayer ions.

Lastly, a detailed theory of the mechanism of swelling will be proposed.

**A Statement of the Problem of the Point Charge between Two Charged Dielectric Slabs (Montmorillonite, Vermiculite, Mica).** — As a starting point for the model, consider that in Fig. 1 of Ref. 6 another platelet is placed symmetrically so as to form a plane ($-2D$, yz). This will be quite similar to Norrish's model (Ref. 4, Fig. 8) except that the platelets are not regarded as conductors.

In terms of electrostatics, the problem may be stated as the interaction between two dielectric interfaces and an array of charges. Thus, we have for $x<-2D$ and $x>0$ two regions mL and mR respectively of the dielectric constant $K_m$, while there is for $-2D<x<0$ a region w of the dielectric constant $K_w$. A set of point charges is located along the plane $x=-D$, and the interfaces $x=-2D$ and $x=0$ have a uniform surface charge of density, $\sigma$. We shall, for purposes of simplification in what follows, regard the interaction of the point charges as additive and, hence, consider only a given point charge $e^*$ located at $(-D, 0, 0)$. In other words, we will consider a cell model, as has been discussed in the introduction.

**A Solution of the Problem.**—The differential equations which must be solved to obtain the potential $V$ and, hence, the electrostatic energy of interaction are:

$$\nabla^2 V=0 \tag{1}$$

in the regions mL and mR and

$$\nabla^2 V=-\frac{4\pi}{K_w}\sum_{j=1} e_j^*\delta(x+D)\delta(y-y_j)\delta(z-z_j) \tag{2}$$

in the region w.

Since we are interested in a single cell, we may consider only one point charge; therefore, Eq. 2 may be written as:

$$\nabla^2 V=-\frac{4\pi}{K_w}\sum e_j^*\delta(x+D)\delta(y)\delta(z) \tag{3}$$

In addition to satisfying Eqs. 1 and 2, the potential must satisfy the usual electrostatic boundary conditions at the interfaces and at infinity.[6]

Since Eqs. 1 and 2 are linear, by a well-known theorem the potential can be written as $V=V_i+V_\sigma$, where $V_i$ denotes the potential due to the point charge and its images, and $V_\sigma$, that due to the surface charge. We can choose $V_\sigma$ as follows:

$$\left.\begin{aligned} V_\sigma &= \frac{2\pi\sigma x}{K_w} && -D<x<0 \\ &= -\frac{2\pi\sigma x}{K_m} && 0<x<\infty \\ &= -\frac{2\pi\sigma(2D+x)}{K_w} && -2D<x<-D \\ &= \frac{2\pi\sigma(2D+x)}{K_m} && -\infty<x<-2D \end{aligned}\right\} \tag{5}$$

Strictly speaking, since the platelets are only effectively infinitive, $V_\sigma$ must be cut off for $x$ at a value sufficiently large so that it tends to zero as $x$ tends to $\infty$.

*[1] In a forthcoming paper (Hurst and St. A. Jordine, *J. Chem. Phys.*, **41**, November 1 (1964)) it is shown that the midway position is favored energetically. See also experimental studies by Brown.[8]
8) G. A. Brown, *Mineralog. Soc. Gr. Britain Clay Mineral Bull.*, **4**, 109 (1950); Quoted in R. E. Grim, "Clay Mineralogy," McGraw-Hill Book Co. Inc., New York, Toronto, London (1953), p. 134.

Applying the method of images in dielectrics we get, for the potential due to the ion and its images in w, mL and mR respectively:

$$V_w - V_\sigma = \sum_{n=0} \frac{\alpha^n e^*/K_w}{\sqrt{[x+(2n+1)D]^2+y^2+z^2}} + \sum_{n=1} \frac{\alpha^n e^*/K_w}{\sqrt{[x-(2n-1)D]^2+y^2+z^2}} \quad (6)$$

$$V_{mL} - V_\sigma = \sum_{n=0} \frac{\alpha^n 2e^*/(K_w+K_m)}{\sqrt{[x-(2n-1)D]^2+y^2+z^2}} \quad (7)$$

$$V_{mR} - V_\sigma = \sum_{n=0} \frac{\alpha^n 2e^*/(K_w+K_m)}{\sqrt{[x+(2n+1)D]^2+y^2+z^2}} \quad (8)$$

where

$$\alpha = (K_w - K_m)(K_w + K_m)^{-1}$$

Having obtained the potential functions for the various regions we can now obtain the energies of interaction, designated $U_w$ and $U_m$.

With the aid of Green's theorem (Ref. 9, p. 160) the energy may be written in general as:

$$U_w = \frac{K_w}{8\pi} \iiint (\nabla V_w)^2 dx dy dz = -\frac{K_w}{8\pi} \Sigma \iint V_w \frac{\partial V_w}{\partial n_i} ds_i \quad (9)$$

$$U_m = \frac{K_m}{8\pi} \iiint (\nabla V_m)^2 dx dy dz = -\frac{K_m}{8\pi} \Sigma \iint V_m \frac{\partial V_m}{\partial n_i} ds_i \quad (10)$$

The significant interaction-energy terms will be those arising from the following cross terms:

a) The real charge with all the images. These are images with respect to the real charge; hence, the integration is only over the surface of the real charge.

b) An image with the successive image induced by it. The first image functions as a virtual charge and as such has an integrable surface.

c) Cross interaction between the two symmetric image sets, but not between images within a given set located behind a platelet or slab.

d) Interaction between images on the left with the free charge or the slab on the right, and vice versa. These terms are quite symmetric.

e) Interaction between the real point charge and the free charge on the two surfaces.

f) Interaction between the free charges on the two platelets. This is a more difficult problem then it would appear; hence, it will be treated in conjunction with e).

g) For the energy of the field in the platelets, the interaction terms follow from the equations for $V_{mR}$ and $V_{mL}$. The terms involving the surfaces of the images are, as in d), fictitious and, hence, zero.

On carrying out the appropriate integrations and putting $e^* = ze$, we obtain:

$$U_w = \frac{z^2e^2}{2DK_w}\left\{-\left(2+\frac{1}{2|1-\alpha^2|}\right)\ln(1-\alpha) + \frac{1}{|1-\alpha^2|}\left(\frac{1}{2}\ln(1+\alpha) - \alpha - \frac{\alpha^3}{3}\right) - \alpha\right\} + \frac{ze\pi\sigma}{K_w}\sum_{n=1}(\alpha^n[\sqrt{(2n+1)^2D^2+ze/2\pi\sigma} - (2n+1)D) + \frac{ze\pi\sigma}{2K_w}(\sqrt{D^2+ze/2\pi\sigma}+D) \quad \text{ergs/ion} \quad (11)$$

and

$$U_m = \frac{2ze\pi\sigma}{(K_w+K_m)}\sum_{n=0}(\alpha^n[\sqrt{(2n+1)^2D^2+ze/2\pi\sigma} - (2n+1)D) \quad \text{ergs/ion} \quad (12)$$

The total electrostatic energy of interaction, designated $U_E$, is:

$$U_E = U_w + U_m \quad (13)$$

In view of the discussion following Eq. 5, it can be shown that, when $2D \to \infty$, the last two terms of Eq. 11 become:

$$\frac{ze\pi\sigma}{K_w}\sum_{n=0}(\alpha^n[\sqrt{(2n+1)^2D^2+ze/z\pi\sigma} - (2n+1)D) \quad (14)$$

Thus eliminating the problem of an energy term which becomes indefinitely large as $2D$ increases.

**The Mechanism of Swelling and the Role of the Hydration Energy of the Interlayer Ions.** — Before applying Eq. 13 to obtain potential energy curves, it is necessary to consider the mechanism of expansion. According to Barshad,[10-12] in the dry montmorillonite, vermiculite, or other expanding clay mineral the platelets are sandwiched together, with interlayer ions present in the cavities of the oxygen framework which forms the boundary of the platelets. It is known that the presence of the interlayer ions is essential to swelling, and that this process is dependent on the size and charge of the ion. An important role is also played by the dielectric constant of the solvent medium. In the crystalline region of swelling a few essential things seem to cccur. Firstly, the solvent molecules, those of water,

for instance, must be adsorbed to the external surface of the crystal; thereafter water molecules penetrate the platelets with the concomitant removal of the ions from the cavities of the platelets and the subsequent coordination of the water molecules by the ions.

In terms of solid state physics, the foregoing process may be considered to be the creation of negative holes in the montmorillonite crystal as a result of the removal of the ions from the cavities. The interlayer ion now functions as a nucleus for the coordination of water molecules to give a heterogeneous crystal of montmorillonite-water. The creation of holes in the montmorillonite and the movement apart of the platelets require energy which must be yielded to the montmorillonite. On the other hand, the incorporation of water into the crystal requires that the water molecules release energy. The processes are, therefore, seen to be complementary, the ions being the main intermediary agents, extracting energy from the water molecules to be yielded to the montmorillonite and to contribute to the swelling potential. All this may be stated more concisely; swelling or crystal growth is a consequence of a defect or imperfection in the montmorillonite crystal. The foregoing essentially describes the process in the region of platelet separation, $0 \leqslant 2D \leqslant 5.4$ Å, corresponding to two complete and continuous monomolecular layers of water between any two platelets.

In order to relate the energy extracted from the water molecules to the hydration energy of the ion, it is necessary to consider the following equation of Bernal and Fowler[13] for the hydration energy of an ion with a valence $z$ and a radius $r$:

$$U_h = \frac{(K_w - 1)z^2e^2}{2K_wR_z} + (nP_{(r,z)} - u_w) \qquad (15)$$

where the symbols have the some meaning as in Ref. 13. The first term in the above equation arises quite logically from the general electric field equations, while the second terms is an empirical relation representing the potential energy change of the water molecules due to coordination by an ion. The term due to the electric field equations has already been partially computed in the general expression for $U_w$, that is, Eq. 11. In addition, the diameter $2R_z$ of the saturation sphere which is the lower boundary of integration takes values such that it coincides with $2D$. From Table VII of Ref. 13, $2R_z = 5.8$, 7.2 and 9.2 Å for $z = 1$, 2 and 3 respectively. This would make the first term zero, since the platelet separation $2D$ corresponds to the upper boundary or the physical infinity. Thus, the first term is, for practical purposes, zero. Herein could lie a partial explanation for the lower heats of the solution of ions when bound to montmorillonite reported by Janert.[14] It must also be borne in mind that some of the energy abstracted from the polar solvent is yielded to the montmorillonite crystal. Jordan,[15] for example, showed that even after the separation of 12 Å had been attained it was still necessary to add polar solvents to commercial montmorillonite-organic complexes in order to obtain further expansion and gelation. This would suggest an energy requirement of the montmorillonite before extensive separation can occur. As has been shown by Barshad,[11] the dielectric constant of the solvent plays a key role. Other factors, such as the size and type of interlayer ions and solvent molecules, are also important, as has been shown by Granquist and McAtee.[16] Whatever the interlayer ion may be, it appears that the solvent should have a high dielectric constant and the ability to solvate the interlayer ion, thus releasing energy, as has been discussed above.

There is no rigorous way of representing the mutual potential energy of the coordination of the water molecules by the ion. Intuitively, this may be represented by an integral function, such as:

$$(nP_{(r,z)} - u_w) = (nP_{(r,z)} - u) \int_0^\infty f(\rho)\,\mathrm{d}\rho$$

Clearly, $f(\rho) = e^{-\rho}$

Proceeding in this empirical manner, the contribution to the total potential energy of the system at any interplatelet separation $2D$ may now be defined as:

$$U_C = (nP_{(r,z)} - u_w) \frac{\int_{D-1}^{D} f(\rho)\,\mathrm{d}\rho}{\int_0^\infty f(\rho)\,\mathrm{d}\rho} \qquad (16)$$

$$= (nP_{(r,z)} - u_w) \int_{D-1}^{D} e^{-\rho}\,\mathrm{d}\rho$$

Since $f(\rho) = e^{-\rho}$,

$$U_C = (nP_{(r,z)} - u_w)(e-1)e^{-D}; \quad (D \geqslant 1) \qquad (17)$$

The interpretation of Eqs. 16 and 17 is that the fraction of the energy under the curve between $(\rho - 1)$ and $\rho$ contributes to the potential energy at $\rho = D$. In a way, the function bears some similarity to a Dirac $\delta$-function.

13) J. D. Bernal and R. H. Fowler, *J. Chem. Phys.*, **1**, 515 (1933).

14) H. Janert, *J. Agri. Sci.*, **24**, 136 (1934): Quoted in R. E. Grim, "Clay Mineralogy," McGraw-Hill Book Co. Inc., New York, Toronto, London (1953), p. 187.

15) J. W. Jordan, *J. Phys. & Colloid Chem.*, **53**, 194 (1948).

16) W. T. Cranquist and J. L. McAtee, *J. Colloid Sci.*, **18**, 409 (1963).

There should also be a term similar to $(nP_{(r,z)}-u_w)$ for the energy yielded to the montmorillonite platelets in order to remove the ion from the cavity. This term could be developed empirically as above for $U_C$, but the sign should be negative. An attempt is now being made to estimate this term theoretically. A possibility exists, however, of estimating its value experimentally. If, for example, montmorillonite flakes of varying ratios of high to low hydration energy ions such as $K^+$; $Na^+K^+$; $Li^+Cs^+$; $Li^+$ are prepared and then allowed to swell, there may exist a critical ratio of ions at which the interplatelet separation takes a value $\geqslant 9$Å. In this way the critical average hydration energy per ion could be obtained and related to the crystal energy term. This term should to all appearances be much less than $(nP_{(r,z)}-u_w)$ for most ions possessing large hydration energies, but it would never be completely satisfied for those ions with relatively small hydration energies.

**Potential Energy Curves and Extensions.**— Except for the unknown term describing the energy of creating a hole in the montmorillonite platelets, it is now possible to obtain potential energy curves from Eq. 13 and its sum with Eq. 17. These are shown below in Figs. 1, 2 and 3 for $z=1$, 2 and 3 respectively. The numerical values of the various parameters in Eqs. 13 and 17 are given in Ref. 7 and 13 respectively.

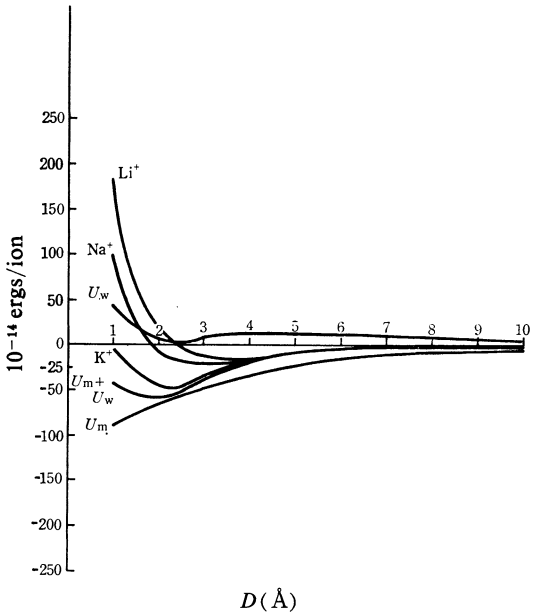

Fig. 1. Energy of interaction between two faces of montmorillonite and monovalent interlayer ions in relation to distance of separation, calculated for varying values of $K_w$ as in Eqs. 13 and 14.

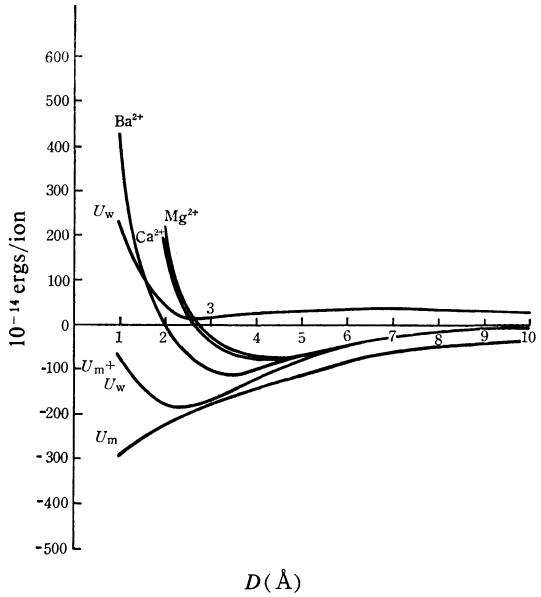

Fig. 2. Energy of interaction between two faces of montmorillonite and divalent interlayer ions in relation to distance of separation, calculated for varying values of $K_w$ as in Eqs. 13 and 14.

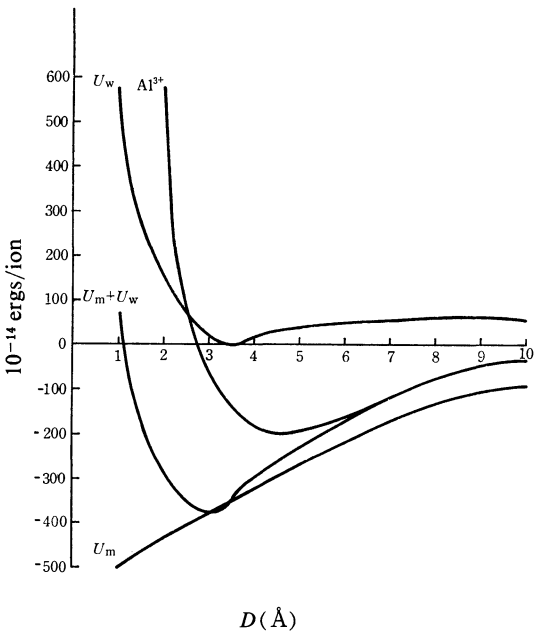

Fig. 3. Energy of interaction between two faces of montmorillonite and trivalent interlayer ions in relation to distance of separation, calculated for varying values of $K_w$ as in Eqs. 13 and 14.

It must be stressed that Eq. 13 is not strictly valid except for $2D \geqslant 5$Å, since the development postulates two complete and continuous

monomolecular layers of water, one on either side of the interlayer ion. In addition, Eq. 17 is completely empirical.

It may be noted that, if the first term in the image series is taken, Eq. 11 reduces to:

$$U_w = \frac{K_w - K_m z^2 e^2}{(K_w + K_m) K_w 2D} + \frac{\pi \sigma z e}{2K_w}(\sqrt{D^2 + ze/2\pi\sigma} + D) \qquad (18)$$

This expression, which is the first order approximation, yields a curve quite similar to that given by Ref. 15, Eq. 8 in Ref. 6, Fig. 2. If, now, the platelets were replaced by uncharged conductors $U_w$ would reduce to:

$$U_w = -\frac{z^2 e^2}{2DK_w} \ln 2 \qquad (19)$$

This result indicates that the energy for small $D$ would always be attractive if the montmorillonite platelets are assumed to be conductors.

From Eqs. 11 and 19 it is clear that the image problem we have solved is essentially that of a one-dimensional ionic crystal lattice. With extensions for computing the lattice sums, it is possible to extend this to a two-dimensional lattice and thus treat several ions and their images as one system. This would indeed yield a more rigorous solution to the problem. For the present, however, Eq. 13 is adequate for both montmorillonite and vermiculite systems.

Lastly, the problem as solved represents the case for two dielectric faces or for two slabs of an infinite thickness. In the work referred to in Footnote *1, a solution is given which takes into account the thickness of the platelets, giving a small correction term to the energy.

## Discussion

From Eq. 13 and its representation in Figs. 1, 2 and 3, it would appear that the electrostatic energy of interaction is such a function of the distance as to exhibit a minimum or an energy well. This minimum arises from the combined effects of dielectric image or polarisation energy terms and Coulombic terms. The experimental values of the equilibrium separation for some of the various ionic forms of montmorillonite are given in Ref. 4 as $D=1.9$Å for $Cs^+$, $D=2.5$Å for $K^+$, $D=6$Å for $Li^+$, and $D=4.5$Å for $Na^+$, $Ba^{2+}$, $Ca^{2+}$, $Mg^{2+}$ and $Al^{3+}$. It would appear from the curves of Eq. 13 in the figures that some other repulsive energy term must be operative. After adding $U_C$ to $U_E$, the total potential energy curves are obtained for the various ions. As was anticipated, the best agreement seems to be obtained for $Al^{3+}$, since the larger the surface element $ze/2\sigma$ the more ideal the image model becomes. From the depth of the minimum in the total potential energy curve for $Al^{3+}$, the binding energy is seen to be about 30 kcal. per mole of ions, a value which is about sixteen per cent that of the sodium chloride crystal. These correlations indicate conclusively why aluminum-montmorillonite does not exhibit macroscopic swelling. On the other hand, the curves for $Li^+$ and $Na^+$ show binding energies of the order of 3 to 4 $kT$. Such minima are shallow enough to permit macroscopic sweelling, as experiment confirms.[4]

Since the binding energies of the various ions determine the potential energy of the surface, this feature may have general biochemical implications. In Figs. 1 and 2 there is a marked difference between the biologically important ions, such as $K^+$, $Na^+$, $Mg^{2+}$ and $Ca^{2+}$, and $Li^+$ and $Ba^{2+}$. Thus, $K^+$ and $Ca^{2+}$, which assist in maintaining the osmotic and structural integrity of living cells, have high binding energies and would thus maintain the surface in a state of stable potential energy. Of course, at the other extreme is $Cs^+$, which would virtually immobilise the surface. $Ca^{2+}$ has perhaps ideal properties for biological functions in that, while it facilitates a good turnover of water, it also has a high binding energy. This could explain its well-known regulatory influence on, for example, the uptake of some other ions by excised plant and animal tissues. These correlations cannot be taken too far, but there does seem to be some relationship between these properties and the potential energy spectrum displayed in the figures.

From the curves representing $U_m$, $U_w$ and $U_E$, it may be seen that in the region of separation under study $U_m$ is the leading term of $U_E$ for $z=1, 2$ and 3 respectively. This evidence does seem to favor the theory of swelling proposed, that there is an energy requirement of the montmorillonite platelets which must be satisfied by cooperative processes between the solvent medium, the interlayer ion, and the platelets before any appreciable expansion can proceed. It may be noted that, if the platelets were conductors $U_m$ would be zero.

In Figs. 1, 2 and 3 the curves of Eqs. 11, 13 and 13+17 all have the typical appearance of potential energy curves for molecular systems. The explosion to a gel by montmorillonite or vermiculite crystals may be regarded as the probability of skating out of the energy well. There is, therefore, a statistical problem concerning a distribution function for the number

of platelets which escape the barrier to demonstrate macroscopic swelling. This is borne out by the X-ray date of Norrish (Ref. 4, Fig. 2) and Norrish and Rausell-Colom (Ref. 17, Fig. 3). It is well to note that the expansion of the first few platelets will act as a trigger mechanism for others, leading to an explosive avalanching process.

Let us consider now the mechanism of this explosive process, known as macroscopic swelling.[4] In an earlier section of this work, an approximation was made in computing the energy terms, e) and f); as soon as the interlayer ions lose their ordered arrangement, the shielding effect is considerably reduced and f) is no longer zero. In other words, the free surface charges of a like sign on adjacent platelets repel each other, since, as has been pointed out earlier, they now act as sinks for sources at infinity. Support for this proposal is found in Ref. 17 and in Weies' work.[18] These workers have shown that, within certain limits, the macroscopic swelling for a variety of clay minerals with various interlayer ions is greater and more explosive the greater the surface charge density. In the second instance, the authors, by perturbing the mobile interlayer ions of lithium-vermiculite with an electric field of a few V./cm., stimulated lithium-vermiculite to exhibit macroscopic swelling almost instantaneously. These crystals thereafter exhibited unexplained electrical properties similar to those described by Garrent and Walker.[19]

Before giving an explanation to the electrical phenomena in 18, it is of interest to describe briefly the procedure for preparing what appears to be lithium-vermiculite. By applying much higher voltages for short intervals to a native sodium-vermiculite crystal immersed in water, the crystal was stimulated to swell some three to four times its original volume within a few minutes. The water was then replaced by a dilute lithium chroride solution, and the perturbation field was maintained for a few more minutes. The crystal was then left overnight in lithium chloride solution, a procedure which is perhaps not essential. It would appear, therefore, that the laborious method of prolonged heat treatment used by many workers in preparing lithium-vermiculite can be simplified. The heat serves largely to increase the ionic conductivity as it would for any ionic crystal lattice. The swollen sodium-vermiculite, when left for a few hours in air, always contracted to one-and-a-half times its original thickness.

17) K. Norrish and J. A. Rausell-Colom, *Clays and Clay Minerals*, **10**, 123 (1963).
18) A. Weies, ibid., **10**, 191 (1963).
19) W. G. Garret and G. F. Walker, ibid., **10**, 557 (1963).

The explanation for all these electrical phenomena seems to lie in a model presented in Ref. 6, that is, the consideration of the vermiculite platelets with the interlayer ions as a pile of plate-shaped conductors. If an electric field is now applied, the mobile interlayer ions or positive charge carriers migrate in the direction of the field and can thus be replaced by other positive-charge carriers. This perturbation destroys the equilibrium distribution of the ions over the surface; hence, towards the anode there is an increased interaction between the surface charge of adjacent platelets leading to repulsion and the growth of the crystal. By applying an a.c. field of a sufficiently low frequency, the mechanical response time of the system could be determined. Preliminary studies by the authors suggest a value of 0.06 sec. The possibility of a permanent dipole moment may be ruled out since there is no preferential direction in the plane of the crystal for growth. It follows the field completely.

## Conclusion

The general theory of images in dielectrics has yielded results which convincingly support Langmuir's[1] preliminary ideas. All the evidence from theory and from current experimental knowledge suggests that, within the limits set by the type and size of solvent and interlayer ion, the swelling and many other colloidal properties of clay minerals are wholly determined by the electrical properties of the system. The influence of the surface density of the charge on the swelling, which was reported in Refs. 17 and 18, points to the fact that double-layer theory should not be applied without reservations to clay mineral systems. As further proof of the importance of the dielectric constant of the medium between the platelets, a comparison may be made of Table VII of Ref. 11 and Table I of Ref. 18. Here it is seen that a calcium-saturated montmorillonite immersed in a mixture of octanol and *n*-pentane gives almost the same X-ray spacing as a montmorillonite saturated with *n*-octylammonium ions in a mixture of *n*-octanol and *n*-octylamine. This result would indicate that, in this range of dielectric constants of the solvent, the alkylammonium ions behave much like any other ions; support is also given to Barshad's[11] proposal regarding the formation of complexes between the solvent and the platelets of montmorillonite. Moreover, these complexes should be regarded as heterogeneous crystals.

Finally, Figs. 1, 2 and 3 provide convincing evidence that the image model describes the system adequately.

## Summary

The method of images in dielectrics is applied to a model consisting of two infinite dielectric slabs and a point charge. When specific effects of the ions such as hydration energies are taken into account, the model describes the electrical aspects of the swelling of the clay minerals satisfactorily. In addition, a detailed theory of the mechanism of swelling is proposed and is shown to be favored by preliminary experimental studies of vermiculite.

One of the present authors (E. St. A. J.) wishes to express his appreciation to Dr. G. H. Cashen for his stimulating critism of a previous work[6] and to Dr. C. A. Hurst for his helpful discussions.

## Appendix I

In order to demonstrated further the agreement between theory and experiment, we may compare Barshad's (Ref. 20, Figs. 2 and 3) experimental results for $\Delta F_w$ with its equivalent, $\partial(U_C+U_w)/\partial D$, or even $\Delta F_m$ (Ref. 20, Fig. 6) with $\partial U_m/\partial D$. Though the units are different, the respective families of curves can be shown to be identical except for units and scale. The units used in Ref. 20 are not obvious, hence no exact comparison can be made until they are clarified and converted to ours. Both experiment and theory agree that the free-energy change of the water is a path of decreasing potential energy as $D$ increases, while for the montmorillonite it is a path of increasing potential energy, rapidly approaching zero from negative values. The total potential energy, $U_C+U_E$, will, therefore, tend to demonstrate a minimum followed by a maximum as $D$ increases. These features can be deduced from the potential energy curves and expressions. The value of $D$ at the maximum increases as the valence of the ions increases. For monovalent ions the maximum occurs at about $D=9$ Å, whereas for polyvalent ions it is greater. This is not surprising, since no polyvalent ion exhibits macroscopic swelling (at least as far as current experiments indicate).

20) I. Barshad, ibid., 8, 84 (1960).

## Appendix II

The case of the added electrolyte has already been treated,*[1] but experimental evidence can be presented to show that excess salt exerts only a secondary influence on the swelling process. In Figs. 5 and 7 of Ref. 4, which depict the experimental X-ray spacings of sodium-montmorillonite in sodium chloride solutions and water respectively, similar progressive interlayer separations of $2D=0$, 9 and 30 Å are demonstrated.

Clearly, though the added electrolyte can inhibit swelling, the primary mechanism of the swelling process is essentially due to the counter ions which neutralise the charge on the platelets. This is the basis of the theory developed in this work.

# Photoreduction of Methylene Blue and Thionine in Ethanol

By Yoshiharu USUI

(Received June 17, 1964)

Studies of the photoreduction of xanthene dyes in alcohol were started by Imamura and Koizumi,[1] and the mechanism has been clarified to some extent since then. However, as for the similar photoreduction of thiazine dyes, there seem to have been no kinetic studies undertaken with the aim of elucidating its mechanism, although a few reports, rather qualitative, have been made, including those of Kutsaya and others.[2]

There are two reasons why the author has started the present investigation. One is to add to our knowledge concerning the photochemical behavior of various dyes is alcohol and, in particular, to compare thiazine dyes with xanthene dyes and acridine, which have been already investigated.[3] The other is to examine the peculiar behavior of the thiazine dyes, which are known to undergo photoreduction in an aqueous solution in the absence of

1) M. Imamura and M. Koizumi, This Bulletin, **28**, 117 (1955).

2) B. F. Kutsaya and Ya. B. Dain., *Ukrain. Khim. Zhur.*, **17**, 820 (1951).

3) S. Kato, S. Minagawa and M. Koizumi, This Bulletin, **34**, 1026 (1961); S. Niizuma and M. Koizumi, ibid., **36**, 1629 (1963).

a reducing agent.[4] It has been found, in sharp contrast to the behavior of xanthene dyes and acridine, that this reaction is second order in respect to the dye. The mechanism is discussed on the basis of the hypothesis proposed by Koizumi et al.[5]

## Experimental

**Materials.** — *Methylene Blue (MB).* — Grübler's reagent was purified according to the procedure described before.[4] The molar absorbance at the 655 mμ peak was $8.8\times10^4$ for an ethanol solution.

*Thionine (Th).*—Merck's reagent was recrystallized twice from purified ethanol and dried under a vacuum. The molar absorbance in an ethanol solution was $7.12\times10^4$ at $\lambda_{max}$ (605 mμ).

*Ethanol.*—Wako Pure Chemical Industry's G.R. grade ethanol was used. After removing traces of aldehyde, water, etc., by the ordinary method, it was fractionally distilled three times. Such a sample, however, did not show, spectroscopically, any noticeable difference compared with the twice-fractionally distilled sample; the ultraviolet spectra of these two samples were essentially identical, thus assuring their purity.*

*Acetaldehyde.*—To obtain an absolute aldehyde, a commercial 80% acetaldehyde aqueous solution (Junsei Chemical Co.) was submitted several times to distillation from a dry-ice methanol to a liquid air bath under a high vacuum.

**Procedure.**—The alcoholic solution of methylene blue was degassed in vacuo four or five times, and then irradiated with a 500 W.-85 V. tungsten projection lamp at 25.0±0.1°C. In the case of methylene blue, the light shorter than 620 mμ was eliminated by means of a Walz WR-2 cut-off filter. For thionine, a Matzuda SO56 filter was used to cut off the light shorter than 560 mμ. The reaction was followed by measuring the change in optical density at the absorption peak by the use of an interference filter. The absorption spectra were measured on a Hitachi EPU-2A or EPS autorecording spectrophotometer. The reaction cell was a quartz spectrophotometer cell ($1\times1\times4$ cm³), the upper part of which was connected to an ampule by a quartz-telex-SB-grade tube.

## Results

**Some General Features of the Reaction.**—*Photobleached Product.* — Figure 1 shows the spectral change of an irradiated solution of methylene blue and thionine in the ultraviolet and visible region. The introduction of the air into the bleached sample restored the original absorption spectra almost completely in both cases. This is considered to be strong evidence that the dye was photoreduced to its leuco form. Further evidence was obtained from a comparison of the absorption spectrum of the photobleached product with that of the chemically prepared leuco dye. The latter compound was prepared by reducing methylene blue with Pd–$H_2$, and its spectrum was measured in a hydrogen atmosphere. Table I gives a comparison of the two spectra.

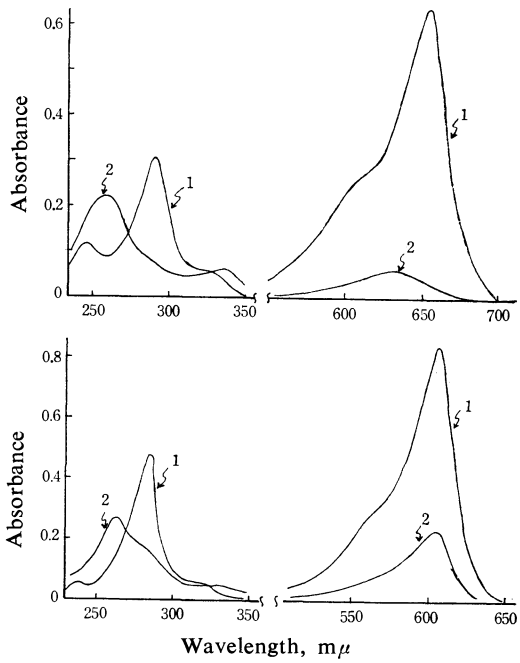

Fig. 1. The absorption spectra of the irradiated ethanol solution of methylene blue (upper) and thionine (lower) in vacuo.
$[MB]_{init}=8.0\times10^{-6}$ M
$[Th]_{init}=1.15\times10^{-5}$ M
1 Before irradiation
2 After irradiation

TABLE I

| | Chemically prepared leuco methylene blue | Photobleached product |
|---|---|---|
| Absorption peak | 261(s)* 315(w) | 261(s) 320(?) |
| $\varepsilon_{max}$ | $3.0\times10^3$ | $3.2\times10^3$ |
| % of recovery by air-introduction | 100 | 90—100 |

* s, strong; w, weak

From the agreement of the position and intensity of the absorption and from the fact that the response is quite similar to the admittance of oxygen or hydrogen peroxide, there is scarcely any doubt that the photobleached product in question consists mainly

* It appeared that the purity or the age of ethanol had a very delicate effect on the reaction rate, even when the solvent was optically pure. In the present investigation, such an obstacle was avoided by using alcohol from the same source.

of leuco dye. Furthermore, aldehyde was detected among the reaction products by gas chromatography. Thus, the overall reaction can safely be written as follows:

$$D^{+*} + C_2H_5OH \rightarrow DH + CH_3CHO + H^+$$

*The Influence of the Addition of Acetaldehyde.* —Since acetaldehyde is produced by the reaction and since a trace of it might have been present as a contaminant in the ethanol used, its effect on the rate of the reaction was examined. It was found that the rate of bleaching increased about six times when 1.16 M acetaldehyde was added to the solution (Fig. 2). On the basis of this experiment, it can safely be said that the small quantity of acetaldehyde produced during the reaction does not affect the rate appreciably. As Fig. 2 shows, the original dye is reformed when the bleached sample is kept in the dark. This is probably due to the gradual oxidation of the leuco dye by acetaldehyde.

**Kinetic Studies.** — *Rate Formula.* — Although the photoreduction of xanthene dyes and acridine, as has already been reported,[1,3] proceeds at a rate simply proportional to the absorption of light, the same can not necessarily be expected with thiazine dyes. In view of the peculiar behavior of thiazine dyes, namely, that they are photoreduced without the addition of any reducing agent, and further, in view of the fact that this reaction in the case of methylene blue and toluidine blue in a phosphate buffer proceeds as a simple second order reaction with regard to the dye concentration,[5] it is necessary in particular to compare the applicability of the first order and the second order rate formula.* As Fig. 3 shows, the second order rate formula is far more satisfactory than the first order one. Although this result by itself appears quite extraordinary, it is not really so if one recalls that the general scheme of the photoreduction of such dyes proposed by Koizumi et al., i. e., the scheme that electron transfer occurs between the excited and the ground state dye molecules, is supported by the flash experiment to some extent.[6] Next, the effect of various factors upon the second order rate constant $k$ (rate$=kC^2$) was examined.

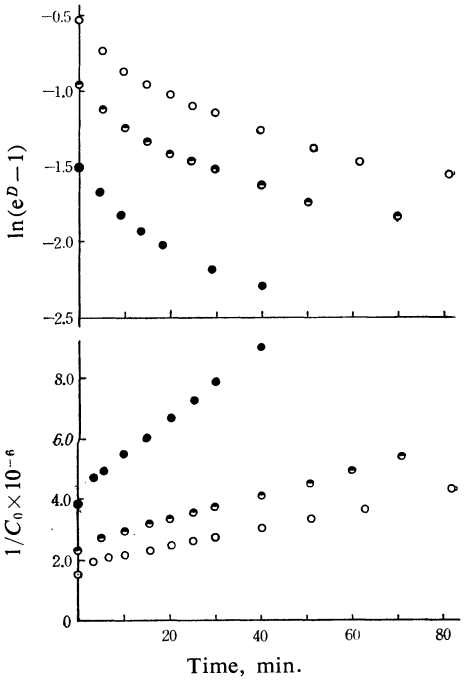

Fig. 3. Comparison of the following two rate formules; second order in dye concentration (lower), and proportional to the absorption of light (upper).

○ $C_0=6.2\times10^{-6}$ M
◓ $C_0=4.5\times10^{-6}$ M
● $C_0=2.7\times10^{-6}$ M

*The Effect of the Light Intensity.* — The intensity of the incident light was varied by means of neutral filters by a factor of about ten. The plot of $k$ against the relative intensity, as may be seen from Fig. 4, gives a good straight line. This implies that the

* The absorption of light is approximately proportional to the dye concentration, since the concentration is low.

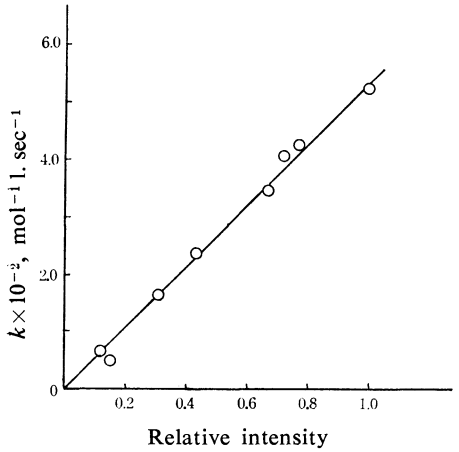

Fig. 4. Intensity effect on the overall rate constant for the second order reaction. ([MB]$=10^{-5}$ M)

net rate is essentially controlled by the interaction of the excited dye and the ground state dye, because the overall rate is of the second order with regard to the dye concentration.

*Quantum Yield.*—The quantum yield ($\Phi$) for the initial stage was evaluated from the inclination of the plot of the dye concentration against the time, together with the number of photons absorbed by the solution in a unit time ($I_{ab}$).

The latter quantity was measured with a combination of a Moll and Burger thermopile and a Shimadzu K2 potentiometer. For $5.95\times10^{-6}$ M methylene blue, $I_{ab}$ was measured as $4.8\times10^{18}$ photons $l^{-1}$ sec$^{-1}$, and the value of $\Phi$ was found to be $1-3\times10^{-3}$ (at 25°C). For $8.5\times10^{-6}$ M thionine, $I_{ab}$ was $3.6\times10^{18}$ photons $l^{-1}$ sec$^{-1}$ and $\Phi$ was $1.1\times10^{-3}$ at 25°C.

**Further Studies of the Basis of the Second Order Rate Formula.**—As has been stated above, the photobleaching of methylene blue in ethanol was accompanied with some degree of demethylation, which caused a slight shift of the absorption maximum toward a shorter wavelength. Although the minimum ratio method was employed in order to exclude the absorption of the demethylated dye, this procedure made the kinetic treatment less exact. In the case of thionine, on the other hand, such a shift does not occur and the kinetic treatment is expected to be simpler and more accurate.

Therefore, a more detailed investigation was carried out, using thionine as well as methylene blue. First, the effect of the initial dye concentration on the rate was examined quantitatively, and second, the effect on the rate of the addition of the leuco dye was investigated quantitatively in order to establish the reaction mechanism. Lastly, the photobleaching in a mixed solvent of water and ethanol was studied.

*The Effect of the Initial Dye Concentration.*—The initial dye concentration, $C_0$, was varied in the region $10^{-6}$—$10^{-5}$ M for both methylene blue and thionine. It was found that the overall second order rate constant, $k$, decreases with the increase in $C_0$ (Table II).

Figures 5a, 5b and 5c give plots of $1/k$ or $1/\Phi$* against $C_0$. The latter plot gives a good straight line; this leads to the following equation:

$$1/k=\alpha C_0(C_0+\beta) \qquad (1)$$

in which $\alpha$ and $\beta$ are constants. The kinetic

TABLE II. THE INITIAL CONCENTRATION EFFECT ON THE SECOND ORDER RATE CONSTANT

Thionine

| $C_0$ M | $k$ mol$^{-1}$ l. sec$^{-1}$ | $\Phi$ |
|---|---|---|
| $1.14\times10^{-6}$ | $1.24\times10^{4}$ | (0.02) |
| $3.80\times10^{-6}$ | $1.38\times10^{2}$ | $6.8\times10^{-4}$ |
| $7.30\times10^{-6}$ | $4.64\times10$ | $4.7\times10^{-4}$ |
| $9.56\times10^{-6}$ | $3.42\times10$ | $4.5\times10^{-4}$ |
| $1.15\times10^{-5}$ | $2.12\times10$ | $3.4\times10^{-4}$ |
| $1.84\times10^{-5}$ | $0.79\times10$ | $2.0\times10^{-4}$ |

Methylene blue

| $C_0$ M | $k$ mol$^{-1}$ l. sec$^{-1}$ | $\Phi$ |
|---|---|---|
| $2.39\times10^{-6}$ | $1.29\times10^{3}$ | $4.6\times10^{-3}$ |
| $3.44\times10^{-6}$ | $1.40\times10^{3}$ | $7.2\times10^{-3}$ |
| $4.95\times10^{-6}$ | $2.16\times10^{2}$ | $1.6\times10^{-3}$ |
| $6.02\times10^{-6}$ | $1.71\times10^{2}$ | $1.5\times10^{-3}$ |
| $9.59\times10^{-6}$ | $1.53\times10^{2}$ | $2.2\times10^{-3}$ |
| $1.04\times10^{-5}$ | $4.81\times10$ | $7.5\times10^{-4}$ |
| $1.9\times10^{-5}$ | $1.76\times10$ | $5.0\times10^{-4}$ |

results so far obtained are quite similar to those for methylene blue and toluidine blue in the phosphate buffer solution.

*The Retarding Effect of the Leuco Dye.*—As has already been stated, acetaldehyde, which is a reaction product, was found to have no significant influence on the rate. The effect of the leuco dye on the rate is more difficult to examine,* since the leuco dye is very sensitive to oxygen and is easily oxidized to the original form.

The procedure employed was as follows. The leuco dye, which was synthesized by reducing thionine with Pd–$H_2$ in alcohol in the dark, was added to the deaerated solution of thionine in vacuo. Using this solution, the experiment was performed and the results were compared with those for an ordinary solution with no leuco dye added. The comparisons are summarized in Table III, in which $k_L$ and $k_0$ are, respectively, the second order rate constants for the solutions with or without the leuco dye.

It is evident that the addition of the leuco dye causes a marked reduction in the rate.

*The Photoreduction of Thionine in a Mixed Solvent of Ethanol and Water.*—The absorption maximum for thionine in an aqueous solution differs from that in ethanol by only 5 m$\mu$. Furthermore, the dye exists solely in the monomeric form when the concentration of ethanol is more than 25% (v/v). These features are thought to make the results easier to interpret.

Once again, the second order rate formula could be applied satisfactorily to all the results, except for a small deviation in the initial stage. Table IV gives the maximum wavelength, its molar absorbance, and the overall second order rate constant ($k$) and the quantum yield ($\Phi$) for various compositions ($C_0=8.0\times10^{-6}$ M).

The values of the quantum yield are plotted against the molar fraction of ethanol ($\chi_R$) in Fig. 6. Evidently, there is a good linear relation between them. Thus, experimentally,

$$\Phi = \Phi^0_{H_2O} + (\Phi^0_R - \Phi^0_{H_2O})\chi_R$$

where $\Phi^0_{H_2O}$ and $\Phi^0_R$ are the quantum yields in the pure aqueous solution and in an ethanol solution respectively.

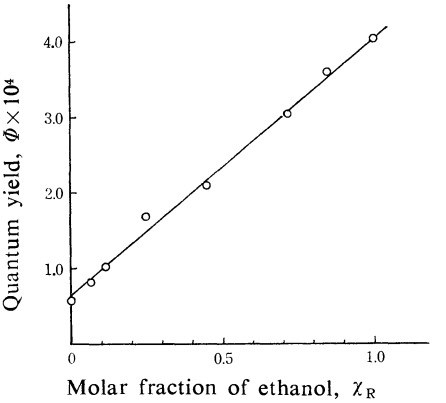

Fig. 6. The effect of water on the quantum yield for a mixed solvent.
$[Th]_0=1\times10^{-5}$ M

* When the deaerated ethanol solution of leucothionine and thionine was kept in the dark for a few days, a queer phenomenon was observed; the peak of the absorption shifted from 605 m$\mu$ to 635 m$\mu$, and the absorption in the wavelength region above 500 m$\mu$ increased. This phenomenon becomes more pronounced when the solution is illuminated.

* Volume percentage of water

From the above results, it is reasonable to assume that similar mechanisms prevail throughout the whole range of composition.

**A Flash Experiment on the Ethanol Solution of Methylene Blue.** — Flash experiments were performed only to compare the transients in alcohol with those in the phosphate buffer solution. Figure 7 shows the transient spectra in the degassed ethanol solution at various delay times. The present results resemble those for the aqueous solution[6] so closely that there is scarcely any doubt that the strong band at ~420 mμ and the weak shoulder at ~520 mμ correspond, respectively, to a half-reduced form and a half-oxidized form. Although it is believed that the triplet state absorption superposes at an early stage, the above two absoptions decay at about the same rate in the latter stage, suggesting that most of the half-reduced and the half-oxidized states revert to the original two dye molecules by the backward reaction.

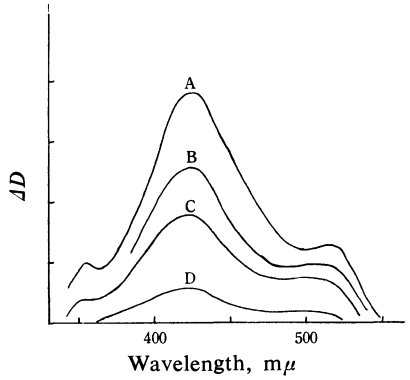

Fig. 7. The absorption spectra of the transient species in ethanol.
$[MB]_0=1\times10^{-5}$ M, $\Delta D$ is the difference in the blackness of two plates.
A : After 20 μsec.
B : After 100 μsec.
C : After 200 μsec.
D : After 400 μsec.

All the results obtained thus support the view that the mechanism of the photoreduction in an alcoholic solution is quite similar to that in an aqueous solution.

**The Effect of Dissolved Oxygen.**—The effect of the oxygen concentration on the rate of the irreversible decomposition of methylene blue in a plain aqueous solution was studied a few years ago.[7] It was found that the quantum yield of the irreversible decomposition of dye by oxygen increased with the rise in oxygen concentration but reached a constant maximum value above a certain oxygen concentration, suggesting that the reaction is competitive with the self-deactivation of the triplet state dye. A similar behavior had been observed for an aqueous solution of xanthene dyes.[1,8] On the other hand, quite a different observation had been made of an alcoholic solution of eosine.[9] When a very small amount of oxygen was added to this solution, the photobleaching was inhibited almost completely, but after a certain induction period, the length of which was proportional to the amount of oxygen, the reaction commenced at almost the same rate as in the

9) M. Imamura and M. Koizumi, This Bulletin, **29**, 899 (1956).

deoxygenated solution. This result was interpreted as being due to a very prompt attack of oxygen on the semiquinone of the dye.

In view of the bimolecular nature of the present reaction, it was thought interesting to investigate the oxygen effect on the photoreduction of an alcoholic solution of methylene blue. The concentration of dye was $8.0\times10^{-6}$ M in all cases. This reaction, however, proved rather complicated. Thus, the rate of the photobleaching decreased with an increase in the oxygen concentration. However, in this case the bleaching was interpreted as consisting of the reversible photobleaching as well as the irreversible decomposition of dye, because the introduction of air after the reaction caused a partial recovery of the dye. Besides, when the partially bleached solution was kept in the dark, the color was restored a little, perhaps due to the oxidation of leuco dye by the existent oxygen. The reversible photobleaching could occur even in the air-saturated solution; its extent was estimated to reach about ten per cent of the total bleaching.

Another feature which complicated the reaction was that significant demethylation accompanied the decoloration. As Fig. 8 shows, the degree of demethylation increases gradually with the progress of bleaching. In spite of all these complicating factors, the general effect of oxygen can be seen from Fig. 9, which gives the rate of bleaching at an initial stage as a function of the concentration of oxygen. A notable fact is that a rather rapid fall of the rate caused by a small amount of oxygen is followed by a very gradual decrease in the range of oxygen concentration beyond that of the dye.

Table V. Initial rates at various oxygen concentrations

## Discussion

In an alcoholic solution, the kinetic result is quite similar to that obtained for methylene blue and toluidine blue in a phosphate buffer solution. Hence, one can feel confident in discussing the results on the basis of a similar scheme. The scheme involves an electron transfer between the triplet dye ($D^t$) and the ground state dye, which produces another transient species (I) consisting of a half-oxidized and a half-reduced dye. Further, both $D^t$ and I are presumed to be deactivated by the ground state dye (D) and the resultant leuco dye (P), the processes being controlled by diffusion.

The above scheme can be written schematically as follows:

Scheme A

From the above scheme, one can easily derive the following equation by means of the steady state method:

$$-\frac{dC}{dt}=\frac{\alpha k_r k_r' C^2}{\left\{\begin{array}{l}\{k_d+k_1^s C+k_2(C_0-C)\}\times\\ \{k_d'+k_r'+k_1' C+k_2'(C_0-C)\}\end{array}\right\}} \quad (2)$$

where $\alpha$, the rate constant for the production of the triplet dye, can be expresse alternatively by $\alpha=\tilde{\varepsilon}\phi_{s-t}I_0$, and where $k_1^s$ is $(k_1+k_r)$. Putting $k_1^{s(\prime)}=k_2'$ and $k_d(k_d'+k_r')\approx 0$, one gets:

$$-\frac{dC}{dt}=\frac{\alpha k_r k_r' C^2}{(k_d+k_2C_0)(k_d'+k_r'+k_2'C_0)}\equiv kC^2 \quad (2')$$

$$k=\frac{\alpha k_r k_r'}{\{(k_d k_2'+k_2 k_d'+k_2 k_r')+k_2 k_2' C_0\}C_0} \quad (3)$$

This is just the same form as experimental relation 1. From relation 3:

$$\frac{1}{kC_0}=\frac{(k_d' k_2+k_2 k_r'+k_2' k_d)}{\alpha k_r k_r'}+\frac{k_2 k_2' C_0}{\alpha k_r k_r'} \quad (4)$$

Alternatively, by multipling $I_0\tilde{\varepsilon}$*:

$$\frac{1}{\Phi}=\frac{k_d' k_2+k_2 k_r'+k_2' k_d}{\phi_{s-t}\ k_r k_r'}+\frac{k_2 k_2' C_0}{\phi_{s-t} k_r k_r'} \quad (4')$$

The values of the slopes and the intercepts of the plots in Figs. 5b and 5c are given in Table VI. From these one may discuss the rate constant of each elementary reaction to some extent.

TABLE. VI. THE CONCENTRATION EFFECT OF DYE

| | Methylene blue | Thionine |
|---|---|---|
| $S_k$ (l. mol$^{-1}$ sec.) | $1.68\times10^8$ | $3.36\times10^8$ |
| $S'\phi$ (l. mol$^{-1}$) | $1.1\times10^8$ | $2.3\times10^8$ |
| $S\phi$ (l. mol$^{-1}$) | $\sim1\times10^8$ | $2.1\times10^8$ |
| $I_k$ (sec.) | $\sim10$ | $4.5\times10^2$ |
| $I'\phi$, $I\phi$ | $\sim6.7$ | $1.2\times10^3$ |
| $S_k/I_k$ | $\sim10^7$ | $7.5\times10^5$ |
| $S\phi/I\phi$ | $(\sim10^7)$ | $2\times10^5$ |

i) The slopes; $S_k$, $S\phi$ and $S\phi'$, and the intercepts, $I_k$, $I\phi$ and $I\phi'$, of each line in Figs. 5b and 5c refer to the same experimental data.

ii) For methylene blue, the values of the intercepts are too small to be treated quantitatively.

If one tentatively assumes $k_2\approx k_2'=10^{10}$—$10^9$ (l. mol$^{-1}$ sec$^{-1}$), which is the value for a diffusion controlled process, then for thionine $k_d+k_d'+k_r'=1.3\times10^4$ (sec$^{-1}$)** and $\phi_{s-t}k_r k_r'=5\times10^{11}$ (l. mol$^{-1}$ sec$^{-2}$), and for methylene blue, $k_d+k_d'+k_r'\approx10^3$ (sec$^{-1}$) $\phi_{s-t}k_r k_r'\sim1\times10^{12}$ (l. mol$^{-1}$ sec$^{-2}$). Inserting $\phi_{s-t}\approx10^{-1}$ as a plausible value, the $k_r k_r'$ values for thionine and methylene blue are, respectively, $5\times10^{12}$ and $10^{13}$. Since the $k_r'$ values for thionine and methylene blue are, respectively, less than $10^4$ and $\sim10^3$, the lowest limits of the $k_r$ value for the two dyes are, respectively, $10^9$ and $\sim10^{10}$. These data conform well with the fact that in the flash experiment a rather large quantity of the intermediate I is produced and that its life is of the order of a millisecond. They also seem to be consistent with the results obtained in the photoreduction of thiazine dyes in the phosphate buffer solution.[5] So far, Scheme A is quite satisfactory.

Next, the effect of leuco dye on the reaction rate will be discussed. According to Scheme A, the following rate formula should hold for the case in which a definite quantity of leuco dye is added beforehand:

$$-\frac{dC}{dt}=k_L C^2=\frac{\alpha k_r k_r' C^2}{\left\{\begin{array}{l}(k_d k_2'+k_d' k_2+k_2 k_r')\{[\mathrm{LTh}]_0+[\mathrm{Th}]_0\}\\ +k_2 k_2'\{[\mathrm{LTh}]_0+[\mathrm{Th}]_0\}^2\end{array}\right\}}$$

For the solution to which no leuco dye is added:

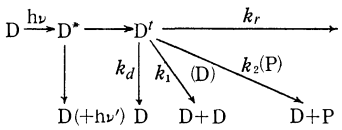
$$-\frac{dC}{dt}=k_0 C^2=\frac{\alpha k_r k_r' C^2}{(k_d+k_2[\mathrm{Th}]_0)(k_d'+k_r'+k_2'[\mathrm{Th}]_0)}$$

where $[\mathrm{LTh}]_0$ and $[\mathrm{Th}]_0$ are, respectively, the initial concentrations of leuco thionine and thionine. Using the value $k_2k_2'/(k_2k_d'+k_2'k_d+k_2k_r')=7.5\times10^5$, $k_L$ can easily be calculated from $k_0$. The values thus obtained are compared with the observed values in the following table:

| Exp. No. in Table III | $(k_L/k_0)_{obs}$ | $(k_L/k_0)_{calcd}$ |
|---|---|---|
| ii | 0.86 | 0.22 |
| iii | 0.55 | 0.10 |
| iv | 0.03 | 0.0009 |

Since the observed effect is much smaller than the calculated one, one can not say that the effect of the addition of the leuco dye is consistent with the proposed scheme. In connection with this discrepancy, it should be noted that a relation quite similar to that of

* $\tilde{\alpha}$ is the average molecular absorption coefficient defined by the relation:



$$I_{ab}=I_0\ (1-e^{-\tilde{\alpha}cd})$$

and $\tilde{\alpha}$ is $2.303\tilde{\varepsilon}$.

From the measurement of $I_0$ and $I_{ab}$ by means of a thermopile, the values of $\tilde{\varepsilon}$ were determined for methylene blue and thionine to be $3\times10^4$ and $2.1\times10^4$ respectively. In view of the magnitude of $\tilde{\alpha}$, one may safely use the approximation, $I_{ab}=I_0\tilde{\varepsilon}C_0$, when $C_0$ is less than $\sim7\times10^{-6}$ M. The $I_0\tilde{\varepsilon}$ values used for MB and Th were 0.67 and 0.71 respectively.

** According to Parker, the $k_d$ value of thionine in an aqueous acidic solution is $5\times10^4$ sec$^{-1}$ (C. A. Parker, *J. Phys. Chem.*, **63**, 26 (1959)).

4 can be derived even when the reaction scheme is such that the primary process consists of the attack of an alcohol molecule on $D^t$. Thus, if one adopts the following scheme:

Scheme B

then:

$$-\frac{dC}{dt}=\frac{I_{ab}\phi_{s-t}k_r}{k_d+k_r+k_1C_0}$$

on the assumption that $k_1\approx k_2$.

Hence,

$$\frac{1}{\Phi}=\frac{k_d+k_r}{\phi_{s-t}k_r}+\frac{k_1C_0}{k_r\phi_{s-t}} \qquad (6)$$

This is formally the same as 4'. In other words, the values for $S\phi$ and $I\phi$ experimentally obtained according to Scheme B are written as follows:

$$S\phi=k_1/k_r\phi_{s-t} \quad I\phi=(k_r+k_d)/k_r\phi_{s-t}$$

Inserting the proper values, one gets, for thionine, $k_1/(k_d+k_r)=2\times10^5$ and $k_r\phi_{s-t}=10^2$. If one assumes that $\phi_{s-t}$ for thionine is of the $10^{-1}$ order, $k_r$ is $\sim10^3\,sec^{-1}$.

The effect on $k$ of the addition of leuco thionine should be as follows, according to Scheme B:

| Exp. No. in Table III | $(k_L'/k_0)_{calcd}$ |
|---|---|
| ii | 0.51 |
| iii | 0.42 |
| iv | 0.033 |

Thus, as far as the effect of leuco dye is concerned, Scheme B seems to be more satisfactory than A.

However, the value for $k_r$ on the basis of Scheme B is unreasonable if one takes the oxygen effect into consideration (the result given in Fig. 9). The reason is as follows.

A rapid decrease in the bleaching caused by a small concentration of oxygen is interpreted by the competition of $D^t+O_2$ (mainly deactivation) and $D^t+D\rightarrow$ according to Scheme A, while only the latter process needs to be replaced by $D^t+alc\rightarrow$ for Scheme B. In either case, it is very plausible to assume that the deactivation of $D^t$ by oxygen is an encounter-rate-determining process. If so, the effect of oxygen should become appreciable at the oxygen concentration given by the following relation:

for Scheme A $\quad k_r[D]\approx k_{diff}[O_2]$ (7)

for Scheme B $\quad k_r\approx k_{diff}[O_2]$ (8)

The $k_r$ values in Eqs. 7 and 8 have the meanings given in Scheme diagrams A and B, and $k_{diff}$ is the rate constant for the diffusion controlled process and is of the order of $10^9$—$10^{10}$ l. $mol^{-1}\,sec^{-1}$.

For Scheme B, the value of $k_r$, $\sim10^3\,sec^{-1}$ requires that the concentration of oxygen in question be $10^{-6}$—$10^{-7}$ M. As Fig. 9 shows, however, the real concentration of oxygen necessary to compete with the reductive bleaching is more than $\sim10^{-5}$ M, a value much larger than the above value. In addition, the fact that a reversible photoreduction takes place to a measurable extent, even in an air-saturated solution, is quite difficult to understand when the above line of reasoning is followed.

For Scheme A, there is no such inconsistency if the value of $k_r$ is large enough; this is plausible, as has already been shown.

Summing up all the results, one cannot decide conclusively whether Scheme A or Scheme B predominates. Yet, Scheme A seems more plausible on the basis of the various results so far obtained. The inconsistency between the second order rate formula and the effect of the leuco dye is the only question which needs to be further studied.

It is to be hoped that more extensive studies of the dye concentration effect on the rates for the degassed solution and the aerated solution will give a more definite conclusion.

Lastly, let us add a brief discussion of the results obtained for a mixed solvent. If the attack of the water molecule and the alcohol molecule on I (in the case of Scheme A) or on $D^t$ (in the case of Scheme B) occurs according to the mass-action law, the rate would be given by:

$$\text{Rate}=\text{const.}\times\frac{k^r_w[H_2O]+k^r_{alc}[C_2H_5OH]}{k^s_w[H_2O]+k^s_{alc}[C_2H_5OH]}$$

where $k^r$ and $k^s$ refer, respectively, to the rate constant of the genuine reaction of I or $D^t$ as the case may be, and the rate constant for the disappearance (the sum of the deactivation and the genuine reaction of I or $D^t$). If $k^s_w=k^s_{alc}$ holds approximately, then the expected rate formula would result.

## Summary

The photochemical behavior of methylene blue and thionine in ethanol is quite different from that of eosine in the same solvent. They are compared from several viewpoints below.

From the preliminary flash experiment and the kinetic results by steady illumination, it has been concluded that interaction between

| | Methylene blue | Eosine |
|---|---|---|
| % of leuco dye | About 100% leuco | Above 50% leuco |
| Quantum yield | $1-3\times10^{-3}$ | $5.6\times10^{-4}$ |
| Air introduction | Complete recovery | No recovery |
| Intensity ($I_0$) effect | Proportional to $I_0$ | Proportional to $I_0$ |
| Rate formula | Second order in dye concentration | Proportional to the absorption of light |
| $O_2$ effect | Very complex oxidative and reductive bleaching simultaneously occur | The reaction is completely suppressed by a trace of $O_2$. |

the ground state and the excited state dye is essential for photoreduction.

It is most probable that the overall scheme for the photoreduction of thiazine dyes in alcohol is similar to that in the case of the same dyes in a phosphate buffer solution.

The author would like to express his deep thanks to Professor Masao Koizumi for his encouragement and many valuable discussions throughout this work. He also wishes to express hearty thanks to Professor Shunji Kato for his helpful advice.

# The Synthesis of *N*-Terminal Acetylpeptides of Ovalbumin and Mammalian Heart Cytochrome c

By Yoshihiko BABA, Fumio SAKIYAMA, Koiti TITANI and Kozo NARITA

(Received June 18, 1964)

In previous publications from our laboratory,[1,2] it has been reported that *N*-acetylglycylserine and *N*-acetylglycylserylglycylisoleucylalanine can be isolated from the enzymatic hydrolysates of ovalbumin; it has also been suggested that these *N*-acetylpeptides are derived from the *N*-terminal position of the protein, because many attempts over the past ten years, to find the terminal group by the usual analysis methods have been unsuccessful. It seems to be important to confirm the structure of such an unusual *N*-terminal peptide by chemical synthesis. *N*-Acetylglycyl-L-serine and *N*-acetyl-L-serylglycine have thus been synthesized. Comparisons of their chromatographic behaviors and of the products of the N→O acyl shift reaction with those of the natural acetylpeptide have been made.

Like ovalbumin, for the *N*-terminal group of mammalian (bovine and equine) heart cytochrome c, conflicting results had also been presented until *N*-acetylglycylaspartylvalylglutamic acid was isolated in a fairly good yield from the enzymatic digest of the cytochrome.[3] The structure of the isolated *N*-acetyltetrapeptide was confirmed by comparison with the synthetic material. The synthesis of the acetyltetrapeptide will be described and the troubles encountered during its synthesis will be discussed in the present communication.

## Experimental[4]

**The Synthesis of Acetylpeptide.**—*N-Chloroacetyl-O-benzyl-L-serine.*—*O*-Benzyl-L-serine[5] (9.8 g.) was dissolved in a mixture of 2 N sodium hydroxide and 2 N sodium carbonate (55 ml.); then into this solution chloroacetyl chloride (8.5 g.) was stirred portion by portion at 0—5°C. After the addition was complete, the reaction mixture was stirred at room temperature for half an hour. The pH of the solution was adjusted to 2.8 with 6 N hydrochloric acid, and white precipitates were collected as a waxy material. Yield, 11 g. (80%). Recrystallization from ethylacetate gave fine crystals. M. p. 114—115°C.

Found: N, 4.77. Calcd. for $C_{12}H_{14}O_4NCl \cdot H_2O$: N, 4.83%.

*N-Glycyl-O-benzyl-L-serine.* — Absolute methanol (200 ml.) in an ice-salt bath was saturated with

1) K. Narita, *Biochem. Biophys. Res. Comm.*, **5**, 160 (1961).
2) K. Narita and J. Ishii, *J. Biochem.*, **52**, 367 (1962).
3) K. Titani, K. Narita and K. Okunuki, *J. Biochem.*, **51**, 350 (1962).
4) All melting points are uncorrected. The $R_f$ values listed were measured on a paper chromatogram developed with *n*-butanol-acetic acid-water (4:1:1, v/v). The specific optical rotation was measured in an acetic acid solution.
5) K. Okawa, This Bulletin, **29**, 486 (1956).

dry ammonia, and pulverized *N*-chloroacetyl-*O*-benzyl-L-serine (9 g.) was added. *N*-Chloroacetyl-*O*-benzyl-L-serine is soluble in pure methanol, but sparingly soluble in the methanol-ammonia. Thus the suspension in a stoppered bottle was allowed to stand at room temperature for thirteen days with occasional shaking. The insoluble material (2.6 g.), which was the starting material, was removed by filtration. When the filtrate was concentrated in vacuo, a crystalline material was obtained. Yield, 4.3 g. When the above recovered starting material was subjected to further amination, an additional 2.2 g. of the dipeptide derivative was obtained. The total yield was 78%. Recrystallization from water-acetone gave fine crystals. M. p. 192—193°C.

Found: C, 57.87; H, 6.39; N, 10.82. Calcd. for $C_{12}H_{16}O_4N_2$: C, 57.13; H, 6.39; N, 11.11%.

*N-Acetylglycyl-O-benzyl-L-serine.*—Glycyl-*O*-benzyl-L-serine was acetylated in a usual manner using acetic anhydride and aqueous alkali. The acetylated dipeptide derivative was recrystallized from water. Yield, 74%. M. p. 105—108°C.

Found: N, 8.73. Calcd. for $C_{14}H_{18}O_5N_2 \cdot H_2O$: N, 8.97%.

*N-Acetylglycyl-L-serine.* — *N*-Acetylglycyl-*O*-benzyl-L-serine (2g.) was hydrogenated on palladium-charcoal in 75% *t*-butanol (60 ml.) in a 90% yield. Recrystallization from water gave pure acetyldipeptide. M. p. 166—167.5°C (decomp.).

Found: C, 40.80; H, 5.96; N, 13.45. Calcd. for $C_7H_{14}O_5N_2$: C, 41.17; H, 5.92; N, 13.72%.

*Carbobenzoxy-L-serylglycine Benzyl Ester.*—Carbobenzoxy-L-serine (6.4 g.) was dissolved in a warm chloroform-dioxane mixture (2 : 1, v/v, 45 ml.) and was coupled with glycine benzyl ester by dicyclohexylcarbodiimide (5.4 g.). After the mixture had been kept at room temperature overnight, dicyclohexylurea (4.6 g.) was filtered off. The filtrate was then concentrated and the residue dissolved in ethylacetate (150 ml.). The solution was washed successively with 0.6 N hydrochloric acid, 5% sodium hydrogen carbonate and water, and finally dried. After the removal of additional precipitates of the urea derivative, the solution was partly evaporated and petroleum ether was added. When the crude product (9.1 g.) was recrystallized from ethylacetate, 7.4 g. (72%) of the product was obtained. M. p. 109—110°C (lit. m. p. 102°C[6]).

Found: C, 62.84; H, 6.09; N, 7.14. Calcd. for $C_{20}H_{22}O_6N_2$: C, 62.16; N, 5.74; N, 7.25%.

*N-Acetyl-L-serylglycine.*—L-Serylglycine (m. p. 204—207°C, decomp.) was obtained from the carbobenzoxydipeptide benzylester by catalytic hydrogenation on palladium-charcoal in 75% *t*-butanol for 5 hr. Into an aqueous triethylamine solution (15% solution, 10 ml.), L-serylglycine (570 mg.) was dissolved, and then acetic anhydride (0.55 g.) was added. The reaction mixture was stirred for half an hour at 0—2°C and then kept for an additional thirty minutes at room temperature. The syrupy product which was obtained by the concentration of the above mixture below 38°C was dissolved in water (2 ml.) and placed on the top of a column of Dowex 50-X2 (H-form, 1×14 cm.). The column was then washed with water until the effluent became neutral. The effluent (30 ml.) was lyophilized. Yield, 480 mg. (68%). M. p. 161—163°C (decomp.).

Found: C, 40.98; H, 5.93. Calcd. for $C_7H_{12}O_5N_2$: C, 41.17; H, 5.92%.

*Carbobenzoxy-L-valyl-L-glutamic Acid Dibenzyl Ester.*—Crystalline carbobenzoxy-L-valine (6.6 g.) and L-glutamic acid dibenzyl ester *p*-toluenesulfonate (15.8 g.) were dissolved in methylene chloride (40 ml.) containing triethylamine (1.5 g.). Into this solution, dicyclohexylcarbodiimide (5.5 g.) in a small amount of the same solvent was then added on an ice-bath. Dicyclohexylurea precipitated immediately. After it had been allowed to stand in an ice-bath, the reaction mixture was left at room temperature for an additional fifteen hours. The urea derivative was removed by filtration, and the filtrate was successively washed with 0.1 N hydrochloric acid, water, 5% sodium hydrogen carbonate and water. It was then dried over anhydrous sodium sulfate, and the solution was evaporated to dryness in vacuo. The crystalline residue was recrystallized from ethylacetate. Yield, 11.2 g. (76.2%). M. p. 148°C. $[\alpha]_D^{27}$ −23.9° (*c* 2.0).

Found: C, 68.66; H, 6.76; N, 5.09. Calcd. for $C_{32}H_{36}O_7N_2$: C, 68.55; H, 6.47; N, 5.00%.

*L-Valyl-L-glutamic Acid.*—Carbobenzoxy-L-valyl-L-glutamic dibenzyl ester (10 g.) was reduced in 70% acetic acid (150 ml.) in the presence of 10% palladium on charcoal (1.0 g.) for two hours. After the removal of the catalyst by filtration, the filtrate was concentrated under reduced pressure. In order to remove the acetic acid completely, the solid residue was dissolved in a minimal volume of water and the solution evaporated to dryness. The above treatment was repeated, and then the crystalline residue was recrystallized from water-ethanol. Yield, 3.7 g. (84.2%). M. p. 227°C (decomp.). $[\alpha]_D^{27}$ +17.4° (*c* 1.4). $R_f$. 0.38.

Found: C, 48.84; H, 7.63; N, 11.30. Calcd. for $C_{10}H_{18}O_5N_2$: C, 48.76; H, 7.37; N, 11.38%.

*L-Valyl-L-glutamic Acid Dibenzyl Ester p-Toluenesulfonate.*—L-Valyl-L-glutamic acid (2.5 g.) *p*-toluenesulfonic acid hydrate (2.2 g.) and benzyl alcohol (20 ml.) were mixed in chloroform (100 ml.), and the mixture was refluxed with Wieland's apparatus (silica gel was used as a desiccant). Within a few hours the partly-insoluble starting material was dissolved entirely. Reflux was continued for ten hours, and then the solvent and the excess benzyl alcohol were removed in vacuo. When the syrupy residue was triturated in ether (150 ml.), a crystalline solid precipitated. It was recrystallized from ethanol-ether. Yield, 5.6 g. (91.8%). M. p. 108~109°C. $[\alpha]_D^{27}$ +0.0° (*c* 2.0). $R_f$ 0.81.

Found: C, 61.66; H, 6.54; N, 4.80. Calcd. for $C_{31}H_{38}O_8N_2S$: C, 62.19; H, 6.40; N, 4.68%.

*Carbobenzoxy-L-aspartyl-L-valyl-L-glutamic Acid Tribenzyl Ester.* — A mixture of L-valyl-L-glutamic acid dibenzyl ester *p*-toluenesulfonate (3.0 g.), triethylamine (0.5 g.), carbobenzoxy-L-aspartic acid β-benzyl ester[7] (1.6 g.) and dicyclohexylcarbodiimide (1.0 g.) was dissolved in methylene chloride

6) J. S. Fruton, *J. Biol. Chem.*, **146**, 463, (1942).

7) A. Berger and E. Katchalski, *J. Am. Chem. Soc.*, **73**, 4083 (1951).

(30 ml.); this solution was then allowed to stand for fifteen hours at room temperature. The precipitated dicyclohexylurea was filtered off and the filtrate was evaporated to dryness. The residue crystallized immediately. It was recrystallized from methanol. Yield, 2.4 g. (63.2%). M. p. 131°C. $[\alpha]_D^{27}$ −24.0° (*c* 1.9).

Found: C, 66.97; H, 6.34; N, 4.99. Calcd. for $C_{43}H_{47}O_{10}N_3 \cdot CH_3OH$: C, 66.73; H, 6.35; N, 5.19%.

*L-Aspartyl-L-valyl-L-glutamic Acid.*—Carbobenzoxy-L-aspartyl-L-valyl-L-glutamic acid tribenzyl ester (2.4 g.) was suspended in 70% acetic acid (100 ml.). Hydrogen gas was bubbled into the above solution for three hours in the presence of 10% palladium on charcoal (0.5 g.). The starting tripeptide derivative was dissolved within fifteen minutes. The catalyst was removed by filtration, and the filtrate was evaporated to dryness in vacuo. The residue was dissolved into water and lyophilized. (Attempts to crystallize it were unsuccessful.) Yield, 1.0 g. (89.0%). M. p. 165°C (decomp.). $[\alpha]_D^{27}$ −6.9° (*c* 1.0). $R_f$ 0.18.

Found: C, 45.46; H, 6.84; N, 11.20. Calcd. for $C_{14}H_{23}O_8N_3 \cdot 1/2\ H_2O$: C, 45.39; H, 6.35; N, 11.34%.

*L-Aspartyl-L-valyl-L-glutamic Acid Tribenzyl Ester p-Toluenesulfonate.*—L-Aspartyl-L-valyl-L-glutamic acid (0.8g.), *p*-toluenesulfonic acid hydrate (0.45 g.) and benzyl alcohol (1.0 ml.) were mixed in chloroform (20 ml.). The mixture was then refluxed with Wieland's apparatus. The solvent and the excess benzyl alcohol were distilled off in a high vacuum. The syrupy residue was dissolved in ether (2 ml.), and *n*-hexane was slowly added until crystalline precipitates appeared. These precipitates were collected and recrystallized from ether-*n*-hexane. Yield, 1.35 g. (78.3%). M. p. 181°C. $[\alpha]_D^{27}$ −21.0° (*c* 2.2). $R_f$ 0.85.

Found: C, 62.97; H, 6.10; N, 5.33. Calcd. for $C_{42}H_{49}O_{11}N_3S$: C, 62.95; H, 6.14; N, 5.23%.

*Acetylglycyl-L-aspartyl-L-valyl-L-glutamic Acid Tribenzyl Ester.*—Into an ice-cooled solution of acetylglycine (0.21 g.) in freshly-distilled dimethylformamide (10 ml.), carbonyldiimidazole (0.3 g.) was stirred. After ten minutes, a solution of L-aspartyl-L-valyl-L-glutamic acid tribenzyl ester *p*-toluenesulfonate (1.2 g.) and an equivalent amount of triethylamine in dimethylformamide (10 ml.) were added. The reaction mixture was then left for four hours at room temperature and diluted with water (20 ml.). The gelatinous product separated was collected by centrifugation, followed by filtration with suction. This was recrystallized from hot ethanol as fine needles. Yield, 0.7 g. (64.2%). $[\alpha]_D^{27}$ −13.0° (*c* 2.1).

Found: C, 63.85; H, 6.20; N, 8.00. Calcd. for $C_{39}H_{46}O_{10}N_4$: C, 64.09; H, 6.36; N, 7.67%.

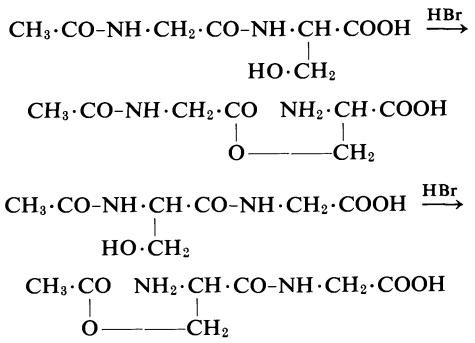
*Acetylglycyl-L-aspartyl-L-valyl-L-glutamic Acid.*—Acetylglycyl-L-aspartyl-L-valyl-L-glutamic acid tribenzyl ester (0.5 g.) was reduced over 10% palladium on charcoal (0.2 g.) in 50% acetic acid (20 ml.) for two hours. The catalyst was then removed by filtration, and the filtrate was concentrated in vacuo. The residue was dissolved in water, (20 ml.) and Amberlite IR-120 (H-form, 3 ml.) was poured in while it was being stirred and cooled. The resin was removed by filtration and washed with three 5 ml. portions of water. The combined filtrate and washings were then lyophilized. The colorless, fluffy material which remained was negative to the ninhydrin reaction. It contained three equivalents of carboxyl groups, as determined by titration with sodium methoxide.[8] M. p. 192°C (decomp.). $[\alpha]_D^{27}$ −29° (*c* 1.3). $R_f$ 0.55 (detected with bromocresol green; the paper strip must be free from acetic acid). Amino acid analysis with automatic equipment gave a molar ratio of 0.9 : 1.0 : 1.1 : 1.1 for glycine, aspartic acid, valine and glutamic acid.

Found: C, 44.62; H, 6.35; N, 11.82. Calcd. for $C_{18}H_{28}O_{10}N_4$: C, 45.19; H, 6.32; N, 11.71%.

**The N→O Acyl Shift Reaction of *N*-Acetylglycylserine and *N*-Acetylserylglycine.** — About 2 mg. of the peptide was suspended in 5 ml. of dry dioxane, and hydrogen bromide gas was passed through until the mixture became clear.[2] The solution was refluxed for a few minutes to complete the N→O shift reaction and then evaporated to dryness in vacuo. The residue was dissolved in a minimum volume of water, and an aliquot was used for paper chromatography (*n*-butanol - acetic acid - water 4 : 1 : 1, v/v). The remaining aliquot was made alkaline by the addition of 5% ammonium hydroxide, and then the solution was kept for 2 hr. at room temperature in order to reverse the shifted products (O→N acyl shift). The solution was evaporated at room temperature in an evacuated desiccator. The characterization of the products of the O→N acyl shift reaction was performed by paper chromatography.

**The Carboxypeptidase A Digestion of the Acetylglycylaspartylvalylglutamic Acid.**—To compare the natural acetyltetrapeptide with the synthetic one, the rate and the extent of the release of amino acids from the peptides by the action of carboxypeptidase A were measured. The crystalline enzyme was purchased from the Worthington Biochemical Corp. (Freehold, New Jersey) and used after three recrystallizations. As has been reported previously,[3] the enzyme hydrolyzed the acetyltetrapeptide most at pH 6.0, in contrast to the usual optimum of pH 8.0, and the digestion was carried out at pH 6.0 (M/7 sodium acetate - M/7 sodium barbiturate - N/10 hydrochloric acid - 8.5% sodium chloride buffer) and at room temperature in the substrate to the enzyme ratio of 1 : 1 by weight. The amino acids released were characterized and estimated as their dinitrophenyl derivatives by paper chromatography.

## Results and Discussion



Although it was quite clear from the structural analysis that the acetyldipeptide isolated from the pronase (the trade name of a protease of *Streptomyces griseus*) digest of ovalbumin was acetylglycylserine,[1,2] two acetyldipeptides, which have opposite amino acid sequences were prepared in order to compare them with the natural acetyldipeptide.

8) J. S. Fritz and N. M. Lisicki, *Anal. Chem.*, **23**, 589 (1951).

Unfortunately, the two synthetic acetyldipeptides behaved identically on a paper chromatogram with the natural peptide ($R_f$ 0.46, *n*-butanol - acetic acid - water, 4 : 1 : 1, v/v) ; moreover, the chromatograms of the hydrazinolysates of the three acetyldipeptides, synthetic and natural, were all the same, showing acetylhydrazide ($R_f$ 0.63, pyridine-aniline-water, 9 : 1 : 4, v/v ; 0.45, collidine-picoline-water, 5 : 3 : 2, v/v), glycine hydrazide ($R_f$ 0.37 ; 0.11) and serine hydrazide ($R_f$ 0.46 ; 0.16).[1,2]

In order to distinguish *N*-acetylglycylserine from *N*-acetylserylglycine, the N→O acyl shift reaction was explored in anhydrous dioxane by passing hydrogen bromide gas through. It may be expected that *O*-[acetylglycyl]-serine will be produced from *N*-acetylglycylserine by the shift reaction[2] while *O*-acetylserylglycine is obtained from *N*-acetylserylglycine, and that the $R_f$ values of the above two products are probably different from one another on a paper chromatogram.

The $R_f$ values of the reaction products of the two synthetic and one natural acetyldipeptides are listed in Table I. It is clear from the table that the shift reaction under the conditions was accompanied by some side reactions. The products of the N→O acyl shift reaction may be recovered as the starting compound by the reverse O→N acyl shift

reaction in an alkaline medium, whereas the products by the side reaction will not be changed under the conditions. As can be seen in Table I, free amino acid resulted from the *C*-terminal amino acid, in some extent as a result of the hydrolytic side reaction. An additional unknown side reaction product, which is ninhydrin-positive, was observed in both cases, but it is not known whether or not the unknown product from acetylglycylserine is the same as that from acetylserylglycine, although their $R_f$ values are quite similar.

At any rate, the behavior of the products of the N→O acyl shift reaction of the natural acetyldipeptide was identical with that of the synthetic acetylglycyl-L-serine. Thus, the

TABLE I. $R_f$ VALUES OF THE PRODUCTS OF N→O ACYL SHIFT REACTION OF *N*-ACETYLGLYCYLSERINE AND *N*-ACETYLSERYLGLYCINE*

| | Standard | Reaction products of N→O acyl shift | | | | |
|---|---|---|---|---|---|---|
| | | Synthetic *N*-acetylglycylserine | | Natural *N*-acetylglycylserine | Synthetic *N*-acetylserylglycine | |

* *n*-Butanol-acetic acid-water (4 : 1 : 1, v/v) was used as a solvent for descending paper chromatography. The ninhydrin reagent was used for the detection of the products. When quite enough amount of *N*-acetyl derivatives are present on a paper and when prolonged heating with an iron after spraying the reagent was used, they colored as pinkish purple. In this experiment, the chlorine-iodide-starch reaction was also employed after the ninhydrin reaction to identify *N*-acetyl derivatives sharply ($R_f$ values are shown as italic figures). *O*-[Acetylglycyl]-L-serine was a generous gift from Dr. Shumpei Sakakibara of the Institute for Protein Research, Osaka University and the other standard peptides were synthesized by the present authors.

** Color intensity of an unknown spot was weak, especially in the case of the reaction product of *N*-acetylserylglycine.

structure deduced for the natural acetyldipeptide isolated from ovalbumin[1] was confirmed without any ambiguity.

We have demonstrated that cytochromes c from bovine and equine hearts terminated at acetylglycylaspartylvalylglutamic acid.[3] At almost same time Margoliash et al.[9] determined the complete amino acid sequence of equine heart cytochrome, their results are consistent with the *N*-terminal sequence we have described above. In order to confirm the *N*-terminal structure of the cytochrome, we attempted the synthesis of *N*-acetylglycyl-L-aspartyl-L-valyl-L-glutamic acid. The first route to synthesize the acetyltetrapeptide of the problem was as follows:

Cbz-L-aspartic acid β-methyl ester + L-Valyl-L-glutamaic dimethyl ester —DCCD→

Cbz-L-aspartyl-L-valyl-L-glutamic acid trimethyl ester

M. p. 171°C, $[\alpha]_D^{22}$, −19.40 (*c* 0.62, acetic acid), 71%

—$H_2$/Pd→ L-Aspartyl-L-valyl-L-glutamic acid trimetyl ester + Cbz-glycine —DCCD→

Cbz-glycyl-L-aspartyl-L-valyl-L-glutamic acid trimethyl ester

M. p. 130—137°C, $[\alpha]_D^{22}$ −36.6° (*c* 0.82), 64%

—$H_2O$→ Cbz-glycyl-L-aspartyl-L-valyl-L-glutamic acid

M. p. 100—111°C, $[\alpha]_D^{22}$ −4.20 (*c* 1.18), 81%

—$H_2$/Pd→ Glycyl-L-aspartyl-L-valy-L-glutamic acid

$[\alpha]_D^{22}$ +4.7° (*c* 0.64), 89%

—Acetic anhydride→ Acetylglycyl-L-aspartyl-L-valyl-L-glutamic acid

M. p. 140°C, $[\alpha]_D^{22}$ −5.1° (*c* 0.78), 83%

(Cbz and DCCD are the abbreviations for the carbobenzoxy group and for dicyclohexylcarbodiimide respectively.)

The acetylglycyl-L-aspartyl-L-valyl-L-glutamic acid thus synthesized (this acetyltetrapeptide is designated as I to distinguish it from the acetyltetrapeptide II which is prepared by the method described in the "Experimental" section) was shown by amino acid analysis to contain an equimolar amount of the constituent amino acids. The chromatographic behavior ($R_f$ 0.72, *n*-butanol - acetic acid - water, 4 : 1 : 1, v/v) of the synthetic acetyltetrapeptide I on a paper was identical with that of the natural acetyltetrapeptide obtained from bovine and equine heart cytochromes c. *C*-Terminal analyses of both the peptides by the hydrazinolysis method gave only glutamic acid. However, when the synthetic acetyltetrapeptide I was incubated with carboxypeptidase A at pH 6.0, the expected amount of glutamic acid and an unexpectedly small amount of valine were liberated, whereas from the natural acetyltetrapeptide almost quantitative amounts of glutamic acid and valine were released. Therefore, we have considered that the valine residue might be partly racemized during its synthesis. Thus, a bioassay of the valine in the acid hydrolysate of the acetyltetrapeptide I was performed.[10] The estimate showed that it was the natural form. Then the products of partial acid hydrolysate (concentrated hydrochloric acid at room temperature for 48 hr.) of the synthetic acetyltetrapeptide I were compared with those of the natural peptide by paper chromatography and electrophoresis. As is schematically represented in Fig. 1, one main spot, aspartylvalylglutamic acid, could be revealed with the ninhydrin reagent in the case of the natural acetyltetrapeptide. However, in the case of the synthetic peptide I, the aspartylvalylglutamic acid spot was quite faint, and another bluish-green spot appeared with the ninhydrin reagent at a slightly lower $R_f$ value on the chromatogram. This bluish-green spot was located at a more negatively-charged position on the paper electrophoregram at pH 3.6 than that of the tripeptide derived from the natural acetylpeptide. The amino acid analysis of this abnormal spot demonstrated that it also contained equimolar amounts of aspartic acid, valine and glutamic acid. Therefore, it seems to be β-aspartylpeptide, since the p*K'* value

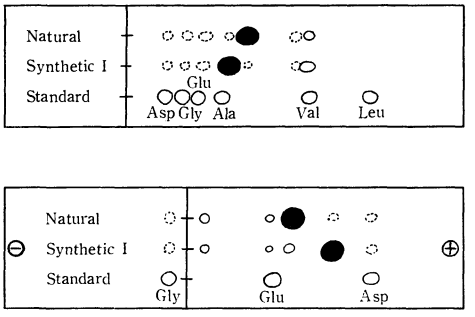

Fig. 1. Paper chromatogram and paper electrophoregram of partial acid hydrolysates of natural and synthetic acetylglycylaspartylvalylglutamic acid I.

Paper chromatography was carried out by descending way using *n*-butanol - acetic acid - water (4 : 1 : 1, v/v). Paper electrophoregram was made after migration for 120 min. at a potential of 3000 V./60 cm. at pH 3.6. Black spot represents aspartylvalylglutamic acid.

9) E. Margoliash, E. L. Smith, G. Kreil and H. Tuppy, *Nature*, **192**, 1125 (1961).

10) The bioassay of valine was kindly performed by the Ajinomoto Research Laboratory.

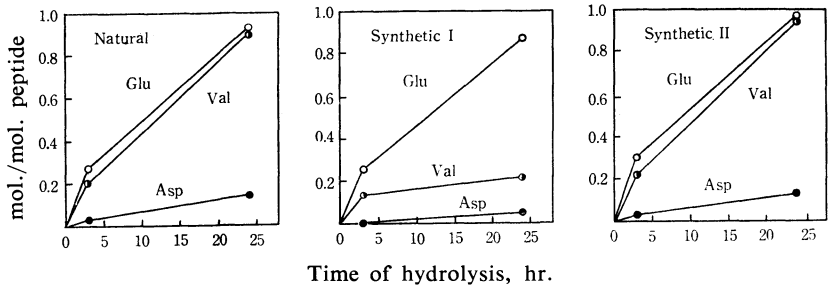

Fig. 2. Releases of amino acids from natural and synthetic acetylglycylaspartylvalylglutamic acids I and II by the action of carboxypeptidase A at pH 6.0. Released amino acids were estimated as their dinitrophenyl derivatives.

of the $\alpha$-carboxyl group (1.995)[11] is lower than that of the $\beta$-carboxyl group (3.910)[11] and the former is more negatively charged than the latter at an acidic medium (pH 3.6). The $\beta$-linkage might be produced during the saponification step of the ester groups of carbobenzoxyglycyl-L-aspartyl-L-valyl-L-glutamic acid trimethyl ester via an assumed succinimide-type linkage.[12] It appears probable that the synthetic acetyltetrapeptide I is acetylglycyl-$\beta$-L-aspartyl-L-valyl-L-glutamic acid.

Thus we next explored the synthesis of the acetyltetrapeptide II, excluding the saponification step of the ester of the side chain of the aspartyl residue, as is described in the "Experimental" section. Namely, only the benzyl ester was used as the protection of the carboxyl groups, and it was removed by catalytic hydrogenation. Furthermore, to avoid alkaline conditions throughout the synthesis, acetylglycine was coupled with the tripeptide tribenzyl ester, in contrast to the use of acetic anhydride under the alkaline conditions to introduce the acetyl group to the tetrapeptide in the previous synthesis of the acetyltetrapeptide I.

The synthesized acetyltetrapeptide II showed behavior identical to that of the natural one in every respect examined. The releases of amino acids from the three acetyltetrapeptides, natural, synthetic I and II, by the action of carboxypeptidase A at pH 6.0 are shown in Fig. 2.

The infrared absorption spectra of the two synthetic acetylpeptides I and II were the same in the 4000—650 $cm^{-1}$ region, but an appreciable difference could be observed between the two in the 900—400 $cm^{-1}$ region. Such a difference should probably be attributed to the difference in the mode of linkage in aspartic acid residues in the synthetic acetyltetrapeptides.

## Summary

In previous studies acetylglycylserine and acetylglycylaspartylalylglutamic acid had been isolated from the enzymatic digests of ovalbumin and cytochromes c of bovine and equine hearts, respectively. Here, in order to confirm the structures of the acetylpeptides isolated, acetylglycyl-L-serine and acetylglycyl-L-aspartyl-L-valyl-L-glutamic acid have been synthesized. It has been proved that the natural acetylpeptides are identical with the synthetic ones in every respect examined. Some troubles encountered during the synthesis of the acetyltetrapeptide have been discussed.

The authors are grateful to the Ajinomoto Co., Ltd., and to Dr. Kunio Fukushima for performing the bioassay of L-valine and the infrared absorption analysis respectively.

# The Radiation-induced Addition of Hydrogen Sulfide to Olefins*

By Ken'ichi SUGIMOTO, Wataru ANDO and Shigeru OAE

(Received June 18, 1964)

In a previous investigation of the radiation-induced addition of hydrogen sulfide to propylene,[1] the formation of *n*-propyl mercaptan and of di-*n*-propyl sulfide have been observed. The radiation-induced addition of hydrogen sulfide to propylene took place very readily, and was completed at room temperature with a relatively small radiation dose. The *G*-values of this reaction were found to be more than ten thousand, while the addition followed the anti-Markownikov rule. Apparently the reaction proceeds through a free radical chain process, where the sulfhydryl radicals formed in the initial step of the radiolysis of hydrogen sulfide undergo a radical addition to the propylene in the following chain propagating step:

$$H_2S \longrightarrow HS\cdot + \cdot H \qquad (1)$$

$$HS\cdot + CH_2{=}CH{-}CH_3 \rightarrow \underset{\displaystyle SH}{CH_2{-}\dot{C}H{-}CH_3} \qquad (2)$$

$$\underset{\displaystyle SH}{CH_2{-}\dot{C}H{-}CH_3} + H_2S \rightarrow \underset{\displaystyle SH}{CH_2{-}CH_2{-}CH_3} + HS\cdot \qquad (3)$$

In the present work, the radiation-induced addition of hydrogen sulfide to propylene has been extended to other various gaseous olefins.

## Experimental

**Irradiations.**—The gamma radiation was provided by a 1000-curie or a 5000-curie cobalt-60 source.[2] Samples were irradiated at fixed positions at which the dose rates were $1.9\times10^5$, $2.8\times10^4$, $1.1\times10^4$, and $5.7\times10^3$ r./hr. respectively. The dose rates were obtained by means of a Fricke ferrous sulfate dosimeter, taking *G* as 15.6.[3]

**Reaction Vessel.**—The irradiation vessel used for this gaseous reaction was a Pyrex tube 25 mm. in outside diameter and 20 cm. long and equipped with a breakoff seal.

**Materials.**—All the olefins except butadiene were purchased from the Takachiho Chemicals Co., Tokyo, and hydrogen sulfide, from the Seitetsu Chemicals Co., Kakogawa; both were purified by vacuum distillations. Butadiene was obtained from the Japan Synthetic Rubber Co., Yokkaichi. The impurities in both the olefins and hydrogen sulfide used were found to be less than 0.5% by gas chromatographic analysis.

**Analysis.**—Conventional high-vacuum techniques were employed throughout the investigation. All the analyses of the irradiated samples were carried out by a combination of fractional distillation and gas chromatographic separation.

*Isobutene with Hydrogen Sulfide.*—The samples were analyzed by the same procedure as was used in the case of propylene.[1]

*cis- and trans-2-Butene with Hydrogen Sulfide.*—The procedure will be explained in the following paper.[4]

*Various Olefins with Hydrogen Sulfide.*—The irradiated samples were first passed through a series of dry ice-acetone cooled traps and then through a liquid nitrogen-cooled trap. The fraction condensed in the dry ice-acetone cooled trap was analyzed qualitatively by a gas chromatograph (Hitachi type KGL-2A), using a 90 m. Golay column coated with squalane. The amount of thiols in this fraction was determined by potentiometric titration with silver nitrate in isopropyl alcohol.[5]

## Results and Discussion

Various amounts of olefins were mixed with hydrogen sulfide, and these mixtures were irradiated at several radiation doses in static systems.

**The Radiation-induced Addition of Hydrogen Sulfide to Isobutene.**—The mixtures of hydrogen sulfide and isobutene were irradiated with cobalt-60 gamma rays; these results are shown in Table I. The addition is undoubtedly initiated by the decomposition of hydrogen sulfide, as is shown by:

$$H_2S \longrightarrow HS\cdot + \cdot H \qquad (1)$$

Then the sulfhydryl radical thus formed attacks isobutene:

$$HS\cdot + CH_2{=}\underset{\displaystyle CH_3}{\overset{\displaystyle CH_3}{C}} \rightarrow HSCH_2{-}\underset{\displaystyle CH_3}{\overset{\displaystyle CH_3}{\dot{C}}}\cdot \qquad (4)$$

4) K. Sugimoto, W. Ando and S. Oae, This Bulletin, **38**, 224 (1965).

5) M. W. Tamele and L. B. Ryland, *Ind. Eng. Chem., Anal. Ed.*, **8**, 16 (1936).

The adduct radical formed can react with hydrogen sulfide, yielding 2-methylpropylmercaptan:

$$HSCH_2-\overset{CH_3}{\underset{CH_3}{C}}\cdot + H_2S \rightarrow HSCH_2-\overset{CH_3}{\underset{CH_3}{CH}} + HS\cdot \quad (5)$$

or with isobutene, giving the propagating radical:

$$HSCH_2-\overset{CH_3}{\underset{CH_3}{C}}\cdot + CH_2=\overset{CH_3}{\underset{CH_3}{C}} \rightarrow HSCH_2-\overset{CH_3}{\underset{CH_3}{C}}-CH_2-\overset{CH_3}{\underset{CH_3}{C}}\cdot \quad (6)$$

Steps 4 and 5 are the chain-carrying steps of the addition of hydrogen sulfide to isobutene, while step 6 is the propagating step of telomer production. The experiments indicate that reaction 5 proceeds in preference to reaction 6.

TABLE I. THE RESULTS OF THE RADIATION-INDUCED ADDITION OF HYDROGEN SULFIDE TO ISOBUTENE

| Dose rate r./hr. | Product | Amount of product mmol. Irrd. time 24 hr. | Irrd. time 48 hr. |
|---|---|---|---|
| $2.8\times10^4$ | 2-Methylpropylmercaptan | 1.53(24%) | 1.35(21%) |
| | Di(2-methylpropyl) sulfide | 1.88(59%) | 2.47(78%) |
| $1.1\times10^4$ | 2-Methylpropylmercaptan | | 1.53(29%) |
| | Di(2-methylpropyl) sulfide | | 2.22(70%) |
| $5.7\times10^3$ | 2-Methylpropylmercaptan | | 1.26(20%) |
| | Di(2-methylpropyl) sulfide | | 1.68(53%) |

Sample: Isobutene, 980 mmHg, 6.33 mmol.; $H_2S$, 700 mmHg, 4.50 mmol.

The telomer was not found in the products. The reactivity of isobutene with hydrogen sulfide is nearly equal to that of propylene with hydrogen sulfide, while that of *trans* or *cis*-2-butene with hydrogen sulfide is one-tenth of that of propylene or isobutene, as shown in Tables II and III. The difference between these reactivities might depend on the reactivity of each olefin. The radiation-indcued polymerization of isobutene did take place and was easy to follow, while no polymerizations of *cis*- and *trans*-2-butenes were recognized. Under the conditions of cationic polymerization,[6] at room temperature, isobutene has been shown to polymerize much more readily than 2-butenes.

**The Radiation-induced Addition of Hydrogen Sulfide to *trans*- or *cis*-2-Butene.**—The results of the radiation-induced addition of hydrogen sulfide to 2-butenes are shown in Tables II and III. In the addition reaction of *trans*- or *cis*-2-butene, a rapid isomerization of 2-butene was found to take pleace simultaneously; hence, in Table II the amounts of *cis*-2-butene isomerized from *trans*-2-butene are also shown. The radiation-induced equilibriation of *trans*- and *cis*-2-butene with hydrogen sulfide is readily, attained. The cis-trans ratio reaches a limiting value, 28 to 72, under various conditions. On the other hand, the *G*-values of the 1-methylpropylmercaptan formed are $4—9\times10^3$, and the rate of reaction has been shown to be linear to the square root of the dose rate.

**The Formation of Thiols by the Radiation-induced Reaction of Hydrogen Sulfide with Olefins.**—When one wants to obtain thiols, it is desirable to employ a large excess of hydrogen sulfide, or to separate the thiols at an early stage of the radiation-induced reaction.[1] Thiols were the only products obtained when the amount of hydrogen sulfide added was 6—8 times more than that of an unsaturated compound in this radiation-induced addition

TABLE II. THE RESULTS OF THE RADIATION-INDUCED ADDITION OF HYDROGEN SULFIDE TO *trans*-2-BUTENE

| Does rate, r./hr. | Product | *G*-value | Amount of product, mmol. Irrd. time 24 hr. | Irrd. time 48 hr. |
|---|---|---|---|---|
| $2.8\times10^4$ | 1-Methylpropylmercaptan | $4.1\times10^3$ | 0.18 (2.6%) | 0.26 (3.7%) |
| | *cis*-2-Butene | | 1.67 (24%) | 1.60 (23%) |
| $1.1\times10^4$ | 1-Methylpropylmercaptan | $7.1\times10^3$ | 0.15 (2.2%) | 0.23 (3.3%) |
| | *cis*-2-Butene | | | 1.60 (23%) |
| $5.7\times10^3$ | 1-Methylpropylmercaptan | $8.5\times10^3$ | | 0.18 (2.6%) |
| | *cis*-2-Butene | | | 1.74 (25%) |

Sample: *trans*-2-Butene, 6.95 mmol.; $H_2S$, 4.10 mmol.

| $5.7\times10^3$ | Di(1-methylpropyl) sulfide | |
| | *trans*-2-Butene | |

Sample : *cis*-2-Butene, 6.95 mmol. ; $H_2S$, 4.10 mmol.

TABLE IV. THE FORMATION OF THIOLS BY THE RADIATION-INDUCED REACTION OF HYDROGEN SULFIDE TO OLEFINS

| Olefin | Amount of thiol formed, mmol. |
|---|---|
| Ethylene | 1.45 |
| Propylene | 1.40 |
| 1-Butene | 0.94 |
| Isobutene | 0.75 |
| *cis*-2-Butene | 0.52 |
| *trans*-2-Butene | 0.50 |
| Butadiene | 0.00 |
| Acetylene | 0.18 |

Dose rate : $1.9\times10^5$ r./hr. Radiation dose : $5.7\times10^5$ r.
Sample : Olefin, 2.15 mmol. ; $H_2S$, 12.6 mmol.

reaction. Here, the addition follows the anti-Markownikov rule. The experiment of the addition of hydrogen sulfide has been extended to various olefins; the results of the radiation-induced addition are listed in Table IV.

Apparently the reactivities of various olefins toward hydrogen sulfide are different in this addition reaction, and the radical chain of these reactions seems to decrease with an increase in the carbon number of olefins. However, all the olefins apparently underwent a similar radical chain process, and the *G*-value dependence of dose rate is also similar to the case of propylene with hydrogen sulfide.[1]

The radiation-induced addition of hydrogen sulfide to butadiene was not observed. The addition of hydrogen sulfide to butadiene was substantially more difficult than that to other olefins. Similar phenomena have been reported by Sivertz[7] in the photo-initiated addition of methyl mercaptan. The photo-initiated addition of methyl mercaptan to isobutene, ethylene and butadiene in the gas phase has yielded overall negative activation energies of $-8900$, $-8800$, $-7900$ and $+2800$ respectively. The rate-determining step is thought to be hydrogn abstraction, for which the activation energy is estimated to lie between 2 and 3 kcal. for all except butadiene, which is considerably higher, about 6 kcal.

## Summary

The radiation-induced free radical addition of hydrogen sulfide to olefins to give the corresponding thiols has been studied. The addition of the thiols to olefins has been found to undergo a free radical chain reaction, readily yielding the corresponding sulfides in the succeeding step. However, the thiols were found to be the only component when an excess of hydrogen sulfide was used. The reactivity of the radical chain reaction decreases with an increase in the carbon number of $\alpha$-olefins.

# The Radiation-induced cis-trans Isomerization of 2-Butenes by Hydrogen Sulfide*

By Ken'ichi SUGIMOTO, Wataru ANDO and Shigeru OAE

(Received June 18, 1964)

The radiation-induced free radical addition of hydrogen sulfide to olefins is a reaction which has been often studied;[1-4] it is considered to involve the following chain propagating steps:

$$H_2S \xrightarrow{\gamma} HS\cdot + H \quad (1)$$

$$HS\cdot + CH_2{=}CHR \rightarrow HS\dot{C}H_2{-}CHR \quad (2)$$

$$HSCH_2{-}\dot{C}HR + H_2S \rightarrow HSCH_2{-}CH_2R + HS\cdot \quad (3)$$

The thiols, once formed, undergo further reaction with olefins to give the corresponding sulfides. The free radical addition of thiols to olefins is considered to involve the following similar chain-propagating steps:[5,6]

$$RCH_2CH_2SH \xrightarrow{\gamma} RCH_2{-}CH_2S\cdot + H \quad (4)$$

$$RCH_2{-}CH_2S\cdot + CH_2{=}CHR \rightarrow RCH_2{-}CH_2S\dot{C}H_2{-}CHR \quad (5)$$

$$RCH_2{-}CH_2S\dot{C}H_2{-}\dot{C}HR + RCH_2{-}CH_2SH \rightarrow (RCH_2{-}CH_2)_2S + RCH_2{-}CH_2S\cdot \quad (6)$$

In a previous paper[7] of this series, evidence was presented for the abstraction of hydrogen atoms from hydrocarbons either by sulfhydryl radicals or thiyl radicals; that is, the reactions which are essentially the reverse of 3 and 6 can occur with ease in certain systems. There is also good reason to believe that reactions 2 and 5 may be reversible as well, in view of several previous works on similar thiol-addition reactions to olefins.[7,8] In studying the addition of methanethiol to isobutene, propylene and ethylene in the gas phase, Sivertz et al.[9] have found negative overall activation energies of 8 to 9 kcal. The photoisomerization of *cis*- and *trans*-2-butenes in the presence of methanethiol has also been studied recently.[10] Especially interesting is the work by Skell and Allen, who demonstrated that the orientation of the free radical addition of $CH_3SD$ is controlled by the strength of the deuterium-bound bond.[11] Meanwhile, experiments in our work[2] have demonstrated the reversibility of the radical-addition reaction in the gas-phase mixtures of hydrogen sulfide and olefins by the rapid isomerization of unreacted olefin during the irradiations at room temperature. This paper will present more detailed data on this reversibility.

## Experimental

**Irradiations.**—The gamma radiation was provided either by a 100-curie or a 1000-curie cobalt-60 source.[12] The dose rates were obtained from the Fricke ferrous sulfate dosimeter, taking $G$ as 15.6,[13] and from the Victoreen rate meter. The $G$-values were calculated from the relation of the products formed and the absorption energy of the gaseous sample. The absorption energies of 2-butenes and of hydrogen sulfide were corrected in electron density from the absorption of air, 83.8 erg./g./r.; 2-butenes correspond to 95.7 erg./g./r., and hydrogen sulfide, to 88.7 erg./g./r. All the irradiations were carried out at room temperature.

**Reaction Vessel.**—The irradiation vessel used for these gaseous reactions was a Pyrex tube 25 mm. in outside diameter and 20 cm. long and equipped with a breakoff seal.

**Materials.**—*cis*-2-Butene and *trans*-2-butene were purchased from the Takachiho Chemicals Co., Tokyo, and hydrogen sulfide, from Seitetsu Chemicals Co., Kakogawa; both were purified by fractional distillations. The impurities in both the 2-butenes and the hydrogen sulfide used were found to be less than 0.5% by gas chromatographic analysis.

**Analyses.**—Conventional high-vacuum techniques

were employed throughout the investigation. All the analyses of the irradiated samples were carried out by a combination of fractional distillation and gas chromatographic separation.

The irradiated sample was passed first through a series of dry ice - acetone cooled traps, then through carbon disulfide - cooled traps, and finally through liquid nitrogen traps. The fraction condensed in dry ice - acetone cooled traps was found to be a mixture of 2-butanethiol and di-2-butyl sulfide. The condensed gas at the carbon disulfide - cooled traps was identified as a mixture of unreacted and isomerized 2-butene. This portion was measured by gas chromatography (Hitachi type KGL-2A), using a 90 m. Golay column coated with squalane and operated at room temperature with a He carrier at 1.5 kg./cm$^2$. The condensed gas at liquid nitrogen was identified as unreacted hydrogen sulfide.

## Results and Discussion

Samples of mixtures consisting of various amounts of pure *trans*-2-butene and hydrogen sulfide were irradiated in a static system as has been described in the "Experimental" section. These were then periodically analyzed by gas chromatography. The results of such experiments are shown in Table I. The isomerized mixtures show the compositions of 72% and 28% for *trans*- and *cis*-2-butenes respectively. Similar experiments carried out on pure *cis*-2-butene gave the results shown in Table I. Here again, the values obtained for trans-cis are nearly identical, i. e., 73%-27%. The radiation-induced equilibrium of *trans*- and *cis*-butenes by hydrogen sulfide obtained under various conditions are shown in Table I; the cis-trans isomerization readily reaches an equilibrium and gives a mixture of 28% and 72% of *cis*- and *trans*-2-butenes. Meanwhile, the *G*-value of 2-butanethiol formation was found to be about $4-9\times10^3$, and the rate was shown to be linear to the square root of the dose rate.

To determine the yield of the radiation-induced cis-trans isomerization in somewhat more detail, mixtures of various amounts of *cis*-2-butene and hydrogen sulfide were subjected to small doses of irradiation. The results of these experiments are shown in Fig. 1. Within these irradiation doses, the amount of

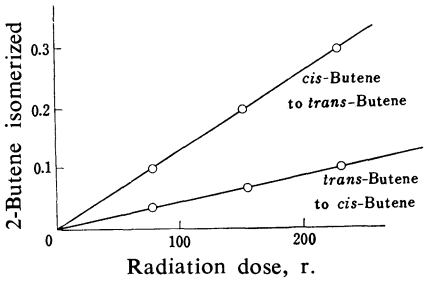
| $1.1\times10^4$ | | trans 72% cis 29% | trans 73% cis 27% |
| $5.7\times10^3$ | | trans 71% cis 29% | |

* Composition of reaction mixtures : 2-butenes, 1140 mmHg ; $H_2S$, 670 mmHg



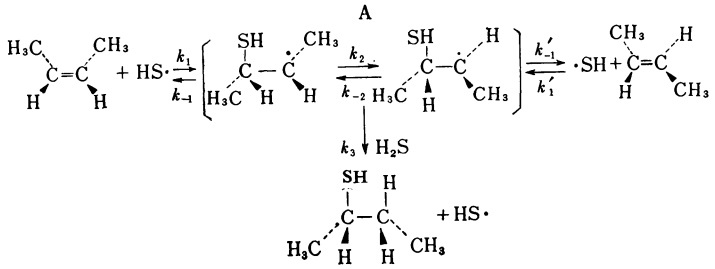


Fig. 1. The radiation-induced isomerization of *trans*- and *cis*-2-butene with hydrogen sulfide. (Sample : 2-butene 2.48 mmol., $H_2S$ 0.90 mmol.)

trans-isomerization is proportional to the energy absorbed, and no thiol and sulfide were detected among the products.

The radiation-induced isomerizations of *cis*-2-butene alone, without any addent, namely direct isomerizations, were also performed. The *G*-value of the direct isomerization is 300, while the *G*-value of the isomerization by sulfhydryl radicals was found to be around $2.5\times10^5$. These results can be well explained by the formation of intermediate radicals (A) by the attack of the sulfhydryl radical on 2-butene.

If one assumes that the initial step of the reaction is the attack of the sulfhydryl radical on 2-butene, one can write the scheme for the reaction as in 7, where $k_3$, the rate of hydrogen abstraction, is much smaller than $k_2$ or $k_{-2}$, the rate of the equilibration of the incipient radical A.

(7)

The intermediate incipient radical presumably readily regenerates the equibrium mixture of *cis*- and *trans*-2-butenes by losing the sulfhydryl radical.

Since the reaction of sulfhydryl radicals with 2-butenes to form the incipient radical A is presumed to be reversible, the trans isomer appears in the unreacted 2-butene in the addition reaction of hydrogen sulfide to *cis*-2-butene by gamma irradiations. It was found that the *G*-value for the formation of *trans*-2-butene from the composite radical was 50 times that of the formation of the addition product by the hydrogen transfer from hydrogen sulfide. The *G*-value for *cis*-2-butene formation is 20 times that for the formation of the addition product. Therefore, the decomposition of the incipient radical into the sulfhydryl radical and 2-butenes is very rapid compared to the hydrogen transfer reaction with hydrogen sulfide.

In this respect, the $\gamma$-ray induced isomerization of 2-butenes by $H_2S$ is essentially the same as that by photochemical isomerization with methanethiol,[10] and it involves the reversible formation of an incipient radical intermediate, as has been described in Eq. 2. The larger *G*-value of the isomerization from *cis*-2-butene than that from the trans isomer seems to suggest that the initial addition and the final loss of the sulfhydryl radical are very fast and that the rate is controlled by the rotation barrier in A. Meanwhile, the rate-determining step in the formation of the addition product is thought to be 3, the activation energy for which is estimated to lie between 2 and 3 kcal.[14]

## Summary

Radiation-induced free radical isomerizations of 2-butenes with hydrogen sulfide at room temperature gave identical mixtures of about 72% *trans*- and 28% *cis*-butenes. The *G*-value of the isomerization is 20 to 50 times larger than that of the formation of the addition product. With gamma irradiation, 2-butenes in the presence of hydrogen sulfide were rapidly isomerized, even with a very small radiation dose. This ready isomerization indicates the ease of the reversibility of the first step of the sulfhydryl-radical addition reactions.

# The Radiation-induced Isomerization of 2-Butenes

By Wataru ANDO, Ken'ichi SUGIMOTO and Shigeru OAE

(Received June 18, 1964)

The cis-trans isomerization of 2-butenes has been investigated under various conditions in order to obtain some critical information about the nature and reactivity of the double bond. Gas-phase thermal isomerization has been known to be of a unimolecular reaction, in which there is a transition to an excited state, which can then undergo a radiationless transition to the ground state with isomerization.[1]

The cis-trans isomerization of 2-butenes through the triplet state provides a straightforward means of conducting the multiplicity exchange:

Sensitizer (triplet) + 2-Butene (singlet) ⟶ 2-Butene (triplet) + Sensitizer (singlet) (1)

Hammond, Leermarkers and Turro[2] have suggested that it is possible to study the mechanisms of various photochemical reactions by determining the formation of the triplet intermediates from the reactants in the presence of such a sensitizer as benzophenone. Cundall and Palmer[3] have also studied the gas-phase

1) B. S. Rabinovitch and K. W. Michel, *J. Am. Chem. Soc.*, **81**, 5065 (1959).

2) G. S. Hammond, P. A. Leermarkers and N. J. Turro, ibid., **83**, 2395 (1961).

3) R. B. Cundall and T. F. Palmer, *Trans. Faraday Soc.*, **56**, 1211 (1960).

isomerization of 2-butene in the presence of various photosensitizers, such as mercury, sulfur dioxide, benzene and a variety of other organic photosensitizers, and have shown that the multiplicity exchanges that lead to the isomerization can be accomplished if the photosensitizing species have energy in excess of approximately 60 kcal. mol.$^{-1}$ above the ground state. If this latter condition is satisfied, reaction 1 occurs at every collision.

It has long been known that a trace of bromine or iodine initiates the cis-trans isomerization of such substances as dimethyl maleate and stilbene; early works in this field have been reviewed by Mayo and Walling.[4] Such an isomerization has been suggested to be a radical-chain process, and the isomerization of dimethyl maleate to dimethyl fumarate by bromine in carbon tetrachloride is known to be induced by light. Thus the isomerization takes place through the reversible addition of bromine atoms, which occurs in the initial step of the reaction:

$$\mathrm{Br}\cdot + \begin{matrix} X \\ H \end{matrix}\!\!>\!C{=}C<\!\!\begin{matrix} X \\ H \end{matrix} \longrightarrow \left[\mathrm{BrCHX\text{-}\dot{C}HX}\right]$$

$$\longrightarrow \begin{matrix} X \\ H \end{matrix}\!\!>\!C{=}C<\!\!\begin{matrix} X \\ H \end{matrix} + \begin{matrix} X \\ H \end{matrix}\!\!>\!C{=}C<\!\!\begin{matrix} H \\ X \end{matrix} + \cdot\mathrm{Br}$$

Since the incipient radical formed can readily rotate around the C–C bond axis, the elimination of the halogen atom gives both isomers, although the more stable isomer is yielded preferentially. The same incipient intermediate radical is also involved in the addition reaction; therefore, the addition reaction usually competes with the isomerization reaction.

In high-energy radiation chemistry, a similar situation arises. The radiation-induced reactions involve a transfer of electronic excitation from one molecule to another. Moreover, all possible excited states, ions and electrons may be produced, and so little or no selectivity can be expected in the product formation. In the process of being thermalized, an electron may induce the excitation of a molecule to a triplet state, and the number of such states may also result from the neutralization of positive ions by electrons, or indirectly by transition from higher excited states. Radicals can also be made by various processes, and different radicals may display different chemical behavior in the overall reaction process.

It, therefore, appears of interest to study a system where such a species leads to the cis-trans isomerization of 2-butenes by either chemical change or energy degradation.

## Experimental

**Materials.**—*cis* and *trans*-2-Butenes were Takachiho research-grade materials. The *trans*-2-butene contained less than 0.05% of the cis material, and the *cis*-2-butene contained less than 0.05% of the trans isomer and 0.05% of butane. 1-Butene, purchased in a cylinder, was purified by repeated distillations in a vacuum. The purities of these materials were confirmed by gas chromatography. Spectrally-pure argon, helium, nitrogen, hydrogen, oxygen, carbon dioxide and carbon monoxide supplied by Takachiho Chemical were used without any further purification. Benzene was washed with sulfuric acid, water and sodium carbonate solution, dried with calcium chloride, and purified by bulb-to-bulb distillation. Ethyl bromide was distilled and stored under vacuum. Nitric oxide and sulfur dioxide were dried with phosphorus pentoxide and purified by repeated vacuum distillations. Diphenyl disulfide, obtained from Tokyo Kasei, was purified by repeated recrystallizations in ethyl alcohol. All the other chemicals used were purified by conventional methods.

**Apparatus and Procedure.** — A conventional vacuum apparatus was employed. The radiation-induced reactions were carried out in a Pyrex glass bulb 20 to 30 ml. in size. The sample in the gas phase was irradiated by a cylinder-type cobalt 60 source giving a radiation dose rate of $1.0\times10^{6}$ roentgen per hour. The dose rate was obtained from the Fricke ferrous-sulfate dosimeter, taking the *G*-value as 15.6, and from the Victoreen rate meter. All the irradiations were carried out at 45±1°C. At the end of the irradiation, the materials were removed for analysis from the reaction bulb to a system consisting of a series of traps and a manometer. The measured samples were analyzed with a Hitachi FID gas chromatograph, with a 90 m. squalane column at room temperature. The chromatograph was capable of handling a sample of $10^{-7}$ mol. with an accuracy of better than 2%.

## Results and Discussion

**The Radical Isomerization of 2-Butene.**—The gamma irradiation of *trans*-2-butene was studied under various conditions. At room temperature and atmospheric pressure, the reaction did not occur markedly. The gas evolved consisted mainly of hydrogen and methane, together with a small amount of butene isomers. A detailed examination of the isomerization by the irradiation of *trans*-2-butene with a dose of $2.4\times10^{7}$ r. showed that little isomerization (only 0.7%) from trans to cis occured. Even the addition of hydrogen, nitrogen, helium, argon, carbon dioxide, carbon monoxide, oxygen or nitrous oxide had only a little effect on the isomerization of *trans*-2-butene, when the pressure was between 10 and 100 mmHg.

Recently the radiation-induced radical isomerization of 2-butene with hydrogen sulfide

has been reported by this laboratory.[5] The cis-trans isomerization (ratio: 0.39) takes place through the formation of an incipient radical intermediate, together with the formation of small amounts of butyl mercaptan and butyl sulfide.

Usually in such a system there arises competition between addition and isomerization. Therefore, the radical isomerization of 2-butene in the vapor phase has been studied by using a variety of radicals formed by the irradiation of gamma rays. Figure 1 gives typical data for the conversion of 2-butene by the bromine radical as a function of the dose.

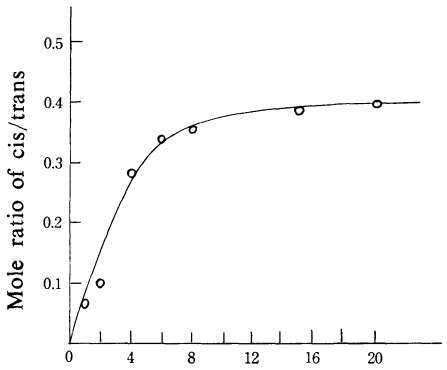

Fig. 1. Effects of ethyl bromide upon *trans*-2-butene as function of dose. (Ethyl bromide, 30 mmHg; *trans*-2-Butene, 100 mmHg)

The effect of the concentration of ethyl bromide upon the isomerization was examined at a constant dose. The isomerization of 2-butene took place very readily and was not affected by the change in the concentration of ethyl bromide, as Table I shows, suggesting that the reaction is a radical-chain process initiated by the bromine atom.

TABLE I. EFFECTS OF ETHYL BROMIDE ON THE 2-BUTENE ISOMERIZATION

| *trans*-2-Butene mmHg | $C_2H_5Br$ mmHg | cis/trans | 1-Butene/*trans*-2-Butene $\times 10^{-2}$ |
|---|---|---|---|
| 100 | 10 | 0.40 | 0.82 |
| 100 | 20 | 0.366 | 1.13 |
| 100 | 30 | 0.394 | 1.11 |
| 100 | 40 | 0.389 | 0.89 |

Irraidiation dose: $1.5 \times 10^7$ r.

It is important to notice also that a very small quantity of bromine-containing by-products were observed.

The addition of an atom or a free radical to an olefin produces a vibrationally-excited adduct radical which contains all the energy of the newly-formed bond and the activation energy required for the reaction. However, such a radical may decompose without requiring any activation energy, or it may be deactivated by a suitable collision.[6] Its lifetime is substantially longer than the period of the internal rotation around the C–C bond, and the isomerization ensues. The work of Dainton shows that such a situation arises upon the addition of a Cl atom to dichloroethylenes; therefore, the isomerization observed in our experiments is explicable if one assumes that it is caused by a bromine atom.

$$C_2H_5Br \xrightarrow{r} C_2H_5\cdot + \cdot Br$$

$$Br\cdot + \textit{trans}\text{-2-Butene} \longrightarrow \cdot C_4H_8Br$$

$$\cdot C_4H_8Br \rightarrow \textit{cis}\text{- or } \textit{trans}\text{-2-Butene} + \cdot Br$$

This mechanism may be supported by the formation of small amounts of 1-butene and other by-products containing bromine.

The radical isomerization for 2-butene was investigated further in a heterogeneous or a homogeneous system. The results are shown in Table II. The relative rate of the isomerization of 2-butene with halogenated compounds decreased in the order, Br>Cl>I, being small with chlorine and less with iodine.

As we have seen in the bromine system, the isomerization caused by a reversible Cl-atom addition is extremely rapid. However, in contrast to the cases with chlorine and bromine, the radical addition of iodine to 2-butene is a marginal proposition. The heat of formation[7] of the $C_4H_8I$ radical may be very roughly estimated as 25 kcal. $mol^{-1}$.* Therefore, the radical formed from 1-butene may be said to be quite unstable, and that formed from 2-butene, slightly more so. On the other hand, Christie et al.[8] have found values of a few kcal. $mol^{-1}$ for the heat of formation of several complexes formed by the interaction of an iodine atom and a hydrocarbon molecule. Rand and Strong[9] have also found a complex formation between an iodine atom and benzene when iodine was flash-photolyzed in a benzene solution.

If the mechanism of the isomerization may be described by the following reactions:

* Values used in this estimation; $H_{f25}(C_4H_{10}) = -29.8$, $D(s\text{-}C_4H_9\text{-}H) = D(s\text{-}C_3H_7\text{-}H) = 94$, $D(H_2) = 103.2$, $D(I_2) = 35.35$, $D(s\text{-}C_4H_9\text{-}I) = 48$, $D(s\text{-}C_4H_8I\text{-}H) = D(s\text{-}C_4H_9\text{-}H)$.

Table II. Radical isomerization of 2-butene in the gamma irradiation

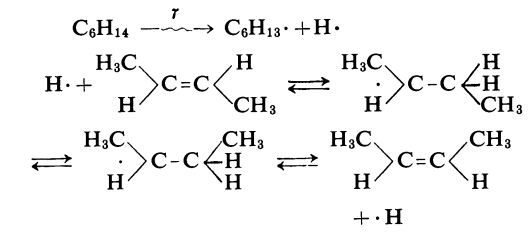
| Radical source | mmHg | cis/trans | 1-Butene / *trans*-2-Butene |
|---|---|---|---|
| $C_2H_5I$ | 30 | 0.0127 | 0.0091 |
| $C_2H_5Br$ | 30 | 0.394 | 0.0111 |
| $C_2H_5Cl$ | 30 | 0.0654 | — |
| $CCl_4$ | 30 | 0.025 | — |
| $CHCl_3$ | 30 | 0.0213 | — |
| $(C_6H_5S)_2$ | 1 g. | 0.365 | — |

*trans*-2-Butene, 100 mmHg; Irradiation dose, $1.5\times10^7$ r.

$$C_2H_5I \xrightarrow{\gamma} C_2H_5\cdot + \cdot I \quad (1)$$

Isomerization

$$\begin{cases} I\cdot + \textit{trans}\text{-2-Butene} \rightarrow C_4H_8I \text{ (radical)} & (2) \\ C_4H_8I \text{ (radical)} \rightarrow I\cdot + \alpha\ \textit{trans}\text{-2-Butene} + (1-\alpha)\ \textit{cis}\text{-2-Butene} & (3) \end{cases}$$



No isomerization

$$\begin{cases} I\cdot + \textit{trans}\text{-2-Butene} \rightarrow C_4H_8I\ (\pi\text{-complex}) & (4) \\ \pi\text{-Complex} \longrightarrow \textit{trans}\text{-2-Butene} + I\cdot & (5) \\ \pi\text{-Complex} + I\cdot \rightarrow \textit{trans}\text{-2-Butene} + I_2 & (6) \end{cases}$$

the complex formed in 4 may be more stable than the radical and have a lower energy barrier for formation. The easy formation of a $\pi$-complex is in agreement with the low isomerization of 2-butene.

Other chemical systems have also been examined for the radical isomerization, with special attention being paid to the effect of radiation-sensitive hydrocarbons. Particularly interesting is the isomerization of 2-butene in hexane or cyclohexane, because they readily liberate hydrogen atoms on irradiation and would eventually lead to the isomerization of 2-butene (Table III).

The hydrogen atom formed from hexane or cyclohexane was found to attack the double bond of *trans*-2-butene, and the formation of new C–H bond easily expelled the other hydrogen atom of 2-butene.

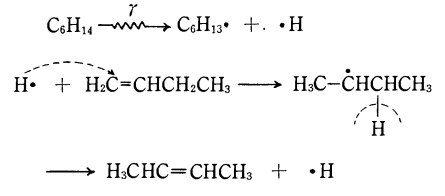
Steinmetz and Noyes,[10] by measuring the relative rates of exchange and isomerization, concluded that the rate constant for the exchange process is about twice that for the rotation process that lead to the isomerization, but that the two have almost identical activation energies of somewhat greater than 3 kcal. The difference is probably caused by the barrier to rotation in the intermediate radical.

10) H. Steinmetz and R. M. Noyes, *J. Am. Chem. Soc.*, **74**, 4141 (1952).

Table III. The effects of hydrocarbon on the isomerization

| *trans*-2-Butene mmHg | $C_6H_{14}$ mmHg | cyclo-$C_6H_{12}$ mmHg | Mole ratio cis/trans | 1-Butene / *trans*-2-Butene |
|---|---|---|---|---|
| 100 | 25 | | 0.1005 | 0.0060 |
| 100 | | 25 | 0.1025 | 0.0051 |

Irradiation dose: $2.4\times10^7$ r.



To demonstrate these possibilities, the exchange of the hydrogen atom was studied by investigating the isomerization of 1-butene in hexane or cyclohexane in the gas phase. The results are shown in Table IV.

Table IV. Isomerization of butene-1 in hydrocarbon

| 1-Butene mmHg | $C_6H_{14}$ mmHg | cyclo-$C_6H_{12}$ mmHg | Mole ratio: *trans*-2-Butene / 1-Butene | Mole ratio: *cis*-2-Butene / 1-Butene |
|---|---|---|---|---|
| 100 | 25 | | 0.0777 | 0.00142 |
| 100 | | 25 | 0.0481 | 0.00231 |

Irradiation dose: $2.4\times10^7$ r.

If the hydrogen exchange reaction does not occur, the isomerization from 1-butene to *trans*- or *cis*-2-butene should not take place. The results showed the rapid isomerization of 1-butene to 2-butene, leading us to the conclusion that the hydrogen-exchange reaction is actually involved. If one assumes the isomerization of 1-butene as arising from the exchange of hydrogen, the reaction involved may be diagramed as:

A similar path can probably account for the isomerization of 1-butene in cyclohexane vapor, and also the fact that hydrogen exchanges in the 1-butene isomerization lead to a similar process for the isomerization of 2-butene. With other hydrocarbons, therefore, one can also find similar processes for isomerization.

**The Isomerization Involving Transfer of Electronic Energy.**—There are a large number of known elementary processes which involve

atoms or molecules in excited electronic states.

Benzene photosensitzation has been successfully applied by Sato et al.[11] to the isomerization of 2-butene. Cundall and Criffiths[12] have also reported that a large amount of benzene triplets are formed during the irradiation of a benzene solution with varying concentrations of *cis*-2-butene, and they have presented strong evidence for the energy transfer from benzene to *cis*-2-butene.

Similar experiments have thus been carried out in the gas phase. The results for the benzene - *trans*-2-butene system are shown in Fig. 2 as function of the dose. The conversion of *trans*-2-butene to the cis isomer increased with the irradiation dose; equilibrium was attained at a cis/trans ratio of around 0.33. Even when the benzene pressure was varied with respect to that of *trans*-2-butene, the rate of isomerization remained nearly constant, as may be seen in Table V.

The process in the gas phase isomerization *of 2-butene is not simple in contrast to the case* in a solution. As we have seen in the previous section, a considerable isomerization of 2-butene was observed with hexane or cyclohexane. Therefore, if hydrogen atoms are formed in the irradiation of benzene, the isomerization should occur in the radical-chain process. However, as Cundall and Mine have suggested,[13] if the isomerization takes place by an energy transfer mechanism involving the benzene triplet, the triplet 2-butene formed by intersystem crossing would not isomerize to 1-butene or isobutene. The possibility of radical-chain reaction in causing isomerization can be seen from the formation of a small amount of 1-butene. In order to study this problem further, experiments were also carried out using 1-butene and benzene (Table VI).

Some isomerization to the other isomer did occur from 2-butene, but in view of other evidence, it seems that the radical-chain reaction is not the main process in the isomerization.

TABLE V. EFFECT OF BENZENE ON *trans*-2-BUTENE

| *trans*-2-Butene mmHg | $C_6H_6$ mmHg | Mole ratio | |
|---|---|---|---|

| 100 | 40 | 0.00556 | 0.00185 |

Irradiation dose: $1.5\times10^7$ r.

These experiments demonstrate that a large number of triplets are formed during the irradiation of benzene and that the energy transfer appears to occur in preference to the radical-chain process for the isomerization of 2-butene. The mechanism which accounts for this is the following:

$$\text{Benzene} \xrightarrow{r} \text{Benzene (triplet)}$$

$$\text{Benzene (triplet)} + \textit{trans}\text{-2-Butene (singlet)} \rightarrow \text{2-Butene (triplet)} + \text{Benzene (singlet)}$$

$$\text{2-Butene (triplet)} \rightarrow \textit{cis}\text{- or } \textit{trans}\text{-2-Butene}$$

Similar experiments were carried out in the gas phase using a variety of organic compounds. The data are summarized in Table VII.

The use of toluene and acetone illustrates a similar energy transfer process for the 2-butene isomerization. Here the case is, however, less unambigous and involves a partial contribution by the radical-chain process to the isomerization. Meanwhile, the effect of acetophenone or acetaldehyde on the isomerization does not seem to be through a clear process of energy transfer. The formation of a large amount of

1-butene may be brought about by the radical-chain process.

The possibility of the triplet states of naphthalene and anthracene causing the isomerization of 2-butene in the irradiation was studied. It is probably safe to assume that energy transfer will not take place readily in these heterogerneous systems; therefore, it is likely that the isomerization proceeds through the radical-chain process by means of a hydrogen atom formed in the irradiation of naphthalene and anthracene.

**The Effects of Inorganic Substances on the Isomerization.**—It has been suggested that the radiation-induced isomerization of 2-butene can take place either by a free-radical chain process or by the energy transfer with a triplet state of an organic molecule with $\pi$-electrons, or by both.

It is, therefore, interesting to see the effect of simple inorganic compounds in the radiation-induced isomerization. Recent work of Cundall and Palmer on the sulfur dioxide-photosensitized isomerization is very interesting in this connection; they have regarded it as involving the triplet state of sulfur dioxide.[3] Their results are in agreement with those of Dainton and Ivin,[14] who showed that the

| 40 | 4.50 | 0.45 |
| 60 | 4.66 | 0.66 |
| 80 | 3.45 | 1.14 |
| 100 | 2.89 | 0.48 |

Sulfur dioxide, 50 mmHg; Irradiation dose, $1.5\times10^7$ r.

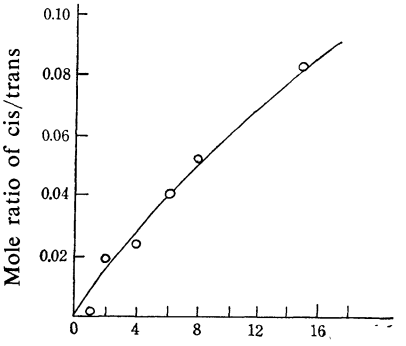

Fig. 3. Effects of sulfur dioxide upon *trans*-2-Butene as function of irradiation dose. (Sulfur dioxide, 100 mmHg; *trans*-2-Butene, 100 mmHg)

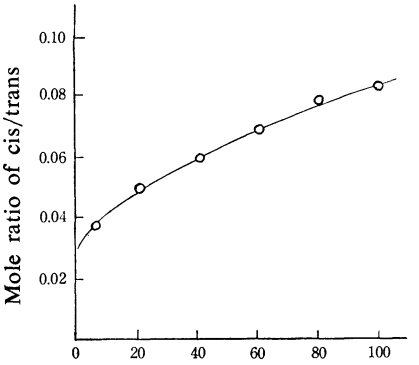

Fig. 4. Effects of sulfur dioxide upon the *trans*-2-butene isomerization (*trans*-2-butene, 100 mmHg; irradiation dose, $15\times10^6$ r.).

photochemical reactions of sulfur dioxide are due to the formation of the first triplet state (73.4 kcal. $mol.^{-1}$.[15]).

A similar experiment was applied to radiation chemistry with gamma rays. The effects of sulfur dioxide upon the isomerization were

15) A. D. Walsh, *J. Chem. Soc.*, 1953, 2266.

examined in a mixture of *trans*-2-butene and sulfur dioxide (Tables VIII and IX).

A marked isomerization was found to occur from trans to cis, but little isomerization to 1-butene was found to take place. The isomerization from 1-butene to *trans*- or *cis*-2-butene was also almost negligible. Further observations as to the function of the dose and the pressure of sulfur dioxide are shown in Figs. 3 and 4.

The isomerization can be explained similary by the following mechanism, which assumes the interaction of the triplet state of sulfur dioxide:

$$SO_2 \xrightarrow{\gamma\sim} SO_2 \text{ (triplet)}$$

$$SO_2 \text{ (triplet)} + \textit{trans}\text{-2-Butene (singlet)} \rightarrow \text{2-Butene (triplet)} + SO_2 \text{ (singlet)}$$

$$\text{2-Butene (triplet)} \rightarrow \textit{cis}\text{- or } \textit{trans}\text{-2-Butene}$$

However, the formation of small amounts of sulfinic acid and of the polymer on the walls of reaction vessels in the case of both 2-butene and 1-butene seems to suggest that at least a portion of the isomerization proceeds via the chain process shown below:

$$\textit{trans}\text{-2-Butene} + SO_2^* \rightarrow \cdot C_4H_8SO_2 \cdot$$

$$\cdot C_4H_8SO_2 \cdot \rightarrow \textit{trans}\text{- or } \textit{cis}\text{-2-Butene} + \text{1-Butene} + SO_2$$

$$\cdot C_4H_8SO_2 \cdot + M \rightarrow \text{Products}$$

Experiments were also conducted with nitric oxide and carbon disulfide. Nitric oxide has been used extensively as a free-radical trap in gas kinetics, and recently the possibility of an attack of nitric oxide on substrate molecules has been considered.[16,17] The effects of nitric oxide upon the isomerization are shown in Tables X and XI, with the function of the dose and the pressure of butene respectively.

These results, as well as others, indicate that the mechanism for the isomerization appears to be similar to that with sulfur dioxide; when 2-butene encounters unpaired electrons, transitions otherwise forbidden may be induced, and the addition to the double bond, followed by dissociation, may occur.

A brief study of the effect of carbon disulfide was made upon the mixture and 1-butene or 2-butene.

With 1-butene, some isomerization to 2-butene did occur, but a major portion underwent

decomposition. With 2-butene, carbon disulfide caused some isomerization, and here again the main product was a large amount of by-products, which consisted of some organo-sulfur compounds and elemental sulfur (Tables XII, XIII and Fig. 5).

The effect of gaseous carbon disulfide in the isomerization has not been reported previously. However, it has been shown that, under flash-photolysis conditions, the absorption spectrum taken a few millisenonds after the illumination of gaseous carbon disulfide gave the characteristic bands of $S_2$ and CS.[18,19] Therefore, one can safely assume the initial interaction of the double bond with the sulfur atom formed by the irradiation of carbon disulfide. The formation of by-products indicates that the isomerization must be carried out through interaction with CS and S, since S is formed in the primary act, while CS is formed both in the primary:

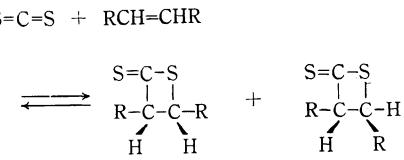
$$CS_2 \xrightarrow{r} CS + S$$

and the secondary acts:

$$CS_2 + S \longrightarrow CS + S_2$$

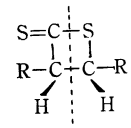
The sulfur atom thus formed presumably induces isomerization by a direct radical attack on the double bond. The following basic processes may be proposed to explain the action of the sulfur atom in the induced isomerization:

$$\textit{trans}\text{-2-Butene} + S \rightarrow \cdot C_4H_8S\cdot$$



$$\cdot C_4H_8S\cdot \rightarrow \textit{cis}\text{- or } \textit{trans}\text{-2-Butene} + S$$

$$\cdot C_4H_8S\cdot + CS \rightarrow \textit{cis}\text{- or } \textit{trans}\text{-2-Butene} + CS_2$$



$$\cdot C_4H_8S\cdot + CS_2 \rightarrow \textit{cis}\text{- or } \textit{trans}\text{-2-Butene} + CS + S_2$$

A similar reaction scheme can be postulated with CS, another radical formed by the initial irradiation of $CS_2$. Isomerization induced by the sulfur molecule would involve the formation of the free radical by the homolytic cleavage of the sulfur, with the subsequent addition of the free radical to the double bond. However, the contribution of this process would not be very large. The explanation of the isomerization mechanism involves the formation of a $\pi$-complex between sulfur and the double bond, as has been suggested for the thermal isomerization of polybutadiene with sulfur.[20] However, this mechanism does not reveal the exact nature of the bonding, either in the radical attack or the $\pi$-complex formation. The $\pi$-complex possibly involves the $\pi$-orbital of the olefin and the anti-bonding $\pi$-orbital of sulfur, but this is a mere conjecture; until further evidence is available, the discussion of the exact nature of bonding in such a complex will not be fruitful.

Another interesting mechanism is the one involving initial addition, followed by subsequent dissociation, as is shown below:

Here, the formation of a large amount of sulfur containing by-products can be also explained if one assumes that the dissociation takes place by A-type cleavage. A similar addition-dissociation was reported very recently

(A)

in the photochemical reaction between thiobenzophenon and olefins.[21] At present, it is difficult to single out the most plausible mechanism for this carbon disulfide-catalyzed isomerization. A detailed investigation of the nature of the by-products would, however, shed further light on the probable pathway of this reaction.

## Summary

A detailed study of the radiation-induced trans-cis isomerization of 2-butenes has been made. The effects of halogenated compounds

upon 2-butene can be explained by the attack of the halogen radicals formed in irradiation, and a radical chain process can be suggested for the isomerization.

The addition of hexane or cyclohexane to 2-butene in the gas phase has shown a rapid isomerization of trans to cis; it has been suggested that this is caused by the hydrogen atom formed in the irradiation of hexane or cyclohexane. The facile isomerization of 1-butene to *trans*-2-butene by the presence of such hydrocarbons suggests that the hydrogen is readily exchanged with the other hydrogen of olefin, thus leading to the isomerization.

Radiation-induced isomerizations brought by benzene, sulfur dioxide, nitric oxide, carbon disulfide and other molecules have also been examined. The effect of benzene on the trans-cis isomerization of 2-butene has been explained by production of vibrationally-excited triplet states. Results with sulfur dioxide have shown that radiation-induced isomerization is due not only to the formation of the first triplet state, but also to the addition to the double bond, followed by dissociation.

# The Formation Constants and the Rate Constants of the Electrode Processes of Thiocyanato-Indium(III) Complexes with the Dropping Mercury Electrode*

By Yoshio NARUSAWA,*1 Jinzo HASHIMOTO*2 and Hiroshi HAMAGUCHI*3

(Received June 20, 1964)

Few authors[1,2] have reported investigations of the formation constants of indium(III) thiocyanate complexes. Sunden[1] has, however, determined the formation constants of thiocyanato-indium(III) complexes potentiometrically. The potentiometric method and the polarographic method, though they have a wide applicability, generally include uncertainties arising from the estimations of a liquid junction potential and those of the activity coefficients of the complex ions present.

The polarographic method proposed by DeFord and Hume[3] for the formation constants, though it has an unknown liquid junction potential, is applicable when the electrode processes are reversible at the dropping mercury electrode.

In the present paper, the formation constants and rate constants of the electrode processes of thiocyanato-indium(III) complexes are presented. Analyses of the present data will show the existence of the mono-, di-, tri- and tetra-coordinated species in a solution, and each consecutive formation constant will be calculated. The rate constants, $(k_0)_B$ and $(k_1)_B$ at the standard potential and $k^0_{f,h}$ at 0 V. vs. NHE, will also be determined.

## Experimental

**Reagents.** — A commercial sodium thiocyanate was dissolved in water and standardized against the standard silver nitrate solution by volumetric titration with uranin as the indicator. An appropriate amount of indium perchlorate, prepared from a commercial indium sesquioxide, was dissolved in water and standardized gravimetrically. A solution of sodium perchlorate was prepared by dissolving a commercial reagent and was standardized by the ion exchange method. A solution of geratine was freshly prepared every time it was used. All the other chemicals were of a reagent grade and were used without further purification. The composition of the solution was obtained by mixing indium(III) ions, perchlorate and variable amounts of thiocyanate solutions, the ingredients being so chosen

that the total ionic strength was kept constant at 2.0 mol./l.

**Apparatus.**—A Yanagimoto PB-105 pen-recording polarograph was used for the measurement of the current-potential curves. The usual polarographic technique was used in this study. The capillary used was $m=1.28$ mg./sec., $\tau=3.74$ sec./drop and 1.47 $mg^{2/3} sec^{-1/2}$ for $m^{2/3} \tau^{1/6}$ (where $m$ is the flow rate of mercury and $\tau$, the drop time) in a solution to be examined at $-0.7$ V. vs. SCE at a height of 70 cm. of the mercury reservoir. The sample solution was connected to the reference electrode through the series of successive bridges of an agar-sodium nitrate, a saturated sodium nitrate solution, and an agar-potassium chloride. The resistance of the cell was found to be 95 ohms when measured by an a. c. bridge. This resistance is very small and it did not change noticeably as the composition of the thiocyanate-perchlorate mixture was varied, so it was neglected in measuring the half-wave potential. Toa-Dempa HM-5 pH meter was used for pH measurements. The pH of the solution of this system measured was about 3.0. All polarographic measurements were made at $25\pm0.1$°C unless otherwise stated. Purified hydrogen gas was used for removing oxygen from a solution before polarograms were obtained.

**Measurements of the Half-Wave Potential.**—The polarograph was always set with an initial voltage of $-0.4$ V. vs. SCE and a span voltage of 0.5 V. The sensitivity used was 0.06 $\mu$amp./mm., without condenser damping. Using the Leeds and Northrup K-type potentiometer as an external potentiometer, the inital and final potentials were measured to within 0.5 mV. All the current measurements used in the calculations were of the average current of an individual oscillation of the polarogram. The average current was taken simply as one-half of the oscillation (the maximum pen excursion).

The half-wave potentials were found by plotting the logarithm of $\bar{i}/(\bar{i}_d-\bar{i})$ (where $\bar{i}$ is the current corresponding to a given potential and $\bar{i}_d$, the diffusion current corrected for the residual current) versus the applied potential. A point was plotted for each individual small oscillation on the polarogram, and at least twelve values were used along the mid-portion of the curve. The plots of the $\log \bar{i}/(\bar{i}_d-\bar{i})$ versus the applied potentials yielded a slightly curved line in a lower half and a straight line in an upper half in perchlorate and/or thiocyanate media (see Fig. 1). These curves of the log-plot are typical of those obtained for the "quasi"-reversible electrode processes. The reversible half-wave potential, $E_{1/2}{}^r$, was calculated by applying the Matsuda-Ayabe theory.[4] Duplicate experiments showed that the reproducibility of the half-wave potential was within 1 mV. Measurements were made with four separately-prepared samples containing 1.09 mmol./l. indium(III) ion, 0.5 mol./l. thiocyanate, 1.5 mol./l. perchlorate and 0.005% gelatine; the individual half-wave potentials obtained were $-0.5670$, $-0.5688$, $-0.5688$ and $-0.5692$ V. vs. SCE respectively. The observed half-wave potentials involve an unknown liquid junction potential. The junction potential is a composite of the potential across the saturated potassium chloride - saturated sodium nitrate boundary and the saturated sodium nitrate - sodium perchlorate, sodium thiocyanate boundary. Although the correct value is unavailable, it will be taken into consideration in the future if it is determined for this system.

## Results

**The Effect of Maximum Suppressors and of the Concentrations of the Supporting Electrolyte.**—When the total ionic strength of the solution was 2.0 mol./l. indium(III) simple ion and thiocyanato-indium(III) complexes, in perchlorate and in thiocyanate media respectively, showed pronounced maxima which could be depressed in the presence of 0.005 per cent gelatin, and "well-defined" waves were obtained. When the concentration of the supporting electrolyte (sodium thiocyanate) was smaller than 0.1 mol./l., the maximum appeared even in the presence of 0.005 per cent gelatine. That the maximum does not appear in the presence of positively-charged gelatine in an acid solution of the pH 3 when the concentration of thiocyanate is greater than 0.1 mol./l., while in the concentration of thiocyanate lower than 0.1 mol./l., the fact that the maximum which appears in the positive branch of the electrocapillary curve can not be eliminated by gelatine means that the maximum is of the first kind.

**The Effect of Mercury Height.**—A typical limiting diffusion current should be proportional to the square root of the effective height of the mercury.[5] At four various applied heights of the mercury column, 70, 60, 50 and 40 cm., the value of $\bar{i}_d/h_{corr}{}^{1/2}$ (where $h_{corr}$ is an effective height of mercury) was found to be $0.785\pm0.005$ $\mu$amp./$cm^{1/2}$ for a solution of 1.09 mmol./l. indium(III), 0.5 mol./l. thiocyanate, 1.5 mol./l. perchlorate and 0.005 per cent gelatine. In these experiments the half-wave potentials were constant within $\pm0.3$ mV. These results indicate that the limiting current is diffusion-controlled.

**The Effect of Temperature.**—From the results with a solution of 2.0 mol./l. potassium thiocyanate, 0.941 mmol./l. indium(III) and 0.005 per cent gelatine, the temperature coefficient of limitting current near 25°C was calculated to be 1.37 per cent/deg.

This value is in fairly good agreement with the usual diffussion-controlled current[6a]. The

6) *a*, *b*, See, e. g., Ref. 5, pp. 92, 234.

half-wave potential became less negative with an increase in the temperature, and the value of $dE_{1/2}/dT$ was 3.4 mV./deg. The positive temperature coefficient which has been seen for the several hydrated metal ions implies that an appreciable activation energy is required in the electrode reaction.[6)b]

**The Calculation of the Reversible Half-Wave Potential, $E_{1/2}{}^r$, According to the Matsuda-Ayabe Theory.** — Figure 1 shows the plot of $\log \bar{i}/(\bar{i}_d-\bar{i})$ versus the applied potential, with a solution 1.09 mmol./l. indium(III) ion, 0.005 per cent gelatine and various thiocyanate concentrations of (0, 0.5 and 2.0 mol./l.). The plots of the upper halves of the curves show straight lines, while the lower halves of the plots are curved lines. The log-plots for all other cases were similar to those shown in Fig. 1. According to the Matsuda-Ayabe theory,[4)] the curves shown in Fig. 1 are considered to be typical of a "quasi"-reversible electrode process, and in such cases $\Lambda\sqrt{\tau}$ (where $\Lambda$ is a kinetic parameter of an electrode process) is obtained from Eq. 1 and falls in the range between 30 and $10^{-2}$. The reversile half-wave potential, $E_{1/2}{}^r$ can also be obtained as follows;

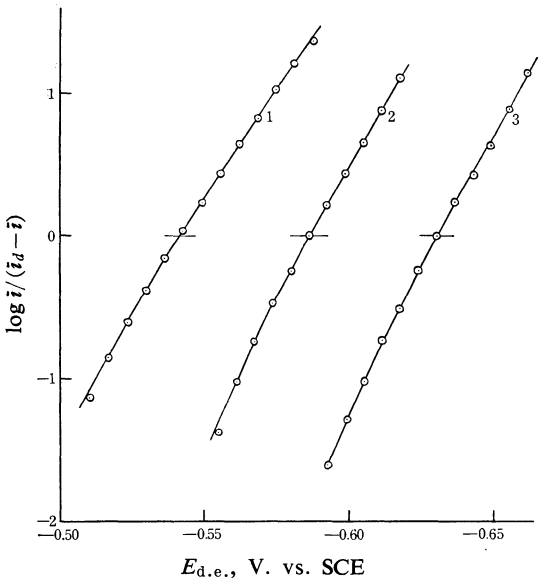

Fig. 1. A log-plot of 1.09 mmol./l. indium(III) ion in the presence of 0.005 per cent of gelatin and various thiocyanate concentration. Curves 1, 2 and 3: 0, 0.50 and 2.0 mol./l. $C_{SCN^-}$, respectively.

$$\log \Lambda = \frac{\alpha nF}{2.3RT}(E_{1/2}' - E_{1/2}{}^r) + \log(\bar{i}_l/\bar{i}_d) - \frac{1}{2}\log\tau + 0.053 \quad (1)$$

$$E_{1/2}{}^r = E_{1/\nu+1} - 2.3\frac{RT}{nF}\left\{\log\left[\nu - \exp\frac{\alpha nF}{RT} \times (E_{1/\nu+1} - E_{1/2}')\right] - \log(\bar{i}_l/\bar{i}_d)\right\} \quad (2)$$

where $E_{1/\nu+1}$ and $E_{1/2}'$ are the potentials corresponding to $-\log\nu$ and zero on the ordinate respectively, $\bar{i}_l$ and $\bar{i}_d$ are average limiting and diffusion currents respectively, and $\alpha$ is the transfer coefficient in the electrode reaction. As the limitting current, $\bar{i}_l$ ($7.02_0$ $\mu$amp.), of simple indium(III) ions in $1.08_6$ mmol./l. agrees fairly well with the value ($7.09_2$ $\mu$amp.) calculated from the original Ilkovic equation, assuming the diffusion coefficient $D$ to be $5.97 \times 10^{-6}$ cm$^2$/sec. (which is the average value calculated from the equivalent conductivity at an infinite dilution of many other trivalent ions such as ferric[7a)] chromic[7a)], aluminium[7a)] and rare earth metal ions[7b)]), the ratio of $\bar{i}_l$ to $\bar{i}_d$ must be unity. For complex ions, $\bar{i}_l$ gradually becomes smaller than $\bar{i}_d$ with an increase in the concentration of thiocyanate. Table I shows some of the experimentally-obtained potentials, $E_{1/2}'$, $E_{1/11}$ and the diffusion currents, together with the results calculated from Eqs. 1 and 2. As is shown in Table I $\Lambda\sqrt{\tau}$ was 0.3 to 0.1, which is in the range of 30 to $10^{-2}$. This means that the electrode process of the indium(III)-thiocyanate system is "quasi"-reversible.

**The Relation between Half-Wave Potentials and Logarithms of Thiocyanate Concentration.** —A relation of the half-wave potentials, $E_{1/2}{}^r$, to the logarithms of thiocyanate is given in Fig. 2; the ligand number can be estimated from the slope of the curve. Figure 2 also shows by a broken line the theoretical slopes corresponding to the ligand number. This indicates that the tetra-coordinated species is present in a solution of an ionic strength of 2.0 mol./l. The slope of the last part, 3.8, is slightly smaller than the theoretical value of 4; this deviation is considered to be due to overlapping with that of the lower ligand numbers, or with di- and tri-coordinated complexes.

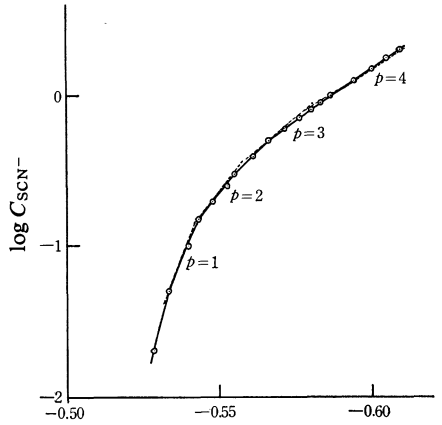

Fig. 2. A relation between $E_{1/2}{}^r$ and log $C_{SCN^-}$. The broken lines indicate the theoretical slopes corresponding to the respective ligand number.

**An Analysis of the DeFord-Hume Function.**— The following paragraph will describe the method of analysis of DeFord and Hume.[3]

The method is applicable when the following conditions are satisfied: (1) the electrode processes of a hydrated metal ion, as well as of a complex ion, are reversible at the dropping mercury electrode; (2) the metal reduced at the electrode is soluble in mercury, or forms an amalgam, and (3) the formation constants are not very large.

The indium(III)-thiocyanate system satisfies these conditions except that the electrode processes of the simple indium(III) ion, like those of complex ions, are "quasi"-reversible in the reduction at the electrode, and the method of DeFord and Hume[3] is supposed to be applicable for this system by the aid of the reversible half-wave potential, $E_{1/2}{}^r$, which is calculated from the experimentally-observable values according to the Matsuda-Ayabe theory.[4]

For the calculation of DeFord-Hume function $F_j(X)$, $E_{1/2}{}^r$ was taken as the half-wave potential of a simple or complex ions. According to the DeFord and Hume's theory,[3] $F_j(X)$ functions are defined as follows;

$$F_0(X) = \sum_{j=0}^{N} \frac{K_j (C_X)^j (f_X)^j}{f_{MX_j}}$$

$$= \text{antilog}\left[0.434 \frac{nF}{RT}\{(E_{1/2}{}^r)_s - (E_{1/2}{}^r)_c\} + \log \frac{I_s}{I_c}\right] \quad (3)$$

$$F_j(X) = [F_{j-1}(X) - (K_{j-1}/f_{MX_{j-1}})]/C_X f_X \quad (j=1, 2, \cdots\cdots, N) \quad (4)$$

where $K_j$ is the formation constant of complex $MX_j$, $C_X$ is the concentration of ligands, $f$'s are the activity coefficients of corresponding ions, $I$'s are diffusion current constants, subscripts $s$ and $c$ refer to simple and complex ions, respectively, and other symbols are used with their usual significances. Substituting the experimentally-measurable quantity on the right-hand side of Eq. 3, the $F_0(X)$ function is calculated. The logarithm of $I_s/I_c$ was so small in comparison with the first term of the bracket of Eq. 3 in the range of ligand concentrations from 0 to 2.0 mol./l. that it was disregarded in the calculation of the $F_0(X)$ function. Furthermore, the $F_j(X)$ functions were calculated from the previous $F_{j-1}(X)$ function by the aid of Eq. 4.

Figure 3 shows the plot of the $F_j(X)$ functions calculated from Eqs. 3 and 4 against the thiocyanate concentration, $C_X$.

By extrapolating the $F_j(X)$ function to $C_X=0$, the value of $K_j$ is obtained as an intersection The formation constant, $K_0$, is the value of $F_0(X)$ corresponding to the zero concentration of ligand; it is unity. The extraporation of the plot of $F_1(X)$, $F_2(X)$, $F_3(X)$ and $F_4(X)$ to zero thiocyanate concentration yielded the values of $K_1$, $K_2$, $K_3$ and $K_4$ respectively. Besides, a value of $F_j(X)$ at zero thiocyanate concentration or a value of $K_j$ is equal to the initial slope of the curve of a previous $F_{j-1}(X)$ function. Equation 4 indicates that $F_j(X)$ is a function of the concentration of ligands, $C_X$. When $F_{j-1}(X)$ is a function of the first power of $C_X$ or is linear with a positive slope against $C_X$, $F_j(X)$ becomes parallel against the $C_X$ axis, and the value of $F_j(X)$ gives that of $K_j$. As is shown in Fig. 3, a tetra-coordinated complex is explicitly present in the solution with the higher ligand concentration, in accordance with the result of Fig. 2. Bock[8] has shown the presence of the tetra-coordinated species $In(SCN)_4^-$ in diethylether by the distribution method. Accordingly, it

8) R. Bock, *Z. anal. Chem.*, 133, 110 (1951).

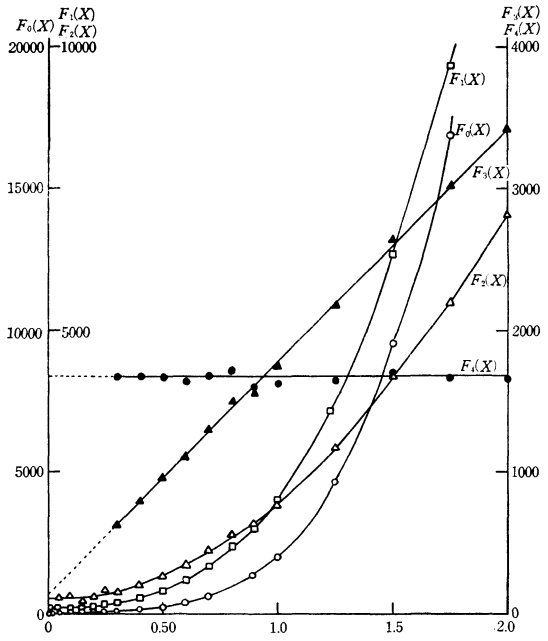

Fig. 3. A relation between $F_j(X)$ and $C_{SCN^-}$.

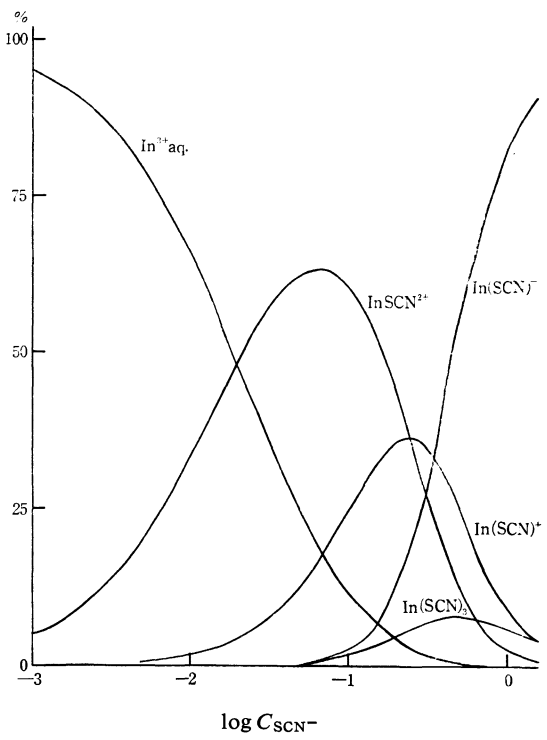

Fig. 4. Concentration distribution of each complex species.

may be reasonable to assume the presence of $In(SCN)_4^-$ in an aqueous solution. The extrapolation of the plot of $F_1(X)$, $F_2(X)$, $F_3(X)$ and $F_4(X)$ to zero thiocyanate concentration yielded values of 50, 200, 120 and 1670 for $K_1$, $K_2$, $K_3$ and $K_4$ respectively. Moreover, the values of 45 to 55, 190 to 220, 110 to 130 and 1650 to 1660 for $K_1$, $K_2$, $K_3$ and $K_4$ were obtained from the initial slopes of the curves. These values are in good agreement with the extrapolated values.

Experimental errors in the determination of $\Delta E_{1/2}{}^r$ were cumulative in the successive calculations of $F_j(X)$; particularly for low concentrations (below 0.3 mol./l.) of a complexing agent, the values of $F_3(X)$ and $F_4(X)$ were so scattered that they were disregarded. As is shown in Fig. 3, however, these plots resulted in a linear relation with a higher thiocyanate concentration than 0.3 mol./l., and a better point at the intersection was obtained by extrapolation.

From the data of Fig. 3, the concentration distribution of each species may be calculated from the following equations.

Indium(III) ions are associated with the excess of thiocyanate as follows:

$$In_{aq}^{3+} + jSCN^- \rightleftarrows In(SCN)_j^{(3-j)+} \qquad (5)$$

The formation constant $K_j$ is given in the following equation:

$$K_j = \frac{[C_{MX_j} f_{MX_j}]}{[C_M f_M][(C_X)^j (f_X)^j]} \qquad (6)$$

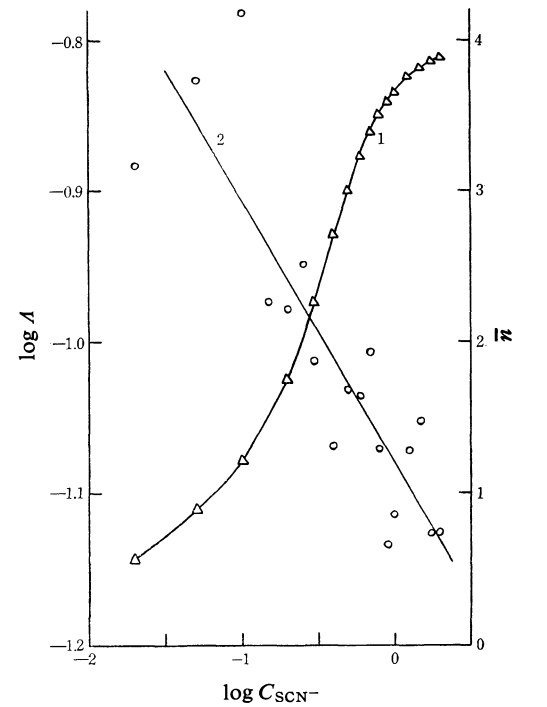

Fig. 5. The mean ligand number $\bar{n}$ (curve 1) and log $\Lambda$ (curve 2) against log $C_{SCN^-}$.

where $[C_M]$ is the simple indium(III) ion non-coordinated in the solution and is written as follows:

$$[C_M]=\frac{\sum_{j=0}^{N}[C_{MX_j}f_{MX_j}]}{\sum_{j=0}^{N}K_j[C_X]^j[f_X]^j[f_M]} \quad (7)$$

Therefore, the concentration of a complex species, $[C_{MX_j}]$, is written is the following equation:

$$[C_{MX_j}]=K_j[C_Mf_M][C_X]^j[f_X]^j/f_{MX_j} \quad (8)$$

In Fig. 4, the distributions of the concentration of all the species calculated from Eqs. 7 and 8 for $\sum_{j=0}^{N}[C_{MX_j}f_{MX_j}]=100\%$ are plotted against $\log C_{SCN^-}$. The activity coefficients, $f$'s, were all assumed to be unity. As is obviously shown in Fig. 4, when the concentration of thiocyanate is greater than 1.5 mol./l, more than 90 per cent of all the species present in the solution exist as tetra-coordinated form $In(SCN)_4^-$. In Fig. 5, the mean values of the ligand number, $\bar{n}$, obtained from the data in Fig. 4 are plotted against $\log C_{SCN^-}$, and also the relation between $\log \Delta$ and $\log C_{SCN^-}$ is shown. The slope, $-0.174$, for the latter curve was obtained by the aid of the least-square method.

## Discussion

Sundén[1] has reported the overall formation constants obtained potentiometrically for $K_1$, $K_2$ and $K_3$ to be $3.8\times10^2$, $4.0\times10^3$ and $4.4\times10^4$ respectively, at an ionic strength of 2.0 mol./l. at 20.0°C. The polarographically-obtained values reported by Radhakrishnan et al.[2] for $K_1$, $K_2$, $K_3$, $K_4$, $K_5$ and $K_6$ are $1.2\times10^2$, $1.6\times10^3$, $1.75\times10^4$, $1.7\times10^4$, $6.5\times10^4$ and $6.9\times10^4$ respectively, at an ionic strength of 2.0 mol./l. at 30°C. On the other hand, the $K_1$, $K_2$, $K_3$ and $K_4$ values obtained from the present data are 50, 200, 120 and 1670 respectively. This discrepancy from the values obtained by Sundén[1] may be largely due to the adsorption of thiocyanate ions on the electrode surface. Furthermore, the slight enhancement of the limiting current, especially in the lower thiocyanate concentration, may be attributed to this adsorption of thiocyanate ions (see Table I). As is shown in Fig. 2, the tetra-coordinated species is evidently present in the higher ligand concentration. Moreover, as Fig. 3 shows, the value of the tetra-coordinated form, $K_4$, is obtained from the analysis of the DeFord and Hume function. Sundén[1] has not obtained the value of $K_4$, and Radhakrishnan et al.[2] have reported the values of $K_5$ and $K_6$. Though the values of $K_5$ and $K_6$ can be obtained by the analysis of DeFord and Hume function, they may include errors because of an obscurity in the half-wave potential measurement.

For the sake of simplicity, it is assumed that one of the complexes, $In(SCN)_p^{(3-p)+}$ ($p=4, 3, 1, 2, 0$), is present predominantly in a solution; it is reduced to an amalgam as follows:

$$In(SCN)_p^{(3-p)+}+3e^-+Hg \rightleftarrows In(Hg)+pSCN^- \quad (p=4, 3, \cdots\cdots, 0) \quad (9)$$

where the following consecutive dissociation and association reactions proceed very fast:

$$In(SCN)_p^{(3-p)+} \rightleftarrows In(SCN)_{p-1}^{(4-p)+}+SCN^- \quad (p=4, 3, 2, 1) \quad (10)$$

The ligand number, $p$, in the electrode reaction is given by the following equation:[4]

$$p=\beta N+\frac{\Delta \log \Delta}{\Delta \log (C_Xf_X)} \quad (10)$$

where $\beta=1-\alpha$, and $N$ is the maximum value of the ligand number of a complex present in a given solution. By substituting the values $\beta=0.27$, $N=3.9$ and the slope $\Delta \log \Delta/\Delta \log (C_Xf_X)=-0.174$ obtained from Fig. 5 into the above equation, $p=0.88$ was obtained at $C_{SCN^-}\simeq2.0$ mol./l. On the other hand, at the concentration of about 0.02 mol./l., $p$ was 0.03, which is nearly equal to zero. This means that two kinds of ions, $InSCN^{2+}$ and $In^{3+}$, are reduced at the D.M.E.

In fact, various complexes $In(SCN)_p^{(3-p)+}$ ($p=4, 3, \cdots\cdots, 0$) are present in a given solution and are reduced to an amalgam at different rates; therefore, the analysis of an individual rate constant is complicated.

According to the Matsuda-Ayabe theory,[9] however, the rate constants, $(k_p)_B$, ($p=4, 3, \cdots\cdots, 0$) at the standard potential, $(E^0)_B$, can be calculated as follows:

$$\Delta \exp\frac{(1-\alpha)n\boldsymbol{F}}{\boldsymbol{RT}}[(E_{1/2}{}^r)_s-(E_{1/2}{}^r)_c]=(1+\sum_{j=0}^{N}K_j)^{1-\alpha}(f_s/\sqrt{D_s})^{1-\alpha}(f_a/\sqrt{D_a})^{\alpha}\times\sum_{p=0}^{N}(k_p)_B(f_XC_X)^p \quad (12)$$

$$(E^0)_B=E_{1/2}{}^r-2.3\frac{\boldsymbol{RT}}{n\boldsymbol{F}}\log\frac{f_N/\sqrt{D_N}}{f_a/\sqrt{D_a}}-2.3N\frac{\boldsymbol{RT}}{n\boldsymbol{F}}\log(f_XC_X) \quad (13)$$

9) H. Matsuda and Y. Ayabe, *Z. Elektrochem., Ber. Bunsenges. physik. Chem.*, **66**, 469 (1962).

where $D_s$, $D_N$ and $D_a$ are the diffusion coefficients of simple indium(III) ions, indium(III) complex ions with the ligand number, $N$, and indium metal in mercury respectively, $f$'s are activity coefficients, and the other symbols are used with the usual significance. Although the half-wave potential of simple indium(III) ions was determined to be $-0.531 \pm 0.003$ V. vs. SCE by Moorhead and MacNevin[10] from the analysis of the log-plot, it was found by the precise analysis of the present data that the reduction of indium(III) ions at the electrode implies some overpotentials. The value, $E_{1/2}{}^r$ ($=-0.5213$ V. vs. SCE), of the simple indium(III) ions obtained by taking the overpotential into consideration is more valid than that of Moorhead and MacNevin.[10] It is, however, not the standard potential of the reaction of $In^{3+}+3e^- + Hg \rightarrow In(Hg)$. The standard potential of the above reaction is unavailable; therefore, it is assumed to be closely equal to the potential ($-0.5138$ V. vs. SCE) calculated from Eq. 13, in which the concentration of thiocyanate is 0.02 mol./l.

As is obviously shown in Eq. 12, the logarithm of the left-hand side must be a linear function of $\log C_{SCN^-}$ if one complex species is present predominantly. In Fig. 6, $\log \Lambda + \{(1-\alpha)nF/2.3RT\}[(E_{1/2}{}^r)_s-(E_{1/2}{}^r)_c]$ are plotted in respect to $\log C_{SCN^-}$; as is shown, the linear relation was not obtained. This indicates that two or more complex species are involved in the electrode reaction.

Further, the left-hand side of Eq. 12 is the experimentally-measurable quantity, which is defined as the $H_0(X)$ function. By extrapolating the $H_0(X)$ function to $(f_X C_X)=0$, the limiting value is given as follows:

$$\lim_{f_X C_X \to 0} H_0(X) = (1+\sum_{j=1}^{N} K_j)^{1-\alpha} \times (f_s/\sqrt{D_s})^{1-\alpha}(f_a/\sqrt{D_a})^{\alpha}(k_0)_B \qquad (14)$$

In general, $H_p(X)$ is defined as follows:

$$H_p(X) = [H_{p-1}(X) - \lim H_{p-1}(X)]/(f_X C_X) \qquad (15)$$

By extrapolating $H_p(X)$ to $(f_X C_X)=0$, the following equation is obtained:

$$\lim_{f_X C_X \to 0} H_p(X) = (1+\sum_{j=1}^{N} K_j)^{1-\alpha} \times (f_s/\sqrt{D_s})^{1-\alpha}(f_a/\sqrt{D_a})^{\alpha}(k_p)_B \qquad (16)$$

The relation of Eqs. 12 and 15 is shown in Fig. 7, in which $H_0(X)$ is linear with a positive slope with respect to the $C_X$ axis. The slope and the intersection of the straight line

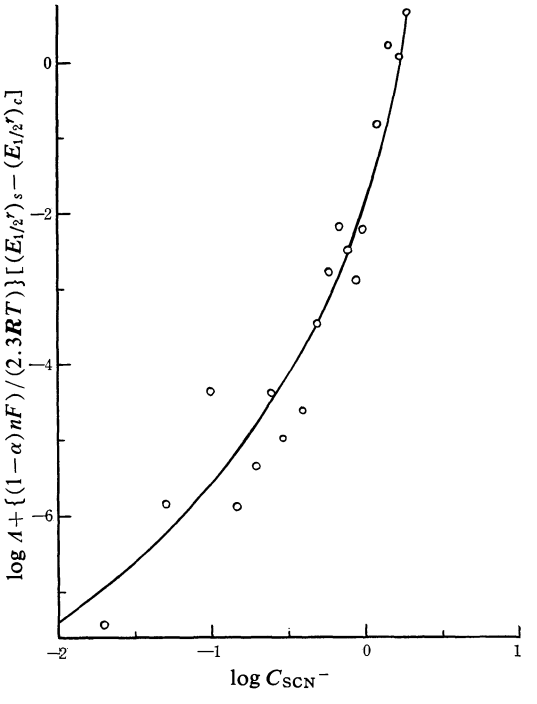

Fig. 6. The logarithmic relation of the left-hand side of Eq. 12 in respect to $\log C_{SCN^-}$.

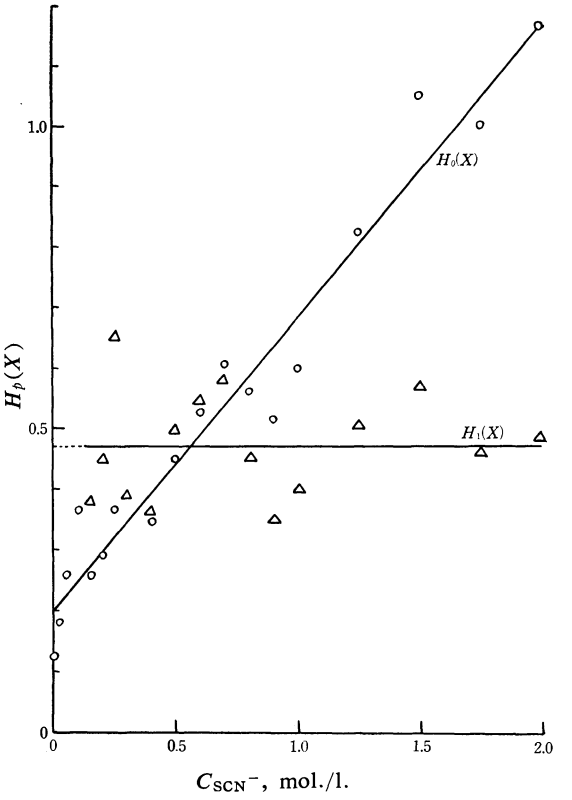

Fig. 7. The relation of $H_p(X)$ functions to $C_{SCN^-}$.

10) E. D. Moorhead and W. M. MacNevin, *Anal. Chem.*, 34, 269 (1962).

with the ordinate were obtained by the least-square method. This relation indicates that $H_0(X)$ is a linear function of $C_{SCN^-}$; $H_1(X)$ is, therefore, constant irrespective of $C_{SCN^-}$, and higher $H_p(X)$ functions are equal to zero. By extrapolating $H_0(X)$ and $H_1(X)$ to $(f_X C_X)=0$, the following values were obtained:

$$\lim_{f_X C_X \to 0} H_0(X) = 0.20 \pm 0.05$$

$$\lim_{f_X C_X \to 0} H_1(X) = 0.47 \pm 0.06$$

$$\lim_{f_X C_X \to 0} H_p(X) \simeq 0 \qquad (p=2,\ 3 \text{ and } 4)$$

From Eqs. 14 and 16, $(k_0)_B$ and $(k_1)_B$ at the standard potential, $(E^0)_B = -0.2678$ V. vs. NHE, are calculated as follows;

$$(k_0)_B = (0.64 \pm 0.16) \times 10^{-4} \text{ cm./sec.}$$

$$(k_1)_B = (1.5 \pm 0.2) \times 10^{-4} \text{ (cm./sec.)/(mol./l.)}$$

$$(k_p)_B \simeq 0 \quad (p=2,\ 3 \text{ and } 4)$$

where the values of $D_s = 5.85 \times 10^{-6}$ cm$^2$/sec., calculated from the Ilkovic equation, and $D_a = 1.47 \times 10^{-5}$ cm$^2$/sec. (at 22°C)[11] were used, and $f_s$ and $f_a$ were assumed to be unity. The $(k_0)_B$ and $(k_1)_B$ values are the rate constants for $p=0$ and 1 respectively in the reaction given by Eq. 9. This means that two kinds of complexes, $In_{aq}^{3+}$ and $InSCN^{2+}$, are reduced at the electrode; the presence of two kinds of complexes is in accordance with the results calculated from Eq. 11.

The logarithm of the forward rate constant, $k_{f,h}$, according to the Koutecky treatment[12] was plotted against the potential in NHE as is shown in Fig. 8 for the data of the simple indium(III) ion. As is shown in Fig. 8, the plot in a less negative potential deviates from a straight line. This deviation is due chiefly to the effect of the backward rate constant, $k_{b,h}$, in the range of this potential. In the range of the potential for the linear portion, however, $k_{b,h}$ may be neglected with respect to $k_{f,h}$.

By extrapolating the linear portion to the standard potential of −0.2678 V. vs. NHE and the potential of 0 V. vs. NHE, the logarithms of the rate constants, $(k_0)_s$ and $k^0_{f,h}$ respectively, are obtained from the following equation:

$$\log k_{f,h} = \log k^0_{f,h} - \frac{\alpha n F}{2.3RT} E \qquad (17)$$

The values of $(k_0)_s = 1.58 \times 10^{-4}$ cm./sec. and $k^0_{f,h} = 4.77 \times 10^{-12}$ cm./sec. were obtained by

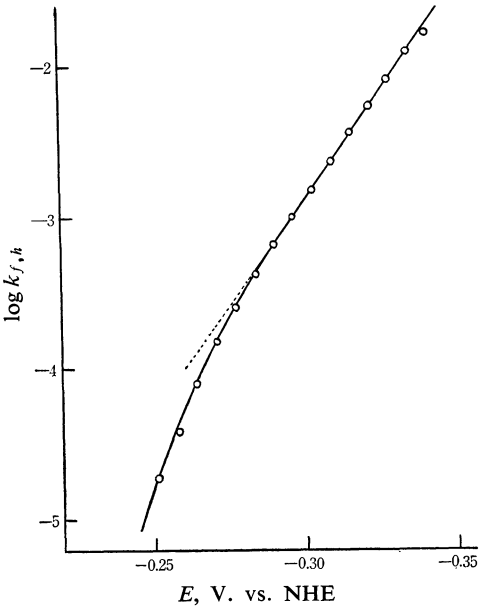

Fig. 8. The potential dependence of the rate constant of the electrode process for indium-(III) simple ion in perchlorate medium.

extrapolating the linear portion in Fig. 8 to −0.2678 V. and 0 V. vs. NHE respectively. The value of $(k_0)_B = (0.64 \pm 0.16) \times 10^{-4}$ cm./sec. is in good agreement with that of $(k_0)_s = 1.58 \times 10^{-4}$ cm./sec. when we consider that the scattering of the points in Fig. 7 is due largely to the errors of $E_{1/2}{}^r$, $A$ and $\alpha$. The latter value, $4.77 \times 10^{-12}$ cm./sec., agrees fairly well with the walue of $4.7 \times 10^{-12}$ cm./sec. (at 26.5°C) determined by Inouye and Imai[13] polarographically. Furthermore, from the slope of the straight line, $\alpha n$ was calculated to be 1.66, from which $\alpha = 0.55$ was obtained by assuming $n$ to be 3. Although the agreement of $k^0_{f,h}$ was fairly good, the polarographic wave obtained by Inouye and Imai[13] was a totally irreversible one whose half-wave potential was about −1.0 V. and whose product $\alpha n$ was 0.66, while the wave obtained in the present paper is "quasi"-reversible, and the half-wave potential and the product $\alpha n$ are about −0.5 V. and 1.66 respectively. Inouye and Imai,[13] however, pointed out that when a chloride, iodide or acetate ion is added to the simple indium-(III) ion, the irreversible wave, $E_{1/2} = -1.0$ V., is changed to a reversible one with $E_{1/2} = -0.5$ V. Likewise, the increase in perchlorate may cause the increase in the reversibility of the wave because the simple indium(III) ion in 2.0 mol./l. perchlorate is reduced at about −0.5 V. in the present paper.

## Summary

The formation constants, $K_j=[\mathrm{In(SCN)}_j^{(3-j)+}]/[\mathrm{In}^{3+}][\mathrm{SCN}^-]^j$ ($j=1$, 2, 3, 4), have been determined to be 50, 200, 120 and 1670 respectively. The electrode reaction proceeds as follows:

(1) At a higher ligand concentration;

$$\mathrm{In(SCN)}_p^{(3-p)+} \rightleftarrows \mathrm{InSCN}^{2+} + (p-1)\mathrm{SCN}^- \quad \text{(fast)} \quad (p=2,\ 3 \text{ and } 4)$$

$$\mathrm{InSCN}^{2+} + 3e^- + \mathrm{Hg} \rightarrow \mathrm{In(Hg)} + \mathrm{SCN}^- \quad \text{(rate constant } (k_1)_B)$$

(2) At a lower ligand concentration:

$$\mathrm{InSCN}^{2+} \rightleftarrows \mathrm{In}_{aq}^{3+} + \mathrm{SCN}^- \quad \text{(fast)}$$

$$\mathrm{In}_{aq}^{3+} + 3e^- + \mathrm{Hg} \rightarrow \mathrm{In(Hg)} \quad \text{(rate constant } (k_0)_B)$$

The rate constants, $(k_0)_B$ and $(k_1)_B$, at the standard potential are $(0.64\pm0.16)\times10^{-4}$ cm./sec. and $(1.5\pm0.2)\times10^{-4}$ (cm./sec.)/(mol./l.) respectively. The rate constant, $k^0_{f,h}$, at 0 V. vs. NHE was $4.77\times10^{-12}$ cm./sec.

The authors wish to thank Dr. Kunio Nakano and Dr. Kenichi Morinaga, Professors of Rikkyo University, Tokyo, for their interest in this work and their ardent discussions.

# The Colloidal Behaviour of Ammonium Purpurate (Murexide) in an Aqueous Solution

By Satendra P. SANGAL

(Received June 22, 1964)

Ammonium purpurate (murexide), which has the following structure:

has been used extensively in the complexometric titrations of calcium. Sangal and Dey[1] used the reagent as a chelatochrome indicator in thorium - ethylenediaminetetraacetic acid titrations also. Murexide gives coloured chelates with scandium and rare earths. During the investigations of the composition and stability of these chelates, it was found that, when the solutions of the reagent used were not very dilute, deviations in the composition from true stoichiometry were observed. Similar deviations had been observed earlier by Mukherji and Dey[2] during their studies of the metal chelates of aluminium; by Srivastava, Seth and Dey during their studies of the metal chelates of sulphodichlorohydroxydimethylfuchson dicarboxylate,[3] *p*-nitrobenzene-azochromotropic acid,[4] and 7-iodo-8-hydroxyquinoline-5-sulphonic acid (ferron),[5] and by Sangal and Dey during their studies of metal chelates of Thoron[6] with different metal ions. It appears, therefore, that murexide, like the above reagents, behaves as a colloidal electrolyte and does nos obey Beer's law in concentrated solutions.

The present communication records the results of our studies of the colloidal behaviour of murexide in an aqueous solution.

## Experimental

Electrical conductance measurements were carried with a Leeds and Northrup Kohlrausch slide wire with an audiofrequency oscillator in the circuit, operated by a 220 V./50 cycl. a. c. mains and using a measuring cell of the dip type, with a cell constant of 0.5875.

All solutions were freshly prepared in conductivity water using a B. D. H. sample of murexide.

## Results and Discussion

The electrical conductance of a series of solutions of murexide was measured at different dilutions at 25C°. A graph was then plotted between the square root of the concentration and the molar conductance (Fig. 1). The curve thus obtained was found to be similar to the curves of the colloidal electrolytes as recorded by McBain.[7] If the solution of Murexide had behaved like true electrolytes, the curve would have been linear and the Debye-Hückel equation would have been applicable.

The specific conductance of murexide was also determined at six temperatures, and by the extrapolation of the curves obtained by plotting the specific conductance against the temperature (Fig. 2), the temperature of the zero conductance was found to be −20°C. This observation confirms the findings of Mushran and Prakash,[8] who described, during their studies on colloidal systems, how although generally the temperature of the zero conductance of true electrolytes lies near −40°C, in the colloidal systems this temperature ranges between −15°C and −35°C.

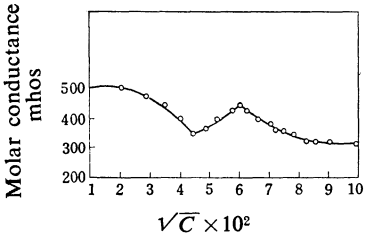

Fig. 1. Variation of molar conductance with concentration.

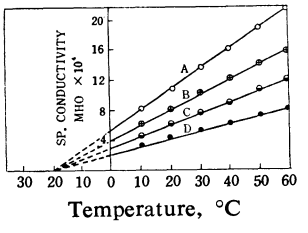

Fig. 2. Variation of specific conductance of murexide with temperature.
Curve A: Concn. of murexide 0.02 M
Curve B: Concn. of murexide 0.01 M
Curve C: Concn. of murexide 0.005 M
Curve D: Concn. of murexide 0.003 M

The temperature coefficients per 1°C per hundred of the conductance at 35°C have also been calculated; the results are as follows:

TABLE I. THE TEMPERATURE COEFFICIENT OF THE CONDUCTANCE

| Cocn. M | Specific conductance at 35°C (from graph) mhos×10⁴ | Temperature coefficient per 1°C | Temperature coefficient per hundred of the conductance |
|---|---|---|---|
| 0.003 | 5.8 | 0.050 | 0.86 |
| 0.005 | 8.4 | 0.100 | 1.19 |
| 0.010 | 11.2 | 0.150 | 1.34 |
| 0.020 | 15.2 | 0.250 | 1.65 |

These results also serve to establish the colloidal nature of murexide in concentrated solutions, as Shivapuri and Prakash[9] reported that usually the temperature coefficient per degree centigrade per hundred of the conductance at 35°C in a colloidal system is found to be below 2.0.

Thus, it may be concluded that murexide behaves as a colloidal electrolyte in concentrated solutions. For physico-chemical measurements, it is advisable, therefore, to work with very dilute solutions of the reagent for only then will the reagent behave as a true solution, as has also been suggested by Dey.[10]

## Summary

By electrical conductance studies it has been found that ammonium purpurate behaves as a colloidal electrolyte and does not obey Beer's law in concentrated solutions. The curve between the square root of the concentration and the molar conductance is not linear and resembles that of a colloidal electrolyte. The temperature of zero conductance has also been determined to be −20°C. The temperature coefficient per degree centigrade per hundred of the conductance at 35°C ranges between 0.86 and 1.65.

# The Formylation of Amino Acids with Acetic Formic Anhydride

By Ichiro MURAMATSU, Masahiro MURAKAMI, Takahiro YONEDA and Akira HAGITANI

(Received June 29, 1964)

The formyl group has been used as a blocking substituent of the amino moiety of amino acids in peptide syntheses[1,2] or in optical resolutions of amino acids. In these procedures, *N*-formylamino acids have been prepared with formic acid[3] or with formic acid and acetic anhydride.[2,4,5] The latter method has been widely used, since the formylation gives good yield without any accompanying racemization.

These methods, however, have the common defect that too much of the reagents are necessary compared with the amount of amino acids employed. It has been presumed that, in the formylation of amino acids with formic acid and acetic anhydride, acetic formic anhydride or formic anhydride may be formed first and that then the anhydride may react with the amino groups to yield *N*-formylamino acids. Therefore, the present authors have tried to formylate amino acids directly with pure acetic formic anhydride. In addition to the ketene - formic acid method,[6] this anhydride has been successfully and conveniently prepared by the reaction of acetyl chloride with sodium formate. In many instances, it has been found that the formylation of amino acids by the present method can be performed in a very simple way under mild conditions, and that only a 2 to 3-molar excess of the reagent is required.

## Results

Acetic formic anhydride was prepared by the following reactions:

$$CH_3COCl + HCOONa \rightarrow HCO\text{-}O\text{-}COCH_3 + NaCl \quad (1)$$

$$HCOOH + CH_2{=}C{=}O \rightarrow HCO\text{-}O\text{-}COCH_3 \quad (2)$$

In method 1, although the purity of acetyl chloride and atmospheric humidity exerted a great influence upon the yield, the anhydride was generally obtained in a 75—91% yield. In method 2,[6] the anhydride was constantly obtained in a 80—90% yield. The refractive indices and the infrared spectra of the anhydrides prepared by the two methods are in agreement with each other (Fig. 1). This anhydride is stable in a refrigerator, but it is decomposed with the evolution of carbon monoxide above about 60°C, above room temperature in formic acid, or even at 0°C in the presence of a small amount of pyridine.

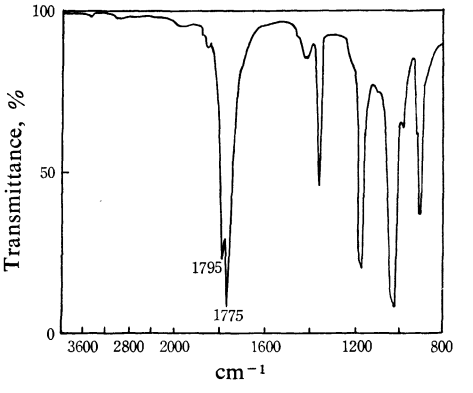

Fig. 1. Infrared absorption spectrum of acetic formic anhydride in carbon tetrachloride.

The formylation of amino acids with acetic formic anhydride was carried out using formic acid as a solvent. The temperature of the reaction was maintained below 10°C during the exothermic period in the reaction by means of an ice bath. After the stirring had been continued subsequently for two hours at room temperature, the mixture was concentrated to a solid mass or syrup under reduced pressure, and the residue was crystallized from a suitable solvent. Even when acetic acid was used as a solvent, formylation took place but acetylation did not. Monoamino monocarboxylic acids (glycine, DL-alanine, L-valine, L-leucine, L-methionine, L-phenylalanine, L-tyrosine and β-alanine) were generally formylated in good yields (70—94%), as was the alanine ester, and their optical activities were retained. The formylation of

glutamic acid by the present method was difficult to carry out with a good yield, unlike that of the amino acids mentioned above. The formylation of other amino acids with three or more functional groups was not attempted in our studies. Special methods[7,8] may be required for the monoformylation of basic amino acids.

## Experimental[9]

**Acetic Formic Anhydride.** — *Method 1.* — Into a solution of 445 ml. of acetyl chloride in 250 ml. of dry ether, 500 g. of sodium formate was added in several portions in such a way that the temperature did not exceed 27°C. The mixture was kept from moisture and vigorously shaken. After the shaking had been continued for 5.5 hr. at 25—27°C, the salt was filtered off. The filtrate was then evaporated under water-pump pressure below 20°C (bath temperature) in order to remove the ether and the remaining reagent. The residual liquid weighed 502 g. (91%). A small amount of free acid was found, by a study of the infrared spectrum, to be present in the anhydride prepared in this way, but the crude anhydride was successfully used in the formylation of amino acids without further purification. When impure acetyl chloride was used, the product decomposed gradually, with forming, during the above procedure.

*Method 2.*—Ketene was prepared from acetone in a ketene lamp which delivered about 0.5 mol. of ketene per hour. The solution of 2 mol. of formic acid (98—100%, E. Merck AG.) in 300 ml. of ether was saturated with ketene in an ice bath. After the evaporation of ether, the residue was fractionated under reduced pressure, and the fractions boiling between 30°C/24 mmHg ($n_D^{20}$ 1.386) and 24°C/9 mmHg ($n_D^{20}$ 1.388) were collected; yield, 163 g. (93%). These fractions were successfully employed for the formylation of amino acids. From the infrared spectra of the distillates, it was found that the first runnings contained only a trace of free acid, while the last ones a small amount of acetic anhydride. The main fraction boiled at 30°C/19 mmHg ($n_D^{20}$ 1.387) (in the lit.,[6] b. p., 27—28°C/10 mmHg, $n_D^{20}$ 1.388); its infrared spectrum is shown in Fig. 1. This spectrum shows absorption bands at 1795, 1775, 1380, 1178, 1037 and 924 $cm^{-1}$ (in carbon tetrachloride). It is very interesting that the difference (20 $cm^{-1}$) between the wave numbers of the two carbonyl bands (1795 and 1775 $cm^{-1}$) of acetic formic anhydride is less than those of ordinary acid anhydrides (about 60 $cm^{-1}$).[10]

***N*-Formylglycine.** — To a solution of 3.76 g. (50 mmol.) of glycine in 20 ml. of formic acid (90%), 13.2 g. (150 mmol.) of acetic formic anhydride was added. The reaction mixture was stirred at a temperature maintained below 10°C by means of an ice bath. After 40 min., the bath was removed. Stirring was continued for a further 80 min., and then the solution was concentrated to dryness under reduced pressure. The solid residue was twice recrystallized from a mixture of ethyl acetate (75 ml.) and ethanol (25 ml.). *N*-Formylglycine was obtained as white crystals; 4.39 g. (85%); m. p. 151—153°C (lit[8] m. p. 153—154°C). (Found: N, 13.41%).

When acetic acid was used as the solvent instead of formic acid in the above instance, *N*-formylglycine was also obtained in a 76% yield.

***N*-Formyl-DL-alanine.** — After 3.57 g. (40 mmol.) of DL-alanine had been acylated with 10.57 g. (120 mmol.) of acetic formic anhydride by a method similar that of to the formylation of glycine in formic acid, the product was recrystallized from ethyl acetate - ethanol to yield 4.41 g. (94%) of pure crystals (m. p. 145—148.5°C; lit.[11] m. p. 147—148°C). (Found: C, 40.93; H, 6.17; N, 11.97%).

***N*-Formyl-L-valine.**—After 3.52 g. (30 mmol.) of L-valine had been treated with 10 g. (113 mmol.) of the anhydride in a similar way, the product was twice recrystallized from ethanol to yield 3.65 g. (84%) of pure crystals. M. p. 150—151°C, $[\alpha]_D^{21}$ +11.7° (*c* 3.97, ethanol); lit.[12] m. p. 156°C, $[\alpha]_D^{20}$ +13.1° (*c* 9.0, ethanol). (Found: C, 49.21; H, 7.81; N, 9.59%).

***N*-Formyl-L-leucine.** — L-Leucine (3.94 g., 30 mmol.) was formylated with the anhydride (7.93 g., 90 mmol.) in 20 ml. of formic acid. The recrystallization of the product from ethyl acetate gave 3.35 g. (70%) of crystals; m. p. 139—141°C. The analytical sample was prepared by further recrystallization from the same solvent; m. p. 140.5—142°C, $[\alpha]_D^{20}$ −17.7° (*c* 4.97, ethanol): lit.[3] $[\alpha]_D^{20}$ −18.4° (*c* 10, ethanol). (Found: C, 52.76; H, 8.30; N, 8.86%).

***N*-Formyl-L-methionine.** — L-Methionine (3.0 g., 20 mmol.) was treated with the anhydride (5.4 g., 60 mmol.) in 4 ml. of formic acid. The crude product obtained in a similar manner was twice recrystallized from ethyl acetate - petroleum ether to give 2.73 g. (77%) of pure crystals; m. p. 86—87°C, $[\alpha]_D^{24.5}$ −10.0° (*c* 2.41, water); lit. m. p. 86—87°C,[13] $[\alpha]_D^{25}$ −10.0° (*c* 0.8, water).[14]

***N*-Formyl-L-phenylalanine.**—L-Phenylalanine (2.65 g., 16 mmol.) was formylated with the anhydride (2.7 g., 30 mmol.) in 4 ml. of formic acid. The first crop of *N*-formyl-L-phenylalanine was taken out by filtration from the reaction mixture, while the second crop was obtained from the mother liquor. They were then washed with water, dried, and combined. Yield, 2.58 g. (83%); m. p. 165—166°C. The analytical sample was obtained by recrystallization from water. M. p. 165.5—166°C,

$[\alpha]_D^{20}$ +72.5° (*c* 1.58, ethanol); lit.[15] m. p. 167°C, $[\alpha]_D^{20}$ +75.2° (*c* 4, ethanol). (Found: N, 7.43%).

***N*-Formyl-L-tyrosine.**—To a suspension of 7.25 g. (40 mmol.) of L-tyrosine in 10 ml. of formic acid, 10.5 g. (120 mmol.) of the anhydride was added. The mixture was allowed to react for 2 hr., water was added thereto, and the solution was concentrated to dryness under reduced pressure. An ice cold *N*-hydrochloric acid was then added to the residue in order to dissolve the remaining tyrosine. The product was collected by filtration and washed with water. 7.05 g. (84%) of *N*-formyl-L-tyrosine was obtained; it melted at 166°C. The recrystallization from ethanol gave an anhydrous compound; m. p. 167°C, $[\alpha]_D^{20}$ +89.7° (*c* 1.78, ethanol), $[\alpha]_D^{20}$ +56.3° (*c* 1.33, water); lit.[16] m. p. 170—171°C, $[\alpha]_D^{10}$ +89.4° (*c* 1.74, ethanol).

Found: C, 57.29; H, 5.51; N, 7.11. Calcd. for $C_{10}H_{11}NO_4$: C, 57.41; H, 5.30; N, 6.70%.

The recrystallization from water generally gave a hydrated compound;[17-19] m. p. 166°C (sinters at 90°C), $[\alpha]_D^{20}$ +53.0° (*c* 1.52, water).

Found: $H_2O$, 7.88% (dried in vacuo at 100°C for 3 hr.). Calcd. for $C_{10}H_{11}NO_4 \cdot H_2O$; $H_2O$, 7.92%.

***N*-Formyl-L-glutamic Acid.** — L-Glutamic acid (4.42 g., 30mmol.) in 6.5 ml. of formic acid was formylated with the anhydride (3.36 g., 38 mmol.). The crude product was recrystallized from ethyl acetate to yield pure crystals of *N*-formyl-L-glutamic acid (1.85 g., 35%). M. p. 110—112°C, $[\alpha]_D^{20.5}$ −7.4° (*c* 2.02, water): lit.[20] m. p. 112—113°C, $[\alpha]_D^{20}$ −7.25° (*c* 2, water). Better yields have been reported in the literature[20,21] from the usual formic acid - acetic anhydride method.

***N*-Formyl-β-alanine.**—β-Alanine (3.1 g., 35 mmol.) was formylated with acetic formic anhydride (11.2 g., 130 mmol.) in a similar manner. The crystallization of the product from ethyl acetate yielded 3.24 g. (79%) of crystals (m. p. 73—74°C; lit.[22] m. p. 75—76°C).

***N*-Formyl-DL-alanine Ethyl Ester.**[23]—Into a solution of 91 g. of DL-alanine ethyl ester in 91 ml. of formic acid, 118 ml. of acetic formic anhydride was added with stirring in an ice bath. After the mixture had been stirred for 3 hr. at room temperature, the mixture was distilled under reduced pressure to afford the formylated ester; yield, 95.3 g. (85%); b. p. 98°C/1 mmHg (lit.[24] b. p. 100°C/1 mmHg).

## Summary

The formylation of amino acids with acetic formic anhydride has been studied. This anhydride is prepared by the reaction of acetyl chloride with sodium formate or, preferably, from ketene and formic acid. When various monoamino monocarboxylic acids are treated with acetic formic anhydride by a simple procedure and under mild conditions, *N*-formyl-amino acids were obtained in satisfactory yields.

# The Anionoid Substitution Reaction of Diethyl 6-Bromoazulene-1, 3-dicarboxylate*

By Tetsuo NOZOE, Kahei TAKASE and Masao TADA

(Received July 3, 1964)

In previous papers[1-3] we have reported on the synthesis of some 5- and 6-substituted azulene derivatives from 5-aminotropolone and 4-acetyltropolone derivatives as a part of a general scheme of the synthetic study of azulenes with the functional group on a seven-membered ring. For synthesizing some 6-substituted azulenes, the present authors studied the anionoid substitution reactions of diethyl 6-bromoazulene-1, 3-dicarboxylate (II), which is the deaminated product of diethyl 2-amino-6-bromoazulene-1, 3-dicarboxylate (I);[4] this paper will describe the results.

The diazotization reaction of I was accomplished in dioxane by the use of a large excess of sulfuric acid and sodium nitrite and without cooling. The decomposition of diazonium salt to yield the corressponding deaminated product was achieved by letting the salt stand at room temperature in the presence of sodium hypophosphite. Thus, diethyl 6-bromoazulene-1, 3-dicarboxylate (II) was obtained in a 25% yield, accompanied by two by-products (III and IV), one of which, III, was a 6-ethoxyazulene derivative, being the intramolecular diazonium-salt type reported by Asao et al.[5] The other one, IV, obtained in a 2% yield, was assumed to be diethyl 2-(1, 3-diethoxycarbonylazulen-6-yl)amino-6-bromoazulene-1, 3-dicarboxylate on the basis of the infrared spectrum, the analytical values and the chemical reactivities of II, as will be described below. The ultraviolet spectrum of II is shown in Fig. 1.

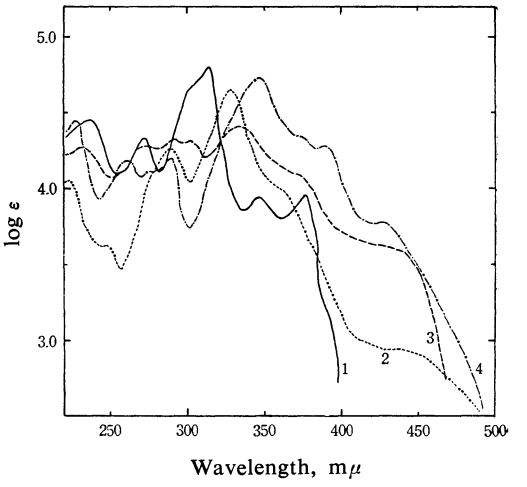

Fig. 1. Ultraviolet absorption spectra in methanol.
1 Diethyl 6-bromoazulene-1, 3-dicarboxylate (II)
2 Diethyl 6-hydroxyazulene-1, 3-dicarboxylate (V)
3 Diethyl 6-hydrazinoazulene-1, 3-dicarboxylate (X)
4 Diethyl 6-[di(2-hydroxyethyl)amino]-azulene-1, 3-dicarboxylate (XIV)

A mild alkaline treatment of II resulted in the replacement of the bromine atom by the hydroxyl group, thus forming diethyl 6-hydroxyazulene-1, 3-dicarboxylate (V), which, on being treated with acetic anhydride, gave an acetate with an absorption at 1764 $cm^{-1}$ for the acetoxy group. However, under more severe conditions, not only V but also II gave 6-hydroxyazulene-1, 3-dicarboxylic acid (VI). Since the alkaline treatment of I give only 2-amino-6-bromo-1, 3-dicarboxylic acid,[4] these results show the bromine atom at the 6-position in II to be more active than in I. The treatment of II with sodium ethoxide or

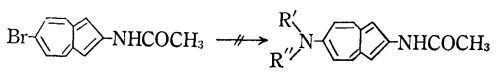
sodium hydrogen sulfide afforded diethyl 6-ethoxyazulene-1, 3-dicarboxylate (VII) or diethyl 6-mercaptoazulene-1, 3-dicarboxylate (VIII) respectively in a good yield.

The reaction of II with liquid ammonia afforded diethyl 6-aminoazulene-1, 3-dicarboxylate (IX), which was identical with an authentic specimen synthesized from 5-amino-2-methoxytropone.[1] Recently, Hafner et al.[6] reported that the reaction of 4, 8-dimethyl-6-chloroazulene with sodium azide, in the presence of dimethyl sulfoxide, afforded 4, 8-dimethyl-6-aminoazulene. In the same way, IX was also obtained from II.



VII: X=$OC_2H_5$
VIII: X=SH
IX: X=$NH_2$

The bromine atom of II was easily replaced, when heated for a short period, with various amines, such as hydrazine, dimethylamine, diethylamine, ethanolamine, diethanolamine, diallylamine, ethyleneimine, pyrrolidine, piperidine, morpholine, aminopropylmorpholine and aniline, and the corresponding *N*-substituted amino derivatives of IX (X—XXI) were obtained in good yields. Under the same conditions, however, the bromine atom of 2-acetamido-6-bromoazulene (XXII)[4] was not replaced by various amines.

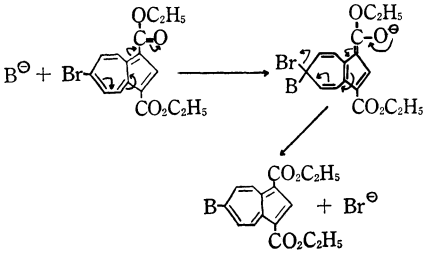
These facts can be understood by reference to the electrophilic nature of the seven-membered ring in azulene, enhanced by the presence of two ethoxycarbonyl groups at positions 1 and 3. This reaction path is shown in Chart I.



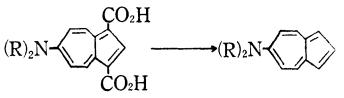


Chart I.

The alkaline hydrolysis of the 6-dimethylamino compound (XI) and the 6-diethylamino compound (XII) gave dicarboxylic acid (XXIII) and (XXIV), both of which, when heated in pyridine, caused decarboxylation, thus giving 6-dimethylaminoazulene (XXV) and 6-diethylaminoazulene (XXVI) respectively. Compared with 6-aminoazulene,[1] XXV and XXVI are more stable and do not change on being left

in air for a long period of time. The ultraviolet spectra of these compounds are shown in Fig. 2.

The reactions of II with active methylene reagents are being investigated and will be reported on in the future.

## Experimental[7]

**The Deamination of I.** — Into a solution of I (2.0 g.) in dioxane (120 ml.) and concentrated sulfuric acid (12 ml.), a solution of sodium nitrite (1.0 g.) in water (5 ml.) was stirred at room temperature. After the solution had been stirred for 50 min., sodium hypophosphite (20 g.) was added to this diazotized solution and the mixture was vigorous stirred for 4 hr. After it had stood overnight, the solution was diluted with water (300 ml.) and extracted with benzene. The extract was washed with water, dried over anhydrous sodium sulfate, and passed through a column of alumina, and then the column was eluted with benzene. From the first effluent, crude crystals of diethyl 6-bromoazulene-1, 3-dicarboxylate (II), m. p. 198—199°C, 0.5 g.), were obtained. The recrystallization from ethanol gave purplish red micro-needles, m. p. 206—207°C.

Found: C, 54.85; H, 4.21. Calcd. for $C_{16}H_{15}O_4Br$: C, 54.70; H, 4.27%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 235 (4.45), 270 (4.30), 312 (4.80), 345 (3.95), 375 (3.95). IR (Nujol): 1684 $cm^{-1}$.

The second effluent gave yellow needles (200 mg.), which showed no depression of melting point on admixture with III and the infrared spectrum of which was identical with that of III.[5]

From the third effluent, crude crystals (15 mg.) were obtained. Recrystallization from a mixture of benzene and ethanol afforded diethyl 2-(1, 3-diethoxycarbonylazulen-6-yl)amino-6-bromoazulene-1, 3-dicarboxylate (IV) as red micro-prisms, m. p. 159—160°C; 10 mg.

Found: C, 59.38; H, 4.75; N, 2.20. Calcd. for $C_{32}H_{30}O_8NBr$: C, 59.44; H, 4.54; N, 2.14%.

IR (Nujol): 3175, 1695, 1684, 1658 $cm^{-1}$.

**Diethyl 6-Hydroxyazulene-1, 3-dicarboxylate (V).** —Into a solution of potassium hydroxide (300 mg.) in 50% aqueous ethanol (8 ml.), II (100 mg.) was stirred, and then the mixture was warmed on a water bath for 5 min. This was diluted with water (25 ml.) and acidified with diluted sulfuric acid. The crystals (80 mg.) which separated were recrystallized from aqueous ethanol to give brownish yellow crystals of V (m. p. 201—201.5°C).

Found: C, 66.84; H, 5.98. Calcd. for $C_{16}H_{16}O_5$: C, 66.66; H, 5.59%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 221 (4.07), 246.5 (3.64), 288 (4.28), 329 (4.67), 357 (4.05)sh, 433 (2.95)sh.

IR (KBr disk): 3260, 1701, 1647 $cm^{-1}$.

*The Acetate of V.*—A solution of V (50 mg.) in acetic anhydride (2 ml). was refluxed for 6 min. The residue obtained by the evaporation of the solvent was recrystallized from aqueous ethanol to give reddish orange crystals (m. p. 129—130°C; 30 mg.).

Found: C, 65.37; H, 5.55. Calcd. for $C_{18}H_{18}O_6$: C, 65.44; H, 5.49%.

IR (Nujol): 1764, 1695, 1681, 1669 $cm^{-1}$.

**6-Hydroxyazulene-1,3-dicarboxylic Acid (VI).**— To a solution of potassium hydroxide (400 mg.) in 80% aqueous ethanol (10 ml.), II (200 mg.) was added. After it had been refluxed for 3 hr., the mixture was diluted with water (30 ml.) and acidified with 6 N sulfuric acid. The separated crystals were dissolved in a diluted potassium hydroxide aqueous solution and reprecipitated with 2 N hydrochloric acid. After these crystals had been washed with water, a dark brown powder (140 mg.) of VI was obtained; m. p. 174—175°C (decomp.).

Found: C, 61.75; H, 4.11. Calcd. for $C_{12}H_8O_5$: C, 62.07; H, 3.47%.

IR (Nujol): 3125, 1653 $cm^{-1}$.

V (200 mg.) also gave VI (140 mg.) under the same treatment.

**Diethyl 6-Ethoxyazulene-1,3-dicarboxylate (VII).** —To a solution prepared from sodium (50 mg.) and absolute ethanol (12 ml.), fine powdered II (400 mg.) was added. After it had been refluxed for 10 min. on a water bath, the mixture was evaporated to dryness under reduced pressure. The residue was dissolved in benzene, and the benzene solution was passed through a column of alumina, giving orange needles (300 mg.; m. p. 129—130°C). The substance was identified with an authentic specimen[6] of VII by a comparison of the infrared spectra.

**Diethyl 6-Mercaptoazulene-1, 3-dicarboxylate (VIII).**—II (50 mg.) and a 27% sodium hydrogen sulfide aqueous solution (4 ml.) were dissolved in ethanol (20 ml.). The solution was then heated on a water bath for 15 min. After it had stood overnight at room temperature, the reaction mixture was diluted with water, acidfied with 6 N sulfuric acid, and extracted with benzene. The extract was washed with water and dried over anhydrous sodium sulfate. The residue obtained by the evaporation of the solvent was recrystallized from benzene, yielding VIII (30 mg.; m. p. 222—224°C) red crystals.

Found: C, 63.45; H, 4.76. Calcd. for $C_{16}H_{16}O_4S$: C, 63.14; H, 5.30%.

IR (Nujol): 2519, 1689 $cm^{-1}$.

**Diethyl 6-Aminoazulene-1, 3-dicarboxylate (IX).** —*a) With Liquid Ammonia.*—A suspension of II (100 mg.) in liquid ammonia was allowed to stand for a week at room temperature. The residue obtained by the evaporation of the ammonia was recrystallized from ethanol to give orange scales (45 mg.), which showed no depression of melting point on admixture with an authentic specimen[1] of IX.

*b) With Sodium Azide.*—A mixture of II (100 mg.) and sodium azide (0.4 g.) in dimethyl sulfoxide (5 ml.) was heated on a water bath for 15 hr. After dilution with water, this reaction mixture was extracted with ethyl acetate and the extract was passed through a column of alumina, yielding IX (30 mg.).

7) All melting points are uncorrected. Shoulders in the UV spectral data are designated by "sh."

**Diethyl 6-Hydrazinoazulene-1,3-dicarboxylate (X).**—To a solution of 80% hydrazine hydrate (2 ml.) in ethanol (2 ml.), II (50 mg.) was added. The mixture was then refluxed for 10 min. on a water bath. After the addition of water (20 ml.), the precipitate thereby formed was recrystallized from ethanol to give X (30 mg.; m. p. 237°C) as brilliant yellow scales.

Found: C, 63.48; H, 6.06; N, 9.64. Calcd. for $C_{16}H_{18}O_4N_2$: C, 63.56; H, 6.00; N, 9.27%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 233 (4.26), 273 (4.28), 289.5 (4.32), 301 (4.32), 333 (4.42), 367 (4.13)sh, 420 (3.65)sh.

IR (Nujol): 3330 (broad), 1642 $cm^{-1}$.

*Acetate of X.*—Pale yellow micro-prisms (from aqueous ethanol), m. p. 232—233°C.

Found: N, 7.85. Calcd. for $C_{18}H_{20}O_5N_2$: N, 8.14%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 224 (4.33), 254 (4.02)sh, 275 (4.17)sh, 282.5 (4.23), 337 (4.73), 371 (4.32), 428 (3.68).

IR (Nujol): 3520, 3330, 3260, 1689, 1656 $cm^{-1}$.

**Diethyl 6-Dimethylaminoazulene-1,3-dicarboxylate (XI).**—To a solution of a 40% dimethylamine aqueous solution (3 ml.) in ethanol (5 ml.), II (100 mg.) was added. The mixture was refluxed for 20 min. on a water bath. After the addition of water, the precipitate thereby formed was recrystallized from ethanol to give XI (75 mg.; m. p. 161—162°C) as yellow silky needles.

Found: N, 4.22. Calcd. for $C_{18}H_{21}O_4N$: N, 4.44%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 225 (4.15), 262 (4.08), 277 (3.99), 288 (4.05), 343 (4.69), 390 (4.27).

IR (Nujol): 1669 $cm^{-1}$.

**Diethyl 6-Diethylaminoazulene-1,3-dicarboxylate (XII).**—To a solution of diethylamine (2 ml.) in ethanol (10 ml.), II (200 mg.) was added. The mixture was then refluxed for 20 min. on a water bath. After the addition of water, the crystals separated were recrystallized from aqueous ethanol to give XII (130 mg.; m. p. 171—172°C) as yellow needles.

Found: N, 3.96. Calcd. for $C_{20}H_{25}O_4N$: N, 4.08%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 225 (4.32), 260 (4.20), 279.5 (4.15)sh, 288 (4.22), 347 (4.71), 373 (4.30)sh, 390 (4.26), 423 (3.77).

IR (Nujol): 1669 $cm^{-1}$.

**Diethyl 6-(2-Hydroxyethylamino)azulene-1,3-dicarboxylate (XIII).**—To a solution of ethanolamine (2 ml.) in ethanol (8 ml.), II (50 mg.) was added. The mixture was then treated as in the case of XI to give XIII (30 mg.; m. p. 165—167°C) as yellow crystals.

Found: N, 3.86. Calcd for $C_{18}H_{21}O_5N$: N, 4.23%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 225.5 (4.17), 253.5 (4.23), 285 (4.23), 332 (4.66), 367 (4.03)sh, 424 (3.90), 476 (3.31)sh.

IR (KBr disk): 3550, 3340, 1678, 1656 $cm^{-1}$.

**Diethyl 6-[Di(2-hydroxyethyl)]aminoazulene-1,3-dicarboxylate (XIV).**—To a solution of diethanolamine (2 ml.) in ethanol (8 ml.), II (50 mg.) was added. The mixture was then treated as in the case of XII to give XIV (25 mg.; m. p. 125—126°C) as brilliant yellow needles.

Found: N, 3.55. Calcd. for $C_{20}H_{25}O_6N$: N, 3.73%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 226 (4.45), 260.5 (4.18), 277 (4.12), 287.5 (4.21), 346 (4.74), 377 (4.33)sh, 391 (4.28), 423 (3.79).

**Diethyl 6-Diallylaminoazulene-1,3-dicarboxylate (XV).**—To a solution of diallylamine (1 ml.) in ethanol (5 ml.), II (50 mg.) was added. The mixture was then refluxed for 20 min. on a water bath. After dilution with water, the reaction mixture was extracted with benzene. The extract was then washed with water and dried over anhydrous sodium sulfate. The residue obtained by the evaporation of the solvent was recrystallized from aqueous ethanol to give XV (20 mg.; m. p. 103—104°C) as brownish yellow crystals.

Found: N, 3.66. Calcd. for $C_{22}H_{25}O_4N$: N, 3.81%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 225 (4.35), 258.5 (4.17), 276.5 (4.12)sh, 286.5 (4.22), 346.5 (4.78), 376 (4.39), 389 (4.31), 425 (3.71).

**Diethyl 6-Ethyleneiminoazulene-1,3-dicarboxylate (XVI).**—To a solution of ethyleneimine (1 ml.) in ethanol (5 ml.), II (50 mg.) was added. The mixture was then refluxed for 10 min. on a water bath. After dilution with water, the reaction mixture was extracted with benzene, and the extract was washed with water. After it had been dried over anhydrous sodium sulfate, this was passed through a column of alumina and the column was eluted with ethyl acetate. From the first effluent, an oily substance was obtained; the yellow crystals obtained from the second effluent were recrystallized from aqueous ethanol to give XVI (15 mg.; m. p. 160—161°C) as yellow fine crystals.

Found: N, 4.56. Calcd. for $C_{18}H_{19}O_4N$: N, 4.47%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 224 (4.18), 260 (4.03), 276 (4.05)sh, 286 (4.11), 340.5 (4.69), 388 (4.15).

**Diethyl 6-Pyrrolidinoazulene-1,3-dicarboxylate (XVII).**—A solution of II (60 mg.) and pyrrolidine (2 ml.) in ethanol (10 ml.) was refluxed for 20 min. on a water bath and concentrated to 1/3 volume under reduced pressure. After the addition of water, the solution was extracted with ethyl acetate and the extract was washed with 2 N acetic acid and water. After the removal of the solvent, the extract gave crude crystals (35 mg.), which were recrystallized from ethanol to give XVII (25 mg.; m. p. 194—195°C (decomp.)) as dark yellow micro-prisms.

Found: C, 69.98; H, 6.49; N, 3.83. Calcd. for $C_{20}H_{23}O_4N$: C, 70.36; H, 6.79; N, 4.10%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε); 225 (4.30), 260 (4.22), 288 (4.20), 345 (4.77), 388 (4.34).

IR (KBr disk): 1669 $cm^{-1}$.

**Diethyl 6-Piperidinoazulene-1,3-dicarboxylate (XVIII).**—A solution of II (60 mg.) and piperidine (2 ml.) in ethanol (10 ml.) was treated as in the case of XVII to give XVIII (25 mg.; m. p. 103—103.5°C) as orange micro-needles.

Found: N, 3.56. Calcd. for $C_{21}H_{25}O_4N$: N, 3.94%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 251 (4.22), 338 (4.63), 458 (3.96).

**Diethyl 6-Morpholinoazulene-1,3-dicarboxylate (XIX).**—A solution of II (60 mg.) and morpholine (2 ml.) in ethanol (10 ml.) was treated as in the case of XII to give XIX (20 mg.; m. p. 101—102°C) as brilliant yellow scales.

Found: N, 3.57. Calcd. for $C_{20}H_{23}O_5N$: N, 3.92%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 228.5 (4.26), 263 (4.18), 287 (4.04), 345 (4.68), 396 (4.32).

IR (KBr disk): 1689, 1669 $cm^{-1}$.

**Diethyl 6-(3-Morpholinopropyl)aminoazulene-1,3-dicarboxylate (XX).**—A solution of II (50 mg.) and aminopropylmorpholine (2 ml.) in ethanol (8 ml.) was refluxed for 30 min. on a water bath. After dilution with water, the solution was extracted with ethyl acetate, and the extract was washed with 2 N acetic acid and water. After it had been dried over anhydrous sodium sulfate, the extract was evaporated to dryness. The residue that was dissolved in benzene was passed through a column of alumina, and the column was eluted with benzene to give yellow crystals (25 mg.). Recrystallization from aqueous ethanol afforded reddish yellow micro-prisms (m. p. 109—110°C).

Found: N, 6.57. Calcd. for $C_{23}H_{30}O_5N_2$: N, 6.76%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 224 (4.27), 286 (4.25), 341 (4.79), 370 (4.30)sh, 420 (3.84).

IR (KBr disk): 3380, 1678, 1664 $cm^{-1}$.

**Diethyl 6-Anilinoazulene-1,3-dicarboxylate (XXI).**—A solution of II (50 mg.) and aniline (1 ml.) in ethanol (9 ml.) was refluxed for 1.5 hr. on a water bath and then concentrated to half volume. After the addition of water (5 ml.), the precipitate thereby formed was recrystallized from ethanol to give XXI (20 mg.; m. p. 182—183°C) as reddish yellow leaflets, and II (5 mg.) was recovered.

Found: N, 3.43. Calcd. for $C_{22}H_{21}O_4N$: N, 3.85%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 227 (4.36), 270 (4.25), 347 (4.69), 399 (4.33).

IR (KBr disk): 3310, 1689, 1658 $cm^{-1}$.

**6-Dimethylaminoazulene-1,3-dicarboxylic Acid (XXIII).**—A solution of XI (150 mg.) and potassium hydroxide (300 mg.) in 60% aqueous ethanol (10 ml.) was refluxed for 3 hr. on a water bath. The solution was then concentrated to half volume under reduced pressure, and this was diluted with water (15 ml.) and acidified with 6 N sulfuric acid. The precipitate was collected by filtration and repeatedly washed with water, by which process XXIII was obtained as a brown crystalline powder; m. p. 167—168°C (decomp.), 100 mg.

**6-Diethylaminoazulene-1,3-dicarboxylic Acid (XXIV).**—When XII (300 mg.) was treated as in the above experiment, XXIV was obtained as brown crystals (200 mg.; m. p. 180°C (blacken)).

**6-Dimethylaminoazulene (XXV).**—A solution of XXIII (100 mg.) in pyridine (2 ml.) was heated at 125—130°C to effect decarboxylation. The residue produced by the evaporation of the excess pyridine was dissolved in benzene, the solution was passed through a column of alumina, and the column was eluted with benzene. From the effluent, orange crystals (15 mg.) were obtained, and recrystallization from benzene afforded pale red scales (m. p. 163—164.5°C) of XXV. The infrared spectrum of XXV shows no absorption for $\nu_{C=O}$ and $\nu_{N-H}$.

Found: N, 7.86. Calcd. for $C_{12}H_{13}N$: N, 8.18%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 307 (4.66)sh, 316(4.70), 390 (4.20)sh, 397 (4.32), 472 (2.84).

*The Picrate of XXV.*—Dark green micro-prisms (from ethanol); m. p. above 280°C.

Found: N, 13.60. Calcd. for $C_{18}H_{16}O_7N_4$: N, 14.00%.

**6-Diethylaminoazulene (XXVI).**—When a solution of XXIV (180 mg.) in pyridine (2.5 ml.) was treated as in the above experiment, XXVI (15 mg.) was obtained. Recrystallization from ethanol afforded pale red scales (m. p. 71—71.5°C). The infrared spectrum of XXVI shows no absorption for $\nu_{C=O}$ and $\nu_{N-H}$.

Found: N, 6.61. Calcd. for $C_{14}H_{17}N$: N, 7.03%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 309 (4.68)sh, 318 (4.72), 392 (4.26)sh, 399 (4.41), 443 (2.94), 476 (2.95).

Expenses for the present series of experiments were defrayed by a grant-in-aid for Scientific Research from the Ministry of Education. The infrared spectra in this paper were measured by using a Shimadzu infrared spectrophotometer IR-27 purchased by a grant-in-aid for Scientific Research from the Toyo Rayon Co., Ltd. The authors wish to express their deep gratitude for these contributions.

# Chlorination by Sulfuryl Chloride. IV.[1] The Effect of Substituents in the Radical Chlorination of Benzaldehydes

By Mannosuke ARAI

(Received July 10, 1964)

In a previons peper of this series,[1] the author has shown that the polar effect of reactant molecules exerts an influence on the reaction rate, an influence based on the relative reactivity of the C–H bond toward the radical chlorination by sulfuryl chloride.

In the present work, the author will investigate whether or not the chlorination of substituted benzaldehydes to the corresponding acid chlorides is governed by the Hammett equation; this will be done in order to estimate the polar effect of substituents. The study was extended to alkylbenzaldehydes with both alkyl and formyl groups on the same benzene-ring in order to establish the change in the reactivity of the groups compared with alkylbenzene or benzaldehyde.

## Experimental

**Materials and Reagents.**—Toluene, of reagent grade, was purified in advance by fractional distillation, and the constantly boiling fraction was redistilled before use.

Substituted benzaldehydes, except *p*-isopropylbenzaldehyde and *p*-*t*-butylbenzaldehyde, all of reagent grade, were fractionated in an atmosphere of nitrogen; constantly boiling fraction was used.

Sulfuryl chloride, of first grade, was fractionally distilled, stored in a bottle wrapped with aluminum foil, and kept in a desiccator.

*p*-Isopropylbenzaldehyde was prepared by the chloromethylation of cumene, followed by heating with hexamethylenetetramine according to Blanc's method.[2] The product was purified through a sodium hydrosulfite adduct, b. p. 91°C/7 mmHg. Semicarbazone, m. p. 210—211°C. Found: N, 20.72. Calcd. for $C_{11}H_{15}ON_3$: N, 20.47%

*p*-*t*-Butylbenzaldehyde was similarly prepapred by the chloromethylation of *t*-butylbenzene, followed by heating with formaldehyde and hexamethylenetetramine following Schaklett and Smith's method;[3] b. p. 129—130°C/27 mmHg. 2,4-Dinitrophenylhydrazone, m. p. 250—251°C. Found: N, 16.25. Calcd. for $C_{17}H_{17}O_4N_4$: N, 16.37%.

**General Procedure for Chlorination.**—The materials to be chlorinated competitively were weighed in a 50 ml. round-bottomed flask equipped with a stirrer, a dropping funnel, and a reflux condenser with a calcium chloride tube on the top. After the air in the system had been replaced by dry nitrogen, benzoyl peroxide (0.1% of the weight of the sulfuryl chloride used) was added to the flask and the system was then heated to 80±1°C. Upon the gradual stirring in of sulfuryl chloride through the dropping funnel, the evolution of gas was observed after some induction period. Heating was continued until the gas evolution ceased. After cooling, the hydrogen chloride formed was driven off by passing nitrogen through.

**Analytical Procedures.** — The reaction mixture obtained by the method described above was weighed, and any loss of weight during the reaction was distributed among the starting materials according to the relative ratio of vapor pressure.

The total amount of chlorides was determined by the procedure described in Part III in the cases of all substituted benzaldehydes except chlorobenzaldehyde. In the case of chlorobenzaldehyde, since Rauscher's method could not be applied, 2 ml. of the reaction mixture was heated under reflux for 2 hr. with 10 ml. of 0.5 N sodium hydroxide in 30 ml. of ethanol, and the chloride liberated was determined by a silver nitrate solution (Mohr's method). Under these conditions, benzoyl chloride is also hydrolyzed quantitatively.

The amount of benzoyl chloride produced was also determined by the procedure described in Part III.

**Chlorination Products of *p*-Tolualdehyde.**—The reaction of 0.2349 mol. of *p*-tolualdehyde and 0.0481 mol. of sulfuryl chloride gave 4.75 g. of *p*-toluoyl chloride, b. p. 72—74°C/4 mmHg. Toluanilide, m. p. 140°C was derived quantitatively. Found: N, 6.80. Calcd. for $C_{14}H_{13}ON$: N, 6.81%. The residue of the above distillation (2.53 g.; positive in a Beilstein test) was boiled in water. Some needles, m. p. 82°C, were obtained. Found: C, 70.78, H, 6.10. Calcd. for $C_5H_5O_2$: C, 70.59; H, 5.88%

## Results and Discussion

As it was experimentally difficult to determine each component in the acid chloride mixture as a result of the direct competitive reaction between benzaldehyde and substituted benzaldehydes, the substituent effect was derived indirectly as follows: the relative reactivity of substituted benzaldehydes was determined against toluene by competitive chlorination at 80°C, and then these values were compared with those obtained by the similar reaction of unsubstituted benzaldehyde and toluene.

1) Part III: M. Arai, This Bulletin, 37, 1280 (1964).
2) G. Blanc, *Bull. soc. chem. France*, [4] 33, 313 (1923).
3) C. D. Shacklett and H. A. Smith, *J. Am. Chem. Soc.*, 75, 2654 (1933).

The relative reactivity of the benzaldehydes to toluene was calculated by by the following equation:

$$ArCHO + \cdot SO_2Cl \xrightarrow{k} ArCO\cdot + HCl + SO_2$$

$$C_6H_5CH_3 + \cdot SO_2Cl \xrightarrow{k_T} C_6H_5CH_2\cdot + HCl + SO_2$$

$$\frac{k}{k_T} = \frac{\log\left([ArCHO]_{int}/[ArCHO]_{fin}\right)}{\log\left([C_6H_5CH_3]_{int}/[C_6H_5CH_3]_{fin}\right)}$$

where $[\ ]_{int}$ and $[\ ]_{fin}$ denote the initial and final concentrations of ArCHO and $C_6H_5CH_3$ respectively.

The value of 3.23 was used for $k_O/k_T$, in which $k_O$ was the $k$ value of unsubstituted benzaldehyde, as was shown in Part III of

this series.[1] The results obtained in the cases of *m*- and *p*-nitrobenzaldehydes, *m*- and *p*-chlorobenzaldehydes, and anisaldehyde are listed in Tables I—V.

A linear relation was found between log $k/k_0$ and Hammett's $\sigma$ values,[4] as is shown in Fig. 1, where $\rho = -0.48$, excepting for anisaldehyde.

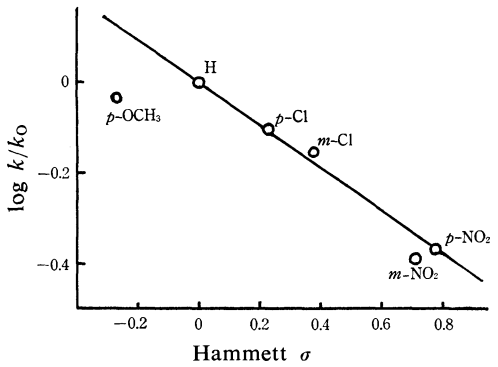

Fig. 1. Correlation of relative reactivities of substituted benzaldehydes with Hammett $\sigma$ values.

As reasons for the deviation of the value for the *p*-methoxy group, (1) the inadequacy of using the $\sigma$ value (the application of the $\sigma^+$ value, etc. should also be considered) and (2) the occurrence of a considerable side-reaction are both conceivable. As for the first factor, it is stated the $\sigma^+$ value is better than the $\sigma$ value when the reactivity of the electron-releasing group is greater than the value expected from the log $k/k_0$—$\sigma$ line determined by the other substituents. The experimental results show the smaller log $k/k_0$ value for the *p*-methoxy group. Although the application of Yukawa's modified Hammett relationship[5] can also be considered, no conclusion can be drawn before more experimental results are available regarding other electron-releasing groups. As the second factor, there is a possibility of chlorination at the methoxy group, since the methylenedioxy group suffers from radical chlorination, as has been shown in Part II of this series.[6]

The chlorination reaction of benzaldehyde by sulfuryl chloride is, by nature, a radical reaction.[7] However, since the reaction follows Hammett rule, the polar effect of substituents is also recognized in the reaction. This effect can easily be understood on the assumption of the following activated complex I:

$$\mathrm{ArC(=O)-H} + \cdot\mathrm{SO_2Cl} \rightarrow \mathrm{Ar\overset{\delta+}{C}(=O)\cdots\dot{H}\cdots\overset{\delta-}{S}O_2Cl} \rightarrow \quad \text{(I)}$$

$$\mathrm{ArC(=O)\cdot} + \mathrm{SO_2} + \mathrm{HCl}$$

I would be more easily formed in the case of the formyl group has more electrons around it, and then, the reaction would be accelerated.

Next, in order to compare the reactivity of the formyl group with that of various alkyl groups at the *p*-position, the reaction was carried out with *p*-tolualdehyde, cuminaldehyde and *p*-*t*-butylbenzaldehyde, using about 1/5 mol. of sulfuryl chloride. The results are smmarized in Tables VI—VIII.

TABLE VIII. ISOMER DISTRIBUTION IN THE CHLORINATION OF *p-t*-BUTYLBENZALDEHYDE AT 80°C[a)]

| Reactant | mol. |
|---|---|
| *p-t*-Butylbenzaldehyde | 0.1558 |
| Sulfury chloride | 0.0408 |
| Product | |
| Total chlorides | 0.0406 |
| *p-t*-Butylbenzoyl chloride | 0.0298 |
| Chloride of $-C(CH_3)_3$ group[b)] | 0.0108 |
| Reactivity of $-C(CH_3)_3$ group[c)] | 0.36 |

a) In the presence of benzoyl peroxide
b) Total chlorides minus *p-t*-butylbenzoyl chloride
c) Reactivity of -CHO group assumed to be 1.00.

Furthermore, two kinds of chlorination products, *p*-toluoyl chloride and *p*-chloromethylbenzaldehydes, were obtained in the reaction of *p*-tolualdehyde. The results are listed in Table VI.

As is shown in Tables VI—VIII, the relative reactivities of the methyl, isopropyl and *t*-butyl groups toward the formyl group are 0.37, 1.11 and 0.36 respectively. These values are close enough to those (0.31, 1.37 and 0.25) resuling from the reaction of toluene, cumene and *t*-butylbenzene toward benzaldehyde.[1)] In the reaction of alkylbenzaldehydes, it is considered that the reactivity of the formyl group is increased by the presence of the alkyl group, while the reactivity of the alkyl group is decreased by the presence of the formyl group. Therefore, the reactions in this series show that the modified reactivity of groups is due to mutual electronic interaction.

The author wishes to express his gratitude to Professor Mamoru Yamaguchi of Tohoku University for his constant guidance through the course of this work.

# The Cyclization of Diethyl 3, 6-Dioxo-azelate

By Choji KASHIMA, Kungtu KUO, Yoshimori OMOTE and Noboru SUGIYAMA

(Received July 15, 1964)

1, 4, 7-Cyclononanetrione (XIX) has many active methylenes and seems to be structurally interesting compound, but its convenient synthesis cannot be found in the literature. It has only obtained in the form of trioxime in a poor yield.[1] In this paper the synthesis of XIX will be attempted through the acyloin condensation[2,3] of the bisethylene ketal derivative (XI) of diethyl 3, 6-dioxo-azelate (I).

It is well-known that diesters of aliphatic dicarboxylic acids afford the corresponding cyclic acyloin by the action of sodium. However, when XI was subjected to this reaction, the reaction product was not the expected acyloin (XVIII). This anomalous result stimulated the present authors to examine these reactions further. Though the ultimate synthesis of XIX was unsuccessful, the synthesis of I and its anomalous cyclization reactions will be reported in this paper.

## Results and Discussion

I was obtained through two synthetic routes. In one route, furyl-acrylic acid (VII) was changed into diethyl 4-oxo-pimelate (II),[4] which was then partially hydrolyzed[5] and converted to an ester chloride (IV). IV was derived into I through malonic ester synthesis.[6] However, it was difficult to obtain pure I by this method. Even after repeated distillation, the product showed infrared absorptions at 1780 ($\nu_{C=O}$, $\gamma$-lactone), 1740 ($\nu_{C=O}$, ester), 1720 ($\nu_{C=O}$, ketone) and 1600 $cm^{-1}$ ($\nu_{C=C}$), indicating the presence of an unsaturated $\gamma$-lactone (X).[7]

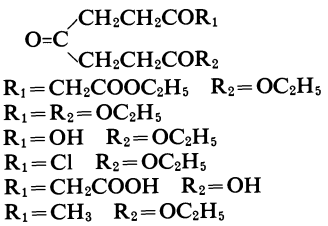
7) F. A. Kuehl, Jr., R. P. Linstead and B. A. Orkin, *J. Chem. Soc.*, **1950**, 2213.



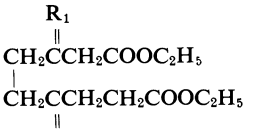
In the other route, I was obtained by the ring opening of ethyl furyl-acryloyl-acetate (IX),[8] which was synthesized from VII by malonic ester synthesis.[6] It was shown by gas chromatography that the reaction product of IX with hydrogen chloride in ethanol consisted of I and ethyl 4,7-dioxo-octanoate (VI),[9] and that I and VI were separated by distillation. I showed strong infrared absorptions at 1740 ($\nu_{C=O}$, ester) and 1720 $cm^{-1}$ ($\nu_{C=O}$, ketone) and produced the corresponding dibasic acid (V) on hydrolysis with an aqueous sodium hydroxide solution.

Before the acyloin cyclization of I is carried out, its keto groups must be protected.[10] Therefore, I was changed into the bis-ethylene ketal derivative (XI). XI showed no infrared absorption at 1720 ($\nu_{C=O}$, ketone), but it did show one at 1740 $cm^{-1}$ ($\nu_{C=O}$, ester).

A dilute xylene solution of XI was added very slowly, through a capillary tube and with vigorous stirring, to xylene in which sodium had been dispersed. After 24 hr. the reaction mixture was then neutralized by acetic acid. The isolated product was proved to be not an acyloin (XVIIII), but 2-ethoxycarbonyl-4,4-ethylenedioxy-1,7-cyclooctanedione (XXII), a partially hydrolyzed compound of a Dieckmann condensation product (XXII).

The structure of XXIII was deduced as follows. XXIII gave a positive ferric chloride test, but a negative Fehling test, indicating the absence of the acyloin structure in XXIII. The infrared absorption spectrum of XXIII showed absorptions at 1740 ($\nu_{C=O}$, ester; keto form), 1720 ($\nu_{C=O}$, ketone; keto form), 1660 ($\nu_{C=O}$, ester; enol form) and 1610 $cm^{-1}$ ($\nu_{C=C}$; enol form), the last two being attributed to the enolizable $\beta$-ketoester.[11] The ultraviolet absorption spectrum of XXIII showed $\lambda_{max}^{EtOH}$ 255 ($\varepsilon$, 4500) and $\lambda_{max}^{alkali\ EtOH}$ 287 m$\mu$ ($\varepsilon$, 10800).

The NMR spectra[12] of XXIII in carbon tetrachloride were assigned to the ethyl group of the ester at 5.71 (quartet) and 8.68$\tau$ (triplet, $J$ 7.0 c.p.s.), to the enolized hydroxyl group at $-2.30\tau$ (singlet), to 4 protons of methylene groups neighbor carbonyl groups at 7.46—7.64$\tau$ (multiplet), to 4 protons of the other methylenes at 7.81—8.35$\tau$ (multiplet), and to 4 protons of the ethylene ketal group at 6.04$\tau$ (singlet).[13] These data indicate that



I $R_1=CH_2COOC_2H_5$ $R_2=OC_2H_5$

one of the ethylene ketal groups at C-7 was hydrolysed to a ketone.

In order to find a reasonable explanation why only the Dieckmann condensation reaction occurred in this case, diethyl azelate was subjected to the same treatment as above; 2-hydroxy-cyclononanone (azeloin)[2] was obtained in about a 25% yield. Even in the presence of ethanol, azeloin was obtained, but in this case, the product was contaminated with a small amount of a Dieckmann condensation product, 2-ethoxycarbonyl-cyclooctanone.

The different behavior of XI and diethyl azelate could be attributed to the presence of two ethylene ketal groups in the former. It is suspected that the relative position of the ketal group and the ethoxycarbonyl group might influence their behavior. In fact, this was proved by the reaction of the ethylene ketal of 4-oxo-azelate (XII)[14] and 3-oxo-azelate (XIV) under the same conditions.

From XIII, the ethylene ketal of XII, acyloin (XX) was obtained. XX gave a positive Fehling test. Its infrared absorption spectrum showed absorptions at 3400 ($\nu_{OH}$) and 1705 $cm^{-1}$ ($\nu_{C=O}$, ketone). Its ultraviolet absorption spectrum showed $\lambda_{max}^{EtOH}$ 260 m$\mu$ ($\varepsilon$, 2600), which shifted to $\lambda_{max}^{alkali\ EtOH}$ 310 m$\mu$ ($\varepsilon$, 3800).

On the other hand, from XV, the ethylene ketal of XIV, a Dieckmann condensation product (XXIV) was obtained instead of the corresponding acyloin (XXI). The structure of XXIV was deduced from the following facts. The product obtained gave a positive ferric chloride test, but a negative Fehling test. Its infrared absorption spectrum showed absorptions at 1705 ($\nu_{C=O}$, ketone) and 1730 $cm^{-1}$ ($\nu_{C=O}$, ester).

Now let us discuss when and why one of the ethylene ketal groups was hydrolyzed in the reaction of XI to XXIII. In the first place, the hydrolysis may be presumed to occur after the ring closure. If it had occurred before the ring closure, the intermediate compound, XVI or XVII, must be subjected to the condensation reaction. Of these two intermediates, only XVI can produce XXIII. However, methylene at C-2 in XVI would be more reactive than methylene at C-8, and the reaction from XVI to XXV must be predominant over the reaction from XVI to XXIII. As the experimental results were not in accord with this reasoning, the formation of the cyclic intermediate (XXII) must precede the hydrolysis of one member of the ethylene ketal group.

Next, let us consider the partial hydrolysis of XXII. The ethylene ketal group at C-7 seems to be less stable than that at C-4, because of the effect of the $\beta$-carbonyl group at C-1 or because of the steric effect of the other ethylene ketal group at C-4 in the medium-size ring. As a model compound of ethylene ketal with a $\beta$-carbonyl group, 4,4-ethylenedioxy-2-pentanone[15] was prepared, and the hydrolysis of the ketal with acetic acid was studied. It was found that only a small amount of 2,4-pentanedione was produced. Therefore, the partial hydrolysis of XXII during the neutralization of the reaction mixture with acetic acid, seems to be effected mainly by the steric hindrance, not by the electron displacement.

As a modified acyloin condensation, liquid ammonia has been used[3] instead of xylene. The acyloin condensation reaction of XI in the presence of sodium in liquid ammonia gave a product different from XXIII. On the basis of infrared spectra at 3400 ($\nu_{OH}$) and 1740 $cm^{-1}$ ($\nu_{C=O}$, ester), a negative Fehling test, and a positive ferric chloride test, the structure of the product was tentatively proposed to be 1-ethoxycarbonyl-3,3,6,6-bisethylenedioxy-1-cyclooctanol (XXVI). The details of this reaction will be reported elsewhere.

## Experimental

All melting points are uncorrected.

**6-Ethoxycarbonyl-4-oxo-hexanoic Acid (III).**—A solution of 120 g. of diethyl 4-oxo-pimelate and 26 g. of potassium hydroxide in 2 l. of ethanol was allowed to stand overnight at room temperature. After the reaction mixture had been concentrated under reduced pressure, it was poured into cold water, acidified with hydrochloric acid, and extracted with benzene. The benzene solution was then dried over anhydrous sodium sulfate. After the benzene had been removed, 10 g. of crude III was obtained. This was recrystallized from benzene-petroleum ether as colorless plates; m. p. 70.5°C. IR: $\nu$ 1730, 1700 $cm^{-1}$.

**6-Ethoxycarbonyl-4-oxo-hexanoyl Chloride (IV).**—A mixture of 10 g. of III and 15 g. of thionyl chloride was allowed to stand overnight at room temperature. After the excess thionyl chloride had been removed, IV was obtained as a colorless oil; b. p. 171—176°C/17 mmHg, yield 6.5 g.

**Ethyl Furyl-acryloyl-acetate (IX).**—To 0.56 g. of magnesium were added 0.5 ml. of absolute ethanol, a few drops of carbon tetrachloride, and 10 ml. of anhydrous ether. After a few minutes, 4.3 g. of ethyl *t*-butyl malonate, 2 ml. of absolute ethanol, and 18 ml. of anhydrous ether were added, and the mixture was refluxed for 4 hr. with stirring. To the mixture, 3.7 g. of furylacryloyl chloride (b. p.

14) S. Hünig and W. Lendle, *Chem. Ber.*, **93**, 913 (1960).

15) P. C. Dutta, P. K. Dutta and K. N. S. Sastry, *J. Indian Chem.*, **31**, 881 (1954); *Chem. Abstr.*, **50**, 838h (1956).

119—120°C/19 mmHg)[8] in 15 ml. of anhydrous ether was then added slowly and the solution refluxed for one hour. The mixture was acidified with 1.8 N sulfuric acid and washed with water. After the ether had been removed, the residue was dissolved in benzene and refluxed for 4 hr. with 100 mg. of *p*-toluenesulfonic acid. The benzenene solution was washed with water, and the solvent was removed. IX was obtained as pale yellow oil; b. p. 77—107°C/3.5 mmHg, IR: $\nu$ 3080, 1730, 1640, 1540 $cm^{-1}$; UV: $\lambda_{max}^{EtOH}$ 342 m$\mu$.

2, 4-Dinitrophenylhydrazone was prepared and recrystallized from ethanol-ethyl acetate; m. p. 179°C.

Found: C, 52.17, 52.26; H, 3.91, 3.97; N, 13.90, Calcd. for $C_{17}H_{16}N_4O_7$: C, 52.58; H, 4.15; N, 14.43%.

**Diethyl 3, 6-Dioxo-azelate (I).**—1) I was obtained from IV in about a 35% yield by a procedure similar to the one described for IX.

2) Dry hydrogen chloride was passed for 45 min. through a hot solution of 25 g. of ethyl furyl-acryloyl-acetate in 70 ml. of 95% ethanol. After the ethanol had been removed under reduced pressure, the residue was poured into an aqueous solution of sodium carbonate and extracted with benzene, and the benzene layer was dried over sodium sulfate. After the benzene had been removed, the residue was distilled under reduced pressure; b. p. 134—135°C/0.8 mmHg, yield 12 g.

Dibenzylamide, m. p. 177°C.

Found: C, 70.68; H, 6.53. Calcd. for $C_{23}H_{16}N_2O_4$: C, 70.03; H, 6.64%.

**3, 6-Dioxo-azelaic Acid (V).**—I was added to an aqueous 3 N sodium hydroxide solution, and the mixture was heated until a clear solution was obtained. After it had cooled, the solution was acidified with dilute hydrochloric acid and extracted with ether. The ether layer was separated and dried over sodium sulfate. After the ether had been removed, the free dibasic acid (V) was obtained; it was then recrystallized from benzene-ethanol; m. p. 139°C, IR: $\nu$ 3050, 1720, 1700 $cm^{-1}$.

Found: C, 48.19, 48.09; H, 5.82, 5.47. Calcd. for $C_9H_{12}O_6 \cdot 1/2H_2O$: C, 48.00; H, 5.82%.

**Diethyl 3, 3, 6, 6-Bisethylenedioxy-azelate (XI).**—The solution of 29.7 g. of I and 15 ml. of ethylene glycol in 200 ml. of benzene was refluxed with 300 mg. of *p*-toluenesulfonic acid under azeotropic distillation for 7 hr. The mixture was washed with water and dried over sodium sulfate. After the benzene had been removed under reduced pressure, XI was obtained as a colorless oil; b. p. 146—154°C/2.5 mmHg, yield 22.4 g.

Found: C, 57.31, 57.09; H, 7.90, 7.98. Calcd. for $C_{17}H_{28}O_8$: C, 56.65; H, 7.83%.

**The Acyloin Condensation of Diethyl Azelate.**—1) With freshly dispersed sodium: In a 200 ml., three-necked, round-bottom flask equipped with a sealed stirrer, a reflux condenser, and a dropping-funnel, 5.2 g. of sodium and 90 ml. of dry xylene were placed. The mixture was refluxed and stirred (3600 r. p. m.) for 10 min. To the mixture was then added 11 g. of diethyl azelate in 50 ml. of xylene over a 24 hr. period, with sufficient stirring under reflux. After all of the xylene solution of diethyl azelate had been added, the reaction mixture was refluxed for another hour, and cooled with water and then with an ice bath. A mixture of 20 ml. of acetic acid and 20 ml. of xylene was then added. All these procedures were carried out during stirring and under a nitrogen atmosphere. The reaction mixture was washed with water and dried over anhydrous sodium sulfate. After the xylene had been removed under reduced pressure, the residue was distilled. 1.4 g. of 2-hydroxy-cyclononanone (azeloin) was thus obtained; b. p. 124—139°C/17 mmHg; IR: $\nu$ 3450, 1700 $cm^{-1}$; UV: $\lambda_{max}^{EtOH}$ 262, $\lambda_{max}^{alkali\ EtOH}$ 286 m$\mu$.

2) With commercial dispersed sodium: Into a mixture of 80 ml. of boiling xylene and 12.0 g. of commercial dispersed sodium in toluene (40%), 10.3 g. of diethyl azelate in 45 ml. of xylene was stirred in over a 24 hr. period. After the solution had been treated as has been described above, 700 mg. of azeloin was obtained.

**The Reaction of XI with Dispersed Sodium.**—The reaction of XI with freshly dispersed sodium was carried out according to the procedure described for azeloin, but no acyloin was detected in the product by a study of its infrared spectrum. The reaction of 11.5 g. of XI and 10 g. of commercial dispersed sodium (40% in toluene) in xylene afforded 1.8 g. of the crude reaction product. By distillation, XXIII was isolated; b. p. 133—137°C/3 mmHg.

Found: C, 58.21, 58.17; H, 6.98, 7.00. Calcd. for $C_{13}H_{18}O_6$: C, 57.77; H, 6.71%.

Bis-2, 4-dinitrophenylhydrazone of XXIII was prepared and recrystallized from ethanol-ethyl acetate; m. p. 167°C.

Found: N, 18.09. Calcd. for $C_{25}H_{26}N_8O_{12}$: N, 17.77%.

**Diethyl 4, 4-Ethylenedioxy-azelate (XIII).**—By refluxing the mixture of 15.7 g. of ketone (XII), 5 ml. of ethylene glycol, and 100 mg. of *p*-toluenesulfonic acid in 150 ml. of benzene, 13.9 g. of XIII was obtained; b. p. 146—151°C/0.13 mmHg, IR: $\nu$ 1740 $cm^{-1}$.

Found: C, 59.62, 59.45; H, 8.93, 8.87. Calcd. for $C_{15}H_{26}O_6$: C, 59.58; H, 8.67%.

**The Reaction of XIII with Dispersed Sodium.**—By the reaction of 3.2 g. of XIII and 4.5 g. of commercial dispersed sodium (40% in toluene) in 50 ml. of xylene, 200 mg. of the corresponding acyloin (XX) was obtained; b. p. 80—90°C/0.02 mmHg.

**6-Ethoxycarbonylhexanoyl Chloride.**—From 8.0 g. of 6-ethoxycarbonylhexanoic acid[16] and 6.2 ml. of thionyl chloride, 7.8 g. of the acid chloride was obtained; b. p. 138—141°C/17.5 mmHg, IR: $\nu$ 1800, 1740 $cm^{-1}$.

**Diethyl 3-Oxo-azelate (XIV).**—The malonic ester synthesis was carried out by a procedure similar to that described for the synthesis of IX. From 650 mg. of magnesium, 0.1 ml. of carbon tetrachloride, 3.6 g. of absolute ethahol, 5 ml. of ethyl *t*-butyl malonate, and 5.4 g. of 6-ethoxy-carbonyl-hexanoyl chloride in 31 ml. of anhydrous

16) J. Walker and J. S. Lumsden, *J. Chem. Soc.*, **79**, 1197 (1901).

ether, 1.5 g. of XIV were obtained; b. p. 105—106°C/0.5 mmHg, IR: $\nu$ 1740, 1720 $cm^{-1}$.

Found: C, 60.13, 60.24; H, 9.24, 9.31. Calcd. for $C_{13}H_{22}O_5$: C, 60.44; H, 8.59%.

**Diethyl 3, 3-Ethylenedioxy-azelate (XV).** — By the same procedure as was used for XI, XV was obtained from 1.3 g. of XIV; b. p. 95—110°C/0.24 mmHg, yield 0.6 g., IR: $\nu$ 1740 $cm^{-1}$.

Found: C, 59.45, 59.49; H, 8.70, 8.75. Calcd. for $C_{15}H_{26}O_6$: C, 59.58; H, 8.67%.

**The Reaction of XV with Dispersed Sodium.**— The reaction of 0.6 g. of XV and 0.5 g. of dispersed sodium (40% in toluene) in xylene afforded only a trace of the product; b. p. 82—87°C/0.05 mmHg; UV: $\lambda_{max}^{EtOH}$ 250 m$\mu$ ($\varepsilon$, 1300).

**The Acyloin Condensation of XI in Liqid Ammonia.**—0.8 g. of sodium was stirred in a nitrogen atmosphere and thus dissolved into a mixture of 200 ml. of anhydrous ether and about 300 ml. of liquid ammonia cooled in an acetone - dry ice bath. To this solution was then added 1.9 g. of XI in 180 ml. of anhydrous ether over a 2 hr. period. After the ammonia had been removed, 2 ml. of methanol and 75 ml. of 5% hydrochloric acid were added slowly. The ethereal solution was then washed with water and dried over anhydrous sodium sulfate. The ether was removed, and the residue was distilled to give 100 mg. of XXVI; b. p. 70—110°C/2 mmHg. XXVI was treated with 2, 4-dinitrophenylhydrazine acidified with sulfuric acid. Bis-2, 4-dinitrophenylhydrazone was prepared and recrystallized from ethanol - ethyl acetate; m. p. 147°C.

Found: N, 19.81. Calcd. for $C_{23}H_{24}N_8O_{11}$: N, 19.04%.

# A Deuteron Magnetic Resonance Study of Urea-$d_4$

By Takehiko CHIBA

(Received July 27, 1964)

Urea is perhaps one of the few compounds whose crystal structure has been extensively investigated. Recent structure analyses of urea include a neutron diffraction study by Worsham, Levy and Peterson[1] and X-ray studies by Vaughan and Donohue,[2] and by Sklar, Senko and Post.[3] The last-named paper includes a study at $-140°C$. The temperature factors determined from these studies are anisotropic and quite large, especially for the nitrogen and hydrogen atoms. This is considered to be due to librational motion about one or more axes in urea. After the present work had been completed, another paper on the X-ay analysis of urea was published by Caron and Donohue.[4] These authors were able to derive mean amplitudes of the translational and librational motion from the temperature factors. On the other hand, from the proton magnetic resonance (PMR) linewidth transition centered at about 50°C, Kromhout and Moulton[5] deduced the setting-in of a free rotational motion of the $NH_2$ group about the C–N bond. In a more recent PMR investigation using a single crystal, Emsley and Smith[6] showed that the angular dependence of the second moment when the crystal is rotated about the c axis can be accounted for not by such a motion, but, instead, by a reorientation of the whole molecule about the C=O bond. They showed that the observed line shape is also consistent with the presence of a reorientation about the C=O axis, but that the line shape could not show whether or not a reorientation about the C–N bond is also present. Though their experimental evidence is quite convincing, the reorientational motion of a large molecule as a whole about the C=O axis seems rather unusual. Since deutron magnetic resonance (DMR) provides a powerful means for the study of the motion of a group with hydrogen atoms,[7] the present study was undertaken in the hope that new information could be obtained concerning both the molecular motion of urea and deuteron quadrupole coupling in amides which has not been observed so far.

Fig. 1. Calculated rotation patterns of the deuteron quadrupole splitting of urea-$d_4$ crystal assuming, (a) a stationary molecule, (b) a molecule reorienting about the C=O axis, (c) a molecule reorienting about C–N axis, (d) a molecule reorienting about the C=O and C–N axes, with $H_0$ in the (110) plane. $\theta$ is the angle between $H_0$ and the c-axis direction. The other member of the satellite pair, which is a mirror image of the one in this figure with respect to the zero-splitting, is not shown.

## Experimental

A single crystal of urea-$d_4$ was prepared by the gradual cooling of a saturated solution of urea-$d_4$ in methanol-d. Urea-$d_4$ was prepared by repeated evaporation of urea solution in heavy water. Methanol-d was prepared by refluxing dimethyl oxalate with potassium carbonate and heavy water,[8] followed by a fractionation. A small amount of deuterated ammonium bromide (a small percentage of the urea) was added to the solution to prevent the urea crystal from growing as long needles.[9]

The apparatus and the procedure of the measurement of DMR have been described elsewhere.[7] Measurements were made at the field strength of 16.6 kgauss.

## Results

**Observation at Room Temperatue.** — Urea crystallizes in a tetragonal form belonging to the space group $D_{2d}^3$–P$\bar{4}$ $2_1$m.[1] All urea molecules in the lattice are in equivalent positions. The planar molecule lies on a plane parallel either to (110) or to (1$\bar{1}$0). At room temperature, the spin-lattice relaxation time, $T_1$, is sufficiently short to give lines with good signal-to-noise ratio while at lower temperature

8) J. Beersmans and J. C. Jungers, *Bull. soc. chim. Belges.*, **56**, 81 (1947).

only poor signal is obtained because of a strong saturation, indicating a long $T_1$. The spectra are observed as a function of the angle of the crystal about the axis perpendicular to the applied dc field. DMR was first observed with the crystal rotated about the c axis. Since the crystal structure is simple, the angular dependence of quadrupole splitting lines could be easily interpreted by assuming a quadrupole tensor in each N–D bond direction, with a small asymmetry parameter. Approximate $eqQ$ and $\eta$ values derived in this way are then used to set up a rotation pattern of quadrupole splitting when the crystal is rotated in the [110] direction. All subsequent observations are made at this crystal orientation. The expected rotation pattern of the quadrupole splitting for the molecule (a) at rest, (b) reorienting about the C=O bond, (c) reorienting about the C–N bond, and (d) reorienting about both the C=O and C–N bonds, are shown in Fig. 1. The observed rotation pattern at room temperature agreed completely with Fig. 1(a), the stationary molecule. $eqQ$, and $\eta$ values and the principal axis directions of $q$-tensor are listed in Table I.

TABLE I. OBSERVED DEUTERON QUADRUPOLE COUPLING, ASYMMETRY PARAMETER AND PRINCIPAL-AXIS DIRECTIONS OF THE FIELD GRADIENT[a] IN UREA-$d_4$

Room temperature

$D_1$ $eqQ/h=210.8\pm1.0$ kc./sec, $\eta=0.139\pm0.010$.
$q_I$, 60.2° from [001] direction, in (110) plane (molecular plane), $q_{II}$ in [1$\bar{1}$0] direction, and $q_{III}$, 28.8° form [001] direction, in (110) plane.

$D_2$ $eqQ/h=210.7\pm1.0$ kc./sec., $\eta=0.146\pm0.010$.
$q_I$, in [001] direction, $q_{II}$ in [110] direction, and $q_{III}$ in [1$\bar{1}$0] direction.

117°C

$D_2$ $eqQ/h=206.3\pm1.2$ kc./sec., $\eta=0.138\pm0.010$.

a) $q_I$, $q_{II}$, $q_{III}$ are the principal components of a field gradient tensor such that $|q_I|>|q_{II}|>|q_{III}|$.

**Observation at Elevated Temperatures.** — As the temperature is raised, the lines D and D' except at $\theta=0°$ and 90°, where $\theta$ is the angle of the rotation of the crystal measured from its c axis parallel to $H_0$, disappear at about 36°C. (The signal of line D already manifests slight broadening at room temperature). Above 100°C the signal corresponding to line E of Fig. 1 (b) begins to appear near $\theta=0°$ and 90°, as is shown by the broken line in the figure, where the frequency separation between line D and line D' is small. This can be explained by the motion assumed in (b), namely, a reorientation about the C=O axis, but not by a free rotational motion. A further raising of the temperature (above 110°C), however, results in a collapse of the line E pattern, even at $\theta=0°$ or 90°, while the intensity and line-width of line C at $\theta=90°$ remains almost unchanged. This can be reasonably explained by assuming the onset of an additional reorientation about the C–N bond, since this motion, which interchanges $D_1$ and $D_2$, alters all the line patterns except the one at $\theta=90°$ of line C. Because of this behavior, the observations of the line-width change due to the reorientation about the C=O bond could only be made over a small range of temperature. Likewise, for the motion about the C–N bond, the behavior of the line-width transition could only be observed on the low temperature side, limited by its melting point of 135°C. The exchange rates derived from these observations, by the procedure described in a previous report,[7b] are shown in Fig. 2. These observations

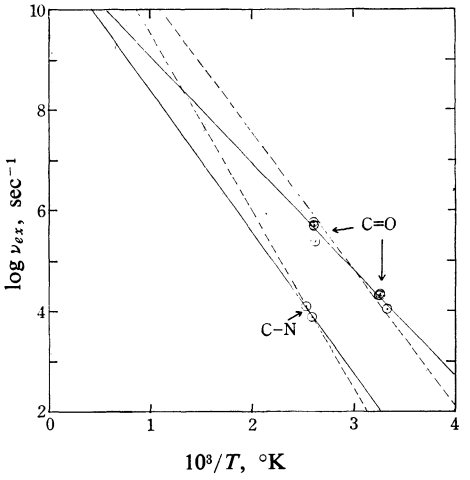

Fig. 2. Observed exchange rate with temperature, for reorientation about the C=O bond and that about the C–N bond. Solid lines are drawn assuming a frequency factor of $10^{11.1}$/sec. and broken line assuming that of $10^{13}$/sec.

are not sufficient for the accurate determination of the potential barriers. However, assuming a frequency factor of $10^{13}$, the order of magnitude often found in the case of hydration water, the barrier height is 12.5 kcal. and 16.1 kcal./mol. for the motion about C=O and for that about C–N respectively. Or, assuming frequency factor of $10^{11.1}$, which best fits the C=O reorientation data, 9.8 and 13.0 kcal./mol. are obtained for the two motions. Therefore, a reasonable estimate would be $11\pm2$ kcal./mol. for the motion about the C=O bond and $15\pm3$ kcal./mol. for that about the C–N bond.

The temperature dependence of the splitting frequency is examined for line A at $\theta=0°$ and

for line D (or E) at $\theta=90°$. The splitting frequency decreases about 3.5 kc. from 0°C to 100°C in the former case and about 2.5 kc. in the latter. $eqQ$ has also been determined for $D_2$ at 117°C, as is listed in Table I. The line structure due to dipolar coupling with the directly-bonded nitrogen atom is observable in some orientations. The three-line structure at $\theta=0°$ of line A or at $\theta=90°$ of line D, which are actually more complicated with the D–D coupling and possibly also with H–D coupling from incomplete deuteration, are observed. The structure becomes obscured at about 70—80°C and coalesces to a broad single peak at about 100°C.

## Discussion

The $eqQ$'s of $D_1$ and $D_2$ are almost identical, and they are close to that of $ND_3$ (200 kc.).[10] The $q_{II}$ direction (see footnote to Table I) is perpendicular to the $ND_2$ plane in accord with the rule observed in the XOD bond.[11] $eQ(q_{III}-q_{II})$ is about 30 kc., a similar magnitude to those found in the OD bond.[11] The direction of the $q_I$ of the $D_1$ deviates 1° from the N–D direction. The direction of the $q_I$ of the $D_2$ is found to be along the c axis, whereas the N–D direction determined by neutron diffraction deviates 3.4° from the c axis (Fig. 3). If the $q_I$ direction of the $D_2$ deviates only slightly from the c axis, the reorientational motion about the C=O bond of even a relatively slow exchange rate can average out the frequency splitting, resulting in an averaged $q_I$ along the c axis. To see if this is the case, an observation of the pattern at −20°C is made of lines A and C, where, judging from Fig. 2, the exchange rate must be about $10^3$/sec. or less. No additional splitting in these lines is found. Therefore, it may be concluded that the $q_I$ of $D_2$ is indeed along the c axis within the limit of 1°.

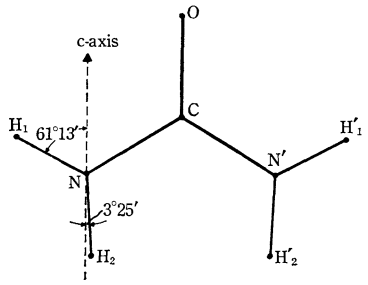

Fig. 3. Molecular structure of urea in the crystal (Ref. 1).

The reorientational motion about the C=O bond, as concluded from the temperature dependence of the line shape, is in agreement with the conclusion of the PMR study by Emsley and Smith. The estimated barrier height though not very accurate for the reason stated earlier, is in fair agreement with that estimated from the PMR, that is, 9 kcal.[6] If one urea molecule rotates 90° about the C=O bond, with all the neighboring molecules fixed, the closest-neighbor H–H distance will be 1.5 Å ($H_1$, $H_2'$) or 1.8 Å ($H_2$, $H_2'$) which is much less than the van der Waals' distance. Therefore, the motion is considered to be some sort of a correlated one which gears in neighboring molecucles as one molecule rotates. Since no phase transitions of the urea crystal in the temperature range of present interest has been reported, such correlated motion would involve a small number of molecules instead of the crystal as a whole. The potential barrier may be considered to be a sum of the hydrogen bond energy of N–D···O and the steric energy. The barrier arising from the hydrogen bond energy may not be greater than a few kcal., and the main origin of potential must be due to the steric effect. Therefore, we can expect a flatness of the potential at the bottom. We can also expect that the potential is somewhat dependent on the temperature, since the expansion of the lattice with the temperature is rather large.[3] The barrier of about 15 kcal./mol. to the motion about the C–N bond is mainly due to the partial double-bond character of the C–N bond. It should be noted that the present value is in fair agreement with the value of 12.24 kcal./mol. calculated by Das.[12]

The decrease in the splitting frequency from 0°C to 100°C for line D at $\theta=90°$ due to a simple torsional oscillation about the C=O bond, assuming that the potential curve $V=(V_0/2)\cdot(1-\cos 2\varphi)$, where $\varphi$ is the angle of the rotation of the molecule, with $V_0=11$ kcal./mol., is calculated to be 1.7 kc., which is in fair agreement with the observed decrease of 2.5 kc. The r. m. s. amplitude of oscillation about the C=O bond obtained by Caron and Donohue is 13.13°,[4] which, by harmonic oscillation approximation gives 3.3 kc. for this frequency decrease, or corresponds to a $V_0$ value of 5.8 kcal. for the $\cos 2\varphi$ type potential. Such an apparent low $V_0$ value seems to indicate the flatness of the potential curve at the bottom, as has been mentioned earlier The torsional oscillation about the C=O bond would not give the temperature dependence of the frequency of line A at $\theta=0°$. On the other hand,

10) G. Herrmann, *J. Chem. Phys.*, **29**, 875 (1958).
11) T. Chiba, ibid., **41**, 1352 (1964).
12) T. P. Das, ibid., **35**, 1897 (1961).

that about the C–N bond can give rise to this frequency change, assuming that the $V_0$ of 15 kcal./mol. amounts to only 0.7 kc. from 0°C to 100°C. Caron and Donohue obtained a mean amplitude for the oscillation about the axis parallel to N–N' of 6.08°, which can give rise to 0.9 kc. for the corresponding frequency decrease. Therefore, these effects can explain only half of the observed value of 3.5 kc. The reason for this is not clear.

The collapse of the line structure due to the dipolar coupling between N and D at 70—80°C is consistent with the PMR findings,[6] that is, at temperatures above the line-width transition the proton second moment indicates no coupling between N and H. The temperature at which N–D coupling disappears is considerably higher than the temperature at which the $^{14}N$ pure quadrupole line disappears.[13] A similar situation in PMR has been already pointed out and discussed by Emsley and Smith, who presented some mechanisms which possibly account for the situation. The vanishing of the $^{14}N$ line at about 22°C is likely to be associated with the reorientation about the C=O bond, as these authors point out. The effect on the $^{14}N$ PQR frequency of this motion can be estimated as follows. The direction of the field gradient tensor at N in urea are not known, but we can reasonably assume that the $q_I$ is perpendicular to the molecular plane and that the $q_{II}$ is along the C–N bond. The reorientation about the C=O bond does not change the $q_I$ provided that the time during the flip is sufficiently short. However, this motion changes the $q_{II}$ and $q_{III}$ directions, and $\eta$ decreases from the 0.32[14] of the stationary molecule to 0.16 in the limit of rapid reorientation. The corresponding change in PQR frequency will be 0.14 Mc. This is of the same order with the corresponding frequency change in the D resonance line due to this motion. The difficulty lies in determining why the $^{14}N$ line should vanish at a temperature more than 10°C below that where the D resonance line vanishes. It is clear this is not due to a $T_1$ broadening of $^{14}N$ because N–D coupling is observable at higher temperatures. The reason is not well understood. However, it can be said that since the absolute magnitude of $^{14}N$ quadrupole coupling is much larger (3.5 Mc.)[14] than that of D, the fluctuation of the field gradient due to the motion may be more effective in broadening the $^{14}N$ line.

## Summary

A deuteron magnetic resonance study has been made on a single crystal of urea-$d_4$. At room temperature deuteron quadrupole coupling corresponding to a stationary molecule is obtained. The $eqQ$ and $\eta$ values determined are: $eqQ/h=210.8\pm1.0$ kc./sec. and $\eta=0.139\pm0.010$ for $D_1$, and $eqQ/h=210.7\pm1.0$ kc./sec. and $\eta=0.146\pm0.010$ for $D_2$ at room temperature, and $eqQ/h=206.3\pm1.2$ kc./sec., $\eta=0.138\pm0.010$ for $D_2$ at 117°C. In both cases the maximum field gradient component and the N–H direction are in good agreement.

The onset of reorientational motion about the C=O bond of a whole molecule has been concluded from the line-width change at high temperatures. Above 110°C the effect on the line-width of the reorientation about C–N bond has also been observed. The barrier heights for these motions are estimated to be $11\pm2$ kcal./mol. for the reorientation about the C=O bond and $15\pm3$ kcal./mol. for that about the C–N bond. The temperature dependence of the quadrupole splitting and that of the dipole coupling between $^{14}N$ and D have been observed and dicussed in relation to the motion of the urea molecule.

The author wishes to thank Professor Yoshinobu Kakiuchi for reading the manuscript and for his helpful discussions.

# Absorptinon Spectra of Dyes. VIII.[1] The Correlation between Thermodynamic Quantities and Chemical Structure in Complex Formation*

By Yoshié TANIZAKI, Toshihiko HOSHI and Noboru ANDO

(Received July 27, 1964)

Previously,[1] the present authors have discussed the ease of the formation of complexes between Chrysophenine G and Chlorazol Sky Blue FF and similar skeletal dyes, from the viewpoints of the magnitudes of the equilibrium constant and of the spectral change. According to the conclusion reached, the partner dyes (to be abbreviated to P) of G (Chrysophenine G) have a negative effect on the complex formation when the P dyes have sulfonic groups at the positions adjacent to azo groups on the naphthalene rings. Further, the larger the number of effective auxochromes of P, the easier the formation of the complex, and the OH groups make the complex formation easier than $NH_2$ does. The above problem may be worth considering from the view-points of the strength of the connection between the component molecules forming a complex, and of the degree of the steric deformation and the restriction inflicted upon the molecule before and after the formation of a complex. Therefore, with the purpose of discussing again the above conclusion on a more rigid foundation, the authors measured a similar sample series at various temperatures. According to the free energy change, enthalpy change and entropy change thus obtained, the above-mentioned problem will be discussed for a 1 : 1 and a 1 : 2 complex formed between P and G.

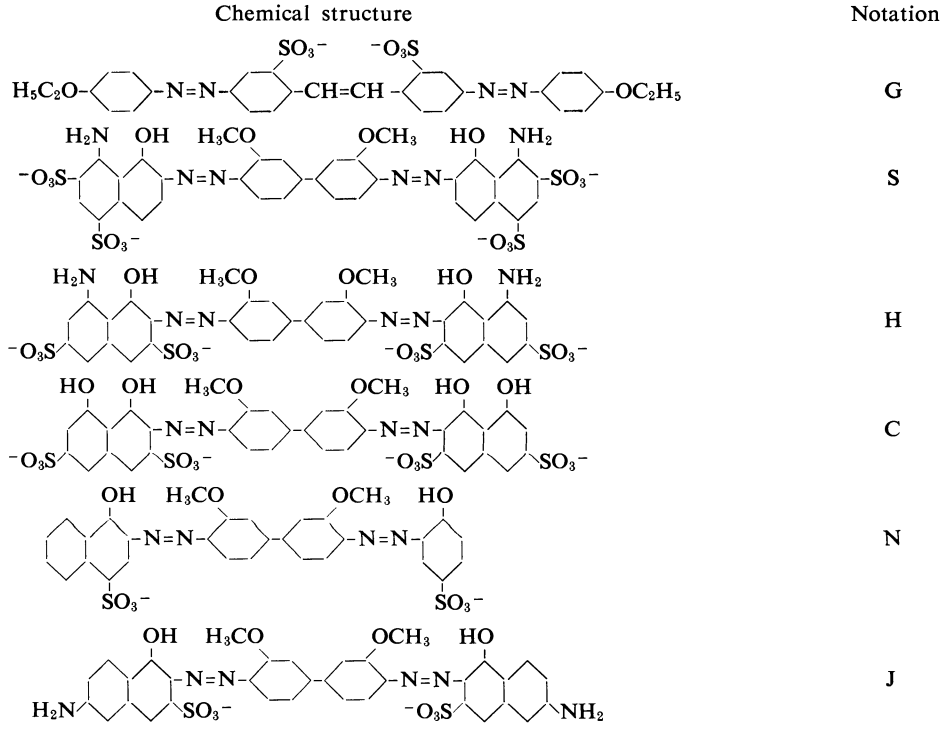

Fig. 1. Chemical structures and their notations.

* Presented at the 15th Annual Meeting (April, 1962) and at the Chūgoku-Shikoku Meeting (August, 1962) of the Chemical Society of Japan.

## Experimental

The chemical structures of the dyes used are shown in Fig. 1, along with the notations to be used here. Excepting G (Chrysophenine G), the notations are taken from the names of the coupling components. These are the same as the purified dyes used in the previous investigations.[1,2]

Water was used as the solvent. The dye solutions were prepared by using a mother solution of about $10^{-4}$ mol./l. All of the concentrations were determined by weight.

The absorption spectra were measured with a Shimadzu QR-50 spectrophotometer, the cell chamber of which was replaced by a larger one which contains cylindrical cells. The temperature of the cells was regulated by a specially-designed apparatus, and so could be kept within ±0.2°C of the desired temperature. The optical path of the cell is 20 mm. long, but it can be used, if necessary, as a 10 mm. path cell by the insertion of spacers.

At each 10°C interval in the 20—60°C temperature range, the absorption spectra of the sample solutions were measured after they had been kept intact more than overnight after having been prepared. It has been confirmed that the temperature of the solution reaches the adjusted point within twenty minutes. All the measurements, therefore, were standardized so as to be started about twenty

minutes after the solution had been kept at a constant temperature.

## Results

Figures 2, 3 and 4 indicate the spectral change of the binary mixture of C and G when the concentration of C is varied, at 20, 40 and 60°C respectively. In every case well-defined isosbestic points exist at about 630 mμ and 660 mμ. The same tendency for the spectra to change was also found for the S-G system, and the appearance was the same as in the result already reported (ca. 27°C).[2] As has already been shown,[1] the first isosbestic points (ca. 630 mμ) of Figs. 2—4 indicate the co-existence of G and CG (1 : 1 complex), and the second, that of G and $CG_2$ (1 : 2). A quite similar tendency was observed for the binary mixture of G with any other dyes used. It is a matter of course, however, that the shapes of the individual bands and positions of the isosbestic points, etc., differed from one another according to the kinds of partner dyes.

Let P stand for the partner dye of G. If the following equilibriums exist for the 1 : 1 and 1 : 2 complex formation between P and G;

$$P + G = PG \qquad (K_1) \qquad (1)$$

$$PG + G = PG_2 \qquad (K_2) \qquad (2)$$

and if the mass action law can be applied, the respective equilibrium constants are expressed as follows;

$$K_1 = [PG]/[P][G] \qquad (3)$$

$$K_2 = [PG_2]/[PG][G] \qquad (4)$$

where [P], [G], etc. represent the respective equilibrium concentrations. $K_1$ and $K_2$ were calculated following the method described in the Appendix. The data are shown in Tables I and II respectively. In the usual way, the free energy change ($-\Delta F$) was obtained from the values of $K_1$ and $K_2$ shown in Tables I and II. The results obtained are given in Tables III and IV respectively. The relation between $\ln K$ and $1/T$ ($T$: absolute temperature) was plotted in Figs. 5 and 6. By the application of the method of least squares,

regarding the relation as linear, we obtained the enthalpy change ($-\Delta H$) and the entropy change ($-\Delta S$) from, respectively, the values

of the slope and the intercept of the straight line and the $\ln K$ axis. The results for a 1 : 1 and a 1 : 2 complex are shown in the corresponding columns of Tables III and IV respectively.

## Discussion

**The Free Energy Change.**—A criterion of the facility of the complex formation in the system under consideration has already been made by means of the magnitude of the equilibrium constant[1] in the relationship $-\Delta F=RT \ln K$. As the free energy change is combined with the equilibrium constant, $-\Delta F$ as well as $K$ can be adopted as a measure of the criterion of the complex formation. In this paper, the discussion will be made in terms of $-\Delta F$.

The plotting of the $-\Delta F$ values against the temperature in Tables III and IV gives the

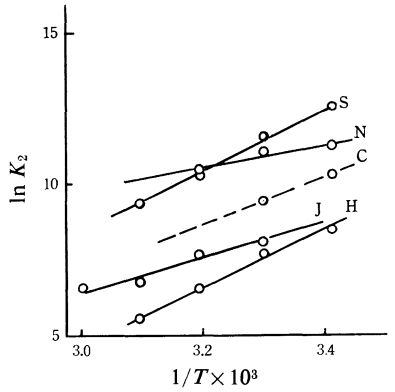

Fig. 6. Plots of $\ln K_2$ vs. $1/T$ for the 1 : 2 P-G molecular complex formations.

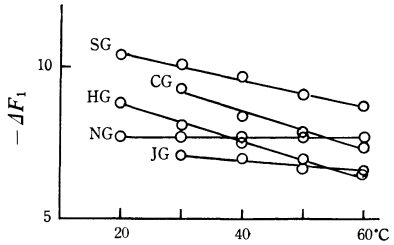

Fig. 7. Relation of $-\Delta F$ vs. temperature.

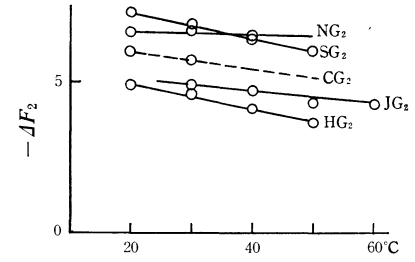

Fig. 8. Relation of $-\Delta F$ vs. temperature.

relations shown in Figs. 7 and 8 respectively. In each case the relation is regarded as linear. According to Fig. 7 the inclinations of lines of S, C and H are large in about the same order, while those of N and J are nearly horizontal. By comparing the chemical structures of these two classes shown in Fig. 1, it may be seen that S, C and H each has four sulfonic groups and two effective auxochromes, while the class of N and J has only two sulfonic groups and two effective terminal auxochromes.[1] It seems that there is some correlation between this fact and the behavior of the $-\Delta F$ value against the temperature.

There are also the following differences among the dyes of the respective classes. The magnitudes of the $-\Delta F$ values at any temperature are in the order of S, C and H (Fig. 7), and the difference in the chemical structures may be seen in the location of the sulfonic group and the sort of auxochrome. The facility of the 1 : 1 complex formation had already been discussed in terms of the difference in chemical structure.[1] Moreover, the conclusion derived from the discussion comes into existence over the temperature range observed here. Again, the relation between the difference of the $-\Delta F$ values of N and J and the positions of the sulfonic groups may be interpreted in terms of conclusion mentioned above.

It is clear from an inspection of Fig. 8 that there is also approximately the same relationship as above in the case of the 1 : 2 complex formation.

The so-called standard affinity ($-\Delta\mu^\circ$) has been used extensively as a measure of the substantivity of dyes. However, $-\Delta\mu^\circ$ and $-\Delta F$ are identical in physical meaning. The expression of $-\Delta\mu^\circ$ involves a quantity which represents a surface volume in the substrate.[3] This can be regarded as a parameter for matching the dimensions of the dye concentrations in both phases of the solution and in the substrate of cellulose. However, it is not always easy to estimate the surface volume. In any case, Table V illustrates the affinity values of S (Chlorazol Sky Blue FF) and G (Chrysophenine G) quoted from those obtained for various cellulose-substrates. If the relation of $-\Delta\mu^\circ$ and temperature is plotted using the

Table V. Standard affinities ($-\Delta\mu^\circ$, cal./mol.) and heats of dyeing ($-\Delta H^\circ$, kcal./mol.)

| D | 60°C | 70°C | 80°C | 90°C | 100°C | $-\Delta H^\circ$ |
|---|---|---|---|---|---|---|
| S | 7500 | 6600 | 6300 | 6100 | 5900 | 22 |
| G | 3800 | 3400 | 3200 | 3000 | 2600 | 14 |

3) T. Vickerstaff, "The Physical Chemistry of Dyeing," 2nd Ed., Oliver and Boyd, London (1954), p. 195.

values in Table V, a tendency similar to that of Fig. 7 will be obtained. The heat of the dyeing ($-\Delta H°$) of S and G are, respectively, 22 and 14 kcal. (Table V). The values for many other direct dyes are also in the same order and correspond to the magnitude of $-\Delta H$ in Tables III and IV. Accordingly, the relative order of substantivity can be compared by the use of $-\Delta F$ values for the complex formation or by the use of $-\Delta H$ values, without using the standard affinity involving various problems.

**The Enthalpy Change.**—The magnitudes of the enthalpy change for the class of S, C, and H, and the class of N and J, classified in the foregoing section apparently differ from each other, as may be seen from Tables III and IV. According to the comparison of the mean values for the respective classes, the $-\Delta H_1$ and $-\Delta H_2$ values for the former class are 2—2.5 times as large as those for the latter. As is well known, the dyeing mechanism of direct dyes believed in at the present time involves mainly the formations of the hydrogen bond and the dispersion force. The magnitude of the dispersion force is considered to be dependent upon the extension of the electron cloud on the faced molecules, namely, in this case the dimensions of the confronted molecular surface. However, such a difference may not be so large with regard to the partner dyes used here. In the meanwhile, the formation of the intermolecular hydrogen bond in the complex under consideration is impossible in the usual way. However, if the auxochromes contribute to the complex formation in some way other than hydrogen bonding, the fact that the class of S, C and H has twice as many auxochromes as the class of N and J corresponds well with the fact that the former class produces an 2—2.5 times as much energy of formation as the latter. In this case, therefore, it is considered that the lone paired electrons on the functional group (auxochrome) play an important role in forming the complex.

The only difference in the chemical structures of C and H is that the OH groups are the auxochromes for the former, while the $NH_2$ groups are for the latter in the same positions. For that reason, the bonding energies should be compared with respect to the distinction of the auxochromes. Unfortunately, however, no conclusion could be obtained for the subject just mentioned because of the small number of proper samples used in the the present experiment.

**The Entropy Change.**—By the use of the entropy change, the degree of the restriction of the partner dye in the complex formation will be compared, and also the deformation of the sterical structure will be discussed. It is a matter of course that the G molecule undergoes a similar change through a complex formation, but the degree of change should be correlated with that of the partner dye. Because G is the common ingredient, it is possible to regard the apparent entropy change as a relative measure of the entropy change of the partner dye itself. The magnitudes of the $-\Delta S$ values in Tables III and IV are divided again into the class of S, C, and H and the class of N and J. The magnitudes of the former class are much larger than those of the latter. This fact may be interpreted as due to the following reason. As has been described above, all of the former, which have twice as many functional groups as the latter, can form a more compact complex, so the component in a complex undergoes the stronger restriction. The freedom is decreased, therefore, and $-\Delta S$ is necessarily increased. Among the classes of S, C and H, S and H differ from each other only in the attached positions of the sulfonic groups, while C and H differ only in the kinds of functional groups (Fig. 1). As for the $-\Delta S_1$ value for a 1 : 1 complex, in Table III the value for S is about 44 e. u. while those of C and H are, respectively, about 57 e.u. and 60 e.u. which are regarded as nearly equal and are considerably larger than that of S. This great difference must be due to the location of the sulfonic groups. The same situation is found in N and J. In the case of a 1 : 2 complex (Table IV), the same relationship can be seen if the result of C which was based on only two experimental values ($-\Delta F_2$) is excluded because of its weak support.

The sulfonic groups of J and those in the inner position of C and H (see Fig. 1) make the plane of the naphthalene nuclei deviate largely from the molecular plane.[2] Accordingly, if it is assumed that all the partner dyes take a similar sterical configuration in the complex state, the above-mentioned difference in $-\Delta S_1$ suggests that partner molecule is more planar in the 1 : 1 complex state than in the free state. This is because a larger deformation is required for C and H than for S to be brought to the similar planar structure. The same thing can be said for the case of N and J.

It may be noticed in Tables III and IV that the $-\Delta S$ values for N are nearly zero through the formation of a 1 : 1 and 1 : 2 complex. In the foregoing discussion solvation has not been taken into account. The effect of solvation should be included naturally in the $-\Delta S$ (and $-\Delta H$) values obtained here. Therefore, the fact that the absolute entropy in the N-G

system is not changed by the complex formation might suggest that, in the course of the complex formation, the solvent molecules which lie between G and N are removed, and that the intermolecular force between G and N formed instead of the hydration restricts the system to the same degree as the hydrated state.

## Summary

1) Using five kinds of dyes of Sky Blue FF and of similar structures, the equilibrium constants for a 1 : 1 and a 1 : 2 complex formed with Chrysophenine G have been determined by means of spectroscopy in the intervals of 20—60°C.

2) A new method of calculating the equilibrium constant has been proposed.

3) The free energy change ($-\Delta F$), the enthalpy change ($-\Delta H$) and the entropy change ($-\Delta S$) for the complex formation have been obtained.

4) The correlation between these quantities and the chemical structure has been discussed and the following facts clarified: The larger the number of effective auxochromes ($NH_2$, OH), the greater $-\Delta H$ and $-\Delta S$ become. The sulfonic group contributes to $-\Delta S$ through the location of that group. The dye molecule in the complex state is more planar than in the free state.

## Appendix

As the method of determining the equilibrium constant by utilizing the change in spectra, the Benesi-Hildebrand method[4] has been applied most extensively. Various other methods are also known. In the case of the present investigation, however, the equilibrium constants can be evaluated easily and precisely by utilizing the two isosbestic points, and by following the treatment described below.

When P, G, PG and $PG_2$ species are in equilibrium and the respective absorption coefficients are $\varepsilon_P$, $\varepsilon_G$, etc. at any wavelength, the optical density, $D$, of the system is expressed as follows:

$$D=[P]\varepsilon_P+[G]\varepsilon_G+[PG]\varepsilon_{PG}+[PG_2]\varepsilon_{PG2} \quad (5)$$

Two isosbestic points appear for the system under consideration. In the wavelength region at which the component G does not absorb light, $\varepsilon_G$ is zero. In this region, and yet in the concentration range in which the first isosbestic point is kept, $[PG_2]=0$; hence, Eq. 5 is simplified to Eq. 6:

$$D=[P]\varepsilon_P+[PG]\varepsilon_{PG} \quad (6)$$

Expressing the initial concentration by $P_0$, the optical density ($D_0$) before G is added is:

$$D_0=P_0\varepsilon_P \quad (7)$$

Hence, we obtain from Eqs. 6 and 7:

$$\Delta D=D_0-D=(P_0-[P])\varepsilon_P-[PG]\varepsilon_{PG}$$
$$=[PG](\varepsilon_P-\varepsilon_{PG})$$

or
$$\Delta D=\varepsilon_1[PG] \quad (8)$$

were $\varepsilon_P-\varepsilon_{PG}=\varepsilon_1$. From Eqs. 3 and 8, therefore, the equilibrium constant, $K_1$, becomes:

$$K_1=\Delta D/\varepsilon_1(P_0-\Delta D/\varepsilon_1)(G_0-\Delta D/\varepsilon_1) \quad (3')$$

where $P_0$ and $G_0$ stand for the respective initial concentrations of P and G.

Next, in the concentration range in which the second isosbestic point is kept, $[P]=0$ because all of the species must be completely changed to the complexes. Therefore, Eq. 5 becomes:

$$D=[PG]\varepsilon_{PG}+[PG_2]\varepsilon_{PG2} \quad (6')$$

By putting $D_0'$ as the optical density for the initial concentration of the PG component corresponding to Eq. 2, and by taking into account the fact that the difference between that initial concentration and [PG] is $[PG_2]$, we obtain the following equation, corresponding to Eq. 8:

$$\Delta D'=D_0'-D=[PG_2](\varepsilon_{PG}-\varepsilon_{PG_2})$$

or
$$\Delta D'=\varepsilon_2[PG_2] \quad (8')$$

where $\varepsilon_2=\varepsilon_{PG}-\varepsilon_{PG2}$. The equilibrium constant, $K_2$, for Eq. 4 may then be expressed as follows:

$$K_2=\Delta D'/\varepsilon_2(P_0-\Delta D'/\varepsilon_2)(G_0-P_0-\Delta D'/\varepsilon_2) \quad (4')$$

Now, when $K_1$ and $K_2$ are evaluated according to Eqs. 3' and 4', the question arises of how $\varepsilon_1$ and $\varepsilon_2$ are determined. This problem can be solved simply by utilizing the isosbestic points as described below. At first, the second isosbestic point (a letter II will be affixed to indicate the position of that wavelength) is noticed in order to determine $\varepsilon_1$. Thus, Eq. 6' holds for the optical density, and besides $\varepsilon^{II}_{PG}=\varepsilon^{II}_{PG2}$; therefore,

$$D^{II}=([PG]+[PG_2])\varepsilon^{II}_{PG} \quad (9)$$

Taking into account that $([PG]+[PG_2])=P_0$ is true in the concentration range where the second isosbestic point is kept, Eq. 9 may be rewritten as Eq. 10;

$$\varepsilon^{II}_{PG}=D^{II}/P_0 \quad (10)$$

On the other hand, as $\varepsilon^{II}_P$ is obtained directly by Eq. 7, $\varepsilon^{II}_P-\varepsilon^{II}_{PG}=\varepsilon^{II}_1$ is determined. Consequently, by substituting $\varepsilon^{II}_1$ and the density-difference $\Delta D^{II}$ at the wavelength of the second isosbestic point, respectively, into $\varepsilon_1$ and $\Delta D$ of Eq. 3', $K_1$ may be evaluated. Similarly, $K_2$ can be calculated by utilizing the first isosbestic point. That is to say, in this case, Eq. 6 holds, $\varepsilon^{I}_P=\varepsilon^{I}_{PG}$, and $([P]+[PG])=P_0$, so that the relation $\varepsilon^{I}_{PG}=D^{I}/P_0$ is derived. On the other hand, with the condition $P_0 \ll G_0$, $\varepsilon^{I}_{PG2}$

4) H. A. Benesi and J. H. Hildebrand, *J. Am. Chem. Soc.*, 71, 2703 (1949).

can be determined as the quotient of the optical density, $D^{I}$, at the wavelength of the first isosbestic point divided by $P_0$. From Eq. 4', $K_2$ can be calculated by using the $\varepsilon^{I}_{2}$ ($=\varepsilon^{I}_{PG}-\varepsilon^{I}_{PG2}$) value thus obtained and the density-difference, $\Delta D^{I}$, at the same wavelength.

# The Rotatory Dispersion and Stereochemistry of Organic Compounds. VII.[1] Monosulfides and Disulfides Derived from Glucose and Glucosamine

By Yojiro TSUZUKI, Koko TANABE, Masuo AKAGI and Setsuzo TEJIMA

(Received July 27, 1964)

In previous papers[1-3] the rotatory dispersion (RD) and stereochemistry of sugar xanthates have been studied, and it has been shown that the Cotton effect is due to the weak absorption band of the $-S-\overset{S}{\overset{\|}{C}}-$ group.

The present paper deals with the studies made of some monosulfides as well as disulfides containing an -S-S- group with the object of investigating the rotatory contribution of the sulfur atoms.

Since it has often been observed[4-7] that optically active disulfides in general are characterized by anomalously large rotations, it appears that it would be particularly interesting to investigate, by means of RD, how the -S-S- group contributes to the optical activity of the disulfides newly synthesized from D-glucose and D-glucosamine.

The following compounds will be investigated:

Bis(2-acetamido-2-deoxy-β-D-glucopyranosyl)-sulfide (compound I),

Bis(2-acetamido-2-deoxy-3, 4, 6-tri-*O*-acetyl-β-D-glucopyranosyl)sulfide (compound II),

Bis(2-acetamido-2-deoxy-β-D-glucopyranosyl)-D-disulfide (compound III),

1, 6-Anhydro-1, 6-sulfide-2, 3, 4-tri-*O*-acetyl-β-glucopyranose (compound IV),

Bis(2, 3, 4, 6-tetra-*O*-acetyl-β-D-glucopyranosyl) sulfide (compound V),

Bis(2, 3, 4, 6-tetra-*O*-acetyl-β-D-glucopyranosyl) disulfide (compound VI).

## Results and Discussion

The structural formulas of compounds I—VI and their molecular rotations (of the D-line) are shown in Fig. 1.

The RD curves of the glucosamine derivatives (compounds I, II and III) are shown in Fig. 2, and those of the glucose derivatives (IV, V and VI) in Fig. 3. The ultraviolet absorption curves of compounds I—VI are shown in Fig. 4.

As may be seen in Fig. 2 and Fig. 3, they

7) C. Djerassi, A. Fredga and B. Sjöberg, ibid., 15, 417 (1961).

all exhibit negative, plain, rotatory dispersion curves, since in the measured wavelength region (from 265 mμ to 700 mμ) these compounds have no optically active absorption bands.

As is evident from Fig. 4, the monosulfides **I**, II and V show no absorption maxima in the measured wavelength region (from 225 mμ to 340 mμ), in accordance with the observations that dialkyl sulfides exhibit strong absorption bands ($\log \varepsilon \sim 3$) only below 210 mμ.[8] Even these "monothiodisaccharides" may be expected to have optically active absorption bands at a shorter wavelength region when we reflect upon the situation described above as well as the detailed considerations[9,10] of the ultraviolet absorption spectra of various sulfides. However, it is natural that the RD curves of I, II and V are plain in the measured wavelength region.

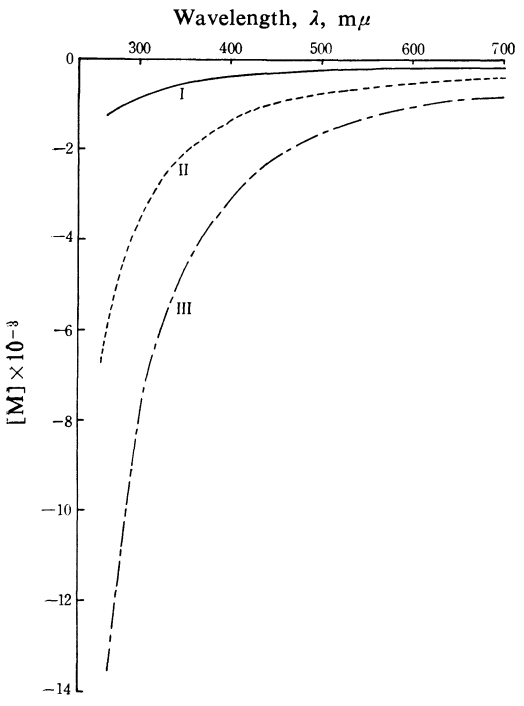

Fig. 2. RD of I—III.

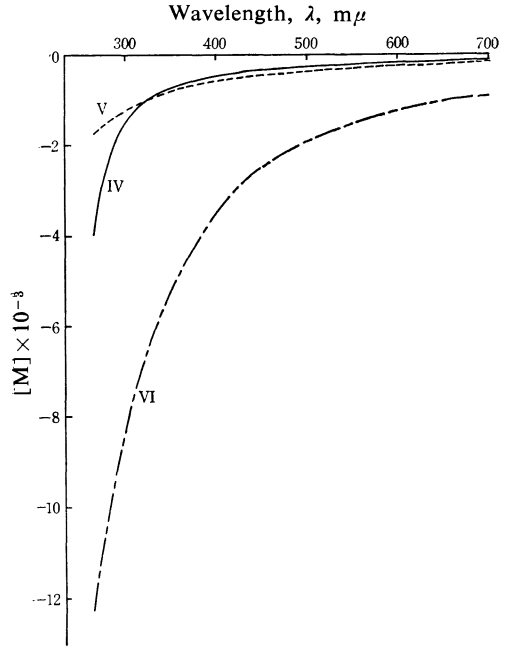

Fig. 3. RD of IV—VI.

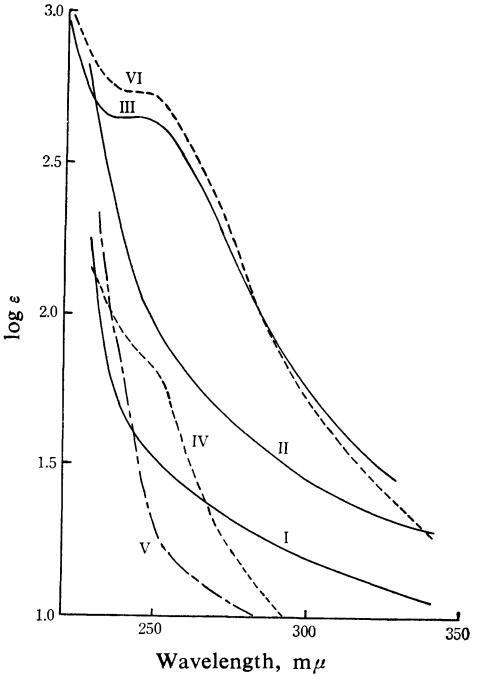

Fig. 4. UV absorption spectra.

Although the absorption due to the $n \rightarrow \pi^*$ transition of the S–S bond varies from 230 mμ to 370 mμ according to the molecular eviron-ment, it has been reported[8,10] that dialkyl disulfides exhibit broad maxima ($\log \varepsilon \sim 2.6$) in the neighborhood of 250 mμ. Compounds III and VI exhibit slight absorption maxima at 235 to 250 mμ, as may be seen in Fig. 4. It is, however, uncertain whether these absorptions are optically active or inactive. Really the dispersion curves of compounds III and VI are plain up to the possible limit of the experiment as compared with the RD curves

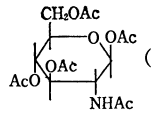
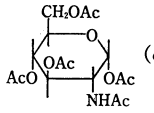
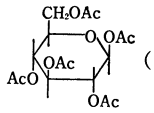
of the other compounds, but they are very steep and their terminals closely approach the first extremes of the possible Cotton effects associated with the absorption bands of the disulfides.

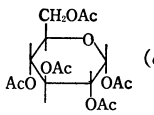
The fact that all the RD curves (I—VI) are negative in sign may be due to the $\beta$-configuration of the $C_1$ of the $\beta$-D-glucopyranosides. The negative rotation of compound II is distinctly greater in value than that of compound I, probably because the optically active absorption is deeper in the former than in the latter, for its acetoxyl group has a larger polarizability than the hydroxyl group.

The following two examples will illustrate the noticeable effect of the sulfur atom in comparison with the oxygen atom on optical rotation. As may be seen in Fig. 3, the RD curve (IV) is plain; however, its absorption curve shows a shoulder near 250 m$\mu$ (Fig. 4, IV), quite in harmony with the fact that heterocyclic sulfur compounds usually show bathochromic shifts in comparison with simple sulfides.[8] The negative RD curve (Fig. 3, IV) also descends steeply toward the absoption region, and its terminal nearly approaches the extreme of the shoulder. In this respect the thiolevoglucosan (compound IV) is distinguished from other simple sulfides. It may be stated positively that this "heterocyclic" sulfur atom contributes a strong negative rotation to thiolevoglucosan, as is evident from a comparison with levoglucosan, its corresponding oxygen compound (1, 6-anhydro-2, 3, 4-triacetyl-$\beta$-D-glucopyranose):









| | $[\alpha]_D$ | $[M]_D$ |
|---|---|---|
| Thiolevoglucosan triacetate | $-65.9°$ | $-201°$ |
| Levoglucosan triacetate | $-45.5°$[11] | $-131°$ |

Next compound V ($\beta$, $\beta$-thiotrehalose octaacetate) was compared with its corresponding oxygen compound, $\beta$, $\beta$-trehalose octaacetate:

| | $[\alpha]_D$ | $[M]_D$ |
|---|---|---|
| $\beta$, $\beta$-Thiotrehalose octaacetate | $-32.6°$ | $-227°$ |
| $\beta$, $\beta$-Trehalose octaacetate | $-18.4°$[12] | $-125°$ |

The negative value of the molecular rotation of the former (V) $[M]_D=-227°$ is far greater than that of the latter, $[M]_D=-125°$. This fact indicates that the sulfur atom of the $C_1$-$\beta$-configuration contributes to a greater negative rotation, as can be expected from the bathochromic shift of the $C_1$-S-$C_1$ group.

TABLE I. THE OPTICAL SUPERPOSITION OF PENTAACETATES OF GLUCOSE AND GLUCOSAMINE

| | | $[\alpha]_D^{20}$ | $[M]_D$ | |
|---|---|---|---|---|
|  | ($\beta$) | + 1.2° | + 4.7= $-A+B$ | $A=180$ $B=184$ |
|  | ($\alpha$) | + 93.5° | +364= $A+B$ | |
|  | ($\beta$) | + 3.8° | + 15= $A+B'$ | $A=191$ $B'=206$ |
|  | ($\alpha$) | +101.6° | +396= $A+B'$ | |

One may get a glimpse into the effect of the acetamido group-$NHCOCH_3$ from a comparison of the glucosamine derivative (II) with the glucose derivative (V). Their configurations differ from each other only in $C_2$.

From Figs. 2 and 3 it is evident that the former compound shows a far stronger RD curve of a negative sign. This fact can be interpreted as follows:

In the first place, the values of $A$ and $B$ of the pentaacetates of glucose and glucosamine must be taken into consideration; they are given by Hudson's rule of optical superposition.[13]

As may be seen in Table I, the values of $B$ and $B'$ are both positive in sign, and the $B'$ value of glucose pentaacetate is distinctly larger than the $B$ value of glucosamine pentaacetate. This fact indicates that the partial rotation of the group $C_2$-NHAc is lower than that of $C_2$-OAc. In a similar way, the $B$ value of compound II is found, by applying Hudson's rule, to be smaller than that of compound V, implying that here also $C_2$-NHAc is lower than $C_2$-OAc in partial rotatory power. Thus, it is reasonable that compound II exhibits a stronger negative RD curve.

### Dispersions Constants

It is to be expected that the dispersion data can be expressed by a single-term Drude equation, since the dispersions exhibit only plain curves.

11) C. Tanret, *Compt. rend.*, **119**, 158 (1894); P. Karrer and A. P. Smirnoff, *Helv. Chim. Acta*, **4**, 819 (1921).
12) C. M. McClosky, R. E. Pyle and G. H. Coleman, *J. Am. Chem. Soc.*, **66**, 349 (1944); "Advances in Carbohydrate Chemistry," Vol. VI, Acad. Press, New York (1951), p. 75.
13) C. S. Hudson and J. K. Dale, *J. Am. Chem. Soc.*, **38**, 1433 (1916).

$$[M]=\frac{R}{\lambda^2-\lambda_0^2}$$

Table II shows the dispersion constants obtained by the usual method of calculation from the dispersion data.

TABLE II. DISPERSION CONSTANTS

| Compound | $R$ | $\lambda_0^2$ |
|---|---|---|
| I | − 56.95 | $0.151^2$ |
| II | −157.26 | $0.212^2$ |
| III | −341.00 | $0.220^2$ |
| IV | − 59.38 | $0.201^2$ |
| V | − 75.43 | $0.196^2$ |
| VI | −380.40 | $0.218^2$ |

As may be seen in Table II, all the values of $\lambda_0$ except that of I are reasonable, representing the most probable, optically active absorption maxima. The dispersion data of III and VI in particular are precisely expressed with the single-term Drude equation, and the relations between $\lambda^2$ and 1/[M] become quite rectilinear (Fig. 5). Moreover, it is noticeable that the factors of the rotational strength, $R$, are especially high in these compounds. This fact suggests that the their ultraviolet absorptions at 235—250 m$\mu$ make so predominant contributions to the optical activity that the minor residual rotations due to other asymmetric centers may practically be ignored.

On the other hand, the dispersion data of compounds I, II, IV and V can not be so precisely expressed by the single-term equation, for the differences between the observed and the calculated values sometimes rise to five per cent, and the relations between $\lambda^2$ and 1/[M] deviate more or less from straight lines, rather drawing slightly convex curves. These facts suggest that the more hypsochromic $C_1$–S–$C_1$ group contributes relatively little to the optical rotation as compared with the disulfide group. Moreover, the residual partial rotation may make a considerable contribution. To elucidate this problem, however, further detailed inquiries should be made in this shorter wavelength region.

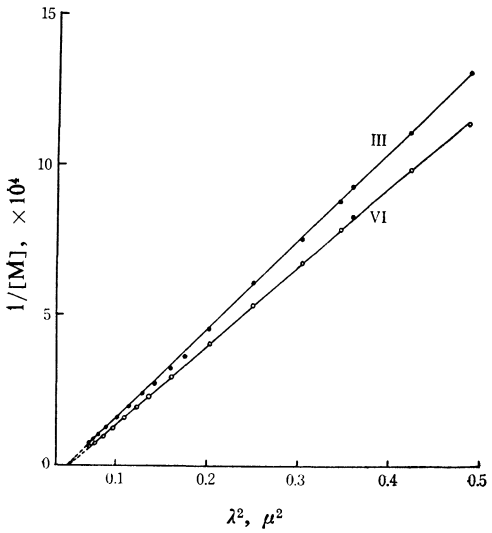


Fig. 5. Rotatory dispersion of disulfides represented as 1/[M] in function of $\lambda^2$.

## Experimental

The rotatory dispersion was measured with a Rudolph spectropolarimeter over the wavelength region from 265 to 700 m$\mu$. The ultraviolet absorption was measured in the same solvent as with RD measurements made with a self-recording spectrophotometer of the Hitachi EPU-II type.

*Bis(2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl)disulfide (Compound VI).*[17] — Colorless crystals, m. p. 143—144°C. $[\alpha]_D=-160°$ (*c* 6.0, $CHCl_3$).[17] The RD was measured at 17.3°C in tetrahydrofuran (*c* 0.3875). $[\alpha]_{700}^{17.3}$ −122°, $[\alpha]_{589}$ −173°, $[\alpha]_{265}$ −1679°.

## Summary

Measurements have been made ot the rotatory dispersions (265 to 700 m$\mu$) and ultraviolet absorptions (225 to 340 m$\mu$) of various thiosugars, namely, there monothiodisaccharides (I, II, V), two dithio disaccharides (III, VI),

14) M. Akagi, S. Tejima and M. Haga, *Chem. & Pharm. Bull.*, **9**, 360 (1961).

and thiolevoglucosan (IV), in order to investigate the effect of sulfur atoms on optical activity.

The monosulfides, I, II and V, exhibit no absorption maxima and plain, negative RD curves. The disulfides, III and VI, exhibit absorption maxima at 235 to 250 m$\mu$. Their negative RD curves are, accordingly, very steep, approaching the first extremes of the possible Cotton effect.

Thiolevoglucosan (IV), containing a "heterocyclic" sulfur atom, shows more bathochromic shifts than simple sulfides, and a stronger optical activity than levoglucosan. The strong rotatory contribution of the sulfur atom is also observed in acetylated thiotrehalose (V).

In thiosugars the acetamido group also shows a smaller rotatory contribution than the acetoxyl group.

The dispersion data have been analyzed by means of the Drude equation, and the physical significance of the dispersion constants has been discussed.

# The Rotatory Dispersion and Stereochemistry of Organic Compounds. VIII.[1] Mono- and Dinitrates of Glucopyranose (Preliminary Report)

By Yojiro TSUZUKI, Koko TANABE and Kikuhiko OKAMOTO

(Received August 17, 1964)

In previous papers it has been reported that the chromophores containing sulfur atoms exercise predominant roles in the rotatory dispersion (RD) of sugar xanthates[2-4] and sugar sulfides[1]. This paper will report on similar studies of the rotatory contribution of a nitrogen-containing chromophore $-O-NO_2$ (nitrate).

Although the nitrate chromophore has never been studied with respect to the RD, it has been reported by Mitchell et al.[5] that dinitrocamphane exhibits an intense negative Cotton effect, and some interesting information has been obtained with several nitro-compounds with regard to the RD.[6,7] Recently Djerassi et al.[8] have studied the circular dichroism and RD of compounds containing a nitro chromophore.

On the other hand, it has been shown with aliphatic nitro-compounds[9,10] that the nitro group exhibits an intense absorption band around 210 m$\mu$ and a weak band around 270 m$\mu$ due to the $n\rightarrow\pi^*$ transition. Similarly, some alkyl nitrates have also been shown to have a feeble absorption band due to the $n\rightarrow\pi^*$ transition.[9] Thus, it can be expected that with sugar nitrates also the nitrate chromophore will exhibit an optically active absorption. In this paper the following compounds will be investigated with the object of studying how the $C_2$- and $C_3$-$ONO_2$ groups affect the RD of glucose:

Methyl 4:6-*O*-benzylidene-$\alpha$-D-glucopyranoside 3-nitrate (compound I),

Methyl 4:6-*O*-benzylidene-$\alpha$-D-glucopyranoside 2,3-dinitrate (compound II),

Methyl 4:6-*O*-benzylidene-$\alpha$-D-glucopyranoside (compound III),

3,4,6-Tri-*O*-acetyl-2-*O*-nitro-$\alpha$-D-glucopyranosyl chloride (compound IV),

1,3,4,6-Tetra-*O*-acetyl-2-*O*-nitro-$\alpha$-D-glucopyranoside (compound V),

3,4,6-Tri-*O*-acetyl-$\alpha$-D-glucopyranosyl chloride (compound VI),

Pentaacetyl-$\alpha$-D-glucose (compound VII).

## Results and Discussion

The RD curves of compounds I, II and III are shown in Fig. 2. Curve III is considered to represent the background rotation of curves I and II. As is shown in Fig. 4, the ultraviolet absorption spectra of compounds I and II are found to have the $\lambda_{max}$ at 250—270 m$\mu$, and their absorption is optically active.

As is evident from Fig. 2, compound I ($C_3$-nitrate) exhibits a positive Cotton effect (the peak at 300 m$\mu$), while compound II (2, 3-dinitrate) shows a very feeble negative Cotton effect. The broad peak around 335 m$\mu$ of curve II is produced from the positive background RD of curve III superposed by a slight negative Cotton effect, the peak of which appears at 295 m$\mu$, nearly identical with the peak (300 m$\mu$) of the Cotton effect of curve I.

Thus, the $C_3$-$ONO_2$ group may be supposed to give rise to a positive Cotton effect, as the $C_3$-xanthate group does in glucose,[2,4] even though the $C_3$-group of glucose is usually believed to make a levo-rotatory contribution because of the $\beta$-type of $C_3$-configuration (i. e., the inversion of the sign of rotation).

In comparing the $C_2$-$ONO_2$ group with the 3-nitrate in rotatory contribution, the value of the $[\alpha]_D$ of the 2, 3-dinitrate (compound II) is lower than that of the 3-nitrate (compound I),

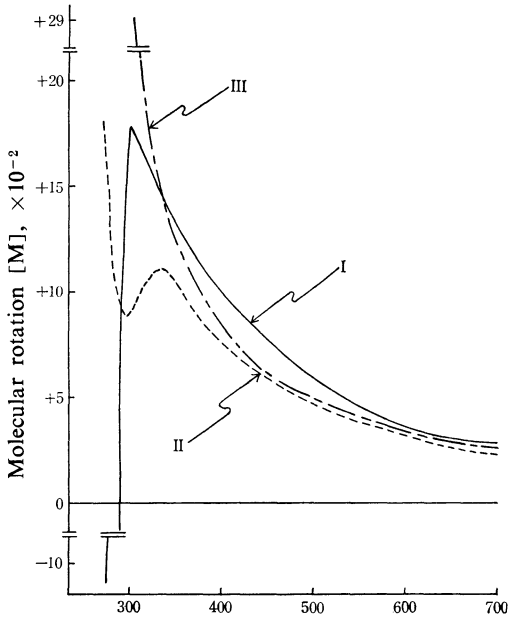

Fig. 2. RD of I—III.

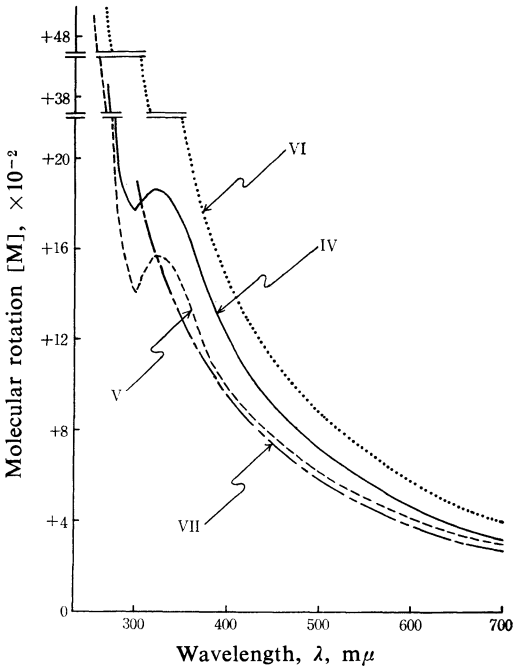

Fig. 3. RD of IV—VII.

and Honeyman et al.[11] have given a value of 104° to the specific rotation of methyl 4 : 6-*O*-benzylidene-$\alpha$-D-glucopyranoside 2-nitrate, which is also lower than that of the corresponding 3-nitrate. These facts suggest that the

11) J. Honeyman and J. W. W. Morgan, *J. Chem. Soc.*, 1955, 3669.

$C_2$-$ONO_2$ group contributes somewhat to the negative rotation.

In order to make a further study of the rotatory contribution of the $C_2$-$ONO_2$ group, compounds IV and V have also been studied.

The RD curves of compounds IV and V are shown in Fig. 3, together with those of VI and VII as illustrations of the background curves. As may be seen in Fig. 2, the absorption maxima appear at the region of 295—300 mμ in the RD due to the nitrate chromophore. The peaks around 325 mμ on the curves of IV and V are properly to be attributed to a small Cotton effect (negative peak around 300 mμ) overlapped on the positive background RD curves. Thus, the Cotton effects of compounds IV and V are to be judged negative in sign, the negative peaks being located respectively at 295 and 300 mμ, quite in coincidence with those of compounds I and II (Fig. 2).

In a previous paper[4] it has been shown that the $C_2$-$OCOCH_3$ group in D-mannose exhibits a negative rotatory contribution; accordingly, the $C_2$ group of D-glucose (of α-configuration) may be presumed to contribute to the positive rotation. However, the Cotton effects of IV and V due to the nitrate group in the $C_2$ position are to be considered negative in sign, as has already been stated and as may be seen in Fig. 3, so the nitrate group may also be assumed to exhibit an inversion effect in the sign of rotation, as has already been observed and pointed out with several xanthates.[2,3]

The ultraviolet absorption spectra of compounds I and II are given in Fig. 4, and those of IV and V, in Fig. 5. The first two curves are distinguished in that both exhibit fine structures in the region of 250—270 mμ, the forms of which structure are almost entirely identical in chloroform as well as in tetrahydrofuran. It is worthy of note that the ultraviolet absorption curves of I and II rather resemble those of alkyl nitrates,[9] although the nitrites exhibit weak absorption bands (ε ~80) of fine structures in the longer wavelength region around 370 mμ.

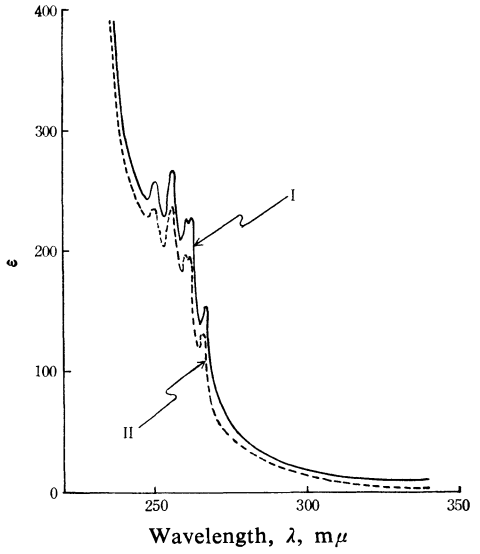

Fig. 4. UV absorption spectra of I and II.

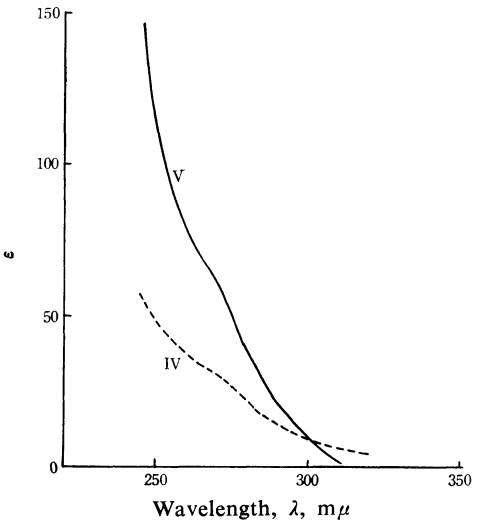

Fig. 5. UV absorption spectra of IV and V.

Compounds IV and V do not exhibit any noticeable ultraviolet absorption in tetrahydrofuran; although in chloroform their curves do show slight anomalies, they do not exhibit so distinct inflections as are observed in alkyl nitrates,[9] which occur around 270 mμ (ε ~20.[12])

Apparently the ultraviolet absorption curves of these compounds (IV and V) have no relation to the behaviors of RD, but it is worthy of attention that the RD curves exhibit optically active absorptions at longer wavelengths of 295—300 mμ, and that also in some nitrites the first peaks of the Cotton effects are situated at longer wavelengths than are the ultraviolet absorption maxima[8] by 10—20 mμ.

With the nitro-chromophore such red shifts have also been observed as with the first peaks of RD, which are displaced toward longer wavelengths from the ultraviolet absorption maxima.

It is thus reasonable, in view of the above-stated facts, to assume that the peaks of the Cotton effects due to the nitrate chromophore are observed at wavelengths about 20 mμ

12) It is likely that distinct absorption maxima will result if the spectra are taken in less polar solvents. See C. N. R. Rao, "Ultra-violet and Visible Spectroscopy," Butterworths, London (1961), p. 22.

longer than the ultraviolet absorption maxima.

Finally, it should be noted that the authors, as usual, have tried to express the RD by means of the equations of Drude, but the complex RD curves could not successfully be expressed. This is probably because the shapes of the curves are peculiar, and because the falls between the peaks of the feeble Cotton effects are too small. The values of the dispersion constants obtained by the usual calculation method often fail to give proper physical significance. Further detailed studies will be necessary for a quantitative analysis and for more comprehensive treatment of the dispersion data.

## Experimental

The derivatives of glucose were prepared according to the methods of the literature. The rotatory dispersion was measured with a Rudolph spectropolarimeter over a wavelength region from about 265 mμ to 700 mμ. The ultraviolet absorption was measured with a self-recording spectrophotometer of Hitachi EPU-II type.

*3,4,6-Tri-O-acetyl-α-D-glucopyranosyl Chloride (Compound VI).*[15] — Needles, m. p. 93—94°C. The RD was measured at 21°C in chloroform (*c* 0.9374). $[\alpha]_{700}^{21}$ +126°, $[\alpha]_{589}$ +184°, $[\alpha]_{500}$ +268°, $[\alpha]_{400}$ +465°, $[\alpha]_{300}$ +1038°, $[\alpha]_{250}$ +1900°.

*Pentaacetyl-α-D-glucopyranoside (Compound VII).*[16] —Colorless crystals, m. p. 112—113°C. The RD was measured at 21°C in chloroform (*c* 1.0820). $[\alpha]_{700}^{21}$ +68.6°, $[\alpha]_{589}$ +102°, $[\alpha]_{500}$ +146°, $[\alpha]_{400}$ +245°, $[\alpha]_{300}$ +486°.

## Summary

The RD and ultraviolet absorption have been observed with some derivatives of glucose carrying a nitrate group in the $C_2$ and $C_3$ positions in order to study the optical contributions of the $C_2$- and $C_3$-ligands with respect to their configurations.

# The Behavior of Fission Products Captured in Graphite Powder by Nuclear Recoil. VIII. Further Studies of Iodine-131 Diffused out of Graphite

By Seishi YAJIMA, Koreyuki SHIBA and Muneo HANDA

(Received July 29, 1964)

In the sixth and seventh papers of this series,[1-2] the chemical state of fission iodine-131 diffusing out of various kinds of ceramic fuels was studied by using a thermochromatograph, and the following experimental results were reported:

1) The fission iodine-131 diffusing out of uranium dioxide, thorium dioxide, and a mixture of graphite and uranium dioxide, all containing fission products, was not an elementary iodine but was composed of iodine compounds.

2) The iodine compounds were fairly stable at high temperatures in a helium atmosphere; i. e., the compound diffusing out of uranium dioxide and the mixture of graphite and uranium dioxide was able to exist as a solid at 580°C; the compound from thorium dioxide was of two kinds of states, one in a solid at 530°C and the other at 430°C.

3) From the behavior of iodine compounds in solvent extraction, it was found that the chemical state of the compounds was iodide.

4) As iodide is a chemical form, it should be thought that iodine combined with other fission products, with impurities in uranium dioxide, thorium dioxide, graphite, etc., or with the fissionable material, i. e., uranium or thorium. Of the above possibilities, that that the fission iodine-131 combined with impurities was eliminated, because the fission iodine-131 diffusing out of the uranium dioxide and that diffusing out of the mixture of graphite and uranium dioxide, the impurities in the two differing from one other, were stable at 580°C in a solid form. The theory that the fission iodine-131 combined with other fission products was weakened by the fact that there was a difference between the fission iodine-131 from uranium dioxide and that from thorium dioxide at the temperature where the iodide existed as solid, even if the fission products yield curves of uranium were different from that of thorium.

On the basis of the above facts, it was assumed that the fission iodine-131 combined with the fissionable material, uranium or thorium. To prove directly the chemical forms of these iodine compounds by the chemical or physical methods was, however, very difficult. This was because the amount of fission iodine-131 in the irradiated sample was extremely small ($\mu\mu$g. level) and, further, because, if the fission iodine-131 existed as a uranium iodide or thorium iodide, these compounds were considerably unstable in the atmosphere.

The present paper will describe further studies made to prove the combining of the fission iodine-131 with fissionable material. A uranium tetraiodide was prepared by the reaction of uranium metal powder with iodine labeled with iodine-131. The behavior of uranium tetraiodide was compared with that of the fission iodine-131 by using a thermochromatograph. The uranium tetraiodide deposited on the same place in a thermochromatotube as the fission iodine-131, in an inert gas atmosphere. Further, the chemical behavior of the uranium tetraiodide toward the oxygen contained in a small amount in the helium stream was compared with that of the fission iodine-131 diffused out of the graphite. The behavior of the uranium tetraiodide toward the oxygen was the same as that of the fission iodine-131. On the basis of above results, it seemed reasonable to assume that the fission iodine-131 diffused out from the graphite as uranium tetraiodide. As for the chemical behavior of the uranium tetraiodide toward the oxygen, it was clarified that the uranium tetraiodide was oxidized to triuranium octoxide and iodine through three intermediates, which deposited on the silica powders heated at temperatures of about 400°C, 300°C and 200°C respectively.

## Experimental and Results

**The Preparation of Samples.** — *Sample No. I (A mixture of natural graphite powder and uranium dioxide containing fission products).*—Natural graphite powder degassed (in a vacuum, 1000°C, 24 hr.) was mixed with a stoichiometric uranium dioxide powder in the weight ratio of 2 : 1, in a glove box filled with purified helium gas. About 100 mg. of

1) S. Yajima, K. Shiba and M. Handa, This Bulletin, **36**, 253 (1963).
2) S. Yajima, K. Shiba and M. Handa, ibid., **36**, 258 (1963).

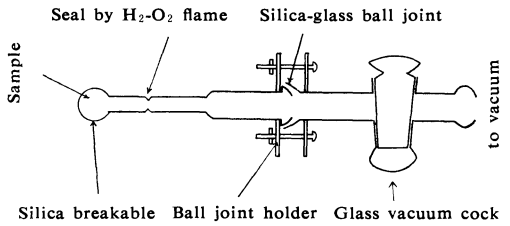

Fig. 1. Assembly to prepare the sample packed in a silica breakable.

the mixture was packed in a silica breakable equipped with a ball joint, a joint which is shown in Fig. 1. Then a cock was attached to the breakable with a ball-joint holder, and the whole assembly was taken out of the glove box. The helium gas in the breakable was evacuated, and the part containing the sample was sealed by an oxygen-hydrogen flame. Then the mixture of graphite and uranium dioxide sealed in the silica breakable was neutron-irradiated in the JRR-1 (a water boiler-type reactor with a thermal neutron flux of about $5\times10^{11}$ n/cm$^2$·sec.) for 15 hr. After irradiation, the mixture was cooled for 5 days to allow the other short-lived isotopes of iodine, as well as the mostly precursor of iodine-131, to decay out. The fission iodine-131 diffusing out of this sample mixture when it was heated was determined to be the iodine-131 contained in the graphite, because about 70% of the fission iodine-131 was captured in the graphite by nuclear recoil[3] and the diffusion coefficient of the fission iodine-131 in the graphite was far larger than in the uranium dioxide.

*Sample No. 2 (Uranium tetraiodide labeled with iodine-131).*—Potassium iodide was added to a commercial aqueous solution of iodine-131, and the potassium iodide was oxidized to an elementary iodine with nitric acid. The iodine labeled with iodine-131 was washed with water to eliminte a potassium nitrate and was dried in a desiccator containing an anhydrous calcium chloride.

By the use of this elementary iodine, uranium tetraiodide labeled with iodine-131 was prepared by the method reported by Gregory.[4] About 100 mg. of the uranium tetraiodide was packed in a silica breakable in a way similar to that used for sample No. 1.

**Packing Material for the Thermochromato-tube.**—Natural graphite powder, with particle sizes less than one micron, or silica powder, twenty-to-thirty mesh, was degassed by heating it in a vaceuum at 1000°C for 24 hr. The treated graphite or silica was kept in a helium gas atmosphere before being used in the experiment.

**Apparatus.**—The apparatus used is shown schematically in Fig. 2. The automatic Toepler pump was attached to the thermochromatograph reported on earlier.[1] The apparatus was modified in order to circulate the carrier gas through the apparatus. A trap for the mercury, cooled with a mixture of alcohol and dry-ice, was installed at the entrance and exit of the thermochromato-tube; the mercury

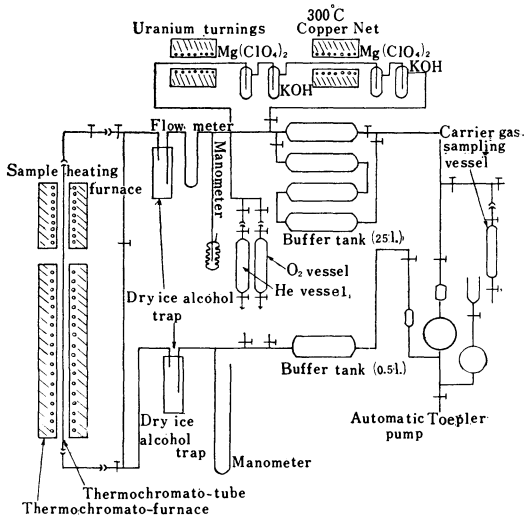

Fig. 2. Thermochromatograph.

was used in the automatic Toepler pump. A buffer tank was set at the entrance and exit of the automatic Toepler pump in order to stabilize the flow rate of the carrier gas; the volumes of the buffer tanks were 0.5 l. and 25 l. respectively. The apparatus had a bypass gas-purification system and made possible the experiments with purified helium carrier gas. The thermochromato-tube was externally heated by a nichrome wire to produce the linear temperature gradient of 600°C to room temperature; the temperature gradient is shown in Fig. 3. The gradient was obtained by changing the

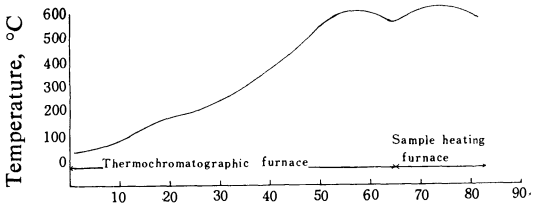

Fig. 3. Condition of two electric furnace (thermochromato-furnace and sample heating furnace) when an equilibrium was attained.

number of windings for each part of the furnace. The thermochromato-tube used was the same as in the previous study, with a transparent silica tube (0.6 cm. in inner diameter and 100 cm. long). Twenty-to-thirty mesh silica powder or fine natural graphite powder was used as the packing material in the thermochromato-tube. The sample-heating furnace was divided in two halves at the center of the furnace, so that the breakable in the thermochromato-tube could be broken from outside with a magnet.

**Procedure.**—Silica powder or graphite powber was packed into the thermochromato-tube. The sample in the silica breakable and its breaker (an iron bar sealed in a silica tube) were located in the center

3) T. Nakai, S. Yajima, K. Shiba, J. Osugi and D. Shinoda, This Bulletin, 33, 494 (1960).
4) N. W. Gregory, UCRL, RL-4, 6, 272 (1944).

of the sample-heating furnace on the packing material in the thermochromato-tube. Then the whole apparatus was evacuated by a rotary pump, and the thermochromato-furnace was heated for 2 hr. to remove the impurity gases adsorbed on the packing powders. Arbitrary volumes of helium and oxygen were introduced into the apparatus to a one-tenth atmosphere; these were then completely mixed by circulating them 5 hr. through the apparatus with the automatic Toepler pump. On the other hand, when the experiment was carried out in an inert atmosphere, only helium was introduced into the apparatus; it was purified by circulating 5 hr. through the gas purification system with the automatic Toepler pump. In both cases, the heating of the sample-heating furnace was then started. After the temperature of the sample-heating furnace reached 600°C, the circulation of the carrier gas was continued for a further 2 hr. The thermochromato-tube was cooled and surveyed along the whole length in order to locate the iodine-131 activities. An RCL-256 channel gamma-ray spectrometer connected with an NaI(Tl) crystal (a lead slit 1 cm. wide was set) was used for measuring the iodine-131 activity.

**Thermochromatograms.** — The thermochromatograms of the fission iodine-131 diffused out of the mixture of graphite and uranium dioxide, and that diffused out of the uranium tetraiodide prepared in a laboratory, for the pure helium carrier gas, are shown in Figs. 4 and 5 respectively. The results obtained for the two samples under various oxygen partial pressures are shown in Figs. 6 and 7 respectively. In the thermochromatograms in Figs. 4 to 7, the axis of the abscissa is shown by the temperature. These thermochromatograms were obtained by replacing each position of the thermochromato-tube with the temperature of the thermochromato furnace, according to Fig. 3.

## Discussion

As is shown in Fig. 4, when thoroughly purified helium was used as the carrier gas (the partial pressure of oxygen was less than $10^{-5}$ atmosphere), the fission iodine-131 deposited on the graphite powder heated at 550°C,*

* In a previous report,[1] it was reported that the fission iodine-131 deposited on the graphite powder heated at 580°C. The deposition temperature of the fission iodine-131 in the thermochromato-tube was mainly influenced by two factors, i. e., the flow rate of the carrier gas in the thermochromato-tube and the temperature gradient of the thermochromato-furnace. In the present experiment the thermochromatograph was modified considerably compared with the previous one, and so the location of the deposition of the fission iodine-131 shifted to a low temperature; it was deposited on graphite powder heated at 550°C. However, when the same thermochromatograph was used for the experiment, the deposition temperature of the fission iodine-131 was reproducible within ±20°C at the same experimental conditions.

temperature near the melting point of the uranium tetraiodide (the melting point of uranium tetraiodide reported in the literature is 506—518°C[5,6]). On the other hand, the uranium tetraiodide prepared in a laboratory deposited on the graphite powder heated at 550°C under the same experimental conditions as that of the fission iodine-131. The data shown in Fig. 6 indicate that, at a constant temperature, the reaction between the fission iodine-131 and oxygen is governed by the partial pressure of the oxygen in the carrier gas. The position of the fission pressure of the oxygen in the carrier gas increased.

When the partial pressure of oxygen was one-tenth atmosphere, the fission iodine-131 was oxidized to an elementary iodine and deposited at the position of 100°C (the melting point of iodine is 113.6°C). The results for the reaction of uranium tetraiodide with oxygen under the same experimental conditions, which are shown in Fig. 7, were the same as those obtained with the thermochromatograms for the fission iodine-131. From the above results, it must be considered that the fission iodine-131 diffusing out of the neutron-irradiated mixture of graphite and uranium dioxide is not an elementary iodine but is in the chemical form of uranium tetraiodide.

To prove the above facts directly, uranium must be detected at the position of the deposition of the fission iodine-131 by neutron activation analysis. These experiments are now planned in the author's laboratory. The intermediates which deposited at 400°C, 300°C and 200°C are thought to be either compounds of uranium and iodine (for example, $UI_6$ and $UI_5$) or compounds of uranium, iodine, and oxygen (for example, $UO_2I_2$ and $UOI_2$), but the existence of these compounds in the solid state is not reported in any literature. The mechanism of the formation of these compounds is thought to be the oxidation, decomposition or disproportionation of uranium tetraiodide or their combinations; the chemical forms and the types of crystallization are now being investigated.

Recently, Hudswell[7] confirmed that the fission iodine diffusing out of uranium-carbide fuel dopsited on the surface of graphite heated at the temperature of 350°C in a helium gas atmosphere. It is thought that Hudswell found one of the intermediates confirmed by the authors. The phenomenon that the fission iodine diffuses out in the chemical form of uranium tetraiodide from ceramic fuels, such as uranium dioxide or a mixture of uranium carbide and graphite, is important in connection with uranium migration in nuclear ceramic fuels; therfore, the mechanism of the formation of uranium tetraiodide in the fuels must be studied further.

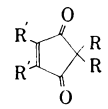
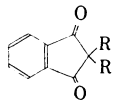
# The Dipole Moments of Some Sesquifulvalene Quinones and Related Compounds



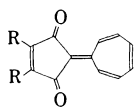
By Shigeyoshi KATAGIRI, Ichiro MURATA,* Yoshio KITAHARA* and Hiroshi AZUMI

(Received August 7, 1964)

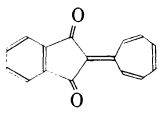


Although it is considered probable, from theoretical considerations, that sesquifulvalene is a highly polar molecule due to a charge transfer from the electron-donating seven-membered ring towards the electron-accepting five-membered ring, experimental evidence for this conclusion has not yet been provided because sesquifulvalene is not stable and easily polymerizes.[1-4] Recently Kitahara et al.[5] have synthesized some stable quinone derivatives of sesquifulvalene—sesquifulvalene-1, 4-quinone (VII) and 2, 3-benzosesquifulvalene-1, 4-quinone (VIII). Each of these quinones has two electron-withdrawing carbonyl groups in the five-membered ring, so that a considerable amount of charge transfer should be expected between the two rings. Accordingly, their dipole moments should provide some information with respect to this charge transfer. In order to obtain more detailed information, however, an investigation of the dipole moments of some diones related to the above quinones must also be undertaken. Therefore, besides those for the sesquifulvalene quinones, the dipole moments were measured for several compounds not having a heptafulvene structure—cyclopentene-3, 5-dione, indane-1, 3-dione, and their halogeno and tropyl derivatives.

## Experimental



The following samples were used: cyclopentene-3, 5-dione (I), m. p. 37—38°C,[6] 4, 4-ditropylcyclopentene-3, 5-dione (II), m. p. 121—122°C,[5] 1, 2-dichlorocyclopentene-3, 5-dione (III), m. p. 163°C,[7] 1, 2-dichloro-4,4-ditropylcyclopentene-3,5-dione (IV), m. p. 103—104°C[5], indane-1, 3-dione (V), m. p. 132—133°C,[8] 2, 2-ditropylindane-1, 3-dione (VI), m. p. 167.5—168°C[5] [reported m. p. 173—174°C[9]]), sesquifulvalene-1, 4-quinone (VII), m. p. 179—180°C,[5] 2, 3-benzosesquifulvalene-1, 4-quinone (VIII), m. p. 244—245°C,[5] and 2, 3-dichlorosesquifulvalene-1, 4-quinone (IX), m. p. 263°C (decomp.).[5]



I R=R'=H
II R=$C_7H_7$; R'=H
III R=H; R'=Cl
IV R=$C_7H_7$; R'=Cl

V R=H
VI R=$C_7H_7$

VII R=H
IX R=Cl

VIII

The dipole moments of these substances were measured in benzene at 25°C using a high-inpedance a. c. bridge method described previously.[10] The benzene was purified as before.[10] The dipole moments were calculated using the method and equation of Halverstadt and Kumler:[11]

$$P_{2\infty}=(\varepsilon_1-1)/(\varepsilon_1+2)\cdot(v_1+\beta)M_2 + 3\alpha v_1 M_2/(\varepsilon_1+2)^2$$

$$\mu=0.012812\sqrt{(P_2-R_D)T}$$

The plots of $\varepsilon_{12}$ versus $w_2$ and $v_{12}$ versus $w_2$ were straight lines within the limits of experimental error. The values of $\varepsilon_1$ and $v_1$ were obtained by the method of least squares. The molar refractions, $R_D$, were calculated from the bond refraction data.[12] For 1, 2-dichlorocyclopentene-3, 5-dione and 1, 2-dichloro-4, 4-ditropylcyclopentene-3, 5-dione, however, because of their low dipole moments, the refractive indices at the D-line were measured using a Purflich refractometer, and the molar refractions were obtained from the following equa-

* The moment values in parentheses were obtained using the $R_D$ value calculated from bond refraction data.

tion, which is similar to Halverstadt and Kumler's:

$$R_D = (n_1^2-1)/(n_1^2+2)\cdot(v_1+\beta)M_2 + 3\gamma v_1 M_2/(n_1^2+2)^2$$

Where $\gamma$ is the slope of $n_1^2$ against $w_2$. The values of $n_1^2$ and $\gamma$ were also obtained by the method of least squares. The molar refractions thus obtained were in substantial agreement with the calculated values. The data are shown in Table I. The dipole moments of the diones and sesquifulvalene quinones are listed in Tables II and III respectively.

TABLE II. THE DIPOLE MOMENTS OF CYCLOPENTENE DIONE, INDANE DIONE AND SOME DERIVATIVES

| Compound | $\mu$, D. |
|---|---|
| Cyclopentene-3, 5-dione | 1.80 |
| 4, 4-Ditropylcyclopentene-3, 5-dione | 1.69 |
| 1, 2-Dichlorocyclopentene-3, 5-dione | 0.76 |
| 1, 2-Dichloro-4, 4-ditropylcyclopentene-3, 5-dione | 0.88 |
| Indane-1, 3-dione | 2.73 |
| 2, 2-Ditropylindane-1, 3-dione | 2.74 |

TABLE III. THE DIPOLE MOMENTS OF SESQUIFULVALENE QUINONE AND ITS DERIVATIVES

| Compound | $\mu$, D. | $\Delta\mu$, D. |
|---|---|---|
| Sesquifulvalene-1, 4-quinone | 2.85 | 4.27 |
| 2, 3-Benzosesquifulvalene-1, 4-quinone | 2.48 | 3.90 |
| 2, 3-Dichlorosesquifulvalene-1, 4-quinone | 4.91 | |

## Results and Discussion

**Cyclopentene- and Indane-diones.**—The fact that the dipole moment of 1, 2-dichlorocyclopentene-3, 5-diones is ca. 1 D. lower than that of unsubstituted cyclopentene-3, 5-dione evidently indicates that the moment of cyclopentene-3, 5-dione is directed towards the methylenic carbon from the center of the ring, the same direction as the carbonyl resultant moment.

In the case of cyclopentene-3, 5-dione, the substitution of two tropyl groups on the methylenic carbon results in a decrease of ca. 0.1 D. (1.69 D. compared with 1.80 D.), whereas with its dichloro derivatives an increase of almost the same value is revealed (0.88 D. compared with 0.76 D.). This indicates that the tropyl resultant moment is in the same direction as the C–Cl resultant and that these two moments are in the direction opposite to that of the C=O resultant; the moment of 1, 2-dichlorocyclopentene-3, 5-dione is, therefore, directed towards the C–Cl resultant. The moment of the tropyl group, therefore, seems to be ca. 0.1 D. larger than the C–H moment when the positive pole of the C–H moment is assumed to lie on the hydrogen atom. On the other hand, in the case of indane-1, 3-dione there is scarcely any change in the moment for a similar substitution of the tropyl groups (2.74 D. compared with 2.73 D.).

If one assumes the five-membered ring to be a regular pentagon, the two C=O groups make an angle of 144°. Using the bond moments $\mu_{C-H}=0$ and $\mu_{C=O}=2.3$ D.,[13] the moments of both cyclopentene-3, 5-dione and indane-1, 3-dione are calculated to be 1.4 D. The observed moments are both larger than those calculated, the difference being 0.4 D. with the former molecule and 1.3 D. with the latter. Such an increase in the moment, called the mesomeric moment, may be attributed to the charge transfer brought about through the resonance interaction from the ethylene or benzene group to the C=O groups, such as:

These values are very close to the incremental moments in going from maleic anhydride (3.91 D.[14]) to succinic anhydride (4.2 D.[15]) and from the latter to phthalic anhydride (5.27 D.[15]).

**Sesquifulvalene Quinone.**—If a change transfer does not occur between the five- and seven-membered rings, one would expect the dipole moments of sesquifulvalene-1, 4-quinone and its benzo derivative to be close to those of the corresponding diones which have been dealt with above. The experimental results for benzosesquifulvalene quinone seem nearly to bear this out, for it has a moment of 2.48 D. compared to the moment of 2.73 D. of indane-1,3-dione. On the contrary, the dipole moment of sesquifulvalene quinone is very high compared with that of cyclopentene dione, the difference in the moment being ca. 1 D. Thus these facts strongly suggest the possibility of a charge transfer interaction between the two rings present in these quinones. Regarding the direction of such a transfer, there are two possibilities to be considered, but one of them, transfer at the charge towards the seven-membered ring, is evidently in contradiction with the experimental data, as can be seen from a comparison of the moment of benzosesquifulvalene quinone with that of the corresponding indane dione. On the other hand, assuming that the transfer is oppositely

13) C. P. Symth, "Dielectric Behavior and Structure," McGraw-Hill Book Co., New York (1955), p. 245.
14) L. G. Wesson, "Tables of Electric Dipole Moments," The Technology Press, Cambridge, Mass. (1948).
15) M. G. A. Rau and N. Anantanarayanan, *Proc. Indian Acad. Sci.*, A5, 185 (1937).

directed towards the five-membered ring and that the moments due to it are 4.7 and 5.2 D. respectively, values which are very large compared with those of the diones, then the observed relationship between sesquifulvalene quinones and the corresponding diones may be satisfactorily explained. Accordingly, the decrease in the moment of sesquifulvalene quinone upon the addition of a fused benzene ring may be understood as being due to the increase in the moment opposed to the charge transfer from the seven-membered ring. If the above reasoning is correct, one would expect a very large moment for the 2, 3-dichloro disubstituted derivative of sesquifulvalene quinone because the C–Cl resultant takes the same direction as the moment of sesquifulvalene quinone. Theoretical calculation predicts a moment of 4.95 D. for such a compound, using the bond moment $\mu_{C-Cl}=1.3$ D. deduced from the moment of *o*-dichlorobenzene (2.26 D.).[14] In fact, a value of 4.91 D. was observed for this quinone, a value in good agreement with the predicted one.

Thus one arrives at the conclusion that a remarkably large amount of charge transfer takes place from the seven-membered ring towards the five-membered ring in these sesquifulvalene quinones and that, consequently, their dipole moments are as a whole in the same direction as the charge transfer, and opposite to the C=O resultant.

By making the reasonable assumption that the five-membered rings of these quinones have regular pentagonal structures, as in cyclopentene dione and indane dione, the C=O resultant is calculated to have a value of 1.4 D., as before. Accordingly, the increase from this value, $\Delta\mu=\mu_{total}-2\mu_{C=O}$, is calculated to be 4.3 D. for sesquifulvalene quinone and 3.9 D. for its benzo derivative by subtracting vectorially the C–O resultant from each observed value; surprisingly, they are both very large and directed from the seven-membered ring towards the five-membered ring, the former being 1.1 times higher than the latter. These incremental moments may be ascribed to the contribution of such polar structures as:

When the inductive effects due to the C=O groups are disregarded, it follows that:

$$\Delta\mu=\mu_{total}-2\mu_{C=O}=\mu^{\pi}{}_{total}-2\mu^{\pi}{}_{C=O}$$

Even though various values, ranging from 1.5 D. to 0.3 D.,[1] have been estimated for the $\pi$-moment of a C=O group ($\mu^{\pi}{}_{C=O}$), it can only be said that the $\pi$-moment of sesquifulvalene-1, 4-quinone should be greater than that of benzosesquifulvalene-1, 4-quinone.

The charge transfer moment towards the five-membered ring may be obtained as follows. Taking the moments opposed to it as equal to 0.4 D. and 1.3 D., which have been found in the dione compounds, then the required transfer moments turn out to be 4.7 D. for sesquifulvalene quinone and 5.2 D. for its benzo derivative, the latter value being 1.1 times higher than the former. Although the above assumption regarding the magnitudes of the opposite moments is open to question, it seems very likely that the charge transfer from the seven-membered ring would be larger in benzosesquifulvalene quinone. The greatest part of these transfer moments may, of course, be considered to be due to the migration to the C=O groups, as may be seen from the contribution of the various polar structures. The charge migration in these sesquifulvalene quinones are also shown by the molecular orbital calculations. The electronic structures and the spectral data of these compounds will be discussed in detail later.

## Summary

The dipole moments of some quinone derivative of sesquifulvalene, the corresponding dione compounds and their several derivatives have been measured in benzene at 25°C. The moments of cyclopentene-3, 5-dione and indane-1, 3-dione are in the same direction as the carbonyl resultant, the mesomeric moments being 0.4 D. and 1.3 D. respectively. On the other hand, the direction of the moments of sesquifulvalene-1, 4-quinone and its 2, 3-benzo derivative is just reversed because of a large transfer from the seven-membered ring towards the five-membered ring, presumably towards the carbonyl groups. The incremental moments, the difference between the observed and the carbonyl resultant, in these quinones are 4.2 and 3.9 D. respectively, while the moments due to the transfer from the seven-membered ring are 4.7 and 5.2 D., suggesting that such a charge transfer is greater in benzosesquifulvalene quinone.

# The Crystal Structure of Monoclinic Phenylhydrazine Hydrochloride, $C_6H_5NHNH_3Cl$

By Chung Hoe Koo*

(Received August 10, 1964)

Crystal structures of hydrazonium salts containing the $N_2H_6^{2+}$ ion, such as hydrazonium fluoride, $N_2H_6F_2$,[1] chloride, $N_2H_6Cl_2$,[2] and sulfate, $N_2H_6SO_4$,[3] and also hydrazinium salts containing the $N_2H_5^+$ ion, such as hydrazinium bromide, $N_2H_5Br$,[4] and chloride, $N_2H_5Cl$,[5] have hitherto been determined by X-ray methods. However, few of the structures of the substituted hydrazine salts have yet been examined. In order to obtain further information about the relationship among these structures of crystals, the substituent effects, and the nature of the chemical bonds in hydrazine salts, the present author has attempted to investigate the crystal structure of phenylhydrazine hydrochloride by means of X-ray analysis. During the preparation of the sample, it was found that this substance was dimorphous, one modification being monoclinic and the other orthorhombic. The crystal structure of the monoclinic modification was first determined; it will be reported on in the present paper and its structure discussed. The structure of the orthorhombic modification will be reported on shortly.

## Experimental

Single crystals for this work were obtained from saturated aqueons solution by slow evaporation at room temperature. The crystals were thin plates elongated along direction of the monoclinic c axis and showed an excellent cleavage parallel to the crystal plane (010).

Ni-filtered Cu$K\alpha$ radiation was employed in all X-ray experiments. The specimens used had the following cross-sections at right angles to the axes of rotation: $0.1\times0.15$ mm. for the c axis rotation, and $0.15\times0.2$ mm. for the a axis. Crystallographic data were obtained from oscillation and from Schiebold-Sauter and Weissenberg photographs of the equatorial and layer lines about two crystallographic axes (c and a). Photographs of the ($hk0$), ($0kl$) and ($hkl$) reflections were taken by means of an integrating Weissenberg camera for each zone, using the multiple-film technique. Intensities were estimated visually with the aid of standard intensity scales prepared by the exposure time method. The intensity ratios among the multiple-films were determined by the Geiger-Müller counter method. The corrections for polarization and Lorentz factors were made in the usual way. Relative values of the observed structure factors were then deduced by the ordinary procedure. No correction for the absorption was made because samll crystals were employed.

## Determination of the Structure

**Unit Cell and Space Group.**—X-Ray examinations show that the crystal belongs to the monoclinic system and has the following cell dimensions:

$$b=7.82\pm0.03\ \text{Å}$$
$$a=30.80\pm0.06\ \text{Å}$$
$$c=3.87\pm0.02\ \text{Å}$$
$$\beta=130.3^\circ\pm0.5^\circ$$

The space group was uniquely determined to be $C_{2h}^5-P2_1/a$ by the observed rules of absent reflections. Though accurate density measurement was difficult and the value thus obtained was rather poor, it was sufficient for the determination of the number of formula units in a cell-four formula units per unit cell. The calculated density is 1.344 g. $cm^{-3}$.

**Approximate Structure.** — Direct sign determination of the structure factors, using Harker-Kasper inequalities and Sakurai's chart,[6] gave only the signs of a few structure factors. Since the crystal has a heavy atom (chlorine), the position of this atom was easily determined by the interpretation of the two-dimensional peak-sharpened Patterson projections along the a and c axes. Further, since the lengths of the a and c axes are short, the positions of the phenylhydrazine group could be determined by a carerful interpretation of these Patterson maps. The approximate position of the chlorine atom was found to be (1/4, 0.05, 0). Ignoring the end nitrogen atom (in the present investigation, $N_{(2)}$), we can consider a symmetry axis of the phenylhydrazine group.

This axis was found to be approximately on (3/4, $y$, 0). The contribution of each atom except the end nitrogen atom $N_{(2)}$ to $F(hk0)$ and $F(0kl)$ of $k=2n+1$ was essentially zero for these approximate atomic parameters. However, by putting the $N_{(2)}$ atom in an appropriate position, the signs of a sufficient number of structure factors with $k=2n$ and a few signs of structure factors with $k=2n+1$ could be determined, so that the calculation of preliminary Fourier projections $\rho(xy)$ and $\rho(yz)$ could be carried out. After each three successive syntheses of Fourier projections along the c and a axes, it was found that the agreement between $F_o$ and $F_c$ in $F(hk0)$ and in $F(0kl)$ with $k=2n$ was much improved, whereas there still remain large discrepancies with $k=2n+1$, suggesting that either the chlorine atom or the symmetry axis of phenylhydrazine, or both, may not lie precisely on the special lines mentioned above.

**Refinement of the Structure.**—*xy-Projection.*—The refinement of the coordinates was carried out by the trial and error method at the first stage to find out the direction of the chlorine atom and the symmetry axis of the phnylhydrazine group from the two-fold screw axes, (1/4, $y$) and (3/4, $y$) respectively. The further refinement of this projection was carried out by successive $(F_o-F_c)$ syntheses. No attempt was made to introduce individual temperature factors. The temperature factor finally employed for all atoms in this projection was $\exp(-3.8\sin^2\theta/\lambda^2)$. The atomic scattering factors used in the calculation of the structure factors were those given by Berghuis et al.[7] The final value of the discrepancy index, $\sum||F_o|-|F_c||/\sum|F_o|$, was 0.15 for all ($hk0$)'s, and 0.10 if the unobserved $F_o$ was omitted. The final electron density map is shown in Fig. 1.

*yz-Projection.*—The refinement of the coordinates was carried out by the trial-and-error method and Fourier syntheses, but no $(F_o-F_c)$ synthesis was tried since all of the atoms in this projection were unresolved. After laborious work, the best $z$ coordinates were finally determined. The values of the discrepancy factor for this zone were 0.16 and 0.12 (if the unobserved $F_o$ was omitted). The temperature factor finally employed for this zone was $\exp(-3.6\sin^2\theta/\lambda^2)$. The final electron density map is shown in Fig. 2.

Two possible structures can be considered from the combinations of atomic coordinates which are determined independently from $\rho(xy)$ and $\rho(yz)$. The best agreement between

$F_o$ and $F_c$ for $F(hkl)$ in these cases was sought so as to find out one reasonable final combination of parameters. Thus, the three dimensional atomic parameters were determined to be as given in Table I.

Table I. Atomic parameters

| Atom | $x$ | $y$ | $z$ |
|---|---|---|---|
| $C_{(1)}$ | 0.7608 | 0.1225 | −0.0233 |
| $C_{(2)}$ | 0.9400 | 0.1429 | 0.0433 |
| $C_{(3)}$ | 0.9367 | 0.1888 | 0.0650 |
| $C_{(4)}$ | 0.7575 | 0.2092 | 0.0083 |
| $C_{(5)}$ | 0.5800 | 0.1883 | −0.0483 |
| $C_{(6)}$ | 0.5833 | 0.1425 | −0.0700 |
| $N_{(1)}$ | 0.7633 | 0.0754 | −0.0500 |
| $N_{(2)}$ | 0.6667 | 0.0492 | 0.0900 |
| Cl | 0.2433 | 0.0480 | 0.0167 |

The interatomic distances and bond angles calculated from the atomic parameters given in Table I are listed in Table II.

**The Accuracy of the Numerical Results.**—The standard deviations of the atomic coordinates estimated from the observed $\rho(xy)$ values are $\sigma(x_C)=0.006$, $\sigma(x_N)=0.005$ and $\sigma(x_{Cl})=0.002$ Å while those from the observed $\rho(yz)$ values are $\sigma(z_C)=0.013$, $\sigma(z_N)=0.012$ and $\sigma(z_{Cl})=0.005$ Å. The standard deviations of the C–N and N–N distances derived from these values are $\sigma(\text{C–N})=0.008$ and $\sigma(\text{N–N})=0.012$ Å.

## Discussion

Figure 3 shows the atomic arrangement in the crystal projected along the c axis. The figure shows the values of the interatomic distances. The N–N distance is 1.432 Å, with the standard deviation of 0.012 Å. This is significantly shorter than the N–N single bond found in the hydrazine molecule (1.47 Å in the gaseous state[8] and 1.46 Å in a crystal[9]). The value seems to be slightly larger than that in $N_2H_6^{2+}$ (1.40—1.42 Å) and smaller than that in $N_2H_5^+$ (1.45 Å), but such differences may not be significant in view of probable uncertainty of these values. Therefore, it is difficult to say that the N–N distance found in the phenylhydrazine ion is really affected by the substituted phenyl group.

The phenyl group has ordinary dimensions in this crystal. The C–N bond distance in the phenylhydrazine ion is 1.455 Å, the standard deviation being 0.008 Å. This is slightly shorter than the C–N single bond distance, 1.475 Å, given by Cox and Jeffrey[10] from a survey of many experimental values. Since this shortening is probably significant, there may exist a slight conjugation effect between the lone orbital on the nitrogen atom $N_{(1)}$ and the $\pi$-bond orbital on the carbon atom of the phenyl group. From the results of conjugation, the nitrogen atom $N_{(1)}$ has a positive net charge and, therefore, the proton affinity will become weak. Thus, when phenylhydrazine acts as a monoacidic base, the end nitrogen, $N_{(2)}$, will attract the acid proton, forming an $-NH_3^+$ group, and $N_{(1)}$ will remain as an imino –NH– group. This is in accord with the results of the present experiment; i. e., the distances of N···Cl show that $N_{(1)}$ should be the imino –NH– group and $N_{(2)}$, the amino $-NH_3^+$ group.

The direction of the N–N bond deviates far from the plane formed by the phenyl group and the N–C bond, the azimuthal angle being 67.2°. This shows that the conjugation between the phenyl $\pi$-orbital and the lone pair orbital on $N_{(1)}$ occurs to a certain extent. As a matter of fact, if the conjugation between the phenyl group and the lone pair on $N_{(1)}$ were sufficiently strong, three bond directions of the imino nitrogen atom (and hence the N–N

bond) would be coplanar with the phenyl group. Although the N–N bond deviates from the plane formed by the phenyl group, as has been observed, and the N–H bond lies on this plane, the conjugation is still possible should the –NH– group have a tetrahedral arrangement.

The phenyl group is significantly distorted. The C–C–C angles at $C_{(1)}$ and $C_{(4)}$ are 127.5° and 126.6° respectively; they are significantly larger than 120°. The C–C–C angles at $C_{(2)}$ and $C_{(5)}$ are significantly smaller than those at $C_{(1)}$ and $C_{(4)}$.

The end nitrogen atom, $N_{(2)}$, has three nearest chlorine neighbors, the N···Cl distances being 3.134, 3.162 and 3.224 Å. Besides, $N_{(2)}$ is in contact with the $N_{(1)}$ belonging to the neighboring molecule, the distance being 3.007 Å. Two of the $N_{(2)}$···Cl contacts, with 3.134 and 3.162 Å, and the $N_{(2)}$···$N_{(1)}$ contact with 3.007 Å may be hydrogen bonds. This arrangement more or less resembles that formed in $N_2H_5Cl$,[5] although the hydrogen bonds in the latter are slightly stronger than those of the former. From the point of view of atomic arrangement, the $N_{(2)}$···Cl with the distance of 3.224 Å is not a hydrogen bond. It is of interest to see that the $-NH_3^+$ groups in aniline hydrochloride[11] and cyclohexylamine hydrochloride[12] have no neighboring chlorine ion which is linked by a hydrogen bond.

The nitrogen atom, $N_{(1)}$, which is linked to the phenyl group has two nearest chlorine neighbors, the N···Cl distances being 3.356 and 3.430 Å. Although these distances are not short enough, the directions connecting $N_{(1)}$ with the two chlorine atoms in question extend in the same proper directions as the NH···Cl bonds. Since only one NH···Cl hydrogen bond is possible for $N_{(1)}$, we must decide which direction is the proper hydrogen bond. If the former is the direction of NH···Cl, the lone pair on the $N_{(1)}$ will lie nearly on the plane formed by the phenyl group, and, hence, the conjugation will not occur. On the other hand, if the latter is the NH···Cl hydrogen bond, the lone pair on the $N_{(1)}$ can reserve a tendency to conjugate with the phenyl group. Therefore, it may be reasonable that the N···Cl with the distance of 3.430 Å should be the weak hydrogen bond required by $N_{(1)}$ and that the N···Cl with the distance of 3.356 Å should be a van der Waals contact. Such very weak hydrogen bonds are also found in the crystal of hydrazinium chloride, where the $-NH_2$ group of $N_2H_5^+$ ion has three chlorine neighbors, and two of the N···Cl have proper directions as NH···Cl hydrogen bonds, the distances being 3.43 and 3.49 Å.

The slightly positive net charge on the $N_{(1)}$ atom due to some conjugation effect, as has been mentioned before, will decrease the proton affinity of $N_{(1)}$. This can explain the fact that the NH···N hydrogen bond (3.007 Å) in this crystal is slightly longer than that found in $N_2H_5Cl$, where the distace is 2.96 Å.

Phenylhydrazine ions are linked by the NH···N hydrogen bonds, which form an infinite zig-zag chain along the c axis. This type of linkage is different from that found in $N_2H_5Cl$ and $N_2H_5Br$, where the NH···N hydrogen bond makes infinite spiral chains.

The projections of the crystal structure along the c and a axes are illustrated in Figs. 3 and 4 respectively. The figures given show the interatomic distances. Each two phenylhydrazine and chlorine ions are linked into a pair by $NH^+$···Cl hydrogen bonds approximately on the (001) plane. Such dimers of

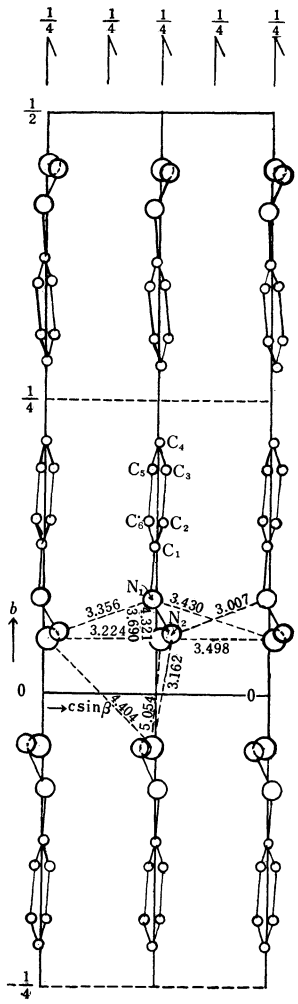

Fig. 4. Atomic arrangement in the crystal projected along the a axis giving interatomic distances.

positive and negative ions linked by hydrogen bonds are found in tropolone hydrochloride.[13] These pairs are linked by weak NH···N hydrogen bonds and are piled up into columns in the c axis direction. Such columns are linked by weak NH···Cl hydrogen bonds formed by $N_{(1)}$ atoms in the a axis direction.

As for the b axis direction, the phenyl groups are in contact with other phenyl groups by van der Waals force only; therefore, the cohesive force is not strong in this direction. This structural feature is compatible with the observed remarkable cleavage along the (010) plane.

It is of interest to compare the structure of the present crystal with those of aniline hydrochloride[11] and cyclohexylamine hydrochloride[12]. The structure of aniline hydrochloride is of a distorted caesium chloride arrangement, such as is also found in the structures of lower-membered alkylamine hydrochloride. On the other hand, cyclohexylamine hydrochloride crystallizes in a layer structure derivable from the sodium chloride arrangement, which is common in the structures of higher-membered alkylamine hydrochloride. It should be noted that the structure of phenylhydrazine hydrochloride has a remarkable layer structure, like cyclohexylamine hydrochloride, that each phenylhydrazine group is surrounded by six chlorine ions, and that each chlorine ion has six phenylhydrazine rings as its first neighbors. The packing is thus closely related to the sodium chloride type.

The author wishes to express his thanks to Professors Isamu Nitta, Tokunosuke Watanabé and Yujiro Tomiie for their continuous guidance and helpful discussions during the course of this research. This investigation was partly supported by a grant from the Ministry of Education. The author is also grateful for a scholarship awarded by the Korean Scholarship Foundation in Japan.

# Heats of Mixing for Binary Mixtures. II. The 1, 3-Butanediol-Methylethylketone System

By Mitsumasa TAKAMI, Sachio MURAKAMI and Ryoichi FUJISHIRO

(Received August 22, 1964)

In the previous paper,[1] we measured the heats of mixing of monoalcohol-ketone systems and estimated the value of the hydrogen-bond energy of the type O–H···O= to be about 4 kcal.

In order to make a further study of the interaction between alcohol and ketone, we measured the heats of mixing of the 1, 3-butanediol-methylethylketone system, together with those of the ethanol-methylethylketone system, in which an ethanol molecule may be regarded as a monomer of a butanediol molecule.

This paper will describe the results of the measurement and will discuss the existence of the intramolecular hydrogen bond in butanediol.

## Experimental

The apparatus used in this study was the one described in the previous paper,[1,2] except for a slight improvement in the calorimeter to make the handling easier. The calorimeter is shown schematically in Fig. 1.

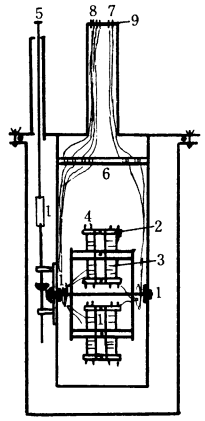

Fig. 1. Calorimeter.

7 Lead wire of the thermocouple
8 Lead wire of the heater
9 Harmetic seal

Commercial 1, 3-butanediol was distilled with a Stedman column through nitrogen gas under reduced pressure, and over the molecular sieves in a vaccum. Ethanol and methylethylketone were purified according to the method described in the literature[3] and were finally distilled over the molecular sieves through a long column.

## Results and Discussion

The heats absorbed when 1, 3-butanediol and methylethylketone were mixed in various proportions were measured at the temperature of 25.0±0.01°C; the results are shown in Table I, Fig. 2 and Fig. 3. The heats of mixing per mole of solution are shown as

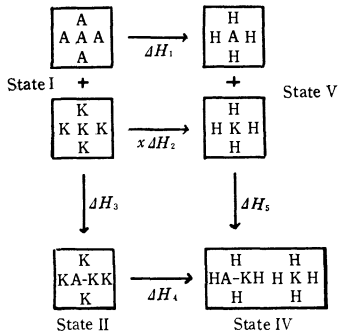

Fig. 4. The thermochemical cycle.

$$\Delta H^M = x_1(1-x_1) \times [1497.2-1673.5(1-x_1)+1698.7(1-x_1)^2]$$

$$\Delta H^M_{x_1} = \Delta H^M/x_1 = (1-x_1) \times [1497.2-1673.5(1-x_1)+1698.7(1-x_1)^2]$$

From these results, the $\lim_{x_1\to 0} \Delta H^M_{x_1}$ values of the butanediol-methylethylketone and ethanol-methylethylketone systems are found to be 1.88 and 1.52 kcal. respectively.

In the previous paper,[1] we estimated the intermolecular hydrogen bond energy of the type O–H···O= for the monoalcohol-ketone system by the use of the following equation, derived from the thermochemical cycle, as in Fig. 4:

$$\Delta H_5 = -\Delta H_1 - x\Delta H_2 + \Delta H_3 + \Delta H_4 \qquad (1)$$

$\Delta H_5$ is the intermolecular hydrogen-bond energy between alcohol and ketone molecules. $\Delta H_1$ is the energy needed to break the hydrogen bonds of pure alcohol by adding a large quantity of hexane, and $x\Delta H_2$ is the heat of dilution of $x$ moles of ketones by a large amount of hexane. $\Delta H_3$ is the energy of transfer from the pure alcohol state to one in which each alcohol molecule makes a hydrogen bonding with a ketone molecule and in which such complexes are surrounded with a

* $\mu$, $\alpha$ and $a$ are dipole moment, the polarizability and the molecular radius of the alcohol-ketone complex, respectively. They are estimated in the same way as that described in the previous paper (Ref. 1). $\Delta G$ and $\Delta H$ are the stabilization free energy and the stabilization enthalpy of the complex molecule in the medium. The suffixes K and H represent the media of ketone and hexane, respectively.

large amount of the ketone medium. $\Delta H_4$ consists of two energy changes. The first one is equal to $(x-1)\Delta H_2$. The second one is due to the different dipolar stabilization energies of the dipole of an alcohol-ketone complex arising from the reaction field with different media.

For the ethanol-ketone system, each $\Delta H_i$ term ($i=1$, 2, 3 and 4) in Eq. 1 may be estimated as follows. The heat of mixing for monoalcohol-hexane systems was measured and reported by Elbe[4] to be 5.8 kcal. at an infinite dilution, which is adopted as $\Delta H_1$ for ethanol. For $\Delta H_2$, we use 1.90 kcal., as measured in the previous paper.[1] $\Delta H_3$ is 1.52 kcal., which was obtained in this study. The dipolar part of the energy change in $\Delta H_4$ is calculated by the method described in the previous paper.[1] The necessary data in this calculation and the results obtained are summarized in Table III.

By using estimated values of $\Delta H_1$ to $\Delta H_4$ and Eq. 1, $\Delta H_5$ is calculated for the ethanol-methylethylketone system as:

$$\Delta H_5 = -5.80 - 1.90x + 1.52 + 2.40 + 1.90(x-1)$$
$$= -3.8 \text{ kcal.}$$

This energy is nearly the same as those derived in the previous paper.[1]

Butanediol is insoluble in any non-polar solvent, and the thermochemical cycle can not be applied to this system. Therefore, we must study the behavior of butanediol from the heats of mixing with ketone. If two hydroxyl groups in a butanediol molecule behave independently of each other, this molecule may be regarded as two ethylalcohol molecules, and the $\lim_{x_1 \to 0} \Delta H_{x_1}^M$ value for the butanediol-ketone system may be expected to be twice that for the ethylalcohol-ketone one, that is, $2 \times 1.52 = 3.04$ kcal., because each of these hydroxyl groups has a possibility of making a hydrogen bond with a ketone molecule. However, the actual value of $\lim_{x_1 \to 0} \Delta H_{x_1}^M$ for the butanediol system is 1.88 kcal., which is 1.16 kcal. ($=3.04-1.88$) lower than the expected value. This decrease may be ascribed to the interaction of two hydroxyl groups in the butanediol molecule. It is not unreasonable to say that a 1, 3-butanediol molecule has so favorable a molecular structure as to make the strong intramolecular hydrogen bond by its two hydroxyl groups, the energy of which may be estimated to be of the same order as that of the intermolecular one. Therefore, if the intramolecular hydrogen bonds are perfectly formed in the ketone medium (an infinitly diluted solution of butanediol in ketone) and are excluded in the pure butanediol state, $\lim_{x_1 \to 0} \Delta H_{x_1}^M$ must be 1.52 kcal., and the corresponding decrease of $\lim_{x_1 \to 0} \Delta H_{x_1}^M$ from the expected value will also be 1.52 kcal., because upon the perfect formation of intramolecular hydrogen bonds of butanediol in the ketone medium there remains only one hydroxyl group available to form a hydrogen bond with a ketone molecule for each butanediol molecule.

Assuming that there are no intramolecular hydrogen bonds in the pure butanediol state and that the energy of the intramolecular hydrogen bond is nearly the same as that of the intermolecular one, the fraction of the intramolecular hydrogen-bonded form will amount to 80% ($=1.16/1.52$) in the ketone medium.

4) G. von Elbe, *J. Chem. Phys.*, **2**, 73 (1934).

In order to confirm the assumption that hardly any intramolecular hydrogen bonds are formed in the pure butanediol, we must estimate the probability that butanediol molecules exist as the intramolecular hydrogen-bonded form. Since a butanediol molecule takes an intramolecular form or an intermolecular one, the probability of the former form is represented in the liquid state of butanediol as:

$$w_A = f_A \exp(-E_A/RT) / [f_{AA} \exp(-E_{AA}/RT) + f_A \exp(-E_A/RT)] \quad (2)$$

where $f_A$ and $f_{AA}$ are the weights at which the intramolecular and intermolecular forms occur, and $E_A$ and $E_{AA}$ are the intra- and inter-hydrogen-bonded energies of alcohol, respectively.

If we replace the butanediol medium which surrounds the butanediol molecule by ketone, we can obtain the state in which the butanediole molecule is surrounded by the ketone medium. This state corresponds to an infinitely dilute solution of butanediol in ketone. In this state, the probability of the intramolecular form is derived in a similar way as:

$$w_B = f_A \exp(-E_A/RT) / [f_{AK} \exp(-E_{AK}/RT) + f_A \exp(-E_A/RT)] \quad (3)$$

where $f_{AK}$ is the weight at which the intermolecular form with a ketone molecule occurs, and $E_{AK}$ is the intermolecular energy between alcohol and ketone molecules. If we tentatively put $E_A = -6$ kcal., $E_{AK} = -4$ kcal. and $w_B = 0.8$ in Eq. 3, we can obtain $f_{AK}/f_A \simeq 10$. To find $w_A$, we must estimate the order of $f_{AA}$. Since $f_{AA}$ and $f_{AK}$ are the weights of an intermolecular form in the alcohol and the ketone media respectively, they may not be very different in magnitude. If we put $f_{AA}/f_{AK} = 2$, that is, $f_{AA}/f_A \simeq 20$, in Eq. 2, considering that a butanediol molecule has a chance of making more intermolecular hydrogen-bonds (usually twice, as a proton donor and an accepter) in the pure state than in the ketone medium, $w_A$ may be estimated to be 5%.

The fact that butanediol liquid is very viscous and insoluble in any non-polar solvent may suggest that strong intermolecular forces act in the liquid state, overcoming the intramolecular forces. Therefore, we may say that, in the pure liquid state of butanediol, the amount of the intramolecular form will be in the range of a few %.

The discussion just mentioned was based on the assumption that the energies of both the inter- and the intra-molecular hydrogen bondings of butanediol are $-6$ kcal. It may easily be shown that as $E_A$ falls off from 6 kcal., the $\lim_{x_1 \to 0} \Delta H^M_{x_1}$ value of the butanediol-ketone system must move from 1.52 to 3.04 kcal. The actual value of 1.88 kcal. may indicate that $E_A$ is nearly equal to or a little less than $E_{AA}$.

Consequently, we may conclude that, in the ketone medium, a considerable amount of butanediol molecules or, rather, nearly all the molecules have intramolecular hydrogen-bonded forms, although in the pure state they are hydrogen-bonded with each other.

## Summary

The heats of mixing of 1, 3-butanediol and ethanol with methylethylketone have been measured. The results obtained for these two systems have been compared with each other, and it has been found that there exist a considerable number of intramolecular hydrogen bonds of butanediol molecules in the ketone medium.

For the ethanol-methylethylketone system, the energy of the intermolecular hydrogen bond with ketone has been estimated to be about 4 kcal. by using the thermochemical cycle; this value is nearly the same as those obtained for other monoalcohol-ketone systems in the previous paper.[1]

The authors wish to thank Dr. Ko Kimura for his kind advice. The cost of this work has been partly defrayed by a grant from the the Ministry of Education.

# Perchloro-(3,4-dimethylenecyclobutene)

By Akira FUJINO, Yoshikuni NAGATA and Takeo SAKAN

(Received July 6, 1964)

The dechlorination of perchloropropene in an anhydrous ether solution with several kinds of aluminum (chips, granules or powder) principally produces perchloro-(3,4-dimethylenecyclobutene) (I)[1-3] in quite good yields. In the sufficiently high dechlorination degree range, I is the only reaction product isolated in many runs. This result is remarkably different from that of Roedig's report,[4] in which perchlorofulvene (II), two perchlorohexatrienes ($\alpha$-: IIIa and $\beta$-: IIIb, respectively) and perchloro-4-methylenecyclopentene (IV) were given as the ordinary products duplicating the carbon atom number of this substrate, and in only two particular runs was there the poorly reproducible formation of I on the dechlorination of perchloropropane with granulated aluminum. Depending mainly on the reaction conditions, I in the product mixture is sometimes accompanied by perchloro-(3,4-dimethylenecyclobutane) (V),[1-5] m. p. 93°C, the dechlorination intermediate first obtained directly from perchloropropene. The identification of V has been established by comparing it with the specimen synthesized from 1,1,2,3,3-pentachloropropene.[6] It has also been found that V is easily dechlorinated with aluminum - aluminum chloride to give I.[1,3]

The aluminum metal used for the dechlorination is a comparatively pure one (ca. 99% for chips), with which alone the reaction does not start readily, as Roedig noted; a small amount of anhydrous aluminum chloride must first be added to the system. Even with this initiation, the autocatalytic acceleration of reaction is so mild that the whole system is necessarily heated to a violent refluxing. It has been found, however, that the pre-amalgamation of aluminum makes the reaction proceed far more smoothly, without the addition of the catalyst, and causes a remarkable increase in the yield of I up to 44% (chips, $D^*=54\%$), 51% (granules, $D=51\%$) and 62% (powder, $D=66\%$). In general, the incomplete corrosion-treament requires a prolonged reaction time, followed by the partial formation of V. The careful examination of Roedig's dechlorination of perchloropropene with the granulated aluminum - aluminum chloride available in the authors' laboratory has unexpectedly resulted in the random production of either I or II. Perchlorohexa-1,5-diene (VI), a primary coupling product of perchloropropene in Prins' method,[7] was not dechlorinated at all to yield I by amalgamated aluminum, but it was dechlorinated quantitatively to yield IIIa.

I (m. p. 147—148°C, colorless prisms with a slightly irritative odor, crystallized in the triclinic system from ether) is stable in the solid state, whereas it gradually decomposes with the evolution of hydrogen chloride, when allowed to stand in such solvents as ether, benzene and carbon tetrachloride; some of these solvents are, however, applicable in its recrystallization. The ultraviolet light irradiation (principally 2537Å) also destroyed I in

hexane at a markedly rapid rate. The detailed work on both the autodegradation in solution and the photochemistry will be reported later.

Contrary to the disordered results observed in the molecular weight determination of I by the Rast method,[8] the cryoscopic measurement with a fresh benzene solution afforded consistent values, which, however, confusedly became higher even after being stored for only 1/2 hr. The observed dipole moment is 0.43 D. This value is not, however, fully reliable as a result of the instability of the material in carbon tetrachloride.

By long heating with concentrated sulfuric acid at 100°C, I was partially converted, with the evolution of hydrogen chloride, to a carboxylic acid, m. p. 146—147°C, one which has not been yet characterized. A mild alkali-fusion test showed no indication that I has suffered from the degradation. I also resisted the bromine addition in chloroform, as commonly observed in perchloro-polyolefins, but it consumed permanganate in acetone almost instantly.

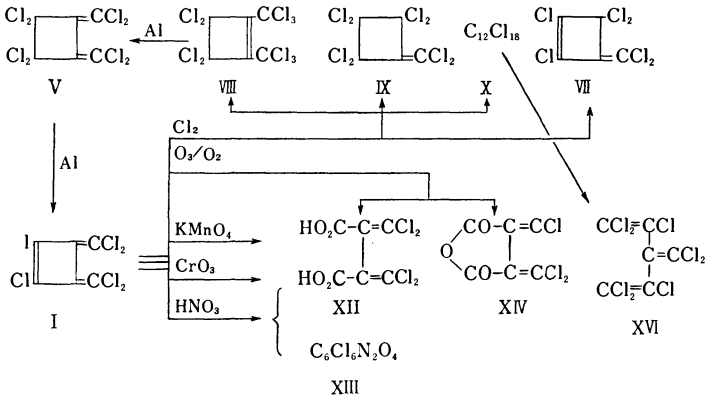
With a small excess of liquid chlorine in a sealed tube, I was converted in low yield to a chlorocarbon, $C_5Cl_6$ (VII), m. p. 77—78°C, to which the structure of perchloro-(3-methylenecyclobutene) has been assigned. When chlorinated with a large excess of the reagent for a short period, three crystalline products and an oily fraction were obtained: $C_6Cl_{10}$, perchloro-(1,2-dimethylcyclobutene), (VIII), m. p. 146—148°C, $C_5Cl_8$, perchloro-(1-methylenecyclobutane) (IX), m. p. 73—74°C; $C_{12}Cl_{18}$, possibly a dimeric chlorinated product (X), m. p. 163°C (decomp.), and an oil, b. p. 110—130°C(bath temp.)/0.008 mmHg. The purity of the oil remains equivocal.

An attempt to reduce I with zinc and alcohol to some hydrocarbon equivalent has been unsuccessful; the product was merely an amorphous solid mass, which had hardly been purified to serve as an analyltical sample.

The oxidation of I with potassium permanganate in acetone, chromic oxide in acetic acid, or fuming nitric acid always gave the same dicarboxylic acid (XII), $C_6Cl_4H_2O_4$, m. p. 215°C (decomp.), always in very low yields. The rate of oxidation is seemingly decreased in this order of reagents. No definite neutral products have been isolated in the first two cases, whereas, in the slowest nitric acid oxidation, a neutral nitrogeneous material (XIII), $C_6Cl_6N_2O_4$, m. p. 114—115°C (decomp.), was obtained. XII is doubtlessly perchloro-(dimethylenesuccinic) acid; it was converted, by refluxing it with acetic anhydride, to the corresponding anhydride (XIV), m. p. 119—120°C. which was then smoothly hydrolyzed to the original acid by heating it with an aqueous bicarbonate solution. Chart II summarizes the reaction schemes related to I.

## Discussion

Obviously, the most interesting feature of the preceding results is the course of reaction, which is distinctly different from that described by Roedig, whose extensive work pioneering this kind of dechlorination has mainly been concentrated on studies of the production of five-membered ring compounds and of acyclic olefinics. The purity of Roedig's aluminum chips has been reported to be 85—87% (with copper, silicon and zinc as the major impurities, in quantities of 4—5, 3—5 and 2—4% respectively), while the authors' chips in the routine use contain far less impurities (Cu, 0.04; Fe, 0.51; Si, 0.25%). Although Roedig noted the unsuitability of pure aluminum for the reaction, it has been



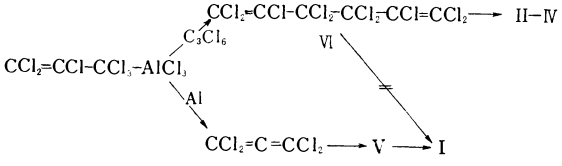


Chart II

8) The observed values are disorderly low as seen in the experimental. Although Roedig reported the value of 279[3] as observed by Rast, it seems highly probable that, with camphor, the thermal decomposition of I above 170°C will affect the determination result.

proved that even a high grade aluminum (99.99%) reacts, after amalgamation, with perchloropropene to give I (in a 55% yield) under essentially the same conditions. It is, therefore, possible to point out that the leading cause of the different results in the dechlorination reactions can be attributed to the quality of the metal, in which some foreign element might function specifically at an early stage of the reaction. The fact that I has not been produced in the dechlorination of VI by the amalgamation procedure strongly excludes the possibility that VI might be an intermediate in the process of the formation of I from perchloropropene. Thus, it is most likely that perchloroallene (XV) is an unstable precursor of V, the formation and the chemical behavior of which have recently been shown in the elaborate synthetic work[3] related to the dehydrochlorination of 1,1,2,3,3-pentachloropropene.

XV

It is also reasonable to assume that the formation of a four-membered ring could be possible only under some specifically accommodated participation of the allene components.[9] This mechanistic speculation would not, however, contradict the observation that I and II have seemed to be incompatible in the product of the Roedig's dechlorinations closely-reexamined with aluminum granules, since, particularly in this case, the metal reagent possibly has a lower and less homogeneous purity than the chips and also a wide-ranging size distribution, both of which more or less affect the reaction process.

The *D*-values determined and the yield of I are illustrated in Table I. So far as the aluminum chips are concerned, the whole reaction appears basically to proceed in a way similar to that of Roedig's reaction in terms of *D*-values (approximately 50—60%). In the runs with granules the *D*-values are much higher than those (less than 5%) reported, and no particular difference has been observed between the "amalgamated" and the "with aluminum chloride." Remarkable indeed is the difference between the two runs with aluminum powder, where the amalgamation causes a tremendous increase in *D* as well as in the yield of I.

Some interesting problems in the course of the structure investigations of I and other related compounds will be briefly discussed below.

The structure of VII is derived from the observation of the very close relationship of the ultraviolet spectral feature of this compouud and that of I, with only a small hypsochromic shift of $\lambda_{max}$ in the former, and from the fact that its infrared spectrum exhibits the $\nu_{C=C}$ doublet (1680 and 1580 $cm^{-1}$)** instead of the

** All IR spectra have been measured with Nujol mull unless noted.

triplet (1695, 1625 and 1550cm$^{-1}$ (KBr)) in I. The first $\nu_{C=C}$ band of I is noteworthy because of its extremely high frequency, which is probably next to the 1810 cm$^{-1}$ value in perchlorocyclopropene,[10] the highest ever observed in the chlorocarbon series. Conceivably, this band is connected with the presence of the endocyclic double bond involved in a four-membered ring. This interpretation further explains the respective presence and lack of band in the corresponding high frequency region in VII and IX. Special caution must be taken before assigning the 1625 cm$^{-1}$ band for VIII, since in position it coincides with the band in IX and rather seems to be for an exocyclic structure. The first reason to favor VIII, however, is its very weak intensity in contrast to the strong one for the double bond of the exocyclic type, as in IX. A >C=C< bond with no chlorine-substituent is suggested here. Secondly, if it has an exocyclic double bond, a considerably intense band can be expected to arise in the 930—900 cm$^{-1}$ range with reference to the $-\underset{|}{C}=CCl_2$ group in the molecule.[11] Only three weak peaks (955 vw, 905 vw and 895 w (cm$^{-1}$)) are practically found in this vicinity, however. In additional consideration of the chemical evidence for the skeletal structure of VIII, established through its dechlorinative conversion to V, the double bond in question can most easily be located at the $C_{1-2}$ position.

The assumption of an exocyclic double bond in IX could also be justified by interpreting the strong 910 cm$^{-1}$ band as characteristically arising from the $-\underset{|}{C}=CCl_2$ group. Although the complete elucidation of the structure of X is a future problem, it may be worth noting here that this chlorocarbon is decomposed above its melting point, or even at a lower temperature under a vacuum, to ε-$C_6Cl_8$ (XVI), m. p. 45°C, which was recently proposed to be perchloro-3-methylene-1, 4-pentadiene by Roedig[2] on the basis of its Raman spectroscopic analysis.

The structure of perchloro-(dimethylenesuccinic) acid was earlier suggested for a carboxylic acid, with an m. p. of 219°C (decomp.), obtained by the alkaline hydrolysis of α, α'-bis-trichloromethylsuccinic acid (XVII),[12] a minor by-product in the reaction of diethyl maleate with benzoyl peroxide in carbon tetrachloride. The re-investigated runs of this reaction have not, however, reproduced XVII and so made the final identification of XII impossible. Nevertheless, the interpretation of the infrared spectrum of XIV leaves little doubt about the structure of XII, since the possible alternatives may all be excluded on the basis of either extremely high carbonyl frequencies (1835 and 1765 cm$^{-1}$) and the magnitude of $\Delta\nu_{C=C}$[13] (70 cm$^{-1}$), or two closely-located bands (930 and 920 cm$^{-1}$) assigned to the two exocyclic dichloromethylene groups. Roedig reported the production of only chloropicrin and oxalic acid dihydrate in the nitric acid oxidation of I, but the small amount of XII and XIII may have been overlooked. The application of ozone to I also affords XII and XIV. It is, however, obscure whether or not the real attack of ozone has occurred in this degradation, because I is very readily decomposed to XII, even with oxygen in some moistened organic solvents, as will be reported in the succeeding paper.

The formation of XIII in the oxidation is interesting enough to mention, since it would be the first case that I is converted to a nitrogeneous compound without losing any chlorine atom in the molecule. The infrared absorption band at 1580 vs and 1315 s (cm$^{-1}$) reveals at least one nitro-group attached to the carbon with two chlorine atoms.[14] The very high intensity of the former band is partially due to the $\nu_{C=C}$ absorption. The investigation is present under way to clarify the structure of XIII.

The ultraviolet absorption spectra data do not seem capable of giving sufficient information about the structural problem of the products mentioned above unless some more compounds of various and appropriate types of four-membered cyclic chlorocarbons are available. However, it is interesting to emphasize that the estimated wavelength values for VII and VIII are in good accordance with those observed, if, on the basis of the available data, the bathochromic displacement factors caused by chlorine substitution (+8.5 mμ for a vinylic substituent,[15] +7.5 mμ for an allylic one,[16] and +10 mμ for a trichloromethyl group attached to the unsaturated carbon,[16]) are taken into account. An extraordinarily large bathochromic shift (+64 mμ) of the $\lambda_{max}$ in the K band from 1, 2-dimethylenecyclobutane[17] to V can also be rationally explained by the con-

11) Unpublished. From the accumulated IR data of perchlorocarbons it may be noted that the compounds holding $-\underset{|}{C}=CCl_2$ group in the molecule generally give a strong absorption band in the range of 930—900 cm$^{-1}$, while those with $-\underset{Cl}{\underset{|}{C}}=CCl_2$ group absorb in some higher frequency range, 965—940 cm$^{-1}$.

sideration that such a larger increment is due to the allylic chloro-substitution on the four-membered ring carbon rather than to that (less than $+5m\mu$) in the case of five-membered cyclic compounds.[18]

Roedig et al.[3] suggested the lack of an extended conjugation in I on the basis of the close relationship between the K bands in the ultraviolet spectra of I and those of the corresponding hydrocarbon,[19] which also exists as a cross-conjugated form. The particularly high reactivity of the $C_{1-2}$ double bond in I suffices to reflect this indication. It is, therefore, eagerly desirable to make, in the near future, an extensive stereochemical study of whether or not the whole molecule, or, more interestingly, the cyclobutene ring itself, of I is twisted under the influence of its vicinal dichloromethylene groups. If the van der Waals radius of 1.80 Å for the chlorine atom operates in I, it is not possible to keep all four chlorine atoms in the groups coplanar; in addition, its spacial requirement appears to be too large to afford the distortion of only two severely interacting C–Cl bonds (one bending up and one down, from the $sp^2$ plane of each methylene carbon).

## Experimental

**Starting Materials.**—Hexachloropropene was prepared from 1,1,1,2,2,3,3-heptachloropropane[20] by dehydrochlorination according to the literature[21]; b. p. 103—104°C/28 mmHg.

*Aluminum Amalgam.*[22]—A necessary amount of aluminum was corroded thrice with 4 ml./g. (Al) of a 10% aqueous solution of sodium hydroxide and then amalgamated thrice with 5 ml./g. (Al) of a 0.5% aqueous mercuric chloride solution. After having been carefully washed with water, ethanol, ether and anhydrous ether, the compound metal was immediately covered with anhydrous ether in the volume necessary for the reaction.

**The Dechlorination of Perchloropropene. The Production of Perchloro-(3, 4-dimethylenecyclobutene) (I) (An example).**—In a three-necked, round-bottomed, 500 ml.-flask, fitted with a mechanical stirrer and a reflux condenser, the top of which was connected to a calcium chloride tube, an aluminum amalgam (5.0 g. Al) was prepared as has been mentioned above; then 20.2 g. (0.081 mol.) of perchloropropene was vigorously stirred into the contents. The volume of the solvent was 75 ml., including that for rinsing. The exothermic reaction soon occurred, and the solution came to have a tinge of yellow. After an 8-hr. refluxing, the reaction mixtre was allowed to cool; it was then separated into the dark brown muddy material and an ether solution by filtration. The former was decomposed with 10% nitric acid, and the latter with water. The residual dark brown amorphous solid was repeatedly extracted with ether.

The combined ethereal solution was washed with water, shaken with the saturated aqueous sodium bicarbonate solution, and dried over calcium chloride. On the removal of the solvent, the residual oil began to crystallize and afforded the crude product of I (7.2 g.; 62% of the theoretical yield). Vacuum sublimation (110—120°C/5 mmHg) and recrystallization from ether produced the analytical sample as colorless prisms; m. p. 147—148°C.

Found: C, 25.57; H, 0.49; Cl, 74.93. Calcd. for $C_6Cl_6$: C, 25.30; H, 0.00; Cl, 74.70%. Mol. Wt. Found: 238, 230 (Rast method with camphor); 289, 278 (cryoscopic method with benzene). Calcd. for $C_6Cl_6$: 285.

The aqueous solutions were combined, and 5 ml. taken from the whole was titrated with a N/10-silver nitrate solution, using uranine as an indicator to determine the degree of dechlorination.

After having been recovered from the bicarbonate solution by acidification and ether extraction, the acidic fraction gave a small amount of a white crystalline solid, which was recrystallized twice from ligroin; m. p. 74—75°C (perchloroacrylic acid[4]; m. p. 76—77°C).

**The Formation of Perchloro-(1, 2-dimethylenecyclobutane) (V).**—In some runs similar to the above, the sublimate of the crude product showed a lower melting point with a wide range (e. g., 118—134°C). The crops collected from the mother liquor in the course of recrystallizations from ether furnished, after several recrystallizations from benzene, hexagonal plates of V with an m. p. of 92—93°C. Although I is a little more volatile than V, an attempted separation of I from V by means of fractional vacuum sublimation was not successful.

Found: C, 20.52; H, 0.69; Cl, 80.38. Calcd. for $C_6Cl_8$: C, 20.26; H, 0.00; Cl, 79.74%.

**The Synthesis of V from 1, 1, 2, 3, 3-Pentachloropropene.**—According to Prins' method,[23] 1,1,1,2,3,3-hexachloropropane (65 g.), b. p. 95—97°C/14 mmHg, $n_D^{24}$ 1.5213, was obtained from chloroform (300 g.), trichloroethylene (131 g.) and aluminum chloride (30 g.). Subsequent dehydrochlorination[24] in carbon tetrachloride (65 ml.) with aluminum chloride (0.78 g.) at 30—40°C for 1/2 hr., followed by refluxing for 4 hr., gave 1, 1, 2, 3, 3-pentachloropropene (44 g., 80%), b. p. 75—76.5°C/19 mmHg. Further dehydrochlorination with the base-paste (potassium hydroxide, 36.9 g.; calcium oxide, 26.3 g., and water, 7.4 g.) suspended in benzene (70 ml. in all) in accordance with the manner previously described[6] resulted in the production of V (17 g., 36.5%). Recrystallization from trichloroethylene-ethanol afforded white prisms, with an m. p. of 91—92°C, which were identical in all respects (mixture m. p. test, ultraviolet and infrared absorption spectra) with those obtained from perchloropropene.

**The Chlorination of I.**—*a) With a Small Excess of Chlorine.*—In a thick-walled sealed glass tube, 3.0 g. of I and 2.0 g. (a 2.8 mol. equivalent) of liquid chlorine were allowed to stand for 3 weeks. After the evaporation of the unreacted chlorine, the residue (4.05 g.) was separated into two parts: 0.09 g. of crystals, m. p. 63—76°C, and the filtrate, from which the second crop (1.05 g.) of the solid material crystallized out. The former was repeatedly recrystallized from ethanol until it became a pure sample, with an m. p. of 78—79°C. UV: $\lambda_{max}^{EtOH}$ 236 (32000), 278 (7000), $\lambda_{sh}$ 228 (26000), 244 (22000), $\lambda_{min}$ 256 (5500) mμ (ε).

Found: Cl, 78.34. Calcd. for $C_5Cl_6$: Cl, 77.99%.

The second crystals, after having been washed with ethanol, melted at 43—60°C. Either vacuum sublimations or recrystallizations from methanol and ethanol gave unpurified samples which showed a fairly intense absorption peak at 310 mμ. The filtered viscous oil was 0.98 g.

*b) With a Large Excess of Chlorine.* — The same amount of I was treated with about three times as much liquid chlorine as in the experiment above. The total content was ca. 6 ml. The reaction mixture became clear in 72 hr., after which period the sealed tube was opened. By passing nitrogen gas through, a viscous crystal sludge was obtained. After filtration, 1.2 g. of a solid, white material was recrystallized from benzene-ethanol as VIII, m. p. 146—148°C. 0.35 g.

Found: C, 17.17; H, 0.39; Cl, 83.18. Calcd. for $C_6Cl_{10}$: C, 16.89; H, 0.00; Cl, 83.11%. UV: $\lambda_{max}^{EtOH}$ 223 mμ (ε 8200).

Methanol was added carefully to a slightly greenish yellow viscous filtrate (3.2 g.) dissolved in benzene. The deposited mass was filtered and recrystallized from ether to afford a colorless pure sample of X, m. p. 163°C (decomp.). 0.20 g.

Found: C, 18.78; H, 0.33; Cl, 81.48. Calcd. for $(C_4Cl_6)_x$: C, 18.42; H, 0.00; Cl, 81.58%. UV: $\lambda_{max}^{EtOH}$ 224 mμ (ε 12000); IR: $\nu_{C=C}$ 1600 s cm$^{-1}$.

After the removal of the solvent, the oily fraction was distilled; b. p. 110—130°C (bath temp.)/0.008 mmHg; a colorless clear distillate.

Found: C, 17.76; H, 0.64; Cl, 81.66%.

This sample turned turbid very gradually. When it was stored over two years about one-fifth of the oil crystallized. The separated solid (0.30 g.) melted at 73—74°C after recrystallization from ether-methanol.

Found: C, 17.47; H, 0.61; Cl, 83.07. Calcd. for $C_5Cl_8$: C, 17.47; H, 0.00; Cl, 82.55%. UV: $\lambda_{max}^{EtOH}$ 223 mμ (ε 6500).

The residual oil weighed 1.50 g.

**The Oxidation of I.**—*a) With Potassium Permanganate.*—Into a solution of 50 g. of I in 350 ml. of acetone, 10.1 g. of potassium permanganate dissolved in 510 ml. of the same solvent was stirred at room temperature. The decolorization of the reagent occurred very quickly. Manganese dioxide was removed by filtration and boiled thrice with 100 ml. of water. The filtrate was, after the evaporation of acetone, dissolved in ether in order to be shaken with a saturated aqueous sodium bicarbonate solution. One gram of crude I was recovered from the dried ether solution. The acidified bicarbonate solution and the concentrates of the combined hot water extracts gave, through separate ether extractions, 45 mg. and 11 mg. of perchloro-(dimethylenesuccinic acid), XII, which were combined and recrystallized from ether to a pure sample; m. p. 214°C (decomp.).

Found: C, 26.41; H, 0.92; Cl, 51.08. Calcd. for $C_6Cl_4H_2O_4$: C, 25.75; H, 0.72; Cl, 50.67%.

*b) With Chromic Trioxide.*—To the 100 ml.-solution of acid containing 1.40 g. of chromic trioxide and a trace of water, 1.00 g. of I was added and the mixture was allowed to stand for 48 hr. After the reduction of the excess oxidizing reagent with methanol, the solvent was removed under diminished pressure. A small amount of water was added, and the product was isolated in the usual manner. The acidic fraction gave only a trace of crystals, m. p. 214°C (decomp.) which were pressed on the clay plate, washed with chloroform, and identified with the XII obtained by the nitric acid oxidation of I through infrared sepectra comparison.

*c) With Fuming Nitric Acid.* — Five grams of I was oxidized with 1.0 ml. of fuming nitric acid (sp. gr. 1.52) by warming it on a steam bath until all the excess oxidizing reagent was evaporated off. The ether solution of the remaining oil gave, after being shaken with a bicarbonate solution and upon the evaporation of the solvent, a viscous oil (0.69 g.), from which the pale yellow crystals were precipitated on cooling. The crystals were collected by filtration; 2.27 g. of XIII; m. p. 103—108°C. Recrystallization from methanol elevated its m. p. to 114—115°C (decomp.).

Found: C, 19.47; H, 0.56; N, 7.48; Cl, 56.31. Calcd. for $C_6Cl_6N_2O_4$: C, 19.12; H, 0.00; N, 7.43; Cl, 56.41%. UV: $\lambda_{max}^{EtOH}$ 318 (14500); $\lambda_{sh}$ 328 (13500); $\lambda_{min}$ 265 (2700) mμ (ε). IR: $\nu_{C=C}$ 1610 m, 1580 vs cm$^{-1}$.

0.13 g. of crystals of m. p. 215°C (decomp.) were obtained from the acidified bicarbonate solution.

Found: C, 26.14, H, 1.44; Cl, 51.13%. UV: $\lambda_{max}^{EtOH}$ 230 mμ (ε 13900); IR: $\nu_{C=O}$ 1790 s; $\nu_{C=C}$ 1580 s, 1560 s cm$^{-1}$.

The oily acidic fraction weighed 1.12 g.

**Anhydride (XIV) Formation from perchloro-(dimethylenesuccinic) Acid.**—Thirty milligrams of XII was refluxed at 140—145°C with 0.5 ml. of acetic anhydride for 1/2 hr. in a small tubing vessel equipped with a cold finger. After the reaction had been completed, the cold finger was taken off and the unreacted acetic anhydride and acetic acid were thoroughly removed by heating the mixture on a steam bath under reduced pressure. Vacuum sublimation was applied to the residue. At ca. 100°C (bath temp.)/5 mmHg, 25 mg. of white crystals were obtained. Repeated sublimations gave a pure sample with an m. p. of 119—120°C.

Found: C, 27.83; H, 0.37; Cl, 54.01. Calcd. for $C_6Cl_4O_3$: C, 27.52; H, 0.00; Cl, 54.15%. UV: $\lambda_{max}^{cyclohexane}$ 227 (13300), 300—303 (12400); $\lambda_{min}$ 250 (3700) mμ (ε); IR: $\nu_{C=O}$ 1835 m, 1765 s; $\nu_{C=C}$ 1580 s, 1543 s cm$^{-1}$.

XIV was heated with a saturated aqueous sodium

bicarbonate solution until the all crystals had dissolved completely. The regenerated material was extracted with ether from the acidified solution, followed by the usual procedure. The acid thus obtained melted at 212°C (decomp.) and gave an infrared chart identical with that of XII.

**The Ozonolysis of I.**—A stream of ozone was passed for 5 hr. under cooling (0°C) through a 40 ml.-chloroform solution in which 2.0 g. of I was dissolved. The removal of the solvent under reduced pressure gave a greenish yellow oil which began to evolve hydrogen chloride when it was left in the air. When heated with a small amount of water for 10 min., the ozonide was thoroughly decomposed.

By the usual procedure, 108 mg. of the crystalline product, XIV, with an m. p. of 119—120°C, was obtained from the neutral oil. The acidic fraction (662 mg.) also partly crystallized to the carboxylic acid, m. p. 215°C(decomp.), identical with that of XII.

**The Dechlorination of V to I.**—In a three-necked, 50 ml.-flask, 360 mg. of I was dissolved in 15 ml. of anhydrous ether. Fifteen milligrams of aluminum powder and 2—3 mg. of anhydrous aluminum chloride were then added to the solution, and the solution was refluxed for 3 hr. under vigorous stirring. The same treatment as the usual dechlorination furnished 276 mg. (95%) of white crystals, m. p. 146—148°C, which were in all respects identical with I.

**The Partial Dechlorination of Perchloro-(1, 2-dimethylcyclobutene) (VIII) to V.**—A mixture of 170 mg. of VIII, 250 mg. of aluminum powder, and 30 mg. of anhydrous aluminum chloride in 15 ml. of anhydrous ether was heated under refluxing for 5 hr. After ordinary handling, the neutral oil was kept in a refrigerator for 5 days. The crstallized solid was filtered and purified by vacuum sublimation. White crystals; m. p. 120—127°C; 40 mg. From ultraviolet and infrared spectra it was inferred that the mixing ratio of V to VIII was ca. 0.8.

**The Dechlorination of Perchlorohexa-1, 5-diene (VI) with Amalgamated Aluminum.**—A mixture of 1.50 g. of VI, synthesized by the action of cuprous chloride on perchloropropene in methanol-water,[7] 0.150 g. of amalgamated aluminum chips (99.99% pure) and 30 ml. of anhydrous ether was stirred for 1.5 hr. at room temperature and then heated under refluxing for the same period. The neutral product was distilled at 110—120°C (bath temp.)/0.09 mmHg. The infrared spectrum of this distillate was identical with the IIIa synthesized by the dechlorination of VI with alcoholic potassium hydroxide in acetone.[25]

The authors wish to express their thanks to Mr. Junichi Goda of Osaka City University, Miss Kiku Koike of the Institute for Protein Research (Osaka University), and Dr. Junichi Kawanami of the Shionogi Pharmaceutical Co. for their elemental analyses; to Miss Hiromi Tokuda of Osaka City University for her infrared spectra measurements, and Dr. Ko Kimura of Osaka City University for the dipole moment datum.

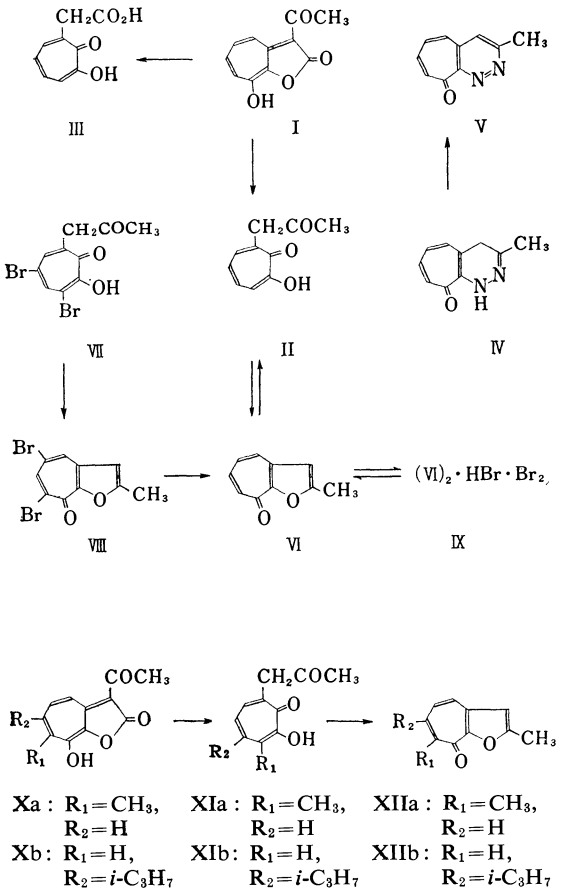
# The Synthesis and Some Reaction of 3-Acetonyltropolones

By Kahei TAKASE



(Received August 19, 1964)

In a previous paper,[1] it was described how 3-acetyl-8-hydroxy-1-oxaazulan-2-one (3-acetyl-8-hydroxy-2*H*-cyclohepta[b]furan-2-one) (I) was obtained by the condensation reaction of 3-bromotropolone and ethyl acetoacetate. By the extension of this reaction to alkyl derivatives of 3-bromotropolone, the alkyl derivatives of I were also synthesized.[1] During the studies of the examination of their chemical behavior, it has been found that the alkaline hydrolysis of I affords 3-acetonyltropolone (II). Since the tropolone derivatives with a carbonyl function in their side-chain are very interesting in the synthetical studies of troponoid, the synthesis and some reactions of 3-acetonyltropolones have now been examined.

When 3-acetyl-8-hydroxy-1-oxaazulan-2-one (I) was heated in hydrobromic acid, it was converted into 3-carboxymethyltropolone (III), as has been reported.[1] However, when heated

1) K. Takase, This Bulletin, 37, 1460 (1964).

in a potassium hydroxide or sodium hydroxide solution, the compound I gave a ketonic compound II, from which an oxime, a semicarbazone, a phenylhydrazone and a 2,4-dinitrophenylhydrazone were derived. The tropolonic nature of II was shown from the facts that it was soluble in alkali, showed a positive ferric chloride coloration, and gave a green copper chelate. Its ultraviolet absorption spectrum, which is similar to that of 3-methyltropolone,[1] also supports its tropolonic structure. From these evidences and its elemental analysis, II is assumed to be 3-acetonyltropolone, produced by the hydrolysis of the lactone ring of I, followed by decarboxylation. It is interesting that, when heated with a sodium methoxide solution, I did not hydrolize into II, but was converted into 3-carboxymethyltropolone (III). It is known that the treatment of acetoacetic esters with dilute alkali gives ketones by ketonic hydrolysis, but with sodium alcoholate, esters are obtained by acidic hydrolysis.[2] In the case of I, it was found that a similar cleavage was also caused by sodium methoxide.

Xa: $R_1=CH_3$, $R_2=H$ XIa: $R_1=CH_3$, $R_2=H$ XIIa: $R_1=CH_3$, $R_2=H$

Xb: $R_1=H$, $R_2=i\text{-}C_3H_7$ XIb: $R_1=H$, $R_2=i\text{-}C_3H_7$ XIIb: $R_1=H$, $R_2=i\text{-}C_3H_7$

Although II produced the normal carbonyl derivatives in the reaction with the usual carbonyl reagents, as has been mentioned above, when heated with hydrazine it gave a bicyclic compound: 1,4-dihydro-3-methylpyridazo[3,4-b]tropone (IV). Its structure was deduced on the basis of the facts that it was insoluble in alkali and showed a negative ferric chloride coloration. Its ultraviolet absorption spectrum is similar to those of alkylidene derivatives of 2-hydrazinotropones,[3] as is shown in Fig. 1, and its infrared spectrum shows the absorption of an N–H stretching vibration of secondary amine at 3270 $cm^{-1}$. The compound IV was dehydrogenated by treatment with nitric acid, affording 3-methylpyridazo[3,4-b]tropone (V), whose ultraviolet absorption spectrum is shown in Fig. 1.

When heated in concentrated sulfuric acid or hydrochloric acid, II gave a basic compound VI, which in turn produced a picrate and a styphnate. This compound did not show the tropolonic enolone or the carbonyl nature;

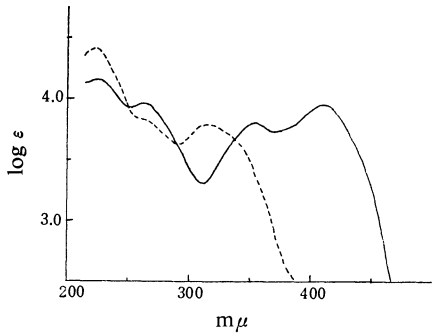


Fig. 1. The ultraviolet absorption spectra of 1,4-dihydro-2-methylpyridazo[3,4-b]tropone (IV); ——, and of 2-methylpyridazo[3,4-b]-tropone (V); ----, in methanol.

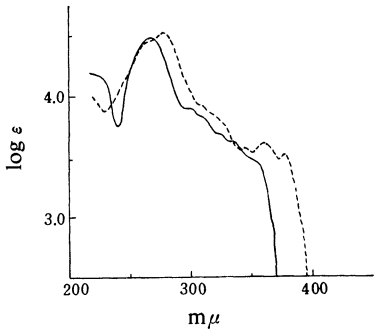

Fig. 2. The ultraviolet absorption spectra of 2-methylfuro[2,3-b]tropone (VI); ——, and of 5,7-dibromo-2-methylfuro[2,3-b]tropone (VIII); ----, in methanol.

2) C. R. Hauser and B. E. Hudson, Jr., "Organic Reactions," Vol. 1, pp. 266-302.

3) K. Takase, This Bulletin, 37, 1288 (1964); T. Nozoe and J. Shin, to be published.

it was insoluble in alkali, showed a negative ferric chloride coloration, and did not give any carbonyl derivative. In its infrared spectrum in KBr, no absorption appears in the region of the stretching vibration of the tropolonic hydroxyl or of the carbonyl of the acetonyl group. However, when VI was heated in a dilute alkali solution, the tropolone (II) was reproduced. These facts show that VI has the same carbon-skeleton as II, but the tropolonic hydroxyl group and the carbonyl group in the side-chain are masked. From these evidences and its elemental analysis, VI is assumed to be 2-methylfuro[2,3-b]tropone produced from II by ring formation under dehydration. Its ultraviolet absorption spectrum, as is shown in Fig. 2, is considerably different from those of tropones or tropolones in the long wave region (300—400 m$\mu$). This fact shows that VI belongs to a new aromatic ring system.

The behavior of II in relation to some cationoid reagents, such as aryldiazonium salt or bromine, was also examined. When treated with a *p*-toluenediazonium chloride solution, II gave an azo compound, in which the position of the azo group is assumed to be at the 5-position, in analogy to the other azotropolone.[4]

The bromination of II in methanol, in the presence of sodium acetate, afforded a dibromo compound VII, which is assumed to be 5,7-dibromo-3-acetonyltropolone since it is soluble in alkali, shows a positive ferric chloride coloration, and gives a 2,4-dinitrophenylhydrazone. The positions of the bromines were inferred from the following evidence. It was expected that the compound which brominated in the acetonyl side-chain would be unstable to alkali, but this compound was stable. On the other hand, it is well-known that the bromination of the tropolone nucleus is easily attained at the 3, 5 or 7-position.[4] When the bromination of II was undertaken in methanol without the presence of sodium acetate, VII could not be obtained, but a dibromo compound VIII was produced, accompanied with the formation of VI. The dibromo compound VIII was also obtained when VII was heated with concentrated sulfuric acid. The ultraviolet absorption spectrum of VIII is similar to that of VI, as is shown in Fig. 2. The reductive debromination of VIII afforded VI. From these facts, VIII is assumed to be 5,7-dibromo-2-methylfuro[2,3-b]tropone. Since VI did not gave any brominated compound under these conditions, the formation of VIII from II is considered to proceed through VII, which is produced by the bromination of II and which then forms the furan ring by the action of hydrogen bromide in a way similar to that of II.

The furo[2,3-b]tropone (VI) changed to 3-acetonyltropolone (II) by alkali, as has been mentioned before, but it was very stable to acid. It resists the action of the cationoid reagents, such as nitric acid, nitrous acid or aryldiazonium salts. The bromination of VI in acetic acid did not give the brominated compound, but it produced a complex compound IX, which easily reproduced VI when treated with a sodium hydrogen sulfite solution. Similar complex compounds of tropone[5] or tropolone[6] and bromine have been known, but IX is more stable than the corresponding tropone- or tropolone-complex; the former could not be converted into an addition or substitution product, while the latter could. When treated with *N*-bromosuccinimide, VI gave a monobromo compound, which is considered from its ultraviolet absorption curves to be a bromo-substituted derivative of VI but the position of the substitution is not yet clear.

The alkyl derivatives of I, 3-acetyl-7-methyl-8-hydroxy-1-oxaazulan-2-one (Xa) and 3-acetyl-6-isopropyl-8-hydroxy-1-oxaazulan-2-one (Xb)[1] also gave 3-acetonyltropolone derivatives (XIa and XIb) by alkaline hydrolysis. These compounds showed a positive ferric chloride coloration and reacted with carbonyl reagents in a manner similar to II. When they were treated with concentrated sulfuric acid, furo[2,3-b]-tropone derivatives (XIIa and XIIb) were obtained. The chemical behaviors of these compounds were similar to those of VI; they were insoluble in alkali and gave a picrate and a styphnate respectively. Their ultraviolet absorption curves are also similar to that of VI.

## Experimental[7]

**3-Acetonyltropolone (VI).** — A solution of I (1.00 g.) in a 2 N potassium hydroxide solution (10 ml.) was heated under reflux for 3 hr., and then the mixture was acidified with 6 N hydrochloric acid and extracted with chloroform. The solvent was evaporated and the residue was recrystallized from cyclohexane to give II (550 mg.) as colorless needles, m. p. 86—87°C.

4) Cf. T. Nozoe, *Fortschr. Chem. organ. Naturstoffe*, **13**, 233 (1956); T. Nozoe et al., "Dai Yuki Kagaku" ("Comprehensive Organic Chemistry"), Vol. 13, Chapters 5, 6, 8 and 9, Asakura Shoten, Tokyo (1960).

7) All melting points are uncorrected.

Found: C, 67.09; H, 6.09. Calcd. for $C_{10}H_{10}O_3$: C, 67.40; H, 5.66%. $\lambda_{max}^{MeOH}$ mμ (log ε): 240 (4.27), 330 (3.95), 392 (3.92).

The same treatment of I (200 mg.) with a 2 N sodium hydroxide solution (2.5 ml.) also afforded II (90 mg.).

*Copper Chelate:* m. p. 253°C, green crystals.

*Oxime:* m. p. 127—128°C, colorless prisms (from ethanol).

Found: C, 61.88; H, 5.70; N, 7.28. Calcd. for $C_{10}H_{11}O_3N$: C, 62.16; H, 5.74; N, 7.25%.

*Semicarbazone:* m. p. 189—189.5°C, colorless silky needles (from ethanol).

Found: C, 56.37; H, 5.59; N, 18.00. Calcd. for $C_{11}H_{13}O_3N_3$: C, 56.16; H, 5.57; N, 17.86%.

*Phenylhydrazone:* m. p. 138 — 138.5°C, yellow needles (from benzene).

Found: C, 71.88; H, 5.88; N, 10.59. Calcd. for $C_{16}H_{16}O_2N_2$: C, 71.62; H, 6.01; N, 10.44%.

*2, 4-Dinitrophenylhydrazone:* m. p. 170.5—171°C, reddish orange needles (from ethanol).

Found: C, 53.37; H, 4.18; N, 15.77. Calcd. for $C_{16}H_{14}O_6N_4$: C, 53.63; H, 3.94; N, 15.64%.

**The Reaction of I with Sodium Methoxide.**—To a sodium methoxide solution prepared from sodium (100 mg.) and methanol (4 ml.), I (200 mg.) was added, and the mixture was heated under reflux for 6 hr. The solvent was then evaporated, and the residue was dissolved in water and acidified with 6 N hydrochloric acid. Continuous extraction with ether for 8 hr. afforded 3-carboxymethyltropolone (III) (120 mg.), m. p. 171°C (decomp.).

**1, 4-Dihydro-3-methylpyridazo[3,4-b]tropone (IV).**—When mixture of II (200 mg.), 80% hydrazine hydrate (150 mg.) and ethanol (1 ml.) was allowed to stand for 2 hr. at room temperature, yellow hydrazine salt (150 mg., m. p. 119°C), was separated out.

Found: C, 54.20; H, 6.60; N, 23.14. Calcd. for $C_{10}H_{16}O_2N_4$: C, 53.55; H, 7.19; N, 24.98%.

This mixture was heated under reflux for 30 min. and then allowed to cool; the crystals thereby obtained were recrystallized from ethanol to give IV (100 mg.) as yellow plates, m. p. 145—146°C.

Found: C, 68.67; H, 5.49; N, 15.98. Calcd. for $C_{10}H_{10}ON_2$: C, 68.95; H, 5.79; N, 16.08%. $\lambda_{max}^{MeOH}$ mμ (log ε): 225 (4.16), 265 (3.94), 350 (3.78), 414 (3.98).

**3-Methylpyridazo[3, 4-b]tropone (V).**—A mixture of IV (90 mg.) and concentrated nitric acid (0.5 ml.) was stirred at room temperature. After the evolution of gas had ceased, the mixture was neutralized with a 2 N potassium hydroxide solution and extracted with chloroform. The crystals obtained after the removal of the solvent were recrystallized from benzene to give V (20 mg.) as pale yellow prisms, m. p. 189°C (decomp.).

Found: C, 69.72; H, 5.01; N, 16.08. Calcd. for $C_{10}H_8ON_2$: C, 69.79; H, 4.68; N, 16.27%. $\lambda_{max}^{MeOH}$ mμ (log ε): 225 (4.40), 315 (3.77).

**2-Methylfuro[2, 3-b]tropone (VI).**—After a mixture of II (200 mg.) and concentrated sulfuric acid (0.5 ml.) had been heated at 100°C for 5 min., it was diluted with water (3 ml.) and extracted with chloroform. The removal of the solvent gave an oily substance, which was solidified by cooling. Sublimation under reduced pressure and recrystallization from a mixture of benzene and petroleum ether gave VI (180 mg.) as colorless needles, m. p. 49—50.5°C.

Found: C, 70.99; H, 5.24; $H_2O$, 5.18. Calcd. for $C_{10}H_8O_2 \cdot 1/2H_2O$: C, 70.99; H, 5.36; $H_2O$, 5.32%. $\lambda_{max}^{MeOH}$ mμ (log ε): 251 (4.48), 300 (3.90), 335 (3.62).

The same result was obtained with concentrated hydrochloric acid in place of sulfuric acid.

*Picrate:* m. p. 142—143°C, yellow needles (from ethanol).

Found: C, 49.31; H, 3.05; N, 11.25. Calcd. for $C_{10}H_8O_2 \cdot C_6H_3O_7N_3$: C, 49.36; H, 2.85; N, 10.80%.

*Styphnate:* m. p. 164 — 165°C, yellow prisms (from ethanol).

Found: C, 47.39; H, 2.87; N, 9.94. Calcd. for $C_{10}H_8O_2 \cdot C_6H_3O_8N_3$: C, 47.42; H, 2.74; N, 10.37%.

**The Reaction of VI with Alkali.**—A mixture of VI (100 mg.) and 2 N potassium hydroxide solution (1.5 ml.) was heated under reflux for 2 hr., it was then acidified with 6 N hydrochloric acid and extracted with chloroform. The solvent was evaporated and residue was recrystallized from cyclohexane to give II (50 mg.), m. p. 86—87°C.

**5-(*p*-Tolylazo)-3-acetonyltropolone.**—To a stirred solution of II (100 mg.) in pyridine (3 ml.), a solution of *p*-toluenediazonium chloride, prepared from *p*-toluidine (70 mg.) in the usual manner, was added, and the mixture was stirred for 1 hr. Water was added, and the crystals obtained were recrystallized from cyclohexane to give the azo compound (160 mg.) as reddish-orange prisms, m. p. 133—134°C.

Found: C, 69.29; H, 5.43; N, 9.84. Calcd. for $C_{17}H_{16}O_3N_2$: C, 68.90; H, 5.44; N, 9.45%. $\lambda_{max}^{MeOH}$ mμ (log ε): 232 (4.31), 290 (4.08), 400 (4.43), 435 (4.41).

**5, 7-Dibromo-3-acetonyltropolone (VII).** — To a suspension of II (90 mg.) and sodium acetate (100 mg.) in methanol (2 ml.), bromine (160 mg.) was added, and the mixture was stirred for 3 hr. under cooling. Water was added, and the crystals thereby obtained were recrystallized from methanol to give VII (120 mg.) as pale yellow needles, m. p. 155—156°C.

Found: C, 35.75; H, 2.54. Calcd. for $C_{10}H_8O_3Br_2$: C, 35.74; H, 2.40%. $\lambda_{max}^{MeOH}$ mμ (log ε): 262 (4.43), 347 (4.10), 428 (3.85).

*2, 4-Dinitrophenylhydrazone:* m. p. 198 — 199°C, orange scales (from ethanol).

Found: C, 37.55; H, 2.51; N, 10.54. Calcd. for $C_{16}H_{12}O_6N_4Br_2$: C, 37.22; H, 2.34; N, 10.85%.

**5, 7-Dibromo-2-methylfuro[2, 3-b]tropone (VIII).**—*a) By the Heating of VII with Sulfuric Acid.*—A mixture of VII (100 mg.) and concentrated sulfuric acid (0.3 ml.) was heated at about 100°C for 5 min. and diluted with water to give VIII (70 mg.). Recrystallization from ethanol afforded colorless needles, m. p. 209°C (decomp.).

Found: C, 37.72; H, 2.05. Calcd. for $C_{10}H_6O_2 \cdot Br_2$: C, 37.65; H, 1.09%. $\lambda_{max}^{MeOH}$ mμ (log ε): 278 (4.52), 362 (3.61), 378 (3.51).

*b) By the Bromination of II.*—To a solution of

II (100 mg.) in methanol (1.5 ml.), bromine (200 mg.) was added, and the mixture was stirred for 1 hr. under cooling. When the solvent was removed and the residue was recrystallized from ethanol, VIII (50 mg.) was obtained as colorless needles, m. p. 209°C (decomp.).

From the mother liquor, an oily substance (40 mg.) was obtained by extraction with chloroform. This oil gave a picrate, m. p. 143°C, undepressed by admixture with the picrate of VI.

**The Debromination of VIII.** — A solution of VIII (120 mg.) and sodium acetate (100 mg.) in methanol (4 ml.) was shaken with hydrogen in the presence of 5% palladium on carbon; 19.4 ml. (at 20°C) of hydrogen was absorbed during 5 hr. After had been filtered off the catalyst, the evaporation of the solvent left an oily substance (50 mg.), which gave a picrate, m. p. 143°C, undepressed by admixture with the picrate of VI.

**The Reaction of VI with Bromine.**—To a solution of VI (160 mg.) in glacial acetic acid (1 ml.), bromine (170 mg.) was added, and the mixture was stirred for 1 hr. under cooling. The complex compound (IX) (200 mg.) was obtained as orange needles, m. p. 135—136°C.

Found: C, 43.00; H, 3.29. Calcd. for $(C_{10}H_8O_2)_2 \cdot HBr_3$: C, 42.81; H, 3.05%.

This compound (100 mg.) was shaken with a sodium hydrogen sulfite solution and extracted with chloroform to give an oily substance (60 mg.), which gave a picrate, m. p. 143°C, undepressed by admixture with the picrate of VI.

**The Reaction of VI and *N*-Bromosuccinimide.**—A solution of VI (500 mg.), *N*-bromosuccinimide (570 mg.) and benzoyl peroxide (10 mg.) in carbon tetrachloride (15 ml.) was heated under reflux for 2 hr. The solvent was then evaporated, and the residue was extracted with chloroform. The evaporation of the solvent left an oily substance containing some crystals. The addition of methanol gave crystals (260 mg.), m. p. 145—150°C, which were recrystallized from methanol to give bromo-2-methylfuro[2, 3-b]tropone as colorless needles, m. p. 169—170°C.

Found: C, 50.57; H, 3.02. Calcd. for $C_{10}H_7O_2Br$: C, 50.24; H, 2.95%. $\lambda_{max}^{MeOH}$ mμ (log ε): 220 (4.17), 278 (4.32).

**3-Acetonyl-7-methyltropolone (XIa).**—A solution of 3-acetyl-7-methyl-8-hydroxy-1-oxaazulan-2-one (Xa) (100 mg.) in a 2 N potassium hydroxide solution (2 ml.) was heated under reflux for 3 hr. The mixture was then acidified with 6 N hydrochloric acid and extracted with chloroform. The evaporation of the solvent and the recrystallization of the residue from cyclohexane gave XIa (60 mg.) as colorless needles, m. p. 106—107°C.

Found: C, 68.90; H, 6.50. Calcd. for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%. $\lambda_{max}^{MeOH}$ mμ (log ε): 245 (4.45), 323 (3.82), 355 (3.77), 370 (3.77).

*2, 4-Dinitrophenylhydrazone:* m. p. 173 — 174°C, orange needles (from ethanol).

Found: C, 55.22; H, 4.43; N, 14.89. Calcd. for $C_{17}H_{16}O_6N_4$: C, 54.84; H, 4.33; N, 15.05%.

**3-Acetonyl-6-isopropyltropolone (XIb).**—A solution of 3-acetyl-6-isopropyl-8-hydroxy-1-oxaazulan-2-one (Xb) (1.00 g.) in a 2 N potassium hydroxide solution (20 ml.) was treated in a manner similar to that used in the above experiment. Recrystallization from methanol gave XIb (590 mg.) as colorless needles, m. p. 101—102°C.

Found: C, 70.73; H, 7.29. Calcd. for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32%. $\lambda_{max}^{MeOH}$ mμ (log ε): 245 (4.47), 328 (3.91), 355 (3.86), 370 (3.84).

*Oxime:* m. p. 125—126°C, colerless scales (from methanol).

Found: C, 66.43; H, 6.95; N, 5.83. Calcd. for $C_{13}H_{17}O_3N$: C, 66.36; H, 7.28; N, 5.95%.

*Semicarbazone:* m. p. 129—130°C, colorless microneedles (from ethanol).

Found: C, 60.35; H, 6.77; N, 15.31. Calcd. for $C_{14}H_{19}O_3N_3$: C, 60.63; H, 6.91; N, 15.15%.

*Phenylhydrazone:* m. p. 110—111°C, yellow needles (from ethanol).

Found: C, 73.41; H, 6.95; N, 9.15. Calcd. for $C_{19}H_{22}O_2N_2$: C, 73.52; H, 7.14; N, 9.03%.

*2, 4-Dinitrophenylhydrazone:* m. p. 162 — 163°C, orange microneedles (from ethanol).

Found: C, 56.91; H, 4.88; N, 14.18. Calcd. for $C_{19}H_{20}O_6N_4$: C, 56.99; H, 5.04; N, 13.99%.

**5-(*p*-Tolylazo)-3-acetonyl-6-isopropyltropolone.**—To a stirred solution of XIb (200 mg.) in pyridine (5 ml.), a solution of a *p*-toluenediazonium chloride solution, prepared from *p*-toluidine (100 mg.) in the usual manner, was added under cooling, and the mixture was stirred for 2 hr. Water was added, and the crystals obtained were recrystallized from benzene to give the azo compound (250 mg.) as reddish silky needles, m. p. 154—155°C.

Found: C, 70.72; H, 6.58; N, 8.28. Calcd. for $C_{20}H_{22}O_3N_2$: C, 70.98; H, 6.55; N, 8.28%. $\lambda_{max}^{MeOH}$ mμ (log ε): 235 (4.29), 295 (4.05), 390 (4.35).

**2, 7-Dimethylfuro[2, 3-b]tropone (XIIa).**—A mixture of XIa (100 mg.) and concentrated sulfuric acid (1 ml.) was heated at about 100°C for 5 min., then diluted with water and extracted with chloroform. The evaporation of the solvent and the recrystallization of the residue from cyclohexane gave XIIa (80 mg.) as colorless prisms, m. p. 62—64°C.

Found: C, 76.07; H, 5.51. Calcd. for $C_{11}H_{10}O_2$: C, 75.84; H, 5.79%. $\lambda_{max}^{MeOH}$ mμ (log ε): 225 (4.12), 268 (4.44), 337 (3.61), 352 (3.49).

*Picrate:* m. p. 110°C, yellow needles (from ethanol).

Found: C, 50.82; H, 3.10; N, 10.66. Calcd. for $C_{11}H_{10}O_2 \cdot C_6H_3O_7N_3$: C, 50.63; H, 3.25; N, 10.42%.

*Styphnate:* m. p. 100 — 101°C, yellow needles (from ethanol).

Found: C, 48.84; H, 3.10; N, 10.24. Calcd. for $C_{11}H_{10}O_2 \cdot C_6H_3O_8N_3$: C, 48.69; H, 3.13; N, 10.02%.

**6-Isopropyl-2-methylfuro[2, 3-b]tropone (XIIb).**—A mixture of XIb (200 mg.) and concentrated sulfuric acid (0.5 ml.) was treated in a manner similar to that used in the above experiment, and the product was distilled under reduced pressure to give XIIb (180 mg.) as a pale yellow oil.

Found: C, 74.00; H, 6.98. Calcd. for $C_{13}H_{14}O_2 \cdot 1/2H_2O$: C, 73.91; H, 7.16%. $\lambda_{max}^{MeOH}$ mμ (log ε): 230 (4.23), 270 (4.39).

*Picrate:* m. p. 158—159°C, yellow scales (from ethanol).

Found: C, 52.64; H, 3.69; N, 9.90. Calcd. for

$C_{13}H_{14}O_2 \cdot C_6H_3O_7N_3$: C, 52.90; H, 3.97; N, 9.74%.

*Styphnate:* m. p. 150 — 151°C, yellow needles (from ethanol).

Found: C, 51.06; H, 3.99; N, 9.25. Calcd. for $C_{13}H_{14}O_2 \cdot C_6H_3O_8N_4$: C, 51.01; H, 3.83; N, 9.39%.

The author wishes to express his sincere gratitude to Professor Tetsuo Nozoe for his kind guidance throughout the course of this study. He is also grateful to Mr. Masaru Ogata for his cooperation in these experiments.

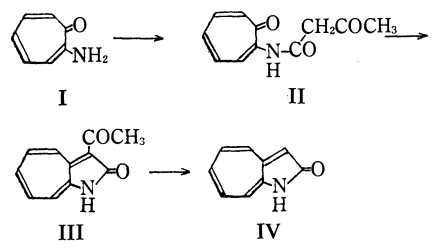
# The Reaction of Aminotropones with Diketene. I. On the Synthesis of 3-Acetyl-1-azaazulenes and Related Reactions

By Kyozo OGURA, Hiroko SASAKI and Shuichi SETO



(Received July 11, 1964)

It has previously been shown that 2-aminotropones react with diethyl malonate in the presence of sodium alkoxide to afford directly 3-ethoxycarbonyl-1-azaazulan-2-ones, from which various 1-azaazulenes can be synthesized.[1-3]

The present authors have now examined the reaction of diketene with some aminotropones and aminotropolones, and have found that the reaction products are useful for the synthesis of 3-acetyl-1-azaazulenes.

When 2-aminotropone (I) was treated with a large excess of diketene, 2-acetoacetamidotropone (II) was obtained in a good yield. The treatment of II with sodium ethoxide gave 3-acetyl-1-azaazulan-2-one (III), whose structure was confirmed from the infrared and ultraviolet absorption spectra and from the chemical evidence that III was transformed to the known 1-azaazulan-2-one (IV)[1] by the action of acid. The treatment of III with phosphorus oxychloride under the usual conditions[1-3] gave two kinds of 1-azaazulene derivatives, yellow needles (V) ($C_{11}H_8ONCl$) and red prisms (VI) ($C_{11}H_7NCl_2$). The former, V, shows a strong absorption band at 1640 $cm^{-1}$ due to a carbonyl group, while the latter shows bands at 1630 and 895 $cm^{-1}$ due to terminal methylene moiety. The ultraviolet spectra of these products are of the 1-azaazulene type,[1-3] as is shown in Fig. 1. From these facts and from the NMR spectra, which will be described later, it was learned that V and VI were 3-acetyl-2-chloro-and 3-(α-chlorovinyl)-2-chloro-1-azaazulene respectively. It may also be observed that the vinyl derivative VI, compared with the acetyl derivative V, shows a bathochromic shift in the visible region and a hypsochromic shift in the ultraviolet region.

I II III IV

V VI

The NMR spectrum of V exhibits a signal for the acetyl group at 7.20τ, while that of VI shows two doublets of the AB type at 4.40 and 4.08τ, with a coupling constant of 1.2 c.p.s. due to the α-chlorovinyl group. Furthermore, a marked difference in the influence by these two substituents at the 3-position is also apparent in the chemical shifts of the protons at the 4-position of V and VI. The signals for the protons on the seven-membered ring of V consist of three parts of a multiplet with an intensity ratio of 3 : 1 : 1, centered at 2.0, 1.4 and 0.3τ respectively. The components at the abnormally low field (0.3τ) can be assigned to the $H_4$, because only this proton is

3) S. Seto and S. Nozoe, ibid., **32**, 756 (1956).

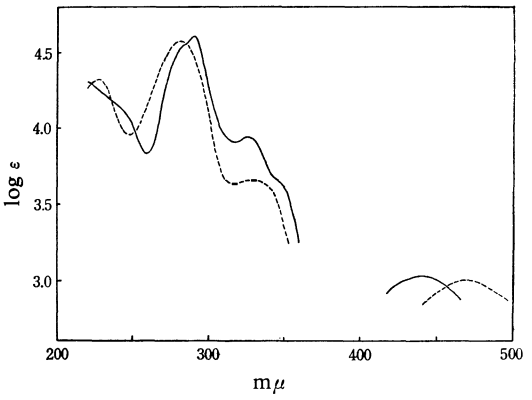

Fig. 1. UV spectra of V (——) and VI (- - -) in methanol.

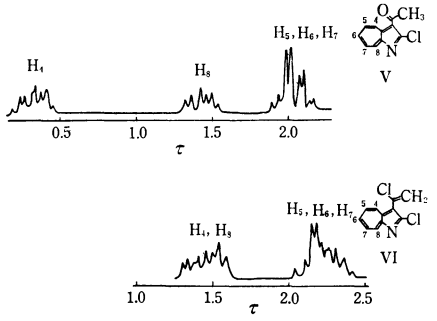
situated at such a position where the magnetic anisotropy of the acetyl group can be effective. The bands at 1.4$\tau$ may be due to the $H_8$, the nearest proton to the nitrogen atom, since the figure of the splitting closely resembles that of the $H_4$, which has almost the same environment in terms of spin coupling. This assignment is also consistent with that to be expected from the order of electron density in 1-azaazulene reported by Kon.[4] Furthermore, it is also supported, as will be described later, by the analysis of the spectra of other derivative bearing substituents on the seven-membered ring. Therefore, the components at the highest field can be assigned to the three protons at the 5, 6 and 7-positions.



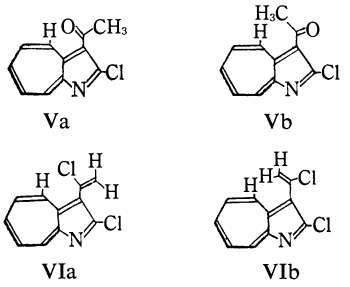


Fig. 2. NMR spectra of V and VI in $CDCl_3$.

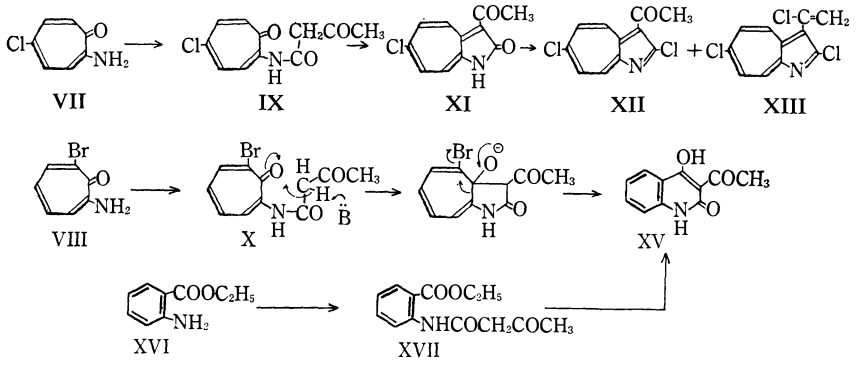
The spectrum of VI shows two separated multiplets, centered nearly at 2.2 and 1.5$\tau$, with an intensity ratio of 3 : 2, corresponding to the protons at the 5, 6 and 7-positions and to the protons at the 4 and 8-positions respectively.

The coplanarity of the acetyl and the $\alpha$-chlorovinyl group with the azaazulene nucleus was suggested by the ultraviolet spectra, and the remarkable effect of these substituents in the NMR spectra noted above indicates that the acetyl group must have predominantly the Va, conformation which is sterically preferable to the other one, Vb. The $\alpha$-chlorovinyl derivative VI also probably prefers VIa to VIb.



Although the mechanism of the formation of VI from III can not be understood with certainty, it is clear that VI is not produced via V, since any treatment of V with phosphorus oxychloride resulted only in the recovery of V.

2-Amino-5-chlorotropone (VII) and 2-amino-7-bromotropone (VIII) reacted with diketene under somewhat more severe conditions than in the case of I to afford the corresponding *N*-acetoacetyl derivatives, IX and X, while 2-amino-3-bromotropone was quite unreactive under the reaction conditions. The reaction of IX with sodium ethoxide gave 3-acetyl-6-chloro-1-azaazulan-2-one (XI), which in turn afforded 3-acetyl-2,6-dichloro-1-azaazulene (XII) by the action of phosphorus oxychloride as a major product. Only a small amount of red crystals that seemed to be the $\alpha$-chlorovinyl derivative XIII was obtained. The structure of XII was determined by the analysis of the spectra in the same way as for V. The NMR spectrum of XII exhibits a signal for the acetyl group at 7.3$\tau$ and less complicated bands in the 2.1—0.3$\tau$ region than those of V and VI due to the ring protons. These bands can be considered to be two sets of a doublet of the AB type to a first approximation; the first doublet in the lower field (0.40$\tau$) and the second at 1.45$\tau$ can be assigned to the $H_4$ and the $H_8$ respectively, while the signals for the $H_5$ and the $H_7$ consist of two just-overlapping doublets at 1.95$\tau$. No splitting by spin coupling between these two protons is observed since these chemical shifts are just the same. The coupling constants, $J(H_4, H_5)$ and $J(H_7, H_8)$, are almost equal, 11.8 c. p. s.

For the sake of comparison, the spectrum of 2, 6-dichloro-1-azaazulene (XIV)[5] was also determined. In this case, the signal for the $H_4$ is moved upfield, as compared with that

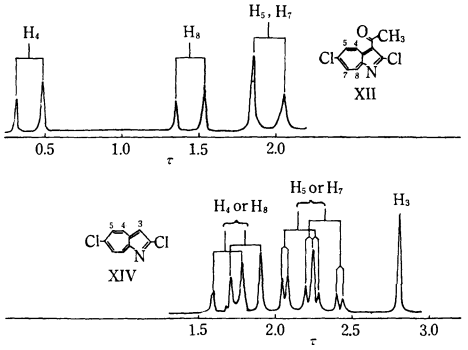
5) T. Toda, to be published.



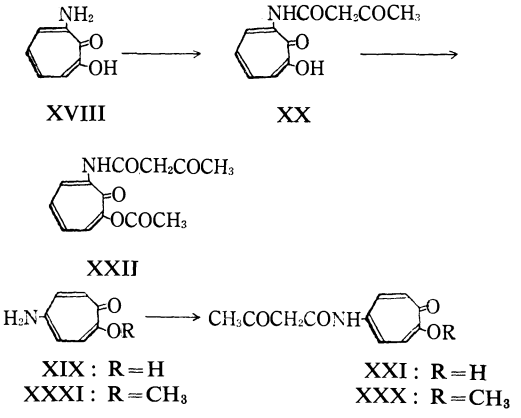


Fig. 3. NMR spectra of XII and XIV in $CDCl_3$.

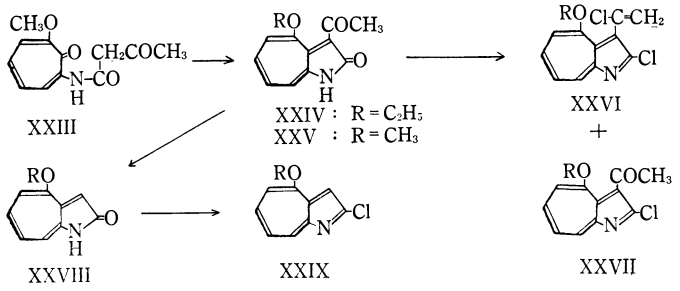
of XII, and is incorporated among the signals for the $H_8$.

Although the chemical shift for each proton can not be determined, the signals at 2.1—2.5$\tau$, which consist of a pair of a quartet, may be assigned to the $H_5$ and the $H_7$ ($J(H_4, H_5) = J(H_7, H_8) = 11.0$; $J(H_5, H_7) = 2.1$ c.p.s.) (Fig. 3). The singlet at 2.80$\tau$ must correspond to the $H_3$.



The treatment of 2-acetoacetamido-7-bromotropone (X) with alkali gave a product which was not a 1-azaazulanone derivative. This product was found to be 3-acetyl-4-hydroxycarbostyril (XV) by comparison with an authentic specimen prepared from ethyl anthranilate (XVI). It was reported that the reaction of ethyl anthranilate (XVI) with ethyl acetoacetate gave an *N*-acetoacetyl derivative (XVII) and that the heating of XVII in dry xylene in the presence of powdered sodium afforded XV.[6] The authors also found that the reaction of diketene with XVI gave the corresponding *N*-acetoacetyl derivative XVII under rather mild conditions, this could then be converted into XV in a fairly good yield, even by mild treatment with alcoholic alkali.

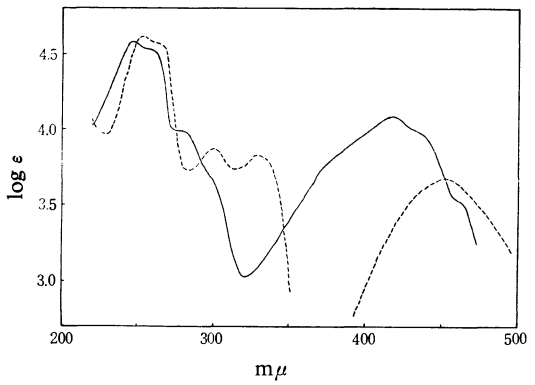
3-Aminotropolone (XVIII) and 5-aminotropolone (XIX) also reacted easily with diketene to afford 3-acetoacetamido- (XX) and 5-acetoacetamidotropolone (XXI) respectively. The compound XX itself did not give any cyclization product on treatment with sodium alkoxide, and the reaction of XX with acetic anhydride gave only its acetate XXII. When

a methyl ether XXIII, obtained by the reaction of XX with diazomethane was treated with sodium ethoxide, a 1-azaazulanone derivative XXIV, $C_{13}H_{13}O_3N$, was obtained. The fact that the treatment of XXII with sodium methoxide gave another 1-azaazulanone derivative XXV, $C_{12}H_{11}O_3N$, suggested that anionoid substitution by alkoxide at the 4-position of the azaazulanone ring might occur during this reaction. The existence of an ethoxy group in XXIV was verified by the NMR spectra of the 1-azaazulene derivative XXVI derived from XXIV. The treatment of XXIV with phosphorus oxychloride gave orange needlers XXVI and a small amount of yellow crystals XXVII. The latter was found from its infrared spectrum to be a likely 3-acetyl derivative. The appearance of a triplet at 8.36$\tau$ and a quartet at 5.66$\tau$ ($J$, 6.4 c. p. s.) in the NMR spectrum of XXVI indicates the presence of the ethoxy group, while two doublets at 4.61

6) K. Tomita, *J. Pharm. Soc. Japan*, **71**, 1100 (1951).

and 4.82$\tau$ ($J$, 0.9 c. p. s.) seem to be attributable to the two protons of the $\alpha$-chlorovinyl group.

It is noteworthy that XXIV was deacetylated with surprising ease when treated with acid at room temperature to give 4-ethoxy-1-azaazulan-2-one (XXVIII). This compound was converted into 2-chloro-4-ethoxy-1-azaazulene (XXIX), whose infrared spectrum indicated the absence of an acetyl group. It was also observed that the introduction of an ethoxy group to the 4-position of both 1-azaazulan-2-one and 2-chloro-1-azaazulene causes a hypsochromic shift (about 15 m$\mu$) of the band in the shorter-wavelength region in the ultraviolet spectrum.



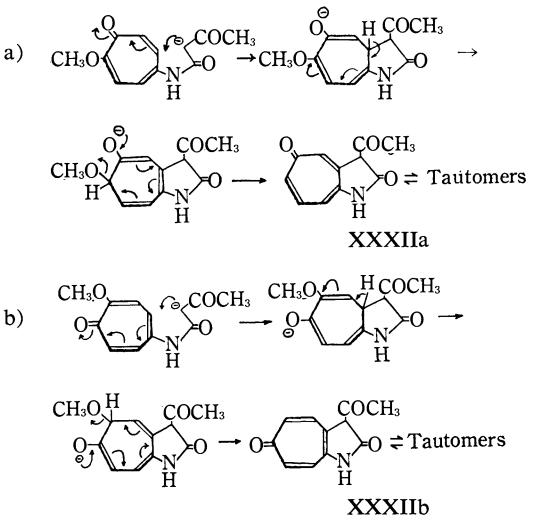


Fig. 4. UV spectra of XXVIII (——) and XXIX (- - -) in methanol.

A methyl ether XXX which had been prepared either by the treatment of XXI with diazomethane or by the reaction of 5-amino-2-methoxytropone (XXXI) with diketene gave yellow crystals XXXII when treated with sodium ethoxide. It is sparingly soluble in organic solvents and shows a characteristic absorption in the ultraviolet spectrum. The treatment of XXXII with acetic anhydride gave a diacetate XXXIII, which has an ultraviolet absorption curve of the 1-azaazulanone type. The infrared spectrum of XXXIII exhibits four bands for the carbonyl group, at 1755, 1710, 1700 and 1650 $cm^{-1}$, suggesting that XXXIII might be an *N*-acetyl-1-azaazulan-2-one derivative, bearing an acetyl group and an acetoxy group on the azaazulanone ring. This was also supported by a spectral comparison between XXXIII and the *N*-acetyl-1-azaazulan-2-one derivative XXXIV prepared from III. Two kinds of structure (XXXIIa and XXXIIb) for XXXII may be expected from a consideration of the reaction mechanism of this abnormal substitution:

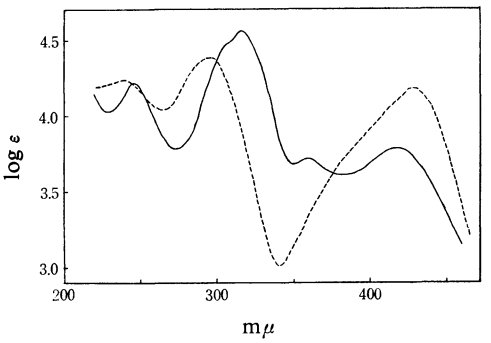

Fig. 5. UV spectra of XXXII (——) and XXXIII (- - -) in methanol.

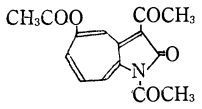
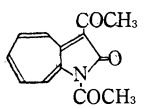
If the product XXXII had the structure XXXIIb, it would be converted into 3-acetyl-2, 6-dichloro-1-azaazulene (XII) by treatment



with phosphorus oxychloride. The treatment of XXXII, however, gave 3-acetyl- (XXXV) and 3-$\alpha$-chlorovinyl derivatives (XXXVI) of 2, 5-dichloro-1-azaazulene derivatives, whose structures were strongly supported by the analysis of the NMR spectra. Consequently, XXXII must have the structure XXXIIa and XXXIII must be *N*, 3-diacetyl-5-acetoxy-1-aza-azulan-2-one.

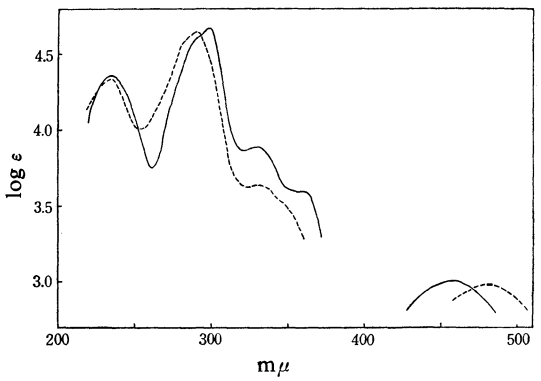


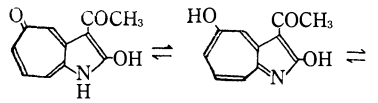
XXXV

XXXVI

XXXIII

XXXIV





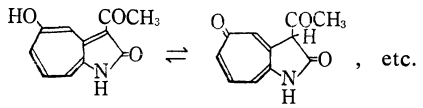


Fig. 6. UV spectra of XXXV (——) and XXXVI (- - -) in methanol.

Although the situation of the tautomerism in XXXII can not be strictly stated, the ultraviolet and infrared spectra indicate that the A form may be predominant.

(A) (B)

(C) (D)

In the NMR spectrum of XXXV the pattern arising from the protons at the 6, 7 and 8-positions of XXXV can be approximately described as an ABX system, where X corresponds to the $H_8$. The lower-field components must arise from the $H_6$, since they show additional splitting by coupling with the $H_4$, which corresponds to a doublet at 0.2$\tau$ ($J$, 2.4 c. p. s.), and the higher-field quartet can be assigned to the $H_7$. A first-order analysis of this spectrum gives the following values:

$J(H_6, H_7) = 10.0$, $J(H_6, H_8) = 1.5$,

$J(H_7, H_8) = 9.3$ c. p. s.

$H_4 = 0.2$, $H_8 = 1.5$, $H_6 = 1.9$, $H_7 = 2.2\tau$

The spectrum of XXXVI also displays almost the same pattern for the protons at the 6, 7 and 8-positions, but the doublet due to the $H_4$ is moved upfield (1.3$\tau$). The signal for the acetyl group of XXXV appears at 7.2$\tau$, and the signals for the $\alpha$-chlorovinyl group in XXXVI represent an AB system at 4.0 and 4.4$\tau$ ($J$, 1.5 c. p. s.). A schematical illustration of these spectra is given in Fig. 7.

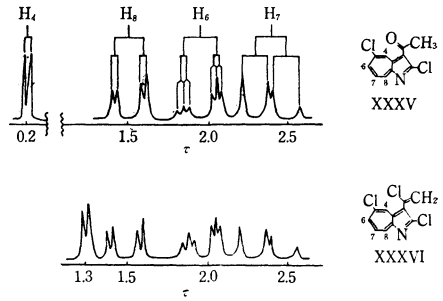

Fig. 7. NMR spectra of XXXV and XXXVI in $CDCl_3$.

The only structures for XXXV and XXXVI that can account for these spectra are 3-acetyl-2, 5-dichloro-1-azaazulene and 2, 5-dichloro-3-($\alpha$-chlorovinyl)-1-azaazulene respectively.

Additional work is in progress to make a further extension of these reactions; it will be reported on in the near future.

## Experimental*

**2-Acetoacetamidotropone (II).**—A solution of 2-aminotropone (2 g.) in diketene (10 ml.) was heated on a water bath for 2 hr.; the complete evaporation of the excess diketene then left colorless crystals, which were collected and recrystallized from methanol to give colorless needels, m. p. 118—121°C. Yield, 3.1 g.

Found: C, 64.12; H, 5.62; N, 6.33. Calcd. for $C_{11}H_{11}O_3N$: C, 64.38; H, 5.40; N, 6.83%.

* All melting points are uncorrected. The microanalyses were carried out by Misses Yôkô Endo and Yukiko Endo of this Institute, to whom the authors are indebted. The measurements of the ultraviolet and infrared spectra were made, respectively, with a Hitachi EPU-2A type spectrophotometer and with a Hitachi EPI Model S-2 spectrophotometer. The NMR spectra were measured with a Varian 4301 high resolution NMR spectrometer.

**3-Acetyl-1-azaazulan-2-one (III).** — A mixture of II (1 g.) and sodium (0.4 g.) in absolute ethanol (50 ml.) was refluxed for 1.5 hr., and then the ethanol was distilled off. When the residual crystals were dissolved in water and neutralized with diluted hydrochloric acid, yellow crystals precipitated; these were collected and recrystallized from ethanol to give yellow needles, m. p. 265—270°C. Yield, 650 mg.

Found: C, 70.90; H, 4.68; N, 7.85. Calcd. for $C_{11}H_9O_2N$: C, 70.58; H, 4.85; N, 7.48%.

**The Deacetylation of III.** — After 50 mg. of III had been heated in hydrobromic acid (1 ml.) at 100°C for 2 hr., the solution was neutralized with sodium carbonate and extracted with ethyl acetate to give yellow needles (25 mg.) of IV.

**3-Acetyl-2-chloro-1-azaazulene (V) and 2-Chloro-3-(α-chlorovinyl)-1-azaazulene (VI).** — A mixture of III (200 mg.) and phosphorus oxychloride (6 ml.) was heated at 85°C for 15 min. After the excess phosphorus oxychloride had been removed under reduced pressure, cracked ice was added to the residue. The solution was then neutralized with sodium bicarbonate and extracted with benzene. The deep yellow crystals obtained by the evaporation of the solvent were chromatographed on an alumina colum, after which elution with benzene-petroleum ether gave red prisms of VI and yellow needles of V. The respective recrystallizations from benzene-petroleum ether afforded red prisms of VI (35 mg.), m. p. 76—77°C and yellow needles of V (140 mg.), m. p. 159—160°C.

V: $\lambda_{max}^{MeOH}$ mμ (log ε): 291 (4.62), 326 (3.95), 440 (3.03).

Found: C, 64.26; H, 3.89; N, 6.67. Calcd. for $C_{11}H_8ONCl$: C, 64.24; H, 3.92; N, 6.81%.

VI: $\lambda_{max}^{MeOH}$ mμ (log ε): 228 (4.32), 281 (4.58), 330 (3.66), 470 (2.99).

Found: C, 59.35; H, 3.16; N, 6.71. Calcd. for $C_{11}H_7NCl_2$: C, 58.96; H, 3.15; N, 6.25%

**2-Acetoacetamido-5-chlorotropone (IX).**—A solution of VII (270 mg.) in diketene (8 ml.) was heated at 100—120°C for 2 hr. The evaporation of the excess diketene left brownish yellow crystals, which were collected and recrystallized from acetone to afford pale yellow needles, m. p. 145°C. Yield, 325 mg.

Found: C, 55.36; H, 3.87; N, 6.15. Calcd. for $C_{11}H_{10}O_3NCl$: C, 55.10; H, 4.21; N, 5.85%.

**2-Acetoacetamido-7-bromotropone (X).** — A solution of VIII (150 mg.) in diketene (1.5 ml.) was heated at 95—98°C for 4 hr. After the evaporation of the excess diketene, the crystals were recrystallized from methanol to give colorless needles, m. p. 114—115°C. Yield, 130 mg.

Found: C, 46.76; H, 3.36; N, 5.23. Calcd. for $C_{11}H_{10}O_3NBr$: C, 46.40; H, 3.89; N, 4.93%.

**3-Acetyl-6-chloro-1-azaazulan-2-one (XI).**—When IX (115 mg.) was added to a sodium ethoxide solution (sodium, 80 mg.; absolute ethanol, 20 ml.), orange crystals appeared immediately. While the mixture was then refluxed for 2 hr., however, the crystals dissolved gradually. After the removal of the solvent, the residue was acidified with 6 N sulfuric acid and adjusted to pH 2; the yellow crystals which had been deposited were collected and recrystallized from methanol to give yellow needles, m. p. 278°C (decomp.). Yield, 185 mg.

Found: C, 59.11; H, 3.44; N, 6.40. Calcd. for $C_{11}H_8O_2NCl$: C, 59.59; H, 3.64; N, 3.22%.

**3-Acetyl-2, 6-dichloro-1-azaazulene (XII).** — A mixture of XI (115 mg.) and phosphorus oxychloride (8 ml.) was warmed at 80°C for 2 hr. After the evaporation of the excess phosphorus oxychloride under reduced pressure, the residue was neutralized with an aqueous sodium bicarbonate solution, adjusted to pH 8, and extracted with ethyl acetate. The solution, after being dried on sodium sulfate, was passed through an alumina column. Elution with benzene gave yellow needles of XII. Recrystallization from benzene gave yellow needles, m. p. 183°C (decomp.). Yield, 100 mg. $\lambda_{max}^{MeOH}$ mμ (log ε): 298 (4.65), 340 (4.04), 450 (3.07).

Found: C, 55.05; H, 2.64; N, 5.97. Calcd. for $C_{11}H_7ONCl_2$: C, 55.00; H, 2.92; N, 5.84%.

Red crystals of XIII were also obtained from the effluent, but in a very poor yield.

**The Reaction of X with Alkali.** — A solution of X (20 mg.) in an alcoholic potassium hydroxide solution (potassium hydroxide, 70 mg.; ethanol, 1 ml.; water, 2 drops) was warmed on a water bath for 30 min. The acidification of the solution with diluted hydrochloric acid caused colorless crystals to precipitate; they were collected and recrystallized from ethanol to give colorless needles, m. p. 246—247°C. This substance was found to be identical with 3-acetyl-4-hydroxycarbostyril (XV) by comparison with an authentic sample.

**Ethyl 2-Acetoacetamidobenzoate (XVII).** — A mixture of ethyl anthranilate (1 g.) and diketene (2.5 ml.) was warmed at 70—80°C for 1.5 hr. After the complete removal of the excess diketene, the resultant oily residue was dissolved in ether and the solution was shaken with diluted hydrochloric acid to remove any unreacted starting material. The concentration of the ether solution gave colorless crystals, which were recrystallized from petroleum ether to yield granular crystals, m. p. 163—165°C. Yield, 1 g.

**3-Acetyl-4-hydroxycarbostyril (XV).**—A solution of XVII (20 mg.) in an alcoholic potassium hydroxide solution (potassium hydroxide, 70 mg; ethanol, 1 ml.; water, 2 drops) was warmed on a water bath for 30 min. After the evaporation of the ethanol, the solution was acidified with diluted hydrochloric acid. The colorless precipitate which was thus deposited was collected and recrystallized from ethanol to afford colorless needles, m. p. 244—247°C. Yield, 10 mg. This product was found, by a comparison of their infrared spectra, to be identical with an authentic sample prepared by Tomita's method.[6]

**3-Acetoacetamidotropolone (XX).** — A mixture of XVIII (500 mg.) and diketene (2.5 ml.) was heated on a water bath for 2 hr. After the removal of the excess diketene under reduced pressure, the residual crystals were recrystallized from methanol to afford colorless needles, m. p. 93—95°C. Yield, 680 mg. IR 3180, 1700, 1680 $cm^{-1}$ (KBr).

Found: C, 59.31; H, 5.17; N, 6.42. Calcd. for $C_{11}H_{11}O_4N$: C, 59.72; H, 5.01; N, 6.33%.

**5-Acetoacetamidotropolone (XXI).** — A mixture

of 5-aminotropolone (4 g.) and diketene (20 ml.) was heated at 80°C for 2 hr. The colorless crystals that separated when the mixture was cooled to room temperature were collected and washed with ether. Recrystallization from acetone-methanol afforded colorless needles (4.16 g.), m. p. 138—139°C.

Found: C, 59.49; H, 4.72; N, 6.45. Calcd. for $C_{11}H_{11}O_4N$: C, 59.72; H, 5.01; N, 6.33%.

**The Acetate (XXII) of XX.** — A solution of XX (50 mg.) in acetic anhydride (0.4 ml.) was heated at 120°C for 4 hr., and then the excess acetic anhydride was removed under reduced pressure. The recrystallization of the residue from methanol gave colorless scales, m. p. 146—148°C. Yield, 30 mg. IR 3270, 1750, 1690 $cm^{-1}$ (KBr).

Found: C, 59.49; H, 4.83; N, 6.37. Calcd. for $C_{13}H_{13}O_5N$: C, 59.31; H, 4.98; N, 5.32%.

**The Methyl Ether (XXIII) of XX.** — To a suspension of XX (630 mg.) in a mixture of ether (18 ml.) and methanol (3 ml.), ethereal diazomethane was added until the evolution of nitrogen ceased. The end point of the reaction was determined by a coloration test with ferric chloride. During this reaction, the crystals (XX) dissolved gradually and colorless needles newly appeared. The needles were collected and recrystallized from ethanol to give colorless needles, m. p. 163—166°C. Yield, 360 mg. IR 3240, 1710, 1675 $cm^{-1}$ (KBr).

Found: N, 6.18. Calcd. for $C_{12}H_{13}O_4N$: N, 5.96%.

**3-Acetyl-4-ethoxy-1-azaazulan-2-one (XXIV).** — A suspension of XXIII (100 mg.) in a sodium ethoxide solution (sodium, 40 mg.; ethanol, 4 ml.) was refluxed for 4 hr., and then the yellow solution thus obtained was concentrated under reduced pressure. When the residue was dissolved in water (2 ml.) and neutralized with diluted hydrochloric acid, yellow crystals separated. The recrystallization of the crystals from methanol yielded yellow needles, m. p. 220—225°C. Yield, 70 mg. $\lambda_{max}^{MeOH}$ mμ (log ε): 252 (4.57), 440 (4.14). IR 1690, 1630 $cm^{-1}$ (KBr).

Found: C, 68.14; H, 6.14; N, 5.72. Calcd. for $C_{13}H_{13}O_3N$: C, 67.52; H, 5.67; N, 6.06%.

**3-Acetyl-4-methoxy-1-azaazulan-2-one (XXV).** — A suspension of XXIII (50 mg.) in a sodium methoxide solution (sodium, 20 mg.; absolute methanol, 3 ml.) was refluxed for 3.5 hr. After the evaporation of the solvent, the residue was neutralized with dilute hydrochloric acid and extracted with ethyl acetate. The removal of the sovlent left yellow crystals, which were then collected and recrystallized from methanol to give yellow needles, m. p. 200—220°C (decomp.). Yield, 20 mg. IR 1690, 1625 $cm^{-1}$ (KBr).

Found: C, 65.82; H, 4.85; N, 6.65. Calcd. for $C_{12}H_{11}O_3N$: C, 66.35; H, 5.10; N, 6.45%.

**2-Chloro-3-(α-chlorovinyl)-4-ethoxy-1-azaazulene (XXVI).** — A mixture of XXIV (100 mg.) and phosphorus oxychloride (3 ml.) was heated at 95—98°C for 1 hr., after which the excess phosphorus oxychloride was removed under reduced pressure. To the residue, ice-cooled water was added, and the solution was neutralized with sodium bicarbonate, adjusted to pH 8, and extracted with benzene. The crystals obtained from the extract were chromatographed on an alumina column, and elution with benzene afforded orange crystals. Recrystallization from benzene-petroleum ether gave orange needles, m. p. 109—111°C. Yield, 95 mg. $\lambda_{max}^{MeOH}$ mμ (log ε): 253 (4.52), 270 (4.51), 304 (399), 332 (3.93), 455 (3.64). IR 1640, 885 $cm^{-1}$ (KBr).

Found: C, 58.51; H, 3.48; N, 5.25. Calcd. for $C_{13}H_{11}ONCl_2$: C, 58.23; H, 4.14; N, 5.22%.

**4-Ethoxy-1-azaazulan-2-one (XXVIII).** — When a solution of XXIV (100 mg.) in concentrated hydrochloric acid (1 ml.) was allowed to stand at room temperature, yellow crystals began to separate out in a few minutes. After it had been allowed to stand for 1 hr., the mixture was neutralized with a sodium bicarbonate solution and the crystals were collected. Recrystallization from methanol gave yellow needles, m. p. 180—183°C. Yield, 80 mg. $\lambda_{max}^{MeOH}$ mμ (log ε): 246 (4.58), 417 (4.09). IR 1670 $cm^{-1}$ (broad) (KBr).

Found: C, 69.66; H, 5.65; N, 7.44. Calcd. for $C_{11}H_{11}O_2N$: C, 69.82; H, 5.86; N, 7.40%.

**2-Chloro-4-ethoxy-1-azaazulene (XXIX).** — A mixture of XXVIII (40 mg.) and phosphorus oxychloride (1.5 ml.) was heated at 90—95°C for 1 hr. The evaporation of the excess phosphorus oxychloride left a dark red residue, which was then dissolved in cold water (5 ml.) and neutralized with sodium bicarbonate. The precipitate which was thus deposited was collected and chromatographed on an alumina column. Elution with benzene gave orange crystals. Recrystallization from benzene-petroleum ether afforded orange needles, m. p. 120—122°C. Yield, 30 mg. $\lambda_{max}^{MeOH}$ mμ (log ε): 252 (4.62), 300 (3.88), 328 (3.84), 452 (3.69).

Found: C, 63.99; H, 4.51; N, 6.99. Calcd. for $C_{11}H_{10}ONCl$: C, 63.62; H, 4.85; N, 6.75%.

**Methyl Ether (XXX) of XXI.**—a) To a suspension of XXI (3.5 g.) in methanol (40 ml.), ethereal diazomethane was added until a portion of the mixture no longer showed coloration with ferric chloride. The colorless crystals that appeared were collected and recrystallized from acetone to give colorless crystals, m. p. 164°C (decomp.). Yield, 2.4 g.

Found: C, 61.06; H, 5.52; N, 5.79. Calcd. for $C_{12}H_{13}O_4N$: C, 61.27; H, 5.57; N, 5.96%.

b) To a solution of 5-aminotropolone (100 mg.) in methanol, ethereal diazomethane was added until a portion of the solution no longer colored with ferric chloride. After the evaporation of the solvent, the addition of a small amount of acetone brought the residue to crystallization. The crystals were collected and recrystallized from acetone to give yellow crystals of 110 mg. of 5-amino-2-methoxytropone (XXXI), m. p. 95—105°C. A mixture of XXXI (110 mg.) and diketene was warmed at 60°C for 20 min., and the crystals that separated out on cooling were collected and recrystallized from acetone to afford colorless crystals of XXX. Yield, 80 mg.

**3-Acetyl-2-hydroxycyclohepta[b]pyrrol(1*H*)-5-one (XXXII).** — After a suspension of XXX (1.5 g.) in a solution of sodium ethoxide (sodium, 600 mg.; absolute ethanol, 84 ml.) was refluxed for 3 hr., the solvent was removed. The residue was then

dissolved in 20 ml. of water, acidified with diluted sulfuric acid, and adjusted to pH 4, and the yellow crystals that separated were collected. Recrystallization from methanol gave yellow crystals, m. p. >300°C. Yield, 800 mg. $\lambda_{max}^{MeOH}$ mμ (log ε): 245 (4.21), 316 (4.56), 360 (3.71), 418 (3.78).

Found: C, 63.47; H, 4.70; N, 6.62. Calcd. for $C_{11}H_9O_3N$: C, 65.02; H, 4.46; N, 6.89%.

***N*, 3-Diacetyl-5-acetoxy-1-azaazulan-2-one (XXXIII).**—A mixture of XXXII (40 mg.), pyridine (0.7 ml.) and acetic anhydride (1 ml.) was warmed at 80—90°C for 10 min. The yellow needles that separated out on cooling were collected and recrystallized from benzene to give yellow needles, m. p. 177—179°C. Yield, 25 mg. $\lambda_{max}^{MeOH}$ mμ (log ε): 245 (4.21), 316 (4.56), 360 (3.71), 418 (3.78).

Found: C, 62.84; H, 4.73; N, 5.59. Calcd. for $C_{15}H_{13}O_5N$: C, 62.71; H, 4.56; N, 4.88%.

***N*, 3-Diacetyl-1-azaazulan-2-one (XXXIV).** — A mixture of III (50 mg.), acetic anhydride (1.5 ml.) and pyridine (1 drop) was heated on a water bath for 10 min. After the mixture had then been cooled to room temperature, the yellow needles that separated out were collected and recrystallized from benzene to give yellow needles, m. p. 190—191°C. Yield, 30 mg. IR 1710, 1695, 1640 $cm^{-1}$ (KBr).

Found: C, 68.23; H, 4.77; N, 6.56. Calcd. for $C_{13}H_{11}O_3N$: C, 68.11; H, 4.84; N, 6.11%.

**3-Acetyl-2,5-dichloro-1-azaazulene (XXXV) and 2,5-Dichloro-3-(α-chlorovinyl)-1-azaazulene (XXXVI).** — A mixture of XXXII (200 mg.) and phosphorus oxychloride (15 ml.) was heated at 80°C for 2 hr., after which the excess phosphorus oxychloride was removed under reduced pressure. The residue was dissolved in water, and the pH was adjusted to 8 with sodium bicarbonate. The extraction of the solution with ethyl acetate afforded orange crystals of a mixture of XXXV and XXXVI. The mixture was chromatographed on an alumina column, and elution with benzene-petroleum ether gave red plates (XXXVI) and yellow needles (XXXV). Recrystallizations from benzene (for XXXV) and benzene-petroleum ether (for XXXVI) gave yellow needles of XXXV, m. p. 179—180°C (35 mg.) and red plates of XXXVI, m. p. 127—128°C (50 mg.).

XXXV: $\lambda_{max}^{MeOH}$ mμ (log ε): 235 (4.36), 298 (4.69), 332 (3.88), 460 (3.00).

Found: C, 55.06; H, 3.14; N, 6.01. Calcd. for $C_{11}H_7ONCl_2$: C, 55.00; H, 2.94; N, 5.84%.

XXXVI: $\lambda_{max}^{MeOH}$ mμ (log ε): 234 (4.34), 290 (4.66), 330 (3.64), 480 (2.97).

Found: C, 51.36; H, 2.61; N, 5.81. Calcd. for $C_{11}H_6NCl_3$: C, 51.08; H, 2.34; N, 5.42%.

The present authors wish to express their thanks to Professor Taro Isobe for his guidance in the analyses of the NMR spectra and to Assistant Professor Tsuneo Ikenoue for his measurement of and advice on the NMR spectra. They are also grateful to Dr. Takashi Toda for the gift of the sample of 2,6-dichloro-1-azaazulene and to the Sankyo Co., Ltd., which defrayed a part of the expense for the present work.

# The Electrical Conduction of Iodine Complexes of Aromatic Diamines*

By Hideaki KUSAKAWA and Shun-ichiro NISHIZAKI

(Received July 14, 1964)

In our previous work[1], we have studied the electrical properties of the *p*-phenylenediamine (*p*-PDA) - iodine complex system. The magnitude and the temperature dependence of the electrical resistivity of this system is dependent upon the iodine content.

As part of the study of a series of aromatic diamine - iodine complex systems, in this paper we have studied the electrical properties of iodine complexes of aromatic diamines, which contain two benzene rings. To examine the effects of the molecular structures of donors, we have selected four compounds from three different types of aromatic diamines: (a) 1, 5-naphthylenediamine (NDA), from diaminopolyacenes, (b) benzidine (BEN) and *o*-tolidine (TOL), from polyphenylenediamines, and (c) *p*, *p*'-diaminodiphenylmethane (APM), from non-conjugated diamines.

## Experimental

**Materials.** — The aromatic diamines and iodine were purified by means of two recrystallizations or sublimations. The complexes were prepared in the following way. A diamine and iodine were dissolved separately in benzene, and then the two

* Presented in part at the 17th Annual Meeting of The Chemical Socity of Japan, Tokyo, April, 1964.

1) S. Nishizaki and H. Kusakawa, This Bulletin, **36**, 1681 (1963).

solutions were mixed in four different proportions, so that the mole ratios of iodine to diamine in the mixtures were 3/4, 4/4, 5/4 and 6/4 respectively. After the mixtures had been kept standing for one day, the precipitates were collected by filtration and dried. In the case of the APM-iodine system, however, no precipitate could be obtained from the solution. Thus to prepare this complex system, the two components were blended in a test tube and heated to the melting point. The iodine contents of the complexes prepared from the solutions were determined by the microanalytical method.

**Resistivity Measurements.** — The experimental method and the conditions for the measurement of the magnitude and the temperature dependence of the electrical resistivity were similar to those described in the previous paper[1] except that, in the present case, the temperature range was from −70°C to 20°C, and carbon electrodes were used instead of the metal electrodes for BEN and TOL complexes. All specimens of the APM and iodine systems are of flowage, so only the resistivity at room temperature was obtained.

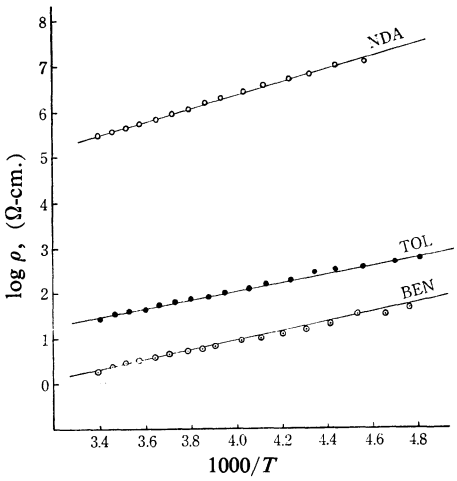

Fig. 1. Temperature dependence of conductivity of aromatic diamine complexes: for determination of thermal activation energy for conduction.

## Results and Discussion

The aromatic diamine - iodine complexes do not have a constant coordination number, and their resistivities are dependent on their iodine content. The correlation of resistivities at room temperature with iodine content is shown in Table I.

Examples of the experimental data on the temperature dependence of the electrical resistivity are shown in Fig. 1. The mole ratio of iodine in the examples shown this figure are 1.01 in the NDA-iodine system, 1.26 in the BEN-iodine system, and 1.29 in the TOL-iodine system. The activation energy, $E_c$, was determined from the experimental data according to the following equation:

$$\rho = \rho_0 \exp(E_c/kT) \qquad (1)$$

The results obtained are listed in the last column of Table I. The resistivity of the complex of BEN with iodine is not in agreement with that obtained by van der Hoek and his coworkers.[2] When metal electrodes were used, however, we also obtained a value similar to that reported by them ($10^2\Omega$-cm. at 20°C). It seems that a reaction takes place between metal electrodes and the specimen during the resistivity measurement, thus causing a high resistivity region in the neighborhood of the electrodes, and hence, an increase in the apparent resistivity.

For the *p*-PDA-iodine system both the resistivity and the activation energy showed

TABLE I. IODINE CONTENTS OF SPECIMENS AND THEIR ELECTRICAL RESISTIVITIES AND ACTIVATION ENERGIES

| Donor | $I_2$/diamine mixed mole ratio | Iodine content | Resistivity at 20°C Ω-cm. | Activation energy, eV. |
|---|---|---|---|---|
| NDA | 0.75 | 0.70 | $6.1\times10^{7}$ | 0.66 |
| | 1.00 | 0.86 | $1.6\times10^{6}$ | 0.42 |
| | 1.25 | 0.90 | $1.0\times10^{6}$ | 0.40 |
| | 1.50 | 1.01 | $3.1\times10^{5}$ | 0.32 |
| BEN | 0.75 | 0.78 | $1.6\times10^{5}$ | 0.34 |
| | 1.00 | 0.94 | $6.2\times10^{2}$ | 0.19 |
| | 1.25 | 1.26 | $2.2\times10^{0}$ | 0.19 |
| | 1.50 | 1.49 | $1.2\times10^{1}$ | 0.19 |
| TOL | 0.75 | 0.94 | $3.5\times10^{3}$ | 0.27 |
| | 1.00 | 1.02 | $2.9\times10^{2}$ | 0.24 |
| | 1.25 | 1.29 | $2.9\times10^{1}$ | 0.18 |
| | 1.50 | 1.53 | $9.1\times10^{1}$ | 0.18 |
| APM | 0.75 | — | $8\times10^{10}$ | — |
| | 1.00 | — | $3\times10^{9}$ | — |
| | 1.25 | — | $2\times10^{8}$ | — |
| | 1.50 | — | $6\times10^{7}$ | — |

TABLE II. CORELATION BETWEEN *Ec* AND $\rho_0$ ON AROMATIC DIAMINE IODINE COMPLEXES

| Donor | *p*-PDA | NDA | BEN | TOL |
|---|---|---|---|---|
| Activation energy, eV. | 0.41 | 0.32 | 0.19 | 0.18 |
| $\rho_0$ in Eq. 1, Ω-cm. | $2.6\times10^{-2}$ | $8.0\times10^{-1}$ | $1.2\times10^{-3}$ | $2.3\times10^{-2}$ |
| Iodine content | 0.82 | 1.01 | 1.26 | 1.29 |

minimum values at an iodine mole ratio of 0.8. In the cases of these aromatic diamines, the minimum appears at a mole ratio above 1.0. This is reasonable because the molecules of these aromatic diamines are longer than that of *p*-PDA.

When a non-conjugated diamine such as APM is used as the electron donor, the charge transfer complex of iodine does not possess a high electrical conductivity at room temperature. In this case, there was no minimum in the resistivity vs. iodine content curve in a 3/4—6/4 range of the mole ratio of iodine to amine. The resistivity of this system decreases with an increase in the iodine content, as with polyiodides.[3]

The results shown in Table II demonstrate that the activation energy, $E_c$, increases in the order; TOL, BEN, NDA and *p*-PDA, but this order is not in agreement with the order of their specific resistivities at room temperature. A linear relation can often be found between the activation energy, $E_c$, and the logarithm of $\rho_0$ in Eq. 1,[4,5] but such a relation can not be observed for aromatic diamine-iodine complexes.

The results obtained in this investigation indicate that polyphenylenediamines, such as BEN and TOL, are better than diaminopolyacenes, represented by NDA, as electron donors for iodine. It is well known that the charge transfer complex, which shows the remarkable electrical conduction, can be formed from the interaction of a strong electron donor with a strong electron acceptor. In the case of aromatic hydrocarbon, the ionization potential of naphthalene is lower than those of biphenyl[6] and benzene.[7] However, not only is the NDA-iodine complex poor in electrical conduction but also its energy of charge transfer transition[8] in the solid state is large compared with that of the BEN-iodine complex. Considering these facts, it is imaginable that the pendant amino group of polyacenes does not interact with iodine so strongly as does that of polyphenylene diamines.

Foster and Thompson have reported[9] that for chloranil, the donor character of *N,N,N',N'*-tetramethylbenzidine is as strong as that of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine. In the case of non-substituted compounds for iodine, BEN is a very strong donor compared with *p*-PDA. On the other hand, if chloranil is used as the acceptor, BEN and TOL behave as weak donors,[10] but the *p*-PDA-chloranil complex shows a conspicuous signal of electron-spin resonance.[11] Concerning the charge transfer complexes of a given donor, its strength of charge transfer interaction seems to vary with the acceptor molecule, depending on its molecule, depending on its molecular size and other properties.

## Summary

The magnitudes and temperature dependence of the electrical resistivities of aromatic diamine - iodine complexes have been studied on four aromatic diamines; 1,5-naphthylenediamine (NDA), benzidine (BEN), *o*-tolidine (TOL) and *p,p'*-diaminodiphenylmethane (APM).

As the donor is a non-conjugated molecule, the electrical conductivity of its iodine complex is inferior to that of the conjugated diamine.

BEN and TOL, which are polyphenylenediamines, are better electron donors for iodine than NDA, a diaminopolyacene; the characteristics of the electron donor for iodine of NDA are as strong as those of *p*-PDA.

The resistivity shows a minimum value at an iodine mole ratio above 1.0 in the cases of the conjugated aromatic diamine which involve two benzene rings. These iodine contents are higher than the corresponding value *p*-PDA-iodine, 0.8.

The authors wish to thanks Mr. Osamu Hashimoto for microanalysis of the aromatic diamine - iodine complexes.

# Properties of the Dilute Solution of Poly-2-methyl-5-vinylpyridine

By Masaji MIURA, Yukio KUBOTA and Teruaki MASUZUKAWA

(Received July 21, 1964)

Polyvinylpyridine has been used as a source material for polyelectrolytes and polysoaps, and several studies[1,2] have given some information on its molecular dimensions. Poly-2-methyl-5-vinylpyridine (PMVP), a derivative of polyvinylpyridine, has been studied by Sato and his co-worker[3] by means of osmotic pressure measurements, but its molecular dimensions are not yet known. It is of interest, therefore, to study the properties of the dilute solution of PMVP by viscosity and light-scattering measurements.

The purpose of this investigation is (1) to establish the relationship between the intrinsic viscosity and the molecular weight of PMVP; (2) to estimate the extension of the polymer chain with the aid of recent theories on the solution behavior of high polymers,[4,5] and (3) to compare the results with those for other vinylpyridine polymers and polystyrene.

## Experimental

**The Preparation of PMVP.**—2-Methyl-5-vinylpyridine was distilled immediately before use, and a middle fraction (b. p. 69.8—71.2°C/13 mmHg) was collected. The polymerization was carried out at 70°C for five days in a nitrogen atmosphere; the conversion rate was found to be about 40%. The polymer produced was first dissolved in methanol and then precipitated by pouring the methanol solution into a large amount of water. This was repeated twice more in order to remove the monomer which remained in the product, and then the precipitate was isolated by filtration; finally this purified material was fractionally precipitated, with methanol as a solvent and water as a precipitant. At first six fractions were obtained from a 3% methanol solution and then each fraction was separated into three to five subfractions by the same procedure, for a total of twenty subfractions; nine of these were finally selected for the viscosity and light-scattering measurements. The results of nitrogen analyses of fractions F-1-2, F-2-2 and F-6-1 were found to be 11.80, 11.94 and 11.97% respectively. These values were in good agreement with the calculated value, 11.76%.

**Solvents.**—The solvents used in this work were purified by the usual methods.

**Viscosity.**—The viscosity was measured at 25± 0.01°C with two Ubbelohde dilution viscometers, whose flow times for methanol were 114.4 sec. and 123.2 sec. The intrinsic viscosities were obtained by extrapolating the plots of the reduced viscosity, $\eta_{sp}/C$, vs. the concentration to infinite dilution.

**Light Scattering.** — The intensity of scattered light was measured at 25°C with both unpolarized blue (4358Å) and green light (5460Å), using a Brice-type light-scattering photometer manufactured by Shimadzu Seisakusho. All solvents and solutions were filtered into a clean semi-octagonal cell through a "Cellafilter fein or mittel" (Membranfiltergesellshaft, Göttingen) under applied pressure. Scattered intensities were measured at angles 45, 90 and 135° to the incident beam, and the data obtained were analyzed according to the usual procedure.[6] The depolarization was found to be negligible. All dissymmetries were corrected for the back reflection of the incident light.[7]

The instrument was calibrated according to two procedures; one refers to the values in the literature for the Rayleigh ratio, $R_{90}$, of benzene,[8] while the other utilizes standard opal glass.[9] With these calibrations, the molecular weight of the standard polystyrene sample was found to be in satisfactory agreement with the value in the literature.[10]

The refractive index increments, $dn/dc$, were measured at 25°C using a Debye-type differential refractometer manufactured by Shimadzu Seisakusho. The $dn/dc$ values of PMVP in methanol were 0.273 and 0.257 at 436 and 546 mμ respectively, both at 25°C.

## Results and Discussion

Abnormal light-scattering behavior, probably due to the ionization of the pyridine nitrogen, was found for all PMVP fractions in methanol. A typical example is shown in Fig. 1. Accordingly, dry ammonia gas was introduced to methanol in order to suppress any possible

ionization (0.02 M $NH_3$).[2] By this procedure the normal plots were obtained. The term *methanol* used hereafter denotes that methanol which contains ammonia in the amount described above. Figure 2 shows the reciprocal reduced intensity, $Kc/R_{90}$, of PMVP fractions in methanol at 4358Å. The results of the viscosity and light-scattering measurements are summarized in Table I. Since the light-scattering properties are in good agreement at both wavelengths, the average values are used in the following discussion. The

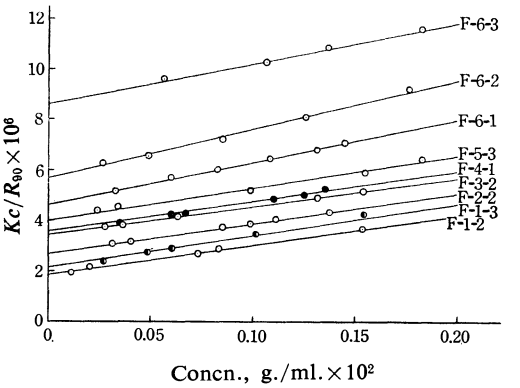

Fig. 2. Reciprocal reduced intensity, $Kc/R_{90}$, of PMVP fractions in methanol at 4358Å.

results of the behavior of PMVP in various solvents are summarized in Table II. There is a satisfactory agreement of the weight average molecular weight, $M_w$, in various solvents.

**The Relation between the Intrinsic Viscosity and the Molecular Weight.**—The log-log plots of the intrinsic viscosity and the molecular weight are shown in Fig. 3. In the range of the molecular weights of our samples, the plots are seen to be on a straight line. The relation between the intrinsic viscosity and the molecular weight is usually represented by the equation:

$$[\eta] = KM^a \qquad (1)$$

The constants $K$ and $a$ were calculated by the method of least squares, and the following equations were obtained:

Table I. The results of the viscosity and light-scattering measurements of PMVP

$$[\eta] = 0.80 \times 10^{-4} M_w^{0.76}$$
in methanol at 25°C (2)

$$[\eta] = 1.39 \times 10^{-4} M_w^{0.65}$$
in MEK at 25°C (3)

**The Dependence of the Root-Mean-Square End-to-End Distance, $(\overline{R^2})^{1/2}$, and the Second Virial Coefficient, $A_2$, on the Molecular Weight.** —Figure 4 shows the relation between $(\overline{R^2})^{1/2}$ and $M_w$. The following equation was obtained by the method of least squares:

$$(\overline{R^2})^{1/2} = 0.49 M_w^{0.57}$$
in methanol at 25°C (4)

As may be seen in Table I, $A_2$ decreases with an increase in the molecular weight. The log-log plot of $A_2$ and $M_w$ in Fig. 5 gives the following relation, which is consistent with the results found for many other polymers:

$$A_2 \propto M_w^{-0.20} \quad (5)$$

**Unperturbed Dimensions.**—As is well known, the unperturbed dimensions may be evaluated from the data of viscosity and light scattering at the theta point.[11] The relations are:

$$[\eta]_\theta = K_0 M^{1/2} \quad (6)$$

$$K_0 = \Phi_0 (\overline{R_0^2}/M)^{3/2} \quad (7)$$

where $[\eta]_\theta$ is the intrinsic viscosity in the theta solvent, $\Phi_0 = 2.87 \times 10^{21}$, and $\overline{R_0^2}$ is the unperturbed mean square end-to-end distance. As our work was not done at the theta point, the values of $[\eta]_\theta$ were not obtained directly from the experiment; $[\eta]_\theta$, however, may be determined on the basis of the $[\eta]$ and $A_2$ values obtained in several solvents.[12] In Fig. 6 $[\eta]$ is plotted against $A_2$ for fraction F-3-2 using the data in Table II. The value of $[\eta]_\theta$ was 0.46. Substituting the values for $[\eta]_\theta$ and $M(4.69 \times 10^5)$ into Eq. 6, we found $K_0$ to be $6.7 \times 10^{-4}$. This value is in good agreement with the results obtained below (cf. Table III).

The recent theories of polymer solutions made it possible to estimate both the unperturbed dimensions and the excluded volume effect from the data in any solvent, good or

poor. According to the theory of Kurata-Stockmayer-Roig,[4]

$$[\eta]^{2/3}/M^{1/3} = K_0^{2/3}+0.363\Phi_0 B[g(\alpha_\eta)M^{2/3}/[\eta]^{1/3}] \quad (8)$$

$$g(\alpha_\eta)=8\alpha_\eta^3/(3\alpha_\eta^2+1)^{3/2} \quad (9)$$

where

$$\alpha_\eta^3=[\eta]/[\eta]_\theta \quad (10)$$

and where $B$ is the parameter of the excluded volume effect. Figure 7 shows the plots of $[\eta]^{2/3}/M^{1/3}$ against $g(\alpha_\eta)M^{2/3}/[\eta]^{1/3}$ as obtained in the usual manner.[13]

Very recently Stockmayer and Fixman[5] proposed the following equation:

$$[\eta]M^{1/2}=K_0+0.51\Phi_0 BM^{1/2} \quad (11)$$

where $K_0$ is the intercept of the plots of $[\eta]/M^{1/2}$ against $M^{1/2}$. The plots are shown in Fig. 8. The $K_0$ values obtained by both Eqs. 8 and 11 are in close agreement, and using the average value the unperturbed molecular parameters were calculated. The results are shown in Table III, together with those of other vinylpyridine polymers and polystyrene.

The quantity $(\bar{R}_0^2/\bar{R}^2_{0f})^{1/2}$ may be used as a measure of the extension of the polymer chain. Here $\bar{R}^2_{0f}$ is the unperturbed mean square end-to-end distance in the absence of any hindrance about each single bond; its value was calculated by assuming a C–C bond length to be 1.54Å and the tetrahedral angle to be 109.5°.

As is shown in Table III, the value of $(\bar{R}^2_0/\bar{R}^2_{0f})^{1/2}$ for PMVP is slightly higher than the values for the other polymers, but the difference is within the range of experimental error. Thus, it can be concluded that the degree of the extension of PMVP is almost the same as those of the other polymers. This is perhaps to be expected from the fact that the methyl substituent of PMVP is relatively small in size and is located at the farthest position with regard to the carbon atom of the main chain. Therefore, the methyl group may make only a minor contribution to the internal rotation about the C–C bonds of the polymer chain.

## Summary

Nine fractionated samples of poly-2-methyl-5-vinylpyridine (PMVP) have been investigated by viscosity and light-scattering measurements at 25°C. In the range of the molecular weights from about $1\times10^5$ to $1\times10^6$, the following relationship between the intrinsic viscosity and

14) S. Arichi, private communication.
15) W. R. Krigbaum and P. J. Flory, *J. Polymer Sci.*, 11, 37 (1953).

the molecular weight in methanol has been obtained: $[\eta]=0.80\times10^{-4}M_w^{0.76}$. The unperturbed molecular dimensions have been obtained using the recent theories of the solution behavior of high polymers. The results have been compared with those of other vinylpyridine polymers and polystyrene, and it has been found that the degree of the extension of PMVP is almost the same as those of the other polymers.

The authors wish to express their thanks to Mr. Shizuo Arichi of this University for his helpful discussions throughout this work. They also wish to thank the Institute of Takeda Yakuhin Co. for making the elementary analysis.

# NOTES

## Studies of Thio Acids. II.[1] The Reaction of Stearic Esters with Sodium Hydrosulfide*1

By Yoshio HIRABAYASHI, Masateru MIZUTA and Tetsuro MAZUME*2

(Received December 26, 1963)

Thio acids can be synthesized as follows: (1) By heating carboxylic acids with phosphorus pentasulfide.[2,3] (2) By saponifying phenyl esters of carboxylic acids with sodium hydrosulfide in absolute alcohol.[4] (3) By treating acid chlorides with alkali hydrosulfide.[1] (4) By treating carbon oxysulfide with a Grignard reagent. (5) By treating carboxylic acid anhydrides with phosphorus sulfide.

It was reported that thio acids were not obtained, while carboxylic acids and mercaptans were obtained, by method 2 when alkyl esters of carboxylic acids were used in place of phenyl esters.[4] The present authors have now treated phenyl, methyl, β-chloroethyl, and cetyl stearates with sodium hydrosulfide in absolute ethanol, and obtained ethyl stearate and stearic acid from alkyl stearates, and thiostearic acid, distearoyl disulfide, ethyl stearate, and a trace of stearic acid from phenyl stearate.

### Experimental and Results

**Stearic Acid Esters.**—Methyl stearate was prepared by the reaction of stearic acid with methanol in the presence of concentrated sulfuric acid as a catalyst; it was then purified by recrystallization (m. p. 38.0—39.0°C).

Phenyl stearate and β-chloroethyl stearate were prepared by the reactions of stearoyl chloride[1] with phenol and ethylene chlorohydrine respectively, and were purified by recrystallization (m. p. 52.0—52.5°C for phenyl stearate and 49.5—50.5°C for β-chloroethyl stearate).

Cetyl stearate was prepared from stearoyl chloride, cetyl alcohol and polished magnesium ribbon according to the directions of Paquot and Boquet;[5] it was then recrystallized from ethanol (m. p. 60.5—61.5°C, saponification value 110.2 (110.2 by calcd.)).

TABLE II. COMPOSITION OF PRODUCTS OBTAINED BY REACTION OF STEARIC ACID ESTERS WITH ETHANOL - SODIUM HYDROSULFIDE

| Stearic acid ester ($R=C_{17}H_{35}-$) | Composition of product |
|---|---|
| $RCOOC_6H_5$ | RCOOH(10%), $RCOOC_2H_5$(20%), RCOSH(50%), RCOSSOCR(20%) |
| $RCOOCH_3$ | RCOOH(54%), $RCOOC_2H_5$(46%) |
| $RCOOCH_2CH_2Cl$ | RCOOH(75%), $RCOOC_2H_5$(20%), sulfur compound[a] |
| $RCOOC_{16}H_{33}$ | RCOOH, $RCOOC_2H_5$, $C_{16}H_{33}OH$, $RCOOC_{16}H_{33}$[b] |

a) A trace of a compound with SH group, confirmed to be not thiostearic acid, was detected in some ethyl stearate-fraction.
b) Too much losses were inevitable during the process of isolation, and an attempt to determine material balance among the components was unsuccessful.

**An Ethanol Solution of Sodium Hydrosulfide.**—This was prepared by the method described in the previous paper.[1]

**The Reaction of Phenyl, Methyl, β-Chloroethyl, Cetyl Stearates with Sodium Hydrosulfide.**—About a 2 N sodium hydrosulfide-ethanol solution (80 ml., or 0.167 mol. NaSH (50 ml., or 0.1 mol. NaSH to the cetyl ester only)) was added to the phenyl ester (12.4 g.), the methyl ester (9.9 g.), the β-chloroethyl ester (11.6 g.) (0.033 mol. for each), or the cetyl ester (10.2 g., or 0.02 mol.). Each mixture was refluxed for 3 hr. under a current of dried nitrogen. The ethanol was then distilled off under reduced pressure, and water was added to the residue. The mixture was acidified with dilute hydrochloric acid and extracted with ether. The ether layer was washed with water and dried over anhydrous sodium sulfate, and the ether was distilled off. The acid value*3 and sulfur content of the products are shown in Table I, in which I refers to the product from phenyl ester, II refers to that from methyl ester, III refers to that from β-chloroethyl ester, and IV refers to that from cetyl ester.

The data evidently indicate that mercaptan or thio acid is not contained in products II and III.

**The Identification of Products.**—Each product was recrystallized repeatedly from hexane, benzene, ether, methanol, or ethanol, giving nine fractions from I, four fractions from II, seven fractions from III and more than ten fractions from IV. The melting points, ultraviolet absorption spectra, neutralization values, saponification values, acetyl values, and sulfur contents (by iodine method and Kitamura's method) of these fractions were measured. The identified products and their yield are shown in Table II.

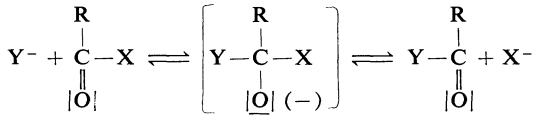
## Discussion

Auger and Billy[4] reported that sodium salts of carboxylic acids and mercaptans were formed when alkyl esters of carboxylic acids (RCOOR') were treated with absolute ethanol - sodium hydrosulfide at 180°C, while thio acids were formed when phenyl esters ($RCOOC_6H_5$) were used, and, further, that heating at 80°C or 120°C was insufficient for the achievement of these reactions. Hence, from their experimental results, it is deduced that splitting may occur between O and R' in RCOOR' and between C and O in $RCOOC_6H_5$.

$$RC(=O)O + R' + NaSH \rightarrow RC(=O)ONa + R'SH \quad (1)$$

$$RC(=O)O-C_6H_5 + NaSH \rightarrow RC(=O)SNa + C_6H_5OH \quad (2)$$

However, in the author's experiments, the products shown in Table II were obtained. It was not investigated whether the methyl ester would form methyl mercaptan or not. In order to examine the formation of mercaptans from alkyl esters, the authors investigated the reaction of the cetyl ester, but compounds with an S-H group were not obtained. After all, in these experiments, the reaction shown in Eq. 1 did not occur, though our conditions for the reaction were slightly different from those of Auger's experiments; that is, a trace of water*4 (principally in alcohol) was present, and heating was at nearly 78°C.



Wiberg[6] states that, in the mechanism of the hydrolysis of carboxylic acid esters by the base $Y^-$ (Eq. 3), the initial addition depends on the nucleophilicity of $Y^-$, but the partitioning of the addition compound to form reactants or products depends on the relative stabilities of $Y^-$ and $X^-$. If $Y^-$ is a weaker base than $X^-$, the reaction will not proceed, but if $Y^-$ is stronger than $X^-$, the reaction will proceed. Accordingly, ester hydrolysis by a general basic catalysis may be expected to occur when the anion formed from the ester is of a basicity at least comparable to the attacking base; therefore, when such esters are chosen in which the

*3 The acid value of the product varies with the concentration of sodium hydrosulfide added and with the heating time.

*4 In Auger's experiments, the water content is unknown, since the method of preparing absolute alcohol is not described.

6) K. B. Wiberg, *J. Am. Chem. Soc.*, 77, 2519 (1955).

alcoholic portion (HX) is more acidic than YH, a general basic catalysis will occur.

(3)

Although it is not a hydrolysis in the strict sense, the above mechanism will be applied to the authors' reaction.

In these experiments, those substances corresponding to HX are $CH_3OH$, $ClCH_2CH_2OH$, $C_{16}H_{33}OH$, and $C_6H_5OH$, in which phenol is more acidic than in the former three. The bases ($Y^-$) present in the sodium hydrosulfide - ethanol solution are $SH^-$, $C_2H_5O^-$, and $OH^-$ (NaSH, $C_2H_5OH$, and $H_2O$) ; for their relative basicities, the sequence $OH^- > C_2H_5O^-(RO^-) > SH^-$ should be taken, while for their nucleophilicities, the sequenee $SH^- > C_2H_5O^-(RO^-) > OH^-$ should be taken.

There is not a great difference between the basicities of $OH^-$ and $OR^-$. Hence, esters of $CH_3OH$, $ClCH_2CH_2OH$, and $C_{16}H_{33}OH$ are replaced by those of $C_2H_5O^-$ or $OH^-$. However, for $SH^-$ basicity ($X^- = (RO^-) > SH^-$), the difference between $X^-$ and $SH^-$ is too large to prompt the reaction. In phenyl ester, it is supposed that $C_6H_5O^-$ is weakly basic and replaced by $SH^-$, $C_2H_5O^-$, $OH^-$, etc.; the quantities of substituted products will depend on their nucleophilicities and concentrations. The results obtained in the experiments are well explained by the above mechanism.

# Heats of Adsorption of Hydrogen and Catalytic Activities of Hydrogenation of Ethylene on Powdered Copper-Nickel Alloys

By Toyosaburo TAKEUCHI

(Received June 15, 1964)

A previous paper[1] on copper-nickel alloys prepared from copper and nickel nitrates demonstrated that the heat of adsorption of hydrogen and the catalytic activity of the hydrogenation of ethylene are closely related to the composition of alloys. In this note we are concerned with the correlation of the heat of adsorption of hydrogen to the rate of hydrogenation of ethylene and the activation energy, which were not discussed in the previous paper.

The correlation may be represented on the basis of the data in the previous paper as in Fig. 1, where the rates of reaction and the activation energies are plotted against the heats of adsorption of hydrogen at a sparse coverage of the corresponding alloy. The activation energies were obtained from further study at various reaction temperatures (100—160°C), study which was carried out in order to supply the deficiency in the previous study. The composition (Ni%) to which each point corresponds is indicated in the figure. Of particular interest is the fact that the correlation of the rate to the heat of the adsorption of hydrogen can be represented as a straight

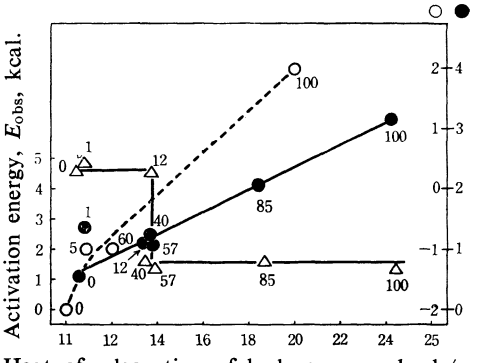

Fig. 1. Relations of the heat of hydrogen adsorption to the rate of catalytic hydrogenation of ethylene and the activation energy of the reaction.
—△— Activation energy.
—●— Rate of hydrogenation of ethylene (120°C) $K$/min.cm$^2$×10$^7$ outside scale of ordinate
—○— Rate of *p*-hydrogen interconversion (−196°C) log $K$ inside scale of ordinate
(Russell et. al.[4,5])

1) T. Takeuchi, M. Sakaguchi, I. Miyoshi and T. Takabatake, This Bulletin, 35, 1390 (1962).

line, and that the rate increases with an increase in the heats of adsorption, unlike the results on pure metals obtained by Beeck[2] and Schuit.[3] A similar correlation has, however, been obtained by Russell and his co-workers[4,5] from their study of the reaction of *p*-hydrogen interconversion and that of the heat of the adsorption of hydrogen on the same type of catalyst.

Since the observed activation energy in our study did not change continuously, notwithstanding the continuous change in the heat of adsorption of hydrogen, the correlation between the rate and the heat of adsorption can not be explained by the following equation obtained from the Langmuir-Hinshelwood kinetics:

$$E_{obs} = E_{true} - q_h - q_e$$

where $E_{obs}$ is the observed activation energy, $E_{true}$, the true activation energy, and $q_h$ and $q_e$, the heats of adsorption of hydrogen and ethylene respectively.

In view of this situation, we attempted to explain the occurrence of the discrepancy of the correlation between alloys and pure metals on the basis of the following hypothesis. If the surface of the catalyst is assumed to be nonuniform with respect to the adsorption of hydrogen and if the distribution of the bond strength of the adsorbed hydrogen against the coverage can be represented as the two cases shown in Fig. 2, and if, moreover, the bond strength of the hydrogen available for the reaction is restricted in the $E \sim E+dE$ range, the available amount of hydrogen on catalyst B in case 1 will be greater than that on catalyst A, when the greater inclination of the distribution curve can be given by the catalyst with the greater initial heat of adsorption. On the other hand, if the inclination is represented as in case 2, the available amount of hydrogen on catalyst A* will be greater than that on B*. Inasmuch as the available amount of hydrogen rules the rate of hydrogenation as well as that of *p*-hydrogen interconversion, it may suffice to say, consequently, that the reaction on pure metals and that on copper-nickel alloys correspond to those in case 1 and case 2 respectively. It was found in the study[6] using tritium as a tracer that the hydrogen adsorbed very strongly and/or very weakly on nickel did not react readily with ethylene. Unfortunately, we have no positive evidence that the heats of adsorption of hydrogen on the alloys can be given as case 2, for the measurement was made only on the sparse coverage. However, the heats on pure metals measured by Beeck[2] may be regarded to be approximately as in case 1.

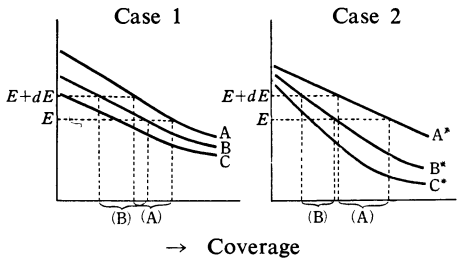

Fig. 2. Possible forms for the variation of bond strength ($E$) of adsorbed hydrogen.

The activation energies can be represented by the distinct series of different values, i.e., about 4.5 kcal. and 1.5 kcal. respectively. Such a discontinuous variation in activation energy is very similar to that found by Couper and Eley[7] in the *p*-hydrogen interconversion on palladium-gold alloys, if the expression of the axis of the abscissa can be replaced by the concentration of nickel on the surface of the alloy. Our previous studies[8,9] indicated that the concentration of nickel on the surface of the powdered copper-nickel alloy differed from that in the interior. It would be possible, however, to assume that the concentration of nickel on the surface increases with an increase in the average concentration of alloy and that the increase in the concentration increases the heat of adsorption of hydrogen. The figure shows that the composition which changed the activation energy is in the range from 12 to 40% nickel. Such a composition is approximately in accord with that to be expected from the proposal by Dowden and Reynolds,[10] even though the compositions indicated in the figure do not mean those of the surface. The activation energies in our study are quite small compared with those which have been reported by many other researchers.[11-16] No

confident explanation for this occurrence of small values can be offered. It can be recalled, however, that the rate of the hydrogenation of ethylene has an optimum at the temperature range of about 150°C.[17] The reaction temperature of our study includes this transition range. This might give the small activation energies.

# The Separation of the Main Constituents of Hiba Oil by Nitromethane Extraction

By Masaaki Ito and Kazuo Abe

(Received June 26, 1964)

Thujaplicin is a valuable terpenoid compound used industrially in a very small amount as a constituent of Thujopsis dolabrata. On the contrary, thujopsene is quantitatively the main constituent. Katsura et al.[1] showed in 1959 that thujaplicin can be isolated by the phosphoric acid treatment of an acidic oil which has been extracted with alkali.

Judging from the results reported by one of the present authors,[2] it is probable that terpene hydrocarbons are insoluble and that terpenoids, except for *l*-menthol and a few other compounds, are soluble in nitromethane. In this paper, the authors will propose a nitromethane method for the separation of the constituents of Hiba oil. It has been found that thujaplicin, can be isolated as a soluble part of the solvent, while thujopsene remains in the insoluble part. Therefore, a nitromethane-*n*-hexane system has been developed for the same separating purpose, because thujaplicin is insoluble and thujopsene is soluble in *n*-hexane, in contrast to nitromethane.

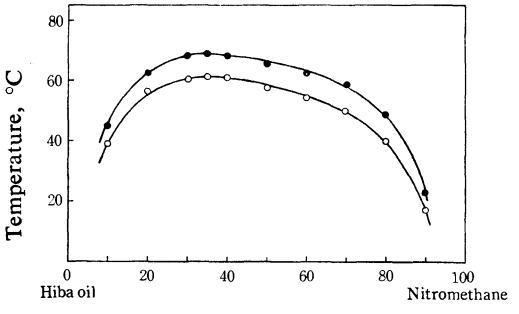

Fig. 1. The Hiba oil - nitromethane system.
○ Natural oil, ● Rectified oil

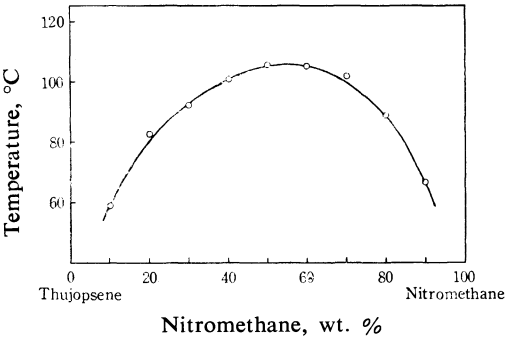

Fig. 2. The thujopsene-nitromethane system.

The mutual solubility curves between Hiba oil, thujopsene and nitromethane are shown in Figs. 1 and 2. The consolute temperature and the corresponding composition for these systems may be recorded as follows:

| System | Consolute temperature °C | Composition | |
|---|---|---|---|
| | | Oil wt. % | Nitomethane wt. % |
| Hiba oil - nitromethane | 61.0 | 35 | 65 |
| Rectified oil - nitromethane | 68.3 | 37 | 63 |
| Thujopsene - nitromethane | 105.8 | 53 | 47 |

The distribution of β-thujaplicin and thujopsene in the nitromethane - *n*-hexane system is shown in Tables I and II.

The extraction of an imitation oil (contents: β-thujaplicin 4.98%, thujopsene 95.02%) with the nitromethane - *n*-hexane system was carried out in order to confirm this separating

method. The crude thujaplicin and thujopsene were recovered quantitatively.

Subsequently, the nitromethane treatment and the nitromethane - *n*-hexane treatment of Hiba oil were carried out. The results are shown in Figs. 3 and 4. The results of the extractions were checked by the measurement of the specific gravity and the refractive index.

The residual oil in the nitromethane extraction and the *n*-hexane layer in the nitromethane - *n*-hexane system treatment was distilled under reduced pressure and rectified through a fractionating column (the number of the theoretical plate, 80) at 10 mmHg. The recovered thujopsene is of good quality.

## Experimental

**Hiba Oil.**—This was obtained by the steam-distillation from sawdust of Thujopsis dolabrata Sieb.; $d_{20}^{20}$ 0.9594, $n_D^{20}$ 1.5117.

**Rectified Hiba Oil.**—This was obtained by the steam-distillation of the above natural oil; $d_{20}^{20}$ 0.9485, $n_D^{20}$ 1.4955.

**Thujopsene.**—This was isolated from Hiba oil by the nitromethane method and then rectified; b. p. 119—120°C/10 mmHg, $d_{20}^{20}$ 0.9362, $n_D^{20}$ 1.5033, $[\alpha]_D^{20}$ −93.68.

**The Distribution of β-Thujaplicin and Thujopsene in the Nitromethane - *n*-Hexane System.**—A sample was distributed in nitromethane - *n*-hexane in a separating funnel which had been dipped into a thermostat. The solvent in each layer was evaporated, and the residual solute was weighed.

**The Extraction of an Imitation Oil with the Nitromethane - *n*-Hexane System.**—The nitromethane - *n*-hexane system (20 ml. of each) was added to the imitation oil (20 g.) and left to stand at −20°C overnight. The nitromethane layer was separated and evaporated. The crude thujaplicin was recovered in about a 100% yield. When it was then recrystallized from petroleum ether, its yield amounted to 70.3%. Also, thujopsene was recovered quantitatively from the *n*-hexane layer.

**The Nitromethane Treatment of Hiba Oil.**—Hiba oil (100 g.) was extracted with a definite volume of nitromethane at 20°C.

**The Nitromethane - *n*-Hexane System Treatment of Hiba Oil.**—A definite volume of nitromethane was added to a mixture of Hiba oil (100 g.) and *n*-hexane (100 ml.) in a separating funnel at 20°C. After the mixture had been shaken, the nitromethane layer was separated and then evaporated.

The authors are very grateful to the Takasago Perfumery Co. for its financial support and to the Hokusyu Wood Co. for the donation of Hiba oil. Also, the authors are indebted to Mr. Kunihiko Sasaki for his eager collaboration.

# A New Spectrophotometric Determination of Gallium with Capri Blue*

By Tsutomu MATSUO, Shunsuke FUNADA and Mikio SUZUKI

(Received July 20, 1964)

It is well known that, when gallium is spectrophotometrically determined with acid dyes, the chlorogallate ion $[GaCl_4]^-$ produced in strong hydrochloric acid media (ca. 6N) reacts with acid dyes to produce chelates, which are then extracted with organic solvents.[1] In previous papers,[2,3] triphenylmethaneamino derivative dyes were used to determine some metal ions. Jankovský[4] and other workers[5] reported that gallium is determined spectrophotometrically with the following two dyes; Malachite green and Brilliant green. We considered, however, that the dyes employed by them were probably unsuitable for this determination because of the small values of their apparent dissociation constants.

Capri blue (3-diethylamino-7-dimethylamino-2-methyl phenazoxonium chloride) is stable in a strong hydrochloric acid solution because its apparent dissociation constant is large.[6] However, it has not yet been applied to the determination of metal ions.

In this paper, a new method is described for the spectrophotometric determination of small amounts of gallium. It is based on the formation of a colored complex of gallium with Capril blue in a hydrochloric acid solution. The complex is extracted with benzene.

## Experimental

**Reagents.**—*Gallium Stock Solution.*—About 3 g. of gallium nitrate crystal ($Ga(NO_3)\cdot 8H_2O$ Mitsuwa Yakuhin Co.) was dissolved in 100 ml. of 6 N hydrochloric acid and titrated with an EDTA standard solution, using Cu-PAN[7] as an indicator. The working solution containing 1 $\mu$g./ml. was prepared from this solution by successive dilution with 6 N hydrochloric acid.

*Capri Blue.*—Two grams of commercial Capri blue (Tokyo Kasei Co.) was dissolved in 100 ml. of 6 N hydrochloric acid.

*Benzene.*—Commercial benzene was purified in the usual manner.

**Apparatus.**—The spectrophotometric absorbances were measured with a Shimadzu spectrophotometer Model QB-50 and a Hitachi photometer Model EPW-4, with 1 cm. cells.

**Procedure.**—Transfer the sample solution (less than 20 $\mu$g. Ga) in 6 N hydrochloric acid to a separate funnel and add 3 ml. of 2% Capri blue in a 6 N hydrochloric acid solution. Shake the solution for 1 min. with 20 ml. of benzene. Make up the benzene layer to 25 ml. with benzene. Centrifuge for 1 min. and measure the absorbance at 655 m$\mu$ (Filter 66) with the reagent blank solution as a reference. Determine the amount of gallium in the sample from a calibration curve prepared similarly.

## Results

**The Effect of the Acidity of Hydrochloric Acid and the Absorption Spectra.**—The absorbance of the sample solution was measured in the 500—680 m$\mu$ range, using the reagent as a

TABLE I. MOLAR EXTINCTION COEFFICIENTS OF VARIOUS DYES

| Dye | Gallium: Concn. mol. | Gallium: Added ml. | Absorbance | Measured wavelength mμ | Molar extinction coefficient |
|---|---|---|---|---|---|
| Capri blue | $5\times10^{-5}$ | 2 | 0.226 | 655 | $5.6\times10^{4}$ |
| Rhodamine b*[1] | $1\times10^{-4}$ | 3 | 0.385 | 570 | $3.2\times10^{4}$ |
| Malachite green*[4] | $1\times10^{-4}$ | 5 | 0.580 | 635 | $2.9\times10^{4}$ |
| Brilliant green*[5] | $1\times10^{-4}$ | 5 | 0.300 | 640 | $1.5\times10^{4}$ |

* Data was obtained by ref. described procedure.

TABLE II. EFFECT OF AMOUNT OF DYE SOLUTION ADDED

| Gallium $5\times10^{-5}$ M ml. | Capri blue: Concn. % | Capri blue: Added ml. | Absorbance | Blank value |
|---|---|---|---|---|
| 2.0 | 2.0 | 2.0 | 0.219 | 0.080 |
| 2.0 | 2.0 | 3.0 | 0.227 | 0.098 |
| 2.0 | 2.0 | 4.0 | 0.228 | 0.101 |

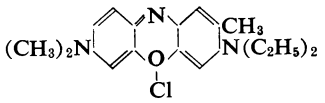

TABLE III. STABILITY OF GALLIUM-CAPRI BLUE COLORED BENZENE SOLUTION

| Standing time, min. | 0 | 30 | 60 | 90 | 120 |
|---|---|---|---|---|---|
| Absorbance | 0.226 | 0.226 | 0.226 | 0.226 | 0.226 |

Gallium taken: 2 ml. ($5\times10^{-5}$ M); Dye soln.: 2%, 3 ml.

reference. The extractability of a gallium-Capri blue complex, with benzene as a function of hydrochloric acid, is shown in Fig. 1. The maximum absorbance of the complex is at about 655 mμ. The absorbance of the sample solution is the greatest, and the absorbance of the blank solution is the smallest, when the complex is extracted from a 6 N hydrochloric acid solution.

The molar extinction coefficient of the gallium-Capri blue complex in benzene is about $5.6\times10^{4}$ at 655 mμ. The molar extinction coefficients of various complexes used for the colorimetric determination of gallium are compared in Table I; the Capri blue complex is very sensitive.

**The Effect of the Amount of the Dye and the Stability of the Colored Complex.** — The amount of Capri blue solution added was varied, the other factors remaining unchanged. The results are shown in Table II. The absorbance is constant on the addition of more than 3 ml. of a 2% Capri blue solution. When too much is added, however, the absorbance of the reference increases. The stability of the colored complex in a benzene solution was investigated as shown in Table III. The complex is stable in benzene for 2 hr.

**Calibration Curve.**—Various amounts of a standard gallium solution containing more than 1 μg. of gallium were used in the manner

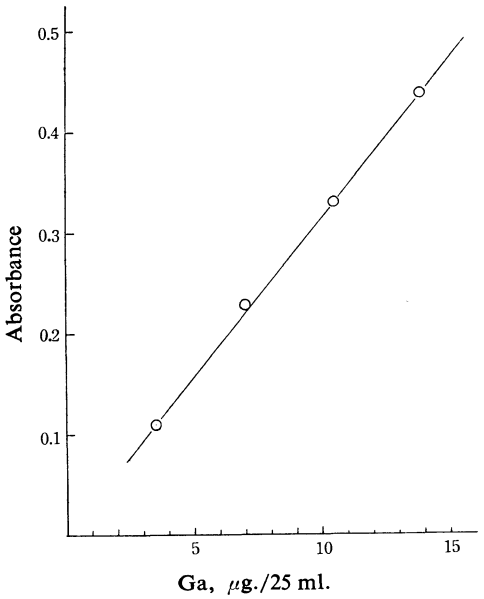

Fig. 2. Calibration curve.
Dye soln.: 2%, 3 ml., measured at 655 mμ

described above. The relationship between the absorbance and the amount of gallium obeys Beer's law for 1—15 $\mu$g. of gallium as is shown in Fig. 2.

**The Effect of Foreign Ions.**—The effect of foreign ions was studied with a solution containing 2 ml. of $5\times10^{-5}$ mol. (8.7 $\mu$g.) of gallium and various ions. Alkali metal salts of the anions were used. Cations were added as chloride or nitrate.

Under these conditions no interference was observed from about fifty-fold (0.5 mg.) amounts of aluminum, antimony, calcium, cadmium, cobaltous, cupric, magnesium, manganese, indium or thallium ions. However, even a minute quantity of iron (both II and III) interferes seriously. Five millimicrograms of iron, for instance, doubled the apparent gallium content. Of the few anions examined, large excesses (1 mg.) of nitrate and sulafte were without effect.

# The Dye-sensitized Photopolymerization of Vinyl Acetate in the Presence of Benzoyl Peroxide

By Koichi TAKAKURA and Gozo TAKAYAMA

(Received July 21, 1964)

Oster[1] reported that the dye-sensitized photopolymerization of vinyl monomers can easily occur in the presence of oxygen when a suitable combination of a dye and a reducing agent is used. Since then, many studies have been made concerning polymerization by means of such sensitizing systems.[2-8] One of the present authors previously found[4] that the riboflavin-sensitized photopolymerization of acrylamide in an aqueous solution was initiated by free radicals arising from the photoredox process between the photoreduced dye and the peroxidic compound produced during an induction period, and, furthermore, that this polymerization readily occurred at or below room temperature, even in the complete absence of oxygen, when a small amount of a peroxide, such as hydrogen peroxide or potassium persulfate, was added to the monomer mixture.

1) G. Oster, *Nature*, **173**, 300 (1954).
2) K. Nakatsuka, *Chemistry* (*Kagaku*), **11**, 218 (1956).
3) H. Oba and I. Fujita, *Chem. High Polymers, Japan* (*Kobunshi Kagaku*), **15**, 445 (1958).
4) Y. Nishijima, K. Takakura, T. Hayahara and Y. Ohno, presented at the 12th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1959; K. Takakura, Master Thesis, Dept. of Polymer Chem., Kyoto University, March, 1959.
5) G. Takayama, *Chem. High Polymers, Japan* (*Kobunshi Kagaku*), **17**, 644 (1960).
6) G. Delzenne, S. Toppet and G. Smets, *J. Polymer Sci.*, **48**, 347 (1960).
7) G. Delzenne, W. Dewinter, S. Toppet and G. Smets, *J. Polymer Sci.*, **A2**, 1069 (1964).
8) Y. Nishijima, T. Fujimoto and K. Shimabayashi, presented at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

These sensitizing systems, including peroxide, seem to be superior to the previous one in that there is no induction period and polymerization can be easily controlled by varying the amounts of the peroxide added. For this reason, the present work was undertaken.

## Experimental

The sample solution, a mixture of the monomer and methanol (80 : 20 by volume), was deaerated by flushing it with purified nitrogen. Then the solution was irradiated with a 500-W. tungsten projector lamp through a color filter which removed the light of wavelengths shorter than 3000 Å.

## Results and Discussion

Table I shows the effects of several organic peroxides on the photopolymerization sensitized by riboflavin and acriflavine at 24°C. The polymerization was markedly accelerated by the addition of small amounts of such peroxides. The polymerization in the dark scarcely occurred under identical conditions, however. The rates of photopolymerization induced by the reaction between BPO and acetamide and by BPO itself are of an order of magnitude lower than that in the presence of both the dye and BPO. In all cases, the fading of the dye commenced immediately on irradiation, and then polymerization occurred. The conversion was increased with the increase in BPO concentration, whereas the polymerization

Temp., 24°C in nitrogen

was markedly retarded at higher dye concentrations. The BPO-catalyzed polymerization of VAc at 60°C in the dark was almost entirely inhibited when riboflavin was present.

Figure 1 shows the course of the polymerization performed at three different temperatures. The overall activation energy was calculated to be 7.4±0.5 kcal./mol., a value which was in good agreement with that of a previous study.[5]

On irradiation the absorption spectra of the reaction mixture in the visible regions began to disappear. The original color of the dye could no longer be recovered by admitting air into the irradiated system. It should be noted that such a spectral change in the polymerizing system was not observed in the dark, even at a high temperature. Therefore, it may be suggested that the photo-excited dyes or some derived species would react with BPO and undergo irreversible decomposition to produce some active free radicals.

Among the dyes examined, fluorescein sodium, acriflavine, rhodamin B and riboflavin

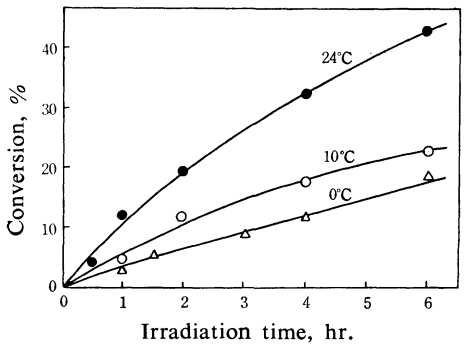

Fig. 1. Time-conversion curve for the photopolymerization of VAc sensitized by acriflavine-BPO: (Acriflavine) $=2.4\times10^{-5}$ mol./l., (BPO) $=8.3\times10^{-4}$ mol./l., (Acetamide) $=0.68$ mol./l.; VAc : methanol $=80:20$ (by vol.), under nitrogen.

are particularly effective. All of them are photoreducible dyes and are characterized by their fluorescence.[9]

This sensitizing system has been successfully applied to the photopolymerization of other vinyl monomers in organic solutions. The preliminary results are summarized in Table II. The effect of BPO is pronounced here also, and the polymerization is always accompanied by the photobleaching of the dye.

The results obtained may be explained in terms of a photo-redox mechanism by which the photoreduced dye is irreversibly oxidized with BPO to produce active initiating radicals.

The authors wish to thank Dr. Masakazu Matsumoto and Dr. Junji Ukida of our laboratory for their helpful discussions during this work.

# The Reaction of Organolithium Compounds with Nickel Carbonyl*

By Song Kwang Myeong, Yoshihiko Sawa, Membo Ryang and Shigeru Tsutsumi

(Received August 3, 1964)

In previous papers we reported that organolithium compounds reacted smoothly with iron pentacarbonyl at −50—−40°C in an ether solution, giving ketones and acyloins as major produts.[1,2] This communication will deal with similar reactions of organolithium compounds with nickel carbonl.

Organolithium compounds were prepared by the ordinary methods, and nickel carbonyl was added to the ether solutions of organolithium compounds at −70°C. The reaction mixture was hydrolyzed with ethanol and hydrochloric acid.

The results of this reaction are given in Table I.

As a general tendency, acyloins were produced from arillithiums and symmetrical ketone alkyllithiums.

Table I.

| Organolithium compound | Main product | Yield* % |
|---|---|---|
| Phenyllithium | Benzoin | 36 |
| *m*-Tolyllithium | *m*-Toluoin | 61 |
| *p*-Tolyllithium | *p*-Toluoin | 71 |
| *p*-Methoxyphenyllithium | *p*-Anisoin | 15 |
| | *p*-Anisil | 23 |
| 2,6-Dimethylphenyllithium | 2,6-Dimethylbenzaldehyde | 22 |
| | 2,2',6,6'-Tetramethylbenzil | 23 |
| *n*-Butyllithium | Di-*n*-butyl ketone | 29 |

* The calculations of yields are based on the amounts of organic halides used.

Whereas the reaction mixture obtained from the reaction of *p*-tolyllithium with nickel carboyl at −70°C gave *p*-toluoin in a 71% yield on hydrolysis with ethanol - 6N hydrochloric acid at −70°C, the extraction of the reaction mixture with anhydrous benzene in a dry nitrogen box at room temperature, i. e., the isolation of the products without hydrolysis, yielded di-*p*-tolyl ketone in a 29% yield.

* This work was presented at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

1) M. Ryang, Y. Sawa, H. Masada and S. Tsutsumi, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), 66, 1086 (1963).

2) M. Ryang, I. Rhee and S. Tsutsumi, This Bulletin, 37, 341 (1964).

When the reaction time was prolonged by stirring for a further 5 hr. at 30—60°C, the subsequent hydrolysis gave *p*-toluoin and di-*p*-tolyl ketone in yields of 36 and 25% respectively (at 35°C) and in yields of 34 and 38% respectively (at 60°C). Thus it is evident that the reaction products were markedly affected by the methods of treating the reaction mixtture.

The present findings suggest that the ketones and acyloins were produced from the same intermediate complexes, but that the acyloins were produced via the dimerization of the intermediate, followed by hydrolysis, while the ketones were produced by the thermal decomposition of the same intermdiates. Hence, the complicated results in the reaction of organolithium compounds with iron pentacarbonyl or nickel carbonyl can be explained by considering the thermal stabilities and chemical reactivities of the intermediates. As for the intermediates, the following three unstable complexes can be postulated:

(a) $R-\underset{\underset{O}{\|}}{C}-Ni(CO)_x$ (b) $[R-\underset{\underset{O}{\|}}{C}-Ni(CO)_x]^-Li^+$

(c) $R-\underset{\underset{O}{\|}}{C}-Li$

The mechanistic aspects of this reaction will be discussed in detail in a forthcoming paper.

## SHORT COMMUNICATIONS

# Reaction Mechanism of the Acetonation of L-Sorbose by Ketal Interchange

By Takasi MAEDA, Masumi KIYOKAWA and Kanji TOKUYAMA

(Received December 14, 1964)

The acetonation of L-sorbose (I) is a very important reaction for the production of L-ascorbic acid. Previously we reported that, from the point of view of the reaction mechanism, the acetonation with acetone ketal[1] is different from the process of the acetonation with acetone,[2] and established the mechanism of the latter as I→1, 2-*O*-isopropylidene-α-L-sorbopyranose (II)[3] → the dimer of II → 2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose

Scheme 1

2) K. Tokuyama, E. Honda and N. Hōki, *J. Org. Chem.*, 29, 133 (1964).

3) H. Ohle, *Ber.*, 71, 762 (1938).

(VIII)[4]+I, in which the last element I takes this route further. In this paper, we present a reaction mechanism of the former acetonation.

The reaction of I with 2,2-dimethoxypropane (acetone dimethyl ketal) in the presence of *p*-toluenesulfonic acid gave a mixture syrup whose thin layer chromatogram exhibited multiple spots. The relative concentrations of the spots varied with the reaction conditions employed. Each component was separated in a pure state by thin-layer and fractional-gas chromatography, and their structures were determined to be 1,2-*O*- (II), 1,2:3,4-di-*O*- (III) and 5-*O*-1'-methoxyisopropyl-1,2:3,4-di-*O*-isopropylidene-α-L-sorbopyranose (IV), and 1,2:3,4-di-*O*- (V), 1,2:4,6-di-*O*- (VI),[1] 3-*O*-1'-methoxyisopropyl-1,2:4,6-di-*O*- (VII), 2,3:4,6-di-*O*- (VIII), 1-*O*-1'-methoxyisopropyl-2,3:4,6-di-*O*- (IX) and 2,3-*O*-isopropylidene-α-L-sorbofuranose (X),[5] respectively, by the infrared and NMR spectra and by the optical rotations. The analytical data are summarized below. III: colorless needles, m.p. 103—105°C (recrystallized from *n*-hexane), $[\alpha]_D^{27.5}$ −91.2 (*c* 1.051, acetone). Found: C, 55.75; H, 7.78. Calcd. for $C_{12}H_{20}O_6$: C, 55.37; H, 7.75%. IV: colorless needles, m.p. 133—135°C (recrystallized from *n*-hexane), $[\alpha]_D^{24.0}$ −82.2 (*c* 1.017, chloroform). Found: C, 57.77; H, 8.37; $CH_3O$, 9.03. Calcd. for $C_{16}H_{28}O_7$: C, 57.81; H, 8.49; $CH_3O$, 9.38%. V: m.p. 80—83°C, $[\alpha]_D^{24.0}$ −69.3 (*c* 1.090, chloroform). Found: C, 55.85; H, 7.91. Calcd. for $C_{12}H_{20}O_6$: C, 55.37; H, 7.75%. VII: syrup, $[\alpha]_D^{24.0}$ +17.5 (*c* 0.561, acetone). Found: C, 57.61; H, 8.26. Calcd. for $C_{16}H_{28}O_7$: C, 57.81; H, 8.49. IX: colorless syrup, $[\alpha]_D^{26.0}$ −10.9 (*c* 1.118, acetone). Found: C, 57.54; H, 8.55%. Calcd. for $C_{16}H_{28}O_7$: C, 57.81; H, 8.49%.

The above acetonated sugars (II→X) were also obtainable by the reaction of II with 2,2-dimethoxypropane; the mild acetonation of I gave II as a major product. On the other hand, the acetonation of X by ketal interchange gave only two products, VIII and IX. Therefore, the first intermediate of the acetonation process must be II.

On the basis of the above facts and the changes with time in the thin layer and gas chromatograms throughout the course of the acetonation by ketal interchange, the acetonation mechanism may be concluded to be as shown in Scheme 1.

# The Radiolysis of Crystalline Oxalatocobalt(III) Complex Salts

By Hirotoshi SANO, Noriko MATSUBARA* and Nobufusa SAITO

(Received October 21, 1964)

Many attempts have already been made to investigate the hot-atom effect in neutron-irradiated metal complex salts.[1-3] The study of radiation effect is quite important in hot-atom chemistry. However, little attention has so far been paid to the radiolysis of these complex salts. Sugimori and Tsuchihashi have studied the radiolysis in trioxalato complex salts of trivalent metals, such as cobalt, chromium, iron, aluminum.[4] The present authors have recently reported that ninety per cent

or more of radiocobalt atoms are found as cationic divalent species after the dissolution of the neutron-irradiated oxalatocobalt(III) complex salts.[5] In this paper, the radiolysis of the oxalatocobalt(III) complex salts will be reported.

The seven kinds of crystalline complex salts listed in Table I were irradiated with Co-60 gamma rays at room temperature, at a dose rate of $2.2-3.0\times10^5$ r./hr. in the presence of air. The irradiated salts were dissolved in water or dilute hydrochloric acid. The amount of cationic cobalt(II) species was determined by the $\beta$-nitroso-$\alpha$-naphthol method[6] or the nitroso-R salt method,[7] after the separation of cobalt(II) species from parent cobalt(III) complex ions by procedures includiding anion exchange or solvent extraction. The results were practically the same irrespective of the analytical method employed.

It was found that the amount of cobalt(II) species produced increases with an increase in the gamma-ray dose. Table I shows the estimated $G(Co^{2+})$ values. It should be mentioned that the $G$ value depends on the content of oxalate ions in the nearest coordination sphere, and that the $G$ value of hexamminecobalt(III) oxalate is definitely greater than that of hexamminecobalt(III) nitrate. The results may be explained by assuming the electron transfer process from oxalate to cobalt ions during the radiation-induced decomposition of complex salts.

# The Synthesis of 2-(1, 8-Dihydroxy-3, 6-disulfo-2-naphthylazo)-phenoxyacetic Acid as a New Reagent and Its Thorium Complex

By Kyoji TÔEI, Haruo MIYATA, Toshiya SHIBATA* and Sadao MIYAMURA**

(Received November 14, 1964)

Neo-thorin (2-(1, 8-dihydroxy-3, 6-disulfo-2-naphthylazo)-benzenearsonic acid)[1,2] has been applied as a reagent for the determination of thorium, zirconium and uranium. The arsono group, $-AsO_3H_2$, is most interesting as a functional group for thorium. The oxyacetic acid group, $-OCH_2COOH$, is also reactive with this element.

The present paper will describe the preparation of 2-(1, 8-dihydroxy-3, 6-disulfo-2-naphthylazo)-phenoxyacetic acid, and the determination of the acid dissociation constant of the reagent by the spectrophotometric method. The complex of the reagent with thorium will also be studied spectrophotometrically.

**The Synthesis of the Reagent.**—The acetylation of *o*-aminophenol with acetic anhydride afforded the acetyl derivative, which was converted into *o*-acetaminophenoxyacetic acid[3] by reaction with monochloroacetic acid in an alkaline medium.

The potassium salt of *o*-aminophenoxyacetic acid[4] was prepared by the reaction of potassium hydroxide and the lactam of *o*-aminophenoxyacetic acid, which had been obtained by the hydrolysis of *o*-acetaminophenoxyacetic acid with hydrochloric acid.

2-(1, 8-Dihydroxy-3, 6-disulfo-2-naphthylazo)-phenoxyacetic acid was prepared by the coupling of chromotropic acid with diazotized potassium *o*-aminophenoxyacetate. Greenish needles of the disodium salt of the product were obtained by recrystallization from water.

**The Spectral Properties of the Reagent and Its Acid Dissociation Constant.**—The absorption

# A Polymerization of Isophthalonitrile Di-*N*-oxide by 1, 3-Dipolar Cycloaddition Reaction

By Yoshio IWAKURA, Masayasu AKIYAMA and Shinsaku SHIRAISHI

(Received December 14, 1964)

We wish to report a novel polymerization of isophthalonitrile di-*N*-oxide with diolefins, *m*-phenylenebismaleimide, ethylene dimethacrylate and biallyl. The polymerization proceeded by the repetition of the so-called 1, 3-dipolar cycloaddition between a nitrile *N*-oxide and a carbon-carbon double bond, forming a 4*H*-isoxazoline ring.[1] The 1, 3-dipolar cycloaddition resembles the Diels-Alder reaction in many respects;[2] on the other hand, it has been shown that polymerizations by the Diels-Alder reaction produce high-molecular-weight polymers.[3,4]

Isophthalonitrile di-*N*-oxide (m. p. 92—94°C decomp.) was prepared by the same method as was terephthalonitrile di-*N*-oxide.[5] The conditions of the polymerizations and the properties of the polymers obtained are presented in Tables I and II.

A typical polymerization is as follows: Into a solution of 0.402 g. (0.002 mol.) of *m*-phenylenebismaleimide (m. p. 201°C) in 4.0 ml. of dimethylformamide, 0.320 g. (0.002 mol.) of isophthalonitrile di-*N*-oxide was added portion

TABLE II. INFRARED ABSORPTTION MAXIMA OF POLYMERS
Nujol mulls

| Polymer | Absorption maxima, $cm^{-1}$ |
|---|---|
| I | 1790, 1725(s), 1605, 1490, 1375, 1310(w), 1180(s) 905, 795 and 685. |
| II | 1740(s), 1600(w), 1340, 1300, 1175, 910, 795 and 685. |
| III | 1640(w), 1580(s), 1440, 1335, 910, 795 and 685. |

by portion, over a period of 30 min. at room temperature. The mixture was then stirred for an additional two hours and poured into methanol. The polymer separated was washed with hot dioxane and hot methanol and dried under vacuum at 110°C, to give an almost colorless powder (90% yield) which did not melt up to 400°C. The polymer showed the infrared absorptions at 1790 and 1725 $cm^{-1}$ characteristic of an imide group, those at 1605 and 1490 $cm^{-1}$ characteristic of a phenyl group, and those at 795 and 685 $cm^{-1}$ characteristic of an *m*-phenylene group. It also gave at 905 $cm^{-1}$ the strong band which was common to all the other polymers obtained in these experiments and which was assigned tentatively to the isoxazoline ring. Absorptions of isophthalonitrile di-*N*-oxide at 2320, 1350 and 1080 $cm^{-1}$, and those of *m*-phenylenebismaleimide at 1150, 830 and 700 $cm^{-1}$, disappeared in the polymer. The infrared spectral data and the high yield of the product strongly support the theory that the polymerization of isophthalonitrile di-*N*-oxide with *m*-phenylenebismaleimide takes place according to Eq. 1.

# A New Spectrophotometric Method for the Determination of Magnesium with Sodium *p*-Aminobenzene-azo-1, 8-dihydroxynaphthalene-3, 6-disulfonate

By Katsuya UESUGI

(Received October 13, 1964)

A new spectrophotometric method for the determination of traces of magnesium has been developed. It is based upon the formation of a stable bluish-violet magnesium complex of sodium *p*-aminobenzene-azo-1, 8-dihydroxynaphthalene - 3, 6 - disulfonate (pontacyl violet 4BSN).

The absorption spectra of the complex are shown in Fig. 1. At pH 11, the maximum absorbance is at 580 m$\mu$. The complex is formed by adding a microgram of magnesium to the mixture of 5.0 ml. of an ammonium chloride - ammonia buffer solution and 2.5 ml. of a 0.2% reagent solution in a 25 ml. volumetric flask. The solution is diluted to the mark with distilled water and thoroughly mixed. The full color develops within five minutes, and its stability is quite adequate for the determination of magnesium. As may be seen in Fig. 2., the magnesium complex has a maximum absorbance in the pH range from 10.8 to 11.3 ($\lambda_{max}$ 580 m$\mu$). Beer's law is obeyed up to a magnesium concentration of 1.0 p. p. m. (Fig. 3, curve 1). At 580 m$\mu$, the molar extinction coefficient is about 19300, and the sensitivity is 0.0013 $\mu$g. Mg/cm$^2$ that corresponds to log $I_0/I$=0.001.

The presence of acetone increases the sensitivity of the reagent to magnesium about 60%. In the addition of 20% vol./vol. with respect to acetone, Beer's law is obeyed up to a magnesium concentration of at least 0.8 p. p. m.

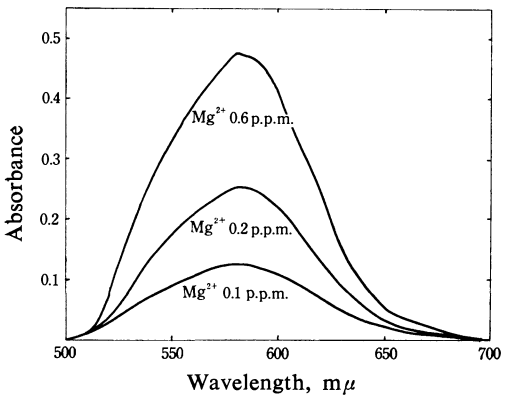

Fig. 1. Absorption spectra on the Mg-complex.
pH 11, reagent 200 p. p. m., against reagent blank.

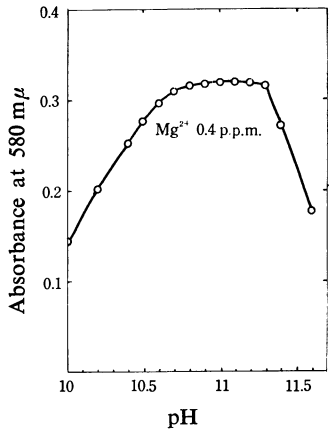

Fig. 2. Effect of pH on the absorbance of the Mg-complex.

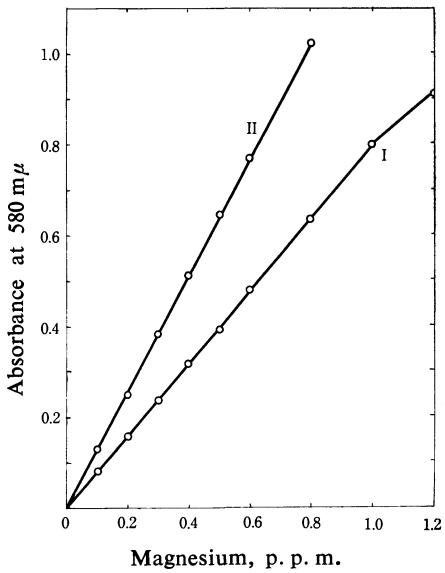

Fig. 3. Beer's law curve.
pH 11. I acetone — II acetone 20%

(Fig. 3, curve II). At 580 m$\mu$, the molar extinction coefficient is about 31300, and the sensitivity is 0.0008 $\mu$g. Mg/cm$^2$ that corresponds to log $I_0/I=0.001$.

Strontium and barium in concentrations up to 10 p. p. m. do not interfere. Calcium in amounts up to 2 p. p. m. also does not interfere; however, the presence of more than that causes a positive error. Chloride, sulfate, and nitrate in concentrations up to 500 p. p. m. have no effect. More than 1000 p. p. m. of chloride leads to poor results.

The details of this study will be reported elsewhere.

# The Synthesis of Local Anaesthetics

By Prithwi Nath BHARGAVA and Phulgan RAM

(Received May 2, 1964)

In view of the significant biological properties exhibited by thiazoles[1] and benzothiazoles[2], the preparation of some 2-(*N*-benzimidazolyl-acetylamino) benzothiazoles and their hydrochlorides was examined in order to ascertain their local anaesthetic properties.

The starting compound, 2-aminobenzothiazole, was prepared by the action of liquid bromine on asymmetrical phenylthiourea in an inert solvent such as chloroform.[3] Similarly, various substituted benzothiazoles have been prepared from the corresponding substituted asymmetrical thioureas. These 2-aminobenzothiazoles were condensed with chloroacetylchloride in dry benzene to obtain the corresponding 2-chloroacetylaminobenzothiazoles, which subsequently, on condensation with benzimidazole and 2-methylbenzimidazole, gave various substituted 2-(*N*-benzimidazolylacetylamino)benzothiazoles. Hydrochlorides of the above mentioned benzothiazoles have been prepared, and their local anaesthetic activity has been tested.[4]

A study of the pharmacological screening has shown that not a single compound is active. The values obtained for these compounds are more than those obtained for procaine-hydrochloride probably because of a heavier hydrophylic end in these compounds.

## Experimental

**2-Chloroacetylaminobenzothiazole.**—To a solution of 2-aminobenzothiazole (20 g.) dissolved in dry benzene (150 ml.), a solution of chloroacetylchloride (10 ml.) in dry benzene (50 ml.) was

gradually added. The reaction mixture was then warmed at 70°C on a water bath for 1.5 hr. The benzene was distilled off, and the residue was washed with a sodium bicarbonate solution and water and then dried. The product was crystallized from alcohol; m. p. 156°C.

Similarly other substituted 2-aminobenzothiazoles were converted into 2-chloroacetylamino-derivatives. Their melting points and analytical data are recorded in Table I.

**2-(*N*-Benzimidazolylacetylamino)benzothiazole.**—To 2-chloroacetylaminobenzothiazole (6 g.) dissolved in absolute ethanol (50 ml.), benzimidazole (3 g.) was added, and the mixture refluxed for 8 hr. After the alcohol had been recovered and the residue washed with a sodium bicarbonate solution and water, the product was crystallized from alcohol as brown crystals; m. p. 245°C.

Similarly, various substituted 2-(*N*-benzimidazolylacetylamino)- and 2-[*N*-(2'-methylbenzimidazolyl)-acetylamino]-benzothiazoles were prepared. Their melting points and analytical data are listed in Tables II and III.

**The Preparation of Hydrochlorides.**—The hydrochlorides of the above-mentioned bases were prepared as usual. Their melting points and analytical data are recorded in Tables IV and V.

**Pharmacological Screening.**—The hydrochlorides prepared above were screened for local anaesthetic activity by the method using a frog's sciatic plexus.

# The Synthesis of Some *S*-Substituted-2-mercapto-3-aryl-4-quinazolones

By Prithwi Nath BHARGAVA and Phulgan RAM

(Received May 2, 1964)

Several 4-quinazolone derivatives and 2- or 4-sulphanilamido-quinazolines have been reported to be therapeutically active.[1,2] Several potential antimalarials belonging to substituted quinazolones and quinazolines have been screened against blood-induced *P. gallinaceum* infection in 7-day-old chicks. Gujral et al. observed the hypnotic activity of 2-alkyl-3-aryl-4(3*H*)-quinazolones in rats.[3]

The above findings have led the authors to prepare *S*-substituted-2-mercapto-3-aryl-4-quinazolones[4,5] as possible antimalarials. In the present investigation, the synthesis of *S*-substituted-2-mercapto-3-aryl-4-quinazolones from anthranilic acid, arylisothiocyanates and alkyl halides has been studied.

## Experimental

**2-Mercapto-3-*m*-chlorophenyl-4-quinazolone.**—A mixture of *m*-chlorophenylisothiocyanate (15 g.), *o*-aminobenzoic acid (15 g.) and absolute ethanol (150 ml.) was refluxed on a water bath for about 2 hr. The product was washed with ethanol, dissolved in 10% sodium hydroxide, precipitated with dilute hydrochloric acid, filtered, and after washing with water, dried.

Similarly, various 2-mercapto-3-aryl-4-quinazolones were prepared from the corresponding arylisothiocyanates and *o*-aminobenzoic acid. Their yields, melting points, and analytical data are listed in Table I.

**2-Ethylthio-3-*m*-chlorophenyl-4-quinazolone.**—To a solution of sodium hydroxide (5 g.) in (85 ml.) of 50% aqueous ethanol, 2-mercapto-3-*m*-chlorophenyl-4-quinazolone (7.5 g.) was added. The solution was then stirred, filtered and treated with ethyl iodide (4 ml.); after being stirred again for an hour, the solution gave a crystalline product which was washed first with water and then with ethanol. Long needles were obtained on crystallization form ethanol.

Similarly, various *S*-substituted-2-mercapto-3-aryl-4-quinazolones have been prepared. Their yields,

melting points, and analytical data are recorded in Tables II to VII.

**2-Carboxymethylthio-3-*m*-chlorophenyl-4-quinazolone.**—An equimolecular quantity of sodium monochloroacetate was added to an alkaline solution of 2-mercapto-3-*m*-chlorophenyl-4-quinazolone, and the mixture was shaken for 6 hr. It was then acidified with dilute hydrochloric acid, and the precipitate obtained was dissolved in sodium bicarbonate solution and reprecipitated with diluted hydrochloric acid. The product was crystallized from ethanol.

Similarly, other 2-carboxymethylthio derivatives of -3-*p*-chlorophenyl-, -3-*p*-bromophenyl-, -3-*p*-methoxyphenyl- and -3-*p*-ethoxyphenyl-4-quinazolones were prepared. Their yields, melting points, and analytical data are also recorded in Tables II, III, IV, VI, and VII.

# Solid State Polymerization of Binary Component System

By Masatoshi MIURA, Takako HIRAI and Shunji KAWAMATSU

(Received May 16, 1964)

During the past few years it has been reported that various vinyl[1-3] and cyclic compounds[4-6] can be polymerized in a solid state by high-energy ionizing radiation. However, there have been few reports on the solid state polymerization of a binary component system. In the solid of a binary component system, there are various states of aggregation, such as a solid solution or mixed crystals, and these states are expected to affect the polymerization and the polymer structure. The present study was undertaken to elucidate the correlation of the polymerization with those aggregation states. Various oxetane derivatives polymerize in a solid state, and the mixture of these may be expected to give solid solution because of the similarity of the molecular structures. Therefore, in this investigation, mixtures of 3-chloromethyl-3-ethyloxetane (CMEO), with 3-fluoromethyl-3-ethyloxetane (FMEO) and with 3,3-bis(chloromethyl)-oxetane (BCMO) were chosen as the binary component system of a solid solution. As the mixed crystals, mixtures of CMEO with diketene and with trioxane were chosen. All of these cyclic compounds have been reported to polymerize in the solid state,[4-6] and the crystal states of these monomers play important roles in the solid state polymerization. Recently Okamura and his co-workers have independently from our study reported[7]

the radiation-induced polymerization of the solid solution of oxetane derivatives. However, no detailed studies of the polymerization behavior of the solid solution have yet been published.

## Experimental

**Monomer.**—CMEO and FMEO were prepared by the method reported previously,[6] while commercially available BCMO (Kōei Chemicals) and diketene (Tokyo Chem. Ind.) were used. All the oxetanes were purified by dehydration with $CaH_2$ and redistillation under reduced pressure in a nitrogen anhydrous stream before use. Diketene was purified, in the same manner as has been described above, using anhydrous sodium sulfate as a drying agent. Trioxan (Tokyo Chem. Ind.) was recrystallized two times from methylene chloride.

The phase diagram of the monomer mixture was made from the freezing or melting curves of the mixtures of various compositions. The rate of cooling or heating was about 0.3°C/min.

**Polymerization.** — *γ-Ray-induced Polymerization.* — The monomer mixture in a glass ampoule was degassed by three successive freezing-by-melting procedures and then sealed. The mixture of CMEO and trioxane was not degassed because of the sublimation tendency of trioxane. The ampoule was set in a Dewar vessel containing a suitable cooling agent and irradiated at an appropriate distance from a source of $^{60}Co$. The cooling agents were as follows: Dry ice-methanol (−80°C). Dry ice-acetone (−86°C), such freezing materials as benzene (5°C), ethyleneglycol (−15.6°C) and 1,2-dichloroethane (−35°C), and cryohydrates of $BaCl_2$ (−8°C), KCl (−11°C), NaCl (−21°C), $CuNO_3$ (−24°C) and $CaCl_2$ (−55°C). The sample irradiated was extracted with methanol and dried in vacuo. To determine the polymer yield, the extraction was performed below the irradiation temperature so as to prevent post-polymerization.

*$BF_3$-catalyzed Copolymerization.* — In a reaction vessel containing 25 g. of the CMEO-BCMO mixture and 75 g. of chloroform, 15 g. of a 1.4 wt. % solution of $BF_3$-etherate was added at room temperature under a gentle stream of nitrogen. The reaction was stopped with less than 10% conversion by the addition of methanol. The polymer obtained was purified by the manner described above. The copolymerization of CMEO and FMEO was carried out by the same procedure with 10 g. of a monomer mixture, 90 g. of chloroform, and 9 g. of a $BF_3$-solution.

**The Characterization of the Polymer.** — The infrared absorption spectra were obtained with an Hitachi EPI-2 Type spectrophotometer. The composition of the copolymer of CMEO and FMEO was determined by measuring the intensities of absorptions at 730 $cm^{-1}$ (C-Cl stretching vibration) and 1010 $cm^{-1}$ (C-F stretching vibration). The composition of the coploymer of CMEO and BCMO was calculated from the chlorine content of the elemental analysis. An X-ray diffraction diagram was obtained by means of the Rigaku D-3F Type diffractometer.

The viscosities of the polymer solution were measured at 42±0.02°C in a chloroform solution. The intrinsic viscosities were calculated by the single-point determination method at a concentration of 0.2 g./100 cc. The melting points of the polymers were determined by means of a hot-stage microscope. The fractionation of the copolymers was carried out using chloroform as a solvent and acetone as a nonsolvent. The polymer blend was fractionated by extracting it with dimethylformamide containing 1% β-naphthylamine as an antioxidant under a nitrogen stream at 50°C.

## Results and Discussion

**The CMEO-FMEO Binary Component System.**—The phase diagram given in Fig. 1 indicates that the binary component system forms a solid solution over the whole range of the composition. γ-Ray-induced polymerization was carried out at −86°C with the solid solution crystallized at a temperature about 5°C below its melting point. Figure 2 shows the melting points of the polymers obtained with 311-hr. radiation at $1.5\times10^4$ r./hr. The melting point is as sharp as that of the polymer obtained from each single component crystal.

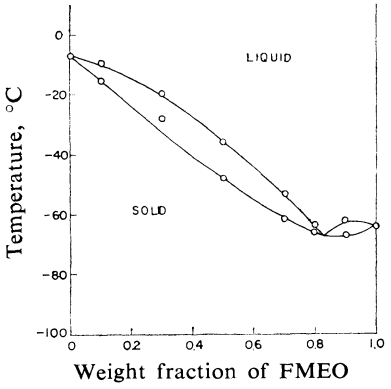

Fig. 1. Phase diagram of CMEO-FMEO binary component system.

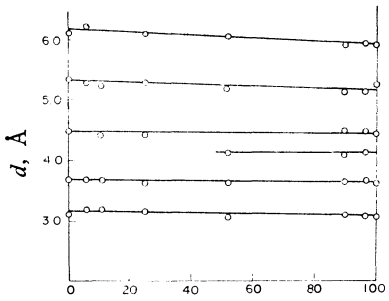

Fig. 3. X-Ray diffraction pattern of CMEO-FMEO copolymer.

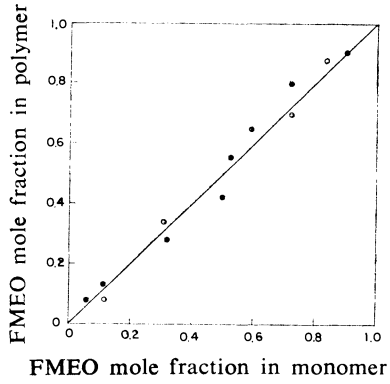

Fig. 4. Copolymer composition curve for CMEO-FMEO binary component system (●) $\gamma$-ray induced solid state polymerization, (○) $BF_3$-catalized liquid state polymerization.

Figure 3 gives the interplanar distances of the polymers as determined by X-ray diffractometry. Figure 3 suggests that all polymers have the same crystal structures, regardless of their compositions, whereas the interplanar distance varies a little. From the facts shown in Figs. 2 and 3, it may be concluded that a copolymer is formed from the solid solution by irradiation of $\gamma$-rays. Figure 4 shows the composition curve of the copolymer obtained by the procedure described above. The composition of the polymer is the same as that of the corresponding initial monomer mixture. $BF_3$-catalyzed copolymerization also seems to give the same result, as is shown in the same figure. However, this agreement is only apparent. A detailed discussion of the polymerization of a solid solution will be given in the following section.

**The CMEO-BCMO Binary Component System.**—The phase diagram of the binary component system is shown in Fig. 5. The system also crystallizes to a solid solution. The solid solution with a 1 : 1 composition by weight was irradiated at 0°C. As is shown in Figs. 6 and 7, the polymerization rate, the saturation polymer yield and the molecular weight of the polymer are all higher in a large crystal grown by slow cooling than in a small crystal. Figure 8 shows that similar behavior is also observed with the solid solu-

tion of a 9 : 1 composition, but that both the rate and the yield are less than those of a 1 : 1 composition. However, in order to compare the results of Figs. 8 and 6, the influence of the irradiation temperature on the polymer yield should be taken into consideration. Figure 9 represents the relation between the irradiation temperature and the polymer yield at various monomer compositions. Each monomer mixture was crystallized at a temperature about 5°C below its melting point. In any composition, the maximum yield was obtained at a temperature 10—20°C lower than the melting point of the corresponding solid solution. The polymerization behavior in Figs. 6 and 9 agrees with that of each single component crystal,[5,6] and its also comfirmed by the fact that crystal structure of the solid solution is almost the same as that of each single component. Figure 10 shows the

polymer yield versus the monomer composition curves at various irradiation temperatures. In the same figure, the maximum yield is plotted against the composition. The polymer yield was at a minimum in the composition with a small quantity of the second component. This can be explained by the

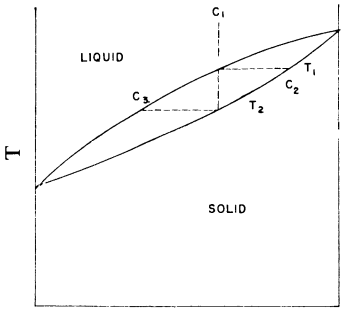

Fig. 16. Phase diagram of binary component system to form a solid solution.

effect of the composition on the crystal state of the solid solution. The sizes and structures of the two component molecules are not exactly the same, so the introduction of the second component in a small quantity may cause a disorder of the crystal lattice to some extent and result in a decrease in the polymer yield. On the other hand, the existence of both the components in equal quantities may give preferable conditions for the crystallization, because the differences in the molecular size are compensated for each other in the lattice. Also, the temperature difference between the starting and the final points of the crystallization of the monomer mixture may help the crystallization into a preferable state; this difference is at a maximum in a 1 : 1 composition. However, the complete elucidation of those phenomena seems to be difficult at the present stage; the further experimental efforts are hoped for.

Furthermore, the characteristics of the polymer obtained were examined. From the investigations of the melting point, X-ray diffraction and fractionation of the polymer, it has been concluded that a random copolymer is formed from the solid solution. As Fig. 11 shows, the melting point of the coploymer is as sharp as that of the homopolymer and decreases with an increase in the CMEO content. Figure 12 shows the X-ray diffraction diagrams of the copolymer and each component homopolymer. The crystallinity of the copolymer was proved to be as high as that of the homoploymer, and the interplanar distance corresponding to the highest peak in the copolymer is located between those in the two homopolymers. The X-ray diffraction pattern of the raw polymer obtained from the irradiated crystal by an extraction of the unreacted monomer is shown in Figure 13. It suggests the orientation of growing chains in the solid solution. This fact was also observed by means of the polarizing microscope. A similar result

has been reported in the polymerization of a single-component crystal.[4]

Figure 14 presents the composition curve of the copolymer obtained from the small crystal with an irradiation dose of $9.1\times10^5$ r. at $-15°C$. The composition of the copolymer obtained from the solid solution is the same over the whole range as that of the monomer mixture within experimental error. On the other hand, the copolymer obtained by $BF_3$ in the liquid state has a composition rich in CMEO, as is shown in the same figure. Those facts suggest that the propagating chain can grow only in a unique way controlled by the crystal lattice and that the difference in reactivities between monomers has little influence on the path of propagation in the solid solution. The above-mentioned mechanism is supported also by the orientation of the polymer chain in the irradiated solid solution.

The integral composition distribution curves of the coploymer are shown in Fig. 15. It is found that the width of the distribution is narrower in the copolymer obtained from a small crystal grown by rapid cooling than in that obtained from a large crystal by slow cooling. The difference would seem responsible for the difference in the distribution of monomer components in the solid solution. As is shown in Fig. 16, a liquid mixture of the composition $C_1$ begins to crystallize at $T_1$ and the initial segregating crystal has the composition $C_2$. When the temperature gets to $T_2$, crystallization is complete; the composition of the portion crystallized at the final stage is $C_3$. The solid solution obtained in such a manner should have a composition distribution from $C_2$ to $C_3$. However, the rapid cooling hinders the fractional crystallization to give a more homogeneous solid solution than does the slow cooling. It is clear that the copolymer obtaned from a more homogeneous crystal has a narrower distribution.

**The CMEO-Diketene Binary Component System.**—From the phase diagram in Fig. 17 it was found that this binary component system formed a mixed crystal. The binary component system polymerized at any composition when it was exposed to $\gamma$-ray at $-35°C$, which was below the eutectic point. The polymer obtained was determined by fractionation to be a blend of two component homopolymers. Infrared spectrum studies have proved that the dimethylformamide-soluble portion was polydiketene and the insoluble portion, polyoxetane. Figure 18 represents the yields of the unfractionated polymer and the fractionated polyoxetane respectively, plotted against the mole fraction of oxetane in the mixed crystal. The results

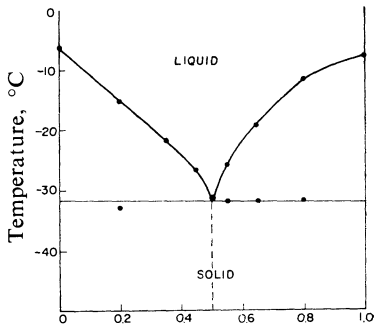

Fig. 17. Phase diagram of CMEO-diketene binary component system.

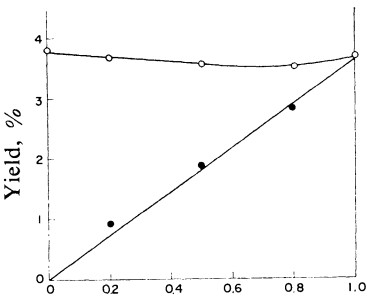

Fig. 18. Influence of monomer composition on polymer yield in the solid state polymerization of CMEO-diketene binary component system: crystallization temperature $-35°C$; irradiation temperature $-35°C$; irradiation dose $2.6\times10^5$ r.; (○) unfractionated polymer yield, (●) fractionated polyoxetane yield.

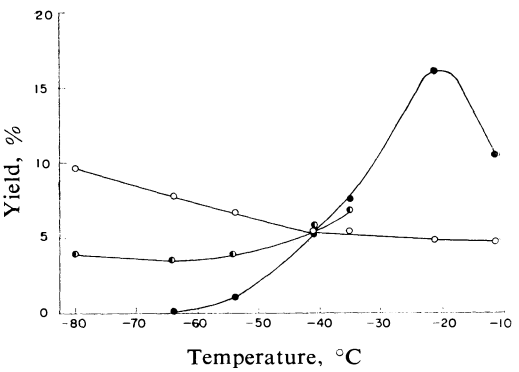

Fig. 19. Influence of irradiation temperature on polymer yield: crystallization temperature, single system $-11°C$, eutectic mixture $-35°C$; irradiation dose $5\times10^5$ r.; (●) 3-chloromethyl-3-ethyloxetane, (○) diketene, (◐) eutectic mixture (composition 1 : 1 mole fraction).

show that yields of polyoxetane and polydiketene are proportional to the mole fraction of the corresponding monomer. Furthermore,

the influence of the irradiation temperature on the polymer yield was examined; it is shown in Fig. 19. The relation between the yield and the temperature is a superposition of those two single component systems. These results suggest that in the mixed crystal the polymerization of each component takes place independently, even in the eutectic mixture.

**The CMEO-Trioxane Binary Component System.**—The phase diagram in Fig. 20 shows that this system also forms a mixed crystal and that its eutectic point is in the side of oxetane. From the infrared spectrum and the elemental analysis, it was found that the mixed crystal gave only polyoxetane at any composition when it was irradiated at −21°C, which was below the eutectic point. As Fig. 21 shows, the polymer yield is proportional to the mole fraction of oxetane, except for a range close to pure oxetane, and the molecular weight of the polymer is not affected by the existence of trioxane. The

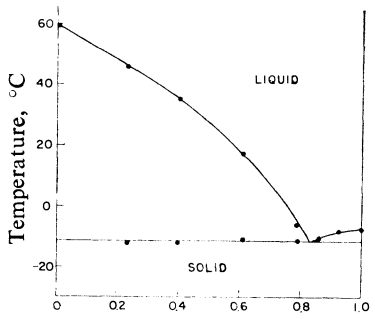

Fig. 20. Phase diagram of CMEO-trioxane binary component system.

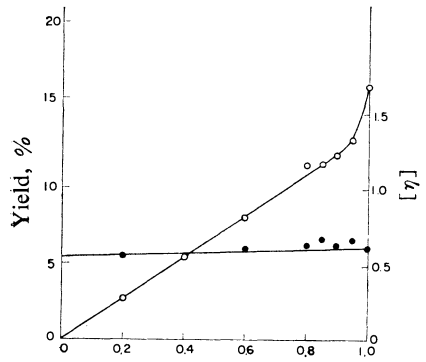

Fig. 21. Influnce of composition on polymer yield and molecular weight in CMEO-trioxane binary component system: crystallization temperature −16°C; irradiation temperature −21°C; irradiation dose $1.7\times10^6$ r.; (○) polymer yield, (●) intrinsic viscosity.

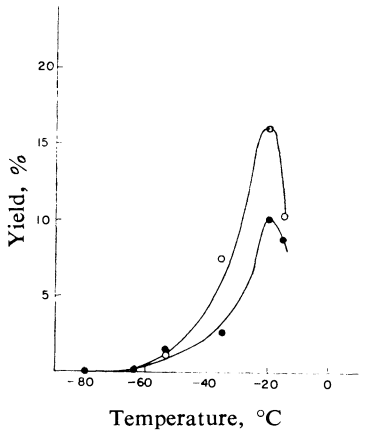

Fig. 22. Influence of irradiation temperature on polymer yield: (●), eutectic mixture of CMEO and trioxane, crystallization temperature −11°C, irradiation dose $9\times10^5$ r.; (○) CMEO crystallization temperature −11°C, irradiation dose $9\times10^5$ r.

data given in Fig. 21 indicate that the temperature dependence of the yield in the eutectic mixture is similar to that obtained in CMEO. When irradiation was done at room temperature, only trioxane was polymerized.

Okamura and his co-workers[8] have reported that trioxane polymerized only in the solid state above 0°C. The temperature range in which trioxane polymerizes is above the melting point of oxetane, whereas oxetane scarcely polymerizes at all in a liquid state.[6] If polymerization occurs independently in each component crystal, it should be impossible to polymerize two components at the same time.

## Summary

The γ-ray irradiation of a solid solution of 3-chloromethyl-3-ethyloxetane and 3,3-bis-(chloromethyl)oxetane has given a copolymer with the same composition as that of the initial monomer mixture, while a $BF_3$-catalyzed copolymerization has formed a copolymer with a different composition from that of the initial monomer mixture. In the polymerization, the solid solution has behaved like each single component crystal in respect to the relation of polymer yield to the irradiation temperature and to the crystal state of the monomers. The copolymer obtained from small crystals grown by rapid cooling has been found to have a narrower distribution of composition than that obtained from large crystals. With a solid solution of 3-chloromethyl-3-ethyloxetane

8) S. Okamura, K. Hayashi and Y. Nakamura, *Isotopes and Radiation*, 3, 416 (1960).

and 3-fluoromethyl-3-ethyloxetance, the polymerization has been studied and similar results obtained.

The mixed crystal of 3-chloromethyl-3-ethyloxetane and diketene gives a polymer blend. The curve of the polymer yield versus the irradiation temperature is a superposition of those in the each component crystal. The mixed crystal of 3-chloromethyl-3-ethyloxetane and trioxane gives only a homopolymer of oxetane, and the temperature dependence of the yield is similar to that of oxetane, even in an eutectic composition.

The authors wish to thank Dr. Hiroshi Kitagawa for his continued interest and encouragement; acknowledgment is also due to Mr. Akimasa Ōyama for his irradiations and Mr. Tetsuo Ino for his assistance in this experiment.

# The Growth Reaction of an $\alpha,\omega$-Dialuminoalkane Compound

By Go HATA and Akihisa MIYAKE

(Received May 27, 1964)

It is well known that ethylene undergoes a stepwise addition to trialkylaluminum to form a long-chain alkylaluminum[1]:

$$R\text{-al}+n C_2H_4 \rightarrow R\text{-}(C_2H_4)_n\text{-al} \quad (\text{al}=1/3\text{Al})$$

If this growth reaction can be applied to an organoaluminum compound with two aluminum atoms attached to both ends of a polymethylene chain, it is expected to synthesize long-chain bifunctional compounds by adding ethylene to the above-mentioned organoaluminum compound; and converting the resulting aluminum compound into other product (diolefin, diol).

With the object of synthesizing an $\alpha,\omega$-dialuminoalkane compound, various attempts have been made by several workers to add dialkylaluminum hydride to $\alpha,\omega$-dienes. Ziegler[2] reported that the reaction of 1, 5-hexadiene with diisobutylaluminum hydride afforded a cyclopentylmethylaluminum compound, instead of the expected 1, 6-dialuminohexane derivative. Zakharkin[3] reported that the reaction of butadiene with diethylaluminum hydride yielded mainly polymeric (di- and trimeric) hydrocarbons, accompanied by a small amount of a 1, 4-dialuminobutane derivative. The present authors[4] previously investigated the reaction between diisobutylaluminum hydride and $\alpha,\omega$-dienes with carbon numbers from five to eleven (molar ratio 1 : 1) and found that the facile ring-closure reaction is specific only to 1, 5-hexadiene and that other $\alpha,\omega$-dienes gave the $\alpha,\omega$-dialuminoalkane compounds. Especially, the 1, 7-dialuminoheptane derivative is stable at the temperature of the growth reaction of alkylaluminum.

These facts suggest that the growth reaction of the 1, 5-dialuminopentane derivative by means of the addition of ethylene can be carried out without forming cyclic compounds. We confirmed, as expected, that the growth reaction of this compound proceeds without ring closure.

## Results and Discussion

The 1, 5-dialuminopentane derivative*1 was prepared by the addition of diisobutylaluminum hydride to 1, 4-pentadiene. The growth reaction of this compound was carried out at an ethylene pressure of 130 kg./cm$^2$ at 100°C for five hours. To avoid the influence of the metal surface of the autoclave which catalyses the displacement reaction of alkylaluminum by ethylene, a glass tube with a small hole was used as the reaction vessel. On hydrolysis, the reaction product

4) G. Hata and A. Miyake, *J. Org. Chem.*, **28**, 3237 (1963).

*1 The initial product from the reaction of 1,4-pentadiene with diisobutylaluminum hydride should be 1,5-bis(diisobutylalumino)pentane (I),

$$(i\text{-Bu})_2\text{Al-}(CH_2)_5\text{-Al}(i\text{-Bu})_2 \quad \text{(I)}$$

which, however, might be converted through alkyl exchange reaction to a mixture of $(i\text{-Bu})_3\text{Al}$, $(i\text{-Bu})_2\text{Al-}(CH_2)_5\text{-Al}(i\text{-Bu})_2$, $(i\text{-Bu})_2\text{Al}\langle^{(CH_2)_5\text{-Al}(i\text{-Bu})_2}_{(CH_2)_5\text{-Al}(i\text{-Bu})_2}$, etc. This sort of alkyl exchange reaction occurs readily at room temperature (K. Ziegler, W. R. Kroll, W. Larbig and O. W. Steudel, *Ann.*, **629**, 53 (1960)). For the sake of simplicity, the product is hereafter called 1, 5-dialuminopentane derivative and written as al-$(CH_2)_5$-al.

afforded a mixture of *n*-pentane, *n*-heptane, *n*-nonane, *n*-undecane, *n*-tridecane and higher hydrocarbons with odd carbon numbers. In addition to the *n*-paraffins, small amounts of 1-pentene (10% of $C_5$ hydrocarbons) and 1-heptene (4% of $C_7$ hydrocarbons) were formed. However, no appreciable amount of $\alpha,\omega$-diene was found. The formation of these *n*-paraffins indicates the occurrence of the following growth reaction (Eq. 1) :

$$\text{al-(CH}_2)_5\text{-al} \xrightarrow{n\text{C}_2\text{H}_4} \text{al-(CH}_2)_5\text{-(C}_2\text{H}_4)_n\text{-al} \quad (1)$$
$$\downarrow \text{H}_2\text{O}$$
$$\text{CH}_3\text{-(C}_2\text{H}_4)_{n+1}\text{-CH}_2\text{CH}_3$$

$$\text{al-(CH}_2)_5\text{-al} \xrightarrow{\text{C}_2\text{H}_4} \text{al-(CH}_2)_3\text{-CH=CH}_2 + \text{al-CH}_2\text{CH}_3$$
$$\downarrow \text{H}_2\text{O} \quad (2)$$
$$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH=CH}_2$$

1-Pentene was formed by the displacement of the 1, 5-dialuminopentane derivative by one mole of ethylene (Eq. 2). The formation of 1-heptene is due to the displacement of the 1, 7-dialuminoheptane derivative by one mole of ethylene and/or to the addition of ethylene to the 4-pentenylaluminum derivative.

The distribution of the hydrocarbons produced by hydrolysis was determined by gas chromatographic analysis. In this procedure, hydrocarbons higher than *n*-heneicosane were neglected, since they were present in very small amounts. The results are shown in Table I and Fig. 1. The average number of added ethylene per aluminum-carbon bond of the 1, 5-dialuminopentane derivative was 1.1.

Table I. Distribution of hydrocarbons obtained by hydrolysis of the product from al-$(CH_2)_5$-al+1.1$C_2H_4$

▨ Observed value
□ Calculated value

Ziegler[1] reported that the distribution of the different chains resulting from the addition of ethylene to trialkylaluminum was found to be very close to that calculated on the assumption that all aluminum-carbon bonds present in the reaction mixture have the same probability of being added to ethylene during the entire period of the reaction (Poisson distribution). If the addition of ethylene to the 1, 5-dialuminopentane derivative proceeds in the same manner as is assumed above, the theoretical distribution of the grown chains can be given by the following equations:

$$X_r = \sum_{p=0}^{r} X_p X_{(r-p)}$$

$$X_p = \frac{n^p e^{-n}}{p!} \qquad X_q = \frac{n^q e^{-n}}{q!}$$

In these equations, $X_r$ is mole fraction of the chain $-(C_2H_4)_p-(CH_2)_5-(C_2H_4)_q-$ in which $p+q$ is equal to $r$ and $n$ is defined, according to the equation $al-(CH_2)_5-al \xrightarrow{2nC_2H_4} al-(C_2H_4)_n-(CH_2)_5-(C_2H_4)_n-al$, as the average number of moles of ethylene taken up per aluminum-carbon bond. The theoretical values in the case of $n=1.1$ are given in Table I and Fig. 1. As may be seen from Fig. 1, the agreement between the observed and the theoretical distributions is relatively good. The slight discrepancies in $C_5$ and $C_7$ hydrocarbons indicate that conditions are somewhat unfavorable for the formation of $C_7$ chain from a $C_5$ chain.

By the displacement of the growth product of the 1, 5-dialuminopentane derivative by ethylene in the presence of a nickel catalyst, $\alpha$, $\omega$-dienes with odd carbon atoms (1, 4-pentadiene, 1, 6-heptadiene, 1, 8-nonadiene and 1, 10-undecadiene) were obtained (Eq. 3):

$$al-(CH_2)_5-(C_2H_4)_r-al \xrightarrow[C_2H_4]{Ni(acac)_2} 2alCH_2CH_3 + H_2C=CH-CH_2-(C_2H_4)_r-CH=CH_2 \quad (3)$$

The two aluminum-carbon bonds of the 1, 5-dialuminopentane derivative are not displaced completely by ethylene, unlike those of the 1, 7-dialuminoheptane derivative and the 1, 9-dialuminononane derivative. The composition of those hydrocarbons with the same carbon number is shown in Table III.

Further investigation is necessary of these different reactivities of the 1, 5-dialuminopentane derivative in growth reaction and in displacement reaction.

TABLE III. DISPLACEMENT REACTION OF THE GROWTH PRODUCT BY ETHYLENE (HYDROLYZED PRODUCTS)

## Experimental

**The Growth Reaction of the 1, 5-Dialuminopentane Derivative.** — The 1, 5-dialuminopentane derivative was prepared from 1, 4-pentadiene (0.03 mol.) and diisobutylaluminum hydride (0.063 mol.) by a method previously reported.[4] The 1, 4-dialuminopentane derivative in 10 ml. of *n*-hexane was introduced into a glass tube with a small hole. This glass tube was then set in an autoclave. The pressure of ethylene and the reaction temperature were kept at 130 kg./cm$^2$ and 100°C respectively for 5 hr. while the mixture was being shaken. The reaction product was decomposed by the successive addition of ethanol, water and 6 N hydrochloric acid. The organic layer was washed with water and dried over sodium sulfate. The hydrocarbons*2 thus produced were analyzed by gas chromatography, using either a squalane column (2.5 m.) or a silicone DC 550 column (2.5 m.). *n*-Pentane, *n*-heptane, *n*-nonane and *n*-undecane were identified by a comparison of their gas chromatographic retention times and infrared spectra with those of authentic samples. *n*-Tridecane, 1-pentene and 1-heptene were identified by gas chromatographic comparison.

**$\alpha,\omega$-Dienes from the Growth Product.**— To the growth product obtained under the same reaction conditions as have been described above, 8 mg. of nickel acetylacetonate and 80 mg. of phenylacetylene in 5 ml. of *n*-hexane were added. The pressure of ethylene and the temperature were kept at 55 kg./cm$^2$ and 70°C respectively for 2 hr. The reaction product was then hydrolyzed and the organic layer separated by gas chromatography, using a squalane column. 1, 4-Pentadiene 1, 6-heptadiene, 1, 8-nonadiene and 1, 10-undecadiene were identified by comparing their gas chromatographic retention times and infrared spectra with those of authentic samples prepared by the method previously reported.[4] 1-Pentene, *n*-pentane, 1-heptene and 1-nonene were identified by gas chromatographic comparison.

**The Growth Reaction of the *n*-Pentylaluminum Derivative.**—*n*-Pentylaluminum derivative was prepared from the reaction of 0.07 mol. of 1-pentene with 0.09 mol. of diisobutylaluminum hydride at 70°C for 16 hr. The growth reaction of this compound was carried out under the same reaction conditions as have been described above.

# Catalytic Asymmetric Benzaldehyde Cyanohydrin Synthesis with Synthetic Optically Active Polymer. II. Cross-linked Poly-(s)-isobutylethylenimine

By Sei TSUBOYAMA

(Received May 28, 1964)

In the previous paper,[1] an asymmetric synthesis of benzaldehyde cyanohydrin performed in the presence of the basic catalyst of several optically active polymers was described. With poly-(s)-isobutylethylenimine (I), the optical yield of the produced (−)-cyanohydrin was relatively high, about 20%. In the present work, an insoluble polymer, obtained from poly-(s)-isobutylethylenimine by cross-linking with tolylene diisocyanate (TDI), was used. The insoluble polymer catalyst can be separated from the reaction mixture containing unstable and viscous compounds and reused. Besides, the cross-linking seems to stabilize the conformation.

(I) (II)

(R=Isobutyl)

**The Cross-linking of Poly-(s)-isobutylethylenimine.**—Among the cross-linking agents tested so far, only TDI gave an insoluble product from the polymer I, while with the others the polymer did not even gelatinize. The TDI cross-linked polymer (II) swells in benzene or toluene, but it repels water in spite of the presence of hydrophilic amino groups; this property seems to be useful for a catalyst in organic solvents. The exchange capacities of the cross-linked polymers are listed in Table I. The infrared spectrum of the polymer reveals the presence of a –NH–CO–N= group by absorptions at 1655 $cm^{-1}$ and at 1525 $cm^{-1}$ as similar to that of phenyl isocyanate-modified polymer (Fig. 1).

Found: C, 58.90; H, 9.66; N, 11.67; Cl, 11.55.
Calcd. for $(C_6H_{13}N)\cdot(C_9H_6N_2O_2)_{0.32/2}\cdot(HCl)_{1-0.32}$: C, 58.85; H, 9.72; N, 12.18; Cl, 15.88%.

**Benzaldehyde Cyanohydrin Synthesis with Cross-linked Polymer.**—The asymmetric synthesis and analysis of the product were carried out in a similar way to those described in the previous paper.[1]

The data in Table II show that the product with the cross-linked polymer and that with the original linear polymer are completely reversed in the sign of the optical rotation. This reversal of sign is independent of whether or not the reaction system is homogeneous, for we observe the same result when a solvent-soluble catalyst partly modified with phenyl or methyl isocyanate is used instead of TDI. Since *symm-n*-butylphenylurea had no catalytic activity for cyanohydrin formation in a benzene solution, the –NH–CO–N= groups themselves may not be related directly to this reversal.

**The Contribution of –NH–CO–N= Groups to the Asymmetric Synthesis.**—In order to elucidate the reversal of sign, several polymers

—□— Methyl isocyanate

containing R-NH-CO-N= groups in various ratios were prepared by the addition of TDI, phenyl or methyl isocyanate to the linear polymer, and the asymmetric cyanohydrin formation was carried out with each of them as a catalyst. The optical yields of the product obtained with various modified polymers as catalysts are given in Table III and illustrated in Fig. 2. In the figure, the optical yield is plotted against the mole ratio of the isocyanate group to the amino group, -NCO/=NH, on the assumption that the added isocyanate had reacted stoichiometrically. It may be seen from the results that: (1) with respect to the TDI series, the optical yield decreases continuously with the additional amount of isocyanate, and the sign of the optical rotation of the product changes from negative to positive. The curve shows that the optical yield reaches a maximum at approximately the ratio of 0.4 and that thereafter it is independent of the ratio, suggesting that TDI reacts with the linear polymer to some extent but not further, for its taking part in the reaction seems to be hindered by the net work structure formed. The benzene solution of the polymer emulsifies near 0.34 and is gelatinized at the ratio of 0.40 (Table III); (2) the curve concerning phenyl isocyanate is similar to that of TDI at values lower than 0.4, but at values over this ratio, the optical yield of the (+)-isomer decreases with the increase in the ratio. As the polymer modified with phenyl isocyanate has no net work, phenyl isocyanate seems to be introduced more easily than TDI into the polymer. However, even when the ratio is 1, the minor amino groups, which are capable of catalyzing, are still likely to remain in the polymer. In any case, both these polymers have almost identical efficiencies for the steric course of the asymmetric reaction, regardless of the reaction phase; (3) in the methyl isocyanate series, the cross-over point of

the curve comes at a value of the ratio lower than those the cases of the former two, and then P% gradually approaches zero by way of a maximum at about 0.4. If the reversal in the sign of the cyanohydrin produced by these polymers depends on only the size of the introduced group, the first two series must be more effective than the methyl isocyanate series, at least within the range of small values of the ratio, and the curves of the former must be steeper than the curve of the latter. However the result obtained refute this assumption; some other explanation, therefore, should be considered.

One possible interpretation is as follow. Amines, and presumably amine polymers, may be converted at a very high rate and with a very low energy to their enantiomers by a molecular vibration of the type known in $NH_3$ molecule (as is shown in the scheme).

In this reaction, therefore, when the carbonyl reagent approaches equivalently to either side of the amine which is vibrating, the cyanohydrins produced at the two sides become enantiomers with each other. Consequently, the selectivity of the reaction may not be recognized. Only when the accessibilty of the reagent is different on the two sides of interconverting amine, as a result of a steric requirement, the reaction will be performed asymmetrically. In the steric requirement, even if the absolute configuration of the polymer remains the same, the accessibility of the reagent and even the direction of its approach appear to change as a result of the change produced by the modification in the arrangement at the circumference of the catalytic center. Each conformation of these modified polymers may be very unlike the original one because of such interaction as intra- and inter-molecular hydrogen bonding between introducing groups or between the amino group and the introducing group. To the newly-formed conformation, the approach of the reagent may become easier on the side opposite to what would the approach be originally. In all cases, it seems that the arrangement of these modified polymers changes markedly until the ratio reaches 0.4 but that thereafter the conformation undergoes no appreciable change. Although the conformation of these polymers has not yet been analyzed, it should be noted that the configuration and

the optical yield of the product in the asymmetric synthesis are not always controlled by the absolute configuration of the catalyst but by the conformation of the circumference of the catalytic center.

## Experimental

**Cross-linking of Poly-(s)-isobutylethylenimine with Tolylene Diisocyanate.**—To an ice-cooled solution of 1.0 g. of the linear polymer I in 25 ml. of toluene was added dropwise a known volume of toluene solution containing 1% of tolylene diisocyanate* with vigorous stirring. The viscous or opaque jelly-like solution formed was then stirred for about 5 hr. at 60°C and allowed to stand overnight at room temperature. The insoluble polymer was filtered off and washed with hot toluene, benzene, ethanol and ether. The pale yellow solid obtained was then ground and screened to 20—40 mesh. To regenerate it, the dried polymer was made to swell thoroughly with benzene and then washed with ethanol, N hydrochloric acid, 4% ammonium hydroxide and finally with deionized water. The exchange capacity was measured for the wet polymer in the presence of N/10 hydrochloric acid and N sodium chloride (Table I).

Other cross-linking agents for the amine polymer, such as ethylene dichloride[2] epichlorohydrine,[3] formaldehyde, tetra- and pentamethylene dibromide, *symm*-dichloroacetone, *p*-xylylene dichloride, and their various combinations, were applied under various conditions. Every mixture of the linear polymer and an agent was heated in a sealed glass tube at 100—180°C for 24—72 hr., but no insoluble product was obtained.

**Phenyl Isocyanate-modified Polymer.**—A solution of a slight excess of phenyl isocyanate in benzene was added with stirring into a solution of the linear I polymer in benzene, and the mixture was left standing overnight at room temperature. The benzene solution was then washed with water to remove the excess of isocyanate. The pale yellow solution obtained was freeze-dried; m. p. 143°C. $[\alpha]_D^{23}$ +71.01 (*c* 2.056, benzene).

Found: C, 71.95; H, 8.36; N, 10.84. Calcd. for $(C_{13}H_{18}N_2O)_n$: C, 71.52; H, 8.31; N, 12.83%.

***symm*-*n*-Butylphenylurea.**—To an ice-cooled solution of 0.7 g. (0.01 mol.) of *n*-butylamine in 5 ml. of heptane, a solution of 1.2 g. (0.01 mol.) of phenyl isocyanate in heptane was added slowly with stirring. The product, *symm*-*n*-butylphenylurea, separated as needle crystals which weighed 1.7 g. and melted at 129—130°C after recrystallization from ethanol.

Found: C, 68.92; H, 8.12. Calcd. for $C_{11}H_{16}N_2O$: C, 68.72; H, 8.39%.

**Asymmetric Synthesis with Several Isocyanate-modified Polymers.**—To every solution of 50 mg. of the linear polymer in benzene was added an appropriate, known volume of benzene solution containing ca. 1% of one of TDI, phenyl and methyl isocyanate (b. p. 39.5—40.5°C),[4] dropwise, with vigorous stirring, and each solution thus prepared was then filled up to 10 ml. with benzene. After 3 hr., the rotation of each solution was measured, and the asymmetric synthesis and analysis of cyanohydrin were carried out in a way similar to that described in the previous report.[1] For the measurment of the optical rotation, all the samples except the gelatinized ones were purifled by distillation.

## Summary

Asymmetric benzaldehyde cyanohydrin synthesis with TDI cross-linked poly-(s)-isobutylethylenimine has been studied. The cyanohydrin obtained was (+)-isomer; its sign is opposite to what it is in the case of the linear polymer. With the linear and soluble polymer which contains some –NH–CO–N= groups, the (+)-isomer was also found to be produced. These results suggest that (1) the reversal of the sign is independent of the reaction phase, and (2) the configuration of the product is not always controlled by the configuration of the asymmetric carbon in the catalyst but by the conformation of the catalytic center.

The author wishes to thank Dr. Masaya Yanagita for many valuable discussions and suggestions.

# Some Cationoid Reactions of 4-Ethyltropolone

By Tetsuo NOZOE, Kahei TAKASE and Keiji UMINO

(Received June 1, 1964)

Since the steric effect of the side-chain in troponoid compounds is generally larger than in benzenoid compounds, because of a planar, seven-membered ring, tropolone and its homologs often show interesting unexpected behavior in some reactions[1] in which benzenoid compounds react normally. Although the chemical and physical properties of 4-methyl- and 4-isopropyl-tropolone have extensively been studied,[2] the properties of 4-ethyltropolone have scarcely been known; it has been synthesized only in a poor yield from 4-ethylcycloheptane-1, 2-dione.[3] In this paper, we wish to report on a new synthesis of 4-ethyltropolone (I) and on some of its reactions.

4-Ethyltropolone (I) was synthesized from 4-acetyltropolone (II)[4] by the Huang-Minlon reduction. When heated with hydrazine, II afforded the hydrazone (III), which gave I when heated with potassium hydroxide in ethylene glycol. The yield of I from II was about 60%. When the reduction was carried out without the isolation of the hydrazone, I was not obtained, but a polymerized substance was formed. Besides the known copper chelate,[3] I gave a cyclohexylamine and dicyclohexylamine salts.

The azo-coupling of I with *p*-toluenediazonium chloride gave a *p*-tolylazo compound (IV).[3] The nitration of I gave a mononitro (V) or dinitro compound (VI), according to the variation in the reaction conditions. The action of 1–3 molar equivalents of fuming nitric acid on I afforded V, while 1–4 molar equivalents of concentrated nitric acid gave mainly VI. However, in one experiment, in which one molar equivalent of concentrated nitric acid was used, a trinitro compound (VII) was isolated in a poor yield, although these results could not be reproduced. The amino compound (VIII) obtained by the catalytic reduction of V was identical with that derived from the azo compound (IV) by similar reduction. Since IV has an azo group at the 5-position,[5] V and VIII were assumed to be 4-ethyl-5-nitro- and 5-amino-4-ethyltropolone respectively. The amine (VIII) was easily diazotized by sodium nitrite and an acid, and 5-chloro-4-ethyl- (IX) and 5-bromo-4-ethyltropolone (X) were prepared by Sandmeyer reaction. The heating of the dinitro compound (VI) in methanol for a few minutes afforded a colorless neutral compound (XI) in a good yield. On the basis of its ultraviolet absorption spectrum, this compound is considered to be a benzenoid compound produced by the rearrangement reaction. From such a similarity in chemical behavior between VI and 4-methyl-5, 7-dinitro-[6] or 4-isopropyl-5, 7-dinitrotropolone,[7] which afforded methyl 3-methyl-4, 6-dinitrobenzoate and methyl 3-isopropyl-4, 6-dinitrobenzoate in the same treatment, the dinitro compound (VI) and the rearranged product (XI) were assumed to be 4-ethyl-5, 7-dinitrotropolone and methyl 3-ethyl-4, 6-dinitrobenzoate respectively. The trinitro compound (VII) was assumed to be 4-ethyl-3, 5, 7-trinitrotropolone from its ultraviolet and infrared spectra, which are similar to those of 3, 5, 7-trinitrotropolone,[8] although it showed a negative ferric chloride coloration and was stable when heated with alcohol.

The bromination of 4-ethyltropolone (I) with a molar equivalent of bromine in methanol afforded as the main product a monobromo compound (XII)[9] which was different from the monobromo compound (X), besides a dibromo compound (XIII) and a tribromo compound (XIV). On the other hand, when two molar equivalents of bromine were used, besides XIV an isomeric dibromo compound (XV) was obtained in a good yield. When three molar equivalents of

9) This compound, m. p. 67.5–69°C, was identical with the monobromo compound, m. p. 66°C, formerly obtained by the bromination of 4-ethylcycloheptane-1,2-dione.[3]

bromine were used in the presence of sodium acetate, the tribromo compound (XIV) was obtained in a good yield. The monobromo compound (XII) is assumed to be 7-bromo-4-ethyltropolone on the basis of the following evidence. The azo-coupling of XII gave a crystalline azo compound (XVI).[5] The infrared spectrum of XII is quite similar to that of 7-bromo-4-isopropyltropolone[10] in the region of out-of-plane C-H deformation vibrations. The dibromo compound (XV) is assumed to be 3, 7-dibromo-4-ethyltropolone, since it was also obtained by the bromination of XII and gave a crystalline azo compound (XVII) by azo-coupling. Therefore, another dibromo compound (XIII) is assumed to be 5, 7-dibromo-4-ethyltropolone. The tribromo compound (XIV) is considered to be 3, 5, 7-tribromo-4-ethyltropolone since it was obtained from X, XII and XV by bromination. The formation of the tribromo derivative (XIV) by the bromination of I shows that the steric hindrance of the ethyl group is smaller than that of the isopropyl group,[11] as was expected. On the other hand, the formation of the dibromo compound (XIII) is similar in tendency to the bromination of 4-isopropyltropolone[2,10] rather than to that of 4-methyltropolone.[2]

The treatment of I with iodine, in the presence of potassium carbonate, afforded 4-ethyl-7-iodotropolone (XVIII), the structure of which was based on the following evidence. The azo-coupling of XVIII gave a crystalline azo compound (XIX),[5] and it was known that the iodination of tropolones, under these conditions, generally give 3 (or 7)-iodotropolones. Furthermore, the infrared spectrum of XVIII is similar to that of 7-iodo-4-isopropyltropolone[12] in the region of out-of-plane C-H deformation vibrations.

When heated in acetic acid or ethanol, the 5-arylazo derivatives of 4-isopropyltropolone are known to give, especially in the presence of acid or benzoquinone, the reddish-purple "hinopurpurine," whose structure was established to be 2-aryl-3, 3-dimethyl-2, 3, 5, 6-tetrahydro-5, 6-cyclohepta[c]pyrazoledione (XX).[13] On the other hand, it has been reported[3] that 4-ethyl-5-(*p*-tolylazo)tropolone (IV) gives, on heating in acetic acid in the presence of hydrochloric acid, no hinopurpurin-like, highly colored compound, but an unidentified brown crystals with a m. p. of 210°C. The reexamination of this reaction gave pale yellow needles with a m. p. of 203°C, which were proved

to be identical with 5-hydroxy-3-methyl-2-(*p*-tolyl)-6(2*H*)-cyclohepta[c]pyrazolone (XXI)[14] obtained by the ring closure of the *p*-tolylazo derivatives of 4-(1-hydroxyethyl)- or 4-(1-acetamidoethyl)tropolone. The mechanism of the formation of XXI from IV is thought to be similar to that of the hinopurpurin-formation,[13] as is shown in Chart 1, the reaction is facilitated in the presence of iodine or benzoquinone, as was to be expected from the inevitable dehydrogenation process. In this case, however, the hinopurpurin-like diketone (XXIa) easily tautomerizes to the more stable enolic form (XXI), since XXIa, being different from hinopurpurin, has a mobile hydrogen at the 3-position.

## Experimental[15]

**4-(1-Hydrazonoethyl)tropolone (III).**—A mixture of 4-acetyltropolone (II) (16.4 g.), ethanol (20 ml.), and 80% hydrazine hydrate (9 ml.) was heated while being stirred in a boiling-water bath until the orange crystals turned yellow. After they had been allowed to cool, the crystals were collected by filtration and washed with ethanol to give III (16.6 g.) as yellow needles, m. p. 193°C (decomp.).

Found: C, 60.51; H, 5.37; N, 15.50. Calcd. for $C_9H_{10}O_2N_2$: C, 60.66; H, 5.66; N, 15.72%.

*N-Acetyl Derivative:* M. p. 188—189°C, yellow prisms (from glacial acetic acid).

Found: C, 60.43; H, 5.19; N, 12.22. Calcd. for $C_{11}H_{12}O_3N_2$: C, 59.99; H, 5.49; N, 12.72%.

**4-Ethyltropolone (I).**—To a solution of potassium hydroxide (8.8 g.) in ethylene glycol (40 ml.), III (16.6 g.) was added; the mixture was then heated at 140—150°C for 10 hr. The reaction mixture was poured into water (600 ml.) and acidified with 6 N hydrochloric acid, and the oily substance which separated out was extracted three times with chloroform. The solvent was evaporated and the residue was recrystallized from petroleum ether to give I (4.83 g.) as colorless rhombic prisms, m. p. 42—43°C; reported[3] m. p. 42°C.

Found: C, 72.05; H, 6.55. Calcd. for $C_9H_{10}O_2$: C, 71.98; H, 6.71%. $\lambda_{max}^{MeOH}$ mμ (log ε); 240 (4.48), 327 (3.87).

*Copper Chelate:* m. p. 157—158°C, reported[3] m. p. 156°C, pale green crystals (from ethanol).

Found: C, 59.39; H, 4.80. Calcd. for $(C_9H_9O_2)_2$-Cu: C, 59.74; H, 5.01%.

*Cyclohexylamine Salt.:* m. p. 159—160°C pale yellow crystals (from cyclohexane).

Found: C, 72.64; H, 9.44; N, 5.65. Calcd. for $C_{15}H_{23}O_2N$: C, 72.25; H, 9.30; N, 5.62%.

*Dicyclohexylamine Salt.:* m. p. 118—119°C, yellow crystals (from cyclohexane).

Found: C, 76.07; H, 9.61; N, 3.59. Calcd. for $C_{21}H_{33}O_2N$: C, 76.09; H, 10.03; N, 4.23%.

**4-Ethyl-5-(*p*-tolylazo)tropolone (IV).**—Into a solution of I (750 mg.) in pyridine (10 ml.) a solution of *p*-toluene diazonium chloride, prepared by diazotizing *p*-toluidine (600 mg.) in the usual manner, was stirred while the mixture was being cooled an azo compound began to separate during the addition. After the mixture had been stirred for an additional 2 hr., water (10 ml.) was added, and the crystals thereby formed were collected and recrystallized from benzene to give IV (1.27 g.) as red needles m. p. 142—143°C; reported[3] m. p. 141—142°C.

Found: C, 71.38; H, 5.89; N, 10.49. Calcd. for $C_{16}H_{16}O_2N_2$: C, 71.62; H, 6.01; N, 10.44%. $\lambda_{max}^{MeOH}$ mμ (log ε); 233 (4.42), 292 (4.07), 395 (4.43).

**4-Ethyl-5-nitrotropolone (V).**—Into a solution of I (300 mg.) in glacial acetic acid (1 ml.), fuming nitric acid (sp. gr. 1.50, 0.1 ml.) was stirred while the mixture was being cooled; a yellow nitro compound began to separate out. After it had been stirred for an additional 2 hr., the reaction mixture was diluted with water (3 ml.) to give V (70 mg.), m. p. 157—163°C, which was recrystallized from methanol to afford pale yellow needles, m. p. 162.5—163°C.

Found: C, 55.51; H, 4.44; N, 6.98. Calcd. for $C_9H_9O_4N$: C, 55.38; H, 4.65; N, 7.18%. $\lambda_{max}^{MeOH}$ mμ (log ε); 245 (4.57), 325 (4.17), 400 (4.19).

**4-Ethyl-5, 7-dinitrotropolone (VI).**—Into a solution of I (300 mg.) in glacial acetic acid (1 ml.), concentrated nitric acid (sp. gr. 1.38, 0.5 ml.) was stirred while the mixture was being cooled; yellow crystals then began to separate out. After stirring for an additional 2 hr., water (5 ml.) was added to give VI (150 mg.), m. p. 123—125°C, which was recrystallized from benzene, affording yellow prisms, m. p. 127—128°C.

Found: C, 45.12; H, 3.16; N, 11.45. Calcd. for $C_9H_8O_6N_2$: C, 45.01; H, 3.36; N, 11.67%. $\lambda_{max}^{MeOH}$ mμ (log ε); 246 (4.44), 405 (4.14).

**4-Ethyl-3, 5, 7-trinitrotropolone (VII).**—To a solution of I (300 mg.) in glacial acetic acid (1 ml.), concentrated nitric acid (sp. gr. 1.38, 0.15 ml.) was added, and the mixture was stirred for 2 hr. with cooling. After dilution with water, the crystals (100 mg.), m. p. 75—82°C, thereby formed were collected and recrystallized from methanol to give VII as pale yellow prisms, m. p. 84—85.5°C.

Found: C, 37.77; H, 2.49; N, 14.58. Calcd. for $C_9H_7O_8N_3$: C, 37.90; H, 2.47; N, 14.74%. $\lambda_{max}^{MeOH}$ mμ (log ε); 255 (3.99), 357 (4.15).

Another experiment under the same conditions gave the dinitro compound (VI) in a poor yield.

**5-Amino-4-ethyltropolone (VIII).**—*a) From the Azo Compound (IV).*—A suspension of IV (1.07 g.) in methanol (12 ml.) was shaken, in the presence of platinum oxide (20 mg.), with hydrogen at room temperature and at atmospheric pressure; 205 ml. of hydrogen was absorbed after 1 hr. The catalyst was filtered off, the solvent was evaporated, and the residue was recrystallized from methanol to give VIII (530 mg.) as yellow needles, m. p. 168—169°C.

Found: C, 65.39; H, 6.54; N, 8.48. Calcd. for $C_9H_{11}O_2N$: C, 65.44; H, 6.71; N, 8.48%. $\lambda_{max}^{MeOH}$ mμ (log ε); 240 (4.38), 360 (4.13), 390 (4.15).

*b) From the Nitro Compound (V).*—A solution

14) T. Nozoe, K. Takase and K. Suzuki, This Bulletin, **38**, 362 (1964).

15) All melting points are uncorrected.

of V (40 mg.) in methanol (5 ml.) was shaken with hydrogen in the presence of platinum oxide; 17 ml. of hydrogen was absorbed after 17 min. The catalyst and the solvent were removed, and the residue was recrystallized from methanol to give VIII (20 mg.) as yellow needles, m. p. 168—169°C.

**5-Chloro-4-ethyltropolone (IX).**—To a solution of VIII (330 mg.) in 50% aqueous dioxane (5 ml.), concentrated sulfuric acid (0.3 ml.) was added, and then a solution of sodium nitrite (150 mg.) in water (0.5 ml.) was stirred in while the mixture was being cooled. After additional stirring (30 min.), the diazotized solution was stirred into a solution of cuprous chloride (680 mg.) in concentrated hydrochloric acid (3.8 ml.). After additional stirring (1 hr.), the mixture was diluted with water (25 ml.); the copper chelate thereby formed was collected and dried (480 mg.). This copper chelate was suspended in chloroform, hydrogen sulfide gas was passed throughly and the copper sulfide thereby formed was filtered off. The evaporation of the solvent from the filtrate left crystals, which were then recrystallized from methanol to give IX (300 mg.) as pale yellow needles, m. p. 128—129°C.

Found: C, 58.51; H, 4.92. Calcd. for $C_9H_9O_2Cl$: C, 58.54; H, 4.91%. $\lambda_{max}^{MeOH}$ mμ (log ε); 243 (4.50), 336 (4.12), 365 (3.81), 379 (3.82).

**5-Bromo-4-ethyltropolone (X).** — A diazotized solution of VIII (330 mg.), prepared as described in the above experiment, was stirred into a solution of cuprous bromide (700 mg.) in concentrated hydrobromic acid (3.8 ml.). The copper chelate thereby formed was decomposed with hydrogen sulfide as described in the above experiment, and the crystals thereby obtained were recrystallized from methanol to give X (350 mg.) as yellow needles, m. p. 128—129°C.

Found: C, 46.69; H, 4.08. Calcd. for $C_9H_9O_2Br$: C, 47.18; H, 3.96%. $\lambda_{max}^{MeOH}$ mμ (log ε); 244 (4.46), 340 (4.20), 383 (3.79), 401 (3.78).

**Methyl 3-Ethyl-4, 6-dinitrobenzoate (XI).** — A solution of VI (100 mg.) in methanol (1 ml.) was heated for 2 min., affording XI (80 mg.) as colorless prisms, m. p. 64—65°C, after recrystallization from ether.

Found: C, 47.56; H, 3.81; N, 10.90. Calcd. for $C_{10}H_{10}O_6N_2$: C, 47.25; H, 3.97; N, 11.02%.

**The Bromination of I.**—*a) With a Molar Equivalent of Bromine.*—Into a solution of I (1.00 g.) in methanol (5 ml.), bromine (1.07 g.) in methanol (2 ml.) was stirred while the mixture was being cooled. After additional stirring (3 hr.), the mixture was allowed to stand overnight and then diluted with water. The crystals (1.47 g.) thereby formed were collected by filtration and fractionally recrystallized from methanol to give *7-bromo-4-ethyltropolone (XII)* (560 mg.), m. p. 63—66°C, which was further recrystallized from petroleum ether, affording colorless needles, m. p. 67.5—69°C, reported[3] m. p. 66°C.

Found: C, 47.23; H, 3.74. Calcd. for $C_9H_9O_2Br$: C, 47.18; H, 3.96%. $\lambda_{max}^{MeOH}$ mμ (log ε); 256 (4.59), 330 (3.91), 380 (3.84).

The crystalline substance, obtained from the filtrate by the evaporation of the solvent, was dissolved in benzene and shaken with a 5% sodium hydrogen carbonate solution; the sparingly soluble sodium salt thereby formed was then collected by filtration. This salt was dissolved in hot water and acidified with 6 N hydrochloric acid, and the crystals thereby formed were collected and recrystallized from methanol to give *5, 7-dibromo-4-ethyltropolone (XIII)* (20 mg.) as pale yellow needles, m. p. 115—116°C.

Found: C, 35.44; H, 2.52. Calcd. for $C_9H_8O_2Br_2$: C, 35.02; H, 2.61%.

The benzene layer left after the removal of the sodium salt was shaken with a 5% sodium carbonate solution, and the sodium salt thereby formed was collected by filtration. This salt was dissolved in hot water and acidified with 6 N hydrochloric acid, and the crystals thereby formed were collected and recrystallized from methanol to give *3, 5, 7-tribromo-4-ethyltropolone (XIV)* (20 mg.) as greenish yellow prisms, m. p. 96.5—97°C.

Found: C, 28.09; H, 1.65. Calcd. for $C_9H_7O_2Br_3$: C, 27.94; H, 1.82%. $\lambda_{max}^{MeOH}$ mμ (log ε); 272 (4.35), 352 (3.93), 430 (3.80).

*b) With Two Molar Equivalents of Bromine.*—Into a solution of I (450 mg.) in methanol (10 ml.), bromine (960 mg.) in methanol (2 ml.) was stirred while the mixture was being cooled. After the mixture had been allowed to stand overnight, the solvent was evaporated and the residue was recrystallized from petroleum ether to give *3, 7-dibromo-4-ethyltropolone (XV)* (350 mg.) as pale yellow prisms, m. p. 90—90.5°C.

Found: C, 35.38; H, 2.51. Calcd. for $C_9H_8O_2Br_2$: C, 35.02; H, 2.61%. $\lambda_{max}^{MeOH}$ mμ (log ε); 267 (4.48), 339 (3.73), 383 (3.59), 415 (3.64).

The crystals obtained by the removal of the solvent from the mother liquor were fractionally recrystallized from methanol to give XIV (20 mg.).

*c) With Three Molar Equivalents of Bromine.*—Into a solution of I (300 mg.) and sodium acetate (820 mg.) in methanol (6 ml.), bromine (960 mg.) in methanol (4 ml.) was stirred while the mixture was being cooled. After additional stirring (3 hr.), the mixture was allowed to stand overnight; the crystals thereby formed were collected and recrystallized from methanol to give XIV (550 mg.) as greenish yellow prisms, m. p. 96.5—97°C.

The crystals obtained by the removal of the solvent from the mother liquor were fractionally recrystallized from methanol to give a small amount of XV.

**The Bromination of 5-Bromo-4-ethyltropolone (X).**—To a solution of X (100 mg.) in methanol (3 ml.), bromine (70 mg.) was added, and the mixture was stirred for 3 hr. The crystals obtained by the addition of water were fractionally recrystallized from petroleum ether to give XIV (40 mg.) as greenish yellow prisms, m. p. 96—97°C; together with the X (40 mg.) was also recovered.

**The Bromination of 7-Bromo-4-ethyltropolone (XII).**—To a solution of XII (100 mg.) in methanol (3 ml.), bromine (70 mg.) was added, and the mixture was stirred for 3 hr. The crystals obtained by the addition of water were recrystallized from

petroleum ether to give XV (60 mg.); m. p. 96—97°C.

**The Bromination of 3, 7-Dibromo-4-ethyltropolone (XV).**—To a solution of XV (100 mg.) in methanol (3 ml.), bromine (60 mg.) was added in the presence of sodium acetate (100 mg.); the mixture was then stirred for 3 hr. with cooling. The crystals obtained by the addition of water were collected and recrystallized from methanol to give XIV (40 mg.), m. p. 96—97°C.

**4-Ethyl-7-iodotropolone (XVIII).**—Into a solution of I (300 mg.) and potassium carbonate (610 mg.) in water (1.5 ml.), a solution of iodine (560 mg.) and potassium iodide (560 mg.) in water (1.5 ml.) was stirred while the mixture was being cooled; the potassium salt separated out. After additional stirring (1 hr.), the excess iodine was destroyed by the addition of sodium sulfite and a yellow potassium salt was collected by filtration. This salt was dissolved in hot water and acidified with 6 N hydrochloric acid; the crystals thereby formed were collected and recrystallized from petroleum ether to give XVIII (490 mg.) as yellow needles, m. p. 76—76.5°C.

Found: C, 38.56; H, 3.38. Calcd. for $C_9H_9O_2I$: C, 39.15; H, 3.28%. $\lambda_{max}^{MeOH}$ (log $\varepsilon$); 230 (4.12), 260 (4.32), 265 (4.33), 340 (3.91), 383 (3.88).

***p*-Tolylazo Compounds of XII, XV and XVIII.**—They were obtained by the treatment described in the experiment with 4-ethyl-5-(*p*-tolylazo)tropolone (IV).

*a) 7-Bromo-4-ethyl-5-(p-tolylazo)tropolone (XVI).*—This was obtained from XII as red needles (from benzene), m. p. 181.5—182°C, in a 78% yield.

Found: C, 55.52; H, 4.24; N, 7.97. Calcd. for $C_{16}H_{15}O_2N_2Br$: C, 55.33; H, 4.32; N, 8.07%.

*b) 3, 7-Dibromo-4-ethyl-5-(p-tolylazo)tropolone (XVII).*—This was obtained from XV as reddish orange needles (from benzene), m. p. 151°C, in an 85% yield.

Found: C, 45.09; H, 3.04; N, 6.61. Calcd. for $C_{16}H_{14}O_2N_2Br_2$: C, 45.06; H, 3.31; N, 6.57%.

*c) 4-Ethyl-7-iodo-5-(p-tolylazo)tropolone (XIX).*—This was obtained from XVIII as dark red needles (from methanol), m. p. 181—182°C, in an 85% yield.

Found: C, 48.14; H, 3.68; N, 7.07. Calcd. for $C_{16}H_{15}O_2N_2I$: C, 48.73; H, 3.81; N, 7.11%.

**5-Hydroxy-3-methyl-2-(*p*-tolyl)-6(2*H*)-cyclohepta[*c*]pyrazolone (XXI).**—To a solution of IV (100 mg.) in ethanol (10 ml.), 6 N hydrochloric acid (0.3 ml.) was added; this mixture was then heated under reflux for 6 hr. The solvent was evaporated, and the residue was recrystallized from ethanol to give XXI (30 mg.) as pale yellow needles, m. p. 202—203°C; this was identified with an authentic specimen[14] by admixture and by a comparison of their infrared spectra.

When this reaction was carried out with the addition of iodine, XXI was obtained in a 50% yield.

The authors wish to express their sincere gratitude to the Sankyo Co., Ltd., which defrayed a part of the expenses of the present work.

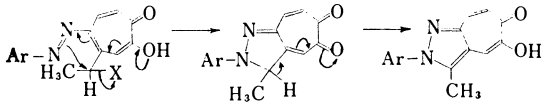
# 2-Aryl-5-hydroxy-3-methyl-6(2*H*)-cyclohepta[c]pyrazolones: The Cyclization Products of 5-Arylazo-4-ethyltropolone and Its Related Compounds

By Tetsuo NOZOE, Kahei TAKASE and Katsumi SUZUKI

(Received June 1, 1964)



In our laboratory, a process has recently been developed for the preparation of 4-ethyltropolone[1] and 4-(1-hydroxyethyl)tropolone[2] from 4-acetyltropolone (I),[3] and the reactions of these tropolones have been investigated.[1,2] During these studies it has been observed that the 5-arylazo derivatives of these tropolones undergo a facile change upon heating, especially in the presence of a mineral acid; thus, 4-ethyl-5-(*p*-tolylazo)tropolone (II) afforded a pale yellow compound (III) with a m. p. of 203°C when heated in an alcoholic solution in the presence of hydrochloric acid.[1] 4-(1-Hydroxyethyl)-5-(*p*-tolylazo)tropolone (IV) also gave the same product (III) when merely heated over its melting point or when heated in an alcoholic solution in the presence of hydrochloric acid.[2] The present authors have prepared 4-(1-acetamidoethyl)-5-(*p*-tolylazo)-tropolone (V) from 4-acetyltropolone (I) and found that this azo compound also afforded the same product (III) when heated in alcohol. The rather curious behavior of these

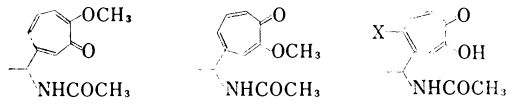
azo compounds prompted us to examine the structure of III. The account of the structural elucidation of III will be described herein, together with the record of some reactions of 4-(1-acetamidoethyl)tropolone.



The catalytic reduction of 4-(1-hydroxyiminoethyl)tropolone (VI)[3] in the presence of palladized charcoal gave an amino compound (VII). The acetylation of VII afforded 4-(1-acetamidoethyl)tropolone (VIII), the structure of which was clear from the positive ferric chloride coloration and from the presence of the amide band at 1667 $cm^{-1}$ in its infrared absorption spectrum. The tosylation of the amine (VII) with *p*-toluenesulfonyl chloride also gave the corresponding sulfonamide (IX).

The treatment of VIII with *p*-toluenediazonium chloride gave a *p*-tolylazo compound (V), the position of the azo group being assumed to be at the 5-position by analogy with the other azotropolones.[4] The heating of the azo compound (V) in ethanol gave pale yellow crystals with a m. p. of 203°C, which was found to be identical with the compound (III) obtained earlier from the azo compound (II and IV). The compound (III), whose elemental analysis corresponds to the formula $C_{16}H_{14}O_2N_2$, gives an orange sodium salt, and, in its ultraviolet absorption spectrum, shows a bathochromic shift of the absorption maxima in an alkaline solution, as is shown in Fig. 1. These results indicate that III is an acidic compound. The presence of the $\alpha$-enolone system was suggested by the positive ferric chloride coloration and by the formation of an orange copper chelate, as well as by the presence of $\nu_{OH}$ at 3350 $cm^{-1}$ in its infrared absorption spectrum. No hydroxyl group was observed in the infrared absorption spectra of its acetyl and

XIX: X=Br

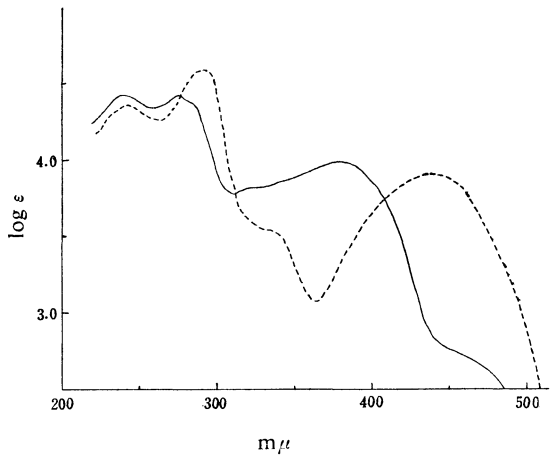

Fig. 1. The ultraviolet absorption of III in methanol (——) and in 0.1 N sodium hydroxide solution (- - -).

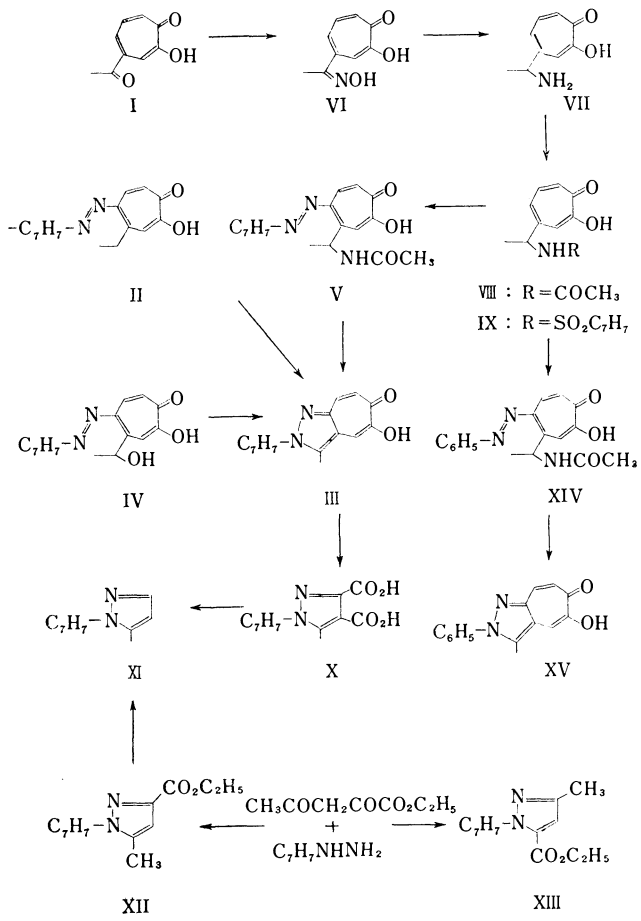
tosyl derivatives, which were neutral and lacked the ferric chloride coloration.



The alkaline permanganate oxidation of III gave a dicarboxylic acid (X). The decarboxylation of X by heating gave an oily substance, which was identified with 5-methyl-1-(*p*-tolyl)-pyrazole (XI)[5] by a direct comparison of their infrared absorption spectra and by an admixture of their picrates. An authentic specimen of XI was synthesized by a modified Finar and Hurlock method[6] as follows: The reaction of ethyl acetopyruvate and *p*-tolylhydrazine gave two isomeric condensation products, ethyl 5-methyl-1-(*p*-tolyl)pyrazole-3-carboxylate (XII) and ethyl 3-methyl-1-(*p*-tolyl)pyrazole-5-carboxylate (XIII). The alkaline hydrolysis of XII, followed by decarboxylation, gave XI. This result shows that the dicarboxylic acid (X) is 5-methyl-1-(*p*-tolyl)pyrazole-3,4-dicarboxylic acid;[5] therefore, the compound (III) contains a pyrazole ring. From the above-mentioned evidence, only one structure, 5-hydroxy-3-methyl-2-(*p*-tolyl)-6(2*H*)-cyclohepta-[c]pyrazolone, is deduced for the compound (III).

4-(1-Acetamidoethyl)-5-phenylazotropolone (XIV), which was obtained by treating VIII with benzenediazonium chloride, also gave a pale yellow compound (XV) when heated in an alcoholic solution. From the elemental analysis, the positive ferric chloride coloration and the ultraviolet absorption spectrum, which are similar to those of III, it seems that the structure of XV is best represented by 5-hydroxy-3-methyl-2-phenyl-6(2*H*)-cyclohepta[c]pyrazolone. The infrared absorption spectrum also supported this structure.

6) I. L. Finar and R. J. Hurlock, *J. Chem. Soc.*, **1958**, 3260.

The formation of the cyclohepta[c]pyrazolone derivatives (III and XV) from the azo compounds (V and XIV) is mechanistically conceivable, as Chart 1 shows. The formation of the same product (III) from the azo compound (IV) can also be explained by the same mechanism. This mechanism is apparently different from the mechanism of the formation of III from 4-ethyl-5-(*p*-tolylazo)tropolone (II), in which the inevitable dehydrogenation process accompanies the ring closure.[1] In the present case, the yield of the cyclization product showed no change upon the addition of the oxidant.[1,7] The reaction path, therefore, is the initial elimination of the acetamido or hydroxyl group, followed by the ring closure to afford the diketone (IIIa), which then enolizes to III.

The methylation of the acetamido compound (VIII) with diazomethane gave two isomeric methyl ethers, XVIa and XVIb. The structures of these ethers were determined by an examination of their infrared absorption spectra, in which the characteristic absorptions appeared at 791 $cm^{-1}$ and at 828 $cm^{-1}$ respectively.[8] These ethers are of interest in that they possess partial structures of colchicine and isocolchicine[9] respectively. The catalytic reduction of the azo compound (V) gave 4-(1-acetamidoethyl)-5-aminotropolone (XVII), from which 5-chloro (XVIII) and 5-bromo (XIX) derivatives were prepared by a Sandmeyer reaction.

## Experimental[10]

**4-(1-Aminoethyl)tropolone (VII).**—To a suspension of 4-(1-hydroxyiminoethyl)tropolone (VI) (1.58 g.) in methanol (25 ml.), concentrated hydrochloric acid (5 ml.) was added. The mixture was then shaken with hydrogen, in the presence of 5% palladium on carbon (300 mg.), at room temperature and at atmospheric pressure; after 4 hr., 430 ml. of hydrogen was absorbed. The catalyst was removed, the

10) All melting points are uncorrected.

solution was concentrated to a small volume and adjusted to pH 5 with potassium hydroxide solution, and the potassium chloride thereby precipitated was filtered off. The filtrate was adjusted to pH 7, and the crystals thereby formed were collected by filtration and recrystallized from methanol to give the monohydrate of VII (1.35 g.) as yellow needles, m. p. 220°C (decomp.).

Found: C, 59.10; H, 6.86; N, 7.54. Calcd. for $C_9H_{11}O_2N \cdot H_2O$: C, 59.00; H, 7.15; N, 7.65%.
$\lambda_{max}^{MeOH}$ mμ (log ε); 243 (4.39), 335 (3.97), 395 (3.68).

**4-(1-Acetamidoethyl)tropolone (VIII).**—A mixture of VII (8.2 g.) and acetic anhydride (9 ml.) was allowed to stand for 1 hr. at room temperature. Water (9 ml.) was then added, and the crystals thereby formed were collected by filtration to give VIII (5.6 g.), m. p. 156°C. From the filtrate, further crops (2.64 g.) of VIII were obtained by extraction with ethyl acetate. Recrystallization from ethanol gave colorless prisms, m. p. 166°C. VIII is green in water or ethanol and red in chloroform with a ferric chloride solution.

Found: C, 63.83; H, 6.00; N, 6.63. Calcd. for $C_{11}H_{13}O_3N$: C, 63.75; H, 6.32; N, 6.76%.
$\lambda_{max}^{MeOH}$ mμ (log ε); 241 (4.43), 324 (3.89).

**4-[1-(*p*-Toluenesulfonamido)ethyl]tropolone (IX).**—To stirred solution of VII (170 mg.) in a 0.5 N sodidum hydroxide solution (5.5 ml.), *p*-toluenesulfonyl chloride (210 mg.) was added at room temperature. After being stirred for 4 hr., the mixture was acidified with 6 N hydrochloric acid, and the brown gummy material thereby formed was triturated in order to crystallize it. Recrystallization from ethanol gave IX (90 mg.) as colorless prisms, m. p. 176—177°C.

Found: C, 60.18; H, 5.37; N, 4.39. Calcd. for $C_{16}H_{17}O_4NS$: C, 59.69; H, 5.34; N, 4.61%.
$\lambda_{max}^{MeOH}$ mμ (log ε); 230 (4.47), 325—330 (3.88).

**4-(1-Acetamidoethyl)-5-(*p*-tolylazo)tropolone (V).**—To a stirred solution of VIII (2.10 g.) in pyridine (20 ml.), a *p*-toluenediazonium chloride solution prepared from *p*-toluidine (1.10 g.) was added with the mixture was being cooled in an ice bath; orage red crystals were separated out during stirring. After 30 min., water (100 ml.) was added and the crystals were collected by filtration and washed with water to give V (2.90 g.); m. p. 153—155°C. Recrystallization from benzene gave orange red needles, m. p. 167°C (decomp.).

Found: C, 66.13; H, 5.61; N, 12.77. Calcd. for $C_{18}H_{19}O_3N_3$: C, 66.44; H, 5.89; N, 12.97%.
$\lambda_{max}^{MeOH}$ mμ (log ε); 235 (4.33), 291 (3.95), 404 (4.36).

**5-Hydroxy-3-methyl-2-(*p*-tolyl)-6(2*H*)-cyclohepta[c]pyrazolone (III).**—A solution of V (1.00 g.) in ethanol (30 ml.) was heated under reflux for 3 hr. On cooling, III (700 mg.) was obtained as pale yellow needles, m. p. 203°C, which showed no depression on admixture with the specimen obtained from 4-ethyl-5-(*p*-tolylazo)tropolone (II)[1] or 4-(1-hydroxyethyl)-5-(*p*-tolylazo)tropolone (IV).[2] Their infrared spectra were also identical.

Found: C, 71.83; H, 5.26; N, 10.59. Calcd. for $C_{16}H_{14}O_2N_2$: C, 72.16; H, 5.30; N, 10.52%.
$\lambda_{max}^{MeOH}$ mμ (log ε); 239 (4.43), 275 (4.44), 379 (3.99).
$\lambda_{max}^{0.1N\ NaOH}$ mμ (log ε); 242 (4.36), 292 (4.58), 435—440 (3.09).

*Acetate*: Obtained by treatment with acetic anhydride in the presence of sulfuric acid; colorless needles (from ethanol); m. p. 205—206°C.

Found: C, 69.98; H, 4.89; N, 9.35. Calcd. for $C_{18}H_{16}O_3N_2$: C, 70.11; H, 5.23; N, 9.35%.
$\lambda_{max}^{MeOH}$ mμ (log ε); 235 (4.42), 263 (4.47), 335—340 (4.20).

*Tosylate*: Obtained by treatment with *p*-toluenesulfonyl chloride in pyridine; pale yellow prisms (from benzene), m. p. 195—196°C.

Found: C, 66.42; H, 4.82; N, 6.76. Calcd. for $C_{23}H_{20}O_4N_2S$: C, 65.69; H, 4.79; N, 6.66%.

**The Permanganate Oxidation of III.**—To a stirred suspention of III (1.06 g.) in a mixture of a N potassium hydroxide solution of (8 ml.) and water (30 ml.), powdered potassium permanganate was added in small portions at room temperature; 3.2 g. of permanganate was consumed during 3 hr. After decomposing an excess of permanganate by the addition of methanol, manganese dioxide was filtered off and washed with water. The combined filtrate and washing were acidified with 6 N sulfuric acid, and the crystals thereby formed were collected by filtration and recrystallized from aqueous ethanol to give *5-methyl-1-(p-tolyl)pyrazole-3, 4-dicarboxylic acid (X)* (600 mg.) as colorless prisms, m. p. 243°C (decomp.).

Found: C, 59.84; H, 4.38; N, 10.59. Calcd. for $C_{13}H_{12}O_4N_2$: C, 59.99; H, 4.65; N, 10.59%.

**5-Methyl-1-(*p*-tolyl)pyrazole (XI).**—*a) From Ethyl 5-Methyl-1-(p-tolyl)pyrazole-3-carboxylate (XII).*—A mixture of XII (8.0 g.), a 2 N potassium hydroxide solution (25 ml.) and ethanol (15 ml.) was heated under reflux for 30 min. The reaction mixture was concentrated to a small volume and acidified with concentrated hydrochloric acid to give *5-methyl-1-(p-tolyl)pyrazole-3-carboxylic acid.* Recrystallization from aqueous ethanol afforded colorless rods of monohydrate (7.2 g.), m. p. 170°C.

Found: C, 61.88; H, 5.86; N, 12.04. Calcd. for $C_{12}H_{12}O_2N_2 \cdot H_2O$: C, 61.52; H, 6.02; N, 11.96%.

This acid (3.0 g.) was heated at 240—260°C for 10 min., and the oily substance thereby formed was distilled to give XI (1.1 g.) as a colorless oil, b. p. 137°C/5 mmHg, b. p. 272°C, reported[5] b. p. 270—280°C.

Found: C, 76.43; H, 6.93; N, 16.10. Calcd. for $C_{11}H_{12}N_2$: C, 76.71; H, 7.02; N, 16.27%.

*Picrate*: m. p. 121°C, yellow needles (from ethanol).

Found: C, 50.91; H, 3.55; N, 17.61. Calcd. for $C_{17}H_{15}O_7N_5$: C, 50.87; H, 3.77; N, 17.45%.

*b) From 5-Methyl-1-(p-tolyl)pyrazole-3, 4-dicarboxylic Acid (X).*—X (250 mg.) was heated at 250—255°C for 15 min., and the oily substance thereby formed was distilled to give a colorless oil. The infrared spectrum of this oil was identical with that of XI, and the picrate of this oil, m. p. 121°C, showed no depression on admixture with the picrate of XI.

**Ethyl 5-Methyl-1-(*p*-tolyl)pyrazole-3-carboxylate (XII) and Ethyl 3-Methyl-1-(*p*-tolyl)pyrazole-5-carboxylate (XIII).**—To a stirred solution of ethyl

acetopyruvate (28 g.) in glacial acetic acid (45 ml.), a solution of *p*-tolylhydrazine (21.6 g.) in the same solvent (20 ml.) was added at room temperature, and the mixture was heated under reflux for 2 hr. After it had been cooled, the mixture was poured into water (270 ml.) and extracted 4 times with ether, and the combined extract was washed with a 10% sodium carbonate solution (30 ml.×3). The solvent was evaporated, and the residue was fractionally recrystallized from ethanol. The sparingly soluble part gave XII (21.7 g.) as colorless scales, m. p. 77°C.

Found: C, 68.68; H, 6.36; N, 11.54. Calcd. for $C_{14}H_{16}O_2N_2$: C, 68.83; H, 6.60; N, 11.47%.

The more soluble part gave XIII (5.2 g.) as colorless needles, m. p. 65°C.

Found: C, 69.01; H, 6.50; N, 11.40. Calcd. for $C_{14}H_{16}O_2N_2$: C, 68.83; H, 6.60; N, 11.47%.

The heating of XIII with potassium hydroxide in aqueous ethanol gave *3-Methyl-1-(p-tolyl)pyrazole-5-carboxylic acid* as colorless needles, m. p. 203°C (decomp.) (from aqueous ethanol).

Found: C, 66.65; H, 5.59; N, 12.96. Calcd. for $C_{12}H_{12}O_2N_2$: C, 66.61; H, 5.34; N, 12.97%.

**4-(1-Acetamidoethyl)-5-phenylazotropolone (XIV).**—To a stirred solution of VIII (420 mg.) in pyridine (5 ml.), a benzene-diazonium chloride solution prepared from aniline (190 mg.) was added while the mixture was being cooled in an ice bath. After being stirred for 1 hr., the mixture was diluted with water and the crystals thereby formed were collected by filtration and recrystallized from benzene to give XIV (540 mg.) as orange red needles, m. p. 141°C.

Found: C, 66.05; H, 5.46; N, 13.53. Calcd. for $C_{17}H_{17}O_3N_3$: C, 65.58; H, 5.50; N, 13.50%. $\lambda_{max}^{MeOH}$ mμ (log ε); 232 (4.35), 288 (4.03), 392 (4.35).

**5-Hydroxy-3-methyl-2-phenyl-6(2*H*)-cyclohepta[c]pyrazolone (XV).**—A solution of XIV (100 mg.) in ethanol (3 ml.) was heated under reflux for 1.5 hr. and allowed to cool. The crystals thereby formed were recrystallized from ethanol to give XV (50 mg.) as pale yellow prisms, m. p. 230—231°C.

Found: C, 71.26; H, 4.75; N, 10.90. Calcd. for $C_{15}H_{12}O_2N_2$: C, 71.41; H, 4.80; N, 11.11%. $\lambda_{max}^{MeOH}$ mμ (log ε); 241 (4.37), 275 (4.43), 378—381 (3.95).

**The Methylation of VIII.**—To a stirred solution of VIII (560 mg.) in methanol (20 ml.), an ethereal solution of diazomethane was added while the mixture was being cooled in an ice bath; the mixture was then stirred for an additional 3 hr. The evaporation of the solvent left an oily substance, which was dissolved in ethyl acetate and chromatographed through an alumina column. The crystal obtained by evaporation of the solvent from the effluent were fractionallized from ethyl acetate to give *6-(1-acetamidoethyl)-2-methoxytropone (XVIa)* (100 mg.) as colorless prisms, m. p. 153.5°C.

Found: C, 65.08; H, 6.85; N, 6.33. Calcd. for $C_{12}H_{15}O_3N$: C, 65.14; H, 6.83; N, 6.33%. $\lambda_{max}^{MeOH}$ mμ (log ε); 240 (4.41), 322 (3.88).

The more soluble part gave *4-(1-acetamidoethyl)-2-methoxytropone (XVIb)* (90 mg.) as colorless prisms, m. p. 162—163°C.

Found: C, 64.91; H, 6.73; N, 6.23. Calcd. for $C_{12}H_{15}O_3N$: C, 65.14; H, 6.83; N, 6.33%. $\lambda_{max}^{MeOH}$ mμ (log ε); 240 (4.39), 346 (3.87).

**4-(1-Acetamidoethyl)-5-aminotropolone (XVII).**—A suspension of V (1.0 g.) in methanol (15 ml.) was shaken with hydrogen in the presence of platinum oxide (50 mg) at room temperature and at atmospheric pressure; 124 ml. of hydrogen was absorbed. After the removal of the catalyst, the solvent was evaporated and the residue was washed with a small amount of benzene and recrystallized from ethanol to give XVII (590 mg.) as yellow needles, m. p. 203°C (decomp.).

Found: C, 59.60; H, 6.15; N, 12.75. Calcd. for $C_{11}H_{14}O_3N_2$: C, 59.45; H, 6.35; N, 12.60%. $\lambda_{max}^{MeOH}$ mμ (log ε); 239 (4.36), 359 (4.11), 388 (4.10).

**4-(1-Acetamidoethyl)-5-chlorotropolone (XVIII).**—To a stirred solution of XVII (220 mg.) in a mixture of dioxane (1 ml.) and 12% sulfuric acid (1.4 ml.), a solution of sodium nitrite (70 mg.) in water (0.4 ml.) was added while the mixture was being cooled in an ice bath. After being stirred for 30 min., the mixture was poured into a solution of cuprous chloride (250 mg.) in concentrated hydrochloric acid (2 ml.); the stirring was then continued for 4 hr. The reaction mixture was diluted with water (15 ml.) and extracted with chloroform, and the chloroform solution was saturated with hydrogen sulfide gas. The copper sulfide thereby formed was filtered off and the solvent was evaporated to give crystals. Recrystallization from methanol gave XVIII (30 mg.) as yellow microneedles, m. p. 227°C.

Found: C, 55.00; H, 5.11; N, 5.79. Calcd. for $C_{11}H_{12}O_3N_2Cl$: C, 54.66; H, 5.01; N, 5.80%. $\lambda_{max}^{MeOH}$ mμ (log ε); 244 (4.37), 330 (3.99).

**4-(1-Acetamidoethyl)-5-bromotropolone (XIX).**—A diazotized solution of XVII (100 mg.) prepared as in the above experiment was poured into a solution of cuprous bromide (150 mg.) in concentrated hydrobromic acid (1 ml.). After being stirred for 5 hr., the mixture was treated with hydrogen sulfide gas as in the above experiment, and the crystals thereby obtained were recrystallized from methanol to give XIX (30 mg.) as yellow needles, m. p. 201°C (decomp.).

Found: C, 46.99; H, 4.28; N, 4.78. Calcd. for $C_{11}H_{12}O_3NBr$: C, 46.17; H, 4.23; N, 4.90%. $\lambda_{max}^{MeOH}$ mμ (log ε); 244 (4.36), 330 (4.03).

The authors wish to express their deep gratitude to the Sankyo Co., Ltd., which defrayed a part of the expenses for the present work.

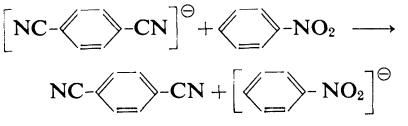
# Electron Transfer between Anion Radicals and Neutral Molecules as Revealed by Electron Spin Resonance Spectra

By Akira ISHITANI and Saburo NAGAKURA

(Received June 1, 1964)

Recently the anion radicals of various aromatic molecules have been prepared and their electron spin resonance and electronic absorption spectra extensively studied from both experimental and theoretical points of view. Anion radicals may be expected to possess low ionization potentials and, therefore, to be strong electron donors. This means that they may be able to form Mulliken type charge-transfer complexes with some electron acceptors.[1] Moreover, there may be a possibility that the complexes of this kind will exhibit interesting electric and magnetic properties. With these expectations, we have undertaken to study the interaction of some anion radicals with neutral aromatic molecules, mainly by measuring electron spin resonance spectra.

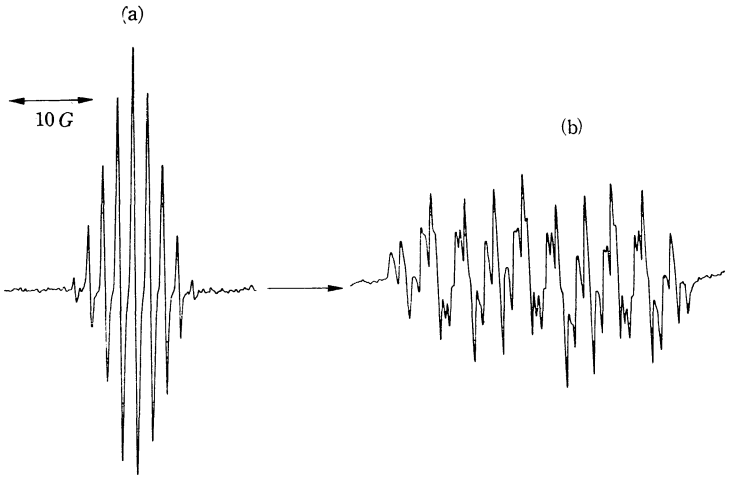


## Experimental

**Materials.** — Commercial pyridine, benzonitrile and nitrobenzene of the G. R. grade were purified by distillation. Commercial *p*-dinitrobenzene, *p*-nitrotoluene, $\alpha$-nitronaphthalene and 9-nitroanthracene of the G. R. grade were purified by repeated recrystallizations from ethanol. Their melting points are 173.5°C, 53.5°C, 61.5°C and 146°C respectively. Commercial terephthalonitrile was purified by repeated sublimations in vacuo; m. p. 222°C. Pyromellitonitrile was synthesized from pyromellitic acid through the following route. Pyromellitimide was obtained by heating ammonium pyromellitate[2] which had been prepared by neutralizing pyromellitic acid with aqueous ammonia. This pyromellitimide was then converted into pyromellitamide by aqueous ammonia. Pyromellitonitrile finally obtained by the dehydration of pyromellitamide was purified by repeated recrystallizations from ethanol. Nitrosobenzene was synthesized by the mild oxidation of phenylhydroxylamine with sodium chromate and purified by recrystallization from ethanol; m. p. 67.5°C. $\beta$-Nitronaphthalene was synthesized from the diazonium sulfate of $\beta$-naphthylamine by the addition of copper(I) oxide. Dimethoxyethane used as a solvent in the present experiment was carefully purified by the method described in a previous paper.[3]

**The Preparation of Anion Radicals and the Measurement of ESR Spectra.** — Anion radicals were prepared by the alkali metal reduction method in vacuo, as has been described in a previous paper.[3] Neutral molecules were added to the anion radical solutions in vacuo by the use of breakable joints. ESR spectra were measured at room temperature with a Hitachi ESR spectrometer model-18 (X band, 100 kc. modulation).

## Results and Discussion



Let us take the nitrobenzene-terephthalonitrile system as an example and explain how the ESR spectrum of an anion radical changes upon the addition of a neutral molecule. First, the terephthalonitrile anion was prepared and the ESR spectrum was measured. The observed hyperfine structure was completely consistent with that obtained by Carrington and Todd[4] (see Fig. 1a). Thereafter, neutral nitrobenzene was added through the breakable joint in vacuo, and the ESR spectrum of the mixed solution was measured. The results are shown in Fig. 1b. The hyperfine structure of the terephthalonitrile anion disappeared and a new pattern, which could safely be assigned to that of the nitrobenzene anion,[5] was observed. At the same time, the color of the solution changed immediately from yellow (the color of the terephthalonitrile anion) to reddish purple (the color of the nitrobenzene anion). This clearly shows that the following electron transfer reaction occurs:

(1)

On the other hand, when neutral terephthalonitrile was added to the solution of the nitrobenzene anion, the hyperfine structure and the color of the solution remained unchanged. The above-mentioned experimental results lead to the conclusion that electron transfer does not occur from the nitrobenzene anion to the terephthalonitrile molecule but takes place only

in the direction shown in Eq. 1, and that, therefore, nitrobenzene is a stronger electron acceptor than terephthalonitrile is.

Similar experiments were carried out with more than ten systems. Typical examples are shown in Table I. All of them failed to show a tendency toward charge transfer complex formation, but, in all, the complete electron transfer occurred under the present experimental conditions. This may conceivably be due to the fact that the anion radicals are surrounded by polar solvent molecules and are stabilized largely by solvation energies. A similar electron transfer phenomenon from the naphthalene anion radical to anthracene has been reported by Wertz.[6]

TABLE I. ELECTRON TRANSFER BETWEEN SOME AROMATIC ANION RADICALS AND NEUTRAL MOLECULES

(a) $\left[\text{C}_6\text{H}_5\text{NO}\right]^- + \text{C}_6\text{H}_5\text{NO}_2 \rightarrow \text{C}_6\text{H}_5\text{NO} + \left[\text{C}_6\text{H}_5\text{NO}_2\right]^-$

(b) $\left[\text{C}_6\text{H}_5\text{NO}_2\right]^- + \text{C}_6(\text{CN})_6 \rightarrow \text{C}_6\text{H}_5\text{NO}_2 + \left[\text{C}_6(\text{CN})_6\right]^-$

(c) $\left[\text{NC-C}_6\text{H}_4\text{-CN}\right]^- + \text{C}_6(\text{CN})_6 \rightarrow \text{NC-C}_6\text{H}_4\text{-CN} + \left[\text{C}_6(\text{CN})_6\right]^-$

(d) $\left[\text{CH}_3\text{-C}_6\text{H}_4\text{-NO}_2\right]^- + \text{C}_6\text{H}_5\text{NO}_2 \rightarrow \text{CH}_3\text{-C}_6\text{H}_4\text{-NO}_2 + \left[\text{C}_6\text{H}_5\text{NO}_2\right]^-$

(e) $\left[\text{C}_{10}\text{H}_7\text{NO}_2\right]^- + \text{C}_{10}\text{H}_7\text{NO}_2 \rightarrow \text{C}_{10}\text{H}_7\text{NO}_2 + \left[\text{C}_{10}\text{H}_7\text{NO}_2\right]^-$

(f) $\left[\text{C}_6\text{H}_5\text{NO}_2\right]^- + \text{N-C}_6\text{H}_4\text{-NO}_2 \rightarrow \text{C}_6\text{H}_5\text{NO}_2 + \left[\text{N-C}_6\text{H}_4\text{-NO}_2\right]^-$

From the experimental results given in Table I, we could determine the order of the electron accepting abilities of various aromatic molecules. The results are shown below:

1) Pyridine < Benzonitrile < Terephthalonitrile < Nitrosobenzene < Nitrobenzene < Pyromellitonitrile < *m*-Dinitrobenzene
2) *p*-Nitrotoluene < Nitrobenzene
3) Nitrobenzene < 4-Nitropyridine
4) $\alpha$-Nitronaphthalene < $\beta$-Nitronaphthalene
5) Nitrobenzene < $\alpha$-Nitronaphthalene < 9-Nitroanthracene

Series 1 shows the effect of substituent groups upon the electron accepting ability. From this it may be inferred that the substituent groups increase the electron accepting ability of the benzene ring in the following order: $-CN < -NO < -NO_2$. In particular, it is noticeable that terephthalonitrile with two CN groups is a weaker electron acceptor than nitrobenzene or nitrosobenzene.

The order in series 2 can be understood by considering the electron releasing hyperconjugation effect of the methyl group. It is noticeable that the electron moves so completely between the two species, notwithstanding so small a difference in electron affinity,

6) J. Wertz, *Chem. Revs.*, 55, 922 (1955).

as in the system of nitrobenzene and *p*-nitrotoluene. Series 3 indicates that the pyridine nucleus is more electron attracting than is the benzene nucleus.

The results in series 4 can be explained by the fact that the nitro group at the $\beta$-position of the naphthalene nucleus is more sterically free and more strongly conjugated with the nucleus than is the nitro group at the $\alpha$-position. This explanation may be said to be supported by the X-ray crystal analysis data showing that the nitro group of 1,5-dinitronaphthalene is twisted by 67° from the aromatic ring plane,[7] while the group of $\beta$-nitronaphthalene is coplanar with the naphthalene nucleus. Series 5 indicates that the electron affinity increases with an increase in the number of conjugated rings. This result seems to be consistent with the order of the magnitudes of the electron affinities evaluated theoretically with benzene, naphthalene and anthracene.[8]

In this stage of the experiments, we can obtain only qualitative information about the electron affinities of aromatic molecules. However, by measuring the ESR spectra at various temperatures it may be possible to obtain some quantitative knowledge about the equilibrium of the $A^- + B \rightleftarrows A + B^-$ type, as was done by Hausser[9] with the diphenylpicryl hydrazyl-tetramethyl-*p*-phenylenediamine system.

The authors wish to express their thanks to Miss Yasuko Maruyama for her kind help in preparing pyromellitonitrile.

# A Study of the Interaction between the Stearic Acid Monolayer and the Calcium Ions by the Radiotracer Method

By Akira MATSUBARA, Ryohei MATUURA and Hideo KIMIZUKA

(Received June 5, 1964)

The composition of the calcium stearate formed on the surface of water through the interaction between the stearic acid monolayer and calcium ions has been studied by several authors.[1-3] Langmuir and Schaefer[1] and Havinga[2] collected the monolayer spread on a solution containing calcium ions and ascertained the composition by means of chemical analysis. Later, Sobotka et al.[3] measured the composition of the built-up film by using radioactive calcium. The composition of the calcium stearate in the film thus measured was discussed by these authors as a function of the pH of the underlying solution.

However, these methods involve the disturbing of the monolayer, i.e., "skimming off" or "building up" the monolayer. It has not yet been confirmed whether or not the composition of the film determined by these methods is the same as that on the surface of water itself. Thus it is necessary to measure the calcium content of the monolayers directly, without disturbing the system. The radiotracer method has, therefore, been used in this study; the state of the monolayer has also been discussed.

## Experimental

**Materials.** — Non-radioactive stearic acid was purified from a commercial sample by fractional distillation through a rectifying column of 65 plates at a reflux ratio of 15, followed by repeated recrystallizations from ethanol. The fraction distilled at 225—225.5°C/10 mmHg was collected. Its melting point was 67.2°C. Radioactive stearic acid, labeled with $^{14}C$, was obtained from Daiichi Pure Chemicals, Tokyo, Japan. Because of the very minute amount of radioactive stearic acid, we followed the method of purification developed by Gaines,[4] which consists of dissolving the sample in reagent grade *n*-hexane and extracting the impurities first with 1 N hydrochloric acid and then

with several portions of water. Monolayers of radioactive and non-radioactive stearic acids gave almost the same pressure-area ($\Pi$-$A$) curve, indicating the purity of radioactive stearic acid. The specific activity of this radioactive stearic acid was 2 mc./mmol.

Calcium chloride of a guaranteed grade was purified by recrystallization from its aqueous solution. $^{45}$Ca-labeled calcium chloride, with a specific activity of 275 mc./g., was obtained from the Oak Ridge National Laboratory, Oak Ridge, Tennessee, U. S. A. The $\Pi$-$A$ curve of the stearic acid monolayer on a solution containing radioactive calcium ions was exactly the same as that on a solution containing purified non-radioactive calcium ions.

The pH of the substrate solution was adjusted by sodium carbonate, sodium bicarbonate and hydrochloric acid, all of which were guaranteed reagents. The water used for these studies was redistilled with a quartz still.

**Method.**—The procedure of measuring the surface excess by the radiotracer technique was essentially the same as one described previously.[5] The apparatus used in the present experiment is shown in Fig. 1. A brass trough A, 15×30 cm$^2$ in inner area, was made, and its surface was plated by chromium. An end-window Geiger-Müller tube B, with a mica window 1.5 mg./cm$^2$ thick was supported by a brass cylinder, C, over the surface of the trough. A brass mount D, with a hole 2 cm. in diameter, was placed on the edges of the trough, A, as is shown in Fig. 1, so that the reproducibility of the geometrical condition could be realized with ease. The inside of the trough and the glass barriers, F, were covered by a thin paraffin film and rinsed with water overnight before use. A radioactive calcium chloride solution of a known concentration and pH was then poured into the trough. The surface of the solution was swept by the barriers, a Geiger-Müller tube was put down to the measuring arrangement and the radioactive counting was started. The same procedure was also carried out after the monolayer of stearic acid had been spread on the surface of the solution.

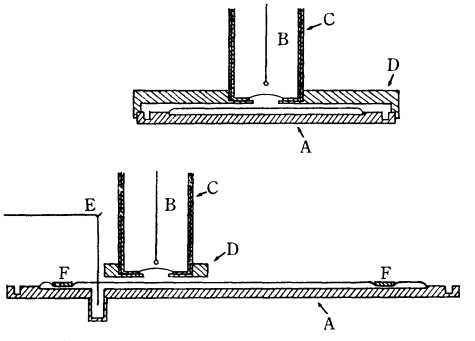

Fig. 1. The measuriug apparatus.

The amount of calcium adsorbed by the stearic acid monolayer, $\Gamma_{Ca}$, in mole per cm$^2$, was calculated according to this equation:

$$\Gamma_{Ca}=\frac{I_m-I}{SA} \qquad (1)$$

where $I$ is the intensity, in count./min., of the radiation due to the substrate without film; $I_m$, the intensity of the radiation due to that with the stearic acid monolayer; $S$, the specific activity, in count./min./mol., of the radioactive calcium in the film and $A$, the surface area, in cm$^2$ within which the radiation is detectable with the Geiger-Müller tube in the present apparatus. Of these quantities, $S$ and $A$ were determined by using a point source, as has been reported already.[5] $\Gamma_{Ca}$ was hence obtained from the measurement of $I$ and $I_m$.

The measurement of the surface pressure of the monolayer was simultaneously carried out by a modified Wilhelmy-type surface balance,[6] E, as is shown in Fig. 1.

All the experiments were carried out at a fixed concentration of calcium ions, 5×10$^{-5}$ mol./l. The temperature of the experiment was ca. 10°C. By preliminary experiments it was confirmed that the variation in temperature from 5 to 15°C modified the $\Pi$-$A$ curves slightly, although the change in the surface excess of calcium with the temperature was within the range of experimental error.

## Results and Discussion

The $\Pi$-$A$ curves of the stearic acid monolayers on the aqueous solutions of calcium

chloride of varying pH values are shown in Fig. 2. The general features are the same as those measured by Sasaki and Matuura.[7] It is obvious from this figure that the condensation of the stearic acid monolayer by calcium ions increases with the increase in the pH of the substrate. This effect has been explained as being due to the formation of calcium stearate, $Ca(St.)_2$.[8]

In the measurement of the surface excess of calcium, the values of $I$ were almost time-independent. On the other hand, the values of $I_m$ increased at once and fluctuated for about thirty minutes or, occasionally, more after the monolayer had been spread. Then, thirty minutes after spreading, the monolayer was compressed at the rate of 1 cm. of a trough scale/min. and at 3 min. intervals and the surface excess of calcium was measured as a function of the surface concentration of stearic acid. In Fig. 3 the amounts of calcium

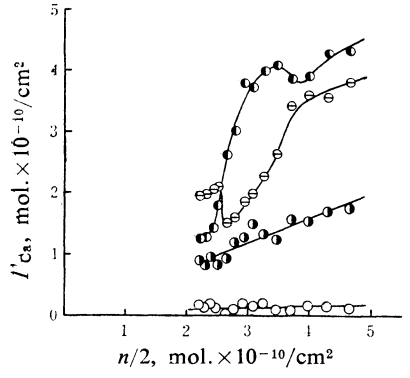

Fig. 3. $\Gamma_{Ca}$ vs. $n/2$ curves at pH=5.30 ○; 6.45 ◑; 8.00 ⊖ and 10.6 ◐.

adsorbed on the stearic acid monolayer, $\Gamma_{Ca}$, are plotted against a half of the surface concentration of the stearyl chain, $n/2$ in mol./cm$^2$, for the typical pH values. If it is assumed that the mole ratio of calcium stearate to stearic acid is constant at a given pH, and, in addition, that the film is homogeneous and compressed uniformly, $\Gamma_{Ca}$ should increase with an increase in the surface concentration of the monolayer along a straight line passing through the point of origin, the slope of the line depending on the pH of the substrate solution. The experimental points in Fig. 3, however, scatter randomly at smaller surface concentrations, especially when the pH of the substrate is high.

The irregularity of the experimental points observed at a smaller surface concentration should be attributed to the inhomogeneity of the monolayer. Harkins et al.[9] has pointed out the existence of a two-phase region by means of surface potential measurements. Some other authors have also confirmed the inhomogeneity of the stearic acid monolayer at low surface pressures by the electron microscopic[10] and radiotracer[11] methods. Unfortunately, these authors have not referred to the large islands of the monolayer. We observed large islands in the present experiment as follows. The $^{14}C$-labeled stearic acid was spread over an area of 37.2Å$^2$/molec. on the surface of a solution containing non-radioactive calcium ions at pH=8.60, and the counting rate as a function of the position was measured by moving the Geiger-Müller tube horizontally and uni-directionally over the surface film. The results are shown in Fig. 4. It may be seen in this figure that the monolayer is localized as large islands, especially around the position where the spreading solution has been dropped. The inhomogeneity of the monolayer found at lower pH values was less pronounced than that at higher pH's. Thus, it is evident that the monolayer consists of concentrated and dilute regions. As the monolayer is compressed, the area of the dilute region decreases until, finally, the monolayer becomes a homogeneous one composed of closely-packed molecules. The surface pressure increases suddenly from this point.

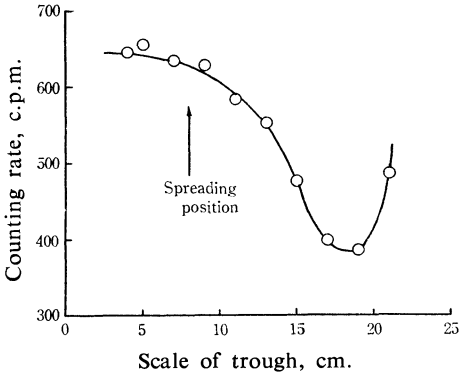

Fig. 4. The radiation from the various position of the $C^{14}$-labeled stearic acid monolayer at $A$=37.2 Å$^2$/molec. on the $5\times10^{-5}$ mol./l. $CaCl_2$ solution at pH=8.60. The measurement was carried out 30 min. after spreading.

10) H. E. Ries, Jr., and W. A. Kimball, *Nature*, **181**, 901 (1958); H. E. Ries, Jr., and D. C. Walker, *J. Colloid Sci.*, **16**, 361 (1961).
11) J. R. Ryan and J. W. Sheppard, *J. Phys. Chem.*, **59**, 1181 (1955); G. L. Gaines, Jr., *J. Colloid Sci.*, **15**, 321 (1960).

From these facts it is clear that the surface excess at each limiting area should be taken into account in determining the true composition of the film. At this area the fraction of the stearyl chain neutralized by, the calcium in the monolayer, $\Phi_{Ca}$ is given by:

$$\Phi_{Ca}=\frac{\Gamma_{Ca}}{n/2} \tag{2}$$

The calculated values of $\Phi_{Ca}$ are plotted against the pH of the substrate solution in Fig. 5. The results obtained by Langmuir and Schaefer[1] and Sobotka et al.[2] are also shown in this figure. The present result is similar to that obtained by Sobotka et al. with regard to the pH range where $\Phi_{Ca}$ sharply changes. It may also be seen in this figure that the curve is shifted to the alkaline side as compared to the dissociation curve of fatty acids. Such a kind of shift has frequently been observed in surface chemical phenomena[12] and has been explained there by regarding the pH at the interface as being lower than that in the bulk of the solution.

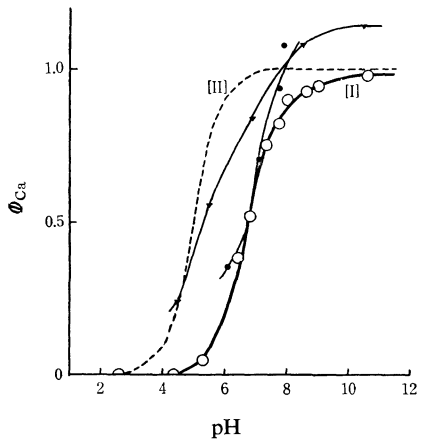

Fig. 5. $\Phi_{Ca}$ vs. pH curves. ○ by the present experiment; ▼ by Langmuir and Schaefer; ● by Sobotka et al. The broken line [II] represents the dissociation curve in bulk for fatty acids.

The monolayer of calcium stearate condenses more than that of stearic acid. Furthermore, it has been pointed out already that the more the formation of calcium stearate increases, the more easily the film forms islands, and even over a large area the molecules in these islands are in a closely-packed state. These facts clearly suggest that the cohesive force between calcium stearate molecules is stronger than that between stearic acid molecules. Hence, the energy of the mixing of stearic acid molecules with calcium stearate molecules in the monolayer should not be zero.

For the following relation:

$$2HSt.+Ca^{2+}=Ca(St.)_2+2H^+$$

$$a_{Ca^{2+}}/a_{H^+}^2=Ka_{Ca(St.)_2}/a_{HSt.}^2 \tag{3}$$

where $K$ is the equilibrium constant and $a$'s are the activities. If this monolayer is assumed to be a mixture not athermal, $a_{Ca(St.)_2}$ and $a_{HSt.}$ are represented by:

$$a_{Ca(St.)_2}=\Phi_{Ca}\exp\{2w(1-\Phi_{Ca})^2\} \tag{4}$$

$$a_{HSt.}=(1-\Phi_{Ca})\exp(w\Phi_{Ca}^2) \tag{5}$$

where $w$ is the interchange energy. Then, by substituting Eqs. 4 and 5 into Eq. 3 the following equation is obtained:

$$a_{Ca^{2+}}/a_{H^+}^2=K'\{\Phi_{Ca}/(1-\Phi_{Ca})^2\}\exp(-4w\Phi_{Ca}) \tag{6}$$

where $K'$ is a constant. For an athermal mixture in which $w$ is equal to zero, the following equation is obtained:

$$a_{Ca^{2+}}/a_{H^+}^2=K'\Phi_{Ca}/(1-\Phi_{Ca})^2 \tag{7}$$

According to Eq. 6, if $a_{Ca^{2+}}$ is constant, $\log\{(1-\Phi_{Ca})^2/a_{H^+}^2\Phi_{Ca}\}$ must be linear against $\Phi_{Ca}$ and, according to Eq. 7, $\log\{\Phi_{Ca}/(1-\Phi_{Ca})^2\}$ must be linear against pH. The former relation was confirmed by the present experimental data as Fig. 6 shows, although the latter one was not confirmed.

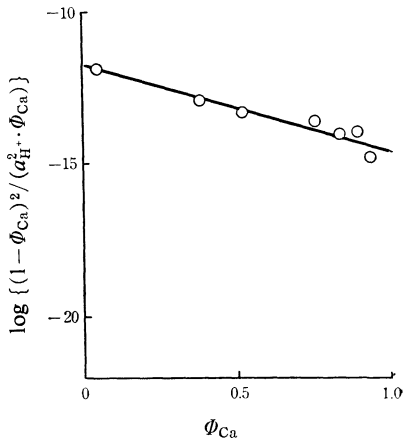

Fig. 6. The test of Eq. 6.

## Summary

Direct measurement by the radiotracer method has been carried out in order to determine the surface excess of calcium on the stearic acid monolayer. It did not provoke any disturbance in the monolayer, such as "skimming off" or "building up". At higher pH values the stearic acid monolayer spread

12) R. A. Peters, *Proc. Roy. Soc.*, **A133**, 140 (1931); J. F. Danielli, ibid., **B122**, 155 (1937), etc.

on a calcium chloride solution shows a very remarkable inhomogeneity. It has been pointed out that this inhomogeneity must be taken into consideration in determining the composition of the monolayer.

The mixed monolayer of stearic acid and calcium stearate satisfies the equation derived by assuming this monolayer to be a mixture not athermal.

# The Micelle Formation of Some Alkyl Sulfates in a Dioxane-Water Mixture

By Keishiro SHIRAHAMA and Ryohei MATUURA

(Received August 24, 1964)

The formation of the micelles of surfactants in aqueous solutions has been known to be affected by various kinds of additives. The effect of added salts has been fully studied by many investigators. As for organic additives, Shinoda[1] and Ooshika[2] showed the decrease in the critical micelle concentration (CMC) of surfactants which resulted when some alcohols were added, correlating it with the number of carbon atoms in an alcohol molecule and in a surfactant molecule. The addition of hydrocarbons also depresses the CMC.[3] However, such substances as lower alcohols, acetone and ethylene glycol are known to increase the CMC.[3-5] Flockhart[4] suggested that the increase is due to the increasing "solvent power" of an ethanol-water mixture. Mukerjee[6] reported the increase in the CMC of dodecylpyridinium iodide in a urea-water mixture and pointed out that this probably results from the urea breaking the "iceberg" structure around the nonpolar part of the surfactant molecule. However, no quantitative explanation of any kind has yet been given of the factors that increase the CMC.

Dioxane is completely miscible with water, just as lower alcohols are, and varies the dielectric constant of its aqueous solution considerably. Therefore, it would be interesting to know how these specific characters of a dioxane-water mixture affect the solutional behavior of surfactants. In the present paper we will report the CMC's of sodium dodecyl sulfate (SDS), sodium tetradecyl sulfate (STS) and sodium hexadecyl sulfate (SHS) in a dioxane-water mixture, and a theoretical consideration will be given to the change in CMC by adding dioxane to aqueous solutions of these surfactants.

## Experimental

**Materials.**—Sodium alkyl sulfates were synthesized from corresponding pure long chain alcohols (obtained by fractional distillation) and sulfuric acid by the method reported earlier.[7] They were purified by repeated recrystallization from butanol and water, and finally extracted by ether for more than 40 hr. Their purity was checked by elementary analysis and surface tension measurements. Dioxane was distilled after refluxing it for more than 8 hr. on metallic sodium. Water was twice distilled.

**Method.**—The CMC's were determined by the electric conductivity method. Solubilities were determined from the weight of the solid deposited by drying up a known amount of a saturated surfactant solution obtained by the mechanical shaking of the solution in the presence of a solid phase for more than 8 hr. at a constant temperature and then filtering it through a glass filter.[8] The titration analysis using bromphenol blue was also used to check the solubilities. The results of the two methods agreed well with each other.

## Results and Discussion

The CMC, determined from a break point on the equivalent conductivity vs. square root of molar concentration curves, is plotted against the concentration of dioxane in the

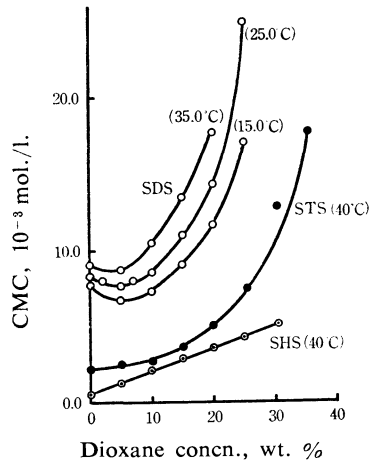

Fig. 1. The CMC of sodium alkyl sulfates (SDS, STS and SHS) as a function of dioxane concentration.

solvent in Fig. 1. No maximum was found around CMC on the conductivity curve at any dioxane concentration, but the break point became obscure as the dioxane concentration increased and eventually faded out. The CMC could not be detected in the region of dioxane more concentrated than that shown in Fig. 1. It should be noted that the CMC of SDS shows a slight minimum and then increases markedly, while that of STS and SHS increases monotonically, even linearly in the case of SHS. The CMC of SDS increases as the temperature rises at any dioxane concentration.

The results may be discussed from two points of view.

**The Solubilization of Dioxane.**—In spite of a strong affinity with water, dioxane is considered to be solubilized partly in the micelle of the surfactant, as in the case of alcohols, resulting in a lowering of the CMC. Shinoda[1] derived an equation which expresses the lowering of the CMC of soap solutions resulting from the solubilization of alcohols. The equation is as follows:

$$\ln(-\mathrm{dCMC}/\mathrm{d}x) = -0.64\,mw/kT + m'w/kT + \text{const.} \qquad (1)$$

where $x$ is the concentration of alcohols, $m$ and $m'$ are the number of carbon atoms in soap and alcohol molecules respectively, and $w$ is the free energy change per methylene group when transferred from water into the micelle phase. Judging from the assumptions included in Eq. 1, it is not unreasonable to apply the same type of equation to the alkyl sulfates-water-dioxane system, which may be expressed as:

$$\ln(-\mathrm{dCMC}/\mathrm{d}x) = -gmw/kT + \text{const.} \qquad (2)$$

where $g$ is a constant (calculated as 0.68) for homologues of sodium alkyl sulfates. Equation 2 means that $-\mathrm{dCMC}/\mathrm{d}x$ decreases as $m$ increases. This effect of lowering the CMC probably competes with a solvent effect, i.e., the effect of raising the CMC, which increases with an increase in the dioxane concentration. The details of this solven effect will be referred to later. It is because of these two compensating effects that the CMC vs. dioxane concentration curve for SDS passes through a minimum. In the case of STS and SHS, the value of $-\mathrm{dCMC}/\mathrm{d}x$ is not so large as to show a minimum on the CMC vs. dioxane concentration curve, even at the lower concentration of dioxane. Indeed, we could determine the unknown constant by substituting the value of $-\mathrm{dCMC}/\mathrm{d}x$ for SDS into Eq. 2 and in turn obtain the values for STS and SHS of $0.386\times10^{-3}$ and $0.089\times10^{-3}$ respectively. These are quite small compared with the $1.72\times10^{-3}$ for SDS.

In order to compare the CMC-lowering effect of dioxane on SDS with that of some lower alcohols, $\log(-\mathrm{dCMC}/\mathrm{d}x)$ is plotted against the number of carbon atoms in an alcohol molecule, and the value of $\log(-\mathrm{dCMC}/\mathrm{d}x)$ for dioxane is placed on this plot, as Fig. 2* shows. We see from this figure that dioxane corresponds, with regard to the CMC-lowering effect, to "an alcohol with one and a half carbon atoms."

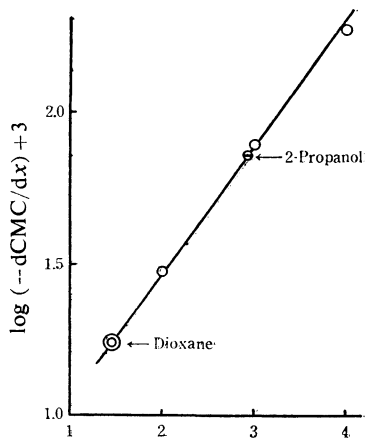

Fig. 2. log $(-\mathrm{dCMC}/\mathrm{d}x)$ vs. number of carbon atoms in an alcohol molecule. The points for dioxane and 2-propanol were placed in order to obtain corresponding number of carbon atoms of straight chain alcohols.

* The data in Fig. 2 for ethanol and propanol were taken from Flockhart's paper (Ref. 4 and B. D. Flockhart and A. R. Ubbelohde, *J. Colloid Sci.*, 8, 428 (1953)) and those for butanol, from Tomoto's (unpublished).

**The Solvent Power of the Dioxane-Water Mixture.**—In the micellar solution the chemical potential of surfactant molecules in the bulk solution is equal to that in the micelle phase. Therefore,

$$\mu_s^\circ + 2RT\ln C = \mu_m^\circ + RT\ln Xf \qquad (3)$$

where $\mu_s^\circ$ and $\mu_m^\circ$ are the standard chemical potential of the surfactant in the bulk solution and that in the micelle phase respectively; $C$ is the CMC, and $X$ and $f$ are, respectively, the mole fraction and the activity coefficient of surfactant in the mixed micelle, both of which become unity when the solvent is pure water. Hereafter, the subscript $x$ refers to the dioxane concentration in the solvent and 0, to pure water.

Then, from Eq. 3;

$$2RT\ln C_x = -(\mu_{sx}^\circ - \mu_m^\circ) + RT\ln X + RT\ln f \qquad (4)$$

Equation 4 becomes simpler, when no solubilized substance is present, as follows:

$$2RT\ln C_0 = -(\mu_{s0}^\circ - \mu_m^\circ) \qquad (5)$$

Subtracting Eq. 5 from Eq. 4 we obtain:

$$2RT\ln(C_x/C_0) = -(\mu_{sx}^\circ - \mu_{s0}^\circ) + RT\ln X + RT\ln f \qquad (6)$$

Equation 6 is quite a general expression for the solvent effect on the micelle formation. Shinoda[1] and Ooshika[2] explained the CMC-lowering effect of alcohols in terms of the entropy of mixing and the reduction of charge density of micelles on adding alcohols, factors which correspond to the second and the third term of the right hand side of Eq. 6 respectively. Namely, in their theory the effect due to the first term is neglected.

In order to evaluate $\mu_{sx}^\circ - \mu_{s0}^\circ$, which is often called the free energy of transfer, solubility measurements are employed. For a 1:1 electrolyte the free energy of transfer, $\Delta F_{tr}$, is correlated with the solubility as:

$$\Delta F_{tr} = \mu_{sx}^\circ - \mu_{s0}^\circ = -2RT\ln(a_x/a_0) \qquad (7)$$

where $a_x$ and $a_0$ are activities of the saturated solution of the electrolyte in mixed and pure solvents respectively. Here, in the case of a micellar solution, we assume that a single surfactant ion in the presence of micelle behaves very much like a surfactant ion in the presence of a solid phase just below the Krafft point. For SHS we see, as has already been stated, that the CMC-lowering effect, and accordingly, the solubilization of dioxane in surfactant micelles, is so small as to be neglected and that only the solvent effect should be considered. We are concerned primarily with this case. Then, combining Eq. 6 with Eq. 7:

$$\Delta F_{tr} = -2RT\ln(a_x/a_0) = -2RT\ln(C_x/C_0) \qquad (8)$$

Taking the accuracy of measurement into account, we can safely use the solubility in place of the activity. The solubility of SHS in a dioxane-water mixture is plotted against the concentration of dioxane at 20, 25 and 30°C in Fig. 3. The result of the numerical calculations of the free energy of transfer from pure water to 20% dioxane-water using (a) solubility data and (b) CMC data is shown in Table I as an example. The rather good agreement between the values from (a) and (b) suggests that the assumptions made above are correct.

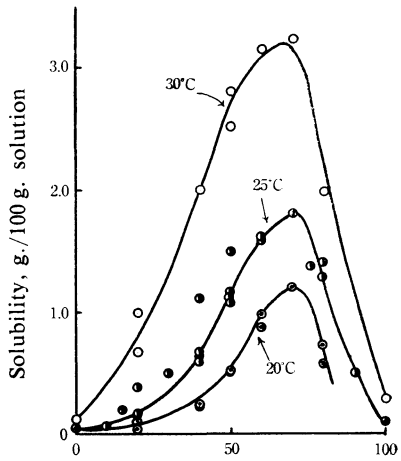

Fig. 3. Solubility of SHS in dioxane-water mixture at 20.0, 25.0 and 30.0°C.

Table I. The free energy of transfer for SHS from pure water to a 20% dioxane-water mixture

| Dioxane % | (a) Solubility g./100g. solvent | | (b) CMC mmol./l. |
|---|---|---|---|
| | 25°C | 30°C | 40°C |
| 0.0 | 0.027 | 0.117 | 0.52 |
| 20.0 | 0.15 | 0.672 | 3.54 |
| $-\Delta F_{tr}$ kcal./mol. | 2.23 | 2.30 | 2.58 |

Now let us try to represent $\Delta F_{tr}$ as an explicit function of the dioxane concentration. In the process of solution an electrolyte experiences various kinds of energy changes, among which the factors that affect the unitary term are given by:

$$\mu_{sx}^\circ = K_1/D + K_2 \qquad (9)$$

where $K_1$ and $K_2$ are constants, and $D$ is the

dielectric constant of the solvent.[9] Equation 9 means that the unitary term can be divided into two parts, i.e., one dependent on, and one independent of, the dielectric constant of the solvent. In fact, for simple inorganic electrolytes the logarithm of solubility is nearly linear against $1/D$ (Born's equation). However, in the case of an amphipathic compound like SHS, the solubility increases at first and then decreases with the dioxane concentration, as is shown in Fig. 3. This suggests that an appreciable hydrophobic contribution must be included in the $K_2$ in Eq. 9. Thus, we should rewrite Eq. 9 as:

$$\mu_{sx}^{\circ} = K/D + L + M \tag{10}$$

where $K$ is a constant, dependent on the geometry of ions; $L$ is a term representing hydrophobic contributions, and $M$ is a constant independent of the nature of the solvent.

In order to express $L$ as a function of the dioxane concentration, we may tentatively utilize the regular solution theory of Hildebrand.[10] In a regular ternary solution the partial molar heat of mixing for component 1 (here the surfactant), $\overline{E}_m$, is expressed as:

$$\overline{E}_m = V_1(\delta_1 - \delta_0)^2\phi_0^2 \tag{11}$$

where $V_1$ is the molar volume and $\delta_1$ is the solubility parameter, each for component 1. $\phi_0$ and $\delta_0$ are given by:

$$\phi_0 = \phi_2 + \phi_3, \quad \delta_0 = \frac{\delta_2\phi_2 + \delta_3\phi_3}{\phi_2 + \phi_3}$$

where the $\phi$'s and $\delta$'s are the volume fractions and solubility parameters respectively, each for the subscript component. When component 1 is extremely dilute, Eq. 11 becomes:

$$\overline{E}_m = V_1\{(\delta_1 - \delta_2) - (\delta_3 - \delta_2)\phi_3\}^2 \tag{12}$$

Neglecting a slight volume contraction on mixing, we can substitute $\phi_3$ for $x$, since the specific gravity of dioxane is about 1.03 at 25°C. Then Eq. 12 may be put into the following form:

$$L(x) = L_0(1 - rx)^2 \tag{13}$$

where $L_0$ is a hydrophobic contribution in pure water and $r$ is a constant correlating with the solubility parameters. $L_0$ may be approximated by the free energy of transfer for hexadecane from water to pure hexadecane, which can be obtained by extrapolating published data for some lower alkanes[11] (Fig. 4). The value is 14.5 kcal./mol.

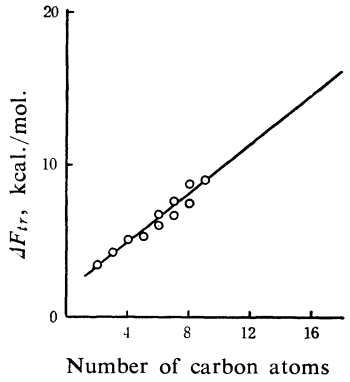

Fig. 4. Free energy of transfer ($\Delta F_{tr}$) for some alkanes from pure liquid to water.

The dielectric constant of a dioxane-water mixture is a nearly linear function of the weight fraction of dioxane, which is expressed empirically as follows:[12]

$$D(x) = 78.6(1 - 0.975\,x) \tag{14}$$

Combining Eqs. 13 and 14 with Eq. 10, we obtain:

$$\mu_{sx}^{\circ} = K/78.6(1 - 0.975\,x) + 14.5(1 - rx)^2 + M \tag{15}$$

Then we have:

$$\Delta F_{tr} = \mu_{sx}^{\circ} - \mu_{s0}^{\circ} = (K/78.6)\{1/(1 - 0.975x) - 1\} + 14.5\{(1 - r\,x)^2 - 1\} \tag{16}$$

The unknown parameters, $K$ and $r$, could be determined by using the data of $\Delta F_{tr}$ from pure water to 20% and 40% dioxane-water mixtures. The values found were $K = 2.1 \times 10^2$ kcal. and $r = 0.61$. Thus, finally we obtain:

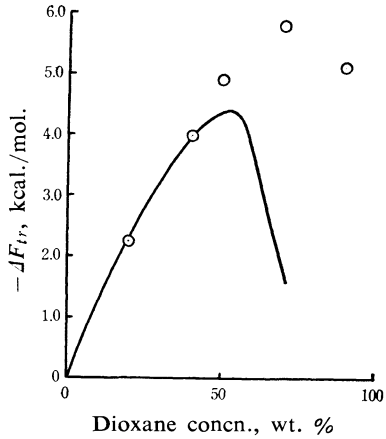

Fig. 5. Comparison of $\Delta F_{tr}$ from solubility data with that from Eq. 17 (solid line) at 25°C.

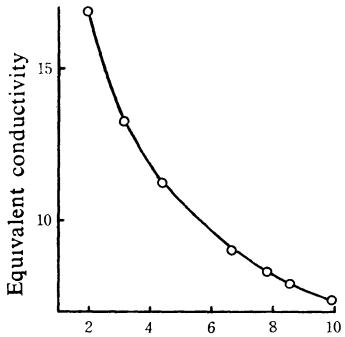

Fig. 6. Equivalent conductivity of SDS in an 80% dioxane-water mixture at 25.0°C.

$$\Delta F_{tr} = (2.1 \times 10^2/78.6)\{1/(1-0.975x) - 1\} + 14.5\{(1-0.61x)^2 - 1\} \quad (17)$$

In Fig. 5 the experimental value of $\Delta F_{tr}$ obtained from the solubility data is compared with the value calculated by using Eq. 17. The agreement is as expected in the dioxane concentration region of less than 50 per cent. Over 50 per cent the experimental values are higher than the theoretical. This may be caused by several factors, one of which is the imperfect dissociation effect. For example, as is shown in Fig. 6, the equivalent conductivity vs. the square root of concentration for SDS in an 80% dioxane-water mixed solvent gives a curved line, while there should be a straight line in a solvent with a higher dielectric constant. The same behavior is expected for SHS. This is probably caused by the imperfect dissociation of the surfactant molecules in a solvent with a low dielectric constant, leading to the diminution of coefficient 2 of Eq. 8 towards unity. Therefore, the effect of imperfect dissociation should reduce the experimental value of $-\Delta F_{tr}$ leading to a better agreement with the predicted value. Another factor which is considered to cause the discrepancy between the theoretical and the experimental values of $\Delta F_{tr}$ in the higher concentration region of dioxane is the effect of selective solvation.

The values of CMC can now be calculated from $\Delta F_{tr}$ of Eq. 17 for each dioxane concentration by using Eq. 8. In Fig. 7 the calculated values of CMC are compared with the observed. For SHS solutions the agreement is satisfactory. For STS, especially for SDS solutions, the same result can not be expected, since in these cases the CMC-lowering effect of dioxane, i. e., the solubilization of dioxane by the surfactant micelles, is not negligible. When the dioxane concentration is large, the formation of the micelles of sodium alkyl

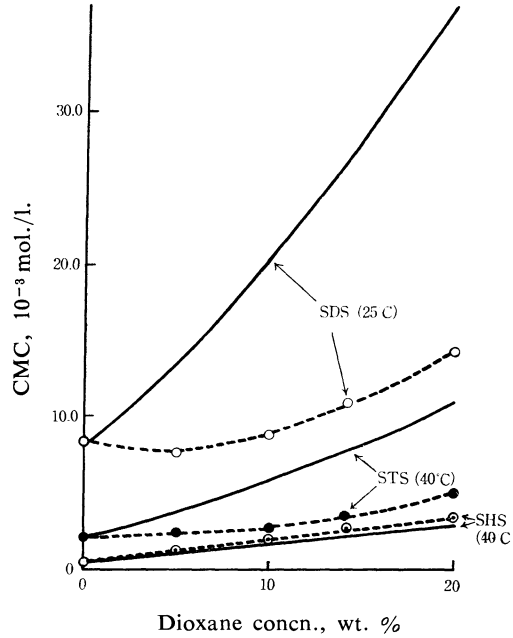

Fig. 7. Comparison of CMC values of sodium alkyl sulfates (SDS, STS and SHS) in dioxane-water mixture with those calculated by using Eq. 17 (solid line).

sulfates is not observable, so the comparison of the theoretical with the experimental values of CMC becomes impossible. However, from the standpoint of the hydrophobic contribution of Eq. 13, we can confirm that the present theory of the solvent power of a dioxane-water mixture is reasonable. For example, in the 50% dioxane solution the calculated value of the hydrophobic contribution is 7.0 kcal., which corresponds to the value of hexane on the plot in Fig. 4. The micelle formation of polar-nonpolar compounds with six carbon atoms has not been believed to be appreciable in an aqueous solution. This corresponds to the fact that the surfactants used in the present study do not seem to form micelles in 50% or more concentrated dioxane-water mixtures, as has been shown in these experiments.

## Summary

The CMC values of three sodium alkyl sulfates with the number of carbon atoms 12, 14 and 16 in a dioxane-water mixture have been measured. The CMC-lowering effect of dioxane, especially appreciable in the case of sodium dodecyl sulfate, has been explained in terms of Shinoda's equation. The CMC-raising effect of dioxane, which is the main effect in the case of sodium hexadecyl sulfate, has been explained by the decrease in the standard chemical potential, i. e., the free energy

of transfer, $\Delta F_{tr}$, of the surfactant. An equation has been derived which expresses $\Delta F_{tr}$ as a function of the dioxane concentration by applying Born's equation and Hildebrand's regular solution theory.

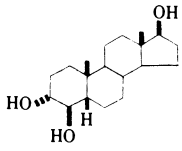
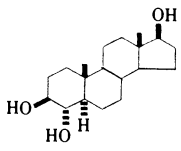
# The Preparation of 5α-Androstane-3β,4α,17β-triol through a Hydroboration Reaction[1]

By Hisao NAKATA



(Received June 29, 1964)

Although the syntheses of a number of androgenic steroids have been reported, only two androstane-3,4,17-triols have been described in the literature. Thus, 5α-androstane-3β,4β,17β-triol (I) was obtained by the catalytic reduction[2] of androst-5-ene-3β,4β,17β-triol, which, in turn, was prepared from androst-5-ene-3β,17β-diol either by direct oxidation with selenium dioxide[2,3] or by the treatment of its dibromo derivatives with bases.[4,5] An isomeric 5β-androstane-3α,4β,17β-triol (II) was prepared[6] by the reduction of 4β,5-epoxy-5β-androstan-17β-ol-3-one 17-acetate with lithium aluminum hydride.



In connection with other steroid studies,[7] we have had occasion to synthesize another isomer of the triol from easily-available starting materials; this paper will deal with the preparation and configurational assignment of the previously unknown 5α-androstane-3β,4α,17β-triol (III).

(I)

(II)

(III)

When testosterone benzoate (IV) was treated with sodium borohydride in methanol, the reduction of the carbonyl group readily took place and androst-4-ene-3β,17β-diol 17-benzoate (V) was obtained in a fairly good yield. The configuration of the 3-hydroxyl group is assigned as such on the basis of the steric course of similar reactions.[8-16] The assignment was confirmed by the fact that, after the benzoate group had been removed by saponification, the product was identical with the known androst-4-ene-3β,17β-diol (VI).[17] A small amount of an isomeric alcohol was also isolated from the reaction mixture. This alcohol is probably androst-4-ene-3α,17β-diol 17-benzoate (VII).

The introduction of an oxygen function at $C_4$ of the steroid nucleus has been accomplished in many ways,[18,19] but the application of the recently-reported hydroboration reaction[20-22] seems most promising because the reaction usually proceeds in a highly stereospecific manner and gives an excellent yield. Thus, the hydroboration of the allylic alcohol (V) yielded a triol monobenzoate as the sole product. Since it is well-established that the

hydroboration reaction is anti-Markownikoff cis-addition and that the attack takes place from the less-hindered side of a given molecule,[20-22] the product may be formulated as 5α-androstane-3β, 4α, 17β-triol 17-benzoate (VIII). A less probable alternative is 5β-androstane-3β, 4β, 17β-triol 17-benzoate (IX).

To discriminate these two possibilities, the rate of lead tetraacetate consumption was measured. Unfortunately, the kinetic data for the 3β, 4α-glycol system have not been found in the literature and so no direct comparisons of the present experiment with references could be made. However, as may be seen from Table I, the observed rate constant, $7.43\times10^{-3}$ l. $mol^{-1}$ $sec^{-1}$, is quite compatible as a steroidal trans-glycol system when compared with the data so far available in the literature.[23,24] If the two hydroxyl groups were cis to each other, as in IX, the rate constant would be expected to be much larger than is actually observed. It is, therefore, safe to conclude that the product is 5α-androstane-3β, 4α, 17β-triol 17-benzoate (VIII).[25] The free triol (III) was obtained after removing the benzoate group by saponification.

TABLE I. RATES OF $Pb(OAc)_4$ CONSUMPTION OF 3,4-DIOLS AT 25°C

| 3,4-Diol | Configuration | $10^3k$ (l. $mol^{-1}$ $sec^{-1}$) | Ref. |
|---|---|---|---|
|  | 3α, 4α- | 112.6 | 23 |
|  | 3β, 4β- | 91.3 | 23 |
|  | 3β, 4α- | 7.43 | Present study |
|  | 3α, 4β- | 0.0357 | 23 |

The physiological properties of the new androstane-triol (III) are now being investigated; the results will be reported elsewhere.

## Experimental

The melting points were determined on a micro hot stage and are uncorrected. The ultraviolet spectra have been measured with a Beckman DK-2 spectrophotometer, while the infrared spectra were taken on a Koken IR-S spectrometer.

**The Reduction of Testosterone Benzoate (IV) with Sodium Borohydride.**—About 5 g. of sodium borohydride was gradually added into a suspension of 5.00 g. of testosterone benzoate (m. p. 191—192°C) in 100 ml. of methanol. After it had been stirred for 2 hr., the mixture became a clear solution. The mixture was then neutralized with a methanolic solution of acetic acid and poured into 300 ml. of water. The precipitated white solid (4.95 g.) was collected. Five recrystallizations from aqueous acetone gave 2.94 g. of androst-4-ene-3β, 17β-diol 17-benzoate (V) as colorless needles, m. p. 173—174°C. $\lambda_{max}^{EtOH}$ 230 mμ (ε 12050), $\nu_{max}^{KBr}$ 1718, 1660 $cm^{-1}$.

Found: C, 79.14; H, 8.67. Calcd. for $C_{26}H_{34}O_3$: C, 79.15; H, 8.69%.

From the mother liquor of the recrystallization, a small amount of the 3α-isomer was obtained. Recrystallization from aqueous methanol gave a pure specimen of androst-4-ene-3α, 17β-diol 17-benzoate (VII) as colorless needles, m. p. 153—154°C. $\lambda_{max}^{EtOH}$ 230 mμ (ε 12000), $\nu_{max}^{KBr}$ 1722, 1658 $cm^{-1}$.

Found: C, 79.24; H, 8.81. Calcd. for $C_{26}H_{34}O_3$: C, 79.15; H, 8.69%.

**The Saponification of Androst-4-ene-3β, 17β-diol 17-Benzoate (V).**—A solution of 0.023 g. of the benzoate (V) (m. p. 173—174°C) in 5 ml. of methanol was refluxed for 5 hr. with a methanolic solution of potassium hydroxide (1 g./10 ml.). The mixture was then diluted with 10 ml. of water, and the product was extracted with chloroform. The evaporation of the solvent and the recrystallization of the residue from aqueous methanol gave 0.012 g. of androst-4-ene-3β, 17β-diol (VI) as

colorless plates, m. p. 153—154°C. The reported melting point[17] is 153—154°C.

Found: C, 78.39; H, 10.22. Calcd. for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41%.

**The Hydroboration Reaction of Androst-4-ene-3β, 17β-diol 17-Benzoate (V).**—A solution of 2.488 g. (6.31 mmol.) of androst-4-ene-3β, 17β-diol 17-benzoate (V) (m. p. 172—174°C) in 50 ml. of diglyme and 0.823 g. of sodium borohydride (purity 82%, 17.83 mmol.) were placed in a three-necked flask equipped with a magnetic stirrer, a pressure-equilibrated dropping funnel, a nitrogen inlet and outlet, and a reflux condenser. The reaction flask was flushed out with nitrogen, and a solution of freshly-distilled boron trifluoride etherate (2 ml., 15.83 mmol.) in 20 ml. of diglyme was added drop by drop over a period of 30 min. After the addition was complete, the mixture was stirred for 18 hr. under nitrogen at 30—40°C.

The reaction mixture was then hydrolyzed with 30 ml. of water. When the evolution of hydrogen had ceased, 20 ml. of 3 N sodium hydroxide was added, and the oxidation reaction was carried out by adding 30 ml. of 30% hydrogen peroxide. The mixture was allowed to cool, 30 ml. of water was added, and then the mixture was extracted with five 100 ml.-portions of methylene chloride. The extracts were combined, washed with water, and dried over sodium sulfate. The removal of the solvent gave a crystalline solid. Recrystallization from aqueous acetone afforded 1.132 g. of colorless needles, m. p. 237—238°C (first crop), and 0.522 g., m. p. 229—231°C (second crop). Repeated recrystallizations gave a specimen with an m. p. of 239—240°C. $\lambda_{max}^{EtOH}$ 230 mμ (ε 12100), $\nu_{max}^{KBr}$ 1710 $cm^{-1}$. The analytical figure shows that this specimen was a mono-hydrate of the desired 5α-androstane-3β, 4α, 17β-triol 17-benzoate (VIII).

Found: C, 72.80; H, 9.07. Calcd. for $C_{26}H_{36}O_4 \cdot H_2O$: C, 72.52; H, 8.90%.

The pure anhydrous sample of VIII, m. p. 239—240°C, was obtained after drying it over phosphorus pentoxide under a high vacuum at 110°C for 36 hr.

Found: C, 75.50; H, 8.72. Calcd. for $C_{26}H_{36}O_4$: C, 75.69; H, 8.80%.

**5α-Androstane-3β, 4α, 17β-triol (III).**—A solution of 0.037 g. of the benzoate (VIII) (m. p. 239—240°C) in 10 ml. of methanol was refluxed for 5 hr. with a methanolic solution of potassium hydroxide (1 g./10 ml.). The mixture was then concentrated to 5 ml. under reduced pressure and diluted with 20 ml. of water. The product was collected (0.029 g.) and recrystallized from aqueous methanol as colorless needles of 5α-androstane-3β, 4α, 17β-triol (III), m. p. 248—250°C.

Found: C, 73.98, H, 10.39. Calcd. for $C_{19}H_{32}O_3$: C, 73.98; H, 10.46%.

**The Kinetic Measurement of Lead Tetraacetate Oxidation.**—Essentially the same procedure as that reported in the literature[28] was used. The lead tetraacetate solution was prepared by dissolving 1.9 g. of lead tetraacetate in 50 ml. of glacial acetic acid. The sample of 5α-androstane-3β, 4α, 17β-triol 17-benzoate (VIII) (m. p. 239—240°C) (208.42 mg., 0.505 mmol.), dissolved in 20 ml. of acetic acid, was then mixed with 20 ml. of the lead tetraacetate solution (ca. 1.7 mmol.), and the volume was adjusted to 100 ml. with glacial acetic acid. Periodically an aliquot (10.0 ml.) was taken and added to 25 ml. of an aqueous solution of 0.5 g. of sodium iodide and 5 g. of sodium acetate, the liberated iodine being titrated with a 0.025 N sodium thiosulfate solution. The oxidation was carried out at 25°C, and the appropriate blank was used with each titration.

The rate constant for the oxidation was calculated in the following manner.[29] The $\log [a(b-x)/b(a-x)]$ was plotted against the time, $t$, where ($a$ is the initial concentration of the sample (VIII) $0.00505_2$ mol./l.), $b$ is the initial concentration of lead tetraacetate (0.0168 mol./l.), and $x$ is the amount reacted at time $t$. The slope of the resultant straight line was calculated and substituted into the equation: $k = (2.303 \times \text{slope})/(b-a)$ l. $mol^{-1}$ $sec^{-1}$ The numerical data are shown in Table II, from which one can obtain the rate constant as $7.43 \times 10^{-3}$ l./$mol^{-1}$ $sec^{-1}$.

Table II. Kinetic measurement of $Pb(OAc)_4$ consumption

| Time sec. | Thiosulfate titre, ml. Sample | Blank | $Pb(OAc)_4$ consumption mol./l. | $\log \frac{a(b-x)}{b(a-x)}$ |

# The Structure and Stereochemistry of Four New Sesquiterpenes Isolated from the Wood Oil of "Kaya" (*Torreya nucifera*)

By Tsutomu SAKAI, Kiichi NISHIMURA and Yoshio HIROSE

(Received July 2, 1964)

In a previous communication,[1] we reported on the composition of volatile oil obtained from the leaves of *Torreya nucifera* Sieb. et Zucc. and on the identity of the torreyol isolated by Shinozaki[2] with δ-cadinol. We have subsequently studied the composition of the volatile wood oil of this species. As has previously been described in a short paper,[3] the wood oil was quite different from the leaf oil, containing four new sesquiterpenes without even trace amounts of ordinary terpenes.

**The Composition of the Neutral Volatile Oil.**—The following components were isolated by the adsorption chromatography of the wood oil on silica gel.

The first eluate was pure dendrolasin (I), which had been isolated previously from the ant *Lasius (Dendrolasius) fuliginosus* Latr. by Quilico et al.[4] and from the sweet potato fusel oil in our laboratory.[5] From the second and third fraction, two new sesquiterpene aldehydes were isolated; for these we propose the names nuciferal (II) and torreyal (III). Two new sesquiterpene alcohols were eluted after the aldehyde fractions. Since it was found that they were the alcohols corresponding to nuciferal and torreyal, they are named nuciferol (IV) and neotorreyol* (V). The last fraction consisted of *o*-methoxycinnamic aldehyde (VI), which had been isolated by Chiba[6] from this oil in the past.

TABLE I. THE COMPOSITION OF THE TRUNK AND ROOT OILS

| Compound | Trunk oil | | Root oil |
|---|---|---|---|
| | Nara Pref. | Hyōgo Pref. | Takarazuka City |
| Yield | % | % | % |
| | 0.46 | 0.13 | 0.09 |
| Dendrolasin (I) | 4 | 11 | — |
| Nuciferal (II) | 8 | — | 6 |
| Torreyal (III) | 27 | 17 | 2 |
| Nuciferol (IV) | 28 | 4 | 11 |
| Neotorreyol (V) | 2 | 5 | — |
| *o*-Methoxycinnamic aldehyde (VI) | 21 | 18 | 71 |
| Rest | 10 | 45 | 10 |

For purposes of comparison, the composition of the root oil of this species was investigated at the same time. These results are listed on Table I.

**The Structures of Nuciferal and Nuciferol.**—The molecular formula of nuciferal was determined to be $C_{15}H_{20}O$ by mass spectrometry (molecular weight=216) and by the elemental analysis of its 2,4-dinitrophenylhydrazone (m. p. 138—139°C) and semicarbazone (m. p. 160—161°C). Nuciferal shows the characteristics of an α,β-unsaturated aldehyde group in the ultraviolet ($\lambda_{max}^{EtOH}$ 222.5 mμ (ε, 15700)) and infrared spectra ($\nu_{max}^{film}$ 2720 (C–H), 1690 (conj. C=O) and 1645 $cm^{-1}$ (conj. C=C)), and gives a positive Tollens reagent test. Since the other ultraviolet bands ($\lambda_{max}^{EtOH}$ 264.5 mμ (ε, 950); 266.5 (880); 273 (800) and 279.5 (370)) and infrared bands ($\nu_{max}^{film}$ 1519 and 818 $cm^{-1}$) are similar to those of α-curcumene, it may be considered that nuciferal is an α,β-unsaturated aldehyde containing the α-curcumene skeleton.

* Since a sesquiterpene alcohol isolated from the leaves of the same plant had already been named "torreyol,"[2] the name of the present alcohol has been revised from "torreyol"[3] to neotorreyol. We wish to thank Professor H. Erdtman and Dr. V. Herout for their suggestions.

The Wolff-Kishner reduction of nuciferal afforded a hydrocarbon, which was identical with α-curcumene* (VII) as checked by infrared spectrometry and gas chromatography. Thus, it may be concluded that nuciferal is 2-methyl-6-(*p*-tolyl)hepten-2-al.

Nuciferol (IV) also shows the characteristic absorptions of a *p*-disubstituted benzene ring and a hydroxy group in the infrared ($\nu_{max}^{film}$ 3340 (OH), 1518 and 819 $cm^{-1}$ (aromatic)) and ultraviolet spectra (Fig. 1). On oxidation with chromium trioxide in pyridine, nuciferol afforded the corresponding aldehyde, which was identical with natural nuciferal. On the other hand, the reduction of nuciferal with lithium aluminum hydride in tetrahydrofuran afforded an alcohol (IV') the infrared, ultraviolet and MS spectra of which were superimposable on those of natural nuciferol. NMR evidence (mentioned below) indicated natural nuciferol (IV) and the alcohol (IV') obtained from nuciferal to be cis-trans isomers with regard to the double bond. These results demonstrate that nuciferol is the corresponding alcohol of nuciferal, and that an isomerization of the double bond occurs upon treatment with chromium trioxide and can be represented by formula IV.

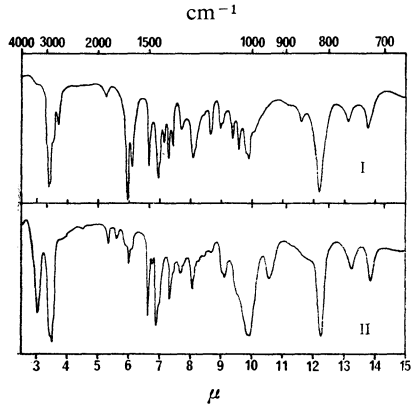

Fig. 2. IR spectra of nuciferal and nuciferol.
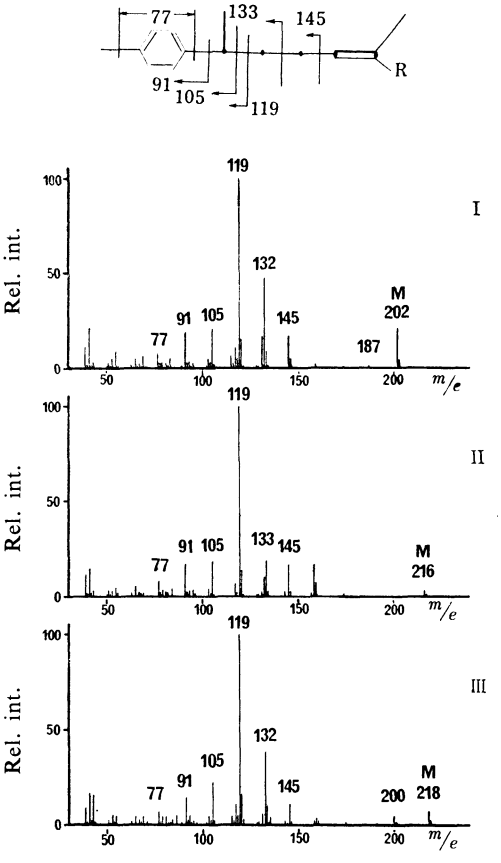
I, Nuciferal II, Nuciferol

The structures of nuciferal and nuciferol were confirmed by their mass spectra, in which the presence of a series of prominent peaks at *m/e* 77, 91, 105, 119 and 133 supported the α-curcumene skeleton, for these peaks are also predominant in the fragmentation pattern of α-curcumene.



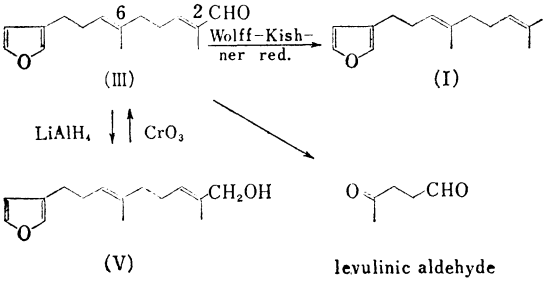


Fig. 3. Mass spectra of α-curcumene type compounds.
I, α-Curcumene II, Nuciferal III, Nuciferol

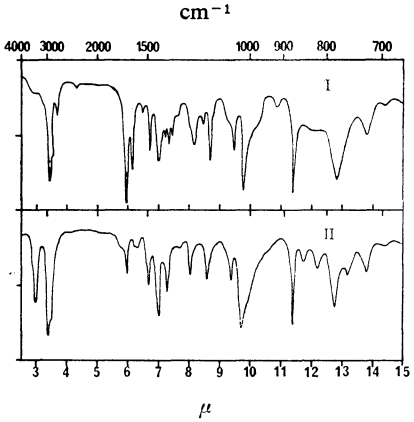
**The Structures of Torreyal and Neotorreyol.** —Molecular weight determination by mass spectrometry (parent peak at *m/e* 232) and the elemental analysis of its crystalline derivatives (2, 4-dinitrophenylhydrazone, m. p. 111—112°C; semicarbazone, m. p. 132—133°C) established the formula $C_{15}H_{20}O_2$ for torreyal. The ultraviolet ($\lambda_{max}^{EtOH}$ 224 mμ (ε, 15940)) and infrared spectra ($\nu_{max}^{film}$ 2720 (C–H), 1690 (conj. C=O) and 1645 $cm^{-1}$ (conj. C=C)) and the positive Tollens reagent test showed the presence of an α, β-unsaturated aldehyde group. The characteristic infrared bands at 1570, 1504, 1164, 1028, 874 and 779 $cm^{-1}$ (similar to dendrolasin) and

* This compound was isolated by fractional distillation and adsorption chromatography from a commercial ginger oil (Polack & Schwarz Co.).

the positive Ehrlich's color test suggested the presence of a furan ring in torreyal.

When torreyal was also subjected to Wolff-Kishner reduction, it afforded dendrolasin in an excellent yield. On the ozonolysis of torreyal, levulinic aldehyde was isolated as its bis-2, 4-dinitrophenylhydrazone (m. p. 238—239°C), but acetone was not detected. These results demonstrate that the aldehyde group conjugated with the ethylenic double bond is not located at C-6 but at C-2. Therefore, the structure of torreyal was deduced to be 2, 6-dimethyl-9(3-furyl)nonadien-2, 6-al.

Neotorreyol (V) is the corresponding alcohol of torreyal, because oxidation with chromium trioxide in pyridine led to torreyal, and the reduction of torreyal with lithium aluminum hydride in tetrahydrofuran yielded neotorreyol. Unlike the case of nuciferal-nuciferol, no isomerization about the double bond took place upon treatment with chromium trioxide. Its infrared spectra data are $\nu_{max}^{film}$ 3360 (OH), 1670 $\left(\begin{matrix}R\\R'\end{matrix}\right)$>C=C<$\left(\begin{matrix}R''\\H\end{matrix}\right)$, 1570, 1504, 1164, 1028, 874 and 779 $cm^{-1}$ (furan).



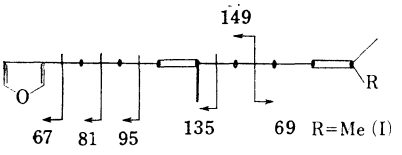


Fig. 4. IR spectra of torreyal and neotorreyol.
I, Torreyal II, Neotorreyol

The structures of torreyal and neotorreyol can be further confirmed by mass spectrometry. The predominance of the peaks at *m/e* 67, 81, 95 are common in alkylated furan compounds.[7] The peak at *m/e* 69, which, in dendrolasin and many other familiar terpenes containing the dimethylallyl group, often constitutes the base peak, is weak in the fragmentation of torreyal and neotorreyol; this suggests that the functional groups are located at the terminal position in both cases.

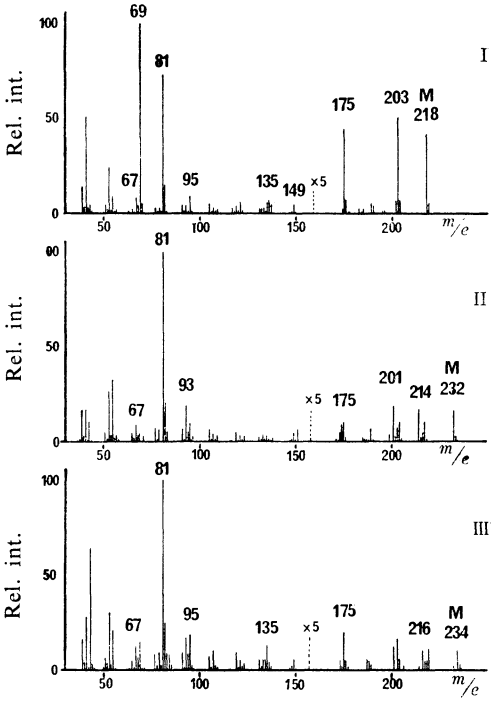

Fig. 5. Mass spectra of dendrolasin type compounds.
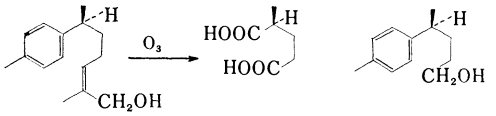
I, Dendrolasin II, Torreyal
III, Neotorreyol

**The Stereochemistry of Nuciferal and Nuciferol.**—There are two points of stereochemical interest in nuciferal and nuciferol, namely, the configurations at the asymmetric center, C-6, and at the ethylenic double bond.

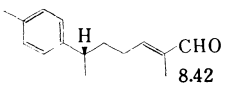


The configuration of the asymmetric center was established by the ozonization of nuciferol, which yielded *S*-(+)-α-methylglutaric acid (VIII), which was identical with an authentic sample.*

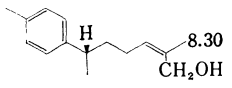
As nuciferal, nuciferol and α-curcumene isolated from ginger oil show a positive optical

7) Unpublished observation.

* We wish to thank Dr. H. Minato, Shionogi Pharmaceutical Institute, for his kind supply of (+)-α-methylglutaric acid.

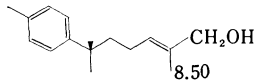


rotation, it may be suggested that they have the same S configuration. This conclusion was further supported by the calculations using the conformational asymmetry method of Brewster,[8] which was used by Marvell and Wiman[9] for the determination of the configuration of the 4-(*p*-tolyl)-1-pentanol (IX) isolated from the product of pulping Douglas fir.



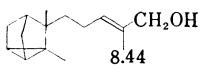
(IV) (VIII) (IX)

The configuration at the side-chain double bond was deduced from the NMR spectral data. Natural nuciferol shows in the NMR spectrum a singlet peak at 8.30 $\tau$, due to the methyl group attached to the double bond, and triplet peaks at 4.87 $\tau$, the vinyl proton. These peaks of the alcohol reduced from nuciferal shift to 8.50 and 4.72 $\tau$, respectively. Usually, in a system of the $X \cdot CH_2C(CH_3)=CHCH_2 \cdot Y$ type, the $\tau$ value of *cis*-methyl (the cis relationship between the methyl group and the vinyl proton) is 8.32 ($J$=1.0—1.5 c. p. s.), lower (by $\tau$ 0.07) than that of *trans*-methyl.[10]

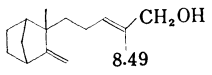


Thus, natural nuciferol was assigned a cis-isomer configuration, and the alcohol reduced from nuciferal, a trans-isomer configuration, they are illustrated by the following formulas:*

Natural nuciferal (II)



Natural nuciferol (IV)



Alcohol reduced from nuciferal (IV')

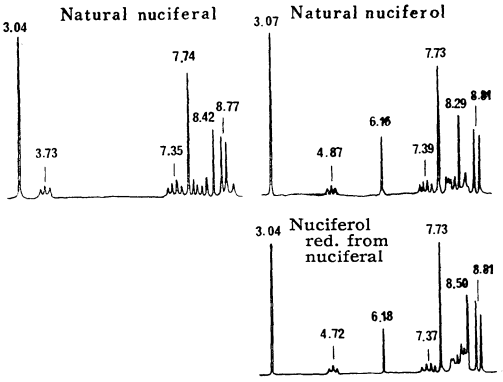
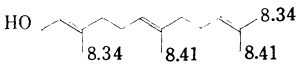
11) G. Brieger, *Tetrahedron Letters*, No. 30, p. 2123 (1963).





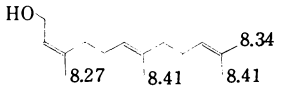


Fig. 6. NMR spectra of nuciferal and nuciferol.

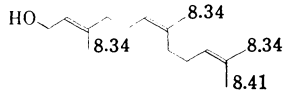
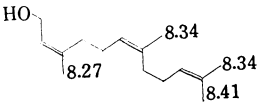
**The Stereochemistry of Torreyal and Neotorreyol.**—As the interconversions between torreyal and neotorreyol involved no isomerization with respect to the configuration of the ethylenic double bond, it is suggested that they have the same configuration.

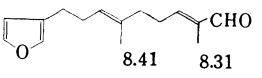


Recently, Bates et al.[12] examined the NMR spectra of four isomeric farnesols; the assigned methyl signals are shown in the following formulas:

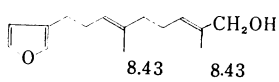


trans-trans

cis-trans

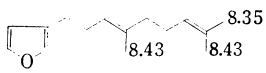


trans-cis



cis-cis

On the basis of these results and by comparison with dendrolasin, it may be concluded that torreyal and neotorreyol are trans-trans isomers which are represented by the following formulas:



Torreyal (III)

## Experimental*1

**The Preparation of the Volatile Oil.** — Crushed chips of a trunk of Kaya (498 kg.) which grew in Nara Prefecture were steam-distilled. The steam-volatile oil (2.3 kg.) was obtained in a yield of 0.46%. This oil was diluted with ether, washed with 5% potassium hydroxide, and dried over sodium sulfate. After the removal of the solvent, the neutral volatile oil (2.1 kg.) was obtained.

Another sample of a trunk (5 kg.) which grew in Hyōgo Prefecture were extracted with methanol. The methanol was evaporated off, and the residue was steam-distilled to give the volatile oil (6.5 g.).

The volatile oil (3.2 g.) from the root (3.4 kg.) was obtained by the same procedure.

**The Separation of the Oil.**—The neutral volatile wood oil (5 g.) was chromatographed on a silica gel column (70 g.). An example of the course of isolation is shown in Table II.

Their properties are recorded and presented below.

Nuciferal (II), b. p. 107.5—108.5°C/0.03 mmHg, $[\alpha]_D^{20}$ +62.07° (*c* 16.55, $CHCl_3$), 2,4-dinitrophenylhydrazone, m. p. 138—139°C (Found: C, 63.60; H, 6.06; N, 14.04. Calcd. for $C_{21}H_{24}N_4O_4$: C, 63.62; H, 6.10; N, 14.13%.), semicarbazone, m. p. 160—161°C (Found: C, 70.24; H, 8.50; N, 15.30. Calcd. for $C_{16}H_{23}N_3O$: C, 70.29; H, 8.48; N, 15.34%.).*3

Torreyal (III), b. p. 124—126°C/0.05 mmHg, $[\alpha]_D^{20}$ +1.90°, 2,4-dinitrophenylhydrazone, m. p. 111—112°C (Found: C, 61.67; H, 5.67; N, 13.74. Calcd. for $C_{21}H_{24}N_4O_5$: C, 61.15; H, 5.87; N, 13.59%.), semicarbazone, m. p. 132—133°C (Found: C, 67.09; H, 8.13; N, 14.48. Calcd. for $C_{16}H_{23}N_3O$: C, 66.41; H, 8.01; N, 14.52%.).

Nuciferol (IV), b. p. 131—132°C/0.05 mmHg, $[\alpha]_D^{20}$ +41.06°.

Neotorreyol (V), b. p. 117—119°C/0.03 mmHg, $[\alpha]_D^{20}$ 0°.

Attempts to prepare crystalline derivatives of the two alcohols were both unsuccessful.

**The Kishner Reduction of Nuciferal.**—The Cook and Linstead procedure[13] was followed. Nuciferal (0.8 g.) was converted into the semicarbazone, which was then heated with a free flame in a distilling flask with solid potassium hydroxide (2 g.). The mass fused, ammonia and nitrogen were given off, and then oily droplets of hydrocarbon began to distill. The residue was dissolved in water and extracted with ether. The distillate and the ether extract were combined, the solvent was removed in vacuo, leaving an oil, and the oil was purified by chromatography over silica gel to yield α-curcumene (0.5 g.), which was identical with an authentic sample isolated from ginger oil. The specific retention time relative to β-elemene (1.00) was 1.76 in GLC at 170°C.

**The Reduction of Nuciferal with Lithium Aluminum Hydride.**—A solution of nuciferal (0.8 g.) in dry tetrahydrofuran (10 ml.) was stirred drop

Table II. The separation of the neutral volatile wood oil

| Eluting solvent | Fr. No. | Eluate, g. | Component |
|---|---|---|---|
| 3% Ether in hexane | 1— 2 | 0.20 | Dendrolasin (I) |

*1 M. ps. and b. ps. are uncorrected. The IR spectra were taken with a Perkin-Elmer (Model 137) and a Hitachi (Model EPI-2) infracord spectrophotometer. The UV absorption spectra were measured in an ethanol solution with a Hitachi (Model FPS-2) spectrophotometer. The NMR spectra were determined in a $CCl_4$ solution with $Me_4Si$ as an internal standard, using a Varian (Model A-60) spectrometer.*2 The mass spectra were measured with a Hitachi (Model RMU-6) mass spectrometer: ionizing voltage, 80 eV.; ion-accelarating voltage, 2 kV.; temp. of ionization chamber, 250°C; vaporizing temp. of sample, 150°C. The GLC was carried out with a Shimadzu (Type GC-2B) gas chromatograph: column, Celite-Carbowax 1500 (10:2), 3 m.; temp., 170°C; carrier gas, $N_2$. For adsorption chromatography Mallinckrodt's silica gel was used.

*2 We wish to thank the Shionogi Pharmaceutical Institute and the Research Laboratory of Takeda Pharmaceutical Industries for their NMR measurements.

*3 The analyses were performed in the Microanalytical Laboratory of the Institute of Polytechnics, Osaka City University.

13) A. H. Cook and R. P. Linstead, *J. Chem. Soc.*, **1934**, 946.

by drop into a suspension of lithium aluminum hydride (0.4 g.) in dry tetrahydrofuran (10 ml.), and then the mixture was heated under reflux for 30 min. The mixture was decomposed by the addition of water in a ice bath and extracted with ether. The solvent was evaporated, and the residue was chromatographed on silica gel to yield a colorless oil (0.68 g.), the infrared and MS spectra of which were identical with that of nuciferol.

**The Oxidation of Nuciferol with Chromium Trioxide.** — (a) A solution of nuciferol (2 g.) in glacial acetic acid (6 ml.) was stirred drop by drop into a solution of chromium trioxide (0.8 g.) in glacial acetic acid (6 ml.) at room temperature. The mixture was then heated on a water bath for 20 min., cooled, poured into water (100 ml.), and extracted with ether. The ether extract was washed with saturated aqueous sodium hydrogen carbonate, dried over sodium sulfate, and evaporated to leave an oil. This residual oil was then dissolved in hexane and chromatographed on silica gel. Elution with 3% ether in hexane yielded an aldehyde (0.6 g.). Its infrared and MS spectra were identical with those of nuciferal, and the melting point of its semicarbazone was undepressed on admixture with an authentic sample.

(b) Chromium trioxide (2 g.) was stirred into pyridine (20 ml.) in an ice bath to give a chromium trioxide-pyridine complex. A solution of nuciferol (1 g.) in pyridine (10 ml.) was added to the complex prepared above in an ice bath and left overnight at room temperature. The reaction mixture was then poured into ice-water and extracted with ether. The ether extract was washed with dilute hydrochloric acid and water, dried over sodium sulfate, and evaporated. The residue was chromatographed on silica gel to yield nuciferal (0.8 g.).

**The Ozonolysis of Nuciferol.** — (a) Nuciferol (3 g.) was dissolved in methyl acetate (10 ml.) and ozonized at 0°C. The ozonide was decomposed by heating it with water (10 ml.) for 10 min., and methyl acetate was distilled off. The distillation residue was extracted with ether and then evaporated in vacuo to leave an aldehyde (1.5 g.). Its 2,4-dinitrophenylhydrazone had a m. p. of 94—95°C (Found: C, 60.13; H, 5.77; N, 15.70. Calcd. for $C_{18}H_{20}N_4O_4$: C, 60.66; H, 5.66; N, 15.72%.), which was identical with that of an authentic sample of $\gamma$-(*p*-tolyl)valeraldehyde 2,4-dinitrophenylhydrazone (prepared from $\alpha$-curcumene).

(b) A stream of ozone was passed into a solution of nuciferol (2 g.) in 90% acetic acid (10 ml.) at room temperature for 50 hr. To the mixture was then added 30% hydrogen peroxide (2 ml.), and the mixture was allowed to stand overnight at room temperature. After water (20 ml.) had been added, the excess hydrogen peroxide was decomposed by heating it with a small amount of a Pd-C catalyst on a water bath for 2 hr. After the usual work-up $\alpha$-methylglutaric acid (0.2 g., m. p. 79—80°C, $[\alpha]_D^{20}$ +17.0° (*c* 0.10, MeOH), was obtained. Its melting point was not depressed by admixture with an authentic sample.

**The Kishner Reduction of Torreyal.** — By the reduction of semicarbazone prepared from torreyal (1.2 g.) in the manner described above for nuciferal, dendrolasin (0.6 g.) was obtained. It was identified by a comparison of its infrared spectra and gas chromatographic retention times with those of an authentic sample. The specific retention time relative to $\beta$-elemene (1.00) is 2.97 in GLC at 170°C.

**The Reduction of Torreyal with Lithium Aluminum Hydride.** — Torreyal (1 g.) in tetrahydrofuran was reduced with lithium aluminum hydride by the procedure described above for nuciferal. When it was worked-up in the usual manner, an alcohol (0.83 g.) was obtained. This was found to be identical with neotorreyol by infrared and MS spectroscopy.

**The Oxidation of Neotorreyol with Chromium Trioxide.** — A mixture of neotorreyol (1 g.) and a chromium trioxide - pyridine complex was allowed to stand overnight at room temperature. The reaction mixture was then treated in the same manner as nuciferol, thus yielding torreyal (0.6 g.).

**The Ozonolysis of Torreyal.**—Torreyal (1 g.) in chloroform (10 ml.) was ozonized at 0°C. After the addition of water (10 ml.) to decompose the ozonide, the mixture was heated on a water bath for 10 min. By distillation on a water bath, a chloroform solution (A) was obtained, while distillation on a free flame produced an aqueous solution (B). From A, no carbonyl derivatives were obtained at all, but from B the presence of levulinic aldehyde was proved as its bis-2,4-dinitrophenylhydrazone (0.2 g., m. p. 238—239°C. Found: C, 44.40; H, 3.54; N, 23.61. Calcd. for $C_{17}H_{16}N_8O_8$: C, 44.35; H, 3.50; N, 24.34%.). The melting point of this derivative was not depressed by admixture with an authentic sample prepared from $\alpha$-methylfuran.

**The Identification of *o*-Methoxycinnamic Aldehyde.**—*Oxidation with Silver Oxide.*—A hot solution of aldehyde (1.7 g.) in ethanol (5 ml.) was added to a suspension of silver oxide prepared from silver nitrate (1.7 g.) in aqueous 10% sodium hydroxide (20 ml.) heated at 55—60°C. The mixture was then heated while being stirred for 10 min. The black precipitate was filtered off and washed with hot water. The filtrate was acidified with hydrochloric acid, and the precipitated acid was collected by filtration. The product was recrystallized from ethanol to furnish needles (0.8 g.; m. p. 184—185°C), identified as *o*-methoxycinnamic acid by mixed melting point determination with an authentic sample.

*Oxidation with Potassium Permanganate.*—To a suspension of *o*-methoxycinnamic aldehyde (1 g.) in water (10 ml.), an alkaline 10% potassium permanganate solution was added; the mixture was then heated while being stirred on a water bath for 30 min. The reaction mixture was worked up by the usual manner to give a crude acid. The crude crystall was recrystallized from hot water to yield *o*-methoxybenzoic acid, m. p. 94—95°C, which was identified by a mixed melting point determination with an authentic specimen.

## Summary

Four new sesquiterpenes, nuciferal (II), nuciferol (III), torreyal (IV) and neotorreyol (V),

together with dendrolasin and *o*-methoxycinnamic aldehyde, have been isolated from the neutral volatile wood oil of Kaya (*Torreya nucifera* Sieb. et Zucc.) by adsorption chromatography on silica gel.

The structures and stereochemistry of these new compounds have been confirmed by infrared, ultraviolet, NMR and MS spectrometry, as well as by chemical methods.

# The Intramolecular Interaction between the N–H Group and π-Electrons. II.[1] Intramolecular Interaction in *N*-Phenethylanilines

By Michinori Ōki and Kiyoshi Mutai

(Received July 13, 1964)

In a previous paper[1] the authors have reported that there is an interaction between the N–H group and π-electrons of the benzyl group in *N*-benzylaniline, this fact being confirmed by infrared spectroscopy.

The same type of interaction, i. e., O–H···π interaction, has been reported in a variety of aliphatic and aromatic hydroxylic compounds with π-electrons in appropriate positions.[2] Since both N–H and O–H groups are known to be hydrogen donors, it is expected that the N–H···π interaction may be possible in a compound analogous to a hydroxylic compound which shows the O–H···π interaction.

Phenethyl alcohol and some derivatives of 3-phenylpropyl alcohol,[2e] as well as benzyl alcohol,[2d] have been reported to show the interaction; hence, it may be reasonable to begin with the investigation of *N*-phenethylaniline. Such a study will provide some data on X–H···π interaction in general and will make it possible to compare O–H···π and N–H···π cases.

## Experimental

**Spectral Measurement and Calculation.** — The infrared spectra were recorded on a Perkin-Elmer model 112-G double-pass high precision-grating infrared spectrometer, provided with a 2 cm. quartz cell and a spectral slit width being 1.0 $cm^{-1}$ in the N–H stretching region. Eastman Kodak spectrograde or redistilled carbon tetrachloride was used as a solvent. The concentration of the solution was 0.005—0.007 mol./l., which was dilute enough to exclude associated solute molecules. The temperature was 25±2°C.

The obtained bands were, if necessary, separated into two or more component bands, assuming that each one was expressed by Lorentz function. The integrated intensities were calculated according to the following equation:

$$A = (\pi/2) \cdot \Delta\nu^{a}_{1/2} \cdot \ln(I_0/I)_{max} \cdot l^{-1} \cdot c^{-1}$$

where $A$ is the integrated intensity; $\Delta\nu^{a}_{1/2}$, the half-band width; $c$, the concentration of the solution (mol./l.), and $l$, the cell length.

The errors in the values analyzed, especially in the absorption maximum position and the half-band width, are difficult to estimate, since the curves were divided by the "trial and error" method. The band shape was an important factor in determining the ease of division. Thus, the spectrometer allowed an accuracy of 0.1 $cm^{-1}$ for an apparent band maximum, but the analyzed values mentioned above were obtained with an accuracy of only ca. ±0.5 $cm^{-1}$.

**Materials.**—The compounds used in the present study were known, unless otherwise stated, and were purified through known methods. Their physical constants agreed well with those reported.

*N-Phenethylanilines.*—Two procedures were adopted for the preparation of this series of compounds; (a) Phenethyl chloride or bromide (0.1 mol.) and a substituted aniline (0.1 mol.) were heated with 30 ml. of 20% aqueous sodium hydroxide for 30 min. After the unreacted halide and aniline had been removed by steam distillation, the residue was taken up in ether and distilled under reduced pressure; (b) A substituted phenylacetanilide (0.05 mol.), recrystallized from 70% ethyl alcohol, was added in small portions into a stirred solution of 4.0 g. (0.105 mol.) of lithium aluminum hydride in 100 ml. of dry ether. The solution was then further stirred at a refluxing temperature for 6—8 hr., and the excess of lithium aluminum hydride was decomposed with ethyl acetate. The reaction mixture was poured into 150 ml. of 30% aqueous sodium hydroxide and extracted with ether. After the solvent had been distilled off, the residue was distilled under reduced pressure.

the new compounds are summarized in the following table.

## Results and Discussion

***N*-(2-Arylethyl)aniline.** — The *N*-phenethylaniline derivatives containing substituents at the *m*- or *p*-position of phenethyl groups were selected for spectral inspection to avoid the formation of the N-H···X hydrogen bond, which is possible in *o*-substituted compounds. The apparent absorption curves in the N-H stretching region for *N*-phenethylaniline, *N*-(*p*-chlorophenethyl)aniline, and *N*-(*p*-nitrophenethyl)aniline are shown in Fig. 1.

Three curves show that two apparent maxima

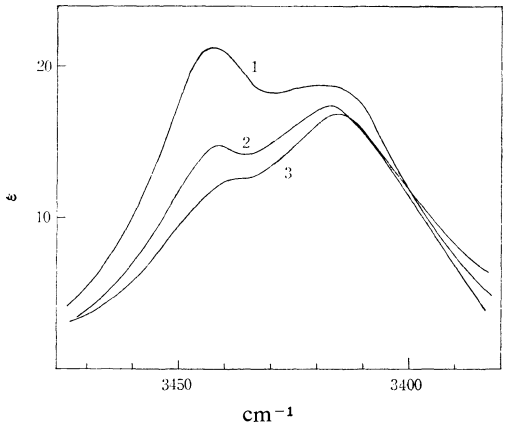

Fig. 1. $\nu_{N-H}$ Absorption of *N*-(*p*-nitrophenethyl)aniline (1), *N*-(*p*-chlorophenethyl)aniline (2) and *N*-phenethylaniline (3).

are present, suggesting that there are at least two bands and, therefore, two isomers. It might be an attractive explanation that they are simple rotational isomers due to the difference in steric conditions caused by the rotation of the N-H hydrogen atom around the N-$CH_2$ bond axis. The positions of the absorption maxima of the divided bands (see Table I) are at nearly the same wave numbers as those of the rotational isomers in *N*-ethylaniline;[1] this fact may be regarded as supporting evidence for the explanation.

However, it should be noted that a substituent effect is observed in the spectra; the extinction coefficient of the higher wave number band increases at the expense of the lower one as the electron-withdrawing power of the substituent increases. This effect suggests that N-H···$\pi$ interaction is the more probable interpretation of the presence of two N-H stretching bands, since a *m*- or *p*-substituent in the phenethyl group should not cause an appreciable difference in steric effect on the N-H group. In order to get firmer evidence for this interpretation, the curves of five *N*-(2-arylethyl)anilines were divided, assuming that they were the overlaps of two symmetrical ones expressed by Lorentz function. The results are shown in Table I.

From Table I, it is evident that the $A_i/A_f$ ratio, where $A_i$ is the integrated intensity of the absorption due to the interacting form and $A_f$, that of the free form, varies with the electron-donating or electron-withdrawing nature of the substituent, and this tendency is indicative of interaction between the N-H

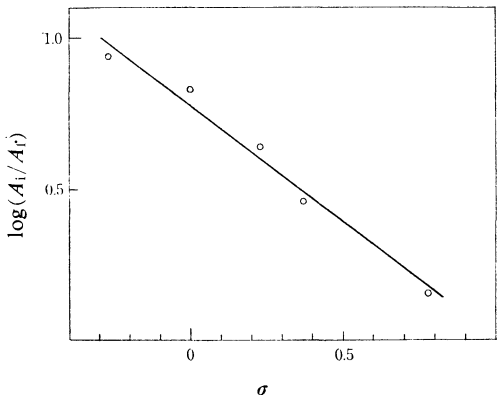

Fig. 2. The relationship between $\sigma$-constant and $\log(A_i/A_f)$ for *N*-(2-arylethyl)aniline.

group and $\pi$-electrons. The summation of the integrated intensities due to the two forms also changes slightly with the substituent, but this is not a significant factor in comparing the $A_i/A_f$ ratio, since the substituent seems to have nearly the same effect on both intensities.

The $\log(A_i/A_f)$ value was plotted against the Hammett $\sigma$ value[3] of the substituent. The $\sigma$ value is believed to be closely related to the electron density[4] at an appropriate carbon atom in a substituted benzene nucleus. As may be seen in Fig. 2, a linear relationship is gained when the $\sigma$ value is so taken as to represent the reactivity of the ring carbon atom which is attached to the anilinoethyl group. As the $A_i/A_f$ ratio corresponds to an equilibrium constant of the system between the two forms and changes with the electron density, the two component bands should be assigned to the interacting and the free forms of the N-H group, the forms corresponding to the higher and lower wave number bands respectively, as denoted in Table I.

A difference may be found between the data in Table I and those obtained with phenethyl alcohol derivatives. The displacement ($\Delta\nu_{max}$) of the absorption maximum of the O-H group by the O-H···π interaction has a tendency to increase as the $\sigma$ value of the substituent decreases, the phenomenon being far more evident than in *N*-phenethylaniline; when the substituent varies from *p*-$CH_3$ to *p*-$NO_2$, the difference of $\Delta\nu_{max}$ is 12.2 cm$^{-1}$ in the O-H···π interaction, while the corresponding difference in the N-H···π interaction is only 2.4 cm$^{-1}$, though the change is in the same direction. There has been general acceptance of a proposal that $\Delta\nu_{max}$ provides an index of the strength of the hydrogen bond ($\Delta H$, the enthalpy of hydrogen bonding),[5] though exceptions to this rule are not rare and the matter should be treated carefully. A comparison of the $\Delta H$'s of the O-H···π interaction in several hydroxylic compounds[6] with those of some derivatives of *N*-benzylaniline[7] has shown that there is no remarkable difference between the two groups. Thus, it must be emphasized that the $\Delta\nu_{max}$ difference between O-H and N-H groups cannot be directly related to the interaction energy.

Another striking difference is the value of $\log(A_i/A_f)$. In *N*-phenethylaniline, even the value of the most unfavorable derivative for the interaction among the compounds investigated, i.e., *N*-(*p*-nitrophenethyl)aniline, does not fall to the minus region. This means that if the absorption strength per molecule is the same for both free and interacting forms, the

interacting form is always favored over the free one. On the contrary, in phenethyl alcohol the interaction is of little advantage and a fairly strong electron-donating group such as a *p*-amino substituent can only make the interacting form exceed the free one by a factor of 1.14.

To discuss the matter more fully, some comments should be made on the rotamer ratio in the corresponding compounds with no $\pi$-electron system available for interaction. The $A$(C–H)/$A$(H–H) ratio in *N*-ethylaniline is 8.7[1] and that in ethyl alcohol,[8] 0.56, where $A$(C–H) denotes the integrated intensity of the rotamer which has its X–H group hydrogen between carbon and hydrogen in the Newman projection (Fig. 3, I), and $A$(H–H), one with the X–H hydrogen between two hydrogens (Fig. 3, II).

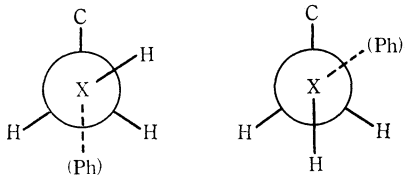

Fig. 3. Possible rotamers with regard to $CH_2$–X bond in C–$CH_2$–X–H.

The band at ca. 3445 $cm^{-1}$ shown in Table I should be assigned to the rotamer II. The fact that the ratio in *N*-ethylaniline is greater by the factor of ca. 15 than that of the alcohol may reasonably be explained by the steric effect of the phenyl group attached to the nitrogen, since the conformation with phenyl between two hydrogens (I) will be favored over one with the group between carbon and hydrogen (II) on account of the greater steric repulsion in the latter.

A comparison of the data in Table I with those of *N*-benzylanilines also shows two interesting points. First, the slope of the line obtained by plotting $\log(A_i/A_f)$'s against Hammett $\sigma$ values is remarkably steeper in *N*-phenethylaniline ($\rho=-0.85$) than that in *N*-benzylaniline ($\rho=-0.40$). Second, the $\log(A_i/A_f)$ values for the latter take both positive and negative signs, but those for the former take only the positive. These are rather abnormal phenomena, because in the *N*-phenethyl derivative the N–H group is separated farther by a methylene group when compared with benzylaniline and, therefore, the situation is unfavorable for the interaction (vide supra). The reasons for these unexpected results can be one or more of the following three: (1) The lower frequency band assigned to the interacting form is, in fact, composed of two bands, due to the interacting form and to the free rotamer, with the absorption maxima of the two at nearly the same position. (2) The absorption intensity per molecule of the interacting form is considerably higher than that of the free form. (3) On establishing the interaction, four- and five-membered rings are formed in *N*-benzyl- and *N*-phenethylaniline respectively. In view of ring strain and the bond angle of $p_\pi$–H–N in the rings, electronic interaction may be more fully effected in the larger ring, the effect leading to a real increase in the number of interacting molecules in spite of the statistical disadvantage.

The maximum positions of the bands due to the rotamers in *N*-ethylaniline are at 3445.2 and 3421.4 $cm^{-1}$, the latter being shifted to a wave number higher by ca. 6 $cm^{-1}$ than the maximum position of the interacting form in *N*-phenethylaniline. If this type of rotamer really exists, especially with a broad band width, it will be difficult to distinguish the bands at 3421 and 3415 $cm^{-1}$. It is even possible that they might in the calculations be regarded as one band in view of the technical uncertainties involved in dividing composite spectra. However, it is noteworthy that Fig. 2 shows a good linear correlation between $\log(A_i/A_f)$ and $\sigma$ values. This may reflect the fact that the contribution of the rotamer to the intensity $A_i$ is small for the reasons to be elucidated below. Let us consider an equilibrium:

$$f_1 \overset{K_i}{\rightleftharpoons} f_2 \overset{K_f}{\rightleftharpoons} i$$

where f and i denote the free and the interacting states respectively, and $f_1$ corresponds to the rotamer I and $f_2$ to the rotamer II in question. $K_f$ and $K_i$ are equilibrium constants. If it is true that the band at the lower wave number corresponds to the sum of the interacting and the free $f_2$ forms, $(f_2+i)/(f_1)$ rather than $(i)/(f_1+f_2)$ should be adopted as $A_i/A_f$. Therefore, $(A_i/A_f)=(f_2+i)/(f_1)=[K_f(f_1)+K_fK_i(f_1)]/(f_1)=K_f(1+K_i)$. In the above equation it is $K_i$ which is directly dependent on the substituent. On the other hand, $K_f$ changes indirectly and may be only a little dependent on the effect. Therefore, the conformity to a linear correlation for the wide range of $\log(A_i/A_f)$ values, as observed in Fig. 2, probably indicates the absence or the presence in only a small portion of $f_2$ in the equilibrium; at any rate the amount of $f_2$ cannot lead to the destruction of the linearity. However, there remains a possibility that $K_f$ and $K_i$ change so that $\log K_f(1+K_i)$ is linear with $\sigma$. Hence, postulate 1 cannot be obviated completely, but it probably is not a major factor.

Postulate 2 is very improbable. If the absorption intensity per molecule of the interacting form were appreciably larger than that of the free form, the sum of the intensities, i.e., $A_1+A_f$, should have increased with the increasing proportion of the interacting form. As is seen in Table I, however, the total intensities of the *p*-methoxyl and *p*-nitro derivatives are $3.93\times10^3$ and $4.02\times10^3$ $mol^{-1}\cdot l.\cdot cm^{-2}$ respectively, within the limit of experimental uncertainties. Hence, the postulate may be disregarded.

On the other hand, the remaining explanation, (3), seems to be more probable. A scale model shows a larger angle of $p_\pi$-N-H for *N*-phenethylaniline. Unfortunately, no literature has been published concerned with the experimental correlation between the hydrogen bond energy and the linearity of the bond in the non-crystalline state, but some theoretical estimations[9] seem to lend support to the explanation that in the hydrogen bond, the larger the deviation angle from linearity, the less the bond energy. The explanation is really consistent with the data obtained. It is probably the most significant factor in the effects; at least it is a major factor.

One further difference between the spectral characteristics of these homologs is concerned with $\Delta\nu_{max}$ values. In *N*-benzylanilines the values range from 30 to 42 $cm^{-1}$, whereas in *N*-phenethylanilines the range is from 29 to 32 $cm^{-1}$. This sharp contrast in the $\Delta\nu_{max}$ range may serve as a key to elucidate the mechanism of the interaction, but no convincing explanation has been obtained so far.

**N-Arylphenethylamines.** — Since the intramolecular interaction between the N-H group and π-electrons has been proved to exist in *N*-phenethylanilines, it seemed of interest to introduce various kinds of substituents into the aniline ring of the compound. The substituents might have an effect on the N-H group through resonance and induction, and, in turn, the effect may appear in the property of the interaction. For this purpose, four derivative were synthesized and their spectra investigated. Their absorption curves are shown in Fig. 4.

A comparison of Fig. 4 with Fig. 1 shows some differences between the spectral features of these series of derivatives. The absorption curves in Fig. 4 do not show two clear maxima. the presence of the latter two having been one of the characteristics of the interaction between the N-H group and the π-electrons. Additionally, three apparent characteristics can be pointed

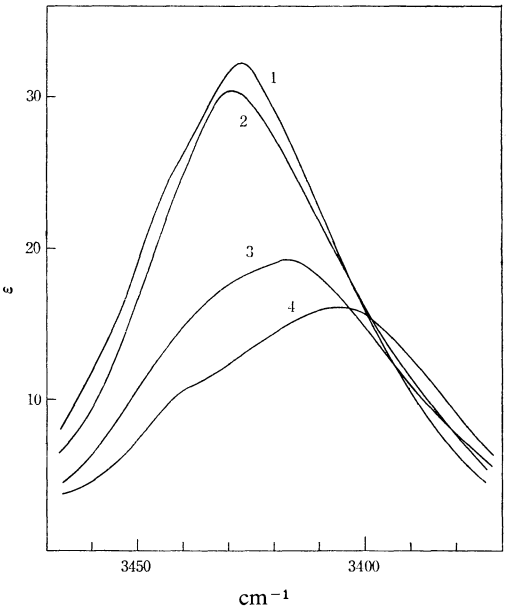

Fig. 4. $\nu_{N-H}$ Absorptions of *N*-(*m*-bromophenyl)- (1), *N*-(*p*-chlorophenyl)- (2), *N*-*p*-tolyl- (3) and *N*-*p*-anisyl-phenethylamines (4).

out in relation to the electronic effect of the substituent; as the electron-withdrawing power of a substituent increases (as the Hammett σ value inrceases), (a) the maximum intensity increases, (b) the half-band width decreases, and (c) the apparent maximum position shifts to a higher wave number. These characteristics, however, are not always peculiar to the N-H···π interaction, because they are also observed in *N*-arylethylamines, which lack a π-electron source for the interaction, as is shown in Fig. 5, and in *N*-methylanilines.[10] Although the substituent effects reveal just the same trend, a close examination of the change in band shape draws attention to the fact that the introduction of a phenyl group to the ethyl group in *N*-arylethylamines produces some changes in shape. The absorption curve of an *N*-arylphenethylamine shows a broader band with a little lower maximum intensity than that of an *N*-arylethylamine with the same substituent. This difference seems to come from the different shape of the side band which appears in the lower wave number region. In *N*-arylethylamines the shape of the band is due to a rotamer, as has already been discussed. On the other hand, the band should be assigned to the interacting N-H group in *N*-arylphenethylamine, though a band due to the free rotamer absorbing in nearly the same region may be a contributing factor.

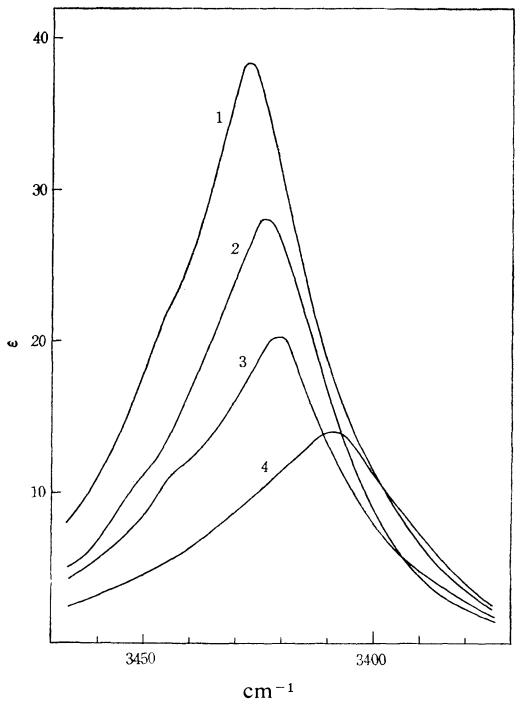

Fig. 5. $\nu_{N-H}$ Absorptions of *m*-bromophenyl- (1), *p*-chlorophenyl- (2), phenyl- (3) and *p*-anisyl-ethylamines (4).

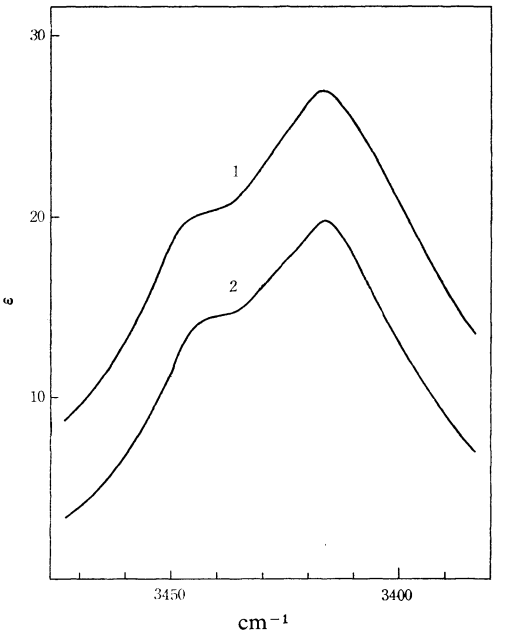

Fig. 6. $\nu_{N-H}$ Absorptions of *N*-*m*-tolyl-(1) and *N*-*p*-biphenylyl-phenethylamines (2). Curve (1) is displaced upward by 5 units.

The different features of the curves in Figs. 1 and 4 deserve comment. As has been reported previously,[1] the half-band width of the interaction band and the $\Delta\nu_{max}$ value in *N*-arylbenzylamine increase as a substituent becomes more electron-donating. Assuming that this relation still holds true in *N*-arylphenethylamine, a derivative with an electron-donating substituent should show a broader interaction band, with a larger $\Delta\nu_{max}$. The overlapping of the interaction band with the free results in a band with only one apparent maximum, on account of a broad band width in the case of an electron-donating substituent. On the other hand, although the half-band width is small in the case of an electron-withdrawing substituent, $\Delta\nu_{max}$ is also small, thus giving the apparent one band. Consequently, *p*-chloro and *m*-bromo derivatives show apparent narrower curves with an obscure shoulder in the higher wave number region, while *p*-methyl and *p*-methoxy derivatives show apparent broad curves. Although clear evidence for these explanations could be obtained by dividing the curves into their components, the band shape precludes this approach. Moreover, even if the division could be made, the experimental uncertainties could not be reduced to a level sufficiently low to permit a confident discussion of the results.

It should, in addition, be noted that the derivatives with a substituent of a nearly zero $\sigma$ value, e. g., *p*-phenyl ($-0.01$) and *m*-methyl ($-0.07$), show band shapes similar to that of unsubstituted *N*-phenethylaniline (see Fig. 6). This phenomenon suggests that the fact that the two maxima are indistinguishable in *N*-arylphenethylamine is not caused by a loss of a hydrogen atom from the benzene ring, but by the electronic effect of a substituent.

The authors are indebted to Professor Yoshiyuki Urushibara and Professor Takehiko Shimanouchi for their valuable discussions and encouragement. The authors are also indebted to the Ministry of Education for a grant-in-aid for Fundamental Scientific Research.

# The Intramolecular Interaction between the N–H Group and π-Electrons. III.[1] Intramolecular Interaction in N-(ω-Phenylalkyl)anilines

By Michinori Ōki and Kiyoshi Mutai

(Received July 13, 1964)

In the previous papers of this series the existence of intramolecular interaction between the N–H group and π-electrons has been reported for *N*-benzylaniline[2] and *N*-phenethylaniline.[1] The predominance of the interacting form over the free form in the latter has now prompted the authors to investigate the higher homologs of *N*-(ω-phenylalkyl)aniline, $Ph\cdot(CH_2)_nNHPh$. In the alcoholic analogs, benzyl[3] and phenethyl[4] alcohols have been reported to show the same type of interaction.

In 3-phenylpropyl alcohol the interaction is absent unless the electron density is raised by the introduction of an electron-donating substituent into the benzene ring.[4] It would be interesting to know the limitation of the interaction by the chain length, since the N–H in an anilino group is known to be favorable toward the interaction.[1] Thus, the present paper is concerned with the determination of the limit of the chain length (the number, *n*) for the interaction and with an examination of its characteristics.

## Experimental

**Spectral Measurements and Calculations.**—They were performed as has been described previously.[1]

**Materials.**—The materials used for the measurement are known compounds, unless otherwise stated. Their physical constants agreed with those in the literature.

*N-(ω-p-Nitrophenylalkyl)anilines.*—All nitro derivatives of this type was prepared by the following method. A corresponding ω-phenylalkyl chloride or bromide was nitrated with a mixture of nitric acid and sulfuric acid. The ω-nitrophenylalkyl halide (*o*- and *p*-isomeric mixture) thus obtained was heated with ca. 4 equivalents of aniline at 180—200°C for 1—1.5 hr. The unreacted aniline was then removed by steam distillation, and the residue was extracted with ether. The solvent was distilled off, and the remaining oil was charged on a column of alumina. Elution with a petroleum ether - benzene mixture gave the desired product in a first eluate. The melting points and the results of elemental analyses are given in the following table.

*N-(3-Arylpropyl)- and N-(4-Arylbutyl)aniline.*—An appropriate hydrocinnamic acid or γ-phenylbutyric acid was heated with ca. 2 equivalents of aniline at a refluxing temperature to give anilide. This anilide, structure of which was confirmed by its infrared spectrum, was then recrystallized from 70% ethyl alcohol and reduced with lithium aluminum hydride, as has been described in a previous paper.[1] Probably because of the poor solubility of the anilide in ether, the yields were generally low.

The physical constants and the results of elemental analyses are given in the following table.

*N-(4-Phenylbutyl)aniline.*—4-Phenylbutyl chloride (12.0 g. or 0.07 mol.) was heated with 25 ml. of aniline at 190—200°C for 1 hr. The reaction mixture was neutralized with an aqueous sodium carbonate solution, the unreacted aniline was removed by steam distillation, and the organic layer was extracted with ether. After the solvent had been removed on a water-bath, the residue was distilled under reduced pressure, affording 8.3 g. (51% yield) of a pale yellow oil; b. p. 158—163°C (2.5 mmHg), $n_D^{22}$ 1.5836.

Found: C, 85.38; H, 8.73. Calcd. for $C_{16}H_{19}N$: C, 85.28; H, 8.50%.

*N-(5-Phenylpentyl)aniline.*—This compound was prepared by the same procedure as was *N*-(4-phenylbutyl)aniline. Pale yellow oil. Yield, 48%. B. p. 160—165°C (2.5 mmHg). $n_D^{22}$ 1.5740.

Found: C, 85.45; H, 9.00. Calcd. for $C_{17}H_{21}N$: C, 85.30; H, 8.84%.

*N-(7-Phenylheptyl)aniline.*—This compound was

## Results and Discussion

***N*-(3-Arylpropyl)anilines.**—Three of the absorption curves measured in the N–H stretching region are shown in Fig. 1.

The shapes of the curves are similar to those of *N*-phenethylanilines. The two apparent maxima and the change in the relative absorption coefficients of the two with the substituent suggest the presence of the N–H$\cdots\pi$ interaction. Each curve was divided into two symmetric bands, each obeying the Lorentz function. No additional band was necessary to achieve a complete division. The data are summarized in Table I, in which the lower wave number band is assumed to be the interaction band.

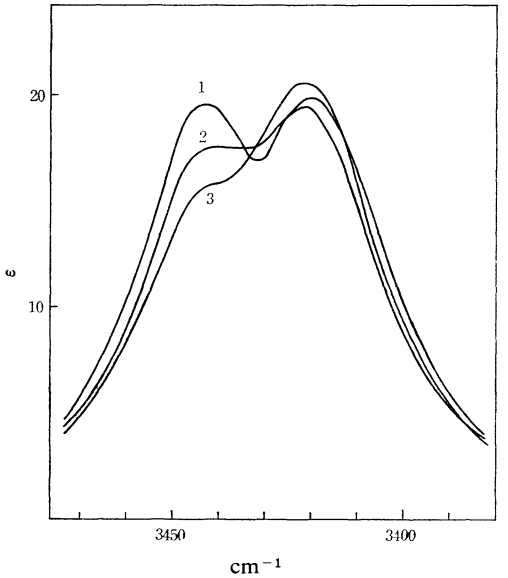

Fig. 1. $\nu_{N-H}$ Absorptions of *N*-(3-arylpropyl)-anilines: (1) *p*-nitro, (2) *p*-chloro and (3) *p*-methoxy.

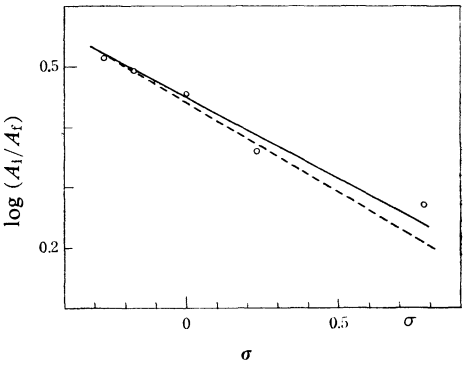

Fig. 2. The relationship between $\sigma$ value and log $(A_i/A_f)$ for *N*-(3-arylpropyl)aniline. Solid line; the value for *p*-nitro derivative ($\sigma=0.78$) is included. Broken line; the value for *p*-nitro derivative is excluded.

In the conventional approach, the $\log(A_i/A_f)$ value is compared with the Hammett $\sigma$ value[5] and, as Fig. 2 shows, a linear correlation is obtained. Hence, it may be said that the interaction exists in this compound.

A comparison of the data in Table I with those for *N*-phenethylanilines shows some interesting points: (1) the straight line is obtained only when the $\sigma$ value is so adopted as to indicate the interaction on the ring carbon atom attached to the aliphatic side chain*; (2) the slope ($\rho=-0.24$ for the solid line) of the line in Fig. 2 is gentler than that observed for *N*-phenethylaniline ($\rho=-0.85$);

5) L. P. Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., New York (1940); H. H. Jaffé, *Chem. Revs.*, 53, 191 (1953); D. M. McDaniel and H. C. Brown, *J. Org. Chem.*, 23, 420 (1958).

* This linearity may have to be discussed with some reserved significance, since the contribution of a free from to the absorption at a lower wave number cannot be neglected, as will be discussed later.

a) i denotes interacting form of N-H group.
b) f denotes free form of N-H group.

(3) the half-band width of the band assigned to the interacting form is narrower than that in N-phenethylanilines; (4) $\Delta\nu_{max}$ does not change appreciably with the substituent, but, again, it is smaller than that observed for N-phenethylanilines by ca. 4 cm$^{-1}$, and (5) log $(A_i/A_f)$ is positive even when a nitro group is introduced to the ring of the π-electron source, but the value is smaller than that of N-phenethylaniline with any corresponding substituent except the nitro derivative.

A comparison of the log $(A_i/A_f)$'s for N-(3-phenylpropyl)anilines with those for N-phenethylanilines show that the formation of a six-membered ring is less likely than that of a five-membered ring. The steeper slope for the latter ($n$=2) may be the result of the more sufficient overlap of the orbitals belonging to the N-H group with those of π-electrons in the five-membered ring. That is, the higher interaction energy is sensitively affected by a little change in π-electron density. Of the derivatives of N-phenethylaniline and N-(3-phenylpropyl)-aniline, only log $(A_i/A_f)$ value which is higher in the higher homolog is obtained for the p-nitro derivative.

This result seems inconsistent with the consideration established above. This anomaly may be explained in the following way. As was noted in an earlier paper,[2] the free form can take two different states, corresponding to the two rotamers observed for N-ethylaniline, one of which absorbs at ca. 3420 cm$^{-1}$. As the electron-withdrawing power of the substituent increases in N-(3-arylpropyl)aniline, the number of the N-H group in the free form increases. In the p-nitro derivative the population of one of the rotamers, the presence of which can be regarded as negligible in lower homologs, may become sufficiently noticeable in the spectrum and may contribute to the intensity to an appreciable extent. Thus, the band assigned to the interacting form in the derivative may be in fact a composite of the interacting form and the free form, both absorbing at nearly the same position. There is supporting evidence for this explanation. As is illustrated in Fig. 2, the value for the p-nitro derivative falls above the line. This deviation suggests an overestimation of $A_i$, to which the intensity due to one of the free forms contributes as well as that of the interacting form. Accordingly, the correlation line in Fig. 2 should be drawn with a modification of the slope (the broken line). By a least-square method, disregarding the p-nitro derivative, the slope is −0.31.

The ratio of the free form to the interacting form in $A_i$ will not be large enough to preclude the presence of the interaction in the derivative, since the log $(A_i/A_f)$ of N-(7-p-nitrophenylheptyl)aniline (see Table III), which is free from the interacting N-H group, is appreciably greater than that of this lower homolog.

**N-(4-Arylbutyl)anilines.**—The data on N-(4-arylbutyl)anilines are given in Table II.

As is shown by the filled circles in Fig. 3, a plot with $\sigma_p$'s for p-substituents does not allow a correlation significant enough to confirm the presence of the interaction. On the other hand, a plot with $\sigma_m$'s changes the situation fairly favorable for its presence. As the open circles in Fig. 3 show, the log$(A_i/A_f)$'s are in the order of corresponding σ values, though not linear. Since one of the free rotamers doubtlessly makes a certain contribution to the intensity assigned to the interaction band, it would be rash to conclude that the improvement of the σ–log $(A_i/A_f)$ relationship by the adoption of the $\sigma_m$ value reflects the actual site of the interaction. Nevertheless, it may be safe to conclude that the interaction does exist in N-(4-phenylbutyl)-anilines, for a comparison of the log $(A_i/A_f)$'s of

unsubstituted (0.540) and *p*-nitro (0.326) derivatives shows a significant difference, one which cannot be explained by any other reason than the N-H$\cdots\pi$ interaction.

This conclusion is important in that, in the hydroxy analog, $C_6H_5(CH_2)_4OH$, no O-H$\cdots\pi$ interaction was observed[4]. Although the conditions for the interaction, especially the distance between the X-H group and the $\pi$-electron source, seem to be unfavorable in these compounds, the following may be added as supporting evidence.

Martin and Gleicher[6] determined the NMR spectra of $\omega$-phenyl-2-methyl-2-alkenes, $C_6H_5\cdot(CH_2)_nCH{=}C(CH_3)_2$. They concluded from the chemical shift of the terminal *cis*-methyl group that the group spends a considerable portion of the time over the plane of the benzene ring in those compounds in which *n* is 2 and 3. This conclusion suggests the likely importance of the number of the ring member in the X-H$\cdots\pi$ interaction and, at the same time, the significance of the restriction of the rotation around the $CH_2$-XH bond, which may be the main reason for the different behavior of the OH and NHPh groups in the interaction.

**Higher Homologs with $n=5$ and 7.**—As an extention, the infrared spectra of *N*-(5-phenylpentyl)- and *N*-(7-phenylheptyl)anilines and of *p*-nitro derivatives were recorded. The N-H stretching absorption curves are shown in Figs. 4 and 5, and the analyzed data, in Table III. The observed spectra (Fig. 4) for *N*-(5-phenylpentyl)aniline and its nitro derivative are slightly different in the higher wave number band, with a higher intensity for the *p*-nitro derivative. The data given in Table III indicate this point more clearly. The log $(A_i/A_f)$ of the *p*-nitro derivative is smaller than that of the unsubstituted compound, but nearly

within the range of experimental error (ca. 0.05). If the observed effect of the substituent is meaningful, that fact should be interpreted as a reflection of the presence of the N-H···π interaction. Although the matter should be treated with great care, it seems that the apparent spectrum which shows the stronger absorption at higher wave number for the nitro compound suggests the existence of such interaction.

Two absorption curves of the higher homolog ($n$=7) (Fig. 5) indicate no substantial difference. Analyzed data also show the same result. The log ($A_i/A_f$)'s for two derivatives are similar within the range of experimental error. From these data, it can safely be concluded that the interaction is absent in *N*-(7-phenylheptyl)aniline.

**General Discussion.**—In summarizing the data for this series of compounds, $Ar(CH_2)_nNHPh$, one can conclude that the intramolecular interaction of the N-H group with π-electrons is present in the cases where $n$ is 1, 2, 3 and 4, and possibly 5. In contrast to this, in the hydroxy analog, $Ar(CH_2)_nOH$, it has been reported[3,4] that the O-H···π intramolecular interaction is present only in the cases where $n$ is 1, 2 and 3. From these results, it is tempting to conclude that the N-H group is more favorable for the interaction with π-electrons than is the O-H group, at least in these species.

As for chemical reactivity, the O-H group is more reactive and has more proton-releasing power than the N-H group. Additionally, and more significantly, it is generally accepted that the tendency of amines to associate is less than that of hydroxylic compounds.[7] The association of aniline in the liquid phase has been investigated by several workers[8-12] by infrared spectroscopy; it has been concluded that the shift of the N-H stretching bands of aniline with a change in concentration is due to N-H···N hydrogen bonding, with a very low energy. Recent ultraviolet spectroscopic studies[13] also show that hydrogen bonding in aniline is not very strong. Although Bellamy and Williams[14] have postulated that the steady shift of the bands to lower frequencies with

an increase in the concentration can be explained by dielectric constant and dipolar effects in the liquid, Rao and his co-workers[15] studied the problem by NMR spectroscopy and confirmed the presence of a N-H···N hydrogen bond in aniline with quite a low energy. All these data suggest that the N-H group, especially in aniline, is much less proton-donating in hydrogen bonding than is the O-H group.

These opposing pieces of evidence raise the question of whether or not the bands observed in the N-H stretching region can be assigned to free and N-H···$\pi$ interacting forms with certainty. Other possible causes affecting two bands may be the Fermi resonance, or the presence of an overtone or a combination band. An inspection of the spectra of some compounds used in this series of papers in the sodium chloride region indicates that such effects cannot be expected for the compounds; on normal vibration band appears between 1650 and 2900 $cm^{-1}$, and it has been reported that there are two N-D stretching bands in *N*-deuterio-*N*-benzylaniline.[16]

Additional evidence for the equality of N-H and O-H groups as hydrogen donors was obtained by the determination of the interaction energy ($\Delta H$). The energies in the intramolecular O-H···$\pi$ interaction reported so far do not, in general, exceed 2.0 kcal./mol. The values for the N-H group have also been found, by a brief study of the energetics of *N*-benzylanilines,[17] to be within the same limits. Hence, O-H and N-H groups should be regarded as, at least, equally affecting functions for intramolecular interaction with $\pi$-electrons.

Probably one of the factors which result in the N-H group being equal with or having the advantage over the O-H group is the different extent of populations of rotamers caused by the rotations around the $CH_2$-NH and the $CH_2$-OH bands in the corresponding compounds. Taking *N*-ethylaniline and ethyl alcohol as reference compounds, the ratios of the state of possible interaction to that of the impossible are 8.7[2] and 0.57[18] respectively. The discrepancy, by a factor of more than 15, may reasonably be attributed to the large steric requirement of the phenyl group.

Finally, mention should be made of the interesting features of the spectra for this series of compounds in connection with the

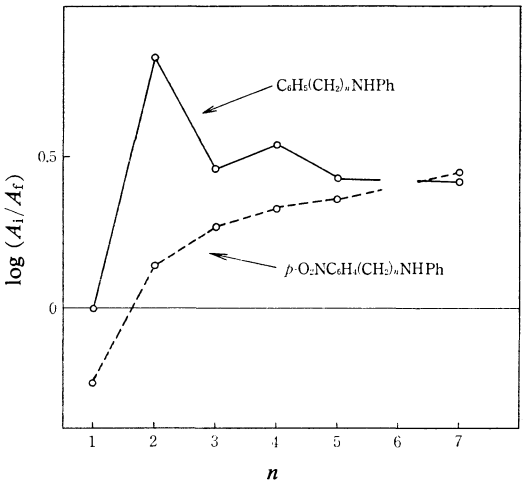

Fig. 6. The relationship between the number of the side chain carbon ($n$) and log ($A_i/A_f$) *N*-($\omega$-arylalkyl)aniline, $RC_6H_4(CH_2)_nNHPh$.

change in log ($A_i/A_f$) with the substituent and the chain length. The values for non-substituted and *p*-nitro derivatives are especially worthy of consideration. As is shown in Fig. 6, log ($A_i/A_f$)'s for *N*-($\omega$-phenylalkyl)anilines change in a zigzag fashion with the number of chain carbon atoms ($n$) and approach a limited value with a decreasing amplitude. The prominent peak at $n=2$ is the reflection of the highly favorable conditions for the N-H···$\pi$ interaction in this homolog. The following zigzag change with a small amplitude is interesting, but experimental uncertainties do not at present allow any unambiguous explanation for this.

On the other hand log ($A_i/A_f$)'s for *p*-nitro derivatives increase with increasing $n$ values and reach a limit. It may seem strange that the curve gives the impression that the longer the chain, the greater the ratio of the interacting form. However, as has been discussed, the $A_i$'s for higher homologs are overestimated when the intensity due to a free form is included. The gradual decrease of $\Delta\nu_{max}$ and its approach to the value for the compound lacking the interaction may be cited as support for this interpretation. The values for $n=3$, 4 and 5 can be explained on this basis, because no complete Hammett correlation is observed for them. The values for $n=1$ and 2 should be regarded as true ratios of $A_i$ and $A_f$, because the plots of log ($A_i/A_f$) against the $\sigma$ value yield good linear correlations.

A comparison of the log ($A_i/A_f$) values for *p*-nitrobenzyl- and *p*-nitrophenethylanilines gives an interesting picture of the molecular conformation. The value for the former, $-0.244$, is appreciably lower than that for the

latter, 0.148. This remarkable discrepancy may be partly the consequence of the preference for the five membered ring conformation in the interacting states. However, the free form absorbing at ca. 3450 $cm^{-1}$ in the *p*-nitrobenzyl derivative should be the conformer with two phenyl groups at an eclipsed or nearly-eclipsed position (see Ref. 2). In this conformation considerable repulsive forces will operate to prevent the two phenyls from becoming eclipsed; therefore, the state will be unstable compared with the interacting form in which phenyls are at trans and which is additionally stabilized by the interaction.

An explanation of this phenomenon will be published in a forthcoming paper.

The authors are indebted to Professor Yoshiyuki Urushibara and Professor Takehiko Shimanouchi for their valuable discussions and encouragement. They are also indebted to the Ministry of Education for a grant-in-aid for Fundamental Scientific Research.

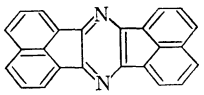
# Studies of Acenaphthene Derivatives. XI.[1] The Reaction of Acenaphthenequinone with Aliphatic Amines

By Otohiko TSUGE and Masashi TASHIRO



(Received July 23, 1964)

In an earlier paper[2] dealing with the reaction between acenaphthenequinone (I) and ammonia, it was shown that the structure of red crystals (II) is neither acenaphthenequinonimide anhydride[3] nor acenaphthazine,[4] but acenaphtho [1, 2-b] isoimidazole-2-spiro - 2' - acenaphthenone.

It had been shown by Rule and Thompson[5] that the reaction of I with aqueous methylamine at 100°C in a sealed tube afforded brown needles (III) (m. p. over 360°C); for these *N, N'* - dimethyldihydroacenaphthazine (IIIa) was assumed on the basis of the nitrogen value and the structure of acenaphthazine (IIIb) suggested by Schönberg and Nedzati[4] for II.

(IIIa)

(IIIb)

2) O. Tsuge and M. Tashiro, This Bulletin, **36**, 970 (1963).

3) C. Graebe and E. Gfeller, *Ann.*, **276**, 1 (1893).

4) A. Schönberg and F. Nedzati, *Ber.*, **54**, 238 (1921).

5) H. G. Rule and S. B. Thompson, *J. Chem. Soc.*, **1937**, 1761.

Since Rule and Thompson's assumption of the structure of IIIa is incorrect, however, it is doubtful whether the structure of III is IIIa or not.

It was also found that naphthalimide was formed, even if the reaction of I with ammonia was carried out under mild conditions. Accordingly, I may be expected to result easily in the formation of the corresponding naphthalimide derivative by an aliphatic amine with a higher basicity than that of ammonia. However, little information is available regarding the formation of *N*-methylnaphthalimide by the reaction of I with methylamine.

The present paper deals with the results of a reexamination of the structure of III and of the reaction of I with methyl-, ethyl- and benzylamine.

## Results and Discussion

The reaction of I with 30% aqueous methylamine at 100°C in a sealed tube according to the Rule and Thompson procedure afforded yellow needles (III), m. p. over 400°C, and *N*-methylnaphthalimide (IV) in low yields due to the formation of a resinous material.

The elemental analytical data on III were in agreement with the formula $C_{24}H_{12}N_2$, whose infrared spectrum did not reveal any bands ascribed to the aliphatic C–H and N–H bonds. As Fig. 1 shows, its ultraviolet spectrum is

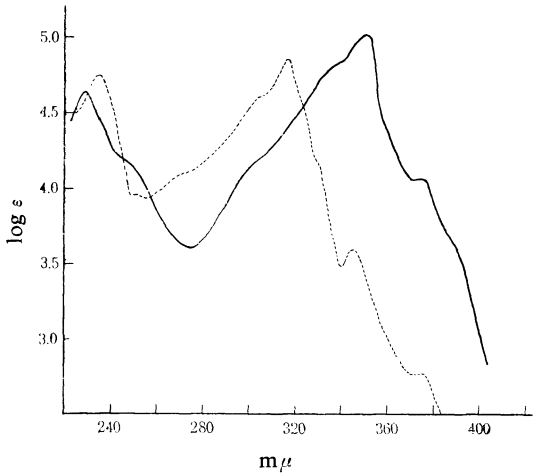

Fig. 1. UV spectra of IIIb and acenaphtho-[1,2-b]quinoxaline in dioxane.
—— IIIb
---- Acenaphtho[1,2-b]quinoxaline

very similar to that of the known compound, acenaphtho[1,2-b]quinoxaline.[6] In addition, the oxidation of III with sodium dichromate in boiling glacial acetic acid resulted in the recovery of III, so it might be considered that III has a stable structure for the oxidation.

These observations are accommodated much better by the structure of acenaphthazine (IIIb) than by IIIa. The mechanism of the formation of IIIb will be discussed below.

On the other hand, IV was identical with an authentic sample prepared by the reaction of naphthalic anhydride and methylamine.[7]

In treatment at room temperature for a long period, IV was formed as the main product, along with a small amount of IIIb.

In view of the fact that IIIb was obtained in the reaction of I with methylamine, it may well be doubted whether or not IIIb can be formed in the reaction of other amines than methylamine with two hydrogen atoms on the α-carbon atom. If IIIb is formed in the reaction with such amines, the structure of IIIb for III is more probable.

In the case of the reaction of I with 70% aqueous ethylamine at 80°C for 15 min., as had been expected, IIIb and *N*-ethylnaphthalimide (V) were obtained in yields of 17.5 and 42.5% respectively. V was proved, by the admixed melting point and by the infrared spectrum, to be identical with an authentic sample prepared by the reaction of naphthalic anhydride and ethylamine.[7]

In the reaction of I with 40% aqueous benzylamine or 100% benzylamine, also, IIIb and *N*-benzylnaphthalimide (VI) were formed in low yields as a result of the formation of a resinous material. Although the reported melting point of VI was 95—96°C,[8] the VI which was obtained by the reaction and by the condensation of potassium naphthalimide and benzyl bromide melted at 195—195.5°C.

Furthermore, benzaldehyde was isolated and and identified as the 2,4-dinitrophenylhydrazone in the reaction with benzylamine. This fact suggests the mechanism of the formation of IIIb in the reaction of I with an amine having two hydrogen atoms on the α-carbon atom.

The formation of IIIb may be as shown in Chart I. That is, *N*-alkylacenaphthenequinonimine (VII), the product of I and one equivalent of amine, rearranges to the Schiff base (VIII). The subsequent hydrolysis of the Schiff base would yield the aldehyde and 1,2-aminoacenaphthenole (IX). The self-condensation of IX leads to the formation of dihydroacenaphthazine (X), which easily dehydrogenates to IIIb.

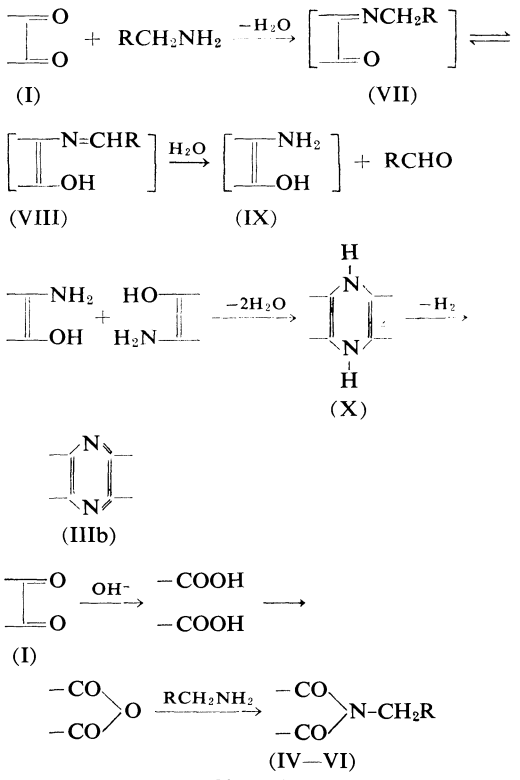

Chart 1.

In the reaction of I with ammonia, acenaphthenequinone monoimine corresponding to

6) This compound was prepared by the condensation of I and *o*-phenylenediamine. (G. Ampola and V. Recchi, *Atti R. Accad. dei Lincei Roma* [5], **8**, 209; *Chem. Zentr.*, **1899**, II, 338.)

7) G. F. Jaubert, *Ber.*, **28**, 360 (1895).

8) S. M. A. Devereux, S. N. J. M. and H. B. Donahoe, *J. Org. Chem.*, **25**, 457 (1960).

VII was isolated.[2] Since the monoimine can not be rearranged to the corresponding Schiff base, it might be considered that the self-condensation of the monoimine resulted in the formation of the isoimidazole derivative mentioned above.

On the other hand, *N*-alkylnaphthalimide is assumed to be formed through naphthalic acid and naphthalic anhydride, as has been shown in a previous paper.[2]

## Experimental[9]

**The Reaction of I with Aqueous Methylamine.**—*a) By the Rule and Thompson Procedure.*—A mixture of 2.0 g. of I and 5 ml. of 30% aqueous methylamine was heated in a sealed tube at 100°C for 6 hr. After it had cooled, the mixture was poured into water and the resinous precipitate was collected; then this was extracted with 100 ml. of methanol, leaving 0.5 g. (28%) of brown crystals, m. p. over 360°C. Recrystallization from nitrobenzene or sublimation afforded acenaphthazine (IIIb) as yellow needles, m. p. over 400°C.

Found: C, 87.79; H, 3.83; N, 8.57. Calcd. for $C_{24}H_{12}N_2$: C, 87.78; H, 3.68; N, 8.53%.

UV $\lambda_{max}^{Dioxane}$ m$\mu$ (log $\varepsilon$): 228.5 (4.64), 348 (5.03).

After the extract had been evaporated, there remained a resinous material, which was then dissolved in benzene and chromatographed on alumina. From the benzene eluate, *N*-methylnaphthalimide (IV) was obtained in the form of colorless needles (Found: C, 74.16; H, 4.32; N, 6.56%). Yield, 0.15 g. (6.3%); m. p. 205°C (lit.[7] m. p. 205°C). This compound was identical with the authentic sample prepared from naphthalic anhydride and methylamine.

*b) At Room Temperaure.*—A suspension of 2.0 g. of I in 20 ml. of 30% aqueous methylamine was stirred in a closed vessel at room temperature for 24 hr. During this time the mixture turned brown. After the reaction mixture had been poured into water, the precipitate was collected, washed with water, dried, and extracted with 50 ml. of hot ethanol, leaving 0.5 g. (28%) of brown crystals, m. p. over 360°C. Recrystallization from nitrobenzene gave yellow needles whose infrared spectrum was superimposable with that of IIIb.

After the ethanol extract had cooled, filtration afforded 1.4 g. (60.3%) of colorless needles, m. p. 195—198°C. Recrystallization from ethanol gave colorless needles, m. p. 205°C, which were proved, by the admixed melting point and infrared spectrum, to be identical with IV.

**The Reaction of I with Aqueous Ethylamine.**—A solution of 2.0 g. of I in 20 ml. of 70% aqueous ethylamine was heated at 80°C for 15 min. The color of the solution turned from green to reddish brown within a few minutes. The reaction mixture was then poured into water, and the precipitate collected, washed with water, dried, and extracted with 200 ml. of ether. The ether-extract was evaporated to give 1.05 g. (42.5%) of pale brown crystals, m. p. 140—145°C. Recrystallization from ethanol afforded pale yellow prisms, m. p. 154—155°C (lit.[8] m. p. 154°C. This compound was found to be identical with the *N*-ethylnaphthalimide (V) which was prepared from naphthalic anhydride and ethylamine.

The ether-insoluble residue was washed with hot benzene, leaving 0.63 g. (17.5%) of brown crystals, m. p. over 360°C. Recrystallization from nitrobenzene or sublimation afforded yellow needles which were identical with IIIb. The benzene-washing was then evaporated, leaving a resinous material which was not investigated further.

**The Reaction of I with Benzylamine.**—*a) With a 40% Aqueous Solution.*—When a solution of 2.0 g. of I in 20 ml. of 40% aqueous benzylamine was heated at 80°C for 1 hr., similar phenomena were observed. The reaction mixture was poured into water to precipitate a brown resinous substance. The precipitate was then collected, washed with water, dried and extracted with ether, leaving brown crystals. The ether-insoluble brown crystals were washed with 100 ml. of hot benzene, leaving 0.2 g. (7.2%) of brown crystals, m. p. over 360°C. Recrystallization from nitrobenzene afforded yellow needles whose infrared spectrum was superimposable on that of IIIb.

The benzene-washings was evaporated to leave 0.8 g. (25.8%) of pale brown crystals. Recrystallization from isopropyl alcohol afforded pale yellow needles m. p. 195—195.5°C.

Found: C, 79.47; H, 4.59; N, 4.91. Calcd. for $C_{19}H_{13}O_2N$: C, 79.43; H, 4.56; N, 4.88%.

This compound was identical with the *N*-benzylnaphthalimide prepared from potassium naphthalimide and benzyl bromide.

Although a reddish violet resinous material was obtained from the ether-washings, it was not investigated further.

*b) With 100% Benzylamine.*—A mixture of 2.0 g. of I and 4 ml. of benzylamine was heated at 80°C for 1 hr. After the mixture had been cooled, filtration afforded a brown precipitate which, on being washed with hot benzene, left 0.4 g. (14.3%) of brown crystals, m. p. over 360°C. Recrystallization from nitrobenzene afforded yellow needles which were identical with IIIb. The combined solution of the filtrate and the benzene-washings was then dried over sodium sulfate and chromatographed on alumina. To the first fraction of the red benzene eluate, a solution of 0.1 g. of 2, 4-dinitrophenylhydrazine in ethanol and then one drop of concentrated hydrochloric acid were added. The resultant solution was heated on a water bath for 30 min. and then cooled. Filtration gave orange crystals (50 mg.), m. p. 235°C, which were proved, by the admixed melting point and by the infrared spectrum, to be identical with benzaldehyde-2, 4-dinitrophenylhydrazone.

From the next fraction of the benzene eluate, *N*-benzylnaphthalimide (VI) was obtained as pale brown crystals. Yield, 0.4 g. (17.9%); m. p. 190—193°C. Recrystallization from isopropyl alcohol afforded pale yellow needles, m. p. 195—195.5°C. Although a resinous material was obtained from the other fractions of the benzene-ethanol eluate, it was not investigated.

9) All melting points are uncorrected.

***N*-Benzylnaphthalimide.**[8] — A mixture of 0.5 g. of potassium naphthalimide, which had been prepared from naphthalimide and potassium hydroxide according to the method of Mattocks and Hutchinson,[10] and 0.4 g. of benzyl bromide in 10 ml. of dimethylformamide was heated on a water bath for 1 hr. After the reaction mixture had been poured into water, filtration gave 0.55 g. (86.7%) of pale yellow crystals, m. p. 189—192°C. Recrystallization from isopropyl alcohol afforded pale yellow needles, m. p. 195—195.5°C (lit.[8] 95—96°C).

# The Spectrophotometric Determination of Anions by Solvent Extraction with Metal Chelate Cations. VI. A New Method for the Determination of Mercury(II)

By Keiya KOTSUJI

(Received July 23, 1964)

Margerum and Banks[1] have reported that the 1, 10-phenanthroline iron(II) chelate cation is extracted as the perchlorate complex into nitrobenzene. Diamond and Tuck[2] and Kuznetsov[3] have recently described how a large anion, such as $ClO_4^-$, $I^-$ or $NCS^-$, can be extracted into nitrobenzene with a large cation of the phenanthroline iron(II) chelate. In a similar fashion, Tribalat and Beydon[4-7] have shown that a large anion, such as $ReO_4^-$ or $TcO_4^-$, can be extracted into a polar solvent with a large cation of an onium compound, such as $Ph_4As^+$ or $Ph_4P^+$.

On the other hand, in the first paper[8] of this series, it has been shown how the 2, 2'-dipyridyl iron(II) chelate cation is extracted into nitrobenzene from an aqueous solution containing perchlorate ion. Moreover, as has previously been reported,[9] mercury(II) can be extracted into 1, 2-dichloroethane with the dipyridyl iron(II) chelate if the aqueous solution contains a large excess of iodide ions; the intensity of the red color of this extract is proportional to the amount of mercury(II). A consideration of these findings led to the present study, which is concerned with the optimum conditions for the determination of mercury(II).

This paper will report on a new spectrophotometric method for the determination of mercury(II) with the 2, 2'-dipyridyl iron(II) chelate, based upon a solvent extraction of the associated complex formed between the colored dipyridyl iron(II) chelate cation and the colorless tetra-iodo-mercury(II) complex anion, and upon the estimation of the chelate absorbance in the organic phase.

For the colorimetric determination of mercury, the dithizone method[10] is most familiar, but other methods are known in the literature, using diethyldithiocarbamate[11] and diphenylcarbazone[12]. Karas and Pinter[13] have shown that the intensity of the red color of the dipyridyl iron(II) chelate is inversely proportional to the amount of mercury(II), since

mercury replaces iron as the dipyridyl mercury chelate. Goto and Suzuki[14] have determined mercury by extracting the tetra-iodo-complex of mercury(II) with isoamylalcohol and by then measuring the absorbance at 305 mμ. Jackwerth and Spekker[15] have also investigated the extraction of this complex with cyclohexanone.

Therefore, the proposed method is different from the previously known methods in the mechanism of the color reaction.

## Experimental

**Apparatus and Reagents.** — Unless otherwise stated, the apparatus and reagents were the same as those described in the preceding paper.[8]

*Standard Mercury Solution.*—Guaranteed mercuric chloride was dissolved in hydrochloric acid and diluted with distilled water to a concentration of 1000 p. p. m. of mercury. Ths standard solution was then diluted to the concentration required for the experiments.

1,2-Dichloroethane was purified according to the method described in the literature.[16]

All the other reagents of an analytical grade were used without further purification.

**Procedure.**—Mix 2,2'-dipyridyl ($8\times10^{-3}$ M), ferrous ammonium sulfate ($2\times10^{-3}$ M), sodium acetate (3 M), potassium iodide (0.3 M) and a standard mercury solution in the proper concentration. Adjust the pH of the solution to the required value with a dilute sulfuric acid or a dilute sodium hydroxide solution, and dilute it to 25 ml. with distilled water. To this, add 10.0 ml. of dichloroethane and shake the solution for 6 min. After the solution has stood for 20 min., transfer the organic layer into a flask containing 1 g. of anhydrous sodium sulfate and shake it vigorously in order to make the solution transparent. Then transfer it into a 10 mm. cell. Measure the absorbance of the solution at 526 mμ, using a reagent blank solution or dichloroethane as a reference. Measure the pH of the aqueous layer after the separation.

## Results and Discussion

**Absorption Spectrum.**—The spectral absorbance curves using dichloroethane as a reference are shown in Fig. 1. They were measured for a dichloroethane solution obtained by extraction from one aqueous solution which contained mercury(II) and one which did not. It was observed that the presence of mercury(II) ions leads to a considerable increase in the absorbance and that both curves have a maximum absorbance at 526 mμ. The absorbance maximum of the chelate cation in the aqueous solution was at 522 mμ, a value which coincides with that found in the literature.[17] This slight red shift in the organic layer may be attributed to the effect of the association between the chelate cation and the complex anion in dichloroethane. Feigl[18] has shown that the 2,2'-dipyridyl iron(II) chelate can be precipitated as red crystals with a divalent complex anion, such as tetraiodo-mercury(II) or cadmium. On the basis of these facts, the chemical formula of the extracted species is assumed to be $Fe(Dip.)_3\cdot HgI_4$.

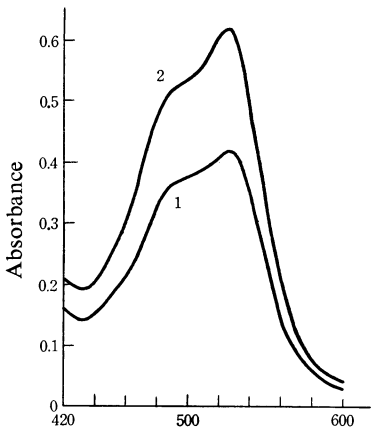

Fig. 1. Absorption spectra.
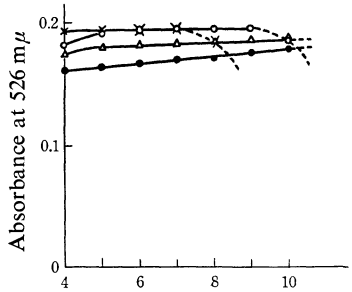
Reference: Dichloroethane, pH: 6.3
Curve 1: Spectrum of organic phase extracted from the aqueous solution (25 ml.) contained Dip. $9.6\times10^{-4}$ M, Fe(II) $2.4\times10^{-4}$ M, NaAc 0.24 M, KI $8.4\times10^{-2}$ M but Hg is absent.
Curve 2: Spectrum of organic phase extracted from the aqueous solution (25 ml.) containing 2 p. p. m. of Hg in addition to the same component as that of curve 1.



The maximum difference in the absorbance between curve 1 and curve 2 is found at 526 mμ. Therefore, the measurement of the absorbance was carried out at this wavelength.

**The Effect of Reagents.**—*A) The Effect of the Ferrous Ammonium Sulfate and Potassium Iodide Concentrations.* — The formation of extractable species is governed mainly by the concentration of the 2,2'-dipyridyl iron(II) chelate cation as well as of the tetra-iodo-mercury(II) complex anion. Moreover, the solution must contain a large excess of potassium iodide for the quantitative formation of the tetra-iodo-mercury(II) complex. The effect

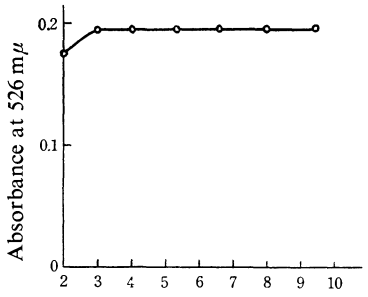
18) F. Feigl, "Spot Test, Part I, Inorganic Application," Elsevier Publishing Company, New York (1954), p. 90.

of such variables on the extraction was investigated.

To a solution containing a constant amount of mercury(II), various amounts of potassium iodide, ferrous ammonium sulfate, and 2,2'-dipyridyl, in which the mole ratio of dipyridyl to ferrous iron was kept constant, were added. The mole ratio was kept at 4 to 1 because a slight excess of the dipyridyl seemed to be necessary for the stoichiometric formation of the chelate cation. The pH of the solutions was kept at 6.3, and the extraction procedure was carried out for such solutions. The results are shown in Fig. 2. If the final concentration



Concn. of potassium iodide $x$ ($\times 1.2\times10^{-2}$ M)

Fig. 2. Effect of ferrous ammonium sulfate and potassium iodide concentrations.
The concentration of acetate in the final solutions was 0.24 M.
Concentration of mercury, 2 p. p. m.
pH of aqueous layer, 6.3
Shaking time, 6 min.
Reference, Reagent blank

| | Concn. of Dip., M | Concn. of Fe(II), M |
|---|---|---|
| —×— | $1.6\times10^{-3}$ | $4.0\times10^{-4}$ |
| —○— | $9.6\times10^{-4}$ | $2.4\times10^{-4}$ |
| —△— | $6.4\times10^{-4}$ | $1.6\times10^{-4}$ |
| —●— | $3.2\times10^{-4}$ | $8.0\times10^{-5}$ |

of the ferrous ammonium sulfate is lower than $1.6\times10^{-4}$ M,* a rather low recovery is observed, although the recovery is improved with increasing concentration of potassium iodide. When the concentration of ferrous ammonium sulfate is kept in the range of $2.4\times10^{-4}$—$4.0\times10^{-4}$ M, the recovery reaches a maximum when the iodide concentration is higher than $7.2\times10^{-2}$ M. However, large excess of iodide or the chelate causes a decrease in the absorbance. Therefore, the concentrations of the ferrous ammonium sulfate and the potassium iodide were kept at $2.4\times10^{-4}$ M and $8.4\times10^{-2}$ M respectively in this work.

*B) The Effect of the 2,2'-Dipyridyl Concentration.*—While keeping other variables constant, a different amount of the dipyridyl was added, and the extraction was carried out according to the procedure described above. Figure 3 shows that the mole ratio of the dipyridyl to iron(II) has to be kept higher than 3. This mole ratio was therefore kept at 4 in this work.

Mole ratio of Dip. to Fe(II)

Fig. 3. Effect of mole ratio of Dip. to Fe(II).
The concentrations of iron(II), iodide, and acetate in the final solutions were $2.4\times10^{-4}$ M, $8.4\times10^{-2}$ M, and 0.24 M respectively.
Concentration of mercury, 2 p. p. m.
pH of aqueous layer, 6.3
Shaking time, 6 min.
Reference, Reagent blank

*C) The Effect of the Sodium Acetate Concentration.* — Sodium acetate was effective in keeping the solution at a constant pH. When the acetate concentration was maintained at 0.2 to 0.3 M in the solution to be extracted, no effect on the recovery was observed. The concentration of the acetate was kept at 0.24 M in this work

**The Effect of the Shaking Time.**—The shaking time for the extraction was varied from 2 to 20 min., while the other variables were kept

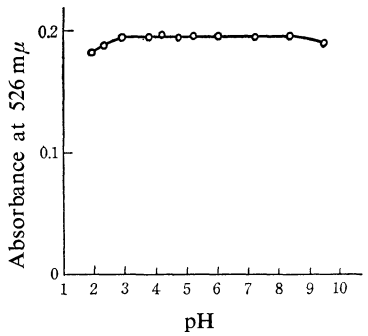


Fig. 4. Effect of pH.
The concentrations of dipyridyl, iron(II), iodide, and acetate in the final solutions were $9.6\times10^{-4}$ M, $2.4\times10^{-4}$ M, $8.4\times10^{-2}$ M, and 0.24 M respectively.
Concentration of mercury, 2 p. p. m.
Shaking time, 6 min.
Reference, Reagent blank

* The concentration of ferrous iron is approximately equal to that of the 2,2'-dipyridyl iron(II) chelate because of the high stability of the chelate.

constant. When the shaking time was shortened to less than 4 min., a lower recovery was noticed. The shaking time of 6 min. was thus chosen in this work.

**The Effect of pH.**—The effect of the pH of the aqueous layer on the extraction is shown in Fig. 4. Low recoveries are obtained in the pH ranges below 3 and above 8.5. The pH of the solution was adjusted to 6.3 in this work.

**The Stability of the Color.**—Color developed immediately at room temperature and was not influenced by the temperature at 10—17°C. The effect of the time of standing on the dichloroethane extract in a transmission cell with a stopper was investigated. The results are shown in Fig. 5. The absorbance remains constant for 60 min. After that the absorbance begins to decrease slightly.

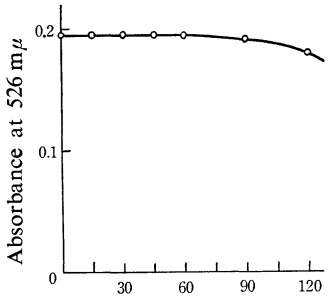

Fig. 5. Stability of color.
The concentrations of dipyridyl, iron(II), iodide, and acetate in the final solutions were $9.6\times10^{-4}$ M, $2.4\times10^{-4}$ M, $8.4\times10^{-2}$ M, and 0.24 M respectively.
Concentration of mercury, 2 p. p. m.
pH of aqueous layer, 6.3
Shaking time, 6 min.
Reference, Reagent blank

**The Choice of Organic Solvent.**—As has been pointed out by Diamond and Tuck[2], not only the size of the cation and the anion, but also the dielectric nature of the solvent, govern the extractivity of the associated complex. Various water-immiscible solvents were tested as extraction solvents. 1, 2-dichloroethane, chloroform, carbon tetrachloride, isoamylalcohol, methylisobutylketone, cyclohexanone, benzene, and nitrobenzene. Among them the most favorable degree of separation occured in 1, 2-dichloroethane. As has previously been reported,[8,19] nitrobenzene is the most available solvent in these systems and behaves similarly to 1, 2-dichloroethane in this case. Unfortunately, the reagent blank was too high to obtain a satisfactory net absorbance value.

19) Y. Yamamoto and S. Kinuwaki, This Bulletin, 37, 434 (1964).

**The Percentage of Extraction.**—The degree of the extraction of mercury(II) was calculated from a measurement of the mercury(II) concentration in the aqueous layer after the extraction. The amount of residual mercury(II) was determined as follows. To the aqueous layer, 20 ml. of a 30% sodium hypophosphite solution and 4 ml. of concentrated hydrochloric acid were added. The mixture was then diluted with distilled water to 50 ml. and was extracted with 10 ml. of isoamylalcohol. The absorbance of the isoamylalcohol extract was measured at 305 mμ, as has been described by Goto and Suzuki.[14] The degree of the extraction using 10.0 ml. of dichloroethane was about 98%.

**Calibration Curve.**—Three milliliters of the 2, 2'-dipyridyl solution, 3 ml. of the ferrous ammonium sulfate solution, 2 ml. of the sodium acetate solution, 7 ml. of the potassium iodide solution, and varying amounts (1—6 ml.) of the standard mercury solution (10 p. p. m.) were mixed and diluted to 25 ml. with distilled water. Then 10.0 ml. of dichloroethane was added, and the mixture was treated according to the procedure previously described. The absorbance for each set of the extract was measured at 526 mμ against the reagent blank. As Fig. 6 shows, Beer's law is followed in the 0.4—2.4 p. p. m. range of mercury(II) ions.

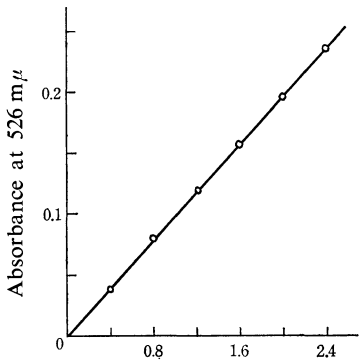

Fig. 6. Calibration curve at 526 mμ.
The concentrations of dipyridyl, iron(II), iodide, and acetate in the final solutions were $9.6\times10^{-4}$ M, $2.4\times10^{-4}$ M, $8.4\times10^{-2}$ M and 0.24 M, respectively.
pH of aqueous layer, 6.3
Shaking time, 6 min.

**The Effect of Diverse Ions.** — A study was made of the effects of several cations and anions. Absorbance measurements were made for the dichloroethane extracts from solutions containing various amount of diverse ions with 2 p. p. m. of mercury(II). The results are given

TABLE I. EFFECT OF DIVERSE IONS ON EXTRACTION AND DETERMINATION OF MERCURY(II)

in Table I. Nitrate and sulfate do not interfere when the concentration is as high as 1000 p. p. m. but at a very large concentration higher results are obtained. The positive errors for zinc(II), cadmium(II), lead(II), and bismuth(III) may be due to the behavior of the iodo complex of these ions being similar to that of the tetra-iodo-mercury(II) complex anion. In order to eliminate the interferences of the diverse ions, the use of ethylenediaminetetraacetate is suggested, because the tetra-iodo-mercury(II) complex[20] is more stable than the mercury(II) chelate of ethylenediaminetetraacetate.[21] Favorable results were obtained when 1 ml. of a 0.05 M disodium ethylenediaminetetraacetate solution was added as a masking agent to the solution to be extracted, as is shown in Table II.

* The absorbance of 2 p. p. m. of mercury(II) without diverse ions.

## Summary

A new method for the determination of mercury(II) has been proposed. The method is based upon the solvent extraction of the associated complex formed between the 2,2'-dipyridyl iron(II) chelate cation and the tetra-iodo-mercury(II) complex anion and upon the estimation of the absorbance belonging to the chelate cation in the organic phase. The interference of diverse ions is eliminated by using ethylenediaminetetraacetate as a masking agent.

The author wishes to express his thanks to Professor Yuroku Yamamoto of Hiroshima University for his kind guidance and encouragement throughout this work. He is also grateful to Professor Shigehiko Hayashi for his kind advice and to Mr. Toshiyuki Sakurai for his assistance in this work.

# Electrolytic Thermocouple for the Determining Soret Coefficients and Heats of Transfer of Hydrochloric Acid

By Toshio IKEDA

(Received July 29, 1964)

It is impossible to determine the Soret coefficients or the ionic heats of transfer directly from the initial thermoelectric power of a thermocell alone, though there is an intimate relation between them. It is possible, however, to determine the value of one electrolyte relative to the other electrolyte when two thermocells with a common electrode system are coupled. This procedure was employed on hydrochloric acid in the present work.

**General Relations.**—We used an electrolytic thermocouple of the following system:

$$\begin{array}{c}\mathrm{Hg/HgCl,\ KCl}(m),\\ T\end{array}$$

$$\begin{array}{ccc}\mathrm{HgCl/Hg/HgCl,\ HCl}(m), & \mathrm{HgCl/Hg} & (1)\\ T+\Delta T & T & \end{array}$$

The initial thermoelectric powers, $\varepsilon_0^{\mathrm{KCl}}$ and $\varepsilon_0^{\mathrm{HCl}}$, for two thermocells constituting the left and right halves of cell system 1 can be written, respectively, as follows:[1]

$$\boldsymbol{F}\varepsilon_0^{\mathrm{KCl}} = -t_{\mathrm{K^+}}^{\mathrm{KCl}}\frac{Q_{\mathrm{K^+}}^{*\mathrm{KCl}}}{T} + t_{\mathrm{Cl^-}}^{\mathrm{KCl}}\frac{Q_{\mathrm{Cl^-}}^{*\mathrm{KCl}}}{T} + S_{\mathrm{Cl^-}}^{\mathrm{KCl}} + S_{\mathrm{Hg}} - S_{\mathrm{HgCl}} - S_{\mathrm{el}} - \frac{Q_{\mathrm{el}}^{*}}{T} \quad (2)$$

and

$$\boldsymbol{F}\varepsilon_0^{\mathrm{HCl}} = -t_{\mathrm{H^+}}^{\mathrm{HCl}}\frac{Q_{\mathrm{H^+}}^{*\mathrm{HCl}}}{T} + t_{\mathrm{Cl^-}}^{\mathrm{HCl}}\frac{Q_{\mathrm{Cl^-}}^{*\mathrm{HCl}}}{T} + S_{\mathrm{Cl^-}}^{\mathrm{HCl}} + S_{\mathrm{Hg}} - S_{\mathrm{HgCl}} - S_{\mathrm{el}} - \frac{Q_{\mathrm{el}}^{*}}{T} \quad (3)$$

where $\boldsymbol{F}$ is the Faraday; $T$ is the absolute temperature; $t_{\mathrm{K^+}}^{\mathrm{KCl}}$ and $Q_{\mathrm{K^+}}^{*\mathrm{KCl}}$ are, respectively, the transport number and the ionic heat of transfer of potassium ions in an aqueous solution of potassium chloride at the molality of $m$, and $t_{\mathrm{Cl^-}}^{\mathrm{KCl}}$ and $Q_{\mathrm{Cl^-}}^{*\mathrm{KCl}}$ are the similar quantities for the chloride ions; $S_{\mathrm{Cl^-}}^{\mathrm{KCl}}$ represents the partial molar entropy of the chloride ions in an aqueous $m$ molal solution of potassium chloride; $S_{\mathrm{Hg}}$ and $S_{\mathrm{HgCl}}$ are, respectively, the molar entropies of the liquid mercury and of the solid mercurous chloride of the calomel electrode, and $S_{\mathrm{el}}$ and $Q_{\mathrm{el}}^{*}$ are, respectively, the molar entropy and the molar heat of transfer of electrons in the metallic leads of the electrodes. Equation 3 may be read in a similar fashion.

Now, if the following two conditions:

$$Q_{\mathrm{Cl^-}}^{*\mathrm{KCl}} = Q_{\mathrm{Cl^-}}^{*\mathrm{HCl}} \text{ and } S_{\mathrm{Cl^-}}^{\mathrm{KCl}} = S_{\mathrm{Cl^-}}^{\mathrm{HCl}} \quad (4)$$

are allowed simultaneously, the resultant initial thermoelectric power, $(\mathrm{d}E/\mathrm{d}T)_0$, for the electrolytic thermocouple of system 1 may be written as follows:

$$\boldsymbol{F}\left(\frac{\mathrm{d}E}{\mathrm{d}T}\right)_0 = -t_{\mathrm{K^+}}^{\mathrm{KCl}}\frac{Q_{\mathrm{K^+}}^{*\mathrm{KCl}} + Q_{\mathrm{Cl^-}}^{*\mathrm{KCl}}}{T} + t_{\mathrm{H^+}}^{\mathrm{HCl}}\frac{Q_{\mathrm{H^+}}^{*\mathrm{HCl}} + Q_{\mathrm{Cl^-}}^{*\mathrm{HCl}}}{T} \quad (5)$$

where the identity conditions, $t_{\mathrm{K^+}}^{\mathrm{KCl}} + t_{\mathrm{Cl^-}}^{\mathrm{KCl}} = 1$ and $t_{\mathrm{H^+}}^{\mathrm{HCl}} + t_{\mathrm{Cl^-}}^{\mathrm{HCl}} = 1$, are used. Further, Eq. 5 can be rewritten in terms of the Soret coefficients, $\sigma^{\mathrm{KCl}}$ and $\sigma^{\mathrm{HCl}}$, as follows:

$$\boldsymbol{F}\left(\frac{\mathrm{d}E}{\mathrm{d}T}\right)_0 = 2t_{\mathrm{K^+}}^{\mathrm{KCl}}\,\boldsymbol{RT}\sigma^{\mathrm{KCl}}B^{\mathrm{KCl}} - 2t_{\mathrm{H^+}}^{\mathrm{HCl}}\,\boldsymbol{RT}\sigma^{\mathrm{HCl}}B^{\mathrm{HCl}} \quad (6)$$

where

$$\left.\begin{aligned}\sigma^{\mathrm{KCl}} &= -(Q_{\mathrm{K^+}}^{*\mathrm{KCl}} + Q_{\mathrm{Cl^-}}^{*\mathrm{KCl}})/2\boldsymbol{RT}B^{\mathrm{KCl}}\\ \sigma^{\mathrm{HCl}} &= -(Q_{\mathrm{H^+}}^{*\mathrm{HCl}} + Q_{\mathrm{Cl^-}}^{*\mathrm{HCl}})/2\boldsymbol{RT}B^{\mathrm{HCl}}\\ B^{\mathrm{KCl}} &= 1 + (\mathrm{d}\ln\gamma_{\pm}{}^{\mathrm{KCl}}/\mathrm{d}\ln m)_{\mathrm{T,P}}\\ B^{\mathrm{HCl}} &= 1 + (\mathrm{d}\ln\gamma_{\pm}{}^{\mathrm{HCl}}/\mathrm{d}\ln m)_{\mathrm{T,P}}\end{aligned}\right\} \quad (7)$$

$\boldsymbol{R}$ is the gas constant, and $\gamma_{\pm}{}^{\mathrm{KCl}}$ and $\gamma_{\pm}{}^{\mathrm{HCl}}$ are the mean ion activity coefficients of potassium chloride and of hydrochloric acid in aqueous $m$ molal solutions respectively.

If the Soret coefficient is known accurately for an aqueous $m$ molal solution of potassium chloride, for example, then one may obtain, by means of Eq. 6, the Soret coefficient of hydrochloric acid at the same concentration and at the same temperature, and may further calculate the heats of transfer by the aid of Eq. 7.

## Experimental

All solutions were prepared from G. R. chemicals by using ordinary distilled water. The concentration of the solution was checked by titration and

1) E. g., H. J. V. Tyrrell, "Diffusion and Heat Flow in Liquids," Butterworths, London (1961).

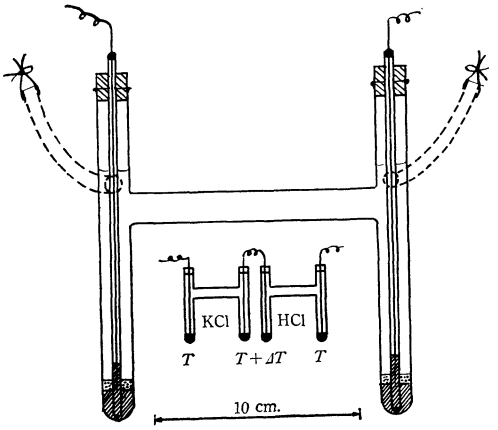

Fig. 1. Cell system, the parts drawn with dotted line representing the side tubes on the front of paper.

was adjusted to yield definite values in molality, values accurate within ±1% in the present work. Two H-shaped glass cells were convenient for the present purpose (Fig. 1). Two H-shaped calomel thermocells involving, respectively, the solutions of potassium chloride and hydrochloric acid at the same concentration were joined together by the legs and then placed in water thermostated in two respective Dewar vessels. The temperature was changed from 17°C to 32°C on only one side of of these two Dewar vessels by adding cold or hot water to yield the mean 25°C, while the temperature on the colder side was always fixed at 17°C. Under a moderate agitation with air bubbling, the thermal equilibrium of the cell system was attained in about ten minutes after the change of the temperature of thermostat water in the Dewar vessels. The temperature was read with a calibrated mercury thermometer with 0.1°C divisions. The terminals of two thermocells were joined together electrically on the warmer side, and the remaining terminals on the colder side were served to the measurements of the e. m. f. The e. m. f., $E$, of cell system 1 was measured for a given temperature difference, $\Delta T$, by the use of a Yokogawa precision potentiometer (Type P-7, for low voltage use, with a sensitivity as low as 0.1 $\mu$V.) by the use of a sensitive galvanometer as a zero indicator.

Here, the sign convention for e. m. f. of system (1) was taken as positive if the sign of the electrode on the colder side of hydrochloric acid was found be positive against the sign of the electrode on the colder side of potassium chloride.

In measuring every care was taken to get accurate and reproducible data. Even the best-prepared thermocells were let stand for about three days after having been prepared in order to bring them to a stationary state. A battery, the electric source, must be connected to the potentiometer for at least three hours prior to measurement so that the normalized state of the potentiometer does not drift. The shielding of the system from inconvenient heat effects is also important.

## Results and Discussion

The plots of the e. m. f., $E$, of 1 against the applied temperature difference, $\Delta T$, fell on a straihgt line, with a definite slope depending on the concentration. Here, the non-linear data were abandoned because they were taken when the system was not in a steady state. The results are presented in Figs. 2 and 3. The initial thermoelectric power, $(dE/dT)_0$, was found to be positive at the present sign

convention; it seems to diminish linearly with the logarithms of molality, as is indicated in Fig. 3.

Early data on the Soret coefficients are not very reliable, but fairly accurate data are available in recent reports, particularly those by Snowdon and Turner.[2,3] These authors determined the Soret coefficients directly by the conductometric method for a number of electrolytes at 25°C. The Soret coefficients at higher concentrations were formerly given by Tanner[4] at a mean temperature of 32°C. Data for medium concentrations are lacking at present.

In the present work, we calculated the Soret coefficient for hydrochloric acid at 25°C by using known $\sigma$ values for potassium chloride and the initial thermoelectric powers for system 1. The results are compared with the literature values in Table I, where the Sasaki values cited for comparison are those observed at the mean temperatures of 40°C[5] and 35°C[6]. Since the Soret coefficient is rather sensitive to the Soret coefficient is rather sensitive to the mean temperature at which it is measured, increasing with an increase in that temperature, it is inappropriate, strictly speaking, to make a direct comparison between Soret coefficients determined at different temperatures. However, as may be seen in Table I, the calculated values and the literature values were found to agree roughly in their magnitudes in a satisfactory manner, apart from details. Calculations for the medium concentrations could not be performed to yield correct values of the Soret coefficients for hydrochloric acid because of a lack of basic data on the Soret coefficients of potassium chloride in the corresponding region of concentration; therefore, tentative calculations were made by using the interpolated values of the Soret coefficients of potassium chloride for 0.1 and 0.5 M. No such peak as those reported by Chipman,[7] Hirota[8] and Sasaki[5] on the Soret coefficient of hydrochloric acid could be found here in the concentration range between 0.5 and 1.0 M. This might be either because the values of the Soret coefficients of potassium chloride used for the calculation were inadequate at higher concentrations, or becanse the basic conditions indicated in 4 can no longer hold at higher concentrations, or to both reasons. At any rate, the present method is likely to be applicable for determining the Soret coefficients at lower concentrations for any electrolyte that can form a thermocell with a convenient electrode system.

**Summary**

We have studied an electrolytic thermocouple formed by coupling two thermocells, consisting of electrodes of the same nature, and with different electrolytes, either hydrochloric acid or potassium chloride, but both of the same concentration; we have demonstrated that the Soret coefficient of hydrochloric acid relative to that of potassium chloride can be estimated from the initial thermoelectric powers of this electrolytic thermocouple, as long as the entropies as well as the heats of the transfer of the chloride ions may be assumed to be the same between these two electrolytes.

Agreements between calculations and observations have been roughly good in the range of concentration between 0.01 M and 1 M, though there are some uncertainties about the Soret coefficients of potassium chloride at higher concentrations. This method may have general applicability, particularly in the dilute region.

# Thermal Decomposition of Acetaldehyde in the Presence of Hydrogen Chloride

By Naomi IMAI, Takeshi FUJII and Osamu TOYAMA

(Received August 1, 1964)

Hydrogen chloride and bromide have been shown to catalyze decompositions of a number of alcohols and other substances in the gas phase.[1,2] The present paper reports, as an additional example of hydrogen halide catalysis, the hydrogen chloride-catalyzed decomposition of acetaldehyde. The study of this reaction was undertaken in connection with our previous work on the hydrogen sulfide-catalyzed decomposition of acetaldehyde and dimethyl ether.[3-7]

The catalytic action of hydrogen sulfide on the pyrolysis of acetaldehyde has been attributed to the replacement of the chain-propagating reactions 8 and 6:

$$CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO \quad (8)$$

$$CH_3CO \rightarrow CH_3 + CO \quad (6)$$

in the decomposition of acetaldehyde alone, by the faster-propagating cycle of reactions 9, 10 and 6:

$$CH_3 + H_2S \rightarrow CH_4 + HS \quad (9)$$

$$HS + CH_3CHO \rightarrow H_2S + CH_3CO \quad (10)$$

both reactions, 9 and 10, being faster than reaction 8. The methanethiol-catalyzed pyrolysis of acetaldehyde[8] and the hydrogen sulfide-catalyzed pyrolysis of dimethyl ether[6] have been explained by similar mechanisms.

Hydrogen chloride may be expected to exert a similar catalytic effect in the pyrolysis of acetaldehyde if reactions 4 and 5:

$$CH_3 + HCl \rightarrow CH_4 + Cl \quad (4)$$

$$Cl + CH_3CHO \rightarrow HCl + CH_3CO \quad (5)$$

proceed faster than reaction 8, as was the case with reactions 9 and 10. That such a situation is very probable may be seen by a comparison of the following reported expressions for the rate constants (in $mol^{-1}$ cc. $sec^{-1}$):

$k_4$: $10^{11.7}\exp(-2100/RT)$[9]
$10^{12.2}\exp(-4500/RT)$[10]
$k_5$: $10^{13.3}\exp(-5000/RT)$[11]
$k_8$: $10^{11.3}\exp(-6800/RT)$[12]

## Experimental

**Materials.** — Acetaldehyde was supplied commercially, purified by repeated bulb-to-bulb distillations, and stored as a liquid below 20°C. Hydrogen chloride was prepared by vaporizing it from concentrated hydrochloric acid, drying it by passing it through phosphorus pentoxide and a trap at −78°C, and purifying it by bulb-to-bulb distillations. The auramine used to absorb the hydrogen chloride was a commercial sample.

**Apparatus and Procedure.**—An ordinary static method was used in this work. The pyrolysis was carried out in a cylindrical glass vessel of about 181 cc. placed in an electric furnace, which was controlled to ±0.5°C by means of a thermocouple-activated controller.

The thermal decomposition was started by introducing the reactant vapor into a reaction vessel already kept at the reaction temperature; the total pressure rise with time due to decomposition was then followed. In some runs, the reaction mixture after the pyrolysis was passed through a trap at the temperature of liquid air and the non-condensable fraction was collected by a Toepler pump. This fraction, consisting exclusively of methane and carbon monoxide, was analyzed by a gas chromatograph on a 2-m Molecular Sieve 5 column at room temperature in use of hydrogen as the carrier. In order to determine the amount of hydrogen chloride remaining unconsumed in the pyrolysis, the condensate in the trap was warmed up to about −120°C and the vaporized fraction was collected by a Toepler pump and measured. This fraction was identified as hydrogen chloride, having been almost completely absorbed by the auramine.

## Results

In Fig. 1 are plotted against time the amounts of methane and carbon monoxide formed by the pyrolysis of a mixture of acetaldehyde and hydrogen chloride, and the amount of hydrogen chloride remaining in the mixture during the pyrolysis. The curve in the figure shows the total pressure rise. It may be seen that the total pressure increase is equal to the pressure of the methane formed as well as to that of carbon monoxide, and also that hydrogen chloride is not consumed during the pyrolysis, its amount remaining constant within 1%. No appreciable amount of hydrogen was detected by gas chromatographic analysis using a nitrogen carrier. These facts indicate that the stoichiometry of the pyrolysis of acetaldehyde,[13] i. e.,

$$CH_3CHO \rightarrow CH_4 + CO$$

13) C. N. Hinshelwood and W. K. Hutchson, *Proc. Roy. Soc.*, **A111**, 380 (1929); C. J. M. Fletcher and C. N. Hinshelwood, ibid., **A141**, 41 (1933); C. A. Winkler and C. N. Hinshelwood, ibid., **A149**, 355 (1935); R. V. Seddon and M. W. Travers, ibid., **A156**, 234 (1936); E. Leifer and H. C. Urey, *J. Am. Chem. Soc.*, **64**, 994 (1942).

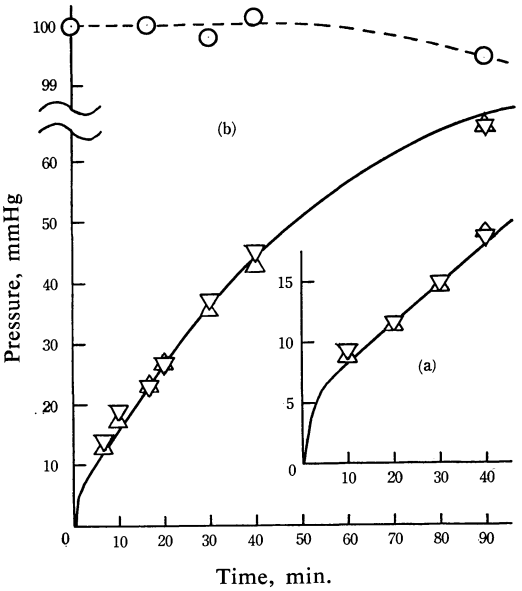

Fig. 1. Pyrolysis of acetaldehyde in the presence of hydrogen chloride.
(a) 401°C; $CH_3CHO$: 100 mmHg; HCl: 50 mmHg
(b) 423°C; $CH_3CHO$: 100 mmHg; HCl: 100 mmHg
▽, $CH_4$; △, CO; ○, HCl. Solid line represents total pressure rise.

is not affected by the presence of hydrogen chloride. Similar results had been obtained in previous studies with hydrogen sulfide[4] and methanethiol[8].

Figure 1 also shows that, at the beginning of the pyrolysis, the rate of decomposition is abnormally higher than in the following period. This initial period with a high rate is fairly long with a fresh vessel, but it is shortened with a "seasoned" one. The phenomenon may be attributed to a chain initiation on the wall, which is poisoned by the progress of pyrolysis or inactivated by seasoning.

Figure 2 shows the dependence of the decomposition rate on hydrogen chloride pressure in the decomposition of 100 mmHg acetaldehyde in the range of temperature from 401 to 433°C. The rate increases with the hydrogen chloride pressure until it attains a constant value, which is about seven times the rate in the absence of hydrogen chloride. This ratio of about seven compares with that of about ten previously found for dimethyl ether decomposition catalyzed by hydrogen chloride[2] and by hydrogen sulfide.[6]

Figure 3 shows the relations between the pressure of acetaldehyde and the rate of decomposition in the presence of 100 mmHg of hydrogen chloride at 401 and 423°C.

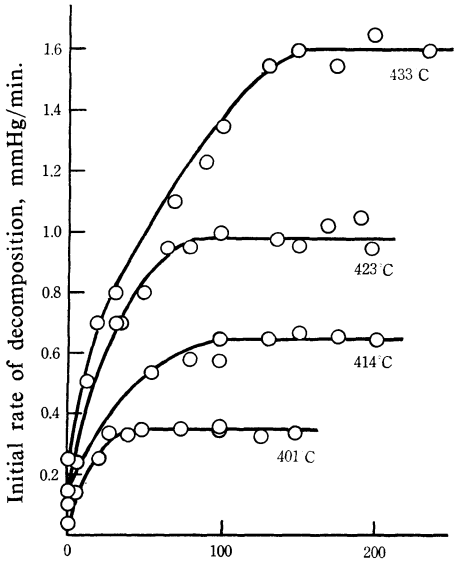

Fig. 2. Dependence of the rate of decomposition on hydrogen chloride pressure.
$CH_3CHO$ : 100 mmHg

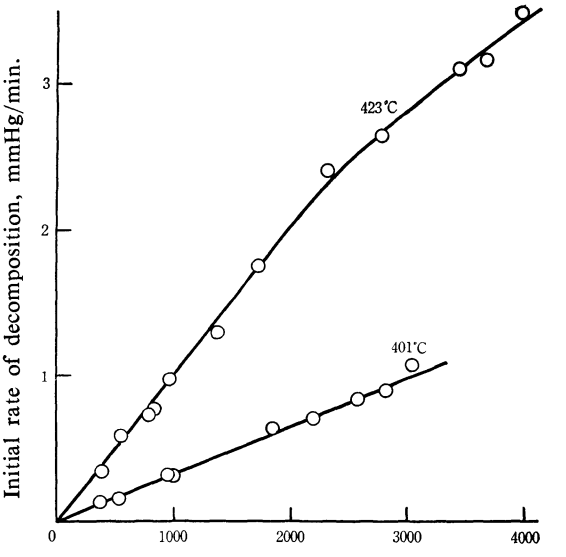

Fig. 3. Dependence of the rate of decomposition on acetaldehyde pressure.
HCl : 100 mmHg

Figures 2 and 3 indicate that the reaction is of the 3/2 order in the aldehyde and is independent of hydrogen chloride when the ratio of the hydrogen chloride pressure to that of the aldehyde is sufficiently high.

## Discussion

A probable reaction scheme that explains the 3/2 order kinetics given above may be presented as follows:

$$CH_3CHO + M \rightarrow CH_3 + CHO + M \quad (1)$$

$$CHO \rightarrow CO + H \quad (2)$$

$$H + HCl \rightarrow H_2 + Cl \quad (3)$$

$$CH_3 + HCl \rightarrow CH_4 + Cl \quad (4)$$

$$Cl + CH_3CHO \rightarrow HCl + CH_3CO \quad (5)$$

$$CH_3CO \rightarrow CH_3 + CO \quad (6)$$

$$Cl + Cl + M \rightarrow Cl_2 + M \quad (7)$$

Applying a steady-state treatment to this scheme, one obtains:

$$-d[CH_3CHO]/dt = k_1^{1/2}k_5k_7^{-1/2}[CH_3CHO]^{3/2} \quad (I)$$

which is in agreement with the experimental results.

Since the chain-propagating steps are reactions 4, 5 and 6, the steady-state condition requires that:

$$k_4[CH_3][HCl] = k_5[Cl][CH_3CHO] \quad (II)$$

or

$$\frac{[Cl]}{[CH_3]} = \frac{k_4[HCl]}{k_5[CH_3CHO]} \quad (III)$$

If the right hand side of Eq. III is very large, the concentration of chlorine atoms is much higher than that of methyl radicals and the chain terminates solely by reaction 7, as is assumed in the above scheme. On the contrary, when the right hand side of Eq. III is small, or when the concentration of methyl radicals is large, the combination of methyl radicals or that of methyl radicals and chlorine atoms will be important in chain termination. The rate then should be smaller than that which can be expected from Eq. I. Thus it is explained why the plots deviate from the straight lines in Figs. 2 and 3 when the relative amount of hydrogen chloride is low. The difference in activation energies $E_4-E_5$ is negative, as may be seen in the expressions of rate constants cited above. This explains the fact that the higher the temperature, the greater is the [HCl]/[$CH_3CHO$] ratio at which Eq. I begins to be applicable, as may be seen in Figs. 2 and 3.

The chain-initiation step given above (reaction 1) is represented as a second-order process. The order of such a chain-initiation step, together with those for the chain termination and decomposition of intermediate radicals, has been discussed by a number of workers. The overall order of the present catalyzed decomposition depends upon the orders of these elementary steps; various possibilities,

| | $\mu\beta'$ | $[A][M]^{1/2}$ | $[A][M]$ | $[A]$ | $[A][M]^{1/2}$ |
| | $\beta\beta$ | $[A]^{1/2}[B][M]^{1/2}$ | | $[A]^{1/2}[B]$ | |
| | $\beta\beta'$ | $[A][B]^{1/2}[M]^{1/2}$ | | $[A][B]^{1/2}$ | |
| | $\beta'\beta'$ | $[A]^{3/2}[M]^{1/2}$ | | $[A]^{3/2}$ | |

as worked out by Goldfinger, Letort and Niclause,[14] are listed in Table I. Here, following the original terminology of Goldfinger et al., $\mu$ denotes a chain-propagating radical that decomposes ($CH_3CO$ in the present case); $\beta$, a chain-propagating atom or radical in the uncatalyzed decomposition that does not decompose further ($CH_3$); and $\beta'$, such an atom or radical formed by hydrogen abstraction from a catalyst molecule by a $\beta$-radical (Cl). A refers to the reactant to be decomposed ($CH_3CHO$); B to the catalyst (HCl), and M to a third body ($CH_3CHO$ and HCl). Since in the case of $\mu\mu$ termination the rate is not enhanced by the presence of a catalyst except by its effect as a third body, this case is omitted in Table I.

The rate expression that best conforms to the experimental results is obviously $[A]^{3/2}$, derived from the $\beta'\beta'$ termination, but $[A][M]^{1/2}$, resulting from the $\mu\beta'$ termination, might as well explain the result when $[M]\approx[A]$. However, the results obtained show that the $[A]^{3/2}$ kinetics does not hold when the ratio [B]/[A] is low, and, moreover, that the $\mu$-radical, i.e., the acetyl radical, is so unstable[15] above 400°C that its participation in the termination may be ruled out.

Table I shows that the overall rate proportional to $[A]^{3/2}$ is given by either of two different combinations of initiation and termination processes. However, the one involving a second-order termination is improbable, since the $\beta'$-radicals are here chlorine atoms. The reaction sequence 1 to 7 thus seems to be the most probable one to explain the 3/2 order kinetics.

The second-order initiation step as given in reaction 1 is further supported by the work of Trenwith,[16] who, in the pyrolysis of acetaldehyde alone, has found a rate of the formation of hydrogen proportional to the square of acetaldehyde pressure.[17]

Table II shows the values of $k_1^{1/2}k_5k_7^{-1/2}$ in Eq. I as determined from the constant values

TABLE II. VALUES OF $k_1^{1/2}k_5k_7^{-1/2}$

| Temp. °C | $k_1^{1/2}k_5k_7^{-1/2}$ ($mol^{-1/2}\,cc^{1/2}\,sec^{-1}$) from Fig. 2 | from Fig. 3 |
|---|---|---|
| 401 | 0.0376 | 0.0363 |
| 414 | 0.071 | |
| 423 | 0.099 | 0.101 |
| 433 | 0.172 | |

of the rates in Fig. 2 and from the slopes of the straight lines in Fig. 3. The values obtained by the two different methods agree within the range of experimental error. The Arrhenius expression obtained from Table II is:

$$k_1^{1/2}k_5k_7^{-1/2}=10^{13.0}\exp(-44000/RT)$$

$$mol^{-1/2}\,cc^{1/2}\,sec^{-1}$$

14) P. Goldfinger, M. Letort and M. Niclause, Volume Commémoratif Victor Henri: "Contribution à l'Etude de la Structure Moléculaire," Liège: Desoer (1948), p. 283.

15) C. A. McDowell and J. H. Thomas, *J. Chem. Soc.*, **1949**, 2217.

16) A. B. Trenwith, ibid., **1963**, 4426.

17) The hydrogen sulfide-catalyzed pyrolysis of acetaldehyde was previously explained with a reaction scheme involving a first order initiation step, $CH_3CHO \rightarrow CH_3+CHO$. In view of the present work and that of Trenwith, it seems preferable to replace this first order initiation by the second order process given in reaction 1. This replacement causes no changes in the other arguments, if the chain termination $CH_3+CH_3 \rightarrow C_2H_6$, at the same time, is replaced by a third order process.

Combining $k_1 = 10^{20} \exp(-73800/RT)$ $mol^{-1}$ cc. $sec^{-1}$ as reported by Trenwith[16] with $k_5 = 10^{13.3}\exp(-5000/RT)$ $mol^{-1}$ cc. $sec^{-1}$ [11] and $k_7 = 10^{17.4}$ $mol^{-2}$ $cc^2$ $sec^{-1}$,[18] one obtains:

$$k_1^{1/2}k_5k_7^{-1/2} = 10^{14.4}\exp(-41900/RT)$$
$$mol^{-1/2}\ cc^{1/2}\ sec^{-1}$$

which is in good agreement with the experimental expression given above.

## Summary

The thermal decomposition of acetaldehyde in the presence of hydrogen chloride has been investigated over the temperature range from 401 to 433°C. Hydrogen chloride, though it is not consumed, enhances the rate of decomposition to carbon monoxide and methane, thus acting as a catalyst. The rate law which holds when the [HCl]/[$CH_3CHO$] ratio is sufficiently high is the same as that which holds in the absence of hydrogen chloride, being represented as $k[CH_3CHO]^{3/2}$ independent of the hydrogen chloride pressure. The most probable reaction scheme for explaining this rate law is $CH_3CHO + M \rightarrow CH_3 + CHO + M$ (1), $CHO \rightarrow CO + H$ (2), $H + HCl \rightarrow H_2 + Cl$ (3), $CH_3 + HCl \rightarrow CH_4 + Cl$ (4), $Cl + CH_3CHO \rightarrow HCl + CH_3CO$ (5), $CH_3CO \rightarrow CH_3 + CO$ (6), and $Cl + Cl + M \rightarrow Cl_2 + M$ (7), yielding the overall rate $k_1^{1/2}k_5k_7^{-1/2}[CH_3CHO]^{3/2}$. The Arrhenius expression obtained from the experimental results, $k_1^{1/2}k_5k_7^{-1/2} = 10^{13.0}\exp(-44000/RT)$ $mol^{-1/2}$ $cc^{1/2}$ $sec^{-1}$, is in harmony with those for $k_1$, $k_5$, and $k_7$ available in the literature.

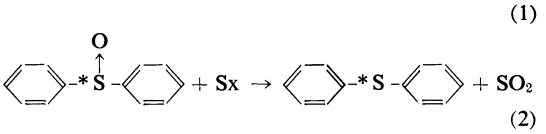
# The Reaction of Elemental Sulfur with Organic Compounds. II. The Reaction of Dibenzyl Sulfide, Sulfoxide and Sulfone, and Their Related Dibenzyl Compounds[1)]

By Waichiro TAGAKI, Sadanori KISO and Shigeru OAE



(Received August 4, 1964)

For many years, the reactions of elemental sulfur with organic compounds at elevated temperatures have been a subject of extensive investigation.[2)] Aromatization, vulcanization and Wilgerodt reactions are only a few of many well-known applications of these reactions. However, many of the mechanistic features of these reactions are yet to be clarified. For example, even in simple reactions of sulfur with olefins, it is not certain whether the reaction proceeds through the heterolytic or the homolytic pathway. Nor do we know whether the reaction is initiated by the abstraction of hydrogen or by the addition of sulfur to the double bond.[2c)]

Many years ago, the reaction of diphenyl sulfone with sulfur was found to give diphenyl sulfide and sulfur dioxide.[3)] Recently, we have investigated the mechanism of this reaction using a $^{35}S$-labeled compound.[1a)] As is illustrated in Eq. 1, the apparent reduction of the S–O bond was found actually to involve the cleavage of the phenyl-S bond and the replacement of the $SO_2$ group by sulfur to the extent of 70—80%:

Meanwhile we have found that the corresponding diphenyl sulfoxide is also reduced to diphenyl sulfide. In this case, however, the reaction is a straightforward reduction of the SO group, involving the cleavage of the S–O bond, as is shown in Eq. 2. These different paths were ascribed to the weaker bond strength of the S–O bond in sulfoxide than in sulfone. We now turn our attention to the problem of how the reaction proceeds when a methylene group is inserted between a benzene ring and a sulfur group, i. e., the reaction with a benzylic compound. Here the reaction depends on the relative importance of hydrogen abstraction and of the cleavage of either the C–S or S–O bond, or both.

Therefore, we have investigated the reactions of sulfur with dibenzyl sulfide, sulfoxide, sulfone, ether and ketone, and this paper will present a detailed account of the investigation.

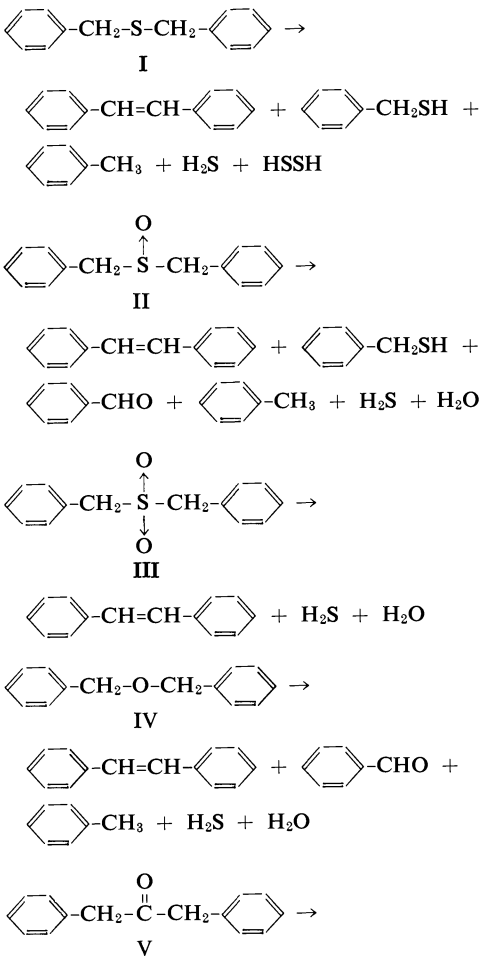
## Results and Discussion

The reaction was carried out by heating a mixture of starting compounds and elemental sulfur under a slow stream of nitrogen gas. The evolution of hydrogen sulfide usually started at around 160°C, and the reaction temperature was maintained near 200°C, substantially lower than that used in the reactions of diphenyl sulfoxide and sulfone (~300°C[1a]). An important though unexpected result was the failure to detect any sulfur dioxide which had been evolved quantitatively in the reactions of diphenyl sulfoxide and sulfone.[1a] In place of sulfur dioxide, a few drops of water were usually observed in all of the oxygen compounds except for dibenzyl ketone. The oily and solid products were separated into pure forms by a combination of gas-, thin-layer-, and column chromatographies and were identified by means of spectroscopic and elemental analyses. The results are shown in Table I and Chart 1.

**The Products from Dibenzyl Sulfoxide.**—Dibenzyl sulfoxide seems to undergo all the possible reactions conceivable for the compound, i. e., hydrogen abstraction, rearrangement, elimination and cleavage reaction. Therefore, a detailed discussion of the reactions of this compound would be most fruitful, for the reactions of the other compounds can then be discussed by referring to their differences from those of dibenzyl sulfoxide.

As is shown in Table I, the reaction products of dibenzyl sulfoxide were hydrogen sulfide (trapped as lead sulfide) (37.2%), oils (38%), solids (39%) and a small amount of water.

Since sulfur is known to yield a sulfur free radical at above 150°C, it is reasonable to consider that the initial step of this reaction involves the formation of the sulfoxide free radical, II-3, by the abstraction of benzylic hydrogen by the sulfur free radical, as Eq. 3 illustrates. The radical, II-3, would then undergo a variety of reactions.



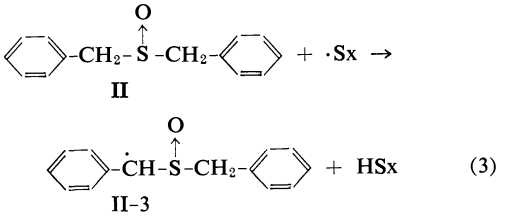


Chart 1. Species of the reaction products.

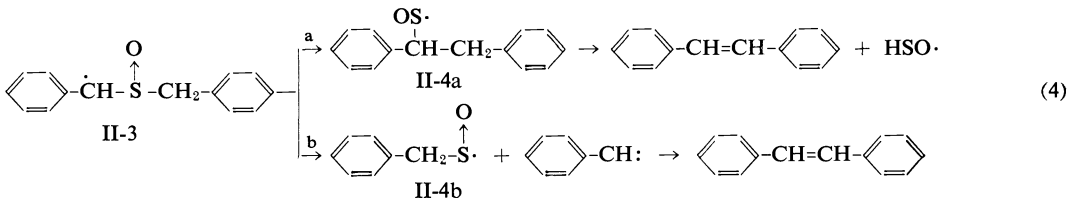

The major portion of the solid product (obtained in a 39% yield) was found to be stilbene. Two possible pathways are conceivable for the formation of stilbene. One is through the rearrangement and elimination of II-3, as is shown in Eq. 4a, and the other is via the

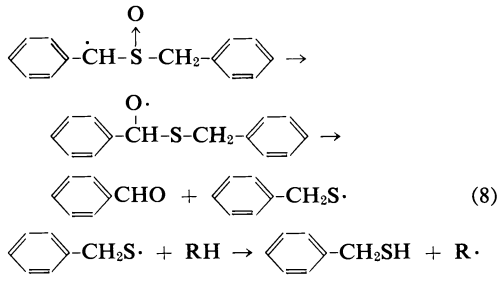
(4)

carbene intermediate, as is illustrated in Eq. 4b. The pathway 4a is a rearrangement involving the C–S bond cleavage of II-3, as in the formation of benzaldehyde, where sulfoxide S–O bond cleavage takes place as is postulated below (Eq. 8). The carbene intermediate leading to stilbene was also postulated in the base-catalyzed carbanion reaction of sulfonyl[4] and sulfonium compounds.[5]

Although there is no conclusive evidence for making any particular choice between these two pathways, we favor the former path, 4a, for the following reasons. A free radical of the Ar–S–O· type has been said to be very stable[6] and has been known to undergo disproportionation to give the corresponding thiolsulfonate.[7] Since the free radical, II-4b, is isoelectronic with Ar–SO·, it would give the thiolsulfonate. However, no such product was detected in the present reaction. Moreover, it also seems difficult for the carbene pathway to account for the reactions of the dibenzyl sulfide and the ether, as will be discussed later.

The oily product (38%) was found to be a mixture of toluene, benzaldehyde and benzyl mercaptan in a ratio of 1 : 8 : 13. The formation of toluene can be explained either by the decomposition of II-3 (Eq. 5—6) or by the direct homolysis of the C–S bond of the starting sulfoxide (Eq. 7), although the latter pathway is rather unlikely. The formation of

(5)



(6)

(7)

benzaldehyde and benzyl mercaptan can be readily explained by assuming an intramolecular migration of sulfoxide oxygen to the benzylic carbon, followed by the homolytic

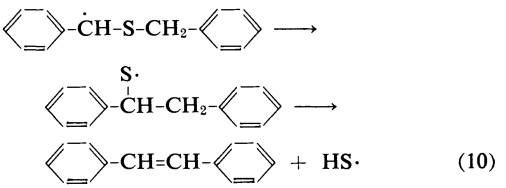
cleavage of the C–S bond, as is shown in Eqs. 8 and 9. The relative importance of these reactions (Eqs. 4—9) will be discussed in a later section.

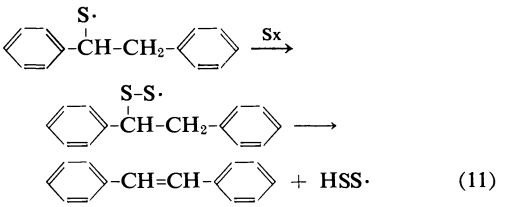
(8)

(9)



A small amount of water seems to be formed by the reduction with hydrogen sulfide, although it is not clear whether the compound to be reduced is the starting sulfoxide or one of the oxygen-containing intermediates shown in the foregoing equations. Related is the finding by Toland and his co-workers that a carboxylic acid or a nitrile is reduced to a hydrocarbon with hydrogen sulfide.[8]

The yield of the residual solid in the reaction flask was 27.8%, based on the original weight of the reactants. Alumina column chromatography and infrared analyses showed that this was mainly composed of elemental sulfur and the starting sulfoxide, and that there was no detectable amount of the other products which could be expected if species such as $C_6H_5CH_2SO$ and $C_6H_5CH{=}SO$ were the real intermediates.

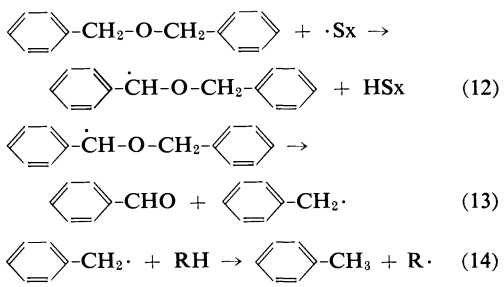


**The Products from the Other Dibenzyl Compounds.**—The mechanism of the reactions with the other compounds appear to be essentially similar to those with dibenzyl sulfoxide, i. e., the initial abstraction of hydrogen by a sulfur-free radical, followed by several competing reactions of the resulting free radicals. The relative importance of such competing reactions, however, varies depending on the nature of the dibenzyl compounds.

The products from the reaction with dibenzyl sulfide were hydrogen sulfide (39.3%), hydrogen persulfide, toluene, benzyl mercaptan and stilbene (41.5%). The formation of toluene, in an amount about equal to that of benzyl mercaptan, suggests three pathways; one is the direct splitting of the C–S bond, such as in Eq. 7, while the others are decompositions of the initially-formed free radical, such as in Eqs 5 and 4b. The direct splitting, however, seems unlikely, and the carbene pathway also fails to account for the yield of toluene, which should be smaller than that of benzyl mercaptan since the carbene would readily dimerize to stilbene. The pathway similar to Eq. 5 would, however, predict the formation of benzthioaldehyde. A related reaction to form benzaldehyde was actually observed in the reaction of dibenzyl ether, as will be described below. However, in the reaction of dibenzyl sulfide, infrared and gas chromatographic analyses failed to detect the formation of such thioaldehyde. Probably thioaldehyde, even when formed, was readily reduced to the corresponding mercaptan by hydrogen sulfide.

An interesting observation was the formation of hydrogen persulfide. The reaction leading to this product seems to be unique only to dibenzyl sulfide, since hydrogen persulfide was not detected in the reactions of the other dibenzyl compounds. Probably the following reactions, 10 and 11, are competing in the formation of stilbene:

(10)



(11)

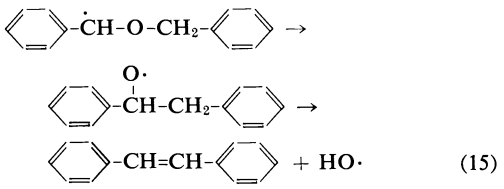
The products of dibenzyl sulfone were hydrogen sulfide (32%), stilbene (68%) and a small amount of water. Although the reaction was carried out several times, in no case was the evolution of sulfur dioxide detected. This observation seems strange when one recalls the quantitative formation of sulfur dioxide in the reaction of diphenyl sulfone.[1a] In this connection, it is interesting to compare the relative yields of lead sulfide and stilbene obtained from the three dibenzyl sulfur compounds. In the case of both sulfide and the sulfoxide, the yields of the two compounds were nearly the same, while the yield of lead sulfide from the reaction with the sulfone was about half of that of stilbene. The formation of water and no evolution of sulfur dioxide undoubtedly indicate that hydrogen sulfide was used for the reduction of the $SO_2$ group.

The major products in the case of dibenzyl ether were hydrogen sulfide (10.2%), benzaldehyde, toluene (60%), stilbene (14.4%), and a small amount of water. The formation of

8) W. G. Toland and R. W. Campbell, *J. Org. Chem.*, **28**, 3124 (1963).

toluene and benzaldehyde can be readily explained by means of Eqs. 12—14, which indicate the initial formation of a free radical, followed by its decomposition. As is illustrated

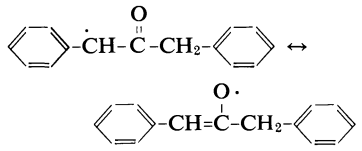
(12)



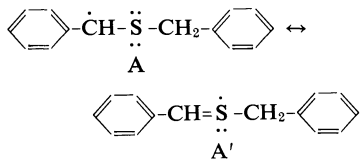
(13)

(14)

in Eqs. 7 and 4b, if the reaction is initiated by the direct splitting of the C–O bond or by the decomposition of the initially-formed free radical to give carbene, we might expect the formation of benzyl alcohol. However, the formation of benzyl alcohol was not detected by infrared and gas chromatographic analyses. These observations, together with the formation of a small amount of water, strongly indicate that the reaction to form stilbene proceeds through the pathway shown in Eq. 15:



(15)



A remarkable feature of the reaction of dibenzyl ketone was the high yield of hydrogen sulfide (72.7%) as compared with the yields of less than 40% for the other compounds. This implies fewer fragmentation products, such as toluene and ketone, than would be expected if reactions of the type shown in Eqs. 5—6 or in Eqs. 12—14 took place. Actually, infrared spectra and alumina column chromatography failed to detect any fragmentation products except for the starting ketone and unidentified polyketones. These observations suggest that the initially-formed free radical is so stable that it undergoes dimerization or polymerization with less fragmentation than in the case of the other compounds.

**General Remarks.** — As has been described above, all these reactions appear to be initiated by the abstraction of benzylic hydrogen by the sulfur free radical. For the present five dibenzyl compounds, the total yield of stilbene plus fragmentation products (the yield of lead sulfide in the case of dibenzyl ketone) amounts to about 70%: i. e., all the compounds appear to undergo a facile abstraction of hydrogen. This is undoubtedly due to the very active nature of the benzylic hydrogen atom. For compounds having less active hydrogen, the reaction somewhat different from those of the dibenzyl compounds. Our preliminary experiments on the reactions of di-*n*-butyl sulfide, sulfoxide and sulfone indicate that these compounds undergo hydrogen abstruction to a much lesser extent than do the dibenzyl compounds under similar reaction conditions.[9] Extreme are the cases of the reaction of diphenyl sulfoxide and sulfone,[1a] as has been described before. The fate of the initially-formed free radical depends on its stability and also on the relative ease of the bond breakings of C–C, C–S, C–O and S–O linkages.

The following resonance stabilization of the initial free radical seems to be responsible for the apparent lack of fragmentation in the reaction with dibenzyl ketone. The dependence of the fragmentation reaction on the stability

of the initial free radical seems also to be manifested in the reactions of dibenzyl sulfide and ether. The free radical of the sulfide (A) can be stabilized by the 3d-orbital resonance of sulfur (A′) as well as by the resonance

stabilization by the phenyl ring, whereas such stabilization is impossible in the ether. This difference seems to be partly responsible for the higher yield of stilbene from the sulfide than from the ether and for the higher yield of fragmentation products from the ether than from the sulfide.

The same view can be derived from the reaction of benzyl cyanide. Recently, Mayer and Scheithauer found that the reaction of benzyl cyanide with sulfur above 175°C gave hydrogen sulfide and *trans*-dicyanostilbene as the major products and a small amount of 1, 2-dicyanodiphenylethane.[10] Although no mechanistic interpretation has been made, the reaction seems to be initiated by the abstraction of benzylic hydrogen by the sulfur free radical, and the initially-formed free radical

9) Unpublished work of these laboratories.
10) R. Mayer and St. Scheithauer, *J. Prakt. Chem.*, **21**, 214 (1963).

seems to be so stable that it readily dimerizes to give 1,2-dicyanodiphenylethane, which is then transformed to dicyanostilbene.

Although it is not easy to compare the relative ease of the bond breakings of C–C, C–O and C–S bonds from the product analyses, the product distribution can often serve as a measure for the comparison of some particular bonds. A good example is the case of the S–O bond in sulfoxide and sulfone. The formation of benzaldehyde and benzyl mercaptan clearly indicates the S–O bond breaking in dibenzyl sulfoxide, while no such bond breaking was detected in the corresponding sulfone except for the formation of water. In the reactions of di-*n*-butyl sulfoxide and sulfone, the S–O bond breaking in the former compound resulted in the formation of di-*n*-butyl sulfide, while no such reaction was observed with the latter compounds.[9] The most clear-cut case is the comparison between those of diphenyl sulfoxide and the sulfone.[1] In all these cases, the S–O bonds in the sulfoxides are found to be much weaker than those of the corresponding sulfones and to be readily cleaved, as had been predicted.[11]

## Experimental

**The Synthesis of the Starting Compounds.**—Dibenzyl sulfide was prepared by the reaction of benzyl chloride with sodium sulfide; m. p. 49°C (lit., 49°C),[12] recrystallized from 70% aqueous ethanol. Dibenzyl sulfoxide was prepared by the oxidation of the sulfide with hydrogen peroxide in acetic acid, m. p. 136—137°C (lit., 132—133°C),[12] recrystallized from *n*-hexane. Dibenzyl sulfone was prepared by the chromic acid oxidation of the sulfide in acetic acid, m. p. 150—151°C (lit., 149.5—150°C),[12] recrystallized from *n*-hexane-benzene.

Dibenzyl ether was prepared by the reaction of benzyl chloride with sodium benzyl alkoxide in dioxane, m. p. 148°C/6 mmHg (lit., 170°C/16 mmHg).[13]

Dibenzyl ketone was prepared by the reaction of benzylcyanide with benzyl magnesium chloride in anhydrous ether, followed by the decomposition of the resulting imino complex with water; m. p. 34—35°C (lit., 35°C),[14] recrystallized from *n*-hexane.

**General Procedure for the Reaction with Elemental Sulfur.** — The reaction apparatus (Fig. 1) was essentially the same as that employed in the previous reactions of diphenyl sulfoxide and sulfone, but here modified to trap volatile products and hydrogen sulfide.

Equimolecular amounts of the starting compound

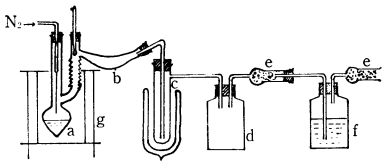


Fig. 1

a, Reaction flask; b, trap for solid or oils; c, trap for volatile oils; d, empty bottle; e, calcium chloride drying tube; f, trap for hydrogen sulfide containing lead acetate.

and sulfur were thoroughly mixed and placed in a Säbel-type flask with a short fractionating column (a) (in Fig. 1). The whole system was first flushed with nitrogen gas at room temperature for about 10 min. The reaction flask was then heated in an air bath (g) under a slow stream of nitrogen. At around 160°C, the evolution of hydrogen sulfide was usually observed. After the temperature had been slowly raised to about 200°C, this temperature was maintained for five to nine hours. The oily or solid product was trapped in (b) (in Fig. 1), the volatile product was trapped in (c) (in Fig. 1), which was cooled in a dry ice-acetone bath (below −50°C), and the hydrogen sulfide was trapped in a vessel as lead sulfide. After the evolution of hydrogen sulfide was no longer observed, the substance which remained in the reaction flask (a) (Fig. 1) was vacuum-distilled. The oily and solid products thus obtained were purified by a combination of gas-liquid and column elution chromatographies and identified by spectroscopy and by elemental analysis. At least three runs were carried out for each compound in order to (test the reproducibility). A typical run with dibenzyl sulfide is described in the next paragraph. Table I gives one representative run for each compound.

**The Reaction of Dibenzyl Sulfide.** — After the reaction had been completed, the hydrogen sulfide trapped as lead sulfide was filtered, washed with water, dried and weighed; it was found to amount to 472 mg. (39.3%). A volatile product in the trap c, was found to be a mixture of hydrogen persulfide and a very small fraction of benzylmercaptan plus toluene as two immiscible liquids. This mixture was mechanically separated from hydrogen persulfide with a syringe and analyzed by gas chromatography and infrared spectrometry. The gas chromatography was carried out using a high-vacuum silicone column and hydrogen carrier gas, at the column temperature of 88.5°C. The retention times of toluene and benzyl mercaptan were 5.2 and 40 min. respectively, and no other component was detected. The oils in trap b were also found to be a mixture of toluene and benzyl mercaptan by infrared and gas chromatographic analyses; the yield was 291 mg. (27.2%). The hydrogen persulfide was identified by its boiling point 73—74°C (lit., 74.5°C and its ultraviolet spectra ($\lambda_{max}$, 261, 268 m$\mu$ in EtOH).

After the mixture of toluene and benzyl mercaptan had been removed from the trap b, the brown residue in the reaction flask was vacuum-distilled to give a pale yellow solid, which was found to be

14) H. Adkins, R. M. Elofson, A. G. Rossow and C. C. Robinson, *J. Am. Chem. Soc.*, **71**, 3629 (1949).

mainly composed of stilbene. The analysis was first made by alumina thin-layer chromatography, using *n*-hexane as the developing solvent. The chromatogram after iodine coloration showed a main spot of stilbene and three other small faint spots. The alumina elution chromatography was carried out using a *n*-hexane-benzene (7 : 3 v/v) mixture as the developing solvent. Over 90% of the eluted fractions was found to be stilbene on the basis of their having the same melting point and the same infrared spectra as those of authentic stilbene. The fractions corresponding to the small spots on the thin-layer chromatogram were not detected by this column chromatography.

The dark brown residue in the reaction flask amounted to 198 mg., and its infrared spectra were found to be almost identical with those of the starting sulfide. This residue was probably composed of the starting sulfide, elemental sulfur and small amounts of unknown products.

**The Reaction of Dibenzyl Sulfoxide.**—Three runs were performed. In each case, the attempt to detect $SO_2$ failed. Hydrogen sulfide was obtained as lead sulfide, as has been described before. The oily product was found to be composed of toluene, benzaldehyde and benzyl mercaptan by infrared spectra and gas chromatography, which was carried out under conditions similar to those described above. The retention times of toluene, benzaldehyde and benzyl mercaptan at 85°C were 5.4, 24.2 and 45.6 min. respectively. The infrared spectra of the oil showed a strong band at 1730 $cm^{-1}$ due to benzaldehyde. The identification of benzaldehyde was also made converting it to the 2,4-dinitrophenylhydrazone m. p. 238—239°C (mixed melting point, 237—239°C). The solid product, m. p. 117—120°C was analyzed by alumina column chromatography to give stilbene as the major fraction and a trace of a yellow solid. Stilbene was identified by the infrared spectra, elemental analysis and a mixed melting point determination with an authentic sample :

Found : C, 92.65 ; H, 6.85. Calcd. : C, 93.33 ; H, 6.60%.

The above unknown yellow solid showed the following properties ; m. p. 116—119°C.

Found : C, 49.65 ; H, 4.45%.

A small amount of white crystals gradually adhered on the inner walls of the trap c as the reaction proceeded. This melts near 0°C and is miscible with water. The presence of the O-H band in the infrared spectra of the non-dried oily product (in the trap b) and the indication of water on the gas chromatogram of the same oily product indicated that the product in the trap c was water.

The identification of the black residue in the reaction flask was attempted. The infrared spectrum was very similar to the starting sulfoxide. This residue was probably mainly composed of the starting sulfoxide and elemental sulfur.

**The Products of the Other Compounds.** — The reaction conditions and the yields of the products are shown in Table I. The analytical methods were essentially the same as those described above.

# Surface Chemistry of the Polyamide Series. I. Effect of Hydrogen Bonding on the Nature of Poly-$\alpha$-amino Acid Monolayers

By Takuya YAMASHITA* and Toshizo ISEMURA

(Received August 5, 1964)

The conformation of protein is maintained mainly by the hydrogen bonding between $\rangle C{=}O$ and $H{-}N\langle$ groups of the peptide linkages. In this connection, the monolayers of poly-$\alpha$-amino acids, or polypeptides as model substances of protein, have been studied by many workers.[1-11] It has been found[8,9] that the monolayers of poly-$\alpha$-amino acids with nonionic side chains are condensed and that their surface viscosities appear at larger areas than the crose-packed areas when they are spread at the air/water interface. This finding has been interpreted by assuming that the polypeptide chain is rigid as a result of the

hydrogen bonding between the peptide linkages of backbones. They are spread in a $\beta$-configration. On the other hand, the monolayers of prolyl polypeptides are of the expanded type and the appreciable surface viscosities are manifested at much smaller areas than their close-packed areas.[8,9] Their chain configurations have been considered to be flexible as a result of the weak interaction due to the decrease in the number of hydrogen bonds between peptide groups. Thus, the hydrogen bonds between $\rangle C{=}O$ and $H{-}N\langle$ groups of peptide linkages are important for understanding the nature of the monolayers of polypeptides, or proteins. Further, such a hydrogen bonding is assumed to play a major role in the stability of the configuration of polyamides of the nylon type.[11] The monolayers of nylons have been studied by some workers,[1,2,4,12-15] but the effect of the number of $CH_2$ groups on polyamide monolayers has never been investigated.

In the studies of this series, the effect of hydrogen bonding on the nature of the monolayers of poly-$\alpha$-amino acids and polyamides of the nylon type have been studied at the air/water and oil/water interfaces in order to elucidate the role of hydrogen bonding in the configurations of the polymers and proteins.

It appears that sarcosyl polypeptides are suitable for the present study, because the sarcosyl residue (that is, the *N*-methyl glycyl residue) cannot form a hydrogen bond with a carbonyl group of another residue, as in the case of the prolyl residue, because it lacks a hydrogen atom to be hydrogen-bonded. Accordingly, in the present work, the effect of hydrogen bonding on the polypeptide monolayers has been studied at the air/water and oil/water interfaces with polysarcosine, copoly-1 : 1-(glycine, sarcosine) and copoly-1 : 1-(DL-alanine, sarcosine). For the sake of comparison, the monolayers of poly-L-alanine and poly-DL-alanine have also been studied. Further, poly-$\alpha$-aminoisobutyric acid has been studied in order to investigate the steric hindrance to the hydrogen bond formation.

## Experimental

**Samples.**—The samples used in the present study were prepared by the polymerization or copolymerization of the *N*-carboxyanhydrides of the corresponding amino acids, using sodium methoxide as an initiator, according to the usual method.[16] The average degree of polymerization was determined by end-group analysis. Poly-DL-alanine ($n$=40), polysarcosine ($n$=27), copoly-1 : 1-(glycine, sarcosine) ($n$=33) and copoly-1 : 1-(DL-alanine, sarcosine) ($n$=40) were spread from solutions in a mixed solvent, water-isopropyl alcohol (1 : 1, v/v). The spreading solvents for poly-L-alanine and poly-$\alpha$-aminoisobutyric acid were trifluoroacetic acid and a mixture of dichloroacetic acid and benzene (3 : 7, v/v) respectively.

**Methods.**—At the air/water interface, the surface pressure was measured using surface balances of both the float and hanging-plate types. The trough used was made of polymethyl methacrylate, the rim of which was coated with purified paraffin.

The surface potential was measured by the ionizing air-electrode method, using polonium as a radiation source. The potential was detected by a Cary Model-31 vibrating reed electrometer. The accuracy was $\pm 3$ mV. The surface moment of the film, $\mu$, was calculated from the observed surface potential, $\Delta V$, utilizing the Helmholtz formula, $\mu = \Delta V A/4\pi$, where $A$ is the area per residue.

The surface viscosity was measured by the rotatory oscillation of a suspended disk on the surface of the liquid; it was calculated by the following formula;[17]

$$\eta_s = \Delta\lambda_{10}\frac{2.303\,I}{2\pi P}\left(\frac{1}{a^2}-\frac{1}{b^2}\right)$$

where $I$ is the moment of inertia of the disk; $P$, the period of oscillation; $\Delta\lambda_{10}$, the difference between logarithm decrements of oscillation in the presence of film and in its absence; $a$, the radius of the disk, and $b$, the radius of the film surrounding the oscillation disk. In the apparatus used in the present experiments, $I$ was 30.25 g. cm.; $P$, 13.06 sec.; $a$, 1.00 cm., and $b$, 4.00 cm.

The compression of the film at the air/water interface was started 20 minutes after the polymer was spread; the film was compressed at the rate of 12 $cm^2$/min.

At the oil/water interface, the interfacial pressure was measured by the ring method. The interfacial concentration of the polymer was changed by the successive injection method, corrected by the Thomas theoretical correction formula.[10,18,19] The diameter of the ring was 3.014 cm. Petroleum ether (b. p. 85—115°C) was used as an oil phase. The interfacial tension at the interface of petroleum ether and distilled water was 49.6 dyn./cm. at 23°C. The measurement of the interfacial pressure was carried out five minutes after each injection. It was ascertained that the interfacial pressure-area curve of polyvinyl acetate agrees closely with that reported by Hotta[13] at the oil/distilled water interface.

All the measurements were performed at room temperature. The change of temperature, however, never exceeded one degree during the course of an experiment.

## Results

The surface pressure-area ($\Pi$-$A$), the surface moment-area ($\mu$-$A$) and the surface viscosity-area ($\eta_s$-$A$) curves of poly-DL-alanine on distilled water are shown in Fig. 1. The $\Pi$-$A$ curve of poly-L-alanine is also represented in the same figure. The surface viscosity of poly-DL-alanine was first detected at the area where the surface pressure is sufficiently low. The area per residue of poly-DL-alanine was much smaller than that of poly-L-alanine.

The effects of sulfuric acid on the surface pressure and surface moment of poly-DL-alanine are shown in Fig. 2. On aqueous sulfuric acid, the film was expanded and an increase in surface moment was observed.

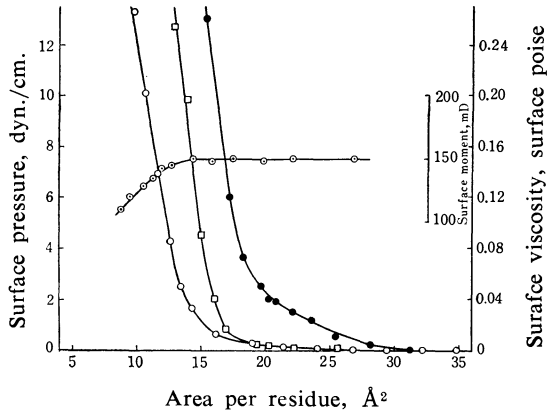

Fig. 1. Monolayers of poly-L-alanine and poly-DL-alanine on distilled water:
poly-L-alanine (15°C)—□, surface pressure
poly-DL-alanine (20°C)—○, surface pressure
⊙, surface moment; ●, surface viscosity.

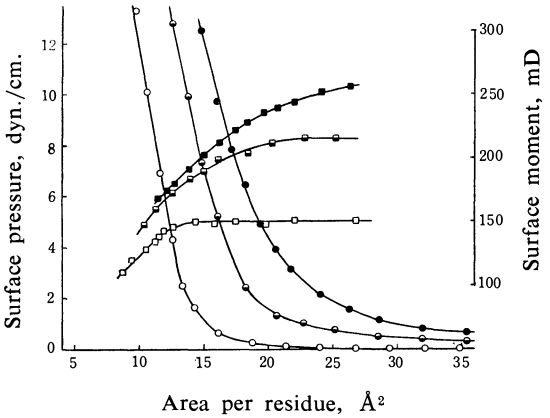

Fig. 2. Surface pressure-area and surface moment-area curves of poly-DL-alanine on distilled water (○, □) at 20°C and on the subsolutions of 3 N $H_2SO_4$ (◒, ◨) and 6 N $H_2SO_4$ (●, ■) at 20°C.

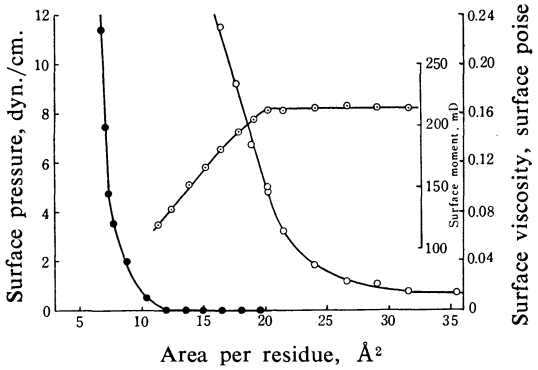

Fig. 3. Monolayer of poly-$\alpha$-aminoisobutyric acid on distilled water at 17°C: ○, surface pressure; ⊙, surface moment; ●, surface viscosity.

The $\Pi$-$A$, $\mu$-$A$ and $\eta_s$-$A$ curves of poly-$\alpha$-aminoisobutyric acid on distilled water are shown in Fig. 3. The film of this polypeptide is much more expanded than that of polyalanine on distilled water, and a higher surface moment was obtained. In contrast with polyalanine, the surface viscosity was found first at a small area where the surface pressure is markedly high.

Figure 4 shows the $\Pi$-$A$ and $\mu$-$A$ curves of copoly-1 : 1-(DL-alanine, sarcosine) on the 3 M potassium chloride solution. The film was of the expended type. The surface viscosity was not detected with our present apparatus because of its lower sensitivity. The surface moment was considerably lower than that of poly-DL-alanine. This might be caused by the partial dissolution of polymer chains in the aquous phase.

The film characteristics of the polymers described above are summarized in Table I, where $A_\delta$ is the area per residue at the minimum compressibility of the film; $A_{\Pi\to 0}$, the

area per residue where the straight portion of the $\Pi$-$A$ curve is extraporated to $\Pi=0$; $A_\mu$, the area per residue where the surface moment, $\mu$, begins to decrease; $\mu(c)$, the constant value of the surface moment, and $A_\eta$, the area per residue where the surface viscosity is first detected or begins to rise.

Although polysarcosine could not be spread as a monolayer at the air/water interface, even on the 3 M potassium chloride subsolution, because of its high solubility, a stable film was obtained at the oil/water interface. Figure 5 shows the interfacial pressure-area ($\Pi_i$-$A$) curves of polysarcosine, copoly-1 : 1-(glycine, sarcosine), and copoly-1 : 1-(DL-alanine, sarcosine), as well as that of poly-DL-alanine. The film of poly-DL-alanine was slightly expanded in a lower surface-pressure region, and above the pressure of 3 dyn./cm., the interfacial, pressure was nearly identical with the surface pressure in the same areas. The $\Pi_i$-$A$ curve of copoly-1 : 1-(DL-alanine, sarcosine) agreed fairly well with that of polysarcosine. Both films can be considerably expanded and compressible. Copoly-1 : 1-(glycine, sarcosine) also gave an expanded film, although the area per residue was much smaller than that of polysarcosine.

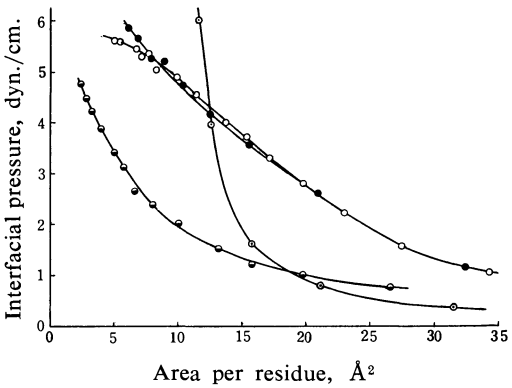

Fig. 5. Interfacial pressure-area curves of poly-DL-alanine (⊙), polysarcosine (○), copoly-1 : 1-(glycine, sarcosine) (◒) and copoly-1 : 1-(DL-alanine sarcosine) (●) at petroleum ether/distilled water interface (15°C).

## Discussion

**The Air/Water Interface.** — *Polyalanine on Disrilled Water.* — The films of poly-L-alanine and poly-DL-alanine on distilled water are of the condensed type. The $\pi$-$A$ curve of poly-DL-alanine is in good agreement with those reported by Isemura et al.[20] and by Glazer and Dogan,[21] and the $\mu$-$A$ curve, with Isemura and Ikeda's.[8] The surface viscosity of this polypeptide is first detected at a much larger area than its limiting area ($A_\delta$ or $A_{\Pi\to 0}$), as Fig. 1 and Table I show, and, accordingly, at the area where the surface pressure is sufficiently low. Similar results have been obtained by Ikeda and Isemura,[9] and by MacRitchie and Alexander.[22] Generally, a monolayer of the condensed type exibits such a suface viscosity-surface pressure relation.[9] In the monolayer of polyalanine, polypeptide chains are probably held together tightly, and the motion of residues or segments is strongly inhibited by the hydrogen bonding and by the partial double-bond nature of the peptide bonds.

It has been generally accepted[1-10] from the measurements of surface pressure, surface potential (or surface moment) and surface viscosity that on the aqueous sufaces poly-$\alpha$-amino acids with nonionic side chains are spread in a $\beta$-configuration, with an alternation of side chains up and down to the surface. The data shown in Table I suggest that such a configuration is also plausible for the monolayers of poly-L-alanine and poly-DL-alanine.

It has been found[3] that the area per residue of the film of poly-$\gamma$-benzyl-L-glutamate is much smaller than that of its DL-isomers.

20) T. Isemura, S. Ikeda, F. Tokiwa and J. Noguchi, This Bulletin, 34, 1236 (1961).
21) J. Glazer and M. Z. Dogan, *Trans. Faraday Soc.*, 49, 448 (1953).
22) F. MacRitchie and A. E. Alexander, *J. Colloid Sci.*, 16, 57 (1961).

Such a difference in area is to be ascribed to the much closer packing of L-polypeptide chains. On the contrary, poly-DL-alanine occupied a much smaller area in the film than poly-L-alanine. The $A_\delta$ value of the former is 13.2 Å$^2$ per residue, much smaller than the area calculated for the film in the $\beta$-form, (ca. 15 Å per residue), while that of the latter is 15.0 Å$^2$ per residue. As is well known, poly-DL-alanine is the only water-soluble polypeptide with nonpolar side chains, whereas poly-L-alanine is insoluble in almost all the solvents. Accordingly, the fact that the area of the film of poly-DL-alanine is smaller than that of its L-isomer may be ascribed to the greater solubility of the former film in the aqueous subphase. In the area, $A_\delta$, a part of the alanyl residues of the DL-isomer might be already submerged into the aqueous subphase, even though in a $\beta$-form. The size of the side chains of polyalanine is smallest in poly-$\alpha$-amino acids, and the van der Waals attractive force between side chains which contribute to the film stability will be quite weak, as will be discussed in a later section. Therefore, the smaller area of the DL-isomer, will be due to its greater solubility, caused by the partial presence of hydrogen bonds between the peptide group and the water molecule, because there may be some irregularity in the chain configuration.

*The Effect of Sulfuric Acid on the Monolayer of Poly-DL-alanine.*—The effect of concentrated sulfuric acid on the nylon monolayers has been studied by Crisp,[12] and by Hibberd and Alexander.[15] The expansion of films[12,15] and the increase in surface moments[15] have been observed by them on the concentrated sulfuric acid subsolutions. These findings were interpreted in terms of the weakening of hydrogen bonds between peptide groups. In the present study, as Fig. 2 and Table I show, a pronounced effect of sulfuric acid on the monolayer of poly-DL-alanine was observed on the 3 N and 6 N solutions. The expansion of the film of this polymer is caused by the increase in the flexibility of the polypeptide chain due to the breaking of hydrogen bonds, as in the case of nylon monolayers. The increase in surface moment seem to be caused by a similar reason. The breaking of hydrogen bonds will make the carbonyl groups more vertical as regards the interface, as was pointed out by Davies[5,7]; as a result, the surface moment increases.

*Poly-α-aminoisobutyric Acid.*—The monolayer of this polypeptide on distilled water is much more expanded than that of polyalanine. The shape of the *Π-A* curve is similar to those of poly-DL-alanine on the sulfuric acid subsolutions. As Table I shows, the discrepancy between the areas at $A_\delta$ and $A_{\Pi\to 0}$ is much greater than those of poly-L- and -DL-alanine on distilled water, as in the case of poly-DL-alanine on the acid subsolutions. In contrast with poly-DL-alanine on distilled water, the $\mu(c)$ value is quite high (214 mD), and the surface viscosity is first detected at a far smaller area than $A_\delta$ or $A_{\Pi\to 0}$ and, consequently, at the area where the surface pressure is sufficiently high.

In general, the monolayers of high polymers are of the condensed type under a strong interaction between constituent monomer units, while of the expanded type under a weak interaction.[8,9] The facts shown above indicate that the interaction between the monomer units or the polymer chains of poly-$\alpha$-aminoisobutyric acid is very weak.

The steric hindrance to the hydrogen bond formation between peptide bonds has been studied with nylon monolayers by Hibberd and Alexander.[15] They found that nylon obtained from the condensation of sebacic acid with $\alpha:\alpha:\alpha':\alpha'$-tetramethyl tetramethylenediamine (Nylon TeMe 410) gives an expanded monolayer with no rigidity, while Nylons 210, 410 and 610 cause condensed monolayers. The anomaly of the film of Nylon TeMe 410 must arise from the considerable steric hindrance to the –CO·NH– groups afforded by the four $\alpha$-substituted methyl groups. Poly-$\alpha$-aminoisobutyric acid possesses two $\alpha$-substituted methyl groups. Therefore, the steric hindrance to peptides bonds must be quite great, as in the case of Nylon TeMe 410. The expanded monolayer with a low surface viscosity can be obtained with this polypeptide because the formation of the hydrogen bonds between peptide groups is hindered. The higher value of the constant surface moment (214 mD) here than that of poly-DL-alanine on distilled water (150 mD) also suggests that there are few hydrogen bonds, as in the case of poly-DL-alanine film on the acid subsolutions.

*Copoly-1 : 1-(DL-alanine, sarcosine).*—This copolymer gives an expanded film on the 3 M potassium chloride solution, one with no viscosity. The sarcosyl residue has no hydrogen atom to be hydrogen-bonded like the prolyl residue in the polypeptide chain. The nature of the film observed is probably caused by the increase in the flexibility of the polymer chain due to the decreases in the number of hydrogen bonds between monomer units and in the double-bond nature of main chain. It has been found[8,9] that the films of prolyl polypeptides are of the expanded type and that their surface viscosities are observed at small areas per residue where the surface pressures are quite

high in contrast with those of nonionic polypeptides. This fact has been ascribed to the decrease in the number of hydrogen bonds between peptide linkages due to the presence of prolyl residues, and it is in good agreement with the results of our present investigation.

**The Oil/Water Interface.**—At the oil/water interface, the film of poly-DL-alanine was expanded slightly in the lower-pressure region, and under a higher pressure the $\Pi_i$-$A$ curve was found to be nearly identical with the $\Pi$-$A$ curve. The expansion of the film at this interface is much less than in the case of poly-DL-phenylalanine.[10] Poly-DL-alanine is a polypeptide with the smallest side chain. Therefore, the van der Waals attraction between side chains is rather weak. This is probably responsible for the slight expansion of the film of this polypeptide at the oil/water interface.

The behavior of the monolayer of polysarcosine is markedly different from that of poly-DL-alanine, even though these polymers have the same side chains. The film of polysarcosine is rather expanded and compressible. Methyl groups attach to nitrogen atoms of the polymer chain in polysarcosine, but to $\alpha$-carbon atoms in poly-DL-alanine. Evidently, the difference between these polymer films is to be ascribed to the absence or presence of hydrogen bonds between monomer units. The absence of the hydrogen bonds makes the polymer chains more flexible. Consequently, the monolayer of polysarcosine is considerably expanded and conpresible. The lack of a double-bond nature in polymer chain might also be responsible for the expansion of the polysarcosine film. On the other hand, the film of poly-DL-alanine is rather condensed, even at the oil/water interface, because its polypeptide chains are held together rigidly by the hydrogen bonds and by the partial double-bond nature of the peptide bonds.

Copoly-1 : 1-(DL-alanine, sarcosine) gives a $\Pi_i$-$A$ curve which is nearly identical with that of polysarcosine. The monolayer of copoly-1 : 1-(glycine, sarcosine) is also of the expanded type, although the area occupied per residue is much smaller. The effect of hydrogen bonding is small with these polymers because of the presence of sarcosyl residues.

## Summary

The effect of hydrogen bonding on the nature of poly-$\alpha$-amino acid monolayers has been studied at the air/water and oil/water interfaces with poly-L-alanine, poly-DL-alanine, polysarcosine, copoly-1 : 1-(glycine, sarcosine), copoly-1 : 1-(DL-alanine, sarcosine) and poly-$\alpha$-aminoisobutyric acid.

Poly-L-alanine and poly-DL-alanine gave monolayers of the condensed type on distilled water, and the surface viscosity of poly-DL-alanine was first detected at a much larger area than its close-packed area where the surface pressure was sufficiently low. This fact suggests that there exists a strong interaction between peptide bonds of polyalanine. Both polymers would assume a $\beta$-configration. On the concentrated sulfuric acid subsolutions, the film of poly-DL-alanine was expanded and an increase in surface moment was observed because of the breaking of hydrogen bonds between peptide linkages.

A steric hindrance to the hydrogen bond formation was observed with the film of poly-$\alpha$-amino isobutyric acid. This polypeptide gave an expanded monolayer on distilled water, and its surface viscosity could be first detected at a very small area where the surface pressure was remarkably high.

The film of copoly-1 : 1-(DL-alanine, sarcosine) was of the expanded type on the 3 M potassium chloride subsolution because of the decrease in the number of hydrogen bonds and that in the double-bond nature of the main chain.

At the oil/distilled water interface, a marked difference was found between the monolayers of poly-DL-alanine and polysarcosine, although these polymers have the same side chains. Poly-DL-alanine gave a considerably condensed monolayer, even at the oil/water interface. On the other hand, the film of polysarcosine was of the expanded type. The difference between the films of these polymers is mainly to be ascribed to the presence or the absence of hydrogen bonds. The 1 : 1-copolymer of sarcosine with glycine or DL-alanine also gave an expanded monolayer.

The authors are grateful to Professor Junzo Noguchi of Hokkaido University and to Dr. Sanshiro Kume of Osaka University for their kind guidance in preparing the polymer samples and in making the ionizing air-electrode respectively.

# Surface Chemistry of the Polyamide Series. II. Effect of the Sarcosyl Residue on the Monolayer of Polyleucine

By Takuya YAMASHITA* and Toshizo ISEMURA

(Received August 6, 1964)

The role of the prolyl residue in polypeptide monolayers has been studied by Isemura and Ikeda.[1,2] The surface viscosity of the poly-DL-alanine monolayer, which is of the condensed type, was found to rise at larger area than its close-packed area. This result was interpreted by assuming that the polypeptide chain is rigid because of the hydrogen bonds between peptide groups. On the other hand, the monolayers of prolyl peptides are of the expanded type, and the appreciable surface viscosities are manifested at much smaller areas than their close-packed areas. Their chain configuration are considered to be rather flexible as a result of the lack of hydrogen bonds between peptide groups.

In the preceding paper,[3] the view that the hydrogen bonds between peptide groups remarkably affect the nature of polypeptide monolayers has been supported by the results of studies of the monolayers of polysarcosine and of the copolymer of sarcosine with DL-alanine or glycine.

In the present investigation, the effect of hydrogen bonding on the polypeptide monolayers has been studied at the air/water and oil/water interfaces with copolypeptides of L-leucine with sarcosine of different compositions. The difference between monolayers of poly-L-leucine and its DL-isomer has also been studied.

## Experimental

**Samples.** — Poly-L-leucine, poly-DL-leucine and polysarcosine were prepared by the polymerization of the N-caboxyanhydride of the respective amino acid, using sodium methoxide as an initiator.[4] Copolymers of L-leucine, with sarcosine of different compositions, were prepared from the mixtures of *N*-carboxyanhydrides of sarcosine and L-leucine by the same method. The spreading solution and the average degree of polymerization of each polymer are shown in Table I.

Table I. Average degrees of polymerization of samples and their spreading solvents

| Polymer | $n$ | Solvent |
|---|---|---|
| Poly-L-leucine | | TFA |
| Poly-DL-leucine | | TFA |
| Copoly-3 : 1-(L-leucine, sarcosine) | | DCA+TFA+IPA (5 : 2 : 3, v/v) |
| Copoly-1 : 1-(L-leucine, sarcosine) | 20 | DCA+TFA+IPA (4 : 3 : 3, v/v) |
| Copoly-1 : 3-(L-leucine, sarcosine) | 28 | DCA+TFA+IPA (5 : 2 : 3, v/v) |
| Polysarcosine | 27 | $H_2O$+IPA (1 : 1, v/v) |

TFA Trifluoroacetic acid
DCA Dichloroacetic acid
IPA Isopropyl alcohol
$n$ was determined by the end group analysis.

**Methods.** — The surface pressure, the potential and the viscosity were measured by a surface balance of the float type, an ionizing air-electrode and an oscillating rotatory disk respectively. The surface moment was calculated from the surface potential using the Helmholtz equation. The interfacial pressure was measured by the ring method. The details of these experimental methods have been described in the preceding paper.[3]

## Results

The surface pressure-area ($\Pi$-$A$), surface moment-area ($\mu$-$A$) and surface viscosity-area ($\eta_s$-$A$) curves of poly-L-leucine and the 3 : 1-, 1 : 1- and 1 : 3-copolymers of L-leucine with sarcosine on distilled water are shown in Figs. 1—4 respectively. $\Pi$-$A$ curve of poly-DL-leucine is also illustrated in Fig. 1.

The film characteristics of these polymers are summarized in Table II, where $A_\delta$ is the area at the minimum compressibility of the film; $A_{\Pi\to 0}$, the area where the straight portion of the $\Pi$-$A$ curve is extraporated to $\Pi=0$; $A_\mu$, the area where the surface moment, $\mu$, begins to decrease; $\mu(c)$, the constant value of the surface moment; $A_\eta$, the area where the surface viscosity begins to rise, and $\Pi_\eta$, the pressure at $A_\eta$.

Poly-L-leucine and poly-DL-leucine gave monolayers of the condensed type. The area per residue of the former at the limiting area, $A_\delta$, was much smaller than that of the latter.

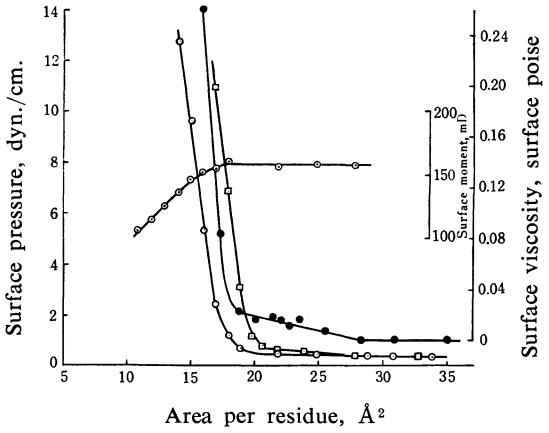

Fig. 1. Monolayers of poly-L-leucine and poly-DL-leucine on distilled water at 16°C: poly-L-leucine— ○, surface pressure; ⊙, surface moment; ●, surface viscosity: poly-DL-leucine— □, surface pressure.

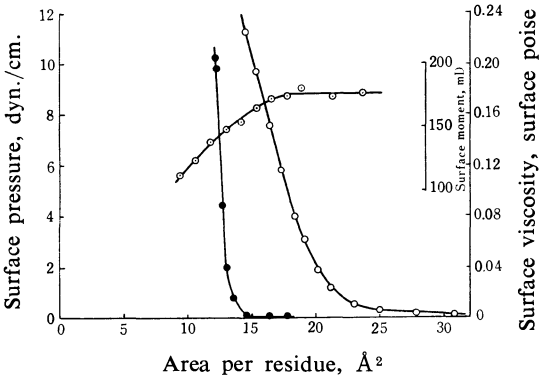

Fig. 2. Monolayer of copoly-3 : 1-(L-leucine, sarcosine) on distilled water at 16°C: ○, surface pressure; ⊙, surface moment; ●, surface viscosity.

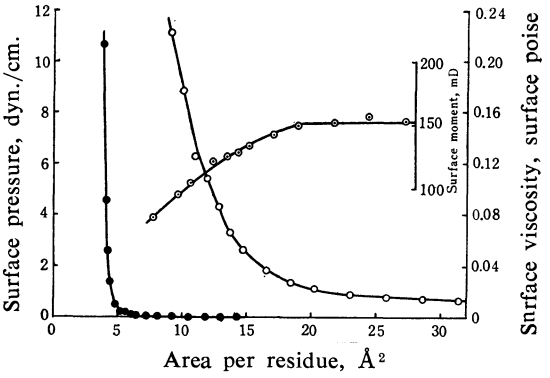

Fig. 3. Monolayer of copoly-1 : 1-(L-leucine, sarcosine) on distilled water at 16°C: ○, surface pressure; ⊙, surface moment; ●, surface viscosity.

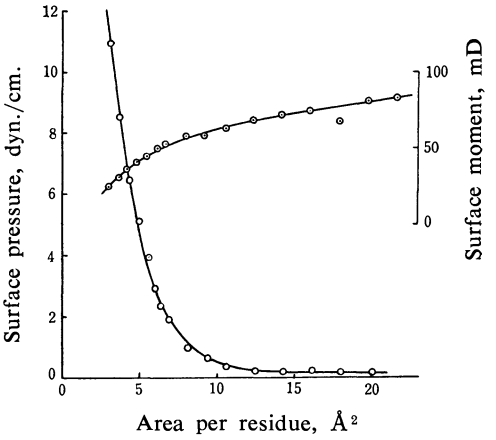

Fig. 4. Monolayer of copoly-1 : 3-(L-leucine, sarcosine) on distilled water at 16°C: ○, surface pressure; ⊙, surface moment.

The surface viscosity of poly-L-leucine was manifested at a larger area than $A_\delta$ and $A_{\Pi\to 0}$. The film characteristics of poly-L-leucine were noticeably affected by the incorporation of the sarcosyl residue in the polypeptide chain. The monolayer of copoly-3 : 1-(L-leucine, sarcosine) was expanded much more than that of poly-L-leucine. In contrast, the surface viscosity could be detected at a much smaller area than $A_\delta$ and $A_{\Pi\to 0}$. The monolayer of copoly-1 ; 1-(L-leucine, sarcosine) was much more compressible than those of the two polymers cited above. The viscosity was first detected at a very small area (5.5 Å² per residue). The *Π-A* curve of copoly-1 : 3-(L-leucine, sarcosine) shifted to a smaller area than that of 1 : 1-copolymer, and the viscosity

TABLE II. FILM CHARACTERISTICS OF POLYLEUCINE AND SARCOSYL POLYPEPTIDES AT THE AIR/WATER INTERFACE

| Polymer | $A_\delta$ Å²/res. | $A_{\Pi\to 0}$ Å²/res. | $A_\mu$ Å²/res. | $\mu(c)$ mD | $A_\eta$ Å²/res. | $\Pi_\eta$ dyn./cm. |
|---|---|---|---|---|---|---|
| Poly-L-leucine | 17.0 | 17.6 | 17.5 | 158 | 28.0 | 0.4 |
| Poly-DL-leucine | 19.0 | 19.6 | | | | |
| Copoly-3 : 1-(L-leucine, sarcosine) | 18.0 | 20.3 | 18.0 | 176 | 14.5 | 10.5 |
| Copoly-1 : 1-(L-leucine, sarcosine) | 11.5 | 14.0 | 19.0 | 152 | 5.5 | 19.0 |
| Copoly-1 : 3-(L-leucine, sarcosine) | 4.4 | 6.5 | | 80* | no viscosity | |

* Surface moment at 20 Å² per residue.

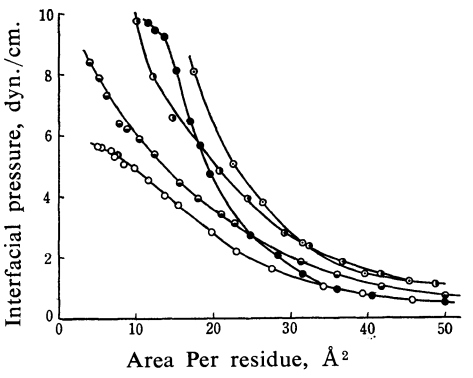

Fig. 5. Interfacial pressure-area curves of copolymers of L-leucine with sarcosine at the petroleum ether/distilled water interface at 17°C: ●, poly-L-leucine; ⊙, copoly-3 : 1-(L-leucine, sarcosine); ◑, copoly-1 : 1-(L-leucine, sarcosine); ◒, copoly-1 : 3-(L-leucine, sarcosine); ○, polysarcosine (15°C).

could not be detected. The low $A_\delta$ and surface moment values suggest that the polymer chain is partially dissolved in the aqueous subphase.

The interfacial pressure-area ($\Pi_i$-$A$) curves of poly-L-leucine and the copolymers of L-leucine with sarcosine (3 : 1, 1 : 1, 1 : 3) at the oil/distilled water interface are shown in Fig. 5. All the films are expanded much more than at the air/water interface. The film of poly-L-leucine was found to be rather condensed in comparison with those of polysarcosine and copolymers containing the sarcosyl residue, although poly-L-leucine is also much more expanded at this interface than at the air/water interface. The compressibility of the copolymer film increased with the increasing content of the sarcosyl residue in the polymer chain; the polysarcosine film was highly compressible.

## Discussion

**Air/Water Interface.**—*Polyleucine.*—The monolayers of poly-L-leucine and poly-DL-leucine are of the condensed type. As is shown in Table II, the $A_\delta$ and $A_{\Pi\to 0}$ values for these films agree fairly well with each other, as in the case of poly-L-alanine and poly-DL-alanine,[3] whereas $A_\delta$ differs to some extent from $A_{\Pi\to 0}$ with the films of sarcosyl polypeptides. The $\mu(c)$ value of poly-L-leucine agrees fairly well with that of poly-DL-alanine (150 mD[3]). The surface viscosity of poly-L-leucine is first detected at a much larger area than $A_\delta$ and $A_{\Pi\to 0}$, as in the case of the poly-DL-alanine monolayer,[2,3] and the surface pressure is quite low at $A_\eta$. These facts suggest that the interaction between the monomer units or the polymer chains of polyleucine is very strong. The polypeptide chains of polyleucine are probably tightly held together, the motion of the residues or segment being strongly inhibited by the hydrogen bonding and by the partial double bond nature of peptide bonds. Judging from the data in Table II, poly-L-leucine is spread in a $\beta$-configuration, as in most polypeptide films,[1,2,3,5,6,9,10] orientating the side chains alternatively up and down in relation to the interface. Poly-DL-leucine is probably also in a $\beta$-form in the monolayer, as has been suggested by Cheesman and Davies,[9] although the area per residue is much larger than that of poly-L-leucine.

The $A_\delta$ value of poly-L-leucine is 17.0 Å² per residue, while that of poly-DL-leucine is 19.0 Å² per residue. The larger area of the L-isomer may be ascribed to the closer packing of the L-polypeptide chains, as in the case of the isomers of poly-$\gamma$-benzylglutamate.[6]

*Copolymers of L-Leucine with Sarcosine.*—The film characteritics of poly-L-leucine are markedly changed by the incorporation of the sarcosyl residue in the polypeptide chains, as Table II shows. The films of the 3 : 1- and 1 : 1- copolymers of L-leucine with sarcosine are of the expanded type. In Fig. 6, the $A_\eta$ and $\Pi_\eta$ values of sarcosyl polyeptides are plotted against the sarcosyl residue content

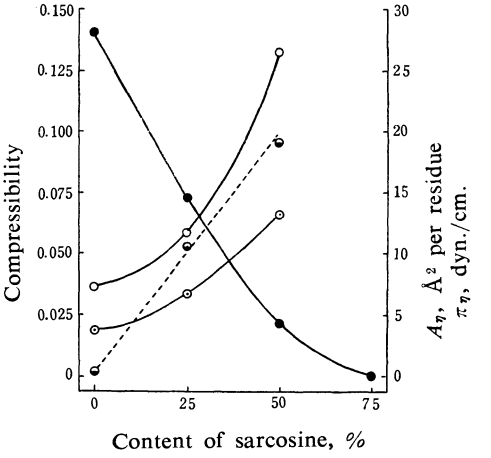

Fig. 6. Variations of compressibilites at 2 dyn./cm. (○) and 5 dyn./cm. (⊙), and of $A_\eta$ (●) and $\Pi_\eta$ (◒) with content of sarcosyl residue in polypeptide chain (at the air/distilled water interface).

in the polymer chain, together with the compressibilities of the film at 2 dyn./cm. and 5 dyn./cm. With the increase in the ratio of the sarcosyl residue in copolymers, the compressibility of the film and the $\Pi_\eta$ value are increased, whereas the area at which the surface viscosity is first manifested is decreased.

In general, a monolayer of a polymer is of the condensed type and the surface viscosity is first observed in a region where the surface pressure is quite low as the result of strong interaction between polymer chains, while a film is of the expanded type and the surface viscosity is first detected in a high surface-pressure region. Ikeda and Isemura[2] found that the films of polypeptides are of the expanded type, and that the viscosities are detected in areas where the surface pressures are quite high. They attributed this finding to the decrease in the number of hydrogen bonds between polymer chains.

The results shown in Fig. 6 suggest that the interaction between polymer chains decreases with an increase in sarcosyl content. The number of hydrogen bonds between peptide groups is decreased when sarcosyl residues are copolymerized in the polypeptide chain because they lack the hydrogen atoms to be hydrogen-bonded in the residues. This is responsible for the weak interaction which has been observed with sarcosyl polypeptides. The flexibility of the segments or the polymer chain will be increased by the decrease in the number of hydrogen bonds and by the decrease in the double-bond nature of the main chain. The view[1-3] that the condensation and the expansion of the polypeptide films primarily depend on the hydrogen bonding between peptide groups has thus been confirmed by the present investigation.

The $A_\mu$ value of poly-L-leucine (17.5 Å$^2$ per residue) is nearly equal with the $A_\delta$ (17.0 Å$^2$ per residue). On the other hand, the film of copoly-1 : 1-(L-leucine, sarcosine) gives a much smaller $A_\delta$ value than $A_\mu$. The $A_\delta$ and the $A_\mu$ of the 1 : 1-copolymer are 11.5 Å$^2$ per residue and 19.0 Å$^2$ per residue respectively. At the $A_\mu$ the electric dipole of the repeating unit begins to change its orientation. The sarcosyl residues of this copolymer begin to be submerged into the aqueous phase at $A_\mu$, accompanying the decrease in surface moment. The $A_\delta$ of the 1 : 1-copolymer corresponds to the area occupied by the leucyl residues and by the sarcosyl residues remaining at the surface as a result of the effect of the hydrophobic leucyl residues. The sarcosyl residues of copoly-3 : 1-(L-leucine, sarcosine) will be more stable at the interface than those of the 1 : 1-copolymer because of the coexistence of a higher leucyl-residue content. This may be the cause of the lack of discrepancy between the $A_\delta$ and the $A_\mu$ values.

Copoly-1 : 3-(L-leucine, sarcosine) gives a somewhat condensed film. The $A_\delta$ value is quite small (4.4 Å$^2$ per residue). The surface moment is low compared with the other polymer films shown in Table II and decreases with compression. When the film is compressed, the sarcosyl residues of this polymer are submerged in the aqueous pahse; at $A_\delta$, only leucyl residues remain at the surface. The $A_\delta$ value agrees closely with the area occupied by the remaining leucyl residues at the surface ($A_\delta$ of poly-L-leucine/4=4.3 Å$^2$ per residue).

**The Oil/Water Interface.** — A pronounced difference has been found[3] between the monolayers of poly-DL-alanine and polysarcosine at the oil/water interface, although the two polymers have the same side chains. The monolayer of poly-DL-alanine was rather condensed, even at the oil/water interface, while polysarcosine gave an expanded monolayer. The difference may be primarily ascribed to the presence or absence of hydrogen bonds between monomer units.

The monolayer of poly-L-leucine is of the expanded type at the oil/water interface. The film of this polypeptide is much more expanded than that of poly-DL-alanine at this interface. This expansion of the film is pbobably caused by the release of van der Waals force between side chains. The effect is much greater because the side chain is much larger than that of poly-DL-alanine.

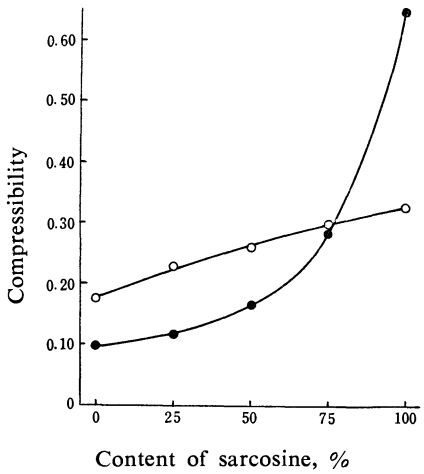

Fig. 7. Variations of compressibilities at 2 dyn./cm. (○), and 5 dyn./cm. (●) with content of sarcoyl residue in polypeptide chain (at the petroleum ether/distilled water interface).

The film of poly-L-leucine, however, is slightly more condensed than those of sarcosyl polypeptides.

Copoly-3 : 1-(L-leucine, sarcosine) gives a much more expanded film than poly-L-leucine, as well as at the air/water interface. A further increase in sarcosyl content increases the film compressibility, even at the oil/water interface, as Fig. 7 shows. This fact suggests that the polymer chain increases in flexibility as a result of the decrease in the number of hydrogen bonds between polymer chains and the decrease in the double-bond nature of the main chain.

## Summary

The effect of hydrogen bonding on the nature of poly-$\alpha$-amino acid monolayers has been studied at air/water and oil/water interfaces with poly-L-leucine, poly-DL-leucine, and the 3 : 1-, 1 : 1- and 1 : 3-copolymers of L-leucine with sarcosine.

Poly-L-leucine and poly-DL-leucine have been found to give condensed monolayers on distilled water. The surface viscosity of poly-L-leucine was first detected at a larger area than its close-packed area. The strong interaction between polymer chains of polyleucine was suggested by these findings.

On the other hand, at both air/water and oil/water interfaces, the compressibility of the film is increased much more by the incorporation of the sarocosyl residue in the polymer chain. At the air/water interface, the films of 3 : 1- and 1 : 1- copolymers of L-leucine with sarcosine are of the expanded type, and the surface viscosities have first been detected at much smaller areas than their close-packed areas. These findings suggest that the interaction between polymer chains diminishes because of the decrease in the number of intermolecular hydrogen bonds.

The authors wish to express their hearty thanks to Professor Junzo Noguchi of Hokkaido University for his kind guidance in preparing the samples.

# Surface Chemistry of the Polyamide Series. III. Monolayers of Nylons from $\omega$-Aminocarboxylic Acids at the Air/Water Interface

By Takuya YAMASHITA*

(Received August 13, 1964)

Polyamides of the nylon type are prepared from diamines and dicarboxylic acids or from $\omega$-aminocarboxylic acids, and they are commonly designated by the numbers of carbon atoms per monomer unit. For example, polyhexamethylene sebacamide, $(-HN(CH_2)_6NHCO(CH_2)_8CO-)_n$, and polyundecanamide, $(-NH(CH_2)_{10}CO-)_n$, are Nylon 610 and Nylon 11 respectively. It has been found that the melting points of nylons with odd numbers of $CH_2$ groups per monomer unit are lower than those with even numbers.[1-4] This fact has been ascribed to the deficient hydrogen bond formation of the former nylons.[1,2] Kinoshita[5,6] has shown that the odd number of $CH_2$ groups in polyamides does not lead to a deficient hydrogen bond formation, but that it in general gives rise to a configuration somewhat similar to the pleated sheets structure proposed by Pauling and Corey[7] for the structure of polypeptide. This configuration was called the $\gamma$-form. On the other hand, polyamides with even numbers of $CH_2$ groups usually contain two different crystalline forms, $\alpha$ and $\beta$, which have the same chain repeat distance and differ only in the side-by-side arrangement of molecules.

In this connection, it is interesting to study the effect of the numbers of $CH_2$ groups on

the nature of the monolayers of a series of nylons. Although the monolayers of several nylons have been studied,[8-15] no studies have been carried out along this line. Accordingly, in the present work, a series of nylons with 2 to 11 $CH_2$ groups per monomer unit (Nylons 3 to 12) prepared from $\omega$-aminocarboxylic acids have been studied at the air/water interface in order to investigate the correlation of the film porperties with the numbers of $CH_2$ groups per monomer unit. The film of Nylon 9 at the oil/water interface and that of polyurea, polynonamethylene urea $(-(CH_2)_9-HNCONH-)_n$, at the air/water interface have also been studied in order to prove the role of the van der Waals attractive force between hydrocarbon groups in polyamide monolayers.

## Experimental

**Materials.** — Nylon 3 (poly-$\beta$-alanine) prepared from acrylamide was supplied by Professor S. Murahashi of Osaka University. The insoluble fraction in boiling water was used in the present experiment. Its intrinsic viscosity was 0.432 (in 90% formic acid at 25°C). Nylon 4 ($n$=87) were prepared from pyrrolidone by Dr. Y. Joh of the Mitsubishi Rayon Co., and Nylon 5 ($n$<25), from piperidone by Mr. T. Konomi of the Toyo Spinning Co. Nylons 7, 8 and 10 were supplied by Dr. Y. Kinoshita and Nylon 12 by Dr. M. Ito of the Toyo Rayon Co. The intrinsic viscosities of these nylons were more than 0.9 (in cresol at 25°C). Nylons 7, 8 and 10 were the same samples as those used in Kinoshita's investigation.[5] Nylon 11 ($m$=16000) was a gift from Dr. V. Ambekar of L'école Supérieure de Physique et de Chimie de Paris. Nylon 6 (Amilan), Nylon 9 and polynonamethylene urea were commercial products.

Nylons 3, 4 and 5 were used without further purification. Nylon 6 was purified by precipitation from a solution in formic acid by adding water. The chips or fibers of Nylons 7 to 12 and polyurea were immersed in benzene for 24 hr. and then in ethyl alcohol for the same length of time. All the samples were dried at 80°C in vacuo for 3—4 hr.

Nylons 3 to 9 were spread from solutions in 90% formic acid, Nylons 10, 11 and 12, from solutions in a 1 : 1-mixture (v/v) of dichloroacetic acid and trifluoroacetic acid, and polyurea, from trifluoroacetic acid. Nylon 9 was also spread from a solution in trifluoroacetic acid. The concentrations of these solutions were 0.2—0.3 mg./ml.

A subsolution containing 40% ammonium sulfate or concentrated sulfuric acid was treated with active charcoal before use in order to remove any surface-active contaminants.

**Methods.** — The surface pressure was measured by the Wilhelmy methods; the surface potential, by the ionizing air-electrode method; the surface viscosity, by the rotatory oscillation method, and the interfacial pressure, by the ring method. The surface moment was calculated from the surface potential using the Helmholtz equation. The details of the experimental methods have already been described in Part I of this series.[16]

## Results

Nylons 3, 4 and 5 were spread on a 40% ammonium sulfate subsolution because stable films were not obtained on distilled water. For the sake of comparison, Nylon 6 was also spread on the same subsolution. The surface pressure-area ($\Pi$-$A$) curves of these nylons are shown in Fig. 1. The film of Nylon 3 was of the condensed type, while those of Nylons 4, 5 and 6 were of the expanded type.

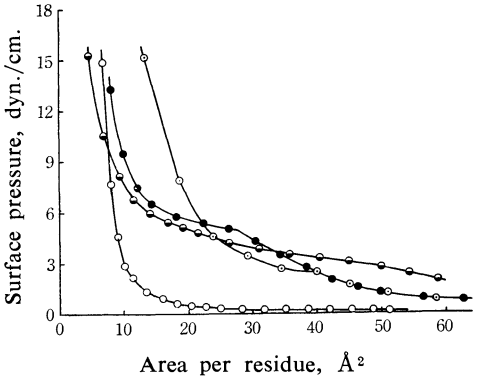

Fig. 1. Surface pressure-area curves of Nylon 3 (○), Nylon 4 (●), Nylon 5 (◒) and Nylon 6 (⊙) on 40% ammonium sulfate at 23°C.

The $\Pi$-$A$, surface moment-area ($\mu$-$A$) and surface viscosity-area ($\eta_s$-$A$) curves of Nylons 6 to 12 on distilled water are shown in Figs. 2 to 8 respectively. The interfacial presssure-area ($\Pi_i$-$A$) curve of Nylon 9 at the petroleum ether/water interface is also shown in Fig. 5. The $\Pi$-$A$ and $\mu$-$A$ curves of Nylons 6 to 9 on the concentrated sulfuric acid subsolutions (3 N and 6 N) are shown in the corresponding figures.

The film of Nylon 6 on distilled water was of the expanded type. The area per residue was somewhat smaller than that on 40% ammonium sulfate. The film of Nylon 7 on distilled water was rather more condensed than that of Nylon 6, although the film was of the expanded type.

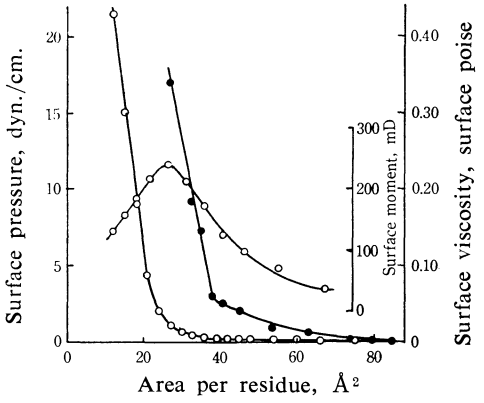

Fig. 7. Surface pressure-area (○), surface moment-area (⊙) and surface viscosity-area (●) curves of Nylon 11 on distilled water at 21°C.

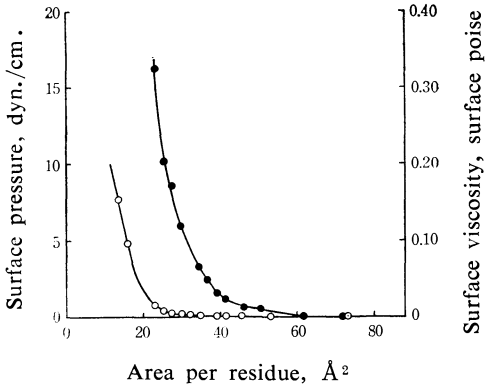

Fig. 8. Surface pressure-area (○), surface viscosity-area (●) curves of Nylon 12 on distilled water at 17.5°C.

The films of Nylons 8 to 12 were of the condensed type on distilled water, and their areas per residue were quite small. Trifluoroacetic acid is one of the strongest hydrogen bond-breaking agents. The film of Nylon 9 spread from a solution in this solvent gave a *Π-A* curve on distilled water (not shown in Fig. 5) completely identical with that spread from a solution in formic acid on the same subsolution (shown in Fig. 5). Further, the *Π-A* curve of this nylon spread from a solution in formic acid on 40% ammonium sulfate (not shown in the figure) was nearly identical with that on distilled water, and the change in the initial spreading areas of Nylons 8 to 12 did not affect practically the *Π-A* relations on distilled water. Judging from these facts, the poor spreadiag of Nylons 8 to 12 seems to be the result of neither the presence of an insoluble fraction in the spreading solution nor the dissolution of polymers in the aqueous phase.

Constant values of surface moments were not obtained with the films of Nylons 8 to 12 on distilled water. The surface moments increased with the compression of the films and they reached the maxima. The surface moment of Nylon 12 was not reproducible. The maximum value, however, was lower than that of Nylon 11.

On the 3 N and 6 N sulfuric acid subsolutions, a remarkable expansion of films and an increase in the surface moment were found with Nylons 6 to 9. The stronger the acidity, the greater the effect.

The *Π-A*, $\mu$-*A* and $\eta_s$-*A* curves of polynonamethylene urea on distilled water are shown in Fig. 9. This polymer also gave a condensed film.

The film characteristics of Nylons 6 to 12 and polyurea are summarized in Table I, where $A_\delta$ is the area per residue at the minimum compressibility of the film; $A_{\Pi\to 0}$,

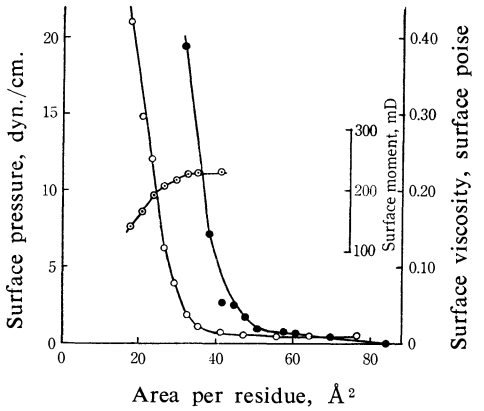

Fig. 9. Surface pressure-area (○), surface moment-area (⊙) and surface viscosity-area (●) curves of polynonamethylene urea on distilled water at 20°C.

TABLE I. FILM CHARACTERISTICS AND CALCULATED CLOSE-PACKED AREAS OF NYLONS 6 TO 12 AND POLYNONAMETHYLENE UREA

the area per residue where the straight portion of $\Pi$-$A$ curve is extraporated to $\Pi=0$; $A_\mu$, the area per residue where the surface moment begins to decrease; $\mu(m)$ and $\mu(c)$, the maximum and the constant values of the surface moment respectively, and $A_\eta$, the area per residue where the surface viscosity is first detected.

For the sake of comparison with the observed limiting areas per residue, namely, the values of $A_\delta$ or $A_{\Pi\to 0}$, the close-packed areas for $\alpha$- or $\beta$-forms of Nylons 6 to 12 were calculated from the unit cell dimensions of their crystals as estimated from X-ray diffraction data. The results are shown in Table I, where the distance between chain atoms of Nylons 6 to 12, and polyurea, with the exception of Nylons 6,[17] 7[18] and 11[18] (for which the X-ray diffraction data are available), is assumed to be 1.23 Å for fully extended chains, judging from the distance between chain atoms of Nylon 6$\left(\frac{17.24^{17)}}{2\times 7}=1.231\text{ Å}\right)$, Nylon 7$\left(\frac{9.35^{18)}}{8}=1.231\text{ Å}\right)$, Nylon 11$\left(\frac{14.9^{18)}}{12}=1.24\text{ Å}\right)$, and Nylon 66$\left(\frac{17.2^{19)}}{14}=1.23\text{ Å}\right)$. The distance between neighboring chains is assumed to be $4.9\times\sin 77^\circ=4.77$ Å on the basis of those of Nylons 7,[18] 11[18] and 66.[19] These values are also used for the calculation of close-packed areas of Nylon 3, Nylon 4 and polynonamethylene urea.

## Discussion

**Nylon 3.**—Nylon 3 gives a film of the condensed type on 40% ammonium sulfate. Its $A_\delta$ and $A_{\Pi\to 0}$ values are 8.2 Å² per residue and 9.0 Å² per residue respectively. These values are much smaller than the calculated close-packed area for a fully extended chain (23.5 Å² per residue). It has been found[20,21] that polyglycine cannot be spread under any conditions because glycyl residues are particularly strongly hydrogen-bonded because of the absence of side chains. As Nylon 3 also lacks side chains, and as the chain repeat distance is rather short, the hydrogen bonds would be very

strong, as in the case of polyglycine. This might be the cause of the poor spreading and the condensation of the Nylon 3 film.

**Nylons 4, 5 and 6.** — In contrast with the condensed film of Nylon 3, the films of Nylons 4, 5 and 6 are of the expanded type on a 40% ammonium sulfate subsolution. Nylon 6 also gives an expanded film on distilled water. Kink points are found in the *Π-A* curves of Nylons 4 and 6.

The kink point of the *Π-A* curve of Nylon 6 appears at 37.5 Å$^2$ per residue on distilled water and at 40 Å$^2$ per residue on 40% ammonium sulfate. The *π-A* curve of this nylon on distilled water has already been reported by some workers.[10,12,14] The present result is in general agreement with theirs. The kink point was also found by them at nearly the same area as in the present study. The surface moment of Nylon 6 on distilled water begins to decrease at 37 Å$^2$ per residue, which is in good agreement with the area at kink point and the $A_\mu$ values reported by Hotta[12] and Inokuchi.[14] The surface viscosity of this nylon begins to rise at 82 Å per residue. This value is much smaller than that found by Isemura and Hamaguchi.[11] The larger area found by them seems to be caused by the interaction between polymer and solvent because they used a mixture of cresol and benzene as a spreading solvent. They, however, found a characteristic area at 80 Å$^2$ per residue, which agrees well with the $A_\eta$ value in the present study.

It has been found[16] that poly-α-aminoisobutyric acid gives a monolayer of the expanded type. A striking difference, however, exists in the surface viscosities between the films of this polymer and Nylon 6. The surface viscosity of the former first appears at an area (12 Å$^2$ per residue) considerably smaller than its limiting area ($A_\delta$=20.0 Å$^2$ per residue), where the surface pressure is remarkably high, while that of the latter is detected at a larger area (82 Å$^2$ per residue) than the calculated close-packed area for fully-extended chains (41.2 Å$^2$ per residue), where the surface pressure is sufficiently low. In the film of the former, interaction between polymer chains is scarce because it is difficult for the hydrogen bonds between keto and imino groups to be formed because of the steric hindrance of α-disubstituted methyl groups. On the other hand, the much larger $A_\eta$ value of Nylon 6 suggests that the interaction between polymer chains is quite strong. Near the $A_\mu$, the polymer molecules at the surface begin to come in contact with each other to construct a loose network structure because of the hydrogen bonding between amide groups.

The areas at the kink points of the *Π-A* curves of Nylon 4 (ca. 28 Å$^2$ per residue on 40% ammonium sulfate) and Nylon 6 (37.5 Å$^2$ per residue on distilled water, 40 Å$^2$ per residue on 40% ammonium sulfate) agree fairly well with the calculated close-packed areas (29.3 Å$^2$ per residue for Nylon 4, 41.2 Å$^2$ per residue for Nylon 6). All the chain atoms of these polymers would lie on the water surface above the areas at the kink points. No kink point is found in the *Π-A* curve of Nylon 5. This polymer, however, might be spread in a state similar to those of Nylon 4 and Nylon 6, because the film is remarkably expanded. The polymer chains of Nylons 4, 5 and 6 are quite flexible at the surface because of the effect of the increased $CH_2$ groups. This might be the cause of the expansion of the films of these nylons.

There is some difference among the films of Nylons 4, 5 and 6 on the 40% ammonium sulfate subsolution, although they are all of the expanded type. Below the surface pressure of ca. 4 dyn./cm., the film of Nylon 5 is most expanded, as Fig. 1 shows. The surface pressure of Nylon 6 is much lower than that of Nylon 5 over the same area. The pressure reduction in the film of Nylon 6 is probably caused by the increased van der Waals attractive force between hydrocarbon groups. The van der Waals force plays an important role in the films of Nylons 7 to 12, as will be discussed in later sections.

**Nylon 7.**—The film of Nylon 7 on distilled water is of the expanded type. The film, however, is somewhat more condensed than that of Nylon 6 on the same subsolution. This is the result of the increased van der Waals attractive force between hydrocarbon groups. The film of Nylon 7 might be in an intermediate state between the expanded films obtained with Nylons 4, 5 and 6, and the condensed films obtained with Nylons 8 to 12.

The surface moment of this nylon is remarkably high, the highest among those of the nylons investigated. The $A_\mu$ value is 40 Å$^2$ per residue, which agrees with the $A_\eta$ value. The surface moments of polyamides of the nylon type are mainly contributed by the C=O dipoles, as in the case of poly-α-amino acid with only hydrocarbon side chains.[22] The more vertical the C=O dipoles become in relation to the interface, the closer the surface moment will approach the maximum value of 360 mD.[23] The observed surface moment of Nylon 7 ($\mu(c)$=355 mD) is in good agreement with this value. Therefore, the C=O groups

22) J. T. Davies, *Biochim. Biophys. Acta*, **11**, 165 (1953).
23) A. E. Alexander and J. H. Schulman, *Proc. Roy. Soc.* **A161**, 115 (1937).

of Nylon 7 might orientate rather vertically to the interface. In such an orientation of C=O groups, the hydrogen bonds can hardly be formed between amide linkages in the area above $A_\mu$. It has already been found for the monolayers of poly-$\alpha$-aminoisobutyric acid[16] on distilled water, and poly-DL-alanine[16] and poly-DL-leucine[20] on the acid subsolutions that the surface moment increases if the number of hydrogen bonds is reduced.

The surface viscosities of polymers primarily depend on the number of hydrogen bonds between different groups, as has been found with prolyl polypeptides,[24] poly-$\alpha$-aminoisobutyric acid[16] and sarcosyl polypeptides.[16,25] The agreement of $A_\mu$ with $A_\eta$ supports the view that hardly any hydrogen bonds can be formed between amide groups in the area larger than $A_\mu$ because the orientation of C=O groups is unfavorable for the hydrogen bond formation.

**Differences in Film Properties between Odd- and Even-Numbered Nylons.** — It has been found[1-5] that the melting points of nylons with odd and even numbers of $CH_2$ groups are quite different from each other. Some film characteristics of Nylons 6 to 12 on distilled water are shown in Fig. 10 against the number of carbon atoms per monomer unit. There exist striking differences between odd- and even-numbered nylons as in melting points. It should be noted here that the amino acid nylons with even numbers of $CH_2$ groups are described by odd numbers, and vice versa.

It is striking that the the *Π-A* curves of Nylons 8, 10 and 12 are nearly identical. Accordingly, the limiting areas, namely, the

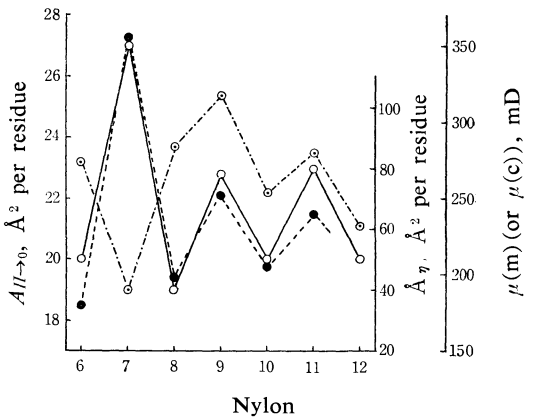

Fig. 10. Plots of $A_{II\to 0}$(○), $A_\eta$(⊙) and $\mu(m)$ (or $\mu(c)$) (●) values against the number of nylon.

$A_\delta$'s or $A_{II\to\phi}$'s of these nylons, are all nearly the same per residue, is as is shown in Table I. Nylon 9 and Nylon 11 also have nearly the same limiting areas per residue, although the areas are somewhat larger than those of even-numbered nylons. The maximum values of the surface moments of odd-numbered nylons are somewhat high compared with those of even-numbered nylons. The surface moment of Nylon 12 is not shown in Table I and Fig. 10 because of its poor reporducibility. Its maximum value, however, is lower than that of Nylon 11. The surface viscosities of odd-numbered nylons, with the exception of Nylon 7, begin to rise at larger areas than those of even-numbered nylons. These differences in film properties between odd- and even-numbered nylons will be discussed in the succeeding sections.

**The Condensation of the Films of Nylons 8 to 12.**—In contrast with the condensed films of Nylon 9 at the air/water interface, the film of this polymer at the oil/water interface is highly expanded, as Fig. 5 shows. It has been found that the films of poly-$\alpha$-amino acids[9,21] and some vinyl polymers[12] are expanded much more at the oil/water interface than at the air/water interface because of the release of van der Waals force between hydrocarbon groups. Accordingly, it seems that the van der Waals attractive force between hydrocarbon groups plays an important role in the remarkable condensation of these nylon films.

The hydrogen bonds between keto and imino groups of amide linkages is also responsible for the condensation of these films, because the film properties of nylons are remarkably affected on a concentrated sulfuric acid subsolution, thus causing the breaking of hydrogen bonds, and the surface viscosities of Nylons 8 to 12 are manifested at quite large areas, as will be discussed in the succeeding sections.

Thus, it seems that both the van der Waals force between hydrocarbon chains and the hydrogen bonds between keto and imino groups of amide linkages are responsible for the remarkable condensation of the films of Nylons 8 to 12 on distilled water.

Holt and Went[26] reported that, with the compression of the films, the hydrophilic amide groups of polyamide films remain at the surface, but that the polymethylene groups are, presumably, pushed out of the surface. The consistency of the observed small limiting areas per residue among even- or odd-numberd nylons suggests that the hydrocarbon chains leave the surface with the compression of the

26) P. F. Holt and C. W. Went, *Proc. 3rd Int. Cong. Surface Activity*, **2**, 49 (1960).

films and are folded because of the van der Waals attractive force between them. The hydrogen bonding between amide groups might also play a significant role in the stability of such folded structures. Similar folded structures have been found by Isemura and Hotta[27] for adsorbed films of long-chain dibasic acids. If the hydrocarbon groups leave the surface and are folded, the contributions of monomer units of even- or odd-numbered nylons to the limiting areas should be identical with each other. The somewhat larger areas of odd-numbered nylons than those of even-numbered ones might be due to the difference in the packings of folded chains. The difference in maximum surface moments between the two series of nylons is caused by the same factor.

The maximum values of the surface moments of Nylons 8 to 11 are between 200 and 250 mD. These values are somewhat higher than the constant values of the surface moments of poly-$\alpha$-amino acids, which are in the range from 150 mD to 180 mD on neutral subsolutions;[16,20-22,25] It has been found that[16], for poly-$\alpha$-aminoisobutyric acid on distilled water and poly-DL-alanine on a acid subsolution (3 N sulfuric acids), the constant values of surface moments are increased to ca. 210 mD because the hydrogen bonds between keto and imino groups are scarce in these films. Probably, the higher $\mu(m)$ values of Nylons 8 to 11 on distilled water than the $\mu(c)$ values of poly-$\alpha$-amino acids on the neutral subsolutions is not caused by a small number of hydrogen bonds, but by a somewhat different orientation of C=O and H-N groups from that in poly-$\alpha$-amino acids, accompanied by a remarkable change in the orientation of these groups during the folding process, because the presence of hydrogen bonds is proved, as has been and will be described in this paper.

**The Surface Viscosities of Nylons 8 to 12.**—The surface viscosities of Nylons 8 to 12 begin to rise at much larger areas than their limiting areas, as Table I shows. Near the area at $A_\eta$, the polymer chains of these nylons begin to come in contact with each other to form a network structure because of the interaction between keto and imino groups of different amide groups.

The $A_\eta$ values of odd-numbered nylons are much larger than those of even-numbered nylons. This fact suggests that hydrogen bond formation between amide groups takes place more easily in the former nylons than in the latter nylons. It also seems that above the areas at $A_\eta$ almost all the chain atoms of these nylons lie on the water surface, because the $A_\eta$ values are larger than the calculated close-packed areas with the exception of Nylon 12, and with a higher compression of films the hydrocarbon groups would leave the surface and be folded.

It has been reported by several authors,[1,2,4,18] concerning the crystals of nylons, that in the fully-extended chains of nylons with even numbers of $CH_2$ groups, all the amide groups on one chain lie directly next to the amide groups on neighboring chains, so that the maximum degree of coupling is attained, while in the fully-extended chains of nylons with odd numbers of $CH_2$ groups, the parallel array leads to a close coupling of only half of the polar groups, although the antiparallel array allows the coupling of all the amide groups. The difference in $A_\eta$ values in the present study between odd- and even-numbered nylons might be related to the difference in the probabilities of hydrogen bond formation between the two series of nylons. Although the deficient hydrogen-bond formation in crystals of nylons with odd numbers of $CH_2$ groups was denied by Kinoshita,[5,6] it might have some effect on the areas where surface viscosities appear because these areas are closely related to the initial stage of hydrogen-bond formation.

**Polynonamethylene Urea.**—The monolayer of this polymer has been investigated in order to prove the role of the van der Waals attractive force between hydrocarbon groups for the stabilization of a folded structure of polyamides of the nylon type. Polyurea, like Nylons 8 to 12, was found to give a condensed film on distilled water, although the limiting area is somewhat larger than those for nylons. The constant value of the surface moment was obtained over a very narrow range; it was 225 mD, which is of the same order of magnitude as the $\mu(m)$ values of Nylons 8 to 12. From these facts, this polyurea is considered to assume a folded structure near the limiting area, like even-numbered nylons, because this polymer contains 9 $CH_2$ groups per residue. Somewhat larger values of $A_\delta$ (27.2 Å$^2$ per residue), $A_{II\to 0}$ (30 Å$^2$ per residue) and $A_\mu$ (32 Å per residue) are probably due to the contribution from another N-H group in the residue. At 84 Å$^2$ per residue, the surface viscosity was first detected. Near this area, the polymer molecules begin to come in contact and to interact with each other. With further compression, the hydrocarbon groups will be folded. The folded structure might be maintained both by the van der Waals attractive force and by hydrogen bonds.

27) T. Isemura and H. Hotta, This Bulletin, 23, 193 (1950).

**The Effect of Sulfuric Acid on the Monolayers of Nylons.**—As has been shown in Figs. 2—5 and in Table I, on concentrated sulfuric acid, a remarkable expansion of films and increase in surface moments are found with Nylons 6 to 9. The stronger the acidity, the greater the effect. It has been reported in Part I of this series[16] that, on concentrated sulfuric acid, poly-DL-alanine film is expanded much more than on distilled water, and that its surface moment increases from 150 mD ($\mu(c)$) to 215 mD ($\mu(c)$) and 256 mD (at 26 Å$^2$ per residue) on the 3 N and 6 N solutions respectively. These changes are due to the breaking of hydrogen bonds between keto-imino groups. The poly-$\alpha$-aminoisobutyric acid monolayer,[16] in which hardly any hydrogen bonds are formed because of the steric hindrance of $\alpha$-disubstituted methyl groups, also gives a high surface moment ($\mu(c)$, 214 mD) compared with poly-DL-alanine on distilled water. The surface moments of nylons on acid subsolutions are much higher than that of poly-DL-alanine on the acid, that of poly-$\alpha$-aminoisobutyric acid on distilled water,[16] and the maximum contribution from the C=O group (360 mD).[23] Accordingly, a different cause must be sought for the remarkably high moments besides the breaking of hydrogen bonds. Such a high surface moment has also been found by Hibberd and Alexander[15] for Nylon 610 (1038 mD per two amide groups at the maximum on 3 N sulfuric acid).

The adsorption of hydrochloric acid by nylon fibers has been studied as a function of the acid concentration.[28] In the concentrated hydrochloric acid solutions, nylon absorbs more acid than would be expected from the number of amino groups present. This excess absorption has been attributed to the interaction of the acid with amide linkages. The amide groups of nylon behave as a base in an acid medium. The interaction of hydrochloric acid with –CONH– groups of nylon has been proved by Larose[29,30] from measurements of the infrared and near-infrared spectra of nylon treated with hydrochloric acid.

The addition of acid to the –CONH– group of nylon can be represented by:

$$-CONH- + H^+ \rightarrow -CONH^+-.$$

Thus, nylon film would be charged positively. As a result of the protonation to amide linkage, the surface moments are increased remarkably.

The folded structures of higher nylons on distilled water are unfolded on the subsolutions of sulfuric acid because the hydrogen bonds which would stabilize the folded structure are broken. The repulsion between charged groups causes a remarkable expansion of the film. The polymer chains are in a rather flexible state.

## Summary

The surface films of a series of nylons prepared from $\omega$-aminocarboxylic acids and with 2 to 11 $CH_2$ groups per monomer unit (Nylons 3 to 12) have been studied at the air/water interface in order to investigate the correlation of the film properties with the numbers of $CH_2$ groups. The film of Nylon 9 at the oil/water interface and that of polynonamethylene urea at the air/water interface have also been studied.

The film of Nylon 3 on the 40% ammonium sulfate subsolution was of the condensed type and the area occupied per residue was quite small, probably because of the especially strong hydrogen bonds between amide groups. On the other hand, the films of Nylons 4, 5 and 6 on 40% ammonium sulfate and that of Nylon 6 on distilled water were of the expanded type. These polymers might be spread in rather flexible states because of the effect of the increased number of $CH_2$ groups.

Nylons 8 to 12 and polyurea gave condensed films on distilled water, their limiting areas per residue being much smaller than the areas calculated for the fully extended chains. The condensation of the films might be primarily caused by the increased van der Waals attractive force between hydrocarbon groups, as has been proved by the remarkable expansion of Nylon 9 film at the petroleum ether/distilled water interface. The small limiting areas of these polymer films have been interpreted by assuming that the hydrocarbon chains are folded near these areas. Nylon 7 was found to give an intermediate film between expanded films, such as Nylons 4 to 6, and condensed films, such as Nylons 8 to 12.

Interesting differences in the film properties of odd- and even-numbered nylons have been found with Nylons 8 to 12. Odd-numbered nylons occupied somewhat larger areas per residue than even-numbered nylons, and the maximum surface moments of the formers were higher than those of the latters. This is the result of the difference in shapes of the folded chains between the two series of nylons.

The surface viscosities of Nylons 8 to 12, with the exception of the last, were first detected at larger areas than the close-packed areas calculated for the fully-extended

chains. The areas found for even-numbered nylons were much smaller than those for odd-numbered ones. This may be attributed to the difference in modes of hydrogen bond formation between amide groups.

A remarkable effect of the concentrated sulfuric acid subsolution on the film properties of Nylons 6 to 9 has been found, and interpreted as being due to the protonation to the amide linkages.

The author wishes to express his gratitude to Professor Toshizo Isemura of Osaka University for his kind guidance throughout the present work, and to Dr. Shoichi Ikeda of the same University for his helpful discussions. He is also indebted to Dr. Yukio Kinoshita and Dr. Masatoshi Ito of the Toyo Rayon Co., Professor Shunsuke Murahashi of Osaka University, Dr. Yasushi Joh of the Mitsubishi Rayon Co., Mr. Tsuyoshi Konomi of the Toyo Spinning Co., and Dr. Vassant Ambekar of L'école Superieure de Physique et de Chimie de Paris for the supply of samples.

# Equilibrium Study of Propylenediaminetetraacetato Complexes of Some Divalent Metal Ions

By Nobuyuki TANAKA and Hiroshi OGINO

(Received August 5, 1964)

Smith has reported the stability constants of propylenediaminetetraacetato complexes.[1] However, the experimental details were not given and the values seem to be somewhat questionable.

In this laboratory, the equilibria of substitution reactions involving ethylenediaminetetraacetato complexes have been investigated and the equilibrium constants of these reactions have been determined.[2,3] In this paper, the method developed previously[2] is applied to the systems involving propylenediaminetetraacetato complexes, and the results are compared with the values reported in literature[1] and discussed.

## Experimental

**Reagents.** — Standard solutions of nickel(II) nitrate, copper(II) nitrate, lead(II) nitrate, cadmium(II) nitrate[2,3] and zinc(II) nitrate[4] were obtained by the same procedures as reported previously. To remove a small amount of contaminant of nickel, a standard solution of cobalt(II) nitrate was prepared in the following way: Hexamminecobalt(III) chloride which was recrystallized three times from water was heated at 400°C in an electric furnace. The residue was dissolved into a dilute nitric acid solution, evaporated to dryness and the same procedure was repeated several times to convert cobalt(II) chloride to cobalt(II) nitrate. Cobalt(II) nitrate thus obtained was dissolved into distilled water and the residue was removed by filtration. The concentration of cobalt(II) was determined with a standardized EDTA (disodium dihydrogen ethylenediaminetetraacetate) solution by amperometric titration.

Propylenediaminetetraacetic acid ($H_4$pdta) was prepared according to the method of Dwyer and Garvan.[5] The stock solution of $Na_2H_2$pdta was prepared from equimolar quantities of $H_4$pdta and sodium carbonate. The concentration of PDTA was determined with all of the standard metal nitrate solutions mentioned above by amperometric titration. The values thus obtained were consistent with each other within experimental error and were in good agreement with the value expected from the weight of $H_4$pdta. Therefore, it may be considered that PDTA can be used in complexometric titration in the same way as in the case of EDTA.

All other chemicals used were of analytical reagent grade.

**Apparatus and Procedure.**—A Yanagimoto PB-4 pen-recording polarograph was used for the measurement of the current-voltage and current-time curves. The dropping mercury electrodes used had the characteristics given in Table I, being measured in an air-free 0.2 M potassium nitrate solution containing 0.01% gelatin at 25°C.

TABLE I. CHARACTERISTICS OF THE DROPPING MERCURY ELECTRODES

| | Flow rate of mercury ($m$) mg./sec. | Drop time ($t_d$), sec. |
|---|---|---|
| Electrode A*1,2 | $2.13_7$ | 3.96 |
| Electrode B*3 | $1.99_5$ | 4.13 |

*1 This electrode was used for the systems containing cobalt(II) ions.
*2 Measured at 63.9 cm. of the mercury height.
*3 Measured at 64.8 cm. of the mercury height.

The measurements of the diffusion currents of copper(II) in acetate buffer solutions were carried out with the following five reaction mixtures at 25°C:

(a) copper(II)-cobalt(II)-PDTA
(b) copper(II)-nickel(II)-PDTA
(c) copper(II)-zinc(II)-PDTA
(d) copper(II)-cadmium(II)-PDTA
(e) copper(II)-lead(II)-PDTA

The ionic strength was adjusted to be 0.2 with potassium nitrate. Gelatin was added as a maximum suppressor by 0.01% in concentration.

It was found in the preliminary experiments that the substitution reactions between copper(II) ions and various kinds of metal(II)-PDTA complexes were more sluggish than those of the corresponding reactions involving EDTA.[2,3] In Fig. 1, a typical example is given. Therefore, in system b, reaction mixtures were kept in a thermostat for 50 days before being subjected to the polarographic measurements. In other systems, as the substitution reactions were completed within 7 hrs., measurements were made after the solutions prepared had been kept overnight.

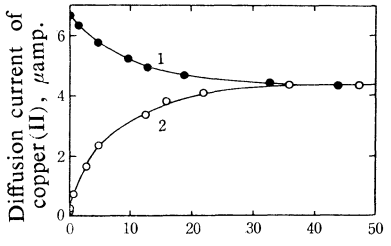

Fig. 1. Diffusion currents of copper(II) as a function of time in the forward (curve 1) and the reverse (curve 2) reactions of the substitution reaction $Cu^{2+}+NiY^{2-} \rightleftarrows CuY^{2-}+Ni^{2+}$, measured in acetate buffer solutions of pH $5.4_5$ at 25°C. Total concentrations are: $[Cu]_t=1.00\times10^{-3}$ M; $[Ni]_t=1.00\times10^{-3}$ M; $[PDTA]_t=0.99_0\times10^{-3}$ M.

## Results

In the acetate buffer solution which contains two different metal ions, $M^{m+}$ and $M'^{m'+}$, and propylenediaminetetraacetate ions, there exist the following equilibria:

$$\begin{Bmatrix} M^{m+} \\ \uparrow\downarrow \\ M(OAc)_n^{(m-n)+} \end{Bmatrix} + \begin{Bmatrix} M'Y^{(m'-4)+} \\ \uparrow\downarrow \\ M'HY^{(m'-3)+} \end{Bmatrix} \rightleftarrows \begin{Bmatrix} MY^{(m-4)+} \\ \uparrow\downarrow \\ MHY^{(m-3)+} \end{Bmatrix} + \begin{Bmatrix} M'^{m'+} \\ \uparrow\downarrow \\ M'(OAc)_{n'}^{(m'-n')+} \end{Bmatrix} \quad (1)$$

where $Y^{4-}$ denotes quadrivalent PDTA ions.

The values of $[Cu^{2+}]_{app}$ in the reaction mixtures of systems a to e which are given by[2]

$$[Cu^{2+}]_{app}=[Cu^{2+}]+\sum_1^n[Cu(OAc)_n^{(2-n)+}] \quad (2)$$

were determined at various concentrations of acetate. Then, the apparent equilibrium constants for Eq. 1,

$$K^M_{M',app}=\frac{[M'^{m'+}]_{app}\{[MY^{(m-4)+}]+[MHY^{(m-3)+}]\}}{[M^{m+}]_{app}\{[M'Y^{(m'-4)+}]+[M'HY^{(m'-3)+}]\}} \quad (3)$$

were calculated and plotted against the acetate ion concentration. These plots for systems a to e are shown in Fig. 2 to Fig. 4.

$K^M_{M',app}$ is rewritten as[2]

$$K^M_{M',app}=K^M_{M'}\frac{\alpha_{MHY(H)}}{\alpha_{M'HY(H)}}\times\frac{1+\sum_1^{n'}K_{M'(OAc)_{n'}}[OAc^-]^{n'}}{1+\sum_1^{n}K_{M(OAc)_n}[OAc^-]^n} \quad (4)^*$$

where

$$\alpha_{MHY(H)}=1+K^H_{MHY}[H^+] \quad (5)$$

$$\alpha_{M'HY(H)}=1+K^H_{M'HY}[H^+] \quad (6)$$

$$K^M_{M'}=\frac{[M'^{m'+}][MY^{(m-4)+}]}{[M^{m+}][M'Y^{(m'-4)+}]} \quad (7)$$

$K_{M(OAc)_n}$ and $K_{M'(OAc)_{n'}}$ represent the overall formation constants of $M(OAc)_n^{(m-n)+}$ and

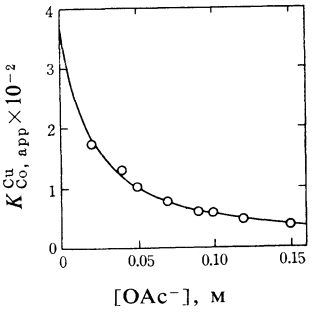

Fig. 2. $K^{Cu}_{Co,app}$ at pH 4.56 as a function of acetate ion concentration.

* $\beta$ and $\beta'$, the symbols that are given in previous papers[2,3] are replaced by $\alpha_{MHY(H)}$ and $\alpha_{M'HY(H)}$ respectively.

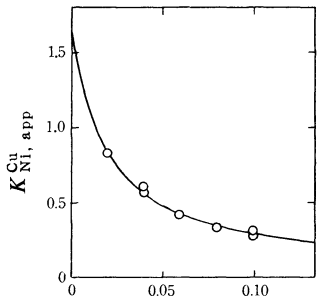

Fig. 3. $K^{Cu}_{Ni,\,app}$ at pH 4.9 as a function of acetate ion concentration.

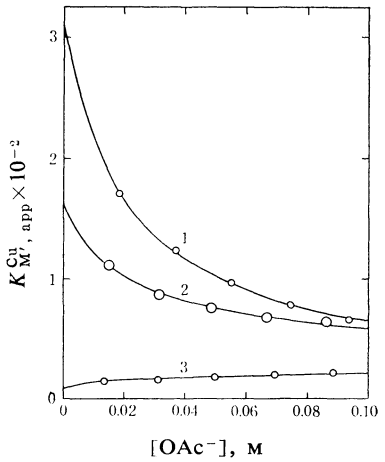

Fig. 4. $K^{Cu}_{Zn,\,app}$ (1), $K^{Cu}_{Cd,\,app}$ (2) and $K^{Cu}_{Pb,\,app}$ (3) at pH 5.4 as a function of acetate ion concentration.

$M'(OAc)_{n'}^{(m'-n')+}$, respectively, and $K^{M}_{M'}$ means the equilibrium constant of reaction given by the equation

$$M^{m+} + M'Y^{(m'-4)+} \rightleftarrows MY^{(m-4)+} + M'^{m'+} \quad (8)$$

It may be reasonable to consider the values of $\alpha_{MHY(H)}/\alpha_{M'HY(H)}$ as being approximately unity under these experimental conditions (pH 4.5—5.5), because this is true in the case of the EDTA complexes,[6] to which the PDTA complexes are closely related.

The experimental values in Figs. 2 to 4 were treated by a least square method with the aid of Eq. 4 and the formation constants of acetato complexes obtained previously,[2,3,7] the values of the equilibrium constants for Eq. 8 ($K^{Cu}_{M'}$) were determined. They are given in Table II.

Table II. Equilibrium constants for the substitution reaction (Eq. 8) involving PDTA complexes at 25°C and ionic strength 0.2

| $K^{Cu}_{Co}$ | $K^{Cu}_{Ni}$ | $K^{Cu}_{Zn}$ | $K^{Cu}_{Cd}$ | $K^{Cu}_{Pb}$ |
|---|---|---|---|---|
| $3.7\times10^{2}$ | $1.6_6$ | $3.2\times10^{2}$ | $1.6_1\times10^{2}$ | 8.8 |

The values of $K^{Cu}_{M',\,app}$ can be calculated as a function of acetate concentration using the $K^{Cu}_{M'}$ values given in Table II, the formation constants of acetato complexes[2,3,7] and Eq. 4. The solid curves in Figs. 2 to 4 are the calculated ones, which are in satisfactory agreement with the $K^{Cu}_{M',\,app}$ obtained experimentally at various acetate concentrations. This fact indicates that the values of the formation constants of acetato complexes obtained previously[2,3,7] are reliable.

## Discussion

Equation 7 means that $K^{M}_{M'}$ is equal to the ratio of the stability constant of the $M^{m+}$-PDTA complex to that of the $M'^{m'+}$-PDTA complex:

$$K^{M}_{M'} = \frac{K_{MY}}{K_{M'Y}} \quad (9)$$

For the sake of comparison, the $K^{Cu}_{M'}$ values in Table II are converted to the relative stability constants to the stability constant of zinc(II)-PDTA complex and the resulting values are given in Table III.

Smith has reported the stability constants of various PDTA complexes.[1] The $K^{M}_{Zn}$ values

Table III. The values of $K^{M}_{Zn}$ of PDTA complexes

| | Temp. °C | Ionic strength | $K^{Co}_{Zn}$ | $K^{Ni}_{Zn}$ | $K^{Cu}_{Zn}$ | $K^{Zn}_{Zn}$ | $K^{Cd}_{Zn}$ | $K^{Pb}_{Zn}$ |
|---|---|---|---|---|---|---|---|---|
| I | 25 | 0.2 | 0.85 | $1.9_0\times10^{2}$ | $3.2\times10^{2}$ | 1 | $1.9_6$ | $3.6\times10$ |
| II | 20 | 0.1 | $1.6\times10^{-2}$ | $1.0_0\times10^{-2}$ | $3.2\times10$ | 1 | 0.63 | $1.2_6\times10$ |

I. Values obtained in the present investigation.
II. Values calculated from the Smith's values.[1]

obtained from his stability constants are also given in Table III. Table IV shows the $K^{M}_{Zn}$ values calculated from the $K^{M}_{M'}$ values of the EDTA complexes obtained previously.[2,3] The $K^{M}_{Zn}$ values of the PDTA complexes obtained in this study do not agree with those calculated from the Smith's data, but are quite similar to the $K^{M}_{Zn}$ values of the EDTA complexs given in Table IV.

TABLE IV. THE VALUES OF $K^{M}_{Zn}$ OF EDTA COMPLEXES AT 25°C AND IONIC STRENGTH 0.2[2,3]

|---|---|---|---|---|---|
| 0.59 | $1.5\times10^2$ | $3.3\times10^2$ | 1 | 1.1 | $6.6\times10$ |

Recently, the stability constants of alkaline earth chelates and the acid dissociation constants (p$K$) of PDTA have been determined by Grimes et al.[8] They reported that the fourth dissociation constant (p$K_4$) of PDTA is higher than that of EDTA, and the stability constants of alkaline earth chelates of PDTA are larger than those of EDTA,[8] explaining that these are attributed to the inductive effect of the methyl group in PDTA.

Nevertheless, it is considered that the increase of stability constants in the presence of methyl group is considered to affect slightly the values of $K^{M}_{M'}$, because it may be considerably compensated. Actually, the change in the stability constants of alkaline earth chelates of PDTA[8] with increase in atomic number is parallel to those of EDTA[9] as shown in Fig. 5. Therefore, the similarity between our data of $K^{M}_{M'}$ values of PDTA complexes and those of EDTA complexes seems to be reasonable.

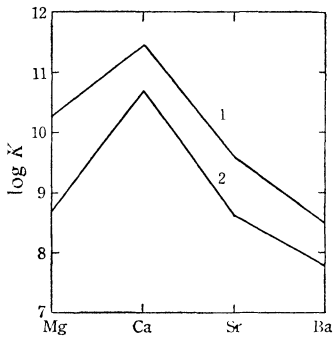

Fig. 5. Logarithms of the stability constants of alkaline earth chelate at ionic strength 0.1: (1) PDTA chelate at 30°C,[8] (2) EDTA chelate at 20°C.[9]

The values reported by Smith are considered to be somewhat erroneous, because his values for $K^{Co}_{Zn}$, $K^{Ni}_{Zn}$ and $K^{Cu}_{Zn}$ are too small.

## Summary

The relative stability constants of propylenediaminetetraacetato complexes ($K^{M}_{M'}=K_{MY}/K_{M'Y}$) of six metal ions were determined at 25°C and ionic strength 0.2 by the polarographic method reported previously.[2] The values obtained are $K^{Cu}_{Co}=3.7\times10^2$, $K^{Cu}_{Ni}=1.6_6$, $K^{Cu}_{Zn}=3.2\times10^2$, $K^{Cu}_{Cd}=1.6_1\times10^2$ and $K^{Cu}_{Pb}=8.8$ and are quite similar to the corresponding values of the ethylenediaminetetraacetato complexes respectively.

# Vibration-Rotation Spectra, the Coriolis Coupling Constants and the Intramolecular Force Field of Symmetric Top Molecules. I. The E-type Fundamental Bands of Methyl and Methyl-$d_3$ Halides

By Yonezo MORINO and Junko NAKAMURA*

(Received August 10, 1964)

It is a current problem in the determination of the intramolecular force field that a set of force constants must be chosen in such a way that they may reproduce not only the vibrational frequencies but also all the available observables that are related to the force field. Many attempts have been made to determine the intramolecular force field by using observed data of the Coriolis coupling constants as additional observables, especially in the case of molecules with methyl groups.[1a,b] As for the methyl halide molecules, however, the reported values of the Coriolis coupling constants are considered to be neither complete nor precise enough for the present purpose.[2-16] A systematic reinvestigation of infrared spectra has, therefore, been undertaken in the present study for the six species of methyl halides ($CH_3Cl$, $CD_3Cl$, $CH_3Br$, $CD_3Br$, $CH_3I$ and $CD_3I$). The present report is limited to the experimental results on the E-type fundamental bands. The results of the force-field calculation and the analyses of overtones and combination bands will be reported in the succeeding papers of this series.

Eighteen vibration-rotation spectra, $\nu_4$, $\nu_5$ and $\nu_6$ of six molecules, were resolved in the present study, and some of the previous subband assignments were revised. Analyses of the vibration-rotation bands gave the Coriolis coupling constants, the rotational constants and the frequencies of the vibrational band origins. A few bands show peculiar features which indicate the presence of perturbations, which probably influence some of the resulting data. Nevertheless, the "parallel nature" observed for the molecules investigated suggests the certainty of the present results. The assumption of the "parallel nature" was also extensively used to estimate the rotational correction terms through which the $r_0$ and $r_e$ structures were estimated.

## Experimental

**Preparation of Samples.** — All the compounds except $CH_3I$ were prepared by the direct halogenation of $CH_3OH$ or $CD_3OH$. Commercial $CH_3I$ was used after low-temperature distillation in vacuo through a U-tube packed with grained potassium hydroxide and calcium chloride. $CD_3OH$ was synthesized by the method described by Edgell and Parts[17] with some modifications; Ethylene carbonate, prepared from sodium ethylene glycolate and ethyl chloroformate, was reduced with $LiAlD_4$ to a complex compound which was then decomposed to $CD_3OH$ with monobutylcarbitol in diethylcarbitol. About 1.6 g. of $CD_3OH$ was obtained by this method starting from 2 g. of $LiAlD_4$.

$CH_3Cl$ ($CD_3Cl$) and $CH_3Br$ ($CD_3Br$) were prepared from alcohols by halogenation with phosphorus trichloride and phosphorus tribromide respectively. Sample gases were purified with potassium hydroxide, concentrated sulfuric acid and phosphorus pentoxide. $CH_3OH$ was iodized to $CD_3I$ by means of hydroiodic acid after the method of Cox, Tunner and Warner.[18]

The purities of the starting and the intermediate reagents as well as of the last products were examined by their physical constants, elemental analyses and spectroscopic analyses. The percentage of deuterium in $CD_3X$ samples was not tested, but the existence of serious impurities ($CH_2DX$, $CHD_2X$,

$CH_3X$, $CD_3OH$, HX, etc.) was not detected in their infrared spectra.

**Spectrometer.**—A Perkin-Elmer 112G grating infrared spectrometer was used throughout the investigation. $CH_3X$ and $CD_3X$ fundamentals were observed with a cell 10 cm. long. In the case of $CH_3X$, a long-path cell (with a net length of about 6 m.) was also used. The pressure of the gas was controlled in each case, ranging from 5 mmHg to some hundreds of mmHg. The resolution of the Perkin-Elmer 112G spectrometer is about 0.6 $cm^{-1}$ at 15 $\mu$ and 0.8 $cm^{-1}$ at 3$\mu$. Because the spectrometer has a slingle-beam system, the presence of water and carbon dioxide in the air seriously disturbs the observation. This difficulty was partially removed by an introduction of the stream of air free from water and carbon dioxide into the whole apparatus, but some bands were still obscured by the bands of residual water or carbon dioxide.

## Results for the E-type Fundamental Bands

All of the E-type fundamental bands were observed as a series of finely-resolved $Q$ branch subbands, with the intensity alternation to be expected for the $C_{3v}$ symmetric top molecules. As has already been pointed out, the origin of the subband peak (the position corresponding to the $J=K$ of ${}^{R}Q_K$ and ${}^{P}Q_K$) should be at the foot of the steeper side of the absorption curve. The observed curves are, however, more or less deformed by the limited resolving power of the instrument, the effect of the slit function, the pressure broadening, and other reasons. Therefore, it is almost impossible to determine the position of the subband origins precisely. The "peak frequencies," namely, the frequencies of the maximum absorption points, were accordingly measured; they correspond to those for $J_m$ in Eq. 24. (See Appendix I)

The criteria for finding the ${}^{R}Q_0$ for the E-type bands have already been discussed by several authors, especially by Overend and Crawford.[19] In many of the present investigations, however, it was found difficult to apply the method recommended by them, for the bands, the ${}^{R}Q_0$ of which could not be easily determined, were apparently irregular or in some cases, only half of the members of the series were observed; under such conditions, the measurement and the summing up of the band intensity were impossible. Consequently, the ${}^{R}Q_0$'s were determined according to the following features of the band:

1) The intensity alternation caused by the statistical spin weight, depending upon the $K$ numbers (strong for the subbands of $K=3m$, weak for $K\neq 3m$, where $m$ is an integer).

2) The gradual increase and decrease in the intensity of the subbands, with a maximum at ${}^{R}Q_0$ (besides the spin weight mentioned above). There may be the cases where the ${}^{R}Q_0$ peaks are abruptly weakened in intensity, but the survey of the peak intensities as a whole offers a reliable criterion.

3) The series of the molecules investigated must have parallel spectroscopic natures as the attached halogen atom changes from Cl to Br and to I.

Typical absorption curves are shown in Figs. 1—3. Observed peak frequencies and the assignments are listed in columns 2 and 3 of Tables I—XVIII respectively. These values were obtained as the most probable values out of several observations with different conditions. The asterisks in the tables show the peaks which were omitted from the least-squares calculations because they either are obscured by the presence of foreign bands, such as those of carbon dioxide and water, or are at apparently irregular positions.

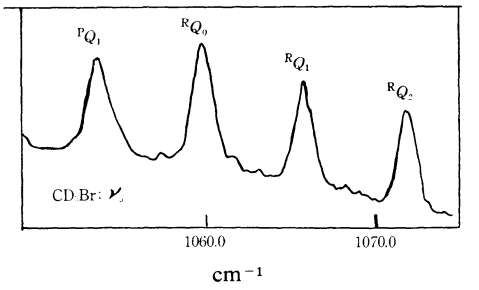

Fig. 1. $CD_3Br$; Part of $\nu_5$ ($\perp$).

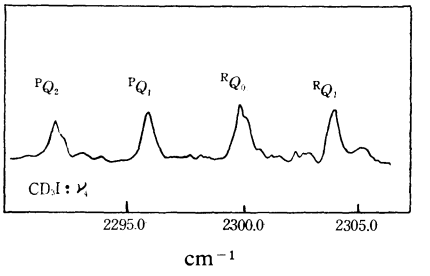

Fig. 2. $CD_3I$; Part of $\nu_4$ ($\perp$).

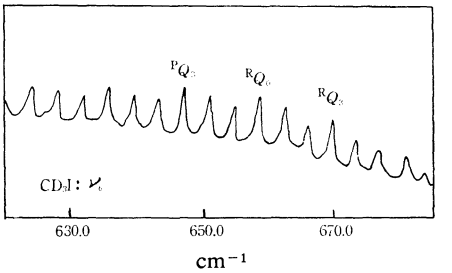

Fig. 3. $CD_3I$; $\nu_6$ ($\perp$).

19) J. Overend and B. Crawford Jr., *J. Chem. Phys.*, **29**, 1002 (1958).

If one ignores the effect of the centrifugal distortion and a slight change in the $J_m$ number in the different $K$ subbands, we should be able to fit, the observed peak frequencies to a quadratic equation of $K$, Eq. 1 :

$$\nu^{sub}=C_0+C_1K+C_2K^2 \quad (1)$$

and the separations of the successive $Q$ branches ($\Delta\nu_K$) plotted against their $K$ numbers should give a straight line with a tangent twice the coefficient $C_2$ (Fig. 4). The values of $\Delta\nu_K$ are listed in column 4 of Tables I—XVIII.

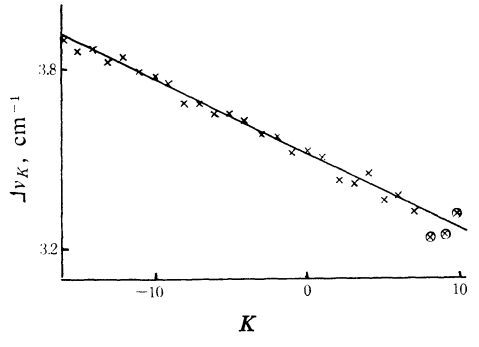

Fig. 4. $\Delta\nu_K=(Q_{K+1}-Q_K)$ : $CD_3Cl$ : $\nu_4(\perp)$ ⊗ : Overlapped with a $CO_2$ absorption.

Some peculiar features observed by the examination of $\Delta\nu_K$'s are as follows :

**(i) The $\nu_4$ Band of $CH_3Cl$.**—Figure 5 shows the irregular nature of the $\nu_4$ band of $CH_3Cl$. As has already been mentioned, each subband the $K$ number of which is a multiple of three has a greater absorption intensity than its neighbors, thus making a series of intensity alternations : strong, weak, weak, strong, etc. In the $\nu_4$ band of $CH_3Cl$, however, the sequence is apparently perturbed at about 3070 cm$^{-1}$. After a rather regular series of peaks assigned as $^RQ_{12}$—$^RQ_3$, three somewhat deformed and broad peaks follow, with a stronger peak as a fourth, from which another sequence of strong, weak, weak, starts. The separations, $\Delta\nu_K$, also change abruptly in this region, and, moreover, the tangents of the two sequences mentioned above differ beyond the range of error of the measurement. These features clearly show the existence of a certain perturbation which has not been considered before.

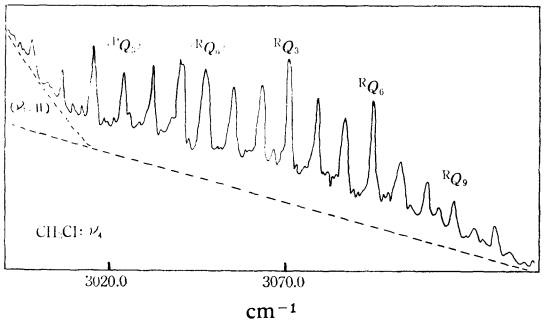

Fig. 5. $CH_3Cl$ : $\nu_4$ ($\perp$).

A similar type of irregularity takes place in the combination bands related to $\nu_4$ (the perpendicular band of $2\nu_4$,[20] and $\nu_1+\nu_4$). For the present, the peak at 3071.30 cm$^{-1}$ was assigned

| 17 | 3138.71 | $^RQ_9$ | 8.27 | 3138.69 | +0.02 |
| 18 | 3146.98 | $^RQ_{10}$ | 8.23 | 3147.01 | −0.03 |
| 19 | 3155.21 | $^RQ_{11}$ | 8.00 | 3155.27 | −0.06 |
| 20 | 3163.21* | $^RQ_{12}$ | 8.23 | 3163.46 | −0.25 |
| 21 | 3171.44* | $^RQ_{13}$ | | 3171.59 | −0.15 |

to $^RQ_3$, because this choice of $K$-numbering seems most reasonable according to the three criteria mentioned above. Three coefficients of Eq. 1 were thus estimated from the data for the bands $^RQ_3$—$^RQ_9$ for convenience.

**(ii) The $\nu_5$ Band of $CH_3I$.**—In the region from 1300 to 1600 $cm^{-1}$, two series of absorbing peaks were observed. One series, which was assigned to the fundamental band $\nu_5$ covers the region from 1378 to 1585 $cm^{-1}$. The $\Delta\nu_K$'s for this series, shown in Fig. 6 as

plotted against $K$, show a remarkable irregularity; i.e., the tangent of the $\Delta\nu_K$'s for the half of the peaks with larger wave numbers is different in value and opposite in sign from that for the other half of the peaks with smaller wave numbers.

Another series which appears in the region 1300—1400 $cm^{-1}$ is slightly weaker in intensity than the previous one. The strongest peak is at 1356.97 $cm^{-1}$. A plot of $\Delta\nu_K$ to $K$ gives a straight line with a large tangent, as is shown in Fig. 6. Three peaks in this series (1346.50, 1356.97 and 1366.98 $cm^{-1}$) coincide with those reported by Bennett and Meyer,[2] Mador and Quinn[13] and Cleveland et al.[14] They did not discriminate these three peaks from those of

$\nu_5$ and treated all peaks as members of $\nu_5$. Lageman and Nielsen[8] also observed the $\nu_5$ band of $CH_3I$, but they did not extend the region of research beyond 1380 $cm^{-1}$. This series of subbands, first observed in the present study, should perhaps be assigned to a binary combination band, $\nu_3+\nu_6$ ($E$). Many other experimental results suggest that the frequency of methyl deformation is in the region from 1440 to 1460 $cm^{-1}$, and the parallel nature of the methyl halide molecules indicates that the band origin of the $\nu_5$ of $CH_3I$ is at about 1435 —1440 $cm^{-1}$, while the observed values for the fundamental $\nu_3$ and $\nu_6$ of $CH_3I$ are 532.8 and 883.0 $cm^{-1}$ respectively. Consequently, a Fermi resonance is expected between the two vibrational states $\nu_5$ and $\nu_3+\nu_6$. This offers a reasonable explanation for the rather strong absorption intensity of the $\nu_3+\nu_6$ combination band. This type of Fermi resonance is expected, however, only in the case of $CH_3I$, because, for the other molecules, the separations $\delta=\nu_5-(\nu_3+\nu_6)$ are too large for any appreciable resonance to take place.

There is as yet no satisfactorily rigorous explanation for the anomaly of the rotational fine structures of these bands in terms of the rotational resonance; hence, only half the members of the subbands, $^RQ_2$—$^RQ_{12}$, were used to estimate the coefficients of Eq. 1 for the $\nu_5$ fundamental band. The values thus obtained are not precise. It is, nevertheless, likely that they do not differ very much from the values expected on the basis of the parallelism of six species of methyl halides.

**(iii) The Determination of $^RQ_0$ of $\nu_5$.**—All the $\nu_5$ fundamental bands of the molecules studied were found to be more or less disturbed, so the determinations of $K$ numbers for the observed peaks were difficult. The first unfavorable situation lies in the fact that the centers of the $\nu_5$ and of the $\nu_2$ ($CH_3$ or $CD_3$ sym. deform.) bands lie close together. As the absorption range of the $\nu_5$ band usually spreads over 180—250 $cm^{-1}$ because of the wide separations of the $Q$ branches, a part of the $^PQ_K$ subbands are more or less overlapped with the strong $R$ branch of the $\nu_2$ band and can, at best, scarcely be observed. This situation occurs most severely in the case of $CD_3I$, where only three subbands of $^PQ_K$ were observed. This is the main reason why the number of the observed peaks is smaller for the $\nu_5$ than for other bands. Secondly, the experimental results show that the $^RQ_0$ lines of $\nu_5$ for $CH_3Cl$, $CH_3I$, $CD_3Cl$, $CD_3Br$ and $CD_3I$ are narrower and weaker than expected and that those for $CD_3Br$ and $CD_3I$ are shifted slightly to a longer wavelength side from the expected positions. The reason for this anomaly has not yet been clarified.

Thirdly the shorter wavelength side of the $\nu_5$ band for the $CH_3X$ molecules more or less overlaps with the absorption of water vapor in the air. The overlapping region is the widest in the case of $CH_3Cl$ and the narrowest in $CH_3I$.

**(iv) The $\nu_5$ and $2\nu_3$ Band of $CD_3I$.**—A weak line with its peak at 996.9 $cm^{-1}$ was observed and assigned to the $Q$ branch of $2\nu_3$. As the $\nu_5$ state has the E symmetry and the $2\nu_3$ state, the A symmetry, no coupling is to be expected between the vibrational energy levels of $\nu_5$ and $2\nu_3$. The observed frequencies and the intensities of the neighboring four subbands which belong to $\nu_5$ are, however, perturbed in this region, perhaps through the second-order rotational resonance, and so the data for them were omitted from the least-squares calculation.

**(v) A Summary of the Observed Data.**—Taking into account the irregularities mentioned above, the coefficients in Eq. 1 were calculated by the least-squares method by using the precisely-determined wave numbers of the subbands. The results may be summarized as follows:

$CH_3Cl$, $\nu_4$; $\nu = 3046.20 \pm 8.405K - 0.0128K^2$ (2)

$\nu_5$; $\nu = 1459.89 \pm 12.022K - 0.0481K^2$ (3)

$\nu_6$; $\nu = 1019.82 \pm 6.942K + 0.0237K^2$ (4)

$CH_3Br$, $\nu_4$; $\nu = 3060.82 \pm 8.946K - 0.0327K^2$ (5)

$\nu_5$: $\nu = 1450.33 \pm 12.002K - 0.0485K^2$ (6)

$\nu_6$; $\nu = 957.16 \pm 7.448K + 0.0273K^2$ (7)

$CH_3I$, $\nu_4$; $\nu = 3064.80 \pm 9.086K - 0.0347K^2$ (8)

$\nu_5$; $\nu = 1444.98 \pm 12.162K - 0.0527K^2$ (9)

$\nu_6$; $\nu = 885.42 \pm 7.707K + 0.0335K^2$ (10)

$CD_3Cl$, $\nu_4$; $\nu = 2284.74 \pm 3.527K - 0.0125K^2$ (11)

$\nu_5$; $\nu = 1064.15 \pm 6.221K - 0.0207K^2$ (12)

$\nu_6$; $\nu = 768.93 \pm 3.373K + 0.0099K^2$ (13)

$CD_3Br$, $\nu_4$; $\nu = 2297.82 \pm 3.710K - 0.0130K^2$ (14)

$\nu_5$; $\nu = 1059.79 \pm 6.273K - 0.0155K^2$ (15)

$\nu_6$; $\nu = 714.59 \pm 3.721K + 0.0114K^2$ (16)

$CD_3I$, $\nu_4$; $\nu = 2300.05 \pm 3.822K - 0.0140K^2$ (17)

$\nu_5$; $\nu = 1053.59 \pm 6.373K - 0.0156K^2$ (18)

$\nu_6$; $\nu = 657.48 \pm 3.875K + 0.0131K^2$ (19)

The wave numbers for the subbands calculated by the use of these equations are shown in column 5 of Tables I—XVIII. The differences between the observed and the calculated wave numbers, shown in column 6, are negligibly small.

**(vi) The "Parallel Nature" of the Methyl Halide Molecules.**—It seems worthwhile to mention here the "parallel nature" of the three coefficients in Eqs. 2—19. As the compounds treated in the present study have a common structure, composed of a methyl group and a halogen atom, their physical constants may be expected to take analogous values with the systematic changes which originate from the nature of the substituents (H ⇄ D and X ⇄ Cl, Br, and I). Therefore, if a set of three arbitrary positions corresponding to the three halogen atoms (Cl, Br and I) is chosen on the abscissa, and if the coefficients are plotted on the ordinate, they make, as expected, parallel lines, depending on whether they are of $CH_3X$ or of $CD_3X$ type and on the vibrational modes shown in Figs. 7—9. The "parallel nature" of these molecules in the sense noted above was used throughout the present investigation to exclude the uncertainties and apparent irregularities of the data. However, serious deviations from the linear relation always occur for the coefficients of the $\nu_4$ band of $CH_3Cl$; this fact again suggests that the coefficients in Eq. 2 do not represent the unperturbed state of the $\nu_4$ band. If the parallel nature of the coefficients among the six species is extensively assumed, Eq. 2 might be replaced by Eq. 20

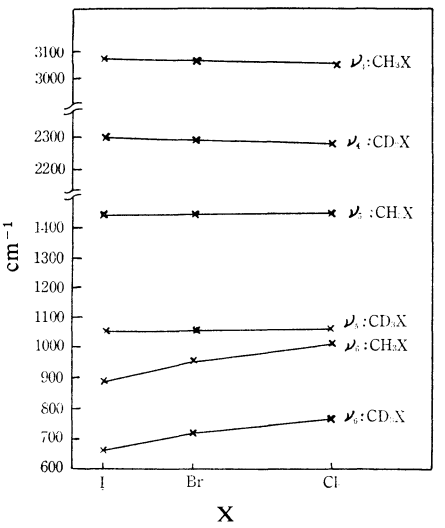

Fig. 7. "Parallel nature" of methyl halides $C_0$ of Eq. 1.

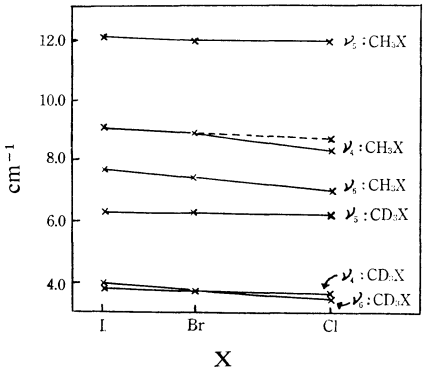

Fig. 8. "Parallel nature" of methyl halides $C_1$ of Eq. 1.

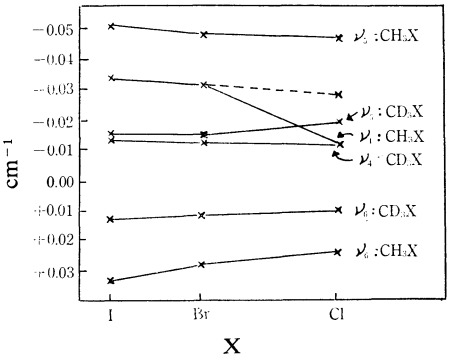

Fig. 9. "Parallel nature" of methyl halides $C_2$ of Eq. 1.

so as to fit the values of the coefficients indicated by the dotted lines in Figs. 8 and 9.

$CH_3Cl$, $\nu_4$; $\nu = 3046.20 \pm 8.720K - 0.0290K^2$ (20)

The values for the $\nu_5$ band of $CH_3I$ show an

accidental coincidence with the expected linearity, even though they are of a perturbed state.

### Coriolis Coupling Constants and Rotational Constants

The vibration-rotation energy levels of a symmetric top molecule in its ground and first-excited states are expressed, to the second order of approximation and by neglecting the effects of centrifugal distortion, by :[21]

$$E_0 = W_0 + B_0 J(J+1) + (A_0 - B_0) K^2 \qquad (21)$$

for the ground state, and

$$E_v = W_v + B_v J(J+1) + (A_v - B_v) K^2 - 2A_v \zeta_v K l_v + A_v (\zeta_v l_v)^2 \qquad (22)$$

for the first excited state, where $W$ denotes the vibrational energies ; $A$ and $B$, the rotational constants about the axes parallel and perpendicular, respectively, to the molecular axis ; $\zeta_v$, the effective Coriolis coupling constant of the degenerate mode (see Appendix II), and $l_v$, the quantum number of the vibrational angular momentum, which is taken as unity for the first excited states of the degenerate vibrations and zero for the non-degenerate vibrations.

The frequencies of the ${}^{R}Q_K$ or ${}^{P}Q_K$ subbands are then expressed as follows when the selection rule, $\Delta J=0$ and $\Delta K=\pm 1$ is taken into account :

$$\nu = \nu_0 + (B_v - B_0) J(J+1) + A_v (1-\zeta_v)^2 - B_v \pm 2[A_v(1-\zeta_v) - B_v] K + [(A_v - A_0) - (B_v - B_0)] K^2 \qquad (23)$$

where the signs + and − before the fourth term refer to the ${}^{R}Q_K$ and ${}^{P}Q_K$ branches respectively.

The experimental conditions are such that the actually-observed frequencies are "peak frequencies" which correspond to the maximum absorbing points of the peaks with certain values of $J$ (denoted as $J_m$). Thus the peak frequencies are expressed as follows :

$$\nu_m = \nu_{0K} + (B_v - B_0) J_m (J_m + 1) \qquad (24)$$

where

$$\nu_{0K} = \nu_0 + A_v (1-\zeta_v)^2 - B_v \pm 2(A_v(1-\zeta_v) - B_v) K + ((A_v - A_0) - (B_v - B_0)) K^2 \qquad (25)$$

The second term of Eq. 24 has a finite value determined by the Boltzmann distribution and the experimental conditions. It would affect the terms in the expression of $\nu_{0K}$ since the $J_m$ is dependent on the $K$ numbers (see Appendix I). Such an effect can, however, be expected to be negligibly small compared with the uncertainty in the measurement of the peak positions, so the second term in Eq. 24 was neglected and the observed data were analyzed according to Eq. 25.

Now the frequencies of the successive $Q$ branches are expressed by the $K$-dependent equation, the coefficients of which are composed of the molecular parameters, $\nu_0$, $A_0$, $B_0$, $A_v$, $B_v$ and $\zeta_v$. Nevertheless, it is impossible to obtain individual values of these parameters directly from a comparison of Eq. 25 with the observed relations, Eqs. 2—19, because there are more than three unknown parameters. At this stage, therefore, various conventional approximations have been proposed. In the present investigation, two alternative methods were tested.

**Method I.**—In the first method of approximation, the following assumptions were used in order to minimize the number of unknown molecular parameters :

i) The Coriolis sum rule was approximated as $\zeta_4 + \zeta_5 + \zeta_6 = B_0/2A_0$.[22]

ii) The coefficient of $K$ in Eq. 25 was replaced by $2(A_v - B_0 - A_0\zeta_v)$.

iii) The values of $B_0$ were taken from the data obtained by the analyses of microwave spectra[23] listed in Table XIX.

iv) The term $B_v - B_0$ was assumed to be zero.

TABLE XIX. THE $B_0$ VALUES OF METHYL HALIDES ($cm^{-1}$)

| | $CH_3Cl$ | $CH_3Br$ | $CH_3I$ | $CD_3Cl$ | $CD_3Br$ | $CD_3I$ |
|---|---|---|---|---|---|---|
| $B_0$ | 0.4434 | 0.3186 | 0.2502 | 0.3616 | 0.2568 | 0.2015 |

Assumptions i and ii are made for the sake of simplicity. Assumption iii requires the use of the effective atomic weights of chlorine and bromine since the microwave results are given for isotopic species. As no band splittings were observed for the isotopic species of $^{35}Cl$ and $^{37}Cl$, nor for those of $^{79}Br$ and $^{81}Br$, in the degenerate bands, the observed bands of $CH_3Cl$ and $CD_3Cl$ were assigned to those of the $^{35}Cl$ species, (accordingly, the $B_0$ values are those of the $^{35}Cl$ species), whereas the $B_0$ values of methyl bromide were taken as the average of the $^{79}Br$ and $^{81}Br$ species because the contributions of these two species to the intensities of the absorption bands were expected to be equal in the case of bromides.

By the use of these assumptions, the coefficients of Eqs. 2—19 lead to the values of $A_0$, $A_v$, $\zeta_v$ and $\nu_0$ shown in Table XX. Set 1 of

| | $\nu_6$ | | 5.169 | 0.208 | 882.4 |
| $CD_3I$ | $\nu_4$ | | 2.572 | 0.178 | 2298.1 |
| | $\nu_5$ | 2.586 | 2.570 | −0.316 | 1049.3 |
| | $\nu_6$ | | 2.599 | 0.178 | 655.9 |

$CH_3Cl$ was calculated by the use of Eqs. 2, 3 and 4, and set 2, by the use of Eqs. 3, 4 and 20.

**Method II.**—It may readily be seen that a more clear-cut treatment is possible if all the rotational correction terms $(A_v-A_0)$ and $(B_v-B_0)$ are known. The knowledge of these values is also indispensable for the determination of the molecular structures at their equilibrium state. Theoretically, the $A_v$ and $A_0$ are expressed as follows:

$$A_v=A_e-\sum_i \alpha_i(v_i+g_i/2)$$

and

$$A_0=A_e-\sum_i \alpha_i(g_i/2) \qquad (26)$$

where $\alpha_i$ is the correction term connected with the $i$th vibrational mode and is a function of the anharmonic terms in the potential function. Similar relations hold for $B_v$ and $B_0$ when we replace $\alpha_i$ with $\beta_i$. Efforts were also made to obtain information about the values of $\alpha_i$ and $\beta_i$. The results obtained to date for the methyl halide molecules are summarized in Table XXI (see Appendix III for the experimental sources). The precise values of $A_e$ and $B_e$ can not be obtained until Table XXI is filled up with appropriate values. However, a close examination of Table XXI suggests the possibility of obtaining rough values of $(B_e-B_0)$ and $(A_e-A_0)$. An interesting relation was obtained when the $\alpha_i/A_0$ and $\beta_i/B_0$ ratios were calculated for all the observed values of $\alpha_i$ and $\beta_i$; that is, the ratios are characteristic of the $i$th vibrational mode and similar for the six species of methyl halides, the deviations being within ±0.1% of $A_0$ (or $B_0$). Therefore, the $\sum_i \alpha_i g_i/2$ and $\sum_i \beta_i g_i/2$ sums can be estimated for all the six species by using the observed data of $A_0$ and $B_0$, with a possible error of only ±0.6%, if at least six $\alpha_i$'s and six $\beta_i$'s for the six normal vibrations are known. An estimate was made as follows in the present case:

TABLE XXI. THE OBSERVED VALUES OF $\alpha_i$ AND $\beta_i$ (cm$^{-1}$)

others: the present study. See Appendix III.

Note added in proof: Recently the authors have been informed by Dr. E. Jones that all the fundamentals, and many overtones and combination parallel and perpendicular bands of methyl halides have been measured and analyzed at Oxford.

1) As for $\beta$'s, all six values from $\beta_1$ to $\beta_6$ are available for $CH_3Cl$. By the use of these values, $B_4$, $B_5$, $B_6$ and $B_e$ were assumed for all the species as follows:

$$B_4 = B_0(1+0.0005)$$
$$B_5 = B_0(1+0.0048)$$
$$B_6 = B_0(1-0.0037)$$

and

$$B_e = B_0(1+0.0082)$$

where the $B_0$ values were taken from Table XIX.

2) There is no information about the absolute values of $\alpha_2$ and $\alpha_3$. However, an examination of the $Q$-branch shapes suggests that these terms have almost the same values but opposite signs ($\alpha_2 < 0$, $\alpha_3 > 0$); $\alpha_2+\alpha_3$ was consequently assumed to be zero.

3) The values of $\alpha_1$ was taken to be 1% of $A_0$.

4) For $\alpha_4$, $\alpha_5$ and $\alpha_6$, the observed values were used.

5) Assumptions 1 to 4 made it possible to estimate all the necessary values of the rotational constants, if another assumption on the Coriolis sum rule, $\zeta_4+\zeta_5+\zeta_6 = B_e/2A_e$, was made together with Eq. 25.

By using these estimated values, the molecular parameters, $A_e$, $A_0$, $A_v$ and $\zeta_v$, of $CH_3X$ and $CD_3X$ can be independently calculated from the observed data of the coefficients $C_0$, $C_1$ and $C_2$. The resultant values of $A_e(H)$ and $A_e(D)$ must satisfy the relation $A_e(H)m_H = A_e(D)m_D$. In the present results, however, the relation did not strictly hold and the deviation from the expected ratio of $A_e(H)/A_e(D)$ was largest for the case 1 of chlorides and was negligibly small for iodides. This inconsistency arose partly because the estimates of $(A_e-A_0)$ and $(B_e-B_0)$ include uncertainties and partly because the experimental data on $CH_3X$ (especially on $CH_3Cl$) include anomalies, so that the $A_e$ and $A_0$ values obtained by using these data must be influenced by the anomalies through the Coriolis sum rule used in the analysis.

At present, therefore, the values $A_e$, $A_v$, $A_0$ and $\zeta_v$ of $CD_3X$ (of which less anomaly was observed in the spectra) were first determined by the method mentioned above. The $A_e(D)$ values thus obtained were then reduced by the $A_e(H)m_H = A_e(D)m_D$ relation to $A_e(H)$, from which the $B_e/2A_e$ ratio and, henceforth, a set of $A_v$s and $\zeta_v$s for $CH_3X$ were so determined as to satisfy the Coriolis sum rule, $\zeta_4+\zeta_5+\zeta_6 = B_e/2A_e$. The final results are shown in Table XXII.

A comparison of the values in Tables XX and XXII provides the useful suggestion that method I, which is simpler than method II,

( ); estimated values: see text.

is a good approximation as far as the determination of $\zeta_v$ is concerned. A third, and the simplest, method of analysis is to use the values of $A_0$ calculated with the structure parameters determined by other experimental methods. This method is, however, less desirable because the uncertainty of $A_0$ values directly influences the value of $\zeta_v$, and, as will be discussed in the next section, the values of $A_0$ estimated by the analysis of microwave spectra differ considerably from those of the present investigation.

When all of the $\zeta_v$ values can be observed, the use of the Coriolis sum rule has the merit that a set of self-consistent molecular parameters, including the observed values of $A_e$ (or at least $A_0$), can be obtained from the analysis of the vibration-rotation spectra. An unfavorable point, however, lies in the fact that the irregularity or uncertainty of one vibrational mode affects all the other values through the sum rule, as was observed in the case of $CH_3Cl$.

## The Structures of Methyl Halides

In the preceding section, the rotational constants, $A_e$, $B_e$, $A_0$ and $B_0$, of the six species of methyl halides were obtained with a number of empirical assumptions and approximations. These rotational constants are related to the moments of inertia, $I_a$ and $I_b$, about the axes

parallel and perpendicular to the molecular axis, respectively, by the equations;

$$A_e = h/(8\pi^2 c I_a{}^e)$$

and

$$B_e = h/(8\pi^2 c I_b{}^e) \quad (27)$$

The terms $I_a{}^e$ and $I_b{}^e$ are, in turn, expressed by the molecular parameters of the equilibrium configuration of the molecule:

$$I_a{}^e = 2m_H r_{He}{}^2(1-\cos\theta_e)$$
$$I_b{}^e = m_H r_{He}{}^2(1-\cos\theta_e) + m_H(m_C+m_X) \times r_{He}{}^2(1+2\cos\theta_e)/M + m_X r_{Xe}[(3m_H + m_e) r_{Xe} + 6m_H r_{He}((1+2\cos\theta_e)/3)^{1/2}]/M \quad (28)$$

where $m_H$, $m_C$ and $m_X$ denote the masses of the atoms H, C and X respectively. $\theta_e$ is the angle HCH of the equilibrium configuration, and $M=(3m_H+m_C+m_X)$ is the total mass of the molecule. Analogous relations hold for $A_0$ and $B_0$. It should be noted that $A_0$ and $B_0$ include terms originating both from the coupling of vibration and rotation and from the anharmonicity of the potential function. Moreover, they have these terms as a result of taking an average of $1/r^2$ over the ground vibrational state. Thus the determination of the so-called "$r_0$ structure" is by no means the final goal of our structure determination. However, it seems interesting to compare the $r_0$ structures of methyl halides estimated from microwave spectra[23] with those estimated by the use of the present $A_0$ values.

Since there are three unknown parameters, $r_{H_0}$, $r_{X_0}$ and $\theta_0$, they can not be determined from the $A_0$ and $B_0$ values alone. On the other hand, the $r_0$ structures obtained from microwave spectra depend on the changes in $B_0$ resulting from the substitution of the isotopes in the molecule, and, although they are uncertain because of the neglect of the changes in the zero-point contributions, the $r_{X_0}$ values are usually determined more precisely than those of $r_{H_0}$ and $\theta_0$. Therefore, the values of $r_{X_0}$ were taken, for the sake of convenience, from the microwave data.[23] Assuming the same values of $r_{X_0}$ for the $CH_3X$ and $CD_3X$ molecules, the other parameters were obtained by the use of the $A_0$ and $B_0$ values determined above. The results are shown in Table XXIII, where the values for $CH_3Cl(1)$ and $CH_3Cl(2)$ correspond to the use of Eqs. 2 and 20 respectively.

TABLE XXIII. THE $r_0$ STRUCTURES OF METHYL HALIDES

| | $r_{X_0}$, Å | PR | | M | |
|---|---|---|---|---|---|
| | | $r_{H_0}$, Å | $\theta_0$ | $r_{H_0}$, Å | $\theta_0$ |
| $CH_3Cl$ (1) | (1.7810) | 1.1050 | 110°12′ | 1.113 | 110°31′ |
| $CH_3Cl$ (2) | (1.7810) | 1.0995 | 110°00′ | | |
| $CD_3Cl$ | (1.7810) | 1.0912 | 110°11′ | 1.104 | 110°43′ |
| $CH_3Br$ | (1.9391) | 1.0978 | 110°46′ | 1.113 | 111°14′ |
| $CD_3Br$ | (1.9391) | 1.0908 | 111°00′ | 1.104 | 111°26′ |
| $CH_3I$ | (2.1392) | 1.0956 | 110°53′ | 1.113 | 111°25′ |
| $CD_3I$ | (2.1392) | 1.0900 | 111°14′ | 1.104 | 111°37′ |

( ): assumed.
PR: Present investigation.
M: Ref. 23.

The structures proposed by Miller et al.[23] (shown for comparison in columns 2, 5 and 6 of Table XXIII) are those determined on the assumption that the difference $r_{H_0}-r_{D_0}=0.009$ Å for all the pairs of $CH_3X$ and $CD_3X$, irrespective of the halogen atoms. The results of the present investigation show, however, that the values of $r_{H_0}-r_{D_0}$ differ slightly according to the change in halogen atoms if the $r_X$ is taken as common for the two species, $CH_3X$ and $CD_3X$. The absolute values of $r_H$ and $r_D$ are smaller than those in column 5. As for the bond angles, the conclusion of Miller et al. that the angle HCH is larger than the tetrahedral one was again confirmed. As a whole, the $A_0$ values estimated by using the $r_H$ and $\theta$ values by Miller et al. are considerably larger than those observed in the present study.

When the configurations of $CH_3X$ and $CD_3X$ in their equilibrium state is assumed to be the same, the $r_e$ structures of methyl halides are obtained from the values of $A_e$ and $B_e$ without further assumptions, as is shown in Table XXIV.

TABLE XXIV. THE $r_e$ STRUCTURES OF METHYL HALIDES

| | $r_{X_e}$, Å | $r_{H_e}$, Å | $\theta_e$ |
|---|---|---|---|
| $CH_3Cl$, $CD_3Cl$ | 1.779 | 1.079 | 110°43′ |
| $CH_3Br$, $CD_3Br$ | 1.936 | 1.080 | 111°35′ |
| $CH_3I$, $CD_3I$ | 2.136 | 1.079 | 112°00′ |

Since the values of $A_e$ and $B_e$ employed are uncertain, these parameters should also include large errors, yet the general tendency, ($r_{Xe} < r_{X_0}$ and $r_{He} < r_{H_0}$) seems reasonable when the anharmonicity of the potential field is thought to have such a form as is expressed by the Morse function. The error of 1% in the $A_e$ value corresponds to the change of $\pm 0.003$ Å in $r_{He}$ and that of $\pm 10'$ in $\theta_e$. The effect of the errors in the $B_e$ values should be more serious.

## Discussion

The theoretical and numerical calculations of the intramolecular force field using the Coriolis coupling constants[1] have proved that these constants are useful observables for the

determination of the force field. This fact, however, means in turn that the experimental values of the Coriolis coupling constants must be determined precisely enough to give a critical check of the force field. The present investigation shows that the accuracy of the observed values of the Coriolis coupling constants is influenced by many factors, such as

1) The accuracy of the spectral measurement,

2) The approximations used in the course of the analysis,

3) The assignment of the $K$ numbering, the existence of the Fermi resonance, and other interactions, and

4) The effect of anharmonicity.

**1)** The first factor depends almost entirely on the uncertainties of the optical instrument used. The minimum requirement is that the individual $Q$ branches are well resolved and that the accuracy of the measurement of peak frequencies is such that the $K$-dependence of the successive $Q$ branch separations can be observed. The methyl halide molecules, of which the three off-axial atoms are all hydrogen or all deuterium, have the largest $A_0$ values among the symmetric top molecules; yet a grating spectrometer of medium dispersion is necessary for the observation of their spectra to satisfy the above requirement.

The maximum uncertainty of the observed frequencies is $\pm 0.1\ \mathrm{cm}^{-1}$. The coefficients of Eqs. 2—20 are determined by the least-squares method, using the observed data, so the accuracy of $C_0$, $C_1$ and $C_2$ in Eq. 1 is a function of the number of observed peaks. The standard deviations of these coefficients are estimated to be of the following orders of magnitude:

$$\sigma(C_0) = \pm 0.05, \qquad \sigma(C_1) = \pm 0.005$$

and $$\sigma(C_2) = \pm 0.0005\ \mathrm{cm}^{-1}$$

The effect of these deviations on the $\zeta$ values is estimated to be less than 0.001.

**2) a)** "*Peak Frequency.*"—The uncertainties due to the "peak frequency" measurement are discussed in Appendix I. As the final result depends on the slit function of the instrument, the estimation of the error is difficult. The upper limit of the error may, however, be $(B_v - B_0)(kT/hB_0)^{1/2}$ for the $C_1$ in the case of ${}^{R}Q_0 - {}^{R}Q_n$. This term amounts to $\pm 0.042\ \mathrm{cm}^{-1}$ for the $\nu_5$ band of $CD_3Cl$, and this leads to an error of $-0.008$ for $\zeta_5$.

**2) b)** *The Approximation of* $(\zeta_v^{(z)})'$ *to* $\zeta_v^{(z)}$.—The difference is of the order of 0.004, as will be estimated in Appendix II.

**2) c)** *The Reducction of the Molecular Parameters from the Observed Coefficients in Eq. 1.* —As the theoretical expression of the subband frequencies (Eq. 25) consists of many molecular parameters, approximations must be introduced so as to determine them by using the observed data. A comparison of two alternative treatments in the preceding section (Tables XX and XXII) will show, however, that the $\zeta$ values are little affected by the method of analysis as long as the value $(A_v - A_0)$ is taken into account and the Coriolis sum rule is used. The difference in the $\zeta$'s given in Tables XX and XXII is less than 0.003.

**3) a)** *The Assignment of the K Numbering.* —As has been discussed in the preceding section, the determination of the $K$ numbers in a series of $Q$ branches is very difficult and, therefore, there sometimes remains an ambiguity in the assignment. The change of assignment, however, results in a fairly large variation in the $\zeta$ values. Revision of the assignment $Q_K$ to $Q_{K+1}$ leads to the change of $C_1$ to $(C_1 - 2C_2)$. The magnitude of $C_2$ is $0.01$—$0.05\ \mathrm{cm}^{-1}$ for the fundamental bands of methyl halides. (Some of the combination bands have greater $C_2$ values.) Accordingly, a revision of $Q_K$ to $Q_{K\pm 3}$ (which occurs rather frequently), with large $C_2$ values, results in a change in $\zeta$ of up to $\pm 0.03$.

**3) b)** *The Effect of Resonance.* — When a series of $Q$ branches is well resolved but has an irregular feature, the existence of rotational resonances must be suspected (e.g., the $\nu_4$ of $CH_3Cl$ and the $\nu_5$ of $CH_3I$). Complete analyses of such bands have not yet been reported. Therefore, the values can not be determined with certainty. For example, Cleveland et al.[14] obtained a value of the $\zeta_5$ of $CH_3I$ ($\zeta_5 = -0.208$) by making all the data fit a quadratic equation of $K$ with equal weights. The present result ($\zeta_5 = -0.244$) is based on the less-perturbed part of the series.

These two factors, a) and b), include errors of an "unknown" order; they may amount to large values if the band in question alone is investigated. In the present investigation, however, the consideration of the "parallel nature" partly excludes such uncertainties, so that the accuracy of the final result may be estimated, after all the factors mentioned are taken into account, to be $\pm 0.02$ in the absolute value of the Coriolis coupling constants.

The last factor, "anharmonicity," represents the question of whether the observed $\zeta$ values can be regarded as $\zeta_e$, in other words, whether the Coriolis coupling constants can be expressed by the equations:

$$\zeta = \zeta_e + \sum_{i,j} \Delta\zeta_{ij}(v_i + g_i/2)(v_j + g_j/2) \qquad (29)$$

or

$$\zeta = \zeta_e + \sum_{i} \Delta\zeta_{i}(v_i + g_i/2) \qquad (29')$$

as in the case of the vibrational or rotational

anharmonic terms. This problem has not yet been elucidated either theoretically or experimentally; the discussion will be postponed to our coming paper on the analysis of the combination bands of methyl halides.

## Summary

The infrared spectra of $CH_3X$ and $CD_3X$ (X=Cl, Br and I) have been observed with a high-resolution instrument in the region 500 —3300 $cm^{-1}$. The rotational fine structures of all the E-type fundamental bands have been resolved and analyzed, giving the Coriolis coupling constants, the rotational constants and the frequencies of the band origins. The uncertainties of the observed molecular constants have been discussed. On the basis of the observed data for the rotational constants and their changes by the excitation of vibration, the structures of methyl halide molecules have been determined.

The authors are greatly indebted to Dr. Chi Matsumura for his kind help in the course of their experiments. This work was supported by a grant-in-aid for fundamental scientific research from the Ministry of Education, to which the authors' thanks are also due.

## Appendix I

The definition of the "peak frequency" is simply the frequency of the maximum absorption point of a peak. The observed values of individual subbands included in Tables I—XVIII are, as mentioned in the text, the "peak frequencies." Strictly speaking, however, the absolute value of the "peak frequency" is influenced by many factors. A certain peak of the $^RQ_K$ or $^PQ_K$ of a symmetric top molecule consists of many lines labelled by the $J$ numbers and is located at the position $\nu=\nu_{0K}+(B_v-B_0)J(J+1)$, and the intensity ratio of these lines is given by:

$$\left.\begin{aligned} I_{^RQ_K} &\propto 2(2J+1)\frac{(J+1+K)(J-K)}{J(J+1)} \\ &\quad \times e^{-F(J\cdot K)hc/kT} \\ I_{^PQ_K} &\propto 2(2J+1)\frac{(J+1-K)(J+K)}{J(J+1)} \\ &\quad \times e^{-F(J\cdot K)hc/kT} \end{aligned}\right\} \quad (30)$$

Cleveland et al.[14] applied these relations directly to the case of methyl halides and gave $J_{max}$ values which depend on the $K$ numbers of the subbands and the rotational constants of the molecule. Such a treatment is, however, correct only if the individual lines of different $J$ numbers are resolved.

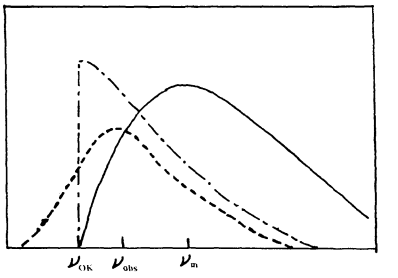

Fig. 10. E type $^RQ_0$ branch (schematic).
———: Intensity distribution by Eq. 30
– – – –: "Averaged" intensity distribution by Eq. 31
– – – –: Observed (re-averaged over the slit function)

In the case of a lower dispersion, the intensity of the lines are averaged over the unequal separations of successive $J$ number lines ($(B_v-B_0)\times(2J+1)$), and, accordingly, the $(2J+1)$ factor of Eq. 30 must be dropped out (See Fig. 10). Thus, the "averaged intensity" is expressed as follows:

$$\left.\begin{aligned} I_{av}(^RQ_K) &\propto \frac{2(J+1+K)(J-K)}{J(J+1)} \\ &\quad \times e^{-F(J\cdot K)hc/kT} \\ I_{av}(^PQ_K) &\propto \frac{2(J+1-K)(J+K)}{J(J+1)} \\ &\quad \times e^{-F(J\cdot K)hc/kT} \end{aligned}\right\} \quad (31)$$

The $K$-dependence of the $J_m$ number for the maximum intensity in Eq. 24 can be derived, after the differentiation of Eq. 31, as:

$$J_m(J_m+1)=(kT/hB_0)^{1/2}(K(K+1))^{1/2} + (1/2)K(K+1) \quad (32)$$

The "peak frequency" in the sense of Eq. 31 is given, instead of as Eq. 24, as follows:

$$\begin{aligned} {}^RQ_K:\ \nu &= \nu_0+(A_v(1-\zeta_v)^2-B_v)+2(A_v(1-\zeta_v)-B_v)K \\ &\quad +((A_v-A_0)-(B_v-B_0))K^2 \\ &\quad +(B_v-B_0)((kT/hB_0)^{1/2}(K(K+1))^{1/2} \\ &\quad +(1/2)K(K+1)) \\ &= \nu_0+(A_v(1-\zeta_v)^2-B_v)+2(A_v(1-\zeta_v) \\ &\quad -B_0-(3/4)(B_v-B_0))K+((A_v-A_0) \\ &\quad -1/2(B_v-B_0))K^2+(B_v-B_0)(kT/hB_0)^{1/2} \\ &\quad \times(K(K+1))^{1/2} \end{aligned} \quad (33)$$

The expression for the $^PQ_K$ is consistent with that for the $^RQ_K$ when $(K+1)$ is replaced by $(K-1)$, except for the sign of the last term. These equations may be visualized thus: the "peak" of the E-type subbands is shifted towards the lower or higher frequency, depending on whether the sign of $(B_v-B_0)$ is negative or positive, and the magnitude of the shift is nearly proportional to $|K|$. The separations of the successive $Q$ branches plotted against their $K$ numbers will, in this case, not lie on a straight line but have a break around the band center, as Fig. 11 shows. The conventional

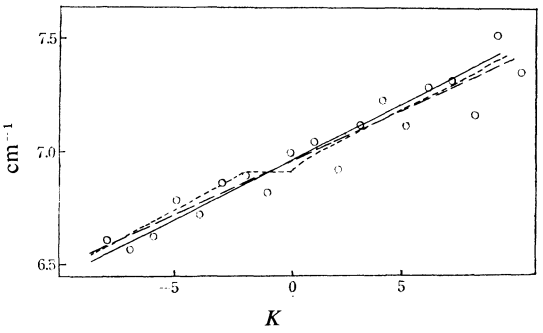

Fig. 11. Effect of the "peak-frequency" measurement.
$\Delta\nu_K=(Q_{K+1}-Q_K)$ : $CH_3Cl$ : $\nu_6$
——: From the subband origin $\nu_{0K}$ of Eq. 25
----: From the "peak frequency" $\nu_m$ of Eq. 24
– – –: Least-squares fit of the observed data to Eq. 1
○ : Observed

fitting of the "peak frequencies" to the quadratic equation of $K$, as was made in the preceding section, will result in small uncertainties for the three coefficients, $C_0$, $C_1$ and $C_2$, of Eq. 1, and the magnitude of the errors depends on the numbers of the observed subbands. For example, the observation of the ${}^RQ_n$ to ${}^PQ_n$ subbands leads to the errors of:

$(3/16)(B_v-B_0)(kT/hB_0)^{1/2}n$ for $C_0$

0 for $C_1$ and

$(kT/hB_0)^{1/2}/(K+1/2)$ for $C_2$.

In another case, that of ${}^RQ_0$ to ${}^RQ_n$, the errors are:

0 for $C_0$

$(kT/hB_0)^{1/2}$ for $C_1$ and

0 for $C_2$.

The above discussion must, however, be again modified when the slit function of the instrument is taken into account. An optimistic expectation is that the effect of the last term in Eq. 33 will be made much smaller after the re-average of the band intensity over the slit function is made. Practically speaking, the dispersions of the observed "peak frequencies" are comparable to or greater than the estimated theoretical "errors," as is shown in Fig. 11; therefore, the contribution of the "peak" measurement is disregarded in the present investigation. The cited values of $\nu_0$ do not include such corrections; corrections of $\pm 0$—$0.4\,cm^{-1}$ should be added to those $\nu_0$ values where the upper sign is for the band origins of $\nu_4$ and $\nu_5$, and the lower sign, for the $\nu_6$.

## Appendix II

According to Nielsen,[21] the energy level of a symmetric top molecule can be expressed as follows:

$$E/hc=W_v+B_vJ(J+1)+(A_v-B_v)K^2\mp 2\tilde{A}_v(\sum l_s\zeta_v^{(z)})K \qquad (34)$$

where $W_v$ is the vibrational energy; $A_v$ and $B_v$ are the rotational constants about the axes parallel and perpendicular to the molecular axis respectively; $z$ denotes the direction parallel to the molecular axis; and $J$ and $K$ are the rotational quantum numbers. $A_v$, $\tilde{A}_v$ and $B_v$ have the following expressions:

$$A_v=A_e-\sum_{s\sigma}\alpha_{s\sigma}(v_s+g_s/2)$$

$$\tilde{A}_v=A_e-\sum_{s\sigma}\tilde{\alpha}_{s\sigma}(v_s+g_s/2)$$

$$B_v=B_e-\sum_{s\sigma}\beta_{s\sigma}(v_s+g_s/2)$$

$$A_e=h/(8\pi^2cI_a^e)$$

$$B_e=h/(8\pi^2cI_b^e)$$

$$\tilde{\alpha}_{s\sigma}=\alpha_{s\sigma}+2\sum_{s'\sigma'}A_e(A_e/g_s\omega_s)\times[(3\lambda_s+\lambda_{s'})/(\lambda_s-\lambda_{s'})](\zeta_{s\sigma s'\sigma'}^{(z)})^2 \qquad (35)$$

where the $\alpha_{s\sigma}$ and $\beta_{s\sigma}$ are correction terms to $A_v$ and $B_v$ respectively, and $v_s$ and $g_s$ are the quantum number and the degeneracy of the $s$-th vibrational mode respectively.

Since the terms $A_v$ and $\tilde{A}_v$ differ slightly from each other, $\zeta_v^{(z)}$ must be modified to $(\zeta_v^{(z)})'$ if Eq. 34 is rewritten in such a way as to include only $A_v$ and $B_v$ as the rotational constants:

$$E/hc=W_v+B_v(J+1)J+(A_v-B_v)K^2\mp 2A_v(\sum l_v(\zeta_v^{(z)})')K \qquad (34')$$

$$(\zeta_v^{(z)})'=\zeta_v^{(z)}[1-2\sum_{s\sigma}\sum_{s'\sigma'}(A_e/g_s\omega_s)\times((3\lambda_s+\lambda_{s'})/(\lambda_s-\lambda_{s'}))(\zeta_{s\sigma s'\sigma'}^{(z)})^2(v_s+g_s/2)] \qquad (36)$$

The non-vanishing elements of $\zeta_{s\sigma s'\sigma'}^{(z)}$ are, in the case of methyl hadides, as follows:

$$\zeta_{4a5b}^{(z)},\ \zeta_{4a6b}^{(z)},\ \zeta_{5a6b}^{(z)}\neq 0$$

Accordingly, a numerical calculation shows that the second term in the brackets of Eq. 36 amounts, for example, to 0.004 in the case of the $\zeta_4$ of $CH_3Cl$; therefore, the difference between $\zeta_v^{(z)}$ and $(\zeta_v^{(z)})'$ is negligibly small when compared with the experimental errors included in the absolute values of $\zeta_v$. Thus, Eq. 34' is used in the present investigation instead of Eq. 34, in which $(\zeta_v^{(z)})'$ is simply expressed as $\zeta_v$.

## Appendix III

Experimental methods for obtaining the correction terms of the rotational constants ($\alpha_i$ and $\beta_i$ of Eq. 26) will be briefly discussed here. Table XXI includes the $\alpha_i$'s and $\beta_i$'s hitherto observed. The superscripts I, M and O designate the experimental methods used (I: infrared, M: microwave, O: infrared overtone), while a)—e) indicate the authors.

An analysis of the microwave spectra gives extremely precise values of $B_0$ and, in some cases, $B_v$. However, the application of this method is limited to the "$\beta_i$" of lower vibrational frequencies, about $2000\,cm^{-1}$ at most.

An analysis of the fine structures of the infrared and Raman spectra also gives the rotational constants, but such an analysis is usually restricted by the low resolving power of the instrument. Accurate values of $\alpha_i$ or $\beta_i$ can be obtained by this method only if the individual rotational lines are well resolved.

For non-degenerate vibrational modes, $\beta_i$ is obtained from a separation of resolved P- and R-branch lines ($\Delta K=0$, $\Delta J=\pm 1$), and $\alpha_i$, from the $K$-dependence of center $Q$-branch lines ($\Delta K$, $\Delta J=0$).

For degenerate vibrations, the values of $\alpha_i$ are obtained from the $K$-dependence of ${}^{R}Q_K$ and ${}^{P}Q_K$ separations ($\Delta J=0$, $\Delta K=\pm 1$). The $\beta_i$'s of the E-type might be obtained if the ${}^{R}P_K$, ${}^{R}R_K$, ${}^{P}P_K$ and ${}^{P}R_K$ lines are resolved. This is the case for the high-resolution studies of $NH_3$, $ND_3$, etc. However, in most cases of the E-type bands of methyl halides, these lines are weak and unresolved, making a smooth background for the prominent ${}^{R}Q_K$ and ${}^{P}Q_K$ lines. Recently, Brown and Edwards[28] observed these lines for some of the combination bands of $CH_3Br$ and $CH_3I$. The resultant values of $\beta$ are, however, not included in Table XXI because these values can not be reduced to those of the individual fundamental modes.

Overtone bands of a degenerate mode are sometimes useful for determining the $\beta_i$ because an overtone band of E-type fundamentals consists of an A- and an E-type band, and the resolved A-type band gives the value $2\beta_i$. The values in Table XXI with the "O" superscripts and referred to as "overtone" in the footnote are one half of the $\beta_{2\nu i}$ values.

When the individual lines are not resolved when their contours are observed (e.g., the $Q$ branch of an A-type band, the ${}^{R}Q_K$ or ${}^{P}Q_K$ peaks of an E-type band, etc.), precise values of $\alpha_i$ or $\beta_i$ are not obtained, as has been discussed in Appendix I. The sign of $\alpha_i$ or $\beta_i$ is, however, known from the shape of the peaks; that is, $\alpha_i$ or $\beta_i$ take a negative sign when the slope is steeper on the lower frequency side of the peak, and a positive sign in the opposite case. The terms in Table XXI with a + or − sign alone indicate that only the signs of $\alpha_i$ or $\beta_i$ were determined in this way by the present investigation. The accuracy of the $\alpha_i$ and $\beta_i$ values depends partly on the precision of the measurement. Another source of error lies, however, in the theoretical treatment; that is, apparent values of the rotational constants can not, in some cases, be expressed by such ordinary equations as are given in Eq. 26.

Two such cases are the rotational higher-order anharmonicity and the resonance through an accidental degeneracy of vibrational modes. Practically, therefore, the $\beta_{\nu i}$ of an E-type fundamental band is not always just one-half of the $\beta_{2\nu i}$, while some of the observed $\alpha_i$ or $\beta_i$ values might be perturbed ones (e.g., the $\alpha_5$ of $CH_3I$). Preliminary work on the effect of rotational resonance on $\alpha_i$, according to the formulation of Nielsen,[21] suggests that the perturbation is fairly large even if the two resonating bands are separated by more than 50 $cm^{-1}$ from each other. Similar situations have been recognized in microwave spectra.

# Vibration-Rotation Spectra, the Coriolis Coupling Constants and the Intramolecular Fore Field of Symmetric Top Molecules. II. Analysis of the Overtones and Combination Tones of Methyl Bromide

By Yonezo MORINO, Junko NAKAMURA* and Seiya YAMAMOTO

(Received August 10, 1964)

The infrared spectra of the overtones and combination tones of methyl bromide, $CH_3Br$, have been studied by many investigators;[1-4] six $A_1$-type bands and ten E-type bands have been observed. For the bands, $2\nu_4$, $\nu_1+\nu_4$, $\nu_1+\nu_5$, $\nu_2+\nu_4$, $\nu_4+\nu_5$ and $\nu_4+2\nu_5$, in particular, the rotational fine structures have been analyzed.

It seems, however, that no study has yet been undertaken with the particular intention of determining the second-order molecular parameters, that is, the vibrational anharmonic terms ($x_{ij}$), the rotational correction terms ($\alpha_i$ and $\beta_i$), and the effective Coriolis coupling constants ($\zeta_{eff}$). The primary object of this paper will be, therefore, to measure the

infrared spectra of methyl bromide for this purpose. The parameters obtained in the present work will be used later to investigate the harmonic and anharmonic potential constants of this molecule.

## Experimental

A commercial sample of methyl bromide was dried by passing it through phosphorous pentoxide. Infrared spectra were recorded on a Perkin-Elmer 112G grating spectrometer, which has a resolution of about 0.6 $cm^{-1}$, an accuracy of the absolute frequency of about 0.5 $cm^{-1}$, and an accuracy of the relative frequency of about 0.05 $cm^{-1}$. A long-path cell (about 6 m. long) was used with a sample pressure varying from 100 to about 760 mmHg.

## Theory

The methyl bromide molecule has the $C_{3v}$ symmetry and six normal modes; three of them belong to the $A_1$-type, and the other three to the E-type. The energy level of the molecule is, to a second order of approximation, given by:[6]

$$T=G(v_1,\ v_2,\cdots)+F_v(J,\ K) \tag{1}$$

where $G$ is the vibrational energy and $F$ is the rotational energy, including the vibration-rotation interactions:

$$\begin{aligned}G=&\sum_i \omega_i(v_i+d_i/2)\\&+\sum_i\sum_{j\geq i} x_{ij}(v_i+d_i/2)(v_j+d_j/2)\\&+\sum_t\sum_{t'\geq t} g_{tt'}\,|l_t|\cdot|l_{t'}|\end{aligned} \tag{2}$$

and

$$\begin{aligned}F=&B_vJ(J+1)+(A_v-B_v)K^2-D_JJ^2(J+1)^2\\&-D_{JK}J(J+1)K^2-D_KK^4-2A_v\sum_t\zeta_tl_tK\\&+A_v(\sum_t\zeta_tl_t)^2\end{aligned} \tag{3}$$

The term $G$ can be referred to the ground state $G(0,\ 0,\ \cdots)$,

$$\begin{aligned}G_0=&\sum_i \omega_i{}^0v_i+\sum_i\sum_{j\geq i} x_{ij}v_iv_j\\&+\sum_t\sum_{t'\geq t} g_{tt'}|l_t|\cdot|l_{t'}|\end{aligned} \tag{4}$$

Where

$$\omega_i{}^0=\omega_i+x_{ii}d_i+1/2\sum_{j\neq i} x_{ij}d_j \tag{5}$$

Here $\omega_i$ is the normal frequency of the $i$th mode: $v_i$, its vibrational quantum number, and $d_i=1$ or 2, depending on whether $i$ refers to a totally symmetric or to a doubly-degenerate vibration. The suffix $t$ denotes a doubly-degenerate mode, and the vibrational angular momentum, $|l_t|$, takes the values $v_t$, $(v_t-2),\cdots$, 1 or 0. The coefficients $x_{ij}$ and $g_{tt'}$ are the vibrational anharmonic terms, and $A_v$ and $B_v$ are the rotational constants which depend on the vibrational state, $v$. The coefficients $D_J$, $D_{JK}$ and $D_K$ are the centrifugal distortion constants and do not depend on the vibrational state in this approximation.[7] The $\zeta_t$ is a first-order Coriolis coupling constant, which does not appear when no doubly-degenerate vibrations are excited.

As may be seen from Eq. 4, the band center of a fundamental $(\nu_i)$ is given by:

$$(\nu_i)=\omega_i{}^0+x_{ii},\ \text{for the } A_1\text{-type mode} \tag{6}$$

and

$$(\nu_t)=\omega_t{}^0+x_{tt}+g_{tt},\ \text{for the E-type mode} \tag{7}$$

If the centrifugal distortion terms are ignored because of their small size, the rotational structure for a parallel band is given by the selection rules $\Delta K=0$ and $\Delta J=0,\ \pm1$:

$$\begin{aligned}{}^QR_{|K|}(J)=&\nu_i+[(A'-A'')-(B'-B'')]K^2\\&+2B'+(3B'-B'')J+(B'-B'')J^2\\{}^QQ_{|K|}(J)=&\nu_i+[(A'-A'')-(B'-B'')]K^2\\&+(B'-B'')J(J+1)\\{}^QP_{|K|}(J)=&\nu_i+[(A'-A'')-(B'-B'')]K^2\\&-(B'+B'')J+(B'-B'')J^2\end{aligned} \tag{8}$$

where $J$ denotes the quantum number of the lower level, and the symbols '' and ' indicate the lower and upper states respectively.

For a perpendicular band whose selection rules are $\Delta K=\pm1$ and $\Delta J=0,\ \pm1$, the rotational structure is given by:

$$\begin{aligned}{}^P_RR_{|K|}(J)=&{}^P_R\nu_o{}^{\text{sub}}+2B'+(3B'-B'')J\\&+(B'-B'')J^2\\{}^P_RQ_{|K|}(J)=&{}^P_R\nu_o{}^{\text{sub}}+(B'-B'')J(J+1)\\{}^P_RP_{|K|}(J)=&{}^P_R\nu_o{}^{\text{sub}}-(B'+B'')J+(B'-B'')J^2\end{aligned} \tag{9}$$

where

$$\begin{aligned}{}^P_R\nu_o{}^{\text{sub}}=&\nu_t+[A'(1-\zeta_t)^2-B']\mp2[A'(1-\zeta_t)\\&-B']|K|+[(A'-A'')-(B'-B'')]K^2\end{aligned} \tag{10}$$

and $J$ and $K$ are the values of the lower state. In Eq. 10, the upper sign corresponds to the $P$ branch, and the lower sign, to the $R$ branch.

**Overtones and Combination Tones.** — The features of the overtones of the fundamentals belonging to the $A_1$-type symmetry are similar to those of the fundamentals since $(a_1)^2=A_1$. The band center of the overtone, $(2\nu_i)$, is given by:

5) Y. Morino and J. Nakamura, This Bulletin, **38**, 443 (1965).

6) G. Herzberg, "Infrared and Raman Spectra II," D. Van Nostrand Company, Inc., Princeton, New Jersey (1945).

7) H. H. Nielsen, *Revs. Mod. Phys.*, **23**, 90 (1951).

$$(2\nu_i)=2(\nu_i)+2x_{ii} \tag{11}$$

The overtones of the E-type fundamentals have two components, $A_1$ and E, since $(e)^2=A_1+E$. The band center of the $A_1$-type component is:

$$(2\nu_t)=2(\nu_t)+2x_{tt}-2g_{tt} \tag{12}$$

and that of the E-type component is:

$$(2\nu_t)=2(\nu_t)+2x_{tt}+2g_{tt} \tag{13}$$

It is important to note that in this case the $\zeta_t$ in Eq. 10 must be replaced by:[8]

$$\zeta_{\text{eff}}=-2\zeta_t \tag{14}$$

Since $a_1\cdot a_1=A_1$, the fine structure of a combination tone between two different $A_1$-type modes is similar to that of the fundamentals, and

$$(\nu_i+\nu_j)=(\nu_i)+(\nu_j)+x_{ij} \tag{15}$$

The fine structure of the combination tone between an $A_1$- and an E-type mode is similar to that of the E-type fundamental, since $a_1\cdot e=E$,

$$(\nu_i+\nu_t)=(\nu_i)+(\nu_t)+x_{it} \tag{16}$$

and

$$\zeta_{\text{eff}}=\zeta_t \tag{17}$$

The combination tones between two E-type modes have two components, since $e\cdot e=A_1+A_2+E$, the $A_2$-type not being infrared-active. The band center is given, for both of the $A_1$ and E components, by:

$$(\nu_t+\nu_{t'})=(\nu_t)+(\nu_{t'})+x_{tt'}+g_{tt'} \tag{18}$$

and, for the E component, by:

$$\zeta_{\text{eff}}=-(\zeta_t+\zeta_{t'}) \tag{19}$$

**The Method of the Analysis of the Observed Bands.**—If we assume that $B'=B''$, the Eqs. 8 for parallel bands become:

$$^{Q}R_{|K|}(J)=\nu_i+(A'-A'')K^2+2B''(J+1) \tag{20}$$
$$^{Q}Q_{|K|}(J)=\nu_i+(A'-A'')K^2$$
$$^{Q}P_{|K|}(J)=\nu_i+(A'-A'')K^2-2B''J$$

The line spacing due to the $J$ value is $2B''$ in the $P$ and R branches, and all lines of different $J$ values coincide with the band center, $\nu_i$, in the $Q$ branch. The spacing due to the $K$ value, on the other hand, is $(A'-A'')(2K+1)$ in the $P$, $Q$, and $R$ branches. In the case of methyl bromide, the value of $(A'-A'')$ is about $0.05\,\text{cm}^{-1}$, though those of different bands are not equal. The value of $2B''$ is $0.63\,\text{cm}^{-1}$. Since the resolving power of the spectrometer used is about $0.6\,\text{cm}^{-1}$, there may be a splitting of the lines which have different $J$ values, and, in fact, the splittings have been observed in several bands. The $K$ splitting may not be observed in the region of small $K$ numbers. In fact, most of the bands did not show their fine structures, and only the envelopes of the $P$, $Q$, and $R$ branches were observed. The $Q$ branches showed two types of envelopes, depending on whether $(A'-A'')$ is positive or negative. When $(A'-A'')$ was negative, the intensity of the absorption increased slowly from the lower frequency side, reached a maximum, and decreased rapidly toward the higher frequency side. The band origin of this band was determined by measuring the frequency at which the absorption disappeared at the higher frequency side. The case must be reversed if $(A'-A'')$ is positive, and the band origin determined at the lower frequency side. Since the envelopes of the $P$ and $R$ branches intersect near the band origin, the frequencies determined by the above method were proved consistent.

For perpendicular bands, if $B'=B''$, then Eq. 9 becomes:

$$^{P}_{R}R_{|K|}(J)=^{P}_{R}\nu_o^{\text{sub}}+2B''(J+1)$$
$$^{P}_{R}Q_{|K|}(J)=^{P}_{R}\nu_o^{\text{sub}}$$
$$^{P}_{R}P_{|K|}(J)=^{P}_{R}\nu_o^{\text{sub}}-2B''J \tag{21}$$

With a few exceptions, no bands show the $J$ splitting in the $P$ and $R$ branches, and lines which originate from different $J$ values form a background for the absorption curve. In the $Q$ branch, all lines of different $J$ values appear at nearly the same point, $^{P}_{R}\nu_o^{\text{sub}}$; therefore, they show a sub-bands series, which have much stronger intensities than the lines of the $P$ and $R$ branches, as peaks above the background with an interval of about $2[A'(1-\zeta)-B'']$. Naturally, they have an unresolved $J$ structure and show envelopes like the $Q$ branches of the parallel bands, due to $(B'-B'')$ and also to a slit function characteristic of the spectrometer used.

If $^{P}_{R}\nu_o^{\text{sub}}$ is rewritten as $\nu(m)$, where $m=-|K|$ in $^{P}Q_{|K|}$ and $m=|K|$ in $^{R}Q_{|K|}$, then:

$$\begin{aligned}\Delta\nu(m)&=\nu(m+1)-\nu(m)\\&=2[(A'-A'')-(B'-B'')]m\\&\quad+2[A'(1-\zeta_{\text{eff}})-B']\\&\quad+[(A'-A'')-(B'-B'')]\end{aligned} \tag{22}$$

If $\Delta\nu(m)$ is plotted against $m$, it lies on a straight line, and $[(A'-A'')-(B'-B'')]$ and $[A'(1-\zeta_{\text{eff}})-B']$ can be determined from the slope and $\Delta\nu(-1/2)$ respectively. If the values of $A''$ and $B''$ are known and if $B'$ is assumed to be equal to $B''$, the parameters $A'$, $\zeta$, and $\nu_t$ can then be determined.

The frequencies of the subbands at the

8) D. R. J. Boyd and H. C. Longuet-Higgins, *Proc. Roy. Soc.*, A 231, 55 (1952).

maximum intensities were measured, and the method described above was taken as a first step of the analysis. The assignment of $m$ was made by the use of the fact that the sub-bands whose $m$ numbers are a multiple of 3 have stronger intensities than the others. The values of $\zeta_{eff}$ obtained in this way were compared with the values to be expected from those of the fundamentals. This procedure confirms whether or not the vibrational assignment is correct. The coefficients of $m$ in Eq. 22 and the values of $A'$, $\zeta$, and $\nu_t$ were then determined by the method of least squares.

The values of $A''$ and $B''$ are taken to be 5.127 $cm^{-1}$ from the results of the analysis of the fundamentals,[5] and 0.3186 $cm^{-1}$ from the results of the microwave spectroscopy[9].

## Experimental Results

**a) Parallel Bands.**—The overtone and combination tone bands of the $A_1$-type fundamentals were all observed. Moreover, the $A_1$ components of the overtones $2\nu_4$ and $2\nu_5$, and the combination tone $\nu_4+\nu_6$, were also observed. Most of them, however, showed only envelopes, and no fine structures were resolved. The bands $\nu_1+\nu_2$ and $\nu_4+\nu_6$ showed fine structures, as Fig. 1 and Fig. 2 show, but the analysis has not been made in detail. For the band of $\nu_1+\nu_3$ it seems that the $Q$ branch was split into fine structures (Fig. 3), but it was difficult to distinguish each line because of the noise,

so the band center was determined from the point of intersection of the envelopes of the $P$ and $R$ branches. Two $Q$ branches observed in the band $2\nu_3$ (Fig. 4) are probably due to $^{79}Br$ and $^{81}Br$. The results are summarized in Table I.

**b) Perpendicular Bands.** — All the E-type bands of the overtones and the combination tones except $\nu_3+\nu_4$, $\nu_3+\nu_5$, $\nu_3+\nu_6$, $\nu_4+\nu_6$ and $2\nu_5$ were observed.

*1) Region 1500 — 2000 $cm^{-1}$.*—A perpendicular band was observed and assigned to $2\nu_6$ (1869 $cm^{-1}$). The quality of the spectra of this region was poor for the following reasons. First, this band has a weak intensity. This band was observed at the pressure of about 760 mmHg. Second, this region was interfered with by a strong absorption band of water. Finally, on the higher frequency side there was an absorption of the $A_1$-type band $\nu_2+\nu_3$. The observed frequencies and molecular constants are given in Table XII.

*2) Region 2000 — 2500 $cm^{-1}$.* — Two bands were observed in this region. They were assigned to $\nu_2+\nu_6$ (2256 $cm^{-1}$) and $\nu_5+\nu_6$ (2389 $cm^{-1}$). These bands were disturbed by the absorption of carbon dioxide. The higher

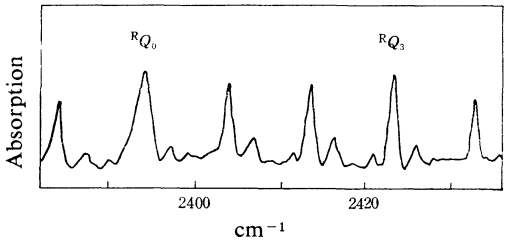

Fig. 5. The perpendicular band $\nu_5+\nu_6$ of $CH_3Br$.

10) I. A. Kraitchman and B. P. Dailey, ibid., **22**, 1477 (1954).
11) C. Hirose, Private communication.

frequency side of $\nu_2+\nu_6$ and the lower frequency side of $\nu_5+\nu_6$ were overlapped by a band of carbon dioxide. Between the lines of the band $\nu_5+\nu_6$, there were other lines (Fig. 5) which were considered to be a hot band or lines due to isotopic species; they are left unassigned. The observed frequencies are given in Tables VIII and XI.

*3) Region 2500—3000 cm$^{-1}$.*—There was one band, which was assigned to $\nu_2+\nu_5$. The observed frequencies are given in Table VII.

*4) Region 3500—4000 cm$^{-1}$.* — One E-type band was observed and assigned to $\nu_1+\nu_6$. This band was disturbed by the absorption of water. The observed frequencies of the sub-bands could not be described by an ordinary quadratic function of $K$ (Fig. 6). It is not clear whether or not this situation originated from an overlapping with the absorption of water alone. The constants were, tentatively, calculated from the observed frequencies of ${}^{P}Q_1$, ${}^{R}Q_0$ and ${}^{R}Q_1$. The observed frequencies are given in Table V.

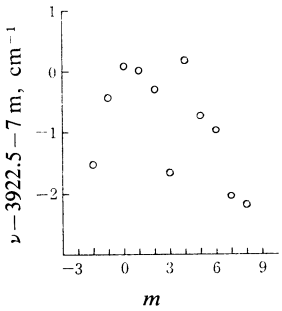

Fig. 6. The observed frequencies vs. $m$ for the perpendicular band $\nu_1+\nu_6$ of $CH_3Br$.

*5) Region 4000—4500 cm$^{-1}$.*—Three E-type bands were observed and assigned to $\nu_2+\nu_4$ (4352 cm$^{-1}$), $\nu_1+\nu_5$ (4411 cm$^{-1}$) and $\nu_4+\nu_5$ (4483 cm$^{-1}$). Brown et al.[4] measured this region with a high resolution spectrometer. Although their first assignments were different from those of this work, their revised values are in good agreement with the present results. An ambiguity lies, however, in the assignment of the ${}^{R}Q_0$ subband. For the band $\nu_1+\nu_5$, two subbands at 4418.25 cm$^{-1}$ and 4452.66 cm$^{-1}$ have about the same intensity. If one takes the latter as the ${}^{R}Q_0$, $\zeta_5$ becomes $-0.18$, whereas the assignment of the former to the ${}^{R}Q_0$ leads to the $\zeta_5$ value of $-0.22$. Therefore, the latter assignment (${}^{R}Q_0=4418.25$ cm$^{-1}$) was preferred in view of the knowledge of the fundamental $\zeta_5$ value of $-0.244$. The ${}^{P}Q_{|K|}$ lines in $\nu_1+\nu_5$ show an anomaly, as Fig. 7 shows. The origin of this anomaly is unknown. The observed frequencies are given in Tables IV, VI and X.

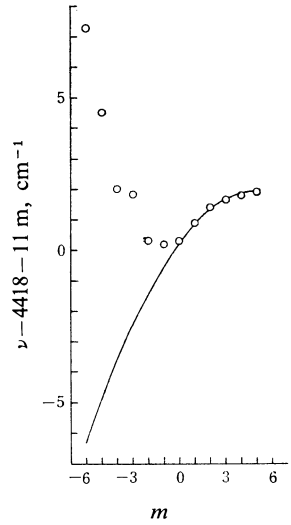

Fig. 7. The observed frequencies vs. $m$ for the perpendicuclar band $\nu_1+\nu_5$ of $CH_3Br$. The solid curve represents the calculated one.

*6) Region 5500—6500 cm$^{-1}$.*—In this region, four perpendicular bands were observed. They were assigned to $\nu_2+\nu_4+\nu_5$ (5781 cm$^{-1}$), $\nu_4+2\nu_5$ (5879 cm$^{-1}$), $\nu_1+\nu_4$ (5941 cm$^{-1}$) and $2\nu_4$ (6095 cm$^{-1}$). The bands $\nu_4+2\nu_5$, $\nu_1+\nu_4$ and $2\nu_4$ have also been observed by Rank et al.[2] Their results are in good agreement with those obtained in the present work.

The spectrum of the band $\nu_2+\nu_4+\nu_5$, given in Fig. 8, shows that the band is disturbed on the higher-frequency side by other absorption lines.

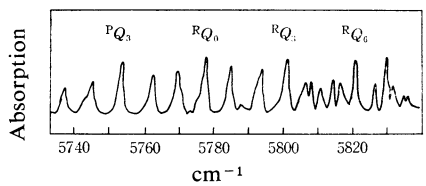

Fig. 8. The perpendicular band $\nu_2+\nu_4+\nu_5$ of $CH_3Br$.

For $\nu_4+2\nu_5$, since $e\cdot(e)^2=A_1+A_2+E+E$, there are two E-type components, that is, the state where $l_4=1$, $l_5=0$ and the state where $l_4=-1$, $l_5=2$. For the former, the predicted value of $\zeta_{eff}$ is 0.059, and for the latter it is $-0.547$. The observed value is $-0.021$; therefore, the observed transition is probably related to the former state, even though the difference between the observed and the predicted values of $\zeta$ is appreciable. There is presumably a resonance among these states. It seems that, because of this resonance, the ternary combination bands, $\nu_4+2\nu_5$ and $\nu_2+\nu_4+\nu_5$, appeared with sufficient intensities.

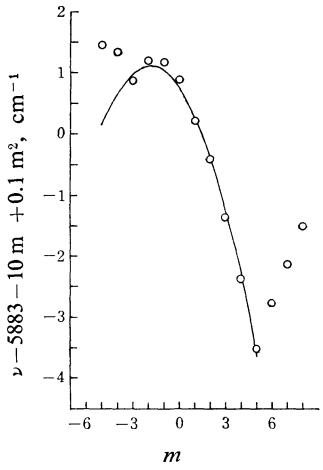

Fig. 9. The observed frequencies vs. $m$ for the perpendicular band $\nu_4+2\nu_5$ of $CH_3Br$. The solid curve represents the calculated one.

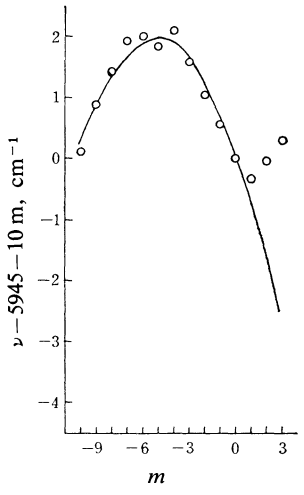

Fig. 10. The observed frequencies vs. $m$ for the perpendicular band $\nu_1+\nu_4$ of $CH_3Br$. The solid curve represents the calculated one.

The observed frequencies are given in Tables III, IX, XIII and XIV. Those of $\nu_4+2\nu_5$ and $\nu_1+\nu_4$ are shown graphically in Figs. 9 and 10 respectively. The anomalies shown in the figures may also be the result of the resonance.

*7) Summary.*—The results described above are summarized in Table XV. The errors associated with the molecular constants given in Tables III through XIV are taken to be 2.5 $\sigma$, where $\sigma$ is the standard deviation; 2.5 $\sigma$ is the 99% confidence interval, and it is thought to be a reasonable limit of error. However, these results do not include systematic errors; for example, the frequencies of the band centers are uncertain by an order of 0.1 $cm^{-1}$, since they are derived from the assumption that $B'=B''$. The values in the brackets in the tables show the subbands which were omitted from the least-squares calculations because they are either obscured by the presence of foreign bands, such as those of carbon dioxide and water, or are at apparently irregular positions.

## Discussion

It can be seen from Table XV that the differences between the observed and the predicted values of $\zeta$ are about 0.03. These differences indicate that the $\zeta$ values of the overtones and combination tones can not be expressed by the sums of those of the corresponding fundamentals. However, before concluding whether this is true or not, one must take into account the resonances among various vibrational states; this has not been done, and it would require complicated computations. The results of this work simply show that the values of the overtones and the combination tones can be expressed by the sums of the corresponding fundamentals, with proper signs, to within 0.03 in the case of $CH_3Br$.

The vibrational anharmonic terms obtained in this work are given in Table XVI. These values are still tentative, because the observed frequencies of the E-type bands are the frequencies of the maximum intensity; they must be corrected for the band origins, as has been discussed in the previous section.

The effective rotational constants for a given vibrational state can be expressed by the following relations:[6,7]

$$A_v=A_e-\sum_i\alpha_i(v_i+d_i/2)$$
$$B_v=B_e-\sum_i\beta_i(v_i+d_i/2)$$

where $A_e$ and $B_e$ are the rotational constants for the equilibrium position and $\alpha_i$ and $\beta_i$ are the rotational correction terms. The value of $(A'-A'')-(B'-B'')$ is obtained as the coefficient of $K^2$ from the analysis of the perpendicular band, and it is rewritten in terms of $\alpha_i$ and $\beta_i$ as follows:

$-\alpha_i+\beta_i$ for the $i$th fundamental,

$-2\alpha_i+2\beta_i$ for the overtone of the $i$th vibration,

$-(\alpha_i+\alpha_j)+(\beta_i+\beta_j)$ for the combination tone between the ith and $j$th vibrations.

The observed values are summarized in the third column of Table XVII. The values due to $(B'-B'')$ are shown in the fifth column. The values $\beta_i$ used are given in Table XVIII. It can be seen that the largest value of $(B'-B'')$ is 0.003 $cm^{-1}$ for $\nu_2+\nu_6$; nevertheless, this is within the range of error of the measurement of $(A'-A'')-(B'-B'')$. Therefore, the assumption that $B'=B''$, which was used in

the analysis of the perpendicular band, seems reasonable.

The appropriate combinations of observed values and the already-known values of $\alpha_i$ or $\beta_i$ determine some unknown rotational correction terms, $\alpha_i$.

The most probable values for $\alpha_i$ are given in Table XVIII. The values $(A'-A'')-(B'-B'')$ calculated by using $\alpha_i$ and $\beta_i$ in Table XVIII are given in the fourth column of Table XVII. They are in rather good agreement with the observed values.

## Summary

The infrared spectra of most of the overtones and combination tones of methyl bromide have been obtained. In the perpendicular band, the rotational fine structures have been observed. The values of the Coriolis coupling constants obtained from the analysis of the rotational fine structures are consistent with those obtained from the analysis of the fundamentals. It has been seen that, if one takes 0.03 as the error of the observed values of the Coriolis coupling constants, one can use the observed values to calculate the force constants.

Most of the vibrational anharmonic terms, $x_{ij}$, have been obtained, but they are tentative yet.

The rotational correction terms, $\alpha_1$ and $\alpha_2$ have been estimated from the combination-bands analyses.

This work was supported by a grant-in-aid for fundamental scientific research from the Ministry of Education, to which the authors' thanks are due.

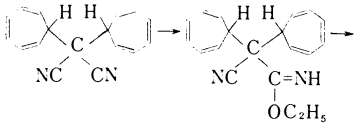
# The Reaction of Tropylmalononitrile and Ethyl Tropylcyanoacetate with Acyl Chloride[1]

By Toshio MUKAI and Tsutomu MIYASHI

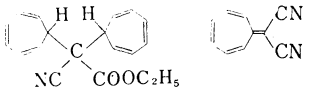
(Received August 12, 1964)

The acylation of tropylmalononitrile (I) or ethyl tropylcyanoacetate (II) would be expected to give a compound of type (A), which, under basic conditions, might be hydrolyzed to a tropyl derivative different from the starting material, might form a heptafulvene by the elimination of hydrogen cyanide, or might give a styrene-type compound through rearrangement.[2] However, the treatment of I or II with acyl chloride in a basic medium led to an unexpected result, which will be described in this paper.



(A)

I : X=CN
II : X=$COOC_2H_5$



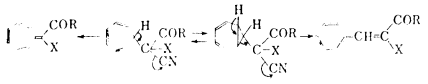
X=CN or $COOC_2H_5$
R=$C_6H_5$ or $CH_3$

The reaction of equimolar proportions of benzoyl chloride and I in a pyridine solution afforded compound (III), $C_{17}H_{14}N_2$, and benzoylcyanoacetamide. The former compound was also obtained when I was treated with acetyl chloride in pyridine. The ultraviolet spectrum of III showed a maximum at 255 m$\mu$ (log $\varepsilon=3.81$) due to the tropyl group;[3] the infrared spectrum had a band at 2260 $cm^{-1}$ (CN group). III may, therefore, be supposed to be ditropylmalononitrile. This was comfirmed by a mixed melting point determination with an authentic sample.[4] In the above reaction, and in several of those following, the products were isolated by chromatography on aluminum oxide,[5] which led to the partial conversion of compound (III) into ditropylcyanoacetamide (IV), which was identical with the compounds obtained by reaction of tropylcyanoacetamide with tropylium ions.

The sodio compound of I, in ethanol, also reacted with acetyl or benzoyl chloride to afford III in a fairly good yield, along with ethyl ditropylcyanoacetate[4] (V). The reaction of I with acyl chlorides in ethanol, in the presence of two molar equivalents of sodium ethoxide, gave compound (VI) $C_{19}H_{20}ON_2$ and 8,8-dicyanoheptafulvene[4] (VII), besides compounds III, IV and V; the yields are given in Table I. The infrared spectrum of VI showed bands at 2240 (CN), 3345 (NH) and 1658 $cm^{-1}$ (C=N). The mild treatment of VI with acid gave V. Furthermore, VI could be obtained from the reaction of III with sodium ethoxide. From these facts, VI is concluded to be ethyl ditropylcyanoacetimidate.

III VI

V VII



It is assumed that 8,8-dicyanoheptafulvene (VII) originates not from the intermediate (A), but from dehydrogenation of I, because the preferential elimination of hydrogen cyanide from A should give 8-cyano-8-acylheptafulvene. Indeed, it was found that the treatment of I with one molar equivalent of sodium ethoxide afforded tropylcyanoacetamide, together with a trace of VII, which is probably formed by the dehydrogenation of I with air.

The reaction of ethyl tropylcyanoacetate (II) with benzoyl or acetyl chloride in pyridine afforded ethyl ditropylcyanoacetate (V). The acylation of a sodio compound of II, in ethanol, also afforded V in the yield shown in Table II.

The formation of the ditropyl compounds (III, V, etc.) in the acylation reaction of I or

1) Presented at the 15th Annual Meeting of the Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, October, 1963.

2) The following reactions would be expected:

5) This transformation did not occur when a neutralized aluminum oxide was used.

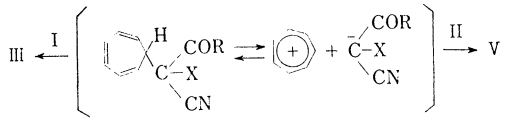

TABLE I. THE RESULTS OF THE ACYLATION OF I

| Medium | Reagent | Yield of products, % III | IV | V | VI | VII |
|---|---|---|---|---|---|---|
| In pyridine | $C_6H_5COCl$ | 82 | 14 | | | |
| | $CH_3COCl$ | 58 | 6.3 | | | |
| In ethanol 1 mol. equiv. of $NaOC_2H_5$ | $C_6H_5COCl$ | 89 | 7 | 4 | | |
| | $CH_3COCl$ | 67 | 5.4 | | | |
| In ethanol 2 mol. equiv. of $NaOC_2H_5$ | $C_6H_5COCl$ | 35 | | 5.5 | 2.6 | 1.5 |
| | $CH_3COCl$ | | 21 | 1.4 | 20 | 0.5 |

TABLE II. THE YIELDS (%) OF V IN ACYLATION OF II

| Reagent | In pyridine | In ethanol 1 mol. equiv. of $NaOC_2H_5$ | In ethanol 2 mol. equiv. of $NaOC_2H_5$ |
|---|---|---|---|
| $C_6H_5COCl$ | 45 | 64 | 21 |
| $CH_3COCl$ | 3.6 | 50 | 30 |

II can be explained as is shown in the following scheme, the first step of which is assumed to be the formation of compound A. The presence of three electron-with drawing groups in A, and the stabilization of the resulting tropylium ions, constitute a strong driving force for the cleavage of A to tropylium ions. The products III or V can result from the reaction of the tropylium ions with I or II.[4] As another pathway to III or V, a nucleophilic attack of I or II on A before its cleavage is also possible.

(A)

It has been pointed out previously that, in general, the fragmentation of tropyl derivatives is brought about by attack Lewis acids[3] or electrophilic reagents.[6] However, it should be emphasized that, in this case, the formation of tropylium ions (or their precursors) occurs readily, even in a basic medium, during the reaction of I or II with acyl chloride.

Attempted acylation of other tropyl compounds containing active methylenes, such as diethyl tropylmalonate, tropylacetylacetone and tropyldibenzoylmethane, did not afford any ditropyl compound, but it did result in the recovery of the starting materials. This is of interest when compared with the fact that diethyl tropylmalonate did not react with tropylium ions.[4]

## Experimental[7,8]

**The Reaction of Tropylmalononitrile (I) with Acyl Chloride in Pyridine.**—*a) With Benzoyl Chloride.*—To a solution of 1 g. (6 mmol.) of I in 3 ml. of pyridine, 0.9 g. (6 mmol.) of benzoyl chloride was added under cooling with ice. After it had been stirred for 20 hr. at room temperature, the reaction mixture was poured into water and extracted with benzene. The benzene-extract was then washed with 2 N hydrochloric acid and 2 N sodium hydroxide successively, dried over sodium sulfate, and evaporated to give 1.92 g. of a brown oil. This oil was dissolved in benzene and chromatographed, using 60 g. of aluminum oxide (Grade I). The evaporation of the benzene-elute gave 650 mg. of colorless crystals (m.p. 103—105°C), which, on recrystallization from ethanol, afforded ditropylmalononitrile (III)[8] as colorless crystals (m. p. 106—108°C). The evaporation of the elute with benzene-methanol (5 : 1) gave 115 mg. of colorless crystals (m. p. 155—162°C), which, on recrystallization from petroleum ether-benzene, gave colorless crystals (m. p. 167°C). They were found to be identical with ditropylcyanoacetamide (IV), which was synthesized as will be described later. The alkaline washings were acidified with 6 N hydrochloric acid and extracted with ether. The ether-extract was dried over sodium sulfate and evaporated to give colorless crystals (m. p. 98—105°C), which, on recrystallization from benzene, gave 30 mg. of colorless crystals (m. p. 134—135°C), assumed to be benzoylcyanoacetamide.

Found: C, 64.03; H, 4.12; N, 14.51. Calcd. for $C_{10}H_8O_2N_2$: C, 63.82; H, 4.29; N, 14.89%.

*b) With Acetyl Chloride.*—The reaction of 2.0 g. (13 mmol.) of I and 1.02 g. (13 mmol.) of acetyl chloride was carried out in a pyridine solution as has been described in a). The evaporation of the benzene extract gave 1.1 g. of a neutral oil, which crystallized when allowed to stand. The recrystallization of crystals from ethanol gave 572 mg. of ditropylmalononitril (m. p. 105—107°C). The mother liquor was then evaporated, and the residue was dissolved in benzene and chromatographed by passing it through a column containing 15 g. of aluminum oxide (Grade I). A further 350 mg. of III (m. p. 105—107°C) were obtained from the benzene elute, and 107 mg. IV (m. p. 165—167°C),

7) All melting points are uncorrected.

8) The microanalyses were carried out by Miss A. Iwanaga and Miss M. Suzuki, to whom the authors wish to express their gratitude.

from the elute with ether-methanol (5 : 1). The alkaline washings were acidified and extracted with ether. The evaporation of the ether-extract gave 320 mg. of an acidic, viscous oil.

**The Synthesis of Tropylcyanoacetamide and Ditropylcyanoacetamide (IV).**—a) To a solution of 6.5 g. (30 mmol.) of tropyl bromide dissolved in 15 ml. of water, 2.5 g. (30 mmol.) of cyanoacetamide was added. The reaction mixture was neutralized to pH 6 by the addition of a 6 N sodium hydroxide solution and stirred at room temperature for 2 hr., during which time colorless crystals separated out. Filtration, followed by recrystallization from benzene, afforded 4.8 g. of tropylcyanoacetamide as colorless needles (m. p. 144—145°C).

Found: C, 69.21; H, 5.44; N, 15.74. Calcd. for $C_{10}H_{10}ON_2$: C, 68.95; H, 5.79; N, 16.08%.

b) To a solution of 77 mg. (0.45 mmol.) of tropyl bromide in 3 ml. of pyridine, 50 mg, (0.3 mmol.) of tropylcyanoacetamide was added, and the reaction mixture was allowed to stand for 12 hr. at room temperature. After the pyridine had been evaporated under reduced pressure, the residue was poured into water and extracted with benzene. The benzene-extract was washed with dilute hydrochloric acid and then with water and dried over sodium sulfate. The evaporation of benzene gave crystals, which, on recrystallization from ethanol, gave 76 mg. of ditropylcyanoacetamide (IV) as colorless crystals (m. p. 167°C).

Found: C, 76.83; H, 5.90; N, 9.99. Calcd. for $C_{17}H_{16}ON_2$: C, 77.25; H, 6.10; N, 10.60%.

Ditropylcyanoacetamide (IV) was also obtained in the chromatography of III using aluminum oxide. A benzene solution of 200 mg. of III was passed through a column containing 6 g. of alumina (Grade 1). From the benzene elute, 170 mg. of III was recovered, while 25 mg. of IV (m. p. 165—167°C) was obtained from the elute with ether-methanol (1 : 1).

**The Reaction of a Sodio Compound of Tropylmalononitrile (I) with Acyl Chloride in Ethanol.**—*a) With Benzoyl Chloride.*—To a solution of sodium ethoxide prepared from 450 mg. (19 mmol.) of sodium and 20 ml. of absolute ethanol, 3 g. (19 mmol.) of I was added; the mixture was then stirred for 1 hr. at room temperature. Under cooling with ice, 2.7 g. (19 mmol.) of benzoyl chloride was added, drop by drop, to the solution. After it had been stirred for 24 hr. at room temperature, the reaction mixture was poured into water and extracted with benzene. The benzene extract afforded 3.51 g. of a neutral oil by the usual treatment. The oil crystallized on standing; these crystals, on recrystallization from ethanol, afforded 705 mg. of III (m. p. 104—105°C). The filtrate was evaporated, and the residue was dissolved in benzene and chromatographed using 60 g. of aluminum oxide (Grade I). The evaporation of the benzene elute gave 1.50 g. of III as colorless prisms (m. p. 105—106°C). The ether elute gave 125 mg. of V as colorless needles (m. p. 125—126°C). From the elute with ether-methanol (5 : 1), 197 mg. of IV (m. p. 167—169°C) was obtained. The alkaline solution, after the extraction with benzene, was acidified with 6 N hydrochloric acid and extracted with ether. From the ether-extract, 770 mg. of an acidic oil was obtained in the usual way; this crystallized on standing. Filtration, followed by recrystallization from benzene, gave 705 mg. of benzoylcyanoacetamide (m. p. 134—135°C).

*b) With Acetyl Chloride.*—In the same way as in a), 2.3 g. of neutral oil and 100 mg. of an acidic oil were obtained from the reaction of 2 g. (13 mmol.) of I, 300 mg. (13 mmol.) of sodium in ethanol and 1.02 g. (13 mmol.) of acetyl chloride. On being allowed to stand, the neutral oil gave crystals, which, on recrystallization from ethanol, gave 630 mg. of III (m. p. 105°C). The filtrate was evaporated, dissolved in benzene, and chromatographed by passing it through a column containing 23 g. of aluminum oxide (Grade I). The benzene elute gave 480 mg. of III (m. p. 105—106°C). Elution with ether-methanol (10 : 1) afforded 90 mg. of IV (m. p. 166°C).

**The Reaction of Tropylmalononitrile (I) with Acyl Chloride in the Presence of 2 Molar Equivalents of Sodium Ethoxide.**—*a) With Benzoyl Chloride.*—To a solution of sodium ethoxide prepared from 584 mg. (26 mmol.) of sodium and 20 ml. of absolute ethanol, 1.95 g. (13 mmol.) of I and then 1.5 ml. (13 mmol.) of benzoyl chloride were added drop by drop under cooling with ice. After it had been stirred for 21 hr. at room temperature, the reaction mixture was treated in the usual way to give 2.46 g. of a neutral oil containing crystals. The addition of a small amount of ethanol, followed by filtration, afforded 496 mg. of colorless crystals, (m. p. 101—107°C), which, on recrystallization from ethanol, yielded 385 mg. of VI as colorless prisms (m. p. 114—115°C).

Found: C, 77.99; H, 6.33; N, 9.31. Calcd. for $C_{19}H_{20}ON_2$: C, 78.05; H, 6.90; N, 9.58%.

The combined filtrate was evaporated, dissolved in benzene, and chromatographed using 70 g. of aluminum oxide (Grade I). The evaporation of the benzene elute gave 530 mg. of colorless crystals, (m. p. 95—102°C), which, on recrystallization from ethanol, gave 140 mg. of III (m. p. 106—107°C). Elution with benzene-ether (5 : 1) gave 150 mg. of crystals with an oil, which, on recrystallization from ethanol, gave 30 mg. of red crystals (m. p. 140—170°C) from the scarcely soluble portion and 103 mg. of colorless crystals (m. p. 121—124°C) from the easily soluble portion. The recrystallization of the former from ethanol gave 8, 8-dicyanoheptafulvene (VII) (m. p. 199°C), while the latter gave V (m. p. 125°C). Elution with ether-methanol (10 : 1) afforded 300 mg. of crystals (m. p. 130—140°C), which, on recrystallization from ethanol, gave tropylcyanoacetamide (m. p. 140—142°C).
