where $J_{ph}(365)$ is the area of the excitation band from 360 to 380 mμ for ligand phosphorescence. The result is given in Fig. 6(b). The values are normalized to 0.9 at $X_{EuD}=0.1$. If intermolecular energy transfer does not occur, $I_{ph}(365)$ should be proportional to the molar fraction of LaD. It is seen that the curve of phosphorescence intensity is located below the 45° line. As shown in Fig. 4,

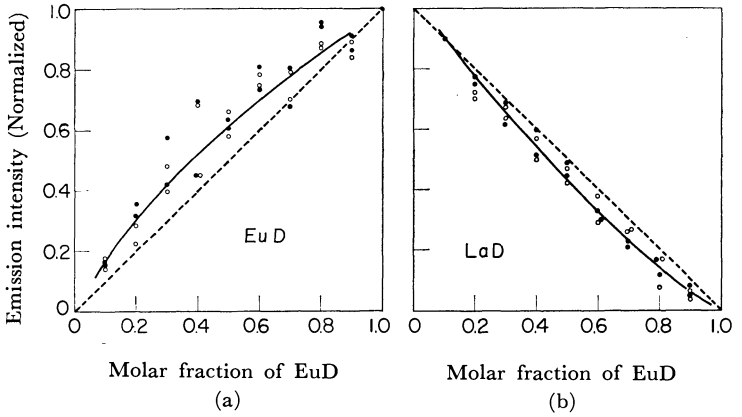

Fig. 6. The relative intensities of (a) europium emission of EuD and (b) ligand phosphorescence of LaD in mixed solutions of EuD and LaD with excitation of the ligand at liquid nitrogen temperature. The mark ● and ○ denote, respectively, that in the measurement the area of the excitation band at 528 and 464 mμ due to europium absorption is referred to.

the decay time of the phosphorescence of LaD is decreased in mixed solutions with higher EuD concentrations. These facts clearly indicate that ligand phosphorescence is quenched by the existence of EuD in solutions because of energy transfer at liquid nitrogen temperature.

Comparing Fig. 6(a) and 6(b), it is seen that enhancement of the europium emission is nearly proportional to the quenching of the phosphorescence of LaD. Therefore, it is quite obvious that intermolecular energy transfer occurs efficiently from the triplet state of LaD to the chelated europium ion in EuD. The possibility that this energy transfer occurs directly from the triplet state of LaD to the excited state of the europium ion in EuD can be rejected, since it was confirmed that in the mixed ethanol solution of europium free ion and free ligand, *i. e.*, dibenzoylmethane, energy transfer from the latter to the former is not observed.

It is, therefore, undoubted that energy transfer takes place from the triplet state of LaD to the triplet state of EuD, and further to the chelated europium ion. Then, in final conclusion, one can say that this fact is clear evidence that intramolecular energy transfer in europium chelates occurs *via* the triplet state of the ligand.

The authors wish to thank Mr. M. Morita in this laboratory for his discussion.

Group Interactions in Polyelectrolytes. I. Amination Kinetics of Chloromethylated Polystyrene

Hiroshi KAWABE and Masaya YANAGITA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received December 2, 1967)

Chloromethylated polystyrene is quantitatively aminated by *n*-butylamine or *n*-dibutylamine in dioxane, but the plot of the logarithmic term in the simple second-order rate equation against the time is not represented by a single straight line, but is divided into two lines which intersect nearly at the half-amination point. These results are interpreted in terms of the step-by-step amination resulting from the steric effect of the already-aminated neighbors which have bulky alkyl groups. By assuming two distinct reactivities of chloromethyl groups according to their neighboring environment, rate equations for two separate steps are derived; these equations give k_1, the rate constant in the first step, and k_2, that in the second step. In the presence of a large excess of amine, the over-all kinetics can be expressed by:

$$dx/dt = [ab/(2k_1 - k_2)][2k_1(k_1 - k_2)e^{-2k_1at} + k_1k_2e^{-k_2at}],$$

where x is the concentration of chloride ions at time t; a is the initial concentration of amine, and b, that of the chloromethyl group. The equation is found to be substantially valid for the values of k_1 and k_2 computed by the equations for the individual steps.

The kinetics of the reaction of chloromethylated polystyrene with triethylamine in dimethylformamide was studied by Noda and Kagawa,[1] who found that the rate conforms to the simple second-order equation. In dioxiane, however, they could measure only the rate at the initial stage, because the quaternized polymer precipitated in the solvent. Fouss *et al.*[2] observed that, in the quaternization of poly-4-vinylpyridine by *n*-butyl bromide in tetramethylene sulfone or in propylene carbonate, the rate becomes less than that corresponding to the simple second-order kinetics as the quaternization proceeds, rapidly beyond half-quaternization; they ascribed this to the charge being built up on the polymer.

The present authors have carried out the amination of chloromethylated polystyrene with *n*-butylamine or di-*n*-butylamine in dioxane and have found that the reaction proceeds quantitatively and that the apparent second-order rate constant decreases markedly beyond the half-amination point. Analysis of the experimental results suggests that the amination proceeds in two steps due to the steric effect of the already-aminated neighboring groups on the polymer, to which bulkyl alkyl groups are introduced by amination. The purpose

of the present study is to derive rate equations for the step-by-step reaction and to evaluate the kinetics data by means of those equations.

Experimental

Materials. The chloromethylated polystyrene was prepared as follows. Styrene, which had been distilled under a reduced pressure (69.5°C/60 mmHg), was polymerized by the suspension-polymerization procedure.[3] Styrene containing 1% benzoyl peroxide was stirred at 90°C for seven hours in a solution of polyvinyl alcohol. The process of polymerization was followed by occasional measurements of the specific gravity of the polymer beads; it reached a constant value of 1.05 after three hours. The chloromethylation of polystyrene was carried out by the procedure reported by Pepper *et al.*[4] Two samples of different degrees of chloromethylation were prepared; they are shown in Table 1. The anhydrous amines, benzyl chloride, and ethylene bromide were distilled before use. All the other chemicals were of a reagent grade, while de-ionized, de-carbonized water was used throughout.

Table 1. Chloromethylation of polystyrene

Code	Content of Cl	Degree of chloromethylation
SC-1	19.79%	0.85
SC-2	12.88%	0.55

Amination of Chloromethylated Polystyrene. Jones[5] found that the amination of chloromethylated polystyrene with ammonia or amines other than tertiary amines brought about cross-linking. Since this cross-linking is to be ascribed to a side-reaction of chloromethyl groups with amino groups formed on the polymer, it can be prevented by avoiding the contact of polymer molecules, by lowering the rate of the side-reaction, and by enhancing the principal reaction. This can be done under the following conditions: (i) a low concentration of the polymer, (ii) a large molar ratio of the amines to the chloromethyl group, and (iii) the use of an amine with a bulky alkyl group. Preliminary experiments carried out to examine these conditions showed that the precipitation of the polymer or the separation of the dissolved phase took place in amination with ammonia or monomethylamine. An experiment with a large excess of *n*-butyl amine proved that the amination proceeded to completion without any precipitation of the polymer or any separation of the dissolved phase. The polymer was also quantitatively aminated by di-*n*-butylamine without any separation of the polymer phase, though a few crystals of the amine hydrochloride precipitated.

Kinetic Measurements. One gram of chloromethylated polystyrene was dissolved in 50 m*l* of a dioxane and thoroughly mixed with 100 m*l* of a dioxane solution containing a large excess of an amine. The molar ratio of the amine to the chloromethyl group was about 20. The temperature of the reaction mixture was maintained within ±0.5°C by means of a thermostat. At appropriate intervals, portions of the solution, which were taken out by a pipet from the reaction vessel or which had previously been distributed in tubes dipped in the thermostat, were poured into aqueous solutions containing an amount of nitric acid sufficient to neutralize the amine. The precipitate of the polymer was then filtered off and washed with water, and the filtrate was potentiometrically titrated with 0.1 N silver nitrate by the use of Beckman's Model G pH meter to determine the chloride ions. The error caused by the titration was less than ±0.3%. The volume concentration of the amine and the chloromethyl group in a reaction mixture were calculated by considering the coefficient of the expansion of dioxane. The experimental conditions are listed in Table 2, where *a* denotes the initial concentration of the amine, and *b* the initial concentration of the chloromethyl group.

(1 mol/l) were added. The temperature of the system was maintained at 30±0.5°C during the course of the reaction. The initial concentrations of methyl iodide and ethylenediamine were 0.0984 mol/l and 0.0160 mol/l respectively. At time intervals aliquots were withdrawn; each was poured into diluted nitric acid and titrated potentiometrically with 0.1 N silver nitrate. An amount of iodide ions nearly equivalent to the quantitative methylation of both amino groups was produced within 48 hr; this amount remained substantially constant even after 100 hr. A blank test for the hydrolysis of methyl iodide in pure water showed that the error caused in amination by the hydrolysis would not exceed 0.8% after six hours, 1.4% after 24 hr, and 2.4% after 48 hr. The *N*-methylation of ethylenediamine was found to be fully inhibited by the presence of excess nitric acid; this was shown by the fact that no production of iodide ions was observed, even after six hours, when ethylenediamine had previously been neutralized with an excess of nitric acid.

Results

Since benzyl chloride is quantitatively aminated in dioxane by *n*-butylamine, its rate can be fully given by the simple second-order equation:

$$dx/dt = k(a - x)(b - x) \quad (1)$$

where x is the concentration of chloride ions at time t; a is the initial concentration of the amine, and b, that of benzyl chloride. Upon integration, Eq. (1) yields:

$$k = \frac{1}{(a-b)t}\ln\frac{b(a-x)}{a(b-x)} = \frac{2.303}{(a-b)t}\log\frac{1-\alpha}{1-\beta} \quad (2)$$

where $\alpha(=x/a)$ is the fraction of converted amine, and $\beta(=x/b)$, that of benzyl chloride. As may be seen in Fig. 1, where the logarithmic term in Eq. (2) is plotted against the time, the linearity of the plots indicates that the amination proceeds normally; a single value of k is obtained from the slope for each temperature. Table 4 summarizes the values of k computed by Eq. (2); the activation energy, E, obtained from a plot of $\log k$ against $1/T$, and the frequency factor, A, computed by the relation $k=A\cdot\exp(-E/RT)$. A value of k at any given temperature may be obtained by:

$$k = (7.88\times10^5)\cdot e^{-12500/RT}\ l/\text{mol min}$$

The amination of a chloromethylated polystyrene, SC-1, in dioxane has been carried out in the presence of a large excess of *n*-butylamine or *n*-dibutylamine. The polymer, as well as benzyl chloride, is quantitatively aminated by the amines without separating polymer phase. This fact suggests that cross-linking can hardly take place. This effective inhibition of the cross-linking may be ascribed to the steric effect of bulky alkylamino groups, which hinder the access of halide groups.

The rate constant for the polymer computed by Eq. (2), in contrast to the case of benzyl chloride, decreases with β, markedly beyond $\beta=0.5$ Figures 2 and 3 show plots of the logarithmic term in Eq. (2) against the time. Each plot seems to consist of two straight lines which intersect near $\beta=0.5$; this implies that the amination proceeds in two steps. This results may be explained by postulating that the amination of chloromethyl groups proceeds normally at the initial stage, but that after the half-amination point it is obstructed by both nearest neighbors, which are already aminated.

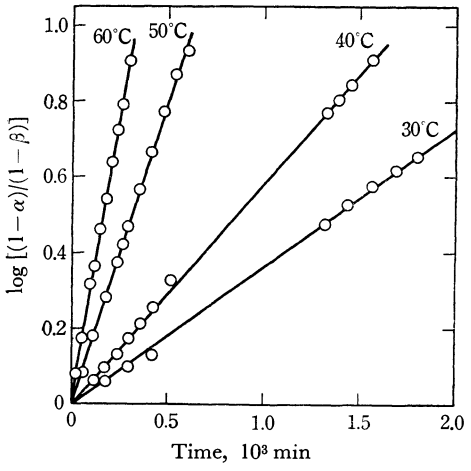

Fig. 1. Amination of benzyl chloride by *n*-butylamine.

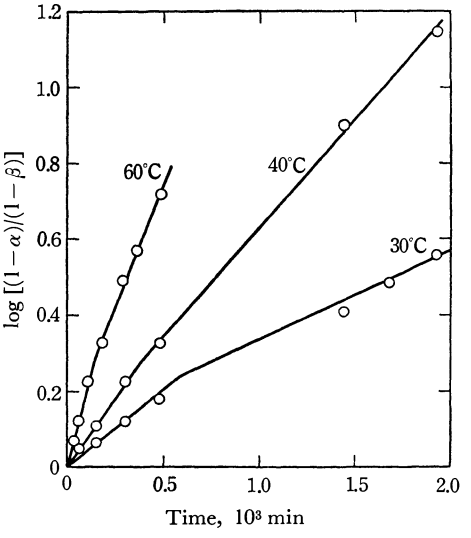

Fig. 2. Amination of SC-1 by *n*-butylamine.

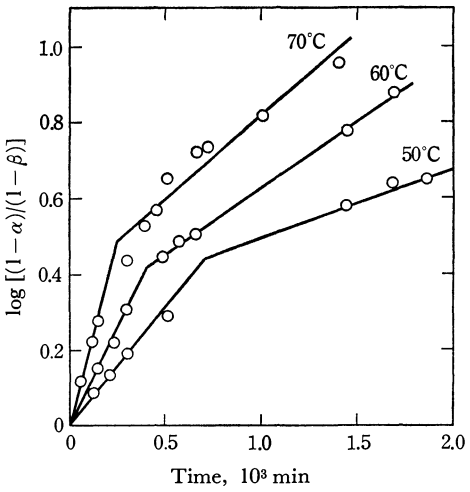

Fig. 3. Amination of SC-1 by di-*n*-butylamine.

The possible effect of this obstruction may be (i) electrostatic and/or (ii) steric. The electrostatic effect is less possible here, since amino groups formed on the polymer may not ionize because of a large excess of amine in the system and because of the rather non-polar property of dioxane as a solvent. The steric effect is more likely, since the amine molecules are presumably hindered from access to a reacting point by its nearest neighbors, which have bulky alkyl groups.

These assumptions have been examined by the aminations of a half-chloromethylated polystyrene, SC-2, and of ethylene dibromide, both of which are shown in Fig. 4. Since the plots are linear, the rates of these reactions are given fully by Eq. (1). The results support the second assumption

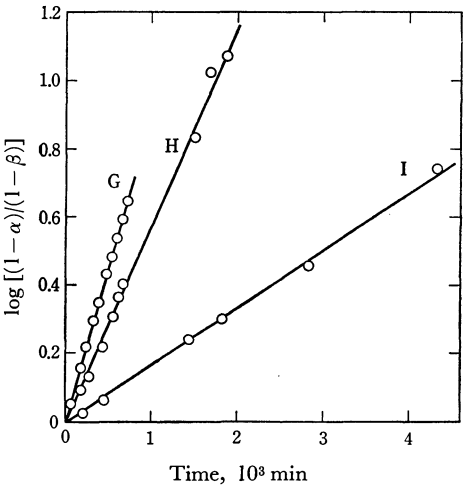

Fig. 4. Amination of half-chloromethylated polystyrene (SC-2) and ethylene bromide.

G: SC-2, *n*-butylamine, 60°C
H: Ethylene bromide, *n*-butylamine, 50°C
I: Ethylene bromide, di-*n*-butylamine, 60°C

(ii). If the effect of charged or polar groups is a dominant factor, the plots will not be linear, especially for ethylene dibromide. The linearity of the plot for SC-2 suggests, moreover, that the spacing of the groups can control the access of amine molecules. The value of k for SC-2, as computed by Eq. (2), is 4.61×10^{-3} l/mol min, which is comparable to that for benzyl chloride at the same temperature, 5.03×10^{-3} l/mol min.

Rate Equations

Derivation of the Rate Equations. In the reaction of chloromethylated polystyrene with the amines, two kinds of reactivity are assumed for chloromethyl groups, which are classified into the isolated ones which have a normal reactivity and the ones under the steric effect, both of whose nearest neighbors are already aminated. If each reaction is bimolecular and takes place separately, the rate constant for each reaction will be given by:

$$k = \frac{2.303}{(a-b)} \cdot \frac{\mathrm{d} \log[(1-\alpha)/(1-\beta)]}{\mathrm{d}t} \qquad (3)$$

In the actual course of reaction, however, the two kinds of reaction may overlap. This situation is illustrated by Fig. 5, where the broken lines represent the assumed separated courses of reaction and the full line, the actual course of reaction. When the isolated chloromethyl groups are almost consumed at point P, only the groups under the steric effect remain and the actual curve lies essentially on the assumed one for the second step. Since the actual curve (full line) in the initial

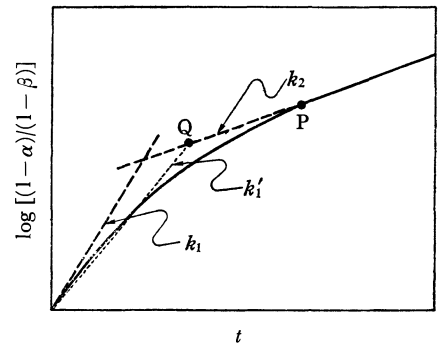

Fig. 5. Illustration of stepwise amination.

stage of reaction can be expressed approximately by the dotted line, the over-all course of the reaction may apparently be expressed by two straight lines intersecting at point Q. The experimental results summarized in Figs. 2 and 3 can be explained by this illustration based on the two-step-reaction concept.

A polymer reaction of this kind may thus be reduced to a reaction between a low molecular compound with two reactive groups and a reagent,

a reaction which is illustrated by the following figure:

where white circles represent unchanged groups and black circles, changed ones. The relationships among the concentrations are:

$$\mu_0 = M - x_1 = (b/2) - x_1 \quad (4)$$

$$\mu_1 = x_1 - x_2 = 2x_1 - x \quad (5)$$

where M is the initial concentration of the compound; μ_0 and μ_1 are the concentration of the unchanged and the partially-changed compound, respectively, at time t; b is the initial concentration of the reactive group; x is the change in the concentration of a reagent or the concentration of the changed group at time t, and x_1 and x_2 are concentrations of the first and second changed groups in the compound, respectively, at that time.

The over-all rate of the above reaction with the rate constants of k_1 and k_2 is given by :

$$\begin{aligned} dx/dt &= (a-x)(2k_1\mu_0 + k_2\mu_1) \\ &= (a-x)[k_1 b - 2(k_1-k_2)x_1 - k_2 x] \end{aligned} \quad (6)$$

where a is the initial concentration of a reagent.

On the assumption that $x \simeq x_1$ in the initial stage of reaction ($\beta < 0.5$) and $x_1 \simeq b/2$ in the final stage of reaction ($\beta > 0.5$), the integration of Eq. (6) yields:

$$k_1 = \frac{1}{[(2-k_2/k_1)a-b]t} \ln \frac{1-\alpha}{1-(2-k_2/k_1)\beta} \quad (7)$$

$$k_2 = \frac{1}{(a-b)(t-\tau)} \left(\ln \frac{1-\alpha}{1-\beta} - \ln \frac{1-\chi/a}{1-\chi/b} \right) \quad (8)$$

where τ is a time and χ is a value of x at a point, where $x_1 \simeq b/2$. An approximate value of k_1 may be obtained by Eq. (9), as is illustrated in Fig. 5:

$$k_1' = \frac{1}{(a-b)t} \ln \frac{1-\alpha}{1-\beta} \quad (9)$$

A value of k_1 can be determined from a value of k_2/k_1' by the use of Eq. (7).

When a large excess of a reagent is used, $(a-x)$ in Eq. (6) is replaced by a and x_1 is given by:

$$x_1 = (b/2)(1 - e^{-2k_1 at}) \quad (10)$$

Thus, Eq. (6) integrates to:

$$x = b\left[1 - \frac{k_1-k_2}{2k_1-k_2} e^{-2k_1 at} - \frac{k_1}{2k_1-k_2} e^{-k_2 at}\right] \quad (11)$$

and the over-all rate is given by:

$$dx/dt = \frac{ab}{2k_1-k_2}[2k_1(k_1-k_2)e^{-2k_1 at} + k_1 k_2 e^{-k_2 at}] \quad (12)$$

Examination of the Equations by the *N*-Methylation of Ethylenediamine. The rate equation should first be tested on a low-molecular compound of two reactive groups as a model of the amination of chloromethylated polystyrene, where steric hindrance is a predominant factor. Since it was difficult to find such a compound, however, the equation have been examined by the *N*-methylation of ethylenediamine. Ethylenediamine is quantitatively *N*-methylated with an excess of methyl iodide in water, but the reaction is inhibited in the presence of excess acid. This fact means that the higher substitution of an amino group is inhibited, probably by the electrical charge formed on the methylated group. When one amino group of ethylenediamine is methylated, the charge of the group may also electrostatically hinder the methylation of another group on the same molecule. Thus, the reaction will proceed in two steps and the rate is given by Eq. (6), where a and b are the initial concentrations of methyl iodide and the amino group respectively. Figure 6, where α and β are fractional conversions of methyl iodide and the amino group respectively, shows that the reaction proceeds in two distinct steps. The value of k_2 is 1.30×10^{-2} l/mol min, a value which is obtained from the slope in the second step according to Eq. (8). An appropriate value for k_1', estimated according to Eq. (9), is 4.79×10^{-2} l/mol min. The values of k_1 obtained from repeated computations by Eq. (7) are 5.97×10^{-2} l/mol min for the first computation, 6.10×10^{-2} for the second, and 6.12×10^{-2} for the third.

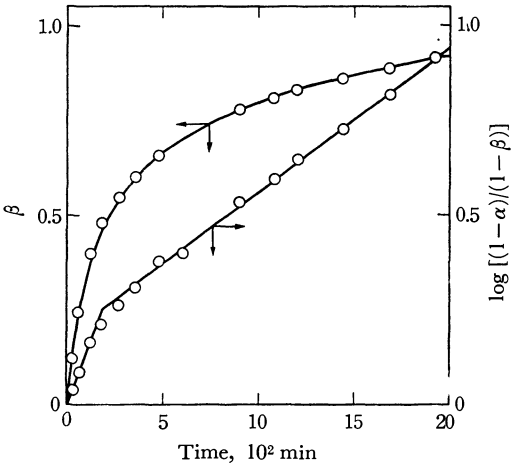

Fig. 6. *N*-Methylation of ethylenediamine in water at 30°C.

Discussion

The rate equations presented in the previous section were applied to the amination of chloromethylated polystyrene; the results of these calculations are summarized in Table 5.

Since a large excess of amine is used for the amination, the over-all course of reaction may be described by Eq. (11), using the values of k_1 and k_2 listed in Table 5. The values are compared in

TABLE 5. RATE CONSTANTS OF AMINATION OF SC-1

○: 50°C ⊙: 60°C ⊖: 70°C

Figs. 7 and 8, where the full lines have been calculated by the use of Eq. (11) and where the circles represent the observed values. The reasonable agreement between the two values justifies the application of the rate equations to the polymer reaction. In Fig. 9, two runs, with *n*-butylamine and with di-*n*-butylamine, are compared; they have almost the same value of k_1. In the figure, β is divided into two components, *viz.* $\beta_1(=x_1/b)$ and $\beta_2(=x_2/b)$, by virtue of Eq. (10); the components apparently illustrate how overall rate is modified by the value of k_2, and also support the validity of the assumptions that $x \simeq x_1$ for the initial stage of reaction and that $x_1 \simeq b/2$ for the final stage.

The rate constants are plotted against $1/T$ in Fig. 10, while the values of E, the activation energy, as calculated by the least-squares method, are

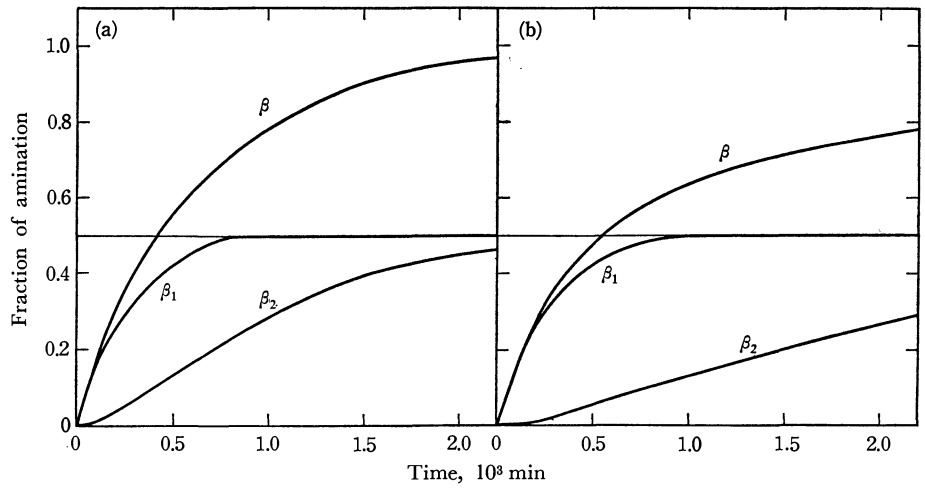

Fig. 9. Dependence of amination kinetics on the group interaction.

(b) Code D, di-*n*-butylamine, $k_1=2.67\ 10^{-3}$ *l*/mol min, $k_2=5.98\ 10^{-4}$ *l*/mol min

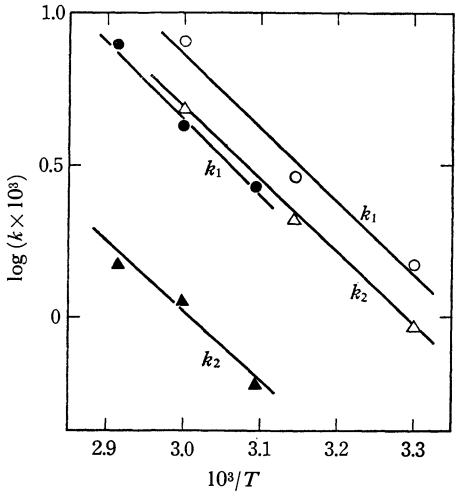

Fig. 10. Dependence of rate constants on temperature.

○, △: *n*-Butylamine
●, ▲: *n*-Dibutylamine

listed in Table 6, as are the mean values of A, the frequency factor, computed by means of:

Table 6. Activation energies and frequency factors of amination of SC-1

Amine		E kcal/mol	$A\times10^{-4}$ l/mol min
n-Butyl	k_1	11.1±1.3	14.5
	k_2	11.1±0.5	9.14
n-Dibutyl	k_1	12.0±0.9	8.69
	k_2	10.2±1.5	1.96

$$k = A\cdot e^{-11100/RT}\ l/\text{mol min}$$

The values of E thus obtained are fairly constant, being comparable to that of the monomeric one. On the other hand, the A value for k_2 is lower than that for k_1, and the difference is significantly larger in *n*-dibutylamine than in *n*-butylamine. These facts also suggest that the abnormal decrease in the rate in the course of amination is due to the steric effect of the neighbors.

The authors wish to express their thanks to Mr. A. Oohata for his helpful assistance in preparing the polymers and in carrying out the measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1524—1532 (1968)

Deuteron Magnetic Resonance of $NiSiF_6 \cdot 6D_2O$ and $NiSnCl_6 \cdot 6D_2O$

Takehiko CHIBA*1 and Gen SODA*2

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received December 15, 1967)

Deuteron magnetic resonance study was made on single crystals of $NiSiF_6 \cdot 6D_2O$ and $NiSnCl_6 \cdot 6D_2O$. Deuteron quadrupole coupling tensors were determined at various temperatures. In $NiSiF_6 \cdot 6D_2O$, the quadrupole coupling at -116°C is that of stationary D_2O, at 23°C and at 70°C that of D_2O under rapid 180°-flip motion and at 150°C that of rapid $Ni(D_2O)_6^{2+}$ reorientation. The eqQ/h values at -116°C, 238.3 ± 1.3 kc and 235.7 ± 1.9 kc do not appear to show marked effect of strong coordination. In $NiSnCl_6 \cdot 6D_2O$, the quadrupole coupling corresponding to D_2O under 180°-flip motion is observed at -53°C, at 25°C, and at 55°C. Spectra corresponding to a stationary D_2O are not observed even at 77°K. From the orientation of quadrupole tensors probable crystal structures of these compounds are proposed. Line width transitions were observed from which the reorientation rate was derived. The estimated activation energies of the 180°-flip motion of D_2O are 7.6 and 4.3 kcal/mol in the fluosilicate and chlorostannate, respectively, and that of $Ni(D_2O)_6^{2+}$ reorientation in the fluosilicate is 19 kcal/mol. Additional measurements of ^{19}F and ^1H resonances indicate the setting in of the SiF_6^{2-} reorientation at -110°—-120°C in $NiSiF_6 \cdot 6H_2O$, and that of the $Ni(H_2O)_6^{2+}$ reorientation in the chlorostannate at approximately the same temperature as the fluosilicate.

It has been shown in recent studies that the deuteron magnetic resonance (DMR) can provide useful informations about the structure and the motion of hydration water in crystals.[1,2] DMR of some O–D···O systems revealed strong dependence

1) T. Chiba, *J. Chem. Phys.*, **39**, 947 (1963).

2) T. Tsang and D. E. O'Reilly, *ibid.*, **43**, 4234 (1965).

of the deuteron quadrupole coupling on the hydrogen bond strength.[3] Temperature dependence of the line-width was used to determine the barrier to the motion of water molecule in crystals.[1-3]

When the position of a water molecule is fixed by hydrogen bondings of X···H–O–H···Y, the activation energy to reorientation may be considered to be the work required to break these hydrogen bondings. Then the activation energy would be a good measure of the strength of the hydrogen bond.

The purpose of the present study is (1) to see the effect of strong coordination of a water molecule to a metal ion on the deuteron quadrupole coupling, and (2) to study the motion of a water molecule where hydrogen bond is to atoms other than oxygen, for instance, to chlorine where hydrogen bond is supposed to be weak, and also to study other possible motions such as an over-all rotation of a cluster ion.

It may be noted that frequently used technique for the study of motions in crystals is the measurement of temperature dependence of the spin-lattice relaxation time T_1, which in the present case is inapplicable, because of the strong relaxation due to the presence of paramagnetic ions.

The compounds studied here are $NiSiF_6 \cdot 6D_2O$ and $NiSnCl_6 \cdot 6D_2O$. The crystal structures of these compounds are isomorphous, consisting of $Ni(H_2O)_6^{2+}$ and $(SiF_6)^{2-}$ or $(SnCl_6)^{2-}$ group ions. According to Pauling's early X-ray analysis,[4] the crystal is trigonal of space group $R\bar{3}$, assuming distorted CsCl-like structure. One formula unit is contained in a unit cell. All the water molecules are in equivalent positions.

Experimental

Preparation of the Crystals. A single crystal of $NiSiF_6 \cdot 6D_2O$ (which had been grown from a solution of this compound synthesized from $BaSiF_6$ and $NiSO_4$ in heavy water) was kindly supplied by K. Kume. The crystal exhibits {110} and {1$\bar{1}$0} faces.

$NiSnCl_6 \cdot 6D_2O$. A solution of this compound was prepared by adding an equivalent amount of $NiCl_2$ into heavy water solution of $SnCl_4$. A single crystal was grown by slowly lowering the temperature of the saturated solution. The crystal exhibits dominant {100} faces.

Measurement of DMR. The apparatus and the method of the measurement of DMR have been described elsewhere.[5] Spectra of quadrupole-split lines are measured at various angles of rotation of the probe perpendicular to the static magnetic field H_0(rotation pattern). Orientation of the crystal on the mounting head of the probe is determined using a reflection goniometer. Measurement of the DMR was made at H_0 of 16600 G.

Results

Deuteron Quadrupole Coupling Tensor. $NiSiF_6 \cdot 6D_2O$. The appearance of the spectral lines is fairly broad throughout the temperature range studied indicating the rapid relaxation due to the presence of paramagnetic ions. Spectra with fairly good signal-to-noise ratio were obtained, however, since high rf level operation was possible.

The crystal structure is such that quadrupole coupling tensors can be transformed to one another by three-fold rotations about the [111] direction; therefore, it is sufficient for the determination of quadrupole coupling tensors to measure the rotation pattern for only one crystal setting provided that the axis of rotation does not coincide with the [111] direction.

A crystal-fixed coordinate (X_C, Y_C, Z_C) is defined here as,

X_C parallel to [1$\bar{1}$0],

Y_C parallel to [11$\bar{2}$],

Z_C parallel to [111].

The laboratory-fixed coordinate (X_L, Y_L, Z_L) is such that H_0 is in the plane of X_LY_L, and θ, the angle of rotation of H_0 is measured from X_L. For the crystal setting in this experiment the transformation matrix $\boldsymbol{U}$ from the crystal-fixed system to the laboratory-fixed system was determined optically as:

	X_C	Y_C	Z_C
X_L	0.4759	−0.8644	0.1624
Y_L	0.7805	0.3300	−0.5309
Z_L	0.4054	0.3794	0.8317

Figure 1(a) shows the rotation pattern of the spectra at −116°C. The paramagnetism of the crystal produces a small shift of central frequency, thus distorting the symmetry of the rotation pattern of high and low frequency satellites as seen in the figure. The effect of paramagnetic ions on the measurement of the quadrupole splitting will now be considered.

The bulk susceptibility of a nonspherical sample can produce a local field component perpendicular to the external field at the nucleus. If this field is large, correct angular dependence of quadrupole splitting may not be obtained. From a crude estimation, however, the shape effect in the present experiment is found to be negligible.

The internal field due to contact and dipolar interactions can give rise to a paramagnetic shift. This shift is small, however, as seen in the figure in the present study, less than 20 kc/sec. Therefore, the nucleus-electron spin interaction can be treated as a first-order perturbation, just like the quadrupole interaction. The effect is only to shift the Larmor frequency, and the correct rotation pattern of

quadrupole splitting can be obtained from the frequency difference between the upper and lower satellites just as in the absence of paramagnetic ions. The situation is analysed in more rigorous manner in the forthcoming paper on $CuSO_4 \cdot 5D_2O$.[6] Paramagnetic shifts in ^1H and ^{19}F resonances of $NiSiF_6 \cdot 6H_2O$ have been studied in detail at the liquid helium temperature by Kume and Sugawara.[7] In this study the paramagnetic shift is not analysed.

The rotation pattern of quadrupole splitting is obtained at -116°C, 23°C, 70°C, and at 150°C. At -116°C, six pairs of lines are obtained corresponding to two nonequivalent deuterons (D_1 and D_2) of D_2O. At room temperature and at 70°C, only three pairs are observed which means that the field gradient tensors (q-tensors) of D_1 and D_2 are averaged to give a single q-tensor by a rapid 180°-flip of D_2O (Fig. 1(b)). At 150°C only one pair is observed (Fig. 1(c)). This shows an additional averaging of q-tensors, corresponding to a setting in of rapid motion which interchanges D_2O at different sites. These motions will be discussed in a later section.

The determination of quadrupole coupling tensors is made as follows. First, the spectra at room temperature and at 70°C will be analysed. The curves A, B and C of rotation pattern of quadrupole splitting are formed as differences between A_+ and A_-, B_+ and B_- and C_+ and C_- of Fig. 1(b). Assume that curve A corresponds to a particular one of the three equivalent q-tensors, $q^{(1)}$, then curve B corresponds to a rotation pattern of $q^{(1)}$ in a crystal setting defined by the transformation matrix UC_3 or UC_3^{-1}, where

$$C_3 = \begin{pmatrix} \frac{1}{2} & -\frac{\sqrt{3}}{2} & 0 \\ \frac{\sqrt{3}}{2} & \frac{1}{2} & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Similarly, curve C corresponds to a crystal setting of UC_3^{-1} or UC_3. Relative sign of the curves A, B and C can be readily found from the fact that the sum of A, B and C should give a rotation pattern of a quadrupole coupling tensor which is axially symmetric about Z_C axis. For the two alternative cases,

$$\left.\begin{array}{l} \text{Curve A}\cdots U \\ \text{Curve B}\cdots UC_3 \\ \text{Curve C}\cdots UC_3^{-1} \end{array}\right\} \text{ and } \left\{\begin{array}{l} U \\ UC_3^{-1} \\ UC_3 \end{array}\right\},$$

$q^{(1)}$ can be determined in the crystal-fixed coordinate system by the procedure described elsewhere.[6] The wrong set gives unrealistic result with large standard deviations and can easily be eliminated.

The low temperature pattern is analysed as follows. Here the assignment of the lines is made by comparison with the estimated rotation pattern from the room temperature data. Since the obtained room temperature quadrupole tensor is a typical of D_2O under rapid 180° flip motion approximate orientation of water molecule can be estimated and the predicted rotation pattern can be drawn by assuming 1) q_{zz} of D_1 and D_2 making an angle of 110° to each other, 2) $\eta = 0.1$, and 3) q_{yy} perpendicular to the molecular plane.[1,3] Here q_{zz} *etc.* are the principal components of q-tensor defined such that $|q_{xx}| \leq |q_{yy}| \leq |q_{zz}|$. The agreement of estimated pattern with the experimental one at -116°C is sufficient for the assignment of each curve of rotation pattern to be readily made. The low temperature rotation pattern is then analyzed in the same way as before and the quadrupole coupling tensors for the D_1 and D_2 are determined.

At 150°C the rotation pattern corresponds to the average of the room temperature pattern and is axially symmetric about Z_C axis. eqQ, η and the principal axis directions are given in Table 1.

$NiSnCl_6 \cdot 6D_2O$. General appearance of the spectra is similar to that of the fluosilicate. In this case three pairs of lines were observed at room temperature as in the fluosilicate indicating the averaging of field gradient tensors by a 180°-flip motion of water molecules. It is found that the line broadening due to this motion takes place at considerably lower temperatures than in the fluosilicate. The rotation pattern of the quadrupole splitting for the flipping water molecule is measured at -53°C, 23°C and at 55°C, and the quadrupole coupling tensor is determined in the same way as in the fluosilicate as shown in Table 1. Line broadening is observed in the temperature range of -85——125°C but spectra corresponding to the stationary deuterons are not observed even at the temperature of liquid nitrogen. Therefore, we were unable to determine quadrupole coupling for each deuteron.

Temperature Dependence of the Linewidth—Motional Effect. $NiSiF_6 \cdot 6D_2O$. As mentioned above, two different motions are observed by DMR, one is a 180°-flip motion of water molecules and the other is a motion which interchanges water molecules at different sites. Fortunately, broadening of spectral lines by these two motions occur in stepwise at different temperature ranges so that separate analysis of the motions can be made.

Temperature dependence of the linewidth at the fast and slow exchange limits of these two motions is observed at various temperatures and at various values of frequency splitting. To reduce the complexity of motional broadening due to dipolar structure the measurements are made at directions where original linewidth is small. These

are used to determine the reorientation rate at various temperatures by the procedure used previously.[1,8] For the 180°-flip motion of water molecules the reorientation rate is determined as shown in Fig. 2. Assuming Arrhenius equation for this motion an activation energy of 7.6 kcal/mol with a pre-exponential factor of about 10^{14} sec^{-1} is obtained.

Three quadrupole coupling tensors of room temperature are averaged by a motion at high temperatures. We assume that this motion is a random reorientation of hydrated Ni ion among three equivalent sites in the equilibrium configuration. If the rate of jump from a site to another is denoted by Ω, we get from a theory,[9] for the slow exchange limit,

$$\Omega = \pi \Delta\nu_M, \tag{1}$$

and for the fast exchange limit,

$$\Omega = \frac{2\pi}{9} \frac{(\nu_1^2+\nu_2^2+\nu_3^2)}{\Delta\nu_M}, \tag{2}$$

where $\Delta\nu_M$ is the width due to the motion, ν_1 is the frequency difference at site 1, *etc.*, from the center of gravity of the spectra (*i.e.*, $\nu_1+\nu_2+\nu_3=0$). $\Delta\nu_M$ is determined from the line width change as before and the reorientation rates from the above equations are shown in Fig. 2.*3 An activation energy of 19 kcal/mol is obtained.

$NiSnCl_6 \cdot 6D_2O$. The line broadening at the fast exchange limit was observed as in the case of the fluosilicate. To estimate the activation energy of reorientation it is necessary to know the frequency difference between the two deuterons of a water molecule at the orientation of the crystal where

(c) 180° flip motion of D_2O in $NiSnCl_6 \cdot 6D_2O$.

linewidth is measured. Since the spectra of stationary state were not measured this is estimated from the high temperature quadrupole coupling tensor. It is assumed that the two deuterons of a water molecule have the same quadrupole coupling tensor nearly axially symmetric about each OD bond making an angle of 110° with each other. With this assumption using the quadrupole coupling data at room temperature it is possible to estimate frequency difference between the lines of two deuterons at a given orientation of the crystal. The result is shown in Fig. 2. The activation energy for reorientation is then estimated to be 4.3 kcal/mol.

Discussion

Quadrupole Coupling Tensor. The value of eqQ and η are nearly the same as those observed in other water of crystallization. There appears to be no marked effect of coordination on eqQ of deuteron.

Crystal structure has not been known for $NiSiF_6 \cdot 6H_2O$ except the lattice constant and space group ($a=6.255$ Å, $\alpha=96°6'$, space group $R3$).[4] A neutron diffraction study has recently been done on $FeSiF_6 \cdot 6H_2O$[10] which was believed to be isomorphous with $NiSiF_6 \cdot 6H_2O$. It was concluded that ferrous fluosilicate has space group $R\bar{3}m$ instead of $R\bar{3}$, presumably due to statistical distribution of two slightly differently oriented structures. If it were also the case in the nickel salts, it could be easily detected as doubling of the number of satellite pairs*4 and/or from the symmetry of observed field gradient tensor. Since no such effects are indicated in nickel fluosilicate and chlorostannate, the crystal symmetry is not $R\bar{3}m$.

It has been known that to a good approximation the q_{zz} direction is in the bond direction and q_{yy} direction perpendicular to D_1OD_2 plane.[3] In the case of $NiSiF_6 \cdot 6D_2O$ the angle between the direction of q_{zz} of D_1 and that of D_2 is 109.8°, and the deviations of the q_{yy} directions of D_1 and D_2 from the normal to the plane defined by the q_{zz} directions of D_1 and D_2 are 5.9° and 3.8° respectively.

The approximate orientation of water molecule can be determined from the present result. If the dispositions of ions in nickel fluosilicate are assumed to be the same as one of the two mirror image structures of the ferrous salt it is found that the q_{zz} directions do not agree with the OH bond directions (deviation being 13° and 26°). Now, the crystal structure of this salt will be considered under the following assumptions.

1) D-O directions are in the q_{zz} directions.

10) W. C. Hamilton, *Acta Cryst.*, **15**, 353 (1962).

*4 If a sufficient rapid exchange motion between the mirror image structures is present the number of satellite pairs will not be doubled, however, in that case one of the principal axes of the q-tensor should be perpendicular to [111], which is readily detectable.

2) Dimension of SiF_6^{2-} ion is the same as that in $FeSiF_6 \cdot 6H_2O$, a regular octahedron with an Si–F distance of 1.71 Å.[10,11]

3) NiO_6 octahedron is regular with an Ni–O distance of 2.07 Å.[11]

4) Ni–O direction must not deviate greatly from the bisector of D_2O*5.

Rotation angles of both positive and negative group ions about the [111] axis are adjusted so as to give reasonable hydrogen-bond distances and angles.

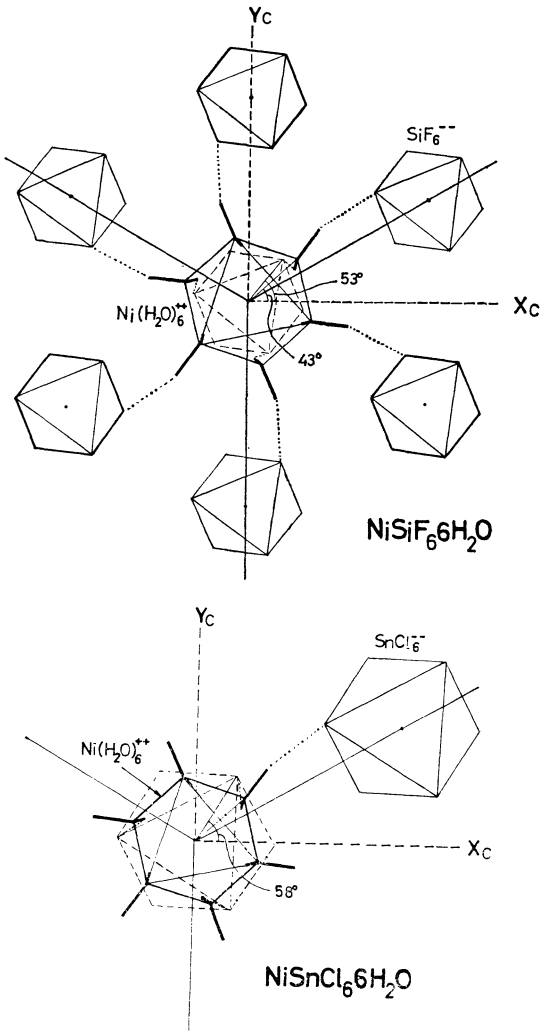

Fig. 3. Proposed crystal structures of $NiSiF_6 \cdot 6H_2O$ and $NiSnCl_6 \cdot 6H_2O$. [111] projection. Hydrogen bonds are indicated by dotted lines. Only one of the six $SnCl_6^{2-}$ ions surrounding $Ni(H_2O)_6^{2+}$ is shown for brevity.

The proposed structure is shown in Fig. 3. The D···F distances are 1.72 Å (D_1···F) and 1.77 Å (D_2···F) with corresponding O–D···F angles of 154° and 156°, respectively. Further improvement of the D···F distances and O–D···F angles may be possible but is hardly meaningful in the present approximations. The hydrogen-bond network in the suggested structure is essentially the same as that of ferrous silicate, one hydrogen-bond being approximately parallel to [111] and the other approximately perpendicular to it.

For $NiSnCl_6 \cdot 6D_2O$, though we were not able to determine eqQ for each deuteron of a water molecule, quadrupole coupling tensors and their orientations of D_1 and D_2 are probably nearly the same as those in the fluosilicate as seen from the close agreement of the room temperature values in Table 1.*6 Pauling gives atomic coordinates for the heavy atoms. However, difficulty is encountered when we try to fit our data of directions of quadrupole coupling tensor to his structure.*7 Trial structure as shown in Fig. 3 is proposed assuming $SnCl_6^{2-}$ as regular octahedron with Sn–Cl=2.45 Å[11] and treated in the same way as above. D···Cl distances are 2.02 Å with O–D···Cl angles of 158° and 139°.

It is hoped that more refined structure analysis of these compounds will be made. We were unable to detect NQR spectra of ^{35}Cl in this compound and the attempt to determine Cl–Sn direction by the Zeeman effect of NQR was unsuccessful.

Reorientational Motions. The barrier to reorientation of water molecules is considerably smaller in the chlorostannate than in the fluosilicate, which is well understood from the difference in hydrogen-bond strength in the two crystals.

A reorientational motion of $M(H_2O)_6^{2+}$ group ions similar to the one observed in $NiSiF_6 \cdot 6D_2O$ at high temperature has been detected by the line-shape transition of the proton resonance in the isomorphous zinc and magnesium fluosilicates by Dereppe *et al.*[12] They conclude that motion is excited in both $SiFe_6^{2-}$ and $M(H_2O)_6^{2+}$ groups in these crystals, the activation energies being 6.6 and 11.6 kcal/mol, respectively, for the magnesium salt.

In nickel fluosilicate the barrier to the $M(H_2O)_6^{2+}$ motion is considerably higher. Since the Z_C component of field gradient is preserved it can be concluded that the motion is not a free rotational one, but is a reorientation among equilibrium sites and even the rotational motion of water molecules is not a free motion. A reorientation about any axis which interchanges adjacent three

11) R. W. G. Wyckoff, "Crystal Structure" (2nd Ed.), Vol. 3, Chapter X, Interscience Publishers, New York (1965).

*5 In $FeSiF_6 \cdot 6H_2O$, Fe–O and the bisector of H_2O are linear within 8.1° (Ref. 10).

*6 At room temperature, q_{xx}, q_{yy} and q_{zz} directions of $NiSiF_6 \cdot 6D_2O$ are in agreement with the corresponding ones of $NiSnCl_6 \cdot 6D_2O$ within 1°, 4°, and 4°, respectively.

*7 An Ni–O distance of 2.40 Å in Pauling's structure is too large compared to the average Ni–O distance of 2.07±0.04 Å of various nickel salts (Ref. 11).

12) J. M. Dereppe, P. W. Lobo and M. V. Meersche, *J. Chim. Phys.*, **61**, 1076 (1964).

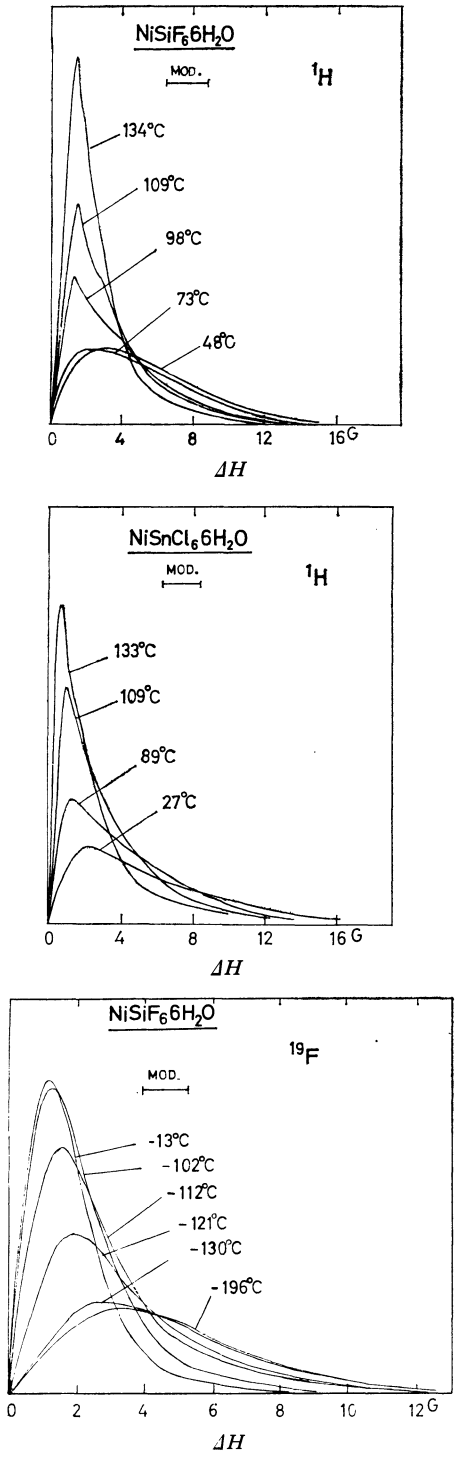

Fig. 4. ^1H and ^{19}F resonance line shapes (a half of the derivative curve) at various temperatures.

water molecules can produce the observed effect. There are four three-fold reorientational modes,*8 one of which is about the [111] axis, and other three four-fold reorientational modes about the O–Ni–O axes. (All these modes except the one about [111] are not pure rotational modes in a rigorous sense because the $Ni(H_2O)_6^{2+}$ ion is not a regular octahedron.) It is not possible to determine which of the two types of motions is operative in the observed averaging process. However, if one considers the number of hydrogen bonds to be broken in the course of reorientation the four-fold motion seems more probable.

For $NiSnCl_6 \cdot 6D_2O$ no measurement of $Ni(D_2O)_6^{2+}$ cluster motion was made on a single crystal. Attempt to observe powder pattern of reorienting $Ni(D_2O)_6^{2+}$ was made on chlorostannate up to 140°C but was unsuccessful (the crystal decomposes at the higher temperatures).

The line shape transition of ^1H resonance on $NiSnCl_6 \cdot 6H_2O$ powder was compared with that of $NiSiF_6 \cdot 6H_2O$ as shown in Fig. 4. Both has similar temperature dependence. The activation energy of $Ni(D_2O)_6^{2+}$ motion in chlorostannate is, therefore, probably nearly the same as that in the fluosilicate.

The line shape transition of ^{19}F resonance of nickel fluosilicate was also measured as shown in Fig. 4. Line width transition centered at -110—-120°C is observed. The temperature of transition is considerably lower than that of magnesium fluosilicate, and the activation energy of SiF_6^{2-} reorientation in the nickel salt is likely to be less than 6.6 kcal/mol. As Dereppe *et al.*[12] point out, the activation energies of reorientation of $M(H_2O)_6^{2+}$ and SiF_6^{2-} should be nearly the same if only the interactions between ions of opposite sign are considered. Their explanation of large difference in activation energies between $Mg(H_2O)_6^{2+}$ and SiF_6^{2-} reorientations is based on the assumption of the same crystal structure for this salt as the ferrous salt. It is clear that such an explanation is not applicable to the nickel salt where no mirror symmetry is observed. Yet the difference in the activation energy of cation and anion reorientation is much larger in the latter case than in the former. There is also another question. For the 180°-flip of a water molecule the observed activation energy is generally reasonable value considered as the energy required to break two hydrogen bonds of the water molecule. Now, if one simply takes hydrogen-bonding energy alone, both the reorientations of $Ni(H_2O)_6^{2+}$ and SiF_6^{2-} should require at least four times the activation energy of 180°-flip of D_2O or 30 kcal/mol, because hydrogen-bonds of four water molecules are broken in the course of the four-fold reorientation. Same order of the observed activation energy for the $Ni(H_2O)_6^{2+}$ reorientation in the chlorostannate as in the fluosilicate is also difficult to understand.

*8 In the three-fold reorientation the motion should be that all the six water molecules move together and not that three move independent of three others, since the latter means the breakage of coordination bonds.

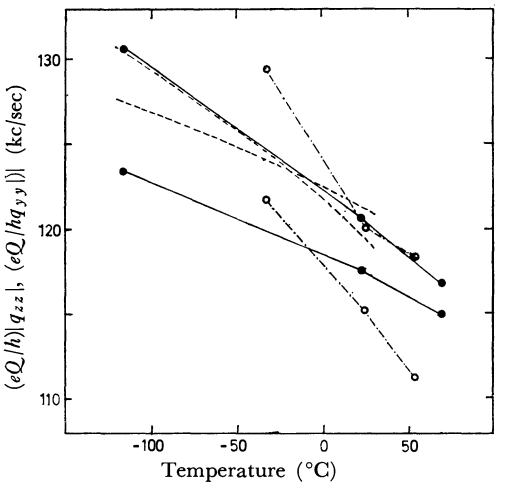

Fig. 5. Temperature dependence of z and y components of averaged quadrupole coupling tensor in D_2O.
—— $NiSiF_6 \cdot 6D_2O$, -·-· $NiSnCl_6 \cdot 6D_2O$,
- - - $Ba(ClO_3)_2 \cdot D_2O$ (Ref. 1).

The experimental results in disagreement with the expectation from such a simple picture indicate that various factors, such as electrostatic energy other than hydrogen-bonding energy, steric effect and nonrigidity of the structure, of cluster ions, are the important factors determining the activation energy of reorientation of a large group of atoms. Although no satisfactory explanation of molecular motions in crystals are available at present, nickel fluosilicate presents as interesting example that three types of reorientational motion, that is, the motion of D_2O, $Ni(D_2O)_6^{2+}$ and SiF_6^{2-} are observed in a single compound.

Torsional Oscillations. $(eQ/h)|q_{zz}|$ and $(eQ/h)|q_{yy}|$ of the quadrupole coupling of D_1OD_2 under 180° flip motion, that is, the quadrupole coupling tensor averaged for D_1 and D_2, are plotted in Fig. 5. (The z direction is perpendicular to the plane of water molecule and the y direction parallel to the direction of D_1–D_2). As discussed in Ref. 1 the temperature dependence of these values can be explained from Bayer's theory[13] in terms of torsional motions of a water molecule. For nickel fluosilicate the temperature dependence of q_{zz} and q_{yy} resembles that of $Ba(ClO_3)_2 \cdot D_2O$ previously obtained.[1] Trend of smaller temperature dependence of q_{yy} compared to q_{zz} is also seen in the present case. This is due to the effect of torsional motion about the D–D axis which only decreases the q_{yy} component. The torsional motions in both cases are probably similar since the activation energy for the two cases is nearly the same (7 kcal/mol for $Ba(ClO_3)_2 \cdot D_2O$).[1,8] Therefore, approximately the same torsional frequencies as obtained in $Ba(ClO_3)_2 \cdot D_2O$ are expected. However, since the oscillation may be more complex and coupling among the modes may be stronger in the present case, no detailed analysis of the torsional frequencies are made. The effect of the torsional motion of $Ni(D_2O)_6^{2+}$ cluster on the temperature dependence of quadrupole coupling is estimated assuming a three-fold cosine type potential of barrier height 19 kcal/mol about the [111] direction. It is found that the change in quadrupole coupling is less than one percent over the temperature range of observation and may be negligible.*9

In the chlorostannate the observed large temperature dependence can be readily expected from the small hindering potential to 180°-flip motion of water molecules. An approximate calculation assuming a cosine-type potential of 4.3 kcal/mol shows for the temperature range of observations (−53°C to 55°C), about 5% of the observed 9% decrease can be explained by the torsional motion about the bisector of D_2O.

We would like to thank Professor Yoshinobu Kakiuchi for helpful dicussions and comments. We are also grateful to Assistant Professor Kiyoshi Kume of Tokyo Metropolitan University for supplying us with a sample of deuterated nickel fluosilicate single crystal and for discussions.

The desorbability of water molecules chemisorbed on the surfaces of metal oxides has been investigated in the cases of α-Fe_2O_3, TiO_2 (rutile) and ZnO. Water vapor adsorption isotherms were determined on the samples treated at various temperatures in a vacuum of 10^{-5} Torr. The BET V_m-values of water adsorption were plotted against the temperature of the pretreatment. The curves obtained show a sharp increase at a moderate temperature which is varied by the nature of solid substance. This fact makes us conclude that, at this temperature, the chemisorbed water on oxide surfaces starts to be removed. The variation in the desorption temperature due to the nature of metal oxide is considered to come from the magnitudes of the bonding force of the surface hydroxyl groups to the surface metal atoms on each solid.

It has become clear that the surface of metal oxide is usually covered by hydroxyl groups in the atmosphere, which have serious effects on such surface properties as selective adsorbability, hydrophilicity, catalytic activity, and surface charge. Their existence and behavior have been investigated by various methods: specific chemical reactions,[1] infrared absorption spectroscopy,[2-6] water-content measurements,[7,8] and nuclear magnetic resonance study.[9,10] However, we still have no exact knowledge of the temperature at which the desorption of chemisorbed water on oxide surfaces starts. The primary purpose of this investigation is to determine this temperature experimentally. Since the bonding force of surface hydroxyl groups to surface metal atoms should vary with the nature of the metal oxide,[11] the desorption temperature may be expected to be characteristic for each substance. The results of this study, therefore, can indicate the extent of the removal of hydroxyl groups on solid surfaces and, accordingly, give a criterion for powder conditioning.

Experimental

Materials. The samples used in this research were hematite (α-Fe_2O_3), rutile (TiO_2), and zinc oxide (ZnO). The hematite, presented by the Nippon Bengara Kogyo Co., had been produced by the calcination of ferrous sulfate. The rutile, presented by the Teikoku Kako Co., had been made by calcining titanium hydroxide formed by the hydrolysis of titanium sulfate. The zinc oxide, presented by the Sakai Chemical Co., had been produced by oxidizing zinc vapor in the atmosphere at a high temperature. The former two samples were repeatedly treated with 0.1 N nitric acid in order to remove basic impurities, carefully treated with 0.1 N ammonia water in order to remove acidic impurities, thoroughly washed with distilled water, and dried at 110°C in the atmosphere.

Measurement of Surface Area. The surface areas of the samples were determined by the BET method using nitrogen, assuming the area of a nitrogen molecule to be 16.2 Å^2. The specific surface areas obtained for α-Fe_2O_3, TiO_2, and ZnO were found to be 13.8, 9.43, and 4.31 m^2/g respectively.

Measurement of Water Vapor Adsorption. The principle of the present investigation was to repeat the measurement of the water vapor adsorption on the same sample, while varying the conditions of the pretreatment. The volumetric method was used to determine the adsorption isotherms of water vapor, and an oil manometer was used to read the equilibrium pressure of the vapor. A sample of about 10 m^2 in total area was taken for every adsorption measurement. Prior to the first measurement of water vapor adsorption, the sample was treated at a high temperature (600°C for α-Fe_2O_3 and TiO_2, 450°C for ZnO) in a vacuum of 10^{-5} Torr in order to remove all the physically-adsorbed water and most of the chemisorbed

water. Then the adsorption experiment of water vapor was carried out at a room temperature (10°C for α-Fe_2O_3, 18°C for TiO_2 and ZnO). Thus, we obtained the first adsorption isotherm. Subsequently, this sample was degassed at 30°C for 4 hr in a vacuum of 10^{-5} Torr in order to desorb water molecules. The preliminary tests showed that the desorption equilibrium can be attained within 4 hr in this process. Again the adsorption isotherm of water vapor was determined at the same temperature as before. After the completion of the second adsorption measurement, the same sample was again evacuated at a higher temperature (*e. g.*, 50°C) than 30°C. In the successive experiments the temperature of the pretreatment was raised step by step. By repeating the adsorption measurements and the desorption treatments alternately, we obtained a series of adsorption isotherms of water vapor.

Measurement of Water Content. The water content of the samples was determined volumetrically by using the same equipment as was used to measure the water-vapor adsorption. The same initial pretreatment as was given to the sample for the adsorption measurement was given to the original sample (600°C for α-Fe_2O_3 and TiO_2, 450°C for ZnO), and then the sample was exposed to saturated water vapor. This sample was degassed at 30°C for 4 hr in a vacuum of 10^{-5} Torr. By keeping the vacuum system closed, the water molecules adsorbed were evaporated at a given higher temperature (*e. g.*, 50°C) for 4 hr and trapped in a vessel kept at the temperature of liquid nitrogen. The amount of the condensed water was determined volumetrically at room temperature after reevaporation. This procedure was repeated on the same sample at various evaporation temperatures up to 1000°C. Since the number of water molecules remaining on the surface at 1000°C was found to be negligibly small, we calculated the water contents at various temperatures by assuming the water content at 1000°C to be zero.

Infrared Absorption Spectrum. The technique of absorption spectroscopy[2] was applied to the surface species of the samples described above. The infrared spectra were measured with an apparatus of the Japan Spectroscopic Co. (IR-G). A small disk of the sample was prepared for infrared spectroscopic measurement at every step of the treatment.

Results and Discussion

The water contents of α-Fe_2O_3, TiO_2 and ZnO are shown in Fig. 1 as a function of the pretreatment temperature. The numerical value of the amount is expressed by the number of surface hydroxyl groups on an area of 100 Å^2, assuming that the water molecules released have been chemisorbed as hydroxyl groups on the surface. It may be seen in Fig. 1 that all the samples lose adsorbed water greatly until 400°C, and then gradually until 800°C. At 1000°C almost all the water molecules have been removed from the surface. The water molecules released at higher temperatures are, of course, those chemisorbed on the surface, while those found at lower temperatures should have been adsorbed both physically and chemically. From the curves of the water content, however, the

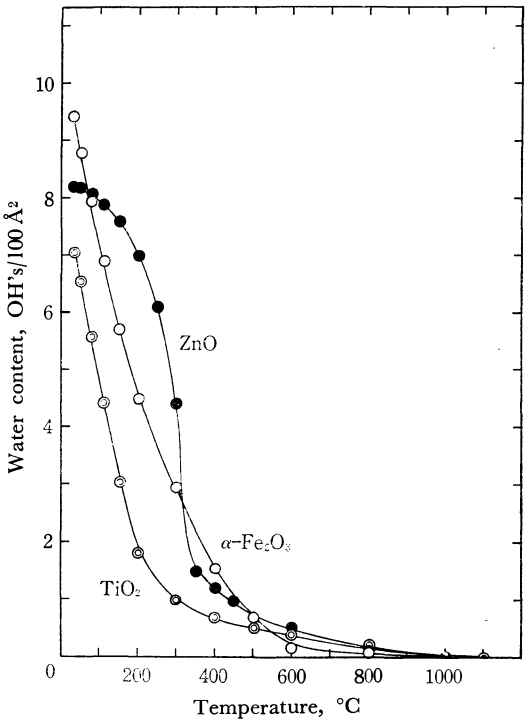

Fig. 1. Water content of α-Fe_2O_3, TiO_2, and ZnO at various temperatures.

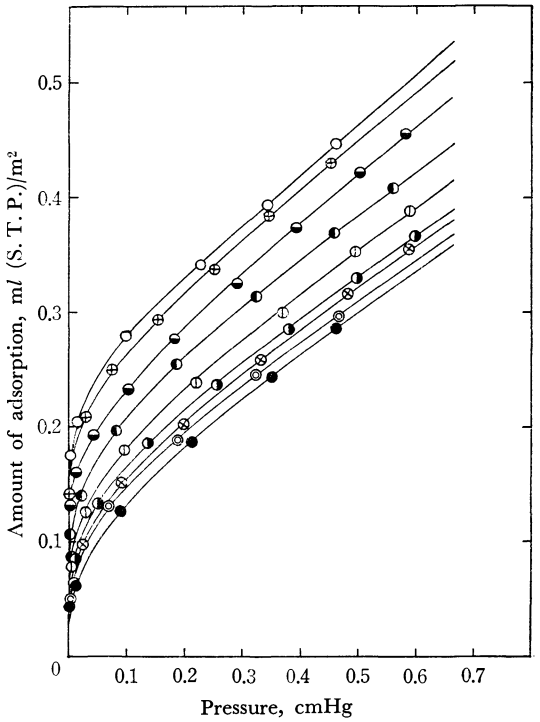

Fig. 2. Adsorption isotherms of water vapor on α-Fe_2O_3 pretreated at various temperatures; degassing temp. ○ 600, ● 30, ◎ 50, ⊗ 80, ◑ 110, ⓘ 150, ◐ 200, ◒ 300, ⊕ 400°C.

temperature at which the removal of chemisorbed water starts can not be recognized.

Figure 2 shows the adsorption isotherms of water on α-Fe_2O_3. The ordinate represents the amount of water adsorbed on the unit surface area of the sample in ml/m^2, which is then converted into the standard temperature and pressure. The first adsorption isotherm which was obtained after degassing at 600°C is much higher than the second one, which was obtained after degassing at 30°C. The amount adsorbed increases gradually with the rise in the pretreatment temperature and closely approaches the value of the original isotherm. All the isotherms are almost the same in shape, except that the amount adsorbed at zero pressure differs slightly from sample to sample.

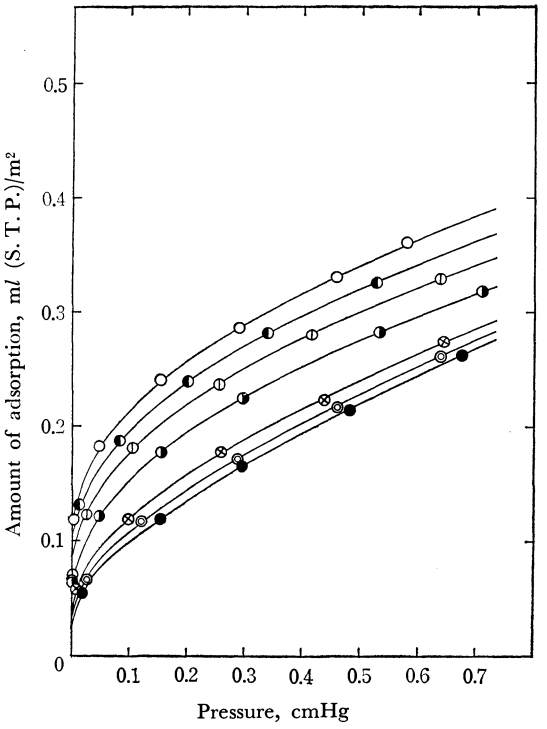

Fig. 3. Adsorption isotherms of water vapor on TiO_2 pretreated at various temperatures; degassing temp. ○ 600, ● 30, ◎ 50, ⊗ 80, ◑ 110, ◫ 150, ◐ 200°C.

Figure 3 shows the adsorption isotherms of water on TiO_2. Although at first sight the characteristics seem to be the same as in the case of α-Fe_2O_3, the isotherms on TiO_2, after degassing at 30°C to 110°C, are close to each other and that of the 200°-degassed sample closely approaches the first adsorption isotherm.

The adsorption isotherms of water on ZnO are given in Fig. 4. The shapes of these curves are quite different from those on TiO_2 and Fe_2O_3, representing a sharp increase in the amount adsorbed at a moderate pressure of the vapor. The

appearance of such humps in the adsorption isotherm has been reported in other systems: carbon and adsorbates such as argon,[12] C_2H_5Cl, $CHCl_3$ and $CFCl_3$,[13] and cadmium bromide or sodium bromide and argon.[14] In the former systems, the surface of carbon was rather uniform and the hump appeared at the boundary between the first and second monolayers of an adsorbate. In the latter cases, the hump has been explained in terms of the interaction between adsorbate molecules and surface hydroxyl groups. In the case of metal oxide, we have no literature reporting the appearance of the hump on the adsorption isotherm. Detailed investigations of this phenomenon in the present system are now in progress. In any case, in the case of ZnO, the adsorption isotherms obtained on the sample treated above 300°C are extremely close to the first adsorption isotherm.

By applying the BET method[15] to the above data, the amount of the monolayer capacity of water on the unit surface, V_m, can be calculated.

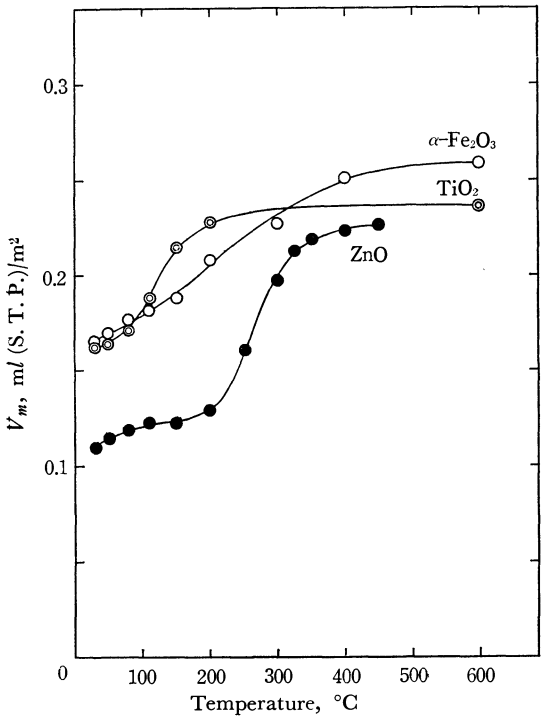

Fig. 5. Relation between V_m-value and pretreatment temperature.

BET plots were satisfactorily linear in the range of relative pressures from 0.05 to 0.35 in the cases of Fe_2O_3 and TiO_2, and from 0.05 to 0.20 in the case of ZnO. In Fig. 5 the V_m-values of the water adsorption are plotted against the temperature of the pretreatment. It may be seen from Fig. 5 that the V_m-values on TiO_2 and ZnO start to increase steeply at 110 and 200°C respectively, while in the case of Fe_2O_3 the value shows only a slow increase.

Even when a series of adsorption measurements were made in order from higher to lower pretreatment temperatures, the results obtained were quite reproducible. The reproducibility of the present experiments is satisfactory in this sense. This implies that the number of sites accepting water molecules is determined by the pretreatment conditions. The solid surface will be hydrated thoroughly after every adsorption measurement. Therefore, after treatments at moderate temperatures sites for both the physical and the chemical adsorption of water will be formed, the latter increasing in number with a rise in the pretreatment temperature.

It has been found that the rate of surface hydration on metal oxide is so fast that it seriously affects the value of immersional heat.[16] The V_m-value obtained, therefore, will contain both physical adsorption and chemisorption. Accordingly, the starting point of the sharp increase in V_m-values that is shown in Fig. 5 will correspond to the commencement of chemisorption in addition to the physical adsorption of water. Jurinak[17] assumed that only physical adsorption would occur on the samples of TiO_2 (anatase), α-Fe_2O_3, and α-FeOOH which were treated at 30°C in a vacuum of 10^{-6} Torr. Hollabaugh and Chessick[18] also considered that all the physically-adsorbed water might be removed near room temperature in a vacuum of 10^{-6} Torr. The present results substantiate the assumptions of these authors. From Fig. 5 we can find the temperature of pretreatment above which the reversible chemisorption sites for water abruptly increase. Moreover, this temperature is found to vary with the nature of the metal oxide, indicating that the surface hydroxyl groups bond to the surface metal atoms with a certain strength characteristic of each substance.

The desorption temperature of chemisorbed

water is much higher in the case of ZnO than in the case of TiO_2. This means that the bonding force of hydroxyl groups to surface metal atoms on ZnO is much stronger than that on TiO_2. The reason for the difference between the two bonding forces may be explained by the structural or coordination factors of the solid substances concerned, but it is not clear at present. In the case of Fe_2O_3, there is no sharp increase in V_m-value. The desorption of chemisorbed water on Fe_2O_3 may start at such a low temperature that the removal of physically-adsorbed water can occur, and continue over a wide range of temperature. The heat of hydration, which was calculated by combining the data of immersional heat and of the water content of the powder, has been found to be 12.1 kcal/mol for Fe_2O_3,[19] and 23 kcal/mol for TiO_2 (rutile)[19] and ZnO.[16] These data have been interpreted in the following way: in the case of Fe_2O_3, the removal of chemisorbed water starts at a relatively low temperature, while on the other hand, the physically-adsorbed water remains until relatively high temperatures. This interpretation seems to be useful in the present case also.

19) to be published.

Figure 6 shows the results of the infrared absorption spectroscopy of the three samples. The absorption band due to physically-adsorbed water appears near 1600 cm^{-1} on all the samples tested at room temperature in the atmosphere; it is extinguished by degassing in a vacuum of 10^{-5} Torr at room temperature in the cases of TiO_2 and ZnO, but it still remains in the case of Fe_2O_3 even after evacuating at higher temperatures. The difficulty of the desorption of chemisorbed water from Fe_2O_3 probably arises from the fact that water molecules have been adsorbed on the inner surface of Fe_2O_3. Healey *et al.*[20] suggested that the desorption of water vapor took place from the inner surface of ferric oxide powder. The X-ray data observed in connection with the present sample of Fe_2O_3 proved the crystallinity to be inferior to that of the other two samples. The behavior of adsorbed water on Fe_2O_3 suggests the existence of an inner surface on which nitrogen molecules can not be adsorbed at the temperature of liquid nitrogen.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1537—1539 (1968)

The Termination Processes of the Autoxidations of Benzene, Toluene and Ethylbenzene in the Aqueous Phase as Studied by Oxygen-18*1,*2

Hiroshi HOTTA and Nobutake SUZUKI

Japan Atomic Energy Research Institute, Takasaki, Gunma

(Received December 22, 1967)

The autoxidations of benzene, toluene and ethylbenzene were investigated at 70°C by using the oxygen-18 enriched Fenton's reagent. The oxygen-18 atom percentage in the products suggests that all the oxygen of benzaldehyde from toluene and of acetophenone from ethylbenzene is donated by molecular oxygen dissolved in the aqueous phase, while the oxygen of the hydroxylation products, namely, phenol from benzene, benzyl alcohol from toluene and methyl phenyl carbinol from ethylbenzene, is donated partly from water and partly from molecular oxygen. From the latter finding, the rate of the carbonium cation formation from the intermediate radicals without their oxidation to the peroxide is in the order of phenyl > α-methyl-benzyl > benzyl.

The autoxidations of benzene[1,2] and toluene[3], catalyzed by metal ions in the aqueous phase have been studied by using a stainless-steel reactor between 100°C and 200°C. Although this oxidation procedure is very suitable to obtain the main product due to the high selectivity, the oxygen-18 enriched Fenton's reagent was used at 70°C for the confirmation of the termination processes,

because this method gives other products in addition to the main one. Since the accuracy in the previous study of toluene[3] was not so good due to the rather carelessness of the sampling method, the present study was carried out by the revised method for benzene, toluene and ethylbenzene.

Experimental

As in the previous study,[3] an oxygen-18 enriched aqueous solution of 1.5% hydrogen peroxide (10 cc) was added drop by drop, over a period of about 90 sec, in the oxygen-18 enriched 0.4 N sulfuric acid solution of 0.01 M ferrous sulfate (100 cc) at 70°C in a 300 cc flask opened to the air, in which 1 cc of aromatic hydrocarbons was suspended by a magnetic stirrer. Acetone (10 cc) was added except the case of benzene to increase the solubility of aromatic hydrocarbons. Such solutions seemed to be homogeneous at 70°C. The aqueous solutions were prepared by using the 1.64_5 ^{18}O-atom-% water.

For reference, the natural compounds (*ca.* 0.2 cc) corresponding to the products were treated for 10 min by the same conditions without hydrogen peroxide and aromatic hydrocarbons.

After the mixture had been stirred magnetically for 10 min from the beginning of dropping and then cooled, the products were extracted in ether and separated by gas chromatography at 165°C using a column of PEG 6000. The procedure after that was revised. That is, the fractions (*ca.* 100 mg) were converted to carbon dioxide by heating them for 12 hr at 500°C with mercuric chloride (100 mg) and mercuric cyanide (100 mg). The oxygen-18 atom percentage in the carbon dioxide was determined by mass spectrometry. Phenol was transformed to tribromophenol[2] in advance.

Results and Discussion

The observed values of the oxygen-18 atom percentage for the oxidation products (x) and the treated compounds for reference (x_0) are shown in Table 1 respectively. The values shown by an asterisk are for phenol produced from benzene at 150°C and 180°C in the ferrous sulfate solution by using a high-pressure reactor in the previous study.[2] As described in the experimental section, the values of x and x_0 for phenol were obtained without addition of acetone. The values of x_0 in the acetonic aqueous solution agreed within experimental error with those in the aqueous solution except benzaldehyde.

When it is assumed that the oxygen exchange reaction with water is of first order, this rate constant, k_e, can be estimated by equation

$$\frac{x_0-0.20_4}{1.64_5-0.20_4} = 1-e^{-k_e t} \qquad \text{(i)}$$

where t is the exchange time, and 0.20_4 is the natural abundance of oxygen-18 in atom%. Since it takes some time for cooling, it is difficult to determine the effective exchange time. The k_e's in Table 1 are estimated on putting $t=10$ min. These values indicate that, as reviewed by Samuel and Silver,[4] aldehyde and ketone exchange oxygen rapidly with water, and methyl phenyl carbinol also does so considerably. On the other hand, phenol, benzyl alcohol and β-phenyl ethyl alcohol do not so practically.

For benzaldehyde and acetophenone, x is smaller than x_0. It is because, at the oxidation process, the product is accumulated gradually and may be partly lost by some secondary reaction during the oxidation time, while, at the reference treatment, all the reactant is present from the beginning and not lost by some secondary reaction. The smaller value of x suggests that oxygen-18 of these products is not enriched during their formation process, but done due to the oxygen exchange with water after their formation.

According to the previous studies,[2,3] the following reaction scheme can be assumed as the propagation processes of the present autoxidation after the formation of hydroxyl radicals:

$$RH + \cdot OH + O_2 \rightarrow R'OO\cdot \qquad (1)$$

TABLE 1

Reactant	Product	^{18}O atom-% x	^{18}O atom-% x_0	k_e min^{-1}	F_w	Temp. °C
Benzene	Phenol	1.17_4	0.21_8	0.0010	0.67	70
		0.48*	—	—	0.18	150*
		0.90*	0.20_8	0.0003	0.47	180*
Toluene	Benzaldehyde	0.53_7	1.34_3	0.20	0	70
	Benzyl alcohol	0.37_7	0.21_1	0.0005	0.12	70
Ethylbenzene	Acetophenone	0.73_9	1.10_0	0.097	0	70
	Methyl phenyl carbinol	1.03_2	0.46_6	0.020	0.48	70
	Unknown	0.38_0	—	—	—	70
	β-Phenyl ethyl alcohol	—	0.21_3	0.0006	—	70

* See Ref. 2.

4) D. Samuel and B. L. Silver, *Advances in Phys. Org. Chem.*, **3**, 123 (1965).

$$RH + R'OO\cdot \rightarrow R\cdot + R'OOH \quad (2)$$

$$R\cdot + O_2 \rightarrow ROO\cdot \quad (3)$$

$$RH + ROO\cdot \rightarrow ROOH + R\cdot \quad (4)$$

$$ROOH + Fe^{2+} \rightarrow RO\cdot + OH^- + Fe^{3+} \quad (5)$$

$$ROOH + Fe^{3+} \rightarrow ROO\cdot + H^+ + Fe^{2+} \quad (6)$$

$$ROO\cdot + ROO\cdot \rightarrow ROOR + O_2 \rightarrow 2\,RO\cdot \quad (7)$$

where R· represents phenyl, benzyl or α-methyl benzyl radical. Reaction (1) represents that hydroxyl radicals give some peroxide in the presence of oxygen as the result of either the hydrogen abstraction from RH or the addition to RH.

From the above findings, the following process independent of the water oxygen is assumed for the formation of benzaldehyde and acetophenone, that is, the elimination process of proton from the oxyradical catalyzed by ferric ion;

$$C_6H_5CH_2O\cdot + Fe^{3+} \rightarrow C_6H_5CHO + H^+ + Fe^{2+} \quad (8)$$

and

$$C_6H_5\dot{C}HOCH_3 + Fe^{3+} \rightarrow C_6H_5COCH_3 + H^+ + Fe^{2+} \quad (9)$$

This is supported by the fact that the content of ferrous ion in the iron ion increases with the production of these products.[3]

For the hydroxylation compounds, *i. e.*, phenol, benzyl alcohol and methyl phenyl carbinol, their oxygen-18 atom percentages in Table 1 are

$$1.64_5 > x > x_0$$

This means that the oxygen of these products is donated partly by water and partly by molecular oxygen dissolved. The fraction of the product, to which oxygen is donated by water, is estimated as F_w in Table 1 by equation

$$F_w = \frac{x' - 0.20_4}{1.64_5 - 0.20_4} \quad \text{(ii)}$$

$$x' = x - \alpha(x_0 - 0.20_4) \quad \text{(iii)}$$

where the oxygen exchange with water after the product formation is corrected by α, which is put tentatively as 0.5.

The reaction

$$RO\cdot + H^+ + Fe^{2+} \rightarrow ROH + Fe^{3+} \quad (10)$$

is assumed as the process by which molecular oxygen is donated to the product after reactions (5) and (7). On the other hand, the reaction

$$R\cdot + OH^- + Fe^{3+} \rightarrow ROH + Fe^{2+} \quad (11)$$

is assumed as the transfer process for the oxygen of water. Reaction (11) is consistent with the reduction of iron ion at the oxidation of benzene to phenol. Reaction (11), which is competitive with reaction (3), postulates the formation of carbonium cation as the intermediate from the radical without oxidation to the peroxide. Such probability is in the order of

$$\text{phenyl} > \alpha\text{-methyl benzyl} > \text{benzyl} \quad (12)$$

from the value of F_w in Table 1. α-Methyl benzyl cation is assumed as the intermediate for the oxygen exchange of methyl phenyl carbinol with water in the acidic solution in comparing the rate with the rate of the racemization.[5] It is acceptable that α-methyl benzyl carbonium cation is more probable than benzyl one. The highest ionization probability of phenyl radical to the carbonium cation without oxidation to phenyl peroxide gives a new subject for us. The less reactivity of phenyl radical towards oxygen is suggested by some investigators.[6,7] The electron affinity of phenyl radical is larger than that of benzyl radical.[8]

The unknown product from ethylbenzene in Table 1 could not be identified. This product has a retention time of gas chromatography close to that of β-phenyl ethyl alcohol, and gives the same highest mass number of the mass spectrum with this alcohol, but the NMR spectrum is quite different from this alcohol.

For phenol in Table 1, the present values, obtained in the 0.4 N acidic solution at 70°C, is higher than the previous value, obtained in the 0.01 N acidic solution at 150°C and 180°C.[2] If the value of F_w increases with an increase of temperature as seen between 150°C and 180°C, the high value of F_w at 70°C suggests the promotion of the carbonium cation formation by hydrogen ions.

The authors wish to express their appreciation to Dr. Toshio Sugiura, for his cooperation in the mass spectrometry, and to Mr. Naohiro Hayakawa, for the measurement of NMR.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1540—1545 (1968)

Heats of Mixing for Binary Mixtures. V

Sachio MURAKAMI, Mituo KOYAMA and Ryoichi FUJISHIRO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received January 6, 1968)

The heats of mixing were measured at 25.0°C for binary mixtures of chloroform+tetrahydrofuran,+ furan, and +2-methyl furan systems and for cyclohexane+chloroform, +tetrahydrofuran, +furan, and +2-methyl furan systems. Using these data and the treatment described in a previous paper [*Bull. Chem. Soc. Japan*, **37**, 1776 (1964)], the intermolecular hydrogen bond energies between chloroform and cyclic ethers were estimated to be $\Delta H=-12$ kJ for the chloroform-tetrahydrofuran-cyclohexane system, $\Delta H=-4$ kJ for the chloroform -2-methyl furan-cyclohexane system, and $\Delta H=-3$ kJ for the chloroform-furan-cyclohexane system. From these results, two types of intermolecular hydrogen bonds between chloroform and cyclic ethers are discussed.

In recent years, extensive studies have been made of the relative strengths of hydrogen bonds formed between alcohols, haloform, and oxygen- and nitrogen-containing Lewis bases. Using a number of techniques, such as infrared spectra,[1] NMR spectra,[2] refractive indices[3] and heats of solution,[4] the equilibrium constants and enthalpies for these complexes have been determined.

We estimated the enthalpy of OH-π type hydrogen bonds from our measurements of the heats of mixing for aromatic alcohol (including *m*-cresol)-aromatic hydrocarbon and aromatic alcohol-cyclohexane.[5] This paper is a continuation of our previous work.[5] The enthalpies of intermolecular hydrogen bonds between chloroform and cyclic ether will be estimated by a method similar to that described in another previous paper.[6]

Experimental

The calorimeter used in this study was a model CM-502 microcalorimeter (Applied Electric Lab. Ltd., Tokyo).[5,7] For the present work, two metal solution cells supported from the lids of an aluminum block by a framework were removed and replaced by copper mixing-cell holders with glass-mixing cells. The shape of the mixing cell was similar to that used by Larkin and McGlashan;[8] it is shown schematically in Fig. 1. Initially, the two components to be mixed were separated by a longitudinal partition and by mercury. The mixing was performed by rotating the calorimeter assembly back and forth through a 180° arc, as has been described in a previous paper.[5]

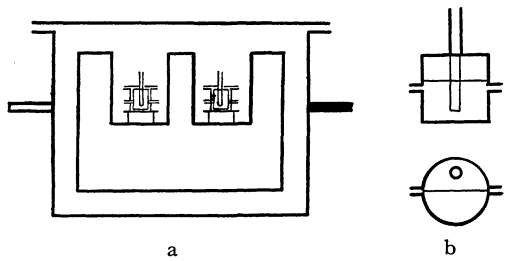

Fig. 1. a. Calorimeter. b. Cross section and upper side view of mixing cell.

The chloroform was washed with concentrated sulfuric acid and a dilute sodium hydroxide solution. Then it was dried over potassium carbonate and distilled before use. Tetrahydrofuran, furan, and 2-methyl furan were supplied by the Kaō Soap Co., Ltd.; all these materials were fractionally distilled before use. The cyclohexane was purified by the method described previously.[5] The purity of all the materials was examined by gas chromatography. The results showed only a single peak.

The physical constants of these materials are given in Table 8.

Results and Discussion

The results of the experimental measurement of the heats of mixing for the seven systems at 25.0°C are given in Tables 1—7, where x_1 is the mole fraction of the component 1; w_i ($i=1$ or 2) is the mass of the component i; Q is the quantity of heat produced during the mixing process, and $\Delta H^{M}_{x_1}$ and ΔH^{M} are the heats of mixing per mole of the

component 1 and per mole of the mixture respectively.

A comparison of our data with those recorded in the literature is only possible for the chloroform-tetrahydrofuran and chloroform-cyclohexane systems. In the former case, our value for ΔH^M at an equimolar mixture agrees with that of Tamres, 677 cal at 25°C.[9] On the other hand, in the latter case, our data agree with those of Baud[10] over the whole concentration range except for around $x_1=0.7$, although his data were measured between 15 to 20°C.

The experimental data for $\Delta H^M_{x_1}$ have been plotted against the mole fraction, x_1, in Figs. 2 and 3. By smoothing and extrapolating the curve to an infinite dilution ($x_1 \to 0$) for each system,

shown in Figs. 2 and 3, we can obtain the heats of mixing at an infinite dilution ($\lim_{x_1 \to 0} \Delta H^M_{x_1}$). They are as follows: 2.70 kJ for the chloroform(1)+cyclohexane(2) system; 3.15 kJ for the tetrahydrofuran(1)+cyclohexane(2) system; 4.20 kJ for the 2-methyl furan(1)+cyclohexane(2) system; 4.50 kJ for the furan(1)+cyclohexane(2) system, −9.20 kJ for the chloroform(1)+tetrahydrofuran(2) system; −1.56 kJ for the chloroform(1)+2-methyl furan(2) system; and −0.57 kJ for the chloroform(1)+furan(2) system.

The values of $\lim_{x_1 \to 0} \Delta H^M_{x_1}$ in the cyclohexane series provide energies sufficient to break up all the interactions existing between molecules in the pure state, that is, dipole-dipole interaction in chloroform and tetrahydrofuran, and dipole-dipole and π-π interactions in 2-methyl furan and furan.

In a previous paper,[6] we estimated the energies of dipole-dipole interaction in *n*-ether, ketones, and tertiary amine as the difference in the dipolar stabilization energy of the dipole arising from the reaction field with different media in Onsager's

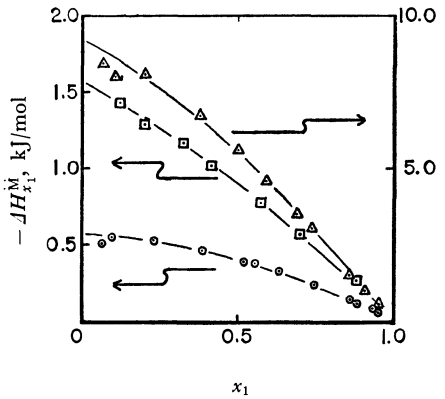

Fig. 2. Heats of mixing of $CHCl_3$+cyclic ether systems: ⊙, furan; ⊡, 2-methylfuran; △, tetrahydrofuran.

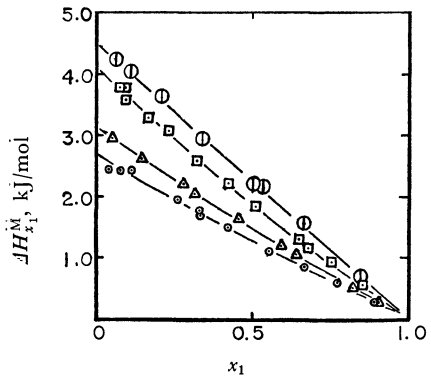

Fig. 3. Heats of mixing of polar liquid+cyclohexane systems: ⊙, $CHCl_3$; △, tetrahydrofuran; ⊡, 2-methylfuran; ⓘ, furan.

treatment of polar liquids. The calculated results seem to agree with the $\lim_{x_1\to 0} \Delta H^M_{x_1}$ values for the polar liquid-nonpolar solvent systems. However, in the 2-methyl furan- and furan-cyclohexane systems of the present investigation, the $\lim_{x_1\to 0} \Delta H^M_{x_1}$ values differ from the results calculated by the above-described method (0.28 kJ for the furan+cyclohexane system and 0.14 kJ for the 2-methyl furan+cyclohexane system). Therefore, the furan derivatives seem to have another interaction, such as a π-π interaction due to a π-electron of the furan nucleus. The energies of such π-π interaction in furan derivatives can not be estimated directly. However, it seems reasonable to regard the value evaluated by subtracting the dipole-dipole interaction energy from the $\lim_{x_1\to 0} \Delta H^M_{x_1}$ value as the energy of π-π interaction—that is, 4.22 kJ (4.50—0.28) for the furan+cyclohexane system and 4.06 kJ (4.20—0.14) for the 2-methyl furan+cyclohexane system.

On the other hand, the values of $\lim_{x_1\to 0} \Delta H^M_{x_1}$ in the chloroform series represent the energies of transfer from the pure chloroform state to one in which each chloroform molecule make a hydrogen bond with an ether molecule, and in which such associated complex molecules are surrounded by a large amount of the ether medium.

Although there are various methods for estimating the energy of the intermolecular interaction, we can estimate the energies of intermolecular hydrogen bonds between chloroform and cyclic ethers in the same way as has been described in a previous paper.[6]

Of the enthalpy cycle shown in Fig. 7 of Ref. 6, ΔH_1, ΔH_2, and ΔH_3 are also measured in the present work, while ΔH_4 in Process 4 is estimated by the same treatment as has been described previously.[6] In the tetrahydrofuran case, two energy changes will contribute to ΔH_4. One, the heat of the mixing of $(x-1)$ mol of tetrahydrofuran with a large quantity of cyclohexane, is equal to $(x-1)\,\Delta H_2$, and the other is ΔH^d_4, due to the enthalpy change from the state in which the associated complex molecules are surrounded by the ether medium to

that in which they are surrounded by the cyclohexane medium. On the other hand, in furan derivatives, another contribution to ΔH_4 comes from the π-π interaction of the associated complex molecules. As this contribution can not be estimated, we shall assume it to be equal to the energies of the π-π interaction in the furan derivative. The contribution due to $\Delta H_4{}^d$ may be calculated by the previously-described method. The physical constants necessary for this calculation are summarized in Table 8, where d, ε, n_D, and μ are the density, dielectric constant, refractive indices, and dipole moment respectively. μ_{12} is the dipole moment of the associated complex molecule. Its value for the tetrahydrofuran system was derived by Weisbecker.[11] He determined it by assuming that a hydrogen atom of chloroform forms a hydrogen bond with an oxygen atom of tetrahydrofuran. On the other hand, the μ_{12} values for the furan derivative systems were calculated by assuming that a chloroform molecule combines on the nucleus of furan and by the vector addition of the dipoles of two component molecules. The reasons for this assumption will be given later.

The $\Delta H_4{}^d$ values thus obtained are as follows: 3.08 kJ for the chloroform-tetrahydrofuran complex; 0.38 kJ for the chloroform-furan complex; 0.35 kJ for the chloroform-2-methyl furan complex; 0.28 kJ for the furan-cyclohexane system, and 0.14 kJ for the 2-methyl furan-cyclohexane system.

By using the $\Delta H_4{}^d$ values calculated above and the other measured values, the intermolecular hydrogen bond energies between chloroform and cyclic ethers, ΔH_5, are found to be:
for the chloroform-tetrahydrofuran-cyclohexane system:

$$\begin{aligned}\Delta H_5 &= -\Delta H_1 - x\Delta H_2 + \Delta H_3 + \Delta H_4 \\ &= -\Delta H_1 - x\Delta H_2 + \Delta H_3 + (x-1)\Delta H_2 \\ &\quad + \Delta H_4{}^d \\ &= -2.70 - 3.15x - 9.20 + 3.15(x-1) \\ &\quad + 3.08 \\ &= -11.97\ \text{kJ};\end{aligned}$$

for the chloroform-furan-cyclohexane system:

$$\begin{aligned}\Delta H_5 &= -\Delta H_1 - x\Delta H_2 + \Delta H_3 + \Delta H_4 \\ &= -\Delta H_1 - x\Delta H_2 + \Delta H_3 + (x-1)\Delta H_2 \\ &\quad + \Delta H_{\pi-\pi} + \Delta H_4{}^d \\ &= -2.70 - 4.50x - 0.57 + 4.50(x-1) \\ &\quad + 4.22 + 0.38 \\ &= -3.17\ \text{kJ, and}\end{aligned}$$

for the chloroform-2-methyl furan-cyclohexane system:

$$\begin{aligned}\Delta H_5 &= -2.70 - 4.20x - 1.56 + 4.20\,(x-1) \\ &\quad + 4.06 + 0.35 \\ &= -3.99\ \text{kJ}.\end{aligned}$$

As may be seen in the above calculations, the energies of the intermolecular hydrogen bonds between chloroform and cyclic ethers are in the order: tetrahydrofuran > 2-methyl furan > furan.

Let us now consider this order. In furan derivatives, π-electron is present, but not in tetrahydrofuran. Therefore, furan has a negative net charge on the ring carbon and a positive net charge on the oxygen atom, as is shown in Fig. 4.[12] The hydrogen-bond forming power of furan with chloroform will be weakened. On the other hand, it is known that the tetrahydrofuran molecule makes

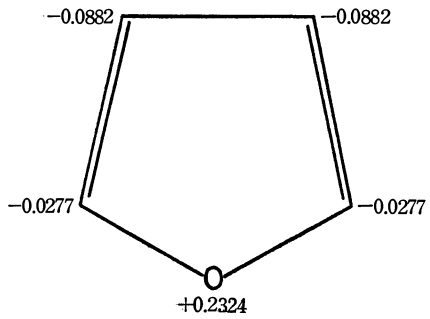

Fig. 4. Net charge on the atoms of furan molecule.

a CH-O type intermolecular hydrogen bond with chloroform.[11] Generally, the hydrogen bond strength is stronger in the H-O type than in the H-π type.[13] As the introduction of a methyl group to the furan ring causes an increase in basicity, the hydrogen bond energy for the 2-methyl furan system increases in comparison with that for the furan system. Furthermore, it is known from the spectroscopic study that the shift in the frequency of the O-H band, $\Delta\nu$, of alcohol is correlated with the hydrogen-bond energy. The frequency shifts, $\Delta\nu$, of phenol due to hydrogen bonding with some heteroaromatics were measured in carbon tetrachloride.[1] The results were arranged in the order of: tetrahydrofuran>2-methyl furan> furan; this order is consistent with that one which we have estimated on the basis of the thermochemical measurements.

The authors wish to thank Professor Zenichi Yoshida, Faculty of Engineering, Kyoto University, for his helpful advice. The authors are also grateful to Dr. Kichisuke Nishimoto for his valuable discussions. Thanks are also due to the Kaō Soap Co., Ltd., Wakayama, for supplying the tetrahydrofuran and furan derivatives, and to the Applied Electric Lab., Ltd., for freely allowing the use of a model CM-502 microcalorimeter. The expenses of this work have been partly defrayed by a grant from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1545—1551 (1968)

Studies on the Delayed Fluorescence by Means of a Flash Technique*[1]

Koichi KIKUCHI, Hiroshi KOKUBUN and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received January 16, 1968)

It has been shown that the delayed and normal fluorescence can be measured accurately by a usual flash apparatus. Such measurements, combined with that of T–T absorption, have enlarged the potentiality of a flash technique to a large extent. As an example, a simple method of differentiation between E-type and P-type delayed fluorescence has been presented. Detailed studies have been made on the T–T annihilation process of anthracene (A) and the probability for Process $A^T+A^T \rightarrow A+A^*$, has been decided. The value obtained is 0.077 ± 0.005. E-Type delayed fluorescence of eosine and proflavine have been studied and the value of $k_t \cdot \phi_{ST}$ (k_t, the rate constant of Process, $T \rightarrow S^*$; ϕ_{ST}, the probability of the intersystem crossing) have been evaluated, to be 3.3_6 and 2.7_8 sec^{-1} respectively. Some advantages of the present method over the sector method have been discussed.

A flash photolytic technique is now extensively used for studying the behavior of intermediates produced in the photochemical reaction of organic substances. The method, however, usually relies upon the measurement of the UV absorption spectra of transient species.

If the measurement is extended to the emission phenomena such as the normal and delayed fluorescence, the potentiality of the flash technique will largely be enlarged. Such attempts have been made by Zahlan *et al.*[1] and by Powell[2] to determine the intersystem-crossing probability of some hydrocarbons in the gaseous state. Wild *et al.*[3] also measured the delayed fluorescence of

*1 A preliminary report was published in *Photochem. and Photobiol.*, **7**, 499 (1968).

anthrancene in glycerol in the temperature range from −20 to 90°C. In spite of these reports, it does not seem that the methodology has been fully established and that its availability has been duly recognized. We believe that various kinds of process such as delayed fluorescence, quenching of fluorescence, T-T energy transfer and other elementary processes in the excited states can be attacked by combining the measurement of the emission-time relation with that of the T-T absorption.

The objective of the present paper is to report firstly, how the time dependence of the delayed fluorescence and of the normal fluorescence (during flash irradiation) can be accurately measured with an ordinary flash apparatus now generally used, and secondly how the method can be applied, as an example, to the investigation of the mechanisms of the delayed fluorescence.

Delayed fluorescence has been studied extensively by Parker and his coworkers[4]; and now it has been well established that there are two types of delayed fluorescence, *i. e.*, E-type and P-type. Choosing anthracene of which the elementary processes in the excited state have been studied in detail, we would like to show how the present method is used for studying the P-type delayed fluorescence, with some advantages over the sector method. For this purpose, the delayed fluorescence of anthracene as well as the sensitized one, using eosine, erythrosine and proflavine as sensitizers, have been studied. E-Type delayed fluorescence of proflavine and eosine have also been studied and the results have been compared with those obtained by other methods.

Experimental

A great advantage of the present method is that the time dependence of the delayed fluorescence and the triplet decay can be compared in the similar experimental condition with the same apparatus. In order to do this, it is, of course, necessary to keep the geometry of the entire apparatus rigorously fixed. It is also required that the intensity of the flash and its time dependence can be controlled reproducibly. These requirements could be achieved with some satisfaction.

In order to investigate the mechanism of the delayed fluorescence, measurement has to be performed of A) the triplet decay and the intensity of the delayed fluorescence as a function of time both in the same condition, and besides, of B) the normal fluorescence intensity (during a flash) and the yield of the triplet state under the same condition which is, however, different from A).

To make an accurate measrement of the time dependence of the delayed fluorescence, it is necessary to remove the effect of the scattered light during a flash and to make the duration of a flash as short as possible. Use of some suitable sensitizers with appropriate filters is very effective for removing the scattered light and accordingly for separating the normal and delayed fluorescence satisfactorily.

Decay of T-T absorption and the change of delayed fluorescence with time, were measured at fixed wavelengths by means of a Nalumi-RM 23 monochromator. Photomultipliers employed, were Hamamatsu TV R106 and R132. A Iwasaki-Tsushinki SS-5004 synchroscope was used. Cells were the standard ones *i. e.*, quartz cells 10 mm in diameter, 100 mm in length or SB glass tubes 10 mm in diameter with two quartz plates pasted on both ends. Energy input to the flash lamp was selected in the region from 10 to 120 joules.

For the measurement of normal fluorescence, which is quite strong, neutral filters were inserted in between the monochromator and the cell. Measurement of the normal fluorescence from an aerated solution was of great help to examine the degree of superposition of the normal and delayed fluorescence. Because the aerated solution gives no delayed fluorescence and the profile of the emission is closely related with that of the flash.[5]

Anthracene, β-acetonaphthone, eosine, proflavine, erythrosine and ethanol were purified by the standard methods.

Method of Analysis and Results

Typical Examples for the Time Dependence of the Normal and Delayed Fluorescence. The intensity of the delayed fluorescence, I_{DF} and the second order decay constant of T-T absorption were measured at the same high energy input to the flash lamp. Figures 1 and 2 give respectively the I_{DF} *vs.* t plots for the case of direct excitation of anthracene and for the eosine-sensitized excitation. The dotted line in Fig. 1 represents the normal fluorescence from the aerated solution. It is evident that the shaded area can be used as the quantity of the delayed fluorescence during the time interval from a to b. A small peak existing

between o and s in Fig. 2 is due to the scattered light during a flash. The area after s gives the quantity of the delayed fluorescence. It is evident that in the case of the sensitized emission, rise and fall of the delayed fluorescence can be measured with enough accuracy. As will be reported elsewhere, the analysis of the rising portion of the curve enables us to evaluate the rate constant for the process of T–T energy transfer. Figure 3 gives the spectrum of the delayed fluorescence of anthracene sensitized by eosine. This was obtained by measuring the decay curves such as shown in Fig. 2, at various wavelengths, and by plotting the intensities at the peak positions against the wavelength. The spectrum agrees satisfactorily with that of the normal fluorescence; this ensures the reliability of the intensity measurement.

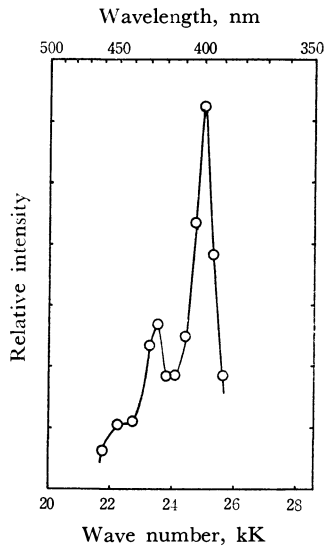

Fig. 3. Delayed fluorescene spectrum of anthacene sensitized by eosine.
[Anthracene] = 3.6×10^{-5} M
[Eosine] = 2.0×10^{-5} M

Normal fluorescence was measured at a low energy input to the flash lamp. Under such a condition, the yield of triplet state could be determined precisely because the decay was practically first order. Figure 4 is an example of the profile of the normal fluorescence of anthracene in the aerated solution. Since this reflects the profile of the flash, the reproducibility of flashing can be checked by making such measurements from time to time. It was found that the reproducibility was quite excellent. The optical density of T–T absorption corresponding to the yield of triplet state, $(D_T)_0$, was decided by extrapolation of the decay curve of T–T absorption to the time-point S'. This is somewhat conventional but was found to be most satisfactory.

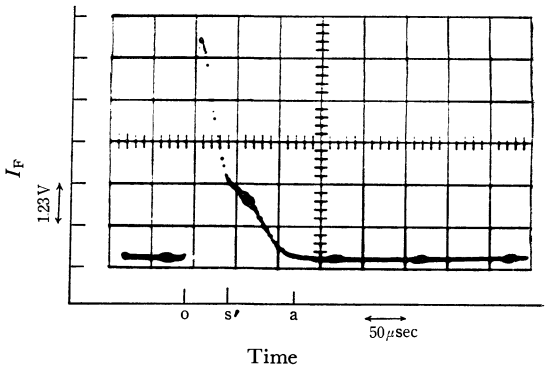

Fig. 4. Normal fluorescence of anthracene during a flash.
[Anthracene] = 1.0×10^{-4} M
Flash energy 80 joule

In the case of E-type delayed fluorescence, the intensity was so weak that it was very difficult to distinguish the delayed fluorescence from the normal one. This was almost impossible in the case of direct excitation. An example of the

delayed fluorescence of eosine in the case of sensitized emission, by β-acetonaphthone, is shown in Fig. 5. Curve a in Fig. 5 is a plot of emission intensity from the deaerated solution and curve *b*, from the aerated solution. Since the latter is due mainly to the scattered light, the shaded area can be used as a measure of the delayed fluorescence. The accuracy is rather poor in this case.

Differentiation between P-Type and E-Type Delayed Fluorescence. It is well known that the delayed fluorescence of aromatic hydrocarbons occurs through the T–T annihilation, $T+T \xrightarrow{k_1} S^*+S$. The details of other processes simultaneously occurring, however, still remain to be studied in future. Here the following scheme is conventionally assumed.

$$T + T \begin{cases} \xrightarrow{k_1} S^* + S \\ \xrightarrow{k_2} T + S \end{cases} \qquad k_{TT} = k_1 + k_2$$

Putting $p=(k_1/k_{TT})$, the intensity of the delayed fluorescence can be written as follows,

$$I_{DF} = \alpha\phi_F p k_{TT}[T]^2 = \alpha\phi_F p k_{TT}[D_T/\varepsilon_T d]^2 \qquad (1)$$

where α is a constant depending upon the apparatus and upon the entire experimental conditions, where ϕ_F is a quantum yield of the fluorescence and where D_T, ε_T and d are respectively the optical density for T–T absorption, molar absorbance for it and the light path of a cell (100 mm in the present case).

Taking logarithm of Eq. (1), one obtains

$$\log I_{DF} = 2\log D_T + \log(\alpha\phi_F p k_{TT}/(\varepsilon_T)^2 d^2) \qquad (2)$$

Eq. (2) requires that the plot of $\log I_{DF}$ *vs.* $\log D_T$ should have a slope of 2. Figure 6 shows that this relation really holds very satisfactorily. This is perhaps the simplest method for verifying the P-type delayed fluorescence. It is somewhat disappointing that the four lines do not coincide. This is, of course, due to the fluctuation in α-values. The smallest value for proflavine may perhaps be attributed to a large value of its molar absorbance at 400 nm, which reaches 8.5×10^3 M^{-1} cm^{-1}. For the other three cases the deviation of α from the average is within ±40%.

E-Type delayed fluorescence was more difficult to study because of its very weak intensity. Moreover, since both eosine and proflavine have more or less absorption in the entire UV region, the dye concentrations should be less than $\sim10^{-5}$ M in order to reduce the perturbing effect of the normal fluorescence.

It is therefore necessary to examine how the energy transfer from β-acetonaphthone to a dye occurs at such a low concentration. Figure 7 shows the decay of T–T absorption of β-acetonaphthone in the presence and in the absence of eosine.

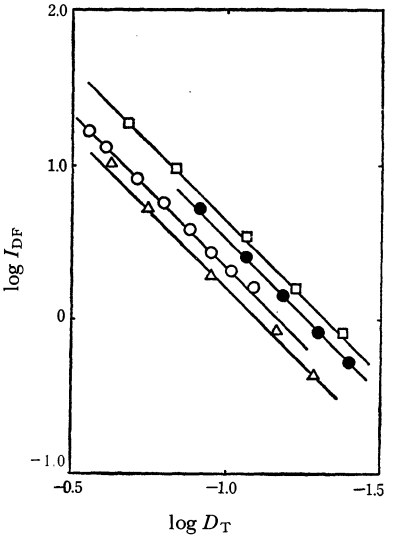

Fig. 6. Confirmation of Eq. (2).

□ [Eosine] = 5.0×10^{-6} M
△ [Proflavine] = 1.2×10^{-5} M
○ [Anthracene] = 8.0×10^{-5} M
[Erythrosine] = 8.0×10^{-6} M

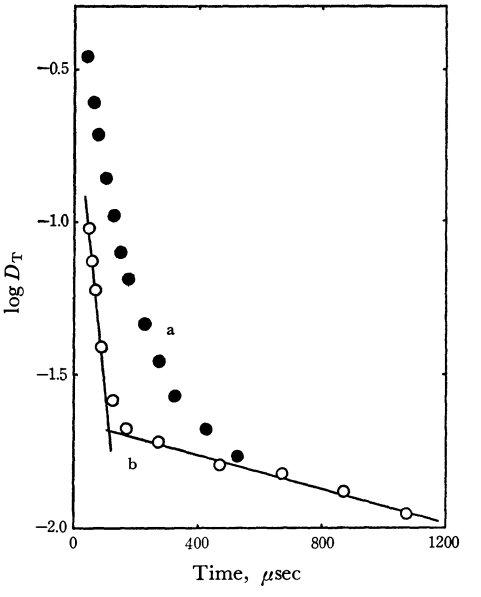

Fig. 7. Decay of T–T absorption of β-acetonaphthone at 430 nm.
● [Eosine] = 0 M
○ [Eosine] = 6.0×10^{-6} M
[β-Acetonaphthone] = 5×10^{-4} M

One can say that the energy transfer is practically complete in 200 μsec. Thus in the present system, the experimental data after 200 μsec should be used. The slow decay in the later stage of curve b, is related with another intermediate produced

by the reaction of the eosine triplet state with ethanol.[5]

It is well-known that the process T→S* for the E-type delayed fluorescence, is a monomolecular thermal activation. Thus I_{DF} is given by the following relation,

$$I_{DF} = \alpha\phi_F k_t[T] = \alpha\phi_F k_t \frac{D_T}{\varepsilon_T d} \qquad (3)$$

where k_t is the rate constant of the T→S* process. Figure 8 gives the plots of $\log D$ and $\log I_{DF}$ against time for the case of eosine, and Fig. 9 gives the similar plots for proflavine. As seen from these figures, the delayed fluorescence and the T-T absorption decay with essentially the same rate constant. This verifies that the delayed fluorescence of these dyes is mainly of E-type. However, there is a tendency, in the case of eosine, that the decay of the T-T absorption is appreciably smaller in the later stage. This is due to the existence of the absorption of another transient intermediate which is produced in the reaction between T and ethanol.[5] In the case of proflavine, the slopes for the $\log D_T$ and $\log I_{DF}$ plots agree quite well in the later stage. In both eosine and proflavine, the slopes of $\log I_{DF}$ at the early stage are somewhat larger. This suggests

the occurrence of P-type delayed fluorescence, as has been established by Parker *et al.*[6]

Experimental Verification of the Relation between the Normal Fluorescence and the Triplet Yield. The intensity of the normal fluorescence is proportional to the absorption of light (per unit time) and can be written as follows,

$$I_F = \alpha\phi_F I_{ab} \qquad (4)$$

Integrating Eq. (4),

$$\int I_F dt = \alpha\phi_F \int I_{ab}\, dt \qquad (5)$$

The yield of the triplet state, on the other hand, can be given by the following equation,

$$[T_0] = \frac{[D_T]_0}{\varepsilon_T d} = \phi_{ST} \int I_{ab}\, dt \qquad (6)$$

where $[T]_0$ and $[D_T]_0$ are respectively the concentration of T and the corresponding optical density immediately after flashing and where ϕ_{ST} is the probability of the intersystem crossing. It is to be noted that this equation holds only when the decay of the triplet state is negligible during a flash. When the flash intensity is set rather weak,

6) C. A. Parker, C. G. Hatchard and T. A. Joyce, *Nature*, **205**, 1282 (1965); *J. Mol. Spectry.*, **14**, 311 (1964).

this holds practically and furthermore, the extrapolation of the triplet decay is easy. From Eqs. (5) and (6), one gets

$$[D_T]_0 = \frac{\varepsilon_T d\phi_{ST}}{\alpha\phi_F}\int I_F\,dt \qquad (7)$$

Figure 10 shows that this relation really holds in the case of anthracene. This is considered to be one of the most fundamental relations in the present method. If, ε_T, ϕ_{ST} and ϕ_F are all known, the value of α can be decided from the slope of the plot in Fig. 10.

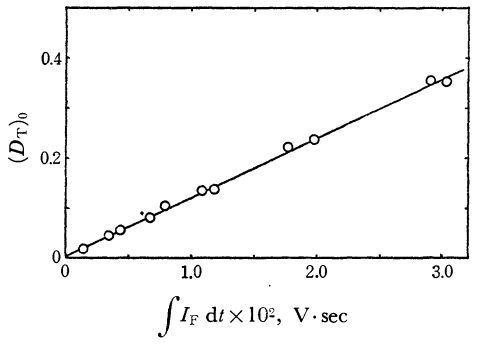

Fig. 10. Confirmation of Eq. (7).
[Anthracene] = 1.0×10^{-4} M

Putting $\varepsilon_T = 6.2\times10^4$ M^{-1} cm^{-1},[7] $\phi_{ST}=0.7$,[8] $\phi_F=0.27$,[9,10] one obtains a value of α to be 1.36×10^5 (at 400 nm). The value of α perhaps depends only on the wavelength when all the other experimental conditions are kept constant. It is most desirable to decide the reliable α-values at various wavelengths.

Analysis of the P-Type Delayed Fluorescence. Integration of Eq. (1) gives

$$\int I_{DF}\,dt = \frac{\alpha\phi_F p k_{TT}}{(\varepsilon_T d)^2}\cdot\int (D_T)^2\,dt \qquad (8)$$

Elimination of α from Eqs. (7) and (8) gives the following relation,

$$\frac{\int I_{DF}\,dt}{\int I_F\,dt} = \phi_{ST} p\,\frac{k_{TT}}{\varepsilon_T d}\,\frac{\int (D_T)^2\,dt}{(D_T)_0} \qquad (9)$$

In this equation, the values of $\int I_{DF}\,dt$, $\int (D_T)^2\,dt$, $\int I_F\,dt$ and $(D_T)_0$ can be obtained experimentally. It is to be noted that the upper and lower limit of the first and the second integrals should respectively be set equal. The k_{TT}/ε value can be obtained by analysing the decay curve of T–T absorption. There is no need to know the value of ε_T. Thus the value of the product $p\cdot\phi_{ST}$ can be evaluated from the data obtained in the flash experiments. The value of ϕ_{ST} is 0.70 according to Medinger and Wilkinson.[8] The values of $p\cdot\phi_{ST}$ and p thus obtained from five different sets of experiments are given in Table 1 along with Parker's value of p.[6] The agreement is satisfactory. We believe that our value is more reliable since it is based only on the experimental data whereas Parker's value was evaluated by using as the k_{TT} value, the diffusion controlled rate constant theoretically calculated.

It is to be added that when the value of α is known (as in the present case), simple insertion of its value into Eq. (2) or into the intercepts of the plots in Fig. 6, gives the value of p. Of course, the same equation can be used to decide the α value if p is a known quantity.

Analysis of the E-Type Delayed Fluorescence. Integration of Eq. (3) gives

$$\int I_{DF}\,dt = \frac{\alpha\phi_F k_t}{\varepsilon_T d}\int D_T\,dt \qquad (10)$$

By eliminating α from Eqs. (7) and (10), one gets

$$\frac{\int I_{DF}\,dt}{\int I_F\,dt} = k_t\phi_{ST}\,\frac{\int D_T\,dt}{(D_{OT})_0} \qquad (11)$$

The upper and lower limits of the integrals $\int I_F\,dt$ and $\int D_T\,dt$ were suitably chosen by taking the perturbing effect of the scattered light into consideration. Thus the value of the product $k_t\cdot\phi_{ST}$ can be obtained in this case; for eosine 3.36 sec^{-1} and for proflavine 2.78 sec^{-1}. The values of the first order triplet decay constant for eosine and proflavine are respectively 1.98×10^3 sec^{-1} and 5.64×10^3 sec^{-1}. The value of ϕ_{ST} for eosine is 0.71 according to Porter.[11] Our recent experiment has given a value of 0.4.[12] Thus the value of k_t for eosine is 8.4 sec^{-1} (at room temperature). This value is compared with 3.77 sec^{-1} at 288°K calculated from the following relation reported by Parker.[9]

$$k_t = 7.4\times10^7\exp\left(-\frac{9.6\text{ kcal}}{RT}\right)$$

Concluding Remarks

In the present paper it has been shown that in suitable systems both the normal and delayed fluorescence can be accurately measured by a flash apparatus. E-Type and P-type delayed fluorescence have been studied to demonstrate the availability of the present method. In particular, the value of p for anthracene (P-type) and the values of $k_t\cdot\phi_{ST}$ for eosine and proflavine (E-type) have been decided. Although there are reliable values for ϕ_{ST} and k_{TT} of anthracene reported in the literature, Parker's p-value for anthracene is the only one ever reported.

A brief description will be added on some advantages of the present method over the sector method.

1) It is possible to compare the triplet decay and the time dependence of the delayed fluorescence, with the same one apparatus and accordingly under quite the similar condition.

2) Since the triplet yield is very high in the flash experiment it is rather easy to make the intensity of the delayed fluorescence large enough to be measureable.

3) P-Type and E-type can be distinguished rather easily by examining the applicability of Eqs. (2) and (3). In the sector method on the other hand, the decay constant of the delayed fluorescence, becomes twice that of the triplet decay, only when the triplet concentration is low enough.

4) In evaluating the $p\cdot\phi_{ST}$ values of the P-type delayed fluorescence, it is unnecessary to know the absolute value of the second order rate constant of the triplet state decay. The knowledge of the apparent second order decay constant of the T-T absorption is enough for this purpose.

There will be no need to say that the present method can be used to investigate other elementary processes pertaining to the excited state. In particular, studies on the mixed T–T annihilation are expected to afford detailed information. Medinger's method for determining ϕ_{ST}[8] also will be easily modified for the present method. Lastly the application of Eq. (7) seems to be very promising, provided the dependence of α upon wavelength is systematically investigated. Studies upon these problems are now in progress.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1552—1557 (1968)

Anomalous Effect of the Concentration of Metal-salt Catalysts in the Liquid-phase Oxidation of *p*-Xylene and Toluene

Kanekichi KAGAMI

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received January 20, 1968)

By studying the relation between the concentration and the oxidation activity of various metal catalysts, mostly naphthenates, oleates, linoleates, and caprates of manganese, cobalt, and nickel salts, as well as mixed catalysts of two kinds, it has been established that, in general, there is an anomalous effect of the catalyst concentration-namely, the catalytic activity disappears above a certain point in the concentration of the catalyst. The anomalous concentration effect of a catalyst is observed in the oxidation of toluene and *p*-xylene with all the catalysts, but chromium naphthenate is a lone exception in the oxidation of *p*-xylene. It has been shown that the anomalous effect is due to the association of the catalyst in the hydrocarbon solvent to be oxidised, and that the associated catalyst does not act to promote oxidation. The association is reversible, being dependent on the concentration of the catalyst, so the anomalous concentration effect of a catalyst disappears on dilution.

While numerous papers and reviews[1] have been published on the liquid-phase oxidation of hydrocarbons in the presence of metal-salt catalysts, little is known of the relation between the concentration and the activity of metal-salt catalysts. George *et al.*[2] and Kamiya[3] have reported on the relation between the concentration of a catalyst and the progress of the reaction in the oxidation of tetralin and ethylbenzene. Shigeyasu *et al.*[4] studied the oxidation of alkylbenzenes in a similar way. In the course of their study of the oxidation of *p*-xylene, Ohta *et al.* found a certain limit of concentration above which the catalytic activity is lost with catalysts of copper salts[5] as well as with a mixed catalyst[6] of the salt of manganese and cobalt. Brook *et al.*[7] observed in the oxidation of lubricating oils, using salts of copper and iron as catalysts, that the oxidation rate reaches a maximum and then gradually falls upon an increase in the concentration of the catalysts. They attributed this phenomenon to the formation of an inactive micelle structure at higher concentrations of Cu and Fe salt catalysts.

Since then there has been, as far as we know, no paper treating the variation in catalytic activity with the variation in the concentration of metal-salt catalysts.

In view of the fact that the concentration of a catalyst has an unexpectedly large influence on the velocity of the liquid-phase oxidation of *p*-xylene and toluene in the presence of metal-salt catalysts, the present author has studied how the catalytic activity varies with the concentration of the catalyst, using such catalysts as Mn, Co, and Ni salts of naphthenic, oleic, linoleic, and capric acids, as well as mixed catalysts of two kinds of these salts. He has found that the catalytic activity diminishes above a certain limit of concentration of the catalyst, and is entirely lost at higher concentrations. In view of this rather peculiar phenomenon, which may be called an anomalous effect of the catalyst concentration, the author has determined the molecular weight of the catalysts at the critical concentration in the medium of the hydrocarbons to be oxidised, and has already published in Japanese all the essential results obtained in connection with the catalytic activity in oxidation. This paper is a brief summary dealing with the author's reports[8-12] on the anomalous effect of the

catalyst concentration (abbreviated as the AC-effect).

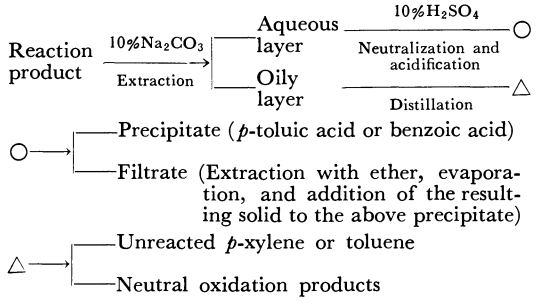
Experimental

The oxidation of *p*-xylene was carried out under the normal pressure of oxygen in a 200 m*l* flask. Temperature of oxidation: 136—137°C; quantity of *p*-xylene: 0.5 mol; duration of oxidation: 4 hr; rate of flow of oxygen: 6 *l*/hr; rate of stirring: 700—1000 rpm.

The oxidation of toluene was effected under compressed air in a 200 m*l* stainless-steel autoclave. Temperature of oxidation: 178±2°C; quantity of toluene: 0.7 mol; duration of oxidation: 4 hr; rate of flow of air: 30 *l*/hr; pressure of reaction: 10 atm; velocity of stirring: 800—1000 rpm.

The catalyst was prepared in the following way: the metal salt, obtained by double decomposition between the sodium salt of the organic acid and the metal nitrate, was washed and dried. The quantity of the metal in the catalyst was determined, and the concentration of the catalyst was expressed in terms of the metal gram atoms per mole of *p*-xylene or toluene times 10^5. For brevity, the metal-salt catalysts will be indicated by the following notations: metal-naphthenates: Me-N; metal-oleate: Me-O; metal-linoleate: Me-L; metal-caprate: Me-; metal-stearate: Me-S.

The separation and analysis of the reaction products was carried out as follows:



The molecular weights of the metal-salt catalysts in the reaction fluids were determined at 37°C in advance of the oxidation reaction in a VPO vessel, model 301, of the Mechrolab Co. by means of studying the vapor-pressure depression. For the preparation of corrected curves, benzil was used as the standard substance. Since the induction period in the oxidation of either *p*-xylene or toluene was nearly constant, irrespective of the concentration of the catalyst (except for the oxidation of *p*-xylene under the catalytic influence of Mn-L), the activated rates of oxidation were expressed in the following manner; the activation of oxidation effected by the metal-salt catalyst in the oxidation of *p*-xylene was estimated by the ratio (in wt%) of the *p*-toluic acid produced or of the sum of the *p*-toluic acid and the neutral oxidation products *vs.* the initial quantity of *p*-xylene measured after 4 hr oxidation.

The rate of oxidation was expressed by the rate of the formation of water, since the two rates were found to be in a nearly parallel relation with the same catalyst.

Similarly, the catalytic activity in the oxidation of toluene was expressed by the rate of the formation (in wt%) of benzoic acid or by the sum of benzoic acid and neutral oxidation products *vs.* the initial quantity of toluene, measured after 4 hr reaction. Furthermore, the rate of the absorption of oxygen in the oxidation of toluene was obtained by determining the quantities of oxygen and carbon dioxide in the waste gas.

Results and Discussion

Figure 1 shous how the catalytic activity in the oxidation of *p*-xylene is related to the concentration of various metal naphthenates (Mn, Co, Ni, Cr and Cu salts).

The AC-effect was observed in all cases except that of the Cr-N catalyst; the effect was particularly remarkable with the Mn-N and Cu-N catalysts. Besides, the AC-effect was observed in all the cases using the following metal-salt catalysts[8-10]: such singl catalysts as Mn-O, Co-O, Ni-O, Mn-L, Co-L, Ni-L, Mn-C, Co-C, Ni-C, and Mn-S, and such mixed catalysts as (Ni-N)+(Co-N), (Cr-N)+(Co-N), (Mn-N)+(Co-N), (Cu-N)+(Ni-N), (Mn-N)+(Ni-N), (Mn-N)+(Cu-N), (Cu-N)+(Co-N), (Cu-N)+(Cr-N), (Mn-O)+(Ni-O), (Mn-L)+(Ni-L), and (Mn-C)+(Ni-C). With the mixed catalysts, however, the AC-effect was observed at lower concentration than with single catalysts.

It has been reported[5,13] that, in liquid-phase oxidation, metal atom of higher valencies (*e. g.*, Mn^{3+}, Co^{3+}) exist in the active state of the metal-salt catalyst. In the oxidation of *p*-xylene with a Mn-N catalyst, the appearance of the reacting solution changed from the light pink color of Mn^{2+} to the dark brown of Mn^{3+} 10—15 min after the introduction of oxygen, as long as the catalyst concentration remaind within the limits, no AC-effect was exhibited, and soon afterwards oxidation set in. Similar color changes were observed, however, even when the oxidation reaction did not start readily in spite of the introduction of oxygen as a result of too high a catalyst concentration (Experiment on the Mn-N catalyst in a concentration of 100 in Fig. 1), but eventually the reaction took place (after 40—50 min). On the other hand, the author has established that the metal ion Mn^{2+} is oxidised to the Mn^{3+} state, even when oxidation does not occur, because of the AC-effect observed; he did this in an oxidation experiment with *p*-xylene and the Mn-N catalyst in a concentration of 100.

Figure 2 gives the relation between the concentration and the rate of oxidation by the Co-N catalyst.

In Fig. 3 is shown the rate of the oxidation of *p*-xylene carried out with a catalyst with a Mn-N concentration of 50 by adding a further quantity (conc. 25) of the Co-N catalyst after an oxidation period of 150 min.

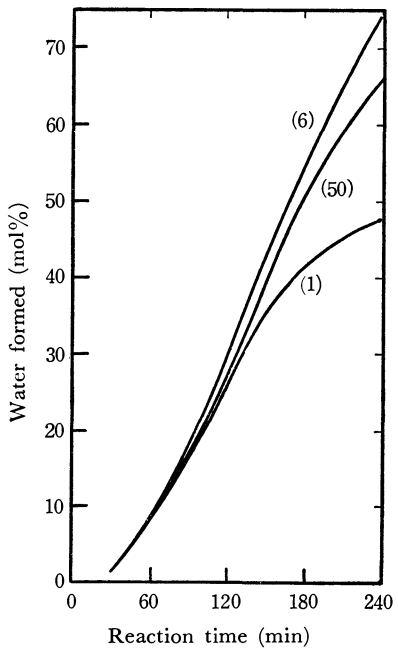

Fig. 2. Relation between rate of water formation and concentration of Co-naphthenate catalyst in the oxidation of *p*-xylene.
The arabic numerals show the concentration of Co-naphthenate [(g·atom of Co/mol of *p*-xylene)×10⁵] Water formed: mol% of water formed based upon *p*-xylene used.

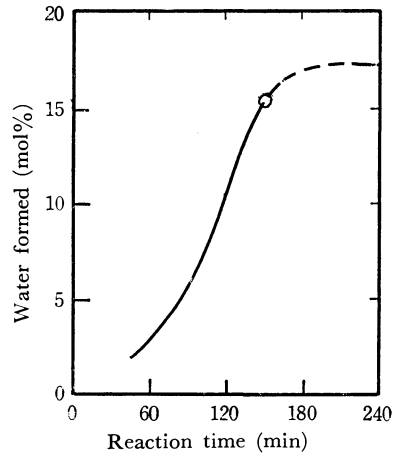

Fig. 3. Effect of the addition of Co-naphthenate to Mn-naphthenate catalyst in the course of oxidation.
○: Co-naphthenate was added at this point.
——: Oxidation in the presence of Mn-naphthenate catalyst [50×10^{-5} g·atom of Mn/mol of *p*-xylene]
----: Oxidation in the presence of Mn-naphthenate [50×10^{-5} g·atom of Mn/mol of *p*-xylene] and Co-naphthenate [25×10^{-5} g·atom of Co/mol of *p*-xylene]

The oxidation of *p*-xylene was not initiated in 4 hr with an Mn-N catalyst in a concentration of 100, as in the case shown in Fig. 1. However, after 0.5 mol of *p*-xylene had been, added, when the concentration of Mn-N became 50 the reaction of oxidation started and proceeded smoothly, *p*-toluic acid and a neutral oxidation product were formed in quanitities of 23.2% and 4.2% respectively, and 65.2% of *p*-xylene was recovered.

The AC-effect appeared during the propagation period in the oxidation of *p*-xylene and was observed as a phenomenon reducing the rate of oxidation. However, when an intense AC-effect appeared, it was recognized as a phenomenon incapable of initiating oxidation.

It was already observed that no reaction is initiated by too high a concentration of a catalyst in the oxidation of *p*-xylene using Cu salts[5] or a mixed catalyst[6] of Mn and Co salts. In view of similar phenomena occurring with a larger number of other catalysts, they may be regarded as quite general with metal-salt catalysts.

The AC-effect of a catalyst is not due to the poisoning phenomenon of the catalyst, but is a reversible phenomenon controlled by the catalyst concentration in the reaction system.

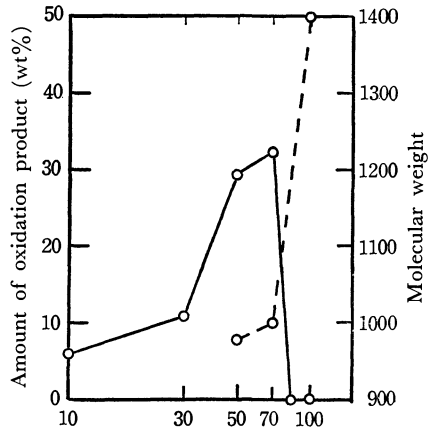

Fig. 4. Relation between concentration of catalyst of Mn-naphthenate and oxidation activity and molecular weight.

----: Molecular weight of Ni-linoleate

Figures 4 and 5 and Table 1 show the relation between the molecular weight of the metal-salt catalyst in *p*-xylene and its catalytic activity in the oxidation of *p*-xylene.

The molecular weight of the metal-salt catalyst rapidly increased in the region in which the catalytic activity rapidly decreased with an increase in the catalyst concentration, although in the region where the activity increased with an increase in the catalyst concentration the molecular weight

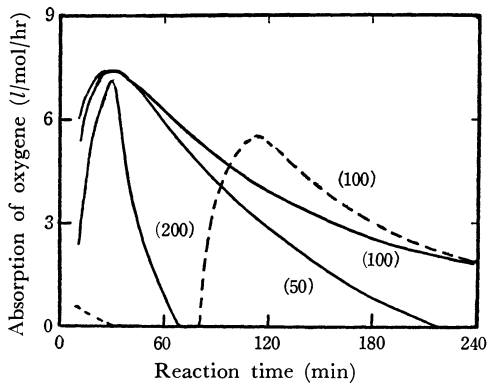

Fig. 7. Relation between concentration of Mn-caprate catalyst and absorption velocity of oxygen in the oxidation of toluene.
Arabic numerals show concentration of the catalyst [(g·atom of Mn/mol of toluene)×10⁵]
----: Absorption rate of oxygene in the oxidation of the solution which was obtained by diluting the reaction mixture with toluene to the concentration of 100 after the oxidation had been carried out for 120 min at the Mn salt concentration of 200.

of the metal-salt catalyst increased only slightly with an increase in the concentration.

Figure 6 shows the relation between the concentration of the Co-L and Mn-O catalysts and the catalytic activity in the oxidation of toluene. Furthermore,[11] in the oxidation of toluene with single catalysts, such as Co-N, Mn-N, Ni-N, Cu-N, Cr-N, Co-O, Mn-L, Mn-C, and Co-C, or with mixed catalysts, such as (Co-N)+(Mn-N), (Co-N)+(Ni-N), (Mn-N)+(Ni-N), (Co-O)+(Mn-O), (Co-O)+(Ni-O), (Mn-O)+(Ni-O), (Mn-L)+(Co-L), and (Mn-C)+(Co-C), the relation between the activity and the concentration of the catalyst was studied; the AC-effect was observed without exception with single as well as with mixed catalysts.

Figure 7 shows the absorption of oxygen during the oxidation reaction of toluene in the presence of Mn-C in concentrations 50, 100, and 200; the dotted line represents the progress of the absorption of oxygen when the catalysts present in a concentration of 200—though this concentration was reduced to 100 by adding toluene after 120 min reaction. Furthermore,[10] a similar tendency was recognized also in the cases of Mn-L and Mn-O.

It was observed[14] with the oxidation of toluene that oxidation rapidly terminated when the catalyst concentration was too small. However, the reaction also terminates at higher concentrations of catalyst above a certain limit (Fig. 7); furthermore,

14) N. Ohta and T. Tezuka, *Kogyo Kagaku Zasshi (J. Chem. Soc. Japan, Ind. Chem. Sect.)*, **59**, 71 (1956).

at a much higher concentration oxidation is not even initiated (Fig. 6). These two new phenomena have led to the discovery of the AC-effect.

Figure 8 exhibits the relation between the catalytic activity and the molecular weight of the Co-L catalyst in toluene; the AC-effect appears at the point of rapidly-increasing molecular weight. A similar phenomenon occurred with the Mn-O[12] catalyst.

The experiments described above suggest that metal-salt catalysts for the oxidation of *p*-xylene and toluene associate in the region where the AC-effect is observed, and that the associated catalyst plays no part in promoing the oxidation.

The author cordially thanks Professor Nobuto Ohta and Dr. Yasuo Takami for their guidance throughout the work. Thanks are also due to Professor Yojiro Tsuzuki for his interest and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1557—1563 (1968)

The Crystal and Molecular Structure of 1,1′-Bis(pentamethyldisilanyl)-ferrocene, (π-$C_5H_4Si(CH_3)_2Si(CH_3)_3)_2Fe$

Ken HIROTSU, Taiichi HIGUCHI and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received January 22, 1968)

Crystals of 1,1′-bis(pentamethyldisilanyl)ferrocene, (π-$C_5H_4Si(CH_3)_2Si(CH_3)_3)_2Fe$, are monoclinic, with $a=6.84$, $b=30.87$, $c=12.67$ Å and $\beta=96.80°$. The space group is $P2_1/n$ and there are four molecules in a unit cell. The structure was solved by Patterson and minimum functions, and further refined by Fourier and difference syntheses, and finally by a least-squares method. The final R value is 14.4% for 883 observed reflections. The two cyclopentadienyl rings are planar, approximately parallel to each other, separated by 3.28 Å and deviated by about 6° from the fully *eclipsed* configuration. The molecular configuration is *gauche* with respect to the two side-chains. The mean values of the bond distances are found to be Fe-C(cyclopentadienyl rings)= 2.05, C-C=1.45, C(cyclopentadienyl rings)-Si=1.87, C(methyl groups)-Si=1.90 and Si-Si= 2.34 Å. All intermolecular separations correspond to the normal van der Waals interactions.

Since the molecular structure of ferrocene had been determined, several of its derivatives have also been studied by means of X-rays to elucidate the spacial configurations of the two cyclopentadienyl rings in the molecules. It was found that in some of the molecules the *staggered* configurations of rings are maintained, while in others, intermediate configurations, between *staggered* and *eclipsed*, are preferred. The differences in these ring configurations might be very interesting.

1,1′-Bis(pentamethyldisilanyl)ferrocene was investigated in order to determine which ring configuration it takes in the crystalline state. Moreover, the present molecule has one substituent (pentamethyldisilanyl group) on each ring, and therefore the configuration of the substituents in the molecule and their arrangement in the crystal would be another interest.

Experimental

The crystals were kindly prepared and supplied by Professor Makoto Kumada of Kyoto University.[1] The specimens, which are suitable for X-ray work, were crystallized from ethanol solution in the form of ferrocene-like orange-yellow plates, elongated along the a axis, with the (010) plane developed. The crystals sublime gradually in air. Multiple Weissenberg intensity data were collected with Ni-filtered Cu$K\alpha$ radiation on the b and the c axes for zero layers, and on the a axis for zero and first layers. 1285 reflections were observed; 402 were too weak to be measured. Intensities were estimated visually with calibrated intensity scales. No correction was applied to absorption and extinction. All intensity data exhibit a high background due to strong fluorescence by the iron atoms. Atomic scattering factors for iron were used after being corrected for the effect of dispersion. After the Lorentz

and the polarization corrections were made, intensities were placed on a common relative scale. The crystal data are given in Table 1.

Structure Determination

At first, the structure projected along the *a* axis was sought by means of the Patterson and minimum functions. The iron atom and two silicon atoms directly bonded to the cyclopentadienyl rings were easily located. The first Fourier synthesis based on these three atoms revealed the iron and all the four silicon atoms clearly, while the positions of carbon atoms were not resolved. They were found and refined by a combination of successive Fourier and difference syntheses, molecular geometry being taken into consideration. The analysis of the *c* axis projection was also done in a similar way to the *a* axis projection.

Refinements were carried out by means of a least-squares method, using all the reflection data. The function minimized was $\sum w(|F_o| - |F_c|)^2$, where w (weights) were set equal to unity for all reflections. After four cycles of the refinement, the discrepancy index R was 14.4% for the observed reflections only.

Table 2 gives the final positional and isotropic thermal parameters, and their e. s.d.'s obtained from the last cycle of the least-squares refinement.

Discussion

The views of the molecule perpendicular to and parallel to the cyclopentadienyl rings are given in Fig. 2. The best planes through the cyclopentadienyl rings are given in Table 4, together with the deviations of the atoms from these planes. These two planes are nearly parallel (the angle between them is 1.02°) to each other and the spacing between them is 3.28 Å, which may be compared with 3.32, 3.32 and 3.30 Å found in ferrocene,[2] biferrocenyl[3] and diferrocenyl ketone,[4] respectively. Si(1) and Si(2) lies 0.05 Å above and below each of the best planes of the cyclopentadienyl rings to which they are attached, with respect to the Fe atom. The angle between plane 1 (see Fig. 2B) and the plane through Si(1), Si(3) and C(1) is 88.7°, while plane 2 and the plane through Si(2), Si(4) and C(6) makes an angle of 92.0°. Therefore, Si(3) lies on the plane which is normal to plane 1 and passes through C(1) and Si(1). This relation also holds for Si(4). Figure 3 shows one half of a molecule viewed along the Si(1)-Si(3) bond and the other half of the molecule viewed along the Si(2)-Si(4) bond. The conformation around the Si(1)-Si(3) and Si(2)-Si(4) bonds is *staggered*, though the dihedral angles seem to be a little different. From the above results, this molecule has roughly a twofold axis through the Fe atom, parallel to both cyclopentadienyl rings.

Ferrocene derivatives with one substituent on each ring have three possible configurations (*cis*, *trans* or *gauche*). It is well shown in Fig. 2A that

the present molecule has the *gauche* form. The angle between the projection of C(1)-Si(1) bond and that of C(6)-Si(2) on the mean plane of five-membered rings is 149°.

The angles φ between the Fe-C bonds projected on the mean plane of the rings are:

C(1)-Fe-C(9)	6.3°
C(2)-Fe-C(8)	4.3°
C(3)-Fe-C(7)	5.8°
C(4)-Fe-C(6)	8.6°
C(5)-Fe-C(10)	5.5°

The average value 6.1° shows that the configuration is almost the *eclipsed* one. Table 5 shows the ring configurations of ferrocene and its derivatives. These results may indicate that in ferrocene and its derivatves the *staggered* position is preferred owing to a small *inter-ring* separation, but this orientation will be easily rotated by stronger intermolecular forces until the *inter-ring* repulsion and intermolecular forces become comparable. In this compound, the substituent on each ring occupies the larger portion of the molecule and the ring configuration will be greatly affected by the arrangement of the substituents. Consequently, a stronger

7 at	$-1/2+x$,	$1/2-y$,	$-1/2+z$
8 at	$-1/2+x$,	$1/2-y$,	$1/2+z$
9 at	$1/2+x$,	$1/2-y$,	$1/2+z$

intermolecular force than the *inter-ring* repulsion may force such an arrangement as $\varphi = 6.1°$.

The bond distances and angles are listed in Table 3 and shown in Fig. 4. The average C(Cp*[2])-C(Cp) bond distances is 1.45 Å (the average e.s.d. value is 0.05 Å), which is comparable to the values observed in the many ferrocene derivatives. The mean bond angle in the five-membered rings is 108.0±2.6°. The distortion in some bond angles from 108° is not significant. The mean Fe-C (Cp) distance, 2.05±0.03 Å, is consistent with those found in ferrocene derivatives. The average bond angle of C(Cp)-C(Cp)-Si is 125.4±2.3°. The average Si-C(Cp) distance, 1.87±0.03 Å is quite consistent with that of phenylsilane,[8] 1.84±0.005 Å. The Si-Si bond distances (2.34 and 2.33 Å) are normal values. The average value of Si-C (methyl group) bonds is 1.90±0.03 Å, which is normal. The average angle around Si atoms is 109.5°, equal to the tetrahedral angle.

The average isotropic temperature factor of carbon atoms is 5.35 Å^2, which is relatively high in view of the fact that the absorption effect might be expected to reduce the temperature factors a little. This shows, together with the comparatively small density (*Dm* is 1.02 g·cm^{-3}), that thermal vibration in this molecule is considerable. The average isotropic temperature factor of Cp-carbons is 4.87 Å^2, and that of methyl carbons 5.84 Å^2. It may be significant that the difference between them is fairly large.

The mode of packing of the molecules in the crystal can be seen in Figs. 5 and 6. Molecules are packed with their long axes arranged along the *b* axis. Sets of molecules related by a twofold screw axis have approximately hexagonal packing. Most of the closest contacts are either of the CH_3---CH_3 or CH_3---CH(Cp) type. All shorter intermolecular distances (<4.2 Å) are given in Table 6.

The authors wish to express their appreciation to Professor Makoto Kumada and Dr. Mitsuo Ishikawa of Kyoto University for kindly supplying the samples for this study, to Dr. Kazumi Nakatsu of our laboratory and Dr. Noritake Yasuoka of Osaka University for their electronic computer programs, and to the Oki Electric Industry Co., Ltd., and the Japan Information Processing Service Co., Ltd., for the use of electronic computers. The present study was partly supported by a Scientific Reserch Grant from the Ministry of Education.

*2 Cp is cyclopentadienyl.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1563—1568 (1968)

An Experimental Study on the Faradaic Impedance of an Electrode Process with a Preceding Chemical Reaction

Kiyoshi MATSUDA and Reita TAMAMUSHI

The Institute of Physical and Chemical Research, Yamato-machi, Kita-adachi-gun, Saitama

(Received January 22, 1968)

The frequency dependence of the faradaic impedance and its phase angle of an electrode process with a preceding chemical reaction was studied with the Cd(II)-EDTA system. The experimental results were analyzed by means of Smith's equation, and the rate constant of the reaction, $Cd^{2+}+HY^{3-}\rightarrow CdY^{2-}+H^{+}$, was estimated to be equal to $2.3\times10^{9}\ l\ mol^{-1}\ sec^{-1}$ at the ionic strength of 0.5 and at 25°C. In connection with this study, the faradaic impedance behavior of simple electrode processes was re-examined with the Cd(II)-, Pb(II)-, and Zn(II)-KCl systems.

The measurement of the faradaic impedance provides a useful method of analyzing the mechanism of electrode reactions. The frequency dependence of the faradaic impedance at reversible electrode potentials was applied by Randles and Somerton[1] and by Gerischer[2] to the determination of exchange currents of relatively simple electrode reactions. Sluyters *et al.* examined the frequency dependence of the faradaic impedance by using the complex impedance plane.[3] The relation between the peak currents on alternating current (a.c.) polarograms and the frequency of the superimposed alternating voltage was studied first

by Breyer, Bauer and Hacobian[4] and later by Bauer and Elving.[5] The faradaic impedance of the polarographic reduction processes of cadmium, zinc, and thallium ions was investigated by Tamamushi and Tanaka as a function of the electrode potential;[6] they also reported that, in the case of cadmium ions, the faradaic impedances measured at 500, 1000, and 2000 cps were inversely proportional to the square root of the frequency.

The effect of preceding chemical reactions to the faradaic impedance was studied first by Gerischer in the absence of a direct current (d. c.) polarization.[7] Recently, theoretical equations were proposed by Smith describing the a. c. polarographic phase angle behavior for electrode processes with coupled chemical reactions,[8] and the equation was applied to the catalytic reduction of titanium(IV) ions in the presence of chlorate ions.[9] The behavior of a. c. polarographic peak currents was applied by Aylward and Hayes to the determination of the rate constant of a coupled following reaction.[10] To authors' knowledge, however, experimental studies on the phase angle-frequency behavior of polarographic electrode processes with preceding reactions have not been reported previously.

This paper presents some experimental results on the faradaic impedance behavior of the polarographic reduction process of cadmium ions in acetate buffer solutions containing ethylenediaminetetraacetate (EDTA) and an excess of calcium chloride; the results are discussed in terms of Smith's equations.[8] In connection with this study, the faradaic impedance-frequency relationship of some simple electrode processes was re-examined in a wider frequency range.

Experimental

The electrolytic cell subjected to the impedance measurement is represented by the scheme,

DME	solution	MPE

where DME means a dropping mercury electrode and MPE a mercury pool electrode of a large surface area.

In the frequency range of 200—4000 cps, the resistance and capacitance components of the equivalent impedance of the cell were measured by an a. c. bridge similar to that described in a previous paper.[11] At lower frequencies (30—200 cps), however, the cell admittance and its phase angle were measured by a potentiostatic a. c. polarograph.[12] The DME was negatively polarized by a d. c. potentiometer against the MPE in the solution. The amplitude of the superimposed alternating voltage was less than 5 mV in the bridge measurement and about 10 mV in the a. c. polarographic measurement, respectively. The faradaic impedance and phase angle reported in this paper are the values for the given constant surface area (0.035 cm^2) of the DME at the end of the life of a mercury drop (drop time, 9 sec).

Vacuum-distilled mercury was used for the DME and the MPE. All solutions were prepared from analytical reagent grade chemicals and redistilled water. In each system except the Cd-EDTA a small amount of polyoxyethylene lauryl ether (LEO) was used as a maximum suppressor. The dissolved oxygen was expelled from the solution by bubbling nitrogen through the solution. All measurements were carried out in a water-thermostat of 25.0±0.1°C.

Results

Cd(II)-, Pb(II)-, and Zn(II)-KCl Systems. In the polarographic reduction of cadmium, lead, and zinc ions in 1 M potassium chloride solutions, both the resistance and the capacitance readings, R_m and C_m, of the bridge gave a peak at the summit potential, E_s, characteristic to the given electrode reaction. The series resistance, R_F, and the series capacitance, C_F, of the faradaic impedance, Z_F, were determined by the vector calculation from the R_m- and C_m-values under the assumption that the R_m- and C_m-values of the supporting electrolyte solution are equal to the resistance of the solution and the double layer capacity, respectively. The frequency dependence of Z_F, R_F, $1/(\omega C_F)$, and $\cot\phi(=\omega C_F R_F)$ of the Cd(II)-, Pb(II)-, and Zn(II)-KCl systems is shown in Fig. 1, where these quantities are plotted as a function of $1/\sqrt{\omega}$ (ω, the angular frequency).

Cd(II)-EDTA System. The polarographic reduction of a cadmium ion (8 mM $Cd(NO_3)_2$) in an acetate buffer solution (pH=3.7; ionic strength, μ, adjusted to be 0.5 by potassium nitrate) containing 1.119×10^{-2} M EDTA and 0.1 M calcium chloride gives a kinetic current due to the dissociation reaction,

$$CdY^{2-} + H^+ \underset{k_2}{\overset{k_1}{\rightleftharpoons}} Cd^{2+} + HY^{3-} \qquad (1)$$

where Y^{-4} means that tetravalent anion of EDTA; the aquo-cadmium and chloro- and acetato-complexes of cadmium then contribute to the charge-transfer process.[13,14] This reduction process

gave an a. c. polarogram and a phase angle change as shown in Fig. 2.

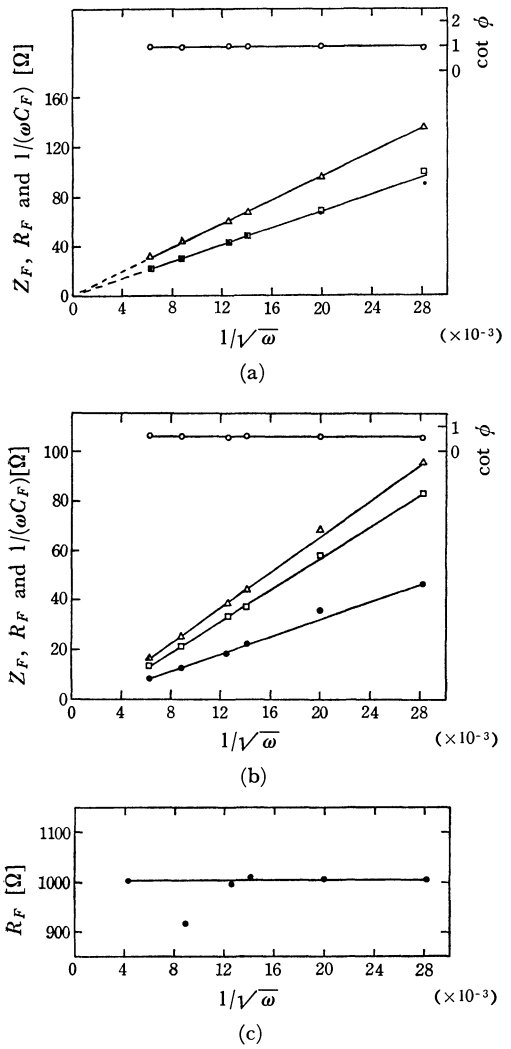

Fig. 1. Frequency dependence of Z_F (-△-), R_F (-●-), $1/(\omega C_F)$ (-□-) and cot ϕ(-○-) at the summit potential: (a), DME/0.5mM $CdSO_4$, 1M KCl, 2×10^{-6}M LEO/MPE; (b), DME/0.5 mM $Pb(NO_3)_2$, 1M KCl, 0.01N HCl, 5×10^{-6}M LEO/MPE; (c), DME/1 mM $Zn(NO_3)_2$, 1M KCl, 2×10^{-6} M LEO/MPE.

An example of the potential dependence of R_m and C_m at higher frequencies is reproduced in Fig. 3. The summit potential, being approximately independent of frequency, was −0.72——0.73 V *vs.* MPE.

The C_m-values of the Cd(II)-EDTA system in the potential region outside the impedance peak did not coincide with the C_m-values of the supporting electrolyte solution (Fig. 3); this is probably due to the effect of the concentration of free EDTA anions on the double layer capacity. Therefore,

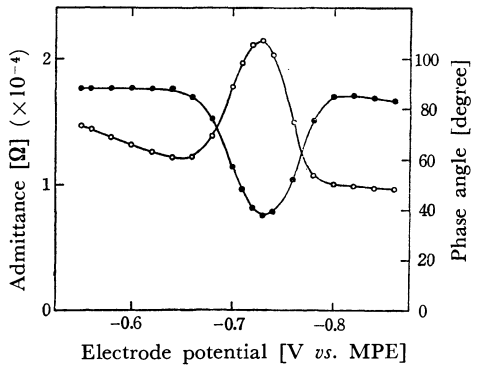

Fig. 2. A. c. polarogram (-○-) and phase angle change (-●-) at 30 cps of 8 mM $Cd(NO_3)_2$ in an acetate buffer solution (pH=3.7, μ=0.5) containing 1.119×10^{-2} M EDTA and 0.1 M $CaCl_2$.

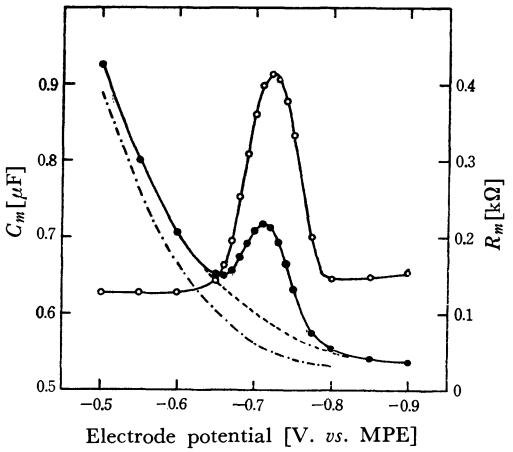

Fig. 3. Potential dependence of R_m(-○-) and C_m(-●-) of the DME/8 mM $Cd(NO_3)_2$, 1.119×10^{-2}M EDTA, 0.1 M $CaCl_2$, acetate buffer (pH=3.7, μ=0.5)/MPE system at 200 cps. (-·-: C_m-values of the supporting electrolyte solution (acetate buffer solution of pH=3.7 and μ=0.5 containing 1.119×10^{-2} M EDTA and 0.1 M $CaCl_2$)).

the double layer capacity of the present system was estimated by the method of interpolation as shown by the dotted line in Fig. 3. In Fig. 4 the values of R_F, $1/(\omega C_F)$, and Z_F of the Cd(II)-EDTA system at the summit potential are plotted as a function of $1/\sqrt{\omega}$.

Discussion

The faradaic impedance of the electrode process is given by a series combination of the charge-transfer resistance which is independent of frequency, and the impedances due to the accompanying processes such as preceding and following chemical reactions, adsorption-desorption process, mass-transfer of reacting species, *etc.* According to the theory of a. c. polarization, these impedances have different

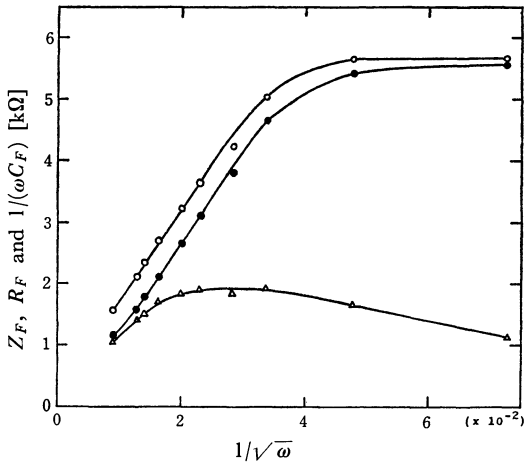

Fig. 4. Frequency dependence of Z_F (-○-), R_F (-●-) and $1/(\omega C_F)$ (-△-) at the summit potential of the DME/8 mM $Cd(NO_3)_2$, 1.119×10^{-2} M EDTA, 0.1 M $CaCl_2$, acetate buffer (pH=3.7, μ =0.5)/MPE system.

frequency dependence; for example, the Warburg impedance due to the diffusion process is expected to be proportional to $1/\sqrt{\omega}$, while the reaction impedance is a more complicated function of frequency.[15]

Cd(II)-, Pb(II)-, and Zn(II)-KCl Systems. The faradaic impedance of a simple electrode reaction mainly consists of the charge-transfer resistance, θ, and the Warburg impedance, Z_W; the faradaic impedance and its components are expected to be linear functions of $1/\sqrt{\omega}$.[15,16] This expectation is supported by the experimental results of Cd(II), Pb(II), and Zn(II) ions in 1 M potassium chloride solutions (Fig. 1).

The polarographic reduction of zinc ions in 1 M potassium chloride solutions is a well-known example of the quasi-reversible electrode reaction with the standard rate constant of the order of 10^{-3} cm/sec.[17] In such a quasi-reversible system, the charge-transfer resistance, θ, at the summit potential is expected to be much larger than the Warburg impedance, Z_W, even at low frequencies, and the resistance component, R_F, of the faradaic impedance at the summit potential will be approximately equal to θ and independent of frequency as shown in Fig. 1 (c).

The theory also suggests that the phase angle, ϕ, of a simple electrode process should be equal to $\pi/4$, being independent of frequency, for a totally reversible system, and it decreases with the decrease in the reversibility. The cot ϕ values of the reversible reduction of cadmium ions in potassium chloride solutions, as given in Fig. 1 (a), are in good agreement with the theory. In the Pb(II)-KCl system, however, the cotϕ value at each frequency studied was smaller than unity inspite of the high reversibility of the system (Fig. 1 (b)); this anomaly in the faradaic impedance may be attributed to the adsorption of the reacting species on the electrode surface.[18,19]

Cd(II)-EDTA System. In the polarographic reduction of the Cd(II)-EDTA system, the plots of Z_F, R_F, and $1/(\omega C_F)$ against $1/\sqrt{\omega}$ gave significant deviations from the linearity at lower frequencies (Fig. 4). These deviations can be explained in terms of the contribution of the reaction impedance due to the preceding chemical reaction (1).

According to Smith's treatment,[8] the cotϕ of the electrode reaction,

$$Y \underset{k_b}{\overset{k_f}{\rightleftharpoons}} O \tag{2}$$

$$O + ne \rightleftharpoons R \tag{3}$$

is given by the equation,

$$\cot\phi = \frac{\frac{\sqrt{2\omega}}{\lambda} + \frac{1}{(1+e^j)}\left\{\frac{1}{1+K}\left[\frac{(1+g^2)^{1/2}+g}{1+g^2}\right]^{1/2} + \frac{K}{1+K} + e^j\right\}}{\frac{1}{(1+e^j)}\left\{\frac{1}{1+K}\left[\frac{(1+g^2)^{1/2}-g}{1+g^2}\right]^{1/2} + \frac{K}{1+K} + e^j\right\}} \tag{4}$$

where

$K = k_f/k_b$, $g = l/\omega$, $l = k_f + k_b$,

$\lambda = k_s f_O^{\alpha} f_R^{\beta} (D_O^{-\beta} D_R^{-\alpha})^{1/2} (e^{-\alpha j} + e^{+\beta j})$,

$\alpha + \beta = 1$, $j = nF(E-E^r_{1/2})/(RT)$

k_f, k_b: forward and backward rate constants, respectively, of reaction (2)

k_s: standard rate constant of reaction (3)

f_O, f_R: activity coefficients of O and R, respectively

D_O, D_R: diffusion coefficients of O and R, respectively

α, β: transfer coefficients

E: electrode potential

$E^r_{1/2}$: reversible half wave potential of reaction (3)

The impedance behavior of the Cd(II)-KCl

system suggests that the value of $(\sqrt{2\omega}/\lambda)$ of the present system can safely be neglected against the following term in the numerator of Eq. (4); this is also supported by the behavior of R_F and $1/(\omega C_F)$ of the Cd(II)-EDTA system at higher frequencies as shown in Fig. 4. Therefore, the cot ϕ is represented by a simplified equation:

$$\cot\phi = \frac{\left[\frac{(1+g^2)^{1/2}+g}{1+g^2}\right]^{1/2} + K + (1+K)e^j}{\left[\frac{(1+g^2)^{1/2}-g}{1+g^2}\right]^{1/2} + K + (1+K)e^j} \quad (5)$$

Figure 5 presents the frequency dependence of cot ϕ at the summit potential ($E_s=-0.72$ V *vs.* MPE for 70—2000 cps, and $E_s=-0.73$ V *vs.* MPE for 30 cps), and the theoretical curves for $l=500$, 1000, and 2000 calculated by Eq. (5) with $K=[Cd]/[CdY^{2-}]=10^{-3.67}$ ([Cd], the total concentration of the electroactive cadmium species) and $E^r_{1/2}=-0.678$ V *vs.* MPE. The K-value was determined by using the equilibrium constants of EDTA, EDTA-complexes of cadmium and calcium ions, and chloro- and acetato-complexes of cadmium as given in the literature,[14] and $E^r_{1/2}$ was assumed to be equal to the half wave potential of Cd(II) in an acetate buffer solution (pH=3.7, $\mu=0.5$ adjusted by potassium nitrate) containing 0.1 M calcium chloride.

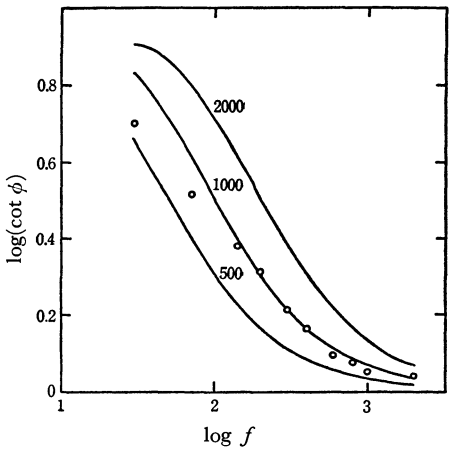

Fig. 5. Relation between log (cot ϕ) and log f (f, frequency) at the summit potential of the Cd-EDTA system; the circles represent the experimental values, and the solid lines correspond to the theoretical curves calculated by Eq. (5) with the l-values given on each curve.

This result shows that the best fit between the experimental and theoretical curves is obtained with $l=1000$. Because of the very small value of K of the present system, the l-value is practically equal to the pseudo first-order rate constant of the formation reaction of CdY^{2-} from the electroactive cadmium species and HY^{3-}, *i. e.*, $l=k'_2[HY^{3-}]=1000$, from which the value of k'_2 is estimated to be $2._4\times10^8\ l\ mol^{-1}\ sec^{-1}$. The rate constant, k'_2, thus determined should be regarded as the overall rate constant of the formation reaction related to the total concentration of the electroactive cadmium species (Cd^{2+}, $CdCl^+$, $CdCl_2$, and $CdOAc^+$). It is generally assumed, however, that only the aquo-cadmium ions react with HY^{3-} to form CdY^{2-}. If this simplified assumption is accepted, the k'_2-value must be multiplied by the factor of $(1+\beta_{CdCl}[Cl^-]+\beta_{CdCl_2}[Cl^-]^2+\beta_{CdOAc}[OAc^-])$, where β_i represents the overall formation constant of the i-species, in order to obtain the rate constant, k_2, corrected for chloro- and acetato-complexes of cadmium; the corrected k_2-value was thus determined to be $2._3\times10^9\ l\ mol^{-1}\ sec^{-1}$.

The rate constants for the formation of cadmium-EDTA have been reported by several authors; some examples of the k_2-values are listed in Table 1. Koryta and Zábranský determined the k_2-value by analyzing the d. c. polarograms of the anodic dissolution of cadmium amalgam in acetate buffer solutions containing EDTA.[20] The same

20) J. Koryta and Z. Zábranský, *Collection Czechoslov. Chem. Commun.*, **25**, 3153 (1960).

method of analysis was examined by Aylward and Hayes;[10] they also applied the faradaic admittance measurement of the anodic dissolution of cadmium amalgam followed by the formation reaction of cadmium-EDTA to the determination of the k_2-values. On the other hand, Tanaka *et al.* studied the kinetic current behavior of cadmium-EDTA at a DME in acetate buffer solutions containing calcium ions;[13,14] they determined the rate constant, k_1, of the dissociation reaction of CdY^{2-}, and then calculated the k_2-value by using the equilibrium constant of reaction (1). A survey of Table 1 shows that our figure is in good agreement with that of Fujisawa and Tanaka.[14]

Finally, the a. c. polarographic studies with the phase angle measurement is concluded to help in analyzing electrochemical mechanisms and in the determination of the rate constant of a coupled preceding reaction.

The authors wish to thank Professor N. Tanaka of Tohoku University and Dr. T. Fujisawa of Yamagata Technical College for valuable discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1568—1572 (1968)

Alternating Current Polarography of Peroxodisulfate and Ferricyanide Ions in the Absence of Supporting Electrolytes

Reita TAMAMUSHI and Kiyoshi MATSUDA

The Institute of Physical and Chemical Research, Yamato-machi, Kita-adachi-gun, Saitama

(Received January 22, 1968)

The admittance and its phase angle of the polarographic reduction of peroxodisulfate and ferricyanide ions in solutions containing no supporting electrolytes were measured at very low frequencies. The series resistance components, measured at 30 cps, of these systems gave anomalously small values at the electrode potentials where the falling-off of the cathodic current was observed on the direct current polarograms. This anomaly in the alternating current polarization behavior was attributed to the negative charge-transfer resistance due to the double layer effect on the charge-transfer process.

The electrochemical reduction behavior of peroxodisulfate and ferricyanide ions has been studied extensively by Frumkin and his coworkers.[1,2] They reported that the cathodic current of these ions in solutions of very low ionic strength shows a remarkable decrease at the electrode potentials more negative than the point of zero-charge; they attributed this anomaly to the double layer effect.

A similar decrease in the cathodic current was observed by the polarographic reduction of In(III)-SCN^-, Ni(II)-SCN^-, and In(III)-Br^- systems in solutions of moderate ionic strength, but in these cases the falling-off of the cathodic current appears at the potentials where the adsorption of the anions on the electrode surface begins to decrease.[3,4] On alternating current (a. c.) polargorams of these systems an anomalous admittance is observed in the potential region where the cathodic current decreases with the increase in the negative polarization.[5] From the measurement of faradaic impedance, the anomalous behavior of the a. c. polarograms was confirmed to be due to the negative charge-transfer resistance.[3,4]

In the absence of supporting electrolytes, the reduction process of peroxodisulfate and ferricyanide ions at a dropping mercury electrode is expected to give a negative charge-transfer resistance because of the large double layer effect. This study deals with the a. c. polarization behavior of peroxodisulfate and ferricyanide ions at very low frequencies; the results are discussed in terms of the double layer effect.

where DME is a dropping mercury electrode, and AE, an auxiliary electrode of a platinum spiral surrounding the tip of the DME; the terminals of AE and SCE were connected by a 220 μF tantalum condenser in order to reduce the impedance between the DME and SCE. The drop time and the flow rate of mercury of the DME used were 8.1 sec and 0.88 mg/sec, respectively, in a 1 M potassium chloride solution at open circuit.

The direct current (d. c.) polarograms were recorded by a potentiostatic polarograph similar to that of Durst, Ross and Hume.[6] The d. c. polarograms of peroxodisulfate and ferricyanide ions have large maxima of the first kind, the appearance of which is affected by the scanning direction of the electrode potential. In this study, the electrode potential of the DME was scanned from the negative to the positive side; by this scanning direction a more well-defined limiting current plateau was obtained at the potentials less negative than the point of zero-charge.

The admittance and its phase angle of the system were measured by a potentiostatic a. c. polarograph as shown in Fig. 1. The electrode potential of the DME, both the d. c. and a. c. components, was controlled against the SCE by means of a stabilized operational amplifier, C, and the alternating current flowing through the cell was amplified by a current amplifier, CA (stabilized operational amplifier), and a tuned amplifier, TA (Model 4403A, Yokogawa-Hewlett-Packard), the output of which was then introduced to a rectifier circuit or to a phase meter, PM (Model PHM-8, Ando Electric Co.,

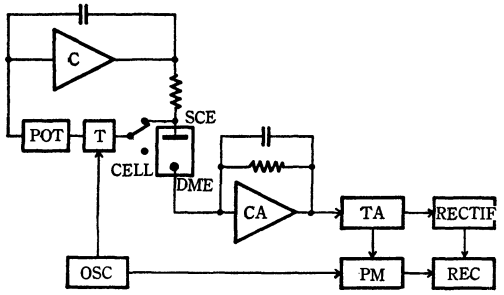

Fig. 1. Potentiostatic a. c. polarograph: C, controller (stabilized operational amplifier); CA, current amplifier (stabilized operational amplifier); TA, tuned amplifier; RECTIF, rectifier; PM, phase meter; REC, recorder; OSC, audio-frequency oscillator; T, transformer; POT, potentiometer (mechanical voltage scanner).

Ltd.). The d. c. component of the electrode potential was applied to the DME by a mechanical voltage scanner, POT, with the scanning rate of about 45 mV/min. The superimposed sinusoidal voltage, whose amplitude was approximately 10 mV and kept constant during each measurement, was supplied by an audio-frequency oscillator, OSC (Model VP-702B, Matsushita Communication Industrial Co., Ltd.). The admittance and phase angle readings were calibrated by using known resistors and capacitors as a dummy cell, and the values measured at the maximum size of a mercury drop of the DME were reported in this paper.

The square-wave polarization behavior was measured by essentially the same circuit as shown in Fig. 1. The square-wave voltage of 50 cps, whose amplitude was about 15 mV, was superimposed to the d. c. electrode potential, and the corresponding current flowing through the cell was observed by a cathode-ray oscilloscope (Tektronix Type 564) at the output of the current amplifier, CA.

The solutions were prepared from the analytical reagent grade chemicals and redistilled water, and vacuum-distilled mercury was used for the DME. The dissolved oxygen in the solution was expelled by bubbling nitrogen through the solution. Peroxodisulfate and ferricyanide ions are subjected to some redox reaction in aqueous solutions; an appreciable change in the solution was observed in a relatively short period of time, especially when the solution was kept in contact with mercury. Therefore, each measurement was carried out with fresh solutions, and the DME and the tip of SCE were introduced into the solution after the deaeration. All measurements were made in a water-thermostat of 25.0±0.1°C.

Results

The d. c. polarograms of 1 mM potassium peroxodisulfate and 1 mN potassium ferricyanide in aqueous solutions containing no supporting electrolytes are shown in Fig. 2, and their a. c. polarograms with the phase angle change at 30 cps in Figs. 3 and 4. In the ferricyanide system, the current decrease on d. c. polarograms was very much sensitive to the concentration of ferricyanide ions; a large decrease appeared in a 1 mN solution, while only a very small one was observed in a 1 mM solution.

From the measured values of admittance and phase angle, the series resistance and capacitance components, R_s and C_s, of the equivalent cell impedance were determined as given in Figs. 5 and 6.

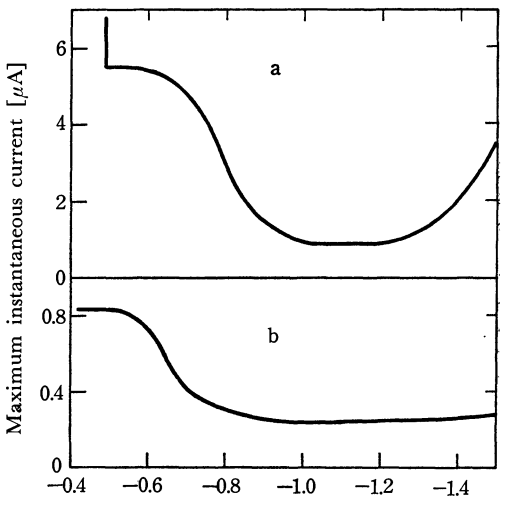

Fig. 2. D. c. polarograms of (a) 1 mM $K_2S_2O_8$ and (b) 1 mN $K_3[Fe(CN)_6]$ in aqueous solutions containing no supporting electrolytes.

Fig. 5. Series resistance and capacitance components, R_s and C_s, of the DME/1 mM $K_2S_2O_8$ system: (a) resistance, and (b) capacitance. Figures on each curve represent the frequency of the superimposed sinusoidal voltage.

An example of the square-wave polarization behavior of peroxodisulfate ions is reproduced in Fig. 7; curve (a) represents the output current observed at the electrode potential on the limiting current plateau, and curve (b), the output current at the electrode potential where the cathodic current begins to decrease with increasing negative polarization. Similar results were obtained with the reduction process of ferricyanide ions.

Discussion

The a. c. polarographic behavior of peroxodisulfate and ferricyanide ions at 30 cps shows an anomalously large phase angle at the electrode potentials in the vicinity of the zero-charge point of mercury (Figs. 3 and 4). This anomaly in the phase angle results in a remarkable decrease in the series resistance component, R_s, as shown in Figs. 5 and 6. The R_s-values at 300 cps are assumed to be approximately equal to the resistance of the solution, but the values at 30 cps are very much smaller than the resistance of the solution, even negative in the case of peroxodisulfate ions, at the electrode potentials where the cathodic currents fall off.

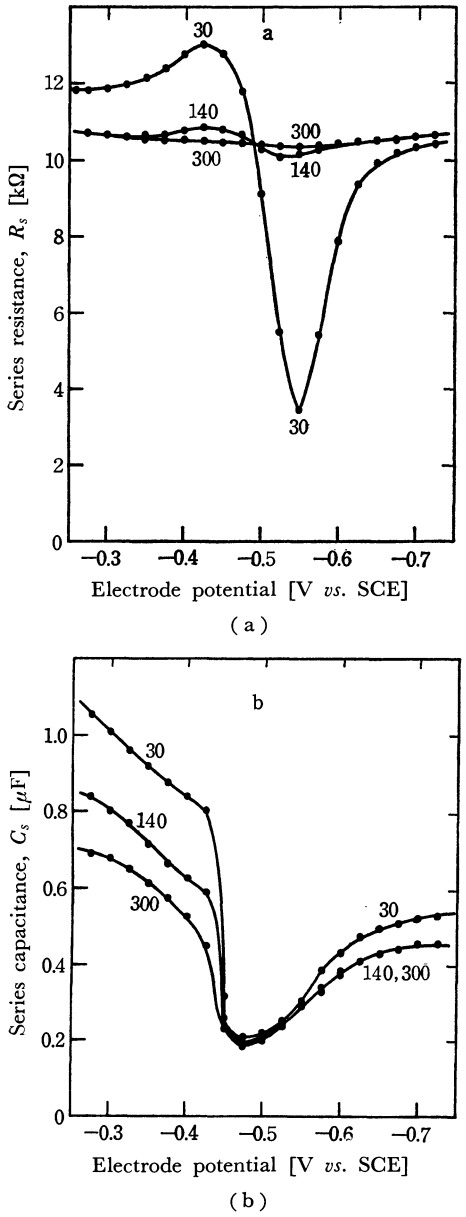

Fig. 6. Series resistance and capacitance components, R_s and C_s, of the DME/1 mN $K_3[Fe(CN)_6]$ system: (a) resistance, and (b) capacitance. Figures on each curve represent the frequency of the superimposed sinusoidal voltage.

The series capacitances, C_s, of the ferricyanide system at the potentials more negative than −0.5 V *vs.* SCE were not very much affected by the frequency, and they may be assumed to be nearly equal to the double layer capacity. On the other hand, the C_s-values of the peroxodisulfate system at 30 cps gave a peak at about −0.63 V *vs.* SCE, which suggests some complication in the electrode process. The details of the capacitance behavior, however, will not be discussed in this paper.

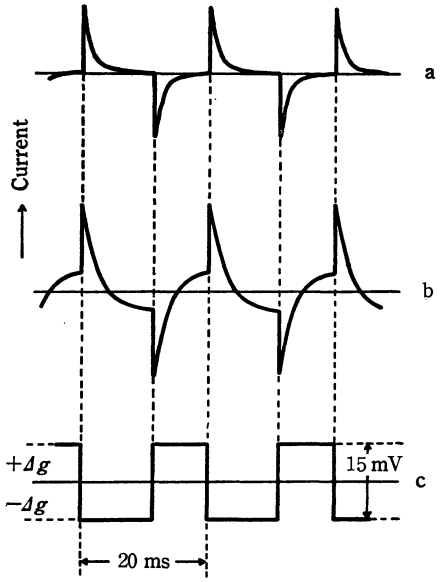

Fig. 7. Square-wave polarization behavior of the DME/1 mM $K_2S_2O_8$ system: (a) $g=-0.50$ V *vs.* SCE; (b) $g=-0.60$ V *vs.* SCE; (c) superimposed square-wave signal. The photographs were taken at the moment just prior to the detachment of a mercury drop from the tip of the DME.

The square-wave polarization behavior of the peroxodisulfate system at −0.60 V *vs.* SCE (Fig. 7, curve (b)) shows that the cathodic faradaic current in the period when the DME is more negatively polarized is smaller than that in the period when the DME is less negatively polarized. This result clearly indicates the decrease in the rate of overall reduction process with increasing negative polarization.

In analogy to the impedance behavior of the polarographic reduction of indium(III) ions in thiocyanate solutions,[3,4] the anomalous decrease in the series resistance component may be attributed to the negative charge-transfer resistance. The negative charge-transfer resistance of the peroxodisulfate and ferricyanide systems can be explained in terms of the double layer effect.

The charge-transfer resistance, θ, of the electrode reaction,

$$O + ne \rightleftharpoons R$$

is given by the equation,

$$\frac{1}{\theta} = \frac{n^2F^2}{RT} k^\circ \left\{ \alpha_+ c_R \exp\left[\frac{\alpha_+ nF}{RT}(g-g^\circ)\right] + \alpha_- c_0 \exp\left[\frac{-\alpha_- nF}{RT}(g-g^\circ)\right]\right\} \quad (1)$$

where k° is the standard rate constant, g, the d. c. component of the electrode potential, g°, the standard electrode potential, c, the d. c. component of the concentration at the plane just outside the

diffuse double layer, and α_+ and α_- are the apparent transfer coefficients for the anodic and cathodic directions, respectively.[7]

At the electrode potentials where the dip in cathodic currents appears, the condition $g<g^\circ$ can be satisfied, and Eq. (1) is simplified as

$$\frac{1}{\theta} = \frac{n^2F^2}{RT} k^\circ \alpha_- c_0 \exp\left[\frac{-\alpha_- nF}{RT}(g-g^\circ)\right] \quad (2)$$

This relation indicates that the sign of θ is determined by that of the apparent transfer coefficient, α_-, for the cathodic direction; θ should be positive when $\alpha_->0$, and should be negative when $\alpha_-<0$.

By assuming the simple Boltzmann-type distribution of reacting species in the diffuse double layer and that the charge-transfer process proceeds at the outer Helmholtz plane, the apparent transfer coefficient, α_-, is represented by Eq. (3) as a function of the electrode potential,

$$\alpha_- = (1-\beta) + \frac{1}{ng}[z_0 - n(1-\beta)](\phi_2-\phi^s) \quad (3)$$

where β $(1>\beta>0)$ is a symmetry factor, z_0, the charge of O with sign, and ϕ_2 and ϕ^s are the inner potentials of the outer Helmholtz plane and the bulk of solution, respectively.[7]

Equation (3) suggests that by the reduction of polyvalent anions in solutions of low ionic strength the apparent transfer coefficient, α_-, may assume negative values especially at the electrode potentials. in the vicinity of the point of zero-charge. No data is available for the double layer behavior of the mercury electrode in peroxodisulfate and ferricyanide solutions, and thus the quantitative estimation of $(\phi_2-\phi^s)$ is not feasible. The double layer effect, however, can reasonably be assumed to be large enough to give negative α_--values for the polarographic reduction of peroxodisulfate and ferricyanide ions in aqueous solutions of very low ionic strength. Peroxodisulfate and ferricyanide ions are supposed to be subjected to a specific adsorption at the DME, the effect of which was ignored in the present discussion. The specific adsorption of these species, if any, will increase the double layer effect.

Frumkin suggested the possibility that the rate determining step of the reduction of ferricyanide ions may be the penetration of the anion through the electric field of the diffuse double layer and not the charge-transfer process.[2] According to Matsuda[8] and Senda and Delahay,[9] the repulsion of the discharged species due to the electric field of the diffuse double layer results in an additional resistance in series with the Warburg impedance in the equivalent circuit of the faradaic impedance. This additional resistance is then expected to increase the resistance component, R_s, and therefore, the remarkable decrease in R_s of the ferricyanide system as shown in Fig. 6 (a) could not be explained without considering the effect of the double layer on the apparent transfer coefficient of the charge-transfer process.

In conclusion, the qualitative behavior of the a. c. polarization of the peroxodisulfate and ferricyanide systems can be explained satisfactorily by assuming the double layer effect on the charge-transfer process. The a. c. polarography with the phase angle measurement, particularly at very low frequencies, was proved to be a useful method of analyzing the mechanism of electrode reactions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1573—1577 (1968)

The Diffusion of Gases at High Pressures. II. The Diffusion of $^{14}CO_2$ in the $^{12}CO_2$-Ar System

Shinji TAKAHASHI

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received January 24, 1968)

The diffusion coefficients of $^{14}CO_2$ in argon and in binary mixtures of normal carbon dioxide and argon were measured at the temperatures of 25, 50 and 75°C in the 15—250 atm pressure range. The measurements were made through a plug of porous bronze in the diffusion cell using the radioactive tracer technique. The products of the binary diffusion coefficient of $^{14}CO_2$ in argon and the density increase with an increase in the density. This tendency is not predicted by Enskog-Thorne's mixed dense gas theory, which requires that the products decrease with an increase in the density. The products of the diffusion coefficient of $^{14}CO_2$ in the mixtures and the density increase slightly with an increase in the density in the region of lower density at each temperature. However, in the region of higher density they decrease slightly at 25 and 50°C and are nearly constant at 75°C. The values extrapolated to 1 atm agree fairly well with the experimental findings of Holsen *et al.* and those predicted by kinetic theory.

Kinetic theory precicts[1,2] that, at low pressures, the effective diffusion coefficient, D, of a trace component, i, in a gas mixture will be given by the equation:

$$1/D = \sum_{j \neq i} x_j/D_{ij} \qquad (1)$$

where x_j is the mole fractions and D_{ij}, the binary diffusion coefficients. This equation has been confirmed by several recent experimental investigations.[3] At high pressures, however, much less is known about the diffusion in a multicomponent system either theoretically or experimentally. Recently, though, a few studies of high-pressure diffusion with ternary systems, $^{14}CO_2$-$^{12}CO_2$-CH_4,[4] $^{14}CO_2$-$^{12}CO_2$-H_2,[5] and $^{14}CO_2$-$^{12}CO_2$-C_3H_8,[5] have been made.

In the present paper the diffusion coefficients of $^{14}CO_2$ in argon and in binary mixtures of normal carbon dioxide and argon at the temperatures of 25, 50, and 75°C in the 15—250 atm pressure range are reported on.

Experimental

The experimental apparatus and procedure have been described in detail in a previous paper.[6] Exactly the same procedure was followed. In the present investigation a type-II porous plug with a grain size of ϕ 60—70 μ was used; the apparatus constant, K_{II}, determined at 25°C is shown in Table 1. K_{II}'s at 50 and 75°C were determined in the previous paper.[6] The proportionality between the ionization current and the concentration of $^{14}CO_2$, essential for the quantitative treatment of diffusion data, was confirmed experimentally for pure argon and for each mixture at a constant temperature and pressure. For example, the results at 50°C are shown in Figs. 1 and 2.

The nonradioactive mixtures were prepared from carbon dioxide and argon, certified to be 99.9 and 99.99% pure, respectively. Except for drying with silica gel, no further purification was attempted. Before measuring the diffusion, bulk mixtures of normal carbon dioxide-argon were prepared in storage cylinders. Their exact compositions were determined by bubbling samples through a potassium hydroxide solution. For this investigation the mixtures are not in the liquid state.[7]

Results and Discussion

The experimental results are given in Table 2. The densities, ρ (mol/l), for argon were calculated from the compressibility factors obtained by Michels *et al.*[8] The densities for carbon dioxide-argon mixtures were calculated by using the compressibility chart*1 with the pseudo critical temperature, T_c, and pressure, P_c, obtained by the following relations:

$$T_c = x_2(T_c)_2 + x_3(T_c)_3 \quad (2)$$

$$P_c = x_2(P_c)_2 + x_3(P_c)_3 \quad (3)$$

where the subscripts 2 and 3 denote normal carbon dioxide and argon. The compressibility calculated above agrees within 2.1% with Abraham's data,[10] which range from 50 to 1000 atm at 50°C. It may be noted that the maximum deviation of the values calculated from Abraham's data by using Weber's chart is 4.6%.

In Fig. 3 the diffusion coefficient-density products, $D\rho$, are plotted against the densities.

The values of $D\rho$ at a unit mole fraction of argon

are equivalent to the binary diffusion coefficients of the $^{14}CO_2$-Ar system. These products at each temperature show a tendency to increase consistently with an increase in the density. The extrapolation of these products to 1 atm provides a basis for comparison with the low-pressure experimental results reported by other investigators. The formula of the experimental binary diffusion coefficients for the carbon dioxide-argon system published by Holsen *et al.*[11] yields values which are in agreement with the extrapolated values of this investigation.

The effect of the density (or the pressure) on the binary diffusion coefficient may be predicted by Enskog-Thorne's mixed dense gas theory,[12] which

is the only theoretical treatment offering any practical application. It is expressed as follows:

$$D_{13}\rho = (D_{13})^\circ \rho/\chi_{13} \quad (4)$$

$$\chi_{13} = 1 + 0.2618 n_3 \sigma_3^3 (8 - 3\sigma_3/\sigma_{13}) \quad (5)$$

where the subscript 1 denotes radioactive carbon dioxide. D_{13} is the first approximation to the diffusion coefficient for dense gases, and $(D_{13})^\circ$ is the first approximation to the diffusion coefficient for dilute gases. The n is the number of molecules per unit of volume, and σ is the effective collision diameter. The empirical combining law, $\sigma_{13} = (\sigma_1+\sigma_3)/2 \fallingdotseq (\sigma_2+\sigma_3)/2$, was employed in the calculation. The collision diameters, $\sigma_2 = 3.996$ Å and $\sigma_3 = 3.418$ Å, were taken from Ref. 1 and are those determined from the viscosity measurements for the Lennard-Jones model. $(D_{13})^\circ$ was calculated by using the formula published by Holsen *et al.*,[11] with a mass correction. As is shown in Fig. 3 by dashed lines, the theory requires the $D_{13}\rho$ products to decrease with an increase in the density. The calculated products are lower by 28% at a density of about 8 moles per liter at each temperature. This poor agreement is in accordance with most of the other high-pressure-diffusion results.[13]

According to Eq. (1), the effective diffusion coefficient, D, of a trace component (radioactive carbon dioxide) in a gas mixture of normal carbon dioxide and argon is given by the equation:

$$1/D = x_2/D_{12} + x_3/D_{13} \quad (6)$$

where D_{12} and D_{13} are the binary diffusion coefficients of radioactive carbon dioxide in normal carbon dioxide and in argon respectively. The values of D_{12} and D_{13} at 1 atm were obtained by applying the mass corrections to the reported values of the self-diffusion coefficient of normal carbon dioxide, D_{22}[14], and to that of the binary diffusion coefficient between normal carbon dioxide and argon, D_{23}.[11] The calculated values of $D\rho$ at 1 atm thus obtained for intermediate concentrations are shown in Fig. 3. These calculated values are in agreement with the extrapolated values.

The Enskog theory has not yet been extended to ternary systems at high pressures. Therefore, the applicability of Eq. (1) to the high-pressure-diffusion coefficient was tested in the form:

$$1/D\rho = x_2/D_{12}\rho + x_3/D_{13}\rho \quad (7)$$

$$x_2 + x_3 \fallingdotseq 1$$

where D, D_{12}, and D_{13} are the values at density, ρ. Equation (7) indicates that $1/D\rho$ may vary linearly with either x_2 or x_3, that $D = D_{12}$ at $x_2 = 1$, and that $D = D_{13}$ at $x_3 = 1$. The values of $D\rho$ were read from the smoothed curves in Fig. 3, while the values of $1/D\rho$ are plotted against the mole fraction of argon, x_3, at 1 atm and $\rho = 2$, 6, and 10 mol/l in Fig. 4. The plots are straight lines at 1 atm. However, they are not straight lines but convex curves at densities above 2 moles per liter.

Conclusion

At high pressures the binary diffusion coefficient of $^{14}CO_2$ in argon can not be predicted by Enskog-Thorne's theory, and the effect of the composition on the diffusion coefficient of $^{14}CO_2$ in $^{12}CO_2$-Ar mixtures does not follow Eq. (1). These facts are understandable, for the above-mentioned theory has been derived for rigid spherical molecules, while Eq. (1) is only for ideal gases.

The author wishes to express his deep gratitude to Professor Hiroji Iwasaki for his kind direction and encouragement throughout this work.

The Polarographic Behavior of Aliphatic Aldehydes in Buffer Solutions Containing *o*-Phenylenediamine

Tamotsu WASA and Sôichirô MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai

(Received August 16, 1967)

Formaldehyde (I), acetaldehyde (II), propionaldehyde (III), *n*-butyraldehyde (IV), *n*-caproaldehyde (V), and *n*-octaldehyde (VI) condense with *o*-phenylenediamine (OPD) to yield products, each of which gives a single, irreversible but well-defined oxidation wave ($E_{1/2}$ *vs.* SCE at pH 8.0: −0.240 V for I, −0.242 V for II, −0.263 V for III, −0.290 V for IV, −0.316 V for V, and −0.338 V for VI). From these findings, it has been deduced that the condensation products of aldehydes with OPD would be benzimidazoline derivatives, which would be oxidized to benzimidazole derivatives at the dropping mercury electrode. Linear relations between the limiting currents of the condensation products with OPD and the concentrations of aldehydes [(1—20) × 10^{-4} M], except for I, were obtained under the following conditions: pH, 6—8 ($pH_{i\ max}$); the concentration of OPD, 2×10^{-2} M; the temperature, 25°C; and the condensation time, 15—60 min. The method was then applied practically in the determination of the purity of a commercial product of II and the quantity of II in the presence of glyoxal.

It has well been known that most aliphatic aldehydes show single reduction waves at the dropping mercury electrode in neutral and alkaline solutions containing lithium or tetraalkylammonium salt as the supporting electrolyte in the range of voltage between −1.6 V and −1.8 V *vs.* SCE, and that these waves can be used in the determination of aliphatic aldehydes.[1-4] However, the limiting current is markedly influenced by the pH and the temperature of the electrolytic solution,[5,6] and also decreases with time in the alkaline region because of the instability of these aldehydes.[7] For analytical use, in order to obtain the wave height proportional to the aldehyde concentration, the experimental conditions must be strictly controlled. To avoid this shortcoming, indirect polarographic methods which involve the chemical reactions of aldehyde with carbonyl reagents have been reported.[8-10]

The authors have previously reported on the oxidation waves of the condensation products of hydroxyaldehydes with *o*-phenylenediamine (OPD) in various buffer solutions, and on the polarographic determination of glycolaldehyde and glyceraldehyde.[11]

The present paper will describe the polarographic behavior of aliphatic aldehydes, *i. e.*, formaldehyde (I), acetaldehyde (II), propionaldehyde (III), *n*-butyraldehyde (IV), *n*-caproaldehyde (V), and *n*-octaldehyde (VI), in various buffer solutions containing an excess of OPD, and will present a method for determining such aldehydes by using this oxidation wave.

Experimental

Formaldehyde was a commercial product (Formalin, about 37%) from Wako Pure Chemical Industries, Ltd.; it was used without further purification. II was prepared from paraldehyde by distillation in the presence of a 1 vol% of concentrated sulfuric acid.[12] All the other aldehydes (III, IV, V, and VI) used were purified by the distillation of their commercial products. Aqueous or ethanolic stock solutions of the aldehydes were prepared at about 10^{-2} M; these concentrations were checked by the titration method.[13] All the other chemicals were the same as those used in previous

works.[11,14,15] As for the buffer solutions, Britton-Robinson buffers (BR) were mainly employed except for examining the effect of the components of the buffer solution. No maximum suppressor was added, since no maximum was observed under the present polarographic conditions.

The apparatus and the experimental procedures were the same as those reported in previous papers.[11,14,15] To minimize the loss of aldehydes, the dissolved oxygen was removed by bubbling nitrogen which had previously been passed through a solution of the same composition. Reference electrode: SCE. Characteristics of capillary: m=1.143 mg/sec, t=4.00 sec/drop in the buffer solution at 0 V *vs.* SCE. The accuracy of the temperature control was ±0.1 °C.

Results and Discussion

Oxidation Waves of the Condensation Products of Aliphatic Aldehydes with OPD. All the aliphatic aldehydes (I—VI) examined show an ill-defined and unstable reduction wave in alkaline media, as may be seen in Fig. 1(a). In buffer solution containing an excess of OPD, however, they give a well-defined oxidation wave (Fig. 1(b)) corresponding to the condensation products, which are probably benzimidazoline derivatives, as has been previously reported for hydroxyaldehydes.[11]

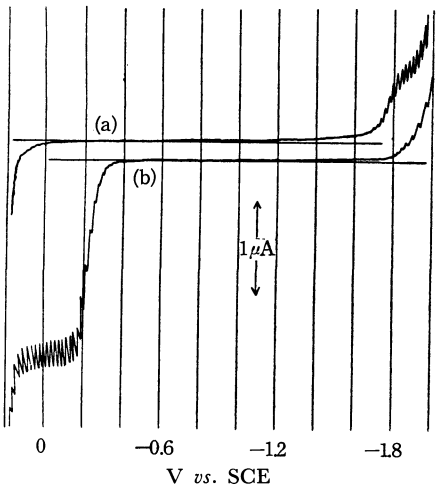

Fig. 1. Polarograms of acetaldehyde with or without OPD at 25°C.
(a) 2×10^{-3} M II in BR buffer (pH, 8.0)
(b) 6.5×10^{-4} M II in BR buffer (pH, 8.0) containing 2×10^{-2} M OPD; Condensation: 60 min

The Effect of pH. When the concentrations of aldehydes and OPD were kept constant and when polarograms were recorded 60 min after the addition of OPD at 25°C, the relationships between the limiting currents of the condensation products and the pH were as shown in Fig. 2. All the aldehydes examined, with the exception of I, exhibit almost the same polarographic behavior: the limiting currents reach their maximum values in the pH range between 6 and 8 and then decrease beyond this pH region. It seems that the decrease in the height of the oxidation waves with an increase in the pH on the alkaline side is related to the decrease in the rate of the condensation reaction, while the other decrease, on the acidic side, is due to some conversion of OPD involving protonation and also to the instability of the condensation products. The limiting current for I, with an increase in the pH, reaches its maximum value at a pH value of about 5.8; then it decreases markedly with a further increase in the pH, while, at the same time, the electrolytic solution becomes turbid. The optimum pH ranges, $pH_{i\ max}$, in which the oxidation wave corresponding to each of the aldehydes shows its maximum value, are presented in Table 1, together with the equilibrium constants (K'). At the $pH_{i\ max}$ the reaction of aldehyde with OPD reached its equilibrium state within 5—10 min after the addition of OPD and the condensation products were comparatively stable. The oxidation wave of the condensation products was diffusion-controlled; there is a proportionality between the limiting currents and the square root of the heights of mercury reservoir.

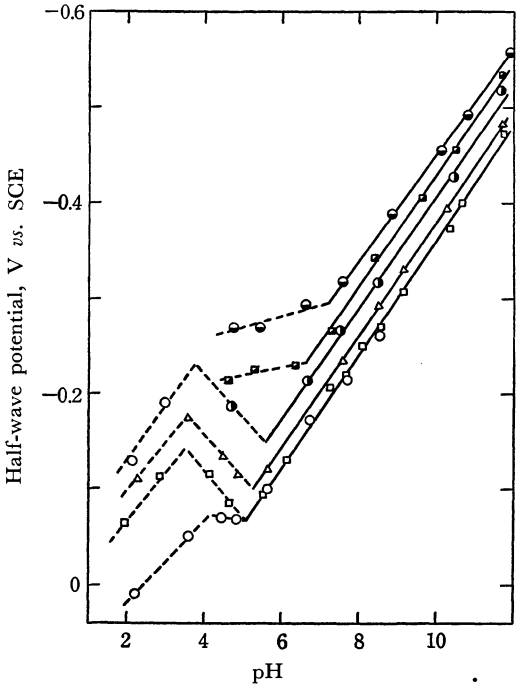

Fig. 3. pH-dependence of the half-wave potentials at 25°C.
Aldehyde: 1×10^{-3} M, OPD: 2×10^{-2} M; Condensation: 60 min, BR buffer; ○—I, □—II, △—III, ◑—IV, ◪—V, and ◒—VI

pH value are shown in Fig. 3. At pH values higher than $pH_{i\ max}$, the half-wave potential of the oxidation wave corresponding to each aldehyde showed a linear relation with the pH value (inclination; −60 mV/pH); this relation shifted to a more negative potential with an increase in the number of carbon atoms in the aldehydes used. At pH values of 4—6, it was also observed that the wave became less steep and that the half-wave potential shifted discontinuously.

The Effect of Concentration of OPD. The relationships between the limiting currents of the condensation products measured 60 min after the addition of OPD at 25°C and the concentration of OPD are shown in Fig. 4, when the concentration of aldehydes was kept constant at the $pH_{i\ max}$ value corresponding to each of the aldehydes. From the data of Fig. 4 and the fact the half-wave potential shifts to a more negative potential with an increase in the concentration of OPD, it may be deduced that the condensation reaction attains

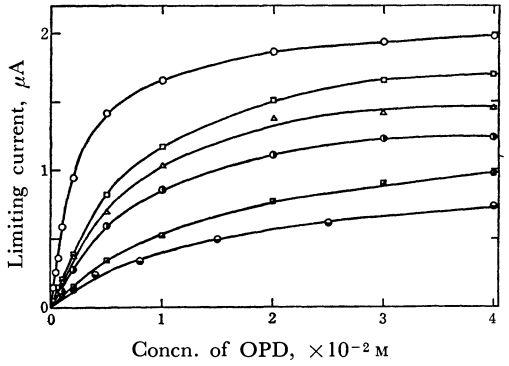

Fig. 4. Relationship between the limiting currents and the concentrations of OPD at 25°C.
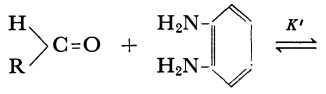
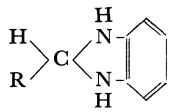
Aldehyde: 5×10^{-4} M; Condensation: 60 min in BR buffer with $pH_{i\ max}$; ○—I, □—II, △—III, ◑—IV, ◪—V, and ◒—VI

an equilibrium state.[11] The reaction may be written as follows:



Aldehyde OPD



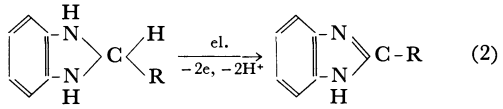
+ H_2O (1)

Benzimidazoline derivative

$R=C_nH_{2n+1}$; n=0, 1, 2, 3, 5, and 7

The equilibrium constants obtained in a manner similar to that previously reported for glyceraldehyde[11] are given in Table 1. Since the equilibrium constants for all the aldehydes are relatively small, for analytical purposes the concentration of OPD in the reaction mixture should be kept in a large excess and should be kept constant.

From the facts that no a. c. polarogram was obtained, except for a small peak which seems to be due to the adsorption, and that no reduction wave was obtained with the oxidation product by means of a controlled-potential electrolysis, the electrode reaction of the condensation products may be concluded to be an irreversible one. Moreover, because the UV-absorption spectra of the electro-oxidation products were in accordance with that of benzimidazole, the electrode process may be expressed as follows:



(2)

The discontinuous change in the half-wave potentials at pH values between 4 and 6, as seen in Fig. 3, seems to be due to the change in the electrode process resulting from the protonation of benzimidazoline derivatives.

The Effect of Bubbling Nitrogen. As a result of the volatility of all the aliphatic aldehydes examined, we desired to ascertain the effect of the deoxygenating time on the constancy of the wave heights of the condensation products by bubbling nitrogen. For that reason, a series of measurements were conducted to check the possible effects due to different bubbling times; the results obtained are summarized in Table 2. No remarkable decrease resulting from the volatility of aldehydes by bubbling nitrogen was observed when a large excess of OPD was present in the reaction mixture. However, a discrepancy apparently due to the oxidation of the condensation product by dissolving oxygen was observed. For analytical purposes, therefore, it is necessary to remove the dissolving oxygen by bubbling nitrogen immediately after the preparation of the electrolytic solution.

TABLE 2. INFLUENCE OF BUBBLING NITROGEN ON THE LIMITING CURRENT OF THE CONDENSATION PRODUCT

Acetaldehyde: *ca.* 1.5×10^{-3} M; Condensation: 2×10^{-2} M OPD, 60 min, 25°C, pH 8.2

Time, min		5	10	15	20	30
i, μA	early stage	4.62	4.62	4.58	4.71	4.65
	final stage	4.08	4.14	4.16	4.28	4.35

The Effect of the Temperature. The time required for the condensation shortened upon a rise in the temperature, but at temperatures higher than 30°C it was also observed that the anodic limting current, after attaining its maximum value, decreased with the time. The changes in the wave heights of the condensation products with the temperature at a pH value of 7.5 are shown in Fig. 5. The smaller temperature coefficients than those observed for the diffusion-controlled currents may indicate that the equilibrium of Eq. (1) is shifted more in the dissociation direction with the temperature.

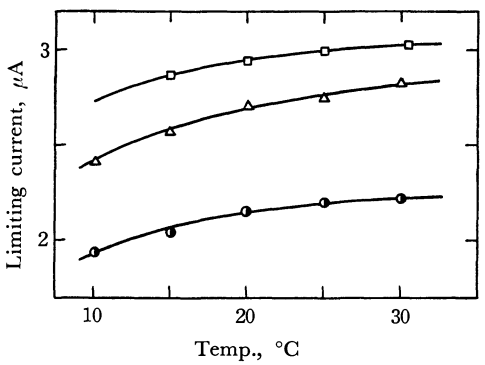


Fig. 5. Effect of the temperature on the limiting currents of the condensation products.

Application to the Determination of Aliphatic Aldehyde. On the basis of the experimental facts described above, the following conditions can be recommended for the determination of aliphatic aldehydes by using the oxidation wave of the condensation products with OPD: $pH_{i\ max}$ for pH, 2×10^{-2} M for the concentration of OPD, 25°C for the temperature, and 15—60 min for the condensation time. These recommended conditions are almost the same as those recommended for hydroxyaldehydes in a previous paper.[11] To obtain a better reproducibility, the dissolving oxygen must be removed by bubbling nitrogen for 10 min as soon as possible after the preparation of the electrolytic solution because of the oxidizable property of the condensation product. Under these conditions, linear relations are obtained between the concentrations of all the aldehydes except for

○—I, □—II, △—III, ◑—IV, ◪—V, and ◒—VI.

I and the limiting currents of their condensation products in the range of $(1—20)\times10^{-4}$ M, as Fig. 6 shows.

The purity of a commercial aqueous solution (about 80%) of II was determined by means of the standard addition method[11] after the proper preliminary dilution of the sample with distilled water free from oxygen, utilizing the optimum conditions previously specified. The results obtained are shown in Table 3, along with those obtained by a modification of Siggia's method.[16] The results obtained by the two methods are in good agreement with each other.

The determination of II in an artificial sample containing II and glyoxal was also carried out; the results of this analysis are listed in Table 4. The presence of glyoxal does not seriously interfere with the determination of II by the polarographic OPD method, but it interferes strongly with the determination of II by the titration method.

The presence of alcohols, carboxylic acids, and esters in the sample does not interfere with the determination of any of the aldehydes examined, since these substances do not show the oxidation wave under the present experimental conditions. Though acetone does show an anodic wave under the present experimental conditions, it does not cause any interference at concentrations of less than 3×10^{-2} M. Sulfite ion strongly interfered with the determination of aliphatic aldehydes. Since the condensation products of all the aliphatic aldehydes and hydroxyaldehydes[11] with OPD behave similarly at the dropping mercury electrode, these aldehydes interfere with the determination of one other.

The present polarographic method is particularly well suited for the determination of aliphatic aldehydes in the presence of some other compounds which are polarographically reducible and not distinguishable by using reduction waves.

Liquidus Curve Measurements in the ZrO_2-MgO System with the Solar Furnace

Tetsuo NOGUCHI and Masao MIZUNO

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya

(Received October 25, 1967)

A liquidus curve in the system ZrO_2-MgO was investigated by the use of a heliostat type solar furnace. The cooling curves of a composition were obtained by the specular reflection method with a brightness pyrometer. Quenched specimens from the melt were examined with an X-ray technique and a petrographic microscope. Newly found anomalies on the liquidus curve were 7.5, 12.5 and 17.5 mol% MgO compositions. The composition of 12.5 mol% MgO quenched from the melt showed the new cubic-like phase of which optic angle of $2V$ equals to $-74°$ and decomposed easily into monoclinic and tetragonal forms by reheating at 1300°C.

Many papers have been published on the phase study of the ZrO_2-MgO system up to present, and the earlier works on the system were surveyed by Dietzel and Tober[1] in 1953. The melting diagram was first studied by von Wartenberg and Werth[2] in 1928 who proposed two eutectic points with 10 and 48 wt% MgO at about 1630 and 1600°C respectively, and with a maximum point with the composition of ZrO_2·MgO at about 2120°C. Ebert and Cohn[3] claimed that an eutectic point with 50 mol% MgO at 2100°C in 1933, and the same result was also estimated by Zirnowa[4] at 2070°C in 1939. Later the subliquidus phase of the system in ZrO_2 side below 2000°C was investigated by Dietzel and Tober, and also Duwez *et al.*[5] in 1952. Recently the phase boundary of the cubic ZrO_2 solid solution above 2000°C was reported by Hinz and Dietzel[6] in 1962, and by Viechnicki and Stubican[7] in 1965 respectively.

However, the data on the liquidus curve on the system with sufficient accuracy have not been published yet. The authors reported on the high temperature phase in ZrO_2-CaO system using a heliostat type solar furnace previously[8] and anomalies on the liquidus curve were found in ZrO_2 rich side region. This paper relates to the liquidus curve measurement on the ZrO_2-MgO system, in which the behaviors of magnesia are similar to those of calcia in the stabilization of zirconia refractory.

Equipment and Materials

The temperature and emissivity measurements were performed with the brightness pyrometer at 0.65 μ by the specular reflection method as reported by the author previously.[9] The standard deviation derived in the transmission measurement of the grey filter in the pyrometer was 1.7% and therefore the recorded value was estimated to be reliable within the error of about 2% as an amount of radiant energy. This corresponds to 10° at 3000°K and 15° at 4000°K calculating from Planck's equation respectively. These values were verified by the calibration with the tungsten filament standard lamp at the focal plane of the solar furnace, and the accuracy of the brightness pyrometer at 3237°K was within $\pm 7°$.[10] The accuracy of derived temperatures in this experiment was thus estimated to be within $\pm 20°$ at 3000°K and $\pm 15°$ at 2000°K including the reading errors of oscillograms. The heliostat type solar furnace used was the combination of the paraboloid of 1.5 m in diameter and 64 cm of focal length, and the heliostat plane mirror of 2.4×2.4 m with sixteen segments of front coated glass. The optical axis of the paraboloidal mirror was fixed horizontally.

Materials used were ZrO_2 of 99.8% purity from the Yokozawa Chemicals Co., Tokyo (including about 1.8% of HfO_2, and ignition loss, 0.05; Cl, 0.04; SO_4, 0.008; Fe, 0.001%) and MgO of 99.7% from the Kanto Chemicals Co., Ltd., Tokyo (ignition loss, 0.11; Cl, 0.002; heavy metal, 0.002; Fe, 0.0004; Zn, 0.002; Ba, 0.0025; Ca, 0.102%). The starting materials were carefully mixed in an agate mortar, calcined in an electric resistance furnace at 1700°C for 6 hr by two heating and grinding cycles, and pressed into $6 \times 6 \times 35$ mm bar under 4000 kg/cm^2 without any lubricant or binder.

Eleven specimens in 10 mol% MgO increments and nine specimens in 2.5 mol% increments from 2.5 to 30 mol% were prepared by the heat treatment as referred to the previous study on ZrO_2-CaO system. Four specimens in 5 mol% MgO increments from 30 to 70 mol% were also added to confirm the eutectic points.

Results and Discussion

Freezing Point Measurement. On the sun's image of 6 mm in diameter on the specimen surface, the variation of the brightness temperature in the area of 0.25 mm ϕ was measured with the brightness pyrometer. The cooling curves of the specimen were obtained with the dual-beam cathode-ray oscilloscope (Multiscope VP 541 A) attached with the Polaroid camera and were shown schematically in Fig. 1. The freezing and melting temperatures of the specimen were also confirmed by the visual observation through the ocular lens of the pyrometer and by the data from the automatic voltage recorder. The cooling rate of the specimens was estimated from 1800 to 2300 deg/sec. The exothermic peak observed after the freezing point might be ascribed to the phase transformation in solid state.

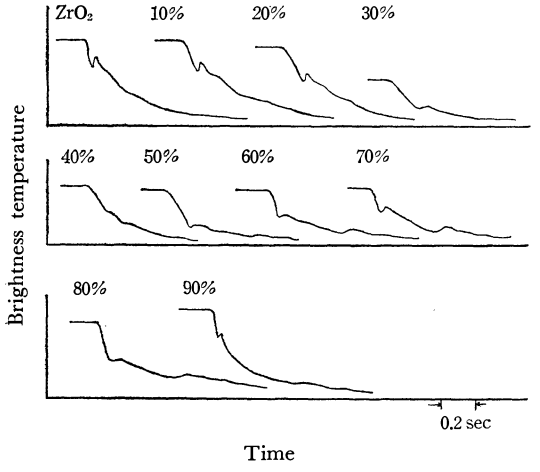

Fig. 1. Cooling curves of the composition in ZrO_2-MgO system.

ZrO_2 showed two weak exothermic peaks accompanied with the crystallization and the similar phenomenon was observed up to 25 mol% MgO composition. In the fusion of MgO specimen vigorous vaporization was observed and failed to give the emissivity data. Only the brightness temperature of the freezing point was hardly obtained and it was difficult to hold the specular reflection surface because of the deposition of vaporized magnesia on the specimen surface. No correction for transmission of magnesia vapor was also possible.

Figure 2 represents the freezing point data obtained in the ZrO_2-MgO system. The freezing point is indicated as the true temperature and both of the 2nd and the 3rd exothermic peaks observed in solid state are indicated by the brightness temperature. The mean value of forty to fifty individual readings on the freezing point is listed in Table 1 with the spectral emissivity data at 0.65 μ. Only the freezing point of MgO was cited from the

* These values were calculated as brightness temperature.

literature[11] because of the difficulty in obtaining the emissivity data and accordingly the true temperature. Anomalies not reported in the liquidus curve previously were found to be at 7.5, 12.5 and 17.5 mol% MgO compositions, showing the maximum point at 12.5 mol%. The tendency of this type was similar to those in ZrO_2-CaO system in ZrO_2 side region, though the maximum point shifted to 7 mol% CaO composition.

It should be noted that the solid state reaction observed in some of these cooling curves in the ZrO_2 rich side region could not be suppressed by the quenching rate as in this study. Since the specimen is heated from its surface at the focus of the solar furnace, the liquid phase formed at the solar image is surrounded by the solid even if the thermal equilibrium is obtained. Therefore, the solid crystal under the liquid layer might become the nuclei on crystallization and accelerate the growth of crystals in the cooling process.

Stoichiometry. The specimen for chemical analysis was prepared with the solar furnace in such a way that a test bar was fused at about 100°C higher than the respective melting temperature for 3 min before quenching. Since the necessary time for each measurement of cooling curve was within 10 sec and repeated measurements across the sun's image were made on five different points in three times, simulation for the heat treatment of a specimen might be considered satisfactory.

The weighed sample of about 50 mg in a platinum crucible was fused with the addition of tenfold sodium pyrosulfate. The extraction with dil. H_2SO_4 (5%) was neutralized with NH_4OH by the addition of NH_4Cl. The pH of the filtrate was then adjusted to 10 and the sample solution was titrated with EDTA solution by the aid of KCN and BT indicator. The results obtained are shown in Table 2 and the deviation of MgO component is clearly observed. These data differ from those claimed by Hinz and Dietzel who applied the argon plasma torch because of the estimated heating temperature of more than 5000°K.

TABLE 2. CHEMICAL ANALYSIS OF QUENCHED SPECIMENS FROM THE MELT BY CHELATE TITRATION IN THE ZrO_2-MgO SYSTEM

Sample	MgO content (Theoretical) wt%	MgO content (Determined) wt%	MgO content (Determined) mol%	Difference mol%
M 10	3.51	3.00	8.64	−1.36
M 30	12.29	9.65	24.61	−5.39
M 40	17.91	14.57	34.26	−5.74
M 50	24.66	21.27	45.22	−4.78
M 60	32.92	29.58	56.21	−3.79
M 70	43.29	36.56	63.78	−6.22
M 90	74.65	62.79	83.76	−6.24

The vaporization rates at melting temperatures for ZrO_2, 50 mol% MgO composition and MgO specimens which were prepared by sintering at 1700°C for 3 hr are 5.3×10^{-4}, 2.3×10^{-3}, and 9.0×10^{-3} g/cm^2 min respectively. These values were obtained by heating the specimen of about 1.5 g and were estimated from the weight decrease in 10 min. Even for the short heating duration as in the experiment, the vaporization of MgO can not be suppressed in air because of the high vapor pressure near the melting point.

X-Ray Analysis of Quenched Specimens from the Melt. The quenched specimens were examined by X-ray technique using a diffractometer of the Shimadzu Diffraction Unit GX-3 and nickel filtered Cu$K\alpha$ radiation. High temperature diffraction patterns were obtained using the Shimadzu HX-II model whose hot stage consists of a platinum-rhodium wound heating element encased in an alumina refractory sleeve. The temperature measurement was made with a platinum *versus* platinum-10% rhodium thermocouple. The results of the powder diffraction patterns of the quenched specimens are shown in Table 3, and sufficient explanation on the anomalies in the liquidus curve was not obtained.

In ZrO_2 rich side region up to 15 mol% MgO composition, the diffraction patterns showed broadening and were not identified as cubic form.

80		C (s)	MgO(s)
90		C (m)	MgO(s)

M: Monoclinic ZrO_2 solid solution,
C: Cubic ZrO_2 solid solution,
C*: Cubic not resolved.

The slow scan pattern of 12.5 mol% MgO composition at 2θ 1/8° min gave no extra reflection up to 2θ 160°, as compared with that of 7 mol% CaO composition. Cubic zirconia was widely observed in the system except the ZrO_2 rich side region. Periclase coexisted from 30 mol% MgO composition through MgO side.

The lattice parameters of cubic zirconia solid solution were obtained from diffraction lines with $2\theta > 85°$ on 12.5 to 70 mol% MgO compositions and the boundary for the cubic zirconia solid solution in the quenched specimen from the melt was located at about 25.5 mol% MgO as shown in Fig. 3, almost identical to the results claimed by Duwez *et al.* at 2000°C. It might be assumed that the solid solution boundary for cubic zirconia above 2000°C up to melting temperature was vertical.

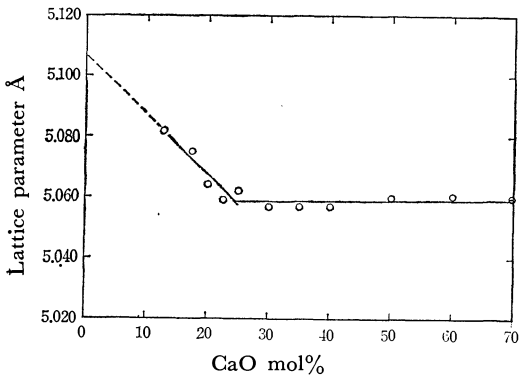

Fig. 3. Lattice parameters of cubic ZrO_2 solid solution.

The lattice parameters of magnesia from 40 to 100 mol% MgO were measured with diffraction lines with $2\theta > 95°$ and were constant at 4.211 Å. Very narrow region for the tetragonal zirconia solid solution *i. e.* the solid solution boundary between tetragonal zirconia and tetragonal zirconia plus magnesia might be assumed at less than 5% of MgO from the results in Table 3.

High temperature X-ray diffraction patterns on the quenched specimens of 5, 10, 12.5, 17.5 and 30 mol% MgO compositions were obtained on 2θ 20—45° and with heating and cooling rates of 20°C/min from 500 to 1300°C. No remarkable change was observed at the heating process and the tetragonal form was not found even at 1250°C except 5 mol% composition. However, in the specimens of 5, 10, 12.5 and 17.5 mol% MgO compositions the monoclinic form appeared at 900—850°C on cooling, and a decomposition of the 12.5 mol% MgO composition into tetragonal and monoclinic forms was observed as in the case of 7 mol% CaO composition.

Microscopic Observation on the Quenched Specimens. The thin section of the quenched specimens in ZrO_2 rich side region from the melt was examined by the petrographic microscope. The analytical data are shown in Table 4.

Table 4. Microscopic data on zirconia modifications in the quenched specimens in ZrO_2-MgO system

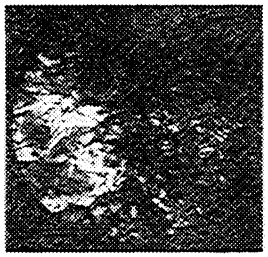
Composition MgO mol%	Monoclinic	Tetragonal	Biaxial negative $2V=-74°$	Isotropic cubic
2.5	+++++			
3	+++	++		
4	++	+++		
6		+++	+++	±
8		+	++++	±
10			+++++	
12.5			+++++	
15			++	++−

The biaxial negative crystals were found besides the monoclinic, tetragonal and cubic forms. The optic angle of the crystals was $2V=-74°$ and different to that of the monoclinic form of $-30°$. The single phase of this modification is limited at about 12.5 mol% MgO composition and Fig. 4 shows the photomicrographs of 3, 12.5 and 15 mol% MgO compositions quenched from the melt. Thus the new cubic like phase might be assumed to be rhombic modification rather than the distorted cubic lattice, though the verification of the presence of this form was not possible by the X-ray diffraction data.

Liquidus Curve in the ZrO_2-MgO System. The liquidus curve obtained by the freezing point measurements was corrected in relation to the

a) 3 mol% MgO composition

b) 12.5 mol% MgO composition



c) 15 mol% MgO composition ×180 Crossed nicols.

Fig. 4. Photomicrographs of the thin section of zirconia modifications in the specimens quenched from the melt.

chemical analysis of the quenched specimens from the melt and is shown in Fig. 5 with that of the ZrO_2-CaO system. The characteristic anomaly in ZrO_2 rich side region shifts to about 10 mol% MgO. The behaviors of MgO in this region at higher temperatures were not understood sufficiently because of the lack of knowledge on the crystal modification above 2300°C to present the complete phase diagram on the system. However, the maximum point observed in ZrO_2 rich side region might indicate the existence of a new cubic like phase, which decomposed easily after reheating into monoclinic and tetragonal forms. The anomalies in this

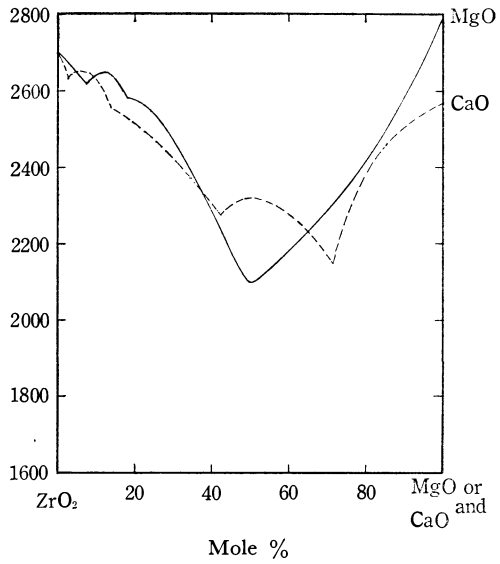


Fig. 5. Liquidus curve in the system ZrO_2-MgO.

experiment were not reported by the previous investigators. Ebert and Cohn[3] have assumed an peritectic point in this region without experimental evidences, however, the accuracy of temperature measurement by them was not described clearly, and it might be estimated within ±50°C at more than about 2500°C by a visual observation method. The eutectic point was found at 50 mol% MgO at 2113 ±15°C. And the other compound such as $Mg_2Zr_3O_8$ or $MgZr_3O_7$ reported in the earlier literatures[1] were not confirmed from this experiment. It is noted that the phase study in ZrO_2 rich side region above 2300°C should be further developed.

The authors wish to express their appreciation to Dr. H. Hayashi for his support in the chemical analysis and microscopic work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1588—1600 (1968)

An Experimental Study on the Role of Water Vapor in the Distribution of Fluorine and Chlorine in Volcanic Rocks

Tsutomu SUGIURA*1

Department of Earth Sciences, Nagoya University, Chikusa, Nagoya

(Received December 2, 1967)

Fluorine and chlorine contents of volcanic rocks were examined with respect to the characteristics of the rocks. Fluorine showed rather linear relationships with some chemical components of the rocks and also with stages in the differentiation of magmas. But any universal relationship covering all the rock types was not found. The cause of this fact is expected to be the loss of halogens from rocks resulted from the interaction between rocks and water vapor, which is believed to be ubiquitous in magma and is gradually emanated from it during or after the formation of rocks. So, in order to make clear the role of water vapor in the distribution of halogens in rocks, the author has distilled fluorine and chlorine from rock samples with water vapor at elevated temperatures and studied following relations; (1) the relationship between the amount of distilled halogens and the fluorine and chlorine contents of the rocks, and (2) the relationship between the amount of distilled halogens and the characteristics of the rocks. In distillation of fluorine and chlorine with water vapor, almost all fluorine remained in each rock specimen at low temperatures below 300°C, and at temperatures above 700°C the ratio of the amount of distilled fluorine to the initial amount of fluorine in rocks fluctuated among specimens. However, there was no relation between patterns of the distilled fluorine and the fluorine content of the rocks, and also the characteristics of the rocks. Meanwhile, distillation curve of chlorine showed various patterns without having any relation to chlorine content of the rocks, and indicated that chlorine was retained more in basic rocks than in acidic rocks at higher temperatures, although no relation was observed between the chlorine content of the rocks and the characteristics of the rocks. Generally the ratio of distilled fluorine to initial fluorine in rocks is smaller than the ratio of distilled chlorine to initial chlorine in rocks at low temperatures. The results of the distillation experiments suggest that the distillation process of halogens with water vapor controlls the distribution of halogens in volcanic rocks more than does the chemical and mineralogical nature of the rocks.

Fluorine and chlorine contents of volcanic rocks are known to vary in wide range from nearly zero to a few thousand ppm. The cause of the variation is not yet exactly known. Many investigators have attempted to find relationships between the halogen contents and the characteristics of the rocks. The relationship between chlorine and silica in rocks is controversial. According to Goldschmidt,[1] Simonen,[2] Behne[3] and others, chlorine is generally more abundant in acidic rocks than in basic rocks. Kuroda and Sandell,[4] Iwasaki *et al.*[5] Correns[6] and others, however, reported no marked association of chlorine with silica in rocks. From the mineralogical point of view, all the fluorine seemed to be fixed in apatite in the case of basaltic rocks.[7] Neverthless, Koritnig,[8] Iwasaki *et al.*[9,10] reported that the concentrations of fluorine and chlorine in rocks could not be explained from their amounts in apatite. Iwasaki and Katsura[11] experimentally concluded that the solubility of hydrogen chloride in volcanic rock melts was reciprocal to the silica content of the melts. The analytical results in Miyakejima leva flow, however, were inconsistent with the experiments mentioned above[12]; that is, the

chlorine concentration in the lava flow is generally higher in acidic rocks than in basic rocks. According to Yoshida *et al.*,[13] the variation in halogen contents of rocks placed in volcanic gases containing much halogens is independent of rock types. Anyway, essential factor affecting halogen contents of volcanic rocks is not decided so far.

Possible factors controlling halogen contents of volcanic rocks may be roughly classified into two groups. One group consists of factors concerning the characteristics of rocks, such as chemical, physical and petrological nature of rocks. The other comprises physico-chemical conditions of environments during or after the formation of rocks.

In the present research, it is aimed to make clear experimentally whether or not the former, the characteristics of the rocks, actually affect the halogen contents of rocks, even in the case where water vapor contained in magma emanates from rocks during or after the formation of rocks. First of all in this study, the distribution of fluorine and chlorine in rocks has been examined with relation to the characteristics of the rocks, such as magma types, rock types, solidification index of rocks and so on. The distribution of halogens in rocks was, thereby, supposed to be more affected by water vapor than the characteristics of the rocks. So, to ascertain the role of water vapor in the distribution of halogens in rocks, the author has heated the rocks in the presence of water vapor at temperatures from 100 to 900°C, and examined the mutual relationships among the amounts of halogens distilled from the rocks with water vapor at elevated temperatures and their concentrations in the rocks and the characteristics of the rocks. For this study, a systematic investigation has necessarily been made for series of rocks differentiated from the same magma; alkaline rocks collected at Okinoshima, Ehime Prefecture, hypersthenic and pigeonitic rocks sampled at Hakone, Kanagawa Prefecture and Oshima, Tokyo Metropolitan, which were already studied chemically and petrologically by Uchimizu[14] and Kuno.*2

Nagashima[15] reported that fluorine was more enriched in hypersthenic rocks than in pigeonitic rocks. Kokubu,[16] on the contrary, mentioned that there is no marked difference in fluorine content of rocks between them. The ranges of fluorine content*3 of rocks studied in the present study were from 40 to 200 ppm for pigeonitic rocks, from 150 to 240 ppm for hypersthenic rocks and from 70 to 980 ppm for alkaline rocks. From these figures, it may be concluded that there is no significant difference in fluorine content between pigeonitic rocks and hypersthenic rocks. Meanwhile, most alkaline rocks contain far much amount of fluorine as compared with other rocks. Chlorine content*4 ranges from 30 to 170 ppm in pigeonitic rocks, from 70 to 180 ppm in hypersthenic rocks and from 10 to 380 ppm in alkaline rocks. The value of 380 ppm chlorine in an alkaline rock is exceedingly larger than the values in other alkaline rocks, and most of the chlorine in this specimen is in water-soluble state. Excluding this value, the range of chlorine in alkaline rocks is from 10 to 175 ppm, which is nearly the same as those in rocks of other types. Although fluorine and chlorine are volatile constituents in rock melts and are expected to behave similarly, no relationship is observed between fluorine and chlorine contents, as shown in Table 1. They are also independent of the values of (+) H_2O and (−) H_2O in rocks. As mentioned above, some authors have claimed that fluorine and chlorine are generally concentrated in acidic rocks rather than in basic rocks. The total chlorine analyzed here, however, has no relation to silica content for any

magma type. Meanwhile, fluorine content generally increases with increasing silica in both pigeonitic and hypersthenic rocks; but the trend is reverse in alkaline rocks; namely, fluorine obviously decreases with increasing silica.

Kogaruko and Gulyayeva[17] reported that alkaline elements in rocks make it difficult for halogens to diffuse from rocks. As shown in Fig. 1, the relation between alkali (Na and K) and chlorine

is not clear for any magma type: On the other hand, fluorine increases with the concentration of the alkaline elements in pigeonitic and hypersthenic rocks, and decreases in alkaline rocks, just like the relationship between fluorine and silica in rocks.

Fluorite is the most stable among simple fluorine compounds and is often found in volcanic rocks. A positive relationship between fluorine and calcium contents, however, is observed only in alkaline rocks.

Mica, amphibole and apatite are generally

considered to be important halogen containing minerals in volcanic rocks. Halogens are easily incorporated in their crystal lattices. Unfortunately, the amount of these minerals in the samples used here were not quantitatively measured except for the calculation of normative apatite. The fluorine and chlorine contents were plotted against the phosphate content of rocks in Fig. 2. A line drawn in the figure shows the relationship between fluorine content and the amount of apatite, assuming that all of phosphate exists as apatite. The relationship between apatite and fluorine is not generally observed, although the relation seemingly exists in pigeonitic rocks. Moreover, no correlation is seen between the amount of apatite and chlorine in rocks. Although the halogen contents of mica and amphibole were not determined

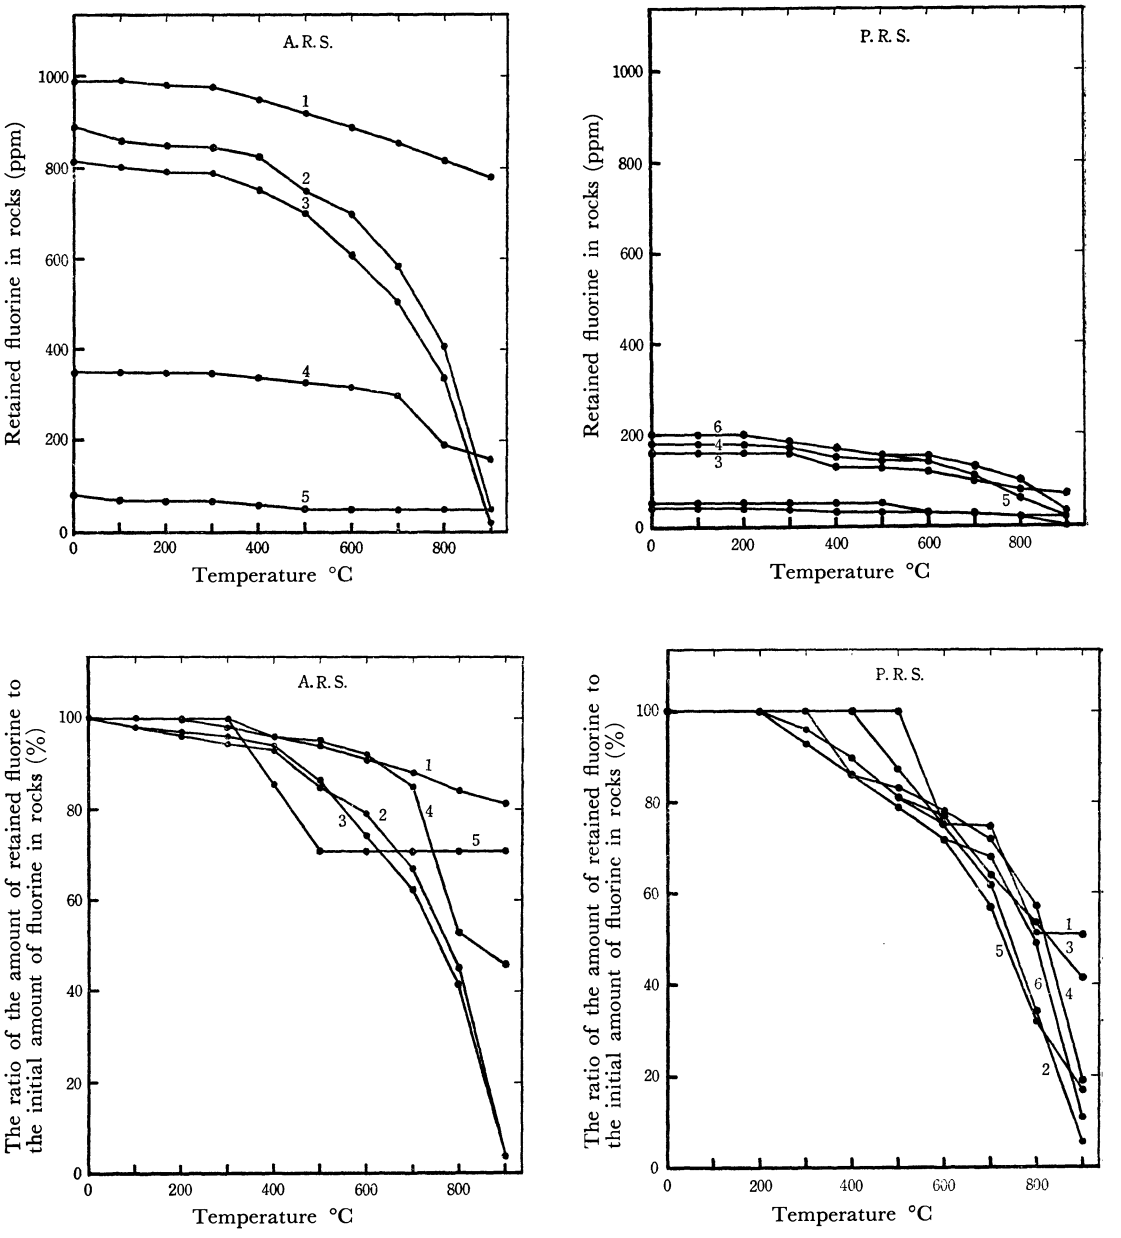

Fig. 5. The relationship between the retained fluorine and

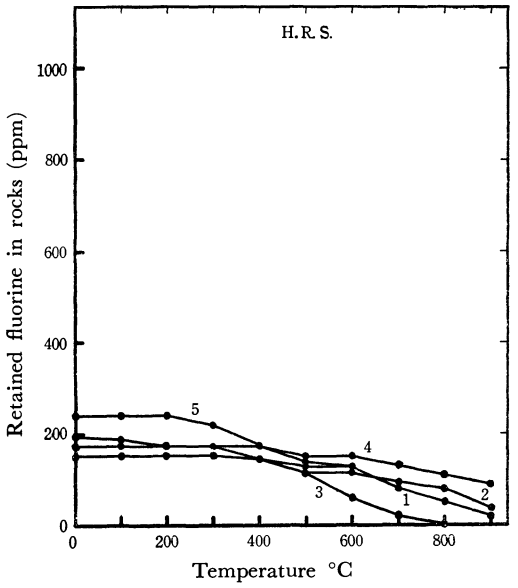

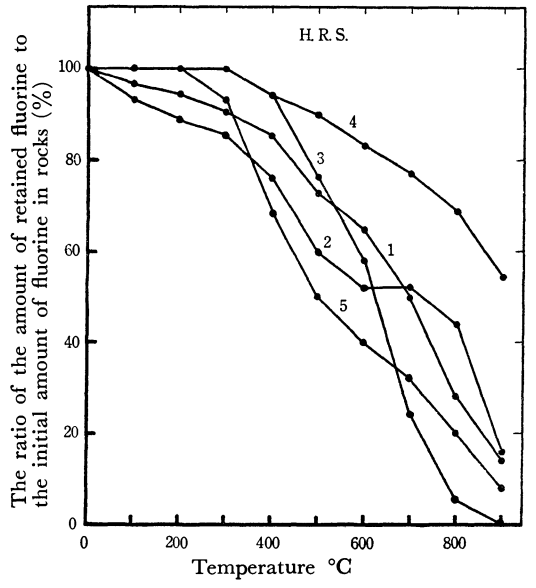

the distillation temperature.

in this study, chlorine in mica is considered to be a small portion of the total amount of chlorine in the rocks.[10]

As to a series of rocks differentiated from the same magma, Greenland and Lovering[18] reported that chlorine is generally more concentrated in differentiates of the later stage than in the earlier one. Figure 3 shows the variations of fluorine and chlorine in each stages expressed in terms of the solidification index given by Kuno *et al.*[19] No regularity is seen for chlorine variation. Fluorine is apparently enriched in later stage pigeonitic and hypersthenic rocks; on the contrary, it decreases in later stage alkaline rocks.

Thus, the variations of fluorine in alkaline rocks are always entirely different from those in other rocks: From the petrological point of view, alkaline rocks are clearly distinguished from others; nevertheless, any petrological evidence for the difference in fluorine content is not found.

From the above results concerning the relationship between the halogen contents of rocks and the chemical, mineralogical and petrological nature of the rocks, it is safely said that halogen contents of rocks are not decidedly controlled by the nature of the rocks considered above. The author considered that halogen contents of rocks would be controlled by water vapor rather than by the characteristics of the rocks. Water is ubiquitous in magma and evaporates from rocks reacting with rocks during or after the formation of the rocks. So, he made following experiments to find out the role of water vapor in the distribution of halogens in volcanic rocks.

Experimental

One gram of a rock sample ground finer than 200 mesh is placed in a boat of silica-glass (I), whch is put into a silica-glass-tubing (G) as shown in Fig. 4. Distilled water is heated to boiling in a distillation vessel (C). A mixture of water vapor from the vessel (C) and nitrogen gas, which is bubbled into the vessel (C) from tank (A) at a flow rate of 30 *l*/hr, is passed through the silica-glass-tubing heated in a furnace (F) at fixed temperatures. The distillate is collected in an absorption vessel (J) containing 5 m*l* of 1 N NaOH solution. About 50 m*l* is collected at each temperature. Fluorine and chlorine in distillates are determined by the methods mentioned above. Reproducibility of the determination is presented in Table 2.

Results and Discussion

Before a rock sample was tested, the possibility of distillation of halogens with water vapor had

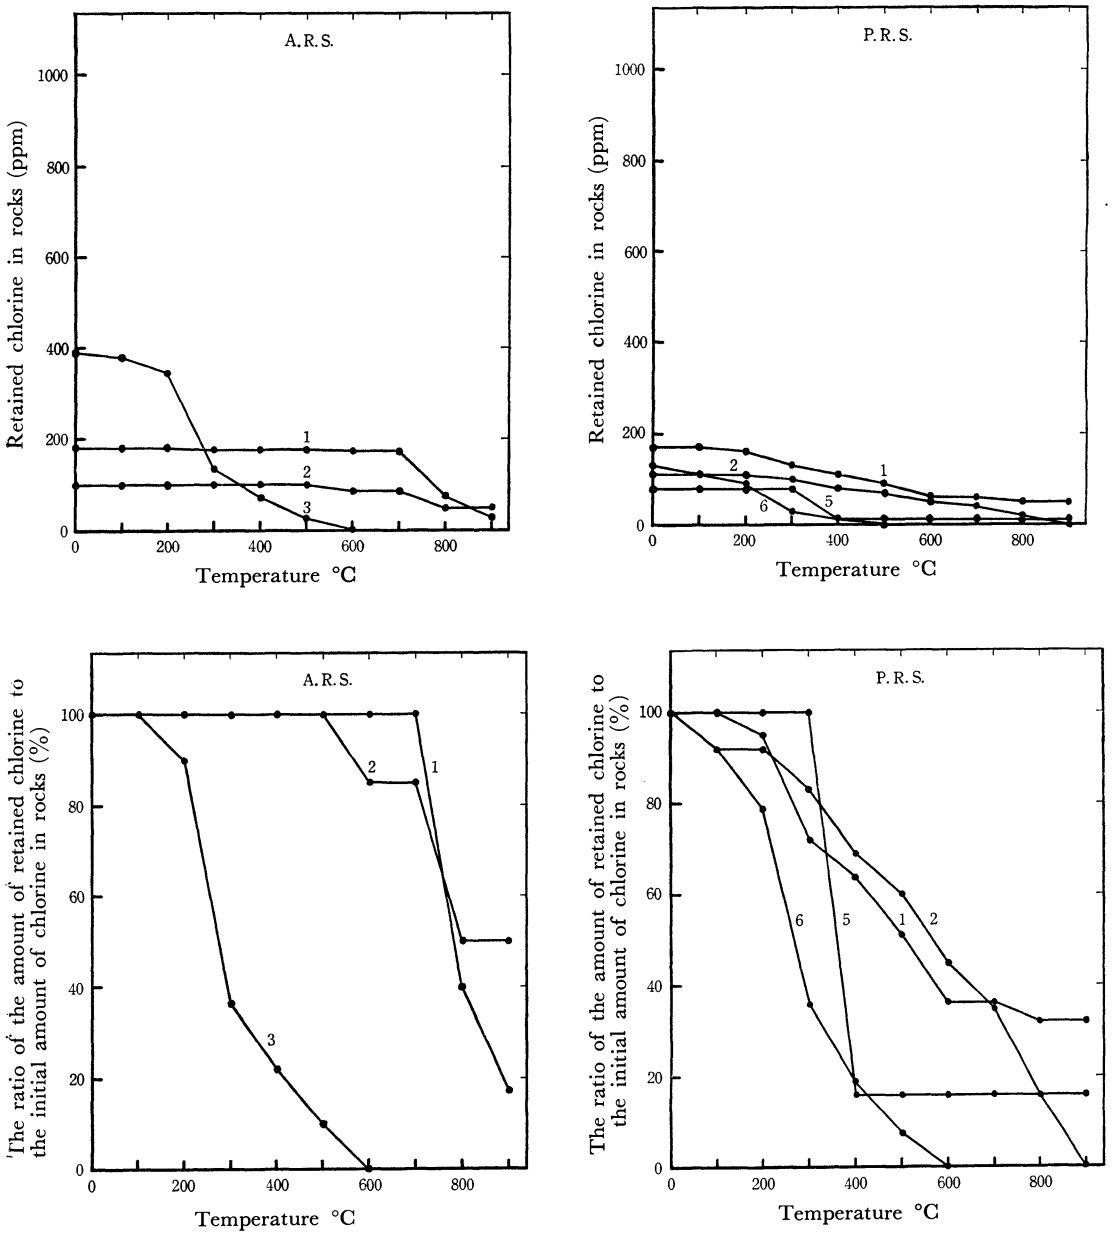

Fig. 6. The relationship between the retained chlorine and

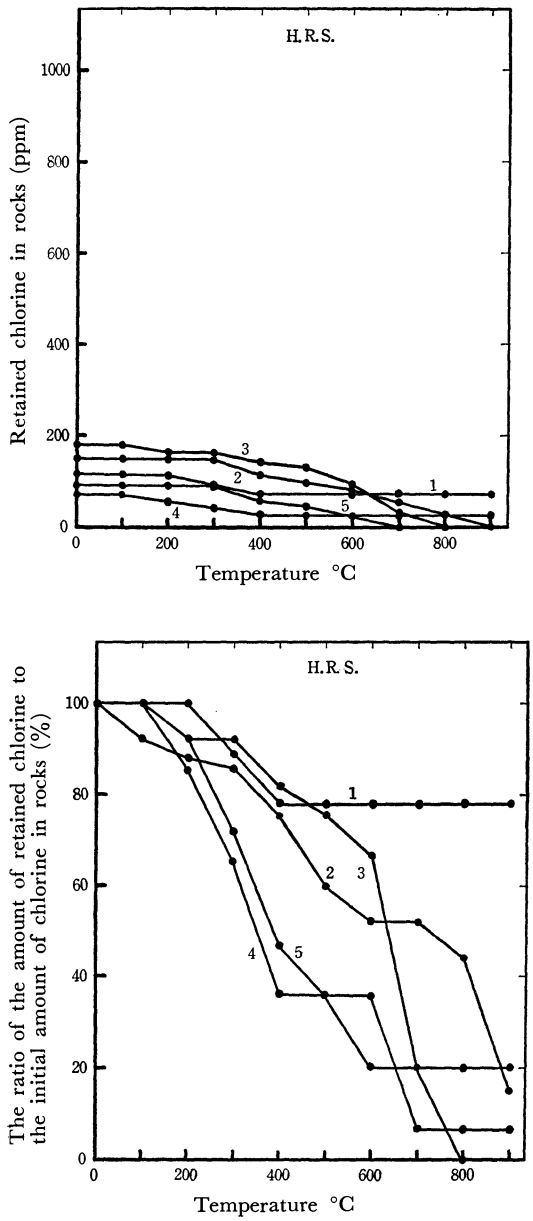

distillation temperature.

been verified for simple compounds containing fluorine or chlorine.

Different patterns of distillation were observed for various compounds containing halogens, as given in Table 3. The initial temperatures at which determinable amount of halogens appeared in distillate were 300°C, 400°C and 600°C for potassium halogenides, calcium halogenides and biotite, respectively. From a mixture of potassium fluoride and potassium chloride, fluorine was more easily distilled than chlorine; in the other materials, the relation was reverse.

The experimental results for rock samples are as follows. The amounts of residual fluorine in rocks at various distillation temperatures are graphically shown in Fig. 5. Almost all fluorine remained in each rock specimen at low temperatures below 300°C, and the lowest temperature at which detectable amount of fluorine appeared was around 400°C. The ratio of the amount of retained fluorine to the initial amount of fluorine in rocks fluctuated among specimens in the temperature range above 700°C. About 70% of fluorine in H. R. S. 1, H. R. S. 3 and H. S. R. 5 was distilled up to 800°C, while most fluorine in A. R. S. 1, A. R. S. 4 and H. R. S. 4 remained in rocks at the temperature. There seemed to be no relation between the pattern of fluorine distillation and rock types. The difficulty of the fluorine distillation was in the order of A. R. S. 1 > A. S. R. 4 > A. R. S. 2 ≈ A. R. S. 3 for alkaline rocks and H. R. S. 4 > H. R. S. 1 ≈ H. R. S. 2 > H. R. S. 3 ≈ H. R. S. 5 for hypersthenic rocks, and is not related to silica content of rocks. The smaller the specimen-number, the more basic the rock. The order of the difficulty of distillation was not clearly observed in pigeonitic rocks. The distillation pattern of fluorine was not related to the fluorine content even in rocks differentiated from a given magma; that is, the order of fluorine content in alkaline rocks was A. R. S. 1 > A. R. S. 2 > A. R. S. 3 > A. R. S. 4, and the difficulty of the fluorine distillation was in the order of A. R. S. 1 > A. R. S. 4 > A. R. S. 2 ≈ A. R. S. 3. The distillation pattern in alkaline rocks containing much fluorine was not essentially different from the patterns in pigeonitic and hypersthenic rocks with low concentration of fluorine.

On the other hand, the distillation pattern of chlorine considerably varied according to specimens as shown in Fig. 6. Chlorine in some specimens was mostly distilled in a lower temperature range, and in some others chlorine was gradually distilled in a higher temperature range. Water-soluble chlorine was naturally expected to be distilled at relatively low temperatures. Nevertheless, there was not a distinct relationship between distillation patterns and the amount of water-soluble chlorine. For instance, A. R. S. 3 contains 295 μg of water-soluble chlorine in one gram of the rock

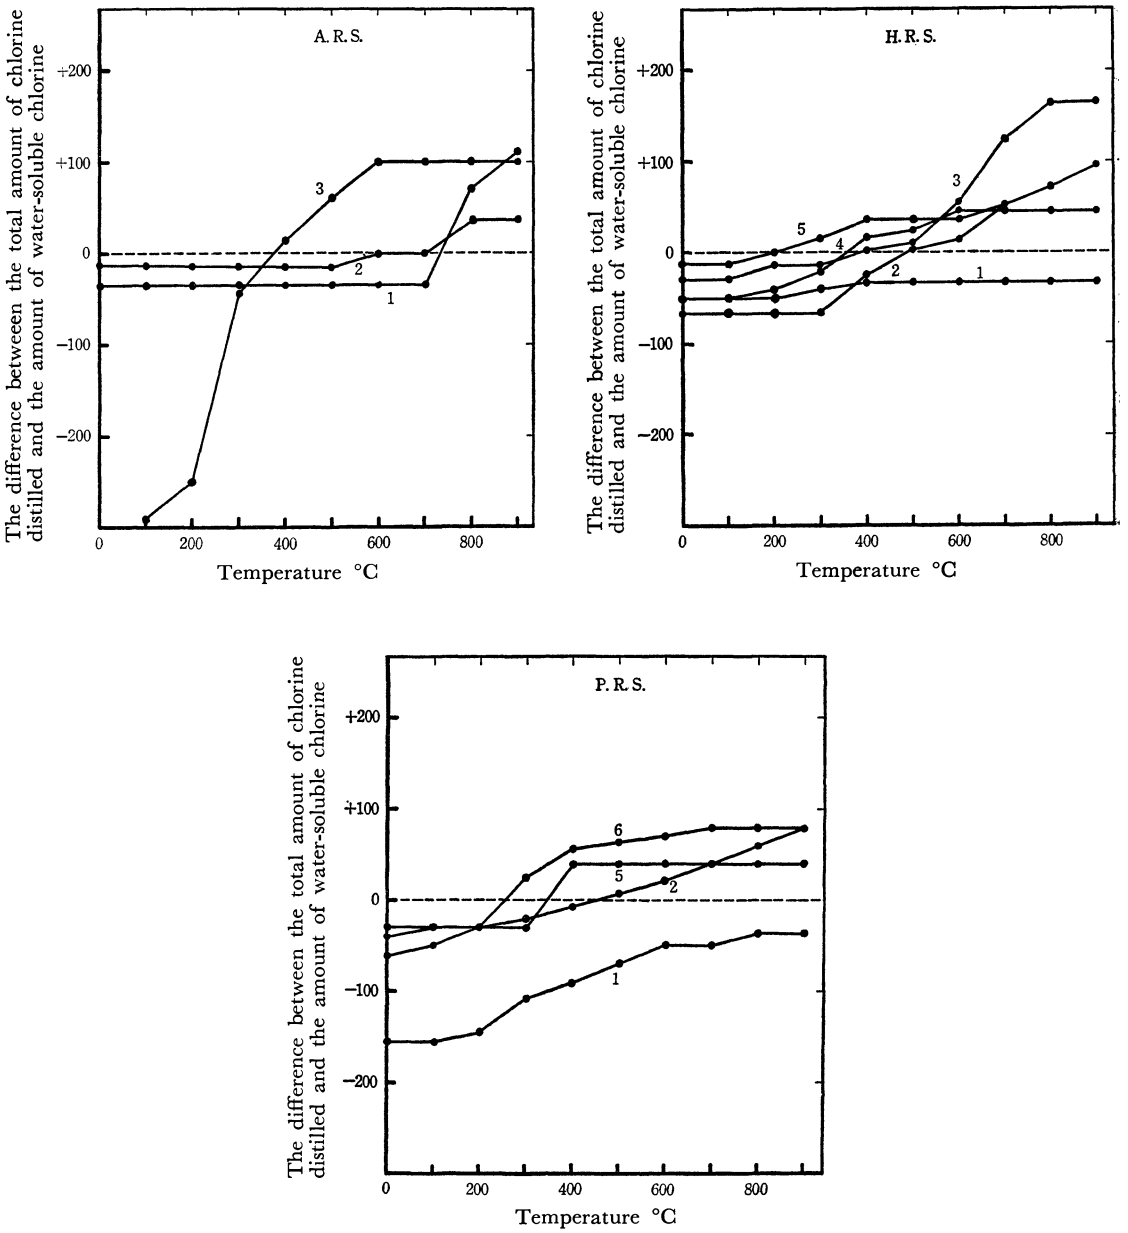

Fig. 7. The difference between the total amount of chlorine distilled and the amount of water-soluble chlorine.

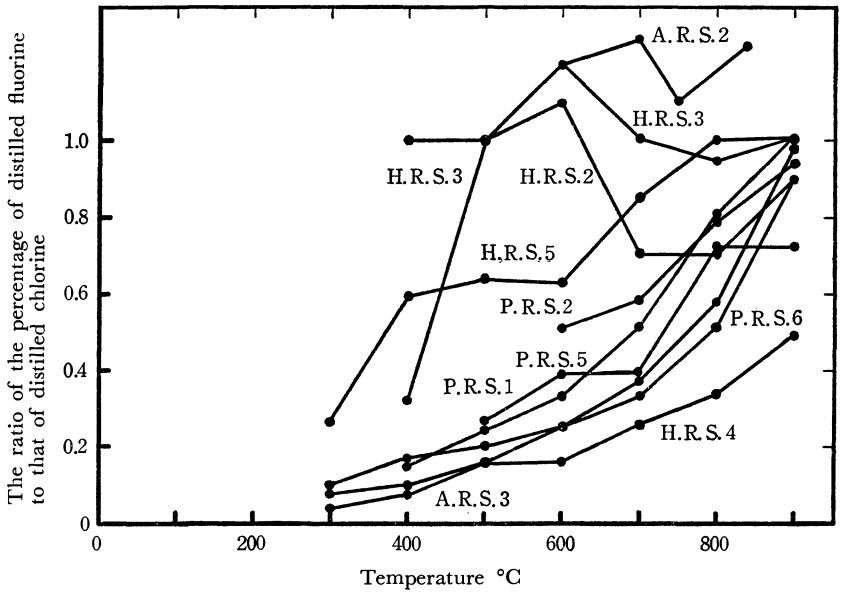

Fig. 8. The ratio of the percentage of distilled fluorine to that of distilled chlorine.

and the amount of chlorine distilled up to 400°C was 305 μg; similarly, from P. R. S. 6 with 60 μg of water-soluble chlorine, 90 μg was distilled, and from H. R. S. 5 with 50 μg, 65 μg was distilled. On the contrary, from P. R. S. 1 with 155 μg of water-soluble chlorine, only 61 μg was distilled up to 400°C; in H. R. S. 1, water-soluble chlorine was 50 μg and distilled chlorine was 20 μg.

The amount of chlorine distilled at temperatures above 500°C and the amount of chlorine remained at 900°C are listed in Table 4. These experiments show that chlorine distilled only at high temperatures and/or remained in rocks at 900°C obviously exists in basic rocks and does not exist in acidic rocks.

The difference between the total amount of chlorine distilled and the amount of water-soluble chlorine was plotted against distillation temperatures as shown in Fig. 7. Negative values in the figure indicate water-soluble chlorine which remains undistilled; the number of the line in the figure corresponds to the order of silica content of rocks. These results suggest that chlorine in basic rocks is generally more resistant to water vapor than in acidic rocks. Although this fact can not be explained reasonably, the chemical nature of rocks might be responsible for this result because it coincides with the experimental result of the chlorine solubility in rock melts reported by Iwasaki *et al.*[11]

The ratio of the distilled percentage of fluorine to that of chlorine at various temperatures is graphically shown in Fig. 8: Generally chlorine is distilled more easily than fluorine at low temperatures. The different behaviors of these elements in water vapor are very important for consideration of fluorine and chlorine contents of volcanic rocks. If rocks are placed in water vapor at a high temperature for a long time, both fluorine and chlorine would diffuse out from rocks at an approximately same rate, but at a low temperature, about 300°C, chlorine would diffuse out from rocks more rapidly than fluorine.

This experimental result also could have a geochemical significance to the origin of halogens in volcanic gases; the halogens in volcanic rocks are easily distilled with water vapor and the ratio of fluorine to chlorine increases with temperature. On the other hand, the ratio of fluorine to chlorine in volcanic gases from some volcanoes is known to be smaller for low temperature fumaroles and larger for high temperature fumaroles.[22,23]

Summary and Conclusion

There have been various interpretations on the effect of the characteristics of rocks on the abundance of fluorine and chlorine in volcanic rocks. This study has revealed that the chlorine content of rocks does not show any relation to the characteristics of rocks of any magma type, and fluorine content decreases in later stage of magmatic differentiation for alkaline rocks and slightly increases for pigeonitic and hypersthenic rocks. Meanwhile, when fluorine in rocks was distilled with water vapor, the pattern of distilled fluorine fluctuated considerably. The pattern, however, seemed to depend on neither the characteristics of the rocks nor fluorine content of rocks.

22) Y. Mizutani, *J. Earth Sci. Nagoya Univ.*, **10**, 125 (1962).
23) T. Sugiura, Y. Mizutani and S. Oana, *ibid.*, **11**, 272 (1963).

Accordingly, fluorine content of rocks can not be explained by the difference in chemical and mineralogical characteristics of rocks, but should be explained by the cooling histry of magma during the formation of rocks.

Chlorine is often reported to be concentrated rather in acidic rocks than in basic rocks. The present study, however, shows that chlorine concontent is independent of rock types. In the experiments, chlorine in basic rocks is more stable than in acidic rocks. From these evidences, it can be concluded that chlorine content of rocks is also controlled mainly by environmental conditions even if the characteristics of rocks might affect the behavior of chlorine in rocks.

In natural environments, water is much emanated from magma during its cooling, and probably carries out halogens with it as shown in the present experiments. The distillation process can be essentially responsible for halogen contents of rocks.

The distillation experiment with water vapor described here is important in considering the origin of halogens in volcanic gases. In order to study the behavior of halogens in volcanic emanation, Yoshida *et al.*[24,25] analyzed halogen compounds driven from rocks heated in nitrogen gas without water vapor. However, water plays essentially an important role in magmatic emanation. Accordingly, the present experiment with water vapor reproduces more closely natural conditions.

The author wishes to express his hearty thanks to Prof. S. Oana, Department of Earth Sciences, Nagoya University who gave him guidance throughout this study. He is also indebted to Dr. N. Nakai, Department of Earth Sciences, Nagoya University for his constant and valuable advice. Thanks are due to Dr. R. Sugisaki, Department of Earth Sciences, Nagoya University who gave him many useful suggestions and Dr. H. Kuno, Department of Geology, the University of Tokyo who supplied him with excellent samples.

(Received December 12, 1967)

Selectivity coefficients of various anions *vs.* chloride or nitrate and water uptake at a saturated vapor pressure with polymeric pentamethylene cobalticinium exchanger were calculated from the experimental data and compared with those of anion-exchange resins. The selectivity coefficient sequence was nearly identical with that for quaternary ammonium type anion-exchangers, and the position of hydroxide ion indicated that the cobalticinium type anion-exchanger was a strong base type. Inspection of selectivity coefficients data revealed that strong base anion-exchangers were more selective than weak base anion-exchangers. The cobalticinium type anion-exchanger was found to have a high selectivity coefficient of iodide *vs.* bromide, even in comparison with strong base anion-exchange resins. Column separation of bromide and iodide using the cobalticinium type anion-exchanger was easily accomplished. The separation factor was three times that of the quaternary ammonium type anion-exchanger. The water uptake at a saturation vapor pressure by the cobalticinium type anion-exchanger in a given form increased with decreasing selectivity coefficient for the same anion. These trends were similar to those for quaternary ammonium type anion-exchanger. The relation between selectivity coefficient sequence of various anions *vs.* a common anion, and solubilities of the salt whose cation was the ionogenic group and anion adsorbed ion was discussed.

One of the weakest points of quaternary base anion-exchange resins is their instability toward heat. In order to exploit possible thermostable anion-exchangers, we synthesized polymeric olygo-

methylene cobalticinium anion-exchangers and investigated their properties (stability toward reagents and heat).[1]

In this paper, the ion-exchange properties of the anion-exchanger are investigated and compared with those of anion-exchange resins.

Experimental

Preparations and Conditionings of Anion-exchangers. The method of synthesis and procedure for conditioning cobalticinium type anion-exchanger were identical with those of a previous paper.[1] Among the series of olygomethylene compounds, pentamethylene compounds (Cl form) were used, being most stable against reagents. Anion-exchange resins (Dowex 1 X-1, Dowex 1 X-8, Amberlite IR-45 and Amberlite IR-4B) were obtained commercially and conditioned in the same manner. Anion-exchangers were converted to the desired salt forms with column operations.

Measurement of Selectivity Coefficients and Distribution Coefficients. The selectivity coefficient K_c is defined in the system of ion-exchange toward uni-valent ions as follows:

$$K_c = K_B^A = \left(\frac{m_A}{m_B}\right)_r \Big/ \left(\frac{m_A}{m_B}\right)_w$$

where K_B^A is the selectivity coefficient in the case of the displacement of anion B in the exchanger by anion A in the solution, r refers to the concentration of anion in the exchanger phase and ω the concentration of anion in the solution phase. The mole fraction of a particular anionic state of the exchanger is designated $X_A^B(=(m_A/(m_A+m_B))_r)$.

Selectivity coefficients were determined by the batch equilibrium method at 25.00±0.01°C using 0.250 g of exchanger. After shaking for 24 hr, concentrations of halogenide ions in the solution were determined with the potentiometric titration method using a solution of 0.1 N silver nitrate and a silver electrode. The anion-exchange systems were arranged in such a way that selectivity coefficients could be obtained by determining the concentration of halogenide ions. Other ions could be calculated by subtracting the amount of halogenide ions from the total amount of anion-exchange capacity.

The distribution coefficient of solute A (a trace constituent) is defined as the total amount of solute A per gram of dry exchanger divided by the total amount of solute A in one milliliter of external solution. Distribution coefficients for perchlorate, thiocyanate, iodide, bromide and chloride ions (trace constituents) against hydroxide ion were measured by the batch method at room temperature. The concentration of trace constituents was 10^{-3} M and that of hydroxide varied from 0.04 M to 2 M. Column operation was used for iodate, bromate, chloride, bromide and iodide ions against nitrate ion, and for iodide and thiocyanate ions against perchlorate ion. Distribution coefficients were calculated according to the following formula for column operation:[2]

$$V = I + mK_d$$

where V is the peak elution volume (ml), I the void space of the column (ml), m the mass of the dry exchanger (g) and K_d the distribution coefficient (ml/g). Determination of micro-amounts of anions was carried out by the colorimetric method[3] after a large excess of hydroxide ion was removed with Dowex 50W (H form) columns.

Measurements of the Amount of Water Adsorbed on the Cobalticinium Type Anion-exchanger in Various Anion Forms. After the cobalticinium type anion-exchanger in various forms were dried over silica gel to constant weight, they were equilibrated with saturated water vapor at room temperature. Then the amount of water adsorbed was calculated.

Solubilities of Cobalticinium and Tetramethylammonium Salts. Cobalticinium salts were obtained by converting the picrate into the desired salt form with Amberlite IRA-410 columns. Tetramethylammonium halogenides were obtained commercially. The halogenate was obtained by converting the chloride in the same manner as cobalticinium salts. The solubility was measured at 0°C and halogenide ions were determined by potentiometric titration with 0.1 N silver nitrate solution using a silver electrode. Halogenate ions were determined as chloride ion after converting them to chloride with Amberlite IRA-410 columns (Cl form).

Results and Discussion

Selectivity coefficients obtained are shown in Table 1. The selectivity coefficient sequence for the cobalticinium type anion-exchanger resembles that for strong base type anion-exchange resins,[4-6] particularly with respect to the position of hydroxide

Table 1. Selectivity coefficients of various anions *vs.* bromide with polymeric pentamethylene cobalticinium exchanger

Ion	X_A^{Br}	K_{Br}^A
BF_4^-	0.987	9.67
NO_3^-	0.926	1.45
Benzoate	0.925	1.44

ion. This fact indicates that cobalticinium type anion-exchanger is a strong base type, which is consistent with an observation that cobalticinium cations form a strong base.[7]

Respective selectivity coefficients on the polymeric pentamethylene cobalticinium exchanger, Dowex 1 X-1, Dowex 1 X-8, Amberlite IR-45 and Amberlite IR-4B are given in Figs. 1 to 5. Great differences in selectivity coefficients with strong base anion-exchangers (cobalticinium, Dowex 1) compared with those with weak base anion-exchangers (Amberlite IR-45 and Amberlite IR-4B) suggest that strong base anion-exchangers are more selective than weak base anion-exchangers. As regards selectivity coefficients for halide ions, cobalticinium type anion-exchanger is more selective than Dowex 1, particularly with respect to the difference between bromide ion and iodide ion. Figure 6 also indicates there is a large difference between bromide and iodide ion in the distribution coefficient, and ion-exchange ideality*1 is evidenced by straight lines with negative unit slopes. Distribution coefficients for various anions are summarized in Table 2. These values are consistent with the tendency seen in selectivity coefficients. The separation of bromide and iodide ion with a column using cobalticinium ion-exchanger was effected more readily than with

*1 The selectivity coefficient for uni-valent anion-exchange is defined by the equation written in the experimental section. If one of the adsorbed ions (A) is in trace concentration, and if ion-exchange reactions occur ideally, the composition of the exchanger is essentially independent of the concentration of the adsorbed trace ion. Then the equation simplifies to

$$K_{d(A)} m_{B(w)} = \text{constant}$$

where $K_{d(A)}$ is the distribution coefficient for A and $m_{B(w)}$ the concentration of B in external solution; $m_{B(w)}$ is equal to the concentration of hydroxide ion in this case. According to the equation, a plot of $\log K_{d(A)}$ *vs.* $\log m_{B(w)}$ should be a straight line with a negative unit slope. This relation has been taken to show ion-exchange ideality.[8]

		OH^-	13.44

ion-exchange resins (Fig. 7). The separation factor calculated by dividing the distribution coefficient of iodide ion by that of bromide ion was about 10, from Fig. 7, which agrees well with the value of Table 2, and is three times that of strong base anion-exchangers.[9]

It may be seen from Table 3 that the water uptake at a saturated vapor pressure by cobalticinium type anion-exchanger in various forms increases with decreasing selectivity coefficient of anions *vs.* nitrate or chloride ion. These tendencies are analogous to that of a quaternary ammonium type exchanger.[10] The results can be understood if the selectivity is assumed caused by the difference in the two different anions adsorbed in their affinity to ionogenic groups. One of the most typical theories, suggesting an interaction

between an ionogenic group and a counter ion was proposed by Gregor.[11] He assumed a dissociation equilibrium between ionogenic groups and adsorbed ions as follows;

$$RA \rightleftarrows R^+ + A^-$$
$$RB \rightleftarrows R^+ + B^-$$

where R's refer to the ionogenic group and A and B to adsorbed ions. The dissociation constants for A (D_A) and B (D_B) are given by

$$D_A = \frac{[R^+][A^-]}{[RA]}, \qquad D_B = \frac{[R^+][B^-]}{[RB]}$$

where the brackets refer to the molality of each species. Neglecting strain energy effects, the molality of unpaired ions in the exchanger phase is related to that of these ions in the external solution according to the Donnan equilibrium condition, or $[A^-]_r/[B^-]_r=[A^-]_w/[B^-]_w$, where the *r*'s refer

Volume of fraction: 4.8 ml

to the exchanger phase and w's to the external solution phase. Then the selectivity coefficient of A *vs.* B (K_A^B) can be related to the dissociation constants as follows:

$$K_A^B = \frac{[A^-]_w D_A + [A^-]_w (D_B - D_A)x}{[A^-]_w D_B - [B^-]_w (D_B - D_A)x}$$

where $$x = \frac{-D_A + \sqrt{D_A^2 + 4[A^-]_w D_A + \frac{4D_A^2[B^-]}{D_B}}}{2\left(1 + \frac{[B^-]_w D_A}{[A^-]_w D_B}\right)}$$

and $[A^-]_w$ and $[B^-]_w$ refer to the molality of anions A and B in the external solution phase, respectively. The above equation indicates that the selectivity coefficient of B *vs.* A increases with decreasing D_B/D_A at a given molality of A or B in the external solution phase. Accordingly, the relation between the water uptake and the selectivity coefficient may be interpreted as the hydration of unpaired ions in the exchanger phase, because unpaired ions may adsorb a greater amount of water than paired ions. These relations between the ionogenic group and the adsorbed ion can be compared to those between the solid phase and solution phase of the salt whose cation is the ionogenic group and anion the adsorbed ion. As shown in Table 4, the solubilities of halogenide salts decrease in the order $Cl^- > Br^- > I^-$, while selectivity coefficients of halogenide ions *vs.* common anion increase in the order $Cl^- < Br^- < I^-$. These results may show the validity of the above mentioned prediction. The solubilities of both cobalticinium and tetramethylammonium halogenates, however, decrease in the order $ClO_3^- > BrO_3^- > IO_3^-$, while the selectivity coefficients of halogenate ions *vs.* a common anion decreased in the order $ClO_3^- > BrO_3^- > IO_3^-$. Considering the Coulomb force, it is expected that the affinities to ionogenic groups decrease in the order $ClO_3^- > BrO_3^- > IO_3^-$ if the structures of the ions in water are the same as that in a crystalline state. These opposite tendencies, presumably, suggest some differences in the nature of interaction (*e. g.*, direction or distance) between the anion-exchangers and the corresponding salts in the crystalline state.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1606—1610 (1968)

Short-Lived Nuclides Formed by (γ, n) Reactions with 20 MeV Bremsstrahlung

Yoshinaga OKA, Toyoaki KATO and Akira YAMADERA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received December 25, 1967)

The most prominent (γ, n) reaction products with half-lives from 10 sec to about 1 min formed by irradiation of some 7 elements with 20 MeV bremsstrahlung have been determined in order to study the applicability of these products to photoactivation analyses. Irradiation was carried out for 1 min with 20 MeV bremsstrahlung radiation with a dose rate of 10^7 R/min. The reactions investigated are $^{24}Mg(\gamma, n)^{23}Mg$, $^{76}Ge(\gamma, n)^{75m}Ge$, $^{78}Se(\gamma, n)^{77m}Se$, $^{92}Mo(\gamma, n)^{91m}Mo$, $^{140}Ce(\gamma, n)^{139m}Ce$, $^{142}Nd(\gamma, n)^{141m}Nd$ and $^{159}Tb(\gamma, n)^{158m}Tb$. The yields of these reactions have also been obtained through the absolute measurement of resultant activities. The isomeric yield ratios have been discussed on the basis of the nuclear properties of the residual nuclides. The observed ratios generally favor the isomer whose spin is closer to that of the target nucleus. For the elements studied, the lower limits of detection averaged about 1 μg under present experimental conditions.

As pointed out in previous reports,[1] the use of high-energy gamma-rays in activation analysis sometimes offers several advantages over the neutron activation method with respect to selectivity and specificity. A number of radioactive species with moderate half-lives (longer than 2 min) arising from photonuclear processes on many elements irradiated with 20 MeV bremsstrahlung have been investigated with respect to yield, and the applicability to activation analysis of those elements.[2]

On the other hand, short-lived nuclides can be obtained selectively with a short-irradiation period, suppressing longer-lived components in the gamma-ray spectra of the activated specimen, and can thereby be used as a rapid, sensitive and non-destructive method of analysis of the relevant element. Until recently, these problems have been investigated exclusively by means of thermal neutron activation, and a number of tabulations or catalogs on gamma-ray spectra of (n, γ) reaction products have been compiled by many workers.[3-8]

The purpose of the present report is to determine gamma-ray spectrometrically most important short-lived (γ, n) reaction products with half-lives from 10 sec to about 1 min, formed in the irradiation of some 7 elements with 20 MeV bremsstrahlung, and to discuss the reaction yields on the basis of the nuclear properties of those nuclides.

Experimental

Samples and Irradiation. Irradiation was carried out with bremsstrahlung radiattion, converted from a 20 MeV electron beam[9] generated from the linear electron accelerator of the Japan Atomic Energy Research Institute. The chemical forms of the sample materials used in these experiments were the elements of magnesium, germanium, selenium and molybdenum, and the oxides of cerium, neodymium and terbium. A definite amount of each sample (5—40 mg) was wrapped in thin aluminum foil and made into a small disk of diameter 5 mm and with a thickness of 1 mm.[10] The bremsstrahlung flux was monitored using a thin sheet of gold (10 μ thick, 5 mm dia.) adjacent to the samples. Each sample with gold monitor was encapsulated in a cylindrical aluminum rabbit[11] together with polyethylene foam to hold the sample tightly. The sample in the rabbit was transferred to the irradiation point immediately behind the photon-producing converter[12] by a pneumatic tube. All irradiations were for one minutes.

The dose rate of the bremsstrahlung photons at the target position was determined by the method of activating a manganese specimen as reported previously.[13] It was estimated at 10^7R/min. Following irradiation, the rabbit was brought back by a reversed air stream,

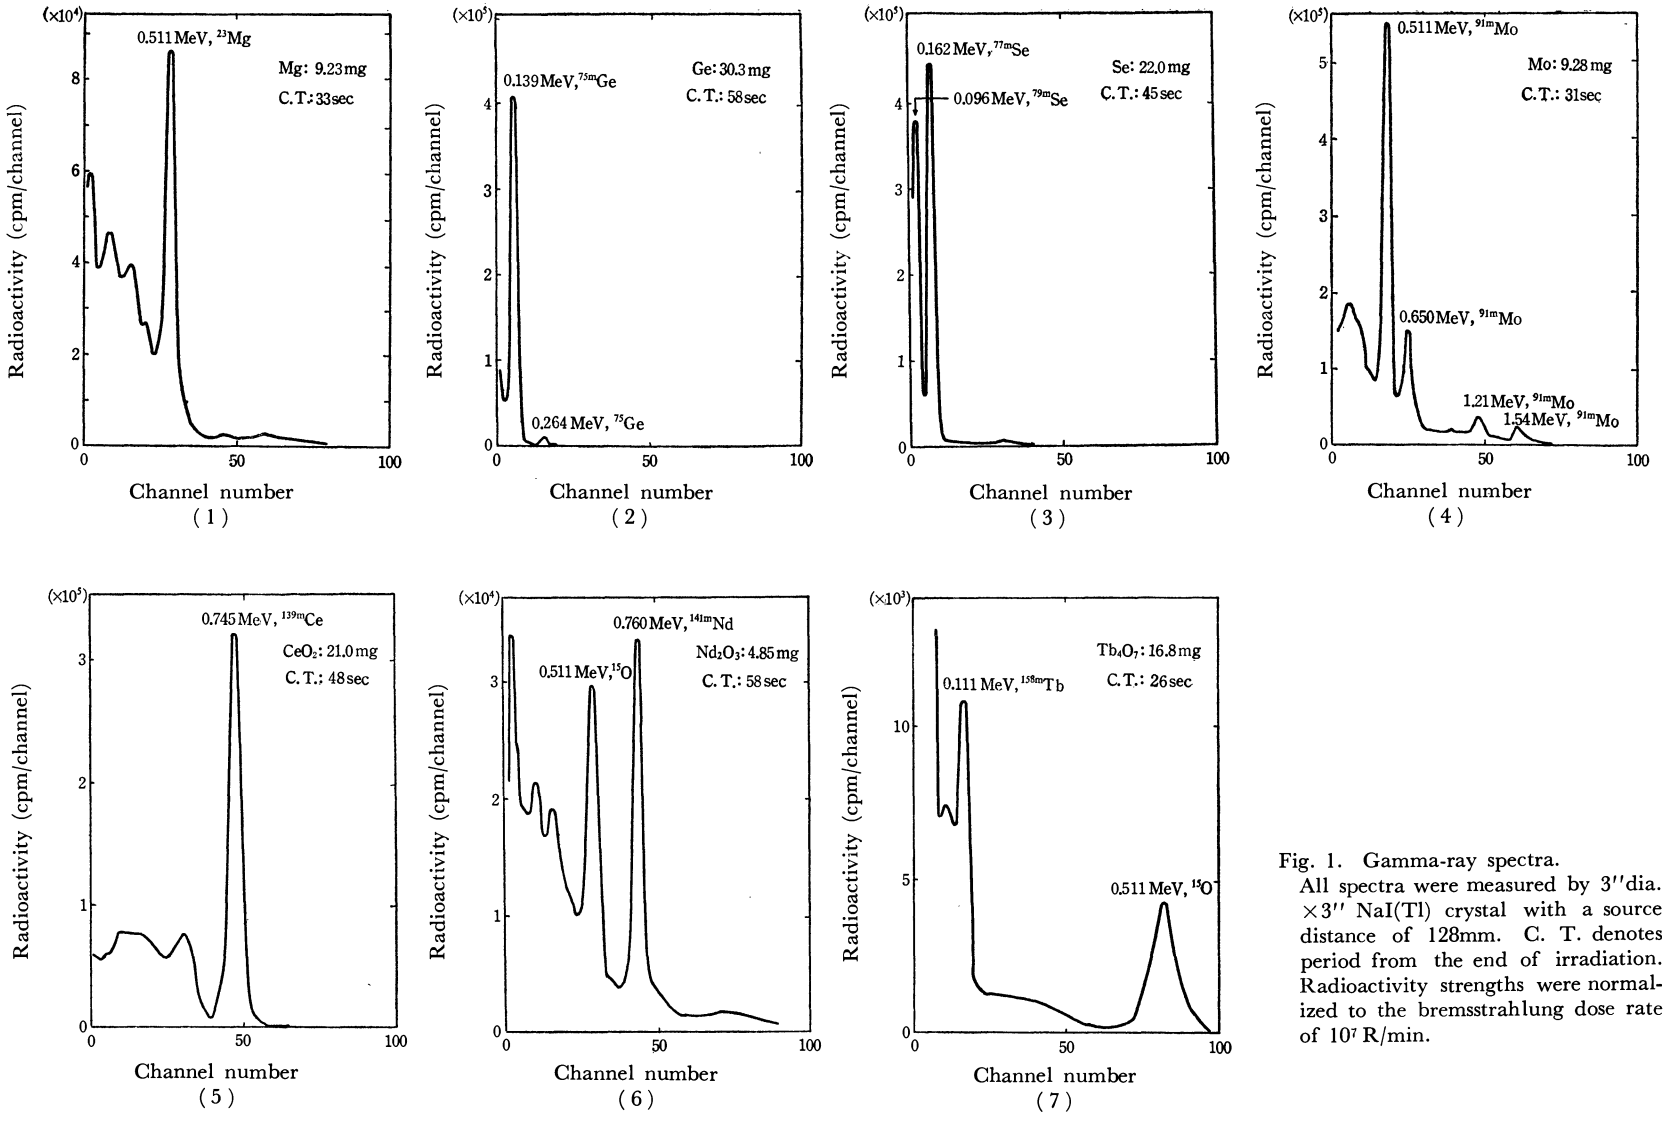

Fig. 1. Gamma-ray spectra.
All spectra were measured by 3″dia. ×3″ NaI(Tl) crystal with a source distance of 128mm. C. T. denotes period from the end of irradiation. Radioactivity strengths were normalized to the bremsstrahlung dose rate of 10^7 R/min.

and the sample disk removed. The travel time of the rabbit was 2 sec.

Radioactivity Measurement. Immediately after the removal of the sample from the rabbit, its gamma-ray spectrum was measured with a 3'' dia. $\times$3'' NaI(Tl) detector coupled to a TMC 400-channel pulse-height analyzer. The memory of the analyzer was subgrouped into 4$\times$100 channels, and a spectrum collected in each subgroup. This method was most efficient for activities with the half-life range from 10 sec to about 1 min.

Data Treatment. The radioactivity of the desired product was evaluated for the spectrum from the gamma-ray photopeak area by drawing a straight line across the bottom of the photopeak and summing up the counts above this line. These data were corrected both for decay during the time of each count and for the dead time of the analyzer. Further normalizations were applied to the activity data for the decay time, the dose rate, sample weight and counting geometry of the detector. Decay curve analyses were performed to separate out the undesired activities.

Nuclide identification was obtained from a knowledge of the target nuclide, the gamma-ray spectra, decay data, and data in the literature for the nuclides.[14,15]

The yield was measured for each (γ, n) reaction through the absolute determination of the resultant radioactivity. To obtain the disintegration rate from the counting rate of the relevant gamma-ray photopeak, appropriate corrections were made for the variation of photopeak efficiency with gamma-ray energy. The decay schemes used were those listed in the Nuclear Data Sheets.[14] The table of internal conversion coefficients[16] was also used.

Results

Induced Radioactivity. As reported earlier,[2] the prominent photoactivation products found in the energy region of 20 MeV bremsstrahlung are those from (γ, n) and (γ, p) reactions. A preliminary experimental investigation of the short-lived photoactivation properties of some 18 elements have indicated the usefulness of the present method for the determination of magnesium, germanium, selenium, molybdenum, cerium, neodymium and terbium.

With these elements, it was possible to let the activities of short-lived products be much larger than those of longer ones produced from irradiation for one minute.[17] The gamma-ray spectra obtained from 7 elements are given in Fig. 1 (1)—(7). Seven nuclides including ^{23}Mg, ^{75m}Ge, ^{77m}Se, ^{91m}Mo, ^{139m}Ce, ^{141m}Nd and ^{158m}Tb were found to be the most prominent species.

Table 1 lists particulars on the products and the data obtained in this experiment. Of the present results, the half-life of ^{23}Mg was determined as 9.9 sec, which is shorter than that listed in the Nuclear Data Sheets (12 sec).[14]

Limit of Detection. The limit of detection was calculated on the basis of the minimum detectable photopeak area. All activity strengths have been expressed in counts per milligram of the element at the end of one-minute irradiation with a counting geometry of 20% using a 3''dia.$\times$3'' NaI(Tl) detector, and have been normalized to a bremsstrahlung dose rate of 10^7 R/min. Because of the short-lives of the products to be determined, the limits of detection were assumed to be the quantities needed to give 1000 cpm under the above condition. These limits of detection are given in the seventh column of Table 1. It is seen that, on the average, these elements can be detected easily down to about 1 μg per sample by the proposed method.

TABLE 1. THE PARTICULARS OF THE (γ,n) REACTION PRODUCTS AND THE DATA OBTAINED WITH 20 MeV BREMSSTRAHLUNG

Nuclide		Half-life of product (sec)	Gamma-ray determined			Limit of detection (μg)	Yield ($mol^{-1}\cdot R^{-1}$)
Parent (Natural abundance, %)	Residual		Energy (MeV)	Branching ratio (%)	Photopeak activity (cpm/mg)[a]		
^{24}Mg(78.60)	^{23}Mg	9.9	0.511	200	2.04×10^6	0.49	8.1×10^4

17) The extraneous activities were due to the reactions, ^{27}Al(γ, n)^{26m}Al (6.6 sec, β^+ emitter) and ^{16}O(γ, n)^{15}O (124 sec, β^+ emitter).

Reaction Yield. The yield ($Y_{(E)}$) was obtained by the absolute measurement of the resultant activity through the following equation.

$$Y_{(E)} = \frac{D_o}{IM(1-e^{-\lambda t})}$$

where D_o is the disintegration rate at the end of irradiation, I the radiation dose rate, M the amount of target nucleus expressed in moles, and λ the decay constant. The data obtained are shown in the last column of Table 1. These values can be taken as the numbers of (γ, n) processes which occurred during the irradiation.

Discussion

It has been pointed out that the photon absorption cross section for a nucleus is an increasing function of Z.[18] In our measurements, through the residual activity method,[19] the yield of radioactive nuclides increases regularly with atomic number from 10^3 to 10^7 orders of magnitude. Of the yields given in Table 1, that for the reaction $^{24}Mg(\gamma, n)^{23}Mg$ is in excellent agreement in absolute magnitude with those expected from the yield curve above. However, the yields for other 6 nuclides, of metastable states, were obtained as $(1—3)\times 10^6$/mol·R, and do not vary significantly with Z values. This implies that the relative yield for the formation of a residual nuclide in its metastable state to that in the ground state should fall for heavier nuclei.

The relative probability of forming each member of a pair of nuclear isomeric states as a result of photonuclear process in the energy region above a giant resonance has been studied by several workers in order to obtain quantitative information about the spin distribution of the excited states.[20-28]

Table 2 shows the results of the isomeric yield ratios obtained for 5 isomeric pairs together with the spins of both the parent nuclei and the residual isomeric states.[29] The isomeric yield ratio has been expressed as a ratio of the yield for the metastable state to the sum of those for both states. Literature values are also included in Table 2.[30]

It has been noted that the formation of both isomeric states follows the steps: formation of the compound state upon electric dipole photon absorption; neutron decay of the compound states to form excited states of the residual nucleus; and gamma-ray cascades from these excited states to the two isomeric levels. In many cases in which an excited state of the residual nucleus can decay to either of the isomers, through intermediate states in gamma-cascades, the gamma-transitions of low multipolarity are accorded preference over those of high multipolarity. Thus the spins of each state of the isomers, as well as the spin differences between states, are the most important factors determining the isomeric yield ratio. Since the absorption of 20 MeV bremsstrahlung by a nucleus can be regarded as $E1$ absorption, the spins of the excited states may not differ remarkably from that of the parent nucleus. The observed ratios generally favor the isomer whose spin is closer to that of

29) The yields for the $^{45}Sc(\gamma, n)$, $^{86}Rb(\gamma, n)$ and $^{90}Zr(\gamma, n)$ reactions are taken from data reported previously.[19]
30) Although experiments were carried out with different excitation energies, there are no significant variations in the observed isomeric yield ratios with change in the bremsstrahlung maximum energy above a giant resonance region.[26]

the target nucleus. The yield of isomers with very high spins, including ^{44m}Sc, ^{75m}Ge, ^{84m}Rb and ^{139m}Ce, as well as ^{77m}Se, ^{141m}Nd and ^{158m}Tb, are found to be low. The result for ^{89}Zr isomers is unusual, and it is planned to investigate the reasons responsible for this behavior in the near future.

For analytical purposes, the lower limit of detection under the present experimental conditions is 1 μg on the average. As discussed above, the yield of short-lived metastable isomers is not as high as expected from the general behavior of the (γ, n) reaction yield curve. In addition, high multipolarity gamma-transitions with large internal conversion coefficients are inherent in the decay of these isomers. Despite these unfavorable properties, the use of short-lived activities in photoactivation analysis should enhance the efficacy of the method because of rapidity, selectivity and specificity.

The Coprecipitation and the Spectrophotometric Determination of Uranium as Dibenzoylmethane Chelate

Tsunenobu SHIGEMATSU, Masayuki TABUSHI, Masakazu MATSUI and Megumu MUNAKATA

Institute for Chemical Research, Kyoto University, Sakyo-ku, Kyoto

(Received December 30, 1967)

The coprecipitation and direct-photometric method was applied to the uranium β-diketonate system; uranyl ion was coprecipitated as dibenzoylmethanate with *o*-phenylphenol and determined spectrophotometrically after the precipitate was dissolved in butyl acetate. The effect of ligand concentration on the per cent coprecipitation-pH curve was studied and the curve was not affected by the ligand concentration in the range from 2×10^{-2} to 4×10^{-4} M. Over the 200 mg of *o*-phenylphenol, an almost quantitative coprecipitation was obtained, though the absorbance slightly decreased with the increase in the coprecipitant amount (about 2% per 1g *o*-phenylphenol). As many diverse ions interfered with the determination of uranium, the solution of calcium-EDTA chelate was used as a masking agent. When a small amount of alkylamine was added, the recovery of uranium became more complete. The effect of alkylamine was probably caused by the adduct formation of uranium chelate with alkylamine.

It has been considered that the coprecipitation of metal chelates with organic compounds is a very attractive problem in the sense of the theoretical treatment[1] and especially of the practical technique. The authors have been much interested in this subject and already reported the coprecipitation of ferric oxinate with some organic compounds and proposed a method for the photometric determination of ferric iron in very dilute solution.[2] The general procedure consists of three steps: Metal ions are allowed to react with a chelating reagent; the metal chelate formed is collected with an adequate organic coprecipitant; and the precipitate separated is then dissolved in a suitable organic solvent, followed by the absorbancy measurements. By this procedure, the metal ion present in much low concentration can be easily concentrated and determined, and the method is suitable, if the chelate-forming reaction is selective to the metal ion to be analysed, or if the absorbance of the metal chelate is not affected by the presence of diverse ions.

In the present research, the coprecipitation and the direct-photometric determination of uranium was investigated by using β-diketone and *o*-phenylphenol (OPP) as a chelating reagent and organic coprecipitant, respectively. Beta-diketones have been widely utilized for the solvent extraction of metal ions,[3] and is recognized to be a very useful reagent for the separation and the photometric determination of uranium, because uranium can

be selectively extracted by masking diverse ions with EDTA-calcium.[4,5] However, most of β-diketones show comparatively high absorption near the absorption maximum of the uranium chelates, and therefore the concentration of the reagent must be kept excactly constant, or the low concentration is desirable. In the coprecipitation method, the almost quantitative recovery was attained even in the low concentration (4×10^{-4} M) of the reagent and when the larger volume of sample solution was handled, the addition of a Lewis base such as *n*-butylamine *etc.* prevented the decrease of the recovery, and accordingly, the determination of uranium was not essentially influenced by the reagent blank. As previously described, OPP is one of the most suitable coprecipitants for such a methal chelate as oxinates.[2]

Experimental

Apparatus. Spectrophotometric measurements were made with a Hitachi Perkin-Elmer 139 UV-VIS spectrophotometer using 1.00 cm transmission cells. A Hitachi-Horiba glass electrode pH meter, model M3 was used for the pH measurements.

Materials. β-Diketones were obtained from the Dozindo Co., Ltd., Research Laboratories. A stock solution of uranium was prepared by dissolving $UO_2(NO_3)_2\cdot6H_2O$ in water; the concentration was determined gravimetrically as U_3O_8. *o*-Phenylphenol (OPP) was purified by the distillation under the pressure of 8—10 mmHg in the nitrogen atmosphere. Butyl acetate was purified by washing with water, followed by distillation. All the other reagents used were the reagent-grade materials and used without further purification.

Procedure. For investigating the effect of various factors, the following procedure was designed: An aliquot of the uranium stock solution, 5 m*l* of 0.2 M EDTA-calcium solution and 1 m*l* of 1 M acetic acid solution are taken in a 100 m*l* Erlenmeyer flask. The solution is diluted to 50 m*l*, and the pH of the solution is adjusted to a desired value with a dilute sodium hydroxide or hydrochloric acid solution. One-half milliliter of a β-diketone-acetone solution ($0.4—8\times10^{-3}$ M) and a suitable amount of *o*-phenylphenol which is previously smashed into fine pieces are added. After shaken with a mechanical shaker, the mixture is filtrated through a glass filter No. 3 and the precipitate is then dissolved in butyl acetate. The organic solution is made clear by filtering through a filter paper, transferred to a 10 m*l* measuring flask and the absorbance is obtained.

Results and Discussion

Because the adding method of the organic coprecipitant in an organic coprecipitation technique is an important factor, its effect on the coprecipitation behavior of uranium was studied by using the uranium-dibenzoylmethane (DBM)-OPP system. The following procedures were examined[4]: (A) OPP, which was freshly precipitated from alkaline solution with an acid, was added to a sample solution. (B) OPP dissolved in an alkaline solution was added to a buffered sample solution. (C) OPP, which was smashed in a mortar, was added to a sample solution. (D) OPP dissolved in acetone was added to a sample solution. As shown in Fig. 1, (A) and (B) were excellent, (C) was fairly effective, but (D) was not so effective. In the subsequent experiment, the procedure (C) was employed, because in the procedure (A) or (B), the pH value of the sample solution must be adjusted again after the addition of OPP. Effect of the concentration of the chelating agent was studied over the range 2×10^{-2} to 4×10^{-4} M, and the per cent coprecipitation-pH curve of uranium is shown in Fig. 2. The curve of uranyl dibenzoylmethanate is not affected by the reagent concentration in the range studied: This indicates that the system is not in a equilibrium state in the concentration over the solubility of DBM. The curve of uranyl thenoyltrifluoroacetone (TTA) complex, on the other hand, shifted to the lower pH value as the TTA concentration was increased. The same tendency was observed in the case of benzoyltrifluoroacetone or benzoylacetone. This difference in the behavior may be caused by the solubility of

β-diketone in water. The curve shifts to lower pH with the increase in the reagent concentration, until it probably arrives at the solubility of the reagent. The phenomenon that uranium acetylacetonate can not be coprecipitated well, may be due to the larger solubility of acetylacetone in comparison with that of other β-diketones. Because the photometric determination of uranium is influenced by the reagent blank (Fig. 3), it is desirable that the amount of the reagent contained in the precipitate is as small as possible. Since β-diketone is coprecipitated together with uranyl β-diketone chelate even when the reagent concentration does not exceed its solubility, the β-diketone which possessed the larger solubility did not always show lower reagent blank than the one which possessed the smaller solubility did. In the proceeding experiments, DBM was used as a chelating reagent, from the consideration described just above and other reasons, that is, uranium could be effectively and almost quantitatively coprecipitated in the relatively low concentration of the reagent, and the extinction coefficient of the uranyl chelate was larger than that of other uranyl β-diketone chelates.

A polar solvent was used for dissolving the precipitate, because the absorbance of uranyl-DBM chelate decreased in the nonpolar solvent (*e. g.*,

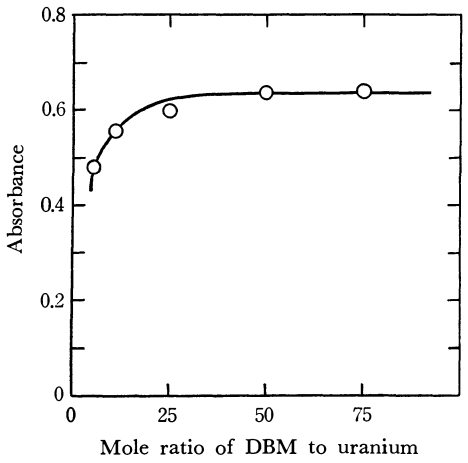

Fig. 4. Effect of reagent concentration.
UO_2^{2+} 4×10^{-5} M, pH 6.0, shaking for 30 min, others are the same as in Fig. 1.

benzene) with the lapse of time.[5] Normal-butyl acetate was an excellent solvent, because of its good separating property from water and of the larger extinction coefficient in comparison with other polar solvents (*e. g.*, *n*-hexyl alcohol, cyclohexanone).

The effect of the mole ratio of DMB to uranium is shown in Fig. 4: The constant absorbance can be obtained when the mole ratio is larger than fifty, while below fifty the absorbance decreases with the decrease of DBM concentration, and this is owing to the incomplete coprecipitation of uranium and to the decomposition of the chelate in the solvent: The decomposition may be caused by OPP.

The effect of the amount of coprecipitant, OPP, is indicated in Fig. 5. The absorbance rapidly diminishes when OPP amount is less than 200 mg. The reason for this low absorbance is attributed to

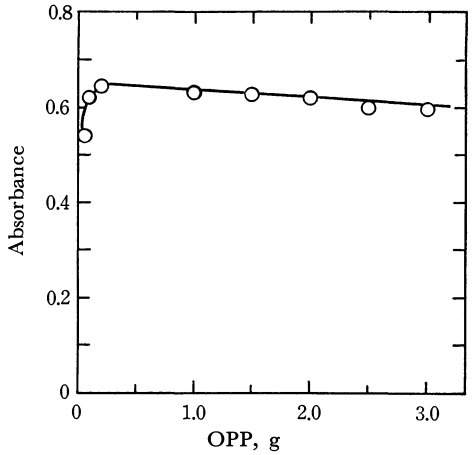

Fig. 5. Effect of coprecipitant, OPP.
UO_2^{2+} 4×10^{-5} M.

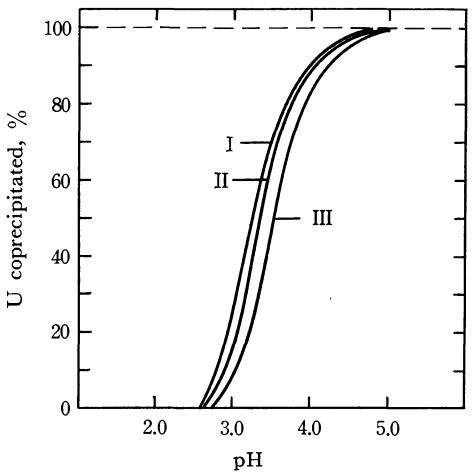

Fig. 6. Effect of OPP amount on per cent coprecipitation *vs.* pH curve.
OPP: I 30 g, II 1 g, III 300 mg

both the loss by the filtration of the precipitate and the decrease in the coprecipitation recovery, because OPP becomes a liquid state in such a small amount. Above 200 mg, the absorbance slightly decreases with the increase in OPP amount (about 2% per 1 g OPP). This unexpected phenomenon is probably resulted from the adduct formation of the chelate with OPP, but not from the coprecipitation yield. Figure 6 indicates the evidence of the adduct formation: The per cent coprecipitation-pH curve shifts somewhat to lower pH as the OPP amount increases, just like in the case of the adduct formation in the solvent extraction of metal chelates.[6]

Determination of uranium may be interfered by many diverse ions, and therefore, an available masking agent must be used. When 5 m*l* of 0.2 M EDTA solution and calcium chloride equivalent to EDTA (0.02 M Ca-EDTA in the final concentration) were added as a masking agent, the per cent coprecipitation-pH curve of uranyl bis-dibenzoylmethane chelate shifts about one pH unit to alkali side, but the extraction coefficient is the same with that obtained in the absence of EDTA in the pH region above 6.0[4] (Fig. 7).

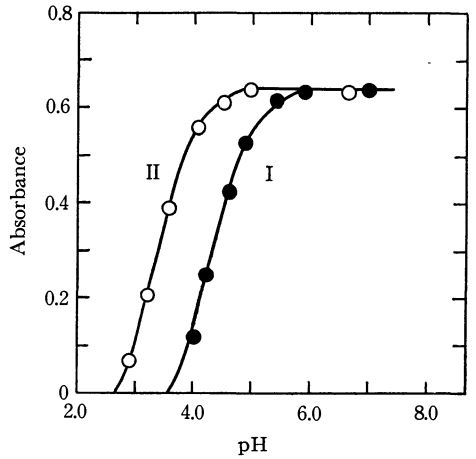

Fig. 7. Effect of masking agent, calcium-EDTA chelate.
I. 0.02 M of Ca-EDTA, II. no masking agent.

From the above experimental results, the conditions for the coprecipitation and the direct-photometric determination of uranium was controlled as follows. The concentration of DBM, acetic acid and EDTA-calcium are 8×10^{-4} M, 0.02 M and 0.02 M, respectively; pH, 6.0; and the volume, about 50 m*l*. One gram of OPP is added and the precipitate was dissolved and diluted to 10 m*l* with butyl acetate.

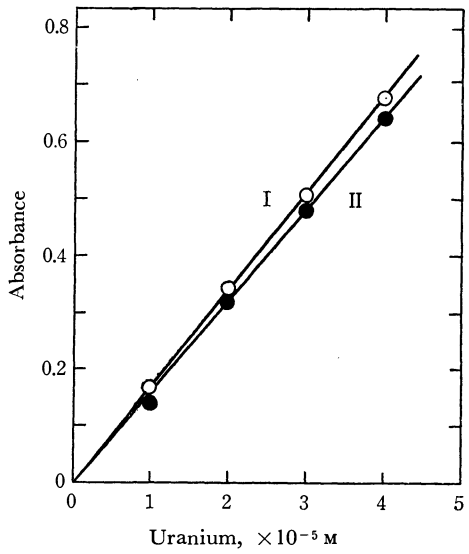

Fig. 8. Calibration curve of uranium.
I. extraction method, II. coprecipitation method

In Fig. 8, calibration curves for uranium are presented. One is obtained by this coprecipitation method and the other is obtained by extracting uranium with 10 m*l* of butyl acetate containing 1 g of OPP, from about 10 m*l* of aqueous solution including 4×10^{-3} M DBM, 0.02 M acetic acid and 0.02 M EDTA-calcium. Beer's law is obeyed up to 10 ppm, and the molar extinction coefficients at 400 mμ are 16100 (this method) and 16800 (liquid-liquid extraction), respectively. This difference may be due to the fact that the coprecipitation recovery of uranium is not precisely quantitative, but about 96 per cent. When a small amount (0.1 m*l*) of *n*-butylamine or *n*-hexylamine was added to the coprecipitation system, the recovery became complete, and two analytical curves quite well agreed. The effect of amines will be described later in this paper.

To investigate the influence of several metal ions, the measurements were made on a solution containing a proper amount of foreign cations with 94 μg of uranium. The results are summarized in Table 1. Aluminum, titanium, silver, tin(IV) and bismuth(III) interfer because of the formation of hydroxide.

Table 1. Influence of diverse ions

	2.0	100.0
Pyridine	0.5	*
Tri-butyl phosphate	0.5	*

* Precipitate became liquid.

Recovery of uranium decreased with the increase in volume of sample solution. Although the element may be quantitatively recovered by rising the DBM amount, then the influence of the reagent blank appears. In order to remove the difficutly, a Lewis base was added to the sample solution. The results are presented in Table 2. Uranium was almost completely recovered from 500 m*l* of sample solution by adding *n*-butylamine or *n*-hexylamine. Pyridine or tri-*n*-butyl phosphate could not be employed, because the precipitate became a liquid state. This effect of Lewis bases on coprecipitation of uranium is probably caused by the adduct formation, and is the same phenomenom as the "synergistic effect" in the solvent extraction of metal chelates.[7-10] By increasing the DBM amount, uranium can be essentially quantitatively collected from larger volume: For example, the use of 4×10^{-5} M DBM and 5 m*l* of *n*-butylamine gave satisfactory yield on 2 *l* of sample.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1615—1618 (1968)

Kinetics of the Aquation of Pentammine Amino Acid Cobalt(III) Complexes

Kazuko OGINO, Tasuku MURAKAMI and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received January 22, 1968)

The rate of aquation of pentamminecobalt(III) complexes of the general formula $[Co(NH_3)_5amH]^{3+}$ (amH stands for an amino acid molecule with proton on the nitrogen atom), containing unidentate glycine, β-alanine, sarcosine and betaine, has been measured at 55°C, and ionic strength 0.1 and 1.0 in the acid concentration range up to 0.5 M. The kinetic term is expressed by

$$\text{Rate} = [\text{complex}](k_{H_2O}+k_{H^+}[H^+])$$

The k_{H_2O} and k_{H^+} values for glycine, β-alanine, sarcosine and betaine complex are respectively as follows (at $\mu=1.0$): k_{H_2O}, 0.40×10^{-6}, $\lesssim0.2\times10^{-6}$, 0.25×10^{-6}, and 0.44×10^{-6} sec^{-1}; k_{H^+}, 2.0×10^{-6}, 26×10^{-6}, 1.8×10^{-5}, and 1.0×10^{-6} M^{-1} sec^{-1}. The k_{H^+} values increase with increase in pK_a values of the amino acids, but are smaller than those for the aquation of carboxylatopentamminecobalt(III) complexes. This difference seems to be due to the electrostatic shielding of the carboxylate group by the protonated amino group.

An amino acid usually coordinates to a metal with its amino and carboxylate group to form a chelate ring. Recently, complexes were also prepared in which the amino acid coordinates as a unidentate ligand only with its carboxylate end, to form pentamminecobalt(III) complex.[1,2] Such a complex is similar to a carboxylatopentamminecobalt(III) complex, in the context that the ligands coordinate to the cobalt(III) ion with the carboxylate end. The reaction kinetics of acid hydrolysis of carboxylatopentamminecobalt(III) complexes was studied by Monacelli, Basolo and Pearson and the mechanism disucssed with special reference to the acid catalysis.[3] It seems interesting to carry out similar kinetic studies with pentammine amino acid cobalt(III) complexes, in which the protonated amino group can be linked with the carboxylate *via* hydrogen bonding. We have measured the rate of acid hydrolysis of the following complexes in aqueous solution,

$$[Co(NH_3)_5amH]^{3+} + H_2O \rightarrow [Co(NH_3)_5H_2O]^{3+} + amH \quad (1)$$

where "am" expresses amino acid anion, and compared the results with those of carboxylatopentammine complexes.

Experimental

Materials. Three complexes of the general formula $[Co(NH_3)_5amH](ClO_4)_3$ were prepared with glycine, β-alanine and betaine as described in the literature[1] and identified by elemental analyses of carbon, hydrogen and nitrogen, and absorption spectra. The sarcosine complex, a new compound, was also prepared by a similar method.

Found: C, 6.97; H, 4.72; N, 15.42; H_2O, 3.46%. Calcd for $[Co(NH_3)_5OOCCH_2NH_2(CH_3)](ClO_4)_3\cdot H_2O$: C, 6.56; H, 4.40; N, 15.32; H_2O, 3.28%.

The ionic strength was adjusted with sodium perchlorate, which was prepared from sodium carbonate and perchloric acid of guaranteed grade. Other reagents were all of guaranteed grade and used without further purification.

Experimental Procedure. A weighed amount of the complex ($\simeq10^{-4}$ mol) was added into an aqueous solution (100 ml) of a given ionic strength (0.1 or 1.0) and acid concentration (0.01—0.5 M) at a given temperature. The complex dissolved rapidly. Aliquots were withdrawn at appropriate intervals, cooled and the absorbances measured, or the amount of liberated amino acid determined with ninhydrin.

Spectrophotometric Method. The progress of reaction was best chased by measuring the change in extinction at 275 mμ, regardless of the kind of coordinated amino acid. The values of ε_{275} for glycine, sarcosine, betaine, β-alanine and aquo complex are 190, 206, 255, 400 and 3.1, respectively. The withdrawn aliquot was placed in a 10 mm quartz cell and the extinction measured at room temperature with a HITACHI EPU-IIA spectrophotometer. The reaction rate was slow enough, so that neither the time taken for the measurement nor the temperature change during the measurement does not affect the result. The pseudo first order rate constant k_{obs} was obtained by plotting

3) F. Monacelli, F. Basolo and R. G. Pearson, *J. Inorg. Nucl. Chem.*, **24**, 1241 (1962).

$\log(\varepsilon-\varepsilon_a)$ *vs. t*, where ε is the apparent molar extinction coefficient of reaction mixture at time t and ε_a that of the aquopentammine complex.

Ninhydrin Method. This method was used only for the glycine complex. Free glycine should be separated from the aquopentammine and the glcyinepentammine complex. A 5 m*l* portion of the reaction mixture was passed through a column (10 mm in diameter, 10 cm in length) of the cation exchanger Amberlite CG-50 (Type 1, H-form) and the column washed with a citrate buffer of pH 5 (total effluent 50 m*l*). The complexes were completely captured by the resin, whereas the free amino acid was quantitatively recovered in the effluent and determined spectrophotometrically at 565 mμ by the Yemm-Cocking's method with ninhydrin.[4] The rate constant k_{obs} is given by plotting $\log(a-x)$ *vs. t*, where a is the initial concentration of the complex and x the concentration of isolated glycine.

Results

The plots of $\log(\varepsilon-\varepsilon_a)$ *vs. t* and $\log(a-x)$ *vs. t* were all linear under the experimental conditions

Table 1. The rate constant at varying initial concentrations of the glycine complex (55°C, $\mu=0.1$, by the ninhydrin method)

a mM	$k_{obs}\times10^6$ sec^{-1}
1.0	0.74
2.0	0.73
3.0	0.73

and the rate constant was independent of the initial concentration of the complex as exemplified in Table 1. Figure 1 shows the relationship between the rate constant k_{obs} and the hydrogen ion concentration for the glycine, the sarcosine, the betaine and the β-alanine complex in aqueous solutions of ionic strength 1.0, and Fig. 2 those for the glycine and the β-alanine complex in solutions of ionic strength 0.1. The results are those obtained by the spectrophotometric method unless otherwise stated. All of these plots are regarded to be linear. Therefore, the observed pseudo first order rate constant k_{obs} can be expressed by Eq. (2), as a linear function of the hydrogen ion concentration.

$$k_{obs} = k_{H_2O} + k_{H^+}[H^+] \quad (2)$$

The uncatalysed rate constant k_{H_2O} and the acid catalysed rate constant k_{H^+} are calculated from the diagrams and shown in Table 2, together with the pK_a values of the amino acids.

It has been known that some pentamminecobalt-(III) complexes tend to liberate ammonia as shown in Eqs. (3) and (4). (X, univalent anion)

$$[CoX(NH_3)_5]^{2+} + H_2O \rightarrow [CoX(NH_3)_4(H_2O)]^{2+} + NH_3 \quad (3)$$

$$[Co(NH_3)_5H_2O]^{3+} + H_2O \rightarrow [Co(NH_3)_4(H_2O)_2]^{3+} + NH_3 \quad (4)$$

The products can further undergo hydrolysis to liberate more ammonia.[5,6] Whenever a spectrophotometric method is used for a slow reaction, contribution of such side reactions should be taken into consideration.

Ammonium ions pass through the exchanger

e) Values at 65°C.
f) Values at 75°C.

column under the given condition and react with ninhydrin to give a similar coloration to that with glycine. Hence the ninhydrin method can easily overestimate the amount of glycine to give apparently greater rate constants. The presence of ammonium ions was confirmed with Nessler's reagent in the reaction mixtures kept at 55°C for more than 50 hr. The rate constant obtained by the ninhydrin method (k_{H_2O}, 0.73×10^{-6} sec^{-1} at 55°C, $\mu=0.1$) is slightly larger than that by the spectrophotometric method (k_{H_2O}, 0.57×10^{-6} sec^{-1}). However the difference is small especially when the rate is calculated from the kinetic data obtained at earlier stages of reaction, as in most cases by the spectrophotometric method. Hence it is quite certain that this method really gives the rate of reaction (1).

TABLE 3. THE ACTIVATION PARAMETERS FOR THE UNCATALYSED AQUATION OF PENTAMMINECOBALT(III) COMPLEXES, AT $\mu=0.1$

Ligand	$\Delta H^{\neq}$ kcal mol^{-1}	$\Delta S^{\neq}$ cal $mol^{-1}\,deg^{-1}$	Ref.
Glycine	29	+1	This work
Acetate	25	−8	3
Trifluoroacetate	26	−2	3

TABLE 4. THE ACTIVATION PARAMETERS FOR AQUATION OF THE GLYCINE COMPLEX, AT $\mu=1.0$

	$\Delta H^{\neq}$ kcal mol^{-1}	$\Delta S^{\neq}$ cal $mol^{-1}\,deg^{-1}$
k_{H_2O}	22	−20
k_{H^+}	29	+ 3

Activation parameters for the glycine complex were obtained by the measurements at 55, 65, and 75°C and ionic strength 0.1 and 1.0. The results are listed in Tables 3 and 4 together with those of related compounds.

Discussion

Equation (2) suggests that two reaction paths are involved in these aquations as exemplified in Eqs. (5) to (7).

$$[(NH_3)_5Co\text{-}O\overset{O}{\overset{\|}{C}}CH_2NH_3]^{3+} + H_2O \xrightarrow{k_{H_2O}} [(NH_3)_5CoH_2O]^{3+} + {}^-OOCCH_2NH_3^+ \quad (5)$$

$$[(NH_3)_5Co\text{-}O\overset{O}{\overset{\|}{C}}CH_2NH_3]^{3+} + H^+ \overset{K}{\rightleftharpoons} [(NH_3)_5Co\text{-}O\overset{H^+O}{\overset{\|}{C}}CH_2NH_3]^{3+} \quad (6)$$

$$[(NH_3)_5Co\text{-}O\overset{H^+O}{\overset{\|}{C}}CH_2NH_3]^{3+} + H_2O \xrightarrow{k'} [(NH_3)_5CoH_2O]^{3+} + {}^-OOCCH_2NH_3^+ + H^+ \quad (7)$$

The reaction (5) is the path independent of the hydrogen ion concentration and its rate constant is k_{H_2O}. The reactions (6) and (7) correspond to the path catalysed by acids and its rate constant k_{H^+} is expressed by Eq. (8).

$$k_{H^+} = k'K \quad (8)$$

Discussion

Equation (2) suggests that two reaction paths are involved in these aquations as exemplified in Eqs. (5) to (7).

$$[(NH_3)_5Co\text{-}O\overset{O}{\overset{\|}{C}}CH_2NH_3]^{3+} + H_2O \xrightarrow{k_{H_2O}} [(NH_3)_5CoH_2O]^{3+} + {}^-OOCCH_2NH_3^+ \quad (5)$$

$$[(NH_3)_5Co\text{-}O\overset{O}{\overset{\|}{C}}CH_2NH_3]^{3+} + H^+ \overset{K}{\rightleftharpoons} [(NH_3)_5Co\text{-}O\overset{H^+O}{\overset{\|}{C}}CH_2NH_3]^{3+} \quad (6)$$

$$[(NH_3)_5Co\text{-}O\overset{H^+O}{\overset{\|}{C}}CH_2NH_3]^{3+} + H_2O \xrightarrow{k'} [(NH_3)_5CoH_2O]^{3+} + {}^-OOCCH_2NH_3^+ + H^+ \quad (7)$$

The reaction (5) is the path independent of the hydrogen ion concentration and its rate constant is k_{H_2O}. The reactions (6) and (7) correspond to the path catalysed by acids and its rate constant k_{H^+} is expressed by Eq. (8).

$$k_{H^+} = k'K \quad (8)$$

The uncatalysed rate constants (k_{H_2O}) tend to decrease slightly with the increase in ionic strength (Table 2), whereas the acid catalysed rate constants (k_{H^+}) are significantly greater in solutions of $\mu=1.0$ than in $\mu=0.1$. The equilibrium constant K between cations such as that expressed by Eq. (6), generally increases with increase in ionic strength. Therefore, the increase in k_{H^+} values with the increase in ionic strength could be ascribed to the increase in K.

Basolo *et al.* reported that the aquations of carboxylatopentamminecobalt(III) complexes, Eq. (9), proceed by similar mechanisms to Eqs. (5) to (7).[3]

$$[Co(NH_3)_5OOCR]^{2+} + H_2O \rightarrow [Co(NH_3)_5H_2O]^{3+} + {}^-OOCR \qquad (9)$$

The rate constants, k_{H_2O} and k_{H^+}, for the acetato and the trifluoroacetato complex are also shown in Table 2 for comparison. The values for the trifluoroacetato complex were obtained by extrapolating their results to 55°C. The aquation of the amino acid complexes is considerably slower than that of the carboxylato complexes. The k_{H_2O} values in solutions of ionic strength 0.1 decrease in the order, trifluoroacetato, acetato, glycine and β-alanine complex. Basolo *et al.* stated that the k_{H_2O} values of carboxylato complexes tend to decrease with increase in pK_a values of the acids. However, the results in Table 2 do not indicate that such a relation fits the amino acid complexes. On the other hand, the k_{H^+} values for the carboxylato and the amino acid complexes increase with increase in pK_a values within each of these two groups of acid. The pK_a values affect the equilibrium constant K of Eq. (6), and hence the k_{H^+} values.

The k_{H^+} values of the amino acid complexes are much smaller than expected from the relationship between pK_a values and k_{H^+} values for carboxylato complexes. Concerning the glycine and the sarcosine complex, the hydrogen bonding between carboxylate and ammonium group could impede the protonation given by Eq. (6) to decrease the k_{H^+} values. The k_{H^+} value of the betaine complex, which cannot form such a hydrogen bond, is, however, still smaller than those of the two amino acid complexes. Therefore the retardation of protonation should rather be ascribed to an electrostatic effect due to the ammonium group present in the neighborhood of the carboxylate group. Thus the carboxylate end is "shielded" from the approach of a hydrogen ion by both the central cation and the ammonium group, to give a smaller K value.

A similar electrostatic effect is also seen in the hydrolysis of organic esters. Walker and Owens measured the rate of acid-catalysed hydrolysis of chloride of cyclohexyl betainate and found that the rate is *ca.* 1/80 of that of cyclohexyl acetate.[7] The retardation is understood as due to the influence of an electron-attracting group (*e.g.*, $-N^+(CH_3)_3$), rather than to that of steric hindrance or salt effect.[8]

The β-alanine complex has a considerably greater k_{H^+} value than α-amino acid complexes. Its ammonium group would shield the coordinated carboxylate group to a less extent than an α-amino acid does. Such a small influence of $-NH_3^+$ group upon the carboxylate seems to be also reflected in the large pK_a value of β-alanine.

The entropy of activation of the glycine complex is more positive than that of the acetato complex (Table 3). Such a difference might suggest that the local orientation of solvent water around the leaving group at the activated state would be less for the glycine complex, in which the negative charge of the carboxylate group is partly compensated by the influence of the ammonium group.

Bunton and Llewellyn disclosed that the aquation of acetatopentamminecobalt(III) complex takes place through the break of Co–O bond on the basis of a tracer study with oxygen-18.[9] On the other hand, the similar aquation of carbonatopentamminecobalt(III) complex proceeds *via* the cleavage of C–O bond,[10] and has an enthalpy of activation 17.1 kcal mol^{-1}.[11] The enthalpy of activation of the glycine complex is nearer to that of the acetato complex than to that of the carbonato complex, so that the break of Co-O bond appears to be more plausible on the aquation of the glycine complex.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1619—1621 (1968)

Spectrophotometric Determination of Cyanide Ion with Mercury(II)-Methylthymolblue Complex

Toshiaki NOMURA

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto

(Received January 24, 1968)

Cyanide ion reacted with mercury(II)-methylthymolblue (Hg-MTB) complex to form a mixed ligand complex. Since the resulting mixed ligand complex had a considerable absorption at 615 mμ, the spectrophotometric determination of cyanide ion was performed by measuring the increase in absorption of mercury(II)-methylthymolblue complex caused by formation of this mixed ligand complex. After excess MTB methanol and mercury(II) nitrate solutions were added to a cyanide sample solution which was adjusted to a definite pH value between pH 7.3 and 7.6 with phosphate buffer solution, it was diluted to exactly 50 m*l* with water. After standing for about 25 min, the absorbance of this solution was measured at 615 mμ against the reagent blank solution. Beer's law was obeyed in the concentration range of cyanide ion from 5 to 80 μg per 50 m*l*, and the molar extinction coefficient was found to be about 5100. Taking 55.0 μg of cyanide ion, the standard deviation and variation coefficient of absorbances in the mean value of 10 runs were 0.0019 and 0.90%, respectively. The molar ratio of cyanide ion to Hg-MTB in the mixed ligand complex was found to be 1 : 1.

Mercury(II) reacts with organic reagents having two diacetic amino groups to form mercury(II) complexes which further react with anions such as SCN^-, CN^-, I^- and Br^-, *etc.*, to form mixed ligand complexes. Nomura *et al.*, reported that ethylenediaminetetraacetate (EDTA),[1] cyclohexanediaminetetraacetate (CyDTA),[2] and cresolphthalein complexone (PC),[3] *etc.*, have the above property among organic reagents. Also, Hashitani[4] reported that alizarin complexone reacts with cerium or lanthanum to form a complex which reacts with fluoride ion to form the same mixed ligand complex.

Methylthymolblue (MTB), having two diacetic amino groups, reacts with mercury(II) to form a mercury(II)-methylthymolblue complex (Hg-MTB or $HgMe^{4-}$),[5] having a considerable absorption at 620 mμ, and the molar ratio of MTB to mercury(II) in this complex is 1 : 1. It was found that cyanide ion also reacted similarly with Hg-MTB to form a mixed ligand complex as thiocyanate ion.[6] Therefore, making use of this fact, the author has developed a rapid method for spectrophotometrically determinating small amounts of cyanide ion by measuring the absorbance of this cyano mixed ligand complex.

Experimental

Reagents. All analytical grade reagents were used without further purification.

Standard Cyanide Solution. The exact concentration of the stock solution of cyanide ion, prepared by dissolving potassium cyanide in water, was obtained through indirect chelatometric titration with $[HgY(CN)]^{3-}$ [7] before use. The working standard solutions were prepared by diluting this stock solution to the concentrations required for experiment.

Methylthymolblue (MTB) Methanol Solution. The MTB methanol solution of 1×10^{-3} M was prepared by dissolving 390 mg of Dotite MTB in a small amount of water, followed by the addition 250 m*l* of methanol, and dilution to exactly 500 m*l* with water. This solution, stored in a brown glass bottle, was stable at least for about three months.

Mercury(II) Solution. The stock solution mercury(II) was prepared by dissolving mercury(II) nitrate in a small amount of concentrated nitric acid and water, and diluting to exactly 1 *l* with water. The exact concentration of this solution was obtained through titration with 0.01 M standard EDTA solution using Cu-PAN as indicator. The working solution of 1×10^{-3} M (F=0.983) was prepared by dilution with water.

Buffer Solution. Buffer solutions having a definite pH were prepared by properly mixing 0.2 M potassium dihydrogen phosphate and 0.2 M disodium hydrogen phosphate solutions.

7) S. Komatsu and T. Nomura, *ibid.*, **87**, 1060 (1966).

Apparatus. Spectrophotometric measurements were made with a Hitachi Perkin Elmer 139 type spectrophotometer with 10.0 mm glass cells. The pH measurements were made with a Hitachi-Horiba 4 type pH meter.

Procedure. The sample solution containing from 5 to 80 μg of cyanide ion was adjusted to a definite pH value between pH 7.3 and 7.6 with 10 m*l* of buffer solution, to each of which 5 m*l* of 1×10^{-3} M MTB methanol solution and aqueous mercury(II) solution were added and the total volume adjusted to 50 m*l* with water. After standing for about 25 min, the absorbance of this solution was measured at 615 mμ against a reagent blank solution which was prepared similarly without the addition of cyanide solution.

Results and Discussion

Absorption Spectra of Hg-MTB and Cyano Mixed Ligand Complex. Spectra are shown in Fig. 1. The maximum absorbances of Hg-MTB were found at 420 mμ and 610 mμ, respectively. However, the absorbance decreased at 420 mμ and increased at 610 mμ when cyanide ion was added to this complex solution. Then, the measurement of increase in the absorbance at 610 mμ caused by the formation of a cyano mixed ligand complex could be made to determine cyanide ion. The wavelength of 615 mμ, at which the cyanide mixed ligand complex had a maximum absorbance, was used practically in all subsequent measurements, because the difference in absorbance between Hg-MTB and the mixed ligand complex was greater at 615 mμ than at 610 mμ, as shown in Fig. 1.

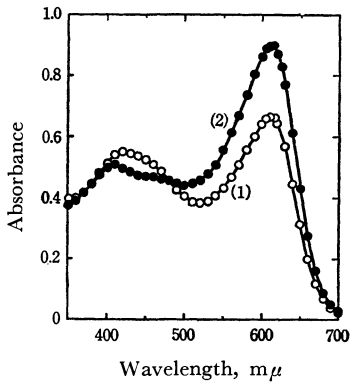

Fig. 1. Absorption spectra of Hg-MTB and cyano mixed ligand complex.
(1) Hg-MTB complex containing each 5 m*l* of 1×10^{-3} M MTB methanol and mercury(II) solutions at pH 7.4.
(2) Cyano mixed ligand complex containing above solutions and 66.0 μg of cyanide ion at pH 7.4.

Effect of pH. This complex was stable between pH 7.3 and 7.6, as shown in Fig. 2. Since the absorbance of Hg-MTB increased with pH,[6] the pH in a practical procedure should be adjusted to a definite value between pH 7.3 and 7.6.

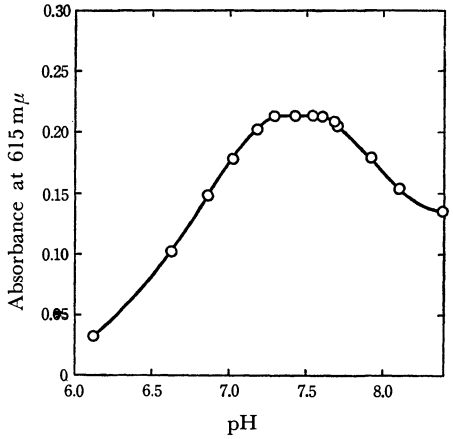

Fig. 2. Effect of pH.
The every absorbances of the mixed solution containing each 5 m*l* of 1×10^{-3} M·MTB methanol and mercury(II) solutions and 55.0 μg of cyanide ion were measured against a reagent blank solution after adjusting to the pH needed with phosphate buffer solution.

Effect of Standing Times. The time required for the complete formation of this mixed ligand complex (blue color) was about 20 min, and the color of this complex showed no change for at least three hours. The procedure for color development was carried out at room temperatures.

Molar Ratio of Hg-MTB to Cyanide Ion. The results are shown in Fig. 3. When Hg-MTB reacted with cyanide ion to form the mixed ligand complex, the molar ratio of Hg-MTB to cyanide ion was found to be 1 : 1. But, above the equivalent point, the mixed ligand complex reacted subsequently with cyanide ion in the same way as the cyano mixed liquid complex $[HgY(CN)]^{3-}$

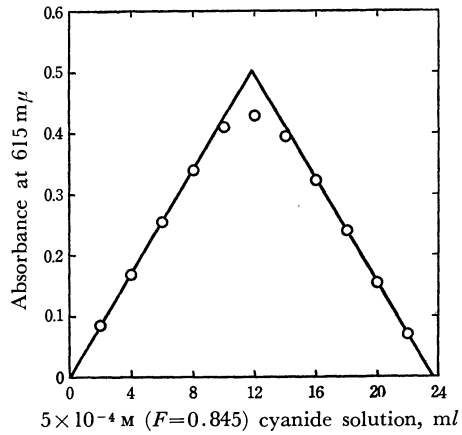

Fig. 3. Molar ratio of Hg-MTB to cyanide ion.
The every absorbances of the mixed solution containing each 5 m*l* of 1×10^{-3} M·MTB methanol and mercury(II) solutions were measured against a reagent blank solution after adding cyanide solution at pH 7.5.

(abbreviated Hg-EDTA as HgY^{2-}) reacted with cyanide ion to form mercury(II) cyanide and EDTA.[7]

$$[HgMe(CN)]^{5-} + CN^- + 2H^+ \rightarrow Hg(CN)_2 + H_2Me^{4-}$$

Hence, the absorbances of this mixed ligand complex solution decreased when an excess amount of cyanide ion (compared with Hg-MTB, in molar ratio) was added. The absorbances of the solutions which were prepared by the addition of different amounts of cyanide sample solution should be measured in order to avoid erroneous measurements, which may be made above the equivalent point.

Calibration Curve. The relationship between cyanide ion content and the absorbance was linear from 5 μg up to 80 μg cyanide ion content per 50 m*l*, as shown in Fig. 4. The molar extinction

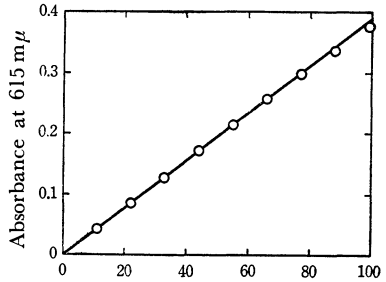

Fig. 4. Calibration curve for cyanide ions. pH 7.4

coefficient was found to be about 5100. Taking 55.0 μg of cyanide ion, the standard deviation and variation coefficient for the mean absorbances of 10 analyses were 0.0019 and 0.90%, respectively.

Effect of Diverse Ions. Results are given in Table 1. Taking 55.0 μg of cyanide ion, the absorbances were measured according to the above procedure in the co-existence of a number of various foreign ions. Measurements that differed from the expected absorbance by more than $\pm 2\%$ were taken as criterion for interference.

Anions such as SCN^-, S^{2-}, I^- and Br^- interfered in this method, because S^{2-} reacted with mercury(II) to form mercuric sulfide, and SCN^-, I^- and Br^- reacted with Hg-MTB to form mixed ligand complexes, as did cyanide ion. Cations, such as Mn^{2+}, Cd^{2+}, Zn^{2+}, Co^{2+}, Bi^{3+}, Ni^{2+} and NH_4^+, interfered since these cations, except NH_4^+, reacted with MTB to form metal-MTB complexes. These interfering ions should be separated or masked properly for the determination of cyanide ion. A method of separation has been reported by Okutani *et al.*[8]

Table 1. Effect of diverse ions

Ion	Added as	Tolerance limit	
SCN^-	KSCN	1.2 μg	+
Br^-	KBr	2.5 μg	+

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1622—1628 (1968)

Kinetics of Electron-transfer Reactions Involving Ethylenediaminetetraacetatochromate(II) Ions as Reductants. I. Reactions with Some Isothiocyanatoammine Complexes of Chromium(III)*[1]

Hiroshi OGINO and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received February 3, 1968)

Kinetics of electron-transfer reactions of ethylenediaminetetraacetatochromate(II) ions with some isothiocyanatoammine complexes of chromium(III), $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$ (n=0, 1, 4 and 6), have been studied. The former ions are present in the forms of both $Cr^{II}(H_2O)edta^{2-}$ and $Cr^{II}(H_2O)Hedta^-$, but the reaction of $Cr^{II}(H_2O)Hedta^-$ with $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$ is not significant in the pH range from 3.6 to 5.3. Second-order rate constants (l mol^{-1}sec^{-1}) of the reactions between $Cr^{II}(H_2O)edta^{2-}$ and $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$ at ionic strength 1.0 and 25°C are $<10^{-2}$ for $Cr(NH_3)_6^{3+}$, 0.2 for $CrNCS(NH_3)_5^{2+}$, 2.3 for $Cr(NCS)_4(NH_3)_2^-$, and 28.2 for $Cr(NCS)_6^{3-}$.

The electron-transfer reactions between chromium(II) ions and various oxidants have been investigated extensively. For example, it is known that the reactions of chromium(II) ions with various cobalt(III) complexes proceed through inner-sphere mechanisms, except haxaammine and tris(ethylenediamine)cobalt(III) complex ions.[1,2] The reactions between chromium(II) ions and acidopentaamminechromium(III) also proceed through inner-sphere mechanisms.[3] On the other hand, the electron-transfer reactions of tris(bipyridine)chromium(II) ions with various cobalt(III) complexes proceed through outer-sphere mechanisms.[2,4] The striking change in these electron-transfer reactions is brought by the complex formation of chromium(II) ions with bipyridine. Therefore, it seems worth while to investigate the electron-transfer reactions involving various chromium(II) complexes as reductants.

Stability constants of chromium(II) and chromium(III) complexes with ethylenediaminetetraacetate (EDTA) have been determined by Pecsok *et al.*[5] Recently, the rate constants of the complex-forming reactions between chromium(II) ions and EDTA have been determined in this laboratory.[6,7] These results have facilitated to investigate the electron-transfer reactions between chromium(II)-EDTA and various oxidants.

In this paper, kinetics of electron-transfer reactions between chromium(II)-EDTA and some isothiocyanatoammine complexes of chromium(III) ions, $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$ (n=0, 1, 4 and 6), are presented. Although Hunt and Earley[8] reported on the semiquantitative experiments of electron-transfer reactions between chromium(II) and hexaaquochromium(III) ions in the presence of number of ligands, rate laws of these reactions were not presented.

Experimental

Materials. Aquohydrogenethylenediaminetetraacetatochromium(III), $[Cr(H_2O)Hedta]$, was prepared by the method of Hamm.[9] The crude material was purified by the following procedures: 24 g of $[Cr(H_2O)Hedta]$ in 25 m*l* of water was dissolved with 10 g of sodium acetate trihydrate. After filtration, 20 m*l* of concentrated nitric acid was added. Crystals were obtained upon heating the solution on the water-bath. The crystals were washed with warm water, ethanol and ether. Infrared spectra of the compound gave two peaks at 1739 and 1639 cm^{-1} in the carbonyl region, which essentially agree with the results reported by Dwyer and Garvan.[10] The peak at 1739 cm^{-1} which could be assigned to the free carboxylic acid group was less intense than the other at 1639 cm^{-1}. The relative intensities of these peaks support EDTA in chromium(III)-EDTA complex functioning as a pentadentate ligand.

Complexes, $[Cr(NH_3)_6]Cl_3$,[11] $[CrNCS(NH_3)_5](SCN)_2$,[12] and $K_3[Cr(NCS)_6]\cdot 4H_2O$,[13] were prepared by the procedures described in literatures. $[CrNCS(NH_3)_5](SCN)_2$ was converted to perchlorate by recrystallization from aqueous perchloric acid. The solution of $(NH_4)_3[Cr(NCS)_6]\cdot 4H_2O$ was obtained by passing the solution of $K_3[Cr(NCS)_6]\cdot 4H_2O$ through Dowex 50W-X8 cation exchange resins in the ammonium form. Then, the solution was evaporated to dryness. The compound $(NH_4)_3[Cr(NCS)_6]\cdot 4H_2O$ thus obtained was purified by recrystallization from 95% ethanol. $NH_4[Cr(NCS)_4(NH_3)_2]\cdot 2/3\ H_2O$ of reagent grade was purchased from Nakarai Chemicals, Ltd.

The results of the chemical analysis of the chromium(III) complexes used in this paper are given in Table 1.

Table 1. Analysis of the chromium(III) complexes

Complex	Cr, %		N, %	
	Found	Calcd	Found	Calcd
$[Cr(H_2O)Hedta]$	14.22	14.47	7.80	7.80
$[Cr(NH_3)_6]Cl_3$	19.92	19.96	31.95	32.26
$[CrNCS(NH_3)_5](ClO_4)_2$	13.31	13.19	21.56	21.32
$NH_4[Cr(NCS)_4(NH_3)_2]\cdot 2/3H_2O$	14.28	14.92	28.25	28.14
$(NH_4)_3[Cr(NCS)_6]\cdot 4H_2O$	9.71	9.87	23.78	23.94

The acidic solution of hexaaquochromium(III) perchlorate was prepared by the reduction of sodium dichromate in perchloric acid with hydrogen peroxide. Solutions of chromium(II) perchlorate were obtained by the reduction of hexaaquochromium(III) perchlorate with zinc amalgam. Chromium(II) chloride solutions were prepared by dissolving chromium metal into hydrochloric acid.

All other chemicals used were of reagent grade.

Procedures. As chromium(II) solutions were air-sensitive, the experiments were carried out in an oxygen-free nitrogen atmosphere. A trace of oxygen was removed from nitrogen gas by passing the gas through a series of acidic chromium(II) solutions.

Total chromium concentration in a given solution was determined spectrophotometrically as CrO_4^{2-} after oxidation with alkaline peroxide.[14]

Chromium(II)-EDTA solutions were prepared by injecting chromium(II) solutions into excess EDTA solutions. The following two methods were used for the determination of the concentration of chromium(II)-EDTA: In the first method, the concentration of chromium(II)-EDTA was taken as equal to that of a known amount of chromium(II) ions. Chromium(II) content was determined by the method reported in the literature.[15] Chromium(II) solutions contained chromium(III) ions as impurity. The chromium(III) ions in the original solution may be $Cr(H_2O)_6^{3+}$ and/or $[CrOH(H_2O)_4]_2^{4+}$, the latter of which is known to be a product upon the air-oxidation of chromium(II) ions.[16,17] The contamination of chromium(III) ions was greater in the more dilute chromium(II) solutions. It was found spectrophotometrically that, when a chromium(II) solution which was contaminated by chromium(III) ions was injected into an excess EDTA solution, the same amount of chromium(III)-EDTA as that of chromium(III) in the original solution was formed within the time of mixing. The absorption spectra of chromium(II)-EDTA and chromium(III)-EDTA complexes which were obtained in this work are as mentioned later (see Fig. 1). In the second method, the following procedure was used: Absorbancy of the chromium(II)-EDTA solution containing chromium(III)-EDTA was measured at a proper wave length. The concentrations of both chromium(II)-EDTA and chromium(III)-EDTA were calculated from the total chromium concentration, the value of absorbancy and the extinction coefficients of both chromium(II)-EDTA and chromium(III)-EDTA. In most cases, this procedure was used, because this was simpler than the first one.

The determination of hydrogen ion concentrations in chromium(II) solutions and acidic hexaaquochromium(III) perchlorate solutions was carried out by the method reported in the literatures.[18,19] Concentrations of zinc(II) ions in the chromium(II) perchlorate solutions were determined polarographically.

Ionic strength of the solution was adjusted to be 1.0 with sodium perchlorate or sodium chloride. The pH of the solutions was regulated by using acetate buffer which was prepared from acetic acid and primary standard sodium carbonate. A Hitachi F-5 pH meter with accuracy of ± 0.01 pH unit was used for the measurement of the pH of the solutions.

The reaction vessels were quartz spectrophotometer cells of 1 cm in length of light path. Kinetic runs were made by recording the change of absorbancy at a given wave length as a function of time, using a Hitachi EPS-3 pen-recording spectrophotometer. In most of kinetic runs, the solutions containing a given amount of chromium(III) complex ions, EDTA, acetate buffer and indifferent salt were added to the cell which was then sealed with a serum cap. After the solution was purged with nitrogen gas for at least ten minutes, chromium(II) solution was added by a calibrated syringe. The mixing of the solutions was performed by passage of a rapid stream of nitrogen gas. In some experiments, the chromium(II) solution was added to the deoxygenated solution containing EDTA, acetate buffer and indifferent salt in a serum capped cell by a syringe and then the solution of chromium(III) complex ions was added as the last reagent by a syringe. In both manners, the first absorbancy reading was obtained within 5 sec.

Temperature of optical cells was controlled to be 25.0 ± 0.1°C by circulating water through cell holder. The deoxygenated solution of chromium(II) or chromium(III) ions in a syringe was also equilibrated at 25°C in the thermostated-bath before mixing.

Results and Discussion

Absorption Spectra of Chromium(II)-EDTA and Chromium(III)-EDTA Complexes. A pentadentate structure of EDTA in chromium(II)-EDTA complex has been proposed by Pecsok *et al.*[5] Therefore, the formula $Cr^{II}(H_2O)edta^{2-}$ will be used in this paper for chromium(II)-EDTA complex.

Schwarzenbach and Biedermann[20] showed that chromium(III)-EDTA complex contains one water molecule in the first coordination sphere. And, Hoard *et al.*[21] reported that in an intermediate pH range from 5 to 9, both $Cr^{III}(H_2O)edta^-$ and $Cr^{III}(OH)edta^{2-}$ are probably converted, though perhaps slowly, into the hexadentate $Cr^{III}edta^-$. In addition, they isolated the hexadentate complex in the solid state. In the present paper, the formula $Cr^{III}(H_2O)edta^-$ is assigned tentatively to chromium(III)-EDTA complex in the solution by the following observations: (a) Infrared spectra of chromium(III)-EDTA complex in solid state supported a pentadentate structure of EDTA as mentioned in the experimental section. (b) Visible and ultraviolet spectra of $[Cr(H_2O)Hedta]$ dissolved in distilled water were essentially identical with those in acetate buffer solution. (c) In this work, the pH of the solutions was restricted within the range from 3.6 to 5.3 by using acetate buffer solutions. No spectral changes in visible and ultraviolet regions were observed by the change of the pH of the solutions.

The spectra of $Cr^{II}(H_2O)edta^{2-}$ and $Cr^{III}(H_2O)edta^-$ at ionic strength 1.0 ($NaClO_4$) in acetate buffer solutions are given in Fig. 1. The concentration of acetate in the buffer was varied from 0.24 to 0.75 M. For comparison, the spectrum of chromium(II) ions in perchloric acid is also given in Fig. 1. The molar extinction coefficients of maximum absorption of $Cr^{III}(H_2O)edta^-$ at 393 mμ and 545 mμ were 112 and 206, respectively, which essentially agree with the results reported by Hamm.[9]

The shape of spectrum of $Cr^{II}(H_2O)edta^{2-}$ resembles that of Cr^{2+} ions, so that the color of a $Cr^{II}(H_2O)edta^{2-}$ solution is sky blue similar to that of a chromium(II) solution. The molar extinction coefficients of maximum absorptions of $Cr^{II}(H_2O)edta^{2-}$ at 715 and 1060 mμ were 18 and 10, respectively. The extinction coefficient of $Cr^{II}(H_2O)edta^{2-}$ is the same with that of $Cr^{III}(H_2O)edta^-$ at 365 and 673 mμ, respectively, as indicated with arrows in Fig. 1.

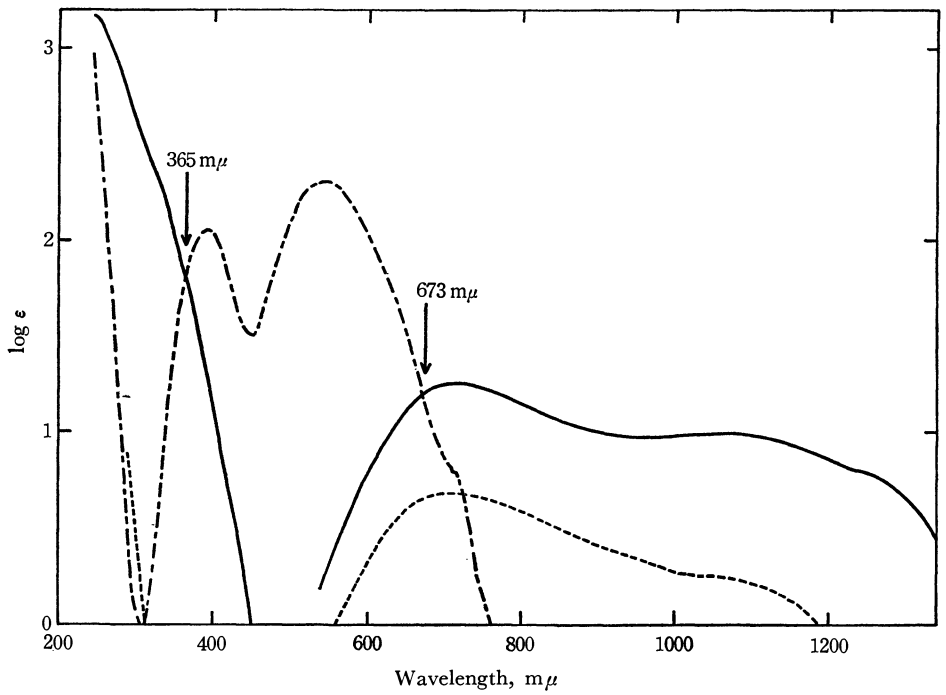

Fig. 1. Absorption spectra of $Cr^{II}(H_2O)edta^{2-}$ in sodium acetate-sodium perchlorate media (——), $Cr^{III}(H_2O)edta^-$ in sodium acetate-sodium perchlorate media (-·-·-) and Cr^{2+} in $HClO_4$ (----).

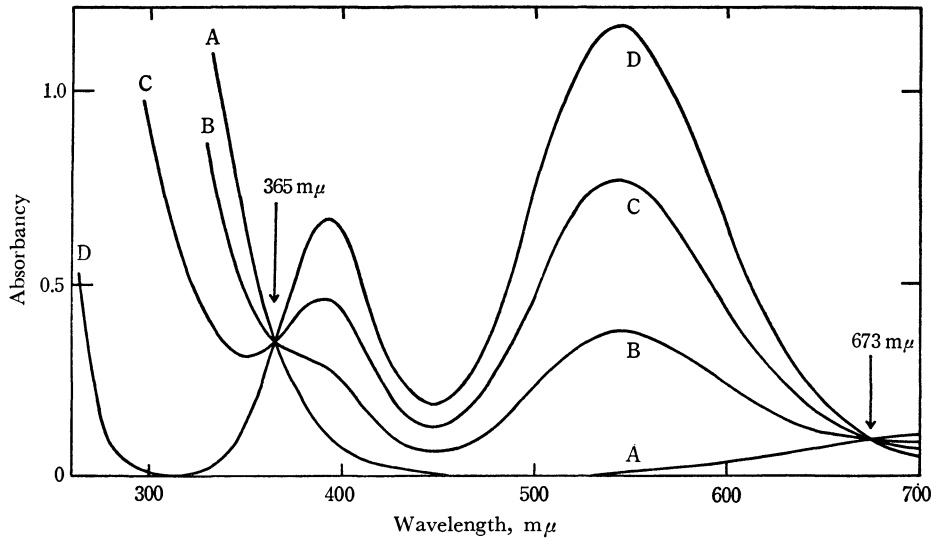

Fig. 2. Spectral change of $Cr^{II}(H_2O)edta^{2-}$ solution in sodium acetate-sodium perchlorate media of ionic strength 1.0: (A) 5.89 mM $Cr^{II}(H_2O)edta^{2-}$; (B and C) Partly oxidized with air; and (D) Completely oxidized with air. The concentration of acetate is 0.24 M.

Figure 2 shows the spectral change of $Cr^{II}(H_2O)edta^{2-}$ solution which occurred when air was bubbled through the solution. Two isosbestic points were observed at 365 and 673 mμ by the addition of appropriate amounts of oxygen. The spectrum obtained after the solution was saturated with air is shown by curve D in Fig. 2. This spectrum is in a satisfactory agreement with that of 5.89 mM $Cr^{III}(H_2O)edta^{-}$. These observations revealed that there was no indication of the formation of intermediates such as dimeric species. Therefore, the spectral change in Fig. 2 can be expressed reasonably with the following equation:

$$2Cr^{II}(H_2O)edta^{2-} + \frac{1}{2}O_2 + 2H^+ \rightarrow 2Cr^{III}(H_2O)edta^{-} + H_2O \quad (1)$$

Kinetics of the Electron-transfer Reactions between $Cr^{II}(H_2O)edta^{2-}$ and $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$. Figure 3 gives a typical example of the spectral change of the $Cr(NCS)_6^{3-}$ solution containing excess EDTA upon the addition of chromium(II) perchlorate solution (spectra A to D). The same spectral change was observed, when a $Cr(NCS)_6^{3-}$ solution was injected into a chromium(II) solution containing excess EDTA. The reaction seemed to be complete within 600 sec, since no change was observed in the spectrum after the measurement of spectrum D in Fig. 3. The shape of spectrum D is in a satisfactory agreement with that of $Cr^{III}(H_2O)edta^{-}$. Therefore, the overall reaction is expressed reasonably as follows:

$$Cr(NCS)_6^{3-} + H_jedta^{(4-j)-} + H_2O \rightarrow Cr^{III}(H_2O)edta^{-} + 6NCS^{-} + jH^+ \quad (2)$$

In Fig. 3, there are three isosbestic points at 380, 404 and 466 mμ. This is also consistent with Eq. (2). The rate of reaction (2) observed in the absence of chromium(II) ions was much slower than the rate of the reaction observed in the presence of chromium(II) ions. It was also found that the rate of the reaction between chromium(II) ions and $Cr(NCS)_6^{3-}$ complexes in sodium chloride-hydrochloric acid media was extremely slow.*2

After the completion of the reaction, the solution was exposed to air, the spectrum of which is shown by curve E in Fig. 3. This spectrum also coincides with that of $Cr^{III}(H_2O)edta^{-}$. The concentration of $Cr^{III}(H_2O)edta^{-}$ which corresponds to the difference in absorbancy in the spectra D and E was found to be equal to the concentration of chromium(II) ions which was initially added. That is, the concentration of chromium(II)-EDTA remained constant during the reaction. As shown in Fig. 1, the absorption of $Cr^{II}(H_2O)edta^{2-}$ is negligible over the range of wave length in Fig. 3 under the experimental condition.

By considering these results, the following mechanism can be deduced for reaction (2):

$$Cr^{2+} + H_jedta^{(4-j)-} + H_2O \rightleftharpoons Cr^{II}(H_2O)edta^{2-} + jH^+ \quad (3)$$

$$Cr^{II}(H_2O)edta^{2-} + Cr(NCS)_6^{3-} \xrightarrow{k} Cr^{III}(H_2O)edta^{-} + Cr^{2+} + 6NCS^{-} \quad (4)$$

*2 The reaction between chromium(II) ions and $Cr(NCS)_6^{3-}$ complexes may be the chromium(II)-catalyzed dissociation reaction of $Cr(NCS)_6^{3-}$ complexes, but, no systematic investigation either on the stoichiometry or on the kinetics of the reaction has been made.

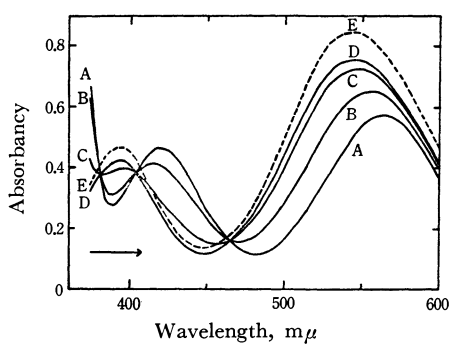

Fig. 3. Spectral change of the $Cr(NCS)_6^{3-}$ solution containing EDTA in sodium acetate-sodium perchlorate media upon the addition of chromium(II) ions: $[Cr(NCS)_6^{3-}]_{t=0}=3.56$ mM, $[Cr(II)]_{t=0}=0.47_2$ mM, $[EDTA]_{t=0}=12.5$ mM, 25°C, $\mu=1.0$, pH 3.71, Scanning speed=3.42 mμ/sec. (A) Spectrum at $t=0$ over the range of all wave length. (B) 10 sec (C) 120 sec and (D) 600 sec after the addition of chromium(II). Times given are for start of scan at 374 mμ. (E) Spectrum of the solution which was exposed to air after spectrum D was measured.

where reaction (4) is the electron-transfer reaction between $Cr^{II}(H_2O)edta^{2-}$ and $Cr(NCS)_6^{3-}$. In this mechanism, reaction (4) is a rate-determining step because the complex-forming reaction (reaction 3) of chromium(II) ions is considered to be very fast.[6,7] The rate law for reaction (2) is expressed as

$$-\frac{d[Cr(NCS)_6^{3-}]}{dt}=\frac{d[Cr^{III}(H_2O)edta^-]}{dt}$$
$$=k[Cr^{II}(H_2O)edta^{2-}][Cr(NCS)_6^{3-}] \quad (5)$$

Since the concentration of $Cr^{II}(H_2O)edta^{2-}$ remains constant during the reaction, the integration of Eq. (5) leads to

$$\ln|D_t-D_\infty| = -k[Cr^{II}(H_2O)edta^{2-}]t+\ln|D_0-D_\infty| \quad (6)$$

where D_0, D_t and D_∞ are absorbancies at time 0, t and infinite, respectively.

An example of the kinetic run of the reaction between chromium(II)-EDTA and $Cr(NCS)_6^{3-}$ ions is shown in Fig. 4. Excellent first-order plots were obtained as expected from Eq. (6).

Table 2 gives the results obtained on the rate of the reaction between chromium(II)-EDTA and $Cr(NCS)_6^{3-}$ ions. The rate constants were independent of the initial concentrations of both

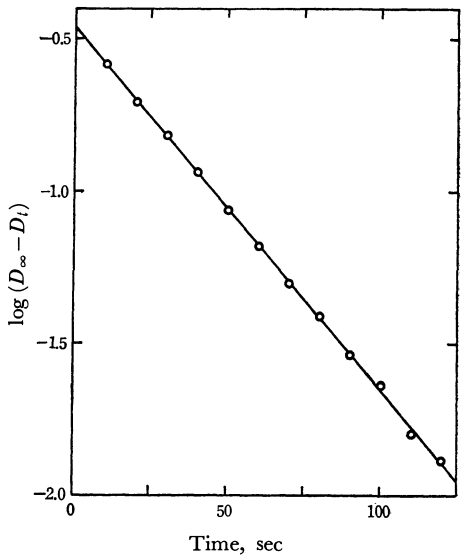

Fig. 4. A typical kinetic run of the reaction between $Cr^{II}(H_2O)edta^{2-}$ and $Cr(NCS)_6^{3-}$ in the presence of EDTA at 510 mμ: $[Cr^{II}(H_2O)edta^{2-}]=0.994$ mM, $[Cr(NCS)_6^{3-}]_{t=0}=3.47$ mM, $[EDTA]_{t=0}=12.5$ mM, pH 5.25.

Table 2. Rate constants of the reaction between chromium(II)-EDTA and $Cr(NCS)_6^{3-}$ at $\mu=1.0$ ($NaClO_4$) and 25°C

pH	$[Cr(NCS)_6^{3-}]_{t=0}$ mM	$[Cr^{II}(H_2O)edta^{2-}]$ mM	k $l\,mol^{-1}\,sec^{-1}$	Wavelength for measurement, mμ
5.25	3.47	0.994	27.6	510
4.93	2.86	1.06	29.5	510
4.92	3.37	1.03	29.3	510
4.87	2.78	2.78	28.4	510
4.81	2.96	5.73	27.7	510
4.80	0.949	1.06	28.8	510
4.74	3.93	1.06	30.0	545
4.73	5.62	1.06	29.0	422
4.60	3.23	0.964	27.2	510
4.48	3.03	0.457	29.2	510
4.28	3.01	0.964	27.8	422
4.17	2.92	2.78	26.7	510
4.11	3.33	5.78	24.5	510
4.00	3.24	0.964	25.3	510
3.81	3.48	0.964	24.6	510

chromium(II)-EDTA and $Cr(NCS)_6^{3-}$. Therefore, the reaction is strictly of second-order. Rate constants obtained at different wave length are in a good agreement. A rigorous treatment of the pH dependence of rates was made, because it is known that $Cr^{II}(H_2O)edta^{2-}$ forms protonated species, $Cr^{II}(H_2O)Hedta^-$, at lower pH's. If the presence of $Cr^{II}(H_2O)Hedta^-$ is considered, the electron-transfer reaction may proceed through the following two simultaneous reaction paths:

$$Cr^{II}(H_2O)edta^{2-} + Cr(NCS)_6^{3-} \xrightarrow{k_1} Cr^{III}(H_2O)edta^- + Cr^{2+} + 6NCS^- \quad (7)$$

$$Cr^{II}(H_2O)Hedta^- + Cr(NCS)_6^{3-} \xrightarrow{k_2} Cr^{III}(H_2O)Hedta + Cr^{2+} + 6NCS^- \quad (8)^{*3}$$

Then, the observed rate constant k can be expressed as

$$k = \frac{k_1/[H^+] + k_2K^H}{1/[H^+] + K^H} \quad (9)$$

where

$$K^H = \frac{[Cr^{II}(H_2O)Hedta^-]}{[Cr^{II}(H_2O)edta^{2-}][H^+]} \quad (10)$$

The value of K^H has been determined to be $10^{3.00}$ at ionic strength 0.1 and 20°C by Pecsok *et al.*[5] Equation (9) is rewritten as

$$k\alpha = \frac{k_1}{[H^+]} + k_2K^H \quad (11)$$

where

$$\alpha = \frac{1}{[H^+]} + K^H \quad (12)$$

Figure 5 shows the plots of $k\alpha$ vs. reciprocal hydrogen ion concentrations in the reaction of chromium(II)-EDTA with $Cr(NCS)_6^{3-}$. The value of k_1 obtained from the slope is equal to 28.2 l mol^{-1} sec^{-1}. The value of the intercept is approximately zero. It could be deduced from standard deviations of the plots that k_2 is less than 50 l mol^{-1}sec^{-1}.

Similar kinetic behaviors were found for the reactions involving other chromium(III) complexes.

Second-order rate constants of the reaction between $Cr^{II}(H_2O)edta^{2-}$ and $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$ are given in Table 3. Although $Cr(NH_3)_6^{3+}$ ions were found to react with chromium(II)-EDTA, only an upper limit of rate constant was obtained, because of extremely slow rate of the reaction. Since $Cr(NH_3)_6^{3+}$ complex has no electron-pair exposed, the mechanism of this electron-transfer reaction is probably of outer-sphere type.

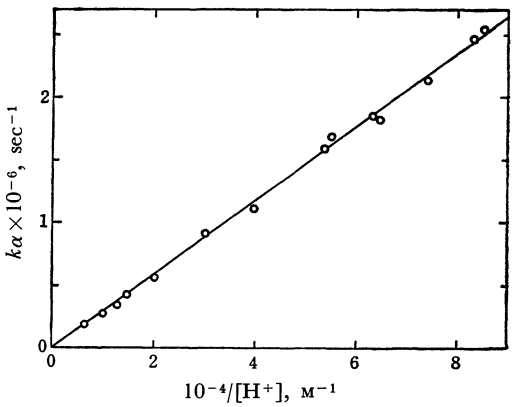

Fig. 5. The values of left hand side of Eq. (11) as a function of reciprocal hydrogen ion concentrations in the reaction between chromium(II)-EDTA and $Cr(NCS)_6^{3-}$.

Table 3. Rate constants of electron-transfer reactions between $Cr^{II}(H_2O)edta^{2-}$ and $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$ at μ=1.0 and 25°C

Complex	Rate constant l mol^{-1} sec^{-1}	Medium	Absorption maxima of ligand field bands $\bar{\nu}\times10^{-3}$, cm^{-1} 1 st band	2 nd band
$Cr(NH_3)_6^{3+}$	$<10^{-2}$	NaCl	21.46	28.41
$CrNCS(NH_3)_5^{2+}$	0.2	NaCl	20.49	27.32
$Cr(NCS)_4(NH_3)_2^-$	2.3	$NaClO_4$	19.08	25.38
$Cr(NCS)_6^{3-}$	28.2	$NaClO_4$	17.67	23.70

The rate constants of $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$ shown in Table 3 increase with the number of thiocyanate anions coordinated, in spite of the increase of electrostatic repulsion between reactants. If these reactions occur *via* activated complexes which involve thiocyanate anions as a bridge between chromium(II)-EDTA and $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$, it may be expected that the rate of electron-transfer reactions increases with the number of groups coordinated to chromium(III) which are able to mediate an electron. However, the increase of the rate constants given in Table 3 is much larger than expected from the statistical factor mentioned above. This suggests a large contribution of the free energy change of the reactions in question.

King and Ball[23] reported that the electron-transfer reaction of chromium(II) ions with $CrNCS(H_2O)_5^{2+}$ ions proceeds through an activated complex which involves a coordinated thiocyanate anion as a bridge between the chromium(II) and chromium(III). Haim and Sutin[24] reported

*3 It should be noted that chromium(III)-EDTA ions are present in the forms of both $Cr^{III}(H_2O)edta^-$ and $Cr^{III}(H_2O)Hedta$ at lower pH's. The pK value for the reaction

$$Cr^{III}(H_2O)edta^- + H^+ \rightleftharpoons Cr^{III}(H_2O)Hedta$$

has been determined to be 3.19[20] or 2.27.[22]

22) C. Furlani, G. Morpurgo and G. Sartori, *Z. anorg. u. allgem. Chem.*, **303**, 1 (1960).

23) D. L. King and E. L. Ball, *J. Am. Chem. Soc.*, **80**, 1091 (1958).

24) A. Haim and N. Sutin, *ibid.*, **88**, 434 (1966).

that chromium(II) ions react with $FeNCS^{2+}$ and various isothiocyanatocobalt(III) complexes to produce both $CrSCN^{2+}$ and $CrNCS^{2+}$. It was shown spectrophotometrically that the chromium(III)-EDTA of the products obtained in this work contained no thiocyanate anion in the first coordination sphere. This was also verified from the behavior of the product on the ion-exchange resins. However, this does not necessarily preclude inner-sphere mechanisms of the reactions investigated in this work. It is considered that the reactions of $Cr^{II}(H_2O)edta^{2-}$ with $CrNCS(NH_3)_5^{2+}$, $Cr(NCS)_4(NH_3)_2^-$ and $Cr(NCS)_6^{3-}$ proceed through an inner-sphere mechanism.[25]

The absorption maxima of the ligand field band of $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$ are also given in Table 3. It is of interest that there is a correlation between the rate constants and the wave numbers of the absorption maxima of $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$.

The authors wish to thank the Ministry of Education for the financial support granted for this research.

Behavior of Methyl Iodide in the Reaction of Acetic Acid Synthesis from Methanol and Carbon Monoxide

Tsutomu MIZOROKI and Mikitake NAKAYAMA

Government Chemical Industrial Research Institute, Tokyo, Meguro-ku, Tokyo

(Received September 2, 1967)

The reaction of methyl iodide with carbon monoxide in the presence of cobalt(II) iodide as the catalyst has been investigated to know the effect of methyl iodide on the acetic acid synthesis from methanol and carbon monoxide catalyzed by the same catalyst. The reaction, $CH_3I+CO+H_2O \rightarrow CH_3COOH+HI$, does not take place before the methyl iodide used has been hydrolyzed completely into methanol and sodium iodide by adding enough amount of sodium acetate ($CH_3I+CH_3COONa+H_2O \rightarrow CH_3OH+NaI+CH_3COOH$). Methyl iodide also strongly inhibits the reaction of methanol with carbon monoxide catalyzed by cobalt(II) ion or dicobalt octacarbonyl, although iodide ion promotes the reaction effectively. The promotion effect of iodide ion has been discussed by considering the effect of an additive on carbonylation reactions in terms of a labilizing ligand and a non-labilizing ligand and a possible reaction scheme of methanol with carbon monoxide catalyzed by cobalt(II) iodide has been proposed.

In the reaction of acetic acid synthesis from methanol and carbon monoxide in the presence of cobalt(II) iodide as the catalyst, hydrocobalt tetracarbonyl and methyl iodide were estimated to be formed in the course of the reaction as follows[1]: $2CoI_2+11CO+3H_2O \rightarrow 2HCo(CO)_4+4HI+3CO_2$, $HI+CH_3OH \rightarrow CH_3I+H_2O$. One may anticipate that the reaction of methyl iodide with carbon monoxide must be catalyzed more effectively by hydrocobalt tetracarbonyl to form acetic acid: $CH_3I+CO+H_2O \xrightarrow{HCo(CO)_4} CH_3COOH+HI$. This reaction, however, practically does not take place under the same conditions as those of the reaction with methanol. In our preceding papers dealing with the absorption spectrum of cobalt(II) ion in the course of the reaction of methanol with carbon monoxide, it was shown that most of cobalt(II) ion does not form dicobalt octacarbonyl, but tetrahedral iodo-cobalt(II) complex, $[Co(CH_3COO)_{4-n}I_n]^{2-}$,[2] and that the reaction is accelerated by adding a small amount of potassium acetate in spite that the presence of such a salt is unfavorable for the formation of methyl iodide from methanol and hydroiodic acid.[3] The addition of potassium acetate, in fact, effectively decomposes methyl iodide into methanol and potassium iodide through the reaction of $CH_3I+CH_3COOK+H_2O \rightarrow CH_3OH+CH_3COOH+KI$. It should be abandoned to discuss these facts in terms of the hydrocobalt tetracarbonyl and methyl iodide as the catalyst.

3) T. Mizoroki and M. Nakayama, This Bulletin, **39**, 1477 (1966).

This work was undertaken to investigate the effect of methyl iodide on the reaction of methanol with carbon monoxide catalyzed by cobalt(II) iodide and to fully discuss the catalytic action of iodide ion and the course of the reaction.

Experimental

The apparatus and materials used in carrying out the reactions were the same as those described earlier.[3] The amounts of methanol, methyl acetate, dimethyl ether, methyl iodide and water were determined by the same gas chromatographic procedure described in the same paper. When the amount of methyl iodide contained in a liquid product was more than 0.1 mol% based on the methanol used (25% based on the cobalt-(II) ion used), it was quantitatively determined by this gas chromatographic procedure.

Results

The Reaction of Methyl Iodide with Carbon Monoxide. Methyl iodide (0.40 mol), water (6.0 mol) and cobalt(II) iodide (0.004 mol) were placed in the autoclave (300 ml in vol) and carbon monoxide (40—50 kg/cm^2) was introduced at a room temperature. It had been heated up to 215°C and kept the temperature constant for about one hour before the carbon monoxide was introduced again up to 350 kg/cm^2. The reaction was carried out at the constant pressure for 2 hr. Under these conditions, practically no carbon monoxide was absorbed and the reaction of $CH_3I+CO+H_2O\rightarrow CH_3COOH+HI$ did not take place. After the reaction, 0.23 mol (58%) of methyl iodide used was hydrolyzed into methanol and hydroiodic acid. While a nearly calculated amount of carbon monoxide was absorbed on adding sodium acetate more than the equimolar amount of methyl iodide used ($CH_3COONa/CH_3I\geqq 1$) and 100% of methyl iodide used reacted with carbon monoxide to form

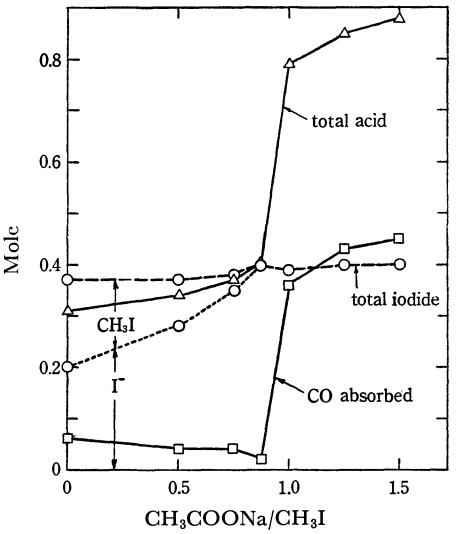

Fig. 1. Plots of the total acid formed and the carbon monoxide absorbed against the amounts of sodium acetate added.

acetic acid. The results are represented in Fig. 1 and Table 1. No carbon monoxide was absorbed as long as the amount of sodium acetate added was less than 0.40 mol ($CH_3COONa/CH_3I<1$). The hydrolysis of methyl iodide was checked by heating the solutions used in the experiments 3 and 6 without introducing any carbon monoxide. As shown in B3 and B6 of Table 1, 0.05 mol (13%) of methyl iodide used remained unchanged in the experiment B3 ($CH_3COONa/CH_3I=0.75$), no methyl iodide, however, was detected in B6 ($CH_3COONa/CH_3I=1.25$). These results show that the absorption of carbon monoxide takes place only when sodium acetate is added enough to hydrolyze the methyl iodide used completely and that the reaction can be represented as

Table 1. Effect of acetate on the reaction of methyl iodide with carbon monoxide

B*6′	1.25	0.83	0.0	0.83	0.0	0.40	0.40

* CH_3OH 0.4 mol, H_2O 5.6 mol, CH_3COOH 0.4 mol, CH_3COONa 0.1 mol, NaI 0.4 mol and CoI_2 0.004 mol.

** The difference in the amounts between total acid (0.31) and I^- (0.20) is probably caused by the formation of formic acid.

follows:

$$CH_3I + H_2O \rightarrow CH_3OH + HI \quad (a)$$

$$HI + CH_3COONa \rightarrow CH_3COOH + NaI \quad (b)$$

$$+ \quad CH_3OH + CO \rightarrow CH_3COOH \quad (c)$$

$$CH_3I + CH_3COONa + CO + H_2O \rightarrow 2CH_3COOH + NaI \quad (d)$$

The acids formed in the experiments 1—4 are the sum of the hydroiodic acid from (a) and the acetic acid from (b), they, however, do not contain the acetic acid formed from (c), because no carbon monoxide is absorbed. The experiment B6′ shown in Table 1 is the result obtained from the reaction of methanol with carbon monoxide under the same condition as that of the experiment 6 except that no methyl iodide was added to the starting materials. The absorption rates of carbon monoxide in the experiments 6 and B6′ are shown in Fig. 2. The amount of carbon monoxide absorbed in the experiment B6′ was nearly the same as that in the experiment 6 and negligibly small amounts of dimethyl ether and acetaldehyde were present in the product, but neither methanol, methyl acetate nor methyl iodide were detected. That the amount of the total acid is more than the calculated one (0.80 mol) is caused by the formation of a small amount of formic acid, because water was added enough to dissolve lots of sodium acetate or sodium iodide completely.

Inhibition of Methyl Iodide in the Reaction of Methanol with Carbon Monoxide. Methanol (1.80 mol), acetic acid (0.20 mol), water (1.33 mol), cobalt(II) iodide (0.008 mol) and methyl iodide (0.016 mol, $CH_3I/CoI_2=2$ or 0.040 mol, $CH_3I/CoI_2=5$) were placed in the autoclave and the reaction with carbon monoxide was carried out for 2.5 hr under the constant pressure, 350 kg/cm² at the temperature, 215°C. Methyl iodide strongly inhibited the absorption rate of carbon monoxide and practically no acetic acid was formed especially when methyl iodide (0.040 mol) was added to the starting materials. While the inhibition was removed again by adding potassium acetate with which methyl iodide was hydrolyzed into methanol and potassium iodide. The result is shown in Fig. 3. The gas chromatographies of the liquid products obtained in the case of adding methyl iodide (0.016 mol) to the starting materials, showed that 0.003 mol of methyl iodide was contained in the product when the amount of potassium acetate added was 0.008 mol ($CH_3COOK/CH_3I=0.5$), while no methyl iodide was detected when it was more than 0.016 mole ($CH_3COOK/CH_3I \geqq 1$). For the purpose of investigating the effect of methyl iodide in the case of using dicobalt octacarbonyl as the catalyst, the following experiment was undertaken. Methanol (1.35 mol), acetic acid (0.15 mol), water (1.00 mol) and cobalt(II) acetate (0.006 mol) were placed in an autoclave (200 m*l*) equipped with another small high pressure vessel (25 m*l* in vol). Carbon monoxide was introduced up to the pressure, 300 kg/cm² at the temperature, 215°C and they were kept constant for about one hour to convert cobalt(II) acetate into dicobalt octacarbonyl,*1 within which period no carbon monoxide was absorbed by the reaction with methanol. Then methyl iodide (0.003—0.024 mol in tetrahydrofuran) which had been

charged in the small vessel was introduced into the autoclave by using a higher pressure of carbon monoxide and the reaction was carried out under the constant pressure, 350 kg/cm² for 2.5 hr. Mass balances of the liquid products are shown in Table 2 and methanol conversion (%) into total acetic acid (free acetic acid+methyl acetate) are plotted against the amount of methyl iodide introduced ($CH_3I/2Co_2(CO)_8$) in Fig. 4 (curve I). When the amount of methyl iodide introduced is 0.0045 mol ($CH_3I/2Co_2(CO)_8 \fallingdotseq 0.8$), methanol conversion becomes maximum and no methyl iodide was detected in the liquid product, the conversion, however, decreases sharply with increasing the amount of methyl iodide and that of dimethyl ether contained in the liquid products gradually increases. The same result is obtained on introducing hydroiodic acid*2 aqueous solution in place of methyl iodide. But it is very different from these results that the methanol conversion increases with increasing the amount of sodium iodide aqueous solution*2 introduced as shown by the curve II in Fig. 4.

Discussion

The following facts are, no doubt, inconsistent with the reaction scheme proposed by Reppe.[1] (i) When sodium iodide is used in place of methyl iodide or hydroiodic acid, the reaction rate of methanol with carbon monoxide increases with increasing the amount of sodium iodide added. (ii) No methyl iodide is detected in the liquid product when the reaction rate is large enough. (iii) In the course of the reaction, most of cobalt-(II) ion does not form dicobalt octacarbonyl, but tetrahedral iodocobalt complex $[Co(CH_3COO)_{4-n}I_n]^{2-}$. The addition of sodium iodide or an acetate is unfavorable for the formation of methyl iodide, because the equilibrium constant of Eq. (e) is much smaller than that of Eq. (f).*3

*2 The total amount of water added was constant in this experimental run (1.00 mol).

*3 The equilibrium constants, $\log K_p$ at 200°C, calculated from $\log K_p = -\Delta H^\circ_{298}/4.575T + \Delta S^\circ_{298}/4.575$ are −0.67 in Eq. (e) and 5.07 in Eq. (f), in which the entropy of CH_3COONa (39.2 cal/mol·°K) is obtained from assuming no change in the entropy of the reaction $CH_3COOH(g) + NaOH(s) \rightarrow CH_3COONa(s) + H_2O(g)$.

$$CH_3OH(g) + NaI(s) + CH_3COOH(g) \rightleftarrows CH_3I(g) + CH_3COONa(s) + H_2O(g) + 0.56\ kcal/mol \quad (e)$$

$$CH_3OH(g) + HI(g) \rightleftarrows CH_3I(g) + H_2O(g) + 11.0\ kcal/mol \quad (f)$$

The reaction rate, therefore, would not be increased by adding sodium iodide in place of methyl iodide or hydroiodic acid, if the formation of methyl iodide were necessary in the course of the reaction. If no detection of methyl iodide in the liquid product were caused by that the formation of methyl iodide were the rate determining step, the rate of the reaction with carbon monoxide would not depend on the pressure of carbon monoxide, nor the amount of cobalt(II) ion added. But, in fact, the higher the reaction pressure, the larger the reaction rate.[3,4]

Promotion Effect of Iodide Ion. Before the catalytic action of iodide ion will be discussed, it must be noticed that in a hydroformylation or a hydroesterification reaction catalyzed by $Co_2(CO)_8$ or $Rh_2(CO)_8$, its reaction rate is increased by adding an organic base such as pyridine[5-7] or *N*-ethylpyrolidine,[6] it is, however, rather strongly inhibited by carbon monoxide[5] or phosphorous compounds[6] such as $P(C_6H_5)_3$ or $P(OC_2H_5)_3$. In his recent paper,[8] Matsuda explained that in the hydroesterification of propylene or acrylonitrile pyridine (Py) would accelerate the insertion step of carbon monoxide to form acylcobalt tricarbonyl represented by $C_3H_7Co(CO)_4 + Py \rightarrow C_3H_7COCo(CO)_3Py$ or $NCC_2H_4Co(CO)_4 + Py \rightarrow NCC_2H_4COCo(CO)_3Py$. Such insertion reactions are well known also in the reactions of $RCo(CO)_4$ with carbon monoxide or phosphorous compounds[9] and of $CH_3Mn(CO)_5$ with carbon monoxide,[10] phosphorous compounds, amines[11] or iodide ion.[12] The question is why neither phosphorous compounds nor carbon monoxide accelerate the carbonylation reactions. According to the classification of ligands defined recently by Angelici,[13] halogen ions amines are labilizing ligands (hard base*[4]), while carbon monoxide and phosphorous compounds are non-labilizing ligands (soft base*[4]). This classification may provide a possible explanation on the effect of an additive on the carbonylation reactions catalyzed by a cobalt carbonyl. The following reaction scheme has been reported as a reasonable one of an oxo-reaction.[9] Although kinetic data have not been found enough, the rate determining step is probably the reaction (iii) in a hydroformilation reaction, while in a hydroesterification reaction it would be the reaction (ii).

$$RCHCH_2 + HCo(CO)_4 \rightleftarrows RC_2H_4Co(CO)_4 \quad (i)$$

$$RC_2H_4Co(CO)_4 \rightleftarrows RC_2H_4COCo(CO)_3 \overset{+CO}{\underset{-CO}{\rightleftarrows}} RC_2H_4COCo(CO)_4 \quad (ii)$$

$$RC_2H_4COCo(CO)_3 + HR \rightleftarrows RC_2H_4COR + HCo(CO)_3 \quad (iii)$$

$$HCo(CO)_3 + CO \rightleftarrows HCo(CO)_4 \quad (iv)$$

$$(R=H \text{ or } OCH_3)$$

The effect of an additive in this scheme, can be explained by considering Eq. (ii'). When L is one of labilizing ligands (Py, halide ion, some solvent), acylcobalt tricarbonyl will become sufficiently reactive, the rate determining step, then, will be the reaction (ii'). On the other hand, when L is one of non-labilizing ligands (carbon monoxide or phosphorous compounds), acylcobalt tricarbonyl will become unreactive, the rate determining step, then, will be the reaction (iii).

$$RC_2H_4Co(CO)_4 + L \rightleftarrows RC_2H_4COCo(CO)_3L \quad (ii')$$

In the reaction of methanol with carbon monoxide, authors postulated $[Co(CO)I_n(CH_3COO)_{4-n}]^{2-}$ and $[Co(OCCH_3)I_n(CH_3COO)_{4-n}]^{2-}$ $(n=1—4)$ as its intermediates.[3] Booth and Chatt[14] reported that $[CoX_2(PEt_3)_2]$ $(Et=C_2H_5,\ X=Cl^-,\ Br^-$ or $I^-)$ reacts with carbon monoxide at a room temperature under an atmospheric pressure to form penta-coordinating and paramagnetic carbonyl complexes $[CoX_2(CO)(PEt_3)_2]$. The order of their stabilities is $I^->Br^->Cl^-$. It would be explained from π-bonding theory that the coordination of carbon monoxide to cobalt(II) ion is facilitated by adding a good donors, as iodide ion, capable of coordinating to the metal ion. They also isolated the acyl complexes, *trans*-$[MX(COR)(PEt_3)_2]$ $(M=Pd$ or Pt, R=alkyl or aryl) from

trans-$[MXR(PEt_3)_2]$ and carbon monoxide[15] and estimated that such complexes would be intermediates in carbonylation reactions, although such cobalt or nickel complexes were too unstable to be isolated.

Inhibition Effect of Hydroiodic Acid. It can not be understood well why both methyl iodide and hydroiodic acid inhibit the reaction of methanol with carbon monoxide. The following facts, however, may provide an explanation on their inhibition effects. The addition of a salts of weak acid (acetate, benzoate, borax *etc*) is very effective for the formation of dicobalt octacarbonyl from cobalt(II) iodide, although it is easily formed under a milder condition without adding any additive when a cobalt(II) salt of weak acid (acetate or carbonate) is used as the starting material. Weak acids salts are good acceptors of hydroiodic acid formed, which results in decreasing the hydrogen ion concentration, because hydroiodic acid is a much stronger acid. This suggests that proton, which is an acceptor of electron, probably inhibits the coordination of carbon monoxide to cobalt(II) ion. On the other hand, Wakamatsu confirmed that the treatment of $RMn(CO)_5$ ($R=CH_3-$, C_6H_5- or $C_6H_5CH_2-$) with hydroiodic acid resulted in forming nearly stoichiometric amounts of RH and $IMn(CO)_5$ against his expectation that RI and $HMn(CO)_5$ would have been formed.[16] The similar reaction would take place between $CH_3Co(CO)_4$ and HI.

A Possible Reaction Scheme. From the above discussion, the course of the reaction of methanol with carbon monoxide catalyzed by cobalt(II) iodide can be represented as follows:

$$Co(II) + CO \underset{k_2}{\overset{k_1}{\rightleftharpoons}} Co(II)\text{-}CO \qquad (v)$$

$$H_2O \overset{K_1}{\rightleftharpoons} H^+ + OH^-,$$

$$CH_3OH + H^+ \overset{K_2}{\rightleftharpoons} CH_3OH_2^+ \qquad (vi)$$

$$CH_3OH_2^+ + Co(II)\text{-}CO \overset{K_3}{\rightleftharpoons} CH_3\text{-}Co(II)\text{-}CO + H_2O \qquad (vii)$$

$$CH_3\text{-}Co(II)\text{-}CO + I^- \xrightarrow{k_3} CH_3CO\text{-}Co(II)\text{-}I \qquad (viii)$$

$$CH_3CO\text{-}Co(II)\text{-}I + HR \xrightarrow{\text{fast}} CH_3COR + Co(II) + H^+ + I^- \qquad (ix)$$

(where R is H, OH or OCH_3 and Co(II) represents $[Co(CH_3COO)_{4-n}I_n]^{2-}$)

The formation of carbonium ion from methanol (Eq. (vi)) is generally accepted in the course of the esterification or dehydration of methanol catalyzed by hydrogen ion. In this scheme, it is postulated that the breaking of the bond between carbon and oxygen of methanol is assisted by hydrogen ion and that the formation of an acyl complex is promoted by iodide ion (Eq. (viii)). On the assumption that the reactions (vi) and (vii) become equilibrium and that the concentration of Co(II)–CO is nearly constant during the reaction, one can derive the following equations, which is qualitatively consistent with the reported results[3,4] obtained from the absorption rate of carbon monoxide.

$$r = k_3[CH_3Co(II)CO][I^-] = \frac{k_1k_3K_1K_2K_3[Co(II)][I^-][p_{CO}][CH_3OH]}{k_2[OH^-]+k_3K_1K_2K_3[CH_3OH][I^-]}$$

$$k_2 \gg k_3K_1K_2K_3$$

$$r = \frac{k_1k_3K_1K_2K_3}{k_2[OH^-]}[Co(II)][p_{CO}][I^-][CH_3OH] = \frac{k_1k_3K_2K_3}{k_2[H_2O]}[Co(II)][I^-][p_{CO}][H^+][CH_3OH]$$

From this reaction scheme, the effect of acetate shown in Fig. 3 can be also explained: the addition of potassium acetate will decrease the concentration of $[H^+]$ which would inhibit the coordination of carbon monoxide to cobalt(II) ion, so k_2 will become smaller and r increases, while the decrease in $[H^+]$ must be unfavorable for the equilibrium concentration of $[CH_3OH_2^+]$, r is, then, decreased again by adding excess amounts of acetate.

The authors wish to express their thanks to Professor Dr. Yukio Yoneda and Dr. Yasukazu Saito, Faculty of Engineering, The University of Tokyo, for their helpful discussions.

A Study of Unnatural Amino Acids and Their Peptides. III. The Syntheses of DL-β-(2-Pyridyl)-α-alanine and Its Peptides*1

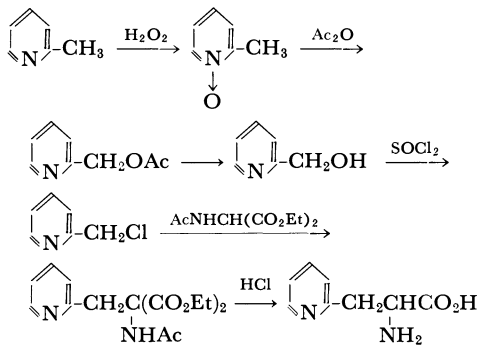
Hiroshi WATANABE, Shigeru KUWATA, Kenzo NAOE*2 and Yoshiteru NISHIDA*3

Laboratory of Chemistry, Faculty of Science, Kōnan University, Okamoto Higashinada, Kobe

(Received October 5, 1967)

DL-β-(2-Pyridyl)-α-alanine has been synthesized in a good yield by the condensation of α-picolyl chloride and diethyl acetamidomalonate and by the subsequent hydrolysis of the product. The *N*-carbobenzoxy derivative of this amino acid, quite different from 3-pyridylalanine reported by Griffith and Harwood, could easily be prepared in a good yield. Only the carbodiimide method and the *N*-bromosuccinimide method proved to be successful in bringing the *N*-carbobenzoxylated amino acid into a peptide-coupling reaction with an amine component. Other methods, *i. e.*, the mixed anhydride method, the azide method and the *p*-nitrophenyl ester method, were unsuccessful. It is noteworthy that, in the former cases, the activation of the carboxyl group occurs *in situ* in the presence of an amine component. No difficulties were encountered in the coupling reaction of the alkyl ester of this amino acid with usual *N*-protected amino acids. The alkaline hydrolysis of the protected dipeptide ester afforded the *N*-protected peptide in a good yield. The catalytic hydrogenation could be used to remove the benzyl ester group as well as the carbobenzoxy group without any damage to the pyridine ring. Decarbobenzoxylation also proceeded smoothly with hydrogen bromide in acetic acid.

In connection with the previous reports[1] of this series, the syntheses of DL-β-(2-pyridyl)-α-alanine and its peptides will be reported in this paper. This amino acid had already been synthesized in several ways.[2-5] In this experiment it was prepared by the condensation of diethyl acetamidomalonate and α-picolyl chloride, easily obtainable from α-picoline, and by the subsequent hydrolysis of the condensation product. Both the condensation and the hydrolysis proceeded smoothly, and the hydrochloride of the amino acid was obtained in a good yield (Scheme I). By treating the hydrochloride with an ion exchange resin, there was obtained free amino acid, which gave a characteristic yellow-brown color in a ninhydrin test on paper.



Scheme I

The carbobenzoxylation of this free amino acid with carbobenzoxy chloride proceeded smoothly in water, with sodium hydroxide as the base, and gave the expected carbobenzoxy derivative in a 77% yield. According to Griffith and Harwood,[6] 3-pyridylalanine is carbobenzoxylated only in a low yield (34%) by usual methods; they attributed this low yield to "the ability of carbobenzoxy-3-pyridylalanine, once formed, to rapidly promote the destruction of unreacted carbobenzoxy chloride." They also examined the carbobenzoxylation of phenylalanine in the presence of an equivalent of pyridine or a one-third equivalent of carbobenzoxy-3-pyridylalanine and observed that "the yield of carbobenzoxyphenylalanine fell essentially to zero." They concluded from these facts that organic soluble pyridine derivatives facilitate the decomposition of carbobenzoxy chloride in aqueous alkali. Therefore, we attempted the carbobenzoxylation of phenylalanine under similar conditions, using 2-pyridylalanine instead of 3-pyridylalanine, with

a view to finding if there were any characteristics similar to those claimed for the latter amino acid derivative. The reaction, however, proceeded normally, and carbobenzoxyphenylalanine was isolated from the reaction mixture in a 90% yield; no unfavorable effect of this amino acid was observed during the carbobenzoxylation. A similar carbobenzoxylation of phenylalanine in the presence of picolinic acid afforded carbobenzoxyphenylalanine in a 78% yield. In the presence of an equivalent of pyridine, the yield of carbobenzoxyphenylalanine dropped to 42% (raw yield), but not to zero, in spite of the description of Griffith and Harwood.

The esterification of this amino acid proceeded smoothly in the presence of *p*-toluenesulfonic acid, giving 2-pyridylalanine benzyl ester in a 83% yield as *p*-toluenesulfonate.

To examine the applicability of common peptide synthetic methods to this amino acid, the coupling of carbobenzoxy-2-pyridylalanine and glycine benzyl ester was tried by the following four methods: mixed anhydride method, dicyclohexylcarbodiimide method, azide method, and *p*-nitrophenyl ester method.

(1) The mixed anhydride method: When ethyl chloroformate was added, drop by drop, to a dichloromethane solution of carbobenzoxy-2-pyridylalanine and an equivalent triethylamine, intense coloration (dark brown) occurred, even under strong cooling, and after the addition of the glycine ester, no expected dipeptide could be isolated from the reaction mixture. The replacement of triethylamine with a weaker base, *N*-ethylmorpholine, reduced the coloration of the reaction mixture, but the dipeptide could not be isolated in this case either.

(2) The dicyclohexylcarbodiimide method: When dicyclohexylcarbodiimide was stirred into a dichloromethane solution of carbobenzoxy-2-pyridylalanine, glycine benzyl ester *p*-toluenesulfonate, and an equivalent of triethylamine under ice-cooling, dicyclohexylurea soon began to be separated. When the reaction was carried out at room temperature, a strong coloration was observed, as in the preceding method, but under good cooling the color of the reaction mixture remained a pale yellow. After the usual treatment, the expected carbobenzoxy-dipeptide benzyl ester was isolated in a 75% yield.

(3) The azide method: Carbobenzoxy-2-pyridylalanylhydrazide could be obtained in a good yield from carbobenzoxy-2-pyridylalanine through its ester in a usual way. Into a solution of the hydrazide in hydrochloric acid, covered with ethyl acetate, there was stirred, drop by drop and under sufficient cooling, a cold concentrated solution of sodium nitrite and, after a few minutes, a 50% potassium carbonate solution. At this stage, a large quantity of an amorphous material, soluble in neither ethyl acetate nor an aquoeus alkaline solution, was separated out. When the ethyl acetate extract was made to react on the glycine ester, with or without this amorphous material, no expected dipeptide could be isolated. The amorphous material, obtained here during the preparation of the azide, melted at about 120°C. It afforded 2-pyridylalanine by hydrolysis, and its molecular weight was found to be 318; thus it was assumed to be carbobenzoxy-2-pyridylalanine amide, formed by the decomposition of carbobenzoxy-2-pyridylalanyl azide.

(4) The *p*-nitrophenyl ester method: To synthesize carbobenzoxy-2-pyridylalanine *p*-nitrophenyl ester, dicyclohexylcarbodiimide was added to a dichloromethane solution of carbobenzoxy-2-pyridylalanine and *p*-nitrophenol. After the removal of the precipitated dicyclohexylurea, the filtrate was, with or without purification, made to react on glycine benzyl ester, but no expected dipeptide could be isolated. This result can be attributed to the lack of success in the active ester synthesis rather than to that in the coupling reaction, because the attempts to obtain carbobenzoxy-2-pyridylalanine *p*-nitrophenyl ester in a crystalline state were all unsuccessful. Another attempt to prepare the *p*-nitrophenyl ester by the reaction of carbobenzoxy-2-pyridylalanine and *p*-nitrophenylsulfite in pyridine at 50°C afforded only a black, tarry material.

From these experiments, we concluded that, in the case of 2-pyridylalanine, it is very difficult to obtain the pyridylalanyl peptide by such methods as the previous activation of the carboxyl group of this amino acid and the subsequent addition of an amine component. On the contrary, only the activation of the acid component *in situ* in the presence of an amine component seems to give the desired peptide, as is the case with the dicyclohexylcarbodiimide method. To confirm these assumptions, another coupling method, the *N*-bromosuccinimide method, was attempted; this method permits the activation of an acid component in the presence of an amine component. According to the instructions of Wolman and his coworkers[7] *N*-bromosuccinimide was added in small portions to a mixture of carbobenzoxy-2-pyridylalanine, glycine benzyl ester *p*-toluenesulfonate, and three equivalents of triethylamine in tetrahydrofuran. From the reaction mixture, the desired dipeptide could be isolated, though the yield was very poor (about 6%).

When pyridylalanine was used as an amine component, no difficulty was encountered in coupling reactions with other ordinary *N*-protected amino acids. As an example, tritylglycine was

7) Y. Wolman, P. M. Gallop and A. Patchornik, *J. Am. Chem. Soc.*, **83**, 1263 (1961); Y. Wolman, P. M. Gallop, A. Patchornik and A. Berger, *ibid.*, **84**, 1889 (1962).

coupled with 2-pyridylalanine benzyl ester by the mixed anhydride method; tritylglycyl-2-pyridylalanine benzyl ester was thus obtained in a 48% yield.

The alkaline hydrolysis of dipeptide esters proceeds smoothly, on whichever side the pyridylalanine residue may be situated, thus enabling carbobenzoxy-pyridylalanylglycine or tritylglycyl-2-pyridylalanine to be obtained from its esters in a good yield.

In the case of peptide synthesis with this amino acid, another problem remains to be clarified: the stability of the pyridine ring during hydrogenation. In order to study this problem, tritylglycyl-2-pyridylalanine benzyl ester was hydrogenated in a quantitative hydrogenation apparatus, using palladium black as a catalyst. One mole equivalent of hydrogen was absorbed very quickly, but then the rate of hydrogenation decreased markedly; even after ten hours, the total volume of the absorbed hydrogen did not amount to two mole equivalents. When the incompletely hydrogenated contents were treated with hot aqueous acetic acid triphenylcarbinol was released, and from the filtrate glycylpyridylalanine was isolated in a chromatographycally-pure state. When carbobenzoxy-2-pyridylalanine was hydrogenated in the presence of sodium hydroxide in the same manner as has previously been reported,[1] one mole equivalent of hydrogen was absorbed very quickly, but then the rate of hydrogenation dropped markedly and only a small quantity of hydrogen was absorbed even after a longer period. All these facts show that the carbobenzoxy- and the benzyl ester-groups can be removed very easily by hydrogenolysis, but that the hydrogenolytic removal of the trityl group proceeds with difficulty, while the pyridine ring is preserved under these conditions. In fact, the simultaneous hydrogenolytic removal of the protecting groups from carbobenzoxy-2-pyridylalanylglycine benzyl ester proved to produce a good yield, accompanied by no reduction of the pyridine ring.

The removal of the carbobenzoxy group with hydrogen bromide in acetic acid proceeded smoothly, without any recognizable side reactions.

Experimental

2-Picolyl Chloride (I). According to the method of Itai and Ogura,[8] 2-pyridylmethanol,[9] obtained from α-picoline through its *N*-oxide and acetate of 2-pyridylmethanol, was converted into 2-picolyl chloride (I) by thionyl chloride. Bp 85—90°C/15 mmHg (lit.[8] bp 70—80°C/5 mmHg). Strongly-irritating pink liquid. Because of its strong resinifying tendency, it was used for the next step immediately after distillation.

Diethyl (2-Pyridylmethyl)-acetamidomalonate (II). To a solution of acetamidomalonate (50 g) and metallic sodium (5 g) in ethanol (300 m*l*), the above chloride (I) (28 g) was added, and then the mixture was stirred for 6 hr under reflux. After the removal of the precipitated sodium chloride by filtration, the filtrate was concentrated and water was added. The crystals separated were recrystallized from ethanol or acetone. Yield, 91%. Mp 92.5—93°C (lit.[4] 90—91°C).

DL-β-(2-Pyridyl)-α-alanine (III). The above malonate (II) (20 g) was boiled with 6 N hydrochloric acid for 8 hr. The solution was concentrated to dryness, and the residue was dissolved in water and treated with Amberlite CG-120 to obtain the free amino acid. Yield, 70%. Mp 200—208°C (lit.[4] 200—210°C). R_f*4= 0.30 (free amino acid); 0.21 (hydrochloride).

Found: C, 57.58; H, 6.06; N, 17.27%. Calcd for $C_8H_{10}O_2N_2$: C, 57.82; H, 6.07; N, 16.86%.

Carbobenzoxy-DL-β-(2-pyridyl)-α-alanine (IV). To a solution of (III) (16.6 g) and sodium hydroxide (4 g) in water (50 m*l*), carbobenzoxy chloride (19 g) and sodium hydroxide solution (sodium hydroxide 4 g; water 20 m*l*) were added under ice-cooling. When the reaction had finished, the mixture was adjusted to pH 4 with acetic acid. A white precipitate was collected by filtration, washed with water thoroughly, and recrystallized from aqueous alcohol to give colorless needles. Yield, 77%. Mp 145—147°C.

Found: C, 64.25; H, 5.45; N, 9.13%. Calcd for $C_{16}H_{16}O_4N_2$: C, 63.99; H, 5.37; N, 9.33%.

DL-β-(2-Pyridyl)-α-alanine Benzyl Ester Di-*p*-toluenesulfonate (V). A mixture of pyridylalanine (III) (16.6 g), *p*-toluenesulfonic acid monohydrate (45 g), benzyl alcohol (20 g), and benzene (200 m*l*) was boiled with occasional shaking and the continuous azeotropical removal of water. After 8.5 hr the solution was cooled, whereupon the crystals which had separated out were collected by filtration, washed thoroughly with ether, and recrystallized from alcohol-petroleum ether. Yield, 83%. Mp 158—159°C.

Found: C, 57.65; H, 5.27; N, 4.60%. Calcd for $C_{29}H_{32}O_8N_2S_2$: C, 57.98; H, 5.37; N, 4.66%.

Carbobenzoxy-DL-β-(2-pyridyl)-α-alanylhydrazide (VI). According to the method of Izumiya and his co-workers,[10] IV (40 g) was converted into the ethyl ester (yield 38.5 g); it was obtained as a yellow syrup and did not crystallize even after having been stored for a long time. To a methanol (120 m*l*) solution of the ester, 90% hydrazine hydrate (10 g) was added and the mixture was allowed to stand for 2 days at room temperature. When the clear solution had been cooled well and triturated, voluminous crystals were formed. Yield, 32.3 g (77.1% from IV). After recrystallization from ethyl acetate, it melted at 131—132°C into a turbid liquid, which became clear at 137°C.

Found: C, 61.14; H, 6.00; N, 17.78%. Calcd for $C_{16}H_{18}O_3N_4$: C, 61.13; H, 5.77; N, 17.83%.

Carbobenzoxy-DL-β-(2-pyridyl)-α-alanyl-glycine Benzyl Ester (VII). *a) The Dicyclohexylcarbodiimide Method.* Into a cold solution of IV (3 g), glycine benzyl ester *p*-toluenesulfonate (3.8 g), and triethylamine (1.5 m*l*) in dichloromethane (80 m*l*), a solution of dicyclohexylcarbodiimide (2.1 g) in dichloromethane (2 m*l*) was stirred, drop by drop. After 2 hrs' stirring under ice-cooling, the mixture was allowed to stand overnight at room temperature. The dicyclohexylurea was then filtered off and washed with dichloromethane. The pale yellow filtrate and the washings were combined and washed successively with 0.5 N hydrochloric acid, N sodium hydroxide, and water, and dried over sodium sulfate. After the removal of the dicyclohexylurea which had separated during the evaporation of the solvent by filtration, the solution was concentrated to dryness. The viscous syrup which remained soon solidified completely. Yield, 3.2 g (72%). Mp 105—107°C (from ethanol).

Found: C, 67.01; H, 5.70; N, 9.26%. Calcd for $C_{25}H_{25}O_5N_3$: C, 67.10; H, 5.63; N, 9.39%.

b) The N-Bromosuccinimide Method. Carbobenzoxy-pyridylalanylhydrazide (1.6 g), glycine benzyl ester *p*-toluenesulfonate (1.7 g), and triethylamine (1.5 g) were dissolved in 30 m*l* of tetrahydrofuran. Into the cold solution solid *N*-bromosuccinimide (1.8 g) was then stirred in small portions. A remarkable evolution of gas was observed, and the color of the reaction mixture gradually changed to yellow brown. After the addition, the mixture was stirred for an additional 20 min, then diluted with water and extracted with ethyl acetate. The extract was washed successively with water, hydrochloric acid, a potassium carbonate solution, and water, and then dried over sodium sulfate and concentrated. The residual red-brown syrup (0.74 g) was dissolved in alcohol, from which mixture crystals were separated by letting it stand in a refrigerator overnight. Yield, 0.17 g (7.6%). Mp 105—107°C (from alcohol). The crystals showed no depression of the melting point when mixed with the preceding specimen.

c) An Attempted Coupling Reaction by the Azide Method. A solution of VI (942 mg) in 1 N hydrochloric acid (9 m*l*) was covered with ethyl acetate (12 m*l*), and then into the mixture there was stirred a solution of sodium nitrite (210 mg) in water (2 m*l*) at 0°C. After 2 min a 50% potassium carbonate solution (3.6 m*l*) was added, and the organic layer was separated. The aqueous layer was extracted with ether. At this stage a large amount of a solid material soluble in neither ethyl acetate and ether nor water was separated. This solid, insoluble also in aqueous alkali, melted at about 120°C. A paper chromatogram of the hydrolysate with hydrochloric acid showed one spot identical with that of an authentic sample of the hydrochloride of pyridylalanine. The molecular weight was determined to be 318 by a cryoscopic method, using 2,4,6-tribromophenol as the solvent. From these evidences, this substance was assumed to be carbobenzoxy-DL-β-(2-pyridyl)-α-alanine amide (molecular weight 299). To the organic layer mentioned above, after it had been dried over sodium sulfate, there was added an ether solution of the glycine benzyl ester (obtained from 1.18 g of glycine benzyl ester *p*-toluenesulfonate), but from the mixture no dipeptide derivative could be obtained.

Carbobenzoxy-DL-β-(2-pyridyl)-α-alanyl-glycine (VIII). VII (2.3 g) was dissolved in methanol (60 m*l* and hydrolyzed with N sodium hydroxide (6 m*l*) for 1 hr at room temperature. The solution was then diluted with water and treated with active charcoal. The clear solution was acidified with acetic acid and allowed to stand overnight in a refrigerator. The crystals which thus separated were collected and washed with water. Yield, 1.3 g (72%). Mp 178—179°C.

Found: C, 60.36; H, 5.35; N, 11.62%. Calcd for $C_{18}H_{19}O_5N_3$: C, 60.49; H, 5.36; N, 11.76%.

DL-β-(2-Pyridyl)-α-alanyl-glycine (IX). *a) By the Hydrogenolysis of VII.* Hydrogen gas was allowed to bubble through a solution of VII (4.0 g) in methanol (150 m*l*) for 4 hr in the presence of a Pd-catalyst (0.4 g). The catalyst was then filtered off, and a large amount of water was added to the filtrate. After treatment with active charcoal, the clear solution was concentrated *in vacuo* to a small volume, and then ethanol was added. The hydrated dipeptide was separated as needles (sintered at about 80°C), which became anhydrous upon being dried at 110°C *in vacuo*. Yield, 1.5 g (75%). Mp 179—180°C. A paper chromatogram showed only one spot (R_f*[4]=0.55).

Found: C, 53.23; H, 5.88; N, 18.78%. Calcd for $C_{10}H_{13}O_3N_3$: C, 53.80; H, 5.87; N, 18.83%

b) By the Action of Hydrogen Bromide in Acetic Acid on VIII. A mixture of VIII (0.36 g) and 20% hydrogen bromide in an acetic acid solution (*ca.* 2 m*l*) was kept for 5 min at about 25°C. Ether was then added, and the crystals were collected and washed several times with ether. Yield, 0.42 g (quantitative). Mp 169—171°C (decomp.). A paper chromatogram showed only one spot. The free dipeptide obtained by the passage of the hydrobromide through the column of an ion exchange resin showed a chromatogram identical with that of the sample obtained by the method *a*. The hydrobromide of the dipeptide obtained by the method *a* melted at 165—167°C (decomp.) and showed no depression of melting point when mixed with the hydrobromide obtained by the method *b*.

Tritylglycyl-DL-β-(2-pyridyl)-α-alanine Benzyl Ester (X). To a stirred solution of tritylglycine (4.7 g) and triethylamine (2.1 m*l*) in dichloromethane (100 m*l*), ethyl chlorocarbonate (1.43 m*l*) was added, drop by drop, under strong cooling. To this mixture, after an additional 30 mins' stirring, there was added a solution of V (9 g) and triethylamine (4.2 m*l*) in dichloromethane (400 m*l*). The solution was left to stand overnight at room temperature, then washed with an aqueous citric acid, an aqueous sodium carbonate, and water, and dried over sodium sulfate. When the solvent was evaporated off, there remained a viscous syrup (6 g) which crystallized when triturated with ethyl acetate and petroleum ether. Yield, 4 g (48%). Mp 119—121°C (large cubes from ethyl acetate).

Found: C, 77.75; H, 6.32; N, 7.22%. Calcd for $C_{36}H_{33}O_3N_3$: C, 77.81; H, 5.99; N, 7.56%.

Tritylglycyl-DL-β-(2-pyridyl)-α-alanine (XI). X (666 mg) was hydrolyzed with N sodium hydroxide (1.5 m*l*) in methanol (20 m*l*) for about 2 hr at room temperature and then treated as usual. Amorphous powder. Yield, 97%. Mp 93—95°C.

Found: C, 74.47; H, 5.69; N, 8.47%. Calcd for $C_{29}H_{27}O_3N_3$: C, 74.82; H, 5.85; N, 9.03%.

Glycyl-DL-β-(2-pyridyl)-α-alanine (XII). *a) From X.* X (2.23 g) was hydrogenated in aqueous

methanol (methanol 100 m*l*; water 20 m*l*) in the presence of a Pd-catalyst (0.2 g) with a quantitative hydrogenating apparatus. In about 50 min 97 m*l* of hydrogen was absorbed, but thereafter the rate of the absorption became so slow that even after 4 hr the volume of hydrogen absorbed amounted only to 34 m*l*. The solution, freed from the catalyst, was evaporated under reduced pressure. The residue was treated with 50% acetic acid on a boiling-water bath for 2 min; water was then added, and the triphenylcarbinol thus separated was filtered off. The filtrate decolorized with active charcoal was concentrated to dryness under reduced pressure. Yield, 0.33 g (37%). Mp 196—200°C (from water - ethanol). A paper chromatogram showed only one spot, R_f*[4]=0.43.

Found: C, 49.51; H, 6.31; N, 17.56%. Calcd for $C_{10}H_{13}O_3N_3 \cdot H_2O$: C, 49.78; H, 6.27; N, 17.42%.

b) From XI. XI (200 mg) was dissolved in 70% acetic acid (5 m*l*) and warmed to about 70°C for 10 min. Water was then added to the reaction mixture, and it was treated as above. Yield, 82 mg (58%). A paper chromatogram afforded an R_f value identical with that of the preceding specimen.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1638—1642 (1968)

Synthetic Reactions by Complex Catalysts. IX. Reaction of Thiol with Isocyanide

Takeo SAEGUSA, Shiro KOBAYASHI, Kiwami HIROTA, Yoshiharu OKUMURA and Yoshihiko ITO

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 19, 1967)

The reaction of a thiol with an isocyanide proceeds in two directions. In the first reaction (course a), the carbon atom of isocyanide with lone-pair electrons is inserted into the sulfur-hydrogen bond of thiol to produce thioformimidate (I). In the second reaction (course b), isothiocyanate (II) and the alkane (III) from the alkyl group of thiol are formed. The proportion of the participation of two reactions depends upon the alkyl group of thiol and upon the reaction conditions including whether or not a catalyst is employed. Primary thiol prefers course a to course b, whereas tertiary thiol prefers course b. In the reactions at 15°C, the Group IB and IIB metal compounds, *e. g.*, copper compounds, catalyzed the course a reaction preferably. At higher temperatures, *e. g.*, at 100°C, thiol reacts with isocyanide quite rapidly, even in the absence of a catalyst. However, the catalyst effect favoring course a is seen even in the high-temperature reactions. The mechanism of the reaction, especially course b, has been discussed. *Syn-anti* structures of thioformimidate were also studied by NMR.

We have reported a series of insertion reactions of isocyanide into the nitrogen-hydrogen bond of amine,[1] the oxygen-hydrogen bond of alcohol[2,3] and the silicon-hydrogen bond of silane.[4]

$$RN{\cong}C: + HNR'R'' \longrightarrow RN{=}CHNR'R'' \quad (1)$$

$$RN{\cong}C: + HOR' \longrightarrow RN{=}CHOR' \quad (2)$$

$$RN{\cong}C: + HSiR'_3 \longrightarrow RN{=}CHSiR'_3 \quad (3)$$

These reactions are all catalyzed by copper compounds to produce the corresponding derivatives of *N*-alkylformimidic acid. This paper will describe our studies of the reaction of thiol with isocyanide. The structure of thioformimidate will also be examined by NMR.

Results and Discussion

Reaction of Thiol with Isocyanide. The reaction of a thiol with an isocyanide proceeds in the following two directions:

$$RN{\cong}C: + HSR' \begin{cases} \xrightarrow{\text{Course a}} RN{=}CHSR' \quad (I) & (4) \\ \xrightarrow{\text{Course b}} RN{=}C{=}S + R'H \quad (II)\ (III) & (5) \end{cases}$$

In the first reaction (course a, Eq. (4)), the carbon atom of isocyanide with lone-pair electrons is inserted into the sulfur-hydrogen bond of thiol to produce thioformimidate (I). In the second reaction (course

b, Eq. (5)), isothiocyanate (II) and alkane (III) from the alkyl group of thiol are formed by a process including the transfer of the sulfur atom from thiol to isocyanide. As will be discussed later, these reactions do not proceed consecutively, but they occur separately.

The proportion of the participation of the two reactions depends on the alkyl group of thiol and on the reaction conditions, including whether or not a catalyst is employed.

The results of the reactions of thiol with cyclohexyl isocyanide are shown in Tables 1 and 2, where the effects of the thiol alkyl group and of the reaction conditions are illustrated. In the reactions at 15°C, the catalyst activities of the Group IB and IIB metal compounds have been clearly demonstrated. However, at higher temperatures, *e. g.*, at 100°C, the reaction proceeds rapidly even without any added catalyst.

The alkyl group of thiol controls the relative participations of the two reactions. Primary thiols, *e. g.*, IV and VI in Tables 1 and 2, prefer course a to course b. On the other hand, tertiary thiols,

b) Reaction conditions; at 20°C for 15 hr.
c) The yield of III was not determined.
d) Copper acetylacetonate.
e) Cadmium acetate.
f) Mercuric acetate.
g) The yield of each product is based on the amount of cyclohexyl isocyanide.

Table 2. Reactions of thiols with cyclohexyl isocyanide[a] (part 2)

RSH	Catalyst	Reaction time (hr)	Yield[b] (%) I	II	III
C_2H_5SH (IV)	None	3	85	8	n. d.[c]
	Cu_2O	3	93	1	n. d.
i-C_3H_7SH (V)	None	1.5	23	64	60
	Cu_2O	3	86	5	n. d.
t-C_4H_9SH (VII)	None	1.5	1	92	81

a) The reactions were carried out at 100°C.
b) The structures of the products are indicated in Table 1. The yield of each product is based on cyclohexyl isocyanide.
c) n. d.; not determined.

e. g., VII, prefer course b. 2-Methyl-2-heptanethiol also takes course b preferably.

Propane and isobutane are, respectively, the alkane products of the course b reactions of 2-propanethiol and 2-methyl-2-propanethiol with isocyanide. No olefinic hydrocarbon was detected in the products of these reactions by NMR analysis.

The Group IB and IIB metal compounds catalyze the thiol-isocyanide reaction and also increase the relative participation of the course a reaction. The effect of the catalyst upon the relative participations of two reactions is well demonstrated in the reaction of cyclohexyl isocyanide with 2-propanethiol. The uncatalyzed reaction is inclined towards course b, producing isothiocyante, whereas the catalyzed reaction preferably proceeds through course a. A similar tendency is seen in the reactions of isocyanide with other thiols. Copper compounds, such as cuprous and cupric oxides and copper acetylacetonate, dissolve in the thiol-isocyanide mixture at room temperature to form a homogeneous system. The compounds of cadmium, zinc, and mercury also accelerate the course a reaction in preference to the course b reaction. Catalyzed reactions (course a) proceeded at fairly high rates. For example, the yield of ethyl *N*-cyclohexylthioformimidate in the reaction of ethanethiol-cyclohexyl isocyanide with copper acetylacetonate at 15°C was 30% at 20 min, 55% at 40 min, 65% at 1 hr, and 86% at 3 hr.

Aromatic thiol also reacts with isocyanide through course a. The reaction of benzenethiol (VIII) with cyclohexyl isocyanide, with or without a catalyst, gave phenyl *N*-cyclohexylthioformimidate exclusively.

Aromatic isocyanides react with thiols to produce the corresponding thioformimidates. For example, *n*-butyl *N*-phenylthioformimidate was produced in a yield of 90% by the reaction of phenyl isocyanide with *n*-butanethiol.

The reactions of the two courses occur separately, but not consecutively. In other words, isothiocyanate (II) and alkane (III) are not formed

by the decomposition of thioformimidate. The reaction between 2-methyl-2-propanethiol and cyclohexyl isocyanide occurs preferably along course b, producing cyclohexyl isothiocyanate and isobutane. However, these products are not formed by the decomposition of *t*-butyl *N*-cyclohexylthioformimidate. It was observed that *t*-butyl *N*-cyclohexylthioformimidate, which was prepared by the thiol interchange between isopropyl *N*-cyclohexylthioformimidate and 2-methyl-2-propanethiol, remained unchanged under the same reaction conditions in the presence of a catalyst.

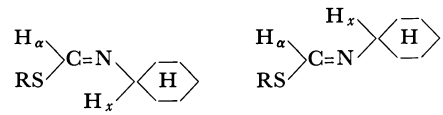
A mechanism involving a free radical may be considered to explain the over-all results of the reactions without any added catalyst.

$$\mathrm{RSH} \xrightarrow{\mathrm{R'\cdot}} \mathrm{RS\cdot} \xrightarrow{\mathrm{R''\text{-}N\rightleftarrows C}} \mathrm{RS\text{-}\dot{C}(H)\text{-}N\text{-}R''} \xrightarrow{\mathrm{RSH}} \mathrm{RSCH{=}NR''} + \mathrm{RS\cdot}$$

$$\mathrm{RS\text{-}\dot{C}(H)\text{-}N\text{-}R''} \xrightarrow[\beta\text{-scission}]{} \mathrm{R''\text{-}N{=}C{=}S} + \mathrm{R\cdot} \xrightarrow[\mathrm{RSH}]{} \mathrm{RH} + \mathrm{RS\cdot}$$

As to the above scheme of a free radical mechanism, it has been observed that the addition of a radical inhibitor such as hydroquinone does not affect the reaction between thiol and isocyanide. Further work is now in progress to elucidate the reaction mechanism, especially the function of the metal catalyst.

***Syn-anti* Structures of Thioformimidate.** For thioformimidate, the *syn* (IX) and *anti* (X) forms are expected as a result of the restricted rotation of the >C=N-bond.

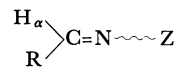


syn (IX) *anti* (X)

In the NMR spectra of thioformimidates in deuteriochloroform and benzene, two signals were obtained in the region of τ 1.7—2.1; both signals were assigned to H_α of IX and X (Table 3).

In Fig. 1, the NMR spectrum of ethyl *N*-cyclohexylthioformimidate is shown as an example. The two signals of H_α have been ascribed to *syn-anti* isomerism on the basis of the solvent effect on the NMR spectrum.[5,6]

Karabatsos *et al.*[5,6] have presented a method for assigning the *syn* and *anti* structures of hydrazone, semicarbazone, and related compounds with this general formula:



This method has been applied to thioformimidate in the present study. Because of the repulsion between the lone-pair electrons of the nitrogen of thioformimidate and the π-electrons of the benzene ring of the solvent, the shielding effect of the benzene ring upon *trans* H_α (*syn* form) is less than that upon *cis* H_α (*anti* form). In Table 3, the two signals of H_α hydrogen have been assigned on the basis of the above consideration. From the peak areas

		anti	487.0	0.0	—
	$CDCl_3$	*syn*	480.7, 482.6	1.9	72
		anti	500.4	0.0	28
(XIV)	C_6H_6	*syn*	481.0, 482.6	1.6	—
		anti	486.6	0.0	—
n-C_4H_9-S-$CH_\alpha=N-$ 	$CDCl_3$	*syn*	487.8	—	8
(XV)		*anti*	492.0	—	92

a) All spectra were recorded at 60 Mc/sec on a modified JEOL JNM-3H-60 spectrometer for 10—15% $CDCl_3$ or C_6H_6 solutions at 23°C. Chemical shifts values are in cps from TMS as an internal standard.

b) No reliable value is obtained in benzene, because the signals of H_α and benzene protons overlap each other.

TABLE 4. SOLVENT EFFECTS ON THE CHEMICAL SHIFTS OF PROTONS (H_α)

Thioformimidate		$\Delta\nu_{cps}$ value ($\nu_{\text{in } CDCl_3} - \nu_{\text{in } C_6H_6}$)
XI	*syn*	9.7
	anti	17.0
XII	*syn*	5.7
	anti	17.5
XIII	*syn*	0.2
	anti	19.7
XIV	*syn*	~0.0
	anti	13.8

of the two H_α signals, the *syn*/*anti* ratio has been calculated. As is indicated in Table 3, *syn* H_α gives a doublet, whereas *anti* H_α gives a singlet. The coupling of *syn* H_α with the α-hydrogen (H_x) of the cyclohexane ring is more pronounced than that of *anti* H_α. This observation corresponds to the fact that the coupling constant between *trans* hydrogens in olefin is larger than that between *cis* hydrogens. Table 4 summarizes the $\Delta\nu$ values ($\Delta\nu = \nu_{\text{in } CDCl_3} - \nu_{\text{in } C_6H_6}$) of four thioformimidates.

Experimental

Reaction of IV with Cyclohexyl Isocyanide. A mixture of 6.2 g (0.1 mol) of IV and 8.8 g (0.08 mol) of cyclohexyl isocyanide was stirred, with or without a catalyst (2 mmol), at the indicated reaction temperature. Then the reaction mixture was subjected to glpc, whereby ethyl *N*-cyclohexylthioformimidate (XI) and cyclohexyl isothiocyanate were identified and quantitatively analyzed. XI was isolated from the reaction mixture by distillation, bp 110—112°C/20 mmHg.

Found: C, 63.02; H, 10.05%. Calcd for $C_9H_{17}NS$: C, 63.10; H, 10.01%.

The structure of XI was established by means of NMR (Fig. 1) and infrared spectroscopy ($\nu_{C=N}$ at 1590 cm^{-1}). The authentic sample of cyclohexyl isothiocyanate was prepared by the reaction of cyclohexyl isocyanide with sulfur.[7]

Reaction of V with Cyclohexyl Isocyanide. The reaction of V with cyclohexyl isocyanide was carried out in the same manner as the above. By glpc analysis, isopropyl *N*-cyclohexylthioformimidate (XII) and cyclohexyl isothiocyanate were identified and quantitatively analyzed. XII was isolated by the distillation of the reaction mixture, bp 135—136°C/20 mmHg.

Found: C, 64.67; H, 10.23; N, 7.62%. Calcd for $C_{10}H_{19}NS$: C, 64.81; H, 10.33; N, 7.56%.

The structure of XII was further established by infrared ($\nu_{C=N}$ 1590 cm^{-1}) and NMR spectra studies. In some experiments, the gas evolved during the reaction was collected in a gas burette and quantitatively analyzed. The evolved gas was identified as propane by glpc and NMR.

7) A. J. Weith, *Ber.*, **6**, 210 (1873).

Reaction of VII with Cyclohexyl Isocyanide. The procedure of the preceding two reactions was adopted. In the glpc analysis of the reaction mixture, *t*-butyl *N*-cyclohexylthioformimidate (XIII) and cyclohexyl isothiocyanate were identified and quantitatively analyzed. The gas evolved from the reaction system was identified as isobutane by glpc and NMR. XIII was isolated by the distillation of the reaction mixture, bp 122—125°C/3 mmHg, mp 56—58°C.

Found: C, 65.98; H, 10.63; N, 7.05; S, 15.53%. Calcd for $C_{11}H_{21}NS$: C, 66.27; H, 10.62; N, 7.03; S, 16.08%.

The structure of XIII was further established by infrared ($\nu_{C=N}$ 1590 cm^{-1}) and NMR spectra studies.

Reaction of Other Thiols with Cyclohexyl Isocyanide. Similarly, VI and VIII were treated with cyclohexyl isocyanide to give *n*-butyl *N*-cyclohexylthioformimidate (bp 129—131°C/3 mmHg) (XVI) and phenyl *N*-cyclohexylthioformimidate (bp 120—122°C/0.1 mmHg) (XIV) respectively. XVI and XIV were identified by means of their infrared and NMR spectra as well as by elemental analysis.

Reaction of VI with Phenyl Isocyanide. Following the procedure described above, a mixture of 9.0 g (0.1 mol) of VI, 8.3 g (0.08 mol) of phenyl isocyanide, and 0.28 g (2 mmol) of cuprous oxide was stirred at 20°C. Then the mixture was distilled to yield *n*-butyl *N*-phenylthioformimidate (XV) (14 g, 90%), bp 151—152°C/20 mmHg.

Found: C, 68.18; H, 7.59; N, 7.11; S, 16.20%. Calcd for $C_{11}H_{15}NS$: C, 68.35; H, 7.82; N, 7.25; S, 16.59%.

The structure of XV was further established by a study of its NMR spectrum.

Exchange of Alkylthio Group of Thioformimidate. A mixture of 5.5 g (0.03 mol) of XII and 9.0 g (0.1 mol) of VII was stirred at 15°C for 1 hr. It was shown by glpc analysis that XII was converted quantitatively into XIII.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1642—1647 (1968)

Hot Atom Chemistry of Phosphorus Compounds. II.[1] Chemical Effects of Neutron Irradiation on Phosphoric Esters of Hexoses*1

Yoshiyuki KISO, Mitsue KOBAYASHI, Yoshinori KITAOKA
Keizo KAWAMOTO and Jitsuya TAKADA

Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka

(Received November 4, 1967)

Phosphoric esters of hexoses were subjected to neutrons and the resulting ^{32}P-labeled recoil products were separated by paper chromatography and paper electrophoresis. The main recoil products were phosphorous and phosphoric acids, independent of the chemical form of the target material and the kind of its salt. A small amount of inorganic acids containing a P–P or P–O–P bond was also found. The yield of the retention product was less than a few percents. The presence of organic diphosphorus compound was supposed by paper electrophoretic analysis. An addition of a small amount of water to the target material before irradiation favored formation of ^{32}P-labeled phosphorus oxyacids in lower oxidation state. The results from irradiation of aqueous solution gave an unexpected chromatographic behavior owing to some unstable complex of recoil ^{32}P atom with water molecule.

Although the elucidation of the chemical effects of neutron irradiation on biologically important compounds will give a clue to that on cells or tissues in a living body, little is known about the effects on such compounds except a few compounds.[2] The neutron irradiation of ATP (Adenosine Tri-Phosphate) has been reported.[3] However, the separation of the recoil products was not so good. The same attempt on DNA (Deoxyribonucleic Acid) have been reported by Halmann who studied on the recoil products and on the physical change due to radiolytic damage.[4] In this case, about one half of ^{32}P-labeled products was found in inorganic phosphorus compounds.

Recently, Yagi and coworkers[5] attempted a phosphorylation of glycerol by irradiating a mixture

of glycerol and phosphoric acid. Almost all radioactivities in recoil products identified by paper chromatography were found in inorganic phosphorus oxyacids. The yield of ^{32}P-labeled organic phosphorus compounds was less than that of inorganic phosphorus compounds.

Thus, systematic study on organic compounds have not yet been made.

As the chemical effects on aromatic phosphorus compounds by bombardment with neutrons have been discussed in the previous paper,[1] we now should like to report the irradiation effects with neutrons on phosphoric esters of hexoses which play an important role in glycolysis. Salts of hexose phosphates chosen were as follows; glucose-1-phosphate dipotassium salt (G-1-P(K)), glucose-6-phosphate barium, potassium and sodium (G-6-P-(Ba, K or Na)), galactose-6-phosphate barium (Ga-6-P(Ba)), fructose-1-phosphate barium (F-1-P(Ba)), fructose-6-phosphate sodium (F-6-P(Na)), and fructose-1,6-diphosphate barium (F-1,6-P(Ba)). After these compounds were irradiated in a reactor, recoil products formed by the ^{31}P $(n,\gamma)^{32}P$ reaction were analyzed by paper chromatography and paper electrophoresis. The effect due to the chemical structure of target material on the production of recoil compounds, and influence by the presence of metallic elements such as barium, sodium and potassium on the recoil reactions are discussed on the basis of the yield of radioactive recoil products, as well as the dilution effcet of the target materials with water on the reaction.

Experimental

Materials. 50% aqueous solution of H_3PO_2 was purchased from Nakarai Chemicals Ltd. and stored in a refrigerator. Crystal H_3PO_3 (95.3%) was used without further purification. Guaranteed grade of H_3PO_4 was used. G-1-P(K) and F-1,6-P(Ba) purchased from Nakarai Chemicals Ltd. and other phosphoric esters of hexoses from Sigma Chemicals were used without further purification. The purity of each sample was checked by activation of chromatographed paper. For preparing phosphoric ester of glucose without containing metallic element, G-6-P(Na) was treated with Dowex 50 ion-exchanger.

Neutron Irradiation of Solid Materials. The sample was sealed into a polyethylene tube and put into a larger polyethylene capsule. The capsule was irradiated for 30—60 min in a pneumatic tube of KUR.*2

Neutron Irradiation of Diluted Solution. G-6-P(Na) (0.157 g) was dissolved in 1.643 g of water free from any cation. Solutions of 1/3, 1/9, 1/27 and 1/81 for the initial concentration were prepared by diluting with water. An aliquot (about 0.5 m*l*) of each solution was sealed in a quartz tube (dia. 5×50 mm). About twenty quartz tubes were put in a larger polyethylene capsule (dia. 10×15 cm) and irradiated for 10 hr in the slant exposual tube of KUR. The flux of thermal neutron in the slant was 2.5×10^{11} n/cm^2 sec, cadmium ratio 7.0 and γ-rays 5.0×10^6 R/hr.

Paper Chromatographic Separation of Recoil Products. After cooling for a week, the irradiated sample was dissolved in water and developed on Toyoroshi No. 50 (2×40 cm) by an assending method for 15 hr, using propanol-ammonia-water (6 : 3 : 1 in volume) as a combined solvent.[6] Radioactive distribution on the chromatographed strip was examined by autoradiography using Fuji Medical X-ray Film (27.9×35.6 cm) or by an autoradioscanner (Aloka, Model JPC-102). The R_f value of known nonradioactive compound was determined by activation of the chromatographed strip. This values was used for identification of the recoil products.

Paper Electrophoretic Separation of Recoil Products. The migration apparatus with multi-compartment cells was used.[7] Background buffer electrolytes of different pH value were adjusted by mixing 0.1 M HCl, 0.1 M citric acid and 0.1 M NH_4OH (ionic strength $\mu=0.1$ over a range of pH=1.0—11). After a paper strip was uniformly dipped in the background electrolyte solution and then the excess of the solution was removed with another filter paper, about 5 μl of a solution (0.05 M) containing irradiated sample was placed on a filter paper (Toyoroshi No. 50, 2×40 cm). The substance was migrated for 1—1.5 hr under a potential gradient of 500 V/34 cm, keeping the temperature of the migration box at 25°C. The strip was taken out, dried by an infrared lamp and followed with autoradioscanning or autoradiography. The mobility of known nonradioactive compound was determined by activation method.

Neutron Activation of the Chromatographed Paper. The chromatographed paper strip was enveloped in a polyethylene envelope and rolled to put into a polyethylene capsule. The capsule containing the rolled papers was irradiated for 30 min in the pneumatic tube. After cooling for a week to reduce radioactivities due to impurities, the radioactivities of phosphorus-32 on the strip were located by autoradiography.

Results and Discussion

Percentage of the radioactivities of recoil products on chromatographed strips are shown in Fig. 1. In general, the yield of hypophosphorous acid in recoil products was small, by taking the fact that the R_f values of H_3PO_4, H_3PO_3 and H_3PO_2 were 0, 0.30 and 0.67, respectively. On the other hand, large amounts of H_3PO_3 and H_3PO_4 were obtained. Although recoil products from G-6-P(Ba) or Ga-6-P(Ba) deposited mostly at the starting position of the filter paper, all of the activities is not considered to be due to phosphoric acid because the activity of phosphoric acid identified by using electrophoresis is not so much. The inconsistency among results obtained by the paper chromatography and the paper electrophoresis was often found when the target material was insoluble in

water. In these cases of barium salts, it is considered that the radioactive recoil product formed with recoil atom in a target material was not completely developed with the solvent, but remained in target materials. Thus, paper chromatography was used for only an aid of paper electrophoresis, especially in recognition of recoil products formed from barium salts. The chromatogram patterns by electrophoresis are shown in Figs. 2 and 3.

The *U* value shows the mobility of the compound relative to that of hypophosphorous anion. The curves in figures show the change of the *U* values as a function of pH. The pH values at inflection points in the curves correspond to consecutive dissociation constants of a given compound, respectively.[8] Thus, the curve of phosphoric acid has three points of inflection, phosphorus acid two and hypophosphorous acid only one. Hexose esters of phosphoric acids have two points which agree with those determined by a titration method.[9]

Another feature of electrophoresis is the fact that the equivalent mobility (mobility/charge number) of the compound is reversely proportional to squear root of the molecular weight,[10] providing that the shape and hydration of molecule are similar.*3 Then, analysis of mobility*U*-pH curve of electrophoresis is useful for identification of the recoil products and to determine the structure of unknown products.[11] Almost all inorganic phosphorus compounds show high *U*-values at a range of high pH-values while organic phosphorus compounds do not show high *U* value because of their higher molecular weight. Qualitative distinction between organic and inorganic phosphorus compounds can be easily made at the high pH region unless the organic compound is unstable. The electrophoretic behavior of the standard compounds is shown in Fig. 2. The mobility of the nonradioactive compound was determined by

activating the chromatographed paper with neutrons. The dotted line shows the *U*-pH curve speculated on the basis of the number of dissociable hydrogen in a molecule. The *U*-pH curves of recoil products in irradiated samples are shown in Figs. 3A—F, respectively for the target materials. Main recoil products or products clearly separated without overlapping of different fractions are qualitatively shown in Fig. 3. The dotted lines show the recoil products detected only in autoradiography. The results of quantitative analysis are shown in Fig. 4.

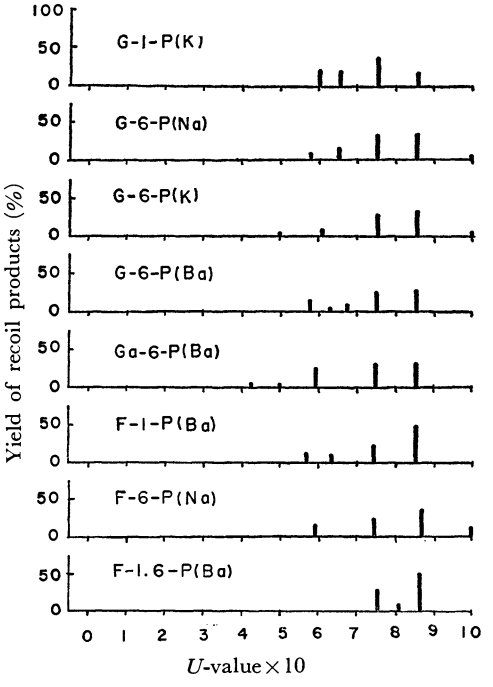

Fig. 4. Distribution of radioactive recoil products separated by electrophoresis at pH=5.

The distribution of activities on the chromatographed strip was obtained by scanning the filter paper migrated at pH=5.0 of background buffer solution. A similar procedure was carried out at pH=3.0, too.

Irradiation of C_1-ester (=G-1-P(K)) in which aldehyde group is blocked by phosphate group gave larger amounts of phosphoric acid (U=0.75) than that of phosphorous acid (U=0.85). On the other hand, irradiation of G-6-P yielded more phosphorous acid than phosphoric acid, independent of the kind of the salts. The tendency found in the case of G-6-P was also observed in irradiation of F-1-P(Ba), F-6-P(Na) or F-1,6-P(Ba). In any case, the yield of hypophosphorous acid was lower, comparing with that of other two inorganic oxyacids. It was concluded from the analysis of the distribution patterns that the yield of hypophosphorous acid is slightly larger in the case of sodium salts than in the case of potassium or barium. In irradiation of F-1,6-P(Ba), hypophosphorous acid was not found even in the autoradiogram.

It was found that P-P or P-O-P bond is included in other inorganic phosphorus compounds formed. As the P-O-P bond is easily formed by heating salts of phosphate,[12] the compounds mentioned above can be expected to be formed also by heat evolved in the nuclear reactions of phosphorus or another metals such as sodium, barium or potassium.[13] The yield of pyrophosphate (R_f= 0.05) estimated from a paper chromatogram was less than a few percents. On the contrary to pyrophosphate, the P-P compound was not formed by heating. When we used the background buffer solution described in Experimental section, the migration zone of $\overset{4}{P}$–$\overset{4}{P}$ compound overlapped with that of phosphorous or/and pyrophosphoric acids in a range of pH=4—5. Thus, in the case of identification of P-P compounds, a background buffer solution containing 0.05 M zinc acetate was specially prepared. Since Fenger[14] has determined the relative mobiliteis of $\overset{2}{P}$–$\overset{4}{P}$ and $\overset{4}{P}$–$\overset{4}{P}$ compounds to be 0.55 and 0.45 at pH=4.2, respectively, the radioactive species located in ranges of 0.4 and 0.5 may be considered compounds including a P-P bond.

The relative mobility of target material itself was smaller at electromigration using usual background buffer solution (0.45 in the case of monoester and 0.60 in diester). Although retention product which is ^{32}P-labeled target material was clearly found in autoradiography, the activities corresponding to that was less than a few percents, which was in agreement with the values theoretically calculated.[2] Irradiating monoester, we always obtained a compound which behaved electrophoretically in a manner similar to F-1,6-P. This seems to be an organic diphosphorus compound which resulted from an attack of recoil phosphorous atom on the target materials. From the facts that isomerization of hexose by γ-rays or neutrons was not found and that the dihalogenide was obtained by neutron irradiation of monohalogenide,[15,16] we can safely suppose the formation of diphosphorus compound in which the positions of phosphorus-32 will be probably statistically distributed. Branching of *U*-pH curves of irradiated materials shows the formation of phosphorous esters of hexoses. The characteristic results obtained from irradiated F-1,6-P(Ba) was the

(C) : glucose-6-phosphate sodium salt(17mg)+H_2O(0.1m*l*).

absence of ^{32}P-labeled monophosphoric ester of hexose. Generally speaking, the ^{32}P-labeled organic compounds containing the same number of phosphorus as target material or more than one are formed in the recoil event of phosphorus, and the oxidation state and the position of phosphorus in a molecule depend on chemical form of target materials.

The results of irradiated phosphate ester which is free from metallic element was shown in Fig. 5A.

In this case, lower oxidation products of phosphorus were obtained in abundance. An addition of a small amount of water to a target material also showed similar tendency as shown in Figs. 5B and C. Although the addition of water into the sample to be irradiated favored formation of hypophosphorous acid, the addition of excess of water, that is, dilution with water, lowerd.

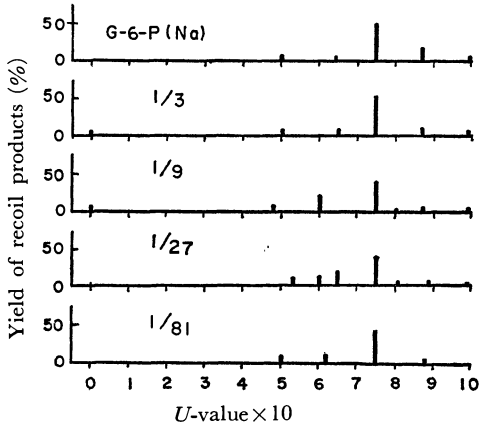

Fig. 6. Distribution of recoil products formed from glucose-6-phosphate sodium salt in diluted solution.

The effects of dilution with water on recoil products are shown in Fig. 6.

As the irradiation position in the reactor and the phase of target material were different from those of the irradiation without water, we can not strictly compare the results shown in Fig. 6 with that shown in Fig. 5, but we can say that the working of water molecule at the recoil event are not simple. Although it was said in early days that the presence of crystal water or of ammonium group in the irradiation sample favors formation of compounds in lower oxidation state, this experimental rule can be applied only within a limited range.

In the case of very diluted solution, the main product was phosphoric acid and the yields of phosphorous and hypophosphorous acids were very small. In addition to the characteristics mentioned above, an abnormal tailing in paper chromatogarm increased with increasing dilution. Such phenomenon was also observed in the irradiation of aqueous solution of phosphorus oxyacids.*4 The abnormal tailing may be due to the formation of an unstable complex by the recoil phosphorus atom with water molecules. A more detailed study on the dilution effect is in progress and will be reported in a near furure.

The authers are grateful to Professor S. Ohashi of Kyushu University for the generous gift of hypophosphoric acid.

*4 The results of phosphorus oxyacids were presented at the 11th Symposium on Radiochemistry, Tokyo, October, 1967.

Polymerizations by 1,3-Dipolar Cycloaddition Reactions. V. The 1,3-Dipolar Polycycloadditions of Dinitrile *N*-Oxides with Diolefins

Yoshio IWAKURA, Shinsaku SHIRAISHI,*1 Masayasu AKIYAMA*2 and Masahiro YUYAMA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received December 19, 1967)

Terephthalonitrile di-*N*-oxide and isophthalonitrile di-*N*-oxide were synthesized from the corresponding hydroxamic chlorides by dehydrochlorination with triethylamine. Their chemical properties and the polycycloadditions with diolefins were examined. The polymers obtained were amorphous and their molecular weights were not so high. The thermal gravimetric analyses of them showed that the polymers were stable up to 300—350°C in air.

Since Werner and Buss[1] reported the formation of benzonitrile *N*-oxide in 1894, the reaction of nitrile *N*-oxides, particularly those involving benzonitrile *N*-oxide, have been thoroughly investigated and it is well known that almost all types of olefins react with nitrile *N*-oxides to form 2-isoxazolines.[2,3] It is also known that, in cycloadditions of nitrile *N*-oxides to mono- or 1,1-disubstituted olefins, the substituents exclusively appear in the 5-position of the 2-isoxazolines.[4]

We have already reported the isolation of terephthalonitrile di-*N*-oxide by the action of triethylamine on terephthalohydroxamic dichloride in the earlier communication[5] and it was the first example of the isolation of dinitrile di-*N*-oxide. By the same procedure, isophthalonitrile di-*N*-oxide was also isolated and its diagnostic investigation in the polycycloaddition has also been reported.[6] In this paper, we wish to present further investigation in the reaction of those nitrile *N*-oxides and their polycycloadditions with diolefins.

Terephthalonitrile di-*N*-oxide (Ia) is rather stable and it can be stored almost unchanged for a few days, while isophthalonitrile di-*N*-oxide (Ib) is less stable and spontaneously changes into yellowish mass which is considered to be polyphenylenefuroxan on the basis of its infrared spectrum.[7,8]

These nitrile *N*-oxides gave the corresponding hydroxamic chlorides reversely by the reactions with hydrogen chloride. The treatment of them with triethyl phosphite afforded terephthalonitrile and isophthalonitrile respectively by deoxygenation in almost quantitative yields.

The 1,3-dipolar cycloadditions of Ia and Ib were carried out with various dipolarophiles to give the corresponding addition products as shown in Tables 1 and 2. When α,β-unsaturated carbonyl compounds were used as dipolarophiles, the reaction proceeded almost quantitatively. In the case of the reactions with olefins, the reaction products, 3,3'-phenylene bis(2-isoxazoline)s, have one asymmetric carbon at 5-position of each isoxazoline ring, where the substituents appear. Therefore, two isomeric products, *dl* and *meso*, should be formed in the each reaction. In fact, we have obtained the two isomers in the case of the reactions with methyl methacrylate, methyl acrylate and vinyl acetate. The NMR spectrum (60 Mc, in CH_3CN) of one of the two isomers obtained from Ib and methyl acrylate, having a lower melting point, has a methine triplet centered at 4.72 τ and a methylene doublet, overlapped with OCH_3 singlet (6.21 τ) centered at 6.30 τ ($J_{CH-CH_2}=9.3$ cps). That of the other, having a higher melting point, has a methine triplet centered at 4.77 τ and a methylene doublet, also overlapped with OCH_3 signal (6.24 τ), centered at 6.32 τ ($J_{CH-CH_2}=9.6$ cps). Methyl 3-phenyl-2-isoxazoline-5-carboxylate of known and unequivocal structure,[9] prepared

from benzohydroxamic chloride and methyl acrylate with use of triethylamine as a hydrogen chloride acceptor, has a methine triplet centered at 4.66 τ and a methylene doublet centered at 6.27 τ (J_{CH-CH_2} = 9.6 cps), one peak of which is overlapped with OCH_3 peak at 6.17 τ. These NMR data indicate the two products are diastereomeric isomers of 3,3'-*m*-phenylene bis-(5-carbomethoxy-2-isoxazoline). The orientation of the cycloaddition may be considered to be the same for the other examples of the reaction summarized in Tables 1 and 2. Similar aspects were reported in the reaction of cyanogen di-*N*-oxide with olefins by Grundmann and his coworkers[10] and also in the reaction of Ia with styrene and with cyclopentadiene by Overberger and Fujimoto.[11] The adducts obtained by the both reactions of Ib with vinyl acetate and with methyl methacrylate have a low crystallinity and therefore the separation of the two isomers was unsuccessful. The reaction products, however, were confirmed to be the corresponding isoxazoline derivatives from their infrared absorption spectra.

The 1,3-dipolar polycycloadditions were conducted with *p*- and *m*-phenylenedimaleimide (IIa and IIb) and with ethylenedimethacrylate (III) as difunctional dipolarophiles. Polymerization proceeded by the repetition of the 1,3-dipolar cycloaddition, in which cyclic shift of electrons accompanied, forming 2-isoxazoline rings along the growing polymer main chains as shown below.

PV: *p*-, PVI: *m*-

The rate of polycycloaddition was considerably fast. Polycycloaddition of Ib with IIb was carried out in an Ubbelohde's viscometer at the concentration of 0.5 mmol of each Ib and IIb in 25 m*l* of dimethylformamide at 30°C and 60°C. After 30 min, no more increase of viscosity of the reaction mixture was observed in either case as seen in Fig. 1.

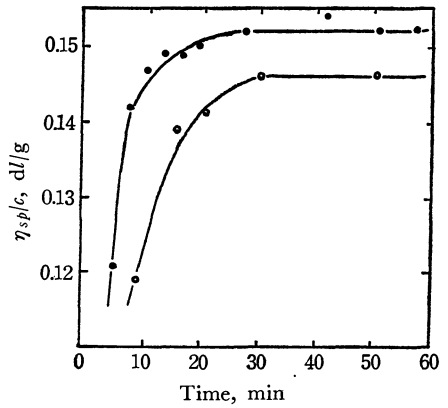

Fig. 1. Viscosity increase *versus* reaction time.
—●— 60°C —○— 30°C
0.5 mmol of each Ib and IIb in 25 m*l* of dimethylformamide.

The polymerization conditions and the results are summarized in Tables 3 and 4. The degree of polymerization was rather low, even in the case of homogeneous polymerization using a polar solvent as a reaction medium. The polymers derived from II are insoluble in benzene, tetrahydrofuran and anisole, and therefore, when such a solvent was used as the reaction medium, precipitation of polymer occurred before a high degree of polymerization was attained. In the case of polymerization of Ia with IIa, the polymer formed precipitated as the reaction proceeded even when a polar solvent was used as the reaction medium. The polymer (PI) was only soluble in concentrated sulfuric acid among the solvents tested.

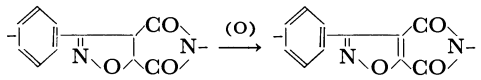
*1 0.2 g/100 m*l* DMF, at 30°C except the parenthesized which were measured at the concentration of 0.5 g/100 m*l* DMF.
*2 Measured by using a capillary tube.
a) Ten mol% less than equivalent amount of isophthalonitrile di-*N*-oxide was allowed to react with IIIa for 15 min, and then the shortage of the nitrile oxide was supplied to attain the equivalency.

The structures of the polymers obtained were verified by means of the comparison of their infrared spectra with those of the model compounds described above. Absorption bands at around 905 and 1180 cm^{-1} of medium intensity were characteristic of the isoxazoline polymers. Besides them, characteristic absorptions of imide carbonyl were observed at 1725 (strong) and at 1790 cm^{-1} (weak) in PI, PII, PIII and PIV. Whereas strong absorption of ester carbonyl was at 1740 cm^{-1} in the case of PV and PVI.

The X-ray diffraction diagrams of the polyphenyleneisoxazolinopyrrolidinediones measured by powder method with use of nickel-filtered Cu$K\alpha$ radiation indicated that PII, PIII and PIV were amorphous and that PI, in which all of phenylene groups were linked at *p*-position, was only slightly crystalline. Such poor crystallinity of them, in spite of their rigid structure, resulted presumably from the random distribution of asymmetric carbons, *i. e.* random ordination of *dl* and *meso* configuration units of the isoxazoline linkages along the polymer chains.

The thermal analyses of PI, PII, PIII and PIV showed that the oxidative degradation occurred at the temperatures above 300°C. The thermal stability of them decreased in the order of PI>PII>PIII>PIV, but even PI showed an abrupt weight loss at 350°C. Figure 2 shows the thermal gravimetric analysis curves of them. The curves may indicate that partial aromatization, besides the oxidative degradation, occurred as shown by the

equation below and consequently the thermal stability was retained temporarily in each case.



Experimental

Terephthalonitrile Di-*N*-oxide (Ia) and Isophthalonitrile Di-*N*-oxide (Ib). To a stirred solution of the corresponding hydroxamic chloride in methanol, a methanolic solution containing an equivalent amount of triethylamine was added dropwise at a temperature below −10°C. The nitrile oxide soon precipitated out of the mixture as colorless powder, which was filtered and washed thoroughly with methanol. The yield was higher than 70% of the theoretical. Ia decomposed explosively when it was put into a bath heated at a temperature above 150°C, and Ib also decomposed abruptly at a temperature above 90°C. When they were heated slowly, only gradual discoloration was observed without melting up to 300°C.

The Reaction of Ia and Ib with Hydrogen Chloride. Hydrogen chloride gas was introduced into a suspension of the corresponding nitrile oxide in methanol with occasional shaking until the suspension turned into a clear solution by exothermal reaction. Then, the reaction mixture was let stand for ten minutes. After that, the mixture was poured into water to give a white precipitate which was identified with the corresponding hydroxamic chloride by melting point and IR spectrum.

The Reaction of Ia and Ib with Triethylphosphite. To a stirred suspension of the corresponding nitrile oxide in methanol, a methanolic solution of triethylphosphite was added gradually with ice-cooling. The reaction was exothermal and almost instantaneous. After the mixture was let stand for an additional hour, methanol and excess triethylphosphite were distilled off under reduced pressure and the residue was recrystallized from aqueous methanol. The products from Ia and Ib were identified with terephthalonitrile and isophthalonitrile respectively.

1,3-Dipolar Cycloadditions of Ia and Ib. A typical example is described below. Ia was added portionwise into a tetrahydrofuran solution of 50 mol% excess of methyl acrylate with stirring. As the reaction proceeded exothermally, Ia dissolved into the solution. A few minutes later than the solution became clear, colorless crystals began to precipitate. The reaction mixture was let stand for an hour and then the precipitate was gathered by filtration and recrystallized twice from ethyl acetate, giving crystals; mp 182—184°C. The mother liquor of the tetrahydrofuran solution was evaporated under reduced pressure. The residual mass was recrystallized twice from methanol, giving colorless crystals; mp 133—136°C. The yield of the sum of those two substances was higher than 70% of the theoretical.

The analytical data and the other reaction products are summarized in Tables 1 and 2.

1,3-Dipolar Polycycloadditions: Materials and Solvent. *p*- (IIa) and *m*-Phenylenedimaleimide (IIb) were prepared in the usual way by the conversion of the phenylenediamines into the maleamic acids, followed by dehydration cyclization with acetic anhydride. IIa melted at 300—303°C when it was inserted into a bath preheated at the temperature, but it did not melt at the temperatures above 380°C, when heated gradually (lit.[12] mp 346—350°C). The melting point of IIb was 198—199°C (lit.[12] 202°C).

Ethylenedimethacrylate was obtained commercially and purified by distillation.

The solvents used were purified by usual way.

Polymerization Procedures. A typical example is as follows: Into a solution of 0.402 g (0.002 mol) of IIb in 4.0 m*l* of dimethylformamide, 0.320 g (0.002 mol) of Ib was added portionwise with stirring at room temperature. Then the mixture was let stand for an additional hour with stirring and poured into methanol. The polymer precipitated was gathered by filtration and washed thoroughly with hot methanol and dried under vacuum at 110°C to give an almost colorless powder.

Polymerizations by 1,3-Dipolar Cycloaddition Reactions. VI. Syntheses of Polyurethans with Isoxazoline or Isoxazole Linkages

Yoshio IWAKURA, Shinsaku SHIRAISHI,*1 Zin ASAKAWA,*2 Masayasu AKIYAMA*3 and Nobuo TANAKA

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo

(Received December 19, 1967)

Polyurethans with isoxazoline or isoxazole linkages in the polymer main chains were prepared by polyadditions of diols with isoxazoline or isoxazole rings and diisocyanates. The diols were prepared by 1,3-dipolar cycloaddition reactions of tere- and iso-phthalonitrile di-*N*-oxides with allyl or propargyl alcohol. Polyurethans of the same structures were also prepared by 1,3-dipolar polycycloadditions of the nitrile oxides with bisallyl or bispropargyl carbamates.

The 1,3-dipolar cycloaddition reaction, first defined and extensively studied by Huisgen and his coworkers,[1] is an interesting method of synthesizing heterocyclic compounds. The high yields of the reaction products have prompted several recent investigations of the syntheses of the polymers with heterocyclic rings by this reaction. We ourselves have already reported[2] the preparation of new diols with heterocycles by the reactions of tere- and isophthalonitrile di-*N*-oxides with allyl or propargyl alcohol. The present paper is concerned with the preparation of new types of polyurethans with isoxazoline or isoxazole rings in their polymer main chains from those diols, and with the preparation of the polymers of the same structures by 1,3-dipolar polycycloadditions. The generalized reaction scheme and the structures of the polymers are shown below:

a) 0.5 g/100 ml of DMF, at 30°C. b) 0.5 g/100 ml of DMSO, at 30°C.

Diols with isoxazoline rings, 3,3'-(*m*- and *p*-phenylene)bis(5-hydroxymethyl-2-isoxazoline) (IIIa and IIIb), and those with isoxazole rings, 3,3'-(*m*- and *p*-phenylene)bis(5-hydroxymethylisoxazole) (IVa and IVb), were prepared by 1,3-dipolar cycloaddition reactions of iso- and tere-phthalonitrile di-*N*-oxides with allyl alcohol and with propargyl alcohol respectively in tetrahydrofuran (THF) solution at room temperature. They were also prepared from the corresponding hydroxamic chlorides and the alcohols mentioned above in THF, in the presence of triethylamines as a hydrogen chloride acceptor. IIIa and IIIb each have two asymmetric carbons to which a hydroxymethyl group attaches; therefore, they should each have two isomers, *meso* and *dl*. Indeed, the melting point of IIIa shows the broad range of 127—135°C, suggesting that it may be a mixture of the two isomers. However, attempts to separate the diastereomers have been unsuccessful. These diols are summarized in Table 1.

The polyaddition reactions of the diols described above were conducted with tetramethylene diisocyanate and with 4,4'-diisocyanatodiphenylmethane to give new types of polyurethans. The polyaddition conditions and the results are shown

TABLE 3. BISALLYL AND X-OCONH-R-

	Compound		Yield (%)	Recryst. solvent
	X	R		
Va	$CH_2=CHCH_2-$	$-(CH_2)_4-$	78.3	50%-CH_3OH
Vb	$CH_2=CHCH_2-$		88.5	95%-CH_3OH
VIa	$CH\equiv CCH_2-$	$-(CH_2)_4-$	91.0	Benzene
VIb	$CH\equiv CCH_2-$		93.0	50%-CH_3OH

in Table 2. The diols with a *m*-phenylene link, IIIa and IVa, gave relatively-high-molecular-weight polymers with inherent viscosities of 0.3—0.7 (0.5 g/100 m*l* of DMF), while the diols with a *p*-phenylene link, IIIb and IVb, gave rather-lower-molecular-weight polymers with inherent viscosities of 0.11—0.22. The latter diols were less soluble in anisole; moreover, the polyurethans derived from them were also insoluble in the solvent. For that reason, the polymer formed precipitated from the reaction mixture before a high degree of polymerization was attained. Some other solvents, such as dimethylformamide (DMF), dimethylacetamide (DMAc), dimethylsulfoxide (DMSO), and hexamethylphosphoramide (HMPA) were also used as reaction media, but high-molecular-weight polymers were not obtained in such cases.

The polymers derived from IIIa and IVa are soluble in such polar solvents as DMF, DMAc, DMSO, and HMPA, but are insoluble in methanol, acetone, THF, anisole, and benzene. Those derived from IIIb and IVb are soluble in DMSO, but are only partly soluble in DMF and DMAc.

Polyurethans of the same structures were also obtained by 1,3-dipolar polycycloadditions of the nitrile oxides with a bisallyl carbamate or with a bispropargyl carbamate. These difunctional unsaturated carbamates were prepared by the reaction of the diisocyanates described above with allyl or propargyl alcohol. The carbamates are summarized in Table 3.

The 1,3-dipolar polycycloadditions were carried out in a THF solution by heating under reflux. When isolated nitrile oxides (II) were used, the molecular weights of the polymers obtained were rather low. The inherent viscosity of the polymers was not larger than 0.2 in any case. On the other hand, relatively-high-molecular-weight polymers were obtained when hydroxamic chlorides (I) were used in the presence of triethylamine as a hydrogen chloride acceptor. This indicates that the *in situ* addition of the nitrile oxide may be favorable to the polymerization reaction. Typical conditions and the results for the polymerization reactions of hydroxamic chlorides with difunctional dipolarophiles in THF are shown in Table 4. When anisole, *o*-dichlorobenzene, *m*-cresol, or DMSO was used as the reaction medium, the results were not better than those in Table 4.

TABLE 4. POLYURETHANS PREPARED BY 1,3-DIPOLAR POLYCYCLOADDITIONS

Polymer	Time (hr)	Yield (%)	η_{inh}	PMT (°C)
PI	0.5	48	0.47[a]	185—206
PII	1	34	0.58[a]	196—209
PIII	1	86	0.17[b]	242—256
PIV	2.5	88	0.23[b]	268—271
PV	1.5	64	0.25[a]	180—208
PVI	1	86	0.23[a]	195—217
PVII	2	70	0.22[b]	250—260
PVIII	2	95	0.23[b]	274—278

a) 0.5 g/100 m*l* of DMF, at 30°C.
b) 0.5 g/100 m*l* of DMSO, at 30°C.

The infrared spectra of the polymers obtained here coincided closely with the corresponding polymers obtained by the polyadditions described above. Their polymer melt temperatures (PMT) also exhibited similar values. As expected, the melting points of the polymers in this series are affected mostly by whether the heterocyclic units are linked by *m*-phenylene or *p*-phenylene groups. The melting points of PI, PII, PV, and PVI, all of which are *m*-phenylene-linked, are in the range of 180—210°C, whereas those of PIII, PIV, PVII, PVIII, which are *p*-phenylene-linked, are in the 250—280°C range.

Among the polymers prepared in this investigation, those with inherent viscosities above 0.3, which are exclusively *m*-phenylene-linked, can all be casted to a self-supporting film from a DMF solution. The film casted from the higher-molecular-weight polymer was tough and transparent.

Experimental

Preparation of the Diols. All of the diols were prepared by the reaction of the corresponding nitrile oxides with allyl alcohol and with propargyl alcohol in

BISPROPARGYL CARBAMATES

Mp (°C)	Anal. (%) Found C	H	N	Calcd C	H	N
76—77	56.33	7.84	11.00	56.23	7.87	10.93
123—124	68.70	6.23	7.92	68.83	6.05	7.65
84—85	57.00	6.56	11.13	57.13	6.39	11.11
163—164	69.74	5.22	7.73	69.60	5.00	7.73

a THF solution at room temperature. They were purified by recrystallization from aqueous methanol in all cases. The analytical data are shown in Table 1. A typical example is as follows: Into a stirred solution of 4 g (0.069 mol) of allyl alcohol in 75 m*l* of THF, there were added, portion by portion, 4.7 g (0.029 mol) of isophthalonitrile di-*N*-oxide (IIa). After the reaction mixture had been let stand overnight, the solvent was evaporated under reduced pressure. The residue was recrystallized twice from 50%-aqueous methanol to give 5.7 g (72% of the theoretical amount) of colorless crystals of IIIa, mp 127—135°C. Further recrystallization did not change the melting point.

Polyaddition of the Diols with the Diisocyanates. A typical example is as follows: 1.380 g (0.005 mol) of IIIa and 0.700 g (0.005 mol) of tetramethylene diisocyanate were placed in 10 m*l* of anisole, and the mixture was stirred and then gently heated to reflux. After the mixture became a clear solution, 15 mg (2.5×10^{-5} mol) of dibutyltin dilaurate was added to the solution as a catalyst. Stirring and heating were continued for 2 more hours. The resinous product separated from the solution and deposited at the bottom of the vessel. After the reaction mixture had cooled, the resinous product was separated and dissolved in DMF. The DMF solution was filtered with a glass funnel and poured into methanol to precipitate the polymer, PI. It was gathered by filtration, washed methanol, and dried at 60°C *in vacuo*. The analytical sample was obtained by treating the polymer with boiling methanol to remove the DMF occuluded in it.

The other polymers were prepared by a similar procedure.

Preparation of the Bisallyl Carbamates and Bispropargyl Carbamates. Bisallyl carbamates were prepared by the reaction of allyl alcohol with the corresponding diisocyanate in petroleum ether, and bispropargyl carbamates were prepared from propargyl alcohol and the diisocyanates in benzene. As the reaction proceeded, in each case the carbamate formed precipitated out of the reaction mixture. When tetrahydrofuran was used as the reaction medium, the solvent was evaporated to obtain the product as a solid. A typical example is as follows: Eight grams of tetramethylene diisocyanate (0.057 mol) and 7 g (0.12 mol) of propargyl alcohol were placed in 20 m*l* of THF, and the mixture was left to stand overnight. The subsequent evaporation of the solvent left a solid. It was recrystallized from benzene to give 12.8 g (91%) of colorless needles of VIa, mp 84—85°C.

The analytical data and the solvents of recrystallization are summarized in Table 3.

Procedures of the 1,3-Dipolar Polycycloadditions. A solution of a dihydroxamic chloride (I) (0.0025 mol) and a bisallyl or bispropargyl carbamate (V or VI) (0.0025 mol) in 5 m*l* of THF was heated under reflux with stirring. To the solution there was then added, drop by drop, 0.006 mole of triethylamine in 5 m*l* of THF. A white precipitate thereupon began to be deposited. The precipitate formed at the earlier stage of the reaction was triethylammonium chloride. The mixture was stirred for an hour, and then the solid deposited was gathered by filtration and dissolved in DMSO. The DMSO solution was filtered with a glass funnel and poured into methanol to precipitate the polymer. It was collected by filtration, washed with methanol, and dried under vacuum.

When other solvents were used as the reaction media, the reaction temperature was kept at a temperature in the range between room temperature and 70°C. The other procedures were similar to those mentioned above.

The polymerization procedures in which isolated nitrile di-*N*-oxides (II) were used as the starting components were the same as those described in a previous paper.[2]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1658—1664 (1968)

Studies of Heteroaromaticity. IX.[1] Stability and Reactivity of 5-Nitro-2-furyl Diazo Compounds

Tadashi SASAKI, Shoji EGUCHI and Atsuyuki KOJIMA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya

(Received December 23, 1967)

(5-Nitro-2-furyl)diazomethane (2), 3-(5-nitro-2-furyl)diazopropene (4), and 1-(5-nitro-2-furyl)diazoethane (6) were prepared by the oxidation of the corresponding hydrazones with active manganese dioxide. The relative stabilities of these diazo compounds were then compared with *p*-nitrophenyldiazomethane in their ethanolic solutions and in their solid states by measuring their decomposition rates spectroscopically; it was found that the stability decreased in the following order:

6 ≃ *p*-nitrophenyldiazomethane > 2 ≃ 4 in ethanol

p-nitrophenyldiazomethane > 2 > 4 > 6 in the solid state.

The reactivities of these diazo compounds were also investigated in the decomposition reactions; the thermal and photolytic decomposition of 2 afforded 1,2-di(5-nitro-2-furyl)ethylene (7) in a low yield, but 4 cyclized readily to 3-(5-nitro-2-furyl)pyrazole (8) in a good yield and 6, to an azine (9) even upon standing at room temperature. 2 was treated with benzoic acid in ether to give 5-nitro-2-furfuryl benzoate (10) in a quantitative yield, and with triphenylphosphine in the same solvent to afford the triphenylphosphazine (13) in a 75% yield; this last substance liberated nitrogen very easily in the presence of cuprous ions to give the phosphonium ylid (14), one of the Wittig reagents. 14 was then considered as a possible starting material for preparing (5-nitro-2-furyl)ethylenic compounds. Similarly, 3-(5-nitro-2-furyl)acrolein triphenylphosphazine (17) was prepared from 4 and triphenylphosphine.

Although the preparation[2] and chemical properties[3] of aromatic diazo compounds have been studied extensively, little is known about heterocyclic diazo compounds, among which 2-furyl-,[4] 2-thienyl-,[4b] phenyl-2-thienyl-[5] and di-2-thienyl diazomethane[5] have been reported.

In this paper we wish to describe the preparation of 5-nitro-2-furyldiazomethane (2), 3-(5-nitro-2-furyl)diazopropene (4), and 1-(5-nitro-2-furyl)-diazoethane (6), and some reaction thereof, from the viewpoint of their chemical reactivities and their antibacterial activity.[6]

Results and Discussion

Of the several methods for the preparation of aromatic diazo compounds, the best way is by the oxidation of the corresponding hydrazones; the choice of the oxidation reagent is known to play a very important role with respect to the yields of the diazo compounds.[2b,7]

5-Nitro-2-furfural hydrazone (1a) was oxidized with active manganese dioxide in ether at 0°C to afford a diazo compound 2 in over an 80% yield, though the oxidation with yellow mercuric oxide or lead tetraacetate, which is known to be very effective reagent for the preparation of dicyanodiazomethane from the corresponding hydrazone,[8] gave 2 in yields of less than 10%. The pyrolytic decomposition[2c] of the sodium salt of 5-nitro-2-furfural tosylhydrazone (1b) afforded 2 in around a 50% yield:

1a ⟶ 2 ⟵ 1b

The similar oxidation of the corresponding

a) Compound 6 was too unstable to obtain satisfactory values of the microanalysis, presumably by loosing nitrogen. b) See also Fig. 1. c) Nitrofuran ring protons signal. d) C-3-H signal. e) C-2-H signal. f) C-1-H signal.

hydrazones, 3 and 5, derived from 3-(5-nitro-2-furyl)acrolein and 5-nitro-2-furyl methyl ketone with active manganese dioxide afforded the corresponding diazo compounds, 4 and 6, in the good yields of 70 and 62% respectively:

$$3 \longrightarrow 4 \qquad 5 \longrightarrow 6$$

The structure of 2, 4, and 6 were confirmed by the analytical and spectral data which are summarized in Table 1. Judging from the data shown in this table ($J_{C-2-H,C-3-H}$=16 cps), 4 may be regarded as having a *trans*-configuration.

The relative stabilities of 2, 4, and 6 to *p*-nitrophenyldiazomethane[9] were measured in their ethanolic solutions from their ultraviolet spectra and in their solid states from their infrared spectra, both as a function of the time at 20°C. The half-lives and the rate constants of their decompositions are summarized in Table 2. From this table, it can be concluded that, in ethanol, 2 has nearly the same stability as 4, but only about a quarter that of 6 or of *p*-nitrophenyldiazomethane, while 2-furyldiazomethane has been reported to be a very unstable red oil.[4] In the solid state, the stability decreased in the following order: *p*-nitrophenyldiazomethane>2>4>6.

In both states, *p*-nitrophenyldiazomethane is the most stable except in the case of 6 in ethanol, where some solvent effects might be expected. This result is in good accordance with our expectations based on the resonance stability of each compound in the ground state. The facts that the final absorption maxima in ethanol were located at 300 $m\mu$ (from 406 $m\mu$) for 2, at 354 $m\mu$ (from 440 $m\mu$) for 4, and at 305 $m\mu$ (from 423 $m\mu$) for 6 showed that the final decomposition products of 2, 4, and 6 were 5-nitro-2-furfuryl ethyl ether (11), 3-(5-nitro-2-furyl)-pyrazole (8), and, presumably, α-(5-nitro-2-furyl)ethyl ethyl ether (12) respectively.

In order to attempt a carbenoid reaction, 2 was decomposed in carbenophilic cyclohexene in the presence of copper powder by heating it until nitrogen gas evolution had ceased; the products were then purified by column chromatography. The only crystalline product isolated was 1,2-di-(5-nitro-2-furyl)ethylene (7); neither insertion- nor addition-products to cyclohexene could be separated. The photolysis of 2 in the presence of a carbenophile, such as cyclohexene, styrene, or α-morpholinostyrene, led to the formation of 7 in a low yield, and in all cases a large amount of an intractable, dark brown mass was produced. These results indicate that 5-nitro-2-furylcarbene, even if produced from 2, is too stable to react further with those carbenophiles, but, rather, affords the dimer 7; consequently, 2 may be concluded to be an unsuitable precursor for the carbenoid reaction.

When 4 was heated over its melting point or was kept standing in ether in the presence of a catalytic amount of triethylamine, intramolecular cyclization occurred to give 8 in a good yield. The structure of 8 was confirmed from the following spectral data: the infrared spectrum showed no diazo-band, but it did show an NH-band at 3165 cm^{-1}, and the nmr spectrum in $CDCl_3$ had signals due to two protons of a pyrazole ring at 2.08 τ (1H, d, J=2.5 cps) and 3.17 τ (1H, d, J=2.5 cps), none of which disappeared on deuteration; a signal due to an NH proton of a pyrazole ring

may be expected to be located in the lower field of around $-3.0\ \tau$,[10] besides those due to two protons of a nitrofuran ring at 2.21 τ (1 H, d, J= 3.8 cps) and at 2.87 τ (1 H, d, J=3.8 cps)[11] and the ultraviolet spectrum in ethanol had an absorption maximum at 354 mμ.[12] Such a facile intramolecular cyclization of unsaturated diazo compounds has also been reported with vinyldiazomethanes:[4a,13]

2 ⟶ 7 4 ⟶ 8

Compound 6 also decomposed very easily either in the solid state or as a benzene solution on only standing at room temperature; it gave an azine derivative 9 as the main product. A similar azine

formation by the decomposition of diaryldiazomethane has also been reported.[14] This shows that nitrofurylcarbene, even if produced from 6, is a rather stable and unreactive species, similar to that produced from 2 described above:

$$6 \longrightarrow 9$$

By far the most common reactions of diazoalkanes are those in which they act as nucleophiles, the α-carbon being most often the nucleophilic center. It is generally believed[15] that the case of reaction decreases with a decrease in the basicity of the α-carbon and that it is affected by the steric effects as well, while the behavior of diazoalkanes as electrophiles is much less pronounced. As an example of a nucleophile, 2 was treated with benzoic acid in ether at room temperature; it afforded the corresponding benzoate, 10, in a quantitative yield. This reaction proceeded very slowly; it took about three days for 2 to be consumed completely even in the presence of an excess amount of benzoic acid, though 2-furyldiazomethane gives the corresponding benzoate in only 30 min.[4b] These results show that the presence of a nitro group in a furan ring causes an increase in the diazomethane stability because of the resonance stabilization and a lowering in the nucleophilicity of 2. Another example is given by the formation of 11 when 2 is left to stand in ethanol, as has been described above. As an example of 2 as an electrophile, 2 was treated in ether with triphenylphosphine at room temperature to afford 5-nitro-2-furfural triphenylphosphazine (13) in a 75% yield. 13 liberated nitrogen readily in the presence of cuprous ions to give 5-nitro-2-furfuryliidene triphenylphosphorane, a phosphonium ylid (14) and one of the Wittig reagents;[16] this provides a novel preparative method for (5-nitro-2-furfuryl)ethylenic compounds, for which the condensation of 5-nitro-2-furfural with active methylene and methyl compounds is the general procedure.[17] A Wittig reaction using 14 is interesting because the preparation of the Wittig reagent by the usual method from 5-nitro-2-furfuryl halides and triphenylphosphine, followed by base-treatment, was unsuccessful because of the facile furan-ring cleavage by a base, though the reaction of 5-nitro-2-furfural with the Wittig reagents has been reported.[18]

Thus, on the treatment of 2 with carbonyl compounds such as benzaldehyde, furfural, and cinnamaldehyde in the presence of triphenylphosphine and cuprous chloride, the corresponding (5-nitro-2-furyl)ethylenic compounds, 16a, b, and c, were obtained, but in low yields. A similar reaction with *p*-nitrobenzaldehyde 5-nitro-2-furfural resulted only in the formation of intractable masses, while that with acetophenone and acetone afforded small amounts of 7 and 5-nitro-2-furfural azine,[19a] with the ketones mostly recovered. The reactivity of the Wittig reaction is known to depend mainly on the charge on the α-carbon atom, and the most stable phosphinemethylenes are completely unreactive; thus, the *p*-nitrophenylmethine triphenylphosphonium ylid gives no olefins at all with benzaldehyde and cinnamaldehyde because of the resonance stabilization.[20]

The above results indicate that nitrofurfuryl phosphobetaine (15) is more basic—in other words, more reactive—than the corresponding *p*-nitrophenyl compound.

The diazo compound 4 reacted similarly with triphenylphosphine in ether to give the corresponding phosphazine (17), which was more labile than 13. Thus, 17 afforded the known β-(5-nitro-2-furyl)acrolein azine[19b] in a good yield upon only being warmed in acetone. Such a facile formation of an azine from phosphazine can be explained by the instability of 17; the decomposition of 17 may afford the corresponding phosphonium ylid, which will be attacked by 4 as an electrophile, this attack to be followed by the elimination of triphenylphosphine from the primary adduct to give an azine.

Experimental[21]

5-Nitro-2-furfural Tosylhydrazone (1b). This was prepared by the usual method from 5-nitrofurfural[22] and tosylhydrazine in a quantitative yield as yellow needles, mp 155—156°C (from methanol): λ_{max}^{EtOH} 352 mμ (ε 15000); ν(KBr) 3170, 1614, 1593, 1528, 1352, 1318 and 1168 cm^{-1}.

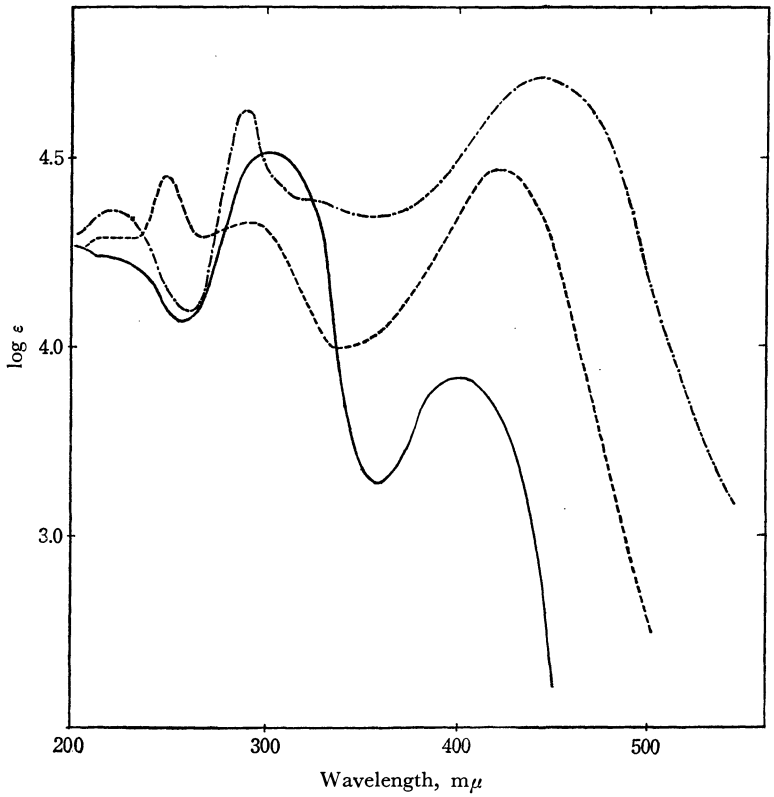

Fig. 1. Ultraviolet absorption spectra of nitrofuryldiazomethane, 2 (——), 4 (-·-·) and 6 (- - -) in ethanol.

Found: C, 46.60; H, 3.35; N, 13.36%. Calcd for $C_{12}H_{11}O_5N_3S$: C, 46.61; H, 3.59; N, 13.59%.

3-(5-Nitro-2-furyl)acroleinhydrazone (3). This was prepared similarly from 5-nitro-2-furylacrolein[23] and 80% hydrazine hydrate in a 52% yield as red needles, mp 150—151°C (from methanol): λ_{max}^{EtOH} 400 mμ (ε 17200): ν(KBr) 3375, 1609, 1572, 1555, 1490, 1356 and 807 cm^{-1}.

Found: C, 46.19; H, 3.95; N, 23.04. Calcd for $C_7H_7O_3N_3$: C, 46.41; H, 3.90; N, 23.20%.

5-Nitro-2-furyl Methyl Ketonehydrazone (5). This was prepared similarly from 5-nitro-2-furyl methyl ketone[24] and hydrazine hydrate in a 35% yield as red needles, mp 162—164°C (from methanol): λ_{max}^{EtOH} 384 mμ (ε 13600); ν(KBr) 3440, 3325, 3240, 1687, 1637, 1580, 1504, 1052 and 810 cm^{-1}; NMR ($CDCl_3$) τ 2.30 (1H, d, J=4.0 cps), 2.57 (2H, s, it disappeared on deuteration), 3.17 (1H, d, J=4.0 cps) and 8.00 (3H, s).

Found: C, 43.05; H, 3.62; N, 24.40%. Calcd for $C_6H_7O_3N_3$: C, 42.60; H, 4.17; N, 24.85%.

Preparation of 5-Nitro-2-furyl Diazo Compounds, 2, 4, and 6. *By Oxidation of the Hydrazones.* A mixture of 1.55 g (0.01 mol) of 1a, mp 162—164°C (dec.) (lit.[25] 164°C (dec.)), 6.20 g (0.07 mol) of active manganese dioxide,[26] and 3 g of anhydrous sodium sulfate in 40 m*l* of dry ether was stirred for 1 hr under ice cooling. The inorganic materials were then removed by filtration and washed with 100 m*l* of ether. The combined ethereal filtrate and washings were evaporated to dryness under reduced pressure to give 1.25 g (81.6%) of 2. The similar oxidation of 3 and 5 gave 4 in a 70% yield and 6 in a 62% yield. The appearance, melting point, and analytical and spectral data of these diazo compounds are summarized in Table 1, and their UV spectra, in Fig. 1.

By Pyrolysis of 1b. Sodium salt of 1b was pyrolyzed by the known procedure[2c] under the reduced pressure of 10^{-3} mmHg at 120—140°C to give 2 in a 50% yield from a sublimed portion.

Stability Measurement of 2, 4, and 6. The decreasing rates of the UV maximum absorption at 406 mμ for 2, at 440 mμ for 4, and 423 mμ for 6 in ethanol were followed as a function of the time at 20°; the half-life of the change and each rate constant were calculated, the results being as given in Table 2. Similarly, the decreasing rates of each diazo absorption band of these diazo compounds at 2110 for 2, at 2100 for 4, and at 2070 cm^{-1} for 6, together with that of *p*-nitrophenyldiazomethane at 2100 cm^{-1}, were followed to give each decomposition half-life in a KBr pellet and each rate constant (*cf.* Table 2).

Identification of the Final Products in Ethanol. After 2 had been kept standing in ethanol at room temperature for several hours, the ethanol was removed under reduced pressure; the residual red oil was identified as 11 spectroscopically (infrared and ultraviolet

23) H. Saikachi and H. Ogawa, *ibid.*, **80**, 3642 (1958).

spectra) by comparison with a specimen prepared by the known method.[27] Similarly, 4 was left in ethanol at room temperature for a while, and then, after the ethanol had been removed, the residual yellow solid, mp 199°C was identified as 8 by the comparison of the infrared spectra and by a mixed-melting-point determination. The similar treatment of 6 afforded a red oil, the amount of which was too small to be purified by distillation; in view of the similarity of the ultraviolet and infrared data to those of 11, we assumed this red oil to be 12.

Decomposition of 2 in Cyclohexene. *By Pyrolysis.* A mixture of 0.5 g (0.003 mol) of 2, and 0.2 g of copper powder in 16 m*l* of cyclohexene was heated at 70° for 40 min; during that time the nitrogen-gas evolution amounted to almost 100% of the theoretical yield. After the excess cyclohexene had been removed under reduced pressure, the oily residue, which showed two spots (R_f=0.50 and 0.01) on a silica-gel TLC*1 (benzene-methanol 95 : 5 vol% as the solvent and iodine as the developer), was chromatographed on a silica-gel (Mallinckrodt, 100 mesh) column, using benzene as the eluent, to give 22 mg (5.8%) of 7 as brownish yellow needles (mp 251—252°C (from benzene)), corresponding to the upper spot on TLC. λ_{max}^{EtOH} 242 mμ (ε 14300), 282 (7950), 406 (38000) and 424 (30400); ν(KBr) 1583, 1533, 1497, 1354, 1250, 1164, 960 and 820 cm^{-1}.

Found: C, 47.77; H, 2.34; N, 10.85%. Calcd for $C_{10}H_6O_6N_2$: C, 48.01; H, 2.42; N, 11.20%.

The fraction corresponding to the lower spot on TLC was eluted with methanol and a methanolic eluate was condensed to give a dark brown, intractable oil as the main product.

The decomposition of 2 in styrene, α-morpholinostyrene, tetrahydrofuran, and benzene as a carbenophile afforded only 7 in 4—6% yields after the purification of the products by silica-gel column chromatography; the main product was always an intractable, dark brown oil.

By Photolysis. A solution of 2 in cyclohexene or styrene was irradiated at room temperature through a Pyrex jacket with a 100-watt, high-pressure mercury lamp (UM-102, Ushio Denki Co., Tokyo, Japan) until nitrogen-gas evolution had ceased; when the products were then examined on TLC, they showed several spots, most of them seeming to originate from the decomposition products, including the nitrofuran-ring cleavage.

After the removal of the solvent, the crude product was purified by silica-gel column chromatography; this gave 7 in 3—5% yields.

3-(5-Nitro-2-furyl)pyrazole (8). A solution of 0.5 g (0.003 mol) of 4 and a few drops of triethylamine in 30 m*l* of ether was kept standing at room temperature for 18 hr. The yellow needles that were thus precipitated were filtered, washed with ether, and recrystallized from ethanol to give 0.26 g (51%) of 8 as faintly yellow needles, mp 199—200°C: λ_{max}^{EtOH} 354 mμ (ε 15300), 230 (11500); ν (KBr) 3165, 1604, 1538, 1500, 1348, 1020 and 810 cm^{-1}.

Found: C, 47.05; H, 3.17; N, 21.71%.[28] Calcd for $C_7H_5O_3N_3$: C, 46.93; H, 2.81; N, 23.46%.

5-Nitro-2-furyl Methyl Ketone Azine (9). A solution of 0.05 g (0.03 mol) of 6 in 20 m*l* of benzene was refluxed for 30 min. The precipitated crystals were filtered with cooling and recrystallized from acetone to give 25 mg (50%) of 9 as yellow needles, mp 189—190°C: λ_{max}^{EtOH} 223 mμ (ε 12000), 367 (32000); ν (KBr) 1610, 1568, 1514, 1473, 1350, 1035 and 812 cm^{-1}.

Found: C, 47.03; H, 3.27; N, 17.92%. Calcd for $C_{12}H_{10}O_6N_4$: C, 47.06; H, 3.29; N, 18.30%.

5-Nitro-2-furfuryl Benzoate (10). A solution of 0.26 g (0.002 mol) of 2 and 0.72 g (0.006 mol) of benzoic acid in 50 m*l* of ether was stirred at room temperature for 3 days, by which time 2 disappeared on TLC. The mixture was then evaporated to dryness to give yellow solids, which were recrystallized from ether to give 0.42 g (99%) of crude 10. Three recrystallizations from ether gave an analytical sample, mp 90—91°C: $\lambda_{max}^{Et_2O}$ 299 mμ (ε 8170); ν(KBr) 1719, 1597, 1533, 1348, 1242, 1021, 810, 749 and 710 cm^{-1}.

Found: C, 58.24; H, 3.50; N, 5.52%. Calcd for $C_{12}H_9O_5N$: C, 58.30; H, 3.67; N, 5.67%.

5-Nitro-2-furfural Triphenylphosphazine (13). To a solution of 0.015 g (0.001 mol) of 2 in 20 m*l* of ether, 0.29 g (0.001 mol) of triphenylphosphine in 10 m*l* of ether was added. After standing for 30 min at room temperature, the mixture was evaporated to dryness under reduced pressure, and the residue was recrystallized from an acetone - *n*-hexane mixture to give 0.31 g (75%) of 13 as deep red plates, mp 159—161°C: λ_{max}^{EtOH} 237 mμ (ε 11600) and 427 (21600); ν (KBr) 1598, 1542, 1500, 1368, 1062, 1026, 815, 736 and 700 cm^{-1}; NMR ($CDCl_3$) τ 1.77—2.52 (16 H, m, phenyl protons and –N=CH–), 2.69 (1H, d, J=3.8 cps, a furan-ring proton) and 3.49 (1 H, d, J=3.8 cps, a furan-ring proton).

Found: C, 65.02; H, 4.40; N, 9.85%. For an aged sample after one month: C, 63.91; H, 4.24; N, 9.57%. Calcd for $C_{23}H_{18}O_3N_3P$: C, 66.55; H, 4.38; N, 10.13%.

1-(5-Nitro-2-furyl)-2-phenylethylene (16a). A mixture of 0.5 g (0.003 mol) of 2, 0.35 g (0.0033 mol) of benzaldehyde, 0.86 g (0.0033 mol) of triphenylphosphine, and 15 mg of cuprous chloride in 30 m*l* of tetrahydrofuran was refluxed for 20 hr. The solvent was then removed under reduced pressure to give a brownish, sticky residue which was dissolved in benzene and chromatographed on a silica-gel column, using benzene as the eluent. The removal of the solvent from the eluate afforded yellow crystals, which were then recrystallized from ethanol to give 0.26 g (36%) of 16a as yellow needles, mp 109—110°C (lit.[29] 111—112°C): NMR ($CDCl_3$) τ 2.68 and 3.48 (each 1H, d, J=3.8 cps, nitrofuran-ring protons), 2.56—2.64 (5H, m, phenyl protons), 2.67 and 3.10 (each 1H, d, J=16.5 cps, olefinic protons).[30]

1-(5-Nitro-2-furyl)-4-phenylbutadiene (16b). A mixture of 0.538 g (0.0035 mol) of 2, 1.0 g (0.0076 mol) of cinnamaldehyde, 0.925 g (0.0035 mol) of

30) This coupling constant shows a *trans*-configuration of the olefin protons for 16a, as expected from the four-centered transition state, keeping bulky phenyl and nitrofuran rings in a *trans*-configuration, as has been shown in 15.

triphenylphosphine, and 16 mg of cuprous chloride in 30 m*l* of tetrahydrofuran was refluxed for 40 hr. After the removal of the solvent, a brownish residue was chromatographed on a silica-gel column, using benzene as the eluent. The eluant was condensed to give yellowish-brown crystals, which were then recrystallized from ethanol to give 0.152 g (18%) of 16b as brownish-yellow needles, mp 137—139°C: λ_{max}^{EtOH} 228 mμ (ε 14100), 300 (24300) and 410 (29300); ν(KBr) 1612, 1593, 1560, 1517, 1506, 1390, 1355, 1246, 1174, 1070 and 809 cm^{-1}; NMR ($CDCl_3$) τ 2.39—3.39 (9H, m, phenyl protons and three olefinic protons), 3.52 (1 H, d, J=3.8 cps, C-3-H) and 3.60 (1 H, d, J=15 cps, C-1-H).

Found: C, 69.40; H, 4.42; N, 5.68%. Calcd for $C_{14}H_{11}O_3N$: C, 69.70; H, 4.59; N, 5.80%.

1-(5-Nitro-2-furyl)-2-furylethylene (16c). A mixture of 0.502 g (0.0033 mol) of 2, 0.312 g (0.0033 mol) of furfural, 0.86 g (0.0033 mol) of triphenylphosphine, and 20 mg of cuprous chloride in 30 m*l* of tetrahydrofuran was refluxed for 20 hr. The reaction mixture was then worked up as above to give 55 mg (10%) of 16 c as reddish-brown prisms, mp 94—96°C (from ethanol): λ_{max}^{EtOH} 208 mμ (ε 12300), 235 (8150), 294 (17600) and 409 (23400); ν(KBr) 1625, 1587, 1554, 1516, 1492, 1395, 1354, 1240, 1020 and 804 cm^{-1}.

Found: C, 58.37; H, 3.49; N, 6.39%. Calcd for $C_{10}H_7O_4N_2$: C, 58.54; H, 3.44; N, 6.83%.

3-(5 - Nitro - 2 - furyl) acrolein Triphenylphosphazine (17). To a solution of 0.22 g (0.00084 mol) of triphenylphosphine in 5 m*l* of ether, a solution of 0.156 g (0.00087 mol) of 4 in 20 m*l* of ether was added. After standing for 1 hr at room temperature, the mixture was concentrated to a volume of about 10 m*l*, thus giving red prisms which were collected to give 0.268 g (72.5%) of 17 with a mp of 144—146°C: λ_{max}^{EtOH} 219 mμ (ε 33500); 314 (19900), and 443 (24500); ν(KBr) 1610, 1592, 1562, 1537, 1504, 1487, 1350, 1254, 1024, 970, 812 and 721 cm^{-1}.

Found: C, 64.72; H, 4.29; N, 8.72%. Calcd for $C_{25}H_{22}O_4N_3P$: C, 65.30; H, 4.83; N, 9.14%.

3-(5-Nitro-2-furyl)acrolein Azine (18). A solution of 61 mg (0.00014 mol) of 17 in 10 m*l* of acetone was warmed at 50—60°C for several hours. After cooling, the precipitated solid was collected to give 12 mg (52%) of the azine as yellow powders, mp 226—228°C (dec.) (lit.[18b] mp 227—228°C (dec.)).

The authors wish to express their thanks to the Ueno Pharmaceutical Co. for kindly supplying the nitrofurfural and to the Dainippon Pharmaceutical Co. for the NMR measurements. The microanalyses were done by Mr. Akiho Ishihara at their laboratories; to him especially the authors are much obliged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1664—1668 (1968)

Photoreduction of Azoxybenzene to Azobenzene

Rikuhei TANIKAGA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received December 26, 1967)

The photochemical reduction of azoxybenzene to azobenzene has been investigated. The direct irradiation of azoxybenzene leads to a rearrangement to 2-hydroxyazobenzene and to *cis-trans* isomerization, whereas the sensitized irradiation leads to a reduction to azobenzene in the presence of a sensitizer with a triplet excitation energy greater than *ca.* 62 kcal/mol. 2-Hydroxyazobenzene and *cis*-azoxybenzene seem to be formed from the excited singlet state of azoxybenzene, and azobenzene, from the excited triplet state. Even without a sensitizer, the irradiation of benzo[*c*]cinnoline *N*-oxide, which is incapable of undergoing rearrangement or isomerization, brings about a photochemical reduction, which is affected by a sensitizer or a quencher, and also by the hydrogen-donating ability of the solvent used (isopropanol>ethanol>cumene>toluene). Acetone is yielded when isopropanol is used as the solvent. On the basis of these results, a mechanism in which benzo[*c*]cinnoline is formed from the excited triplet state of benzo[*c*]cinnoline *N*-oxide, followed by hydrogen abstraction from a solvent, is proposed.

The photochemical rearrangement of azoxybenzene to 2-hydroxyazobenzene[1-4] is assumed to start from a $\pi \rightarrow \pi^*$ excitation, because the emission of the lines above 300 mμ in a mercury arc lamp causes the rearrangement, but it has not been established whether or not an excited triplet state

intermediate is involved. In order to clarify this situation, we irradiated a solution of azoxybenzene in the presence of benzophenone, we thus found the reaction to take a completely different course, *i. e.*, azobenzene was formed as the major product.[5] This photoreduction seems to be similar to the deoxygenation from an excited triplet state of pyridine *N*-oxide or of picoline *N*-oxide in the gas-phase photolysis.[6]

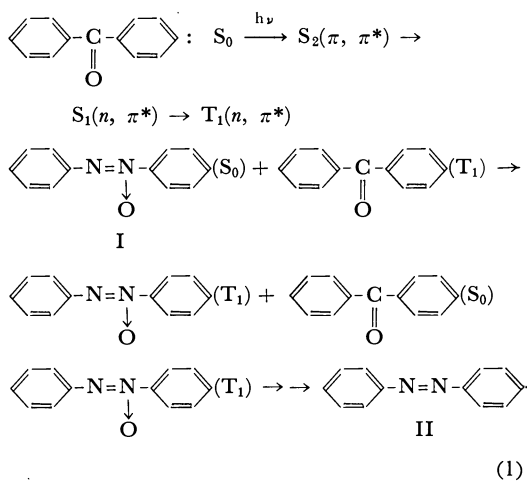
A principal objective of this work is to discuss the photochemical reduction of azoxybenzene to azobenzene, and to give some suggestions regarding the photochemical oxygen migration and the *cis-trans* isomerization.

It is also interesting to note that the photochemical deoxygenation process of a compound containing a N→O bond may be involved in the photoreduction of nitrosobenzene to azoxybenzene.[7]

Results and Discussion

Photoreduction of Azoxybenzene (I) to Azobenzene (II). The irradiation of a degassed ethanolic solution of *trans*-azoxybenzene (I) in a quartz or Pyrex tube with a high-pressure mercury arc lamp afforded 2-hydroxyazobenzene (III) and *cis*-azoxybenzene (IV), but no azobenzene (II). On the other hand, II was obtained as the major product by the photolysis of a degassed solution of I, containing benzophenone as a sensitizer, in a quartz tube. The results of the irradiation of I in a quartz tube are given in Table 1.

Scarcely any II was formed in the presence of oxygen, presumably because the excited triplet state, T_1, of I was quenched by oxygen. Although it is desirable to use a $n\rightarrow\pi^*$ transition (λ_{max}^{EtOH} = 333 mμ, ε=160) of benzophenone in any discussion of its photosensitization, the $n\rightarrow\pi^*$ excitation is not expected to occur in the presence of I because of the strong absorption of I (λ_{max}^{EtOH}=323 mμ, ε=14700). In fact, the photosensitization did not occur when a Pyrex filter was used. Thus, the photosensitization of benzophenone shown in Table 1 may result from its $\pi\rightarrow\pi^*$ transition (λ_{max}^{EtOH} =253 mμ, ε=18000).[8] A possible mechanism for the formation of II with a wavelength of about 250 mμ is as follows:



(1)

The irradiation of I without benzophenone never afforded II. This result indicates that III and IV may be formed directly from the excited singlet state, S_1, of I, but not through the excited triplet state, T_1.[9] The formation of III and IV even in the presence of benzophenone may be due to the direct photoreaction of I with a wavelength longer than 300 mμ, as is shown in Eq. (2):

$$I(S_0) \xrightarrow{h\nu} I(S_1(\pi, \pi^*)) \rightarrow\rightarrow III \qquad (2)$$

Table 1 shows that a side reaction took place from the sensitized photolysis. The by-products have not yet been identified, but hydrazobenzene and aniline derivatives may be formed by the reduction of II and III, because the azo bridge is able to abstract hydrogen atoms or free radicals upon

irradiation.[10-12] At any rate, irradiation for many hours is not desirable for the investigation of the photoreduction of I to II.

I could be photochemically reduced to II with the ketones other than benzophenone. The following ketones were efficient photosensitizers: acetophenone (triplet excitation energy $E_{T_1}=74$ kcal/mol[13]), benzaldehyde (72), benzophenone (69), thioxanthone (65), phenylglyoxal (63), and anthraquinone (62). On the other hand, the following ketones were not efficient: flavone (62), Michler's ketone (61), 2-acetonaphthone (59), biacetyl (55), benzil (54), and fluorenone (53). From these results, the T_1 state of I is assumed to be about 62 kcal/mol.

In order to discuss the solvent effect on the photoreduction of I, ethanol and *n*-hexane were used as solvents transparent above 210 mμ. Since the sensitized photoreduction is derived from a $\pi\rightarrow\pi^*$ transition of benzophenone, it is essential to use such a solvent as ethanol or *n*-hexane without any absorption about 250 mμ. Reduction was easier in ethanol than in *n*-hexane, as is shown in Table 1, but it cannot be determined which stage of Eq. (1) is affected by a solvent. Therefore, for a more detailed discussion it was desirable to irradiate an azoxybenzene derivative with a high efficiency for intersystem crossing without a sensitizer. One possibility was to use an azoxybenzene derivative containing a keto group. Therefore, a degassed solution of 4,4'-diacetylazoxybenzene or 4,4'-dibenzoylazoxybenzene in ethanol was irradiated. However, no azobenzene derivative was obtained. A heavy-atom effect was also expected to promote intersystem crossing. The irradiation of a degassed solution of 4,4'-dichloroazoxybenzene or 4,4'-dibromoazoxybenzene never led to reduction. Azobenzene was not formed from the photolysis of I in such a solvent as methylene chloride or methylene bromide containing heavy atoms. Interestingly, I thus contrasts with pyridine *N*-oxide, which is reduced to pyridine through an excited triplet state in methylene chloride or *n*-propyl bromide as a result of a heavy-atom effect.[14]

When a solution of benzo[*c*]cinnoline *N*-oxide (V), incapable of undergoing *cis-trans* isomerization nor oxygen migration, was directly irradiated, V was found to lead to a photoreduction to benzo[*c*]cinnoline (VI). Therefore, V can be chosen as a model compound in consideration of the solvent effect on the photoreduction of I to II.

Photoreduction of Benzo[*c*]cinnoline *N*-Oxide (V) to Benzo[*c*]cinnoline (VI). The results of the photolysis of a solution of benzo[*c*]cinnoline *N*-oxide (V) in ethanol ($\lambda_{max}=332$ mμ, $\varepsilon=8700$) are given in Table 2.

The effect of oxygen and benzophenone can be explained if benzo[*c*]cinnoline (VI) is assumed to proceed *via* an excited triplet state of V. Moreover, the identification of the triplet state as a reactive intermediate is consistent with the quenching effect of 1-chloronaphthalene in the irradiation of an ethanolic solution of V with a wavelength longer than 350 mμ. A light longer than 300 mμ was efficient for photoreduction, but it cannot been determined what excitation is the first stage of the reaction, because no electronic spectrum of V has yet been assigned.

The results of the photolysis of degassed solutions of V in various solvents for 3 hr with a

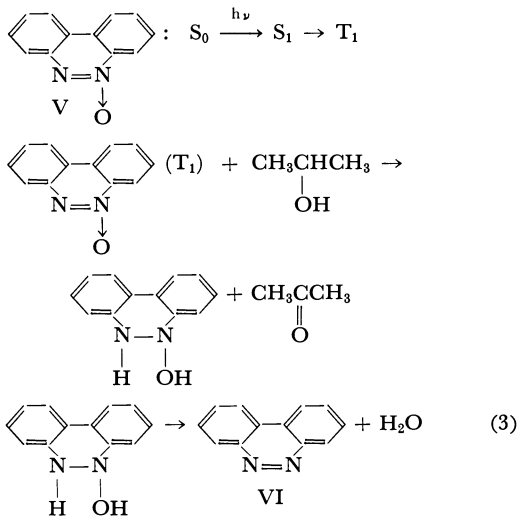
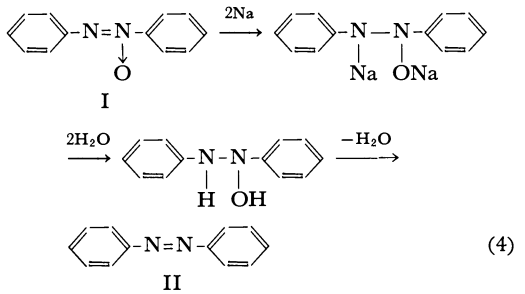
Pyrex filter are given in Table 3.

Table 3 shows that the reduction of V was promoted and that a side reaction was suppressed in a solvent with a great hydrogen-donating ability. Besides, V was similar to benzophenone in its competitive hydrogen abstraction reaction, *i. e.*, isopropanol : cumene : toluene = 9.3 : 3.4 : 1.0.[15] The importance of hydrogen abstraction was implied by the fact that no VI was yielded upon the irradiation of V in carbon tetrachloride or in a solid phase; moreover, it was confirmed by the formation of acetone and water from the photolysis of V in isopropanol. Since the yields of acetone and water corresponded roughly with the amount of V reacted, VI may be produced by the following reaction sequence:



The hydrogen abstraction is a rate-determining process in the photoreduction of V to VI, although an intersystem-crossing process controls the reactivity of the photoreduction of pyridine *N*-oxide.[14] The mechanism shown in Eq. (3) is, interestingly, similar to that for I in reduction with an alkali metal:[16]



From these results, the reduction process from the excited triplet state of I to II may also be supposed to be followed by hydrogen abstraction.

The photochemical deoxygenation of a compound containing a N→O bond *via* an excited triplet state seems important in the photoreduction of dimeric nitrosobenzene to azoxybenzene.[7] This problem is currently being investigated.

Experimental

Materials. Azoxybenzene (I) was prepared by the reduction of nitrobenzene with sodium hydroxide in methanol, and was then recrystallized from methanol (mp 35.5°C).[17] Benzo[*c*]cinnoline *N*-oxide (V) was prepared by the reduction of 2,2'-dinitrodiphenyl with sodium sulfide in ethanol, and was then recrystallized from ethanol-water (mp 139.5°C).[18]

Photolysis of Azoxybenzene (I). The irradiation source was a 100 W, high-pressure mercury arc lamp fitted with a water-cooled immersion well (Eikosha Halos PIH 100). The degassed or oxygen-saturated solution (3 m*l*) of I was irradiated in a quartz tube (inner diameter 13 mm) directly attached to the lamp, and was thermostated at 25.0±0.1°C. The other reaction conditions, such as the solvent used, the irradiation time, and the concentration of benzophenone, were as shown in Table 1. After the irradiation, each component was separated by thin-layer chromatography (TLC) on silica gel (Merck silica gel G according to Stahl; an *n*-hexane - benzene mixture (2 : 1 in volume)) and was identified by the comparison of the infrared and ultraviolet spectral data, the melting point, and the R_f value with those of an authentic sample. The yield of the product was determined as follows. After the irradiation, the solution was left at *ca.* 40°C for one day to transform the *cis*-isomer into the more thermally-stable *trans*-isomer. 4,4'-Dichloro-2-hydroxyazobenzene (VII) was then added as an internal standard. Each component was then separated by TLC on silica gel and extracted with chloroform. The yield was determined from the intensity of the maximum absorption of the extract in an electronic spectrum, whose extinction coefficient had been previously determined by means of an authentic sample. The extinction coefficients used in this work were: I$\varepsilon_{326m\mu}$=14800, II$\varepsilon_{319m\mu}$=18500, III$\varepsilon_{325m\mu}$=18000 and VII$\varepsilon_{339m\mu}$=19500 (in chloroform).

Photolysis of Benzo[*c*]cinnoline *N*-Oxide (V). A solution (2 m*l*) of V was irradiated in a quartz or Pyrex tube (inner diameter : 13 mm) with a 100-W, high-pressure mercury lamp at 25.0±0.1°C. The other reaction conditions were as shown in Table 2 or 3. The products were separated by TLC (silica gel, chloroform), and their yields were determined as has been described above. 1-Benzeneazo-2-naphthol (VIII) was used as an internal standard. The extinction coefficients used in this work were: V$\varepsilon_{333m\mu}$= 8700, VI$\varepsilon_{309m\mu}$ = 8600 and VIII$\varepsilon_{317m\mu}$ = 7470 (in chloroform).

Photolysis of V in Isopropanol. A degassed solution (5 m*l*) of V (5×10^{-2} M) in isopropanol (purified by drying over magnsium ribbon and by fractional

distillation) was irradiated in a Pyrex tube for 30 hr as has been described above. The yields of V and VI were then determined by TLC on silica gel, while that of acetone was determined by gas chromatography (Yanagimoto GCG-5DH, polyethylene glycol 20 M 4.5 m, 80°C, He). The presence of water was established by titration with a Karl-Fischer reagent (Mitsubishi Chemical Industries, Ltd.; Karl-Fischer Reagent SS). The yields of the products were as follows: V, 37%; VI, 56%; acetone, 70%, and water, 75—85%.

The author wishes to thank Professor Ryozo Goto for his helpful discussions and encouragement throughout the course of this work. He is also indebted to Professors Aritsune Kaji and Kazuhiro Maruyama for their valuable discussions.

(Received December 27, 1967)

We investigated the acetylation of the endgroups of the polymer chain resulting from the polymerization of formaldehyde in liquid carbon dioxide in the presence of acetic anhydride. The thermal stability and the toughness of the resulting polymer were examined. All of the endgroups of polymer chains were satisfactorily acetylated by means of heating, between 140 and 150°C, the solid polymer, which was separated by discharging the unreacted monomer and carbon dioxide after polymerization. The acetic anhydride which was added in the beginning of the polymerization at a concentration of 5 mol% per monomer, was sufficient to stabilize the polymer thermally. On the acetylating of the polymer, the presence of air or acetic acid in the amount used to initiate the polymerization had no effect on the properties of the acetylated polymer. A simplified purification procedure for the acetylated polymer was presented.

Polyoxymethylene, ended with hemiformal groups, can be subjected to degradation by several processes; stepwise thermal depolymerization from the chain ends, autoxidative degradation leading to chain scission (observed at temperatures above 170°C), acidolytic scission of the acetal linkages of the main chain, and thermal chain scission at temperatures higher than 270°C.[1,2] In order to stabilize the polyoxymethylene by means of preventing the stepwise thermal depolymerization, acetylation,[3-5] etherification,[2,6,7] and other methods have been proposed. However, these stabilizing treatments must be carried out in separated processes. Wagner *et al.* have proposed a process of polymerizing formaldehyde in acetic anhydride as a solvent, followed with heating, *in situ*, the resulting polymer.[8] The acetic anhydride which is used in this process must, however, be drastically purified in order to remove the acid present in it.

The authors have previously reported on a cationic polymerization of formaldehyde in liquid carbon dioxide to produce high-molecular-weight polyoxymethylene.[9,10] The present work was

carried out in order to simplify the stabilization process by means of acetylating the polymer by acetic anhydride, which had already been added to the system at the beginning of the polymerization of formaldehyde in liquid carbon dioxide.

Experimental

Materials. The formaldehyde monomer was prepared as has been previously described.[9] The acetic anhydride was purified only by distillation at normal pressure, so that it usually contained acetic acid in a concentration slightly above 1 wt%. The amount of acetic acid used as a catalyst was, therefore, determined with due regard to this concentration. In the case of adding a large quantity of acetic anhydride, it was necessary to use extremely-purified acetic anhydride so that excess acetic acid did not mix in the polymerization system. The acetic anhydride was, therefore, purified from acetic acid by reacting it with carbodiimide, thus producing a non-volatile compound.[11] That is, acetic anhydride was mixed with dicyclohexylcarbodiimide, kept at 100°C for one hours and then distilled (bp 51.7°C/60 mmHg). The concentration of acetic acid in the acetic anhydride thus prepared was found to be less than 0.1 wt%.

Procedures for Polymerization and Stabilization. The polymerization was carried out in the same manner as has been described in the previous papers,[9,10] except that the reaction temperature was not carefully controlled.

After the unreacted monomer and carbon dioxide has been discharged, the resulting polymer was taken out from the the autoclave in an atmosphere of carbon dioxide or air, and transferred into a glass tube which was afterwards sealed. Then, the sample was held in an oil bath kept at a fixed temperature. The polymer which resulted from the polymerization or which was obtained after heat treatment was washed with cooled ethyl ether and with acetone, and dried *in vacuo*.

In the some experiments, the polymer was heated as it was in the autoclave after the inner pressure had been reduced. Then, the polymer was purified by removing the unreacted acetic anhydride and other compounds only by means of evacuating the autoclave under heating.

Measurements of the Properties of the Resulting Polymer. The degree of polymerization was determined by viscosity measurements in a manner which has previously been described.[9]

The thermal stability of the resulting polymer was determined by the continuous measurement of the thermal degradation in a nitrogen atmosphere, which was kept constant at 222°C in a vapor bath of boiling methyl salicylate; it was represented as a first-order reaction rate constant. When a plot of the log of the weight per cent under composed versus the time gave two straight lines, the rate constants, k_{222}, calculated from each straight line are listed together with the range of decomposition (noted in parentheses).

The acetyl and hydroxyl groups of the resulting polymer were determined by means of a study of the infrared spectrum, which was measured with a polymer film prepared by cold pressing. The degree of acetylation was calculated as the molar ratio of the acetyl endgroup to the total endgroup, which was estimated by the following equation;

$$\text{Degree of acetylation} = \frac{D_{C=O}}{\alpha D_{OH} + D_{C=O}} \quad (1)$$

Here, $D_{C=O}$ and D_{OH} are the absorption intensities of the carbonyl group at 1750 cm^{-1} and of the hydroxyl group at 3500 cm^{-1} respectively; they were measured on the infrared spectrum of a polymer film. An α factor, which is a ratio of the molar extinction coefficient of the two bands, was experimentally determined on six samples; it was 2.46 ± 0.05.

The degree of toughness was measured by the folding endurance test described below. The polymer, which was mixed with 1% portions of both 4,4'-butylidene-bis-(6-tertiary butyl metacresol) and polyamide, was heated under compression to mold a film 120 μ thick. The folding endurance test was carried out using an MIT folding endurance tester according to ASTM D 643—43. The number of creasing cycles until the film breaks off is referred to as the "degree of toughness." The value indicated in the table is the mean value for five runs.

Result and Discussion

Influence of Acetic Anhydride Concentration. In order to establish the effect of the acetic anhydride concentration on the acetylation of the resulting polymer in the stabilizing process, the monomer was polymerized in liquid carbon dioxide at 30°C, using acetic acid as the catalyst. After polymerization, a part of the unwashed resulting polymer was transferred into a sealed tube in an atmosphere of carbon dioxide and then heated at 140°C. The results are shown in Table 1.

It was found that the polymer yield in the polymerization was reduced by increasing the concentration of acetic anhydride, and that a part of the resulting polymer had already been acetylated. Acetic anhydride at a concentration above 5 mol% was also found to be sufficient to acetylate all of the endgroups of the polymer chain. Moreover, the film which was molded from the polymer mixed with the antioxidants exhibited satisfactory degree of toughness.

Influences of Heating Temperature and Time. The effects of the temperature and the time in the stabilization process on the properties of the polymer were studied by an experiment in which the polymer produced in the polymerization in the presence of acetic anhydride (5 mol%) was divided into sealed tubes in an atmosphere of carbon dioxide and then heated. The results are shown in Table 2. The heating temperature at 120°C was too low to perform sufficient acetylation, whereas the decomposition of the polymer was appreciable at 160°C. As a result, the optimum operation temperature in the stabilization process was in a range of 140 to 150°C, and a reacton time of more than 2 hr was not required.

1730	0.76(0—11%) 0.32(11—%)	98

a) temp., 140°C; time, 2 hr.

Influence of Atmosphere. The crude polymer resulting from the polymerization was divided in an atmosphere of carbon dioxide or dry air into sealed tubes and heated 140°C for 1 hr. Table 3 shows these results. The presence of air caused the thermal stability of the resulting polymer to deteriorate somewhat, but this deterioration was not serious.

Influence of Acetic Acid. The polymerization of formaldehyde in liquid carbon dioxide is initiated by carboxylic acid as a catalyst, as has been described previously in this series. On the other hand, the acidolytic scission of acetal linkages of the main chain by carboxylic acid has been reported.[1] Therefore, the influence of acetic acid, as a sample of carboxylic acid, on the degree of polymerization and thermal stability of the resulting polymer in the stabilization process was investigated. The results are shown in Table 4. It was found that acetic acid reduced the thermal stability in a part of the resulting polymer, but 0.1 mol% per monomer, that is, the amount which was used as a catalyst, had no effect.

b) Crude polymer was divided in the atmosphere of carbon dioxide. temp., 140°C; time, 2 hr.

Procedure of Purifying the Resulting Polymer. After the unreacted monomer and carbon dioxide had been discharged, the polymer was a solid material and was wet with acetic anhydride. In addition to the polymer, the materials which exist in the stabilization process are acetic anhydride, carboxylic acid, carbon dioxide, and by-products which are volatile at the operating temperature. Therefore, these compounds can easily be removed by evacuating the reaction vessel under heating. The properties of the polymer purified by such a simple procedure were studied.

The polymerization was carried out under the condition shown in Table 5. After the autoclave had been heated at 150°C for 1 hour and then the inner pressure been reduced, the reaction vessel was evacuated under heating. The polymer, which was not washed or dried, exhibited satisfactory properties, as Table 5 shows. This result permitted the purification of the stabilized polymer to be simplified.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1672—1679 (1968)

Cationic Polymerization of Formaldehyde in Liquid Carbon Dioxide. IV. A Kinetic Study of the Polymerization in the Presence of Acetic Anhydride*1

Hisao YOKOTA*2 and Masatsune KONDO*2

Takarazuka Radiation Laboratory, Sumitomo Atomic Energy Industries Ltd., Takarazuka

and Tsutomu KAGIYA and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 27, 1967)

The influence of acetic anhydride on the polymerization of formaldehyde, which was carried out by means of initiation with an acidic catalyst in liquid carbon dioxode, was studied at 20 to 40°C. Acetic anhydride decreased the polymer yield and the degree of polymerization of the polymer resulting from the polymerization with acetic acid. Moreover, the over-all rate of polymerization with acetic acid in the presence of acetic anhydride deviated from a first-order equation with respect to the monomer concentration. On the other hand, the polymerization which was initiated by dichloroacetic acid was not affected by the presence of acetic anhydride. On the basis of a kinetical consideration, it can be said that the termination which was proportional to the square of the concentration of the initiating species was caused by the presence of acetic anhydride in the polymerization with acetic acid. The rate constants and the activation energies of the elementary processes were estimated, and a rate equation satisfying the experimental results was presented.

As has been described in previous papers,[1,2] the present authors have already disclosed that formaldehyde monomer which is prepared by the thermal decomposition of α-polyoxymethylene without additional purification polymerizes in liquid carbon dioxide both with and without a carboxylic acid catalyst to give a polymer with a high molecular weight, and that this polymerization follows a cationic mechanism and belongs to a type of successive polymerization with rapid initiation and no termination.

It has also been reported by the present authors[3] that acetic anhydride, which has already been added to the reaction system at the beginning of polymerization, acetylates the endgroups of polyoxymethylene by heating the resulting polymer after discharging the unreacted monomer and carbon dioxide at the end of the polymerization.

The purpose of the present work is to determine quantitatively the effects of acetic anhydride on the elementary steps of the polymerization of formaldehyde in liquid carbon dioxide.

Experimental

The methods of preparing the monomer and the additives, such as acetic acid, and mono-, di- and trichloroacetic acids, and the experimental procedure for the polymerization were the same as have previously been described.[1,2] Acetic anhydride was carefully prepared to remove acetic acid, as has also previously been reported.[3] The acetic anhydride used contained less than 0.1 wt% acetic acid.

The concentration of formaldehyde in the monomer solution was 60 wt%, and the loading density, which was represented as a ratio of the amount of solution fed in to the volume of the reaction vessel used, was 10 g/30 m*l*.

Results and Discussion

Influence of the Addition of Acetic Anhydride on Polymerization with Various Acids. The influence of acetic anhydride on the polymerizations initiated by acetic and dichloroacetic acids studies, as is shown in Table 1. In polymerization with dichloroacetic acid, acetic anhydride had no effects on the polymerization. On the other hand, added acetic anhydride decreased both the polymer yield and the degree of polymerization of the resulting polymer in polymerization with acetic acid.

Table 1. Influence of the addition of acetic anhydride on the polymerization with various acids

Acid	Acetic anhydride	Polymer yield g	Polymer yield wt%	$\overline{P}_n$
Acetic acid	presence	1.734	28.9	1100
Acetic acid	absence	3.265	54.4	1750
Dichloroacetic acid	presence	4.032	67.2	1750
Dichloroacetic acid	absence	4.052	67.5	1800

monomer solution, 10 g ; $[M]_0 = 20$ mol/l ; $[CH_3COOH] = 0.02$ mol/l ; $[(CH_3CO)_2O] = 1.0$ mol/l ; temperature, 30°C ; time, 30 min ; reaction vessel, 30 ml.

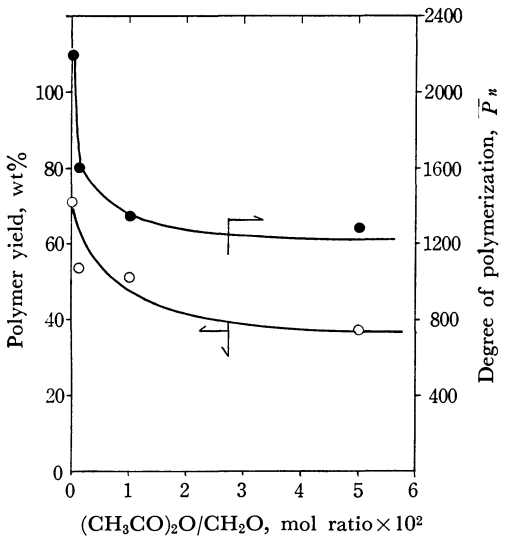

Fig. 1. Effect of acetic anhydride on the polymerization initiated by acetic acid.

Monomer solution, 10 g ; $[M]_0 = 20$ mol/l ; $[CH_3COOH] = 0.02$ mol/l ; temperature, 30°C ; time, 10 min ; reaction vessel, 30 ml.

In order to determine the effect of acetic anhydride, the influence of the amount of acetic anhydride on the polymerization with acetic acid was examined. As Fig. 1 shows, both the polymer yield and the degree of polymerization of the resulting polymer decreased rapidly with an increase in the concentration of acetic anhydride. Moreover, the number of moles of the polymer chain, which was calculated as a ratio of the polymer yield to the degree of polymerization, was almost constant. Because the amount of acetic anhydride added was less than 5 mol% that of the monomer, the results suggest that the decrease in the polymer yield with an increase in the concentration of acetic anhydride is not due to the decrease in the amount of the initiating species or of the monomer concentration, but to the increase in the termination reaction.

Influence of the Addition of Stronger Acids on Polymerization in the Presence of Acetic Anhydride. On polymerization in the absence of acetic anhydride, it has been established[1] that the polymer yield, the number of moles of the polymer chain, and the degree of polymerization of the resulting polymer all increase as the acidity of the acid used is increased. Analogously, the effects of acetic acid and mono-, di-, and tri-chloroacetic acids on polymerization in the presence of acetic anhydride were studied.

Table 2. Influence of various acidic catalyst on the polymerization in the presence of acetic anhydride

Catalyst	pK_a	Polymer yield g	Polymer yield wt%	$\overline{P}_n$	N_p mol ×10^5
Trichloroacetic acid	0.66	3.253	54.2	1200	9.0
Dichloroacetic acid	1.25	2.441	39.0	950	8.2
Monochloroacetic acid	2.87	1.512	25.2	900	5.6
Acetic acid	4.75	0.715	11.9	520	4.5

The experimental condition was the same as described in Table 1, except that the reaction time was 10 min.

The results are presented in Table 2. Here, pK_a and N_p represent the logarithmic value of the dissociation constant of the acid measured in water at 25°C, and the number of moles of the polymer chain (represented as a ratio of the polymer yield to the degree of polymerization), respectively. Results similar to those in the absence of acetic anhydride described previously[1] were obtained in the polymer yield, the degree of polymerization, and the number of moles of the polymer chain.

Using the results listed in Table 2, the logarithmic ratios of the polymer yield (log Y_0/Y) and of the number of moles of the polymer chain (log N_{p_0}/N_p) are plotted against the relative acidity of the catalyst (ΔpK_a) in Fig. 2. Here, Y_0/Y and N_{p_0}/N_p are calculated as the ratio of the polymer yield by trichloroacetic acid to that by another acid, and a similar ratio of the number of moles of the polymer chain, respectively, and ΔpK_a is the difference between the pK_a values of trichloroacetic acid and another acid. It was found that (log Y_0/Y) and (log N_{p_0}/N_p) were proportional to ΔpK_a, and that the ratio of the slopes of these straight lines was about 2. This value was just the same as that calculated in the polymerization in the absence of acetic anhydride which was previously reported.[1] In addition, the degree of polymerization of the resulting polymer also increased proportionally with a decrease in the pK_a value of the acid used. These results agree well with the behavior in the polymerization without acetic anhydride. Hence, it seems that the mechanisms of the initiation and propagation are the same whether acetic anhydride is present or not.

Polymerization with Dichloroacetic Acid. The finding that acetic anhydride did not affect the polymerization with dichloroacetic acid, a stronger acid than acetic acid, was quantitatively confirmed, as Fig. 3 shows. For comparison, the previously-reported date obtained in the polymerization without acetic anhydride[2] are also shown in the same figure.

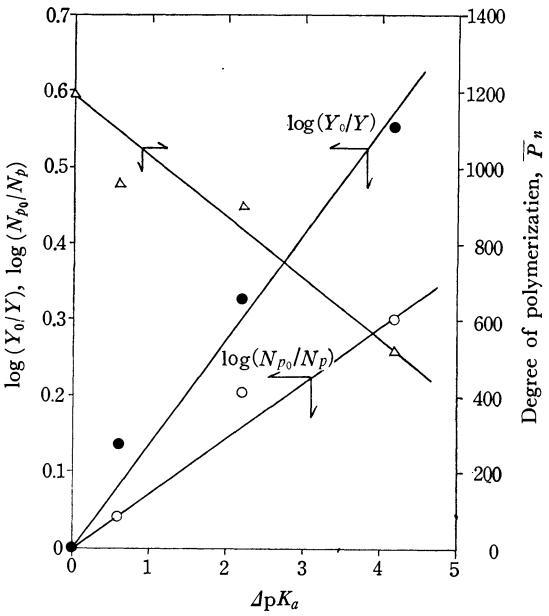

Fig. 2. Effect of acidity on the polymerization in the presence of acetic anhydride.

Monomer solution, 10 g ; $[M]_0=20$ mol/l ; [acid] $=0.02$ mol/l ; $[(CH_3CO)_2O]=1.0$ mol/l ; temperature, 30°C ; time, 10 min ; reaction vessel, 30 ml ; ●, $\log(Y_0/Y)$; ○, $\log(N_{p_0}/N_p)$; △, degree of polymerization.

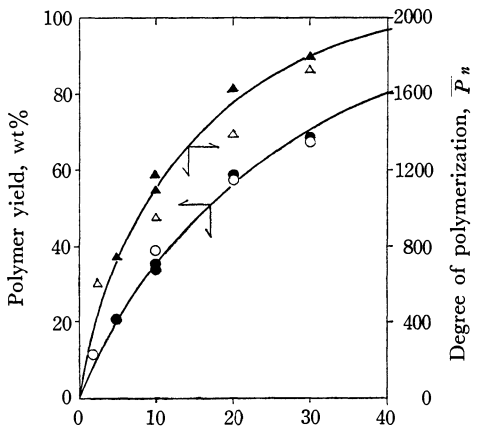

Fig. 3. Effect of the reaction time on the polymerization initiated by dichloroacetic acid.

Monomer solution, 10 g ; $[M]_0 = 20$ mol/l ; $[CHCl_2COOH]=0.02$ mol/l; temperature, 30°C; reaction vessel, 30 ml ; ○, △, in the presence of acetic anhydride of 1.0 mol/l ; ●, ▲, in the absence of acetic anhydride.

The behavior of the polymerization in this case was the same as that without acetic anhydride. It was, therefore, concluded that the polymerization by an acid stronger than acetic acid is not affected by acetic anhydride, and that the rate of polymerization follows a first-order equation with respect to the monomer concentration. Accordingly, the polymerization belongs to a type of successive polymerization with rapid initiation and no termination.

Polymerization with Acetic Acid. As has already been reported, the termination was apparently negligible in the polymerization in the absence of acetic anhydride, and also in the polymerization in the presence of acetic anhydride initiated by a stronger acid, such as dichloroacetic acid. On the other hand, termination was assumed in the polymerization with acetic acid in the presence of acetic anhydride, as has been described above. To determine quantitatively the effect of acetic anhydride on the polymerization with acetic acid, the influence of the reaction time and the temperature on the polymerization was also studied, as is shown in Table 3.

TABLE 3. EFFECT OF THE REACTION TIME AND TEMPERATURE ON THE POLYMERIZATION WITH ACETIC ACID IN THE PRESENCE OF ACETIC ANHYDRIDE

Time min	Polymer yield		$\overline{P}_n$
	g	wt%	
	Temperature, 20°C

15	0.426	7.1	530
30	0.589	9.8	1000
30	0.756	12.6	1100
60	1.025	17.1	1600
60	0.934	15.6	1200
	Temperature, 30°C		
2	0.247	4.1	380
5	0.773	12.9	970
10	0.907	15.1	780
10	0.715	11.9	520
20	1.172	19.5	1050
30	1.734	28.9	1100
60	2.231	37.2	1300
	Temperature, 40°C		
2	0.977	16.3	320
5	1.483	24.7	820
10	2.186	36.4	1000
30	3.275	54.6	1200

Experimental conditions were the same as those in Table 1, except temperature and time.

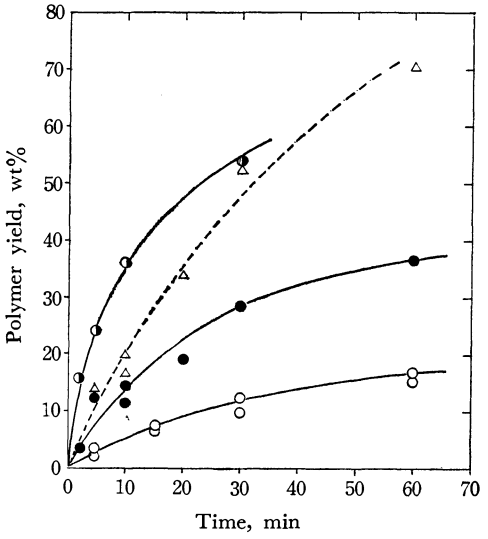

Fig. 4. Influence of reaction time and temperature on the rate of the polymerization in the presence of acetic anhydride.

Monomer solution, 10 g ; $[M]_0 = 20$ mol/l ; $[CH_3COOH] = 0.02$ mol/l ; $[(CH_3CO)_2O] = 1.0$ mol/l; reaction vessel, 30 ml; ○, 20°C; ●, 30°C; ◑, 40°C ; △, 30°C without acetic anhydride.

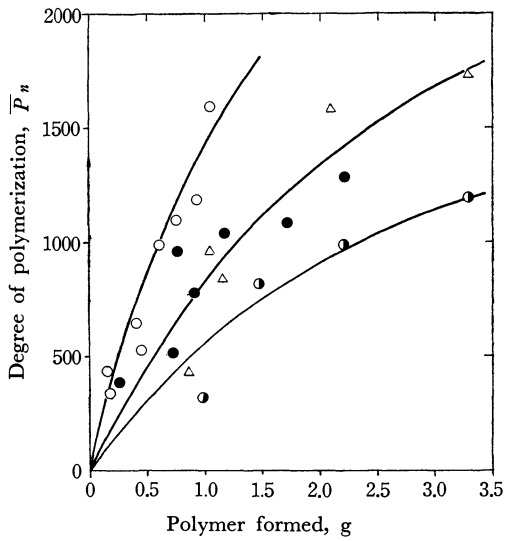

Fig. 5. Degree of polymerization *versus* polymer yield.

Reaction condition are the same as in Fig. 4.
with acetic anhydride : ○, 20°C ; ●, 30°C ; ◑, 40°C
without acetic anhydride : △, 30°C

Figure 4 is the plot of the polymer yield against the reaction time at each temperature, using the data listed in Table 3. The results[2] of the polymerization which was carried out at 30°C with acetic acid in the absence of acetic anhydride are also shown for the sake of comparison. The rate of polymerization in the early stages was almost the same as that without acetic anhydride. Two characteristics of the behavior of the polymerization with acetic anhydride were that the rate in the later stages decreased rapidly with the reaction time and that the polymer yield tended to reach a saturated value.

In Fig. 5, the degree of polymerization of the resulting polymer is plotted against the polymer yield, using the data listed in Table 3. It was found that the degree of polymerization increased with the polymer in the same way as in the polymerization without acetic anhydride. This indicates that the rate of chain transfer in this case is also considerably smaller than that of propagation.

Deviation from a First-order Rate Equation. In the polymerization with acetic acid in the presence of acetic anhydride, the rate of polymerization decreased rapidly with the progress of the polymerization, as has been described above. The following kinetical treatments of the polymerization were focused on the elucidation of this behavior.

As Fig. 6 shows, the over-all rate of polymerization, which was calculated by using the data in

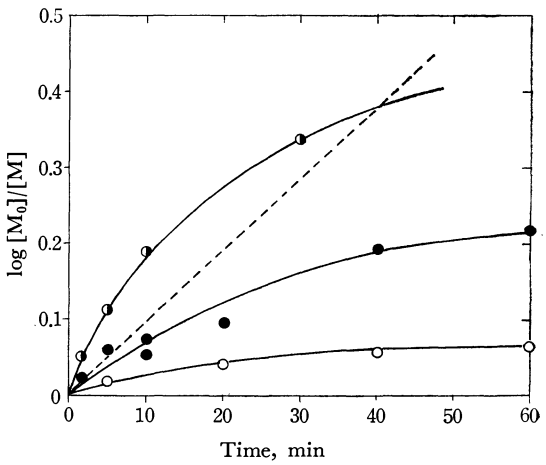

Fig. 6. Deviation of the polymerization rate from a first-order rate equation.

○, 20°C ; ●, 30°C ; ◑, 40°C ; Broken line is the same as in Fig. 4.

Table 3, deviated from the first-order equation with respect to the monomer concentration. The deviation from the first-order rate equation is a peculiarity observed only in the polymerization initiated by acetic acid in the presence of acetic anhydride. This characteristic fact let to the assumption that the decrease in the rate of polymerization may be attributed to a termination reaction between the growing polymer chain and a component which was originally present in the reaction system or which was produced as a by-product.

Kinetics in the Polymerization with Acetic Acid in the Presence of Acetic Anhydride. *Elementary Processes.* It may be concluded, in view of the characteristic behavior described above, that polymerization initiated with acetic acid in the presence of acetic anhydride belongs to the type of non-stationary successive polymerization, with rapid initiation.

In almost the same manner as in the polymerization without acetic anhydride, using the graphical method proposed by Kagiya *et al.*,[4] the elementary processes were postulated to be as follows:

Initiation:

$$C + M \xrightarrow{k_i} P^*, \qquad R_i = \text{rapid} \tag{1}$$

$$\int R_i dt = [P^*]_0 \tag{2}$$

Propagation:

$$P^* + M \xrightarrow{k_p} P_n^*, \quad R_p = k_p[P^*][M] \tag{3}$$

$$\int R_p dt = [M_p] \tag{4}$$

Chain Transfer:

$$P_n^* + Y \xrightarrow{k_{tr}} P_n + Y^*, \quad R_{tr} = k_{tr}[P^*][Y] \tag{5}$$

$$\int R_{tr} dt = \frac{k_{tr}[Y]}{k_p} \int \frac{R_p}{[M]} dt \tag{6}$$

Here R_i, R_p and R_{tr} are the rates of initiation, propagation, and chain transfer; k_p and k_{tr} are the rate constants of propagation and chain transfer; and $[P^*]_0$, $[P^*]$, $[M]$, $[M_p]$, and $[Y]$ are the concentrations of the initiating species, the monomer, the polymerized monomer, and the chain transfer agent respectively.

Termination:

$$P_n^* + Z \xrightarrow{k_d} P_n, \quad R_d = k_d[P^*][Z] \tag{7}$$

where R_d, k_d, and $[Z]$ are the rate of termination, the rate constant of termination, and the concentration of the terminator respectively. The experimental results could not be interpreted successfully on the assumption that $[Z]$ in Eq. (7) is constant during the course of polymerization. Hence, it was assumed that the concentration of the terminator is proportional to that of the growing polymer chain; then the following equation was derived from Eq. (7).

$$R_d = k_d'[P^*]^2 \tag{8}$$

Accordingly, the integration of R_d gives the following equation when Eq. (3) is substituted into Eq. (8):

$$\int R_d dt = \frac{k_d'}{k_p^2} \int \frac{R_p^2}{[M]^2} dt \tag{9}$$

Estimation of the Concentration of the Initiating Species and the Rate Constant of Chain Transfer. Because there is no termination caused by recombination between the growing polymer chains, the following equation for the degree of polymerization is given, in the same manner as has been reported in a previous paper[1]:

$$\frac{1}{\bar{P}_n} = \frac{\int R_i dt}{\int R_p dt} + \frac{\int R_{tr} dt}{\int R_p dt} \tag{10}$$

By substituting Eqs (2), (4), and (6) into Eq. (10), we derive:

$$\frac{[M_p]}{\bar{P}_n \int \frac{R_p}{[M]} dt} = \frac{[P^*]_0}{\int \frac{R_p}{[M]} dt} + \frac{k_{tr}[Y]}{k_p} \tag{11}$$

Here, $[M_p]$, $\bar{P}_n$, R_p, and $[M]$ are graphically determined by using the values in Figs. 4 and 5; of these, R_p was estimated from the tangent of the curve in Fig. 4. The estimated values are listed in Table 4. Here, the value of $\int \frac{R_p}{[M]} dt$ was calculated by a graphical integration.

In order to evaluate graphically the values of $[P^*]_0$ and $k_{tr}[Y]/k_p$, the relation between the values of $\frac{[M_p]}{\bar{P}_n \int \frac{R_p}{[M]} dt}$ and $\frac{1}{\int \frac{R_p}{[M]} dt}$ was plotted; it is shown in Fig. 7. The existence of linear relations in the same figure proves the validity of the assumption that the polymerization is rapidly initiated and that the reaction of chain transfer is quite slow.

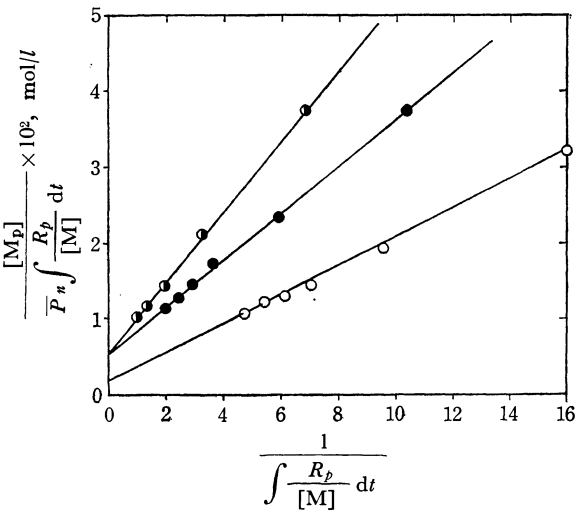

Fig. 7. Estimation of the concentration of initiating species and the rate constants of chain transfer.
○, 20°C; ●, 30°C; ◑, 40°C.

The $k_{tr}[Y]/k_p$ ratio, as shown in Table 5, was evaluated from all the intercepts on the ordinate, while the concentration of the initiator, $[P^*]_0$, was evaluated from the slopes of all the lines in

Fig. 7. The previously reported values[2] for the rate constants of the elementary processes are also listed in Table 5 for convenience in comparing the two polymerizations, initiated by acetic acid in the presence and absence of acetic anhydride.

Estimation of the Rate Constants of Propagation and Termination. The concentration of the growing polymer chain [P*] can be expressed by the following equation:

$$[P^*] = \int R_i dt - \int R_d dt \qquad (12)$$

By substituting Eqs. (2), (3), (4), and (9) into Eq. (12), it follows that:

$$\frac{R_p}{[M]\int \frac{R_p^2}{[M]^2}dt} = \frac{k_p[P^*]_0}{\int \frac{R_p^2}{[M]^2}dt} - \frac{k_d'}{k_p} \qquad (13)$$

The values of $\frac{R_p}{[M]\int \frac{R_p^2}{[M]^2}dt}$ and $\frac{[P^*]_0}{\int \frac{R_p^2}{[M]^2}dt}$, which were calculated in a way similar to that described above, are also listed in Table 4. The relation

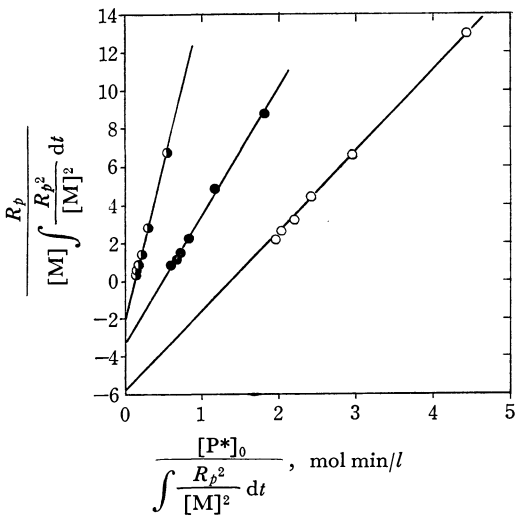

Fig. 8. Estimation of the rate constants of propagation and termination.
○, 20°C; ●, 30°C; ◑, 40°C.

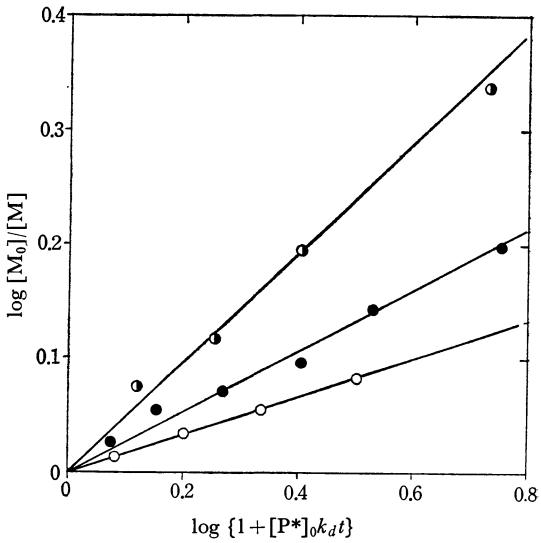

Fig. 9. Coincidence of the rate equation with the experimental results.
○, 20°C; ●, 30°C; ◑, 40°C

between the two values is plotted in Fig. 8. A distinct linear relation exists between them at each temperature. This fact indicates that the rate of termination is proportional to the square of the concentration of the growing polymer chain. The rate constants of propagation and termination were then estimated in the manner described above; they are listed in Table 5. Using the values of k_p, the $k_{tr}[Y]$ values were also estimated.

Over-all Rate Equation. It was concluded from the above considerations that the termination apparently ocurred according to a second-order equation with respect to the concentration of active species. Consequently, the concentration of the growing polymer chain may be represented as follows by integrating Equation 8:

$$[P^*] = [P^*]_0 \left\{ \frac{1}{1 + [P^*]_0 k_d t} \right\} \tag{14}$$

The rate of polymerization can, therefore, be expressed by the following equation by introducing Equation 14 into Eq. (3):

$$R_p = -\frac{d[M]}{dt} = k_p[M][P^*]_0 \left\{ \frac{1}{1+[P^*]_0 k_d t} \right\} \tag{15}$$

Hence;

$$\ln \frac{[M]_0}{[M]} = \frac{k_p}{k_d} \ln \{ 1 + [P^*]_0 k_d t \} \tag{16}$$

Figure 9 shows a plot of the logarithmic values of $[M]_0/[M]$, a plot which has been calculated by using the data in Table 3, against the value of $\log\{1+[P^*]_0 k_d t\}$, which was calculated by using the values of $[P^*]_0$ and k_d shown in Table 5. The linear relation observed proves the validity of Eq. (16).

In conclusion, the over-all rate of polymerization is proportional to the monomer concentration, and rate of termination is proportional to the square of the concentration of the intiating species.

Activation Energies of Each Elementary Process. By using the Arrhenius plot of the rate constants listed in Table 5, the activation energies for each elementary process were calculated to be as follows; 9.4, 12, 15 and 2.2 kcal/mol for initiation, propagation, chain transfer, and termination respectively. The activation energies in each process were larger in the polymerization with acetic anhydride than in that without acetic anhydride.

Comparison between the Kinetic Features of Polymerization both with and without Acetic Anhydride. The above-mentioned considerations and a previous paper[2] established that the polymerizations of formaldehyde in liquid carbon dioxide which were initiated by acetic acid in both the presence and absence of acetic anhydride were of the successive-polymerization type with a rapid initiation. The concentration of active species and the rate constant of propagation in the polymerization with acetic anhydride were almost the same as those in the polymerization without acetic anhydride at 30°C. Moreover, a small contribution of chain transfer was observed in both cases.

While the polymerization without acetic anhydride was a stationary successive polymerization, the polymerization with acetic anhydride was of the non-stationary successive polymerization type. The reaction of termination in the latter polymerization was attributable to the reaction of the growing polymer chain with a compound which was originally present in the reaction system or

which was produced as a by-product during the polymerization.

The increase in the rate constant upon the addition of acetic anhydride, which was observed in spite of the increase in the activation energy, may ascribed to the considerable increase in the entropy caused by the addition of acetic anhydride, and hence the decrease in the free energy as a whole.

The mechanism of the polymerization will be reported in a subsequent paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1679—1681 (1968)

Studies of the *N*-Oxides of *N,N*-Dialkylamino Acids. I. The Syntheses of *N,N*-Dimethyl Neutral Amino Acids and Corresponding *N*-Oxides

Yoshikazu IKUTANI

Laboratory of Organic Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka

(Received December 30, 1967)

The *N,N*-dimethyl derivatives of neutral amino acids, such as glycine, L-alanine, DL-alanine, L-valine, DL-valine, L-leucine, L-phenylalanine, and L-tyrosine, were prepared by the catalytic reductive condensation of the corresponding amino acids with formaldehyde. The *N*-oxides were satisfactorily synthesized by the oxidation of the *N,N*-dimethyl derivatives with an aqueous mixture of hydrogen peroxide and acetic acid. The reaction conditions, the analytical data, and some properties of the products are presented.

As a part of an investigation of the syntheses and reactions of *N,N*-dialkylamino acids, the syntheses of *N,N*-dimethyl neutral amino acids and the corresponding *N*-oxides have been studied. Although several reagents, such as methyl iodide, dimethyl sulfate, and diazomethane, are available for the alkylation of the amino group, the most suitable method is the catalytic reductive condensation of amino acid with aldehyde.[1,2] In an earlier paper, Sweely and Horning reported the synthesis and ferric ion - catalyzed reactions of *N,N*-dimethylglycine *N*-oxide.[3] However, the melting point of the substance was indistinct, and the results of elementary analysis were not identical with the calculated value. The present author has prepared the various *N, N*-dimethyl neutral amino acids in good yields and has oxidised them to the corresponding *N*-oxides satisfactorily. The *N, N*-dimethylations were carried out at 50°C by the catalytic reductive condensation of an aqueous solution of neutral amino acid and formaldehyde in the presence of a silk-palladium catalyst, which showed no reductivity in responce to any aldehyde.[4] The period of the reduction depends on the solubility of the parent amino acid; for example, the *N,N*-dimethylation of L-tyrosine in an aqueous suspension proceeded very slowly. The reaction product was a mixture consisting of the *N, N*-dimethyl derivative and a trace of the unchanged parent amino acid. The *N*-monomethyl derivative has not been obtained in any case. The analytical data and some properties of the *N, N*-dimethyl derivatives are summarized in Table 1.

Generally the oxidation of aliphatic tertiary amine with aqueous hydrogen peroxide gives the corresponding *N*-oxide. However, in the case of *N,N*-dimethylamino acid, no reaction occurred at either room temperature or 60°C and the starting substance was recovered unchanged. Sweely and Horning prepared *N,N*-dimethylglycine *N*-oxide by the oxidation of *N,N*-dimethylglycine in an aqueous mixture of hydrogen peroxide and barium hydroxide. The present author oxidized the *N,N*-dimethylamino acids to the corresponding *N*-oxides using an aqueous mixture of hydrogen peroxide and acetic acid at 60°C. The most suitable oxidation conditions were detected by paper chromatographic studies of the reaction mixture. After the oxidation, the same volume of water was added to the reaction mixture and the solution was concentrated carefully below 40°C under reduced pressure. After this procedure had been repeated until the distillate gave a negative reaction in a potassium iodide starch test, the residue was dried up under reduced pressure. When the crude *N*-oxides were recrystallized from ethanol-acetone, the *N*-oxides obtained were of a high purity.

a) Same procedure was used as described in Table 1.
b) This substance was obtained as monohydrated crystal.
c) This substance was anhydrous powder.

N,N-Dimethyl-L-tyrosine *N*-oxide crystallized as monohydrate, and the crystal water was removed at 80°C under reduced pressure over an 8-hr period. The *N*-oxides show the infrared absorption band in the 960—980 cm^{-1} region, as does ordinary aliphatic tertiary amine *N*-oxide.[5] The basicity of the *N*-oxides are weaker than those of the corresponding *N,N*-dimethyl derivatives. The elementary analyses and some properties of the *N*-oxides are summarized in Table 2. The *N*-oxides were easily reduced to the parent *N,N*-dimethylamino acids by catalytic reduction.

Experimental

N,N-Dimethylglycine. A mixture of 19 g of glycine, 1.5 g of a silk-palladium catalyst, 80 m*l* of 37% aqueous formaldehyde, and 120 m*l* of water was placed in an autoclave, which was then filled with hydrogen. The mixture was shaken at 50°C for 7 hr, by which time the theroretical amount of hydrogen had been taken up. The catalyst was then filtered off, and the filtrate was evaporated under reduced pressure. A small amount of paraformaldehyde was present in the product; it was removed by re-evaporation with water. The residual syrup was dissolved in a small volume of ethanol, and the solution was dried up to remove a trace of water. After this procedure had been repeated three times, the crystalline product appeared. About 50 m*l* of acetone was added in small portions to the precipitates, and the crystallization was complete. The resulting crystalline precipitates were collected by filtration, washed with acetone several times, and then dried under reduced pressure. The yield of the crude product was almost equal to the theoretical yield. The crude product was dissolved in a minimum volume of hot ethanol, decolorized with a small amount of charcoal, and filtered. About 150 m*l* of acetone were added in small portions, and the mixture was stored in a refrigerator overnight. Fine crystals were then collected by filtration, washed with acetone, and dried under reduced pressure. The yield was 21.7 g (83%). This substance was very hygroscopic and deliquescent, and was soluble in ethanol and almost insoluble in acetone.

Other N,N-Dimethyl Derivatives of Neutral Amino Acids. *N,N*-Dimethyl derivatives of all the other neutral amino acids except L-tyrosine were

5) R. Mathis-Noel, R. Wolf and F. Gallais, *Compt. rend.*, **242**, 1873 (1956).

obtained by a similar method. *N,N*-Dimethyl-L-alanine and *N,N*-dimethyl-DL-alanine were very hygroscopic and deliquescent prisms. *N,N*-Dimethyl-L-valine and *N,N*-dimethyl-DL-valine were slightly hygroscopic. *N,N*-Dimethyl-L-leucine and *N,N*-dimethyl-L-phenylalanine were not hygroscopic. The *N,N*-dimethylation of 6.2 g of L-tyrosine in 20 m*l*-tyrosine 20 m*l* of 37% aqueous formaldehyde and 230 m*l* of water proceeded very slowly for about 22 hr. By a treatment similar to that described above, a crude product was obtained. The crude product was dissolved in a minimum volume of hot water, decolorized with charcoal, and filtered. To the filtrate, 50 m*l* of acetone were added, and the resulting mixture was rapidly cooled in a refrigerator. Fine filamentous needles were then collected by filtration, washed with acetone, and dried under reduced pressure. The yield was 6.0 g (83%). In another recrystallization, when a hot, saturated aqueous solution was allowed to cool slowly, short prisms were obtained. They showed almost the same properties, except that slight differences were observed in the infrared absorption spectra.

N,N-Dimethylglycine N-Oxide. A solution of 4 g of *N,N*-dimethylglycine, 20 m*l* of 30% aqueous hydrogen peroxide, and 40 m*l* of acetic acid was warmed at 60°C for 7 hr. To a reaction mixture, about 50 m*l* of water were added, after which the mixture was concentrated to about a half volume while being gently warmed below 40°C under reduced pressure. After this procedure had been repeated until the distillate gave a negative reaction to a potassium iodide starch test, the solution was evaporated to dryness under reduced pressure. The residual syrup was dissolved in a small volume of ethanol, and the solution was dried up under reduced pressure. This procedure was repeated twice, after which the residue was crystallized. The crude products were collected with acetone, washed with acetone, and dried under reduced pressure. The product thus obtained was recrystallized by a method similar to that described above. The yield of dimethylglycine *N*-oxide was 3.8 g (83%).

Other N,N-Dimethyl Neutral Amino Acid N-Oxides. The *N*-oxides of *N,N*-dimethyl-L-alanine, *N,N*-dimethyl-DL-alanine, *N,N*-dimethyl-L-valine, *N,N*-dimethyl-DL-valine, *N,N*-dimethyl-L-leucine, and *N,N*-dimethyl-L-phenylalanine were obtained in the same manner. However, *N,N*-dimethyl-L-tyrosine *N*-oxide was obtained as monohydrated crystals and the water was removed by heating at 80°C for 8 hr under reduced pressure.

The Reduction of N,N-Dimethylglycine N-Oxide to N,N-Dimethylglycine. A mixture of 2.4 g of *N,N*-dimethylglycine *N*-oxide, 1.5 g of a silk-palladium catalyst, and 150 m*l* of water was placed in an autoclave with hydrogen. The mixture was shaken at 40°C for 30 min. When the reaction mixture was then treated in the manner described above, 1.7 g of a product was obtained. The melting point of this sample was not depressed by admixture with authentic *N,N*-dimethylglycine, and the two substances had completely identical infrared absorption spectra. The recovery of *N,N*-dimethylglycine was 1.6 g (80%).

Found: C, 46.48; H, 8.98; N, 13.49%. Calcd for $C_4H_9O_2N$: C, 46.59; H, 8.80; N, 13.58%.

The author is indebted to Professor Eizo Matsumura for his constant guidance in the course of the work, and to Professor Yoshiharu Izumi of Osaka University for his valuable advice and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1682—1686 (1968)

Initiation and Propagation in the Copolymerization of *N*-Phenylethylenimine with β-Propiolactone

Tsutomu KAGIYA, Tomizo KONDO and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 30, 1967)

In the copolymerization of *N*-phenylethylenimine with β-propiolactone, the mechanisms of the initiation and propagation reactions were investigated. The rate of the copolymerization was markedly increased by the addition of propionic acid. When a mixture of triethylamine and propionic acid was used as additive, the rate decreased with an increase in the amount of triethylamine, while with an equimolar mixture the rate was almost equal to that without any catalyst. No polymer was obtained with an excess of triethylamine. With Brönsted acid, the composition of the copolymer was independent of the concentration of the catalyst, but it varied with the pK_a value. The monomer reactivity ratio of *N*-phenylethylenimine increased with a decrease in the pK_a value. While that of β-propiolactone decreased.

We have reported in a previous paper that *N*-phenylethylenimine and β-propiolactone copolymerized without any catalyst at 0°C in an acetonitrile solution, giving a powdery or a resinous polymer.[1] The copolymer had the ester structure of $-(-N(C_6H_5)-CH_2CH_2OC(=O)-CH_2CH_2-)_n-$ in the mainchain, and the monomer reactivity ratios of *N*-phenylethylenimine (r_I) and β-propiolactone (r_L) were estimated to be $r_I=7.5$ and $r_L=0.15$ respectively.

In this paper, the initiation mechanism of the copolymerization without any addition of the catalyst was first studied. Secondly, in order to elucidate the role of the catalyst in the propagation reaction, copolymerization by various acids was studied.

Experimental

Reagents. The method of the synthesis of *N*-phenylethylenimine, and that of the purification of β-propiolactone and acetonitrile, have been described in our previous paper.[1] Guaranteed reagents of acids and dimethylaniline were used without further purification. Triethylamine was purified by the usual method.

Copolymerization Procedure. Measured amounts of a catalyst and a solvent were placed into a glass ampule under a nitrogen atmosphere, β-propiolactone and *N*-phenylethylenimine were then added to this system at −78°C. The ampule was sealed and maintained at 0—1°C for the duration of the reaction. The products were then washed with chloroform and diethylether, separated by a centrifuge, and dried *in vacuo*.

Determination of the Composition of the Copolymer. The composition of the copolymer was determined by the method described in the previous paper.[1]

Results and Discussion

Initiation Mechanism in the Polymerization Without any Catalyst. The copolymerization was carried out in acetonitrile without any catalyst and at 0°C. The relation between the total conversion and the mole per cent of β-propiolactone in the monomer feed is shown in Fig. 1. The conversion of each monomer was obtained from the data of the total conversion and the composition of the copolymer. In Fig. 2 the rates of the consumption of the two monomers, defined as the ratio of the conversion of each monomer to the

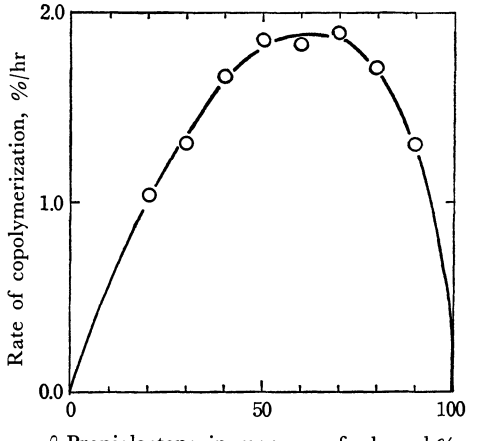

Fig. 1. Copolymerization of *N*-phenylethylenimine and β-propiolactone without any catalyst.

1) "Copolymerization of *N*-phenylethylenimine and β-propiolactone," T. Kagiya, T. Kondo, S. Narisawa and K. Fukui, This Bulletin, **41**, 172 (1968).

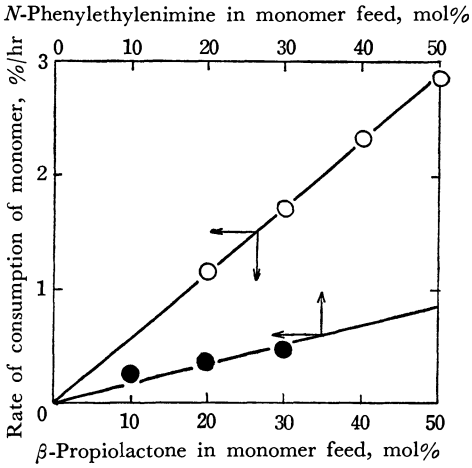

Fig. 2. Rates of the consumption of *N*-phenylethylenimine and β-propiolactone in the copolymerization.
○: *N*-phenylethylenimine ●: β-propiolactone

reaction time, are plotted against the amount of the comonomer in the monomer feed. The rate of the consumption of *N*-phenylethylenimine or β-propiolactone increased proportionately with an increase in the amount of the comonomer. Furthermore, Fig. 2 shows that the rate of the consumption of *N*-phenylethylenimine was about three times larger than that of β-propiolactone. From these results, it may be concluded that the effect of β-propiolactone on the polymerization of *N*-phenylethylenimine is greater than that of *N*-phenylethylenimine on the polymerization of β-propiolactone.

In order to elucidate the effect of the β-propiolactone on the polymerization of *N*-phenylethylenimine, and that of *N*-phenylethylenimine on the polymerization of β-propiolactone, the copolymerization was carried out using propionic acid or dimethylaniline respectively as substances analogous to the hydrolyzed compound of β-propiolactone and *N*-phenylethylenimine. The rate of the copolymerization was slightly increased by the addition of dimethylaniline, while the rate was remarkably increased by the addition of propionic acid (Fig. 3). The above facts suggest that the copolymerization without any catalyst was initiated by the acid present in β-propiolactone.

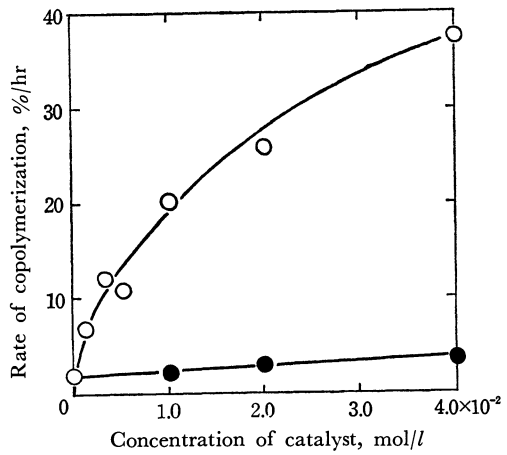

Fig. 3. Rates of copolymerization with propionic acid or dimethylaniline as additive.
○: propionic acid
●: dimethylaniline

Moreover, in order to study the role of the acid in the polymerization, the copolymerization was carried out using a mixture of triethylamine and propionic acid. As is shown in Fig. 4, the rate of the copolymerization markedly decreased with an increase in the amount of triethylamine, while in the case of an equimolar mixture of triethylamine and propionic acid the rate was almost equal to that without any catalyst. No polymer was obtained with an excess of triethylamine. This fact may be due to the neutralization of the acid present in β-propiolactone with triethylamine. These results are consistent with the initiation mechanism described above.

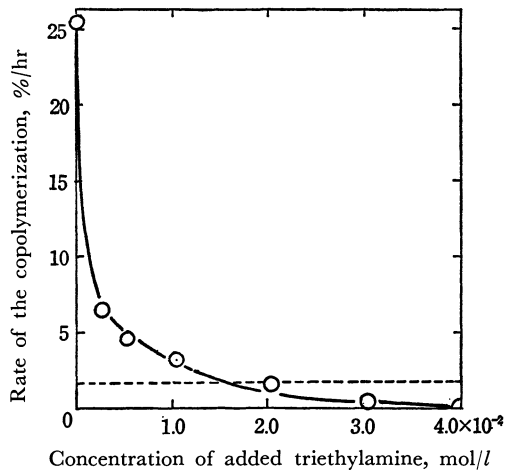

Fig. 4. Copolymerization with the mixture of propionic acid and triethylamine.
Concentration of propionic acid: 2.0×10^{-2} mol/*l*
----: Rate of copolymerization without any catalyst.

The Role of Various Brönsted Acids. Copolymerization was carried out by using various Brönsted acids as catalysts (pK_a=2.85—15.7). The relationship between the logarithm of the rate of copolymerization and the pK_a of the acids is shown in Fig. 5. Because the rate increased with a decrease in the pK_a of the catalyst, it has been concluded that the copolymerization was initiated by proton acids and that it proceeded by a cationic mechanism.

The relation between the rate of the consumption of *N*-phenylethylenimine (or β-propiolactone) and the pK_a of the acids is shown in Fig. 6. The rates

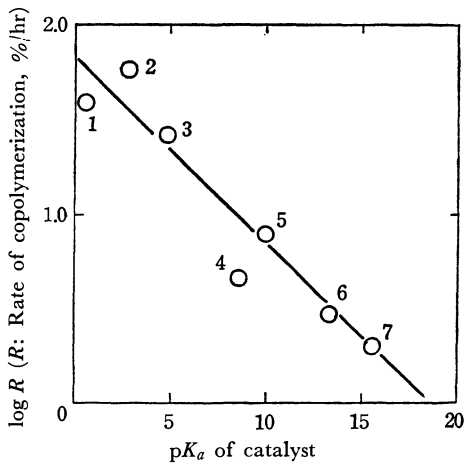

Fig. 5. Plots of rate of copolymerization against the pK_a of the catalyst.
Catalyst 1: Trichloroacetic acid, 2: Monochloroacetic acid, 3: Propionic acid, 4: Nitroethane, 5: Phenol, 6: Diethyl malonate, 7: Water

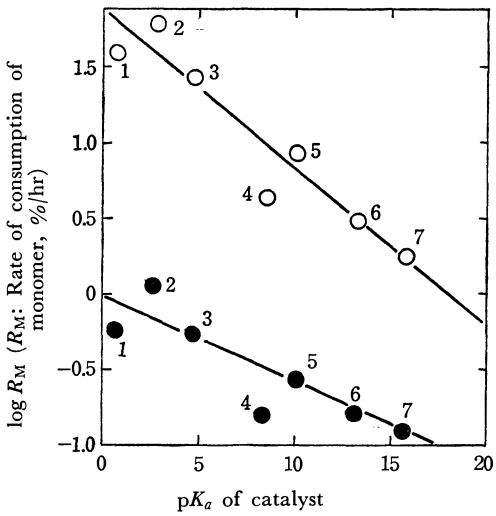

Fig. 6. Plots of rates of consumption of *N*-phenylethylenimine and β-propiolactone against pK_a of the catalyst in copolymerization.

●: β-propiolactone
The number of the catalyst is the same as shown in Fig. 5.

of the consumption of both monomers decreased with an increase in the pK_a of the catalyst. The slopes of the lines in Fig. 6 show that the effect of the pK_a of the catalyst on the rate of the consumption of *N*-phenylethylenimine was greater than that of β-propiolactone. The cause of the lower dependency of the consumption rate of β-propiolactone than that of *N*-phenylethylenimine on the pK_a of the acid is not clear, but it may be that, as will be discussed below, the separation of the counter anion from the propagating oxonium ion is restricted by the electrophilic action of the carbonyl carbon of β-propiolactone on the counter anion.

The composition of the copolymer was independent of the concentration of the catalyst, but it varied with the pK_a of the acid, and the composition of *N*-phenylethylenimine in the copolymer decreased with an increase in its pK_a value (Fig. 7). This fact indicates that the rate of the propagation was influenced by the electronic nature of the counter anion.

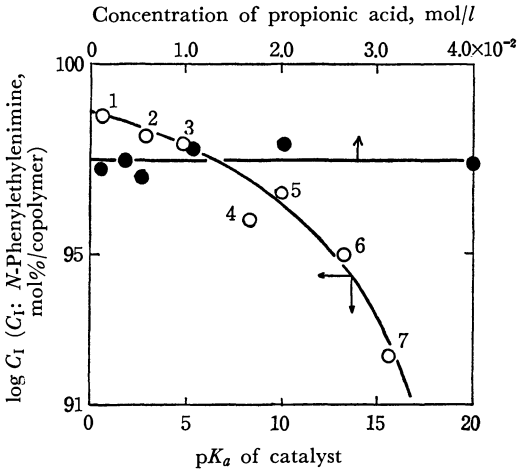

Fig. 7. Relation between composition of *N*-phenylethylenimine in copolymer and the pK_a of the catalyst or concentration of propionic acid.
The number of the catalyst is the same as shown in Fig. 5.

In order to investigate the role of the counter anion of the catalyst in the propagation reaction, the copolymerization was carried out using water, phenol, or propionic acid. The relation between the mole per cent of β-propiolactone in the copolymer and that in the monomer feed is shown in Fig. 8. The monomer reactivity ratios of *N*-phenylethylenimine (r_I) and β-propiolactone (r_L) were

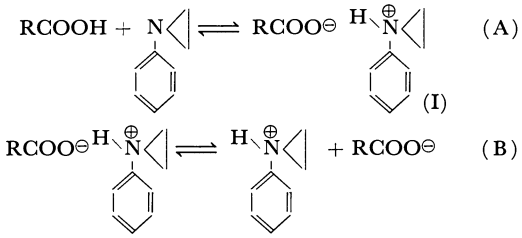
●: β-propiolactone

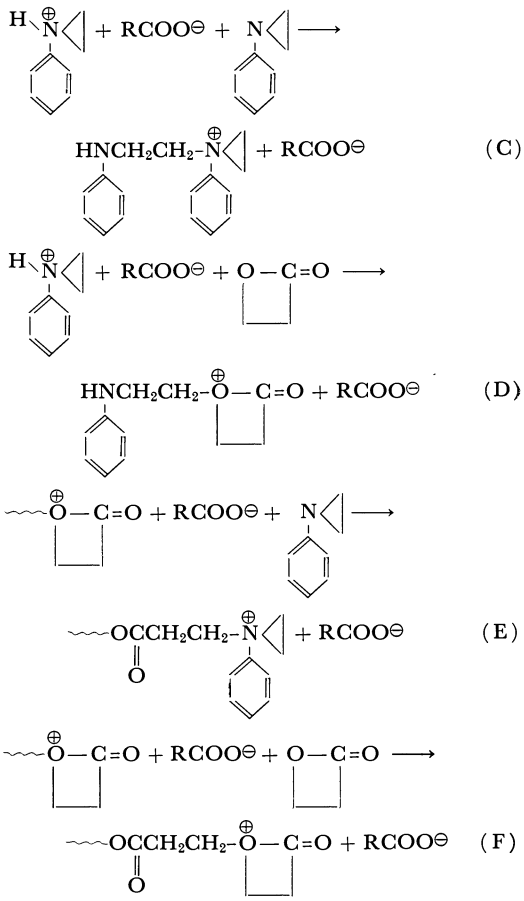
estimated from these curves by the method described in the previous paper[1] (Table 1). The relations between $\log r_I$ (or $\log r_L$) and the pK_a of the acid are plotted in Fig. 9. The monomer reactivity ratio of *N*-phenylethylenimine increased with a decrease in the pK_a of the catalyst, but, on the contrary, that of β-propiolactone decreased. The fact that the slope of the line for *N*-phenylethylenimine was larger than that for β-propiolactone shows that the effect of the pK_a of the acid on the monomer reactivity ratio of *N*-phenylethylenimine is much larger than that of β-propiolactone.

The Mechanism of the Copolymerization. From these experimental facts, the copolymerization mechanism was postulated to be as follows:

Initiation:



Propagation:



The initiation reaction is considered to be the reaction of the acid with *N*-phenylethylenimine to produce compound (I). The counter anion is separated from the immonium ion as shown in Eq. (B). It is considered that the equilibrium constant of the reaction (B) increases with a decrease in the pK_a of the catalyst, similar to the dissociation of the acid in water.

In the propagation, each monomer attacks a dissociated quarternary immonium ion or an oxonium ion. The rates of the consumption of the two monomers are expressed by the following equations:

$$-\frac{d[I]}{dt} = (k_{II}[I^{\oplus}] + k_{LI}[L^{\oplus}])[I] \quad (1)$$

$$-\frac{d[L]}{dt} = (k_{IL}[I^{\oplus}] + k_{LL}[L^{\oplus}])[L] \quad (2)$$

where [I], [L], [I⊕], and [L⊕] are the concentrations of *N*-phenylethylenimine, β-propiolactone, dissociated immonium ions, and oxonium ions respectively. The monomer reactivity ratios, r_I and r_L are given by Eqs. (3) and (4) respectively:

$$r_I = k_{II}/k_{IL} \quad (3)$$

$$r_L = k_{LL}/k_{LI} \quad (4)$$

Since r_I is larger, and r_L, smaller than unity, and since the immonium ion (three-membered ring) is more reactive than oxonium ion (four-membered ring), the rate constant in the propagation reaction is considered to decrease in the order:

$$k_{II} > k_{IL} > k_{LI} > k_{LL} \tag{5}$$

Furthermore, the propagating species is almost entirely the immonium ion, because the amount of β-propiolactone consumed is less than that of *N*-phenylethylenimine. Therefore, Eqs. (1) and (2) may be approximated as Eqs. (6) and (7) respectively:

$$-\frac{d[I]}{dt} \fallingdotseq k_{II}[I^{\oplus}][I] \tag{6}$$

$$-\frac{d[L]}{dt} \fallingdotseq k_{IL}[I^{\oplus}][L] \tag{7}$$

Taking the logarithm of Eqs. (6) and (7), and subtracting the latter from the former, Eq. (8) is derived:

$$\begin{aligned}\log r_I &= \log k_{II} - \log k_{IL} \\ &= \log(-d[I]/dt) - \log(-d[L]/dt) \\ &\quad + \log([I]/[L])\end{aligned} \tag{8}$$

From Fig. 6, the two empirical equations (9) and (10) are obtained:

$$\log(-d[I]/dt) = 1.7 - 0.102\, pK_a \tag{9}$$

$$\log(-d[L]/dt) = 0.04 - 0.042\, pK_a \tag{10}$$

substituting Eqs. (9) and (10) into Eq. (8), we obtain:

$$\log r_I = 1.66 - 0.06\, pK_a + \log([I]/[L]) \tag{11}$$

Considering that the concentration of *N*-phenylethylenimine is almost equal to that of β-propiolactone during the initial period of the copolymerization, Eq. (11) is approximately expressed by Eq. (12):

$$\log r_I \fallingdotseq 1.66 - 0.06\, pK_a \tag{12}$$

Equation (12) interprets the experimental finding that the monomer reactivity ratio of *N*-phenylethylenimine increases with a decrease in the pK_a value of the acid.

On the other hand, the empirical equation (13) is obtained from Fig. 9:

$$\log r_I = 1.51 - 0.06\, pK_a \tag{13}$$

The agreement of Eq. (13) with Eq. (12) indicates that the postulated mechanism of copolymerization and the method of approximation are suitable.

In the monomer reactivity ratio of β-propiolactone, the empirical equation (14) is obtained from Fig. 9:

$$\log r_L = -1.30 + 0.01\, pK_a \tag{14}$$

This result may be explained in the following way. If linear relations exist between $\log k_{LI}$ (and $\log k_{LL}$) and the pK_a of the acid as with k_{II} and k_{IL}, these relations may be expressed as:

$$\log k_{LI} = C_1 - C_2\, pK_a \tag{15}$$

$$\log k_{LL} = C_3 - C_4\, pK_a \tag{16}$$

where C_1, C_2, C_3, and C_4 are positive constants; C_2 is larger than C_4 since the effect of the pK_a value of the acid on the rate of the consumption of *N*-phenylethylenimine is greater than that of β-propiolactone. Subtracting Eq. (15) from Eq. (16), we obtain:

$$\begin{aligned}\log r_L &= \log k_{LL} - \log k_{LI} \\ &= (C_3 - C_1) + (C_2 - C_4)pK_a \\ &= C_5 + C_6\, pK_a \quad (C_6 > 0)\end{aligned} \tag{17}$$

where C_5 and C_6 are constants. Equation (17) interprets the fact that $\log r_L$ decreases with a decrease in the pK_a of the catalyst.

Further work on the effect of the solvent on the copolymerization will be reported in a subsequent paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1687—1689 (1968)

Ring-opening Polymerization of the Macrocyclic Ester

Kentaro YODA and Kazuyuki KIMOTO

Katata Research Institute, Toyobo Co., Ltd., Honkatata-cho, Otsu

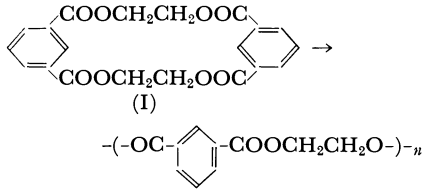
(Received January 10, 1968)

The ring-opening polymerization of cyclic bis(ethylene isophthalate) (I) was carried out in the presence of various metallic compounds as catalysts. Among the polycondensation catalysts for ethylene terephthalate, antimony and tin compounds were very effective in the ring-opening polymerization of I. On the other hand, titanium, zinc, calcium, and aluminum compounds did not show high catalytic activity. The polymerization of I proceeded even at temperatures below the melting point of I. As the melting point of the resulting poly(ethylene isophthalate) was much lower than the polymerization temperature, the reaction system gradually melted in consequence of the progress of the polymerization reaction.

With regard to the macrocyclic esters of aliphatic carboxylic acids, many investigations[1,2] have been carried out. Recently, the presence of families of macrocyclic oligoesters containing aromatic nuclei has been demonstrated in a number of technically important synthetic polyester resins.[3-6] On the other hand, it is well known that some cyclic esters with more than two ester groups, such as lactide, glycolide, and salicylide, can be polymerized to produce linear polyesters by the use of a metallic compound as the catalyst.[7-11]

Goodman and Nesbitt[5] obtained poly(ethylene terephthalate) by the ring-opening polymerization of macrocyclic oligo(ethylene terephthalates).

The present paper will be concerned with the ring-opening polymerization of cyclic bis(ethylene isophthalate)[4] (I) by various catalysts.



(I)

Experimental

The melting points were determined on a Yanagimoto electric micromelting-point apparatus. All the melting points are uncorrected. The infrared absorption spectra were obtained in a KBr disk using a Hitachi EPI-S2 infrared spectrophotometer. The NMR spectra were taken in trifluoroacetic acid, using tetramethylsilane as the external reference, on a Varian A-60 NMR spectrometer; their chemical shifts are presented in terms of δ values. All the solvents were purified and dried according to the ordinary methods.

Catalysts. Calcium acetate and zinc acetate, G. R. grade, were obtained from Nakarai Chemicals. Antimony trioxide, G. R. grade, was obtained from E. Merck AG. Di-*n*-butyltin oxide and di-*n*-butyltin dibenzoate were supplied by Yoshitomi Pharmaceutical Industries. Aluminum butoxide, triphenyl stibine, and titanium tetraglycoxide were prepared according to known procedures.[12-14]

Cyclic Bis(ethylene isophthalate) (I). The ring dimer of ethylene isophthalate was prepared by a procedure described in the literature[4] and was purified by vacuum sublimation, followed by recrystallization from dimethylformamide; mp 326—328°C (lit. 325—327°C).

Found: C, 62.75; H, 4.19%. Calcd for $C_{20}H_{16}O_8$: C, 62.50; H, 4.20%.

The infrared spectrum and the NMR spectrum of I are shown in Figs. 1 and 2 respectively. A fine powder (smaller than 200 mesh) of I was used as the starting material in the polymerization experiments.

The General Procedure for the Polymerization of I. A mixture of I and a catalyst was placed in a glass ampoule under a nitrogen atmosphere. Then the system was evacuated twice and sealed under a nitrogen flow. The polymerization was carried out

at a given temperature for a definite period. The polymer produced was dissolved in chloroform, and the insoluble, unpolymerized I was filtered off. *n*-Heptane was added to the chloroform solution to precipitate the polymer. Then the separated polymer was dried under reduced pressure. The intrinsic viscosity of the polymer was measured by an Ubbelohde's viscometer in a mixed solvent composed of phenol and tetrachloroethane (6 : 4) at 30°C.

Results and Discussion

The experimental results are shown in Table 1. The polymerization of I proceeded even at temperatures below the melting point of I. However, no polymeric material was obtained by heating I at 265°C for 120 min.

Among the polycondensation catalysts[15,16] for ethylene terephthalate, antimony and tin compounds were very effective in the ring-opening polymerization of I. However, titanium, zinc, calcium, and aluminum compounds did not show any high catalytic activity.

When antimony trioxide was used as a catalyst, a white, powder-like polymer was obtained, while a slightly brownish polymer was obtained by the use of the di-*n*-butyltin oxide catalyst. These polymers were confirmed to be poly(ethylene isophthalate) by comparing their melting points, solubilities, infrared spectra, and NMR spectra with those of the poly(ethylene isophthalate) prepared by the melt polycondensation of bis-β-(hydroxyethyl isophthalate). The infrared spectrum and the NMR spectrum of the polymer are shown in Figs. 3 and

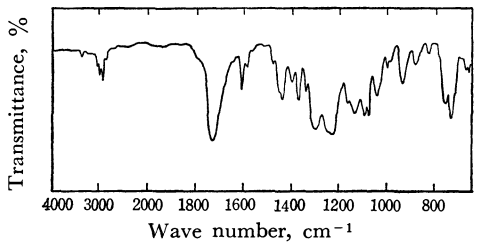

Fig. 3. Infrared spectrum of poly(ethylene isophthalate).

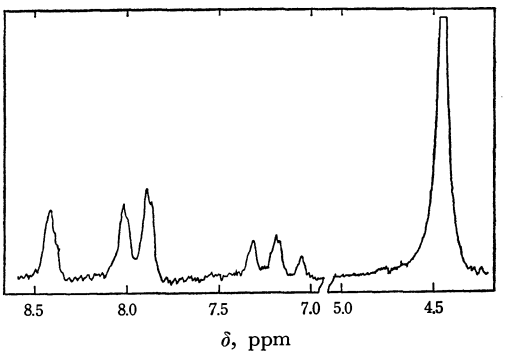

Fig. 4. NMR spectrum of poly(ethylene isophthalate).

4 respectively. In the NMR spectrum of poly(ethylene isophthalate), the complicated signals which appear at 8.42, 8.02, 7.88, 7.32, 7.20, and 7.06 ppm are due to the four protons attached to the benzene nucleus.[17] The singlet at 8.42 ppm may be due to the proton on C-2 surrounded by two ester groups. It should be noted that this singlet in the NMR spectrum of linear poly(ethylene isopthalate) shifts to 8.67 ppm in the spectrum of I (Fig. 2). The difference in the chemical shift of the proton on C-2 between linear and cyclic structures suggests that the structural conformation of a resonance system including two carbonyl groups and a benzene nucleus is different in poly(ethylene isophthalate) and in I, and that, therefore, the anisotropic effect of the resonance system is different in the linear polymer and in I.

As the melting point[18] of poly(ethylene isophthalate) was much lower than the polymerization temperature, the reaction system gradually

melted in consequence of the progress of the polymerization reaction.

In the polymerization of I by antimony trioxide at 292°C, a high-molecular-weight polymer was obtained in spite of its low rate of conversion. Such a figure would indicate that the ring-opening polymerization of I is of a rather chain-reaction type; if so, the conversion should express the rate of polymerization. The polymerization proceeded heterogeneously, and the rate of polymerization of I was slow until the reaction time of 35 min had passed, as is shown in Fig. 5. After 35 min, the reaction system changed to a liquid and the polymerization reaction proceeded rapidly.

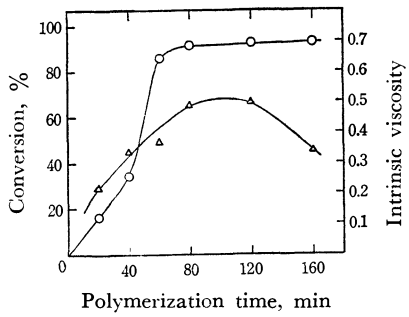

Fig. 5. Time dependences of conversion and intrinsic vicosity.
○ Conversion, △ Intrinsic viscosity
Polymerization temp. 292°C
Cyclic bis(ethylene isophthalate) 1.3×10^{-5} mol
Catalyst: Sb_2O_3 1.3×10^{-3} mol

The polymerization reaction proceeds in a heterogeneous state, and the rate of polymerization is affected by the particle size of the starting material and the degree of mixing with the catalyst. Therefore, the kinetic study is accompanied with some difficulty.

No polymeric substance was obtained by the solution polymerization of I in α-methylnaphthalene at 200°C for 600 min in the presence of diethylzinc, triethylaluminum, or triphenylstibine as a catalyst. Furthermore, an attempt at the radiation polymerization of I at room temperature by Co-60 γ-rays (total dose: 5.4×10^6R) failed.

The authors are much indebted to Mr. Murano of this Institute for the measurement of the NMR spectra.

Aminobutadienes. XIII. Anion-exchange Resins from Imidobutadiene Polymers[1]

Kenichi MURATA and Akira TERADA[2]

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka

(Received January 18, 1968)

A method of preparing new-type anion-exchange resins from 1-phthalimido-, 1-succinimido-, and 2-phthalimido-1,3-butadiene polymers is shown. The procedure consists of two steps, the hydrolysis of the imido groups into free amine, followed by heating with hydrochloric acid to make the amino groups into the hydrochloride, and *N*-methylation by the Schotten-Baumann method. The anion-exchange resins obtained from the former two polymers show high exchange capacities, such as 5.85 and 7.21 meq/g of dry resin respectively. However, their salt-splitting capacities are not high. The mechanisms of their crosslinking on hydrolysis and of their heat-aging are also discussed.

During the studies of aminobutadiene chemistry which have been carried out in our laboratory, we attempted to prepare a new type of anion-exchange resin from the imidobutadiene polymers we had previously obtained. For the use of anion-exchange resin, a high exchange capacity per unit of volume is the chief requirement. From this point of view, it would be advantageous to use a monomer which had an amino group in a highly concentrated state per unit of weight. Since 2-phthalimido-1,3-butadiene (2-PB), on bulk polymerization by radical initiators, usually affords a tough resin as a homogeneous gel, as has already been reported,[3] we initially thought that the use of gelation agents such as divinylbenzene, divinylether, and divinylsulfide for the formation of crosslinkage in the 2-PB polymer could be unnecessary, and also that the gelation tendency of the 2-PB monomer itself was the most convenient way to introduce the exchange groups into the resin particles in a high concentration. On the other hand, in the case of 1-phthalimido-1,3-butadiene (1-PB) and 1-succinimido-1,3-butadiene (1-SB) polymers, it was usually possible to prepare soluble polymers.[4] However, insoluble gels were always afforded in the hydrolysis stage of their imido groups; this would also facilitate the preparation of the crosslinked polymers of anion-exchange-resin particles.

Although imido groups as those used here for the protection of the primary amino group can be altered into the corresponding primary amino group by a somewhat severe hydrolysis using either strong acid or alkali, hydrazinolysis by heating with hydrazine hydrate is a more effective and more moderate method for the same purpose. Several workers[5-7] have recommended the use of hydrazinolysis in preparing primary amino compounds from the corresponding phthalimides. The procedure usually consists of two cources. The first is hydrazinolysis, which gives primary amine and phthalhydrazide, commonly less soluble in solvents, while the second is treatment by hydrochloric acid, which changes the free amine into hydrochloride usually soluble in water. If a large excess of hydrazine is used, the formation of primary amine will be encouraged, as may be seen in Fig. 1.

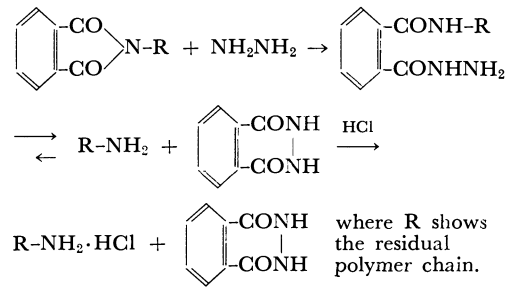

Fig. 1

A good example of this in a polymer reaction has been shown in the preparation of polyvinylamine

from polyvinylphthalimide;[6] it was concluded that the reaction took place quantitatively.

The present paper deals with the hydrazinolysis of our imidobutadiene polymers and with the following quaternarization to make a new type of anion-exchange resin.

Experimental

Materials. Polymers of 1-PB, 1-SB, and 2-PB, and a copolymer of 2-PB with *N*-vinylphthalimide were prepared by radical polymerization, either in bulk or in solution process, according to the method previously reported (see also the footnotes of Table 1).[3,4]

Nitrogen Analysis. The nitrogen contents of the starting and the resulting polymers were determined by the usual Micro-Dumas method.

Hydrolysis of Imidobutadiene Polymer. On the hydrolysis of the imidobutadiene polymers, the following convenient type of procedure was usually carried out. For example, a mixture of 0.74 g of the 1-PB polymer and 16 m*l* of 80% hydrazine hydrate was refluxed for 15 hr. The mixture, which was a clear solution in the first stage of the reaction, coagulated after a while, and then a sponge-like mass separated. This cake was repeatedly washed with water to remove the excess hydrazine, and was then heated in 15 m*l* of 20% hydrochloric acid in a boiling-water bath for 6 hr to convert the free aminobutadiene polymer to the corresponding hydrochloride and to remove any phthalhydrazide formed. After the hydrochloride had been repeatedly washed with water, it was immersed in a large amount of 5% aqueous sodium hydroxide and gently heated for a while so as to generate free amine again; then it was repeatedly washed with hot water to remove any alkali and dried under a vacuum at room temperature. The yield was 0.23 g.

***N*-Methylation of Aminobutadiene Polymer.** A sample of 0.21 g of aminobutadiene resin, in a dried free-amine form, in 15 m*l* of ethanol was methylated with 5 g of methyl iodide by the Schotten-Baumann method in the presence of a small excess of 10% alcoholic potassium hydroxide. After the mixture had been refluxed for 10 hr, the resin was collected on a glass filter and washed with water. The resulting I-type resin was converted to the OH-type resin by treating it with 5% aqueous potassium hydroxide, and finally to the Cl-type resin by treating it with hydrochloric acid. This resin was then sufficiently washed with ethanol and dried under a vacuum at room temperature over potassium hydroxide pellets. The yield was 0.34 g.

Determination of Salt-splitting Capacity. A sample of dried Cl-type resin, exactly weighed and found to be from 100 to 200 mg, was immersed in 100 m*l* of 1 N sodium hydroxide for 24 hr at room temperature, and then repeatedly washed with water to remove the excess alkali. The resin was immersed in 100 m*l* of 1 N sodium chloride for 24 hr, gathered on a glass filter, and repeatedly washed with other portions of 1 N sodium chloride; the final volume of the filtrate with the gathered washings was then exactly adjusted to 200 m*l* using a volumetric flask. A 50 m*l* portion of the solution was titrated with 0.1 N hydrochloric acid in the presence of a methyl orange indicator to determine the amount of free alkali.

Determination of Total Anion-exchange Capacity. The sample used in the above salt-splitting-capacity determination was again immersed in 100 m*l* of 1 N hydrochloric acid for 24 hr, washed completely with methanol until the washings became neutral to remove the excess acid, and then immersed in 100 m*l* of 1 N sodium sulfate for 24 hr. The resin was repeatedly washed with other portions of 1 N sodium sulfate, after which the total volume of the filtrate and the washings was exactly adjusted to 200 m*l*. A 50 m*l* portion of the solution was titrated as usual with 0.1 N silver nitrate to determine the quantity of free chloride ions present.

Aging Test of the Cl-type Resin. The aging test of the *N*-methylated resin at room temperature and on heating under an atmospheric pressure was carried out using two different samples, which had been obtained from 1-PB and 1-SB polymers respectively. Both samples were successively heated at 60, 90 120, 150, and 180°C in that order for 24-hr periods; at the end of each heating step, the total anion-exchange and salt-splitting capacities were measured as mentioned.

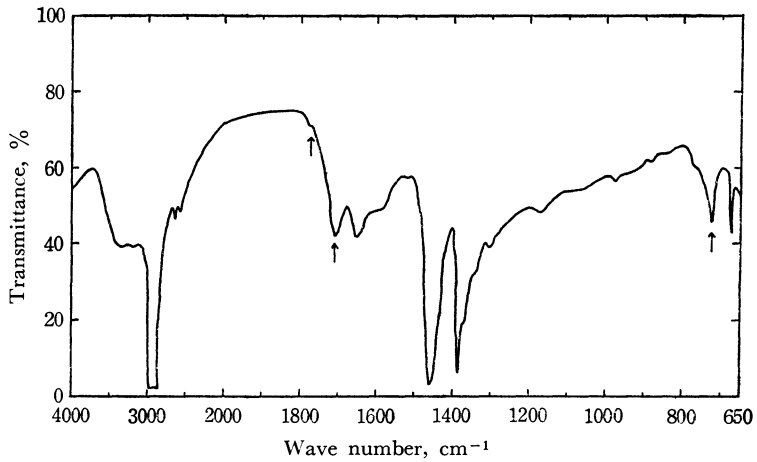

Fig. 2. Infrared spectrum of 2-aminobutadiene polymer (sample No. 6) in Nujol paste.

Results and Discussion

The hydrazinolysis and subsequent hydrochloric acid treatment of the 1-PB and 1-SB polymers gave crosslinked aminobutadiene polymers in good yields; they could be recognized as almost pure samples by their nitrogen contents. In the case of the 2-PB polymer, however, this treatment was unsatisfactory, giving a quite different result. The hydrolysis of the 2-PB polymer did not take place smoothly, and the resulting aminobutadiene polymer had less nitrogen content than in the other cases. Moreover, the yields were low, as Table 1 shows. This low yield seems to indicate a considerable loss of the used sample during the hydrolysis procedures.

Their low nitrogen contents may be considered to indicate a difficulty in the hydrolysis of the phthalimido group in the 2-PB polymer, because

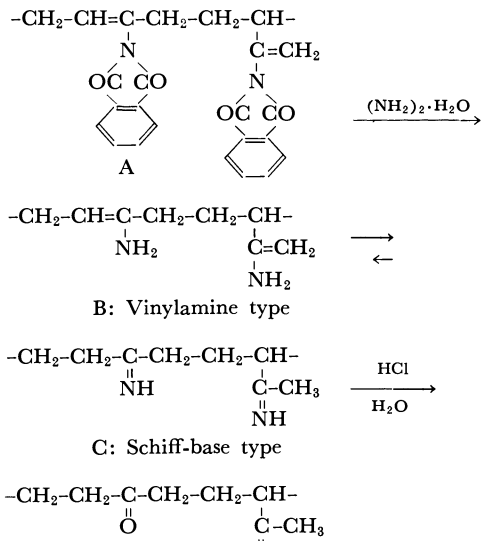

Fig. 3.

the infrared spectrum of the sample No. 6, for example, leaves phthalimido-carbonyl bands at 1770 (shoulder) and 1710 cm^{-1} and an *O*-disubstituted benzene band at 725 cm^{-1}, as is shown in Fig. 2. On the other hand, the 2-PB polymer, on hydrolysis, always gives a vinylamine structure in each of monomer unit, and this structure is generally in an equilibrium state with the ketimine structure—indeed, the latter form is usually preferable (Fig. 3, B and C).[8] This ketimine can be easily hydrolyzed partially with the concentrated hydrochloric acid of the post-treatment, and affords a ketone structure, which must reduced the nitrogen content of the resulting polymer less than the original one. On the direct hydrolysis of the 2-PB polymer with concentrated hydrochloric acid or 10% aqueous sodium hydroxide, the resulting polymers showed nitrogen contents of 1.92 and 2.62% respectively. This may show phthalimide elimination during hydrolysis, as is shown in Fig. 4, because of the phthalimido group attached to the carbon of the double bond.

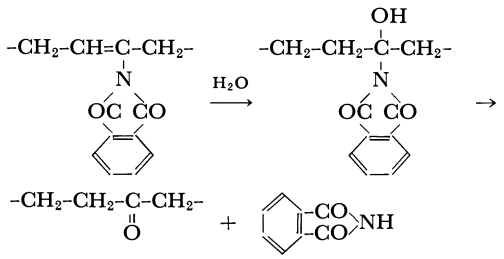

Fig. 4.

Also, both the 1-PB and 1-SB polymers contain approximately 80% of the 1,4-configuration and 20% of the 3,4-configuration.[4] On hydrolysis, the structure of the latter configuration should afford an aldmine structure analogous to that above. As to the crosslinking of these hydrolyzed polymers, some assumptions are possible. Some of these aldmine and ketimine will preferentially react with hydrazine to form their hydrazones

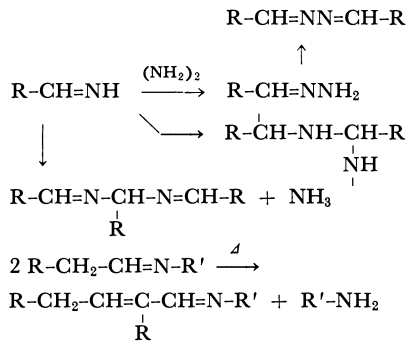

Fig. 5.

by exchange reactions,[9] and these ammonia- and hydrazine-derivatives of the carbonyl groups will partially react with each other to form intra- and inter-molecular crosslinking spontaneously,[10] as with the samples shown in Fig. 5. Carbon-carbon condensations of the aldol type often occur if there is an α-methylene group.[10]

The results of the *N*-methylation of the aminobutadiene polymers obtained from the above hydrolysis are shown in Table 2. Their total anion-exchange capacities were in the range between 2.6 and 7.2 meq/g of dry resin; however, their salt-splitting capacities were not high. For

Table 2. *N*-Methylation of aminobutadiene polymers[a] and their anion-exchange capacities

Sample No.	Weight (g)	Methyl iodide (g)	Ethanol (ml)	Reaction time (hr)	Yield[b] (g)	Nitrogen[c] content (%)	Total anion-exchange capacity (meq/g of dry resin)
1	0.21	10	15	10	0.28	11.87 11.46	5.85
2	0.21	5	15	10	0.34	11.28 11.54	7.21
4	0.11	5	8	10	0.12	7.37 7.85	3.22
5	0.07	5	7	10	0.09	6.87 7.14	2.62
6	0.13	5	10	14	0.20	8.57	3.52

a) The reactions were carried out under reflux.
b) The yields show those of the Cl-type resins.
c) As Cl-type resins vacuum-dried at room temperature.

Table 3. Heat-aging test of *N*-methylated resin hydrochlorides

Temperature (°C)	Sample No. 1		Sample No. 2	
	Salt-splitting capacity (meq/g of dry resin)	Total anion-exchange capacity (meq/g of dry resin)	Salt-splitting capacity (meq/g of dry resin)	Total anion-exchange capacity (meq/g of dry resin)
60	1.19	5.83	1.05	6.78
90	0.52	5.36	0.69	5.85
120	0.38	4.80	0.53	5.09
150	0.20	4.43	0.31	4.65
180	—	2.85	—	3.08

example, sample No. 1 showed a value of 0.84, while No. 2 showed 1.01 meq/g of dry resin.

The aging test of the *N*-methylated resin hydrochlorides showed that the usual keepting of them for two years under an atmospheric pressure and at room temperature was harmless to their total anion-exchange capacities. Table 3 shows the results of the heat-aging test.

The more rapid decrease in the rate of the salt-splitting capacity than in the rate of the total anion-exchange capacity indicates that there is a methyl chloride elimination[11] from a quaternary ammonium chloride group which reduces the salt-splitting capacity.

The authors wish to thank Professor Shizunobu Hashimoto of Doshisha University and Dr. Isao Shiihara of this Institute for their helpful suggestions during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1694—1696 (1968)

Aluminum Silanolates
Acid Strength and Polymerization Catalyst Activity

Takeo SAEGUSA, Takashi UESHIMA and Kunioki KATO

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received January 24, 1968)

Two aluminum silanolates, diethyl(trimethylsiloxy)aluminum (I) and tris(trimethylsiloxy)-aluminum (II), were compared with the corresponding aluminum alcoholates in terms of their acid strength and in their catalyst behavior in the polymerizations of cyclic ethers and vinyl ether. The reference aluminum alcoholates were diethylaluminum *t*-butoxide (III) and aluminum *t*-butoxide (IV). The Lewis acid strength was examined by means of two methods, the Hammett indicator method and the shift of the IR carbonyl band ($\Delta\nu_{C=O}$) of *n*-butyraldehyde. Four aluminum compounds, I—IV, were weaker Lewis acids than triethylaluminum; *i. e.*, the replacement of the ethyl group of triethylaluminum with either a siloxy group or an alkoxy group brought about a decrease in the acid strength. The acid strength of I and II were demonstrated to be stronger than that of the reference alcoholates, III and IV. A difference in polymerization catalyst activity was also observed between aluminum silanolates and the reference alcoholates; it was reasonably explained by the difference in acid strength.

In a series of studies of metal alkyls and metal alcoholates as polymerization catalysts, we have reported that the triethylaluminum-trialkylsilanol system is an effective catalyst for the polymerizations of cyclic ethers such as tetrahydrofuran and epichlorohydrin, isobutyl vinyl ether and acetaldehyde.[1]

The purpose of the present study is to examine the acid characters and the polymerization catalyst activities of two aluminum silanolates, diethyl-(trimethylsiloxy)aluminum (I) and tris(trimethylsiloxy)aluminum (II), in comparison with those of two reference aluminum alcoholates, diethylaluminum *t*-butoxide (III) and aluminum *t*-butoxide (IV).

A difference between II and IV in their catalytic behavior in the Tishchenko reaction has previously been reported.[2]

Results and Discussion

Table 1 shows the results of the acid-strength measurements of aluminum silanolates and aluminum alcoholates as well as of triethylaluminum.

The acid strength was examined by two methods. The one was the Hammett indicator method,[3,4] while the other was based upon the magnitude of the shift of the ir carbonyl band of *n*-butyraldehyde, which was adapted as the reference base. The indicator method showed that both aluminum silanolates and aluminum alcoholates were weaker Lewis acids than triethylaluminum. This acid-strength difference was also demonstrated by the ir technics; *i. e.*, triethylaluminum caused a shift of the ir carbonyl band of xanthone ($\Delta\nu_{C=O}=83$

a) Indicators: I=Neutral red; II=Methyl red; III=Phenylazonaphthylamine; IV=Butter yellow V=Dicinnamalacetone; VI=Benzalacetophenone. A; acidic color; B: basic color.
b) Error=±3 cm^{-1}.

cm^{-1}), whereas two aluminum silanolates and two aluminum alcoholates did not. Thus, the replacement of the ethyl group of triethylaluminum by either a siloxy group or an alkoxy group decreased the acid strength. However, aluminum silanolates were stronger acids than the corresponding alcoholates. The magnitudes of the $\Delta\nu_{C=O}$ values of *n*-butyraldehyde caused by aluminum silanolates were higher than those caused by the reference aluminum alcoholates. This observation was partly supported by the indicator method; *i. e.*, II was acidic toward neutral red and methyl red, whereas IV was basic to these indicators. This acid-strength difference can not be explained by a simple consideration of electronegativity. From the electronegativities of carbon and silicon, the electron definciency of aluminum alcoholates is considered to be higher than that of aluminum silanolates. Hence, the former might be expected to be stronger acids. However, the reverse is true in the present case. The stronger acid character of aluminum silanolates in comparison with the reference aluminum alcoholates may be due, at least in part, to the electron-withdrawing effect of the silicon atom through the d_π—p_π bond of the silicon-oxygen linkage.[5]

The catalyst activities of these aluminum compounds in the polymerizations of cyclic ethers and vinyl ether were interpreted in terms of their acid strength. The data of the ethylene oxide polymerization are summarized in Table 2, in which the polymer yield and the yield of the dioxane byproduct, the cyclic dimer of ethylene oxide, are indicated. All four aluminum compounds induced the ethylene oxide polymerization. However, dioxane was formed only in the runs with aluminum silanolates catalysts. The dioxane formation is quite clear in the case of I, which implies the mechanism of cationic polymerization. In our mechanistic study[6] of the catalyst behavior of organoaluminum compound systems, we have established that the formation of dioxane as a byproduct in the ethylene oxide polymerization is an indication of cationic polymerization.

6) T. Saegusa, T. Ueshima and S. Tomita, *Makromol. Chem.*, **107**, 131 (1967).

Aluminum silanolates caused the polymerization of some cationically-polymerizable monomers, whereas the corresponding aluminum alcoholates did not do so (Table 3).

These cationic catalyst activities of aluminum silanolates correspond to their stronger Lewis-acid characters.

Experimental

All the experiments were conducted under a nitrogen atmosphere.

Reagents. *Monomers, Solvents and Cocatalysts.* All the reagents were carefully purified by the usual procedures.

Catalysts. I was prepared by a reaction between triethylaluminum and trimethylsilanol and was purified by fractional distillation; bp 103°C at 1.1 mmHg. II was synthesized according to the method reported in the literature.[7] III was prepared by the reaction of triethylaluminum with *t*-butanol which was sublimed at 90°C under reduced pressure (0.1 mmHg). IV was synthesized from *t*-butanol and aluminum foil and was purified, just prior to use, by being recrystallized from benzene five times. In the present study, it has been found that IV is not so stable and that it decomposed even at room temperature. The decomposition product, which was insoluble in hot benzene, was a stronger acid than IV. Therefore, it was necessary to purify IV by recrystallization just before use. Otherwise reliable results could not be obtained.

Others. Dioxane, methanol, and benzene were commercial reagents of a high purity and were used without further purification.

Acid-strength Measurements. The Hammett method was performed as has been described before.[4] The shifts of the carbonyl-stretching vibration of *n*-butyraldehyde were measured in Nujol.

Polymerization. Polymerization was performed in a sealed tube. The after-treatments of BCMO,[8] THF,[9] and IBVE[10] polymerization systems were the same as those described before.

In the ethylene oxide polymerization, the volatile matter was first evaporated from the reaction mixture at 80°C under reduced pressure (below 0.5 mmHg), and then analyzed by vpc for dioxane. A reference experiment showed that dioxane, if it was present in the polymerization mixture, could be detected and quantitatively analyzed by the above procedure. The evaporation residue was treated with a mixture of benzene and ammonia water and dried up. The polymer was then dissolved again in benzene. The catalyst precipitate was removed, and the polymer was recovered from the filtrate.

3d-Orbital Resonance in Divalent Sulfides. XIV. Free Radical Copolymerization of Ketene Diethylmercaptal with Styrene[1,2]

Waichiro TAGAKI, Tsutomu TADA,[3] Ryuichi NOMURA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received January 24, 1968)

Free radical copolymerization reactions of ketene diethylmercaptal (I) and *p*-methylmercaptostyrene (III) with styrene have been carried out. The *Q*-values for I and III are found to be 2.7 and 3.3 respectively, and these and other related observations are discussed in terms of electron-sharing conjugation involving 3d-orbital of sulfur atom.

The ability of sulfur atom to stabilize carbanion has been well known for positively charged sulfur compounds.[4] The major factor for such stabilization is believed to be 3d orbital resonance of sulfur atom. As for divalent sulfides, we have also presented evidence for 3d orbital resonance in the base-catalyzed hydrogen exchange reactions of mercaptals.[5] Thus it seems to be clear that sulfur atom, regardless of its valence state, does stabilize carbanion, presumably by accepting negative charge into its vacant 3d orbital. This ability of

sulfur atom sharply contrasts with that of oxygen atom which does not have available d-orbital for such stabilization, and moreover α-oxygen group appears to destabilize carbanion.[5a,6]

Meanwhile, in carbonium ion reaction, electron donating conjugation becomes predominant, *i. e.*, nitrogen and oxygen compounds are generally more reactive than the corresponding sulfur analogs. In the free radical reaction, however, our present knowledge is not quantitative enough to predict satisfactorily the course of reaction or the extent of stabilization of an odd electron by sulfur atom. If a free radical center is electrophilic in nature, one might expect that electron-donating conjugation is more dominating over electron-accepting conjugation. In accord with this, the following resonance of the types of (1) and (2) has been suggested by Russell and his coworkers, which accounts for greater reactivity of nitrogen compound than that of the analogous sulfur compound toward the abstraction of α-hydrogen atom:[7]

$$\rangle\ddot{N}\text{-}\dot{C}H_2 \longleftrightarrow \rangle\dot{N}^+\text{-}\ddot{C}H_2^- \qquad (1)$$

$$\text{-}\ddot{S}\text{-}\dot{C}H_2 \longleftrightarrow \text{-}\dot{S}^+\text{-}\ddot{C}H_2^- \qquad (2)$$

On the other hand, another type of conjugation has been postulated by Price and Oae: electron-sharing conjugation of the type of (3) is conceivable for divalent sulfur compound where sulfur atom accepts odd electron by expanding its valence shell:[4]

$$\text{-}\ddot{S}\text{-}\dot{C}\text{-} \longleftrightarrow \text{-}\dot{S}^-\text{=}C\text{-} \qquad (3)$$

The importance of the latter type of 3d orbital resonance of the sulfur atom has been displayed in several radical reactions, *i. e.*, in free radical addition reaction to the double bond,[8] in peroxide decomposition,[9] and in radical copolymerization reaction,[10] etc. Unfortunately, most of these data are either qualitative or fragmental. Moreover the relative importance of the opposing effects of the type of (2) and (3) should depend on types of reaction, attacking radical and its acceptor.

In the free radical copolymerization reactions, Price and his coworkers found that vinyl sulfide and divinyl sulfide were much more reactive toward growing polystyryl radical than the corresponding oxygen analogs.[10] They treated the data by their *Q-e* scheme.[10c] Although this *Q-e* scheme is purely empirical, it has been shown in a number of cases that larger resonance stabilization of a growing radical seems to be associated with larger *Q* value, and it has been proved to be useful for quantitative estimation of resonance stabilization of a growing radical. For example, the *Q* value of vinyl sulfide is larger than that of vinyl ether, and this has been suggested to be due to the resonance stabilization of the growing radical according to the type of (3). One way to test this concept is to determine the *Q* value of ketene mercaptals, since, just as in the case of base catalyzed hydrogen exchange reactions of mercaptals, the substitution of one additional mercapto group in ketene mercaptal would increase *Q* value substantially over that of vinyl sufide, if *Q* value is a measure of such resonance.

As one of our broad interest in the nature of sulfur bonding, we have now carried out the copolymerization of ketne diethylmercaptal and *p*-methylmercaptostyrene with styrene and compared with those of the corresponding oxygen analogs.

Results and Discussion

All of the compounds, ketene diethylmercaptal (I), ketene diethylacetal (II) and *p*-methylmercaptostyrene (III), were prepared by the known methods as described in the experimental section. Their copolymerizations with styrene were conducted at 60°C with azoisobutyronitrile as the free radical initiator. The monomer, III, gave its copolymer in a satisfactory yield with each monomer ratio. The copolymerization of I was not entirely satisfactory, since, with higher proportion of I, we were unable to isolate any polymer. However, four mixtures (Table 4) gave enough copolymer for the *Q-e* analysis. Unfortunately, the monomer II did not give copolymer. Instead, the only polymer obtained was concluded to be polystyrene, leaving II unreacted (Table 6). This is not surprising in view of the expected increase of negative e-value, probably less than that of I, -2.1, and resulting in an increased difference between the e-values of styrene and the acetal. Perhaps a similar argument cannot be applied to the failure of obtaining copolymer of I in a higher monomer ratio, since, in this case, no polymer, not even polystyrene, could be isolated.

The *Q* and *e* values, thus obtained, are shown in Tables 1 and 2 together with those of the related compounds. Table 1 indicates: (1) The *Q* values of oxygen compounds are very small, especially for ketene diethylacetal (II) which underwent negligible copolymerization. (2) The *Q* values of the sulfone and the silicon compounds are also small. (3) In contrast, the divalent sulfur compounds have large *Q* values. (4) Substitution of one additional mercapto group for vinyl sulfide to ketene diethylmercaptal (I) results in a remarkable increase in *Q* values, much greater

increase than that from vinyl sulfide to divinyl sulfide.

The smaller Q values of the oxygen compound compared with those of the sulfur compounds suggests that in this free radical addition reaction to the double bond the type (2) resonance is less important than the type (3) resonance. In an effort to extend the concept of the electron-sharing conjugation of the type (3), the hydrogen abstraction reaction with various compound substituted at α-carbon atom by heteroatom has been investigated. It was found, however, that the transition state of the hydrogen abstraction reaction by t-butoxy or even by phenyl radical is considered to assume a partial carbonium ion character when one judges from the substituent effect on the rates and the negative ρ-value. Thus the order of reactivity of the compounds substituted by hetero atom at α-position is in the order of nitrogen->oxygen-> unsubstituted compound.[14] However the situation is different with the mercapto-substituent whose rate-enhancing effect is somewhat larger than that of the corresponding oxygen substituent, despite of the less electron-releasing conjugative effect of mercapto group than that of the corresponding oxygen-compounds. This small anomaly has been suggested to be due to a small contribution of the electron-sharing conjugation of type (3). Meanwhile, ρ-values for the reactions of vinyl phenyl sulfides toward attacking polystyryl radical have been shown to be positive,[15] indicating that the transition state for this addition reaction resembles more carbanion rather than carbonium ion. Unusually low reactivity of the oxygen compounds is consistant with this view, since it has been shown in the carbanion forming reaction that α-alkoxy group even destabilizes the incipient carbanion.[5a,6] Importance of the type (3) resonance can be seen in the small Q-values of the sulfone and the silicon compounds which have no available lone electron pair for such conjugation. On the other hand, the abstraction of α-hydrogen atom from the sulfonyl compound has been noted to be extremely difficult.[14] Therefore the moderate Q value of methyl vinyl sulfone also seems to suggest the carbanion type transition state, for sulfonyl group is known to delocalize the charge very effectively.

Incidentally, as one can easily notice, the "electron-sharing" conjugation of the type (3) is possible only with groups bearing lone electron pair such as divalent sulfides that can expand the outer valence shell beyond octet to accomodate an odd electron from the adjacent carbon atom.

We believe that the observations, (3) and (4), together with (1) are good indications of the occurrence of such 3d orbital resonance. The large Q value of ketene diethylmercaptal (I) is in accord with the large rate enhancement in the base-catalyzed hydrogen exchange reaction in going from diethyl mercaptal to triethyl orthothioformate.[5a] The resonance stabilization of growing radical of I could be achieved by the contributions of the resonance structures shown in Ia-Ic, *i.e.*, the electron-sharing conjugation of the type (3).

the copolymerization of styrene.[16] Their method suggests the Q value of III to be unusually high. So is the value of 2-vinylthiophene. A likely explanation would be that while a hetero atom combined directly to vinyl double bond could destabilize growing radical by either inductive or lone electron-pair repulsion or by both, the removal of the hetero atom away from the reaction center, for example to the *p*-position of styrene, definitely reduces such effect, and hetero atom, in turn, would display more effective conjugation through phenyl ring, mobilizing an odd electron from its lone pair.

Table 3 shows the UV spectra of I together with those of the related compounds. The large red shift in divinyl sulfide than in vinyl sulfide has been suggested to be partly due to the "through conjugation".[4a] Although such through-conjugation is impossible, similar order of red shift is found in I. This would suggest a non-bonding interaction between the two sulfur atoms in I in the photo-excited state.[5b]

Experimental

Preparation of Materials. *Ketene Diethylmercaptal* (I)[18] was prepared by the acid catalyzed elimination of ethyl mercaptan from triethyl orthothioacetal (bp 121°C/10 mm), 80°C/15 mmHg., n_D^{20} 1.5304 (lit., 1.5306[18]).

Ketene Diethylacetal (II)[19] was prepared by the elimination reaction of triethyl β-bromoorthoacetate (bp 80°C/10 mmHg), with dispersed sodium metal in anhydrous benzene, bp 68°C/100 mmHg (lit., 68°C/100 mmHg[19]), n_D^{27} 1.4095 (lit., 1.4110[19]).

p-Methylmercaptostyrene was prepared starting from *p*-bromoacetanilide. *p*-Bromoacetanilide was converted to *p*-bromothioanisole by the diazotization, followed by the reaction with methyl mercaptan, bp 103—105°C/14 mmHg, mp 40°C (lit. mp 40°C[20]). *p*-Bromothioanisole was converted to Grignard reagent in tetrahydrofuran and reacted with acetaldehyde. The resulting alcohol was dehydrated with potassium hydrogen sulfate at 260°C under vacuum to give *p*-methylmercaptostyrene, bp 82°C/3 mmHg. (Lit. bp 83—85°C/3 mm[21]), identified by IR, and NMR spectra.

a) Each tube contained 35 mg of azoisobutyronitrile.
b) These values indicates that there was practically no copolymerization.

Copolymerization with Styrene. The reaction mixture was prepared by mixing styrene with each monomer and azoisobutyronitrile and sealed under high vacuum. The polymerization was carried out by shaking the sealed tubes in a constant temperature bath (60°C). Polymer was isolated by pouring the contents of the tube into 200 ml of cold methanol. The dried precipitate was dissolved in benzene again and reprecipitated in cold methanol. Dried pure sample, thus made was subjected to analysis and the results are listed in Tables, 4, 5 and 6.

From the data in Table 4 the copolymerization ratios, r_1 and r_2 were estimated by the intersection method using Eq. (4). The Q and e values were then calculated using Eqs. (5) and (6)[10c] and assuming the Q and e values for styrene as 1.00 and −0.8, respectively.[17]

$$r_2 = \frac{M_1}{M_2}\left[\frac{dM_2}{dM_1}\left(1+\frac{M_1}{M_2}r_1\right)-1\right] \quad (4)$$

$$r_1 = (Q_1/Q_2)e^{-e_1(e_1-e_2)} \quad (5)$$

$$r_2 = (Q_2/Q_1)e^{-e_2(e_2-e_1)} \quad (6)$$

The Wolff Rearrangement. IV. The Silver-salt Catalyzed Decomposition of α-Diazoacetophenones in Benzene Solution*[1]

Matsuji TAKEBAYASHI and Toshikazu IBATA

Department of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received January 26, 1968)

The decomposition of α-diazoacetophenone (I) in benzene solution has been studied using a silver benzoate-triethylamine catalyst at 50°C in an atmosphere of nitrogen. The reaction gave 3-benzoyl-4-hydroxy-5-phenylpyrazole (II) and β-phenylpropiophenone (III). In the decomposition of the substituted compounds, such as *p*-methoxy-, *p*-methyl- and *p*-nitro-α-diazoacetophenones, the corresponding substituent products of II and III were also obtained. The formation of II and III is reasonably explained by assuming two kinds of reactions between phenylketene and I.

It has been recognized that the photochemical, thermal, and silver-salt catalyzed decompositions of diazoketones in protic solvents give carboxylic acids and their derivatives (Wolff Rearrangement).[1] Although these products have been interpreted in terms of ketene intermediates,[2] the high reactivity of normal ketenes does not allowed the isolation of them but leads to the carboxylic acids, esters, and amides, respectively, after reacting with water, alcohols, and amines existed in the reaction system.[3]

On the other hand, the decomposition of the diazoketones in aprotic solvents affords the β-lactam[4,5] and 1,2-diazacyaclobutane derivatives[6] in the presence of azomethine and azo compounds respectively.

Recently, one of the authors (T. I.) has made a

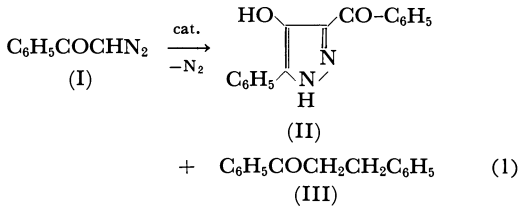
kinetic study on the decomposition of substituted α-diazoacetophenones in various kinds of alcohols and in toluene solution,[7] using a solution of silver benzoate in triethylamine as a catalyst,[8] and has found that the substituent effect in alcohols is similar to that in toluene, and also has confirmed that the both reaction mechanisms are alike in the formation of ketene intermediates. In the experiments mentioned above, the evolution of nitrogen was almost quantitative and the corresponding phenylacetic esters were obtained in good yields in alcohols, while the evolution of nitrogen was not quantitative in toluene solution. A possible reason for the decrease in the evolution of nitrogen is given to the reaction between unreacted diazoketone and a ketene intermediate, when reactive substances with ketene are not present in the reaction medium. Therefore the investigation of the reaction products seems to be important. However, only a few studies of the decomposition of diazoketones in aprotic solvents, under the condition leading to rearranged products, have been published;*2 the photolysis of diazomethyl *t*-butyl ketone and of α-diazoacetophenone (I) in the absence of solvent has been reported by Wiberg,[11] and the thermal decomposition of napthalene-1,2-diazoxide in xylene and that of α-diazoacetophenone (I) in dodecane by Yates.[12,13]

The authors investigated the silver benzoate catalyzed decomposition of α-diazoacetophenones in benzene solution and obtained interesting results differed from those reported by Wiberg and Yates.



(I) (II) (III) (1)

Results

The decomposition of α-diazoacetophenone (I) in benzene solution was carried out in the presence of a 1/10 molar equivalent of silver benzoate, dissolved in a possibly smaller amount of triethylamine, at 50°C in an atmosphere of nitrogen. The reaction mixture turned to dark-brown color accompanied by the evolution of nitrogen gas. The evolution of nitrogen was ceased after about 60—70%*3 of its theoretical amount was generated (4—5 hr), and no evolution of nitrogen was recognized by further addition of the silver benzoate solution to the reaction mixture. After being left to stand at room temperature overnight, the reaction mixture was extracted several times with a saturated aqueous solution of sodium bicarbonate in succession with a 4 N solution of sodium hydroxide, and was separated in three fractions: (A) acidic fraction (soluble in sodium bicarbonate solution), (B) weak acidic fraction (soluble in sodium hydroxide solution), (C) neutral or basic fraction (soluble in benzene). Fraction (A) gave benzoic acid and a trace of phenylacetic acid. The benzoic acid is thought to be produced from silver benzoate, used as a catalyst, during the reaction or after treatment of reaction mixture, and the phenylacetic acid seems to be formed by the reaction of the phenylketene intermediate with a trace of water contained in the reaction medium.

On the acidification of fraction (B) by a concentrated hydrochloric acid under cooling with ice, followed by recrystallization from ethanol solution, 3-benzoyl-4-hydroxy-5-phenylpyrazole (II)[14] was obtained in the yield of 38%. However, 3-benzoyl-4-phenyl-5-hydroxypyrazole (IV),[14] the isomeric compound of II, and the ketene dimer (V)[15,16] were not detected in this fraction.

On vacuum distillation of neutral fraction (C) after evaporating the solvent, β-phenylpropiophenone(III)[17-19] was obtained in 13% yield with very small amount of two kinds of compounds containing carbonyl groups. The structure of the ketone (III) was ascertained by the comparison of the IR and NMR spectra with those of authentic β-phenylpropiophenone, and still more ascertained

by the Beckmann rearrangement of its oxime (VI) to α-chloro-β-phenylpropionanilide (VII) in the presence of phosphorus pentachloride.

$$\underset{\text{(III)}}{\text{PhCOCH}_2\text{CH}_2\text{Ph}} \xrightarrow{NH_2OH} \underset{\text{(VI)}}{\text{Ph-C(=N-OH)-CH}_2\text{CH}_2\text{Ph}} \xrightarrow{PCl_5} \underset{\text{(VII)}}{\text{PhNH-C(=O)-CHCl-CH}_2\text{Ph}}$$

$$\xrightarrow[OH^-]{\text{hydrolysis}} \text{PhCH=CHCOOH} + \text{HCl} \quad (2)$$

$$\xrightarrow[H^+]{} \text{PhNH}_2 \xrightarrow{\text{PhCOCl}} \underset{\text{(VIII)}}{\text{PhCONHPh}} + \text{HCl} \quad (3)$$

When the reaction mixture was diluted further with benzene, the evolution of nitrogen was increased with the increase of the ketone (III) to 38%, and the amount of pyrazole (II) was decreased to 4% as shown in Table 1.

The catalytic decomposition of *p*-methoxy-, *p*-methyl-, and *p*-nitro-α-diazoacetophenones also gave the corresponding derivatives of pyrazole and β-phenylpropiophenone. The results are listed in Table 2.

These results are quite different from those reported by Wiberg and Yates, and also from those obtained in the copper-salt catalyzed decomposition of α-diazoacetophenone in benzene, yielding 1,2-dibenzoylethylene.[9,20]

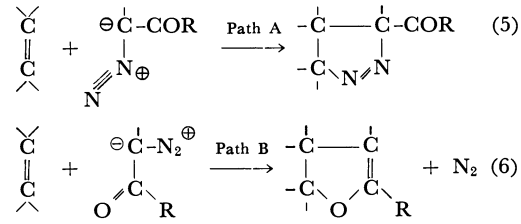
Discussion

Yates and his co-workers have obtained pyrazole derivatives (II) and (IV) besides benzoic acid, acetophenone and 3-benzoyl-5-phenyl pyrazole (IX) in the alkali catalyzed decomposition of α-diazoacetophenone.[14a,e,g] However, the mechanism of the formation of II in the reaction, which was carried out by Yates, will not be similar to that in our silver-salt catalyzed decomposition of α-diazoacetophenone, because both experimental conditions are quite different.*4

In the silver-salt catalyzed decomposition, the α-diazoacetophenone is converted, at first, to phenylketene (Eq.(4)) as has been reported previously.[7]

$$\underset{\text{(I)}}{\text{PhCOCHN}_2} \xrightarrow[-N_2]{\text{catalyst}} \underset{\text{(X)}}{\text{PhCH=C=O}} \quad (4)$$

The presence of ketene intermediate (X) is also confirmed by the isolation of a trace of phenylacetic acid, which is produced by the reaction between phenyketene (X) and water. The ketene will then add with its double bond to another molecule of α-diazoacetophenone (I). In general, the addition of diazoketones to the carbon-carbon double bond of unsaturated compounds takes place in two paths (A) and (B):

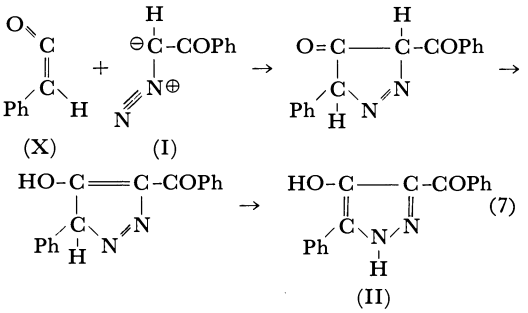


*4 As is shown in the Experimental section, consumption of the diazoketone in the reaction mixture was confirmed by the IR spectra before the alkaline extraction. Moreover, the shaking of a benzene solution of I with 4 N sodium hydroxide solution at room temperature in an extracting funnel gave yellowish color to the alkaline layer, but no II was obtained.

20) M. Takebayashi, T. Ibata and H. Kohara, unpublished.

For example, the formation of 3,4,5-tribenzoyl-2-pyrazoline (XI)[21] by the reaction of *trans*-1,2-dibenzoylethylene with α-diazoacetophenone and that of pyrazoline derivative (XII)[22] by the reaction of ethyl α-isopropylacrylate with diazoacetone have been recognized to proceed according to the path (A). However, the reaction between ketenes and diazoketones to give pyrazole derivatives has not been reported yet.

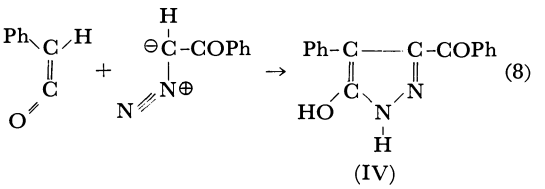
In the present decomposition, the reaction of phenylketene with the diazoketone takes place in a type of 1,3-dipolar cyclo-addition according to the path (A), followed by the enolization and proton shift, to give the product (II) as is shown in Eq. (7).*5



(X) (I)

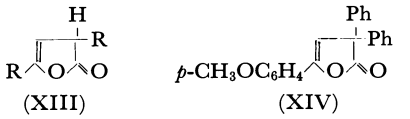
(II) (7)

The absence of the isomer (IV) in the reaction products suggests that the direction of addition does not submited to the Eq. (8).



(IV) (8)

On the other hand, γ-enol-lactones, such as 3,5-di-*t*-butyl-1,2-dihydrofurane-2-one (XIII, R=*t*-Bu),[11] 3,5-diphenyl-1,2-dihydrofurane-2-one (XIII, R=Ph)[13] and 3,3-diphenyl-5-*p*-anisyl-1,2-dihydrofurane-2-one (XIV),[25,26] have been obtained by the photochemical decomposition of diazomethyl-*t*-butylketone, by the thermal decomposition of α-diazoacetophenone, and by the reaction of diazomethyl-*p*-methoxyphenylketone with diphenylketene, respectively.



(XIII) (XIV)

The formation of these compounds is explained by the interaction of a ketene intermediate and another molecule of diazoketone according to the path (B).*6

Then, the formation of β-phenylpropiophenone (III) will be elucidated as follows: The phenylketene (X) adds to unreacted α-diazoacetophenone to give γ-enol-lactone (XVII) according to the path (B). When the enol-lactone (XVII) was hydrolyzed, the α-phenyl-β-benzoylpropionic acid (XVIII) produced will be converted to β-phenylpropiophenone (III) by decarboxylation.

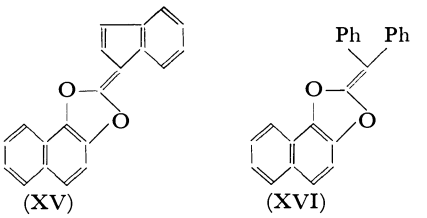
26) A. S. Kende, *Chem. & Ind. (London)*, **1956**, 1053.

*6 Besides, the addition of diazoketones to the carbonyl double bond of ketenes also has been reported. For example, the thermal decomposition of *o*-naphthoquinonediazide[12] and the reaction of the quinonediazide with diphenylketene[12,27] afford XV and XVI, respectively.



(XV) (XVI)

27) W. Ried and R. Rietrich, *Ann.*, **666**, 135 (1963).

If the formation of β-phenylpropiophenone (III) proceeds by the following free radical mechanism, acetophenone and carbon monoxide must be produced during the reaction.

$$\underset{\text{(I)}}{\text{PhCOCHN}_2} \xrightarrow{\text{cat.}} \underset{\text{(XIX)}}{\text{PhCOCH:}} + \text{N}_2 \quad (11)$$

$$\underset{\text{(XIX)}}{\text{PhCOCH:}} + \text{S-H} \rightarrow \text{PhCOCH}_2\cdot + \text{S}\cdot \quad (12)$$

$$\text{PhCOCH}_2\cdot + \text{S-H} \rightarrow \underset{\text{(XX)}}{\text{PhCOCH}_3} + \text{S}\cdot \quad (13)$$

$$\text{PhCOCH}_2\cdot + \text{PhCH=C=O} \rightarrow \text{PhCOCH}_2\dot{\text{C}}\text{HPh} + \text{CO} \quad (14)$$

$$\text{PhCOCH}_2\dot{\text{C}}\text{HPh} + \text{S-H} \rightarrow \underset{\text{(III)}}{\text{PhCOCH}_2\text{CH}_2\text{Ph}} + \text{S}\cdot \quad (15)$$

(S-H: benzene, triethylamine, *etc.*)

However, no acetophenone (XX) was obtained, and no peak of carbon monoxide was observed in the gas chromatogram of gaseous products. Moreover, *cis*- and *trans*-1,2-dibenzoylethylene, which should be produced in the reaction of benzoylcarbene (XIX) and diazoacetophenone (I), were not recognized in the reaction products. Therefore, the free radical mechanism is not suitable for the formation of β-phenylpropiophenone (III). The mechanism will be discussed in detail compared with that of photolysis of diazoketone.

Experimental*7

Materials. *The Substituted and Unsubstituted α-Diazoacetophenones* used in this investigation were prepared by the reaction of the corresponding acid chlorides with diazomethane according to the method of Newman and Beal.[28] An ether solution of benzoyl chloride was added dropwise to the ether solution of a small excess of diazomethane and an equivalent amount of triethylamine below 0°C with vigorous stirring. After the reaction mixture was allowed to stand overnight at room temperature, the precipitated triethylamine hydrochloride was filtered off. The filtrate was washed with water, saturated sodium bicarbonate, and water successively, and drived over anhydrous magnesium sulfate. The solvent was removed *in vacuo* and yellowish residue was collected. Several recrystallizations from ligroin or benzene gave pale yellow crystals. The melting points of diazoacetophenone were shown below:

unsubstituted: 47.5—48.0, *p*-CH_3: 52.0—52.8, *p*-CH_3O: 87.5—88.5, *p*-NO_2: 118.0—119.0°C

The diazoacetophenones obtained were stored in a dark place to prevent the decomposition by diffused light.

*7 All melting and boiling points are uncorrected. Infrared spectra were obtained with the Hitachi EPI-S2 model spectrophotometer. The NMR spectra were determined with the Varian Associates model A-60 instrument. Chemical shifts are given in τ units using tetramethylsilane as an internal standard. Gas chromatographic measurement was carried out using a Yanagimoto Gas Chromatograph model GCG-3DH.

28) M. S. Newman and P. F. Beal, *J. Am. Chem. Soc.*, **71**, 1506 (1949).

Benzene and Triethylamine were redistilled over metallic sodium to remove a trace of water dissolved in these materials.

The Silver Benzoate was prepared by the reaction between an equivalent molar amount of silver nitrate and sodium benzoate as has been reported previously.[7] The silver benzoate produced was collected on a hot-funnel, washed several times with hot water to remove sodium benzoate and benzoic acid, dried and stored in a dark place.

General Procedure. A solution of silver benzoate (0.5 g, 2.2 mmol) in 5 m*l* of triethylamine was added at a time to the solution of 5.0 g (33 mmol) of α-diazoacetophenone dissolved in 20 m*l* of benzene, which has already been deoxygenated by bubbling of nitrogen gas. The evolution of nitrogen began at once, and the mixture gradually turned to dark-brown. The reaction mixture was maintained at 50°C as long as the gas evolution was continued. After about 60—70% of theoretical amount of nitrogen was evolved, the silver-amine catalyst was added furthermore. However, no nitrogen was generated. The reaction mixture was allowed to stand overnight at room temperature, and the precipitated silver metal was filtered off. The IR spectra of the benzene solution have no characteric absorption band of diazoketone at 2120 cm^{-1} region. The precipitate was washeds everal times with each 10 m*l* of benzene. The combined benzene solution was further diluted with benzene up to 100 m*l*, and extracted twice with 20 m*l* of a saturated sodium bicarbonate solution. The benzene solution was furthermore extracted several times with 20 m*l* of 4 N sodium hydroxide solution until alkaline layer showed no reddish color. The sodium bicarbonate solution was acidified with 6 N hydrochloric acid. The precipitate produced was extracted with ether. On evaporation of ether, white crystals were obtained yielding 0.10 g. The IR spectra indicate that the crystalline product is a mixture of benzoic acid and a trace of phenylacetic acid. After several recrystallizations from petroleum benzine, the IR spectra and the melting point (122—123°C) were completely consistent with authentic benzoic acid.

The sodium hydroxide solution was acidified with concentrated hydrochloric acid with stirring in the presence of ice. A pale yellow powder was obtained, mp 209.5—210.5°C (from ethanol), yield 1.70 g (38%).

Found: C, 72.82; H; 4.79; N, 10.30%. Calcd for $C_{16}H_{12}N_2O_2$: C, 72.71; H, 4.58; N, 10.60%.

This compound showed wine-red color in aqueous solution of sodium hydroxide, decolorized alkaline solution of potassium permanganate, and converted an alcoholic solution of ferric chloride to dark-green. The chemical properties and the absorption spectrum data of IR (KBr disk, 3350 (m), 3250 (s), 1625 (s), 910 (s) cm^{-1}) and UV (λ_{max}^{EtOH} 276 mμ, log ε 4.51: 287 mμ, log ε 4.33) were in accord with those of 3-benzoyl-4-hydroxy-5-phenyl pyrazole (II) reported by Yates.[14]

The benzene layer was distilled under diminished pressure into two fractions (bp 130°C/1 mmHg, bp 130°C/2 mmHg). The low boiling fraction was found to be a mixture of two components containing carbonyl groups by means of gas chromatography,*8 but their structure

*8 The experimental conditions are as follows: carrier gas, H_2 65 m*l*/min at 200°C: 2 meter column packed with Apiezone Grease L; retention time, 46 min and 52 min.

was not determined because of their low yields. The high boiling fraction was crystallized after being left on standing in a refrigerator for several days. Several recrystallizations from petroleum ether (bp 55—60°C) gave white plates, $C_{15}H_{14}O$, 71.0—72.0°C, yield 13%. The IR absorption spectra (KBr, 1680 (s), 1595 (m) cm^{-1}) of this compound (III) showed the presence of carbonyl and phenyl groups. The NMR spectra of (III) in carbon tetrachloride solution showed absorption bands at 2.00—2.70 τ (multiplet, 5H, phenyl-H bonding to carbonyl group), at 2.83 τ (singlet, 5H, phenyl-H bonding to methylene), at 6.95 τ (A_2B_2type of quasi-quartet, 4H, $-CH_2CH_2CO-$). The melting points and the elemental analyses of the oxime (mp 83.0—84.0°C, lit. mp 83.5°C,[17] $C_{15}H_{15}NO$), the 2,4-dinitrophenylhydrozone (mp 179—181°C, lit. 182—183°C,[18] $C_{21}H_{18}N_4O_4$) and the semicarbazone (mp 144—145°C, lit. mp 144.0—144.8°C,[19] $C_{16}H_{17}N_3O$) derived from this compound are consistent with those of β-phenypropiophenone (III)[17-19]

The Beckmann Rearrangement of the Oxime (VI). The oxime (VI) (0.50 g) was treated with 2.0 g of phosphorus pentachloride in 50 m*l* of ether for 10 hr at room temperature. After quenched the reaction mixture with 10 m*l* of water, the ether solution was treated with 10 m*l* of saturated sodium bicarbonate solution, and the ether layer was dried over anhydrous magnesium sulfate. On evaporation of ether, white crystals were obtained, mp 124.5—125.0°C (from petroleum benzine), yield 0.45 g. This product showed positive Beilstein test. IR (KBr): 3240, 1660, 1605, 1550, 1325 cm^{-1}.

Found: C, 69.80; H, 6.18; N, 5.08; Cl, 13.74%. Calcd for $C_{15}H_{14}NOCl$: C, 69.36; H, 5.43; N, 5.39; Cl, 13.65%.

This product corresponds to α-chloro-β-phenylpropion anilide (VII), lit.[29] mp 125°C.

Alkali Catalyzed Hydrolysis of the Amide (VII). This amide (VII) (0.12 g) was hydrolyzed with an aqueous alcoholic solution of potassium hydroxide for 3 hr. After evaporating alcohol *in vacuo*, the reaction mixture was extracted twice with 10 m*l* of ether. On acidification of the alkaline solution, 0.04 g of white crystals were obtained, mp 134.5—135.0°C. The IR spectra of this product were closely agreed with those of authentic cinnamic acid, and the mixed-melting point test showed no depression. The ether layer and the acid layer gave no product besides resinous matter.

Acid Catalyzed Hydrolysis of the Amide (VII). The amide (VII) was hydrolyzed with an ethanol solution of hydrochloric acid (ethanol, 10 m*l*; c.HCl, 5 m*l*; H_2O, 5 m*l*) for 15 hr. The reaction mixture was turned violet *via* pink color. After evaporation of alcohol, 20 m*l* of water was added. The acidic and neutral substances in the reaction mixture were eliminated by the extraction with ether, and then the aqueous acidic solution was made basic with sodium hydroxide. The oily product produced was extracted three times with 20 m*l* of ether, and an excess of benzoyl chloride was added to the ether solution after drying with anhydrous magnesium sulfate. After being left on standing overnight at room temperature, the reaction mixture was washed with sodium bicarbonate solution to remove unreacted benzoyl chloride, and then dried. By evaporation of ether, 0.20 g of white crystals were obtained, mp 162°C (from ethanol and water). The IR spectra and melting point were closely consistent with authentic benzanilide. The IR and NMR spectra of the ketone-(III) were also superimposed completely with those of authentic β-phenylpropiophenone, which prepared by the reduction of benzalacetophenone by zinc powder and acetic acid.[30] The mixed melting point test also showed no depression.

Preparation of β-Phenylpropiophenone (III). An acetic acid (50 m*l*) solution of benzalacetophenone*[9] (10 g, 0.05 mol) was refluxed with 6.5 g (0.10 g atom) of zinc powder for 8 hr. After cooling, unreacted zinc was filtered off, and the solvent was distilled off *in vacuo* giving rise to β-phenylpropiophenone, bp 145°C/3 mmHg, mp 71.0—72.0°C.

Silver Benzoate-Catalyzed Decomposition of *p*-Methyl-α-diazoacetophenone in Benzene Solution. The reaction was carried out using 5.0 g of diazoketone, 0.60 g of silver benzoate, and 4.0 m*l* of triethylamine in 40 m*l* of benzene at 40°C, and the reaction mixture was treated with sodium bicarbonate and sodium hydroxide, successively. From the sodium bicarbonate solution, a small amount of benzoic acid was obtained, while *p*-methylphenylacetic acid was not detected by the measurement of the IR spectra. From the sodium hydroxide solution, 1.20 g (26%) of yellow crystals were obtained, mp 251.0—252.0°C. IR (KBr); 3350, 3260, 1605, 907 cm^{-1}.

Found: C, 73.89; H, 5.55; N, 9.53%. Calcd for $C_{18}H_{16}N_2O_2$: C, 73.95; H, 5.52; N, 9.58%.

These data and chemical properties suggest that the product is 3-*p*-toluyl-4-hydroxy-5-*p*-tolylpyrazole. From the benzene layer, 0.50 g (12%) of white needles were obtained, mp 64.5—65.5°C. IR (KBr), 1680, 1515, 1270, 1180, 800 cm^{-1}. NMR (in CCl_4), 2.25 τ and 2.87 τ (symmetric doublet, 4H, aromatic-H bonding to carbonyl group), 3.04 τ (singlet, 4H, aromatic-H bonding to methylene), 7.00 τ quasi-quartet of A_2B_2type, 4H, $-CH_2CH_2CO-$), 7.64 τ (singlet, 3H, *p*-CH_3) and 7.74 τ (singlet, 3H, *p*-CH_3). The data show that this product is β-*p*-tolyl-*p*-methylpropiophenone.

Silver Benzoate Catalyzed Decomposition of *p*-Methoxy-α-diazoacetophenone. The reaction was carried out using 5.0 g (0.029 mol) of diazoketone, 0.60 (0.0026 mol) of silver benzoate and 5.0 m*l* of triethylamine in 40 m*l* of benzene at 40°C. The reaction mixture was treated as described above. From sodium bicarbonate solution, 0.17 g of an yellow precipitate was obtained. The IR spectra showed that the precipitate was a mixture of benzoic acid and a trace of *p*-methoxyphenylacetic acid with undecided yellow compounds. Recrystallization of the precipitate gave benzoic acid. From the hydroxide solution, pale yellow crystals were obtained on acidification, mp 207.0—208.0°C (from ethanol), yield 0.55 g (12%). IR (KBr), 3350, 3250, 1620, 910 cm^{-1}.

Found: C, 66.61; H, 5.24; N, 8.73%. Calcd for $C_{18}H_{16}N_2O_4$: C, 66.66; H, 4.97; N, 8.64%.

*9 The benzalacetophenone was prepared by the alkali catalyzed reaction of benzaldehyde and acetophenone in ethanol. "Organic Syntheses," Coll. Vol I p. 78, (1948).

These results and the chemical properties show that this product is 3-*p*-anisoyl-4-hydroxy-5-*p*-anisylpyrazole. From the benzene layer, white needles were obtained, mp 84.0—85.0°C, yield 0.86 g (19%). IR (KBr), 1700, 1510, 1250, 1180, 820 cm^{-1}.

Found: C, 75.38; H, 6.73%. Calcd for $C_{17}H_{18}O_3$: C, 75.53; H, 6.71%.

From these results, this compound was assigned to β-*p*-anisyl-*p*-methoxypropiophenone. Another fraction of the benzene layer (bp 170°C/1 mmHg) (0.51 g) gave no detectable product.

Silver Benzoate Catalyzed Decomposition of *p*-Nitro-α-diazoacetophenone. The reaction was carried out using 5.0 g (0.029 mol) of diazoketone, 1.2 g (0.0052 mol) of silver benzoate and 5.0 m*l* of triethylamine in 80 m*l* of benzene at 50°C, and the reaction products were treated as described above. From the sodium bicarbonate solution, a small amount of benzoic acid and *p*-nitrophenylacetic acid were obtained. On acidification of the sodium hydroxide solution, 1.2 g (26%) of a yellow precipitate was obtained. This substance could not be purified by recrystallization because of its extremely low solubility in most organic solvents. mp>300°C. IR (KBr), 3350, 1730, 1515, 1350 cm^{-1}.

Found: C, 55.77; H, 3.56%. Calcd for $C_{16}H_{10}N_4O_6$; C, 54.24; H, 2.85%.

Although the analytical data do not agree with the calculated values, the chemical properties and the IR spectra resemble to those of (II). This product is also thought to be a *p*-NO_2-substituted pyrazole derivative of type (II).

The authors wish to express their hearty thanks to Mr. Y. Kawanishi for his experimental aid. This work has been supported in part by a grant-in-aid for Scientific Research from the Ministry of Eductation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1707—1711 (1968)

Photochemischer Zerfall von Benzoylphenylacetyl- und Benzoyl-*p*-chlorphenylacetyl-peroxyden in Toluol

Tadashi SUEHIRO, Shuji HIBINO und Tadashi SAITO

Chemisches Institut, Gakushuin Universität, Toshima-ku, Mejiro, Tokio

(Eingegangen am 2. Februar, 1968)

Benzoylphenylacetylperoxyd und Benzoyl-*p*-chlorphenylacetylperoxyd zerfallen photolytisch in Toluol bei −5——10°C in die Benzoyloxy und Benzyl bzw. *p*-Chlorbenzyl Radikale unter Bildung von Kohlendioxyd, Benzoesäure, Benzoesäure-benzyl- bzw. -*p*-chlorbenzyl-ester, Bibenzyle, Methyldiphenylmethane, Diphenylmethane und Methyldiphenyle. Eine Umlagerungsreaktion vom Peroxyd in den Benzylkohlensäurebenzoesäureanhydrid verläuft nebenbei und dieser Anhydrid liefert durch Einwirkung auf Benzoesäure, Kohlendioxyd, Benzylalkohol und Benzoesäureanhydrid. Die freie Radikale Reaktion und die Umlagerung in den Kohlensäureanhydrid vom Peroxyd finden im Verhältnis *ca.* 2 : 1 statt. Aus dem Lösungsmittel, Toluol, entsteht Benzyl Radikale während der Photolyse durch Einwirkung von Benzoyloxy Radikal, dies wurde durch das Vorkommen von Bibenzyl und *p*-Chlorbibenzyl bei der Photolyse von Benzoyl-*p*-chlorphenylacetylperoxyd in Toluol nachgewiesen.

Benzoylphenylacetylperoxyd zerfällt in Toluol bei Raumtemperatur heterolytisch in Benzyl Kation und Benzoat Anion unter Kohlendioxyd Abspaltung, das Benzyl Kation bei der Einwirkung auf Elektronen Donator Aromaten Diphenylmethanderivaten liefern kann, oder verwandelt sich das Peroxyd monomolekular in den Benzoesäurebenzylester und in den Benzylkohlensäurebenzoesäureanhydrid, und freie Radikale Reaktion vom Peroxyd konnten wir erst mittels Radikalabfängers in weniger als 10% Ausbeute erfassen.[1] Um die freie Radikale Reaktion vom Peroxyd genau zu ermitteln, haben wir die Photolyse von Benzoylphenylacetylperoxyd und Benzoyl-*p*-chlorphenylacetylperoxyd untersucht.

Ergebnisse und Diskussion

Benzoylphenylacetylperoxyd zerfällt bei der Photolyse in Toluol bei −5——10°C in freien Radikale ohne Begleitung von der thermischen Zersetzung vom Peroxyd. Wenn man das Peroxyd unter Stickstoff mit Nieder- oder Hoch-druck Brenner belichtet, bilden sich Kohlendioxyd, Carbonsäure, Bibenzyl, Benzoesäurebenzylester, Diphenylmethan, *o*-, *m*- und *p*-Methyldiphenyle, *p*-Methyldiphenylmethan und Benzylalkohol (Nr. 1 und 4 der Tabelle 1). Bibenzyl darunter ist der Beweis für das Auftreten

a) Benzoylphenylacetylperoxyd, b) Benzoyl-*p*-chlorphenylacetylperoxyd, c) Ausbeute, berechnet. d) Benzoesäurebenzylester, e) Benzoesäure-*p*-chlorbenzylester, f) Bibenzyl, g) *p*,*p*'-Dichlorbibenzyl, h) *p*-Chlorbibenzyl, i) *p*-Methyldiphenylmethan, j) Spuren, nicht bestimmt., k) Diphenylmethan, l) *p*-Chlordiphenylmethan, m) Benzylalkohol, n) *p*-Chlorbenzylalkohol, o) *p*-Chlorbenzylkohlensäurebenzoesäureanhydrid, p) Ausg. Peroxyd, q) Peroxyd, das aus Kaliumjodid in verd. Essigsäure Jod frei machen kann.

der freien Radikale Reaktionen, weil dessen Ausbeute bei der Belichtung unter Sauerstoff (Nr. 2) stark unterdruckt wird und peroxydische Substanzen, die beim Versetzen mit Kaliumjodid in verdünnter Essigsäure Jod frei machen, d. h. anders als Benzoylphenylacetylperoxyd, werden in 36% Ausbeute gebildet. Dazu noch zu erwähnen ist, dass das Molverhältnis der entstandenen *o*-, *m*- und *p*-Methyldiphenyle 70 : 12 : 18 ist. Diese Werte sind etwas mehr in der *o*- und *p*- Isomeren als die berechneten aus der *partial rate factors* von Phenylierung Toluols mit *N*-Nitrosoacetanilid.[2] Diese Tatsache erklärt sich für die zugenommene Selektivität der Arylierung bei der tieferen Reaktionstemperatur. Diese Befunde sprechen für die Zwischenprodukte, Benzyl und Phenyl Radikale, bei der Photolyse. Dass Toluol allein unter den Reaktionsbedingungen kein Bibenzyl gibt, wurde experimentell festgestellt. Bemerkenswert sind die Ausbeuten von Benzoesäurebenzylester und Diphenylmethan, auf die kein Einfluss von Sauerstoff ausgeübt hat : diese Verbindungen können deshalb heterolytisch oder in "cage" homolytisch gebildet worden sein. Wir sind der Meinung lieber vom letzteren Mechanismus deswegen, weil unter Stickstoff (Nr. 1) in 36% Ausbeute eine Kombinationsreaktion freien Benzyl Radikals zu Bibenzyl ausserhalb "cage" auftritt, und für diese Benzyl Radikale mussen so und so viele Benzoyloxy Radikale auch gebildet werden. Es ist auch bekannt, dass die "cage" Reaktion in viskosen Lösungsmitteln öfter stattfindet als in den nicht viskosen.[3] Es kann also viel "cage" Reaktion in der Kälte verlaufen als in der Wärme. Weiter wurde es auch gezeigt, dass die Ausbeuten der Diphenylderivaten bei der thermischen Zersetzung von Benzoylperoxyd in Aromaten, wenn auch unter Sauerstoff, unverändert bleiben oder etwas zunehmen.[4] Von der hohen Ausbeute von Benzoesäurebenzylester aber werden wir nachher im Zusammenhang mit der des Benzylalkohols bei der Um-Umsetzung von Benzoyl-*p*-chlorphenylacetylperoxyd (Nr. 3) erwähnen.

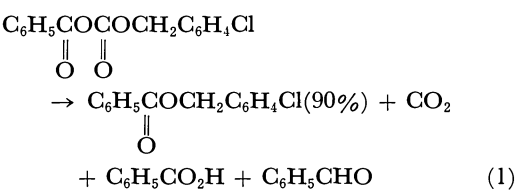
4) M. Eberhard und E. L. Eliel, *J. Org. Chem.*, **27**, 2289 (1962); R. T. Morrison, J. Cazes, N. Samkoff und C. A. Howe, *J. Am. Chem. Soc.*, **84**, 4152 (1962); K. Tokumaru, K. Horie und O. Simamura, *Tetrahedron*, **21**, 4152 (1965).

Die Stoffbilanz der Benzyl Gruppe bei Nr. 1 bewährt nicht (142%).*1 Es besteht eine Möglichkeit der Mitwirkung vom Lösungsmittel Toluol in der Bilanz. Die Bilanz der Benzoyloxy Gruppe verliert auch enorm (66%).*1 Eine Ursache von dem letzten käme aus der Umwandlung vom Peroxyd über Benzylkohlensäurebenzoesäureanhydrid in den Benzoesäureanhydrid: wir konnten die Entstehung vom Kohlensäureanhydrid durch die IR-Bande bei 1800/cm von dem Reaktionsgemisch nach der Entfernung vom zurückgebliebenen Peroxyd festellen, leider war es uns nicht gelungen, die Menge vom Kohlensäureanhydrid zu bestimmen, wie bei der thermischen Zersetzung vom Peroxyd,[1] wegen der Schwierigkeit der Darstellung von 100% reiner authentischer Verbindung. Diese Probleme konnten wir durch Anwendung von Benzoyl-*p*-chlorphenylacetylperoxyd lösen.

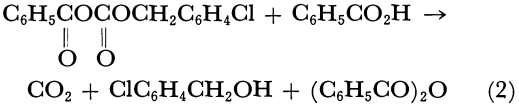
Benzoyl-*p*-chlorphenylacetylperoxyd zerfällt in Toluol bei Raumtemperatur ziemlich rasch mit k_{ap} (20°C)$=8.24\times10^{-5}$ Sek^{-1} und $E_a=22.1$ Kcal, Mol.$^{-1}$ Das Verhalten ist sehr ähnlich wie von Benzoylphenylacetylperoxyd. Die Produkten der Photolyse von dem *p*-Chlorperoxyd (Nr. 3) sind mit denen von Nr. 1 zu vergleichen. Die Bildung von *p*-Chlorbibenzyl, Bibenzyl und sogar das klein aber deutliche Auftreten von Benzoesäurebenzylester, weisen ohne Zweifel auf das Benzyl Radical aus Toluol als Zwischenprodukt hin. Was das aus Toluol Wasserstoff Atom abziehende Radikal betrifft, ist es wahrscheinlich Benzoyloxy Radikal, wobei Benzoesäure sich bilden muss. Die Carbonsäure, die nach der Zersetzung vom zurückgebliebenen Peroxyd mit Natriumjodid-Aceton ausgezogen wurden, bestehen immer aus mehr Benzoesäure als Phenylessigsäure oder *p*-Chlorphenylessigsäure. Die Carbonsäure in der Tabelle wurden titrimetrisch nach der Zersetzung vom Peroxyd ermittelt und wir nehmen an die Carbonsäure als Benzoesäure auf Grund der grössere Beständigkeit von Benzoyloxy Radikal als die von Acetyloxy Radikal.[5]

Das Reaktionsgemisch von Nr. 3 zeigte nach der Entfernung vom Peroxyd die IR-Banden bei 1800 und 1745/cm von *p*-Chlorbenzylkohlensäurebenzoesäureanhydrid neben der 1725/cm Bande von Benzoesäure-*p*-chlorbenzylester, und die Bestimmung von dem Kohlensäureanhydrid nach IR-Methode gab 16% Ausbeute. *p*-Chlorbenzylkohlensäurebenzoesäureanhydrid zerfällt thermisch bei Gaschromatographie in 90% Ausbeute in Benzoesäure-*p*-chlorbenzylester und der Rest besteht aus Benzoesäure und Benzaldehyd, aber fast keinem *p*-Chlorbenzylalkohol (1).



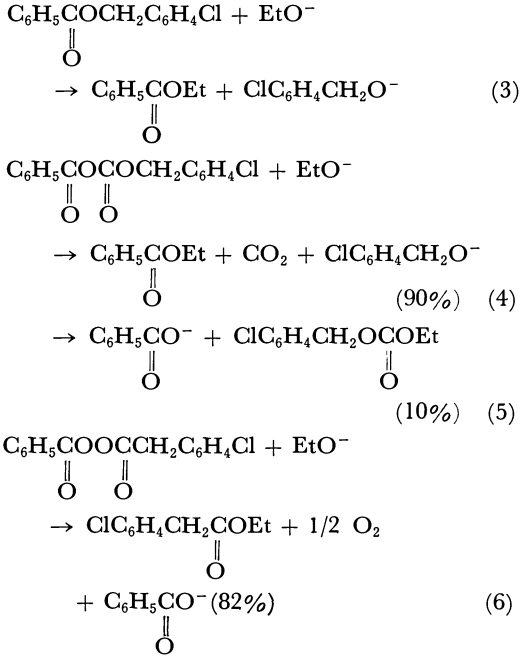
(1)

Die Ausbeute von Benzoesäurebenzylester in der Tabelle wird um so mehr, je mehr Kohlensäureanhydrid bei der Gaschromatographie da ist. Kohlensäureanhydrid ist weiter sehr empfindlich gegen Carbonsäure so stark wie Benzoesäure,[1,6] und er zerfällt schon bei Zimmertemperatur allmählich in Kohlendioxyd, Benzylalkohol und Benzoesäureanhydrid (2).



(2)

Wenn Benzoesäureanhydrid auch mal gebildet wird, kann man ihn leider nicht entfernen, ohne die anderen Produkte wie Estern oder Kohlensäureanhydrid zu beschädigen. Die IR-Bande von Benzoesäureanhydrid 1785/cm lagert sich sehr über die von 1800/cm von Kohlensäureanhydrid, wenn der letztere viel dabei ist. Wir haben deshalb versucht, das Reaktionsgemisch mit Äthylat bei 0° umzusetzen und die gebildeten Benzoat Anionen zur freien Benzoesäure zu überführen und sie nach der Methylierung mittels Diazomethans als Benzoesäuremethylester zu bestimmen. Die erhaltene Ausbeute von Benzoesäuremethylester bei Nr. 3, 38%, korrigiert man für Benzoesäureanhydrid nach den folgenden Blind-Reaktionen (3)—(8):



(3) (4) (5) (6)

*1 Berechnet auf Grund des angesetzten Peroxyds.

5) L. Jaffe und E. J. Prosen, *J. Chem. Phys.*, **27**, 416 (1957); A. Yamamoto, N. Inamoto, N. Morikawa und O. Simamura, 19. Jahrestagung der Chem. Gesellschaft, Japan, April 1966. Vordruck III, 113.

6) T. B. Windolz, *J. Org. Chem.*, **23**, 2044 (1958).

$$\rightarrow ClC_6H_4CH_2\overset{\overset{O}{\|}}{C}O^- + 1/2\ O_2$$

$$+ C_6H_5\overset{\overset{O}{\|}}{C}OEt(18\%) \qquad (7)$$

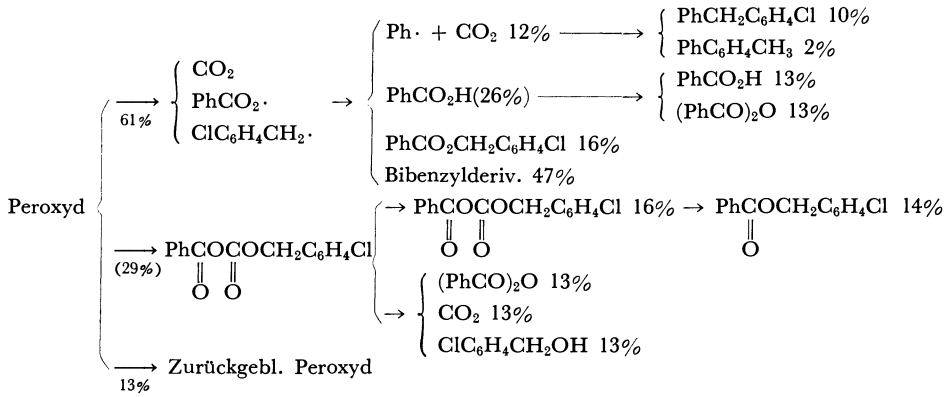
$$(C_6H_5CO)_2O + EtO^-$$

$$\rightarrow C_6H_5\overset{\overset{O}{\|}}{C}OEt + C_6H_5\overset{\overset{O}{\|}}{C}O^- \qquad (8)$$

Man erhält 12.7%*2.

Die berechnete Menge von Benzoesäureanhydrid stimmt gut mit der Ausbeute *p*-Chlorbenzylalkohols, 14%, überein, dieser Alkohol kann nach der Gleichung (2) entstehen.

Die Werte in der Tabelle, die direkt aus der Chromatographie usw. ermittelt wurden, muss man mit Rücksicht auf die Reaktionen (1) und (2) korrigieren, um die erste Stufe der Photolyse klar zu machen. Für Kohlendioxyd, z. B., erhält man 85−13=72% nach Gleichung (2), weil etwa 13% Kohlendioxyd in der zweiten Stufe der Reaktion entstanden ist. In der Weise errechnet man für *p*-Chlorbenzylkohlensäurebenzoesäureanhydrid 29% (=16+13 nach Gl. 2), für Benzoesäure-*p*-chlorbenzylester · 15.6%, und für Benzoesäure 26%. Auf Grund dieser korrigierten Werte kann man für die Photolyse Nr. 3 folgendes Schema mit einigen % Fehler zeichnen:



Kritischen Fehler findet man in der Bilanz der *p*-Chlorbenzyl Gruppe, *ca.* 15% zu viel. Die grösste Gründe dafür seien die fehlerhafte Bestimmung von Bibenzylderivaten, besonders der vom hohen Siedepunkt mit relativ flüchtigen inneren Standard bei Gaschromatographie.

Die Quantenausbeuten waren 0.49 bei Nr. 1 und 0.44 bei Nr. 3 und sie sind beide grösser als 0.25, die Walling und Gibian[7] bei der Benzophenon sensibilisierten Photolyse von Benzoylperoxyd erhielten.

Bei der Hochdruck Brenner Belichtung ist die Ergebnis fast genau so wie bei Niederdruck Brenner Belichtung und es ist noch zu früh den kleineren Unterschied der beiden Ergebnisse zu diskutieren.

Beschreibung der Versuche

Peroxyde. *Benzoylphenylacetylperoxyd* wurde nach der Angabe von Wieland und anderen[8] hergestellt. Schmp. 33.5—34°C, zers. Reinheit beträgt 95—97% nach Jodmetrie mit Natriumjodid-Aceton.

Benzoyl-p-chlorphenylacetylperoxyd wurde wie bei oben aus perbenzoesaurem Natrium und *p*-Chlorphenylacetylchlorid bei −5—−10°C in wässr. Aceton hergestellt und aus Toluol-*n*-Hexan umkristallisiert. Farblose Nadeln vom Schmp. 48—49°C, zers. Reinheit 93—95% nach Jodmetrie. Gef.: C, 61.94; H, 4.12%. Ber. für $C_{15}H_{11}O_4Cl$: C, 61.97; H, 3.81%. Zerfallsgeschwindigkeitskonstanten in Benzol, k_{ap}(20°C)=8.24×10^{-5} Sek^{-1} und k_{ap} (30°C)=2.92×10^{-4} Sek^{-1}. E_a=22.1 Kcal, Mol^{-1}, $\Delta S^{\neq}$=−4.2 cal, Grad^{-1}, Mol^{-1}. Versuche zur Darstellung von *Benzoyl-p-methoxyphenylacetylperoxyd* wurden wie bei oben durchgeführt. Man erhält eine peroxydische kristalline Substanz bei −50°C, sie wurde aber ein Öl bei −10°C unter Koholendioxyd Entwicklung. Aufarbeitung von einem Öl (Peroxyd Reinheit 16%) gab Benzoesäure-*p*-methoxybenzylester vom Schmp. 35—36°C. Er wurde durch Mischprobe mit der authentischen Verbindung[9] identifiziert.

***p*-Chlorbenzylkoholensäurebenzoesäureanhydrid.** Der Anhydride wurde nach der Methode von Tarbell und Longosz[10] aus Chlorameisensäure-*p*-chlorbenzylester und Benzoesäure in Gegenwart von Triäthylamin hergestellt. Farblose Nadeln vom Schmp. 40.5—41.5°C. Ausbeute 40%. Er hält länger bei 0°C. Gef.: C, 62.26; H, 4.22%. Ber. für $C_{15}H_{11}O_4Cl$: C, 61.97; H, 3.81%.

Belichtung. Ein Quecksilber Niederdruck Brenner von Rikosha, UVL-1000 Q von 160W wurde unter

*2 Man rechnet folgendermassen: 38—13 (freie Carbonsäure)−16×0.1 (Koholensäureanhydride)−13×0.82(zurückgebl. Peroxyd)=12.7

7) C. Walling und M. J. Gibian, *J. Am. Chem. Soc.*, **87**, 3413 (1965).

8) H. Wieland, T. Ploetz und H. Indest, *Ann.*, **532**, 166 (1937).

9) M. Tiffeneau und K. Fuhrer, *Bull. soc. chim. France*, [4] **15**, 170 (1914).

10) D. S. Tarbell und E. J. Longosz, *J. Org. Chem.*, **24**, 774 (1959).

Luft-Kühlung verwendet und die Peroxyd-Lösung wurde von aussen bis zum −5——10°C gekühlt. Bei der Belichtung mit dem Hochdruck Brenner, H-400P von 400W von Toshiba, wurde die Peroxyd Lösung in einem 100 ccm Quarz Kolben gestellt und den Kolben hält man in einem Pyrexglas Dewar Gefäss von −5—−10°C. Man Belichtet von aussen.

Aufarbeitung. Nach der Belichtung titriert man das zurückgebliebene Peroxyd jodmetrisch und zieht die Carbonsäure mit Carbonat Lösung aus. Die Carbonsäure methyliert man mit Diazomethane und bestimmt gaschromatographisch. Die Lösung von neutralen Produkten engt man unter vermindertem Druck ein und führt damit die IR- und gaschromatographische Bestimmungen. Zur Bestimmung von Carbonsäure titriert man das Reaktionsgemisch mit Bariumhydroxyd Lösung nach der Entfernung von zurückgebliebenem Peroxyd. Zur Bestimmung von Benzoesäureanhydrid versetzt man das Reaktionsgemisch mit Äthylat über Nacht bei 0°C und man verwandelt das gebildete Benzoat Anion über Benzoesäure in den Benzoesäuremethylester mittels Diazomethans, und untersucht den Methylester durch Gaschromatographie. Die Blindprobe des Versetzens von Äthylat mit *p*-Chlorbenzylkoholensäurebenzoesäureanhydride gab 10% Benzoesäuremethylester, mit Benzoyl-*p*-chlorphenylacetylperoxyd 82% Benzoesäuremethylester und 18% *p*-Chlorphenylessigsäuremethylester, und mit Benzoesäureanhydride 100% Benzoesäuremethylester. Die IR-Spektren wurden mit einem Gerät von Hitachi EPI-S Typ mit 0.5 mm Zell durchgeführt. Die molaren Extinktionskoeffizienten waren für Benzoesäure-*p*-chlorbenzylester 323 bei 1725/cm und für *p*-Chlorbenzylkohlensäurebenzoesäureanhydrid 371 bei 1745/cm, jede im Bereich von 10^{-2} Mol/*l*.

Gaschromatographie erfolgte mit einem Gerät von Hitachi KGL-2A Typ und die Kolonne Bedingungen waren wie folgenden: a) Silicon DC 200 bei 176°C, 3 m lang. He, 64.2 ccm/Min für Methylestern von Benzoesäure, Phenylessigsäure und *p*-Chlorphenylessigsäure, mit dem inneren Standard Essigsäurephenylester, b) Silicon DC 200 bei 206°C, 3 m lang. He, 85.6 ccm/Min für Diphenylmethan, *p*-Chlordiphenylmethan,[11] Benzoesäurebenzylester, Benzoesäure-*p*-chlorbenzylester vom Schmp. 56—57°C. Gef.: C, 68.01; H, 4.42%. Ber. für $C_{14}H_{11}O_2Cl$: C, 68.16; H, 4.49%, *p*-Chlorbibenzyl,[12] *p,p'*-Dichlorbibenzyl,[13] mit dem inneren Standard Dibenzyläther, c) Shimalite B-Apiezon L 25% bei 206°C, 7 m lang. He, 85.6 ccm/Min für Bibenzyl, *o*-, *m*- und *p*-Methyldiphenyle und *p*-Methyldiphenylmethan. Die Molverhältnisse von *o*-, *m*- und *p*-Methyldiphenyle waren 70 : 12 : 18. *p*-Methyldiphenylmethan kommt gleich nach dem grossen Signal von Bibenzyl und wir konnten die anderen isomeren Methyldiphenylmethane nicht bestimmen. Die Signale von Benzoesäurebenzylester und von *p*-Chlorbibenzyl stimmen vollkommen überein, so war es auch mit denen von Benzoesäure-*p*-chlorbenzylester und von *p,p'*-Dichlorbibenzyl. Folglich wurden die Mengen von Estern aus der Abnahme des Signales nach der Verseifung von Estern berechnet. Die oben erwähnten authentischen Verbindungen wurden nach den bekannten Methoden hergestellt.

Quantenausbeute: Die Ausbeute wurde nach der Methode von Parkar mit Kalium Eisen(III)trioxalat[14] bestimmt. Die Licht Intensität vom Niederdruck Brenner war 2.15×10^{19} Quanta/Min. Die Quantenausbeute der Photolyse Nr. 1 war 0.49 und die von Nr. 3 war 0.44.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1711—1716 (1968)

Reactions of Dimethylaniline with Some Resonance-stabilized Radicals

Renji OKAZAKI and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received February 16, 1968)

Reactions of dimethylaniline with some resonance-stabilized radicals were studied. 2-Cyano-2-propyl radicals and 2-methoxycarbonyl-2-propyl radicals reacted to give *N*-methyl-*N*-(3,4-dicyano-3,4-dimethylpentyl)aniline and the corresponding 3,4-dimethoxycarbonyl derivative, respectively, while benzyl radicals and α-methoxycarbonylbenzyl radicals did not give reaction products with dimethylaniline. Mechanism of these reactions was proposed and it was pointed out that electron transfer from dimethylaniline to radicals was an important stage in these reactions.

Previously, one of the authors (N. I.) has studied the reaction of α,α'-azobisisobutyronitrile (AIBN) with some aromatic compounds and found that dimethylaniline reacts with 2-cyano-2-propyl radicals generated from AIBN.[1] We wish to report in this paper similar reactions of dimethylaniline with some resonance-stabilized radicals.

1) N. Inamoto, *Yuki Gosei Kagaku Kyokaishi (J. Soc. Org. Synth. Chem. Japan)*, **17**, 174 (1959).

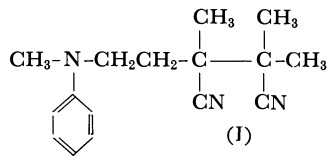
generated by the thermal decomposition of azo compounds or organomercurials.

Results

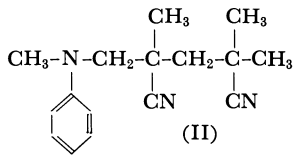
Reaction with AIBN. The reaction of dimethylaniline with AIBN at water-bath temperature gave *N*-methyl-*N*-(3,4-dicyano-3,4-dimethylpentyl)-aniline (I)[2] in a 2.7% yield. The structure of I was determined by the NMR spectrum (Fig. 1) and the elemental analysis.

$$C_6H_5N(CH_3)_2 + (CH_3)_2C(CN)-N=N-C(CN)(CH_3)_2 \rightarrow$$

AIBN



(I)



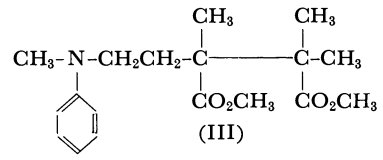
(II)

The NMR spectrum showed a singlet at τ 8.58 (9H, *C*-methyl protons), a multiplet between τ 7.8—8.5 (2H, methylene protons on C_β), a singlet at τ 7.13 (3H, *N*-methyl protons), a triplet at τ 6.55 (2H, J=7 cps, *N*-methylene protons), and a multiplet between τ 2.8—3.5 (5H, aromatic protons). That the structure of the product is not an isomeric one (II) was further confirmed by spin-spin decoupling technique. Thus, irradiation of the triplet at τ 6.55 caused the methylene multiplet between τ 7.8—8.5 to collapse to a typical AB type quartet. This fact shows that the methylene protons are on the carbon atom (C_β) adjacent to both the *N*-methylene group and the asymmetric center (C_γ).

Reaction with Dimethyl α,α'-Azobisisobutyrate (MAIB). The reaction of dimethylaniline with MAIB at *ca.* 100°C gave rise to *N*-methyl-*N*-(3,4-dimethoxycarbonyl-3,4-dimethylpentyl)aniline (III) in a 6% yield.

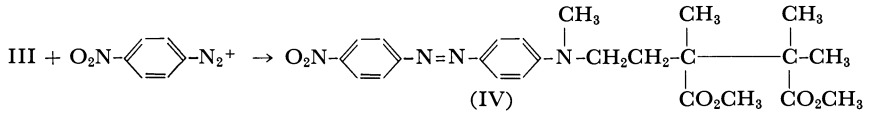
$$C_6H_5N(CH_3)_2 + (CH_3)_2C(CO_2CH_3)-N=N-C(CO_2CH_3)(CH_3)_2 \rightarrow$$

(MAIB)



(III)

The compound (III) was identified by elemental analyses and NMR spectra of both III and its azo derivative. The compound (III) is very viscous but distillable oil. It did not give crystalline derivatives; the picrate, hydrazide, quaternary ammonium salt and *N*-oxide were oily products, all of which could not be purified. *p*-Nitrobenzenediazonium salt, however, reacted with III to give a reddish brown crystalline product, which was identified to be an azo-coupling product (IV) by the elemental analysis and the NMR spectrum.



(IV)

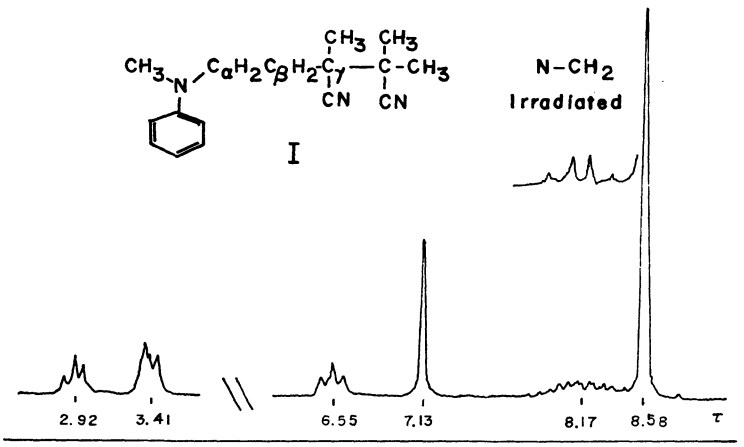


Fig. 1. NMR spectrum of the compound (I) in CCl_4 at 100 Mc.

2) The previously assumed structure[1] was found to be incorrect.

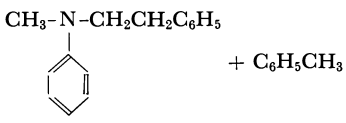
Reactions with Dibenzylmercury and Bis(α-methoxycarbonylbenzyl)mercury. The reaction of dimethylaniline with dibenzylmercury, which is known to generate benzyl radicals by heating,[3] was carried out at 120—160°C under nitrogen. The reaction products obtained were only those derived from the thermal decomposition of dibenzylmercury; mercury (99%), bibenzyl (75%), and toluene (4%), no reaction products between dimethylaniline and benzyl radicals being obtained.

The reaction of dimethylaniline with bis(α-methoxycarbonylbenzyl)mercury (V)[4] was performed at 120—180°C under nitrogen. In this case, again, products were those attributed to the thermal decomposition of V; mercury (95%), *meso* form of dimethyl diphenylsuccinate (71%), and methyl phenylacetate (15%). However, in addition to these products a trace of bis(4-*N*,*N*-dimethylaminophenyl)methane was obtained.

Discussion

It has been shown in the present study that dimethylaniline reacts with 2-cyano-2-propyl radicals and 2-methoxycarbonyl-2-propyl radicals, but not with benzyl radicals, the latter were expected to form such a substitution product as follows.

$$C_6H_5N(CH_3)_2 + 2C_6H_5CH_2\cdot \rightarrow$$



$$+ C_6H_5CH_3$$

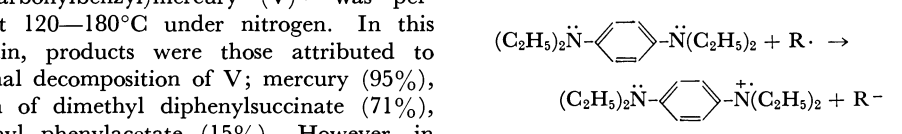
This fact suggests that in these reactions electron transfer as shown in Eq. (1) is an important process, because the reaction occurred only with radicals having electronegative groups which make the radicals R· more electrophilic and the corresponding carbanion more stable.

$$C_6H_5\overset{\overset{CH_3}{|}}{\underset{+\cdot}{N}}-CH_3 + R\cdot \rightarrow C_6H_5\overset{\overset{CH_3}{|}}{\underset{+\cdot}{N}}-CH_3 + R^- \qquad (1)$$

It is known, indeed, that aromatic amines are readily subjected to one electron oxidation. Horner[5] and Imoto[6] have shown that the first stage in the reaction of dimethylaniline and benzoyl peroxide is electron transfer process from the former to the latter.

$$C_6H_5N(CH_3)_2 + (C_6H_5CO_2)_2 \rightarrow C_6H_5\overset{\overset{CH_3}{|}}{\underset{+\cdot}{N}}-CH_3 + C_6H_5COO\cdot + C_6H_5COO^- \qquad (2)$$

Franzen[7] has reported that *N*,*N*,*N'*,*N'*-tetramethyl-*p*-phenylenediamine is oxidized by various types of radicals, including 2-cyano-2-propyl radical, to give a stable cation radical, Wurster's salt.



The conclusion that the more electrophilic the radicals R· are, the more readily the electron transfer occurs, has been drawn from the observation that, in radical polymerizations in the presence of dimethylaniline, the chain transfer for dimethylaniline becomes more effective when the end of a growing radical is more positive.[8]

On the basis of the facts described above, the mechanism of formation of I and III is considered as follows.

$$(CH_3)_2\dot{C}X + C_6H_5\ddot{N}(CH_3)_2 \rightarrow$$

(VI)

X=CN, $COOCH_3$

$$(CH_3)_2\bar{C}X + C_6H_5\overset{+\cdot}{N}(CH_3)_2 \qquad (4)$$

(VII) (VIII)

$$(CH_3)_2\bar{C}X + C_6H_5\overset{+\cdot}{N}(CH_3)_2 \rightarrow (CH_3)_2CHX + C_6H_5\overset{\overset{CH_3}{|}}{N}-CH_2\cdot \qquad (5)$$

(IX)

$$2(CH_3)_2\dot{C}X \rightarrow (CH_3)_2CHX + CH_2{=}C(CH_3)X \qquad (6)$$

$$C_6H_5\overset{\overset{CH_3}{|}}{N}-CH_2\cdot + CH_2{=}C(CH_3)X \rightarrow C_6H_5N(CH_3)CH_2CH_2\dot{C}(CH_3)X \qquad (7)$$

(X)

$$C_6H_5N(CH_3)CH_2CH_2\dot{C}(CH_3)X + (CH_3)_2\dot{C}X \rightarrow C_6H_5N(CH_3)CH_2CH_2-\overset{\overset{CH_3}{|}}{\underset{\underset{X}{|}}{C}}-\overset{\overset{CH_3}{|}}{\underset{\underset{X}{|}}{C}}-CH_3 \qquad (8)$$

(I or III)

3) A. G. Goble, A. G. Lidstone and P. J. S. Pauwels, *Chem. & Ind.*, **1959**, 1489.

4) Reutov and his coworkers have reported the synthesis of this mercurial compound (V) and described its melting point was 140—141°C. However, although we synthesized V by the same method as that of Reutov and identified by the elemental analysis and the NMR spectrum, the melting point of V prepared by us was 181—183°C (dec.). The reason for this discrepancy was not clear but it seems to be attributed to stereochemical isomerism due to asymmetric carbons. See experimental part.

6) M. Imoto and S. Choe, *J. Polymer Sci.*, **15**, 485 (1955).

7) V. Franzen, *Chem. Ber.*, **88**, 1697 (1955).

8) M. Imoto, T. Otsu, T. Ota, H. Takatsugi and M. Matsuda, *J. Polymer Sci.*, **22**, 137 (1956).

$$C_6H_5N(CH_3)CH_2\cdot + (CH_3)XC{=}CH_2 \rightarrow C_6H_5N(CH_3)CH_2\text{-}\underset{\underset{X}{|}}{\overset{\overset{CH_3}{|}}{C}}\text{-}CH_2\cdot \quad (7')$$

(XI)

$$C_6H_5N(CH_3)CH_2\text{-}\underset{\underset{X}{|}}{\overset{\overset{CH_3}{|}}{C}}\text{-}CH_2\cdot + (CH_3)_2\dot{C}X \rightarrow C_6H_5N(CH_3)CH_2\text{-}\underset{\underset{X}{|}}{\overset{\overset{CH_3}{|}}{C}}\text{-}CH_2\text{-}\underset{\underset{X}{|}}{\overset{\overset{CH_3}{|}}{C}}\text{-}CH_3 \quad (8')$$

(II) X=CN

A cation radical (VIII) formed by electron transfer is deprotonated by a carbanion (VII) yielding a radical (IX). This radical (IX) adds to an olefin formed by disproportionation of a radical (VI) to give a radical (X), which successively couples with the radical (VI) to form the final product (I or III). Since the radical (X) is more stable than an isomeric one (XI) owing the conjugation with methyl and X groups, the addition reaction like Eq. (7') and hence Eq. (8') are not considered to occur.

Although direct hydrogen abstraction like Eq. (9) may be possible, it can be ruled out by the facts that (1) the radical (VI) is a poor hydrogen abstractor and (2) that, if the reaction proceeds by direct hydrogen abstraction, reactions like Eqs. (10) and (11) should occur in the reaction with benzyl radicals.

$$C_6H_5N(CH_3)_2 + (CH_3)_2\dot{C}X \rightarrow C_6H_5N(CH_3)CH_2\cdot + (CH_3)_2CHX \quad (9)$$

$$C_6H_5N(CH_3)_2 + C_6H_5CH_2\cdot \rightarrow C_6H_5N(CH_3)CH_2\cdot + C_6H_5CH_3 \quad (10)$$

$$C_6H_5N(CH_3)CH_2\cdot + C_6H_5CH_2\cdot \rightarrow C_6H_5N(CH_3)CH_2CH_2C_6H_5 \quad (11)$$

The reason is not clear why the reaction between dimethyaniline and V (Eq. (12)) did not occur, because a radical (XII) generated from V is thought to be rather electrophilic like radicals VI.

$$C_6H_5N(CH_3)_2 + \underset{(V)}{[C_6H_5CH(COOCH_3)]_2Hg} \rightarrow C_6H_5N(CH_3)CH_2\text{-}\underset{\underset{H}{|}}{\overset{\overset{COOCH_3}{|}}{C}}\text{-}C_6H_5 \quad (12)$$

$C_6H_5\dot{C}HCOOCH_3$ (XII)

However, the formation of a trace amount of bis(4-*N*,*N*-dimethylaminophenyl)methane (XIII) may be considered to show that the reaction between dimethylaniline and the radical (XII) takes place at least to some extent, for the formation of the compound (XIII) can be explained reasonably by the reaction of dimethylaniline with formaldehyde (Eq. (13)) which is probably, though not conclusive, formed according to the following reactions.

$$C_6H_5\ddot{N}(CH_3)_2 + R\cdot \rightarrow C_6H_5\overset{+}{\ddot{N}}(CH_3)_2 + R^- \rightarrow \underset{(IX)}{C_6H_5N(CH_3)CH_2\cdot} + RH$$

$$IX + O_2 \rightarrow C_6H_5N(CH_3)CH_2OO\cdot \rightarrow C_6H_5N(CH_3)CH_2O\cdot \rightarrow C_6H_5\dot{N}CH_3 + CH_2O$$

$$2\,C_6H_5N(CH_3)_2 + CH_2O \rightarrow (CH_3)_2N\text{-}C_6H_4\text{-}CH_2\text{-}C_6H_4\text{-}N(CH_3)_2 \quad (13)$$

(XIII)

The oxidation of the radical (IX) is considered to be due to a small amount of oxygen dissolved in the reaction solution.

Experimental

Materials. α,α'-Azobisisobutyronitrile (AIBN) was used after recrystallization of commercial product from ether, mp 103—104°C. Dimethyl α,α'-azobisisobutyrate (MAIB) was prepared from AIBN[9] and recrystallized from petroleum ether, mp 29—31°C. Dibenzylmercury was prepared by the method of Jones and Werner,[10] mp 110—111°C.

Bis(α-methoxycarbonylbenzyl)mercury(V) was prepared according to the directions of Reutov.[11] However, there was a great difference between the description by Reutov and our observation. Reutov and his coworkers have reported that the shaking of methyl α-bromophenylacetate with mercury for 2 hr gave 80% of methyl α-bromomercuriphenylacetate, mp 92.5—94.0°C, which reacted with ammonia in the chloroform solution to give rise to V in a 74% yield, mp 140—141°C. On the other hand, we found that the reaction of 40 g (0.18 mol) of methyl α-bromophenylacetate with 201 g (1 g atom) of mercury at room temperature for 3 hr gave 44 g of very viscous oil, which reacted with ammonia in the chloroform solution to form only 7.3 g (10%) of a crude mercurial compound. The crude product was recrystallized from ethanol. The purified one mostly but not perfectly melted at 155—157°C to become grey and turbid liquid, which melted perfectly at 181—183°C. NMR (in $CDCl_3$): τ 6.24 (6H), 6.03(2H), and 2.58(10H).

Found: C, 43.22; H, 3.67%. Calcd for $C_{18}H_{18}O_4Hg$: C, 43.33; H, 3.63%.

Different products were formed under a slightly vigorous condition. Thus, the reaction of 60 g (0.27 mol) of methyl α-bromophenylacetate with 270 g (1.35 g atom) of mercury at room temperature for 3 hr and then at 60°C for one hour resulted in the formation of 21 g (55%) of *meso* form of dimethyl diphenylsuccinate, mp 217—219°C (lit.,[12] 219—220°C),

12) H. Wren and C. J. Still, *J. Chem. Soc.*, **111**, 1023 (1917).

3.5 g (9%) of racemic form of the same ester, mp 172—173°C (lit.,[13] 173—174°C) and a small amount of compound containing mercury, which was not identified.

Reaction with AIBN. a) The azonitrile (4.92 g, 0.030 mol) was added in small portions during one hour to dimethylaniline (18.15 g, 0.15 mol) heated on a steam bath, and the reaction solution was heated for additional few hours. The reaction solution was distilled under a current of steam in order to remove unchanged dimethylaniline and tetramethylsuccinodinitrile. The residue was extracted with ether, ether was evaporated, and 1 g of picric acid in alcohol was added. The precipitates thus obtained were recrystallized from ethanol to give 0.2 g (1.38%) of picrate, mp 150—151°C. When the reaction was carried out under the same condition as described above except further addition of 11.1 g of *n*-butanol to dimethylaniline, 0.35 g (2.4%) of the same picrate was obtained.

Found: C, 54.50; H, 5.24; N, 17.00%. Calcd for $C_{22}H_{24}N_6O_7$: C, 54.54; H, 4.99; N, 17.35%.

The picrate(0.3 g) was warmed with 20 m*l* of 28% aqueous ammonia to give a homogeneous solution. The reaction mixture was extracted with ether, the ethereal solution was dried with anhydrous potassium carbonate, ether was evaporated, and the residue was recrystallized from petroleum ether to give 100 mg (63.3%) of a compound, mp 72—73°C.

b) The same reaction was carried out using 90.8 g (0.75 mol) of dimethylaniline and 24.6 g (0.15 mol) of AIBN. After the reaction solution was distilled under atmospheric pressure to remove 2.1 g (10.1%) of isobutyronitrile, and then under reduced pressure to remove unchanged dimethylaniline and tetramethylsuccinodinitrile, the residue was extracted repeatedly with petroleum ether (bp 50—80°C). Condensation of the extract yielded crystals, which were recrystallized from petroleum ether to give 1.05 g (2.7%) of a compound of mp 72—73°C, which was the same as that obtained by the decomposition of the picrate in the procedure a).

Found: C, 75.25; H, 8.70; N, 16.39%. Calcd for $C_{16}H_{21}N_3$: C, 75.25; H, 8.29; N, 16.46%.

The IR spectrum of this compound (KBr disk) showed the presence of C≡N (2240 cm^{-1}) and N–CH_3 (2810 cm^{-1}). The NMR spectrum was shown in Fig. 1.

Reaction with MAIB. a) The reaction of 23 g (0.10 mol) of MAIB with 62 g (0.51 mol) of dimethylaniline was carried out by a similar procedure to that described in the reaction with AIBN. To the residue of steam distillation was added a saturated alcoholic solution of picric acid to give 0.29 g (1.9%) of crude picrate, which was brown viscous oil and could not be crystallized.

b) The azoester (69 g, 0.30 mol) was added in small portions to dimethylaniline (180 g, 1.50 mol) heated at 100—110°C and the reaction mixture was heated for 11 hr at this temperature. After methyl isobutyrate and dimethylaniline were distilled off, the residue was distilled under high vacuum in order to remove dimethyl tetramethylsuccinate, which distilled out up to 160°C (0.5 mmHg). The residue was 5.9 g of colorless and very viscous oil which distilled at 160—186°C (0.18 mmHg). The elemental analysis of the oil showed 3.8% of nitrogen content (calcd for $C_{18}H_{27}NO_4$: N, 4.36%), which indicated that it contained about 90% of the amine (III). The picrate of the crude amine was boiled with conc. aqueous ammonia to obtain free amine. Then it was twice purified by column chromatography on silica gel with benzene-ether (9 : 1) mixture as eluent.

Found: C, 67.21; H, 8.67; N, 4.51%. Calcd for $C_{18}H_{27}NO_4$: C, 67.26; H, 8.47; N, 4.36%.

The NMR spectrum of the purified amine in CCl_4 at 60 Mc: τ 8.90 and 8.85 (9H in total), 7.8—8.6 (multiplet, 2H), 7.17 (singlet, 3H), 6.76 (triplet, 2H, J=7 cps), 6.42 (singlet, 6H), and 2.7—3.7 (multiplet, 5H). Attempts to obtain crystalline derivatives were not successful except for a diazo-coupling product; the treatment of the crude amine with picric acid, hydrazine hydrate, methyl iodide, perbenzoic acid and conc. hydrochloric acid in order to obtain the corresponding picrate, hydrazide, ammonium salt, *N*-oxide, and free carboxylic acid, respectively, did not give crystalline products. The amine, however, underwent a diazo-coupling reaction with *p*-nitrobenzenediazonium chloride to yield reddish brown solid, which was recrystallized from carbon tetrachloride, mp 172—173°C. The NMR spectrum of the azo compound in $CDCl_3$ at 60 Mc: τ 8.76 (singlet, 9H), 7.5—8.5 (multiplet, 2H), 6.92 (singlet, 3H), 6.65 (triplet, 2H, J=7 cps), 6.25 (singlet, 3H), 6.33 (singlet, 3H), and 3.3—1.6 (multiplet, 8H).

Found: C, 60.85; H, 6.73; N, 12.18%. Calcd for $C_{24}H_{30}N_4O_6$: C, 61.16; H, 6.43; N, 11.91%.

Reaction with Dibenzylmercury. The solution of 15 g (0.04 mol) of dibenzylmercury in 24 g (0.2 mol) of dimethylaniline was heated under nitrogen at 120°C for one hour and at 160°C for half an hour. After mercury (7.94 g, 99%) was removed, the reaction mixture was distilled with steam. The distillate was extracted with ether and the ether solution was shaken with conc. hydrochloric acid. The aqueous layer was neutralized by aqueous solution of sodium carbonate, and extracted with ether. The ether solution was dried with anhydrous sodium sulfate and distilled to give only dimethylaniline. The ether layer was dried with anhydrous sodium sulfate, concentrated, and analyzed with glc using an apiezon grease column; 75% of bibenzyl and 4% of toluene were detected. The residue of the steam-distillation was extracted with ether, ether was evaporated, and then ethanol was added. Addition of picric acid to the ethanol solution gave only a trace amount of brown tarry compound, which was not identified.

Reaction with Bis(α-methoxycarbonylbenzyl)-mercury(V). The reaction between 13 g (0.11 mol) of dimethylaniline and 4.9 g (0.01 mol) of V was performed under nitrogen. Mercury began to deposit at about 120°C. The reaction temperature was gradually raised to 180°C during 30 min and kept at this temperature for 30 min. When the reaction solution was cooled, large quantities of white crystals precipitated. The precipitates were dissolved by adding of acetone and mercury isolated (1.87 g, 95%) was filtered off. To the acetone solution was added petroleum ether to give 2.1 g (71%) of white precipitates, which were identified by IR and mp (217—219°C) as *meso* form of dimethyl diphenylsuccinate. After distillation under reduced pressure in order to remove dimethylaniline, the filtrate was steam-distilled. The

13) H. Wren and C. J. Still, *ibid.*, **107**, 1453 (1915).

residue was extracted with methylene dichloride, the extract was dried, and methylene dichloride was evaporated to leave a small amount of purple oil. To the oil was added a saturated solution of picric acid in alcohol to form yellow precipitates. After ethanol was added enough to dissolve the yellow precipitates under reflux, the solution was cooled giving 0.29 g of crystals. Further recrystallization from ethanol gave yellow crystals of mp 180—181°C.

Found: C, 49.06; H, 3.69; N, 15.48%. Calcd for $C_{29}H_{28}N_8O_{14}$: C, 48.88; H, 3.69; N, 15.73%.

The picrate was decomposed by aqueous sodium hydroxide, the reaction solution was extracted with ether, and ether was evaporated leaving an almost white crystals. It was recrystallized from ethanol to give white crystals, mp 88—89°C. It was identified as bis(4-*N*,*N*-dimethylaminophenyl)methane (lit.,[14] mp 90°C). The NMR spectrum in CCl_4 at 60 Mc: τ 2.91 (12H), 3.71 (2H), 6.42, 6.63, 6.86, and 7.00 (8H, in total).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1716—1723 (1968)

Magnesium Ammonium Phosphates, Related Salts and Their Behavior in Compound Fertilizers

Jumpei ANDO, Takashi AKIYAMA and Matsusaburo MORITA

Department of Industrial Chemistry, Faculty of Science and Engineering, Chuo University, Bunkyo-ku, Tokyo

(Received December 5, 1967)

Fluorine forms a previously unknown compound $MgNH_4HFPO_4$ (MAFP) when monoammonium phosphate made from wet-process phosphoric acid is treated with magnesium hydroxide above about 75°C in the presence of moisture. When treatment is conducted with a large quantity of water, fluorine forms a gelatinous material which resembles MAFP in chemical composition. Wet-process phosphoric acid ammoniated and reacted with magnesium hydroxide above about 75°C gives a very thick slurry, which almost solidifies due to the formation of gelatinous material, while the acid treated in the same way after being defluorinated gives a less viscous slurry in which most of the magnesium is present in the form of $MgNH_4PO_4 \cdot H_2O$ (MH). Fluorine shows less effect at lower temperature. When treated below about 60°C, most of the magnesium combines to form $MgNH_4PO_4 \cdot 6H_2O$ (M6H) and $Mg(NH_4)_2(HPO_4)_2 \cdot 4H_2O$ (M4H). M6H and M4H decompose during drying at about 100°C, losing ammonia and water of crystallization to form amorphous materials. The decomposition is promoted by the presence of potassium salts resulting in the formation of water-insoluble potassium. Another previously unknown compound, $MgKHFPO_4$ (MKFP), which is isomorphic with MAFP has also been identified. MKFP is less soluble in water while MAFP decomposes in water to precipitate amorphous material and M6H. Solid solutions of MAFP and MKFP are often present in commercial fertilizers, and provide a small amount of water-insoluble potassium. M4H decomposes rapidly in water to precipitate M6H. M6H and MH are less soluble in pure water but are considerably soluble in water which contains acidic salts, such as monoammonium phosphate.

Recently a large number of compound fertilizers containing magneisum with grades 12—26—10—5, 12—16—14—4, 11—11—11—4, *etc.* have been produced in Japan. The main source of magnesium is magnesium hydroxide precipitated from sea water, while serpentine and olivine are used in a few plants. It has been generally thought that most of the magnesium would combine to form $MgNH_4PO_4 \cdot H_2O$ (NH) and $MgNH_4PO_4 \cdot 6H_2O$ (M6H) in the fertilizers, both of which are less soluble in water and have good agronomic response as slow release fertilizers.

The present quantitative X-ray analysis on commercial products, however, showed that M6H is seldom present in the final products, and that although MH is often present, the yield is usually much lower than expected. Moreover, there are the following problems: (1) The products of reaction of magnesium hydroxide with ammonium phosphate and other materials are usually so sticky or viscous that cause much trouble in granulation.

(2) A considerable amount of potassium, up to 10% of the total, is sometimes changed into a water-insoluble form.

(3) Usually 30 to 35% of magnesium in the products is soluble in water when tested by the standard Japanese method.

The reasons for the above problems were not clear. The authors studied the forms and properties of magnesium compounds in compound fertilizers, and their behavior during production processes in order to clear up these problems.

Examples of Commercial Compound Fertilizers Tested

Ten examples of commercial compound fertilizers containing magnesium are shown in Table 1.

Sample No. 1 was produced with wet-process phosphoric acid, ammonia, amonium sulfate, urea, potassium chloride and magnesium hydroxide. Samples No. 2 and 3 were produced with ammonium chloride instead of the ammonium sulfate and urea of sample No. 1. Samples No. 4 and 5 were produced with potassium sulfate instead of the potassium chloride of sample No. 1. Samples No. 6 to 8 were made with powdered monoammonium phosphate made from wet-process phosphoric acid, ammonium sulfate, urea, potassium sulfate and magnesium hydroxide. Samples No. 9 and 10 were produced with wet-process phosphoric acid, sulfuric acid, olivine, ammonia and potassium chloride. Samples No. 6 to 8 were granulated at 50 to 60°C, others at 80 to 90°C. All of the granulated products were dried at about 100°C.

The water-solubility of the magnesium present in the samples ranged from 31 to 34%. The water-solubility of potassium ranged from 95 to 98% for samples No. 1 to 5 which were granulated at 80 to 90°C, and 90 to 92% for samples No. 6 to 8 which were granulated at 50 to 60°C.

Materials Used

For preparation tests in the laboratory, five samples of commercial ammonium phosphate made from wet-process phosphoric acid, and one sample each of wet-process phosphoric acid and magnesium hydroxide made from sea water were used. The chemical compositions of these samples are given in Table 2.

X-Ray tests of the ammonium phosphate samples showed that the water-soluble P_2O_5 of samples A, B, C and D was present as monoammonium phosphate, while that of sample E was present as

both monoammonium and diammonium phosphates. Considerable amounts of ammonium sulfate and a water-insoluble compound "S",[1] which is likely to have the formula $Al_3(NH_4)_5H_2 \cdot (PO_4)_4F_4$,[2] were present in all samples of ammonium phosphate.

Reagent grade monoammonium and diammonium phosphates, magnesium hydroxide, ammonium fluoride, hydrofluoric acid, ferric and aluminum phosphates, *etc.*, were also used for the tests.

Experimental and Results

Preparation of Standard Samples. Standard samples of $MgNH_4PO_4 \cdot H_2O$ (MH), $MgNH_4PO_4 \cdot 6H_2O$ (M6H) and $Mg(NH_4)_2(HPO_4)_2 \cdot 4H_2O$[3] (M4H) were prepared in the following way with reagent grade chemicals:

MH: In 500m*l* of phosphoric acid (30% P_2O_5), 100 g of magnesium hydroxide was dissolved. Concentrated aqueous ammonia was added to the solution at 95°C until the pH reached about 8. The precipitate was filtered, quickly washed with hot water and acetone, and dried at 50°C.

M6H: Concentrated aqueous ammonia was added to the magnesium phosphate solution below 50°C. The precipitate was filtered, washed with water and acetone, and dried at 50°C.

M4H: A mole of finely ground monoammonium phosphate and a half mole of magnesium hydroxide were mixed and allowed to react at about 50°C by the repeated addition of small amounts of water and mixing. The product was dried at 50°C.

Chemical and X-ray analyses of the products showed they were sufficiently pure for standard samples. All of the products consisted of small crystals of less than 5 microns, similar to those present in commercial and granulator products of compound fertilizers containing magnesium.

Quantitative X-Ray Analysis. The amounts of MH, M6H and M4H present in the commercial and laboratory products were determined by quantitative X-ray analysis using spinel as an internal standard.[4,5] Calibration curves for the determinations were obtained through tests with synthetic samples. The diffraction angle and height ratio of the peaks of each compound to that of spinel at a 2θ of 36.8° by Cu$K\alpha$ ray when each compound and spinel are present in equal amounts are shown in Table 3.

TABLE 3. DIFFRACTION ANGLE (2θ, Cu$K\alpha$) AND HEIGHT RATIO

Compound	2θ	Ratio
MH	31.8	0.78
MH	10.0	0.50*
M6H	15.7	0.33*
M6H	21.3	0.28
M6H	33.2	0.28
M4H	17.0	0.38

* Less reliable because the height varies considerably with crystal size and shape.

Magnesium Compounds in Commercial Products. A quantitative X-ray analysis of magneisum compounds was conducted on eight samples of commercial products.

Most of samples contained MH, while M6H and M4H were not detected in any of the samples. The amounts of MH present and the yields (MgO present as MH per cent of total MgO) are shown in Table 4.

TABLE 4. THE AMOUNT AND YIELD OF MH

Sample No.	1	2	3	6	7	8	9	10
MH, %	15	4	3	0	1	1	4	10
Yield, %	53	23	17	0	4	4	21	53

The yields were less than about 50%, and was especially low for samples No. 6 to 8, which were granulated at 50 to 60°C and dried at about 100°C. Unreacted magnesium hydroxide was detected only in small amounts in samples No. 1 to 3. Considerable amounts of an unknown compound were detected in samples No. 1 to 3. Other magnesium compounds were not detected.

These results indicate that a considerable portion of magnesium may be present as the unknown compound in samples No. 1 to 3, and as amorphous material in other samples.

Reaction Products of Reagent Grade Monoammonium Phosphate and Magnesium Hydroxide. Finely powdered reagent grade monoammonium phosphate and magnesium hydroxide were blended together in various ratios, and allowed to react at temperatures between 40 and 100°C for 30 min in water vapor. The products were checked by quantitative X-ray analysis. The relations among temperature, mole ratio P_2O_5/MgO and compound formed is shown in Fig. 1.

MH formed above 75°C, M6H below 65°C and the mixture between 65 and 75°C as were previously reported.[6] In addition, M4H formed below 65°C when the mole ratio was greater than 0.5. M4H did not form but M6H did in the presence of a large quantity of water, even when

(MH=$MgNH_4PO_4 \cdot H_2O$, M6H=$MgNH_4PO_4 \cdot 6H_2O$, M4H=$Mg(NH_4)_2(HPO_4)_2 \cdot 4H_2O$)

the mole ratio was greater than 0.5 and treatment was carried out below 65°C. In all of the tests, magnesium hydroxide reacted rapidly and quantitatively.

Reaction of Magnesium Hydroxide with Ammonium Phosphate made from Wet-process Phosphoric Acid. Similar tests were conducted with reagent grade magnesium hydroxide and the five samples of commercial ammonium phosphate made from wet-process phosphoric acid.

When the four samples of monoammonium phosphate A, B, C and D were treated above about 75°C in water vapor, only a part of the magnesium formed MH, and the yield of MH decreased linearly as the mole ratio P_2O_5/MgO increased (Fig. 2). During treatment, magnesium hydroxide reacted completely and an unknown compound,

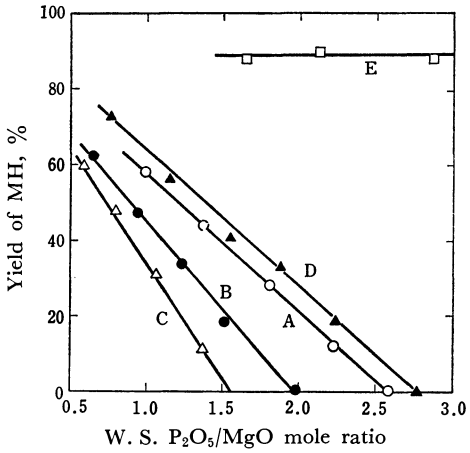

Fig. 2. Relation between the yield of $MgNH_4PO_4 \cdot H_2O$ and the mole ratio of water-soluble P_2O_5 of ammonium phosphate to MgO of magnesium hydroxide.

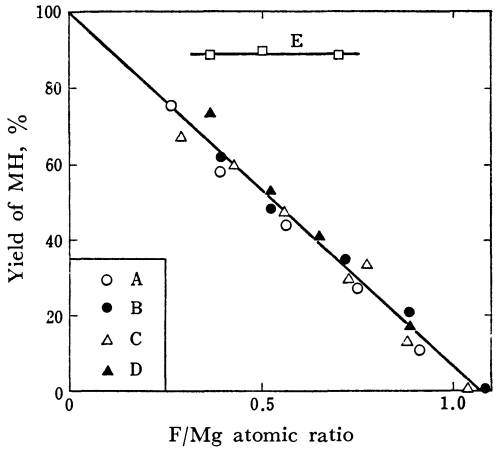

Fig. 3. Relation between the yield of $MgNH_4PO_4 \cdot H_2O$ and the F/Mg atomic ratio.

similar to that detected in commercial compound fertilizers No. 1 to 3, formed.

Through further tests it was found that fluorine in the samples of monoammonium phosphate was the cause of the formation of the unknown compound and the decrease in yield of MH. Figure 3 shows that for samples A, B, C and D, the yield decreases linearly on the same line as the atomic ratio F/Mg increases. Figure 3 also indicates that the unknown compound contains fluorine and magnesium in the atomic ratio of 1.

When sample E, which contained diammonium phosphate besides monoammonium phosphate, was used, magnesium hydroxide reacted very slowly releasing much ammonia; nearly 90% of the magnesium combined to form MH, regardless of the P_2O_5/MgO and F/Mg ratios (Figs. 2 and 3). The unknown compound formed in small amounts.

When samples A, B, C and D were allowed to react with magnesium hydroxide above about 75° in the presence of a large quantity of water or in a slurry state, the yield of MH decreased with increase in F/Mg ratio in the same manner as in the above tests, but the unknown compound was not detected in the products. An amorphous material formed instead of the unknown compound.

Fluorine showed less effect at lower temperature. Most of the magnesium combined to form M6H and M4H when the samples of ammonium phosphate were treated with magnesium hydroxide below about 60°C.

Tests were also conducted with magnesium hydroxide which was made from sea water and ground to minus 30 mesh. The results were similar to those obtained with reagent grade hydroxide, except that the hydroxide obtained from sea water reacted slowly because of the larger grain size.

Synthesis and Characterization of the Unknown Compound. The unknown compound was prepared in several ways using reagent

grade chemicals. The best sample was obtained by the following method:

One tenth mole of magnesium hydroxide was mixed with equimolecular ammonium fluoride. An amorphous material formed, losing ammonia. Two tenths mole of monoammonium phosphate was mixed with the above product and the result heated at 90 to 100°C for one hour in water vapor. The product was washed with 2% aqueous ammonium fluoride solution on a fritted glass filter with suction, and then washed with acetone and dried at room temperature. The chemical composition of the product is shown in Table 5.

Table 5. Chemical composition of the synthetic sample

	MgO	$(NH_4)_2O$	HF	P_2O_5
Composition (%)	22.49	16.50	11.58	41.83
Mole ratio	1.00	0.56	0.99	0.53

From chemical analysis, this compound was identified as $MgNH_4HFPO_4$, which should be called magnesium ammonium hydrogen filuroide phosphate and will be abbreviated to MAFP. Synthetic MAFP consisted of very small crystals of less than 0.1 μ in size. X-Ray diffraction data are shown in Table 6.

Table 5 shows that $(NH_4)_2O$ and P_2O_5 are present in slight excess. It is likely that a small amount of ammonium phosphate is absorbed by the fine crystals of MAFP. Excessive ammonium phosphate was used for preparation to promote the formation of MAFP. It was difficult to remove all of the remaining ammonium phosphate because the fine crystals of MAFP tend to decompose in washing.

Chemical analysis also shows that a considerable amount of water (about 8%) is contained in the product. By heating the product at 100°C in air, nearly all the water was removed, which resulted in considerable shrinkage of the crystal lattice as shown in Table 6. Shrinkage with heating hardly occurred when ammonium phosphate coexisted.

When the preparation of MAFP was conducted in a slurry by adding a large amount of water, an amorphous material or a mixture of MAFP with amorphous material was obtained. The amorphous material contained nearly equimolecular MgO and HF, similar to MAFP, but contained less $(NH_4)_2O$ and P_2O_5 than was contained in MAFP.

An amorphous material instead of MAFP formed also when preparation was conducted below about 60°C either with much or little water.

When preparation of MAFP was conducted at 90 to 100°C in the presence of a small amount of water using a mixture of monoammonium and diammonium phosphates, magnesium hydroxide reacted very slowly releasing ammonia; the product contained MH and less MAFP in the same manner as in the test with commercial ammonium phopshate E, indicating that only a part of the fluorine forms MAFP at high pH.

Another previously unknown compound, $MgKHFPO_4$ (MKFP), magnesium potassium hydrogen fluoride phosphate, was prepared in a similar way, treating one tenth mole each of potassium fluoride and magnesium hydroxide with one tenth mole of monopotassium phosphate at 90 to 100°C in water vapor, and washing with 2% aqueous potassium fluoride solution and acetone.

X-Ray diffraction data on MKFP are shown in Table 6. The synthetic MKFP also contained 5% water. Heating at 100°C removed the water and a slight shrinkage of the crystal lattice occurred. The synthetic MKFP consisted of small crystals less than 0.1 micron in size.

MKFP is isomorphic with MAFP and they form a continuous solid solution in each other. The unknown compound detected in the commercial products No. 1 to 3 was identified as a solid solution of MAFP and MKFP. The solid solution also consisted of small crystals less than 0.1 μ in size. X-Ray diffraction data on the solid solution obtained from sample No. 2 by removing water-soluble salts rapidly with small amount of water are also shown in Table 6. Considerable shrinkage of the crystal lattice was also observed to occur upon heating the solid solution at 100°C.

Table 6. X-Ray diffraction data on MAFP, MKFP and the solid solution

Viscosity of the Slurry formed by Reaction of Magnesium Hydroxide with Ammonium Phosphate. The wet-process phosphoric acid (Table 2) was ammoniated with geseous ammonia to a pH of 4 to 5. Magnesium hydroxide obtained from sea water ground to minus 30 mesh was added to the amount to give equimolecular MgO to P_2O_5 and stirred at about 90°C. The viscosity of the slurry increased remarkably as the hydroxide reacted, and the slurry almost solidified in about 30 min. During the reaction, only a small portion of magnesium

formed MH and a larger portion formed a gelationous material which resembled MAFP in chemical composition, as was already mentioned.

A similar test was conducted with wet-process phosphoric acid from which about 90% of the fluorine had been removed by adding the correct amount of potassium chloride to form potassium fluorosilicate and removing the precipitate. In this test, nearly all of the magnesium formed MH, and the slurry was fluid with a viscosity of about 1 poise.

When potassium chloride was added to the acid and the mixture used without the separation of fluorosilicate, the fluorosilicate decomposed during ammoniation and fluorine reacted to depress the formation of MH and to increase the viscosity.

Tests with reagent grade phosphoric acid, hydrogen fluoride, potassium fluorosilicate, ammonia and magnesium hydroxide also showed the remarkable effect of fluorine on the viscosity.

In another series of tests, magnesium hydroxide was first added to wet-process phosphoric acid and then ammoniated to a pH of 4 to 6. In these tests, the slurry became quite viscous and almost solidified even when the acid had been defluorinated.

Water-Slolubility of Magnesium Compounds. A test with synthetic MAFP (Table 5) showed that 25% of Mg, 55% of N and 58% of P_2O_5 were water-soluble by the standard Japanese method, in which 5 g of sample is shaken for 30 min in 400 m*l* water, made up to 500 m*l* and then filtered. X-Ray analysis showed that essentially all MAFP decomposed during the standard treatment to precipitate an amorphous material and M6H. MKFP was less soluble; about 30% decomposed and 13% of magnesium was soluble in the standard method.

X-Ray tests were also conducted on commercial products No. 1 and 3 (Table 1) which contain a solid solution of MAFP and MKFP. It was found that about 90% and 60%, respectively, of the solid solution decomposed during the standard treatment. MAFP, MKFP and the solid solution are entirely soluble in 2% citric acid.

M4H decomposed rapidly in water to precipitate M6H; 18% of the magnesium was soluble in the standard method.

MH and M6H are less soluble; only 2% of magnesium dissolved in the standard method. In 100 m*l* water, 5.9 mg of MgO of MH and 4.0 mg of MgO of M6H dissolved.

Tests were made on the effect of the coexistence of several salts on the solubility of magnesium of MH and M6H. The synthetic sample (1 g each) was shaken for 30 min in 100 m*l* of 0.1, 0.5 and 2.5% aqueous solutions of monoammonium phosphate, ammonium sulfate, ammonium chloride, potassium chloride, diammonium phosphate and urea. The amounts of MgO (mg) which dissolved in 100 m*l* of the solutions of monoammonium phosphate, ammonium sulfate and ammonium chloride are shown in Table 7.

Table 7. MgO dissolved in 100 m*l* of the solutions (mg)

Salt	Form of magnesium compound	Concentration 0.1	0.5	2.5
$NH_4H_2PO_4$	MH	24.9	35.3	58.9
	M6H	11.5	—	40.1
$(NH_4)_2SO_4$	MH	12.6	14.7	16.5
	M6H	3.9	4.2	8.3
NH_4Cl	MH	12.1	13.1	15.4
	M6H	4.0	4.2	7.1

Table 7 shows that the water-solubility is increased remarkably by $NH_4H_2PO_4$, and significantly by $(NH_4)_2SO_4$ and NH_4Cl. Tests with the other compounds showed that potassium chloride and urea have little effect, and that diammonium phosphate reduced the solubility slightly. The solubility depends mainly upon the pH of the solutions.

Tests were also made on the solubility when a mixture of salts was present. When 15 parts of MH was blended with 15 parts of NH_4Cl, 20 parts of KCl, 40 parts of $(NH_4)_2SO_4$ and 10 parts of $NH_4H_2PO_4$ to give a 15-13-12-4 grade fertilizer and tested by the standard method, 44.3% of the magnesium present dissolved. When M6H, instead of MH, was used, 34.0% dissolved.

These results show that water-soluble magnesium in commercial fertilizers can be derived from the above magnesium compounds.

Thermal Changes. Thermal gravimetric analysis curves of the synthetic samples of MH, M4H, M6H and MAFP obtained during heating at a rate of 2°C/min are shown in Fig. 4.

Iwata[6] reported that M6H (crystals 20 to 120 μ in size) converted to MH at about 150°C. The

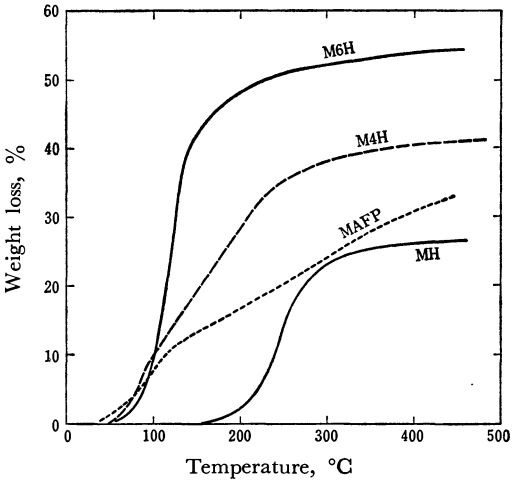

Fig. 4. Weight loss (%) during heating at a rate of 2°C/min.

present test showed that M6H began to decompose at about 60°C, losing water of crystallization and ammonia, and changed into an amorphous material at about 100°C; essentially no MH formed during heating to and above 150°C. Presumably the small crystal size (under 5 μ) is the reason for the instability.

M4H also started to decompose at about 60°C, losing water of crystallization and ammonia to form an amorphous material at about 100°C. M6H and M4H are sometimes present in the pre-mixer products and the granulator products of compound fertilizers containing magnesium. M6H and M4H in the products also consist of small crystals of less than 5 μ in size and undergo similar thermal decomposition (to be mentioned later). MH did not show any change below 150°C, and started to decompose above 160°C.

The synthetic MAFP lost about 8% water upon heating to 100°C, resulting in a considerable shrinkage of the crystal lattice, as previously mentioned. Above 100°C, MAFP started to lose ammonia, and slowly changed into an amorphous material.

A test on synthetic MKFP showed that no decomposition occurred with heating up to 150°C.

Formation of Water-insoluble Potassium. The water solubility of potassium present in compound fertilizers is apt to decrease when magnesium is present. The present tests have shown that one of the reasons for the decrease is the presence of a solid solution of MAFP and MKFP. The commercial fertilizers No. 1 to 3 (Table 1), the solubility of which ranges from 95 to 98%, contain the solid solution which partly remains undissolved in the standard treatment, as mentioned previously.

The potassium of samples No. 6 to 8 is less soluble (90 to 92%). Tests have shown that the decrease in water-solubility occurred during the drying of the granulated product at about 100°C. When magnesium hydroxide was mixed with monoammonium phosphate, ammonium and potassium sulfates and urea at 50 to 60°C for granulation, magnesium formed mainly M6H and M4H, and more than 98% of potassium was water-soluble. Both M6H and M4H decomposed into amorphous materials and the water-solubility of potassium decreased during the drying. Most of the fluorine present was in the form of potassium fluorosilicate before and after drying. The fluorosilicate was almost completely soluble in water in the standard method.

Laboratory tests have been conducted to study the relation between the decomposition of M6H and M4H and the decrease in solubility of potassium. Potassium chloride or sulfate ground to pass through a 150 mesh screen was mixed with synthetic M6H in a mole ratio MgO/K_2O of 1 : 1 and heated at temperatures between 80 and 120°C from 30 min to 7 hr. A remarkable decrease in the solubility of potassium occurred as shown in Fig. 5.

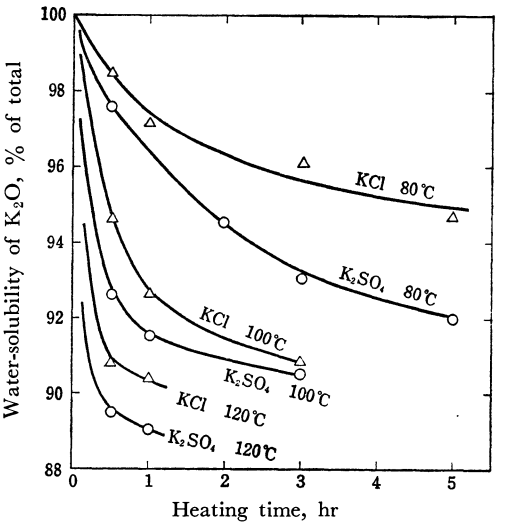

Fig. 5. Decrease of water-solubility of potassium during heating and $MgNH_4PO_4 \cdot 6H_2O$ (mole ratio $MgO/K_2O=1$).

Potassium salts were found to promote the thermal decomposition of M6H. For example, the loss of ammonia with heating at 100°C for an hour was 35% without potassium salts, 58% when potassium chloride was present, and 64% when potassium sulfate was present. Apparently, potassium combined with the amorphous material which formed by the decomposition of M6H and became insoluble in water.

An other series of tests with potassium sulfate showed that the per cent of insoluble K_2O of the total K_2O was nearly proportional to the mole ratio MgO/K_2O (Fig. 6).

Potassium nitrate gave a similar result as potassium chloride, while monopotassium phosphate showed a smaller decrease in water-solubility.

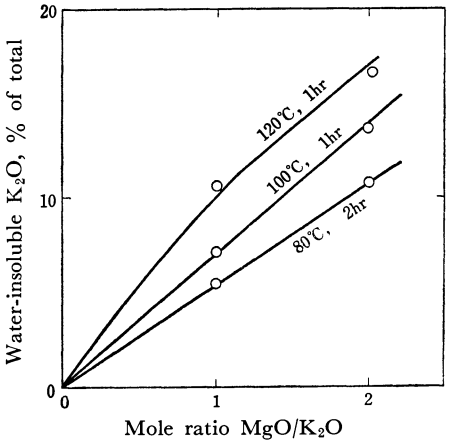

Fig. 6. Relation between mole ratio MgO/K_2O and insoluble K_2O formed by the reaction of $MgNH_4PO_4 \cdot 6H_2O$ and K_2SO_4.

For example, when mixtures of M6H and potassium salts ($MgO/K_2O=1$) were heated for an hour at 120°C, the water-solubility was 90.8% when potassium nitrate was used and 94.0% when monopotassium phosphate was used.

M4H also decomposed and combined with potassium salts during heating. The amount of insoluble potassium was roughly half that formed with M6H. For example, when a mixture of M4H and potassium sulfate ($MgO/K_2O=1$) was heated for an hour at 100°C, the water insoluble potassium was 4.1% while it was 8.6% with M6H.

MH was stable up to 150°C and did not react appreciably with potassium salts up to 130°C.

The potassium which combined with the amorphous material and became insoluble in the standard method was found to dissolve very slowly in water. For example, the water solubility of a smaple which was 89.7% by the official method increased to 92.5% when the sample was dipped in water for 5 days, and to 96.2% after 13 days.

Discussion

The present tests show that fluorine has remarkable effects on compound fertilizers containing magnesium when treated at relatively high temperatures. The weight ratio F/P_2O_5 of both wet-process phosphoric acid and ammonium phosphate made from the acid ranges from 0.05 to 0.1, and most of fluorine is usually present in fairly reactive forms. Consequently, by reaction above about 75°C, fluorine combines with 30 to 60% of the magnesium in fertilizers which have a P_2O_5/MgO weight ratio of about 3 (14-18-14-6, *etc.*), and with 50 to 100% of the magnesium in fertilizers which have a ratio about 5 (12-26-10-5, *etc.*). Fluorine thus forms MAFP, MKFP, the solid solution and a similar amorphous material, and depresses the formation of MH.

The high viscosity of the reaction products may be due to the above fluoride compounds, which consist of very small crystals under 0.1 μ in size, or a gel.

In order to eliminate the high viscosity which causes difficulties in plant operation, and to obtain products which contain most of their magnesium in the form of MH, a large portion of the fluorine should be removed or converted into a less reactive form.

Potassium fluorosilicate readily reacts with magnesium hydroxide and ammonium phosphate above about 75°C. There are indications that ammonium and sodium fluorosilicates are also fairly reactive. Those fluorosilicates should be removed from the system to eliminate the effects of fluorine. If fluorine can be converted into a less reactive form such as K_2NaAlF_6, the removal might not be necessary.

Another way to form a lot of MH in the presence of fluorine is to carry out treatment at high pH where a lot of ammonia is released. This treatment might not be favorable for plant operation because equipment for the recovery of ammonia would be necessary, the reaction of magnesium hydroxide would occur very slowly at the high pH, and moreover, the reaction products would still be fairly viscous.

The conversion of most of the magnesium into M6H and M4H when commercial monoammonium phosphate was treated with magnesium hydroxide below about 60°C is due to the poor reactivity of the fluoride compounds in the phosphate (such as $Al_3(NH_4)_5H_2(PO_4)_4$[2]) at low temperature; a test showed that fluorine, in the form of ammonium fluoride, depressed the formation of M6H and M4H below even 60°C.

M6H and M4H which forms in the pre-mixer and granulator at commercial scale plants usually consist of very small crystals less than 5μ in size and readily decompose during drying at about 100°C to form amorphous materials resulting in a remarkable decrease in the water-solubility of potassium. To prevent the great decrease in water-solubility, the drying temperature should be kept low, or magnesium hydroxide should be reacted above 75°C to prevent the formation of M6H and M4H.

By reaction at higher temperature, a solid solution of MAFP and MKFP is apt to form, giving a small amount of water-insoluble potassium. If the wet-process phosphoric acid was defluorinated or treated to convert fluorine into a less reactive form and reacted with ammonia and magnesium and potassium salts above 75°C, essentially all of the magnesium would form MH which is stable during drying, and essentially all of the potassium would be soluble in water.

Fluorine thus causes great trouble in the production of compound fertilizers containing magnesium. However, exploratory agronomic tests on barley have indicated that MAFP and the solid solution have good fertilizer value which might even be superior to MH. Further agronomic tests are in progress.

NOTES

An Acid-catalyzed Reaction of Methyl Ethers with Acetyl Fluoride. Syntheses of 1-Fluorobicyclo[2.2.2]octanes[1]

Zennosuke SUZUKI and Ken-ichi MORITA

The Basic Research Laboratories, Toyo Rayon Company, Ltd., Kamakura

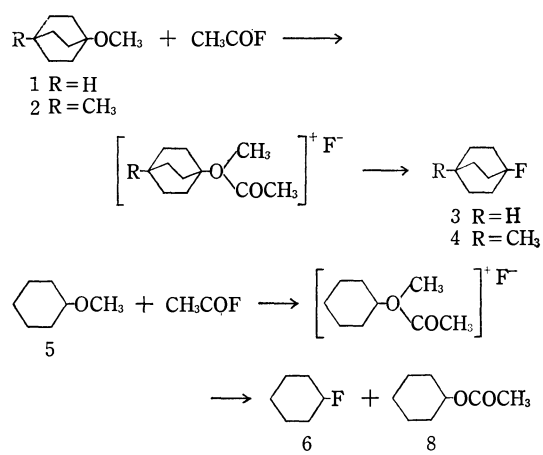
(Received May 29, 1967)

We have previously reported convenient methods for the syntheses of 1-chloro-, 1-bromo-, and 1-iodobicyclo[2.2.2]octane by the reaction of 1-methoxybicyclo[2.2.2]octane with acetylhalides in the presence of an acid catalyst. The reaction has now been extended to the preparation of 1-fluorobicyclo[2.2.2]octane derivatives.[2-4]

It has been theorized that the reaction of ethers with acyl halides proceeds *via* acyl oxonium ions.[1] The synthetic utility of acyl oxonium ions as a carbonium ion generator has been confirmed. Diazonium ions,[4] isocarboxonium ions,[5] and carboxylium ions[6] have been established as carbonium ion sources.

The treatment of 1-methoxybicyclo[2.2.2]octane (1) with an excess of acetyl fluoride in the presence of a catalytic amount of anhydrous stannic chloride gave a mixture (*ca.* 1 : 1) of 1-fluoro- and 1-chlorobicyclo[2.2.2]octane in about an 80% yield. When the boron trifluoride-phosphoric acid complex was used as a catalyst, the reaction between 1 and acetyl fluoride afforded 1-fluorobicyclo-[2.2.2]octane (3), mp *ca.* 152°C (most of it sublimes without melting) in a 70% yield. Among the other catalysts examined were boron trifluoride etherate and zinc fluoride, in which cases 3 was also obtained.

An analogous treatment of 1-methoxy-4-methylbicyclo[2.2.2]octane (2) with acetyl fluoride in the presence of the boron trifluoride-phosphoric acid complex gave 1-fluoro-4-methylbicyclo[2.2.2]octane (4) in a 74% yield, bp 165—170°C, (760 mmHg), semi-solid, NMR τ 9.21 (CH_3) (in CCl_4). The reaction of methoxycyclohexane (5) with acetyl fluoride in the presence of the boron trifluoride-phosphoric acid complex furnished a mixture of fluorocyclohexane (6) (25%), cyclohexene (7) (6%), and acetoxycyclohexane (8) (18%).



The formation of 1-acetoxybicyclo[2.2.2]octanes could not be detected when either 1 or 2 was reacted with acetyl fluoride in the presence of an acid catalyst. The formation of acetoxycyclohexane (8) in the case of 5 suggests that a 1-bicyclo[2.2.2]-octyl cation is more stable than a cyclohexyl cation. The mass spectra imply that a methyl carbonium ion is less stable than an ethyl carbonium ion[7]

and that the latter is in turn less stable than a 1-bicyclo[2.2.2]octyl ion.[8] No data concerning the stability of a cyclohexyl ion is available, however.

Experimental

1-Fluorobicyclo[2.2.2]octane (3). *A. The Boron Trifluoride-phosphoric Acid Complex as a Catalyst.* To a stirred mixture of 2.84 g (0.02 mol) of 1 and 3.10 g (0.05 mol) of acetyl fluoride,[9] twelve drops of the boron trifluoride-phosphoric acid complex were added with ice-bath cooling. After the mixture had been stirred for thirty minutes at 0°C, the reaction temperature was allowed to rise to 10—20°C, after which stirring was continued for 3 more hours. The reaction mixture was then poured onto cracked ice, and the mixture was stirred for 10 min and extracted three times with 25-m*l* portions of ether. The ether layers were then combined, washed with aqueous sodium bicarbonate and water, and dried over anhydrous calcium chloride. The ether was distilled off through a 10-in packed column, and the residue was sublimed to give 1.8 g (70%) of 3 mp *ca.* 152°C (most of it sublimes without melting).

Found: F, 14.7%. Calcd for $C_8H_{13}F$: F, 14.82%.

B. Boron Trifluoride Etherate as a Catalyst. An experiment similar to that described above was carried out using 0.5 m*l* of boron trifluoride etherate instead of twelve drops of the boron trifluoride-phosphoric acid complex; we thus obtained 1.6 g of 3.

C. Zinc Fluoride as a Catalyst. To a stirred suspension of 0.5 g (4.8 mmole) of zinc fluoride in 1.2 g (8.6 mmol) of 1, 2 m*l* of acetyl fluoride were added at 0°C over a 15-min period. The reaction temperature was then allowed to rise at room temperature (15—20°C), and stirring was continued for 24 hr. After the usual treatment (described for Procedure A), 1.0 g of an oil was obtained. Gas chromatographic analysis (PEG 6000 column at 180°C) showed that the product was about a 1-to-1.5 mixture of 3 and the starting material(1).

D. Stannic Chloride as a Catalyst. To a stirred mixture of 1.2 g (8.6 mmoles) of 3 and 2.1 g of acetyl fluoride 0.1 m*l* of stannic chloride was added with ice-bath cooling. An exothermic reaction was observed. The reaction mixture was then stirred for 4 hr at 4°C. After the usual treatment, the residue was crystallized from aqueous methanol to give 0.75 g of crystals with a mp of 112—123°C (in a sealed capillary tube). Gas chromatographic analysis (PEG 6000 column at 180°C) showed that the product was *ca.* a 1-to-1 mixture of 3 and 1-chlorobicyclo[2.2.2]octane.[10] The two materials were separated by preparative v.p.c. and identified.

1-Fluoro-4-methoxybicyclo[2.2.2]octane (4). To a stirred mixture of 3.12 g (0.02 mol) of 2 and 3.1 g (0.05 mol) of acetyl fluoride, fifteen drops of the boron trifluoride-phosphoric acid complex were added with ice-bath cooling. The mixture was then stirred for 3 hr at about 10°C. After the usual treatment, the product was collected by distillation (bp 165—170°C at 760 mmHg) to furnish 2.1 g (74%) of 4, n_D^{20} 1.4501, semi-solid, NMR τ 9.21[11] (in carbon tetrachloride).

Found: F, 13.3%. Calcd for $C_9H_{15}F$: F, 13.36%,

Fluorocyclohexane (6). To a stirred mixture of 4.56 g (0.04 mol) of methoxycyclohexane (5)[12] and 6.2 g (0.1 mol) of acetyl fluoride, twenty drops of the boron trifluoride-phosphoric acid complex were added with ice-bath cooling. After the mixture had been stirred for thirty minutes at 0°C, the reaction temperature was allowed to rise to 3—5°C and stirring was continued for two more hours. After the usual treatment, we obtained 2.83 g of an oil. The oil was separated by preparative vapor-phase chromatography (DC 550 column at 145°C) to give 1 g (25%) of fluorocyclohexane (6), n_D^{20} 1.4145 (lit.[13], n_D^{25} 1.4130), (Found: F, 18.25%. Calcd for $C_6H_{11}F$: F, 18.61%), 1 g (18%) of acetoxycyclohexane (8) and 0.2 (6%) of cyclohexene (7). The identity of 7 and 8 was established by a comparison of their infrared spectra and v.p.c. retention times with those of authentic samples.

The Sulfonation of Crosslinked Polystyrene Copolymerized with Polar Vinyl Compounds

Yoichi UTSUNOMIYA and Hiroshi KUYAMA

Research Lab., Tokyo Organic Chemical Ind., Ltd., Toshima, Kita-ku, Tokyo

(Received October 24, 1967)

At present, most of strongly acidic cation-exchange resins are made by the sulfonation of crosslinked copolymers prepared from styrene and divinylbenzene. With a copolymer having a high degree of crosslinking, a long time is required for sulfonation because of its slow reaction rate. Although the reaction rate is increased by the addition of some catalyst[1] or solvent in order to swell the crosslinked copolymer,[2] no method has been reported to increase the rate of sulfonation by a modification of chemical composition of the crosslinked copolymer.

The present authors have found that the rate of sulfonation increases upon the introduction of small amounts of polar vinyl compounds, such as acrylonitrile, methyl acrylate and methylvinylketone, into crosslinked polystyrene as copolymerizable compounds.

Experimental

Copolymer beads (30—40 mesh) of styrene crosslinked with divinylbenzene (D. V. B.) were prepared by Pepper's method[3] in the presence of a 1.0% benzoyl peroxide initiator. In the copolymerization of styrene and D. V. B. with a polar vinyl monomer, some sodium chloride was added to the aqueous layer. The sulfonation of the crosslinked copolymer was carried out at different temperatures with a five-fold excess of 97.5% sulfuric acid under mechanical agitation.

To obtain a quantitative comparison of the sulfonation rate for each crosslinked copolymer, the increase in cation-exchange capacity was measured by the usual method,[4] this capacity was produced by the sulfonation of crosslinked polystyrene.

Results and Discussion

The crosslinked polystyrenes made by the copolymerization consisting of 92% of styrene, 8% (by weight) of D. V. B., and 0.02 mol% of acrylonitrile (AN), methyl acrylate (MA), methyl methacrylate (MMA) and methylvinylketone (MVK), were each sulfonated by sulfuric acid of a 36 normal solution at 110°C. The degree of sulfonation of these copolymers versus the reaction are shown in Fig. 1. These results indicate that the sulfonation rates of crosslinked polystyrenes made by the copolymerization of styrene, D. V. B., and polar vinyl compounds are much larger than that of styrene-D. V. B. copolymer, and that the use of acrylonitrile as the comonomer has a remarkable effect.

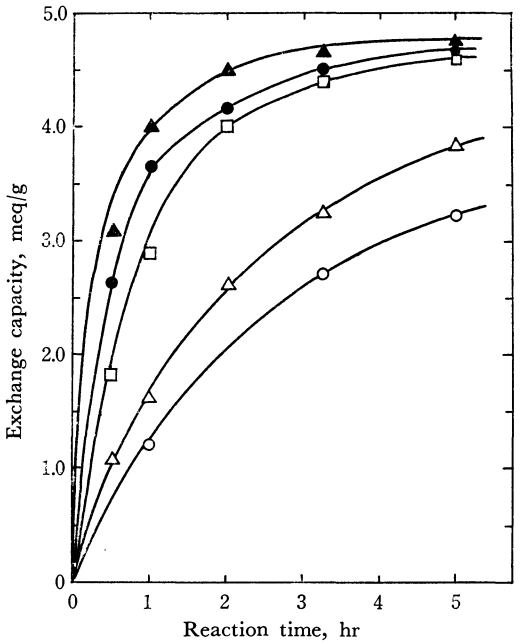

Fig. 1. Sulfonation of crosslinked polystyrene copolymerized with various vinyl compounds. (sulfonation temp. 110°C)
○ Homopolymer, copolymer with □ 1% AN, ● 1.7% MA, △ 2.0% MMA, ▲ 2.9% MVK

It has been described that, on the one hand, the rate of the sulfonation of crosslinked polystyrene is diffusion-controlled, since the reaction is entirely heterogeneous.[5] On the other hand, Reichenberg has reported that the difference in the sulfonation rates of crosslinked copolymers lies in the chemical rate, not in the diffusion.[6]

6) G. D. Jones, "Chemical Reactions of Polymers," ed. by E. M. Fettes, Interscience Publishers, New York (1964), p. 282.

Recently, Wiley and Venkatachalam[7] have shown that, as kinetic evidence for diffusion control in the sulfonation of crosslinked polystyrene-bead copolymers, a plot of the square of the capacity against the time would be linear.

The results of the applications of Wiley's theory to the sulfonation of the crosslinked polystyrene copolymer with 1%, with 3%, and with 5% acrylonitrile at different temperatures did not show any linear relationships except in the case of a much higher reaction rate. When the sulfonation of crosslinked polystyrene is assumed to be a first-order reaction with respect to the polystyrene molecule, the following Eq. (1) is obtained:

$$Ps\frac{dx}{dt} = kPs(1-x) \qquad \ln\frac{1}{1-x} = kt \qquad (1)$$

where x is the degree of sulfonation, P represents the concentration of polystyrene (mol/l), and k is the rate constant.

Applying Eq. (1) to the sulfonation of the above-described copolymers, the linear slopes shown in Fig. 2 could be obtained.

In view of the above facts, it seems reasonable to assume, as in Reichenberg's description, that the sulfonation process of crosslinked polystyrene is controlled by the reaction rate itself, not by the diffusion rate.

The rate constants of the sulfonation reaction calculated from the linear slopes of Fig. 2 and the activation energy values obtained from the individual rate constants are given in Table 1. From the results, it may be seen that the activation energy for sulfonation decreases with an increase in the acrylonitrile content in the copolymer.

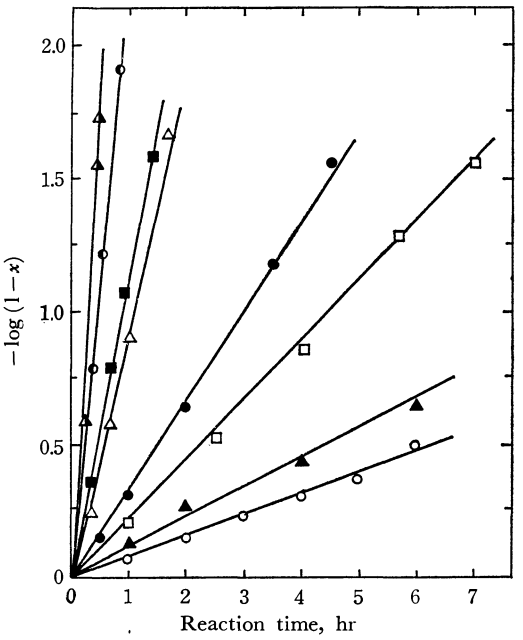

Fig. 2. First order plott of the sulfonation of crosslinked polystyrene copolymerized with acrylonitrile (AN).

	Copolymer with	Sulfonation temp., °C		Copolymer with	Sulfonation temp., °C
□	Homopolymer	110	△	Homopolymer	130
○	1%	100	△	1%	120
●	3%	100	◐	3%	120
▲	5%	80	■	5%	100

Table 1. Rate constant and activation energy

AN(%)	Rate constant k (hr^{-1}) at different sulfonation temperatures, (°C)					Activation energy E, (kcal/mol)
	80	100	110	120	130	
0	—	—	0.466	—	8.01	43.6
1.0	—	0.174	—	2.38	—	38.1
3.0	—	0.678	—	6.48	—	32.9
5.0	0.308	2.93	—	—	—	29.5

This decrease in activation energy is considered to be caused by the neighboring-group effect of such a polar vinyl monomer as acrylonitrile copolymerized in crosslinked polystyrene; this is a characteristic feature of a chemical reaction on the polymer.

The rate constant of a sulfonation reaction using very small copolymer beads (80—100 mesh) consisting of 1% acrylonitrile by 97.5% sulfuric acid was observed to be $k=2.84\ hr^{-1}$ at 80°C. On the contrary, no reaction was observed when the same sized copolymer beads but without acrylonitrile were used under the same conditions.

This fact seems to indicate that the sulfonation in the crosslinked polystyrene containing polar vinyl compounds is increased, but the precise mechanism remains to be investigated in the future.

Spectrophotometric Study of the Complex of Hg(II)-X-Diphenylcarbazone [X: I, Br]*1

Tadao OKUTANI

Faculty of Science and Engineering, Nihon University, Chiyoda-Ku, Tokyo

(Received November 13, 1967)

Mercury(II) forms a reddish-violet complex with diphenylcarbazone which may be easily extracted by benzene.[1] Ions such as cyanide which react with mercury(II) decrease the color intensity.[2] However, in the presence of iodide or bromide ions, the color intensity increases slightly with an increase in the ions in the first step, while the color intensity decreases greatly above an equimolor concentration of mercury(II)[3] (see Fig. 1).

From these results, it is considered that a mercury-(II)-diphenylcarbazone complex containing iodide or bromide will be formed, although the composition of this complex has not yet been reported.

We have previously reported a spectrophotometric method for the determination of minute quantities of such anions as chloride,[4] thiosulfate,[5] sulfide,[6] cyanide,[7] sulfite,[8] iodide,[9] and bromide[9] ions by using a complex formed of mercury(II), iodide (or bromide), and diphenylcarbazone.

This paper will report the results of more detailed studies of the reaction of mercury(II), iodide (or bromide), and diphenylcarbazone, and of the composition of the complex.

Experimental Results and Discussion

Reagents and Apparatus. *So-Called Diphenylcarbazone (DC).* The reagent is a molecular compound of diphenylcarbazone and diphenylcarbazide, and its color is orange.[10]

$C_6H_5NHNHCONHNHC_6H_5 \cdot C_6H_5N=NCONHNHC_6H_5$ (mp 153°C).

Diphenylcarbazone (H_2DCN). Pure orange-yellow diphenylcarbazone was prepared by the removal of diphenylcarbazide from the so-called diphenylcarbazone using the method of Gerlach.[11]

$C_6H_5N=NCONHNHC_6H_5$ (mp 118—120°C).

Diphenylcarbazide (H_4DCD). White crystals were used.

$C_6H_5NHNHCONHNHC_6H_5$ (mp 170°C).

These solutions of various concentrations were prepared by dissolving the reagent in ethanol, and a 1 m*l* portions of the solution were used in all the experiments.

Mercuric Nitrate Solution. A mercuric nitrate solution was prepared by dissolving 8.5 g of mercuric nitrate in water containing 2 ml of concentrated nitric acid, and by then diluting it to 500 m*l* (about 0.05 mol/*l*). This solution was standardized by Volhards method, and then stored in a brown glass bottle. The working solutions were prepared by diluting the stock solution properly.

The other materials and apparatus used in this investigation were the same as those described in previous papers.[4-9]

Formation of a Mercury(II)-Diphenylcarbazone Complex Containing Iodide or Bromide. Ten milliliters of a aqueous solution containing mercury(II), H_2DCN, and X^-(X^-; iodide or bromide ions) in which the pH was kept at 7, 2.5, or 1.4, and 10 m*l* of benzene were placed in a brown separatory funnel. Then the separatory funnel was shaken for about 1 min. The absorbance of benzene phase was measured at 562 mμ against pure water as a reference. The experimental results are plotted in Fig. 1. From Fig. 1 it may be considered that a complex of mercury(II)-diphenylcarbazone containing X^- is formed in the first step, and that then the color of all such complexes except one containing bromide at pH 7 fade as a result of the formation of HgX_2.

Therefore, mole ratio method was applied in order to clarify the relations of mercury(II) and X^- in the presence of H_2DCN (the molar concentration of H_2DCN was adjusted so as to be equal to that of X^-).

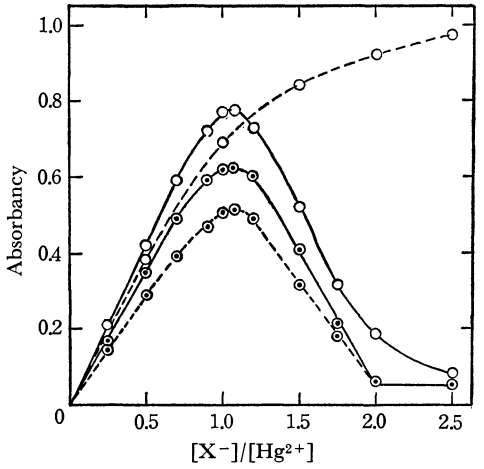

Fig. 2. Mole ratio method
Hg^{2+} ; 2.0×10^{-5} mol/*l* $[H_2DCN]=[X^-]$
Wavelength ; 562 mμ, at 25°C
—— I^-, - - - Br^-, ○ pH 7.0, ⊙ pH 2.5

As is shown in Fig. 2, all the curves except that of a complex containing bromide at pH 7 have a maximum absorbance in about an equimolar concentration of X^- and Hg^{2+}.

Similar experiments were carried out in which the molar concentration of H_2DCN was adjusted so as to be twice that of X^-. The maximum absorbance was also obtained in about an equimolar concentration of X^- and Hg^{2+}.

It may be considered that the diphenylcarbazone forms a complex with HgX^+ which is in a state of equilibrium as follows:

$$Hg^{2+}+X^- \rightleftharpoons HgX^+$$

These experiments (Figs. 1 and 2) were carried out using DC, and the experimental results were in agreement with the above results.

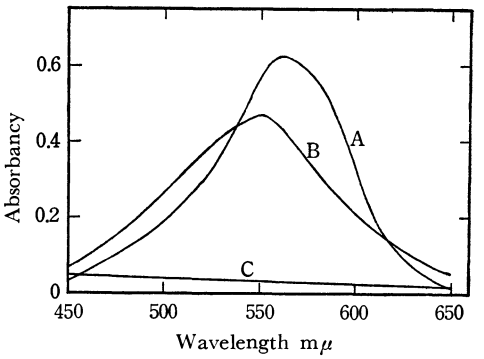

Fig. 3. Absorption spectra of Hg^{2+}-H_2DCN and HgI^+-H_2DCN complexes
Hg^{2+}(or HgI^+); 1.3×10^{-5} mol/*l*
H_2DCN; 2.6×10^{-5} mol/*l*
pH 7.0, at 25°C
A : HgI^+, B : Hg^{2+}, C : H_2DCN alone

Absorption Spectra. The absorption spectra of the benzene solution of the complex are shown in Fig. 3. The Hg^{2+}-H_2DCN complex has a maximum absorbance at 552 mμ, while the HgX^+-H_2CDN complex has its at 562 mμ, indicating that they are different.

Composition of the Complex. The compositions of the Hg^{2+}-H_2DCN and HgX^+-H_2DCN complexes were determined by the continuous-variation method. Mixed solutions of the Hg^{2+} (or HgX^+) and H_2DCN in various ratios were prepared, and the pH values of the solutions thus prepared were adjusted to 7.0, then the absorbances of the extracted benzene phase were measured at 562 mμ.

The results are shown in Fig. 4. The figure shows that either the Hg^{2+} or HgX^+ complex forms a 1-to-1 complex with H_2CDN. Moreover, the continuous-variation method was carried out using DC and H_4DCD. The mole ratio of DC and

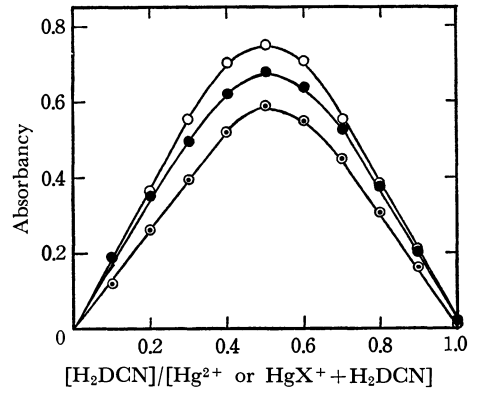

Fig. 4. Continious variation method
$[Hg^{2+}$ or $HgX^+] + [H_2DCN] = 4\times15^{-5}$ mol/*l*
Wavelength ; 562 mμ, at 25°C, pH 7.0
-○- HgI^+, -●- $HgBr^+$, -⊙- Hg^{2+}.

Hg^{2+}(or HgX^+) was also 1-to-1; on the other hand, H_4DCD did not form a complex at the concentration of 4×10^{-5} mol/*l*. The experimental results indicate that Hg^{2+} or HgX^+ forms a 1-to-1 complex with the H_2DCN which is present in the DC. These results were also conformed by further experiments using the mole-ratio method.

Gerlach *et al.*[11] have also reported a mole ratio of 1-to-1 between mercury(II) and diphenylcarbazone; on the other hand, a 1-to-2 complex has been reported by Feigl *et al.*[12]

If the so-called diphenylcarbazone(DC) is assumed to be a true diphenylcarbazone(H_2DCN), the mole ratio between mercury(II) and DC may become the 1-to-2 shown by Feigl *et al.*[12]

12) F. Feigl and F. L. Lendere, *Monatsh*, **45**, 115 (1924).

The reactions between mercury(II) or HgX^+ and H_2DCN may be expressed by the following equations;

$$Hg^{2+} + H_2DCN \rightleftharpoons HgDCN + 2H^+$$

$$HgX^+ + H_2DCN \rightleftharpoons HgXHDCN + H^+$$

As may be seen in Figs. 1 and 2, all the complexes are more stable at pH 7 than at pH 2.5. With regard to the effect of light, it has previously been reported[4] that the complex of HgXHDCN is more stable than that of HgDCN. The formation of the HgClHDCN complex is difficult under these conditions.[1]

The author wishes to express his gratitude to Professor Satori Utsumi of Nihon University for his kind guidance throughout this study.

Electrolytic Production of Lead Cyanamide

Kazuhide MIYAZAKI

Central Research Laboratory, Mitsui Mining & Smelting Co., Mitaka-shi, Tokyo

(Received November 20, 1967)

Lead cyanamide is an insoluble yellowish colored lead salt of cyanamide, designated as $PbCN_2$ or $Pb(HNCN)_2$ for its molar composition, and has been used fairly widely as anticorrosive pigment and is known to exhibit excellent protective performance, particularly in the field of marine applications.

However, production of the pigment seems to be relatively limited mainly because of its rather high production cost. The lead cyanamide has so far been synthesized through roundabout processing steps *via* intermediate soluble salts of lead such as acetate and nitrate[1] or insoluble lead compounds including litharge, PbO,[2] to provide the source of lead to combine cyanamide radical which usually comes from the leach of nitro-lime. Therefore, the production cost of lead cyanamide becomes substantially higher than those of many other anticorrosive lead pigments such as litharge which can be supplied in most cases *via* much fewer processing steps.

In this work an attempt has been made to establish a straightforward precipitation of lead cyanamide directly starting from metal lead as the source of lead to eliminate the need for the costly intermediate lead compounds, by applying the technique of soluble anode electrolytic process, and some of the important electrolytic variables are investigated to obtain the high grade lead cyanamide product.

Experimental

Materials. A commercial fertilizer grade nitro-lime whose cyanamide content as $CaCN_2$ was about 60% was leached with water and the leached solution was desulfurized by adding ferrous sulfate according to the conventional method. The concentration of $CaCN_2$ was controlled to from several to 10 g per liter of the purified leach. Sodium chlorate was then added as solubilyzer of lead anode in an amount of 10—80 g per liter and the final solution was provided as the electrolyte.

High purity lead of more than 99.9% Pb was cast into the form of electrodes with dimensions of 4 cm × 7 cm × 1 cm. The plate of anode was placed in between two plates of cathodes with anode-cathode distance of 5 cm.

Procedures. Electrolysis was carried out with a 2-liter experimental electrolytic cell with continuous circulation of electrolyte with fresh supply of cyanamide to maintain as homogeneous concentration as possible throughout the electrolytic run. The amperage was adjusted in the range of 1 to 3.5 A/dm^2, and the duration of electrolysis per each run was 8 hr.

Content of nitrogen as cyanamide form in the lead cyanamide precipitate was analyzed by the use of silver

1) *E. g.*, E. Blasiak and Z. S. Matsuszewski, Pol. Pat. 42862 (1960).
2) V. Koutnik and V. Novak, *Chem. Prumsi*, **9**, 18 (1959), *Chem. Abstr.*, **58**, 17445 (1959).

cyanamide precipitation method.[3-6] A quantity of 0.5 g of the lead cyanamide sample was dissolved with dilute nitric acid and the solution was passed through an ion exchange column which contained H^+-form Amberlite IR-120 resin to replace lead ion of the solution with hydrogen ion. Ammoniacal solution of silver nitrate was then added to the effluent to secure the cyanamide into the form of silver cyanamide, which was then dissolved with dilute nitric acid and the content of the cyanamide was determined by titrating the combined silver according to the Volhard method with a potassium thiocyanate solution using ferro-ammonium alum as indicator.

As for the alternative in expressing the composition of lead cyanamide, Costa and Bolis-Cannella[7] demonstrated that the analytical composition of their laboratoy-produced pigment was Pb 81.760, N 9.830, C 4.282, H 0.144, O and undetermined impurities of inorganic nature 3.984%, which was very near to $PbCN_2$ rather than $Pb(HNCN)_2$. The thermal work[8] on silver, copper, lead, and cadmium cyanamides exhibited that these compounds developed N, $(CN)_2$, CO_2 or CO when heated in air, and partially polymerized $(CN)_x$ when heated *in vacuo*,, respectively, with no decomposition product containing H. A recent work of Sole and Yoffe[9] to determine the nature of the bonds in the sodium, thallium, mercury, and lead cyanamides also showed that while sodium cyanamide was an ionic solid, silver and lead cyanamide salts were covalent ones. Accordingly, the composition of the product obtained in the present work was also expressed in terms of $PbCN_2$ basis instead of $Pb(HNCN)_2$.

Results and discussion

A series of experimentations have been carried out varying the composition of electrolyte and the current density, and the $PbCN_2$ content of the electrolytically obtained product is enlisted in Table 1. It is observed that the high grade lead cyanamide, the $PbCN_2$ content of which is more than 90%, has been obtained through one-step electrolytic process directly starting from the metal lead being attacked by the electrolyte composed of calcium cyanamide, supplier of CN_2^{-2} ion, and sodium chlorate, solubilyzer of the lead, with cell voltage of about 2—3 V.

It is seen that the increase in sodium chlorate concentration of the electrolyte increases the $PbCN_2$ content of the electrolytically precipitated product as illustrated in Fig. 1. The higher anodic current

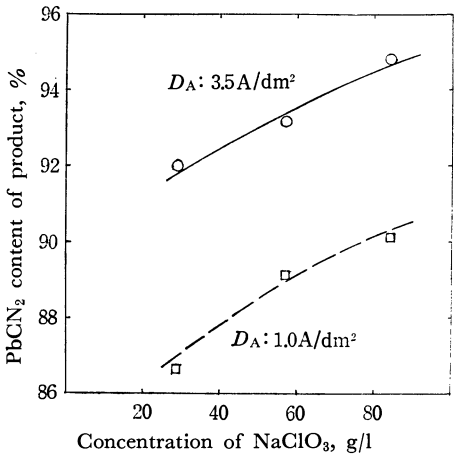

Fig. 1 Amount of $NaClO_3$ added to the electrolyte of 8 g $CaCN_2$/l *versus* grade of lead cyanamide obtained, in terms of applied current density.

density produces, the higher grade of lead cyanamide, *i. e.*, 92—95% of $PbCN_2$. The balance of the constituent is not yet definitely identified, however it may probably exist in the form of a basic oxide of lead. The values of $PbCN_2$ content in Table 1 is remarkably higher in comparison with those of the commercially available products marketed elsewhere including a sample from overseas which were found to be in the range of 82—84% $PbCN_2$ by the same analytical method.

It is to be noted, however, as is seen from Fig. 2, that when the original concentration of calcium cyanamide in the electrolyte is low, the increase of sodium chlorate will rather lower the grade of the pigment especially under higher current density. This is understood in such a way that the lead ion which is supplied from the anode in relatively excess amount over the cyanamide ion present in the electrolyte forms basic salts of lead to coprecipitate and dilute lead cyanamide content for the run.

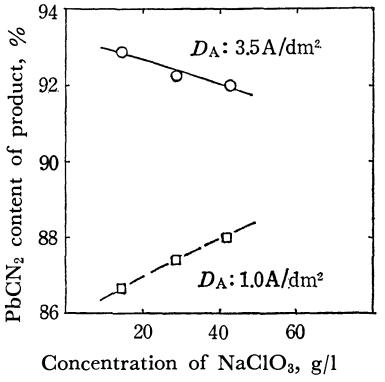

Fig. 2. Amount of $NaClO_3$ added to the electrolyte of 4 g $CaCN_2$/l versus grade of lead cyanamide obtained, in terms of applied current density.

The runs No. 1 through No. 6 and No. 7 through No. 12 in Table 1 divide total runs of experiment into two groups of $CaCN_2$ concentrations, *i. e.*, 8 and 4 g/*l*, while having same mixing ratios of $CaCN_2$ and $NaClO_3$ for the each adjacent runs respectively. It is interesting to note that the $PbCN_2$ content of a product obtained with a given $CaCN_2$-$NaClO_3$ combination will not depend solely on the mixing ratio of $CaCN_2$ and $NaClO_3$ even under a same anodic current density, but is largely determined by the concentration of the existing $CaCN_2$. It is seen that the higher concentration of $CaCN_2$ in the electrolyte gives rise to the higher grade of lead cyanamide.

It should be pointed out, therefore, that the proper choice of conditions is necessary to run favorable electrolysis of high quality lead cyanamide pigment. Continuation of electrolysis down to a too low concentration of $CaCN_2$ with high current density should cautiously be avoided.

Summary

Electrolytically precipitating process has been examined to obtain anti-corrosive lead cyanamide pigment, eliminating the need for the conventional intermediate lead compounds such as litharge. A soluble electrolysis of metallic lead anode has been carried out with calcium cyanamide electrolyte which contains a proper amount of sodium chlorate as a solubilyzer of anode. The electrolytically operated product was of a higher grade of lead cyanamide of 92—95% $PbCN_2$, in comparison with the conventionally available pigment of 82—84% $PbCN_2$. The $CaCN_2$-$NaClO_3$ ratio, $CaCN_2$ concentration and anodic current density have been found to be of major importance which primarily govern the quality of product.

Bakkenolide-E, a Minor Component of the Bud of *Petasites japonicus*, subsp *giganteus* Kitam.

Kunikatsu SHIRAHATA*, Nobuo ABE**, Tadahiro KATO* and Yoshio KITAHARA*,[1]

I R_1=H R_2=H

II R_1=OAc R_2=OCOC(=CHCH_3)CH_3

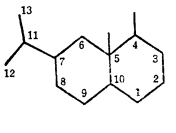
III R_1=OH R_2=OCOC(=CHCH_3)CH_3

IV R_1=OAc R_2=OCOC(=CHSCH_3)H

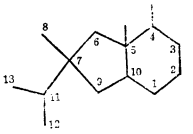
VII R_1=OAc R_2=OCOC(=CHCH_3)CH_3

VIII R_1=OH R_2=OH

These compounds belong to a new type of sesquiterpenoids and have the novel carbon skeleton (V), to which the authors propose to give the name "bakkane." Since many sesquiterpenoids with the eremophilane skeleton (VI) have been isolated[4,5] from the same genus, *Petasites*, the bakkane is biogenetically related with the eremophilane skeleton. The mode of the biogenesis of the bakkane might be bond fission at C_8 and C_9, with a concomitant bond formation at C_7 and C_9 of the eremophilane, but we can not yet define the direct precursor with the eremophilane skeleton and the oxidation stages at C_8, C_{11} and C_{12} of bakkenolide-A, from which the other bakkenolides might be biosynthetized. It is, therefore, desirable to make clear the components which might be expected to be biogenetically important intermediates so as to discuss the biogenesis of the bakkenolides of the plant.



VI



V

From this point of view, the minor components of the essential oil of the plant were investigated in detail.

The gas chromatograph of the oil shows the presence of at least nine components, in addition to compounds I—IV, from which the new compound, bakkenolide-E, was isolated.

Bakkenolide-E, (VII), mp 168°C (from ethanol) has the molecular formula of $C_{22}H_{30}O_6$ (found: C, 67.90; H, 8.00%). The IR spectrum (KBr) of VII suggests the presence of the following groups; γ-lactone at 1792 cm^{-1}, two different types of carboxylates at 1740 and 1700 cm^{-1} (acetate and tiglate), and exocyclic methylene at 1650 and 910 cm^{-1}.

VII, when hydrolysed with 25% potassium hydroxide in aqueous methanol, affords tiglic acid (identified by comparison with an authentic sample) and 1,9-dihydroxybakkenolide-A (VIII). The latter compound was also obtained from II, III, and IV by the same treatment, thus indicating that VII is a derivative of bakkenolide-A with tiglate and acetate (from IR and NMR) groups.

The similarities of the NMR spectra of bakkenolides-E and -B (Table 1) demonstrate that the acetate and tiglate groups of VII are located at C_9 and C_1 of bakkenolide-A respectively.

The other, minor components of the oil are now being investigated.

The authors wish to acknowledge their indebtedness to Messrs. S. Sakata, H. Kamata and M. Saga for their assistance with the collection and extraction of the plant material. One of the authors (N. A.) wishes also to thank Professor R. Onoda of Akita University for his kind encouragement.

SHORT COMMUNICATIONS

Isotope Effects on the Hydrogen Formation Reaction in the Radiolysis of Cyclopentanone

Kinya UNOURA, Masayuki AIKAWA and Meiseki KATAYAMA[1]

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received April 12, 1968)

Hydrogen gas has been found to be one of the major products of the radiolysis of cyclopentanone in the liquid phase[2,3] but not in the photolysis,[4] while there are many common major reaction products in the two processes. The uniqueness of the hydrogen formation in this sense led us to study the reaction in detail in the hope of acquiring a knowledge of the excited species in the radiolysis different from the well-defined ones in the photolysis.[4,5]

Either a degassed sample, containing 0.5—1 m*l* each of cyclopentanone, cyclopentanone-d_8, and 2,2,5,5-cyclopentanone-d_4, or a mixture of cyclopentanone and cyclopentanone-d_8, was sealed into a reaction vessel and irradiated with γ-rays from a cobalt-60 source at a dose rate of 3.7×10^6 rad/hr. The amount of hydrogen formed was proportional to the absorbed dose, as has been reported previously.[2] The isotopic composition of the hydrogen gas was analyzed by means of a mass spectrometer.

The mechanism of the hydrogen formation may be summarized as:

$$\text{cyclopentanone} \xrightarrow{\Phi} (\text{cyclopentanone}^*)$$

$$\begin{cases}\rightarrow \text{hydrogen gas} + \text{residue} & (1)\\ \rightarrow \text{hydrogen atom} + \text{residue} & (2)\end{cases}$$

$$\text{hydrogen atom} + \text{cyclopentanone} \rightarrow \text{hydrogen gas} + \text{residue} \quad (3).$$

The yields of protium, $G(H_2)$, from cyclopentanone and of deuterium, $G(D_2)$, from cyclopentanone-d_8 were 0.60 ± 0.12 and 0.22 ± 0.04 respectively. The $G(H_2)/G(D_2)$ ratio was about 3, apparently indicating that such a rate constant as Φ is about three times larger in cyclopentanone than in cyclopentanone-d_8.

The $H_2 : D_2 : HD$ ratio in the hydrogen formed from the 1 : 1 mixture of cyclopentanone and cyclopentanone-d_8 was 5.6 : 1.0 : 3.6 It can readily be shown[6] that, in the mixture, if the isotope effects do not exist in such steps as (3), the ratio of $H_2 : D_2 : HD$ will range from approximately 3.0 : 1.0 : 2.0 to 3.0 : 1.0 : 0, depending on the magnitude of the molecular hydrogen contribution, *i. e.*, such second steps as are shown in reaction (1). The deviation of these values from the experimental value indicates the existence of such an isotope effect as well as the molecular hydrogen contribution. The ratio of $H_2 : D_2 : HD$ in the hydrogen formed from 2,2,5,5-cyclopentanone-d_4 was 1.5 : 1.0 : 2.9.*1 It can also be shown[6] that the ratio will be 1.0 : 1.0 : 2.0 if no such isotope effect, no molecular hydrogen formation, and no difference in the reactivities between hydrogens attached to α and β positions to the carbonyl group are assumed. The difference between the ratio found and that predicted in the partially-deuterated cyclopentanone suggests the existence of the isotope effect also or of different reactivities in addition to the isotope effect. Although the contribution of molecular hydrogen is indicated by the presence of 2-cyclopentenone among the radiolysis products[2b] as well as by the analytical results mentioned above, the contribution of "hot hydrogen" is also suggested by the fact that a relatively large amount of HD was found in the mixture of cyclopentanone and cyclopentanone-d_8, as well as by the fact that the amount of hydrogen reduced by the addition of such radical scavengers as DPPH was rather small.[2b]

A Preparation Method of Dicyano-Cobalt(III) Complexes using Silver Cyanide

Nobufumi MAKI, Taihei HAMAZAKI and Shukichi SAKURABA

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received March 13, 1968)

The CN^- ion is located at the end position of the spectrochemical series and has the strongest coordinating ability of cobalt(III) complexes of the Werner-type, while Cl^- ion is located above this. Such a difference in bonding character between them is the reason why direct substitution[1] is difficult. For example, the $[Co(CN)_2en_2]^+$ ion can be obtained only *via* the $[Co(S_2O_3)_2en_2]^-$ ion.[2]

In the present report, however, the substitution of Cl-ligands has been found possible even in water solution under the condition that CN^- ions are present in a very dilute concentration. For this purpose, we have adopted silver cyanide, the solubility of which in water is $2.2\cdot10^{-5}$ g/100 g water (20°C), and succeeded in obtaining directly dicyano-cobalt(III) complexes including new compounds, *cis*-$[Co(CN)_2dip_2]NO_3\cdot7H_2O$ and *cis*-$[Co(CN)_2phen_2]NO_3\cdot6H_2O$.[3]

Preparation of cis-$[Co(CN)_2en_2]NO_3$. To a suspension of *trans*-$[CoCl_2en_2]NO_3$(20 g) in 200 m*l* of water were added 20 g of AgCN powder. The paste-like mixture was further diluted with 500 m*l* of water after half an hour and heated on a water bath (90°C) for three hours. The solution was filtered, and the yellow filtrate obtained was concentrated on a water bath by evaporation and allowed to stand. On cooling, yellow crystals separated from solution. The crude product was recrystallized once from hot water. Found: Co, 19.77; C, 24.09; N, 33.59; H, 5.83%. Calcd for $[Co(CN)_2en_2]NO_3$: Co, 20.10; C, 24.58; N, 33.44; H, 5.50%.

The perchlorate was similarly prepared by using *trans*-$[CoCl_2en_2]ClO_4$ as the starting complex instead of the nitrate. Found: Co, 17.91; C, 21.63; N, 25.17; H, 4.90%. Calcd for $[Co(CN)_2en_2]ClO_4$: Co, 17.82; C, 21.80; N, 25.42; H, 4.88%.

Preparation of cis-$[Co(CN)_2dip_2]NO_3\cdot7H_2O$. Dicyanobis(2,2'-dipyridyl)cobalt(III) complex was prepared by the following method: Fifteen grams of *trans*-$[CoCl_2dip_2]NO_3$[4] were mixed with AgCN (10g) and a few milliliters of water. The paste-like mixture was allowed to stand for a while and further diluted with 500 m*l* of water. The mixture was heated on a water bath (70—80°C) for an hour and filtered. The residue was repeatedly extracted with hot water. The extracted solution and filtrate were added together and concentrated by evaporation. On cooling, lustrous needle-shaped yellow crystals deposited from solution, which were then filtered and washed with cold water, ethanol and ether. The product was recrystallized once from hot water. Found: Co, 11.98; C, 54.19; N, 19.95; H, 3.41%. Calcd for $[Co(CN)_2dip_2]NO_3$: Co, 12.14; C, 54.45; N, 20.20; H, 3.32%.

Preparation of cis-$[Co(CN)_2phen_2]NO_3\cdot6H_2O$. Twenty grams of *trans*-$[CoCl_2phen_2]NO_3$[5] were treated with 15 g of AgCN in 500 m*l* of water at 60—70°C for an hour. Silky yellow crystals deposited from the filtrate. Found: Co, 10.87; C, 58.31; N, 18.11; H, 3.38%. Calcd for $[Co(CN)_2phen_2]NO_3$: Co, 11.05; C, 58.55; N, 18.38; H, 3.02%. The NMR spectra in 99.75% D_2O indicated that the complexes were cis-isomers, as shown in Fig. 1.

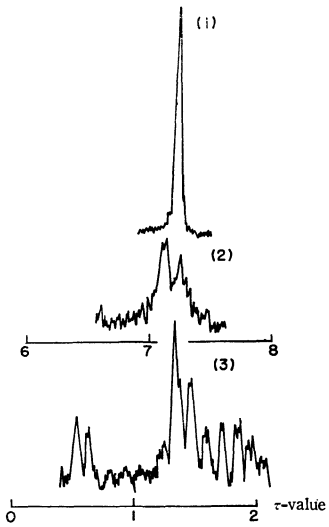

Fig. 1. The NMR spectra of dicyano-cobalt(III) complexes obtained in 99.75% D_2O; (1) *trans*-$[Co(CN)_2en_2]NO_3$, (2) *cis*-$[Co(CN)_2en_2]NO_3$, (3) *cis*-$[Co(CN)_2dip_2]NO_3\cdot7H_2O$.

On the ESR Studies of the Photoisomerization of Triethylphosphite

Kinichi TERAUCHI and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Oaza-Yamada-Kami, Suita, Osaka

(Received March 26, 1968)

Although a number of inorganic phosphorus compounds have been studied by means of the ESR technique, a few reports have been published on the organic phosphorus compounds especially, UV-irradiated trialkylphosphite has never been subjected to ESR measurements. In this study, we wish to report the results obtained by the ESR measurements using the elevated-temperature method. We undertook those measurements in order to investigate the mechanism of the following photoisomerization reaction[1]:

$$P(OEt)_3 \xrightarrow{h\nu} EtP(O)(OEt)_2$$

This reaction has recently been reported on by LaCount *et al.*,[2] also but they have not suggested any mechanism for the photochemical formation of the phosphonate.

When a degassed sample of neat triethylphosphite (TEP) was irradiated at 77°K with a 400 Watt high-pressure mercury arc, two kinds of ESR signals were observed, as is shown in Fig. 1a. The (P_1) spectrum has an anisotropic doublet of 370—600 gauss separation and a high g value (2.02), while the other (spectrum C) contains an sixfold line of 25.6 gauss separation and a g value close to the free spin value. The P_1 spectrum showed a characteristic change upon the elevation of the temperature; when the temperature was raised to 100°K, the P_1 spectrum disappeared completely and a new ESR signal (P_2 spectrum) with an anisotropic doublet of 713—870 gauss separation and a g value of 2.03 appeared (Fig. 1b). The observed g and A values of P_1 and P_2 are summarized in Table 1. At 110°K, the P_2 signal vanished.

TABLE 1. LIST OF PHOSPHORUS-RELATED RADICALS FORMED IN IRRADIATED TEP

	$A_\perp$(G)	$A_\parallel$(G)	$\bar{g}$
P_1 Spectrum	596	369	2.021
P_2 Spectrum	860	713	2.032

On the other hand, the C spectrum did not show any significant change except for a great decrease in the intensity during the ESR measurements. The C spectrum as is shown in Fig. 1c, was identified as an ethyl radical. It is well known that the phosphorus atoms in trivalent phosphorus compounds take p^3-hybrid and partially sp^3 hybrid, while in tetravalent phosphate compounds the phosphorus atoms take stable sp^3 hybridization. There fore, the spectra with regard to phosphorus radicals obtained from the trivalent phosphorus compounds may be expected to have a large anisotropic character of a hyperfine structure. When we calculated the orbital spin density of an unpaired electron of these radicals from the isotropic and anisotropic parts of the hyperfine coupling tensor, it is estimated that P_1 has 12.3% 3s- and 73.9% 3p-character, while P_2 has 21.3% 3s- and 50.8% 3p-character. Thus, we may assign the P_1 radical to the $\rangle PO\cdot$-type radical with a p^3 hybrid and the P_2 radical to the $\rangle \dot{P}(O)$-type radical with a sp^3 hybrid. Therefore, the photochemical primary processes of TEP may be depicted as follows:

An Estimation of the Propagation Rate Constant for the Radiation-Induced Polymerization of Gaseous Isobutene

Yasuyuki NORO, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering Nagoya University, Chikusa-ku, Nagoya

(Received April 23, 1968)

In a previous paper,[1] we have shown that the cationic mechanism dominates in the radiation-induced polymerization of gaseous isobutene. Since it is well established by a number of studies in the field of radiation chemistry that ammonia is an efficient proton acceptor and neither a radical nor electron scavenger, ammonia may be used for an estimation of the propagation rate constant on the basis of the assumption that the mechanism of radiation-induced polymerization of gaseous isobutene is cationic.

In this communication, we report the propagation rate constant and the mean lifetime of the propagating ion estimated in a quantitative study of the effect of ammonia on this polymerization.

Figure 1 shows a plot of the G-value for monomer consumption *vs.* the mole ratio of isobutene to ammonia at 500 Torr and 20°C. In Fig. 1, a straight line can be drawn through the experimental points at low concentrations of ammonia. We put on this result an interpretation that the linear portion of the curve indicates the retardation by ammonia of the polymerization due to ions surviving as a result of diffusional loss of electrons on the vessel wall and the curved portion at higher concentrations of ammonia corresponds to that due to ions which undergo gas-phase recombination.

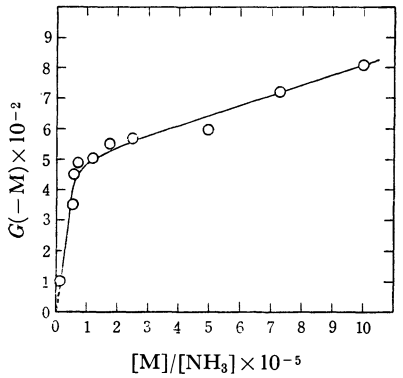

Fig. 1. The dependence of the polymerization yield on the mole ratio of isobutene to ammonia.

We apply the Klots-Anderson theory[2] to an estimation of the fraction of gas-phase recombination, f. A dimensionless parameter, κ, is defined by $\kappa^2=R^4I\alpha/D_+D_-$, where R is the radius of the vessel, I is the rate of ion-pair generation per unit volume, α is the bimolecular recombination coefficient, and D_+ and D_- are the diffusion coefficients for positive ions and electrons respectively. Taking $R=4$ cm, $I=2\times10^{11}$ ions $cm^{-3}sec^{-1}$, $\alpha=10^{-7}$ $cm^3ions^{-1}sec^{-1}$, $D_+=3\times10$ cm^2sec^{-1} and $D_-=2\times10^2$ cm^2sec^{-1}, we obtain $\kappa=920$. From Fig. 1 of Klots and Anderson, it can be estimated that this corresponds to 90% gas-phase recombination, $f=0.9$, and 10% loss by diffusion, $1-f=0.1$.

We can now evaluate the propagation rate constant, k_p, using the relation[3]

$$G(-M) = G_x \frac{k_p}{k_r} \frac{[M]}{[NH_3]} + G_c(-M), \qquad (1)$$

where k_r is the rate constant for termination by ammonia, which is of the order $10^{10\pm1}$ $M^{-1}sec^{-1}$, and $G_x=G_i\times(1-f)$, G_i is the ion-pair yield per 100 eV absorbed. From the slope of the linear portion in Fig. 1 and Eq. (1), we obtain $k_p=8.3\times10^{6\pm1}$ $M^{-1}sec^{-1}$.

The mean lifetime of a propagating ion during growth in the pure monomer is given by

$$\tau_p = G_0(-M)/G_xk_p[M]. \qquad (2)$$

Using the value $G_0(-M)=1000$ for pure isobutene and the previous values for G_x and k_p, we obtain $\tau_p=10^{-2\pm1}$ sec.

Since there is some ambiguity in the recombination coefficient and the diffusion coefficients in addition to the rate constant for termination by ammonia, the values for k_p and τ_p should be taken as representing the order of their magnitudes.

A New Synthesis of 3-Hydroxyfurans. The Reaction of Sulfonium Ylids with Ketene Dimer

Hisashi TAKEI, Moriaki HIGO, Kunio SAITO and Teruaki MUKAIYAMA

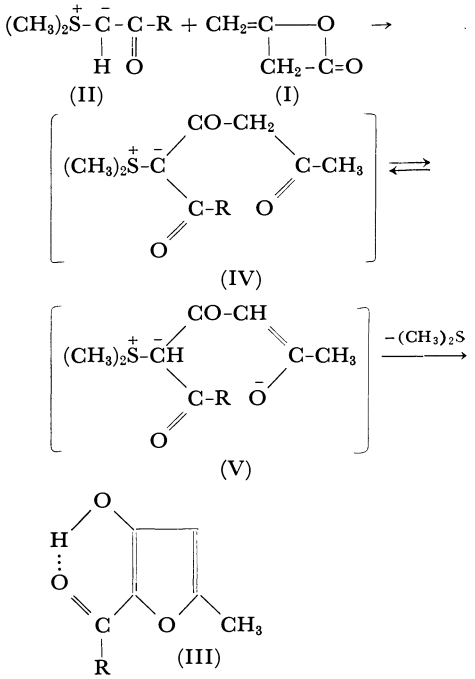
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 25, 1968)

This communication reports a convenient method for the synthesis of 3-hydroxyfuran derivatives, structurally resemble to isomaltol which is obtained from lactose,[1] by the reactions of ketene dimer (I) and some stabilized ylids. A typical run was as follows; ketene dimer was added to a dry benzene solution of dimethylsulfonium *p*-bromophenacylid (IIa) at room temperature under nitrogen. When the solution was refluxed for a short time, evolution of dimethyl sulfide was observed by its characteristic odour. After removal of the solvent, a resulting yellow precipitate was purified by a silica gel column to afford slightly yellow crystals, 2-(*p*-bromo benzoyl)-3-hydroxy-5-methylfuran (IIIa).[2]

Similarly, 2-(*p*-substituted benzoyl)-, 2-acetyl-, 2-ethoxycarbonyl- and 2-diethylcarbamoyl-3-hydroxy-5-methylfurans were successfully synthesized by the reactions of the ylids, IIb-d, IIe, IIf and IIg, with ketene dimer in high yields. The results are summarized in Table 1.

The reaction can be considered to proceed through an initial formation of dimethylsulfonium acetoacetyl-(acyl)-methylid (IV) from II and I. The ylid IV, subsequently, is transformed into its tautomeric structure (V), which, on heating, decomposes to give III and dimethyl sulfide by an intramolecular nucleophilic displacement as shown below.



In conclusion, it is noted that this method enables to convert ketene dimer into 3-hydroxyfuran derivatives accompanied with ring expansion by the so-called methylene transfer.

The Catalytic Activities and Electron Configuration of Poly-Negative Phthalocyanine Complex Films with Lithium

Masaru ICHIKAWA, Mitsuyuki SOMA, Takaharu ONISHI and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received April 30, 1968)

It was previously reported that various phthalocyanines exhibit marked heterogeneous catalytic activities in many reaction systems, such as the H_2-D_2 exchange reaction, the hydrogenation of olefins, and the isomerization of butenes, at room temperature when they are exposed to a small amount of sodium or lithium.[1]

In this communication it will be demonstrated that such catalytic activities of the phthalocyanine electron donor-acceptor (EDA) complex films are not responsible for the reduced central metal ions of phthalocyanines, but for the poly-negatively-charged porphyrin ligands, where the excess electrons ($n=1$ to 4) are seemingly distributed in the π-systems.

Taube and other workers[2] have prepared many types of poly-negative ions of phthalocyanines, and their properties have been partly established by the iodine titration and measurements of the magnetic susceptibility of their stoichiometric salts with lithium.

In these experiments 50 mg portions of Fe-, Co-, Ni-, and Zn-phthalocyanines were reacted with lithium benzophenone ketyl, Li-naphthalene, Li, and Na in tetrahydrofuran at various stoichiometric ratios. The stoichiometric complex solutions exhibited their characteristic visible spectra. Various kinds of poly-negative ion complex films were prepared over silica wool (their surface areas were *ca.* 10 m^2) by the evaporation of the solvent from each complex solution. The results of the iodine titration of the complex films were in agreement with the expected stoichiometry. The reactions were carried out in the temperature range between 20 and 120°C over each complex film in a closed circulating system (the dead-volume was *ca.* 140 m*l*). The reaction product was analyzed by gas chromatography using an alumina column. Some typical results are summarized in the table, as are the relative activities for the hydrogen-exchange reaction between molecular hydrogen and the hydrogen in each of the complex films, the H_2-D_2 exchange reaction, the hydrogenation of propylene, and also the electron configuration of each poly-negative ion of the phthalocyanines,

TABLE

Complex	Electron configuration	D_2-HZ[a] $3+\log k$	H_2-D_2[b] $3+\log k$	$C_3+H_6+H_2$[c] % conversion
FePc	d_6	—	—	—
LiFePc	d_7	—	—	—
Li_2FePc	d_8	0.1	0.2	—
Li_3FePc	$d_8+\pi$	0.6	0.9	10
Li_4FePc	$d_8+\pi^2$	2.0	2.1	70
NiPc	d^8	—	—	—
LiNiPc	$d^8+\pi$	0.4	0.3	5
Li_2NiPc	$d^8+\pi^2$	1.3	1.3	28
Li_3NiPc	$d^8+\pi^3$	1.7	2.0	60
Li_4NiPc	$d^8+\pi^4$	2.1	2.5	82

a) HZ represents the EDA complexes. $k(hr^{-1})$ at 60°C, $P_{D_2}=12.5$ cmHg

b) $k(hr^{-1})$ at 60°C, $P_{H_2+D_2}=15$ cmHg, H_2:D_2=1:1

c) C_3H_6:H_2=1:2 at 60°C in 20 hr.

which were reported by Taube.

It is suggested in this table that the catalytic activities for the hydrogen exchange and hydrogen chemisorption are not observed even at higher temperatures over the $FePc^{-1}$, $FePc^{-2}$, and $CoPc^{-1}$ complex films with lithium cations, in which one or two electrons are localized in their bivalent central metal ions. However, the H_2-D_2 exchange reaction and the hydrogenation of propylene takes place at a considerable rate at room temperature over the $FePc^{-3}$, $FePc^{-4}$, $CoPc^{-2}$,…, $CoPc^{-5}$, $NiPc^{-1}$…, $NiPc^{-4}$, and $ZnPc^{-1}$, $ZnPc^{-4}$ complex films, in which excess electrons are delocalized in the π-system of the porphyrin ligands. In addition to this, such complex films of higher negative ions as $NiPc^{-4}$ and $NiPc^{-3}$, $CoPc^{-5}$, and $FePc^{-4}$ are much more active for the reactions than the complex films of a lower negativity under similar reaction conditions. As the number of delocalized electrons in the porphyrin ligand increases, the reactivities of the porphyrin are markedly enhanced. Upon contact with hydrogen gas, the absorption peaks of $FePc^{-4}$ (620 and 860 mμ) gradually decrease and new peaks appear in the regions of 570 mμ and 520 mμ; these peaks resemble those of $FePc^{-3}$ and $FePc^{-2}$. The spectra were restored completely to that of the $FePc^{-4}$ complex film by evacuation at 40°C for several hours.

A New Ion-exchange Method for the Determination of Polymerization Number of Metal Salt in Nonaqueous Solutions

Hirohiko WAKI and Nobuyuki UEMURA

Department of Applied Analytical Chemistry, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received April 23, 1968)

Although studies on ionic species present in solution with ion-exchange resins have been made by a number of workers, almost all of them have been on the determination of the ionic charge or stability constants of metal complexes, and polymerization equilibria have been left because of difficulties in theoretical treatment.

The polymerized molecule of a metal salt MA_a may be ionized in nonaqueous solvents of low dielectric constants in the following form:

$$2M_nA^0_{an} \rightleftarrows M_nA^+_{an-1} + M_nA^-_{an+1} \quad (1)$$

The equilibrium constant for Eq. (1) is written as

$$K_{ioniz} = \frac{[M_nA^-_{an+1}]^2}{[M_nA^0_{an}]^2} \quad (2)$$

In such a solvent most part of the salt may remain unionized as the neutral $M_nA^0_{an}$ and the ionic species of higher charges $|i| \geqq 2$ may hardly be produced. In an anion exchange resin phase these neutral and cationic complexes may be converted into the anionic form $M_nA^-_{an+1}$ to a large extent by combining with the resin counter ion A^-. Under these conditions, the distribution coefficient of M is given in the following form:

$$D \equiv \frac{[\sum M]_R}{[\sum M]} \approx \frac{[M_nA^-_{an+1}]_R}{[M_nA^0_{an}]+2[M_nA^-_{an+1}]}$$

$$= \frac{[M_nA^0_{an}]_R}{[M_nA^0_{an}]} \cdot \frac{\beta_R}{1+2\sqrt{K_{ioniz}}} \cdot [A^-]_R \quad (3)$$

where $\beta_R = [M_nA^-_{an+1}]_R/[M_nA^0_{an}]_R[A^-]_R$. Neglecting the neutral complexes of the metal salt present in the resin phase, uncomplexed $[A^-]_R$ is given as:

$$[A^-]_R = C - \frac{1}{n}[\sum M]_R \quad (4)$$

where C represents the exchange capacity of the anion exchange resin. Assuming that $[M_nA^0_{an}]_R/[M_nA^0_{an}]$, K_{ioniz} and β_R are effectively constant, the following equation can be derived from Eqs. (3) and (4).

$$\log D = \log(C - \frac{1}{n}[\sum M]_R) + K \quad (5)$$

where K is a constant. Hence by comparing the slope of experimental curve of log D vs $[\sum M]_R$ with those of theoretical curves obtained by inserting $n=1,2,\cdots$ into $\log(C-1/n[\sum M]_R)$ for corresponding $[\sum M]_R$, n can be presumed.

In case of $AlCl_3$-tetrahydrofuran (THF) solution, the following type of ionization is presumed from conductivity data.

$$2Al_nCl^0_{3n} = Al_nCl^+_{3n-1} + Al_nCl^-_{3n+1}$$

The experiment was carried out by passing $AlCl_3$-THF solutions of various concentrations through a small column containing 1 g of the resin Amberlyst

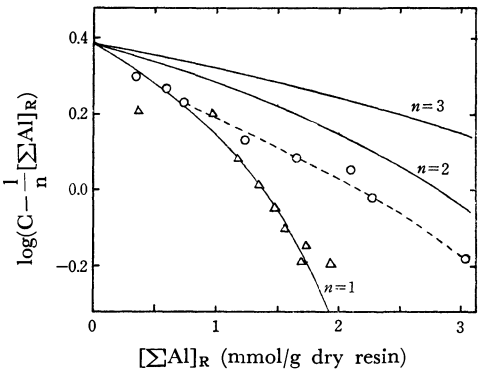

Fig. 1. The determination of the polymerization number "n" of $AlCl_3$ in THF by anion-exchange. ○: 24 hr △: 96 hr

A-27 Cl^- type of commercial particle size, followed by stripping the sorbed aluminum with diluted HNO_3 after equilibrium, and determining Al by EDTA titration. D was calculated in an ordinary way.

The experimental plots of log D *vs.* $[\sum Al]_R$ are compared with the theoretical lines of log $(C-1/n[\sum Al]_R)$ *vs.* $[\sum Al]_R$ in Fig. 1. It may be seen from the graph that the dimer species $Al_2Cl^{0\mp1}_{6\pm1}$ is predominant in THF solution for the Al concentration range larger than 0.2 mol/*l* in solution 24 hr after the preparation of $AlCl_3$-THF stock solution, and the monomeric $AlCl^{0\mp1}_{3\pm1}$ is predominant for the whole concentration range of Al at 96 hr after. These results may indicate that the dimer or higher Al-Cl complexes are produced immediately after the solution of $AlCl_3$ and the Cl-bridge in $\rangle Al\langle^{Cl}_{Cl}\rangle Al\langle$ gradually disappears by the attack of THF molecules.

The proposed method seemed to be valid in the system of low polymerization number like metal salts dissolved in nonaqueous solvents. Details of this work will be reported later.

The Formation of 3-Methyloctan-4-one and Polyketones by the Oxo Reaction of Butadiene

Masayuki DOKIYA and Ken-ichiro BANDO

Government Chemical Industrial Research Institute, Tokyo, Meguro-ku, Tokyo

(Received April 30, 1968)

It has previously been established that nonan-5-one, together with *n*- and isovaleraldehyde, is formed by the oxo reaction of butadiene catalysed by dicobalt octacarbonyl,[1,2] but neither branched-chain C_9-ketone nor polyketones.

We have found that 3-methyloctan-4-one (I) and polyketones ($C_4H_9\cdots(CC_4H_8)_n\cdots C_4H_9$, II, O) are also formed by the oxo reaction of butadiene.

The reaction of butadiene (8.1 g) with synthesis gas ($H_2/CO=1.3$: initial pressure, 230 kg/cm^2 at room temp.) was carried out at 165±5°C for 2 hr in a stainless-steel autoclave (100 m*l*) using cyclohexane (30 m*l*) as the solvent and dicobalt octacarbonyl (0.68 g) as the catalyst.

The gas chromatogram of the reaction products showed the presence of Compound I (0.77 g), which had a retention time near to that of nonan-5-one, and several compounds of a longer retention time in addition to the previously-known products (*n*-C_5-aldehyde: 1.34, iso-C_5-aldehyde: 0.75, *n*-C_5-alcohol: 0.33, iso-C_5-alcohol: 0.15, nonan-5-one: 1.48 g). A white, waxy material, II (4.6 g), was separated from the reaction products by the addition of aqueous methyl alcohol after the decobaltation.

The IR spectrum of I showed the existence of a carbonyl group (1715 cm^{-1}). The NMR spectrum, measured in $CDCl_3$, with tetramethylsilane used as the internal standard, showed bands at 9.1 (multiplet, $-C-CH_3$, 6H), 8.9 (doublet, $-\overset{\overset{O}{\|}}{C}-CH_3$, 3H), 8.6 (multiplet, $-C-CH_2-C-$, 6H) and 7.6 τ (multiplet, $C-\overset{\overset{O}{\|}}{C}H-C-$, 3H). Found: mol wt 142 (by mass spectrum). Calcd for $C_9H_{18}O$: mol wt 142. It was concluded from these results that I was 3-methyloctan-4-one.

The IR spectrum of II was essentially identical with that of I in the NaCl region. The NMR spectrum of II showed bands at 9.1 (broad, $-C-CH_3$, 22%H), 8.5 (broad, $-C-CH-C-$, 43%H) and 7.9 τ (broad, $-C-\overset{\overset{O}{\|}}{C}H-C-$, 35%H). Found: C, 72.60: H, 10.90%: mean mol wt 1180 (V.P.O. in benzene). Calcd for $(C_6H_{11}O)_n$: C, 72.8: H, 10.6%. The IR and NMR spectra showed no peaks characteristic of C=C, ester, aldehyde, or carboxylic acid. It was concluded from these results that II was mainly a mixture of polyketones, $C_4H_9\cdots(CC_4H_8)_n\cdots C_4H_9$, O, in which carbonyls were not always inserted regularly.

The yield of polyketones increased with the amount of charged butadiene under the same reaction conditions (Table 1).

Table 1. The yield of products (g)*1

Charged butadiene	5.4	8.1	10.8	13.5	16.2
C_5-aldehyde (*n*+iso)	1.81	2.09	2.40	1.94	0.41
Nonan-5-one	1.07	1.48	2.15	2.43	0.68
3-Methyl-octan-4-one	0.40	0.77	1.16	1.50	0.24
Polyketones	0.4	4.6	7.3	9.5	14.5

*1 The reaction conditions were similar to that described in the example.

The reaction scheme of the formation of polyketones may be represented as follows:

The Specific Hydrogen Bonding of Riboflavin Derivatives to an Adenine Compound

Yoshimasa KYOGOKU and Byung Sul YU

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo

(Received May 9, 1968)

Riboflavin-2',3',4',5'-tetraacetate was prepared by the reaction of riboflavin with acetic anhydride in pyridine. Yellow flaky crystals were obtained (mp 246°C). In the infrared spectrum of the 0.02 M solution (in $CDCl_3$) of riboflavin tetraacetate (R), a strong band due to the free imino group of the isoalloxazine ring is observed at 3380 cm^{-1} (Fig. 1 R), indicating that most of the riboflavin tetraacetate molecules are present as monomers. The infrared spectrum of 9-ethyladenine (A) shows two strong bands at 3527 and 3416 cm^{-1} which are due to the non-bonded amino group[1] (Fig. 1 A). When both solutions are mixed together, however, the association bands of the R-A complex appear at 3485, 3330, 3255 and 3200 cm^{-1} (Fig. 1 R+A). Using procedures described previously[1], the association constant for the formation of the R-A complex at 25°C was determined to be 130 (*l*/mol of dimer), as compared with the self dimerization constant of riboflavin tetraacetate (4.5) and of 9-ethyladenine (3.1).

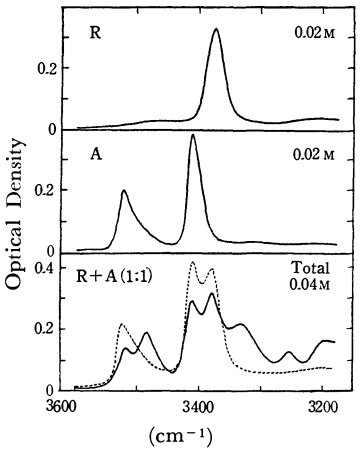

Fig. 1. Infrared spectra of the deuterochloroform solutions in a 1 mm quartz cell. Solid line: observed spectra. Dotted line: calculated sum of the upper two spectra.

From the mixing curve (the intensity of the association bands *vs.* mole fraction) and also from an analysis of the spectra in the carbonyl stretching region, the R-A complex was found to be the 1 : 1 cyclic dimer in which two hydrogen bonds are formed between the amino group of the ethyladenine molecule and one of the carbonyl oxygen atoms of the isoalloxazine ring and between the imino group of the riboflavin molecule and the nitrogen atom, probably, of the adenine ring. It has also been found that riboflavin tetraacetate does not associate with 1-cyclohexyluracil, 2',3'-benzylidine-5'-trityl-guanosine and -cytidine to any observable extent at 0.008 M. A similar experiment has been made with riboflavin tetrabutyrate.*1 The results were quite similar to those obtained for riboflavin tetraacetate.

Present results suggest the formation of the coplanar complex of the adenine and isoalloxazine rings in the flavin adenine dinucleotide (FAD) molecule, in contrast with the ring-stacking model proposed by Tsibris *et al.*[2]

Recently it has been shown that barbiturates form strong specific hydrogen bonds with the adenine residue.[3] The association constant for the formation of the phenobarbital-9-ethyladenine complex is 1200. Barbiturates are known to be inhibitors in the respiratory chain in mitochondria, where FAD serves as an electron carrier. It is suggested, therefore, that barbiturates inhibit respiration by disrupting the structure of FAD: it takes the adenine moiety from the intramolecular adenine-isolloxazine complex.

Stable Free Radicals Derived from 4-Arylazo-2,6-di-*t*-butylphenols

Eiichiro MANDA

Government Chemical Industrial Research Institute, Tokyo, Honmachi, Shibuya-ku, Tokyo

(Received May 24, 1968)

It is well known that 2,6-di-*t*-butylphenol derivatives give stable phenoxy radicals (I) by oxidation.[1]

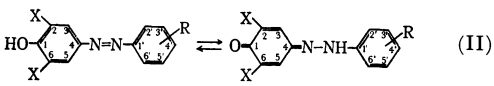
(I) X: *t*-butyl

In this study, 4-arylazo-2,6-di-*t*-butylphenols (II) were synthesized, and stable radicals were derived from them by KOH-$K_3Fe(CN)_6$ oxidation.

Seven derivatives of II were prepared from 2,6-di-*t*-butyl-*p*-benzoquinone and the corresponding arylhydrazine hydrochlorides by letting the aqueous-alcoholic reaction mixtures stand for five days at room temperature. The seven derivatives were as follows: R=4'-methoxy (II-A); R=4'-methyl (II-B); unsubstituted (II-C); R=4'-chloro (II-D); R=4'-nitro (II-E); R=2',4'-dinitro (II-F); R=2',4',6'-trinitro (II-G).

II-A, II-B, II-C, II-D, and II-E give a sharp OH absorption at 3670 cm^{-1}, but no NH absorption at 3300 cm^{-1} in benzene, and *vice versa* with II-F and II-G. Almost all the derivatives show two absorption maxima, near 360 mμ, and 450 mμ, in benzene (II-G shows only one peak, at 425 mμ), but their molecular coefficients vary with the substituents.

From the above data, it can be concluded that II-G exists exclusively in the hydrazone form, but the other six compounds show azo-hydrazone tautomerism in benzene.[2]



(II)

azo-form hydrazone-form

When the benzene solutions of II were treated with a large excess of an aqueous KOH-$K_3Fe(CN)_6$ solution, the benzene layers turned red immediately. After having been shaken for three minutes, the benzene layers were washed and degassed with cooling by dry ice and methanol, and then the ESR spectra were measured as soon as possible.

All the samples gave ESR signals, and the signals remained for a few days at room temperature in a sealed tube. The lifetimes of the radicals were three days (II-A, II-B, II-D, II-E), one day (II-C), and more than ten days (II-F, II-G).

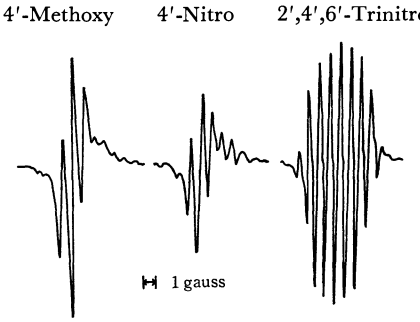


Fig. 1. Some ESR spectra of free radicals derived from II.

With the exception of II-G, the shapes of the ESR spectra suggest that two radical species exist in the sample solution. It is considered that the one species, which gives three lines, is derived from azo-tautomer, and the other, which gives nine lines, is derived from hydrazone-tautomer.

The details will be reported in the future.

Butadiene Hydrogenation by Pentacyanocobaltate(II) in Glycerin Solvent

Kimio TARAMA and Takuzo FUNABIKI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 31, 1968)

Pentacyanocobaltate (II) has catalytic activity for the hydrogenation of conjugated dienes such as butadiene[1,2]. In the study of this complex, water has been used as a solvent exclusively. In the present communication, we report that the butadiene hydrogenation by pentacyanocobaltate in glycerin-methanol (MeOH) has very different characteristics from that in water, and that butadiene is hydrogenated without H_2 even in alcoholic solvent.

The reaction was carried out in closed system at 20°C. The reaction gas was circulated vigorously through the magnetically stirred solution of cyanocobaltate, which was prepared by mixing the glycerin-MeOH solution of KCN with the MeOH solution of $CoCl_2$ in N_2 atmosphere (Fig. 1) or in H_2 atmosphere (Fig. 2). Butadiene was supplied continuously to maintain atmospheric pressure, and the gas sample was analyzed by gaschromatography every 10 or 20 min. The reaction medium was always homogeneous.

As shown in Fig. 1, composition of the isomeric butenes produced in glycerin-MeOH solvent without H_2 changes very sharply with the ratio of CN/Co (=R). In the region of R<5.2, butenes are produced in the order of *trans*-2->>1->*cis*-2-butene as in water, but the order in the region of R>5.2 is *cis*-2>1->>*trans*-2-butene and this order markedly differs from that in water (1->>*trans*-2->*cis*-2-butene). When H_2 was absorbed (*cf.* Fig. 2) similar result was observed except 1->*cis*-2->>*trans*-2-butene at R>5.2.

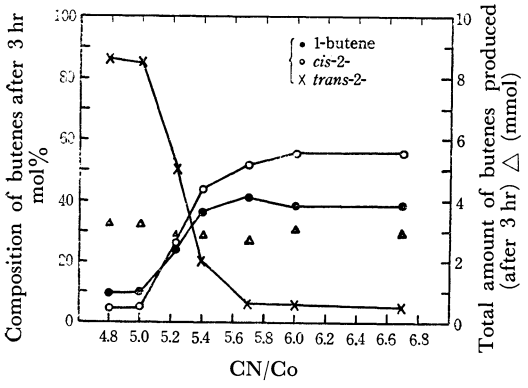

Fig. 1. Effect of CN/Co ratio.
$CoCl_2$=10 mmol
Solvent: glycerin 35 ml+MeOH 15 ml
without H_2 at 20°C

Because this hydrogenation was performed without H_2 in this solvent, hydrogen source should be alcoholic solvent.

Figure 2 shows the effect of some additives at R=5.7. When water was added in this solvent system, the formation of *cis*-2-butene was greatly suppressed and approached to the result in water. Addition of ethylenediamine increased the formation of *cis*-2-butene.

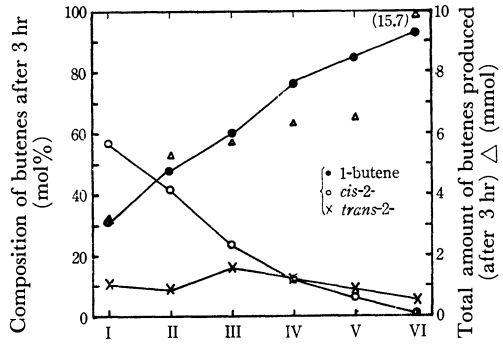

Fig. 2. Effect of additives.
$CoCl_2$=10 mmol
H_2 was absorbed for 2 hr before butadiene was added at 20°C.

I	Glycerin 35 ml+MeOH	10 ml+En	5 ml
II	Glycerin 35 ml+MeOH	15 ml	
III	Glycerin 35 ml+MeOH	10 ml+H_2O	5 ml
IV	Glycerin 35 ml+MeOH	5 ml+H_2O	10 ml
V	Glycerin 35 ml+MeOH	0 ml+H_2O	15 ml
VI	H_2O	50 ml	

(En=ethylenediamine)

It is noteworthy that *cis*-2-butene is very much producible at R>5.2 in glycerin-MeOH solvent. This result can not be explained by the π-allyl complex mechanism[1,2] acceptable in the case of water solvent. Detailed discussion of the mechanism of this reaction will be given in the forthcoming paper.

Formation of α-Nitroso Carbonyl Compounds from Esters through β-Keto Sulfoxides

Yoshio OTSUJI, Hideo YABUNE and Eiji IMOTO

Department of Applied Chemistry, Faculty of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

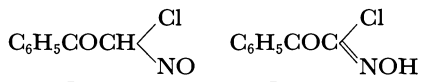
(Received May, 31, 1968)

Aliphatic and aromatic carboxylic esters have been converted to β-keto sulfoxides by the reaction of the esters with methylsulfinyl carbanion.[1,2] Becker and Russell[3,4] have found that the treatment of dimethyl phthalate with methylsulfinyl carbanion and the acidification of the resulting mixture with hydrochloric acid give 2-chloro-2-methylmercapto-1,3-indanedione, which can then be readily converted to ninhydrin upon hydrolysis. This reaction has been supposed to proceed through 2-methylsulfinyl-1,3-indanedione as an intermediate.[3,4] We now wish to report a new reaction of esters, one which leads to α-nitroso carbonyl derivatives through β-keto sulfoxides.

A solution of methylsulfinyl carbanion in dimethyl sulfoxide (DMSO) was prepared by the method of Becker and Russell[2] from 2 g (0.05 g-atom) of potassium, 50 m*l* of *t*-butyl alcohol, and 40 m*l* of DMSO. To this mixture 3.8 g (0.025 mol) of ethyl benzoate in a stream of nitrogen were added at room temperature. The reaction mixture was agitated by a stream of nitrogen for 2 hr, and then most of the solvent was evaporated under reduced pressure. A solution of 5.2 g (0.075 mol) of sodium nitrite in 30 m*l* of water was added to the residue, and the mixture was extracted with 30 m*l* of ether. The aqueous layer was acidified with 40 m*l* of 6 N hydrochloric acid to give a yellow oil. The oil solidified on standing overnight. The recrystallization of the solid from chloroform gave 3.6 g (80%) of ω-chloro-ω-nitroso acetophenone (I), mp 132—133°C (lit.[5] 131—132°C).[6] The infrared spectrum (in KBr disk) showed that I exists predominantly in the form of hydroxamoyl chloride (Ia).

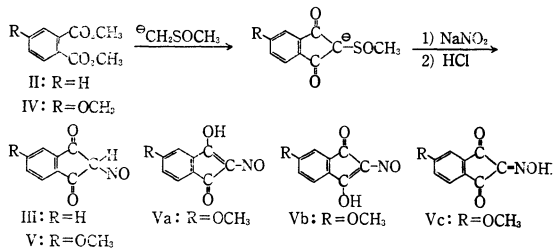
$$C_6H_5CO_2C_2H_5 + \bar{C}H_2SOCH_3 \rightarrow$$

$$C_6H_5\bar{C}OCHSOCH_3 \xrightarrow[2)\ HCl]{1)\ NaNO_2}$$



I Ia

In the second example, the similar treatment of dimethyl phthalate (II) afforded 2-nitroso-1,3-indanedione (III), mp 196—198°C, in a 37% yield. In this case methylsufinyl carbanion was prepared from DMSO and sodium methoxide[3,4]; the compound III thus obtained was identical in every respect with the authentic sample[7] prepared by the nitrosation of 1,3-indanedione.



In the third example, when the reaction of dimethyl 4-methoxyphthalate (IV) with methylsulfinyl carbanion and sodium nitrite was carried out by a method similar to that described for ethyl benzoate, 5-methoxy-2-nitroso-1,3-indanedione (V), mp 204—206°C (decomp.), was obtained in a 66% yield. The infrared spectrum (in KBr disk) of V showed a hydroxyl absorption at 3500 cm^{-1} and carbonyl absorptions at 1730 and 1690 cm^{-1}. The hydroxyl absorption at 3500 cm^{-1} was sometimes missing, however; instead, a broad absorption appeared at 3150 cm^{-1}. The NMR spectrum (in DMSO-d_6) showed an acidic proton at τ 4.25 (1H, broad singlet), an aromatic proton at τ 2.02—2.15 (1H, broad doublet), two aromatic protons at τ 2.50—2.65 (2H, broad doublet), and a methoxy singlet at τ 6.00 (3H). These results suggest that V exists in an equilibrium among the Va, Vb, and Vc structures in polar solvents. In fact, V could be converted to the corresponding monoacetylated product, mp 185—189°C (decomp.), on acetylation with acetic anhydride in pyridine.

The scope and mechanism of these reactions are now being investigated and will be reported on in a subsequent paper.

Fragmentation of *n*-Hexadecane by Electron Impact

Yoshio NIWA and Kozo HIROTA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received June 8, 1968)

It has often been concluded[1] that the MO theory for mass spectra is completely inadequate to explain the mass spectra of normal paraffins obtained by electron impact, because it always predicts that bond-scission will occur at, or nearly at, the central bond of the C-C skeleton of higher paraffins; this is contrary to the ordinary mass spectra, where C_3 and C_4 fragments are the most abundant. In order to explain this discrepancy, secondary bond-scissions have been suggested by the present authors.[2,3] The purpose of this communication is to show that this suggestion is plausible.

Generally, fragmentation caused by electron impact is assumed to consist of two kinds of processes:[3] *i. e.*, the primary process, in which the superexcited species takes the main part, and the secondary process, in which the primary product undergoes slow further decomposition due to the localization of excess energy at a particular bond. The primary process is very fast and occurs before the localization of the excess energy, which becomes larger as the ionizing voltage and the temperature of the ionization chamber increase. Therefore, the fragmentation due to the primary process becomes independent of the ionizing conditions.

The MO-theory on mass spectra has to be applied to this primary process, and the statistical theory of Rosenstock *et al.*,[4] to the secondary processes, because the latter theory is applicable to those chemical processes which proceed *via* the activated complex.

Since the secondary processes are suppressed by a decrease in the ionizing voltage and in the temperature of the ionization chamber, one can confirm the above fragmentation scheme experimentally, if both effects on the bond-scission probability are investigated. Of course, the ionizing voltage may affect the secondary process much more than does the temperature. Therefore, the lower the ionizing voltage, the more evident becomes the effect of the temperature.

In order to confirm the above scheme, we investigated the mass spectra of *n*-hexadecane *n*-$C_{16}H_{34}$ in detail. The observed energy-dependence of its fragment distribution indicates that the abundant fragments shift to the C_9 and C_{10} fragments from the C_3 and C_4 fragments with a decrease in the electron energy. The fragment distribution at an ionizing voltage of 10 eV were measured at various temperatures of the ionization chamber. The C_8, C_9 and C_{10} fragments are the most abundant in the range from 100 to 200°C. With a rise in the temperature, the yields of these fragments decrease, while those of the lower fragments increase; C_5 and C_6 fragments come to be the most abundant at 285°C. The mass spectra, however, are practically independent of the temperature when the electron energy is above 15 eV.

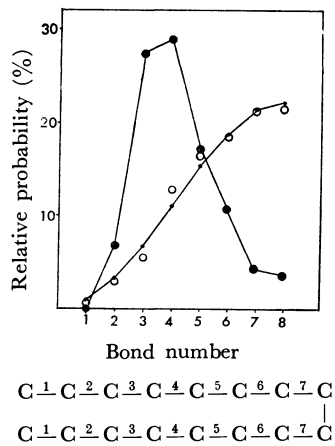

Fig. 1. Relative scission probability *vs.* number of skeletal bond.

—○— 10V, 90°C —•— Calculated
—●— 80V, 200°C

Some of the results are shown in Fig. 1, where the scission probability in % is plotted against the bond number, and where the calculated probability is obtained by the same procedure as was used in a previous study.[2] As expected, the observed values obtained at a low ionizing voltage (*ca.* 10 V) and at a low temperature of the ionization chamber (90°C) coincide well with the calculated values.

Phase Transitions and Thermodynamic Properties of Rubidium and Cesium Cyanides*1

Masayasu SUGISAKI, Takasuke MATSUO, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received December 21, 1967)

Heat-capacity measurements were performed for rubidium and cesium cyanide crystals between 15 and 300°K. It is found that each crystal has only one anomalous peak in its heat capacity curve, being located at 110.3°K and 193.1°K for rubidium and cesium cyanides, respectively. By the comparison of the present data with those for potassium and sodium cyanides, it was shown that these anomalous heat capacities can be interpreted in terms of the orientational ordering processes of cyanide ions in the crystals. It was suggested that there should exist the residual entropy due to the frozen-in state in their orientational configuration and they were estimated as $R \ln 4$ for rubidium cyanide and $R \ln 2$ for cesium cyanide.

In the two previous papers,[1,2] we have reported the results of our investigation on potassium and sodium cyanide crystals. In each salt we have found two kinds of phase transition which were interpreted as the orientational order-disorder phenomenon with respect to the distinction of carbon and nitrogen atoms in cyanide ion as well as to the random orientation of the carbon to nitrogen bonds. As a series of our study concerning the orientational motion of cyanide ion, we have studied the phase transition phenomenon of rubidium and cesium cyanides with paying special attention to the effect of the difference of their size of cation on the orientational motion of cyanide ion.

According to the X-ray analysis by Lely,[3] rubidium cyanide is of NaCl-type, while cesium cyanide is reported to have CsCl-type at room temperature. This is in contrast to the fact that both potassium and sodium salts have the same NaCl-type.

Thus, it seems interesting to study the effect of the difference of size of cation in rubidium salt and further of the difference in crystal structure for cesium cyanide on an appearance of phase transition.

We have measured heat capacity of these salts between 13 and 300°K and found only one anomalous peak of the heat capacity in each salt. This remarkable difference in the behavior of the temperature dependence of their heat capacities was attempted to interpret in connection with the thermal motion and ordering process of cyanide ion in the crystalline field.

Experimental

Samples. a) Rubidium Cyanide.[4] Commercial rubidium hydroxide (Nakarai Chemicals Co., Ltd.) was dissolved in the absolute ethyl alcohol and the insoluble substances supposed to be mainly of rubidium carbonate were removed by filtration. Liquid hydrogen cyanide was then poured slowly to the phase separated solution which consisted with liquid benzene over the ethanol solutions mentioned above. Rubidium cyanide crystal was first produced at the interfacial layer and then it was deposited to the bottom of the container with a solution of absolute methyl alcohol and absolute diethylether. After the product was filtrated, the sample was recrystallized twice from the solution of water and methyl alcohol. The final product thus obtained was dried *in vacuo* (about 10^{-3} mmHg) carefully for several hours at 120°C to remove the solvents completely.

b) Cesium Cyanide. The crystal was prepared by the same method as mentioned above. The cesium hydroxide used for preparation is the product of Nakarai Chemicals Co. Ltd.

By a spectroscopic analysis, all the impurity contents of carbonate ion were confirmed to be less than 0.1 mole percent, and the traces of metallic ions (Na^+, K^+, Si^{2+}, Mg^{2+}, and Ca^{2+}) were also found.

Heat-Capacity Measurement. Measurements of heat capacities were made on the sample of 0.2899 mol of rubidium cyanide and 0.2357 mol of cesium cyanide, sealed in a gold calorimeter cell (18 K) with a small amount of helium gas. The low-temperature adiabatic type calorimeter, the details of which were described in the previous paper,[5] was used between 15°K and 300°K.

The reported values are based on a formula weight of 111.49 for rubidium cyanide and 158.92 for cesium cyanide, and also on the basic relations 0°C=273.15°K and 1 cal=4.1840 abs. joules. Temperature measurements were carried out with platinum resistance thermometer calibrated in terms of the International Temperature Scale between 90 and 500°K and the provisional scale of the National Bureau of Standards between 11 and 90°K.

Experimental Results

Heat Capacities. The heat capacities obtained from 15 to 300°K are listed in Table 1 for rubidium cyanide and in Table 2 for cesium cyanide. The heat-capacity curves are given in Figs. 1 and 2 for rubidium and cesium cyanides, each of which shows only one phase transition, respectively.

Thermodynamic Properties. Thermal data on phase transition are listed in Table 3, and the thermodynamic functions are given in Table 4 for rubidium cyanide and Table 5 for cesium cyanide. The values below 15°K are obtained by extrapolation on the assumption of the Debye T^3-law. As is shown in the previous paper,[5] the error in the values of the heat capacity is within $\pm 0.3\%$ above liquid nitrogen and $\pm 1\%$ in liquid hydrogen temperature regions, respectively.

Discussion

Behavior of Thermal Motion of Cyanide-groups. In order to investigate the mode of motion of the cyanide-group in these cyanide crystals, the torsional heat capacity was sorted out from the total heat capacity by following the same procedure taken in the previous papers.[1,2] By assuming the simple harmonic oscillation model for each cyanide group and also by making a flat portion in the Debye-temperature curve with suitable estimation of their oscillator frequencies, we have obtained the wave numbers of 185 cm^{-1} and 160 cm^{-1} for rubidium and cesium salts, respectively. Further, we have estimated the contributions of torsional motion of the cyanide-groups to the heat capacities which are given in Fig. 3. The potential barrier heights for the torsional motion at higher temperature, *i.e.* for the hindered rotational motion derived from these curves based on the Pitzer-Gwinn method[6] are 8.0 and 7.4 kcal/mol for the low temperature phases of rubidium and cesium cyanides, respectively. Finally this motion approaches the state of the free rotation where the heat capacity amounts to 2 cal/mol degK per two degrees of freedom. The fact that the heat capacity at room temperature is about 3 cal/mol degK in the range of relevant temperature

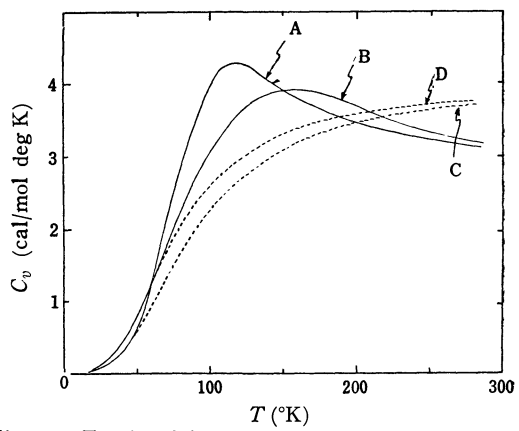

Fig. 3. Torsional heat capacity curves of cyanide-groups.

D: assumed harmonic oscillator with its wave number $\omega=160\ cm^{-1}$.

shows that the rotation of the cyanide-group is still hindered considerably. The potential barrier heights of this hindered rotational motion are 1.7 and 1.1 kcal/mol for rubidium and cesium cyanides, respectively. It may be noted here that the potential barriers hindering the rotation of the cyanide-group estimated above are comparable with those for sodium and potassium cyanides.

6) K.S. Pitzer and W.D. Gwinn, *J. Chem. Phys.*, **10**, 428 (1942).

Possible Existence of the Residual Entropy. *a) Rubidium Cyanide.* In this compound we can observe only one peak of anomalous heat capacity at about 110°K. The value of entropy associated with amounts to be 1.38 e.u. which is corresponding to $R \ln 2$. This circumstance is markedly different from those of sodium and potassium cyanides in which two anomalous heat capacities are observed. They have been interpreted in terms of the stepwise cooperative phenomena concerning the reorientational motion of the cyanide-group in the crystalline phase. The cubic symmetry of the rubidium cyanide crystal at room temperature suggests that all cyanide-groups may orientate themselves equally at random in the directions of four body-diagonals of its unit cell as in the case of the highest temperature phases of sodium and patassium cyanides. In this case, the configurational entropy with respect to the possible orientations of the cyanide-groups comes out to be $R \ln 8$ if we can distinguish the individuality of carbon and nitrogen atoms. The amount of observed entropy change of $R \ln 2$ at the transition point leads us to expect that the configurational entropy in the low-temperature phase might be $R \ln (8/2) = R \ln 4$. As one of the explanation of such a value of entropy change as $R \ln 2$, we may refer to Parry's model[7] for the low temperature phase of rubidium cyanide. Based on the detailed X-ray analysis of the metastable monoclinic phase of potassium cyanide, he proposed that the crystal structure of the low temperature phase of rubidium cyanide is closely similar to the disordered structure of the metastable monoclinic phase of potassium cyanide. In this metastable phase, all cyanide-groups are at rest with their principal axis approximately parallel to the one direction of body-diagonals of the original cubic phase, the potassium ions being displaced alternately vertical to (110) plane by about 1/4 Å, as is shown in Fig. 4.

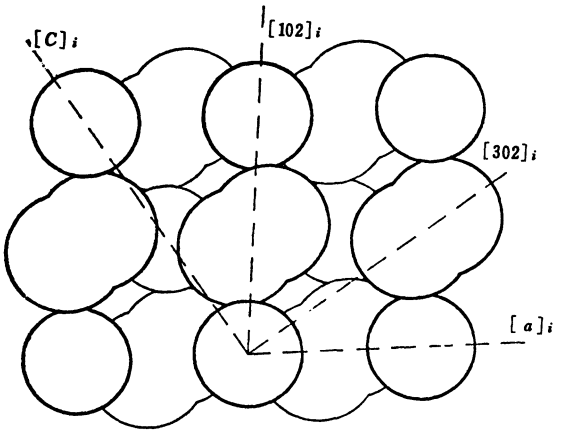
If the two kinds of y-parameter of the potassium ions are assumed te be zero and the new axis is taken as,

$$a = 1/2[a]_i, \quad c = 1/2[102]_i,$$

here, $[a]_i$ and $[102]_i$ represent the a-axis and direction of [102] of the original monoclinic cell, respectively. Then, the dimension of new unit cell becomes as follows;

$$a = 4.45, \quad b = 4.53, \quad c = 6.36 \text{ Å}, \quad \beta = 94.6°.$$

Comparing these dimensions with those of rubidium cyanide, the differences in the axial lenghts a, b and c of the two unit cells are found to be 0.28, 0.35 and 0.31 Å, respectively. Taking into account of the difference in ionic radii between the potassium and the rubidium ions, it gets clear that this unit cell seems to correspond to the unit cell of the low temperature phase of rubidium cyanide, its dimensions being $a = 4.78$, $b = 4.88$, $c = 6.67$ Å and $\beta = 94.5°$.



[G. S. Parry, *Acta Cryst.*, **15**, 601 (1962)]

Fig. 4. Proposed structure for the monoclinic low-temperature form of potassium cyanide projected on to $[010]_i$ which corresponds to [110] of the original cubic cell. The displacement $y(K^+)$ is perpendicular to the plane of this figure and has been established experimentally to be of the order of 1/4 Å. The orientation of the cyanide-group has not yet been experimentally confirmed, but is based on a self-consistent interpretation of the cell dimensions.[7]

Therefore it may not be so unreasonable to suppose that the cyanide ions are in the disordered state with two kinds of their orientation. If the carbon and the nitrogen atoms of the cyanide-groups are distinguished in this phase, the entropy change of $R \ln 2$ may be explained on this model.

Furthermore, the behavior of the rest of configurational entropy in low temperature region below 13°K will be an interesting problem. In our present measurement of the heat capacity from 13 to 320°K, no further anomalous heat capacity in addition to the anomaly at 110°K was observed. This implies that the degree of orientational freedom of the cyanide-group in low temperature phase will freeze and this frozen-in state will persist down to the lowest temperatures. Comparing the potential barrier (8 kcal/mol) hindering the rotation of the cyanide ions with the thermal excitation energy, it seems reasonable to suppose that there may persist the residual entropy of $R \ln 4$ at the absolute zero.

7) G. S. Parry, *Acta Cryst.*, **15**, 596, 601 (1962).

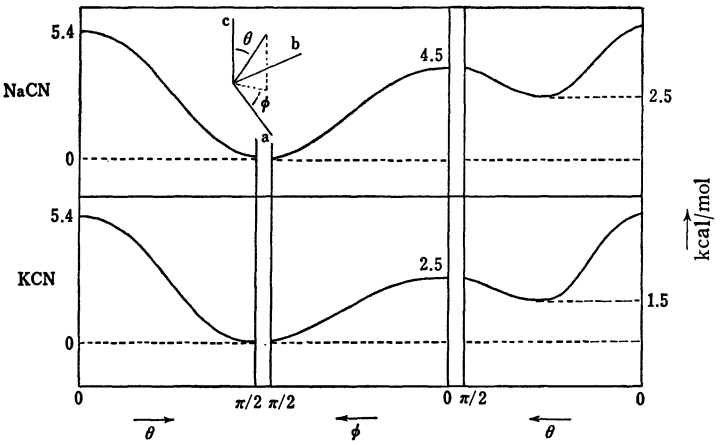


Fig. 5. The potential curves hindering the reorientation of cyanide groups of low temperature forms of potassium and sodium cyanide crystals.[8]

b) Cesium Cyanide. The entropy change of the phase transition of cesium cyanide at 193°K amounts to 2.6 e.u., nearly equal to $R \ln 4$, which is equivalent to those of the upper phase transitions of sodium and potassium cyanides at 288.1 and 168.3°K, respectively.

It is also shown that behavior of temperature dependence of torsional heat capacity of cesium cyanide is quite similar to those of both sodium and potassium salt, *i.e.*, in each case there appears hump of heat capacity near the phase transition. Thus, it is concluded that cyanide-groups are at rest along the three fold axis of the unit cell below the transition point, whereas they are in hindered rotational state above the transition point. This conclusion is consistent with the crystal structure determined by X-ray analysis.

The fact that the lower phase transitions of sodium and potassium cyanides are reasonably interpreted in terms of order-disorder phase transition with respect to the distinction of carbon and nitrogen atoms of cyanide-groups suggests that there is also the possibility of appearance of another phase transition of this kind for cesium cyanide. As a matter of fact, however, we can not find any further anomalous effect in its heat-capacity curve.

Consequently, the situation of cyanide-group in the low-teperature form of cesium cyanide crystal is such that the cyanide-groups are at rest along the three fold axis with no distinction of their heads and tails. This implies that a temperature region exists where the cyanide-groups are frozen in its fixed orientation and can no longer reorientate themselves.

The Appearance of the "Frozen-in" State and the Potential Barrier Hindering the Reorientation of Cyanide-groups. It is not definitely clear as to the reason why the cyanide-groups of rubidium and cesium cyanides behave differently from those of sodium and potassium cyanides in spite of the fact that they have nearly equal amount of potential barriers. It must be mentioned, however, that the potential barrier-height obtained from the analysis of the calorimetric data is such an averaged one over all possible directions, and it seems possible that a symmetry difference of the unit cell of potassium and sodium salts from the others may give rise to a somewhat lower barrier-height favourable to reorientation of cyanide-group in particular direction.

According to Nagamiya and Matsubara's calculation[8] for the case of the low temperature modification of sodium and potassium cyanides, the potential curve hindering the reorientation of cyanide-group has an anisotropy, *i.e.*, the potential barrier-height in the direction of c-axis is larger than that in the direction of a-axis. In the case of sodium cyanide this anisotropy is not so large, but in the case of potassium cyanide the anisotropy is so much larger that barrier-height along c-axis is larger by twice than that along a-axis (see Fig. 5). Moreover, it is characteristic to sodium or potassium cyanides that there exists a saddle point in the respective potential curves. Therefore, this saddle point provides a high transition probability concerning the reorientational motion of cyanide-group. Following the method used by Naga-

8) T. Matsuhara and T. Nagamiya, *Scientific Papers from the Osaka University*, **No. 14**, 17 (1949).

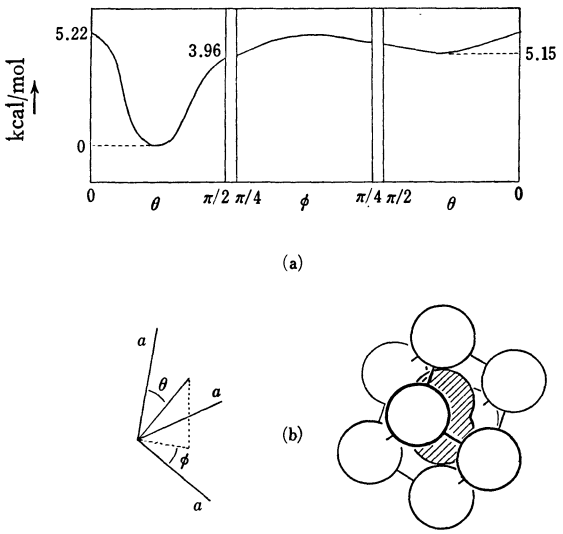

Fig. 6. (a) The potential curve hindering the reorientation of cyanide group of the low temperature form of cesium cyanide crystal.
(b) The unit cell of low temperature form of cesium cyanide crystal. This crystal structure is of a deformed *CsCl*-type. Hollow circles represent cesium ions, and a shaded deformed circle stands for cyanide group.

miya and Matsubara we have calculated the potential curve hindering the reorientation of cyanide-group of cesium cyanide. In this case the interaction due to a quadrupole effect will be neglected for approximate estimation of an anisotropy of the potential curve. The results obtained is given in Table 6. In the table W_{--} stands for the repulsive potential due to interaction between cyanide-groups, W_{+-} the repulsive potential for the interaction between cesium and cyanide-groups.

The potential form obtained is depicted in Fig. 6. As is seen there is no distinct anisotropy and the possibility of saddle point with appreciable low value is not expected.

TABLE 6. THE REPULSIVE LARTS OF THE HINDERING POTENTIAL FOR THE ROW-TEMPERATURE FORM OF CESIUM CYANIDE CRYSTAL (in kcal/mol)

(θ, ϕ)	W_{--}	W_{+-}	$W = W_{--} + W_{+-}$
$\pi/4$ $\pi/4$	1.47	7.43	8.90
0 0	5.04	8.91	13.95
$3\pi/4$ $\pi/4$	2.39	11.74	14.12
$\pi/4$ 0	1.79	11.07	12.86
$3\pi/4$ $3\pi/4$	2.82	11.56	14.39
0 $3\pi/4$	2.46	11.59	14.05

Accordingly it may be said that the realization of orientational frozen-in state of rubidium and cesium cyanides is closely related with the nonexistence of the appreciable anisotropy or a saddle point in their potential curves.

Finally, based on the same viewpoint we should like to infer the occurrence of a metastable phase of potassium cyanide. The saddle point of potassium cyanide is lower than that of sodium cyanide, so that the state probability on the saddle point, which corresponds to the [111] direction of the high temperature form, is larger for potassium cyande. In that case all cyanide-groups are frozen in the [111] direction of the original cubic form, and this structure is really corresponding to the monoclinic metastable phase. The corresponding one of sodium cyanide has not been found. This fact is certainly connected with the difference of the height of the saddle point in these two salts.

The authors should like to express their sincere thanks to Mr. Nobukatsu Fujino of Sumitomo Metal Industries, Ltd. for the spectroscopic analysis of metal ions in the specimens. They also wish to express their sincere thanks to the Toyo Rayon Co., Ltd. who defrayed a part of the financial support for the present investigation.

A Relation between Ion-exchange Selectivity Coefficient and Degree of Distribution for Model Compounds in Solvent Extraction

Tadao KENJO

Graduate School of Science and Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

and Takuji ITO

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 25, 1967)

An analogy of solvent extraction to ion-exchange was taken to explain anion affinities to anion-exchangers. Distributions of the model compound whose cation was the ionogenic group of an anion-exchanger and whose anion the counter ion, between water and an organic solvent, were investigated. The degree of distribution of the model compound for a solvent layer was expected to increase with increasing anion affinities to the corresponding anion-exchanger. Cobalticinium, benziltrimetylammonium and benzildimethylamine salts were employed as model compounds for the polymeric olygomethylene cobalticinium anion-exchanger, the strong base anion-exchange resin and the weak base anion-exchange resin, respectively. The distribution sequences in solvent extraction were essentially identical with the ion affinity series in anion-exchange. From these correlations, the selectivity coefficient for an anion was explained as the affinity of an anion to an ionogenic group with the use of an ion-pair concept. Some differences between ion-exchanges and solvent extractions were discussed.

In recent years, many attempts have been made to predict selectivity coefficients for ion-exchange systems. It has been thought that the activity coefficient in an ion-exchanger phase and the strain energy of the molecular network in an ion-exchange copolymer most seriously influence selectivities. The former was found to be dominant for ion-exchange resins[1,2] and the latter cannot be attributed to osmotic pressure but to the diffusion of network molecules because ion-exchangers are not bound by semipermeable membranes from the external solution. The strain energy effect seems to be difficult to estimate. This paper pays attention to the activity coefficient only.

The relation between the selectivity coefficient and the activity coefficient, or the evaluation of the latter from the former, has been studied by many workers.[3-6] However, the difference in activity coefficients for different anions has not been explained as affinities of adsorbed ion to ionogenic groups. According to thermodynamic considerations, a lower activity coefficient, or a higher selectivity coefficient, is interpreted as the higher sorbability to ion-exchangers. If the affinity of an anion to the same monomeric cation as the ionogenic group is similar to that in the corresponding exchanger, the salt whose cation is the ionogenic group and whose anion the counter ion may be suitable as a model compound for the ion-exchanger. The affinity should increase in organic solvents of low dielectric constant. From this point of view, cobalticinium (π-dicyclopentadienyl cobalt(III)), benziltrimethylammonium and benzildimethylamine salts were selected as model compounds for the polymeric pentamethylene cobalticinium anion-exchanger, the strong base anion-exchange resin and the weak base anion-exchange resin, respectively. Some interrelations between them were found.

Experimental

Preparation of Cobalticinium, Benziltrimethylammonium and Benzildimethylamine Salt Solutions. Cobalticinium picrate ($(C_5H_5)_2CoOC_6H_2(NO_2)_3$) was obtained by the method mentioned in a previous paper.[7] The desired form of the cobalticinium

salt was obtained by passing the picrate solution through Dowex 1 X-8 columns. The concentration of the resulting solution was 0.0444 M. The benzyltrimethylammonium salt ($C_6H_5CH_2N^+(CH_3)_3X^-$) was obtained commercially. It was converted to the perchlorate by adding 2 M sodium perchlorate solution, and the perchlorate was purified by recrystallization. The perchlorate solution was converted to the desired salt forms by the same procedure as for the cobalticinium salt. The concentration of the resulting solution was 0.0500 M. Benzildimethylamine ($C_6H_5CH_2N^+H(CH_2)_2X^-$) was obtained commercially. The procedure for preparing the solution was similar to that used for the benzyltrimethylammonium salt solution. The concentration of the solution was 0.0500 M.

The Solvent Extraction of Various Ions and Their Determination in the Organic Solvent Layer. *n*-Butanol, *n*-pentanol, *n*-hexanol, chloroform and benzene were used as organic solvents (obtained commercially). An aqueous solution of the salt (10 m*l*) and 10 m*l* of the solvent were shaken together for 10 min at room temperature. The solvent layer was separated and the concentration of salts determined colorimetrically using 1 cm quartz cells and a spectrophotometer (Hitachi EPU-2 A). The wavelength employed was 340 mμ for cobalticinium and 262 mμ for both benzyltrimethylammonium and benzildimethylamine. Calibrations were made by dissolving a known amount of perchlorate or picrate in a known amount of each solvent saturated with water.

Adsorption spectra in the UV region were measured on a Shimadzu multipurpose recording spectrophotometer.

Calculation of the Degree of Distribution. The degree of distribution of an anion A^- (K_A) was calculated according to the equation

$$K_A = \frac{[R^+]_w[A^-]_w}{[RA]_r},$$

where $[RA]_r$, $[R^+]_w$ and $[A^-]_w$ are the concentrations of RA in the solvent layer and cation R^+ and anion A^- in the aqueous layer, respectively. $[R^+]_w$ was always equal to $[A^-]_w$ in this experiment.

Results and Discussion

According to Bjerrum's theory,[8] the probability of an ion-pair formation increases with increasing concentration. Accordingly, ion-pair formation in ion-exchangers might be quite possible since the density of counter-ion arround an ionogenic group is very high. Further, many thermodynamic data for univalent cation exchanges[9-12] show that enthalpies decrease when entropies decrease in systems of decreasing free energy. This fact appears to support the assumption of ion-pair formation. One of the most typical theories of an ion-exchange equilibrium introducing the ion-pair concept has been proposed by Gregor.[5] He introduced a dissociation constant for ion-pair formation between an ionogenic group and a counter ion in an exchanger phase. For the processes of ion-pair formation,

$$RA \rightleftharpoons R^+ + A^- \quad \text{and} \quad RB \rightleftharpoons R^+ + B^-$$

dissociation constants D_A and D_B are given by

$$D_A = \frac{[R^+][A^-]}{[RA]}, \quad D_B = \frac{[R^+][B^-]}{[RB]},$$

where R's refer to ionogenic groups, A^- and B^- to exchange anions and brackets to the molality of each species. Neglecting strain energy effects, the molality of unpaired ions in the exchanger phase is related to that of these ions in the external solution according to the Donnan equilibrium condition and one obtains the equation

$$\frac{[A^-]_r}{[B^-]_r} = \frac{[A^-]_w}{[B^-]_w}$$

Then, selectivity coefficients K_A^B are given by

$$K_A^B = \frac{[B]_r}{[A]_r}\cdot\frac{[A^-]_w}{[B^-]_w} = \frac{[B^-]_r+[RB]}{[A^-]_r+[RA]}\cdot\frac{[A^-]_w}{[B^-]_w},$$

where A or B refers to the total amount of the species in the exchanger phase, subscript r and w to the exchanger and external solution phase, respectively. Additional conditions are

$$[R^+] = [A^-]_r + [B^-]_r$$
$$[RA] + [RB] + [R^+] = 1$$
$$[A^-]_w + [B^-]_w = 1$$

Then K_A^B is obtained as a function of $[A]_r$ or $[B]_r$ by a combination of the following equations:

$$K_A^B = \frac{D_A[A^-]_w + (D_B - D_A)x[A^-]_w}{D_B[A^-]_w - (D_B - D_A)x[B^-]_w}$$

and

$$\frac{[B]_r}{[A]_r} = \frac{D_A[B^-]_w + (D_B - D_A)x[B^-]_w}{D_B[A^-]_w - (D_B - D_A)x[B^-]_w},$$

where

$$x = \frac{-D_A + \sqrt{D_A^2 + 4D_A[A^-]_w + \dfrac{4D_A^2[B^-]_w}{D_B}}}{2\left(1 + \dfrac{D_A[B^-]_w}{D_B[A^-]_w}\right)}$$

Figure 1 shows the selectivity coefficient-molality curves calculated from the above equation for various D_A and D_B values. The figure indicates that a larger selectivity coefficient for anion A^- than for anion B^- means a smaller dissociation constant for A^- than that for B^-.

Ion-pair formation between an ionogenic group and the counter-ion can be analogized to the Langmuir adsorption process; that is, the dissociation constant in an ion-exchange corresponds to the eqilibrium constant of the process

adsorbed molecules in a solid phase $\rightleftharpoons$ free molecules in a gas phase + vacant sites.

Therefore, the dissociation constant can be understood as an equilibrium constant for the process

paired ions $\rightleftharpoons$ unpaired ions + unpaired ionogenic groups.

This process can be compared to the distribution of the model compound between a solvent layer and an aqueous layer,

paired ions in solvent layer*1 $\rightleftharpoons$ cations in an aqueous layer + anions in an aqueous layer

From these analogies for ion-pair formation between an ion-exchanger and an organic solvent phase, it can be assumed that some correlation exists between selectivity coefficient sequences against a common anion and distribution sequences in solvent extraction for corresponding model compounds.

Tables 1, 2 and 3 give the degree of distribution for cobalticinium, benziltrimethylammonium and benzildimethylamine, respectively. From a comparison of selectivity coefficients in ion-exchange with the degree of distribution in solvent extraction, it is found that they are related to each other in sequences

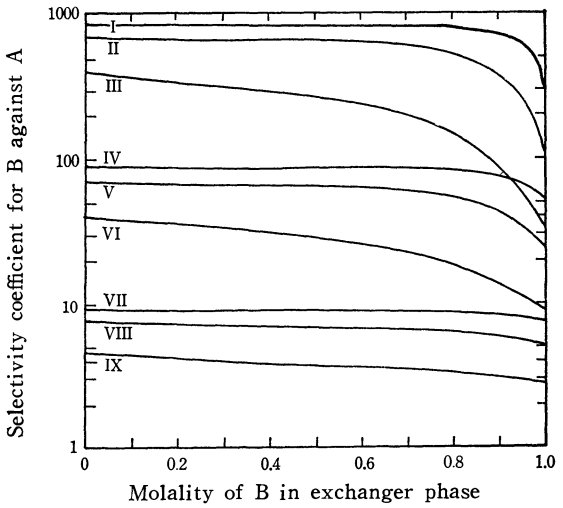

Fig. 1. Calculated curves for selectivity of anions A and B for the following sets of postulates;
I: $D_A=10^{-2}$ $D_B=10^{-5}$; II: $D_A=10^{-1}$ $D_B=10^{-4}$;

VII: $D_A=10^{-2}$ $D_B=10^{-3}$; VIII: $D_A=10^{-1}$ $D_B=10^{-2}$;
IX: $D_A=1$ $D_B=10^{-1}$

of values, except for the position of BrO_3^- and ClO_4^-.

A possible difference between ion-exchange and solvent extraction is the effect of freedom of rotation. In the case that A is a monoatomic anion and B a polyatomic anion, the effect of freedom of rotation between A and B would be greater in ion-exchange than in solvent extraction; that is the effect promotes the dissociation of polyatomic anions from ionogenic groups in ion-exchange more readily than in solvent extractions, because ionogenic groups are fixed to one another while the corresponding cation is moving freely in solvents. However, the trend mentioned above was not found to be very remarkable in the experimental results; the affinity of the poly-

atomic anion BrO_3^- was greater in the system of the cobalticinium type anion-exchanger and Amberlite IR-45 than in the corresponding solvent extraction systems. Accordingly, the effect of rotation of anions might be not very important.

Differences in interionic interactions between ion-exchange and solvent extraction can be mainly attributed to the difference in solvents. Possibly because of the effect of hydration, affinities of the counter ion to an ionogenic group in an aqueous layer are weaker than those of the same anion to the corresponding cation in solvents. The greater amount of water a solvent contains, the more similar to ion-exchange the solvent extraction system may be. In the system of benzene for cobalticinium halogenate (Table 1), the sequence is opposite to the affinity series for ion-exchange, and consistent with the order of solubilities.[14] This behaviour, perhaps, can be ascribed to the extremely low water content in the benzene layer. Because of the much lower dielectric constant of an organic solvent compared with that of water, an anion could approach a cation more closely in organic solvents than in water. Therefore, factors which are effective in a very short range *e.g.*, polarizability are more effective in an organic solvent than in water. Table 4 gives absorption peaks of UV spectra for benziltrimethylammonium in the *n*-butanol layer. It indicates that the absorption peak shifts to longer wavelength with increasing affinities. This result suggests some relation between the polarization of charge on ammonium cations and the interactive force between a cation and an anion.

TABLE 4. THE WAVELENGTH OF ABSORPTION PEAKS FOR BENZILTRIMETHYLAMMONIUM SALTS IN *n*-BUTANOL LAYER

	Wavelength (mμ)		Wavelength (mμ)
IO_3^-	215.3	ClO_3^-	219.8
Cl^-	218.4	SCN^-	226.0
BrO_3^-	218.6	ClO_4^-	220.2
Br^-	219.1		

Thus, these systems which consist of solvent extractions and model compounds have a possibility of being adequate models for ion-exchange although some differences can be pointed out.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1761—1765 (1968)

Kinetic Studies of Ammonia Oxidation in Shock Waves. IV. Comparison of Induction Periods for the Ignition of NH_3-O_2-N_2 with Those for NH_3-O_2-Ar Mixtures

Hajime MIYAMA

Basic Research Loboratories, Toyo Rayon Company, Ltd., Tebiro, Kamakura, Kanagawa

(Received August 14, 1967)

Induction periods for ammonia oxidation in the NH_3-O_2-Ar and NH_3-O_2-N_2 mixtures were measured by monitoring an ultraviolet absorption of ammonia in reflected shock waves. For the NH_3-O_2-Ar mixtures, induction periods in the temperature range of 1450—2730°K were found to be expressed by

$$\log \tau_i[O_2]\,(\mathrm{mol}\cdot l^{-1}\mu\mathrm{sec}) = -(16.24\pm0.17) + (10080\pm320)/T$$

when oxygen content is in the range of 4—10%, and by

$$\log \tau_i(\mu\mathrm{sec}) = -(2.55\pm0.14) + (8810\pm220)/T$$

when the oxygen content is less than 1%. Values of induction periods for the 0.5% NH_3-0.5%O_2-99% N_2 and 1% NH_3-1% O_2-98% N_2 mixtures were also measured and compared with those for the NH_3-O_2 mixtures highly diluted with argon. Both results agreed well by taking into account vibrational relaxation of the reacting system if appropriate values of vibrational relaxation times for N_2 dilute in NH_3 is assumed. Therefore, possibility of coupling of vibrational relaxation of N_2 and oxidation reaction was considered to be small.

In the first paper of this series[1,2] we found a linear relationship between $\log \tau_i[O_2]$ and $1/T$ for the shock-heated NH_3-O_2-Ar mixtures where τ_i was induction period determined by the reaction between NH_2 and O_2. Thereafter, we[3] measured induction periods for the mixtures of 90% N_2-6% NH_3-4% O_2 and 90% N_2-4% NH_3-6% O_2, and made Arrhenius plots by assuming two possible cases; (a) nitrogen is relaxed translationally, rotationally and vibrationally, and (b) nitrogen is relaxed translationally and rotationally. Comparison of these plots with a plot for the NH_3-O_2-Ar mixtures showed that data calculated for the case (b) are very close to the plot for the NH_3-O_2-Ar mixtures at higher temperatures but those for the case (a) approach to the latter plot at lower temperatures. This phenomenon was attributed to the effect of vibrational relaxation of nitrogen which became comparable to the induction period of ammonia oxidation in certain temperature range. Also, it was considered that the coexistence of NH_3 and O_2 might shorten the vibrational relaxation time of N_2.

In order to minimize the effect of these additives and to examine the effect of vibrational relaxation of N_2 on the oxidation reaction, measurement of induction periods was performed for the NH_3-O_2 mixtures highly diluted with nitrogen and compared with those for the NH_3-O_2 mixtures highly diluted with argon.

Experimental

The experimental details have been described previously.[1-4] Induction periods were measured in reflected shock waves by monitoring the absorption of NH_3 at 2245 Å, 2300 Å or 2400 Å. One of these wavelengths was chosen depending on the NH_3 concentration because the extinction coefficient of NH_3 was higher at shorter wavelength. The mixtures used and experimental conditions were summarized in Table 1, where data for the mixtures VIII and X were taken from the previous report.[1]

Results and Discussion

The Induction Periods for NH_3-O_2-Ar Mixtures. Arrhenius plots of $\tau_i[O_2]$ for the mixtures I—XI are shown in Fig. 1. Here, data for the mixtures containing more than 4% oxygen are expressed by a straight line, a least-squares expressions of which is as follows:

$$\log \tau_i[O_2](\mathrm{mol}\cdot l^{-1}\cdot\mu\mathrm{sec}) = -(16.24\pm0.17) + (10080\pm320)/T \quad (1)$$

This indicates that the linear relation between

XIII	1	1	0	98	1530—2300 (1660—2600)	1.49—4.55 (1.45—4.47)	0.0956—0.364 (0.0804—0.328)	6—1600 (NH_3 2245 Å)

Note : Shock parameters calculated for mixtures XII and XIII correspond to case (a), and those corresponding to case (b) are shown in parentheses. T_5 and P_5 are temperature and pressure behind reflected shock waves.

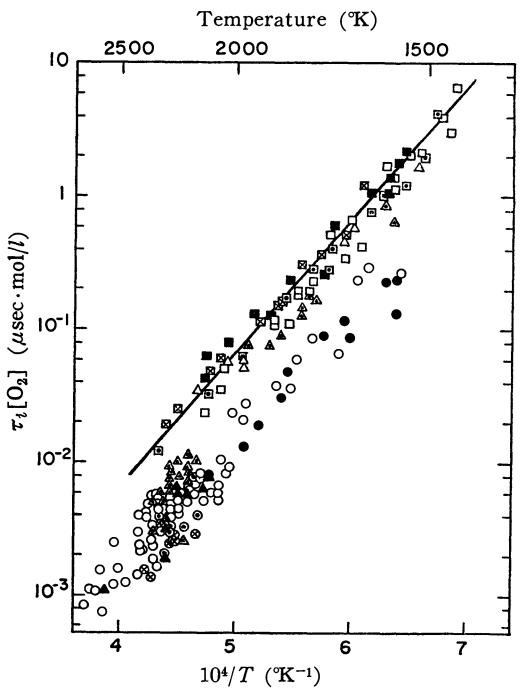

Fig. 1. Arrhenius plot for $\tau_i[O_2]$.

Marks ●, ⊗, ⊙, ○, ▲, ◬, △, ⊠, ⊡, ■, and □ refer to mixtures I, II, III, IV, V, VI, VII, VIII, IX, X, and XI respectively.

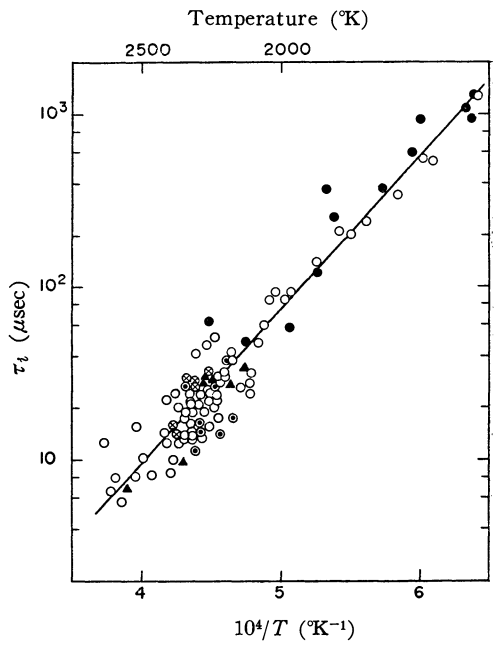

Fig. 2. Arrhenius plot for τ_i.
Marks are the same as in Fig. 1.

$\log \tau_i[O_2]$ and $1/T$ obtained previously[1] holds over a wide range of oxygen concentration (4—10%).

However, when the oxygen content is less than 3%, $\log \tau_i[O_2]$ decreases as the former decreases. Especially, when the oxygen content is less than 1%, the result is well expressed by a linear plot of $\log \tau_i$ *via* $1/T$ as shown in Fig. 2, where the solid line obtained by a least-squares calculation is expressed by :

$$\log \tau_i(\mu\text{sec}) = -(2.55\pm0.14) + (8810\pm220)/T \quad (2)$$

In order to explain this relationship from the viewpoint of chemical kinetics, available experimental data are not enough.

The Induction Periods for NH_3-O_2-N_2 Mixtures and Vibrational Relaxation of Nitrogen. According to the preliminary experiment, the dependence of τ_i on the oxygen content observed for NH_3-O_2-N_2 was similar in tendency to that for NH_3-O_2-Ar. In order to examine the effect of vibrational relaxation of nitrogen, it is desirable to use mixtures of small ammonia and oxygen contents. Therefore, detailed measurments were performed for the mixtures XII and XIII. The results are shown in Fig. 3, where a solid line is calculated by Eq. (2) and open and closed marks correspond to cases (a) and (b), respectively. These two cases were assumed to calculate reflected shock temperatures and oxygen concentrations from the initial pressures and incident shock velocities. As described previously,[4] nitrogen is considered to be relaxed translationally, rotationally, and vibrationally for (a), and to be relaxed translationally and rotationally for (b). In both cases, it was assumed that the internal degrees of freedom of ammonia and oxygen are completely relaxed. From the figure, it is obvious that data calculated for the case (b) agree with the plot for the NH_3-O_2-Ar mixtures at higher temperatures and those for the case (a) at lower temperatures.

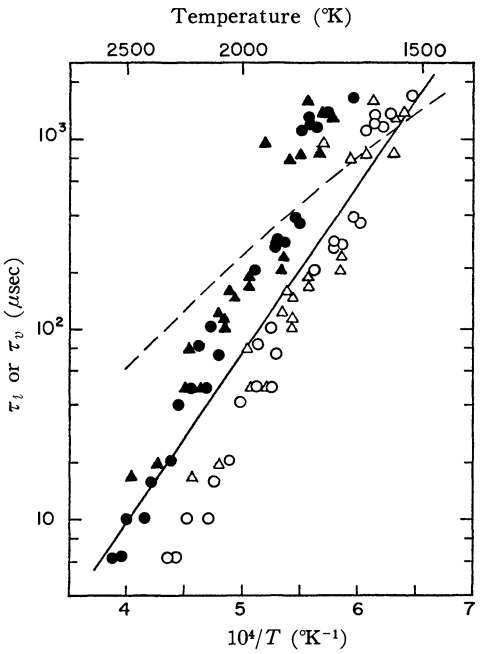

Fig. 3. Arrhenius plot for τ_i and $\tau_{N_2\text{-}N_2}$.
Triangles and circles refer to mixtures XII and XIII, respectively, open marks correspond to case (a) and closed marks to case (b), and a solid and a broken line were calculated from Eqs. (2) and (3).

Vibrational relaxation time of nitrogen, $\tau_{N_2\text{-}N_2}$, is given by the expression of Milliken and White[5] as follows.

$$\log P\tau_{N_2\text{-}N_2}(\text{atm}\cdot\text{sec}) = 102T^{-1/3} - 11.24 \quad (3)$$

Values of $\tau_{N_2\text{-}N_2}$ calculaletd by substituting $P=3.0$ atm, which is an average of pressures behind reflected shock waves for the mixtures XII and XIII, are also shown in Fig. 3 by a broken line. From the figure, it is seen that $\tau_{N_2\text{-}N_2}$ is equal to τ_i for the NH_3-O_2-Ar mixtures at 1570°K, and that $\tau_{N_2\text{-}N_2}<\tau_i$ below this temperature and $\tau_{N_2\text{-}N_2}>\tau_i$ above it. Therefore, it is expected that the case (a) is applicable at lower temperatures and (b) at higher temperatures. However, the crossover temperature from (a) to (b) in Fig. 3 is higher than that expected. This is considered to be due to the effect of NH_3 and O_2 in shortening the vibrational relaxation time.[3]

It is well known[6] that translational temperature of polyatomic gas behind the shock wave decreases exponentially with time t as follows.

$$\frac{T-T_a}{T_b-T_a} = \exp\left(-\frac{C_p t}{C_p'\tau_v}\right) \quad (4)$$

Here, T_a and T_b are shock wave temperatures corresponding to the cases (a) and (b), C_p is average specific heat at constant pressure, C_p' is C_p minus vibrational contribution, and τ_v is vibrational relaxation time. For the system diluted with argon, the temperature behind shock front is almost constant during the induction period. However, for the system diluted with nitrogen, the temperature decreases from T_b and approaches to T_a during the induction period according to Eq. (4). Therefore, instead of constant temperature in the case of argon dilution, average temperature must be adopted to define temperature of the system diluted with nitrogen. Thus, temperature T of the reaction system during the induction period τ_i is given as follows by using Eq. (4).

$$T=\frac{1}{\tau_i}\int_0^{\tau_i} T dt$$

6) T. L. Cottrell and J. C. McCoubrey, "Molecular Energy Transfer in Gases," Butterworths, London (1961), p. 54.

$$= \frac{\tau_v}{\tau_i}\cdot\frac{C_p'}{C_p}(T_b-T_a)\left\{1-\exp\left(-\frac{C_p\tau_i}{C_p'\tau_v}\right)\right\} + T_a \quad (5)$$

Therefore, if τ_v is known, it is possible to calculate temperature of the system from Eq. (5). According to the empirical expression of Millikan and White[7] (which is not correct theoretically but very useful) where only translation-to-vibration energy conversion was assumed, τ_v of the present system is expressed as follows.

$$(P\tau_v)^{-1} = \phi_{N_2}(P\tau_{N_2\text{-}N_2})^{-1} + \phi_{NH_3}(P\tau_{N_2\text{-}NH_3})^{-1} + \phi_{O_2}(P\tau_{N_2\text{-}O_2})^{-1} \quad (6)$$

Here, relaxation times with two subscripts refer to relaxation of the first species when it is present at high dilution in the second-named gas at a total pressure of P atm, and ϕ_s' are mole fractions of components. Although $\tau_{N_2\text{-}O_2}$ is not known, this can be estimated by using an empirical formula of Millikan and White[7] and was found to be comparable to $\tau_{N_2\text{-}N_2}$. Since $\phi_{N_2} \gg \phi_{O_2}$ in the present experimental conditions, the third term in Eq. (6) can be neglected. Therefore, Eq. (6) is expressed as follows.

$$(P\tau_v)^{-1} = \phi_{N_2}(P\tau_{N_2\text{-}N_2})^{-1} + \phi_{NH_3}(P\tau_{N_2\text{-}NH_3})^{-1} \quad (7)$$

Here, $\tau_{N_2\text{-}N_2}$ is given by Eq. (3), but no information about $\tau_{N_2\text{-}NH_3}$ is available. How-

ever, recently, White[8] found that $\tau_{N_2\text{-}He}$, $\tau_{N_2\text{-}C_2H_2}$, and $\tau_{N_2\text{-}CH_4}$ are approximately double, equal to, and 60% of $\tau_{N_2\text{-}H_2}$ in the range of 1600 to 2500°K. Since vibrational frequencies of NH_3 are not close to those of N_2, much more rapid vibration-to-vibration exchange between N_2 and NH_3 compared with that between N_2 and C_2H_2 or CH_4 is not expected and $\tau_{N_2\text{-}NH_3}$ may be comparable to $\tau_{N_2\text{-}C_2H_2}$ or $\tau_{N_2\text{-}CH_4}$, that is, to $\tau_{N_2\text{-}H_2}$. Therefore, as a rather reasonable approximation, let us assume

$$\tau_{N_2\text{-}NH_3} \fallingdotseq \tau_{N_2\text{-}H_2} \tag{8}$$

By using an expression for $\tau_{N_2\text{-}H_2}$ given by White,[9] $\tau_{N_2\text{-}NH_3}$ is expressed as follows.

$$\log P\tau_{N_2\text{-}NH_3} \fallingdotseq 35.0(T^{-1/3} - 0.0176) - 8.00 \tag{9}$$

From Eqs. (3), (5), (7), and (9), temperature of the present system can be calculated with a computor by using known values of T_a, T_b, P, C_p/C_p' and τ_i as shown in Table 2, where reflected shock pressure P is an average of those for (a) and (b) since difference between them is less than 0.5% at maximum. Also, calculated values of the temperature T are shown in the table. Thus, in Fig. 4, values of τ_i is plotted against newly obtained values of T. Here, excellent agreement between both polts for NH_3-O_2-N_2 and NH_3-O_2-Ar is observed. This agreement suggests that τ_i for the NH_3-O_2-N_2 is the same as that for NH_3-O_2-Ar and possibility of coupling of vibrational relaxation and oxidation reaction is small. However, we cannot say that it is conclusive unless $\tau_{N_2\text{-}NH_3} \fallingdotseq \tau_{N_2\text{-}H_2}$ is proved. It is a very challenging problem to measure vibrational relaxation times for N_2 dilute in NH_3 and to obtain more detailed informations about kinetics of NH_3–O_2–N_2 system.

The author wishes to express his thanks to Dr. Soji Tsuchiya for his helpful advice, to Mr. Kazutoshi Sugiyama for his help in the experiment, and to Mr. Takashi Suzuki for reviewing the manuscript.

Studies of Photosensitive Resins. III. The Thermal Hardening of Polyvinyl Cinnamate

Kenichiro NAKAMURA, Toshifumi SAKATA and Shinichi KIKUCHI

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received November 16, 1967)

The thermal hardening of polyvinyl cinnamate was investigated. The IR spectrum of the thermally-hardened polyvinyl cinnamate was measured, and the change of its structure by heat was studied. The results showed that the structure of the resin hardened by heat was the same as that of the illuminated resin. The kinetics of the crosslinking by heat was also evaluated; the activation energy for the crosslinking was estimated to be 25.4 kcal/mol. The critical hardening value of polyvinyl cinnamate was also measured and estimated to be about 1.3 crosslinking per polymer molecule.

It is well-known that polyvinyl cinnamate is crosslinked by ultraviolet light[1] and becomes insoluble to any solvent. However, its thermal character has not yet been made clear. Therefore, the mechanism and kinetics of thermal hardening were studied by measuring the IR spectra.

Inami and Morimoto[2] measured the IR spectra of polyvinyl cinnamate before and after light-irradiation, and concluded that the α,β double bond of the cinnamoyl group was broken to the single bond by light. Kirsh *et al.*[3] also measured its IR spectra and obtained the quantum yield and the critical hardening exposure. They estimated that the hardening ratio at the critical point was 0.02%. However, such a method may not be the best way of estimating the critical hardening value, for the resin is not hardened uniformly by light, but is, rather, hardened exponentially with

the depth. On the other hand, the resin is hardened uniformly by heat. Therefore, the present authors also tried to ascertain the hardening ratio at the critical point.

In a previous paper,[4] the ESR spectrum of the irradiated polyvinyl cinnamate was investigated and it was established that two free radicals, the main-chain radical and the cinnamoyl radical, were produced by the irradiation of the resin. The photocrosslinking mechanism has been made fairly clear by such studies as have been described above, but its thermal hardening is still the subject of frequent discussion.

The sensitized polyvinyl cinnamate is sensitive to light in the ultraviolet and visible regions, while the nonsensitized one is sensitive only in the ultraviolet region. Tsuda[5] discussed the sensitization mechanism of the resin on the basis of the triplet-state mechanism. When a sensitizer is added to the resin, it is hardened by light in the region with longer wavelengths than intrinsic ones. The critical and activation energies for the hardening will be kinetically investigated. The thermal hardening of the photosensitive resin is important for the "afterhardening" process and for preservation in the dark. Therefore, the authors also intend to obtain data on such a process.

Experimental

Polyvinyl cinnamate was synthesized by the pyridine method.[1] The synthesized resin was dissolved into a cellosolve acetate solution, and coated on KBr tablet. The samples were heated at various temperatures, and their IR spectra were measured with a Nippon Bunko infrared spectrophotometer, DS-301. When the heated samples were introduced into water after IR measurements, the thin films of resin remained on the surface of the water. These films were put into the solvent, and their residual weights were measured in order to get information on their solubilities.

The authors estimated the hardening rate of the resin by measuring the concentration of the α,β double bond. The amount of the double bond was evaluated by means of the integrated area of the IR absorption signal at 1640 cm^{-1}. The calibration curve was obtained by means of the IR spectra of films with various depths. Beer's law could be applied to them fairly well.

Results and Discussion

The IR Spectrum of the Heated Polyvinyl Cinnamate. The IR spectra of polyvinyl cinnamate before and after illumination are shown in Fig. 1. The resin was exposed for 160 min with a 1000 W Xe lamp. The IR spectrum of the irradiated polyvinyl cinnamate has already been measured by Inami and Morimoto,[2] who reported that absorption band resulting from the double bond, $\nu_{C=C}$ (1640cm^{-1}), δ_{CH} (1315 cm^{-1}), and δ_{CH} (975 cm^{-1}), disappeared and the $\nu_{C=O}$ (171 8cm^{-1}) band shifted to a higher frequency band upon exposure. However, they could not detect any newly-appeared band becaus eof the photocrosslinking.

Figure 1 also shows evidence for the disappearance of the absorption bands resulting from the double bond and the shift of the $\nu_{C=O}$ band. The results agree with those

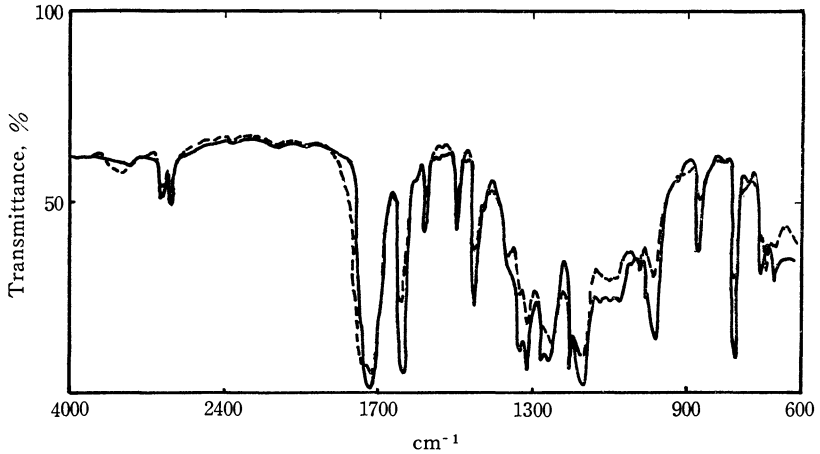

Fig. 2. IR spectra of polyvinyl cinnamate.
—— before heating, ---- after heating

obtained by Inami *et al.*, but Fig. 1 shows that the δ_{CH} band newly appears at 1375 cm^{-1} and that the absorption strengths of all the bands decrease upon exposure to light. It seems that the band is due to the bending vibrational absorption of the saturated CH, which is produced by light-irradiation. Kirsh *et al.*[3] reported that all the absorption bands decreased upon illumination, and concluded that this was caused by the change in electronic structure.

The IR spectrum of the heated polyvinyl cinnamate is shown in Fig. 2. The IR spectra after light-irradiation and after heating are the same. It may, therefore, be concluded that there is no difference between the thermal hardening and photo-hardening of polyvinyl cinnamate with regard to the crosslinking reaction. The disappearance of the $\nu_{C=C}$ (1640 cm^{-1}), and δ_{CH} (1315, 980 cm^{-1}) bands, the decrease of all absorption bands, and the appearance of a new absorption band (1375 cm^{-1}) may also be seen in Fig. 2.

Kinetics of the Thermal Hardening. The rate of the thermal hardening of polyvinyl cinnamate is estimated by measuring the IR spectra. The extent of the double bond was determined by means of the absorption of $\nu_{C=C}$ (1640 cm^{-1}). In the IR spectra of polyvinyl cinnamate, the absorption of the bands resulting from the double bond disappears upon heating, while all the other absorption bands decrease with illumination, as has been described previously. When the sensitized polyvinyl cinnamate was irradiated by a 350 $m\mu$ light, the same IR spectral results as with a non-sensitized one were obtained. The light may not be sufficient to decompose the resin, for its energy is only about 82 kcal/mol, while more than 100 kcal/mol may be necessary to decompose it. Therefore, it seems reasonable to assume that the decrease in the spectrum is not due to the decomposition of the resin, but is caused by the change in electronic

structure proposed by Kirsh.[3] The electronic structural change can be found only in the crosslinked group, and the non-crosslinked group is not affected by it. Therefore, the authors concluded that the IR-determining method of the double bond might be useful.

Relations between the heating times and the rates of the non-crosslinked cinnamoyl group at various temperatures are shown in Fig. 3 and Table 1.

The thermal hardening of polyvinyl cinnamate can be expressed by the formula:

$$\frac{dC}{dt} = -aC \qquad (1)$$

where a is a rate constant and C is the concentration of the non-crosslinked cinnamoyl group. Therefore, we obtained the following expression:

$$\log x = \log\frac{C_0}{C} = at \qquad (2)$$

where C_0 is the initial concentration of cinnamoyl groups. This formula shows that there is a linear relation between $\log x$ and t. In Fig. 3, the linear relation is satisfactory, so it may be concluded that, in the thermal-hardening process, the reaction can be expressed by the first order, as is shown in formula (1).

When polyvinyl cinnamate was heated to more than 250℃, the decomposition reaction took precedence over the crosslinking and the sample was colored, while the resin is rapidly hardened at more than 200℃. Therefore, in the "afterhardening process" it is better to keep the temperature at about 200℃. After the values at various temperature were estimated by means of formula (2), they were plotted against $1/T$. The relation is shown in Fig. 4. In Fig. 4 the good linear relation between them can be seen. The activation energy of the thermal crosslinking reaction can be obtained from the slope of the line: it is evaluated as 25.4 kcal/mol. About one hundred kcal per mole is necessary to harden polyvinyl cinnamate by light, but a much smaller energy is sufficient to harden it by heat. The energy level of the lowest triplet state of polyvinyl cinnamate was inferred to be 57.2 kcal/mol from the ground state by measuring the phosphorescence spectrum of cinnamic acid.[6] The activation energy is smaller than the triplet state energy. The critical energy of the sensitization should correspond to the triplet-state energy.[7] The above results suggest that the critical energy of sensitization can be diminished to 25.4 kcal/mol if the triplet-state energy is degraded by some methods such as introduction of substitutional groups to the benzene ring of the cinnamoyl group. The following expression can be derived from data in Table 1:

$$y = 1 - \exp(-at) \qquad (3)$$

where y is a hardening ratio and where:

$$a = a_0 \exp(-E/\boldsymbol{k}T)$$
$$a_0 = 4.22\times10^7 \text{ sec}^{-1}$$
$$E = 25.4 \text{ kcal/mol}$$

When the hardening ratio is very small, formula (3) can be expressed by:

$$y = at \qquad (4)$$

The solubilities of the thermally-hardened resin were investigated, thus making it clear that all the resins, which had been ascertained by IR measurements to be hardened, were insoluble in any solvent.

The critical hardening ratio of polyvinyl cinnamate was evaluated from formula (4). The resin become insoluble in the solvent when kept at 147℃ for 10 min. The average degree of polymerization of the resin was 2000, and the degree of esterification was estimated to be 76.5% by the method proposed by Tsuda.[8] The critical hardening ratio was

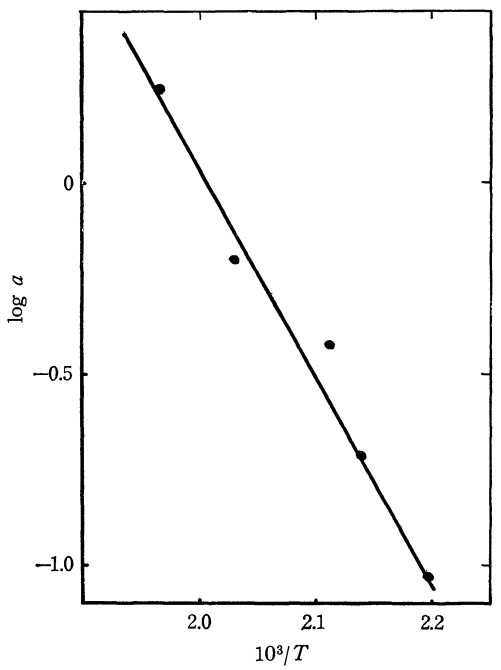

Fig. 4. Rate constants against $1/T$.

6) K. Nakamura and S. Kikuchi, This Bulletin, in press.
7) M. Tsuda, International Conference on Photographic Science, Tokyo, 1967.
8) M. Tsuda, *Kogyo Kagaku Zasshi* (*J. Chem. Soc. Japan, Ind. Chem. Sect.*), **66**, 1365 (1963).

calculated to be 7.68×10^{-4} by formula (4). Therefore, the number of crosslinked cinnamoyl groups per polymer molecule was computed to be 1.17. On the other hand, the critical value of the resin (the degree of polymerization was 1400, and the degree of esterification was 68.5 %) was found to be 15.36×10^{-4}, and the number of hardening groups was 1.47 groups per polymer molecule. Therefore, it seemed that the critical hardening value of polyvinyl cinnamate was about 1.3.

Formerly, the present authors showed that the minimum exposure time, t_{min}, for the photo-crosslinking of the resin could be expressed by[9]:

$$t_{min} = \frac{2\gamma_c Cd}{S_\phi \lambda} \qquad (5)$$

where γ_c is the critical hardening value, C is the concentration of the cinnamoyl group, d is the depth of the polymer layer, λ is average degree of polymerization, and S_ϕ is the quantum photosensitivity. The quantum photosensitivity can be evaluated by using the critical hardening value.

On the basis of above results, it was concluded that the most suitable temperature for the "afterhardening process" was about 200℃, that the activation energy for the thermal hardening was 25.4 kcal/mol, and that the critical hardening value was about 1.3 groups per polymer molecule.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1769—1775 (1968)

The Primary Photochemical Process of 4-Nitropyridine *N*-Oxide

Norisuke HATA*[1]

Department of Applied Science, Tokyo Electrical Engineering College, Kanda Nishiki-chô, Chiyoda-ku, Tokyo

and Eiichi OKUTSU and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 25, 1967)

In order to clarify the primary photochemical process of 4-nitropyridine *N*-oxide in solution, investigations by means of a steady-light irradiation and a flash spectroscopic method were carried out. 4-Nitropyridine *N*-oxide changes photochemically to 4-hydroxypyridine *N*-oxide nitrate (Process I) or 4-hydroxylaminopyridine *N*-oxide (Process II), depending on the reaction conditions. In either case, Process I and Process II, the photochemical reaction was found to proceed through the common intermediate species A. We concluded from the experimental results that Process I involves a bimolecular interaction between the intermediate A and the unexcited 4-nitropyridine *N*-oxide molecule, while Process II involves a hydrogen-abstracting reaction from a solvent molecule.

Recently, pyridine and quinoline-*N*-oxides and their several derivatives have been reported by various workers to cause a photochemical change in the N-O group when they are irradiated with ultraviolet light in either a solution or vapor.[1-4] The introduction of nitro group into the 4-position of pyridine *N*-oxide, has been found to cause a photochemical change completely different from those of pyridine- and 2-picoline-*N*-oxides in solution.[5,6] That is, 4-nitropyridine *N*-oxide in ethanol changes photochemically in two

ways, depending on the reaction conditions, to give 4-hydroxypyridine *N*-oxide nitrate or 4-hydroxylaminopyridine *N*-oxide, while the N-O group remains unchanged.[5,6] Therefore, in order to clarify the primary process of such an interesting photochemical reaction of 4-nitropyridine *N*-oxide, we carried out investigations by means of a steady-light irradiation and also a flash spectroscopic method in solution.

Experimental

Materials. The 4-nitropyridine *N*-oxide used in this experiment was synthesized by Ochiai's method,[7] and the product was purified by several recrystallizations from acetone. Ethanol and glycerol were reagent-grade products of Wako Pure Chemical Industries, the spectro-grade ethanol was also used.

Steady-light Experiment. The light source employed was a Toshiba high-pressure mercury lamp (H-400 P), while for the 3130 Å irradiation a filter combination of a nickel sulfate solution with a UV-31 Toshiba filter was used. Sample solutions in various concentrations were added to the quartz cylindrical reaction cell and then placed in a thermostated box with two quartz windows, through which collimated light passed to irradiate the sample solutions. In order to determine the quantum yield of the 4-nitropyridine *N*-oxide disappearance, the light intensity was measured with a potassium ferrioxalate actinometer. The absorption spectra were taken with a Hitachi recording spectro-photometer, EPS-2 U.

Flash Spectroscopic Experiment. The photolysis flash lamp consisted of a quartz tube 200 mm in length and about 20 mm in diameter, filled with xenon gas to about 150 mmHg. By discharging a bank of a condenser with a capacity of 25 μF charged to 4 kV, 200 joules of energy were dissipated; the half-width of the discharge time was about 50 microseconds. The reaction cell, consisting of a quartz tube 70 mm in length and 20 mm in diameter, was set parallel to the photolysis lamp. The reaction cell and the photolysis lamp were surrounded by a reflection plate. The flash lamp for the spectrograph was constructed much like to the photolysis lamp, but the capacity was 8 μF charged to 3.2 kV, the energy was about 40 joules, and the half-width of the discharge time was about 20 microseconds.

Experimental Results

Before describing the experimental results, it will be usefull for understanding the primary photochemical process of 4-nitropyridine *N*-oxide to mention briefly the photochemical reaction in an ethanol solution. The absorption spectrum of 4-nitropyridine *N*-oxide (*ca.* 10^{-4}—10^{-3} mol l^{-1} in ethanol) decreases progressively in intensity, and a new absorption band with its maximum at 269 mμ appears, as the irradiation time increases. Figure 1 shows the results for the 5×10^{-5} mol l^{-1} ethanol solution. After concentrating the irradiated solution under reduced pressure, the oily residues (Prod. X) are gradually crystallized to afford 4-hydroxypyridine *N*-oxide nitrate.[7] This photochemical reaction is referred to as Process I. When the concentrated ethanol solution of 4-nitropyridne *N*-oxide (*ca.* 10^{-2} mol l^{-1}) is irradiated with a 3130 A light in a nitrogen atmosphere, however, the nitro group of the 4-position is photochemically reduced to yield 4-hydroxylaminopyridine *N*-oxide.[6] The progressive change in the absorption spectrum of 4-nitropyridine *N*-oxide at 3130 Å irradiation is shown in Fig. 2, where two isosbestic points are observed at 254 mμ and 308 mμ.[6] This photochemical reaction is referred to as Process II.

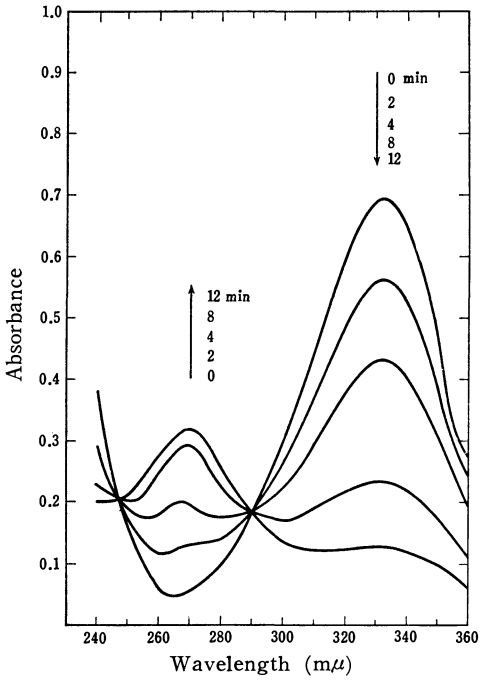

Fig. 1. The progressive spectral change of 4-nitropyridine *N*-oxide on 3130 Å irradiation in ethanol (5×10^{-5} mol l^{-1}). Numbers refer to irradiation time.

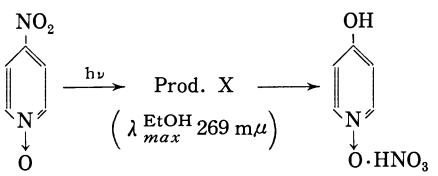
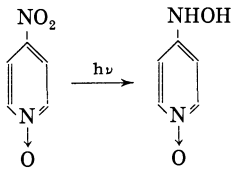


Process I

7) E. Ochiai, *J. Org. Chem.*, **18**, 535 (1953).

Process II



In order to examine the concentration dependency of the photochemical reaction, the 3130 Å irradiation was carried out in ethanol solutions with various concentrations of 4-nitropyridine *N*-oxide. Whether Process I or Process II was determined from the ultraviolet absorption spectrum of the irradiated solution, the results thus obtained are shown schematically in Fig. 3. As can be seen from Fig. 3, Process II proceeds both in a solution with an extremely low concentration (less than *ca.* 2×10^{-5} mol l^{-1}) and in a solution with a high concentration (over *ca.* 10^{-4} mol l^{-1}), whereas Process I proceeds strikingly in a solution with a medium concentration (*ca.* 10^{-4}—10^{-5} mol l^{-1}). The results obtained for the deaerated solution indicate that Process II can be facilitated by excluding any oxygen dissolved in the solution, and that Process I can proceed even in a deaerated solution.

Next, we examined the effect of the viscosity on the photochemical process and the effect of the concentration on the quantum yield of the 4-nitropyridine *N*-oxide disappearance. Figure 4 shows the progressive spectral change in 4-nitropyridine *N*-oxide when it is irradiated with 3130 Å light in glycerol and also in a glycerol solution mixed with various amounts of ethanol. Although Process II proceeded in a highly viscous solution, a lowering of the viscosity of the solution was observed to lead to a switch in the photochemical reaction from Process II to Process I. As is shown in Fig. 5, the quantum yield of 4-nitropyridine *N*-oxide disappearance in ethanol, where Process I takes

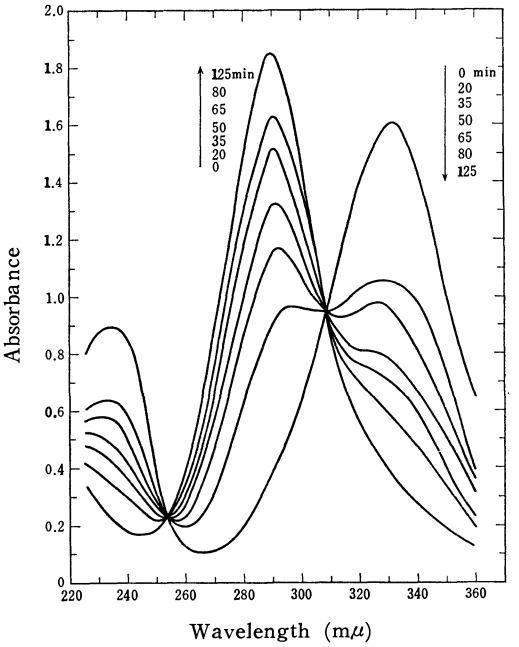


Fig. 2. The progressive spectral change of 4-nitropyridine *N*-oxide on 3130 A irradiation in ethanol (1.8×10^{-2} mol l^{-1}). Numbers refer to irradiation time.

place, increased markedly with an increase in the concentration, giving a maximum value (1.6—1.8) in the region of about 6×10^{-4} mol·l^{-1}. A further increase in the concentration caused a decrease in the quantum yield. On the other hand, the quantum yield in glycerol, where Process II takes place, was independent of the concentration and showed an average value of about 0.7. Figure 6 shows the temperature dependence of the quantum yield where the quantum yield of 4-nitropyridine *N*-oxide disappearance was observed to increase with a rise in the temperature. Although the quantum yield mentioned above was measured in a solution which had not

been degassed, a comparison with the results for a solution degassed by flushing with nitrogen at 30°C indicated that there is possibly no effect of the oxygen dissolved in the solution on the quantum yield.

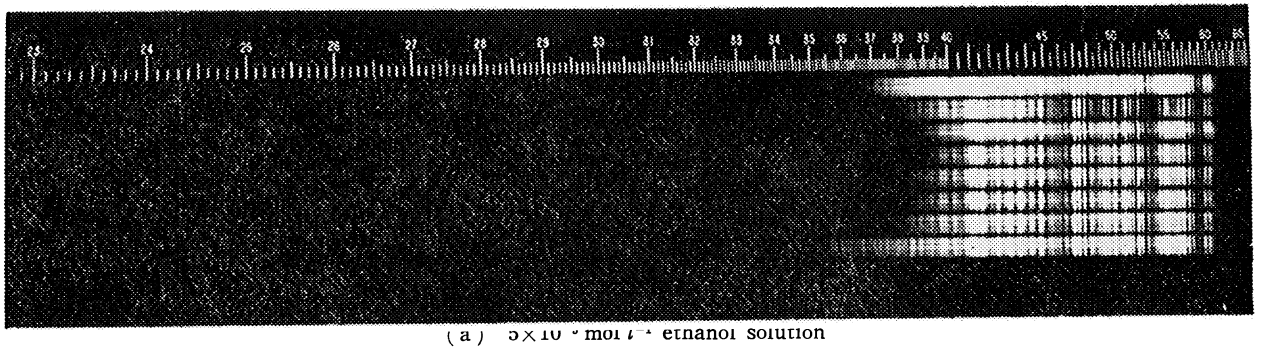
Finally, in order to get information on the photochemical intermediate which may be formed during the reaction, the flash spectroscopic examination was carried out in both ethanol and glycerol. In the case of a 5×10^{-5} mol l^{-1} ethanol solution (Fig. 7 (a)), transient absorptions were observed around 370 mμ and 570 mμ, but they disappeared within about 10^{-4} sec to give a shorter wavelength absorption (260 mμ—270 mμ) corresponding to the Prod. X being formed in Process I. In the case of a glycerol solution (4×10^{-5} mol l^{-1}), the same transient absorptions as in the case of an ethanol solution appeared around 370 mμ and 570 mμ, as is shown in Fig. 7 (b); these absorptions decayed within about 10^{-4} sec to give the absorption of 4-hydroxylaminopyridine *N*-oxide via Process II. Figure 7 (c) shows the results for the flash illumination in a very dilute ethanol solution (2×10^{-5} mol l^{-1}), which indicated the appearance of the same transient absorption, followed by Process I and Process II. In all these experiments, the transient absorption common to all three cases was independent of the presence or absence of oxygen in the solution.

Discussion

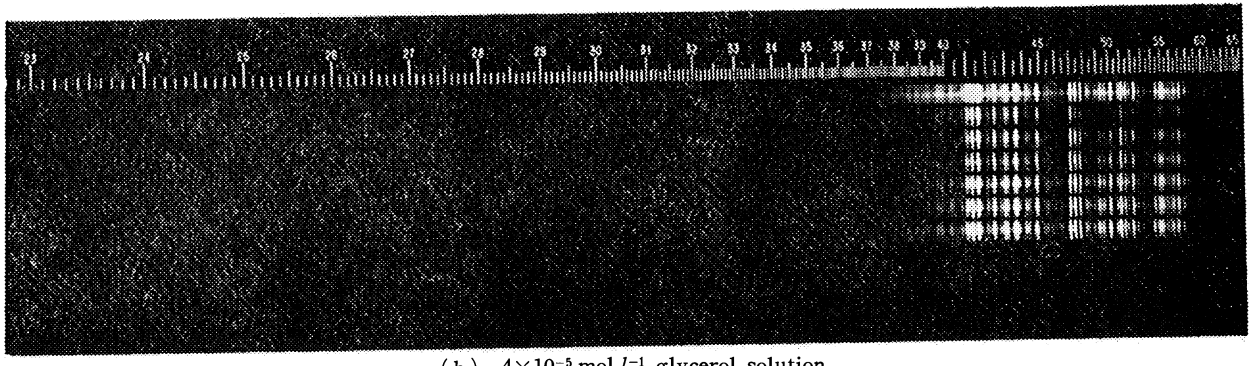
In the present paper, we propose the primary process shown schematically in Fig. 8 for the photochemical reaction of 4-nitropyridine *N*-oxide in solution, where S_0 and S_1 denote, respectively, the ground and the lowest excited singlet-state molecules, while both A and B represent intermediate species.

The following conclusions have been drawn from the flash spectroscopic experiments: 1) Both Process I and Process II proceed through the intermediate A. 2) The absorption spectrum of the intermediate A is always observed around 370 mμ and 570 mμ, regardless of the dissolved oxygen in solution, possibly meaning that the intermediate A is not a triplet state. 3) The intermediate A has a relatively long lifetime (*ca.* 10^{-4} sec), which suggests the possibility of a bimolecular interaction between the intermediate A and unexcited 4-nitropyridine *N*-oxide (S_0).

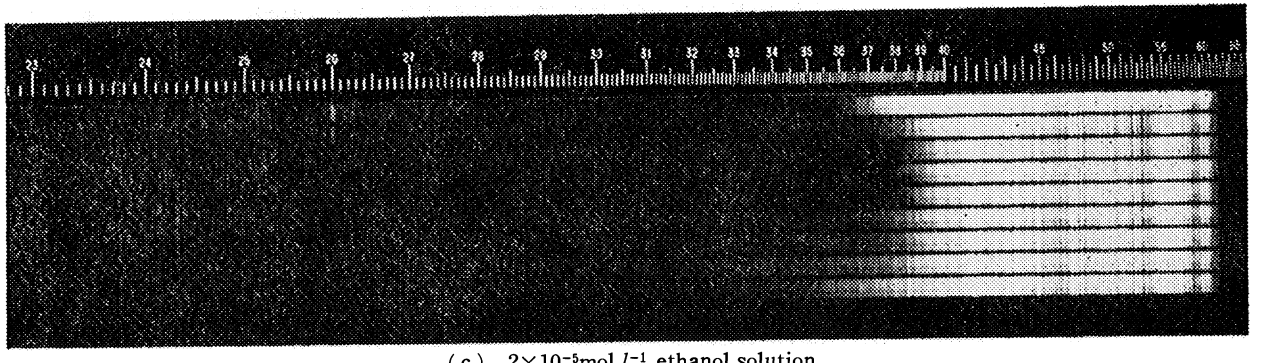
It is very difficult to bring the intermediate A together with an unexcited *N*-oxide molecule (S_0) in a glycerol solution because of the high viscosity of the solvent. As has been reported in a previous paper,[6] Process II involves a hydrogen atom-abstracting process from a solvent molecule, and thus an intermediate A probably abstracts a hydrogen atom from a glycerol molecule to form 4-hydroxylaminopyridine *N*-oxide finally. As to the hydrogen atom-abstracting species, however, it is not possible to say anything about whether it is an intermediate A or an intermediate B transformed further from an intermediate A. In any case, the intermediate A is responsible for Process II. Similarly, in a very dilute solution of 4-nitropyridine *N*-oxide the intermediate, either A or B, is considered to make an abstraction of a hydrogen atom from an ethanol molecule before colliding with an unexcited *N*-oxide molecule (S_0). In fact, the experimental results show that only Process II takes place in these solutions.



(a) 5×10^{-5} mol l^{-1} ethanol solution



(b) 4×10^{-5} mol l^{-1} glycerol solution



(c) 2×10^{-5}mol l^{-1} ethanol solution

Fig. 7. Flash photolysis of 4-nitropyridine *N*-oxide.

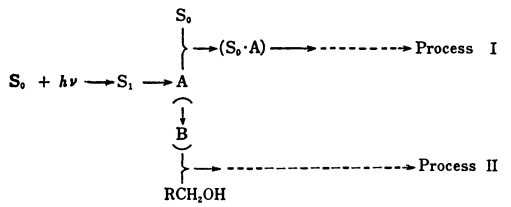


Fig. 8. The primary photochemical process of 4-nitropyridine *N*-oxide in solution.

On the other hand, as the concentration of 4-nitropyridine *N*-oxide in ethanol increases, the possibility of a collisional encounter of the intermediate A with an unexcited *N*-oxide molecule (S_0) becomes more likely; therefore, a bimolecular reaction between them can be expected to take place. This is confirmed by the experimental results on the concentration dependence of the photochemical reaction (Fig. 3) and on the quantum yield of 4-nitropyridine disappearance (Fig. 5). Moreover, further support for it is given by the following experimental results: 1) As the viscosity of the glycerol solution is lowered by adding various amounts of ethanol, the photochemical reaction is converted from Process II to Process I (Fig. 4). 2) The quantum yield of the 4-nitropyridine *N*-oxide disappearance in an ethanol solution increases gradually with a rise in the tempreature (Fig. 6), from which fact the activation energy is estimated to be about 5 kcal mol^{-1}, which is considered to correspond to the activation energy of diffusion.

However, the following experimental results are not clearly explained: 1) In a very concentrated ethanol solution Process I does not proceed; rather, Process II takes place. 2) In connection with 1), the quantum yield of the 4-nitropyridine *N*-oxide disappearance decreases with an increase in the concentration after reaching its maximum value. One possible explanation for these facts is to assume the formation of a transient weak complex between A and S_0. That is, with an increase in the concentration, most of the weak complex formed may be quenched by collision with an unexcited *N*-oxide molecule (S_0), thus reproducing S_0 and A, and the intermediate species, A, thus reproduced may be responsible for Process II. Further studies of these points, including the details of Process I and II and the nature of the intermediate A, are now in progress and will be reported on later.

In conclusion, the authors wish to express their hearty thanks to Professor S. Kato of Osaka University and Dr. Y. Mori of the Tokyo Institute of Technology for their valuable suggestions.

and Akihiko YABE, Hiroko MURAYAMA and Masako HAYASHI

Faculty of Home Economics, Ochanomizu University, Otsuka, Tokyo

(Received January 9, 1968)

The aggregation of dyes in an aqueous or alcoholic solution has been studied spectroscopically by a method named the "maximum slope method." The method can ascertain the molar absorptivity and formation constant of dye aggregate when a simple equilibrium model between a monomer and an *n*-mer is assumed to be operative, and when the absorptivity of monomer is given. Further, the molar absorptivities of the monomer and the polymers and the formation constants of the polymers are adjusted, in order to minimize the mean deviation, by an other method, named the "minimum deviation method." Using the latter method, the parameters of an equilibrium system including a monomer and several polymers can also be calculated. Aggregations of Benzopurprine 4 B and Sky Blue FF in aqueous salt solutions were studied by the above two methods. Aggregations of these dyes in aqueous alcoholic solutions were also discussed.

In resent years, the solvent-assisted dyeing of wool goods by acid dyes has been developed for the industrial use, and several fundamental discussions of the mechanism of solvent dyeing have been reported.[1,2]

Yabe and Hayashi[3,4] have already reported on the extraordinarily quick and high absorption of direct dyes on cellulose in the H_2O/*n*-BuOH dyebath system, and compared the absorption spectrum of the cellophane dyeings from normal and solvent-assisted systems.

A new way of determining the aggregation numbers of organic substances including dyes in solution has to be developed, as the physical state of direct dyes in solution is supposed to influence greatly on that of dyes on the substrates. This report may contribute to clarify the aggregation of dye molecules in solution.

When a dye aggregates in solution, the molar absorptivity (ε) changes with an increase in the dye concentration; it shall be given by a weighted mean of the molar absorptivities of each aggregate (Eq. (1)):

$$\varepsilon = \sum_{i=1}^{n} f_i \varepsilon_i, \qquad (1)$$

where ε_i is the molar absorptivity of the pure *i*-mer, and f_i, the corresponding molar fraction. Since the equilibrium constant, K_i and ε_i can not be determined from Eq. (1) alone, a simple equilibrium between the monomer and a polymer of only one distinct degree of aggregation is assumed*1; then:

$$\varepsilon = f_1\varepsilon_1 + f_n\varepsilon_n, \qquad (2)$$

$$1 = f_1 + nf_n. \qquad (3)$$

If the activity coefficients are assumed to be constant in the concentration range studied, we have:

$$f_n = K_n C_1{}^n C, \qquad (4)$$

where C_1 and C are the monomer and the total dye concentration respectively. By combining Eq. (2) with Eqs. (3) and (4), we get Eq. (5):

$$\log C(\varepsilon_1-\varepsilon) = n \log C(\varepsilon-\bar{\varepsilon}_n) + \log nK_n(\varepsilon_1-\bar{\varepsilon}_n)^{1-n}. \qquad (5)$$

In Eq. (5), ε_n/n is designated as $\bar{\varepsilon}_n$. Hence, if $\log C(\varepsilon_1-\varepsilon)$ is plotted against $\log C(\varepsilon-\bar{\varepsilon}_n)$, the points should lie on a straight line, the slope of which gives the degree of aggregation (n), and the equilibrium constant (K_n) can

*1 This simplifying assumption of the monomer-*n*-mer equilibrium model has been accepted as being consistent in many dye aggregation systems.

be calculated from the intercept. By assuming suitable values for ε_1 and $\bar{\varepsilon}_n$, Kuhn[5] has shown that the association degree of sodium phthalocyaninetetrasulfonate is 2 and 4 in, respectively, lower and higher concentration ranges in aqueous solutions, while Zanker[6] and Mataga[7] suggested neglecting the $\bar{\varepsilon}_n$'s of basic dyes in the calculation of Eq. (5), as they are too small compared with ε and ε_1. However, the values of ε_1 and $\bar{\varepsilon}_n$ are not always determined accurately, or $\bar{\varepsilon}_n$ cannot be neglected, especially when the polymer band does not differ very much from the monomer band. In such cases, therefore, it seems difficult to obtain reliable results by the use of Eq. (5).

In an attempt to avoid these difficulties, Hosoya and Nagakura computed the ε_1, ε_2 and K_2 of benzoic acid in the dimerisation stage in an aqueous solution by means of least-squares calculation.[8] The method developed by them affords the most reliable results, but the computations must be carried out on a computer, since the least-squares calculation had to be repeated until the parameters converge to certain values.

The present authors have, therefore, developed a method, named the "maximum slope method,"*2 which involves a simpler computation and less supposition, and which still gives more reliable results.

Theoreticals

(1) **Maximum Slope Method.** Equation (6) is derived from Eq. (5):

$$\frac{1}{n-1}\log(\varepsilon_1-\varepsilon)-\frac{n}{n-1}\log(\varepsilon-\bar{\varepsilon}_n)=\log\alpha C,$$
$$\alpha=(nK_n)^{1/(n-1)}(\varepsilon_1-\bar{\varepsilon}_n). \qquad (6)$$

Taking $\log\alpha C=X$, Eq. (6) reads:

$$\frac{1}{n-1}\log(\varepsilon_1-\varepsilon)-\frac{n}{n-1}\log(\varepsilon-\bar{\varepsilon}_n)=X. \qquad (7)$$

The curve of ε *vs.* $\log C$ can be correlated with the curve of ε *vs.* X as follows.

(1) The two curves can be superposed on each other by sliding over the abscissa for some distance ($\log\alpha$); equilibrium constant (K_n) can thus be calculated.

(2) The maximum slope of the tangents of two curves ($\varepsilon-\log C$ and $\varepsilon-X$) are equal to each other; that is,

$$(\mathrm{d}\varepsilon/\mathrm{d}(\log C))_{\max}=(\mathrm{d}\varepsilon/\mathrm{d}X)_{\max}$$
$$=-2.3\left(\frac{\sqrt{n}-1}{\sqrt{n}+1}\right)(\varepsilon_1-\bar{\varepsilon}_n)$$

(3) The maximum slope is proportional to $(\varepsilon_1-\bar{\varepsilon}_n)$. The values of $\bar{\varepsilon}_n$, K_n and n are obtained by the following procedure on the basis of these three correlations:

(1) The maximum slope (m_0) of the tangent of the plotted curve ($\varepsilon-\log C$) is determined, and the absorptivity ε_1 is evaluated by extrapolating to an infinite dilution.

(2) On substituting a suitable value for $\bar{\varepsilon}_n$, and 2 for n, the X's corresponding to ε's are computed from Eq. (7).

(3) Then the maximum slope (m) of the tangent of the curve ($\varepsilon-X$) is determined. In general, m is not equal to m_0, because $\bar{\varepsilon}_n$ is not the true value. However, $\bar{\varepsilon}_n$ can easily be adjustable to its true value ($(\bar{\varepsilon}_n)_0$) by Eq. (9):

$$m_0/m=(\varepsilon_1-(\bar{\varepsilon}_n)_0)/(\varepsilon_1-\bar{\varepsilon}_n) \qquad (9)$$

(4) The curve ($\varepsilon-X$) is slided over the abscissa until the two tangential maximum-slope are superposed.

(5) These fitting processes are also carried out on $n=3$, 4, and so on.

(6) Then, we determine the theoretical n value which best fits the experimental curve.

Hosoya and Nagakura's results on the dimerisation of benzoic acid in an aqueous solution[8] have been analysed by this maximum slope method, and the final values of ε_1, ε_2 and K_2 and the accuracy were compared with those obtained by the repeated least-squares method by the above authors (Table

1). Table 1 shows that the accuracy of the maximum slope method is as good as that of the repeated least-squares method.

(2) The Minimum Deviation Method. In spite of its usefulness, the maximum slope method has the defect that one should assume a definite value of ε_1, for an error involved in the evaluation of ε_1 may result in some uncertainty in the $\bar{\varepsilon}_n$, K_n or even n value estimated. In this respect, the values, ε_1, $\bar{\varepsilon}_n$ and K_n obtained from the maximum slope method must be readjusted to minimize the possible errors by the minimum deviation method. The mathematical procedure is as follows:

The zero approximations, $(\varepsilon_1)_0$, $(\bar{\varepsilon}_n)_0$ and $(K_n)_0$, are chosen as the values obtained by the maximum slope method. The calculated absorptivities, ε_{calc}, are obtained from Eq. (2') using the monomer concentrations, C_1, obtained by solving Eq. (10):

$$\varepsilon_{calc} = (\varepsilon_1 C_1 + n\bar{\varepsilon}_n K_n C_1^n)/C \quad (2')$$

$$C = C_1 + nK_n C_1^n \quad (10)$$

A mean deviation (Δ) is given by Eq. (11):

$$\Delta = \frac{1}{N}\sum |\varepsilon_{calc} - \varepsilon_{obs}|/\varepsilon_{obs}$$

The effects (δ) of changing each parameter by 0.1% on the mean deviation are determined to be:

$$\left.\begin{aligned} \delta_1 &= \Delta(1.001\,\varepsilon_1, \bar{\varepsilon}_n, K_n) - \Delta(\varepsilon_1, \bar{\varepsilon}_n, K_n) \\ \delta_2 &= \Delta(\varepsilon_1, 1.001\,\bar{\varepsilon}_n, K_n) - \Delta(\varepsilon_1, \bar{\varepsilon}_n, K_n) \\ \delta_3 &= \Delta(\varepsilon_1, \bar{\varepsilon}_n, 1.001\,K_n) - \Delta(\varepsilon_1, \bar{\varepsilon}_n, K_n) \end{aligned}\right\} \quad (12)$$

Then, all the parameters are simultaneously changed in proportion to $\varepsilon_1\delta_1$, $\bar{\varepsilon}_n\delta_2$, and $K_n\delta_3$, respectively, until no further decrease in the mean deviation is found. Thus, the new parameters, the higher approximations, are obtained, and again their effects on the mean deviation are determined; the same fitting process continues until no further decrease in the mean deviation is possible.*3

The results refined by the minimum deviation method are compared with those obtained by the maximum slope method and those obtained by the least-squares method in Table 1. It can be seen that a combination of the maximum slope method with the minimum deviation method can give the best fit of the experimental curves of ε *vs.* $\log C$. Also, it is noticeable that the results obtained by the maximum slope method do not differ much from the best values.

When the mean deviations of several monomer-n-mer models are similar to one another, one should also consider models including all or some of those n-mers; that is,

$$mD \rightleftarrows D_{m_1} + D_{m_2} + \cdots + D_{m'} \quad (m = \sum m_i) \quad (13)$$

In this case the monomer concentration is obtained by solving Eq. (14), instead of Eq. (10), and ε_{calc} is computed by Eq. (15):

$$C = C_1 + m_1 K_{m_1} C_{1m_1} + \cdots + m' K_{m'} C_1^{m'} \quad (14)$$

$$\varepsilon_{calc} = (\varepsilon_1 C_1 + \varepsilon_{m_1} K_{m_1} C_{1m_1} + \cdots + \varepsilon_{m'} K_{m'} C_1^{m'})/C \quad (15)$$

The ε_i and K_i values of each polymer, as evaluated by the above-described procedure, were taken as the zero approximation and were treated by a process similar to the minimum deviation method.

Results and Discussions

(1) Benzopurprine 4B (C.I. Direct Red 2) in an Aqueous Salt Solution. Benzopurprine 4B did not aggregate in an aqueous solution; no change in absorptivity was observed in the concentration range between 10^{-7} and 10^{-4} mol/l.*4

On the other hand, upon the addition of

*3 In actuality the process was stopped when Δ increased with variations in ε_1, $\bar{\varepsilon}_n$, and K_n by $\varepsilon_1\delta_1$, $\bar{\varepsilon}_n\delta_2$, and $K_n\delta_3$ respectively.

*4 The constancy of molar absorptivity does not always preclude the existence of aggregates in solution. Much work has to be done in this connection.

salt (NaCl) the absorption spectrum shifted both hypso- and hypochromicaly; this shows the formation of dye aggregates in an aqueous salt solution. Table 2 shows the aggregation parameters at a salt concentration of 20 mmol/l and also the mean deviations of models, including monomer to tetramer; the latter appear to be similar to one another, although the deviation of the monomer-dimer system is the least. Unfortunately, we could not decide from the point of view of statistical analysis which model was preferable, because of the inevitable experimental errors.

The parameters at a salt concentration of 40 mmol/l are compared in Table 3. A statistical analysis showed that the monomer-dimer and monomer-dimer-trimer-tetramer models could be discarded, because of their large deviations. Thus, the monomer-dimer-trimer, monomer-trimer, and monomer-tetramer models are preferable in this case from the point of view of statistical analysis. On the other hand, Fig. 1 shows that the monomer-trimer model approximates the monomer-dimer-trimer model because of the negligible contribution of the dimer fraction in this case. If we assume that, in the aggregation stage of Benzopurprine 4B, several polymers exist together rather than a single polymer, and if the monomer - n-mer model can be considered as an approximation of the model including the monomer and all or some of the polymeres up to n-mer, the most preferable model among the models shown in Table 3 is the monomer-dimer-trimer model. Hence, the most preferable model at a salt concentration of 20 mmol/l may be determined to be among the monomer-dimer, monomer-trimer and monomer-dimer-trimer models. Figure 2 shows that the contribution of the dimer at a salt concentration of 20 mmol/l is larger than that at 40 mmol/l.

The deviations of the twenty models including all or a part of the monomer to heptamer at a salt concentration of 80 mmol/l are also compared. The monomer-tetramer-pentamer-hexamer-heptamer, the monomer-hexamer-heptamer, and the monomer-pentamer-hexamer-heptamer models may be preferable from the point of view of statistical analysis. The parameters of these models are also shown in Table 4.

TABLE 5. THE EXTINCTION COEFFICIENTS PER MOLECULE OF AGGREGATE (Benzopurprine 4B)

	NaCl concentration		
$\bar{\varepsilon}_n$	20 mmol/l	40 mmol/l	80 mmol/l
ε_1	0.50	0.50	0.48
$\bar{\varepsilon}_2$	0.43	0.36	—
$\bar{\varepsilon}_3$	0.43	0.42	—
$\bar{\varepsilon}_4$	0.42	0.43	0.36
$\bar{\varepsilon}_5$	—	—	0.35
$\bar{\varepsilon}_6$	—	—	0.37
$\bar{\varepsilon}_7$	—	—	0.36

Thus, it may be concluded that Benzopurprine 4B tends to form higher aggregates in more concentrated salt solutions. Further, it is noteworthy that the extinction coefficients per molecule of aggregates are all approximately the same (Table 5), and that the logalism of K_n increases in arithmetical progression (Fig. 3); that is,

$$\log K_n = 5.3(n-1)^{*5}$$

*5 This may suggest the constancy of the molar free energy of aggregation; the subject will be discussed further elsewhere.

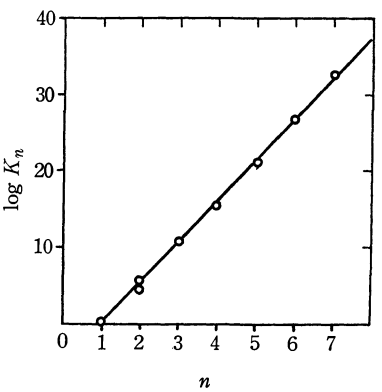

Fig. 3. Plot of $\log K_n$ *vs.* n (Benzopurprine 4B).

Alexander and Stacey observed the formation of the aggregation of Benzopurprine 4B by the light-scattering method; they estimated the degree of aggregation ($n>6$) in solutions of above 10^{-4} mol/l dye and above 10 mmol/l NaCl.[10] Table 6 shows that the dye did not scatter light below 10^{-4} mol/l dye and 20 mmol/l or 40mmol/l salt, but that it did scat-

10^{-4}	0.1	1	44	100	100

*A value at dye concentration 10^{-4} mol/l are chosen as τ_0.

ter light markedly above 10^{-5} mol/l dye and 80 mmol/l salt.

It has been shown that the reduced scattering (C/τ) is in a linear relationship with the reciprocal of the molecular weight.[10] Thus:

$$\text{const. } n^2(dn/dC)^2(C/\tau) = \frac{1}{M} + B_c,$$

where $\tau = I_S/I_0$, and I_S denotes the intensity of the light scattered at a right angle to the incident beam. By supposing that each aggregate scatters light independently, that the interaction term (B_c) is negligible, and that the refractive index (n) may be taken to be nearly constant, the scattering may be approxmately represented by Eq. (15):

$$\tau = I_S/I_0 \propto (\sum i^2 f_i)CM_0, \qquad (15)$$

where the index, i, ranges over the polymers included, f_i is the molar fraction of the i-mer, and M_0 is the molecular weight of monomer. Then the relative scattering (τ/τ_0) can be written as:

$$\tau/\tau_0 = \frac{(\sum i^2 f_i)C}{(\sum i^2 f_i)_0 C_0}, \qquad (16)$$

where τ_0 denotes the scattering of the most concentrated solution. In the fifth and the sixth columns of Table 6, the observed relative scatterings are compared with that calculated by Eq. (16); the molar fractions of the aggregates were computed by the use of the parameters of the monomer-hexamer-hpetamer model.

(2) **Benzopurprine 4B in an Alcoholic Solution.** The plots of the absorptivities against the log C of Benzopurprine 4B in an alcoholic solution were not sigmoid, but in an L shape. This means that the aggregation numbers and or formation constants are very large. If n is taken to be very large, Eq. (6) can be rewritten as Eq. (6'):

10) P. Alexander and K. A. Stacey, *Proc. Roy. Soc. A*, **212**, 274 (1952).

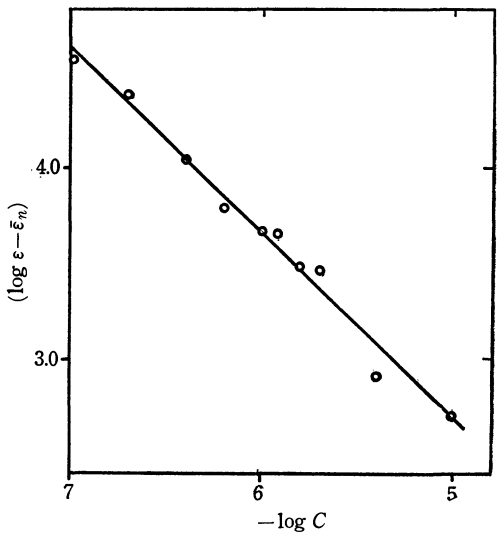

Fig. 4. Plot of log($\varepsilon-\bar{\varepsilon}_n$) *vs.* log C in 90% n-butanol aqueous solution (Benzopurprine 4B). ($\bar{\varepsilon}_n = 5.25\times10^4$)

$$\log(\varepsilon-\bar{\varepsilon}_n) = -\frac{n-1}{n}(\log C + \log\alpha) \qquad (6')$$

Thus, a plot of log($\varepsilon-\bar{\varepsilon}_n$) *vs.* log C gives a straight line with a slope of $-(n-1)/n$, near to -1, and an intercept of $[-(n-1)/n]\log\alpha$. As a typical example, Fig. 4 illustrates the aggregation in a 90% n-butanol aqueous solution in a high polymer ($n \doteqdot 30$). However, the equilibrium between the monomer and a single higher polymer may not be natural.

All from the monomer to the n-mer can be included, if it is assumed that all the absorptivities per molecule of n-mer's, except for the monomer, are identical, and that $K_n = K^{n-1}$. Then we have Eqs. (18) and (19):

$$C = \sum_i i k^{i-1} C_1{}^i \qquad (17)$$

$$C = \varepsilon_1 C_1 + \bar{\varepsilon}_n \sum_i i K^{i-1} C_1{}^i \qquad (18)$$

By combining Eq. (17) with Eq. (18), we obtain:

$$C_1/C = \frac{\varepsilon-\bar{\varepsilon}_n}{\varepsilon_1-\bar{\varepsilon}_n}. \qquad (19)$$

The sum of the progression in Eq. (17) may be calculated as:

$$C = \frac{C_1\{1-(n+1)(kC_1)^n + n(kC_1)^{n+1}\}}{(1-kC_1)^2} \qquad (20)$$

If kC_1 is taken to be much larger than unity, Eq. (20) can be written as follows:

$$kC \doteqdot n(kC_1)^n \qquad (21)$$

By substituting Eq. (19) into Eq. (21), we

get Eq. (22).

$$\log(\varepsilon-\bar{\varepsilon}_n) = -\frac{n-1}{n}(\log C+\log(\varepsilon_1-\bar{\varepsilon}_n)^n k^{1-n}/n) \quad (22)$$

when $(n-1)/n$ is near to unity, Eq. (22) is identical with Eq. (6′). Thus, Eq. (22) can give a physical meaning of Eq. (6′), derived by the monomer-n-mer model. The aggregation number in an n-butyl alcoholic aqueous solution (80%) is obtained as 30 by the linear plots of $\log(\varepsilon-\bar{\varepsilon}_n)$ *vs.* $\log C$. In this case kC_1 calculated by Eq. (23) is much larger than unity, since $\log k(\varepsilon_1-\bar{\varepsilon}_n)^{-1}$ is calculated as 5.3, and $\log C(\varepsilon-\bar{\varepsilon}_n)$ has values ranging between −2.4 and −2.3*6

$$kC_1 = k(\varepsilon_1-\bar{\varepsilon}_n)^{-1}C(\varepsilon-\bar{\varepsilon}_n) \quad (23)$$

(3) Sky Blue FF (C.I. Direct Blue 1) in Aqueous Salt and Alcoholic Solutions. Sky Blue FF aggregates in polymer form not more than in trimer form in an aqueous salt solution. The parameters are compared in Tables 7, 8 and 9.

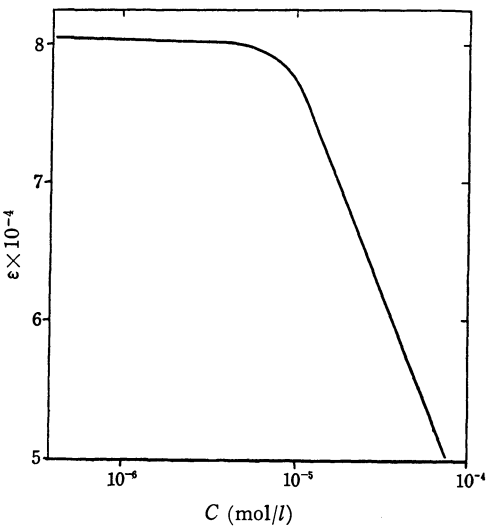

Fig. 5. Change of molar absorptivity of Sky Blue FF with the concentration in butanolic solution.

In aqueous ethanolic solutions the molar absorptivity did not change in a range of the dye concentrations between 10^{-6} and 10^{-4} mol/l. However, we cannot decide from the spectroscopic measurements alone whether Sky Blue FF in aqueous solutions is present in the monomeric or the polymeric state.

On the other hand, the dye in aqueous n-butanolic solutions aggregated suddenly into a very high polymer, or into particles, above 10^{-5} mol/l (Fig. 5). This fact might be connected with the dyeing behavior of the dye in this solvent, but more work is required in order to elucidate this connection.

Experimental

The dyes have been purified several times by the Robinson-Mill method, until no variation in the

*6 If $kC_1 \ll 1$, which is the case in an aqueous ethanolic solution, then :

$$\sqrt{\varepsilon-\bar{\varepsilon}_n} = \sqrt{\varepsilon_1-\bar{\varepsilon}_n} - \frac{k}{\sqrt{\varepsilon_1-\bar{\varepsilon}_n}}C(\varepsilon-\bar{\varepsilon}_n).$$

Hence, k and $(\varepsilon_1-\bar{\varepsilon}_n)$ can be obtained from a plot of $\sqrt{\varepsilon-\bar{\varepsilon}_n}$ *vs.* $C(\varepsilon-\bar{\varepsilon}_n)$.

absorption spectra was found. All the dye solutions were allowed to stand for 24 hr at 30°C after having been prepared, and their absorption spectra were measured at the same temperature.

Computations by the minimum deviation method were carried out on a HITAC 5020 E computer (the Tokyo University computation Center). The computation program used in these calculations was similar to that by Lepse.[11]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1783—1787 (1968)

Dynamic Mechanical Behaviour of Organic Molecular Crystals. II. Elastic Constants of Single-Crystal Anthracene

Takaaki DANNO and Hiroo INOKUCHI

Department of Chemistry, Tokyo Gakugei University, Koganei, Tokyo, and The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received January 10, 1968)

The thirteen elastic constants, C_{ij}, and the elastic compliances, s_{ij}, of monoclinic single-crystal anthracene were determined from sound velocities measured by the ultrasonic pulse method at room temperture. The observed elastic constants were $C_{11}=8.92$, $C_{12}=4.63$, $C_{13}=4.49$, $C_{15}=-2.58$, $C_{22}=13.8$, $C_{23}=8.45$, $C_{25}=-2.59$, $C_{33}=17.0$, $C_{35}=-2.88$, $C_{44}=2.42$, $C_{46}=1.14$, $C_{55}=2.84$ and $C_{66}=3.16$ (in units of 10^{10} dyn/cm^2). The hydrostatic linear compressibilities, β, of the anthracene molecular crystal were then calculated from these elastic constants and compliances; the β along [100] was 12.7×10^{-12} cm^2/dyn, $\beta_{[010]}=4.41\times10^{-12}$ cm^2/dyn, and $\beta_{[001]}=3.59\times10^{-12}$ cm^2/dyn.

It is well known that the general forces of the cohesion, or van der Waals forces, between the polycyclic aromatic molecules play an important part in the building up of organic crystals. The dynamic mechanical properties of these organic molecular crystals provide a sensitive test of the forces, but those studies on this problem have scarcely been undertaken.[1]

In a preceding paper,[2] the dynamic elastic moduli and losses of organic crystals, perylene, anthracene, coronene, 1,2,3,4-dibenzanthracene, and their complexes with trinitrobenzene were observed by a forced-resonance vibration method. By this method, however, only information on the dynamical mechanical properties of the crystals along the longest axis, mainly the b-axis, was obtained.

Since the crystal structures of polycyclic aromatic crystals belong to the monoclinic or the triclinic system, thirteen elastic constants for the monoclinic system and twenty-one constants for the triclinic system must be measured if we are to ascertain all their dynamic mechanical properties exactly.

This paper will present experimental results of acoustic velocity measurements in monoclinic single-crystal anthracene, $C_{14}H_{10}$, by the ultrasonic pulse technique, and the thirteen elastic constants calculated from them.

Experimental Procedures

Sample Preparation. Anthracene, purified by means of zone-refining, was grown by the Bridgman method. The sample, a clump composed of a moderately large single crystal, 20 mm×20 mm×10 mm, was cut along the cleavage plane with a razor blade. The cleavage plane lies parallel to the ab crystalline axes. Further, the direction of the b-axis was decided on the cleavage plane by means of the double refraction method.[3]

Then, four parallelepipeds of anthracene crystals, about 5 mm×5 mm×5 mm, as shown in Fig. 1, were cut out and rubbed on benzene-soaked leather until the surface became clear. The ultrasonic pulse technique requires a pair of plane parallel faces for transmitter and receiver mounting. Therefore, two surfaces of the crystal specimen were polished on benzene-soaked deer leather. This procedure was repeated until the desired parallelism and smoothness of the end surfaces of the crystal were obtained.

The crystal structure of anthracene is of the monoclinic symmetry, with a $P2_1/a$ space group, and with $a=8.56$ Å, $b=6.04$ Å, $c=11.16$ Å, and

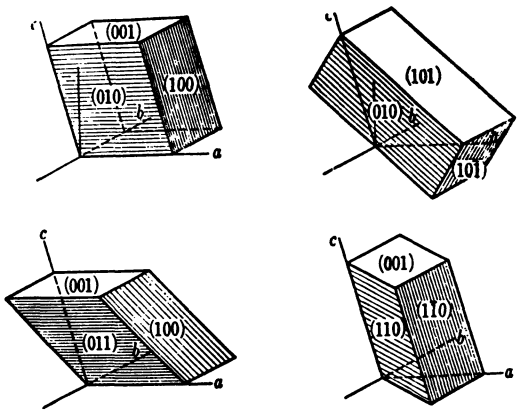

Fig. 1. Four parallelepipeds used for sound velocity measurement.

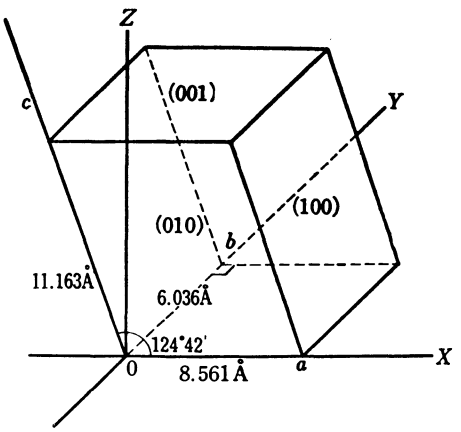

Fig. 2. The relation between XYZ orthogonal system and crystal axes.

$\beta=142°40'$.[4,5] The formulation of the strain-energy function for a monoclinic crystal results in thirteen independent elastic constants. The XYZ orthogonal system of coordinates was used for calculation in the following way: The Y-axis is the monoclinic b-axis of the crystal, the X-axis, the a-axis, and the Z-axis is perpendicular to the ab cleavage plane, as is shown in Fig. 2. The thirteen elastic constants may be shown, in accordance with Cady,[6] as:

$$\begin{vmatrix} C_{11} & C_{12} & C_{13} & 0 & C_{15} & 0 \\ C_{12} & C_{22} & C_{23} & 0 & C_{25} & 0 \\ C_{13} & C_{23} & C_{33} & 0 & C_{35} & 0 \\ 0 & 0 & 0 & C_{44} & 0 & C_{46} \\ C_{15} & C_{25} & C_{35} & 0 & C_{55} & 0 \\ 0 & 0 & 0 & C_{46} & 0 & C_{66} \end{vmatrix}. \quad (1)$$

Using the observed values of the velocities of longitudinal and transverse sound waves along the three principal axes, the three diagonal terms of elastic constants, that is C_{22}, C_{44}, and C_{66}, may be calculated easily; the results are shown in Table 1.

TABLE 1. THE WAVE DIRECTIONS USED AND THE VELOCITIES MEASURED FOR DETERMINING THREE DIAGONAL CONSTANTS

Direction of propagation	Direction of particle displacement	Measured velocity	Constants determined
[010]	[010]	v_{YY}	$C_{22}=\rho v_{YY}^2$
[100]	[010]	v_{XY}	$C_{66}=\rho v_{XY}^2$
[001]	[010]	v_{ZY}	$C_{44}=\rho v_{ZY}^2$

TABLE 2. THE WAVE DIRECTIONS USED AND THE VELOCITIES MEASURED FOR DETERMINING THE REMAINING THREE DIAGONAL AND SEVEN OFF-DIAGONAL CONSTANTS

Direction cosines of propagation direction l	m	n	Measured velocity	Related constants
0	1	0	$v_{YX}v_{YZ}$	$C_{44}C_{66}C_{46}$
1	0	0	$v_{XX}v_{XZ}$	$C_{11}C_{55}C_{15}$
0	0	1	$v_{ZZ}v_{ZX}$	$C_{33}C_{55}C_{35}$
0.254	0	0.852	v_{t_1}	$C_{44}C_{66}C_{46}$
			$v_{NN}v_{t_2}$	$C_{11}C_{33}C_{55}$ $C_{13}C_{15}C_{35}$
$1/\sqrt{2}$	$1/\sqrt{2}$	0	$v_1v_{t_1}v_{t_2}$	$C_{11}C_{22}C_{44}C_{55}$ $C_{66}C_{12}C_{15}C_{25}$ C_{46}
0	$1/\sqrt{2}$	$1/\sqrt{2}$	$v_1v_{t_1}v_{t_2}$	$C_{22}C_{33}C_{44}C_{55}$ $C_{66}C_{23}C_{25}C_{35}$ C_{46}

However, the calculation of the remaining three diagonal terms and the seven off-diagonals is somewhat complicated. In order to determine these diagonal and off-diagonal terms of C_{ij}, it is necessary to carry out the acoustic velocity measurements along other than the principal axes of the crystal. We chose to make velocity measurements along the following three directions: [110], [011] and [101]. Adopting the method of calculation which was used by Aleksandrov[7] for the monoclinic crystal, the remaining three diagonal constants and seven off-diagonal terms were obtained from the measurement of the transversal and longitudinal velocities along each direction, assuming that the density of anthracene $\rho=1.25$ g/cm^3.*1 Table 2 summarizes the wave directions and the velocities measured in determining these constants.

Velocity-measurement Apparatus. The ultrasonic pulse technique was used in this work; the pulse duration time was less than 1 μ sec. Figure 3 shows a schematic diagram of the ultrasonic pulse apparatus. The pulsed high-frequency generator was triggered by a negative pulser, which was similar to that described by Shimoda.[8] Further,

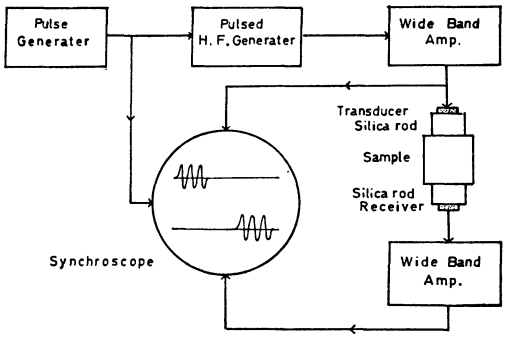

Fig. 3. The schematic diagram of the measurement of ultrasonic velocity across the anthracene crystal.

the synchroscope was triggered by a negative pulse simultaneously. Figure 4 shows the circuit of the high-frequency generator.

The anthracene specimen was sandwiched between two fused silica rods, 5 mm in diameter. A pair of Pb-Zr-titanate ceramics, 4 mm in diameter and 0.6 mm thick, having a fundamental resonance at 3 Mc/sec, were used as the transmitter and the receiver respectively. The transducers were cemented to the fused silica rods using silicone grease. After the transmitter and the receiver had been attached, the assembly was mounted in a holder which contained conductive rubber electrodes pressed against the transducers by a micrometer screw, as is shown in Fig. 5. The micrometer screw permitted a precise control of the acoustic path length.

The signal, transmitted through the specimen, was received by the ceramic receiver and was then amplified by a wide-band amplifier. After the signals from both the specimen and the delayed line had been led to a dual-beam synchroscope, the

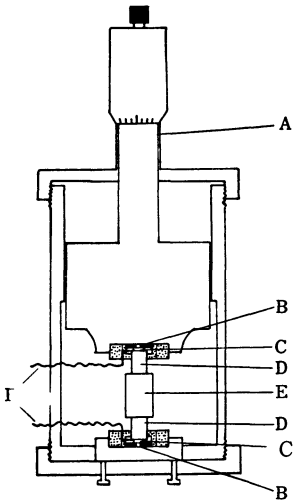

Fig. 5. The assembly for sound velocity measurement across organic crystal. A micrometer screw, B conductive rubber electrodes, C tansmitter, D fused silica rods, E sample, F lead wire and receiver.

sound velocity in the specimen was calculated.

Results and Discussion

The measured sound velocities along each direction of crystal are summarized in Table 3, while Table 4 shows the calculated elastic constants of the anthracene crystal.

The elastic compliances, s_{ij}, were calculated from the elastic constants, C_{ij}, by the following equation:

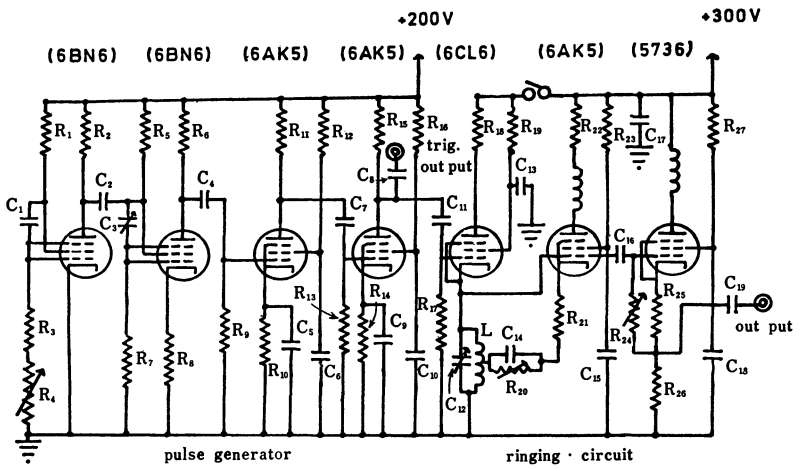

Fig. 4. The circuit of the pulsed high frequency generator, where R_1, R_5 30 kΩ; R_2, R_6 2 kΩ; R_3, R_{11}, R_{15} 1 kΩ; R_4, R_{24} 500 kΩ; R_7, R_{22}, R_{27} 20 kΩ; R_8 500 kΩ; $R_9, R_{12}, R_{13}, R_{16}$ 10 kΩ; R_{10}, R_{14} 180 Ω; R_7 250 kΩ; R_{18}, R_{26} 2 kΩ (20 W); R_{20} 5 kΩ; R_{21} 100 Ω; R_{23} 70 kΩ; R_{25} 150 Ω; C_1, C_{14} 50 pF; C_2 30 pF; C_3 100 pF; C_4, C_{16} 0.01 μF; C_5, C_9, C_{11}, C_{18} 0.1 μF; $C_6, C_{10}, C_{13}, C_{15}$ 0.5 μF; C_7, C_8, C_{16}, C_{19} 0.01 μF; C_{17} 5 μF and C_{12} 400 pF.

$$s_{ij}=\bar{D}_c\begin{pmatrix} i \\ j \end{pmatrix}\Big/D_c, \qquad (2)$$

The calculated elastic compliances are summarized in Table 5.

When a monoclinic crystal anthracence is compressed under hydrostatic pressure, the linear compressibility, β, is related to the elastic compliance and the direction cosine as follows:

$$\beta=(s_{11}+s_{12}+s_{13})l^2+(s_{21}+s_{22}+s_{23})m^2 + (s_{31}+s_{32}+s_{33})n^2+(s_{15}+s_{25}+s_{35})ln. \qquad (3)$$

Therefore, the linear compressibility along [100], [010] and [001] are calculated by means of Eq. (3); that is:

$$\beta_{[100]}=12.7\times10^{-12}\ \text{cm}^2/\text{dyn}$$
$$\beta_{[010]}=-4.41\times10^{-12}\ \text{cm}^2/\text{dyn}$$
$$\beta_{[001]}=3.59\times10^{-12}\ \text{cm}^2/\text{dyn}.$$

The elastic constants of anthracene are one-tenth or one-hundredth those of valence crystals, ionic crystals, or metals, because of the van der Waals coupling between molecules. The facts that the s_{11} elastic compliance, is the largest and s_{33} is the smallest seem reasonable in view of the packing of the molecules in the monoclinic anthracene crystal.

Further, the pressure-dependence of the electrical properties of the anthracene single crystal is consistent with the results of the compressibility reported here; the electron-drift mobility in the crystal along the direction perpendicular to the ab plane is approximately constant up to a pressure of 6.6 kbar, but the drift mobilities at 6.6 kbar along the a and b axes increase to 1.3 times the atmospheric pressure-value.[9]

In an X-ray investigation of some organic monoclinic molecular crystals, linear polyphenyls, the linear compression was reported to be a 5.4% contraction along the c axis under a pressure of 10 kbar.[10] Our results tend to support this.

Appendix

1) In general, when a plane wave propagates along a direction of which the direction cosine is (lmn), the velocity of this wave is given as the root of the next equation[11]:

$$\begin{vmatrix} \lambda_{11}-\rho v^2 & \lambda_{12} & \lambda_{13} \\ \lambda_{12} & \lambda_{22}-\rho v^2 & \lambda_{23} \\ \lambda_{13} & \lambda_{23} & \lambda_{33}-\rho v^2 \end{vmatrix}=0 \qquad (A\text{-}1)$$

where ρ is the density, and λ is the function of both the direction cosine (lmn) and the elastic constants, C_{ij}, as follows:

$$\begin{aligned}
\lambda_{11} &= l^2C_{11}+m^2C_{66}+n^2C_{55}+2mnC_{56} \\
&\quad +2nlC_{15}+2lmC_{16} \\
\lambda_{22} &= l^2C_{66}+m^2C_{22}+n^2C_{44}+2mnC_{24} \\
&\quad +2nlC_{46}+2lmC_{26} \\
\lambda_{33} &= l^2C_{55}+m^2C_{44}+n^2C_{33}+2mnC_{34} \\
&\quad +2nlC_{35}+2lmC_{45} \\
\lambda_{12} &= l^2C_{16}+m^2C_{26}+n^2C_{45}+mn(C_{25}+C_{46}) \\
&\quad +nl(C_{14}+C_{56})+lm(C_{12}+C_{66}) \\
\lambda_{13} &= l^2C_{15}+m^2C_{46}+n^2C_{35}+mn(C_{36}+C_{45}) \\
&\quad +nl(C_{36}+C_{55})+lm(C_{14}+C_{56}) \\
\lambda_{23} &= l^2C_{56}+m^2C_{24}+n^2C_{34}+mn(C_{23}+C_{44}) \\
&\quad +nl(C_{36}+C_{45})+lm(C_{25}+C_{46})
\end{aligned} \qquad (A\text{-}2)$$

2-a) Solving the above determinant (A-1), three equations related to wave propagation along the Y axis to the elastic constants are obtained:

$$C_{22}=\rho v_{\mathrm{Y}}^2{}_{\mathrm{Y}} \qquad (A\text{-}3)$$
$$C_{44}+C_{66}=\rho v_{\mathrm{Y}}^2{}_{\mathrm{X}}+\rho v_{\mathrm{Y}}^2{}_{\mathrm{Z}} \qquad (A\text{-}4)$$
$$C_{44}C_{66}-C_{46}^2=\rho^2 v_{\mathrm{Y}}^2{}_{\mathrm{X}} v_{\mathrm{Y}}^2{}_{\mathrm{Z}} \qquad (A\text{-}5)$$

9) T. Kajiwara, H. Inokuchi and S. Minomura, This Bulletin, **40**, 1055 (1967).
10) S. S. Kabalkina, *Soviet Phys. Solid State*, **4**, 2288 (1963).
11) M. J. P. Musgrave, *Proc. Roy. Soc.*, **A 226**, 339 (1954).

The six analogous equations are obtained from the wave propagations along the X and Z axes respectively:

$$C_{66} = \rho v_{XY}^2 \tag{A-6}$$
$$C_{11} + C_{55} = \rho v_{XX}^2 + \rho v_{XZ}^2 \tag{A-7}$$
$$C_{11}C_{55} - C_{15}^2 = \rho^2 v_{XX}^2 v_{XZ}^2 \tag{A-8}$$

and

$$C_{44} = \rho v_{ZY}^2 \tag{A-9}$$
$$C_{33} + C_{55} = \rho v_{ZZ}^2 + \rho v_{ZX}^2 \tag{A-10}$$
$$C_{33}C_{55} - C_{35}^2 = \rho^2 v_{ZZ}^2 v_{ZX}^2 \tag{A-11}$$

2-b) As for the propagation along the [101] direction, of which the direction cosine is $l=0.254$, $m=0$, and $n=0.852$, the following three equations are derived from Eqs. (A-1) and (A-2).

$$0.274\,C_{66} + 0.726\,C_{44} + 0.893\,C_{46} = \rho v_{t_1}^2 \tag{A-12}$$
$$0.274\,C_{11} + C_{55} + 0.726\,C_{33} + 0.893\,(C_{15} + C_{35}) = \rho v_{NN}^2 + \rho v_{t_2}^2 \tag{A-13}$$
$$\{0.274\,C_{15} + 0.726\,C_{35} + 0.446\,(C_{13} + C_{55})\}^2 - (0.274\,C_{11} + 0.726\,C_{55} + 0.893\,C_{15}) \times (0.274\,C_{55} + 0.726\,C_{33} + 0.893\,C_{35}) = \rho^2 v_{NN}^2 v_{t_2}^2 \tag{A-14}$$

where v_{NN}, v_{t_1}, and v_{t_2} are the velocities of one longitudinal and two transverse waves respectively.

2-c) As for the propagation along the [110] direction, the next determinant is obtained when the direction cosine is $l=1/\sqrt{2}$, $m=1/\sqrt{2}$ and $n=0$.

$$\begin{vmatrix} C_{11}+C_{66}-2\rho v^2 & C_{12}+C_{66} & C_{15}+C_{46} \\ C_{12}+C_{66} & C_{22}+C_{66}-2\rho v^2 & C_{25}+C_{46} \\ C_{15}+C_{46} & C_{25}+C_{46} & C_{55}+C_{44}-2\rho v^2 \end{vmatrix} = 0 \tag{A-15}$$

2-d) Analogously with the propagation along the [110] direction, the determinant for the propagation along the [011] direction is:

$$\begin{vmatrix} C_{66}+C_{55}-2\rho v^2 & C_{25}+C_{46} & C_{46}+C_{35} \\ C_{25}+C_{46} & C_{22}+C_{44}-2\rho v^2 & C_{23}+C_{44} \\ C_{46}+C_{35} & C_{23}+C_{44} & C_{44}+C_{33}-2\rho v^2 \end{vmatrix} = 0 \tag{A-16}$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1787—1792 (1968)

Analysis of Vapor Pressure of Some Molecular Crystals*1

Hideaki CHIHARA and Nobuo NAKAMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received January 22, 1968)

Vapor pressure equations of the form $\log PT^{n/2}=a/T+b$ were derived, using high temperature Thirring expansion, which are applicable to crystals of polyatomic molecules. The exponent n is determined by the type of motion of molecules in the crystal, libration or rotation. If combined with the heat capacity data, the method of analysis may be used to derive such vibrational propoerties as static energy, zero point energy, geometric mean frequency, and molecular libration frequency. Examples of the analysis of existing vapor pressure data are given for solid iodine, iodine monochloride, and high temperature modifications of nitrogen, hydrogen chloride, and methane.

A vapor pressure equation for monatomic crystals was derived by Salter[1] using high temperature expansion for the Gibbs energy of the crystal. He was also able to show that the vapor pressures could 'see' the effect of vacancy formation near the triple point of solid argon. Salter's treatment was later extended to the case of alkali halides by Leadbetter and Newsham.[2]

The present paper is an extention of Salter's equation to molecular crystals in an attempt to extract information about molecular motion in crystalline solids from available vapor pressure data. The result turns out to be rather against our expectation but it will be shown that in certain cases some useful deductions can be made from vapor pressures if combined with other experimental information such as heat capacity and entropy.

Vapor Pressure Equations

What we are interested in is to incorporate the molecular rotational degrees of freedom in solid into Salter's formulation. It will be assumed that the temperature is sufficiently high so that Thirring expansion holds for the free energy of the crystal but not too high so that we can ignore anharmonic terms in the vibrations.

The molar Gibbs energy of a molecular crystal may be written as

*1 Presented before the 19th Annual Meeting of the Chemical Society of Japan, Yokohama, March 31, 1966; Abstract of Paper 1S005.

2) A. J. Leadbetter and D. M. T. Newsham, *ibid.*, **61**, 1646 (1965).

$$G^c = G^c_{\text{trans}} + G^c_{\text{vib}} + G^c_{\text{rot}} + G^c_{\text{exp}} \quad (1)$$

Here the terms represent contributions from translational, vibrational (intramolecular), and rotational degrees of freedom and from thermal expansion. At high temperatures ($T > \Theta_D/6$), the translational part may be expanded into a series of the form[1]

$$G^c_{\text{trans}} = E_0' + 3\boldsymbol{N}\boldsymbol{k}T\Big[\ln(\boldsymbol{h}\nu_g/\boldsymbol{k}T) + \sum_{n=1}^{\infty}(-1)^{n-1}B_{2n}/2n(2n)! \times \eta_{2n}(\boldsymbol{h}/2\pi\boldsymbol{k}T)^{2n}\Big] \quad (2)$$

where E_0' is the pseudo-static lattice energy, $\boldsymbol{N}$ the Avogado's number, ν_g the geometric mean frequency for the translational lattice modes, B_{2n} the Bernoulli number, and η_{2n} the $2n$th moment of the translational part of the lattice frequency spectrum. The static lattice energy E_0 is related to E_0' by

$$E_0 = E_0' - E_{z,\text{lib}}$$

because '*translationally static*' lattice may still possess the zero-point kinetic energy $E_{z,\text{lib}}$ of molecular libration. For monatomic crystals or crystals in which all molecules are rotating, E'_0 is of course equal to E_0.

The vibrational part of the Gibbs enrgy is given by[3]

$$G^c_{\text{vib}} = \boldsymbol{N}\boldsymbol{k}T\sum_i[\ln(\boldsymbol{h}\nu_i^c/\boldsymbol{k}T) - \boldsymbol{h}\nu_i^c/2\boldsymbol{k}T + 1/24(\boldsymbol{h}\nu_i^c/\boldsymbol{k}T)^2 + \cdots] + \sum_i \boldsymbol{N}\boldsymbol{h}\nu_i^c/2 \quad (3)$$

where ν_i^c is the frequency for the ith intramolecular vibration mode, the last term being the vibrational zero point energy.

The rotational part of the free energy can not be treated in a general way since the Schrödinger equation for three-dimensional rotation of a molecule in a general periodic potential field can not be solved. We shall therefore be content with two extreme cases, *viz.* either librational motion or free rotation.

In the harmonic librational case, G^c_{rot} assumes exactly the same form as Eq. (3). In the case of free rotation it is given by[3]

$$G^c_{\text{rot}} = -\boldsymbol{N}\boldsymbol{k}T\sum_j \ln[(1/n_j)(8\pi^2 I_j \boldsymbol{k}T/\boldsymbol{h}^2)^{1/2}] \quad (4)$$

where I_j is the moment of inertia and n_j is the symmetry number of the rotational potential. Finally, the expansion part contributes

$$G^c_{\text{exp}} = \boldsymbol{N}pv_c \quad (5)$$

to the total Gibbs energy, p and v_c being the pressure and the volume per molecule.

The corresponding Gibbs energy of a mole of vapor is

$$G^v = G^v_{\text{trans}} + G^v_{\text{vib}} + G^v_{\text{rot}} + G^v_{\text{exp}} \quad (6)$$

and terms on the right-hand side are given in a standard textbook[3]:

$$G^v_{\text{trans}} = -\boldsymbol{N}\boldsymbol{k}T[\ln(2\pi m\boldsymbol{k}T/\boldsymbol{h}^2)^{3/2} + \ln v_v - B(T)/v_v + 1] \quad (7)$$

$$G^v_{\text{vib}} = \boldsymbol{N}\boldsymbol{k}T\sum_i[\ln(\boldsymbol{h}\nu_i^v/\boldsymbol{k}T) - \boldsymbol{h}\nu_i^v/2\boldsymbol{k}T + (1/24)(\boldsymbol{h}\nu_i^v/\boldsymbol{k}T)^2 + \cdots] + \sum_i \boldsymbol{N}\boldsymbol{h}\nu_i^v/2 \quad (8)$$

$$G^v_{\text{rot}} = -\boldsymbol{N}\boldsymbol{k}T[\sum_j \ln(8\pi^2 I_j \boldsymbol{k}T/\boldsymbol{h}^2)^{1/2} - \ln(\sigma/\pi^{1/2})] \quad (9)$$

$$G^v_{\text{exp}} = \boldsymbol{N}pv_v \quad (10)$$

where m is the mass of a molecule, $B(T)$ is the second virial coefficient, and v_v is the volume per molecule. v_v may be approximated by

$$v_v = \boldsymbol{k}T/p. \quad (11)$$

For a linear molecule, the symmetry number σ of the molecule in Eq. (9) is to be replaced by $\sqrt{\pi}\sigma'$, where σ' is 2 or 1 according as the molecule has the center of symmetry or not.

From the condition for vapor-solid equilibrium, we obtain the equation of the form

$$\ln P(T^{1/2})^n = a/T + b \quad (12)$$

The exponent n is determined by whether the molecule executes libration or rotation and a is given by

$$a = E'_0/\boldsymbol{N}\boldsymbol{k}, \quad (13)$$

and therefore a linear plot of $\ln(PT^{n/2})$ against $1/T$ gives the static lattice energy from its slope, and its intercept b should give the geometric mean frequency ν_g. Values of n and expressions of b are given in Table 1 for typical cases. Other cases can be evaluated easily. It is evident that Eq. (12) reduces to Salter's equation for monatomic case.[1] In deriving b, it has been assumed that

$$\boldsymbol{h}\nu_i/\boldsymbol{k}T < 1, \quad \boldsymbol{h}\eta_{2n}^{1/2n}/2\pi\boldsymbol{k}T \ll 1, \quad B(T)/v_v \ll 1. \quad (14)$$

The first of these assumptions may be justified only in the case of the low frequency librational modes in the solid state. While it may not be valid for intramolecular vibrations, the terms containing ν_i enter only as a difference between the gaseous and the crys-

TABLE 1. THE VALUES OF n AND THE EXPRESSIONS OF b TO BE USED IN EQ. (12). APPROPRIATE FOR DIFFERENT MODELS OF MOLECULAR MOTION

Model	n	b
Linear molecule; librations about two axes	3	$\ln[8\pi^2(2\pi m/k)^{3/2}\cdot 1/\sigma'\cdot I_v\nu_g^3\cdot\nu_t^2\nu_c^{\text{intra}}/\nu_v^{\text{intra}}]$
Linear molecule; libration + rotation	2	$\ln[(8\pi^2)^{1/2}(2\pi m)^{3/2}\cdot 1/k\cdot n_c/\sigma'\cdot I_v/I_c^{1/2}\cdot\nu_g^3\nu_t\cdot\nu_c^{\text{intra}}/\nu_v^{\text{intra}}]$
Linear molecule; rotations about two axes	1	$\ln[(2\pi m)^{3/2}\cdot 1/k^{1/2}\cdot n_1n_2/\sigma'\cdot I_v/(I_{c1}I_{c2})^{1/2}\cdot\nu_g^3\cdot\nu_c^{\text{intra}}/\nu_v^{\text{intra}}]$
Non-linear molecule; librations about three axes	4	$\ln[8\pi^5m^{3/2}\cdot 1/k\cdot 1/\sigma(I_{v1}I_{v2}I_{v3})^{1/2}\cdot\nu_g^3\cdot\nu_{t1}\cdot\nu_{t2}\cdot\nu_{t3}\cdot\prod_i(\nu_{ci}/\nu_{vi})]$
Non-linear molecule; rotations about three axes	1	$\ln[(8\pi)^{1/2}m^{3/2}\cdot 1/k^{1/2}\cdot n_1n_2n_3/\sigma\cdot(I_{v1}I_{v2}I_{v3}/I_{c1}I_{c2}I_{c3})^{1/2}\cdot\prod_i(\nu_{ci}/\nu_{vi})]$

talline states and therefore the higher order terms of $h\nu_i^v/kT$ and $h\nu_i^c/kT$ would give only trivial effects on the results derived here.

We have ignored the effect of vacancy formation or any other type of defects but these can be taken into account if the energy and the combinatory factor associated with the defect formation can be evaluated. If the molecules in the vapor associate to form dimers or higher polymers, the effect has also to be and can be taken into accout provided that the molecular structures and concentrations of the associated species are known. Equation (12) is also applicable to such a case of NH_4Cl that dissociation is accompanied with vaporization.

Analysis of Experimental Vapor Pressures

All that one may anticipate to deduce from the application of Eq. (12) to experiment are, besides E_0 and ν_g, whether the molecules are librating at a certain frequency or rotating almost freely. Yet the application is not straightforward since the appropriate value of n is not known in advance. One obvious way is to decide n by trial-and-error procedure and see which value gives the best fit to Eq. (12). This is possible only when extremely accurate vapor pressure data are available over a reasonably wide temperature range. Usual situation is, as illustrated by the three equally well fitted straight lines in Fig. 3, that the exponent n can not be determined unambiguously. If the primary pressure and temperature values were sufficiently accurate, one should, in principle, be able to discriminate between different values of n. However in order for this to be practical, it appears that the accuracy of measurements will have to be improved by a factor of 10 or to within ± 0.005 Torr. Under these circumstaces, the analysis by use of Eq. (12) must be assisted by other information. Figure 1 is the diagram of cycles devised for this purpose. What is aimed at here is to use a and b of Eq. (12) for deriving other vibrational properties and at the same time examining the internal consistency of the calculation. It is noted that the derived properties all refer to a volume at some mean tem-

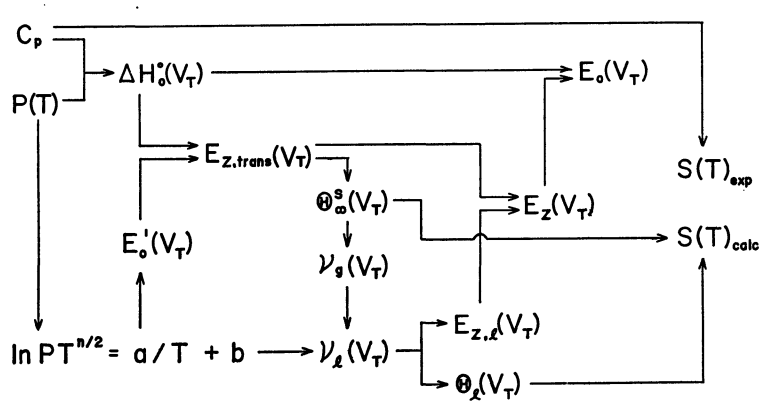

Fig. 1. Correlation diagram.

perature of the vapor pressure measurements.

Thus $\Delta H_0^\circ(V_T)$ is the heat of sublimation as 0°K corresponding to the crystal volume at temperature T; it is calculated from the relation

$$\Delta G^\circ/T = \boldsymbol{R}\ln(760/P) = \Delta(G^\circ - H^0)/T + \Delta H_0^\circ/T \qquad (15)$$

ΔG° is the standard Gibbs energy of sublimation at temperature T and $\Delta(G^\circ - H_0^\circ)$ may be obtained from heat capacity values. The translational zero point energy $E_{z,\mathrm{trans}}(V_T)$, obtained by

$$E_{z,\mathrm{trans}}(V_T) = -E_0'(V_T) - \Delta H_0^\circ(V_T),$$

is related to the limiting Debye temperature (from entropy) Θ_∞^S and the geometric mean frequency ν_g through[2,4]

$$E_{z,\mathrm{trans}} = \frac{9}{8}\boldsymbol{N}\boldsymbol{k}\Theta_\infty^S \doteqdot \frac{9}{8}e^{1/3}\boldsymbol{N}\boldsymbol{h}\nu_g$$

n the quasi-harmonic approximation. $\nu_l(V_T)$ is the molecular libration frequency and may be obtained as an average over the degrees of freedom (two or three) by inserting appropriate figures to the expression of b. The solid-state shift of the intramolecular frequencies is usually small so that it may be ignored if spectral frequencies in solid are not available. Knowledge of $\nu_l(V_T)$ may be directly compared with Raman or far-infrared spectral data on what is called '*lattice modes*' or with ν_l derived from temperature dependence of nuclear quadrupole resonance frequency. It also leads to the harmonic librational zero point energy $E_{z,\mathrm{lib}}(V_T)$ and Einstein temperature $\Theta_l(V_T)$; the former gives, together with $E_{z,\mathrm{trans}}(V_T)$, the total zero point energy $E_z(V_T)$ and the static lattice energy $E_0(V_T)$.

An overall check for internal consistency may be done by the help of entropy $S(T)$. Thus two characteristic temperatures Θ_∞ and Θ_l give an entropy for translational and librational modes to which intramolecular contributions are added. This $S(T)_{\mathrm{calc}}$ is then compared with the calorimetric entropy. Entropy may look a rather insensitive quantity for the purpose of consistency check. However the value of b is very sensitive to the choice of the exponent n in Eq. (12) and this outweighs the insensitivity of the entropy.

Results of Calculation

Results of calculations are displayed in Tables 2 and 3.

I_2 and ICl

The case of solid iodine probably serves best to illustrate how our analysis works. Molecules in solid iodine are undergoing librational motion (though perhaps not isotropic) in the orthorhombic crystal. Figure 2 shows the plot of $\log(PT^{3/2})$ *vs.* $1/T$, from which

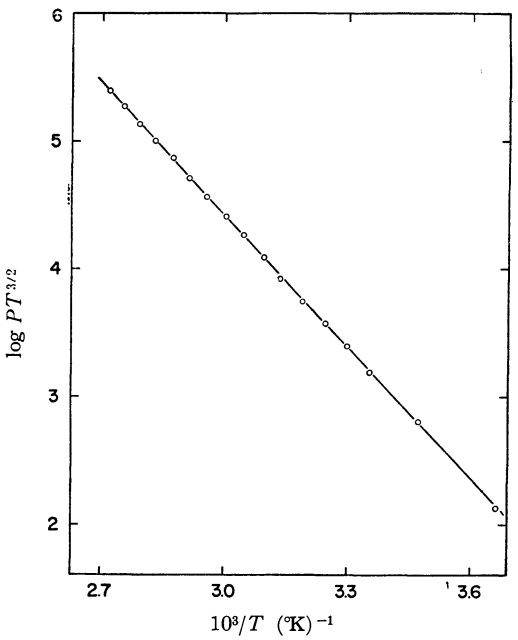

Fig. 2. The plot of $\ln PT^{3/2}$ against T^{-1} for solid iodine.

the static lattice energy 15970 cal/mol and the average libration frequency $\nu_l = 59.5\,cm^{-1}$ were obtained. These two values, combined with the heat of sublimation at 0°K obtained by the calorimetric method, give the librational zero point energy 170 cal/mol (2 degrees of freedom) and the translational zero point energy 142 cal/mol. The libration frequency of $59.5\,cm^{-1}$ compares favorably with $69.5\,cm^{-1}$ obtained from analysis of low temperature heat capacities[5] if one considers that the former corresponds to a larger volume of the crystal. Far infrared spectrum of solid iodine shows two translational lattice frequencies at $41\,cm^{-1}$ and $65\,cm^{-1}$ at 77°K.[6] An average of these two gives a Debye temperature of 74°K as compared with $\Theta^s_\infty = 63.5$°K given in Table 2. Also a Mössbauer study around 150°K led to $\Theta = 60$°K.[7] The entropy deviation is only 1.6%. Thus we believe that we have a fairly nice picture for solid iodine. The situation with respect to solid iodine monochloride is similar. The various quantities derived take values of reasonable magnitude in comparison with those of iodine although no other independent informations are available.

N_2

The high temperature phase of nitrogen was examined in two alternative models; *i.e.* the molecule undergoes libration about two axes ($n=3$) or rotates about one axis while doing libration about the other axis ($n=2$). Entropy consideration favors the one-axis rotation model slightly over the two-axes libration. The total zero point energy is then 153 cal/mol, of which 112 cal/mol comes from translational motion. Kohin estimated $E_{z,trans}$ theoretically to be 213 cal/mol.[8] Her estimate is based on the low temperature phase and therefore we see that the high temperature structure has a smaller zero point energy. Recent X-ray diffraction study suggested that the molecules precess about the c-axis of the high temperature hexagonal crystal.[9] They will of course be undergoing nutation also. This type of motion is consist-

ent with nuclear quadrupole resonance results: We have made a rough estimate, using Scott's unpublished data,[10] that the molecular axis makes an angle of 54°17′ with the precession axis at a precession frequency greater than 4.10^6 Hz. We also calculated the low temperature libration frequency as 31.5 cm^{-1} at 35.6°K from the nuclear quadrupole frequencies[10] by the method described elsewhere.[11] This ν_l is to be compared with 28.8 cm^{-1} in Table 2.

CH_4

It has been shown that methane is in effectively free rotation in the highest temperature solid phase.[12] Our analysis of vapor pressure does not provide a clear-cut interpretation but leads to very large discrepancy of the entropies. This is probably due to in sufficient accuracy in the pressure determinations.

HCl

The structure and molecular motion in solid HCl have been extensively discussed elsewhere.[13] In short, neutron diffraction study on DCl favors a disordered orientation model above the transition point,[14] whereas nuclear magnetic and quadrupole studies point to a hindered rotation model.[13] The vapor pressure plots of Fig. 3 alone do not allow to differentiate one from the other possibilities in Table 2. The entropy considerations (Table 3) seem to clearly indicate that a combination of one-axis rotation and one-axis libration is by far appropriate than other models. This may be reconciled to nuclear resonance results if we consider that our treatment of vapor pressures here developed corresponds only to extreme cases of free molecular rotation or harmonic libration. What is actually happening is probably an intermediate, *i.e.* hindered rotation about two axes.

Attempts were also made to examine vapor pressures of solid chlorine, bromine, and the low temperature phases of hydrogen chloride and nitrogen. But these led either to very small E_z or to very large $\Delta S/S$. The failure

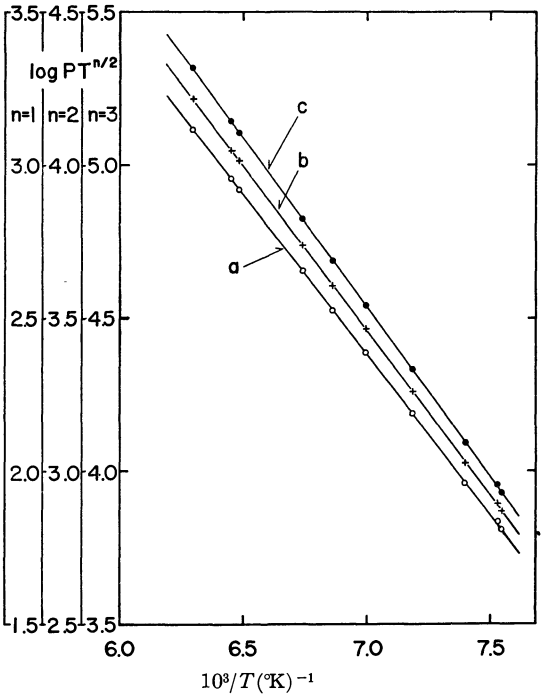

Fig. 3. The plot of $\ln PT^{n/2}$ against T^{-1} for the high temperature phase of solid hydrogen chloride. (a: $n=1$; b: $n=2$; c: $n=3$)

is perhaps due partly to poor accuracy in the vapor pressure determinations and partly to the breakdown of the high temperature approximation.

Conclusion

It has been demonstrated that accurate vapor pressure values of molecular crystals serve to provide useful informations about the lattice vibrational properties such as the static energy, the geometric mean frequency, the molecular libration frequency, and the zero point energy, in combination with heat capacity data. When the accuracy of the pressure allows, it is possible to detect molecular rotational states in solids. However, most of the presently available data are not accurate enough to deduce the information on higher order effect and the effect of vacancy formation.

The authors are grateful to Professor T. A. Scott of University of Florida for sending us his recent unpublished results on the nuclear quadrupole resonance of solid nitrogen.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1793—1968 (1968)

Ionization and Dissociation of Formic Acid, Acetic Acid, Propanoic Acid, and Butanoic Acid under Electron Impact

Yoko Ono, Tutomu Makita and Kumasaburo Kodera

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received January 29, 1968)

The mass spectra of DCOOD, DCOOH, CD_3COOD, CD_3COOH, CH_3COOD, C_2H_5COOD, and C_3H_7COOD are compared with spectra of the H-containing compounds. Besides, the ^{18}O-labeled acetic acid is measured. The labeling helps to determine the origin of a number of fragment ions. It is found that the two fragment ions $C_3H_5O_2^+$ and $C_4H_7O_2^+$ are produced by the removal of the hydrogen atom from the alkyl group and have the structures of $C_2H_4CO_2H^+$ and $C_3H_6CO_2H^+$ respectively. Neither $CH_2CO_2H^+$ nor $CH_3CO_2^+$ is produced. The rerrangement ion CH_3O^+ is found to have the structure of CH_2OH^+, one of whose hydrogen atoms comes from the carboxyl group. The origins of the hydrogen atom and the oxygen atom in the other rearrangement ions are also determined. The mechanisms for the fragmentation of the molecular ions are discussed.

Mass spectrometric studies of the ions from the carboxylic acids have been carried out by several investigators.[1-5] Melton[3] discussed the fragmentation of formic acid by a comparison of the mass spectra of an H-containing compound and a deutero-isomer. Other works have concerned themselves only with the appearance potentials. However, there have been no studies of either acetic acid or of the higher acids.

In this paper we will discuss the ionization and the ionic fragmentation of formic acid, acetic acid, propanoic acid, and butanoic acid molecules, each of which consists of an alkyl group and a carboxyl group. Emphasis has been placed in the atomic rearrangement during the fragmentation. For this purpose, it is useful to study the systems in some detail with the help of suitably-labeled compounds. In the present work the deuterium and the oxygen-18 labeling have been utilized particularly for the study of some rearrangement processes as well as for the identification of some fragment ions. Also, the presence of the metastable ions and the ion-molecule reactions have been utilized.

Experimental

Materials. The purest commercial acids were used without purification. Three deuterated compounds, CD_3COOD, CDOOD, and D_2O, were obtained from Merck, Ltd., while the other deuterated compounds were synthesized as follows: CD_3COOH: the deuterium atom of the carboxyl group of CD_3COOD was replaced by a hydrogen atom by bubbling gaseous hydrogen chloride through the acid.

DCOOH: The deuterium atom of the carboxyl group of DCOOD was replaced by a hydrogen atom by the addition of H_2O.

CH_3COOD and n-C_3H_7COOD: The anhydride of each acid reacted with D_2O at room temperature or higher.

Apparatus. The mass spectra were taken with a CEC 21-401 Mass Spectrometer, modified in order to determine the appearance potentials of the ions. The standard conditions for analysis were as follows: electron-accelerating voltage, 70 V; ion-accelerating voltage, 210 V; total emission current, 10.0 μA; temperature of the ion source, 250±0.2°C. When necessary, the temperature of the ion source, the repeller voltage, and the electron energy were changed.

As the compounds are adsorbed strongly on the walls, precaution was taken against the effects of adsorption. In advance the sample inlet-system was sufficiently flashed with argon and then with the sample. The contamination of the sampling systems was examined by the measurement of the background of the mass spectra with a flow of argon. In order to avoid as much as possible the influence of the isotope exchange during the measurement, the mass spectra were taken as soon as

possible after the sample had been introduced.

Results and Discussion

Certain ions in the mass spectra of the H-containing and deuterated acids are given in Tables 1—4. The intensities are expressed as the intensities relative to those of the parent ions except in the cases of n-C_3H_7COOH and i-C_3H_7COOH. In these cases, the intensities are expressed as the percentages of total ionization. It was possible to give the structural formulas for the various ions by comparing the mass distribution of the normal compound with that of the deutero-isomer. These formulas are given in the third column of Table 1. When it is likely that more than one ion is associated with the intensity as the given mass, the measured intensity has been partitioned among the contributing ions. The assignments of the individual contributions were made somewhat arbitrarily, assuming that the loss of an H or D atom in the deutero-isomer occurred with the same probability as the loss of H in the H-containing compound. Similarly, the loss of a given group such as methyl was assumed to occur with the same probability in both isomers.

Fragment ions: $C_nH_{2n}CO_2H^+$ or $C_nH_{2n+1}CO_2^+$. It is of interest to determine whether the hydrogen atom is eliminated from the

* Ion abundance in % of total ionization

alkyl group or from the carboxyl group.

In the spectrum of HCOOH the relative intensity of the CHO_2^+ ion ($m/e=45$) is 73.9. In the spectrum of the deutero-isomer DCOOH, the intensities of CO_2H^+ ($m/e=45$) and DCO_2^+ ($m/e=46$) are 35.7 and 41.0 respectively. Therefore, the ions at the mass (M−1) in the spectrum of HCOOH must be HCO_2^+ and CO_2H^+, occurring in the same abundance.

In the spectrum of CH_3COOH the ion at the mass (M−1) was not observed. In the spectra of the other acids, $C_2H_3O_2^+$ ($m/e=59$) was never observed. This ion may be unstable, or the $C_2H_3O_2$ fragment may have the negative charge more stably.*1

In the mass spectrum of C_2H_5COOH the relative intensity of $C_3H_5O_2^+$ ($m/e=73$) is 59.4. The mass spectrum of the deutero-isomer C_2H_5COOD shows that the corresponding intensity has moved to mass 74. Therefore, $C_3H_5O_2^+$ must be $C_2H_4CO_2H^+$.

The ion of this type was found in the mass spectrum of C_3H_7COOH. The occurrence of the metastable ions provides further information concerning the process leading to this ion. In the mass spectra of both n-C_3H_7COOH and i-C_3H_7COOH the metastable ion peak of mass 60.6 was found. In the mass spectrum of the deuterated-compound n-C_3H_7COOD, this metastable ion peak shifted to mass 61.5. The transitions consistent with these masses are:

$$C_3H_7CO_2H^+(88) \longrightarrow C_2H_4CO_2H^+(73)+CH_3(15)$$
$$m^*=\frac{(73)^2}{88}=60.6,$$
$$C_3H_7CO_2D^+(89) \longrightarrow C_2H_4CO_2D(74)+CH_3(15)$$
$$m^*=\frac{(74)^2}{89}=61.5.$$

In the mass spectrum of C_3H_7COOH, the relative intensity of $C_4H_7O_2^+$ ($m/e=87$) is 36.2. In the mass spectrum C_3H_7COOD, the corresponding ion intensity moved to mass 88. In the same way as in C_2H_5COOH, the $C_4H_7O_2^+$ ion must have the structure of $C_3H_6CO_2H^+$.

From the above discussion, we are led to the conclusion that, except for HCOOH and CH_3CO_2H, the $C_{n+1}H_{2n+1}O_2^+$ ions in the mass spectrum of $C_nH_{2n+1}CO_2H$ have the C_nH_{2n}-CO_2H^+ structure.

Fragment Ion R-C≡O$^+$. It is well known that the carbonyl compounds produce very stable ions, R-C≡O^+, the oxygen atom of which has a triple bond.[6] In the spectra of the acids these ions occur in appreciable amounts. The H-C≡O^+ ion in the mass spectra of HCOOH will be discussed later.

Although, in the mass spectrum of CH_3-

*1 The ion at mass 59 has been measured appreciably on the background of the negative ion mass spectra. This ion is thought to come from the oil of the diffusion pumps. *Cf.* our unpublished data.

6) I. Kanomata, This Bulletin, **34**, 1964 (1961).

COOH, the CH_3–C≡O^+ ion peak is the highest of all, neither the C_2H_5–C≡O^+ from $C_2H_5CO_2H^+$ nor the C_3H_7–C≡O^+ from $C_3H_7CO_2H^+$ is so high as expected. This may be partly because C_2H_5–C≡O^+ and C_3H_7–C≡O^+ are not stable, further decomposing to $C_3H_7^+$, $C_2H_5^+$, CO^+, *etc.*

Rearrangement Ion CH_2OH^+. It is well known that, in the mass spectra of many esters,[7] the rearrangement ion CH_3O^+ (mass 31), with the CH_2OH^+ structure, occurs as the most abundant ion. In the spectrum of CH_3COOH, the relative intensity of the CH_3O^+ ion (mass 31) is 2.53. In view of the CH_3COOH structure, it seemed of interest to investigate closely the process responsible for the production of this ion.

The spectra of the three deutero-isomers CH_3COOD, CD_3COOH, and CD_3COOD show that the corresponding ion intensity has moved to masses 32, 33, and 34 respectively. These ions must be CH_2OD^+, CD_2OH^+, and CD_2OD^+ respectively. The appearance potentials of all these ions are the same within the limits of experimental error. These ions proved to be primary ions judging from the effect of the repeller voltage and the sample pressure on the intensities of these ions.

In order to obtain further information on the process producing this type of ion, measurements were made with ^{18}O. The oxygen-18-labeled acetic acid was synthesized by the reaction of $H_2{}^{18}O$ (oxygen-18 atomic % 7) with CH_3COCl.

In the spectrum of the oxygen-18-labeled isomer, half of the intensity of CH_2OH^+ ion has moved to mass 33. This shows that the oxygen atom in this ion may, with equal probability, be either of the two oxygen atoms in CH_3COOH. The reason for this may be either that the two oxygen atoms in the molecular ion are equivalent due to resonance, or that it is essentially impossible to replace the hydroxylic oxygen atom selectively with oxygen-18.

Also, in the spectra of C_2H_5COOH and *n*-C_3H_7COOH, the CH_3O^+ (mass 31) occurs in an appreciable abundance. A comparison of the mass spectra of C_2H_5COOH and *n*-C_3H_7-COOH with those of C_2H_5COOD and *n*-C_3H_7-COOD respectively shows that the CH_3O^+ ion must have the CH_2OH^+ structure.

To summarize, the CH_3O^+ ion (mass 31) must be CH_2OH^+, two of whose hydrogens come from the alkyl group and the rest, from the carboxyl group. The origin of the carbon and the oxygen atoms can not be determined. An experiment with ^{13}C is desirable.

Rearrangement Ion and Fragment Ion CHO^+. The spectrum of HCOOH shows that the CHO^+ ion (mass 29) occurs with the highest abundance except for the parent ion. This ion also occurs in the spectra of CH_3-COOH, C_2H_5COOH, and C_3H_7COOH. In order to determine the mechanism of producing this ion, the same method was used as for the CH_2OH^+ ion.

In the case of HCOOH, the spectra of HCOOD and DCOOH were compared with that of HCOOH. The relative intensity of the HCO^+ ion (mass 29) is 77 in the mass spectrum of HCOOH. In the spectrum of DCOOD, the corresponding ion, whose intensity is 68.6, has moved to mass 30. On the other hand, in DCOOH, two ions, COH^+ and DCO^+, occurred; their relative intensities were 14.6 and 66.7 respectively. The reason why the intensity of the COH^+ is weaker than that of DCO^+ may be that, while DCO^+ is formed by a one-bond fission, the formation of COH^+ requires the fission of two bonds. In addition, DCO^+ has a stable structure, D–C≡O^+, which is well known in carbonyl compounds. From these facts it may be supposed that two structures, H–C≡O^+ and C–OH^+, contribute to the mass 29.

Also, in the spectrum of CH_3COOH, the CHO^+ ion (mass 29) occurs with a relative intensity of 11.8. In the spectrum of CD_3-COOH the corresponding ion must be considered to be CDO^+ and CHO^+, whose intensities were 6.44 and 3.17 respectively. The deuterium of CDO^+ must have come from the methyl group of the acetic acid, so this ion is the rearrangement ion. In CH_3COOD, CDO^+ and CHO^+ were found also, indicating that rearrangement had occurred. Their intensities were 5.33 and 7.78 respectively. Of course, the appearance potentials of these ions were the same within the limits of experimental error, and the examination of the effect of the repeller voltage and the pressure shows that these ions are primary ions.

From the mass spectrum of acetic acid containing oxygen-18, the origin of the oxygen atom in this ion was not determined unequivocally, as in the case of CH_2OH^+.

We can conclude that, in the spectrum of CH_3COOH, CHO^+ (mass 29) consists of the simple fragment ion COH^+ and the rearrangement ion HCO^+. The hydrogen of the former comes from the carboxyl group, and that of the latter, from the methyl group. The abundance of the simple fragment ion is

7) E. W. Godbole and P. Kebarle, *Trans. Faraday Soc.*, **58**, 1897 (1962).

TABLE 5. THE RELATIVE INTENSITY* OF REARRANGEMENT IONS TO THE LOWER ACID

	M−CH_2		M−C_2H_4		M−C_3H_6	
	Ion	Intensity	Ion	Intensity	Ion	Intensity
CH_3COOH	$CH_2O_2^+$	0.4—0.5	——	——	——	——

n-C_3H_7COOH	$C_3H_6O_2^+$	11	$C_2H_4O_2^+$	2080	$CH_2O_2^+$	11.5
i-C_3H_7COOH	$C_3H_6O_3^+$	6	$C_2H_4O_2^+$	35	$CH_2O_2^+$	5.3

* The relative abundance with each parent ion peak being taken as 100%

equivalent to, or a little less than, that of the rearrangement ion. In the spectra of C_2H_5-$COOH$ and C_3H_7COOH, the mass-29 ion also occurs, but we could not determine the origin of this ion because of the presence of the $C_2H_5^+$ ion, which gives a strong peak at the same mass.

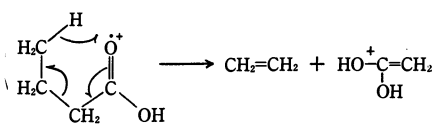
Rearrangement Ion $C_nH_{2n}O_2^+$. The spectrum of n-C_3H_7COOH shows that $C_2H_4O_2^+$ occurs very abundantly. This ion has the same mass as the acetic acid molecular ion, so it is considered to be a rearrangement ion. Other ions of the same type as this are also observed. The relative intensities of these ions; $CH_2O_2^+$, $C_2H_4O_2^+$, and $C_3H_6O_2^+$, are given in Table 5. Except in the case of CH_3COOH, many ions of this type produced in the acids. It is of interest to discuss the mechanism for producing these rearrangement ions. As for $C_2H_4O_2^+$, in the spectra of n-C_3H_7COOH a metastable ion peak of mass 40.9 was observed. The transition consistent with this mass is:

$$C_3H_7COOH^+(88) \longrightarrow C_2H_4O_2^+(60) + C_2H_4(28)$$

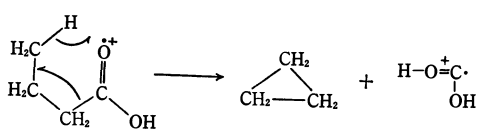
$$m^* = \frac{(60)^2}{(88)} = 40.9$$

The neutral fragment C_2H_4 has the stable structure[8] $CH_2{=}CH_2$. The high intensity of the $C_2H_4O_2^+$ ion may be due to this stability.

The mechanism for this rearrangement ion may be speculated to be as follows:



and for $CH_2O_2^+$



The ring-formation mechanisms shown above are well-known in the electron impact of organic compounds.

In the mass spectra of C_2H_5COOH and i-C_3H_7COOH, no such rearrangement mechanism can be expected in view of the orientation and steric hindrance. In spite of this, the mass spectra of C_2H_5COOH and i-C_3H_7COOH show that $CH_2O_2^+$ and $C_2H_4O_2^+$ occur in an appreciable abundance. Therefore, for these ions we must consider other mechanisms.

Ion-molecule Reaction "Protonated Molecular Ions" The mass spectra of acids show ions of appreciable intensities whose masses are larger than that of the molecular ion by one mass.

Sharkey[9] and Kebarle[7] have pointed out

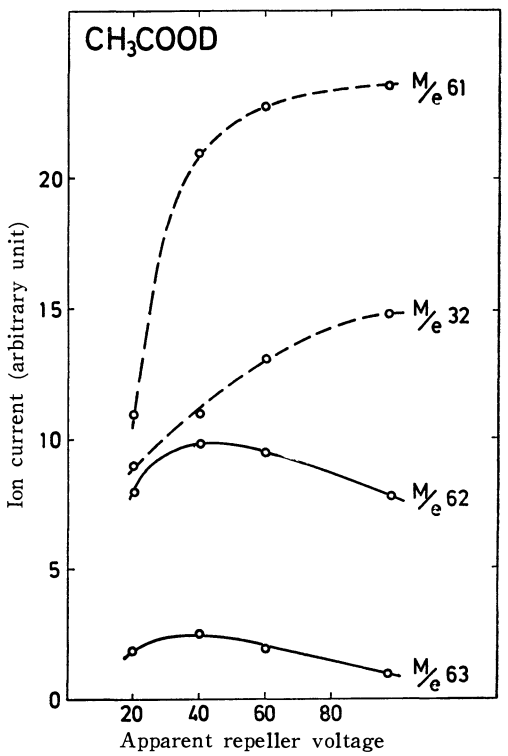


Fig. 1. The effect of the repeller voltage on the ion intensity

8) F. W. McLafferty "Mass Spectrometry of Organic Ions," Academic Press, New York and London (1963).

9) A.G. Sharkey, Jr., J.L. Shultz and R.A. Friedel, *Anal. Chem.*, **31**, 87 (1959).

that analogous ions occur as rearrangement ions in appreciable intensities in the mass spectra of most aliphatic esters.

The mass spectra of the deuterated acids show that some of the corresponding ions have moved to a mass larger than that of molecular ions by one mass or two—such as the ion of mass 50 in DCOOD(48), that of mass 66 in CD_3COOD, and those of mass 64 and mass 65 in CD_3COOH. Those ions were observed in appreciable amounts when the sample pressure in the ionization chamber was higher than 10^{-6} mmHg. The intensities of these ions were in proportion to the square of the sample pressure.

Generally, the intensity of the primary ion increases as the repeller voltage increases (*cf.* Fig. 1). However, the intensities of these protonated molecular ions decreased as the repeller voltage increased. These properties are those of secondary or higher-order ions. Therefore, these ions may be considered to be produced by the ion-molecule reaction.

Summary

The mass spectra of several carboxylic acids, *i.e.*, HCOOH, DCOOH, DCOOD, CH_3COOH, CH_3COOD, CD_3COOH, CD_3COOD, C_2H_5COOH, C_2H_5COOD, n-C_3H_7COOH, i-C_3H_7COOH, and n-C_3H_7COOD, were examined. The ions of the mass spectra were then classified into the simple fragment ions, the rearrangement ions, and the ion-molecule reaction ions.

The main fragment ions were R^+, RCO^+, and CO_2H^+. One of the most interesting fragment ions was $C_nH_{2n}CO_2H^+$ ($n \geqq 2$), which was found to occur upon the loss of one hydrogen atom from the alkyl group. $CH_2CO_2H^+$ was not observed in any case.

Among the rearrangement ions, CH_3O^+ ($m/e=31$) was of special interest; two of its hydrogen atoms were proved to come from the alkyl group, and the rest, from the carboxyl group. From this, we concluded the structure to be CH_2OH^+.

About half of CHO^+ ($m/e=29$) was also proved to be a fragment ion whose hydrogen atom came from the alkyl group, while the other half was the simple fragment ion COH^+.

In addition, we observed protonated molecular ions which had been produced by the ion-molecule reactions.

Intrachain Force Field and Normal Vibrations of Polyethylene Glycol

Hiroatsu MATSUURA and Tatsuo MIYAZAWA

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received January 29, 1968)

Normal vibrations of polyethylene glycol and the perdeuterated species were treated. Intrachain force field was expressed in terms of local-symmetry coordinates. Force constants were adjusted by the method of least squares, with reference to observed infrared and Raman frequencies. A set of force constants was obtained, which reproduces the observed frequencies with an r.m.s. deviation of 0.9%. The values of the force constants thus refined were discussed in comparison with corresponding values of related molecules. Vibrational assignments of the observed infrared absorption bands and Raman lines were revised on the basis of potential-energy distributions refined in the present treatment.

The chain vibrations of an isolated helical molecule are specified with the phase difference δ between the vibrational displacements of the corresponding atoms in neighboring repeat units. The selection rules for the infrared absorption and Raman scattering are related with the angle θ of rotation, per unit, about the helix axis. Thus, the infrared bands arise from the chain vibrations with $\delta=0$ or θ and the Raman lines arise from the vibrations with $\delta=0$, θ, or 2θ.[1,2] For the neutron scattering, there is no selection rule

2) T. Miyazawa, *J. Chem. Phys.*, **35**, 693 (1961); *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **88**, 111 (1967); H. Sugeta and T. Miyazawa, *J. Chem. Phys.*, **47**, 2034 (1967).

and accordingly the frequency-distribution peaks give rise to inelastic scattering peaks.

The X-ray diffraction and infrared and Raman spectra of polyethylene glycol have been studied, and this polymer chain has been found to contain seven chemical units of CH_2CH_2O and two helical turns per fiber period.[3-6] The internal-rotation conformation about the O-CH_2, CH_2-CH_2, and CH_2-O bonds are trans, gauche, and trans, respectively. The vibrational frequencies calculated for the 7_2 helix conformation agree satisfactorily well with the observed frequencies of the far-infrared bands below 300 cm^{-1}.

For the polyethylene-glycol chain, the repeat unit contains seven atoms, and accordingly, there are twenty-one branches of the chain vibrations. In the region below 600 cm^{-1}, there are six branches associated with C-C-O and C-O-C angle-bending modes and internal-rotation modes about C-C and C-O bonds. From dispersion curves (frequency *versus* phase difference) for these branches, frequency distribution of the chain vibrations has been calculated,[7] in comparison with neutron inelastic scattering peaks.[8] Also, Young's modulus along the chain axis may be treated by the use of the intrachain force field. For the polyethylene-glycol chain, the calculated value[7] of 0.008 mdyn/Å^2 agrees closely with the experimental value[9] of 0.010 mydn/Å^2.

Thus, the infrared and Raman frequencies, frequency distribution and neutron inelastic scattering, and Young's modulus may be treated systematically on the basis of the intrachain force field. An extensive study on the force field of the polyethylene-glycol chain is also important for analyses of infrared and Raman spectra of model molecules[10] $RO(-CH_2CH_2O-)_pR$ [R: H, D or CH_3; p= 1−7] and of molten polyethylene glycol.[11]

In the present study, the intrachain force field of polyethylene glycol was refined, by the method of least squares, with reference to the observed infrared and Raman frequencies.[4,5] Nature of the infrared and/or Raman active vibrations was elucidated, referring to the calculated potential-energy distributions.

Normal Coordinate Treatment

For the 7_2 helix conformation of polyethylene glycol, the unit rotation about the axis is given as $\theta=4\pi/7$. Also, as confirmed by the analysis of the parallel infrared bands, the molecular chain has two twofold axes per repeat unit; one axis bisects the C-O-C bond-angle while the other axis intersects the C-C bond at right angle. Accordingly, the non-degenerate A vibrations (with $\delta=0$) are classified into the A_1 and A_2 vibrations which are symmetric and antisymmetric, respectively, with respect to the twofold axes.[12] The parallel infrared bands of polyethylene glycol are due to the A_2 vibrations with $\delta=0$ while the perpendicular bands are due to the E_1 vibrations with $\delta=4\pi/7$. The Raman lines are due to the A_1, E_1, or E_2 vibrations with $\delta=8\pi/7$.

In the present study, the A_1, A_2, and E_1 vibrations were treated for the normal species $(-CH_2CH_2O-)_p$ and the perdeuterated species $(-CD_2CD_2O-)_p$ of the polyethylene-glycol chain. The general method for treating the helical chain vibrations[2] was used. The stretching (Δr), angle-bending ($\Delta\phi$), and internal-rotation coordinates (Δt)[13] were denoted with the atom indices given previously[4] (see also Fig. 1). The internal coordinates

were then transformed into the local-symmetry coordinates ($\sigma's$),[14] namely σ_{ss} (CH_2 symmetric stretching), σ_{as} (CH_2 antisymmetric stretching), σ_{sc} (CH_2 scissoring), σ_{wa} (CH_2 wagging), σ_{tw} (CH_2 twisting), σ_{ro} (CH_2 rocking), σ_{CCst} (C-C stretching), σ_{COst} (C-Ostretching), σ_{CCO} (C-C-O bending), σ_{COC} (C-O-C bending), σ_{CCto} (C-C internal-rotation), and σ_{COto} (C-O internal-rotation). These coordinates were grouped into four vectors,

$$\boldsymbol{R}^s_n,\ \boldsymbol{R}_{n+1/4},\ \boldsymbol{R}^s_{n+1/2},\ \text{and}\ \boldsymbol{R}_{n+3/4}.$$

$$\begin{aligned}
\boldsymbol{R}^s_n:\quad & \sigma_{COC}=\Delta\phi(C_{n-1/4}\text{-}O_n\text{-}C_{n+1/4})\\
\boldsymbol{R}_{n+1/4}:\quad & \sigma_{ss}=[\Delta r(C_{n+1/4}\text{-}H_{m+1/4})+\Delta r(C_{n+1/4}\text{-}H_{l+1/4})]/2^{1/2}\\
& \sigma_{as}=[\Delta r(C_{n+1/4}\text{-}H_{m+1/4})-\Delta r(C_{n+1/4}\text{-}H_{l+1/4})]/2^{1/2}\\
& \sigma_{sc}=[4\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}H_{l+1/4})-\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}C_{n+3/4})\\
& \qquad -\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}O_n)-\Delta\phi(H_{l+1/4}\text{-}C_{n+1/4}\text{-}C_{n+3/4})\\
& \qquad -\Delta\phi(H_{l+1/4}\text{-}C_{n+1/4}\text{-}O_n)]/20^{1/2}\\
& \sigma_{wa}=[\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}C_{n+3/4})-\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}O_n)\\
& \qquad +\Delta\phi(H_{l+1/4}\text{-}C_{n+1/4}\text{-}C_{n+3/4})-\Delta\phi(H_{l+1/4}\text{-}C_{n+1/4}\text{-}O_n)]/2\\
& \sigma_{tw}=[\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}C_{n+3/4})-\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}O_n)\\
& \qquad -\Delta\phi(H_{l+1/4}\text{-}C_{n+1/4}\text{-}C_{n+3/4})+\Delta\phi(H_{l+1/4}\text{-}C_{n+1/4}\text{-}O_n)]/2\\
& \sigma_{ro}=[\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}C_{n+3/4})+\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}O_n)\\
& \qquad -\Delta\phi(H_{l+1/4}\text{-}C_{n+1/4}\text{-}C_{n+3/4})-\Delta\phi(H_{l+1/4}\text{-}C_{n+1/4}\text{-}O_n)]/2\\
& \sigma_{COst}=\Delta r(C_{n+1/4}\text{-}O_n)\\
& \sigma_{CCO}=[5\Delta\phi(C_{n+3/4}\text{-}C_{n+1/4}\text{-}O_n)-\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}H_{l+1/4})\\
& \qquad -\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}C_{n+3/4})-\Delta\phi(H_{m+1/4}\text{-}C_{n+1/4}\text{-}O_n)\\
& \qquad -\Delta\phi(H_{l+1/4}\text{-}C_{n+1/4}\text{-}C_{n+3/4})-\Delta\phi(H_{l+1/4}\text{-}C_{n+1/4}\text{-}O_n)]/30^{1/2}\\
& \sigma_{COto}=\Delta t(C_{n+1/4}\text{-}O_n)\\
\boldsymbol{R}^s_{n+1/2}:\quad & \sigma_{CCst}=\Delta r(C_{n+1/4}\text{-}C_{n+3/4})\\
& \sigma_{CCto}=\Delta t(C_{n+1/4}\text{-}C_{n+3/4})
\end{aligned}\qquad (1)$$

The elements of the $\boldsymbol{R}_{n+3/4}$ vector may be derived from the $\boldsymbol{R}_{n+1/4}$ vector by interchanging the subscripts, $n \leftrightarrow n+1$, $n+1/4 \leftrightarrow n+3/4$, $l+1/4 \leftrightarrow m+3/4$, and $m+1/4 \leftrightarrow l+3/4$.

The inverse kinetic-energy matrix $\boldsymbol{G}$ or the potential-energy matrix $\boldsymbol{F}$ for the infinite helical chain may be factored into the matrices associated with the symmetry coordinate vectors for the phase difference δ. The symmetry coordinates for polyethylene glycol were constructed as follow,

$$\begin{aligned}
\boldsymbol{S}_1(\delta)&=(2/N)^{1/2}\sum_n \boldsymbol{R}^s_n\cos n\delta\\
\boldsymbol{S}_3(\delta)&=(2/N)^{1/2}\sum_n \boldsymbol{R}^s_{n+1/2}\cos(n+1/2)\delta\\
\boldsymbol{S}_5(\delta)&=(1/N)^{1/2}\sum_n[\boldsymbol{R}_{n+1/4}\cos(n+1/4)\delta+\boldsymbol{R}_{n+3/4}\cos(n+3/4)\delta]\\
\boldsymbol{S}_6(\delta)&=(1/N)^{1/2}\sum_n[\boldsymbol{R}_{n+1/4}\cos(n+1/4)(\delta+2\pi)+\boldsymbol{R}_{n+3/4}\cos(n+3/4)(\delta+2\pi)]
\end{aligned}$$

and

$$\begin{aligned}
\boldsymbol{S}_1'(\delta)&=-(2/N)^{1/2}\sum_n \boldsymbol{R}^s_n\sin n\delta\\
\boldsymbol{S}_3'(\delta)&=-(2/N)^{1/2}\sum_n \boldsymbol{R}^s_{n+1/2}\sin(n+1/2)\delta\\
\boldsymbol{S}_5'(\delta)&=-(1/N)^{1/2}\sum_n[\boldsymbol{R}_{n+1/4}\sin(n+1/4)\delta+\boldsymbol{R}_{n+3/4}\sin(n+3/4)\delta]\\
\boldsymbol{S}_6'(\delta)&=-(1/N)^{1/2}\sum_n[\boldsymbol{R}_{n+1/4}\sin(n+1/4)(\delta+2\pi)+\boldsymbol{R}_{n+3/4}\sin(n+3/4)(\delta+2\pi)]
\end{aligned}\qquad (2)$$

where $(2/N)^{1/2}$ or $(1/N)^{1/2}$ is the normalization factor. The symmetry coordinate $S(\delta)$ is symmetric with respect to the twofold axis passing through the zeroth oxygen atom, whereas $S'(\delta)$ is antisymmetric with respect to this axis. Accordingly, the inverse kinetic-energy matrix (or potential-energy matrix) for the phase difference δ is factored into the $\boldsymbol{G}(\delta)$ [or $\boldsymbol{F}(\delta)$] associated with $S(\delta)$'s and the other identical one associated with $S'(\delta)$'s.

For calculating $\boldsymbol{G}(\delta)$ matrices, the bond lengths of r(C-C)=1.54 A, r(C-O)=1.43 A, and r(C-H)=1.09 Å, and tetrahedral bond angles were used. From these bond lengths and angles and the fiber period[15] of 19.25 Å,

14) T. Shimanouchi, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **86**, 261, 768 (1965); Symposium on Molecular Structure, Tokyo, 1964; Toyonaka, 1966.

15) E. R. Walter and F. P. Reding, National Meeting of the American Chemical Society, San Francisco, 1958.

the internal-rotation angles about the C-C and C-O bonds were calculated as 63°55′ and 188°51′, respectively, by the use of equations for helical parameters.[3,16] The atomic masses of 12.01115 for carbon, 15.99940 for oxygen, 1.00797 for hydrogen, and 2.01410 for deuterium were used for calculating the $\boldsymbol{G}(\delta)$ matrix elements.

For degenerate vibrations, phase angles $\varepsilon(\delta)$ are useful for describing phase relations in normal modes. Setting $\varepsilon=0$ for internal coordinates $\boldsymbol{R}^s_n(\delta)$, the phase angle for $\boldsymbol{R}^s_{n+1/2}(\delta)$ is given as $\varepsilon=\delta/2$. The phase angles for $[\boldsymbol{R}_{n+1/4}(\delta)]_k$*1 and $[\boldsymbol{R}_{n+3/4}(\delta)]_k$ are given as $\varepsilon_k=\delta/2-\varepsilon'_k(\delta)$ and $\varepsilon_k=\delta/2+\varepsilon'_k(\delta)$, respectively, where the values of $\varepsilon'_k(\delta)$ may be calculated from the eigenvector components for the kth coordinates.[2] Then, the phase-angle difference between $[\boldsymbol{R}_{n+1/4}(\delta)]_k$ and $[\boldsymbol{R}_{n+3/4}(\delta)]_k$ is $\Delta\varepsilon_k(OCH_2\text{-}CH_2O)=2\varepsilon'_k(\delta)$. Vibrational modes with $\Delta\varepsilon_k(OCH_2\text{-}CH_2O)\sim0$ and $\sim\pm180°$ are quasi-symmetric and quasi-antisymmetric, respectively, with respect to the twofold axis that intersects the CH_2-CH_2 bond. The phase-angle difference between $[\boldsymbol{R}_{n-1/4}(\delta)]_k$ and $[\boldsymbol{R}_{n+1/4}(\delta)]_k$ is $\Delta\varepsilon_k(\text{C-O-C})=\delta-2\varepsilon'_k(\delta)$. Vibrational modes with $\Delta\varepsilon_k(\text{C-O-C})\sim0$ and $\sim\pm180°$ are quasi-symmetric and quasi-antisymmetric, respectively, with respect to the twofold axis that intersects the C-O-C angle. It may be remarked that the phase-angle differences for the A_1 and A_2 vibrations are $\Delta\varepsilon=0$ and 180°, respectively.

Numerical calculations in the present treatment of normal vibrations were carried out with a HITAC 5020 E computer (Hitachi, Limited) at the University of Tokyo and a NEAC 2200-500 computer (Nippon Electric Company, Limited) at Osaka University.

Potential Function

In a previous study,[4] the Urey-Bradley force field (UBFF)[17] with supplementary terms was used, and the potential constants were transferred from polyethylene, dimethyl ether, and propyl alcohol. In the present treatment, however, a more generalized potential function (local-symmetry force field)[14] was used. Accordingly, the infinite potential-energy matrix of the infinite polyethylene-glycol chain is expressed in terms of the local-symmetry coordinate vectors. Nonzero submatrices in the lower half columns associated with $\boldsymbol{R}^s_n$, $\boldsymbol{R}_{n+1/4}$, $\boldsymbol{R}^s_{n+1/2}$, and $\boldsymbol{R}_{n+3/4}$ are shown below:

	$\tilde{\boldsymbol{R}}^s_n$	$\tilde{\boldsymbol{R}}_{n+1/4}$	$\tilde{\boldsymbol{R}}^s_{n+1/2}$	$\tilde{\boldsymbol{R}}_{n+3/4}$
$\boldsymbol{R}^s_n$	$\boldsymbol{A}^a_0$			
$\boldsymbol{R}_{n+1/4}$	$\tilde{\boldsymbol{F}}^a_{1/4}\boldsymbol{C}_0$			
$\boldsymbol{R}^s_{n+1/2}$	0	$\boldsymbol{F}^b_{1/4}$	$\boldsymbol{A}^b_0$	
$\boldsymbol{R}_{n+3/4}$	0	$\boldsymbol{C}^b_{1/2}$	$\tilde{\boldsymbol{F}}^b_{1/4}$	$\boldsymbol{C}_0$
$\boldsymbol{R}^s_{n+1}$	0	0	0	$\boldsymbol{F}^a_{1/4}$
$\boldsymbol{R}_{n+5/4}$	0	0	0	$\boldsymbol{C}^a_{1/2}$
$\boldsymbol{R}^s_{n+3/2}$	0	0	0	0

where the matrices with tilde are the transposed matrices. The elements of the submatrices are given below:

$$\boldsymbol{A}^a_0=[f(\text{COC})]$$

$$\boldsymbol{A}^b_0=\begin{bmatrix} f(\text{CC st}) & 0 \\ 0 & f(\text{CC to}) \end{bmatrix}$$

where the elements denoted with asterisk are related with the UBFF's repulsion constants, F(HCO), F(HCC), and F(HCH).

The force constants f(ss), f(as), f(sc), f(wa), f(tw), f(ro), f(CC st), f(CO st), f(CCO), f(COC), f(CC to), and f(CO to) are diagonal elements associated with the local-symmetry coordinates shown in parentheses. The non-diagonal elements of UBFF, namely, f(sc, wa), f(sc, CCO), f(wa, CCO), f(tw, ro), f(CO st, CCO), f(CO st, CO st), f(CO st, COC), f(CC st, CO st), f(CC st, CCO), and F(HCO), F(HCC), and F(HCH) were taken as independent force constants. The potential constants denoted with primes f'(wa, wa), f'(tw, tw), f'(ro, ro), f'(CCO, CCO), f'(ro, CCO), and f'(COC, CCO) are not found in the simple UBFF. However, these constants were also taken into account as supplementary elements, which are associated with the vibrational interactions between the adjacent methylene groups or between the adjacent skeletal-bond angles.

In the beginning, the modified UBFF constants of the previous studies[4,7] were transformed into the constants of the local-symmetry force field (LSFF). The LSF Fforce constants were then adjusted by the method of least squares,[18] with reference to the infrared absorption frequencies of the normal and perdeuterated species of polyethylene glycol,[4,5] and the Raman frequencies of the normal species.[19,20] The observed frequencies[21] of *p*-dioxane and *p*-dioxane-d_8 were also used in the refinement, since these molecules consist of the same chemical units of CH_2CH_2O and CD_2CD_2O, respectively, as those of the normal and perdeuterated species of this polymer. The force constants thus obtained are shown in Table 1. The observed and calculated frequencies are listed in Table 2—5, together with the potential-energy distributions (P. E. D.)[22] defined as follows,

$$(P.E.D.)_{ia}=(F_{ii}L^{2}_{ia}/\lambda_a)\times 100 \qquad (3)$$

where F_{ii} is the ith diagonal element of the potential-energy matrix, L_{ia} is the ith element of the ath eigenvector, and λ_a is the

ath eigenvalue (frequency parameter).

For E_1 vibrations listed in Tables 3 and 5, phase-angle differences $\Delta\varepsilon(OCH_2\text{–}CH_2O)$ are given for CH_2 (or CD_2) sym. and antisym. stretch., scissor., wag., twist., and rock. modes and CCO bend. mode, while $\Delta\varepsilon$(C-O-C) are given for CO stretch. and internal-rotation modes.

Potential Constants

The potential constants for the polyethylene-glycol chain are listed in Table 1. By the use of these constants, calculated frequencies agree closely with observed frequencies, with a root-mean-square deviation as small as 0.9%.

The potential constants of methylene groups of polyethylene glycol (Table 1) may be compared with those of hydrocarbons[14] and polyethylene.[23] For example, symmetric- [f(ss)] and antisymmetric-stretching [f(as)] and scissoring constants [f(sc)] are nearly the same for polyethylene glycol (4.71 and 4.69 mdyne/Å and 0.58 mdyn·Å) and for propane (4.74 and 4.66 mdyn·Å and 0.59 mdyn·Å). However, the wagging constant [f(wa)] of polyethylene glycol (0.74 mdyn·Å) is appreciably larger than those of propane (0.64 mdyn·Å), and polyethylene (0.67 mdyn·Å), possibly due

to the effect of nonbonded interaction between methylene-hydrogen atoms and oxygen or carbon atoms. Since the C-O bond length (~1.43 Å) is appreciably shorter than the C-C bond length (~1.54 Å), the repulsive interaction to the methylene-hydrogen atoms of [O-CH_2-C] is expected to be greater than for [C-CH_2-C]. In fact, the repulsion constant of F(HCO)=0.89 mdyn·Å (Table 1) is much larger than F(HCC)=0.32 mdyn/Å. Then, the repulsive interaction is expected to be even greater for polyoxymethylene $[-CH_2-O-]_p$, where a methylene group is bonded to two oxygen atoms. In fact, the wagging constant of polyoxymethylene[24] [f(wa)=0.83 mdyn·Å] is larger than for polyethylene glycol. In accordance with the variation of the wagging constant, the rocking [f(ro)] and twisting constants [f(tw)] increase for the series of polyethylene (0.69 and 0.64 mdyn·Å) or propane (0.73 and 0.66 mydn·Å), polyethylene glycol (0.78 and 0.68 mydn. Å), and polyoxymethylene (1.05 and 0.76 mdyn. Å).

Before comparing the present force field with the force field of earlier normal coordinate treatments, Urey-Bradley force constants of K(CC), K(CO), F(CCO), F(COC), F(HCO) and F(HCC) may be transformed into local-symmetry force constants. Thus, the C-C and C-O stretching constants of polyethylene glycol in earlier treatments[4,6] are derived as f(CC st)=4.72 or 5.11 mdyn/Å and f(CO st)=4.26 or 4.68 mdyn/Å. These values of f(CC st) are much larger than for propane (4.35 mdyn/Å) and polyethylene (4.24 mdyn/Å). On the other hand, the previous values of f(CO st) are much smaller than for dimethyl ether[14] (5.20 mdyn/Å). However, in the present study, the C-C and C-O stretching constants were refined by the method of least squares and now these constants of f(CCst) =4.21 mydn/Å and f(CO st)=5.23 mdyn/Å agree closely enough with the corresponding constants for propane, polyethylene or dimethyl ether. Accordingly, the present set of force constants is considered to be more reasonable than those of earlier treatments. Because of considerable refinements in the force field, vibrational assignments (potential-energy distributions) in the region 1200—800 cm^{-1} were revised as will be presented in the next section.

The internal-rotation constants about the C-C and C-O bonds of polyethylene glycol were refined as f(CC to)=0.113 mdyn·Å and f(CO to)=0.099 mdyn·Å. These values correspond to the internal-rotation potential $V=V_3(1-\cos 3t)/2$ with the barrier height of V_3=3.6 and 3.2 kcal/mol for the C-C and C-O

24) H. Sugeta and T. Miyazawa, Annual Meeting of the Chemical Society of Japan, Tokyo, 1967.

bonds, respectively. These values may be compared with the corresponding values of polyethylene [f(CC to)=0.107 mdy. Å and V_3=3.4 kcal/mol][23] and polyoxymethylene [f(CO to) =0.108 mdyn. Å and V_3=3.5 kcal/mol].[24]

Vibrational Assignments

For the helical chain of polyethylene glycol $[-CH_2-CH_2-O-]_p$, there are seven atoms per repeat unit, so are 10 A_1 and 9 A_2 vibrations, 20 pairs of E_1 and 21 pairs of E_2 vibrations. The A_1, E_1 and E_2 vibrations are Raman active while the A_2 and E_1 vibrations are infrared active giving rise to parallel and perpendicular bands, respectively.

Polarized infrared spectra of polyethylene glycol were measured by Miyazawa *et al.*[4] and Tadokoro *et al.*[5] The Raman effect with mercury-lamp excitation was recorded by Matsui *et al.*[19] Referring to selection rules for infrared and Raman spectra and to observed dichroism of infrared bands, observed frequencies were already assigned[4,6] reasonably to symmetry species of A_1, A_2 or E_1. Recently, Schaufele[20] observed the Raman effect with helium-neon laser excitation (6328 Å) and found a number of Raman lines in the region 3000—25 cm^{-1}. Almost all the A_1, A_2 and E_1 frequencies of the normal species and the A_2 and E_1 frequencies of the perdeuterated species have now been observed as infrared bands and/or Raman lines. These observed frequencies are listed in Tables 2—5, together with frequencies, potential-energy distributions and phase-angle differences calculated in the the present study. Revised vibrational assignments of observed frequencies will be discussed, in contrast to previous assignments.[4,6]

Polyethylene Glycol $(-CH_2CH_2O-)_p$. Infrared bands due to fundamental vibrations of polyethylene glycol in the region 3000—2800 cm^{-1} were identified, with reference to vibrational frequencies of related molecules. Thus, the parallel band at 2890 cm^{-1} and perpendicular band at 2885 cm^{-1} are assigned to the A_2 and E_1 CH_2 symmetric-stretching vibration.[4] The strong Raman line at 2890 cm^{-1} corresponds to the infrared band at 2885 cm^{-1}. The medium-intensity Raman line at 2939 cm^{-1} and the perpendicular infrared band at 2950 cm^{-1} are assigned to the A_1 and E_1 antisymmetric stretching modes, respectively.

The parallel infrared band (doublet at 1463 and 1457 cm^{-1}) and perpendicular bands at 1470 and 1453 cm^{-1} are assigned to the A_2 and E_1 CH_2 scissoring vibrations. The strong Raman line at 1484 cm^{-1} is assigned to the A_1 scissoring vibration while the weak line at 1449 cm^{-1} corresponds to the infrared band at 1453 cm^{-1}.

The Raman line at 1398 cm^{-1} (weak) and parallel infrared band at 1345 cm^{-1} (strong) are assigned to the symmetric (A_1) and antisymmetric (A_2) wagging modes of CH_2-CH_2 groups (Table 2). The two perpendicular bands at 1415 and 1364 cm^{-1} correspond to the CH_2 wagging frequencies of the E_1 species, calculated at 1401 cm^{-1} (with $\Delta\varepsilon$=53°) and at 1353 cm^{-1} (with $\Delta\varepsilon$=−129°), respectively (Table 3). The calculated values of $\Delta\varepsilon$ indicate that the higher-frequency vibration is associated with quasi-symmetric wagging mode of CH_2-CH_2 groups while the lower-frequncy vibration is associated with quasi-antisymmetric mode. The weak band at ~1410 cm^{-1} and strong band at ~1360 cm^{-1} have also been observed for higher oligomers $HO[-CH_2CH_2O-]_pH$ in the crystalline state.[25]

The parallel infrared band at 1244 cm^{-1} is due to the A_2 vibration associated with the antisymmetric twisting mode of CH_2-CH_2 groups. The perpendicular bands at 1283 (medium) and 1236 cm^{-1} (weak) are due to quasi-symmetric ($\Delta\varepsilon$=−40°) and quasi-antisymmetric twisting modes ($\Delta\varepsilon$=146°), respectively, of CH_2-CH_2 groups.*2 It may be remarked that the intensities of the infrared bands at 1244 and 1283 cm^{-1} compare with the intensities of the bands (at 1345 and 1364 cm^{-1}) due to CH_2 wagging modes (see Fig. 2 of Ref. 4). Strong absorption of twisting modes of C-CH_2-O groups has been discussed previously[4] in relation with dissimilarity of C-C and C-O bonds (as for polarity or conformation).

The Raman line observed at 1235 cm^{-1} appears to correspond to the perpendicular infrared band at 1236 cm^{-1} (E_1 species). The Raman line due to the A_1 vibration calculated at 1252 cm^{-1} is possibly overlapped by the Raman line at 1235 cm^{-1}.

Infrared bands and Raman lines in the region 1150—800 cm^{-1} are due to C-C and C-O stretching modes and CH_2 rocking mode. Two parallel infrared bands are assigned to A_2 vibrations (Table 2). The very strong band

25) H. Matsuura and T. Miyazawa, *Spectrochim. Acta*, **23A**, 2433 (1967).

*2 In a previous treatment[4] of potential-energy distributions, CH_2 wagging and twisting modes were considerably mixed for vibrations in the region 1430—1230 cm^{-1}. However, with the force field refined in the present study, vibrations calculated above 1340 cm^{-1} are almost purely associated with CH_2 wagging modes and vibrations below 1290 cm^{-1} are associated with twisting modes.

at 1102 cm^{-1} is associated almost exclusively with the C-O-C antisymmetric stretching mode while the strong band at 963 cm^{-1} is associated primarily with the antisymmetric rocking mode of CH_2-CH_2 groups.

The medium-intensity Raman lines at 1126 and 861 cm^{-1} are assigned to the A_1 vibrations calculated at 1137 and 866 cm^{-1}, respectively (Table 2). As for potential-energy distributions, these lines are due to hybridized vibrations of the CH_2-CH_2 symmetric rocking mode and C-O-C symmetric stretching mode. For the A_1 species, the C-C stretching mode is coupled with the C-O-C symmetric stretching mode, to yield the vibration calculated at 1073 cm^{-1}. However, a corresponding Raman line has not been identified, possibly because of overlap with the medium-intensity line at 1064 cm^{-1}.

The Raman line at 1143 (strong), 1064 (medium) and 846 cm^{-1} (strong) correspond to the perpendicular infrared bands (E_1 species) at 1149 (strong), 1062 (medium) and 844 cm^{-1} (strong). The vibration calculated at 1142 cm^{-1} is associated with quasi-symmetric C-O stretching mode and CH_2 rocking mode,*3 whereas the vibration calculated at 847 cm^{-1} is associated with quasi-antisymmetric ($\Delta\varepsilon=-149°$) CH_2 rocking mode and quasi-symmetric ($\Delta\varepsilon=-9°$) C-O stretching mode. The vibration calculated at 1060 cm^{-1} is also associated with the C-O stretching ($\Delta\varepsilon=-102°$) and CH_2 rocking mode ($\Delta\varepsilon=70°$).

The strong perpendicular band at 1119 cm^{-1} is primarily due to quasi-antisymmetric ($\Delta\varepsilon=136°$) C-O stretching mode as coupled with the C-C stretching mode. The medium-intensity band at 947 cm^{-1} is due largely to CH_2 quasi-symmetric ($\Delta\varepsilon=42°$) rocking mode and C-C stretching mode. This perpendicular band at 947 cm^{-1} together with the bands at 963 and 844 cm^{-1} have been discussed[26-29] in relation with the conformation of O-CH_2-CH_2-O groups. However, vibrational assignments of these bands are now established after the refined treatment of the present study.

A weak Raman line has been observed at 930 cm^{-1} by Matsui *et al.*[19] or at 936 cm^{-1} by Schaufele.[20] This line does not correspond to any calculated A_1 frequencies or to perpendicular infrared bands (E_1) in this region. As mentioned previously, E_2 vibrations are infrared inactive but they are active in the Raman effect. Accordingly, the Raman line at 936 cm^{-1} may be assigned to the E_2 vibration (with the phase difference of $\delta=2\theta$) calculated at 922 cm^{-1}. This E_2 vibration is associated with the C-C stretching and C-O stretching modes.

Chain vibrations of polyethylene glycol in the region below 600 cm^{-1} are associated with C-C-O and C-O-C bending modes and internal-rotation modes about C-C and C-O bonds. Raman lines have been observed at 537, 363, 279, 216 and 160 cm^{-1}, parallel infrared bands at 529, 508 and 107 cm^{-1}, and perpendicular bands at 216 and 165 cm^{-1}. In the present study, a weak band was found at 363 cm^{-1} for Carbowax 6000 (high molecular-weight polyethylene glycol from Carbide and Carbon Chemicals Corporation).

The parallel band (doublet at 529 and 508 cm^{-1}) corresponds to the A_2 vibration calculated at 533 cm^{-1}. This is the C-C-O bending vibration as coupled with the CH_2 rocking mode. The doublet splitting is either due to Fermi resonance with combination vibrations or to interchain ineractions in the crystalline lattice.[4] In the present study, therefore, the infrared absorption (600—400 cm^{-1}) was measured for solid solutions of Carbowax 6000 and *n*-octacosane ($C_{28}H_{58}$)*4 with the mixing weight-ratio of 1 : ~50. At this low concentration, any interchain effect is reduced negligible. However, the peak positions and relative intensities of the doublet in the solution are still the same as in the crystalline state. This observation indicates that the doublet splitting is possibly due to Fermi resonance rather than to interchain interactions. Therefore, the dispersion curves (frequency *versus* phase difference) of the polyethylene-glycol chain[30] were reviewed, for possibilities of Fermi resonance with the A_2 fundamental calculated at 533 cm^{-1}. In fact, the splitting may now be ascribed to the Fermi resonance between the A_2 fundamental

*3 In previous treatments[4,6] the potential energy for the A_1 vibration at 1126 cm^{-1} and the E_1 vibration at 1149 cm^{-1} was largely associated with the C-C stretching mode, because the C-C stretching constant was perphaps too large and the C-O stretching constant was too small.

*4 In the region 600—400 cm^{-1}, *n*-octacosane exhibits only aweak peak at 564 cm^{-1}.

*5 Another resonance may also be expected between the A_2 fundamental and the binary combination of B_1 (calc. 196 cm^{-1}) and B_2 (calc. 289 cm^{-1}) vibrations. The symmetry species for overtones and combinations have been given.[12,31]

and the binary combination of the E_1 vibrations [363+165=528 cm^{-1}].*5

The Raman lines at 537 cm^{-1} (E_1) and 279 cm^{-1} (A_1), Raman line and infrared band (perpendicular) at 363 cm^{-1} (E_1) are assigned to the hybridized vibrations of C-O-C and C-C-O bending modes. The perpendicular band at 216 cm^{-1} is assigned to the E_1 vibration associated with the quasi-symmetric C-C-O bending mode and C-C internal-rotation mode. The weak Raman line at 216 cm^{-1} corresponds to this E_1 vibration and/or to the A_1 vibration (calculated at 218 cm^{-1}) which is associated with the C-O-C bending mode and symmetric internal-rotation mode about C-O bonds.

The perpendicular infrared band at 165 cm^{-1} (and corresponding Raman line at 160 cm^{-1}) is due to the hybridized vibration of the C-C internal-rotation mode and quasi-antisymmetric internal-rotation mode about C-O bonds. The parallel band at 107 cm^{-1} is due to the antisymmetric internal-rotation mode about C-O bonds.

A weak infrared band[2] is observed at 580 cm^{-1} and the corresponding Raman line[20] at 584 cm^{-1}. Accordingly, this vibration is assigned to the E_1 species. There is no E_1 fundamental calculated around this frequency. However, the observed vibration may be assigned reasonably to the combination (E_1 species) of the A_1 vibration at 216 cm^{-1} and the E_1 vibration at 363 cm^{-1}. Supporting this assignment, the corresponding band (shoulder) is observed[6] around 500 cm^{-1} for the perdeuterated species, just as expected for the combination of the A_1 and E_1 vibrations calculated at 192 and 320 cm^{-1}, respectively.

The Raman lines at 126 and 75 cm^{-1} can not be explained as due to chain vibrations of A_1, E_1 or E_2 species, and are possibly due largely to lattice modes. Intensities or positions of the bands due to lattice vibrations are sensitive to temperature changes. In fact, Schaufele[32] observed that, at lower temperature, the Raman lineat 126 cm^{-1} intensifies relative to the line at 75 cm^{-1}.

Polyethylene-d_4 Glycol $(-CD_2CD_2O-)_p$. The strong parallel band of polyethylene-d_4 glycol at 1117 cm^{-1} is due to the A_2 vibration associated with the antisymmetric C-O stretching and CD_2 wagging modes (Table 4). Similarly the strong perpendicular band at 1145 cm^{-1} is due to the E_1 vibration associated with quasi-antisymmetric C-O stretching ($\Delta\varepsilon=-158°$) and CD_2 wagging modes ($\Delta\varepsilon=164°$). On the other hand, the E_1 vibration at 1121 cm^{-1} is due to quasi-symmetric C-O stretching mode ($\Delta\varepsilon=19°$) as coupled with quasi-antisymmetric CD_2 scissoring mode ($\Delta\varepsilon=122°$) (Table 5). The infrared bands, at 1050 and 1087 cm^{-1}, primarily due to CD_2 scissoring modes are weak and not well-defined. The C-C streching mode is strongly coupled with quasi-symmetric CD_2 wagging mode, giving rise to the medium-intensity infrared band at 1255 cm^{-1} (E_1). Infrared bands in the region 1000—700 cm^{-1} are due to hybridized vibrations of CD_2 wagging, twisting and rocking modes and C-O stretching mode.

In the region below 500 cm^{-1}, infrared bands due to skeletal bending and internal-rotation modes are observed. Similar to the doublet bands (529 and 508 cm^{-1}) of the normal species, doublet bands with parallel dichroism are again observed at 453 and 434 cm^{-1} for the perdeuterated species. This doublet, in fact, corresponds to the A_2 vibration calculated at 455 cm^{-1}, which is associated with the CCO bending mode heavily coupled with the CD_2 rocking mode. The doublet splitting is reasonably ascribed to the Fermi resonance between the A_2 fundamental and the combination of E_1 vibrations [320+156=476].*6 The perpendicular bands at 458 and 183 cm^{-1} are largely due to quasi-antisymmetric and quasi-symmetric bending modes, respectively, of O-C-C-O groups. The infrared bands of the deuterated species at 95 cm^{-1} (parallel) and 156 cm^{-1} (perpendicular) correspond to the bands of the normal species at 107 and 165 cm^{-1}, respectively, and are assigned to internal-rotation modes about C-O and C-C bonds.

Nuclear Quadrupole Resonance Study of Antimony Pentachloride and Its Phase Transition

Hideaki CHIHARA, Nobuo NAKAMURA, Hideo ŌKUMA and Syûuzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received February 16, 1968)

A phase transition was found in solid antimony pentachloride at 212°K by the nuclear quadrupole resonance and the differential thermal analysis. In the high temperature solid phase, five resonance lines were observed that were all assigned to antimony resonances and that were dependent on temperature only slightly. The quadrupole coupling constant of ^{121}Sb was 84.54±0.01 MHz (asymmetry $\eta=1.0\pm0.3\%$). Chlorine resonances were not detected above the transition point. In the low temperature phase, many resonance lines were observed due both to chlorine and antimony; the latter gave the coupling constant for ^{121}Sb 186.43±0.03 MHz ($\eta=79.54\pm0.02\%$) and 172.8±0.3 MHz ($\eta=79.2\pm0.3\%$). There are two nonequivalent sites for antimony. The structure in the two solid phases was suggested as being trigonal bipyramidal above 212°K and a dimerized Sb_2Cl_{10} bridged by two chlorine atoms with hexa-coordinated antimony atoms below 212°K.

Pentahalides of phosphorus and its homologues are an interesting group of compounds in that they may exist in ionic or molecular form or in both forms in the solid state.[1] Other compound such as $NbCl_5$ exists in a dimeric molecular structure.[2a]

Phosphorus pentachloride dealt with in our previous paper exists in an ionic structure $PCl_4^+ \cdot PCl_6^-$ though a molecular solid does form as a metastable modification.[3] On the other hand antimony pentachloride has been shown to assume the trigonal bipyramidal structure as shown in Fig. 1 by the X-ray diffraction study.[4] Since antimony is a quadrupolar nucleus, it was also hoped to detect antimony resonance by virtue of small distortion of the bipyramid. The result turned out that the solid exhibits an unusual phase transition by which molecules are dimerized at lower temperatures. The present paper describes the results of the nuclear quadrupole resonance (NQR) of chlorine and antimony in solid antimony pentachloride together with differential thermal study of the phase transition.

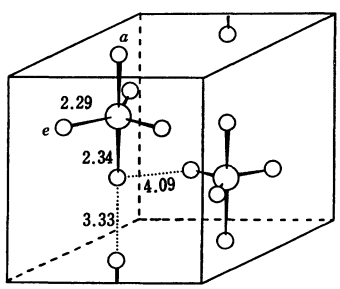

Fig. 1. Crystal structure of HTP at −30°C.[4] The numbers in the figure are internuclear distances in Å and *a* and *e* stand for axial and equatorial chlorine atoms.

In the rest of the present paper, we identify the chlorine atoms in the basal plane as 'equatorial' chlorines and the other two lying on the threefold axis of the molecule as 'axial' chlorines (see Fig. 1).

Experimental

Antimony pentachloride (Wakô Pure Chem. Ind., Ltd.) was distilled at 79°C under reduced pressure of 30 mmHg, condensed into the NQR cell and sealed off under reduced pressure. A small thermal anomaly caused by impurities, probably elementary chlorine, was observed at 170°K by the differential thermal analysis (DTA)[5] of the commercial speci-

men as obtained. Purification removed such a thermal anomaly and gave the melting point of 274.7±0.2°K. This is to be compared with 276.2°K found in the literature.[6] Both impure and purified specimens were used for NQR experiments for the reason to be described in the following section.

A Dean type super-regenerative spectrometer was used for measurements of chlorine and antimony resonances. The resonance was searched between 7.5 and 60 MHz, the maximum sensitivity of the spectrometer being in the range 25 to 45 MHz.

Digital frequency determinations and the cryostat have been described elsewhere.[3] The accuracy of the frequency determination was within 0.001 MHz.

Results and Discussion

General Features of Phase Transition. A thermal anomaly in solid phase was found at 211.8±0.4°K by the DTA as shown in Fig. 2. It is convenient to denote the phase below the transition as the low temperature phase (LTP) and that above as the high temperature phase (HTP).

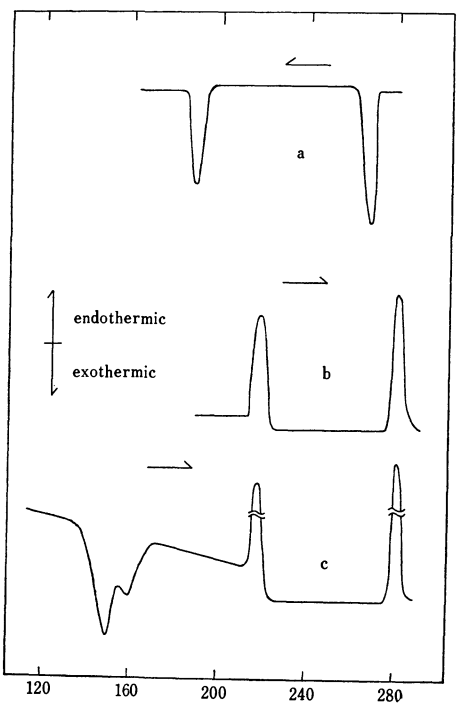

Fig. 2. The DTA curves of $SbCl_5$.
a : slow cooling curve
b : heating curve of slowly cooled sample
c : heating curve of rapidly cooled sample. The ordinate scale is enlarged 5 times of that for curve b. The transition and the melting point coincide with those of curve b.

A typical DTA curve in the cooling direction is shown in Fig. 2a, where the HTP is supercooled down to about 190°K for an impure sample, and to still lower temperature for a pure one. The LTP is superheated only by about 1°.

The area of the transition peak under the DTA curve b in Fig. 2 was about half of that of the melting peak where 2.4 kcal/mol is absorbed.[6] This phase transition is probably of the first order or of the isothermal type because there is a marked hysteresis in transition temperature[7] and also because NQR frequencies change abruptly at the transition as discussed later in this paper.

Figure 2c is the DTA curve (at the heating rate 10°/min) of $SbCl_5$ quenched by immersion of the liquid into liquid nitrogen (several minutes to reach 77°K); here exothermic peaks were observed before the phase transition took place. The exotherm occurred in two stages, one peak at 150°K and the other at 160°K. These peaks were displaced to lower temperatures by about 10° respectively at a slower rate of heating (1°/min) and the second peak became a shoulder of the first.

It is probable that $SbCl_5$ forms a glass by rapid cooling of the liquid to 77°K although a search for a glass transition was not successful. The exothermic peaks may be attributed to the crystallization of the glass into the LTP. This crystallization is likely to occur in the sequence

glass ⟶ HTP (supercooled) ⟶ LTP

in accordance with law of successive transformation.[8] In support of this view, the relative area under the exothermic peaks in Fig. 2c was found to be 1 : 2.1 in comparison with 1 : 2.3 for the ratio of the areas of transition and fusion. There is an indication that a quenched specimen also contains a certain amount of LTP because the exothermic peak area is much smaller than the endothermic peak area. A quantitative estimate of that amount, however, did not seem meaningful.

The phase transition appeared to be sluggish particularly in the cooling direction. Thus the resonance lines of LTP were broad and weak after first cooling through the transition point although the HTP resonances

disappeared abruptly. It was therefore necessary to anneal the LTP, before the measurements on the LTP were started, by subjecting it to heating and cooling cycles across the transition point. Thus, the sample was first cooled to just below the transition temperature while watching for the disappearance of an HTP signal and then warmed up so that the signals from both phases could be seen. The temperature was then lowered slightly to aid in crystallization of LTP. Such cycle was repeated several times until the resonance lines of LTP were observed distinctly. This procedure enhanced the intensity of the chlorine resonances, but the antimony resonances were generally much broader and weaker than the chlorine resonances.

Although the resonance frequencies were independent of the purity of the sample, the line intensity of unpurified sample was stronger than that of pure one probably because the rate of the transition was faster. Annealing was more effective for an impure sample. Therefore, the frequencies were determined by use of unpurified specimen.

One outstanding feature of the transition is the large abrupt change in the antimony resonance frequencies at the transition point; in fact it is so large that it could hardly be accounted for merely by a change in the crystal structure.

All available evidences are consistent with a possibility that the transition is accompanied with a change in the valence state of the antimony atom. It is perhaps significant to note that one of the HTP resonance lines (ν_5') was observed in supercooled HTP, even at 180°K, about 30° below the transition point. Its frequency was practically independent of the temperature, remaining the same as that at the transition point (25.391 MHz). Similarly, the intensity did not change until the transition started. The intensity decrease was used to monitor the progress of phase transition.

High Temperature Phase. Five strong NQR lines were observed in HTP between 7.5 and 40 MHz as listed in Table 1a together with their assignments. The frequency values agree well with those reported by Schneider and DiLorenzo[9] within experimental errors. All of these lines were ascribed toantimony nuclei. The quadrupole coupling constants e^2Qq/h and asymmetry parameters η are calculated[10,11] and listed in Table 1b.

As expected from the trigonal bipyramidal molecular structure of the HTP (Fig. 1), the coupling constants of central atoms (antimony nuclei) are small but they do not vanish be-

TABLE 1a. RESONANCE FREQUENCIES IN HTP AND THEIR ASSIGNMENTS

Resonance line	Frequency (MHz) 215°K	274°K	Assignment
ν_1'	——	7.71*	$^{123}Sb(3/2\leftrightarrow1/2)$
ν_2'	——	12.682	$^{121}Sb(3/2\leftrightarrow1/2)$

cause the bond lengths from antimony to equatorial chlorines are different from those to axial chlorines. Furthermore the field gradient is almost axially symmetric.

As is seen from Fig. 3, all the resonance frequencies are only slightly dependent on temperature in HTP (*e.g.* 0.5 kHz/deg for ν_5') in comparison with those of LTP. This behavior is rather extraordinary though there are examples of this sort (for instance ν_1 of ionic solid PCl_5[3]). If the molecules are undergoing librational motion, it should cause much greater decrease in frequency as the temperature is raised.[12]

Another experimental fact to be noted is that chlorine resonances are entirely missing in the range of 7.5 to 40 MHz*1 whereas antimony resonances are observable.

An off-hand approach to a plausible interpretation for these experimental results is to assume a reorientational motion about the threefold axis of the $SbCl_5$ molecule. X-ray diffraction study[4] shows a deformed chlorine electron density suggesting a large angular amplitude perpendicular to the molecular axis. Disappearance of resonance due to equatorial chlorine atoms may be explained by such reorientation. Similar situation has been found in the case of *trans*-1, 2-dichloroethane which undergoes reorientation about the Cl···Cl axis.[13] However, the disappearance of resonances of axial chlorine atoms must be due to some additional effect. Now, if one examines the molecular packing in the crystal, the intermolecular approach of axial chlorine atoms are found considerably shorter (3.33 A) than the sum of van der Waals radii (3.60 Å). Since it is difficult to imagine a special type of interaction between these chlorine atoms, we assume that the distance found is actually the one between the average positions of the chlorine atoms and that the molecule precesses about its figure axis. Nutation is very likely to be superposed upon the precession. Actual instantaneous separation between the intermolecular chlorines would then be longer than 3.33 Å and the field gradient at the axial chlorine nucleus would be disturbed severely to the extent that its resonance frequency falls below 7.5 MHz. The effect of the precession upon the resonance frequency may be evaluated by the formula[14]

$$\nu = \nu_Q(3\cos^2\theta - 1)/2,$$

where ν_Q is the resonance frequency corresponding to the static lattice and θ is the angle of precession. If the chlorine frequency is reduced greatly by precession, the same factor must apply to the antimony frequency.

Therefore, using the relation

$$\frac{\nu^{Cl}}{\nu^{Sb}} = \frac{\nu_Q{}^{Cl}}{\nu_Q{}^{Sb}}$$

and substituting $\nu_Q{}^{Cl} = 35$ MHz, $\nu^{Cl} \leq 10$ MHz, and $\nu^{Sb(121)} = 12.682$ MHz $(3/2 \leftrightarrow 1/2)$, we obtain $\nu_Q{}^{Sb} = 44.38$ MHz which corresponds to $|e^2Qq(^{121}Sb)/\boldsymbol{h}| = 295$ MHz. While this is not of unconceivable magnitude in comparison with the atomic $|e^2Qq(^{121}Sb)/\boldsymbol{h}| = 410$ MHz, we get more or less embarassed with a large angle of precession (43°) necessary to give rise to the reduction of the resonance frequency. In the present instance of $SbCl_5$, X-ray diffraction does not indicate a possibility of such a large angle of precession.

Very short relaxation time associated with chlorines can also explain the disappearance of their resonances by virtue of extremebroadening of the resonance lines as suggested by Schneider, *et al.* However the reason for shortening of chlorine relaxation time and not for antimony relaxation time is rather difficult to find.

Another possibility is to take account of a special intermolecular effect. Thus, if an axial chlorine atom forms a charge transfer bond to an equatorial chlorine atom on the neighboring molecule and if such bonds are switched owing to reorientation about the threefold axis, the effect would be seen not in antimony resonances but only in chlorine resonances. The effect could be so large as to cause a broadening of chlorine resonance by, say, 1 MHz. However, quantitative explanation based on this mechanism does not seem feasible with our present knowledge on the nature of Sb–Cl bond and the electronic structure of chlorine atom.

Low Temperature Phase. After the first cooling, a number of spurious signals appeared in addition to the LTP resonances and supercooled HTP resonances. The extraneous absorptions may have been due to a piezoelectric effect and could be sorted out by application of weak magnetic field to the specimen. Annealing did eliminate many of them but several lines persisted even after annealing. Altogether sixteen resonance absorption lines were observed at liquid nitrogen temperature and seven of them are shown in Fig. 3. They are also listed in Tables 2 and 3 indicating

our assignments. An independent study of this material by Schneider *et al.* was helpful in making these assignments.

Generally, antimony resonances were broader (width being 30—40 kHz) than chlorine resonances (2—3 kHz). It is seen that chlorine resonances appear in pairs (ν_3 and ν_4; ν_5 and ν_6; ν_7 and ν_8); ν_1 of ^{35}Cl also seems to have a doublet structure above 100°K though it was not made definite because the intensities were very weak and their separation was about twice the quench frequency of the spectrometer. The corresponding ^{37}Cl resonances were not obrerved in the frequency range covered. All the chlorine resonances observed are in agreement with the result by Schneider *et al.* With regard to antimony resonances, we did not detect two absorptions, which Schneider *et al.* reported at 27.93 and 54.22 MHz, but instead were able to observe absorptions at 47.3±0.1 (ν_{16}), 49.8±0.1 (ν_{17}), and 51.00±0.01 (ν_{18}) MHz. Extremely weak ν_{17} was not assigned; this may have been a spurious signal but the effect of magnetic field was not evident.

TABLE 2. RESONANCE FREQUENCIES OF ^{35}Cl IN LTP AT SELECTED TEMPERATURES AND THEIR ASSIGNMENTS BASED ON THE DIMER STRUCTURE

Site II			
$^{121}Sb'$	172.8 ±0.3	79.2 ±0.3	ν_{14}, ν_{16}
$^{123}Sb'$*	221	79	——

* These values were derived by taking 1.278 times the coupling constant of ^{121}Sb's and assuming the same η as ^{121}Sb.

From the observed frequencies and the assignments given in Table 3a for antimony nuclei, the quadrupole coupling constants and the asymmetry parameters were calculated by help of the tables of eigenvalues for spins 5/2[10] and 7/2[11]. They are listed in Table 3b. ν_{19}, ν_{20}, and ν_{21} were not detected, either because the intensities were weak or because of the noise disturbance from external sources between 34 and 36 MHz.

There are two nonequivalent antimony sites, one having slightly lower coupling constant than the other and both having about 79% asymmetry. We ascribe the small difference in the coupling constant between the two sites to crystallographic nonequivalence.

Structure of the Low Temperature Phase. We shall now consider what structure of the low temperature phase would be consistent with the experimental results. A drastic change in the antimony resonances, particularly its asymmetry parameter, across the transition point strongly suggests that the transition is related to a change in molecular structure. There are several possibilities, ionic $SbCl_4^+ \cdot SbCl_6^-$ structure, dimerized structure Sb_2Cl_{10}, and tetramer or higher polymer structure. In the following these different structural models will be separately examined.

a) Ionic Structure, $SbCl_4^+ \cdot SbCl_6^-$. Since

phosphorus pentachloride exists in this structure in the stable solid phase, there is a good reason to assume this type of ionic units. We previously measured[3] the chlorine resonance frequencies in $PCl_4^+ \cdot SbCl_6^-$ to aid in the assignment for PCl_5 and found them at 24.03 and 24.96 MHz at 77°K. A comparison with the frequencies in Table 2 implies that $SbCl_6^-$ is not a likely species in LTP. Also large asymmetry in the electric field gradient at Sb is not compatible with the symmetric chlorine arrangements in $SbCl_4^+$ or $SbCl_6^-$.

b) Dimer Structure, Sb_2Cl_{10}, and Higher Polymars. Dimerized form of molecules are not rare although few compounds possess corresponding monomers as stable species. Ex-

b. Tetramer.

Fig. 4. The suggested molecular structure in LTP. Filled circles are antimony and open circles are chlorine atoms; *a*, *b*, and *t* denote axial, bridging and terminal chlorines.

amples are $NbCl_5$, $NbBr_5$, $TaCl_5$, $MoCl_5$,[2a] $NbOCl_3$,[2b] UCl_5,[15] $AlBr_3$, $AuCl_3$, ICl_3[2a] and others. Some pentahalides take a molecular shape shown in Fig. 4a. It is interesting to note that the niobium resonance frequencies in $(NbCl_5)_2$ give a rather small coupling constant 78 MHz and a large asymmetry parameter 32%[16] as in the present case of $SbCl_5$.

Many investigators also observed bridging and terminal halogen resonances of dimerized trihalogen compounds as summerized in Fig. 5. The figure shows the frequency ratio of the terminal and bridge halogen *vs.* the electronegativity difference between the halogen

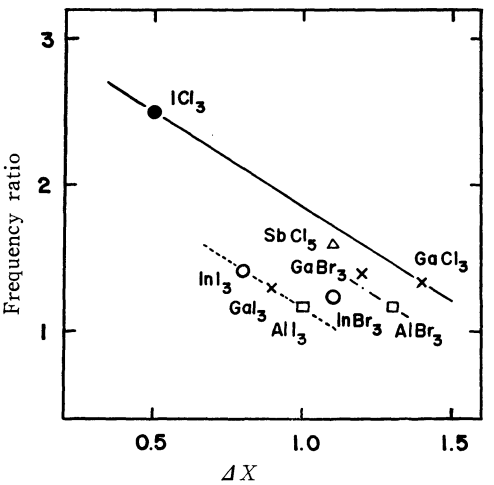

Fig. 5. Ratio of the resonance frequencies for terminal and bridging halogen atoms *vs.* electronegativity difference of central atom and halogen. The resonance frequencies were taken from É. I. Fedin and G. K. Semin, 'Use of Nuclear Quadrupole Resonance in Chemical Crystallography II', in 'The Mössbauer Effect and its Applications in Chemistry,' Consultants Bureau Enterprises, Inc., New York (1964).

and the central atom. It is seen that different ligands lead to different but parallel straight lines on each of which various central atoms are arranged according to their electronegativity. This empirical relationship may be useful in making assignments. Now, the four higher frequencies (ν_5 to ν_8 in Table 2) can be assigned to the terminal chlorines (identified with *t* in Fig. 4a), the three medium frequencies (ν_2 to ν_4) to the axial chlorines (*a* in Fig. 4a), and the remaining ν_1 to the bridge chlorine (*b* in Fig. 4a). The ratio of the average of ν_5 through ν_8 to ν_1 is then 1.6 and is included in Fig. 5; the point lies close to the chloride line. We agree with Schneider *et al.* on this assignment.

The differential thermal analysis experiments also support dimerization model or any type of polymerization model. Thus, the slow transition in the cooling direction can be explained by the difficulty in perfect pairing of monomers; annealing does help to grow dimer nuclei larger. The reverse reaction, the decomposition, can proceed quickly upon heating.

Tetramer structure as shown in Fig. 4b is known for $TaCl_4F$[17a] and $SbCl_4F$.[17b] However bridge atoms are not chlorine but fluorine.

16) A. H. Reddoch, *J. Chem. Phys.*, **35**, 1085 (1961).
17 a) H. Preiss, *Z. Anorg. Allg. Chem.*, **346**, 272 (1966). b) H. Preiss, *Z. Chem.*, **6**, 350 (1966).

Similarly, polymer chains are known for $BeCl_2$.[2c] We consider that tetramer or higher polymers are rather unlikely for $SbCl_5$ for two reasons; (a) chlorine polyhedra usually share edges rather than corners or faces in forming polymer chains and if $SbCl_5$ should form a polymer chain, the six-coordinated polyhedra must share corners and (b) the number and distribution of chlorine resonances are not readily reconciled with such a polymer structure while keeping the number of nonequivalent antimony sites two.

We are inclined to think that the dimer structure is the most probable structure for the low temperature phase of antimony pentachloride. Crystal structure determination of the low temperature phase is very desirable in order to correlate the asymmetry parameter and the coupling constant of antimony with the geometry of the dimer. It would also be interesting to study kinetics and detailed mechanism of the phase transition since this is one of very few phase transitions which accompany a change in the valence state, perhaps to our knowledge the sole example for a molecular crystal.

When the measurements of the present study were completed, Professor R. F. Schneider of New York State University at Stony Brook drew our attention to that he and his colleague were also studying the same compound. We were benefited in making some of the assignments through his courtesy of showing us his results prior to publication for which we extend our gratitude.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1815—1820 (1968)

The Crystal Structure of the 1 : 1 Complex of 1, 2, 4, 5-Tetracyanobenzene and Hexamethylbenzene

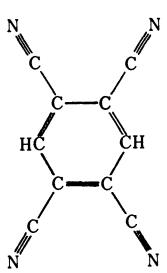
Nobuo NIIMURA, Yuji OHASHI and Yoshihiko SAITO

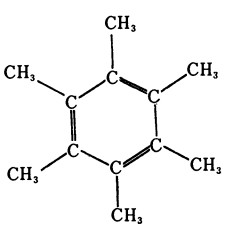
The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received February 19, 1968)

The crystal structure of the 1 : 1 complex formed between hexamethylbenzene and 1, 2, 4, 5-tetracyanobenzene has been determined by X-rays. The crystal is monoclinic, with two formula units of the complex in a cell of dimensions ; $a=15.07$, $b=8.92$, $c=7.41$ Å and $\beta=104.9°$. The space group is $P2_1/n$. The structure was deduced from a three-dimensional Patterson synthesis, and refined by block-diagonal least-squares method. The constituent molecules are stacked alternately in infinite columns along the c-axis. The relative configuration of the donor and acceptor molecules is consistent with the theoretical calculation.

The complex between 1, 2, 4, 5-tetracyanobenzene (TCNB) and hexamethylbenzene (HMB) is the third member of the series of charge transfer complexes containing TCNB as an electron acceptor, of which the crystal structures have been determined in this laboratory. The structure of the complex between





TCNB and N, N, N', N'-tetramethyl-p-phenylenediamine (TMPD)[1] indicated specific interaction localized between the nitrogen atoms of the donor and the cyano groups of the acceptor, whereas the structure of the TCNB-naphthalene complex[2] was found to exhibit π-π interaction between the donor and the acceptor, and was consistent with the result of the theoretical calculation and the electronic spectra.[3] It is expected that in the crystals of the complex between TCNB and typical π-donor such as benzene or hexa-

methylbenzene, the relative arrangement of the donor and acceptor molecules may be consistent with the result of theoretical calculation involving the π-π interaction only. In the present paper, haxametylbenzene was selected as a donor. The relative configuration of the donor and the acceptor of this complex has been presumed theoretically.[4] It may be of interest to see whether this presumption is correct or not and to compare the crystal structure with those of the related molecular complexes.

Experimental

The molecular complex of TCNB and HMB crystallizes as yellow needles. They decompose easily when exposed to X-rays in the air. Specimens had to be sealed in thin-walled borosilicate glass capillaries. The crystals are monoclinic and the cell dimensions and the space group were determined from oscillation and Weissenberg photographs taken around the b- and c-axes using Cu$K\alpha$ radiation (λ=1.542 Å). They are listed in Table 1.

TABLE 1. CRYSTAL DATA

TCNB-HMB
Monoclinic
a=15.07±0.01 Å
b= 8.92±0.01 Å
c= 7.41±0.04 Å
β=104.9±0.4°
Z=2
$P2_1/n$
μ=5.6 cm^{-1} (Cu $K\alpha$)

Intensity data were recorded on the equi-inclination Weissenberg photographs taken around the b- and c-axis up to the fourth layer, respectively, using multiple film technique. The relative intensities, estimated visually with a set of standard scales, were corrected for Lorentz and polarization factors, and spot shape, and were put on a common scale. The absorption correction was neglected in view of the small size of the specimen and the small value of the linear absorption coefficient. 587 independent reflections were observed.

Structure Determination

From the systematic absences the space group was uniquely determined to be $P2_1/n$. Since there are only two pairs of component molecules in the unit cell, the centers of gravity of each molecule must lie on a set of special positions. In order to obtain familiar mixed stacks, the TCNB and HMB molecules must be centered at positions, (000), (1/2 1/2 1/2) and (0 0 1/2), (12/ 1/2 0) respectively.

The trial structure was readily deduced from the three-dimensional Patterson synthesis. The structure thus obtained was refined by difference syntheses projected along the b- and c-axes, and later by a three-dimensional block-diagonal least-squares method with HBLS program written by Ashida. After a few cycles of this refinemet, anisotropic temperature factors were introduced. A weighting scheme,

$$w=1 \quad \text{if} \quad F_o \geq 2.0$$
$$\text{otherwise} \quad w=0.2$$

was employed.

The final discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$ became 0.154 for all the observed reflections. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[5] Final atomic parame-

TABLE 2. ATOMIC PARAMETERS

The expression of the temperature factor is $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+hkB_{12}+hlB_{13}+klB_{23})]$

ters and their standard deviations are listed in Table 2. The observed and calculated structure factors are tabulated in Table 3.

Description of the Structure and Discussion

The component molecules are stacked alternately in infinite columns along the *c*-axis. Both the TCNB and HMB molecules are planar within the experimental errors and the mean planes are expressed by:

$$-0.3747x + 0.3132y + 0.9400z = 0$$

and

$$-0.3221x + 0.2903y + 0.9538z = 3.5435$$

respectively, where x, y and z are coordinates (in Å) with respect to the crystal axes a, b and c.

Bond distances and angles in each molecule are listed in Table 4 and they are also shown in Fig. 1. The C(5)-C(4′) distance of 1.41 Å found in TCNB molecule is longer than the C(3)-C(4) distance of 1.38 Å or C(3)-C(5) distance of 1.39 Å. This deformation of the aromatic ring in the TCNB molecule is also found in the complex between TCNB and naphthalene, and is consistent with the result of theoretical calculation.[2)]

Intermolecular atomic distances less than 3.6 Å are indicated in Fig. 2 and listed in Table 5. These distances are of the same order as generally accepted van der Waals distances.

The nature of the anisotropic thermal motion is illustrated in Fig. 3. For HMB molecule, the motion appears to be simply

rigid-body libration about the center of gravity, chiefly in the molecular plane. The thermal motion of the less rigid TCNB molecule is more complex and defies rigorous analysis. However, it is at least certain that the out-of-plane vibration of the cyano groups is appreciable.

The molecules overlap each other as shown in Fig. 4, with interplanar spacing of 3.54 Å. The molecular plane of TCNB makes an angle of about 2° with that of HMB. This spacing is about 0.11 Å larger than that found in TCNB-naphthalene complex.[2] This difference is clearly due to the difference in the thickness of the donor molecules.

Iwata, Tanaka and Nagakura[4] calculated the electronic structures of this molecular complex only by considering the interaction between π-electrons of the donor and the acceptor. They concluded that the center of the donor molecule should lie above the carbon atom or the C-C bond of the benzene ring of the acceptor molecule in the stable configuration. As shown in Fig. 4, their conclusion agrees well with the determined structure. It is particularly noteworthy that the relative arrangement of the donor and acceptor molecules in the crystal agrees with the result of the theoretical calculation based on the π-π interaction only. It is certain that the relative arrangement of the donor and the acceptor molecules will be affected by various interactions other than the charge tranfer interaction, such as van der Waals, repulsive interactions etc. Actually the packing of the molecular stacks along the *c*-axis seems to be determined mainly by van der Waals interactions. But, as for the relative arrangement of the component molecules, the following conditions seem to enable the theoretical conclusion to be consistent with the result of the structure analysis. Firstly both the acceptor and the donor molecules are planar. Especially, the donor molecule which is surrounded by six methyl groups is disc-shaped. The relative translation of one component molecule with respect to another does not result in any particular stable molecular packing. Secondly the donor molecules contain neither nitrogen nor oxygen atom having lone pair electrons. Consequently any localized interaction between the component molecules

cannot be expected. Therefore the relative arrangement of the donor and the acceptor molecules in the molecular stack is mainly determined by the π-π interaction. The same situation will also be found in the case of the TCNB-naphthalene,[2] TCNE-naphthalene,[6,7] TCNE-pyrene[6,8] and TCNE-perylene[9] complexes.

Calculations were carried out on FACOM 202 computer at this institute and on HITAC 5020 at the Computer Center of the University.

The authors are grateful to Professor S. Nagakura and Dr. S. Iwata for kind supply of the specimens and valuable discussions. Part of the cost of the study was defrayed by a Scientific Research Grant of the Ministry of Education, to which the authors' thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1821—1829 (1968)

Infrared Spectrum of Deoxyribonucleic Acid —— Effects of Base Composition and of ^{15}N-Substitution ——

Masamichi Tsuboi, Katsuichi Shuto and Shigesada Higuchi

Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received February 22, 1968)

Infrared absorption spectra have been observed in the 4000—500 cm^{-1} region of deuterated and undeuterated films of deoxyribonucleic acids (DNA's) obtained from *Micrococcus lysodeikticus* (guanine plus cytosine content or GC content 72%), from *Bacille de Calmette-Guérin* (GC 65%), from *Pseudomonas aeruginosa* (GC 65%, ^{15}N-substituted), from calf thymus (GC 44%), and from *Cancer borealis* (GC 3%). Of the undeuterated DNA, 14 absorption bands have been assigned to the GC pair and 17 absorption bands to the adenine-thymine (AT) pair. Of the deuterated DNA, 19 absorption bands have been assigned to the GC pair and 16 to the AT pair. For 4 bands of undeuterated DNA and 13 bands of deuterated DNA, appreciable ^{15}N isotopic shifts have been observed. A discussion has been given of a few of these bands on the basis of the observed ^{15}N shift and some other data.

This work is a part of our attempt to establish a basis of an infrared base-analysis which should eventually give the amount of guanine-cytosine, adenine-thymine, and adenine-uracil base pairs and the amounts of unpaired guanine, cytosine, adenine, thymine, and uracil base residues in a given polynucleotide sample. In our present knowledge, every native deoxyribonucleic acid (DNA) obtained from a bacterium or a higher organism contains only the guanine-cytosine (GC) and adenine-thymine (AT) pairs, and practically no unpaired bases. Some of such DNA's have high GC contents and some very low. Therefore, infrared absorption bands assignable to the GC and AT pairs are considered to be found by comparing infrared absorption spectra of these DNA's. This has been the case as will be described below. In additon, the ^{15}N-substitution effect on the spectrum of a DNA with a GC content 65% has been examined. From the result in combination with data previously obtained, some nature of the normal vibration of each of the absorption bands has been clarified. A preliminary account of this work appeared already elsewhere.[1,2] It should also be mentioned here that Fritzsche[3] made independently an observation of the infrared spectra of a few deuterated DNA's with different GC contents.

Experimental

The DNA samples used are listed in Table 1.

DNA from *Micrococcus lysodeikticus* was prepared by ourselves. Mostly, the procedure described by Marmur[4] was followed. For dissociating the nucleic acid from protein, however, not only the

Marmur's method but also the method described by Kay, Simmons, and Dounce[5] was adopted. The molecular weight of the product was estimated to be 3.2×10^6 from the sedimentation coefficient. DNA from *Bacille de Calmette-Guêrin* (B. C. G.) was pre-

pared by Professor Toru Tsumita in the Institute of Medical Science, University of Tokyo, and kindly placed at our disposal by him. ^{15}N-DNA from *Pseudomonas aeruginosa* was donated by Dr. Ts'ai-Ying Cheng, now at the Institute for Cancer Research, Fox Chase, Philadelphia, Pennsylvania, U. S. A. This was obtained by the Marmur's method[4] from *P. aeruginosa* grown for many generations in $^{15}NH_4Cl$ as the sole nitrogen source. In this DNA sample, practically all of the nitrogen atoms is considered to be ^{15}N, on the basis of the manner of preparation. Calf thymus DNA was purchased from Sigma Chemical Company. The "light DNA" from *Cancer borealis*, which contains 97 mol percent of deoxyadenylate and deoxythymidylate in predominantly alternating sequence,[6,7] was again a gift from Dr. Cheng.

For the infrared absorption measurements oriented or unoriented films were prepared on AgCl plates. The control of the humidity of the air over the sample and deuteration of the sample were made by the method described by Sutherland and Tsuboi.[8] The instruments used were a model DS-402 G double-beam grating spectrometer of Japan Spectroscopic Company, a Perkin-Elmer model 12C Spectrometer with CaF_2, NaCl, and KBr prisms, and a Perkin-Elmer model 221 Spectrometer. For obtaining polarized radiation an AgCl polarizer was used.

Absorption Bands Assignable to the GC and AT Base Pairs

Infrared absorption spectra of an oriented film of the "light DNA" from *Cancer borealis* observed with the polarized radiation are shown in Fig. 1. As may be seen in the figure, many details of the spectra of this DNA are different from what are observed of calf thymus DNA.[8,9] Some parts of the infrared absorption spectra of unoriented films of the five DNA's (see Table 1) observed with the ordinary radiation are given in Figs. 2—6. The spectral features are found to depend

markedly upon the base compositions of the DNA samples. All of these spectra were observed at 92% relative humidity. At this humidity, the DNA fiber takes the B-form irrespective of the base compositions.[10,11] The geometrical structures of DNA's with different base compositions are so similar that practically no difference can be found in their X-ray diffraction patterns.[10,11] Therefore, the marked difference in their infrared spectra are to be ascribed solely to the difference in the normal vibrations of the structure with the GC pair and that with the AT pair. In most of the vibrational modes corresponding to the absorptions in the 4000—500 cm^{-1} region, the displacements of atoms are localized within relatively small atomic groups. In addition, the vibrational coupling between the adjacent two nucleotide residues would not be great. Therefore, most of the absorption bands of DNA in the spectral region now in question are expected to be classified into three groups: (i) bands assignable to some vibrations localized in the guanine-cytosine (GC) base pair, (ii) bands assignable to some vibrations localized in the adenine-thymine (AT) base pair, and (iii) bands assignable to some vibrations localized in the phosphate-deoxyribose main-chain. An examination of the spectra was made first with this expectation in mind.

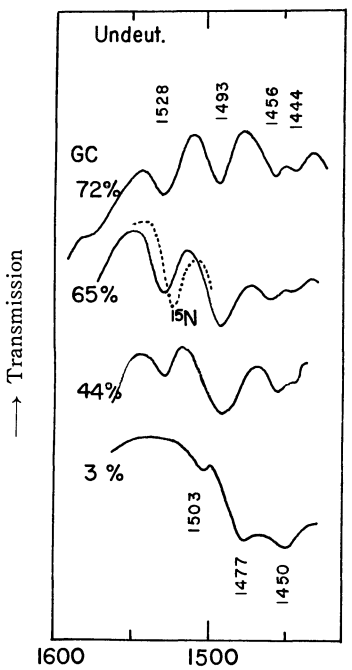

Fig. 2. Infrared absorption spectra in the 1560—1440 cm^{-1} region of undeuterated films of the five DNA's listed in Table 1. Observed at 92% relative humidity.

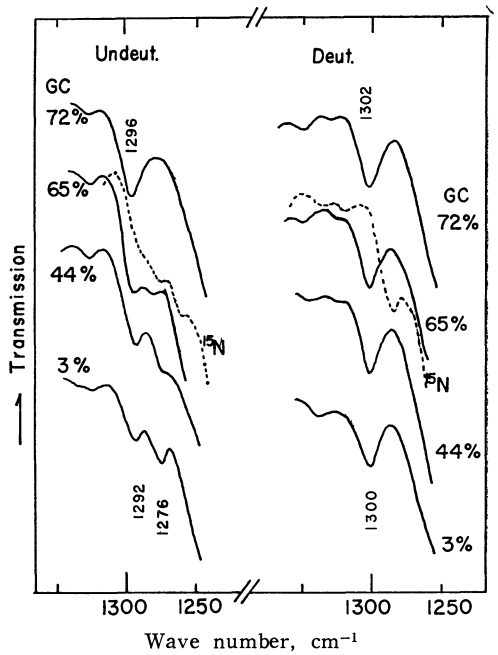

Fig. 3. Infrared absorption spectra in the 1340—1250 cm^{-1} region of undeuterated and deuterated films of the five DNA's listed in Table 1. Observed at 92% relative humidity.

In Fig. 2, an absorption band at 1528 cm^{-1} is found to become weaker with the GC content. Therefore, this band may be assigned to the GC base-pair. The weak band at 1503 cm^{-1} and another band at 1477 cm^{-1} of the light DNA of cancer are not observed in DNA's with higher GC contents. Therefore, these should be assigned to the AT pair. The occurrence of a broad band at about 1490 cm^{-1} of the calf thymus DNA may be interpreted as a result of a superposition of 1503, 1477, and the 1493 cm^{-1} bands. The last one is to be assigned to the GC pair.

As has been pointed out previously,[1] the 1276 cm^{-1} band is attributed solely to the AT pair (see Fig. 3). On the other hand, the absorptions around the 1292—1296 cm^{-1} region are caused by both of the AT and GC pairs. Here, however, the absorption bands due to the AT and GC pairs seem to be situated at

slightly different frequencies. On deteration, both of the 1296 and 1276 cm^{-1} bands disappear, and a slightly stronger band appears at about 1300 cm^{-1}. Both of the AT and GC pairs give a band here, but again at slightly different frequencies.

In a similar way, we may pick up the absorption band at 831, 795, and 763 cm^{-1} (see Fig. 4) as those assignable to the AT pair and the absorption band at 778 cm^{-1} as one assignable to the GC pair.

The absorption spectra of deuterated DNA's in the 1700—1450 cm^{-1} region are rather complicated (Fig. 5). As has been mentioned by Sutherland and Tsuboi,[8] almost all the absorption bands in this region are assignable to in-plance vibrations of bases. It was difficult, however, to proceed a further analysis by examining the calf thymus DNA only. It is now safely concluded that the absorptions at 1687, 1659, 1638, 1618, 1571, 1476, and 1458 cm^{-1} are due to the AT base pair, because at these frequencies the AT-DNA of cancer

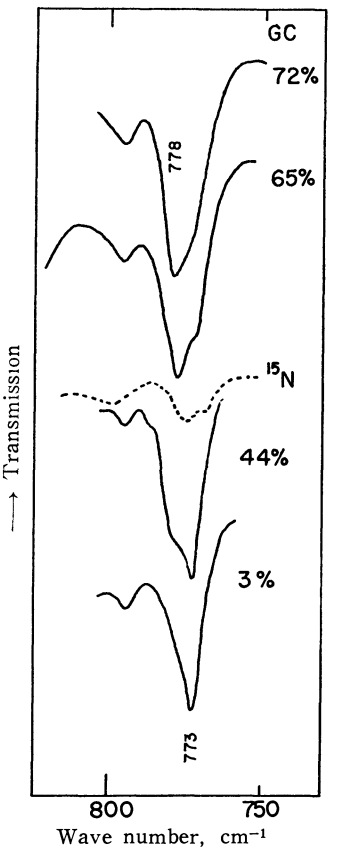

Fig. 6. Infrared absorption spectra in the 800—750 cm^{-1} region of deuterated films of the five DNA's listed in Table 1. Observed at 92% relative humidity.

gives absorption peaks (Figs. 1b and 5) but DNA's with higher GC contents do not (Fig. 5). The absorptions at 1676, 1648, 1576, 1523, 1501, and 1453 cm^{-1} are ascribed to the GC pair, because the Micrococcus DNA with GC 72% gives absorption peaks at these frequencies. The absorption curves of DNA's with the GC contents of 65% and 44% are interpreted in an approximation as proper superpositions of the absorption curves of DNA's with the GC contents 72% and 3% (Fig. 5).

As may be seen in Fig. 6, both of the GC and AT pairs give sharp peaks around 780 cm^{-1}. The former, however, gives a peak at a slightly higher frequency (778 cm^{-1}) then the latter (773 cm^{-1}). Therefore, the fact[8] that the calf thymus DNA gives a shoulder at 778 cm^{-1} besides the sharp peak at 773 cm^{-1} is now quite understandable on the basis of its base compositions.

Absorption bands at 1218, 1087, 1069, 1050, 1018, 967, and 650 cm^{-1} appear in every DNA and show almost no changes in their frequencies and intensities on deuteration. Therefore, they are assignable to some vibrations of atomic groups other than the bases.

As has been illustrated so far nearly all the absorption bands of DNA observed in the 1800—500 cm^{-1} region can be classified into the three groups, (i), (ii), and (iii), defined above, and a spectrum of any DNA appears, at least qualitatively, to be an assembly of the absorption bands of these groups with a proper set of intensities which depends upon the GC content of the DNA. The frequencies of the absorption bands belonging to these three groups are listed in Tables 2 and 3, with their intensities.

Most of the absorption bands assignable to the GC or AT base pair are found to be strongly polarized, if they are observed in the oriented films, either along the perpendicular direction to the fiber axis or along the parallel direction to it. This fact is understandable, because, in the B-form of DNA, base residues are arranged with their planes perpendicular to the fiber axis,[10] and because the normal vibrations localized in the base residues should take place with their transition moments either in their plane or perpendicular to the plane. Among the absorption bands of bases, what are strongly polarized along the perpendicular

direction to the fiber axis are assigned to some in-plane (*i*) vibrations, and what are strongly polarized along the parallel direction to some out-of-plane (*o*) vibrations. These are also indicated in Tables 2 and 3.

^{15}N Isotope Shifts in the Vibrational Frequencies

The ^{15}N-DNA from *Pseudomonas aeruginosa* (GC 65%) shows an infrared absorption spectrum similar in its general feature to that of the DNA from *Bacille de Calmette-Guérin* (GC 65%). Many of the absorption maxima of the former DNA, however, are found to be shifted towards the lower frequencies from the corresponding maxima of the latter DNA (Figs. 2—7).

In principle, the ^{15}N isotope effect on an infrared spectrum of DNA should be found by comparing the ^{15}N-DNA and ^{14}N-DNA obtained from the same organism. Unfortunately, these were not available in our laboratory, and the ^{15}N-^{14}N comparison has been made between different species of bacteria having the same GC content as above. Practically, however, this is justified, because the DNA's from *Pseudomonas* and *B.C.G.* are expected to make no difference in their infrared spectra. These DNA's are different only in the sequence and arrangement in the GC and AT base pairs. The infrared spectrum in the spectral region now in question is not sensitive to the sequence and arrangement. Absorptions of a base residue might appreciably be different depending upon the neighbours. Such a difference, however, should disappear in an average, unless the nearest neighbour sequence frequencies of the two DNA's are greatly different; the nearest neighbour sequence frequencies have been found to be rather similar for natural DNA's from different sources but with almost equal GC contents.[12]

The significance of the observed shift may be judged, not only on the basis of the above consideration, but also by examining the experimental results given in Figs. 2—7. For example, the positions of relatively sharp bands at 1528 cm^{-1} (Fig. 2), at 1302 cm^{-1} (Fig.

12) J. Josse, A. D. Kaiser and A. Kornberg, *J. Biol. Chem.*, **236**, 864 (1961).

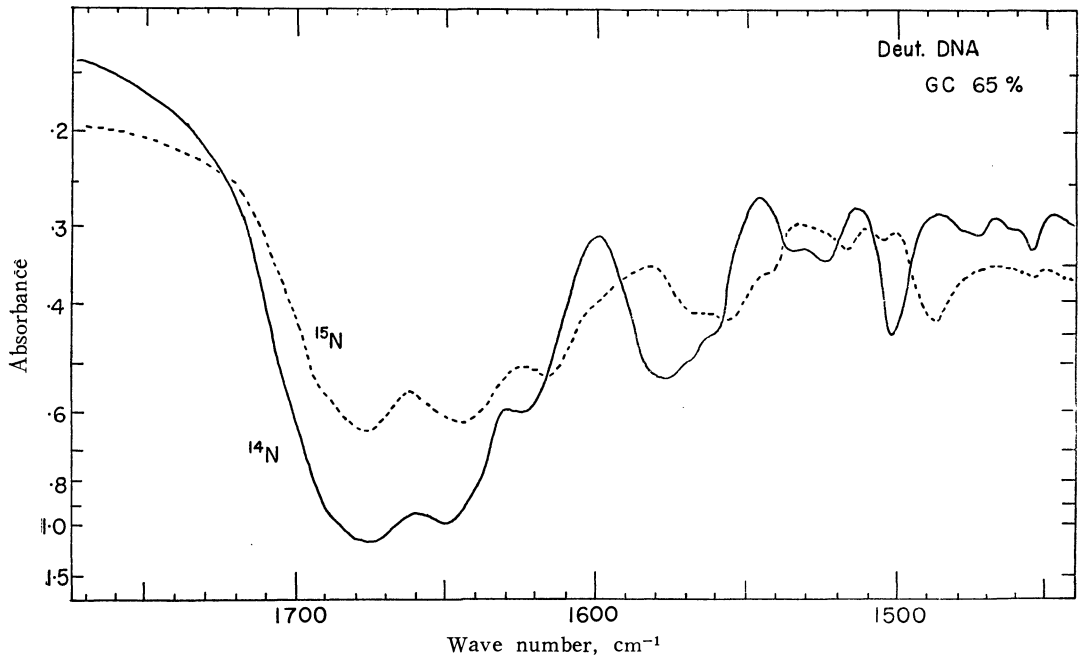

Fig. 7. An expanded recording of the infrared absorption spectra of deuterated films of DNA from *Bacille de Calmette-Guérin* (——) and of ^{15}N-DNA from *Pseudomonas aeruginosa* (·····). Observed at 92% relative humidity.

3), at 778 cm^{-1} (Fig. 4), at 1501 cm^{-1} (Fig. 5), and at 778 cm^{-1} (Fig. 6) are all found to remain constant within 2 cm^{-1} for ^{14}N-DNA's from Micrococcus, B. C. G., and calf thymus, while the corresponding bands are found at 3—17 cm^{-1} lower frequencies for the ^{15}N-DNA. This fact indicates that the frequencies of these bands are not sensitive to the origin of the DNA samples, and observed shifts are solely ascribed to the $^{14}N \rightarrow {}^{15}N$ substitution in the base residues.

The amount of the frequency shift was measured for each absorption band by repeating a recording of the ^{14}N and ^{15}N spectra alternately in a small spectral range with a low scan speed and with an expanded wavenumber scale (see Fig. 7, for example). The results of such measurements are given in Tables 2 and 3. For sharp and isolated absorption peaks, the amounts of shift were determined almost as accurately as those for simpler samples,[13] within 0.5 cm^{-1} or so. Sometimes, however, the measurement can be made only less accurately because the band in question is too broad or because the shifted absorption maximum is obscured by another absorption band. Such a case is indicated by * in Tables 2 and 3. The data of ^{15}N-isotope shifts are in general useful for judging the nature of the normal vibrations by which the absorption bands are caused. The judgement is often made through the amount:

$$\frac{\Delta\lambda}{\lambda^\circ} = \frac{\lambda(^{15}\mathrm{N}) - \lambda(^{14}\mathrm{N})}{\lambda(^{14}\mathrm{N})} \qquad (1)$$

rather than through the frequency shift $\Delta\nu$ itself. Here, $\lambda = 4\pi^2 c^2 \nu^2$, c being the velocity of light and ν the observed frequency (in reciprocal centimeters). This amount $\Delta\lambda/\lambda^\circ$ directly reflects how much movements of nitrogen atoms take place in the normal vibration now in question. Thus, on the basis of what Miyazawa[14] showed,

$$\frac{\Delta\lambda_k}{\lambda_k^\circ} = -\sum_N (L_{Nk})^2 \Delta m \qquad (2)$$

where, L_{Nk} is the amount of the displacement of each nitrogen atom relative to the center of gravity of the molecule, which is caused by the unit displacement (a deformation of the whole molecule) along the kth normal coordinate of the molecule. If the normal coordinate is expressed by the unit Å (atomic mass unit)$^{1/2}$ the unit of $(L_{Nk})^2$ should be (atomic mass unit)$^{-1}$. The isotopic mass change Δm is practically +1 in the atomic

13) M. Tsuboi, *Spectrochim. Acta*, **16**, 505 (1960); M. Tsuboi, T. Takenishi and A. Nakamura, *Spectrochim. Acta*, **17**, 634 (1961); M. Tsuboi, T. Takenishi and A. Nakamura, *ibid.*, **19**, 271 (1963).

14) T. Miyazawa, *J. Mol. Spectroscopy*, **13**, 321 (1964).

mass unit in the present case, and therefore this factor Δm can be ignored in the numerical calculation on Eq. (2). The summation is to be conducted for all the nitrogen atoms, on which the isotopic replacement has taken place.

In a less strict discussion of an infrared spectrum, the vibrational mode for each absorption band is often expressed in terms of the internal symmetry coordinate, such as NH_2 scissoring or NH out-of-plane deformation. Even in a complicated large molecule, a normal coordinate can sometimes be expressed approximately by an internal symmetry coordinate or by a linear combination of only a few internal symmetry coordinates. Therefore, it would be convenient to know the ^{15}N isotopic frequency shift for a hypothetical vibration along an internal symmetry coordinate t. This can be obtained by the formula,[13]

$$\frac{\Delta\lambda}{\lambda^\circ} = \frac{\Delta G_{tt}}{G_{tt}^\circ} \qquad (3)$$

where $\Delta \boldsymbol{G} = \boldsymbol{G} - \boldsymbol{G}^\circ$, $\boldsymbol{G}$ and $\boldsymbol{G}^\circ$ being the inverse kinetic energy matrices for the ^{15}N and ^{14}N species, respectively.

The $\Delta\lambda/\lambda^\circ$ values calculated by Eq. (1) from the observed frequencies are also given in Tables 2 and 3.

Discussion

The assignments of the infrared absorption bands of DNA were previously made on the basis of the deuteration effects, humidity effects, anisotropy of the absorptions, and the knowledge on the molecular vibrations of hypophosphites and other simple compounds. The effects of the base composition and of a ^{15}N-substitution are now obtained as new data. Based upon these new date, a few additional aspects of the nature of some of the absorption bands listed in Tables 2 and 3 are given below.

A strong band at 1705 cm^{-1} of undeuterated calf thymus DNA was found to be characteristic of its secondary structure.[15,16] It has now be shown that both of the GC and AT base pairs contribute to this band. The dipole oscillation takes place in the base plane in both base pairs. On the basis of the frequency and on the basis of the observed deuteration effect (see Fig. 1, for example), an NH_2 or NH in-plane deformation vibration is considered to take part in the normal vibration now in question. The observed amount of ^{15}N isotopic shift ($\Delta\lambda/\lambda_\circ = -0.006$) of the 1705 cm^{-1} band of the GC pair is almost equal to the calculated value ($\Delta\lambda/\lambda^\circ = -0.007$) for a pure (C-)$NH_2$ scissoring vibration and also to the calculated value ($\Delta\lambda/\lambda^\circ = -0.007$) for a pure NH in plane deformation vibration (on Eq. (3)). This, however, does not necessarily mean that the 1705 cm^{-1} band should be assigned to either an almost pure NH_2 scissoring or an almost pure NH in-plane deformation. It is possible, for example, that the actual mode of vibration is a combination of the NH_2 scissoring, NH deformation, C-N stretching and C=O stretching.

No normal coordinate treatment has yet been made of adenine, thymine, guanine, or cytosine. For cyanuric acid, however, which is somewhat similar structure to thymine, a normal coordinate treatment was made by Dr. Issei Harada (Master Thesis, 1963, and Doctor Thesis, 1966, University of Tokyo). His calculation was made of a hydrogen-bonded sheet in the cyanuric acid crystal. According to his calculation, there should be hree infrared-active vibrations at 1752, 1745, and 1696 cm^{-1} (There are actually three or four strong bands observed in the 1780—1715 cm^{-1} region). In all of these vibrations the C=O stretching motions are predominant but there are appreciable contributions from C-N stretching and NH in plane deformation vibrations. By applying Eq. (2) on the result of his calculation, it has been found that the three frequencies 1752, 1745, and 1696 cm^{-1} should give ^{15}N-shifts, $\Delta\lambda/\lambda^\circ = -0.015$, -0.013, and -0.003, respectively.

It is noteworthy that the band at 1705 cm^{-1} of base residues shifted towards lower frequency (but not towards higher) on breaking the base pairing. A possible explanation has been given elsewhere[15] on the basis of an assumption that the vibration in question involves the C=O and C=N stretching modes.

A strong absorption at 1680 cm^{-1} of deuterated calf thymus DNA was also found to be characteristic of its secondary structure.[15,16] This absorption is now found to be a superposition of the two bands: the 1676 cm^{-1} band of the GC pair and the 1687 cm^{-1} band of the AT pair (Fig. 5). The 1676 cm^{-1} band does not shift at all on ^{15}N substitution (Fig. 7). Therefore, this band is assignable to a vibration in which the main contribution comes from the carbonyl stretching motions in the GC base pair.

The 1576 cm^{-1} band of the deuterated DNA is due to the GC pair (Fig. 5). This is further assigned to the guanine moiety of the GC

15) Y. Kyogoku, M. Tsuboi, T. Shimanouchi and I. Watanabe, *Nature*, **189**, 120 (1961).
16) Y. Kyogoku, M. Tsuboi, T. Shimanouchi and I. Watanabe, *J. Mol. Biol.*, **3**, 741 (1961).

pair, because deuterated guanosine gives a very strong absorption band at 1570 cm^{-1} while deuterated cytidine does not.[17] Also, deuterated poly (G+C) gives a strong absorption band at 1577 cm^{-1} [18] while deuterated poly (I+C) does not.[19] On the basis of its frequency and on the basis of the observed amount of ^{15}N isotope shift ($\Delta\lambda/\lambda = -0.021$), this band is associated to a C-N stretching vibration in the guanine residue. According to the calculation made by Dr. Harada (mentioned above), cyanuric acid (undeuterated) should have vibrations at 1542, 1473, and 1459 cm^{-1}. In each of these vibrations, C-N stretching motions are predominant. If Eq. (2) is applied to the results of his calculation, it is concluded that the three frequencies should give ^{15}N-shift of the amounts $\Delta\lambda/\lambda^\circ = -0.040$, -0.021, and -0.021, respectively.

The 1501 cm^{-1} band of the deuterated DNA, which has been assigned to the GC pair, may further be assigned to the cytosine moiety. A strong absorption is found here in the spectra of deuterated cytidine,[17] and deuterated polyribocytidylic acid,[20] and deuterated poly (I+C)[19] whereas no strong absorption is found in the spectum of deuterated guanosine.[17] Because it is shifted greatly ($\Delta\lambda/\lambda^\circ = -0.019$) on ^{15}N-substitution, it is assigned to a C-N stretching vibration in the cytosine residue.

As was mentioned earlier,[8,20,21] the absorptions around 780 cm^{-1} of deuterated polynucleotides are noticeable ones. The fairly strong and sharp absorption peaks in this region are assigned to some out-of-plane vibrations in the base residues involved in wet polynuclotides. As has been mentioned above, it is now clear that the absorption peak at 773 cm^{-1} is due to the A-T base pair and that at 778 cm^{-1} to the G-C base pair. These absorption peaks appear only for deuterated DNA's and not for undeuterated ones. Therefore, the absorptions may be associated with the N-D and/or ND_2 groups. If the vibration for each of these bands were a pure N-D out-of-plane deformation vibration, however, the ^{15}N-isotope shift should be as high as $\Delta\lambda/\lambda^\circ = -0.028$ (Eq. (3)). If it were a pure ND_2 out-of-plane deformation vibration, the ^{15}N-isotope shift should be as high as $\Delta\lambda/\lambda^\circ = -0.023$. Actually observed ^{15}N-shift is only $\Delta\lambda/\lambda^\circ = -0.008$ for the 778 cm^{-1} band of the G-C base pair, and hence the normal vibration at 778 cm^{-1} would be a mixture of an N-D and/or ND_2 out-of-plane motion with some other out-of-plane modes of the G-C base-pair structure.

We wish to express our deep thanks to Dr. T. Cheng for the samples of ^{15}N-DNA from *Pseudomonas aeruginosa* and the "light DNA" from *Cancer borealis*, and to Professor T. Tsumita for the sample of DNA from *Baciile de Calmette-Guérin*. The work was supported partly by a grant from the Ministry of Education of Japan and partly by a grant from the U.S. Public Health Service (GM 10024-03).

Note : After the completion of the manuscript of this paper, a paper by H. Fritzsche (*Biopolymers*, **5**, 863 (1967)), which reports the infrared spectra of DNA's with different base compositions, has appeared. His assignments of the 1505 and 1573 cm^{-1} bands respectively to C and G are in agreement with ours.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1830—1834 (1968)

Rheological Properties of Hydrogels of Agar-agar. III. Stress Relaxation of Agarose Gels

Mineo WATASE and Kiyoshi ARAKAWA

The Department for Liberal Arts, Shizuoka University, Shizuoka and Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received February 26, 1968)

A stress relaxation experiment on hydrogels of agarose isolated from agar-agar was made by means of a chainomatic balance relaxometer for the purpose of investigating the mechanism of gelation. The measurements were made on the agarose gels of the concentration range from 1.2 to 2.0 wt%, and also on agar-agar gels for the comparison, at various temperatures from 25 to 55°C. The relaxation curves obtained were represented approximately by a mechanical model consisting of three Maxwell models in parallel. The apparent activation energy, ΔH, which was calculated from the temperature dependence of the longest relaxation time, τ_1, was about 5 kcal/mol for all gels treated in this study, which was nearly the same magnitude as that for agar-agar gels. It was observed in the curves obtained that the relaxation curves for agarose gels had quite similar characteristics to those for agar-agar gels of the same concentration and was observed that the total instantaneous modulus of the former gels amounted to about 80% of that of the latter gels. From these results it may be concluded that agarose is a main constituent in the network structure in agar-agar gels and that the hydrogen bonding plays a major role in the agar-agar gels as well as in the agarose gels.

In the preceding papers[1,2] the authors reported the results of stress relaxation experiments made for hydrogels of agar-agar. The hydrogels of agar-agar is well-known as a typical example of thermoreversible gels, and has long been the object of rheological and colloid-chemical studies. It is believed at present that a dominant factor governing the mechanism of gelation of agar-agar gels is the balance between the hydrophilic and the hydrophobic properties of the molecule of agar-agar, or the balance between the affinity to water and the tendency of formation of microcystalline structures in agar-agar molecules.[3-6] The detailed mechanism of gelation has not yet been cleared.

According to a series of studies made by Araki *et al.*[7] agar-agar is composed of two polysaccharides, agarose and agaropectin. Agarose is the major component. In the present paper, an attemt is made to measure the stress relaxation of the hydrogels of agarose isolated from agar-agar, and the results are compared with the data of agar-agar gels themselves.

Experimental

A sample used was the powder of agar-agar obtained from Nihon Kaiso Kogyo, Co., Ltd. The ash content of the sample is 0.95 wt%, and the intrinsic viscosity in the aqueous solution obtained with Ostwald viscometer,*1 $[\eta]_{25°C}$, is 15.6 (100 cc/g). The molecular weight of the sample calculated from the intrinsic viscosity was 4.2×10^4.[5]

Agarose was isolated from agar-agar as follows:[8] agar-ggar, 1% by weight, was dissolved into water, and then acrynol*2 was added to make the solution of 0.1 mol/*l*. Agarose was separated from the solution by centrifuge (6000 rpm). Agarose gel separated was heated to melt, mixed with ethyl alcohol,

and centrifuged again to separate agarose. This purification with alcohol was repeated until the yellow color due to acrynol vanished. The intrinsic viscosity of purified agarose in aqueous solution is 15 (100 cc/g) at 25°C.

The test piece of agarose gels was prepared by the same procedure as that of agar-agar gels reported previously.[1] The concentrations of agarose gels prepared was 1.25, 1.43, 1.67 and 2.0 wt% respectively. The concentration of agar-agar gels was 2.0 wt%.

Stress relaxation curves up to 4 hr were obtained with a chainomatic balance relaxometer. The details of the apparatus and the experimental procedures were reported previously.[9] The measurements were made at temperatures from 25 to 55°C.

Results

Stress Relaxation Curves. The relaxation Young's modulus of hydrogels of agarose and agar-agar was obtained. The results are shown in Figs. 1 (a)—(e). These relaxation curves are approximately represented by a six-element mechanical model composed of three Maxwell models in parallel. In this model the relaxation Young's modulus, $E_r(t)$, is expressed as:

$$E_r(t) = \sum_{i=1}^{3} E_i \exp(-t/\tau_i) \qquad (1)$$

where E_i and $\tau_i(\tau_1 > \tau_2 > \tau_3)$ are the elastic constant and the relaxation time for the ith Maxwell element respectively, and t is the time. All relaxation curves obtained were fitted with Eq. (1), and the parameters in it are shown in Table 1.

Constant, E_1. The values of E_1 at 25°C, thus obtained for agarose gels, are plotted against the concentrations in Fig. 2.

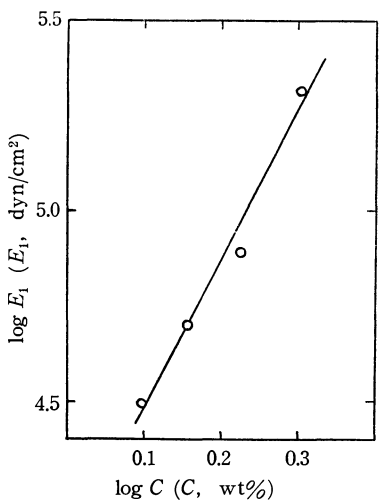

Fig. 2. Concentration dependence of the elastic constant, E_1, for agarose gels at 25°C.

The concentration dependence of E_1, which is the elastic constant of the Maxwell element with the longest relaxation time, τ_1, is approximately represented by an equation

$$E_1 = k_1 C^4 \qquad (2)$$

where k_1 is a constant and C the concentration. According to N. Hirai, who made similar studies on various kinds of gels,[10] the elastic modulus of gels, E_0, which corresponds to $\sum_{i=1}^{3} E_i$ in our case, was found to be proportional to about 4th power of concentration below a certain critical concentration, C_0, and to be proportional to about 2nd power above C_0. The critical concentration C_0 was found to be 0.85% for the hydrogels of agar-agar.[10] Our results are proportional to the 4 th power of concentration as is shown by Eq. (2), and therefore the critical concentration C_0 of agarose gels should be higher than that of agar-agar gels.

Relaxation Times and Activation Energy. The values of $\log \tau_1$ have been found

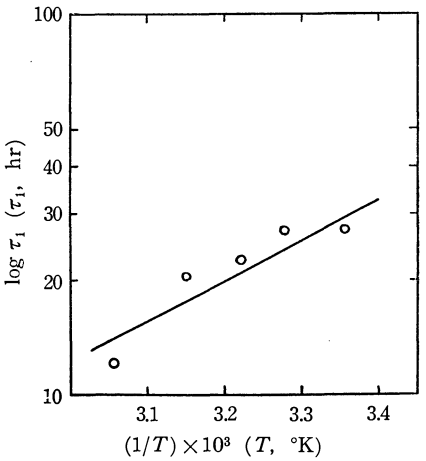

Fig. 3 (a). Temperature dependence of the relaxation time, τ_1, for the 2.0 wt% agarose gels.

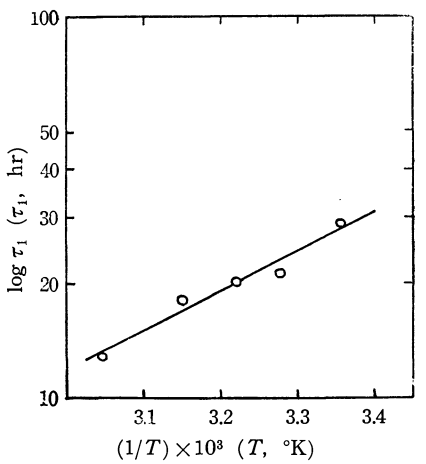

Fig. 3 (b). Temperature dependence of the relaxation time, τ_1, for the 2.0 wt% agar-agar gels.

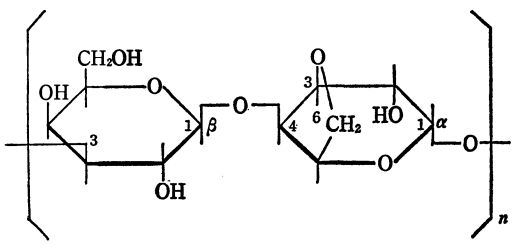
TABLE 2. ACTIVATION ENERGY ΔH

Agarose gel	Concn. wt%	ΔH kcal/mol
	2.0	5.1
	1.6_7	4.5
	1.4_3	4.8
Agar-agar gel	2.0	5.0

to change approximately linearly with $1/T$. The $\log \tau_1$ is plotted against $1/T$ for the 2.0 wt% agarose gel and 2.0 wt% agar-agar gel in Fig. 3 (a) and (b) as illustrative examples. The apparent activation energy ΔH obtained from the plots is given in Table 2. The activation energy is about 5 kcal/mol for hydrogels of agarose, which is nearly equal to that of agar-agar gels reported in the preceding paper.[2]

Discussion

According to Araki and his coworkers[7] agar-agar is a mixture of agarose and agaropectin. Agarose, which is a major component of agar-agar, is composed of residues of β-D-galactopyranose and 3,6-anhydro-α-L-galactopyranose arrayed alternatively. The molecular constitution of agaropectin is not clear. The most of uronic acid and sulfuric acid ester in agar-agar are known to be contained in agaropectin as its components. The possible chemical structure of agarose proposed by Araki is shown in Fig. 4.



D-Galactose 3,6-Anhydro-L-Galactose

Fig. 4. Possible structure of agarose.[7]

The stress relaxation curves of 2 wt% agarose shown in Fig. 1 (a) are quite similar to those of agar-agar gels of the same concentration given in Fig. 1 (e). The similarity is also seen in the calculated values of relaxation times given in Table 1, where the relaxation times of agarose are nearly equal to that of agar-agar gels. The magnitude of ΔH of the main network structure in gels is about 5 kcal/mol for both gels. As is seen in Table 1, the magnitude of instantaneous elastic modulus, $E_0 = \sum_{i=1}^{3} E_i$ for agarose gels is about 80% of E_0 for the agar-agar gels of the same concentration. These facts show that agarose plays a major role in the gel formation of agar-agar gels.

In conclusion, the mechanical behavior of hydrogels of agarose is quite similar in its character to that of hydrogels of agar-agar, and agarose is a component of agar-agar gels which plays a major role in the gel formation.

As has been shown by Araki *et al.*, agarose contains only a small amount of ionic groups,[11] and in the gelation mechanism of aqueous solutions of agarose the electrostatic interaction is of little importance. The magnitude of ΔH for agarose gels obtained in this experiment is about 5 kcal/mol, which is of the order of magnitude of that for the breaking of hydrogen bond. From these facts as well as from the possible chemical structure of agarose shown in Fig. 4 it may be concluded that the hydrogen bonding plays a major role in the gelation mechanism of agarose gels, and also concluded that it is the case in agar-agar gels since agarose plays a major role in the gel formation of agar-agar gels.

The authors wish to express their heartiful thanks to Miss Yuko Endo for her cooperation in performing this study.

Infrared Studies of Transition-Metal Nitrosyl (^{14}NO and ^{15}NO) Complexes—Nitrosylruthenium(III),*1 Nitrosylchromium(II)*1 and Nitrosylcobalt(II)*1 Complexes

Eiichi MIKI

Department of Chemistry, College of Science, St. Paul's (Rikkyo) University, Nishi-Ikebukuro, Tokyo

(Received December 21, 1967)

For $K_2[RuX_5(NO)]$ (X=Cl and Br), $K_3[Cr(CN)_5(NO)]\cdot H_2O$, $[Cr(NH_3)_5(NO)]X_2$ (X=Cl and ClO_4) and black-$[Co(NH_3)_5(NO)]Cl_2$, it was attempted to determine the coordinating atom of the nitrosyl group to the metal atom and to assign the skeletal vibrations between the metal and the nitrosyl group by measuring the effect of the nitrogen isotope ^{15}N on infrared spectra. The isotopic shifts for the ^{15}NO-complex to the ^{14}NO-complex were calculated for two kinds of a linear three-body model, M-N-O and M-O-N (M=metal atom), and the calculated shifts were compared with the observed ones. For nitrosylruthenium and nitrosylchromium complexes, the M-N-O arrangement was found, and of the two absorption bands in the region 530—620 cm^{-1}, the higher wave number was assigned to the M-N stretching vibration and the lower one to the M-N-O bending vibration. For black-$[Co(NH_3)_5(NO)]Cl_2$, the Co-O-N arrangement was found.

It has been conventionally described that the nitrosyl group of the transition-metal nitrosyl compounds is bound to the metal atom through the nitrogen atom. There have been some studies on whether the nitrosyl group is coordinated to the metal atom through the nitrogen atom or through the oxygen atom. A neutron diffraction study of $Na_2[Ru(OH)(NO_2)_4(NO)]\cdot 2H_2O$[1] clearly showed that the nitrogen atom of the nitrosyl group is coordinated to the ruthenium atom, and that the Ru-N-O group is linear; infrared studies of black-$[Co(NH_3)_5(NO)]Cl_2$,[2] including an examination of its chemical properties, suggested the Co-N-O arrangement. On the other hand, visible-ultraviolet spectroscopic studies of the red-pentamminenitrosylcobalt(II) complex[3] have led to the Co-O-N arrangement. Moreover, an infrared study of $Co(NO)(CO)_3$ and its ^{15}NO-complex[4] determined the coordinating atom of the NO group to the cobalt atom, and led to the assignment of the absorption bands due to the Co-N stretching vibration and the Co-N-O bending vibration. The infrared study of $Na_2[Fe(CN)_5(NO)]\cdot 2H_2O$[5] in polarized light has enabled the assignment of the absorption bands due to the Fe-N stretching vibration and the Fe-N-O bending vibration.

This paper presents the determination of the coordinating atom of the NO group to the metal atom, and assignments of the skeletal vibrations between the metal and the NO group by measuring the effect of the nitrogen isotope ^{15}N on the infrared spectra for $K_2[RuX_5(NO)]$ (X=Cl and Br),[6] $K_3[Cr(CN)_5(NO)]\cdot H_2O$, $[Cr(NH_3)_5(NO)]X_2$ (X=Cl and ClO_4) and black-$[Co(NH_3)_5(NO)]Cl_2$.

Experimental

Preparations of Transition-metal Nitrosyl Compounds. ^{15}N enriched potassium nitrate, containing ^{15}N more than 92 atom %, used to prepare the ^{15}NO-complexes was obtained from the Institute of Physical and Chemical Research in Japan. The ^{15}NO-complexes were prepared on a semimicro scale. These preparations on a semimicro scale were thought to give the correct products because the prepared ^{14}NO-complex gave the same infrared spectrum as that prepared on an ordinary scale.

*1 The oxidation number is given according to Rule 7323 of IUPAC Nomenclature of Inorganic Chemistry, because the oxidation state of the metal bound to the nitrosyl group can not be determined from the sole criterion unequivocally.

The infrared spectra of the ^{15}NO-complexes prepared showed that the NO group in the complexes retained almost the same ^{15}N-atom percentages as those of the starting ^{15}N-materials.

$K_2[RuX_5(NO)]$ (X=Cl and Br). Compounds with normal nitrogen isotopes were prepared by conventional methods.[7] The ^{15}N-labeled compound was prepared on a semimicro scale using a vacuum line. Nitrosylruthenium(III) solution could be prepared with a good yield by bringing an excess of ^{15}NO gas derived from 50—200 mg $K^{15}NO_3$ (^{15}N atom %= 92 and 96.9) in contact with ruthenium halide (10—30 mg ruthenium) in hydrohalogenic acid solution, and then closing off the reaction vessel and allowing it to stand for 1—2 days at room temperature. A small excess of potassium halide was added to the nitrosylruthenium(III) solution and the solution evaporated to obtain the ^{15}NO-complex. The separation of ruthenium (III and IV) and nitrosylruthenium (III)*2 showed that ruthenium ion was converted to nitrosylruthenium ion almost completely (more then 99.9%) in this semimicro scale preparation.

Found: K, 20.1; Ru, 25.7; N, 3.66%. Calcd for $K_2[RuCl_5(NO)]$: K, 20.23; Ru, 26.15; N, 3.62%. Found: K, 12.7; Ru, 16.3; N, 2.38%. Calcd for $K_2[RuBr_5(NO)]$: K, 12.85; Ru, 16.60; N, 2.30%.

$K_3[Cr(CN)_5(NO)]\cdot H_2O$ and $[Cr(NH_3)_5(NO)]X_2$ (X=Cl and ClO_4). The pentacyano- and pentammine-nitrosylchromium(II) compounds with normal nitrogen isotopes were prepared by the methods of Griffith[8] and Mori,[9] respectively. The ^{15}NO-complexes were prepared on a scale 1/10—1/20 that of ordinary methods. $K_3[Cr(CN)_5(^{15}NO)]\cdot H_2O$ was obtained with ^{15}N-substituted hydroxylamine hydrochloride prepared according to the method of Ogata and Hirono,[10] who used sodium nitrite instead of potassium nitrate. $[Cr(NH_3)_5(^{15}NO)]X_2$ was prepared by Mori's method[9] using nitrogen-15 enriched potassium nitrate (^{15}N atom %=97.6) instead of sodium nitrite.

Found: K, 33.1; Cr, 15.0; C, 17.46; N, 24.74%. Calcd for $K_3[Cr(CN)_5(NO)]\cdot H_2O$: K, 33.77; Cr, 14.97; C, 17.29; N, 24.19%. Found: Cr, 21.5; N, 34.22; H, 6.00; Cl, 29.6%. Calcd for $[Cr(NH_3)_5(NO)]Cl_2$: Cr, 21.84; N, 35.30; H, 6.36; Cl, 29.78%. Found: Cr, 14.2; N, 22.76; H, 3.95%. Calcd for $[Cr(NH_3)_5(NO)](ClO_4)_2$: Cr, 14.20; N, 22.96; H, 4.13%.

Black-$[Co(NH_3)_5(NO)]Cl_2$. The black chloride with normal nitrogen isotopes was made according to the method of Moeller and King[11] and of Odell *et al.*,[12] but external cooling was not necessary in the reaction of Co(II)-ammoniacal solution with NO gas. The ^{15}NO-complex was prepared on a semimicro scale using ^{15}NO gas derived from about 1 g $K^{15}NO_3$ (^{15}N atom %=99.3 and 99.8). By cooling with liquid nitrogen, a slight excess of ^{15}NO gas was trapped in a reaction vessel containing an aqueous ammoniacal solution of cobalt(II) chloride freshly prepared, the concentration of ammonia in the solution of cobalt(II) chloride being about 10 mol/*l*. The reaction vessel was shaken in running water for about 20 min until the frozen solution was molten and the black chloride was formed as gray powder. The black chloride prepared by this procedure gave the same infrared spectra as those reported by several workers.[13,14] In the preparation of deuterated black chloride, deuterated aqueous ammonia obtained from magnesium nitride and deuterium oxide was used.

Found: Co, 24.1; N, 33.55; H, 6.01; Cl, 28.9%. Calcd for $[Co(NH_3)_5(NO)]Cl_2$: Co, 24.05; N, 34.30; H, 6.17; Cl, 28.94%.

Infrared Spectra. Infrared spectra were measured over 200—4000 cm^{-1} in Nujol mull, hexachlorobutadiene mull and a potassium bromide disk. The spectra were recorded on JASCO DS-301 (700—4000 cm^{-1}), DS-402 G (400—4000 cm^{-1}), DS-401 G (300—700 cm^{1-}) and Hitachi EPI-L type (200—700 cm^{-1}) infrared spectrophotometers. Reproducibility was about ± 1 cm^{-1} in the region 200—3000 cm^{-1}, and ± 10 cm^{-1} in the region 3000—4000 cm^{-1}.

Results

Assignments of Infrared Spectra. The assignments of the N-O stretching and the skeletal vibrations between the metal and the NO group were based first on the observation of isotopic shifts. As for the skeletal vibrations, a set of two absorption peaks in the range 530—620 cm^{-1} was selected and the assignment of each absorption was then determined so as to obtain agreement between the calculated isotopic shifts and the observed ones.

The assignments of vibrations other than those mentioned above were in accordance with the following references:

Ref. 15 for the stretching vibrations of Ru-X (X=Cl and Br),

Ref. 17 for the characteristic absorption bands on ammine complexes and
Ref. 18 for perchlorate ion.

The infrared bands and their assignments for $K_2[RuX_5(NO)]$ (X=Cl and Br) are shown in Table 1. The two very strong absorption peaks in the region 1840—1920 cm^{-1} correspond to the N-O stretching vibration reported by Lewis *et al.*[19] The two absorption bands in the region 550—610 cm^{-1} are thought to be skeletal vibrations between the ruthenium atom and the NO group as reported by Gans[20] and Cleare.[21] The weak absorption bands at 588 cm^{-1} for $K_2[RuCl_5(^{15}NO)]$ and at 572 cm^{-1} for $K_2[RuBr_5(^{15}NO)]$ are thought to be due to the presence of a small amount of the corresponding ^{14}NO-complex.

The assignment of the infrared spectra of $K_2[RuBr_5(NO)]$ can be carried out in a similar manner.

The absorption band of the N-O stretching vibration split into two peaks for $K_2[RuX_5(NO)]$, and the wave number of the stronger peak was used to calculate the isotopic shifts.

The infrared bands and their assignments for $K_3[Cr(CN)_5(NO)]\cdot H_2O$ are given in Table 2. The strong band of the ^{14}NO-complex at 1643 cm^{-1} was assigned to the N-O stretching vibration[8]; this band shifted to 1610 cm^{-1} for the ^{15}NO-complex. The absorption bands at 620 cm^{-1} and 610 cm^{-1} (shoulder) seem to correspond to skeletal vibrations between the chromium and the NO group[20]; these absorption shifted and appeared separately as two peaks at 617 and 600 cm^{-1} upon ^{15}NO-substitution.

TABLE 2. FREQUENCY (cm^{-1}) AND ASSIGNMENT OF INFRARED ABSORPTION BANDS IN $K_3[Cr(CN)_5(NO)]\cdot H_2O$

Table 3 shows the infrared bands and their assignments for $[Cr(NH_3)_5(NO)]X_2$ (X=Cl and ClO_4). For the chloride, the absorptions due to the N-O stretching and the skeletal vibrations were assigned according to Cleare and Griffith.[21] For the perchlorate, similar assignments could be made. The strong band at 626 cm^{-1} due to perchlorate ion[18] did not disturb the weak absorptions (577 cm^{-1} for ^{14}NO-complex and 574 cm^{-1} for ^{15}NO-complex) due to one of the skeletal vibrations.

Table 4 and Fig. 1 show the infrared bands and their assignments for black-$[Co(NH_3)_5(NO)]Cl_2$. Absorptions caused by impurities were found as reported by Bertin[13] and Raynor.[14] These impurities are discussed later. Griffith *et al.*[2] assigned the absorption

ing vibrations.[23,24] Hence, the absorption of the ^{14}NO-complex at 1614 cm^{-1} was assigned to the N-O stretching vibration. The frequencies of the nitrosyl stretching vibration for the deuterated ^{14}NO- and ^{15}NO-complexes were also measured to eliminate interfering absorptions due to the NH_3 degenerate deformation in the 1600 cm^{-1} region. This degenerate deformation was found to have no effect on the observed frequency value for the N-O stretching vibration as shown in Table 5.

Mercer *et al.*[22] assigned the absorptions at 578 and 644 cm^{-1} to the Co-N-O bending and Co-N stretching vibrations, respectively. In the present measurement, no definite absorption peak was observed at 644 cm^{-1}, instead the peak at 578 cm^{-1} was quite definitely split into two peaks at 581 and 564 cm^{-1}, which were shifted to 579 and 558 cm^{-1}, respectively, for the ^{15}NO-complex (Table 4 and Fig. 1).

On the other hand, for the deuterated complexes only one absorption was found in the region 560—580 cm^{-1}; the absorption at 572 cm^{-1} for the ^{14}NO-complex shifted to 561 cm^{-1} for the ^{15}NO-complex as shown in Table 5 and Fig. 2.

To assign the observed peaks and calculate the isotopic shifts, the following cases are considered: Case-1. For the NH_3-complex, the two peaks in the region 560—580 cm^{-1} are due to skeletal vibrations, while for the ND_3-complex these two peaks happen to overlap. Case-2. One of the two peaks observed with

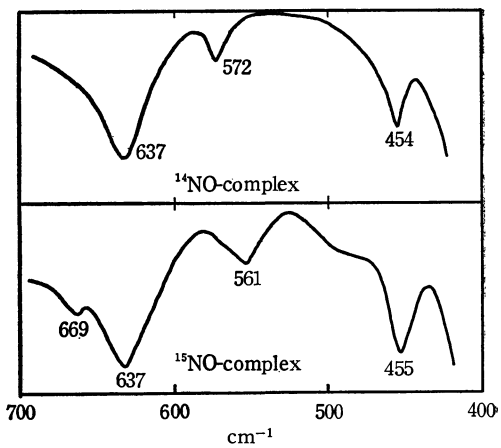

Fig. 2. Infrared spectra of black-$[Co(ND_3)_5(NO)]Cl_2$ in the region 400—700 cm^{-1}.

the NH_3-complex is due to an impurity. The absorption intensity of an other skeletal vibration is very weak, and this absorption is assumed to be in the 570 cm^{-1} region because two skeletal vibrations between the metal and the NO group are within the limited region observed for the nitrosyl complexes examined.

Impurities in Black-$[Co(NH_3)_5(NO)]Cl_2$. Bertin[13] and Raynor[14] reported that the absorption band at *ca.* 1170 cm^{-1} for the black chloride is due to the NH_3 symmetric deformation of hexamminecobalt(II) impurity in the black chloride. However, a recent magnetic study by Asumussen *et al.*[25] has shown that carefully prepared black chloride gives $\chi_g = +0.17 \times 10^{-6}$ cgs units at room tempera-

ture; that is, the black chloride is essentially diamagnetic. Examples of magnetic susceptibilities of black chlorides used in this study are $\chi_g = 1.25$ (288°K), 1.58 (237°K), 2.16 (173 °K) and 3.05×10^{-6} (115°K) cgs units. These show the temperature dependence, and also that the chloride is paramagnetic. So the black chloride may be contaminated by strong paramagnetic compounds (Co(II)-ammine complexes such as $[Co(NH_3)_6]Cl_2$). Magnetic data reveal the presence of as much as 25% $[Co(NH_3)_6]Cl_2$ in the black salt, assuming that the black chloride is essentially diamagnetic and the impurity is only $[Co(NH_3)_6]Cl_2$.

An infrared study has shown that the black salt contains cobalt atoms in the +3 oxidation state.[13] The wave numbers of the NH_3 rocking vibration in ammine complexes are characteristic of the oxidation state of the central atom.[26] Moreover, the wave numbers of the NH_3 symmetric deformation for cobalt-ammine complexes seem to be characteristic of the oxidation state of the cobalt atom. Infrared absorptions of $[Co(NH_3)_6]Cl_3$ and $[Co(NH_3)_6]Cl_2$ are listed in Table 6 as representative of cobalt(III)-ammine and cobalt(II)-ammine complexes, respectively. If most of the impurities are hexamminecobalt(II) or cobalt(II)-ammine complexes, assignment of infrared spectra for the black chloride can be reasonably made by comparing the infrared spectra for the black chloride (Tables 4 and 5) with those for hexamminecobalt(III) and hexamminecobalt(II) chlorides (Table 6). The absorption bands at 1166 and 1167 cm^{-1} for the deuterated ^{14}NO-complex and ^{15}NO-complex in Table 5 were assigned to the ND_3 degenerate deformation due to the deuterated black chloride and cobalt(II)-ammine complex impurities. The absorption bands at 1293 cm^{-1} for the ^{14}NO-complex and at 1292 cm^{-1} for the ^{15}NO-complex were shifted by deuterium substitution to 991 and 996 cm^{-1}, respectively, which were assigned to the NH_3 symmetric deformation of the black chloride; the absorptions at 1172 cm^{-1} for the ^{14}NO-complex and at 1173 cm^{-1} for the ^{15}NO-complex were shifted by deuterium substitution to 899 and 901 cm^{-1}, respectively. These bands were assigned to the NH_3 symmetric deformation of the cobalt(II)-ammine complex impurities in the black chloride. The absorption bands at *ca.* 820 cm^{-1} for the ^{14}NO- and ^{15}NO-complexes were shifted by deuterium substitution to 637 cm^{-1}. These bands are due to the NH_3 rocking vibration for the black chloride. The absorptions at *ca.* 640 cm^{-1} for the ^{14}NO- and ^{15}NO-complexes were shifted by deuterium substitution to *ca.* 455 cm^{-1}. These bands are due to the NH_3 rocking vibration of cobalt (II)-ammine complex in the black chloride. These magnetic and infrared data lead to the conclusion that the black chloride used in this study may be contaminated by cobalt(II)-ammine complexes.

Calculation of Isotopic Shifts. Crystal X-ray studies of $K_2[RuCl_5(NO)]$,[27] $K_3[Cr(CN)_5(NO)]$,[28] black-$[Co(NH_3)_5(NO)]Cl_2$ [29] and electron spin resonance studies of $[Cr(NH_3)_5(NO)]^{2+}$ and $[Cr(CN)_5(NO)]^{3-}$ [30] have shown an approximately linear arrangement of the metal and the NO group, although crystallographic X-ray studies are not now thought to be able to distinguish nitrogen from oxygen. Hence, the two linear three-body models, M-N-O and M-O-N were used to calculate the isotopic shifts for all of the nitrosyl complexes examined here. For the skeletal vibrations between the metal and the NO group, two assignments are possible. Assignment 1 is that, of the two absorptions assumed due to skeletal vibrations, the higher wave number is assigned to the stretching vibration between the metal and the NO group, and the lower one to the bending vibration. Assignment 2 is the reverse of Assignment 1. Then, by the Valence Force Field method, the calculation of the isotopic shifts for absorptions due to the N-O stretching, the metal-nitrosyl stretching and the metal-nitrosyl bending vibrations was carried out for the four cases corresponding to the two models (M-N-O and M-O-N) and the two possible assignments (Assignment 1 and

Assignment 2: The reverse of Assignment 1.

$\Delta\nu_{obs.}=\nu^{14}$NO-complex (obs.) $-\nu^{15}$NO-complex (obs.). $\Delta\nu_{calc.}=\nu^{14}$NO-complex (obs.) $-\nu^{15}$NO-complex (calc.).

(νNO): The N-O stretching vibration.

2). The secular equation for the calculation of isotopic shifts was set up in accordance with Wilson's procedure.[31] The calculated shifts were compared with the observed ones.

Table 7 shows the observed and calculated isotopic shifts for $K_2[RuX_5(NO)]$ (X=Cl and Br), $K_3[Cr(CN)_5(NO)]\cdot H_2O$, $[Cr(NH_3)_5(NO)]X_2$ (X=Cl and ClO_4) and black-$[Co(NH_3)_5(NO)]Cl_2$. For black-pentammine-nitrosylcobalt complex, the isotopic shifts for the NH_3-complex calculated by assuming Case-1 are compared with the observed isotopic shifts.

The calculated isotopic shifts in Table 7 were calculated neglecting off-diagonal interaction constants. Calculations were also performed with off-diagonal interaction constants of 0.4 mdyn/Å and 0.2 mdyn/Å for $K_2[RuCl_5(NO)]$ and $[Cr(NH_3)_5(NO)]Cl_2$, respectively. However, these latter calculated isotopic shifts differed only negligibly from those in Table 7.

The electron spin resonance study of $K_3[Cr(CN)_5(NO)]\cdot H_2O$ by McGarvey and Pealman[32] has shown that the Cr-N-O or Cr-O-N bond is bent slightly. Calculation of the isotopic shifts was made over a bond angle ranging from 170—180°. However, in this angle range, the range of shifts was very small.

Arrangement and Assignment. Comparison of observed isotopic shifts with calculated ones shows that the calculated isotopic shifts in the case of the M-N-O arrangement with Assignment 1 are in agreement with the observed ones for both the nitrosylruthenium(III) and nitrosylchromium(II) complexes. For black-$[Co(NH_3)_5(NO)]Cl_2$, the following conclusions were obtained. For the NH_3-complex is Case-1, the calculated isotopic shifts for the Co-O-N arrangement with Assignment 2 are in agreement with observed values. For the ND_3-complex in Case-1, the Co-O-N arrangement is found and only one absorption in the region 560—580 cm^{-1} is thought mainly attributable to the Co-O stretching vibration. In Case-2, the Co-O-N arrengement is also found but the distinction between skeletal vibrations cannot be made. However, the calculated isotopic shifts in all cases of possible assignments supported the Co-O-N arrangement for the black-pentam-minenitrosylcobalt complex.

Discussion

The agreement between the observed isotopic shifts and calculated ones is excellent for the nitrosylruthenium(III) complexes with the Ru-N-O arrangement and Assignment 1, but less so for the nitrosylchromium(II) complexes with the Cr-N-O arrangement and Assignment 1 and for black-$[Co(NH_3)_5(NO)]Cl_2$ with the Co-O-N arrangement. In the latter cases, however, the poorer agreement is attributable to the use of the three-body model in calculating the isotopic shifts.

The wave numbers of the normal vibrations calculated for the ^{15}NO-complexes from the observed wave numbers for the ^{14}NO-complexes by the three-body model are expected to

a) Calculated by Dr. Jiro Hiraishi (Department of Chemistry, Faculty of Science, The University of Tokyo) using the eight-body model.
b) Calculated by the author using the three-body model.
c) Taken from Ref. 4.

31) E. S. Wilson, Jr., *J. Chem. Phys.*, **7**, 1047 (1939); **9**, 76 (1941).
32) B. R. McGarvey and J. Pearlman, *ibid.*, **46**, 4992 (1967).

be smaller than those calculated by a complete treatment because of interactions of vibrations neglected in the three-body model. Thus, the shifts calculated with the three-body model ($\nu_{obs.}$ (^{14}NO-complex) $-$ $\nu_{calc.}$ (^{15}NO-complex)) would be larger than the observed shifts.

In the case of $K_2[RuX_5(NO)]$ (X=Cl and Br), the central metal atom and ligands other than the NO group are much heavier than nitrogen and oxygen. The three-body model can be expected to be a good approximation, and good agreement is actually obtained between the calculated and observed shifts. In Table 8, the calculated isotopic shifts using the three-body model for $K_2[RuCl_5(NO)]$ are compared with those obtained using the eight-body model,*3 and good agreement is found also between these. However, for the Ru-N stretching and the Ru-N-O bending vibration the isotopic shifts obtained using the three-body model are slightly larger than those obtained with the eight-body model. Since the three-body model is a good approximation for pentachloronitrosylruthenium(III) ion, the results based on the three-body model for $K_2[RuX_5(NO)]$ lead to the conclusion that the complexes have a Ru-N-O arrangement and, of the two absorptions in the region 570 —610 cm^{-1}, the higher wave number is assigned to the Ru-N stretching vibration and the lower one to the Ru-N-O bending vibration.

On the other hand, the central metal atom and ligands other than the NO group in $K_3[Cr(CN)_5(NO)]\cdot H_2O$, $[Cr(NH_3)_5(NO)]X_2$ (X =Cl and ClO_4) and black-$[Co(NH_3)_5(NO)]Cl_2$ are lighter than ruthenium and halide ion in $K_2[RuX_5(NO)]$. So, for the chromium and the cobalt complexes examined, the difference between the calculated isotopic shifts obtained using the three-body model and the observed shifts can be expected to be greater than the difference for the ruthenium complexes.

McDowell *et al.*[4] have determined the Co-N-O arragement and assigned the skeletal vibrations between the cobalt and the NO group by comparing the calculated isotopic shifts using the nine-body model with the observed ones for $Co(NO)(CO)_3$ and its ^{15}N-substituted compound. In order to demonstrate the relation between the results obtained with the three-body model and a more complete model, the present author calculated the isotopic shifts with the three-body model using McDowell's data for $Co(NO)(CO)_3$. In Table 8, these calculated isotopic shifts are compared with the observed ones and with the calculated ones of McDowell. The calculated isotopic shifts of McDowell are nearly equal to the observed ones, and for the Co-N stretching and Co-N-O bending vibrations, are slightly smaller then the isotopic shifts calculated by the author. The N-O stretching vibration would be less affected by the other vibrations than the two skeletal vibrations between the metal and the NO group would be. Thus, the isotopic shifts calculated with the three-body model are greater than the observed ones, especially for the skeletal vibrations between the metal and the NO group. These considerations support the following conclusions: the nitrosylchromium(II) complexes examined in this study have a Cr-N-O arrangement and of their two absorptions in the region 530—620 cm^{-1}, the higher wave number is assigned to the Cr-NO stretching vibration and the lower one to the Cr-N-O bending vibration; black-$[Co(NH_3)_5(NO)]Cl_2$ has a Co-O-N arrangement.

For black-$[Co(NH_3)_5(NO)]Cl_2$, the very strong absorption at about 640 cm^{-1} due to hexamminecobalt(II) impurity interfered considerably with the skeletal vibrations between the cobalt and the NO group, as the absorption at 637 cm^{-1} due to the ND_3 rocking vibration of the deuterated complex did for black-$[Co(ND_3)_5(NO)]Cl_2$; there may be some uncertainty concerning values of the wave numbers for the skeletal vibrations. However, this uncertainty is not thought to be great enough to change the conclusion on arrangement.

The Ru-N-O arrangement found for pentahalogenonitrosylruthenium(III) complexes is in agreement with the result of a neutron diffraction study.[1] The Cr-N-O arrangement for the nitrosylchromium(II) complexes examined is very interesting when the great affinity of Cr(III) for oxygen is considered. The nitrosyl group of black-$[Co(NH_3)_5(NO)]Cl_2$ is found to coordinate to the cobalt atom through the oxygen atom. The Co-O-N arrangement is not in agreement with the assumption by Griffith[2] and Mercer *et al.*[22] The present result is the first to establish the Co-O-N arrangement for black-$[Co(NH_3)_5(NO)]Cl_2$.

The assignments of the skeletal vibrations between the metal and the NO group for the nitrosyl complexes examined have been reported by several workers.[20-22,33-35] However,

*3 The calculated isotopic shifts by the eight-body model were kindly provided by Dr. Jiro Hiraishi (Department of Chemistry, Faculty of Science, The University of Tokyo).

their assignments have been tentative, or a distinction between the two skeletal vibrations has not been made. Clear assignments of the skeletal vibrations for the compounds examined, except for the black chloride, are established by this study.

For metal-nitrosyl complexes, calculation of the ^{15}N-isotopic shifts using the three-body model of the metal and nitrosyl group is a useful method for the determination of the coordinating atom of the NO group, and a clear assignment of the skeletal vibrations between the metal atom and the NO group.

The author would like to express his gratitude to Professor Yuzo Kakiuchi and Mr. Hiroshi Saito of St. Paul's (Rikkyo) University, and Assistant Professor Ichiro Nakagawa and Dr. Jiro Hiraishi of the University of Tokyo for their valuable suggestions concerning measurement of the infrared spectra and calculations of normal vibrations. Thanks are also due to Dr. Ryohei Nakane of the Institute of Physical and Chemical Research in Japan for making available the ^{15}N potassium nitrate.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1844—1854 (1968)

Cationic Effect on the Polarographic Reduction of Nickel(II) in Acetonitrile

Shigero IKEDA and Eiki ITABASHI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received December 27, 1967)

The polarographie behavior of nickel(II) acetate salts dissolved in acetonitrile solvent containing small quantities of acetic acid has been investigated in various natures and concentrations of supporting electrolytes. A single reduction wave is observed in the solutions of lithium perchlorate or sodium perchlorate. The limiting current has an intermediate nature of both diffusion- and kinetic controlled polarographic current. A double wave, on the other hand, is observed in the solutions of tetraalkylammonium perchlorate supporting electrolyte such as $(CH_3)_4NClO_4$, $(C_2H_5)_4NClO_4$ or $(n\text{-}C_4H_9)_4NClO_4$. The limiting current of the first step exhibits an intermediate nature of both diffusion and kinetic currents, and that of the second step is kinetic in nature. The effect of the nature and concentration of electrolyte on the visible absorption spectra of acetatonickel(II) complexes in acetonitrile containing small quantities of acetic acid are also discussed. On the basis of evidence, a mechanism which involves a substitution reaction of acetatonickel(II) complexes with the supporting electrolytes is proposed. The substitution reaction in tetraalkylammonium perchlorate solutions is thought to be the rate-determining step. The first step of a double wave is also thought to be due to the inhibition of charge transfer process by the weakly absorption of tetraalkylammonium cations of supporting electrolytes on the DME.

The supporting electrolyte effects in a non-aqueous electrochemistry have been reported by several investigators and, especially Murray and Kenneth Hiller[1] have done extensive works on the polarography of metal β-diketone chelate compounds.

The polarographic behaviors of nickel(II) ion in an acetonitrile solvent have been reported by several investigators. Kolthoff and Coetzee[2] observed a single reversible reduction wave with the half-wave potential of -0.33 V *vs.* SCE in an acetonitrile solution containing a 0.1 M sodium perchlorate. Popov and Geske,[3] on the other hand, obtained a double wave with the half-wave potentials of -0.69 V and -1.22 V *vs.* Ag-$AgNO_3$ electrode, in the same solvent containing 0.1 M

tetra-*n*-butylammonium perchlorate. Two-reduction steps for nickel(II) ion have also investigated in an acetonitrile[4] or a benzonitrile solvent[5] containing 0.1 M tetraethylammonium perchlorate. Iwamoto *et al.*[5] attributed the two-steps to the reduction of two kinds of nickel(II) species, and concluded that the second step involves the reduction of hydrated nickel(II) ions. The more easily reduced species, however, was not understood except the case of the presence of chloride ions. The first step in an acetonitrile solvent containing 0.1 M tetraethylammonium perchlorate and a small amount of chloride ions was involved the reduction of nickel(II)-chloride complex ions and the catalytic nature of the first wave has been established by Nelson and Iwamoto.[4]

The cationic effect of the supporting electrolyte for the polarographic reduction of nickel(II) ions has been carried out in an aqueous solvent[6,7] and an ethanol solvent,[8] respectively.

A distorated polarographic waves of nickel(II) ions in various kinds of natures and in various concentrations of supporting electrolyte solutions were initially reported by Gierst[6] and were later expanded by Dandoy and Gierst.[7] Dandoy and Gierst interpreted the polarographic behavior of nickel(II) ions in non-complexing media in terms of the dehydration kinetic current.

In the course of the studies for the reduction of acetatonickel(II) complexes in an acetonitrile solvent, the present authors observed a pronounced variation of the polarographic behaviors with the supporting electrolytes employed. Acetatonickel(II) complexes containing a small amount of acetic acid gave a single reduction wave in lithium perchlorate or sodium perchlorate supporting electrolytes, the two-reduction steps, on the other hand, were observed in the solutions of various tetraalkylammonium perchlorate supporting electrolytes.

The limiting current exhibited an intermediate nature of both diffusion and kinetically controlled polarographic currents, that of the second step in tetraalkylammonium perchlorate solutions, especially, was kinetic in nature.

The cationic effect is discussed on the basis of the chemical reaction of acetatonickel(II) complexes with cations of supporting electrolytes proceeding to the charge transfer process, and the inhibition of the charge transfer of nickel(II) ion, freeing of acetate ions from acetatonickel(II) complexes, by the weakly adsorption of tetraalkylammonium ions on the dropping mercury electrode.

Experimental

Reagents. Extra pure reagent acetonitrile purchased from Nakarai Chemicals Ltd. (Kyoto) was purified by a modified procedure of Forcier and Olver's method.[9] The purity was checked by the polarographic and spectrophotometric method.[10] The content of water was determined with Karl Fisher titration. Water content was approximately 2 to 5 mM.

Guaranteed reagent acetic acid and acetic anhydride were purified with the procedures given in the literature.[11]

Analytical reagent nickel(II) acetate salt ($Ni(CH_3COO)_2 \cdot (H_2O)_4$) was recrystallized three times from an aqueous solution containing 5 M acetic acid. The analysis of nickel(II) acetate salt gave the following result.

Found: C, 19.53; H, 5.79%. Calcd for $Ni(CH_3COO)_2(H_2O)_4$: C, 19.31; H, 5.67%.

Hexaaquonickel(II) perchlorate was prepared and recrystallized with the procedure given in the literature.[12] $Ni(H_2O)_6(ClO_4)_2$ was dried under a vacuum oven to constant weight at 110°C for 60 hr, and the formula $Ni(H_2O)_2(ClO_4)_2$ was obtained as reported by Hill and Nyholm.[13] The analysis of $Ni(H_2O)_2(ClO_4)_2$ gave the following results.

Found: Ni, 19.0±0.8, ClO_4, 65.8±1.4%. Calcd for $Ni(H_2O)_2(ClO_4)_2$: Ni, 19.99, ClO_4, 67.74%.

Lithium perchlorate was prepared by neutralizing the aqueous solution of lithium hydroxide, to pH about 5 with perchloric acid, evaporating and recrystallizing three times from water.

Anhydrous lithium perchlorate was obtained by drying in a vacuum oven at 150 to 160°C for 60 hr.

Anhydrous sodium perchlorate was obtained by drying sodium perchlorate monohydrate (B. D. H.) in a vacuum oven at 110 to 115°C for 40 hr.

Tetramethylammonium perchlorate was prepared by neutralizing a 10% tetramethylammonium hydroxide solution (Tokyo Kasei Kogyo Co., Ltd.) to pH 6 with 3 M perchloric acid. After evaporating at

room temperature in a desicator containing calcium chloride under lower pressure, the salt was recrystallized three times from a purified acetonitrile solvent, and dried in a vacuum oven at 60 to 65°C for 40 hr. Tetraethylammonium perchlorate was prepared with the procedure in the literature,[4] recrystallized several times from water and subsequently three times from a purified acetonitrile, and dried in a vacuum oven at 60 to 65°C for 40 hr.

Tetra-*n*-butylammonium perchlorate was prepared by neutralizing a 40% tetra-*n*-butylammonium hydroxide solution (B. D. H) to pH 6 with perchloric acid. The salt was recrystallized several times from ethyl alcohol, and dried in a vacuum oven at 80°C for 40 hr.

Tetramethylammonium acetate ($(CH_3)_4NCH_3COO$) was prepared by a similar procedure with the one given in the literature,[14] and recrystallized three times from a purified acetonitrile and dried in a vacuum oven at 50 to 55°C for 30 hr. The analysis of tetramethylammonium acetate gave the following results.

Found: C, 54.01; H, 11.48; N, 10.49%. Calcd for $(CH_3)_4NCH_3COO$: C, 54.11; H, 11.35; N, 10.52%.

Procedures. Current-potential curves and current-time (*i-t*) curves during the life of a mercury drop at the constant potential were obtained with a Underkofler and Shain type potentiostat[15] based on operational amplifier K2-XA and stabilized amplifiers K2-P and K2-PA of Philibrick Researches Inc. (Boston). Polarograms were recorded with a Yokogawa X-Y Recorder, PRO-11A type. Current-time curves were recorded with a Riken Denshi SP-G2 type recorder.

In the following section, the word "current" denoted by means of the maximum current obseved just before the mercury drop. Measurements were made at 25±0.1°C unless otherwise stated. A beaker type cell was used. The test solution was connected to an aqueous saturated calomel electrode (SCE) through a pair of glass frit junctions arranged to prevent water contamination of the test solution. A platinum foil electrode served as the counter electrode was placed in the glass tube with a glass frit, the glass tube was contained with the test solution.

The dissolved oxygen in the solution was removed by bubbling a pure nitrogen gas through the solution. The two-type dropping mercury electrodes were used. The electrode A had an *m* value of 1.48_2 mg/sec and a drop time, t_d, of 5.02 sec in a deaerated 0.1 M sodium perchlorate acetonitrile solution at −0.70 V *vs.* SCE and at 50 cm mercury height. The electrode B and an *m* value of 1.33_4 mg/sec and a drop time, t_d of 4.98 sec in a deaerated 0.1 M lithium perchlorate acetonitrile solution at −0.8 V *vs.* SCE and at 60 cm mercury height.

The measurements of the visible and ultraviolet absorption spectra were carried out with a Hitachi EPS-3T spectrophotometer at a room temperature.

Results

The current-potential curves of acetatonickel(II) complexes were obtained in the acetonitrile solutions of various natures and concentrations of supporting electrolytes. The typical current-potential curves are given in Fig. 1.

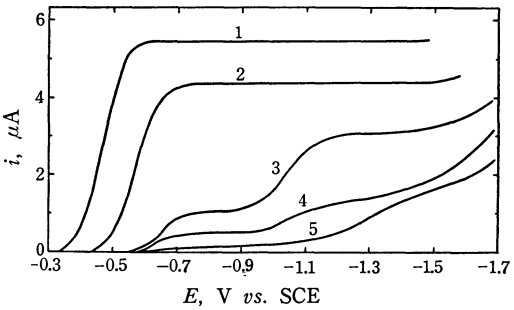

Fig. 1. Current-potential curves of 0.5 mM acetatonickel(II) complexes in various supporting electrolyte solutions containing 0.4% acetic acid and 0.2% acetic anhydride: (1), 0.05 M $LiClO_4$; (2), 0.05 M $NaClO_4$; (3), 0.05 M $(CH_3)_4NClO_4$; (4), 0.05 M $(C_2H_5)_4NClO_4$; (5), 0.05 M $(n\text{-}C_4H_9)_4NClO_4$. (Electrode A)

Figure 1 shows the current-potential curves in the solutions of various univalent electrolytes containing 0.4% acetic acid and 0.2% acetic anhydride in volume. The polarographic data of acetatonickel(II) omplexes in various supporting electrolyte solutions are summarized in Table 1.

b) 1st. reduction step.
c) 2nd. reduction step.
d) Not determined because of maximum.

A single irreversible reduction wave was obtained in the solution of lithium perchlorate or sodium perchlorate. In the tetraalkylammonium perchlorate electrolyte solutions, on the other hand, the wave was found to split into two-steps; the first step was observed at the potential range from −0.5 V to −1.1 V *vs.* SCE, and the second one at more negative potential regions than −1.1 V *vs.* SCE. The limiting current decreased with the increasing radius of cations of supporting electrolytes, and was found not to be purely diffusion controlled from the results of the measurements of current-time curves. In a solution of tetraalkylammonium perchlorate supporting electtrolyte, especially, the limiting current of the second reduction step was found to be kinetic in nature.

Effect of Acetic Acid, Acetic Anhydride and Water. The effects of the concentration of acetic acid, acetic anhydride and water on the current-potential curves were investigated. Table 2 presents the limiting currents, half-wave potentials and slopes of the log-plots which are obtained at 0.5 mM acetatonickel(II) complexes in a 0.1 M lithium perchlorate solution containing the various concentrations of acetic acid.

TABLE 2. EFFECT OF ACETIC ACID ON THE REDUCTION OF 0.5 mM ACETATONICKEL(II) COMPLEXES IN 0.1 M $LiClO_4$ SOLUTIONS (Electrode B)

Concen. CH_3COOH %	i_l μA	$E_{1/2}$ V *vs.* SCE	Reciprocal slope of log-plot mV
0.2	4.83	-0.47_0	82
0.4	4.79	-0.47_3	80
0.8	4.80	-0.47_5	82
2.0	4.74	-0.47_8	87
4.0	4.66	-0.48_2	107
10.9	4.43	-0.49_3	110

No appreciable change was observed in the half-wave potential with the change of the concentration of acetic acid. On the other hand, the decrease of the limiting currents and the increase of the slopes of the log-plots were found with the increasing concentrations of acetic acid.

The polarographic behavior of nickel(II) ions in acetic acid solvent has been investigated by Coulter and Iwamoto,[16] who reported that nickel(II) ions in an acetic acid solvent containing a 1.0 M lithium perchlorate gave a single irreversible reduction wave with the half-wave potential of −0.645 V *vs.* SCE and the slope of the log-plot of 127 mV.

In this experiment, the current-potential curves were drawn out in an acetonitrile solution containing the higher concentration of acetic acid than 10% in volume.

The limiting currents, half-wave potentials and slopes of the log-plots at 0.5 mM acetatonickel(II) complexes in a 0.1 M lithium perchlorate and 0.4% acetic acid solution containing various concentrations of acetic anhydride are represented in Table 3.

TABLE 3. EFFECT OF ACETIC ANHYDRIDE ON THE REDUCTION OF 0.5 mM ACETATONICKEL-(II) COMPLEXES IN 0.1 M $LiClO_4$ CONTAINING 0.4% ACETIC ACID (Electrode B)

Concen. of $(CH_3CO)_2O$ %	i_l μA	$E_{1/2}$ V *vs.* SCE	Reciprocal slope of log-plot mV
0	4.85	-0.47_2	82
0.1	4.86	-0.47_0	81
0.2	4.84	-0.47_8	81
0.4	4.80	-0.47_6	81
1.0	4.77	-0.48_1	83
4.0	4.71	-0.48_5	82
10.0	4.61	-0.48_3	83

No appreciable change was observed in the half-wave potentials and slopes of the log-plots, but the limiting currents decreased gradually with the increasing concentration of acetic anhydride.

In the solution of tetraalkylammonium perchlorate electrolytes in the absence of acetic anhydride, on the other hand, a maximum wave appeared at the second reduction step when the measurements were made at a higher concentration of acetatonickel(II) complexes than 1.5 mM, the maximum wave, however, was suppressed by addition of 0.2% acetic anhydride in volume.

In the following sections, acetic anhydride was not added unless otherwise stated, because the measurements were carried out at the concentration of 0.5 mM acetatonickel(II)

TABLE 4. EFFECT OF WATER ON THE REDUCTION OF 0.5 mM ACETATONICKEL(II) IN 0.1 M $LiClO_4$ SOLUTIONS CONTAINING 0.4% ACETIC ACID (Electrode B)

Concen. of water %	i_l μA	$E_{1/2}$ V *vs.* SCE	Reciprocal slop of log-plot mV
0.04	4.78	-0.47_2	79
0.2	4.73	-0.47_8	81
0.4	4.72	-0.48_2	80
0.8	4.70	-0.49_8	83
2.0	4.67	-0.53_5	83
4.0	4.61	-0.60_5	85

complexes.

The effect of water content on the reduction wave in a 0.1 M lithium perchlorate solution was also investigated as shown in Table 4.

The half-wave potentials and slopes of the log-plots were not affected up to 0.4% water content. At higher concentrations than 2% water, the half-wave potentials shift to more negative potentials and the limiting currents decrease, with the increasing concentrations of water.

Effect of Concentration of Lithium Perchlorate. Appreciable variations were observed in the current-potential curves for the reduction of acetatonickel(II) complexes by changing the natures and concentrations of supporting electrolytes. The typical current-potential curves for the reduction of 0.5 mM acetatonickel(II) complexes containing 0.4% acetic acid and various concentrations of lithium perchlorate are reproduced in Fig. 2.

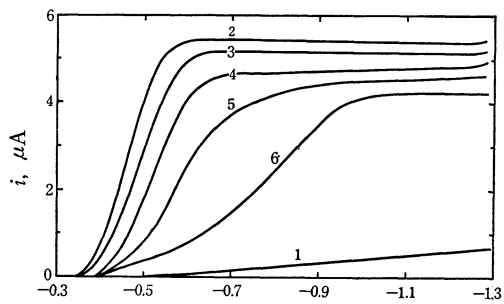

Fig. 2. Effect of concentration of lithium perchlorate on the current-potential curves of 0.5 mM acetatonickel(II) complexes containing 0.4% acetic acid: (1), 0 M; (2), 0.05 M; (3), 0.1 M; (4), 0.2 M; (5), 0.4 M; (6), 1.0 M $LiClO_4$. (Electrode A)

The limiting current decreases and the reduction potentials shifts to more negative potentials, with the increasing concentrations of limthium perchlorate. An ill-defined reduction wave was observed in the absence of supporting electrolyte.

Effect of Mixed Electrolytes. Stepwise addition of lithium perchlorate up to a concentration of about 10 mM to 0.5 mM acetatonickel(II) complexes in tetraalkylammonium perchlorate solution causes an increase in heights of the limiting currents and a shift of the reduction potential to less negative potentials.

A double wave obtained in a tetramethylammonium perchlorate solution changes gradually to a single one by the stepwise addition of lithium perchlorate up to a concentration of about 5 mM as presented in Fig. 3.

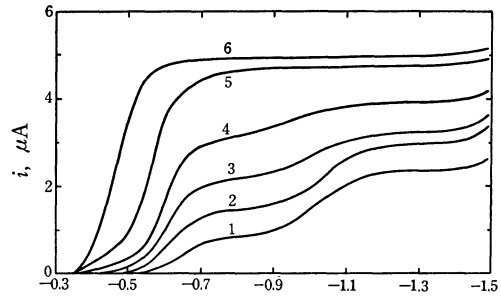

Fig. 3. Current-potential curves of 0.5 mM acetonickel(II) complexes in tetramethylammonium perchlorate solutions containing 0.4% acetic acid and various concentrations of lithium perchlorate at ionic strength 0.05: (1), 0 M; (2), 2×10^{-4} M; (3), 5×10^{-4} M; (4), 1×10^{-3} M; (5), 5×10^{-3} M; (6), 5×10^{-2} M $LiClO_4$. (Electrode B)

TABLE 5. EFFECT OF LITHIUM PERCHLORATE ON THE REDUCTION OF 0.5 mM ACETATONICKEL (II) COMPLEXES IN $(CH_3)_4NClO_4$ SOLUTIONS CONTAINING 0.4% ACETIC ACID AT IONIC STRENGTH 0.05 (Electrode B)

Concen. of $LiClO_4$ mM	1st wave i_l μA	1st wave x at $i_l=kt^x$	2nd wave i_l μA	2nd wave x at $i_l=kt^x$
0	0.85	0.52	2.35	0.62
0.1	1.20	0.46	2.72	0.56
0.2	1.50	0.43	2.98	0.56
0.5	2.22	0.41	3.20	0.53
1.0	3.20	0.39	3.88	0.46
3.0	4.18	0.38	4.43	0.46
5.0	4.70	0.35	4.75	0.42
50	4.96	0.31	5.02	0.30

At the potentials of −0.82 V and −1.30 V *vs.* SCE corresponding to the potentials to the first and the second reduction step, respectively, in a tetramethylammonium perchlorate solution, the measurements of current-time curves were made at various concentrations of lithium perchlorate. Table 5 shows the limiting currents and slopes of the plots for $\log i$ *vs.* $\log t$ which are obtained from the current-time curves of the first drop.[17] The currents increase and the slopes of the plots of $\log i$ *vs.* $\log t$ decrease with the increasing concentrations of lithium perchlorate at the constant ionic strength.

At more concentrations than 5 mM lithium perchlorate, no appreciable difference was observed in the currents and slopes of the plots

17) J. Kůta and I. Smoler, "Progress in Polarograhy," Vol. 1, ed. by P. Zumann and I. M. Kolthoff, Interscience Publishers, New York (1962), pp. 43—63.

of both the first and second steps.

Similar changes of the current-potential curves and the current-time curves by the stepwise addition of lithium perchlorate were observed in the solutions of tetraethylammonium perchlorate or tetra-*n*-butylammonium perchlorate supporting electrolytes.

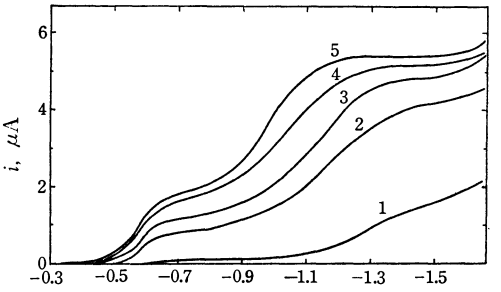

Fig. 4. Current-potential curves of 0.5 mM acetatonickel(II) complexes in tetra-*n*-butylammonium perchlorate solutions containing 0.4% acetic acid and various concentrations of lithium perchlorate at ionic strength 0.05: (1), 0 M; (2), 1×10^{-3} M; (3), 2×10^{-3} M; (4), 5×10^{-3} M; (5), 1×10^{-2} M $LiClO_4$. (Electrode A)

Figure 4 shows the current-potential curves obtained in a tetra-*n*-butylammonium perchlorate solution containing various concentrations of lithium perchlorate.

In this case, the limiting current of the second step increases with the increasing concentrations of lithium perchlorate up to about 10 mM. The limiting current of the second step obtained in a solution containing 40 mM tetra-*n*-butylammonium perchlorate and 10 mM lithium perchlorate becomes nearly equal to the limiting current obtained in a solution of 0.05 M lithium perchlorate alone. On the other hand, no appreciable enhancement of the limiting current of the first step by the stepwise addition of lithium perchlorate is observed as compared with the degree of the increase of that of the second step.

Spectral Studies. The measurement of the visible absorption spectrum of acetatonickel(II) complexes were carried out in the solutions of various kinds of electrolyte. Figure 5 shows the spectra of 50 mM nickel(II) acetate salts in various natures of electrolyte solutions at the constant concentration.

The absorption bands shifted to shorter wavelengths with the decreasing radius of cations of electrolyte. Similar shifts of the absorption bands were also obtained by the increasing concentrations of electrolyte. The

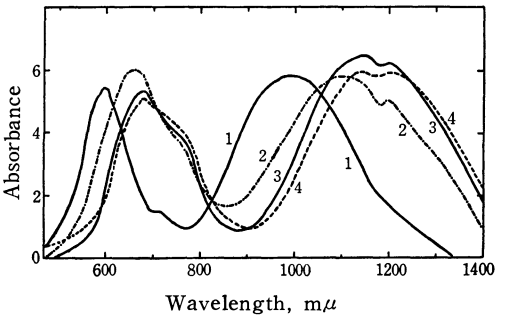

Fig. 5. Visible absorption spectra of 50 mM acetatonickel(II) complexes in various electrolyte solutions containing 1.6% acetic acid: (1), 0.01 M $HClO_4$; (2), 0.25 M $LiClO_4$; (3), 0.25 M $NaClO_4$; (4), 0.25 M $(C_2H_5)_4NClO_4$.

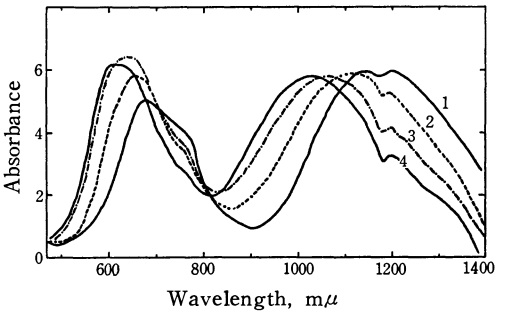

Fig. 6. Visible absorption spectra of 50 mM acetatonickel(II) complexes in various concentrations of lithium perchlorate solutions containing 1.6% acetic acid: (1), 0 M; (2), 0.1 M; (3), 0.5 M; (4), 1.0 M $LiClO_4$.

typical absorption spectra of acetatonickel(II) complexes in various concentrations of lithium perchlorate are reproduced in Fig. 6.

No appreciable change of the absorption bands in the case of tetraalkylammonium perchlorate electrolyte was observed.

Discussion

Spectrophotometric Studies. Nickel(II) acetate salt ($Ni(CH_3COO)_2(H_2O)_4$) does not dissolve in an acetonitrile solvent alone, but dissolves easily in the same solvent in the presence of a small amount of acetic acid or acetate salts such as tetramethylammonium acetate or tetra-*n*-butylammonium acetate which dissolve in an acetonitrile solvent alone.

The visible absorption spectrum of acetatonickel(II) complexes in an acetonitrile containing 1.6% acetic acid shows four bands and, the band positions are nearly equal to those of hexaaquo-nickel(II) ion in an aqueous solvent or the nickel(II) acetate salt dissolved in an aqueous solvent containing 20%

TABLE 6. ABSORPTION MAXIMA OF NICKEL(II) COMPLEXES IN AQUEOUS AND ACETONITRILE SOLVENTS

Compound	Solvent	Band position*				Ref.
$Ni(OAc)\cdot 4H_2O$	CH_3CN, 1.6% Acetic Acid	8.55(0.78)	13.33(0.66)	14.82(0.71)	25.13(1.46)

** Nickel(II) acetate salt was dissolved in acetonitrile containing 1.6% acetic acid, and then the solution was titrated with anhydrous perchloric acid dissolved in acetic anhydride.

acetic acid, as seen from Table 6.

The absorption spectra of a number of octahedral nickel(II) complexes have been listed in Table 6. The extinction coefficients of acetatonickel(II) complexes in an acetonitrile containing 1.6% acetic acid are larger than those of hexaaquonickel(II) ions in an aqueous solvent or nickel(II) acetate salts dissolved in the same solvent containing 20% acetic acid. In an aqueous solution, the intensity of the absorbance of nickel(II) ions is enhanced by the addition of acetate ions, because of the formation of the species, $Ni(OAc)_2$ or $Ni(OAc)^+$, as have been reported by Watelle-Morion.[21]

These results suggest that appreciable quantities of acetato complexes of nickel(II) are formed in an acetonitrile solvent containing a small amount of acetic acid and, that acetatonickel(II) complexes in the same solution is in an octahedral configuration coordinated with six oxygen atoms.

A potentiometric titration of acetatonickel(II) complexes in an acetonitrile solvent containing a small amount of acetic acid with an anhydrous perchloric acid shows that acetatonickel(II) complexes are quantitatively titrated in the same solvent, at a mole ratio of two of perchloric acid to one of nickel(II) acetate salt.[22] In addition to the potentiometric titrations, the color of the solution changes successively from green to blue with the increasing concentration of perchloric acid, the spectra of the solution at the equivalent point is similar to those of $Ni(H_2O)_2(ClO_4)_2$ salt dissolved in an acetonitrile as shown in Fig. 5 and Table 6.

Consequently, it is found that acetatonickel(II) complexes in an acetonitrile solvent containing a small amount of acetic acid is in an octahedral configuration coordinated with two acetate ions and four neutral acetic acid or water molecules.

Table 6 also indicates that appreciable quantities of $(Ni(CH_3CN)_6)^{2+}$ are present in the solution when acetatonickel(II) complexes were titrated with an anhydrous perchloric acid or, $Ni(H_2O)_2(ClO_4)_2$ salt was dissolved in an acetonitrile.

The fact that nickel(II) ion forms a complex ion with acetonitrile, thus freeing acetate ions for the reaction with the acid titrant, may be explained by the following reaction:

$$\{Ni(OAc)_2(HOAc)_x(H_2O)_{4-x}\} + 2HClO_4 + n\,CH_3CN \longrightarrow Ni(CH_3CN)_n^{2+} + 2ClO_4^- + (2+x)HOAc + (4-x)H_2O \quad (1)$$

where HOAc refers to acetic acid.

In the case of addition of lithium perchlorate to the acetonitrile solutions containing acetatonickel(II) complexes and a small amount of acetic acid, the spectrophotometric measurements shows that the spectra of acetatonickel(II) complexes shift to lower wavelengths with the stepwise addition of lithium perchlorate as seen from Fig. 6, the spectra, however, is not consisted with those of nickel(II) perchlorate in an acetonitrile solvent, at the mole ratio of twenty times of lithium perchlorate to nickel(II) acetate salt. Similar shifts of spectra of acetatonickel(II) complexes to shorter wavelengths were observed by addition of the other perchlorate salts. The magnitude of the shift to lower wavelengths decreases in the order of $LiClO_4$, $NaClO_4$, $(CH_3)_4NClO_4$, $(C_2H_5)_4NClO_4$ and $(n\text{-}C_4H_9)_4NClO_4$ at the constant concentration of perchlorate salts, and in the case of the addition

of tetraalkylammonium perchlorate the shift is very small.

A reasonable explanation of these results is possible by considering the substitution of acetate ions by acetonitrile in acetatonickel-(II) complexes which may be written by the following equation.

$$\{Ni(OAc)_2(HOAc)_x(H_2O)_{4-x}\} + 2\,MClO_4 + n\,CH_3CN \rightleftharpoons Ni(CH_3CN)_n^{2+} + 2\,ClO_4^- + 2\,MOAc + x\,HOAc + (4-x)H_2O \quad (2)$$

where M refers to the cation of electrolyte.

The above reaction is considered to proceed quantitatively on employing perchloric acid as an electrolyte, and to be in equibrium in the case of the other electrolytes such as alkali metal perchlorates or tetraalkylammonium perchlorates.

Polarographic Studies. On the polarographic studies, the limiting currents of acetatonickel(II) complexes in various supporting electrolytes at the constant concentration, decrease with the radius of cation of the supporting electrolyte present in the solution.

A single irreversible reduction wave is observed in the solutions of lithium perchlorate or sodium perchlorate, the limiting current shows an intermediate nature of both diffusion- and kinetic-controlled polarographic currents, which were found from the results of the measurement of current-time curves.

The two-reduction steps, on the other hand, are observed in the solution of tetraalkylammonium perchlorate, the limiting current of the second step is kinetic in nature, as seen from Table 1.

The character of the limiting current is also seen from the temperature coefficients of the limiting current. It has been stated that if the temperature coefficient is greater than +2% per degree, the current is probably not a diffusion-controlled.[23] The measurement of the limiting current for the reduction of nickel(II) perchlorate in an acetonitrile solvent containing 0.1 M lithium perchlorate as a supporting electrolyte were made at the temperature over range 0.3 to 35°C, indicating that the temperature coefficient was 1.9% per degree. The result of the measurement of the current-time curve also suggest that the limiting current for the reduction of nickel-(II) perchlorate in an acetonitrile containing 0.1 M lithium perchlorate is diffusion-controlled.

In the case of the reduction of acetatonickel-(II) complexes in the same solvent containing 0.4% acetic acid, the temperature coefficients in a 0.1 M lithium perchlorate solution are 2.3% per degree at lower temperatures and, 3.5% per degree at higher temperatures than 20°C. The temperature coefficients in a 0.05 M tetramethylammonium perchlorate solution, on the other hand, are 4.4% and 6.1% per degree for the first and the second step, respectively, at the temperature range over 0.3 to 35°C.

Consequently, the limiting currents for the reduction process of acetatonickel(II) complexes in an acetonitrile solvent containing 0.4% acetic acid and various supporting electrolyte are undoubtedly not entirely diffusion-controlled.

The authors assume that the chemical reaction expressed in Eq. (2) is a rate determining step and, $\{Ni(OAc)_2(HOAc)_x(H_2O)_{4-x}\}$ in Eq. (2) is an electro inactive and $Ni(CH_3CN)_n^{2+}$, produced by freeing of acetato ions from nickel(II) acetate, is electroactive polarographically.

This assumption may be suggested from the results of the spectrophotometric studies, the dependence of the limiting current on the nature of cation of the supporting electrolytes present in the solution and the enhancenment of the limiting current in a tetraalkylammonium perchlorate supporting electrolyte solution with the stepwise addition of lithium perchlorate.

The polarographic inactivity of $\{Ni(OAc)_2(HOAc)_x(H_2O)_{4-x}\}$ is ascertained from the following experiments. Nickel(II) acetate salt dissolved containing 0.4% acetic acid gives an ill-defined and little reduction wave in the absence of a supporting electrolyte as seen from Fig. 2. If acetatonickel(II) complexes are electroactive, a well-defined and apparent reduction wave with a migration current would be observed.

Nickel(II) acetate salt dissolved in an acetonitrile solvent in the presence of 1 mM tetramethylammonium acetate and 0.05 M tetramethylammonium perchlorate, on the other hand, undergoes two reduction steps with the half-wave potentials of −1.7 V and −2.25 V *vs.* SCE, respectively, as shown in Fig. 7.

In an acetonitrile solution containing acetic acid, the reduction wave of acetatonickel(II) complexes at more negative potentials than −1.8 V *vs.* SCE is not observed by discharge of hydrogen ion. For that reason, the measurements of current-potential curves of acetatonickel(II) complexes were carried out in the absence of acetic acid.

With a 1 mM tetramethylammonium acetate

23) L. Meites, "Polarographic Techniques," Interscience, New York (1955), pp. 78—82.

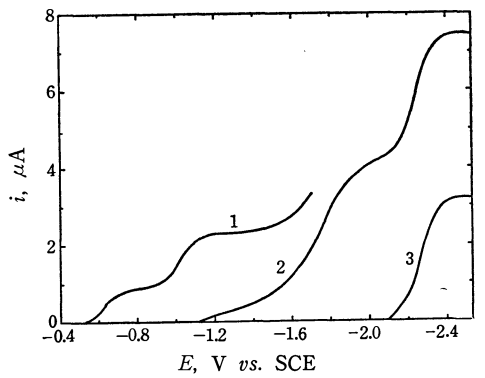

Fig. 7. Current-potential curves of 0.5 mM acetatonickel(II) complexes (curves 1 and 2), and 1 mM tetramethylammonium acetate (curve 3) in 0.05 M $(CH_3)_4NClO_4$ solutions.
(1) 0.5 mM $Ni(OAc)_2$, 0.4% acetic acid
(2) 0.5 mM $Ni(OAc)_2$, 1 mM $(CH_3)_4NOAc$
(3) 1 mM $(CH_3)_4NOAc$. (Electrode B)

and 0.05 M tetramethylammonium perchlorate solution in the absence of nickel(II) acetate salt, a single reduction step with the half-wave potential of −2.23 V *vs.* SCE is observed.

The second reduction step in the presence of nickel(II) acetate salts suggests that it involves the reduction of acetate ions.

The ill-defined first reduction step may be due to the reduction of nickel(II) ions, although it is uncertain whether nickel(II) ions are acetatonickel(II) complexes or nickel(II)-acetonitrile complexes, which are produced by freeing of acetate ions from acetatonickel(II) complexes. The limiting current of the first reduction step is not a pure diffusion-controlled, but shows an intermediate nature of both diffusion and kinetic controlled currents. Under these conditions, consequently, the reduction wave obtained in an acetonitrile solution dissolved nickel(II) acetate salts with a small amount of acetic acid is not thought to involve the polarographic reduction of nickel(II) ions coordinated with acetate ions could not proceed up to the potentials of −1.7 V *vs.* SCE.

The increase of the limiting current with the decreasing radius of the cation of supporting electrolyte present in the solutions, indicates the increase of the equilibrium concentrations of $Ni(CH_3CN)_n^{2+}$.

The addition of lithium perchlorate in the solutions of tetraalkylammonium perchlorate electrolytes causes an enhancement of the limiting current and also a decrease of the slopes of the plots of $\log i$ *vs.* $\log t$ during a life of mercury drop at the constant potential, as presented in Table 5 in the case of the results in tetramethylammonium perchlorate solutions, indicating that the equilibrium concentrations of $Ni(CH_3CH)_n^{2+}$ increase gradually with increasing concentrations of lithium perchlorate, and the rate-determining step change gradually from the chemical reaction (2) to the diffusion process of $Ni(CH_3CN)_n^{2+}$.

A similar enhancement of the limiting current in tetraalkylammonium perchlorate electrolyte solutions is also observed by addition of a small amount of sodium perchlorate instead of lithium perchlorate, lithium perchlorate being more efficient than sodium perchlorate for the enhancement of limiting current at the constant ionic strength.

The two reduction steps in a solution of tetramethylammonium perchlorate electrolyte changes to a single one at a less mole ratio of lithium perchlorate to nickel(II) acetate salts than ten.

On the other hand, a double wave in the solutions of tetraethylammonium perchlorate or tetra-*n*-butylammonium perchlorate electrolyte is also observed under the conditions that the enhanced limiting current of the second step becomes nearly equal to the limiting current obtained in the solution of lithium perchlorate electrolyte alone, as shown in Fig. 3.

These data indicate that the charge transfer reaction of nickel(II) ion is inhibited by the weakly absorption of tetraalkylammonim ions at the dropping mercury electrode.

The conclusion is also supported by the results presented in Fig. 8.

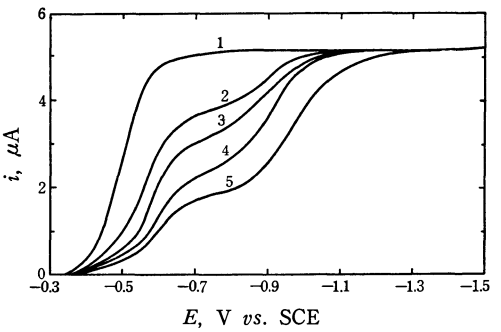

Fig. 8. Effect of tetra-*n*-butylammonium perchlorate on the current-potential curves of 0.5 mM acetatonickel(II) complexes in lithium perchlorate solutions containing 0.4% acetic acid at ionic strength 0.1: (1), 0 M; (2), 5×10^{-3} M; (3), 1×10^{-2} M; (4), 2.5×10^{-2} M; (5), 5×10^{-2} M $(n\text{-}C_4H_9)_4NClO_4$. (Electrode A)

A single wave obtained in the solution of lithium perchlorate supporting electrolyte is

found to split into the twosteps by the addition of tetra-*n*-butylammonium perchlorate. The limiting current at the potential over range −0.6 V to −1.0 V *vs.* SCE is not only suppressed but also becomes gradually independent on the heights of a mercury reservoir, with the increasing concentrations of tetra-*n*-butylammonium perchlorate, and reduction potentials shift to more negative potentials.

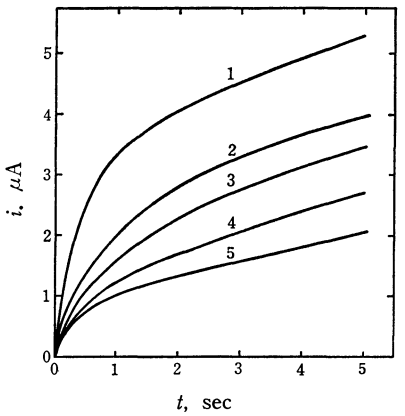

Fig. 9. Current-time curves of 0.5 mM acetatonickel(II) complexes measured at −0.75 V. *vs.* SCE in lithium perchlorate solutions containing 0.4% acetic acid and various concentrations of $(n\text{-}C_4H_9)_4NClO_4$ at ionic strength 0.1: (1), 0 M; (2), 5×10^{-3} M; (3), 1×10^{-2} M; (4), 2.5×10^{-2} M; (5), 5×10^{-2} M $(n\text{-}C_4H_9)_4NClO_4$ present. (Electrode A)

This unusual situation is also evident from the results of the measurements of the current-time curves given in Fig. 9. The stepwise addition of tetra-*n*-butylammonium perchlorate at the ionic strength 0.1 causes to decrease the maximum current observed just before the mercury drop and also to depress the current from the initial stage of the formation of a mercury brop. The current at the first step observed at −0.75 V *vs.* SCE, in the presence of a 50 mM tetra-*n*-butylammonium perchlorate shows the property of the kinetic current. At more negative potentials than −0.8 V *vs.* SCE, the reduction current rises again and reaches to a full height, and becomes almost independent on the presence of tetra-*n*-butylammonium perchlorate.

The profiles of the current-time curves changes successively from the curve 5 to 1 in Fig. 9 in the presence of 50 mM tetra-*n*-butylammonium perchlorate by means of the shift of the potential from −0.75 V to −1.3 V *vs.* SCE. A single wave obtained in the sulotion of lithium perchlorate supporting electrolyte also splits into a double one by the stepwise addition of the other tetraalkylammonium perchlorate instead of tetra-*n*-butylammonium perchlorate. But the suppressing action is found to decrease in the order of $(n\text{-}C_4H_9)_4N^+$, $(C_2H_5)_4N^+$ and $(CH_3)_4N^+$ at the definite concentration.

These phenomena may be explained by taking into consideration the weak absorption of tetraalkylammonium cations on the DME. It is well known theoretically[24] and experimentally[25] that the weakly surface-active substances with considerably higher concentrations make the limiting current decrease and also change successively the drop life dependence of the instantaneous current from a $t^{1/6}$ to a $t^{2/3}$.

Tetraalkylammonium ions in an aqueous solvent has been found to act as a relatively strong surface-active substances on DME.[26] In an acetonitrile solvent, however, they would act as a weakly surface-active substance.

In conclusion, with nickel(II) acetate salts dissolved in an acetonitrile solvent containing a small amount of acetic acid the nickel(II) ion is in an octahedral configuration coordinated with two acetate ions and four neutral acetic acid or water molecules.

The reaction mechanism of the polarographic reduction of acetatonickel(II) complexes can probably be represented by the following sequence:

$$\{Ni(OAc)_2(HOAc)_x(H_2O)_{4-x}\} + 2\,MClO_4 + n\,CH_3CN \overset{K_{eq}}{\rightleftharpoons} Ni(CH_3CN)_n^{2+} + 2\,ClO_4^- + 2\,MOAc + x\,HOAc + (4-x)H_2O \quad (2')$$

$$Ni(CH_3CN)_n^{2+} + 2\,e \longrightarrow Ni(Hg) + n\,CH_3CN \quad (3)$$

where HOAc refers to acetic acid, $MClO_4$ represents a supporting electrolyte, K_{eq} the effective equilibrium constant in the bulk solution, substance $\{Ni(OAc)_2(HOAc)_x(H_2O)_{4-x}\}$ is not reduced at the potential at which $Ni(CH_3CN)_n^{2+}$ is reduced under the experimental conditions.

The limiting current obtained in lithium perchlorate or sodium perchlorate supporting electrolyte solutions exhibits an intermediate nature of both diffusion and kinetic controlled currents. In tetraalkylammonium perchlorate supporting electrolyte solutions, the chemical reaction (2′) is a rate-determining step. The first step of a double-wave in a tetraalkyl-

ammonium perchlorate solution is due to the inhibition of charge transfer of nickel(II) ion by the weak adsorption of tetraalkylammonium ions on the DME.

Distribution of Thenoyltrifluoroacetone and Its Scandium Chelate in Ketone Solvent System

Toshiki WAKABAYASHI, Katsuko TAKAIZUMI, Kunio SETO, Nobuo SUZUKI*1 and Ken-ichi AKIBA*1

The College of General Education, Tohoku University, Kawauchi, Sendai

(Received January 24, 1968)

The distribution equilibria of thenoyltrifluoroacetone (TTA) and its scandium chelate between aqueous solutions with an ionic strength of 0.1 and ketones at 25°C have been studied. The distribution of TTA was correlated with the solubility parameters of the ketones and the correlation between the distribution coefficients of TTA and those of scandium chelate was confirmed. The characteristic properties of ketones were discussed in comparison with those of other oxygen containing solvents.

The excellent properties of methyl-isobutyl ketone (hexone) as a solvent for solvent extraction, not only in ion association systems but also in chelate systems, have been shown by many authors. However, few systematic studies on ketone solvents are to be found.

In order to clarify the relation between some physico-chemical properties of solvents and the distribution coefficients of extractable species, the authors studied the partition equilibria of some β-diketones and those of scandium chelate in some solvent systems; *i.e.*, so called inert solvents,[1-3] alcohol solvents[4,5] and ester solvents.[6] As a further example, the distribution of oxine in inert solvent systems was also studied.[7] It was shown that solubility parametr theory provides a useful approach to the problem, and that the solubility parameters of solvents are more important factors than other parameters such as dielectric constants and dipole moments, which have often been used to explain the role of solvents, in the case where the specific interaction between solute and solvent is not significant.

The present authors will detemine the distribution coefficients of TTA and its scandium chelate in ketone solvent systems, demonstrate the relation between the distribution coefficients and the solubility parameters of the solvents and discuss the characteristic properties of ketone solvents in comparison with other solvents.

Experimental

Materials. Thenoyltrifluoroacetone was obtained from Dojindo Co., Ltd., and was purified by sublimation. Solvents were purified by distillation. Other chemicals were all GR grade. Scandium-46, obtained from the New England Nuclear Corp. (USA) as chloride in a hydrochloric acid solution, was used as a tracer after substituting perchlorate in a perchloric acid solution. The carrier solution of scandium was prepared from scandium oxide of 99.9% purity.

Determination of Distribution Ratio of TTA. A volume 5 m*l* of a ketone solution containing a known amount of TTA was equilibrated by shaking with an equal volume of aqueous solution with an ionic strength of 0.1 adjusted with sodium perchlorate and perchloric acid in an air thermostat at 25 °C. To minimize the error accompanied by volume

change due to the mutual solubility, both phases were pre-saturated with each other previous to preparing the TTA solution. After centrifuging, the concentration of TTA in the aqueous phase was determined photometrically; an aliquot of the solution was transferred to a constant volume of 0.6 M phosphate buffer of about pH 6.5 and then the absorbance at 337 mμ resulting from the enolate ion of TTA was measured against a blank run at 25°C. It was confirmed by the preliminary experiment that under the conditions the optical density of the solution closely obeys Beer's law. The distribution ratios thus obtained in a pH region below 4 are equal to the distribution coefficients with an error of less than 1 per cent, as previously shown.[1]

Measurement of Absorption Spectra of TTA in Ketone Phase. The spectra of TTA in ketone phases equilibrated with aqueous phase were measured with a Hitachi EPS-3 recording spectrophotometer using a thin layer cell in order to cancel out strong absorption by the solvent in the UV region.

Determination of Enol Content in Ketone Phase. To determine the enol content of TTA, defined as the ratio of the concentration of enol form to the total concentration of TTA in organic phase, the NMR spectrum was measured with a Varian A-60 NMR Spectrometer. The concentration of TTA was about 0.5 M in all solvents. The enol content was determined from the area ratio of the spectrum for the vinyl type protons to that for protons in the thiophen ring.

Determination of Distribution Ratio of Sc. The procedure and experimental conditions were almost the same as TTA. After two phases were separated, γ-activities of each phase were measured by a well-type scintillation counter. The carrier concentration was 10^{-6} M throughout the experiment, except in the case of examining the influence of carrier concentration on the distribution ratio of scandium.

For almost all ketones, complete equilibrium was attained in several hours in a normal extaction; however, a shorter time of 2 hr was required in the back extraction. To confirm the equilibrium, the normal and back extractions were carried out for all solvents. In the case of back extraction, the concentration of TTA in the aqueous phase was determined in the manner described above. The pH of the aqueous phase at equilibrium was measured with a glass electrode pH meter. Although it should be taken into account that the the pH value obtained above for the aqueous solution containing organic solvent is only an apparent one, the value was adopted without any correction because the solubilities of the solvents in water are of the order of a per cent or less.

Results and Discussion

Distribution of TTA. As shown in Fig. 1, TTA is in a keto-enol equilibrium in the ketone phase, while in inert solvents it exists almost completely as the enol form. Taking into account the spectrum of the aqueous solution below pH 4, the peaks at 266 mμ and 292 mμ may be attributed to the ketohybrate.[8] In the case of petanone, the absorption due to the enol form near 320 mμ does not appear as a peak, while in the case of diisobutylketone containing more carbon atoms, the peak at 320 mμ is clearly seen. It was shown that the spectra are independent of hydrogen ion concentration over the pH range 1—4. In a pH region higher then 5, the absorption at 340 mμ in the organic phase increases with pH in the aqueous phase, which corresponds to the absorption at 337 mμ due to the enolate ion in the aqueous phase. At a higher temperature, the peak at 340 mμ becomes stronger.

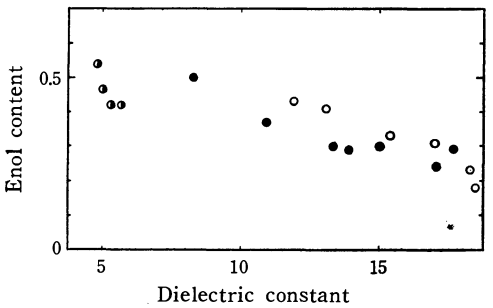

Fig. 2. Enol content of TTA in oxygen containing solvents equilibrated with aqueous solution with pH 2 as a function of dielectric constant of solvent.
● Alcohol, ○ Ketone, ◑ Ester

These facts are common to all the ketones examined. It is, therefore, thought that in the ketone phases, TTA is found as an enolate ion or a sodium salt in a higher pH region.

In the last column of Table 1, the enol contents, r_e, in ketone phases equilibrated with the aqueous phase in a pH range below 4 are summarized. In Fig. 2, the enol contents in oxygen containing solvents under the same conditions are plotted as a function of the dielectric constant of the solvent, though the dielectric constant for the solvent saturated with water should be referred to in order to discuss the influence of dielectric constant on the keto-enol equilibrium. On the whole, there is a trend that the enol content increases with the dielectric constant of solvent.

The distribution ratios of TTA for ketone solvents are shown in Table 1. These values are larger, on the whole, by two or three times than those found in the case of inert solvents, and it is true also in the case of esters.[6] The reason why the distribution coefficients of TTA in the former are larger than those in the latter is understood by considering the fact that in the inert solvents the enol form is almost the only species in the organic phases, while in the case of oxygen containing solvents the enol form is rather a minor species and it is in equilibrium with the keto-hydrate. In alcohol solvents,[4] the distribution ratios are comparable to values in the inert solvents in spite of the similar circumstances to other oxygen containing solvents with respect to the keto-enol equilibrium in the organic phase. In this case, the effect of hydrogen bonding among the solvent molecules should be considered; that is, it may act as if the mole fraction of the solvent were reduced.

As previously reported,[1] the following equation is derived for the distribution coefficient of the enol form of TTA defined as the ratio of the mole fractions in the two phases, P_e,

$$\frac{\log P_e}{\delta_{aq}-\delta_{solv}} = \frac{V_e}{2.30\,RT}(\delta_{aq}+\delta_{solv}-2\delta_e) \quad (1)$$

were δ stands for the solubility parameter for the species corresponding to the subscript. Solubility parameters for some ketones have not been reported. It is possible, however, to estimate the values from the boiling point of the solvent according to the Hildebrand rule.[9] In Table 1, the estimated parameters are listed together with the values found in the literature.[10] In order to apply Eq. (1), it is required to know the distribution coefficients of the enol form. The following relation is established between the distribution coefficient of the enol form and that of the overall forms, D_{HA},

$$P_e = D_e\frac{V_{solv}}{V_{H_2O}} \quad \text{and} \quad D_e = r_e\frac{K_e}{K_a}D_{HA} \quad (2)$$

where K_e, K_a and D_e stand for the dissociation constant of enol, the apparent dissociation constant of TTA and the distribution coefficient of enol form TTA in terms of molarity, respectively. The enol contents of Table 1 are regarded as approximate ones for the present purpose because the values are for a 0.5M TTA solution, and the values

9) J. H. Hildebrand and R. L. Scott, "Regular Solutions," Prentice-Hall, Inc., Englewood Cliffs, New Jersey (1962).
10) J. H. Morrison and H. Freiser, "Solvent Extraction in Analytical Chemistry," John Wiley and Sons Corp., New York (1957).

required are for more dilute solutions of the order of 10^{-2} M, and because there is considerable error in estimating the areas of NMR spectra. However, since no more accurate data are available, the distribution coefficients for the enol form were estimated using the enol contents of Table 1. An attempt to determine the enol ratios more accurately is now undertaken.

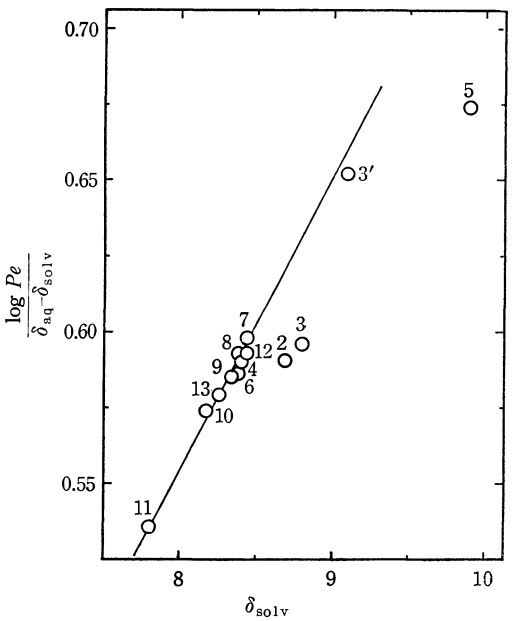

Fig. 3. A relation between distribution coefficients of TTA and solubility parameters of solvents.
Numbers refer to Table 1. 3′ is a corrected value of 3 by Eq. (3).

Since the solubility parameters for aqueous solution and for enol in Eq. (1) are considered constant in all present systems, there should be a linear relation between the left-hand side of the equation and the solubility parameters of the solvents, provided that the equation is valid in the present systems. The result is shown in Fig. 3. For some solvents, such as pentanones, cyclohexanone and butanone, are found considerable deviations from the straight line. The fact may be ascribed to the considerable mutual solubility of water and the solvents. If there are data available on the mutual solubility, it may be possible to correct the solubility parameters for the solvents with the following equation, as is the case of 3-pentanone;

$$\bar{\delta}_{solv} = \phi_{solv}\delta_{solv} + \phi_{H_2O}\delta_{H_2O} \qquad (3)$$

where $\bar{\delta}_{solv}$ and ϕ denote the corrected parameter and the volume fraction of each component in the organic phase, respectively. As the solubility parameter for water, the value of 16.3$_5$ which was obtained previously[1] was used also in the present work. The applicability of Eq. (1) is examined further by the slope of the line which should be related to the molar volume of the reagent. The slope of the line corresponds to a volume of near 140 cc, which is about 10 per cent less than in the previous case.

The reason that the application of the solubility parameter theory is approximately possible even in the present systems may be ascribed to the circumstance that the dispersion effect is dominant among the effects contributing to the cohesive energy, even in polar solvents such as ketones.[11]

Distribution of Scandium. As previously described,[2] the distribution of Sc(III) can be expressed as

$$D_M = \frac{D_{M,0}K_{i=3}[A^-]_{aq}^{\,3}\{1+\Sigma K_j[HA]_{org}^{\,j}\}}{1+\Sigma K_i[A^-]_{aq}^{\,i}}$$

and

$$pA = -\log[A^-]_{aq} = pK_a - pH - \log[HA]_{aq},$$

where K_i is the overall formation constant for $ScA_i^{+(3-i)}$, K_j the overall formation con-

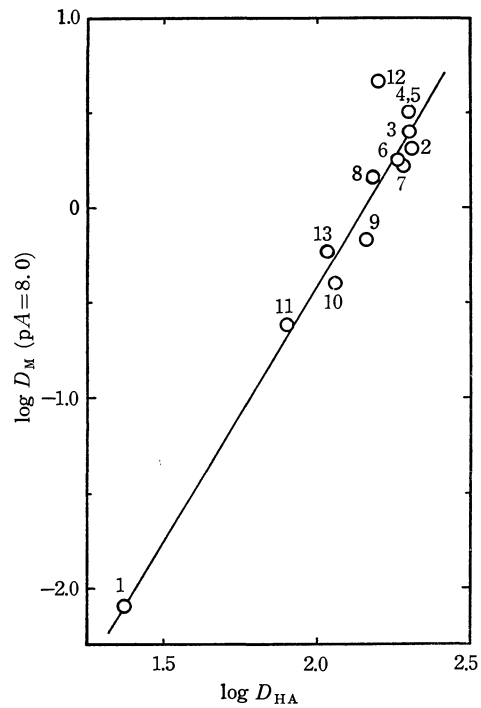

Fig. 4. A correlation between distribution ratios of TTA and those of its scandium chelate in ketone solvent systems.

stant corresponding to additive compound formation in the organic phase and $[HA]_{aq}$ the total concentration of the reagent in the aqueous phase determined photometrically. For all ketones, the plotting of $\log D_M$ against pA 8. Considering the fact that, so long as the plotting was carried out against pA, the distribution curves for Sc(III) were common to the various runs under different conditions with respect to the concentration of TTA in the organic phase and pH, it is concluded that the extractable species is of the type ScA_3 alone, except in the case of 2-butanone, in which the ion associated complex with perchlorate ion was extracted. In Table 1, the distribution ratios of scandium at a constant pA of 8.0, which are proportional to the distribution coefficients in each solvent, are summarized.

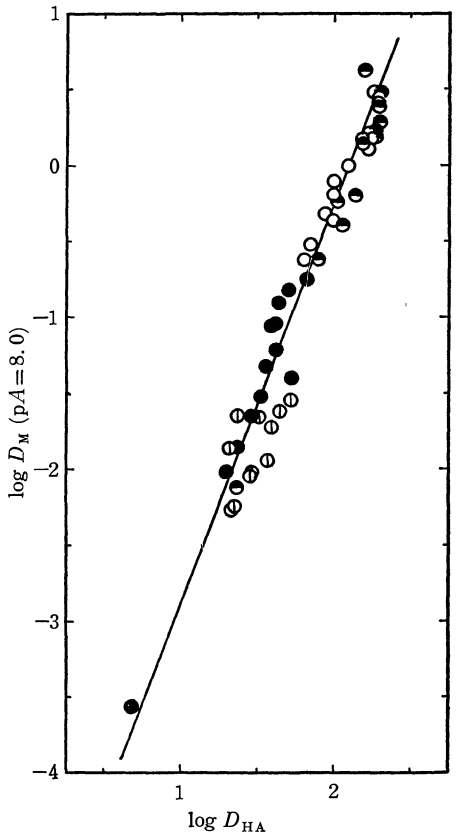

Fig. 5. A correlation between distribution ratios of TTA and those of its scandium chelate in various solvent systems.
● Inert solvent ◓ Ketone
ⓘ Alcohol ○ Ester

There is a distinct correlation between the distribution coefficients of the reagents and those of the chelate, as shown in Fig. 4. In Fig. 5, all of the data obtained until now are plotted similarly. Through all of the solvents, a common straight line can be drawn. Although the relation may be ascribed to the similarity, as already discussed,[2,3] of the interactions with solvent molecules in both cases of free TTA and of that bound to scandium, it should be noted that the abscissae in Figs. 4 and 5 express not the distribution coefficients for the enol form but the overall ones. It cannot be asserted that the enol form should be preferable to the other form of TTA in describing the relation, for the relation is only an approximate one and is not so strict that the difference in interactions between the two forms of TTA and solvent molecules can be considered.

The Bromination of Tris(3-phenyl-2,4-pentanediono)cobalt(III)*1

Yukito MURAKAMI and Katsuyuki NAKAMURA*2

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received January 30, 1968)

Tris(3-phenyl-2,4-pentanediono)cobalt(III) has been treated with three kinds of bromination reagents; bromine in the presence of pyridine, pyridine perbromide, and *N*-bromosuccinimide. Components of the product species have been detected by means of thin-layer chromatography and fractionated by liquid-chromatography. The characterization of bromination products has been performed by the aid of infrared and nuclear magnetic resonance spectroscopy. The bromination has taken place with the chelate ring remaining intact, and converted methyl groups in the coordinated ligands to bromomethyl. The cleavage of coordinate bonds, which has occurred afterward, has resulted in the formation of a metal-absent brominated ligand. Among various bromination products, the one with lowest bromination degree (monobrominated chelate) has been fully characterized in accordance with the experimental facts: elemental analysis, the appearance of a new infrared band at 1248 cm^{-1} which is attributable to CH_2 wagging vibration of the CH_2Br group, and two doublet NMR peaks at 3.55, 3.69, 3.94 and 4.09 in δ-value which are due to nonequivalent protons of the CH_2Br group. Reaction mechanism has been discussed in terms of electrophilic substitution process.

Much work has been carried out on the halogenation of metal chelate compounds of β-diketones in relation to the quasiaromatic nature of the chelate rings.[1-5] In order to extend the halogenation reaction to the metal complexes formed with 2,4-pentanediones which carry an aromatic substituent at the 3-position, tris(3-phenyl-2,4-pentanediono)-chromium(III)*3 has been treated in the previous study.[6] In pursuing this type of reaction with the same purpose, tris(3-phenyl-2,4-pentanediono)cobalt(III)*4 was brominated in this work and the resulting products were characterized by means of infrared and nuclear magnetic resonance spectroscopy. In addition, these results were compared with the reactivity of the chromium chelate.

Experimental

Bromination of $Co(PAA)_3$ with Bromine. (a) $Br_2/Co(PAA)_3=2$. A solution of bromine (0.96 g, 6 mmol) in 10 m*l* of chloroform was added dropwise, with stirring, to a solution of $Co(PAA)_3$ (1.75 g, 3 mmol) and pyridine (0.48 g, 6 mmol) in 150 m*l* of chloroform in 30 min at 25°C, and the stirring was continued for another 15 min. The resulting reaction mixture was evaporated under reduced pressure below 15°C, and extracted with benzene. The extraction residue of blue solid was identified as the pyridine-cobalt(III) complex. The benzene extract was evaporated to remove benzene (A), washed with water, and then dissolved in a small amount of methanol. The methanol solution was allowed to stand overnight in a refrigerator and the resulting green solid (B) was collected. The thin-layer chromatograms with a combination of Wakogel B-O (silica gel with no binder) and chloroform for materials A and B along with other related ones are shown in Fig. 1. The brominated material A was then fractionated into five components by means of liquid-chromatography with a combination of silica gel (60—80 mesh) and benzene. The solid materials recovered from the eluted fractions were recrystallized from chloroform-methanol. These products are (see Fig. 1): i) yellow liquid; ii) green crystals (bromination prod-

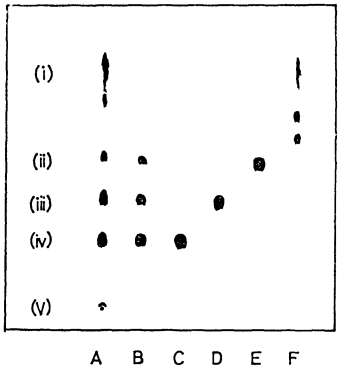

Fig. 1. Thin-layer chromatograms of various bromination products obtained with a combination of Wakogel B-O and chloroform: A, bromination product obtained from the reaction of $Co(PAA)_3$ with bromine at 1:2 molar ratio; B, green solid obtained from A; C, $Co(PAA)_3$; D, BRP-1; E, BRI-2; F, BRP-3.

uct 2*[5]), mp 140—140.5°C (dec.), yield a few mg, R_f 0.30; iii) green crystals (bromination product 1*[5]), mp 161—162.5°C (dec.), yield 100 mg, R_f 0.20; iv) green crystals (unreacted cobalt chelate), mp 183—184°C (dec.), 240 mg, R_f 0.15; v) greenish brown solid (unidentified).

Found for BRP-1: C, 59.83; H, 5.01%. Calcd for $C_{33}H_{32}O_6BrCo$ (monobromochelate): C, 59.74; H, 4.86%.

(b) $Br_2/Co(PAA)_3=6$. A solution of bromine (2.88 g, 18 mmol) in 10 m*l* of carbon tetrachloride was added, with stirring, to a solution of $Co(PAA)_3$ (1.75 g, 3 mmol) and pyridine (2.5 g) in 200 m*l* of carbon tetrachloride in 20 min at 9—11°C. The stirring was continued for another 10 min at 9°C, and the mixture was evaporated under reduced pressure at room temperature. The residue was extracted with benzene, washed with water and then dried over sodium sulfate. The thin-layer chromatogram for this benzene extract is shown in Fig. 1 (bromination product 3*[5]). However, the liquid-chromatographic separation of this extract into components was not successful.

Bromination of $Co(PAA)_3$ with Pyridine Perbromide. A solution of pyridine perbromide (0.72 g, 3 mmol) in 10 m*l* of chloroform was added dropwise, with stirring, to a solution of $Co(PAA)_3$ (1.75 g, 3 mmol) in 150 m*l* of chloroform in 90 min at 1°C, and the stirring of another 60 min was performed at the same temperature. The resulting bluish green solution was evaporated under reduced pressure to remove solvent, and the residue was washed several times with each small portion of water. Into this residue was added a small amount of methanol, and the mixture was allowed to stand overnight in a refrigerator to afford a green precipitate. This solid was then washed with cold methanol and petroleum ether successively; 0.89 g. Repeated liquid-chromatographic separation and purification of this green substance with a combination of silica gel (60—80 mesh) and benzene, followed by recrystallization from benzene, afforded green crystals; mp 161—162°C, yield 10 mg, identified as BRP-1. The unreacted cobalt chelate was also recovered; 0.71 g.

Bromination of $Co(PAA)_3$ with *N*-Bromosuccinimide. A 1.60 g (9 mmol) sample of *N*-bromosuccinimide was added to a solution of $Co(PAA)_3$ (1.75 g, 3 mmol) in 250 m*l* of carbon tetrachloride. Then, the mixture was placed in an oil-bath (85—90°C) and refluxed for 15 min with vigorous stirring. After being cooled down by the use of an ice-water bath, the reaction mixture was filtered off. The filtrate was then concentrated *in vacuo* to recover green solid (1.66 g). Liquid-chromatographic separation of the green material into components with the combination of silica gel (60—80 mesh) and benzene afforded BRP-1 (a few mg), BRP-2 (very small amount), and the unreacted cobalt chelate (1.6 g).

Bromination of $Cr(PAA)_3$ with Bromine. A solution of bromine (5.75 g, 36 mmol) in 30 m*l* of carbon tetrachloride was added dropwide, with stirring, to a solution of $Cr(PAA)_3$ (3.45 g, 6 mmol) and pyridine (2.85 g, 36 mmol) in 500 m*l* of carbon tetrachloride in 35 min at 15°C, and the stirring was continued for another 20 min. Then, the mixture was filtered off, and the filtrate was concentrated *in vacuo* and then extracted with benzene. The thin-layer chromatogram with a combination of Wakogel B-O and benzene for the benzene extract is shown in Fig. 2. The product was then fractionated into components by means of liquid-chromatography with a combination of silica gel (60—80 mesh) and benzene: i) yellow oily liquid, 530 mg; ii) green solid, 150 mg; iii) and iv) dark yellow solid, 220 mg; v) brownish violet solid, 430 mg; and vi) unreacted chromium chelate, 560 mg.

Spectral Measurements. The infrared spectra were obtained on a Koken Model DS-301 spectrophotometer equipped with sodium chloride optics.*[6]

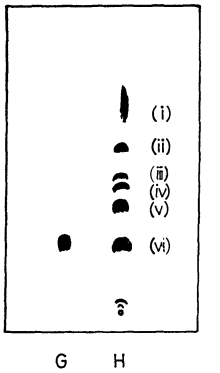

Fig. 2. Thin-layer chromatograms of Cr-$(PAA)_3$ (G) and its bromination product (H) obtained with a combination of Wakogel B-O and benzene.

*[5] Bromination products 1, 2 and 3 are designated as BRP-1, BRP-2, and BRP-3, respectively, throughout this paper.

*[6] Measurements were carried out by Miss Y. Tomita of this Department.

The NMR spectra were recorded on a Varian A-60 spectrophotometer*7 operating at 60 Mc. Chemical shifts are reported in ppm from internal tetramethylsilane (TMS) and data are good to 0.5 cps. The spectra were calibrated by the use of chloroform signal (436 cps from TMS) as the secondary reference. Chloroform used as solvent was purified by the standard method and was free from alcohol. Fractional distillation of this solvent was carried out just before use.

Characterization of Bromination Products

As described in the preceding section, the brominated material obtained from $Co(PAA)_3$ consists of various species of different bromination-degree. Among these reaction products, however, BRP-1 was obtained in the highest yield, relative to others, under mild conditions. BRP-1 was isolated in the form of green crystals and eluted from a chromatographic column before the unreacted chelate $Co(PAA)_3$. First of all in characterizing this material, elemental analysis confirms this undoubtedly to be a monobrominated chelate. Infrared spectra, which are illustrated in Fig. 3, provide the second information. Among various alteration of absorption peaks in the brominated product with reference to the starting chelate $Co(PAA)_3$, the appearance of a new peak at 1248 cm^{-1}, which can be assigned to CH_2 wagging vibration of the CH_2Br group,[6,7] is most significant and provides the decisive evidence for the characterization of the bromination product. In addition, the following changes in absorption bands are observed: absorption peaks due to asymmetric and symmetric deformation of CH_3 group in $Co(PAA)_3$, which appear at 1423 and 1349 cm^{-1} respectively, diminish their intensity in the bromination product. On the other hand, in the brominated material the 1433 cm^{-1} band assigned to CH_2 deformation is detected and the 1300—1400 cm^{-1} region, where the CH_3 symmetric deformations demonstrate their peaks, becomes more crowded by the appearance of other peaks at 1387 and 1368 cm^{-1}. Moreover, the CH_3 rocking vibration absorb-

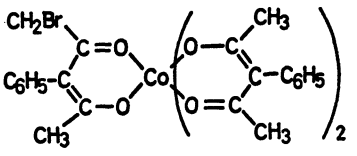
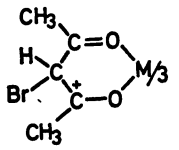
i ng at the 1000 cm^{-1} region increases its band-intensity as $Co(PAA)_3$ is converted to the brominated substance. The NMR spectrum is to be investigated in the third place. Figure 4 shows the NMR spectrum for the bromination product in part, where proton signals characteristic of CH_3 and CH_2X group can be observed. A NMR signal at δ 2.08 is attributed to CH_3 protons, while four signals at 3.55, 3.69, 3.94 and 4.09 in δ-value are due to protons of the CH_2Br group. Judging from the steric interaction of the CH_2Br group with the phenyl in the brominated chelate, it is reasonable to consider that the former is somehow fixed in space relative to the latter. This may provide a small chemical shift difference between two protons of the CH_2Br group (CH_aH_b type) and then produces two doublets as a result. In conformity with the above experimental evidence, structure I is now assigned to BRP-1, where only one methyl is brominated to bromomethyl (CH_2Br) among six methyl groups in the chelate.



I



VI

BRP-2 was isolated as green crystals and eluted from chromatographic column faster than BRP-1. All the significant changes in infrared spectrum noticed for BRP-1 become more apparent in BRP-2, and in addition the 929 cm^{-1} band in the unbrominated chelate attributable to the coupling stretching vibration of C–CH_3 and CO[8] reduces its intensity

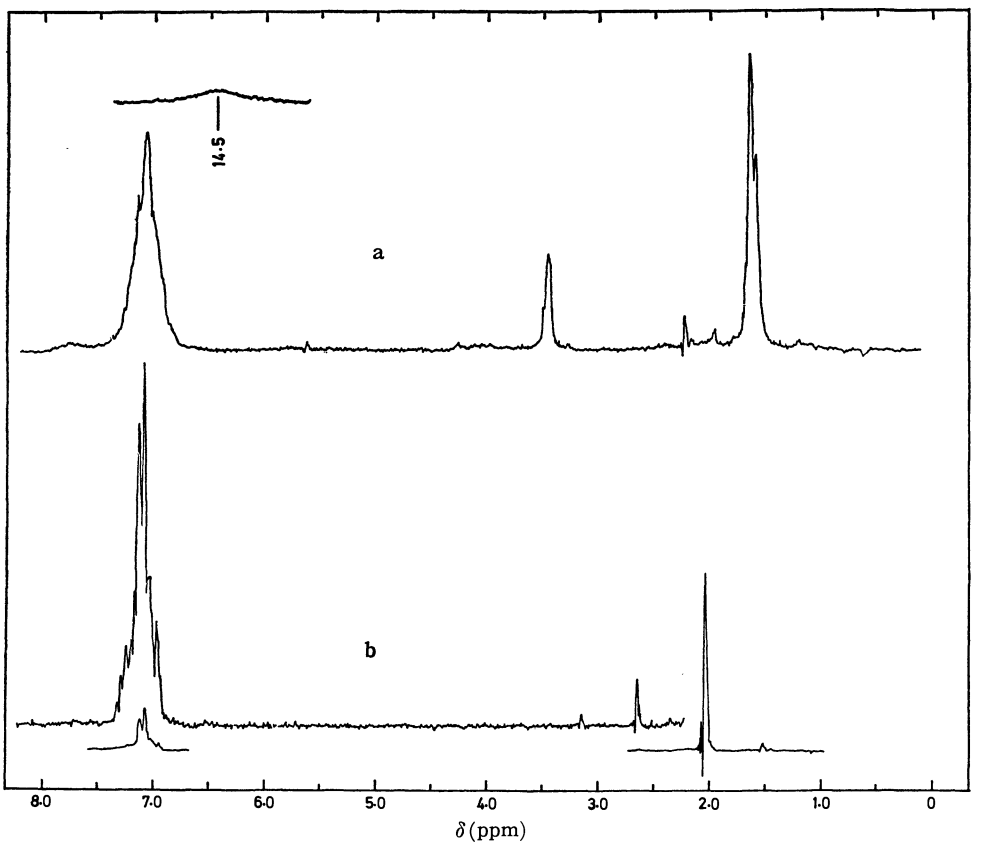


Fig. 5. NMR spectra of 2,4-pentanediones: a, yellow liquid (the metal-free bromination product of $Co(PAA)_3$); b, 3-bromo-3-phenyl-2,4-pentanedione.

II III IV V

in this product. The above experimental facts suggest that the material is of higher bromination-degree with more bromomethyl groups relative to BRP-1.

It is evident that BRP-3 contains two kinds of cobalt complexes as thin-layer chromatogram indicates (Fig. 1). But characterization of these species was not performed since these cobalt complexes were not made completely free from yellow oily liquid. Nevertheless, investigation and comparison of chromatographic behavior and infrared spectra of bromination products of $Cr(PAA)_3$ with those of $Co(PAA)_3$ suggest that above brominated cobalt complexes contain more bromomethyl groups than BRP-2 does.

Yellow liquid which came off first from a chromatographic column was not stable in the air at room temperature, and turned brown by evolution of white acidic fumes upon overnight standing. Since this yellow substance freshly obtained from a chromatographic column reacted with copper acetate to yield the corresponding metal chelate species, it is evident that this yellow substance still hold the β-diketone moiety. The NMR spectrum for the yellow substance obtained when 2 mol of bromine reacted with 1 mol of $Co(PAA)_3$ is shown in Fig. 5. The NMR signals located at 1.64, 3.48, 7.13 and 14.5, which can be assigned to protons of CH_3, CH_2Br, C_6H_5, and OH respectively, demonstrate their intensity ratio to be approximately 4:1:5:1. Thus, the NMR evidence suggests that this yellow liquid consists of 3-phenyl-2,4-pentanedione and 1-bromo-3-phenyl-2,4-pentanedione at approximately equal ratio. Moreover, it is clear that no bromine has been introduced at the 3-position of 3-phenyl-2,4-pentanedione, as understood by comparison of the NMR spectrum for 3-bromo-3-phenyl-2,4-pentanedione with the above one (Fig. 5 a, b).

The comparison of the bromination products for $Cr(PAA)_3$ with those obtained previously in this laboratory[6] by means of spectroscopic and other physical and chemical methods confirms the bromination product ii stated in the preceding section to be the highly brominated chelate (with hexa or pentabromomethyl groups) in agreement with the previous results, while the later fractions from a chromatographic column (iii—v) were identified as less-brominated compounds.

Discussion

3-Phenyl-2,4-pentanedione undergoes substitution with bromine at the 3-position to yield 3-bromo-3-phenyl-2,4-pentanedione, while the metal-absent material (yellow liquid) obtained by the bromination of $Co(PAA)_3$ and $Cr(PAA)_3$ carries only a bromomethyl group. Thus, the bromination takes place undoubtedly with the chelate ring remaining intact, and the cleavage of coordinate bonds occurs afterward. In the halogenation reaction of metal complexes formed with the unsubstituted 2,4-pentanedione, the reagents employed for that purpose were considered to be electrophilic.[9] If the same situation can be applied to the present reaction, an activated complex, which is formed through deprotonation of methyl groups, may be represented by resonance structures III—V. In accordance with our previous spectroscopic studies on the metal complexes of 3-phenyl-2,4-pentanedione,[10,11] it became evident that the phenyl ring interacts electronically with the chelate ring and the π-electron delocalization in the chelate ring increases as a result relative to the corresponding metal complexes of the unsubstituted 2,4-pentanedione. This effect may help to stabilize the above-mentioned activated state and thus facilitate the reaction. Moreover, the effect of metal species on the reactivity was also noticed in this work. At 2:1 molar ratio of bromine to $Cr(PAA)_3$, no bromination product was detected, while various bromination products were obtained in the reaction of $Co(PAA)_3$ under comparable experimental conditions. Judging from this result, the cobalt chelate is more reactive than the corresponding chromium chelate. This may be ascribed to the greater π-electron delocalization in the chelate rings of $Co(PAA)_3$ than in those of $Cr(PAA)_3$ as became evident by spectroscopic studies.[10,11]

9) J. P. Collman, *Angew. Chem., Internat. Edit.*, **4**, 132 (1965).
10) Y. Murakami and K. Nakamura, This Bulletin, **39**, 901 (1966).

Meanwhile, Kluiber[1] has put forward an activated complex shown by VI for the bromination of 2,4-pentanedione complexes, where the chelate ring remains intact throughout the transformation. In the bromination of either $Co(PAA)_3$ or $Cr(PAA)_3$, however, a great steric hindrance of the phenyl group seems to be exerted against a bromine approaching to the 3-position, and this interaction prohibits the formation of an activated complex similar to VI. As a result, this effect fails to give any kind of the 3-brominated compounds.

In summary, the bromination of both $Co(PAA)_3$ and $Cr(PAA)_3$ proceeds with retention of coordinate bonds. The reactivity of 3-phenyl-2,4-pentanedione complexes suffers metal-dependency and $Co(PAA)_3$ is more reactive than $Cr(PAA)_3$. On the other hand, a bromomethyl group seems to destabilize the coordinate bonds in the brominated complexes and the metal-free brominated ligand was also produced as a result.

(Received February 29, 1968)

The reaction of cupric acetate with the reaction mixture of γ-aminopropyl alcohol and substituted salicylaldehydes in ethanol gave dimeric copper(II) complexes. The postulated structure of these complexes makes it possible to test the substituent effect transmitted to the coordinating atoms which are not in the superexchange pathway between copper(II) ions in a pair. The magnetic moments observed at room temperature were corrected for the temperature variations to those at 25°C by graphic method based on Bleaney and Bowers' equation. The observed substituent effect on the relation between $\mu_{\text{eff}}^{25°C}$ and λ_{max} is different from that observed for dimeric cupric halides complexes of substituted pyridine *N*-oxides. In these complexes the substituent effect transmits to the bridging oxygen atom in the superexchange pathway. As compared with the parent complex (H), methyl, chloro and benzo groups weakened the magnetic interaction but nitro group strengthened it. An interpretation of the substituent effect is given based on the idea of the mutual influences on the coordinate bonds.

The correlation of the magnetic interaction between copper(II) ions in a pair in dimeric copper(II) complexes or of some other physicochemical properties of the complexes with their chemical structures has primarily been our interest.[1-3] Several papers of investigation along this line have recently been pub-

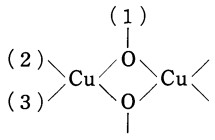
lished.[4-9] Unfortunately, however, the observed phenomena are often too complicated to give consistent, clear-cut interpretation throughout the whole studies. In the preceding communication,[3] we reported some empirical rules which were observed for dimeric complexes of cupric halides with pyridine *N*-oxide derivatives. In these complexes, the effect of substituents attached to the pyridine ring essentially propagates to the bridging oxygen atoms in the superexchange interaction pathway.[10,11]

This study reports observations in which the substituent effect transmits to the coordinate bonds not in the pathway of magnetic interaction. Such bonds are shown as (2) or



I

(3) in I. The most suitable compounds for the study of this problem are those with unidentate ligands at (2) or (3) because in such a case the pathway of transmission of the substituent effect is definitely established. However, very few stable dimeric copper(II) complexes with an unidentate ligand containing a variety of substituents have been reported.

For the present purpose, chelation between positions 2 and 3 should not as a first approximation, introduce any important complexity in the interpretation of obtained data. However, the coordinate bonds at (2) or (3) should be electronically insulated from that of (1). The postulated structure of the complexes reported here essentially satisfies the above structural conditions (*cf.* structure II): The mesomeric effect of substituent X is insulated by three methylene groups, between the π-electron system being attached to X and the bridging alcoholic oxygen atoms. The inductive effect of X can also be ignored at the bridging alcoholic oxygen atom owing to its rapid attenuation through the three methylene groups.

In addition to such structural characteristics, these compounds have the following advantages: 1) They are so stable that they do not decompose in boiling sodium hydroxide solution. 2) The bridging oxygen atoms do not have any vacant orbitals of π character capable of accepting the d-electrons of the metal. This makes the mutual influence of the coordinate bonds quite simple and the experimental results can be interpreted unambiguously.[12-19]

Experimental

Materials. Salicylaldehyde and its 5-chloro, 5-nitro and 5,6-benzo derivatives were obtained commercially. The 5-methyl derivative was prepared by the Reimer-Tiemann reaction of *p*-cresol with chloroform.[20]

The Preparation of the Copper(II) Complexes. The reaction mixture of a slight excess of γ-aminopropyl alcohol and salicylaldehyde or one of the derivatives in ethanol was added to the ethanol solution of cupric acetate monohydrate acidified with few drops of glacial acetic acid. Complete dissolution of cupric acetate monohydrate in ethanol

is not required. The mixture was stirred at an elevated temperature for a while. The product precipitated and was filtered off on a glass filter, washed with ethanol and dried. The crude material was recrystallized from pyridine. To obtain a better yield, some ethanol or methanol can be added to the pyridine solution. The preparation was repeated at least twice for each type of compound. The analytical data are listed in Table 1.

Magnetic Susceptibility Determinations. These were obtained by the Gouy method at room temperature. The effective magnetic moment, μ_{eff}, per copper atom was calculated from the expression $\mu_{eff}=2.83\sqrt{\chi_M \cdot T}$ B. M., where χ_M is the molar susceptibility corrected using Pascal's constants[21,22] for the diamagnetism of all the atoms in the compounds. The temperature-independent paramagnetism associated with the copper ion was not included in the calculation of μ_{eff} throughout this work. The magnetic moments were corrected for minor room temperature variations to those at 25°C, $\mu_{eff}^{25°C}$, by using Bleaney and Bowers' equation[23] assuming $g=2.2$. The actual correction was made by a graphic method as described in the next section. The susceptibility measurements were made of two different preparations for each compound. The two corrected moment values for each compound coincided within 0.01 B. M. at maximum deviation. The magnetic data were given in Tables 2 and 3.

Graphic Method for Correction of Magnetic Moments for Room Temperature Variations. The Bleaney and Bowers' equation is rearranged as

$$\begin{aligned} J &= kT \ln\{3(g^2/\mu_{eff}^2-1)\} \\ &= 2.303\,kT\{0.4771+\log_{10}(g^2/\mu_{eff}^2-1)\} \\ &= 2.303\,kTX \end{aligned} \quad (1)$$

where

$$X = 0.4771 + \log_{10}(g^2/\mu_{eff}^2-1) \quad (2)$$

J is the energy difference between the singlet and triplet states, k, Boltzmann's constant, and g, the Landé splitting factor.

Taking advantage of the constancy of J, from (1) we obtain

$$T_1X_1 = T_2X_2 \quad (3)$$

Assuming $g=2.2$ in Eq. (2), a graph of the plot of X *versus* μ_{eff} (B. M.) is prepared (Fig. 1). X_1 corresponding the μ_{eff} observed at T_1 is read from the graph. From Eq. (3) one obtains the value of X_2 for T_2 to which the correction is to be made. The μ_{eff} corresponding to X_2 is obtained from the graph.

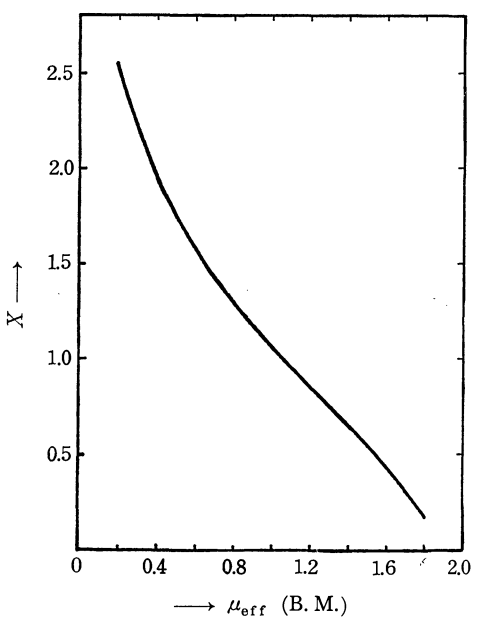

Fig. 1. Plot of X *versus* μ_{eff} (B. M.) in Eq. (2), where $g=2.2$ is assumed.

Diffuse Reflectance Spectra. The diffuse reflectance spectra of the complexes were measured in 400—1000 mμ region on a Shimadzu QR-50 spectrophotometer with a reflectance attachment. Magne-

sium carbonate (heavy) was used as the standard of light reflectance and as the base material to dilute the complexes to obtain appropriate intensities in the reflected light. The preparation of the samples for the spectral measurements involves the following steps: A compound was first ground up in a small agate mortar and it was transferred into another agate mortar containing magnesium carbonate which was previously ground up well. The ground complexes and carbonate were mixed up in the mortar. The mortars and other tools for use were kept in a desiccator. The spectrophotometer was checked for wavelength before and after each measurement at 546.1 mμ by use of a mercury lamp. The temperature of the room should be kept as constant as possible during measurement to obtain a good accuracy in wavelength. Using this procedure the greatest variation in the wavelengths at the band maxima was ± 1 mμ. The band maxima, λ_{max}, are recorded in Table 3.

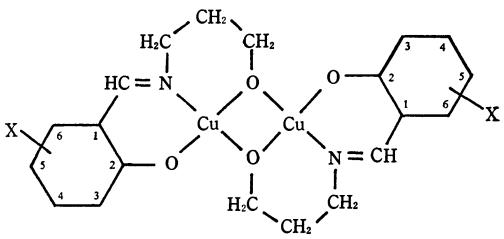
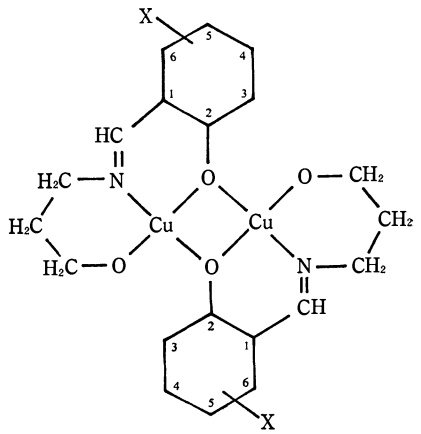
Results and Discussion

Postulation of Structure. The dimeric nature of the parent compound has been established by molecular weight determinations by Yamada *et al.*[*1d] and Nakahara *et al.*[*1e] Two dimeric structures are possible for the complexes under study; one with bridging alcoholic oxygen atoms (II) and the other with bridging phenolic oxygen atoms (III): The data reported here are more in line with structure II and this structure is postulated throughout this study. It was also postulated by Nakahara and coworkers.[*1e] Various physicochemical studies of these complexes are presently in progress by our group and Nakahara's group.[*1e] The data reported here seem to indicate that structure II is the preferred one. Nakahara and coworkers also



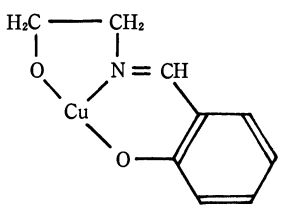
II



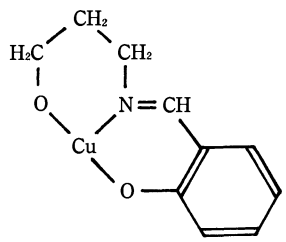
III

prefer this structure. Several experimental facts seem to point in this direction.

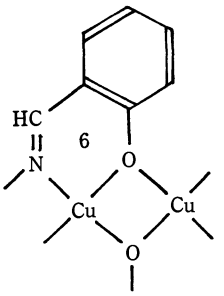
The first is related to the various synthetic efforts to make the complexes with the two ligands given in structure IV and V. The stability of the dimeric complexes should essentially be determined by the nature of the bridging groups and the electronic atmosphere of its neighbors in the chelate ring. If the phenolic oxygen atoms bridge between the two copper ions the stability of the two complexes represented in IV and V should be about the same since the electronic atmosphere in the chelating rings are the same (structure VI). On the other hand if the alcohol oxygens are the bridging atoms, the stabilities of the two complexes should be quite different. As structures VII and VIII show the sizes of the chelate rings involving the bridging oxygen are different in the two cases.



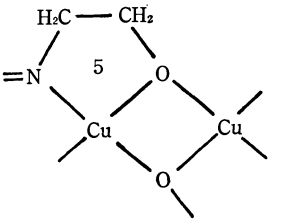
IV



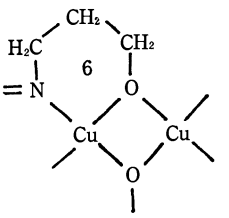
V



VI



VII



VIII

Nakahara and coworkers[24] have reported that they were able to prepare the monomeric complex of IV with a water molecule occupying the fourth coordination position. This complex could not be prepared for the ligand from V. On the other hand, the dimeric complex can be prepared with ligand V but not with ligand from IV. Such differences would be expected if the structural difference were large enough such as shown in VII and VIII. Nakahara and coworkers*[1e,24-26] are presently investigating the correlation between the stability of complexes with fused rings and the number of members in the fused ring.

The second experimental fact is related to magnetic studies. Comparative studies of magnetic studies of dimeric copper(II) complexes indicate that the magnetic moments of complexes with bridging phenolic oxygen atoms are usually greater than those of complexes with bridging alcoholic oxygen atoms.*[1a,b,27-29] The observed moments of about 0.5 B.M. for copper(II) ion for the complexes are much smaller than those complexes containing phenolic oxygen bridges.

Diffuse Reflectance Spectra. The five complexes investigated show essentially the same absorption characteristics and are very similar to that of the parent complex given in Fig. 2. The monomeric complexes of some

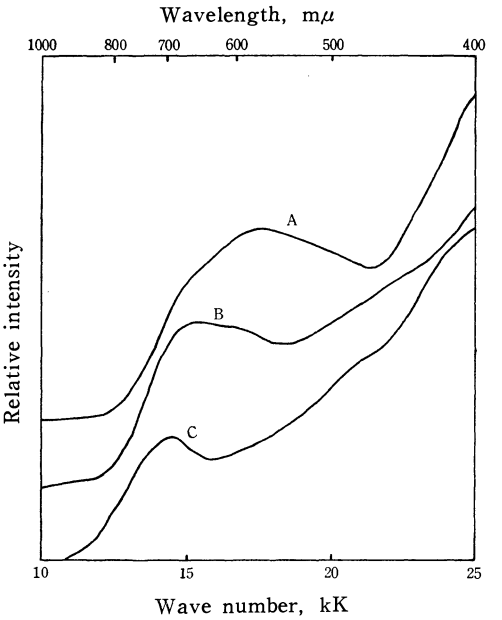


Fig. 2. Diffuse reflectance spectra of *N*-*n*-propanolsalicylaldiminato-copper(II) (A), bis (*N*-methylsalicyl-aldiminato)-copper(II) (B), and bis(*N*-phenylsalicylaldiminato)-copper(II) (C).

of these ligands have been studied by X-ray analysis and were found to be planar: [bis-(*N*-phenylsalicylaldiminato)-copper(II)[30] and bis(*N*-methylsalicylaldiminato)-copper(II)[31]]. For comparison, in Fig. 2, are given the reflectance spectra of these complexes. Their solution spectra have also been reported.*[1d,32,33] A comparative study of the spectra of the dimeric and monomeric complexes indicates that both types can be described as square coplanar.[34,35] Even though in the dimeric

complexes the ratio of the number of oxygen atoms to the number of nitrogen atoms is greater than in the monomeric complexes, the d-d bands of the dimers occur at shorter wavelengths than the monomers. This seems to indicate that the ligand fields of the alcoholic oxygen atoms are stronger than those of the imino nitrogen atoms.[36]

Sacconi and Ciampolini[37] determined the λ_{max} of a series of planar monomeric bis-salicylaldimine-copper(II) complexes with variation in substituent X. They found a maximum difference of 90 mμ in λ_{max} with variation in X.

Careful measurements of the dimeric complexes of the series reported have shown a maximum difference of only 5 mμ. Since the number of substituent X in dimeric complexes is one per one copper atom compared to two in the monomeric complexes, it would be expected that the monomeric complexes should show a larger substituent effect. However, this effect is very much larger (20 times) in the monomeric species. A study is under way to clarify this anomaly which cannot be explained at the present time.

Relation of Spectra and Magnetism. A linear relationship[3] between λ_{max} and $\mu_{eff}^{25°C}$ has recently been shown to exist for the dimeric complexes of copper(II) halides with substituted pyridine *N*-oxides. The parent complex (X=H) has a greater μ_{eff} and its λ_{max} is at longer wavelength than the X=CH_3, Cl, *etc.* In the complexes reported in this study, however, the parent complex (X=H) has a smaller μ_{eff} and a larger λ_{max} than those complexes in which X=Cl, CH_3, benzo. The nitro substituted complex again behaves normally just as found for the nitro-substituted pyridine *N*-oxide complex; As was observed in the previous study[3] a smaller value in $\mu_{eff}^{25°C}$ leads to a shorter wavelength for λ_{max}.

The mechanism which determines the relation between $\mu_{eff}^{25°C}$ and λ_{max} seems to be different for the dimeric copper(I) complexes of substituted pyridine *N*-oxides and the dimeric copper(II) complexes under investigation here. This must be due to the fact that the pathway for transmission of the substituent effect is different for the two types of complexes.

On first thought it might be argued that this observed difference might be due to differences in the structures of the two types of complexes. This, in turn, would then lead to differences in the superexchange pathway since in the pyridine *N*-oxide complexes this pathway is through bridging oxygen atoms slightly out of the plane, whereas in the salicylaldiminato-complexes, the superexchange occurs through bridging oxygen atoms in the plane. However, as Goodenough points out[38] as long as the Cu-O-Cu angle remains about 90° the superexchange pathway is not effected by the structural differences between the pyridine *N*-oxide and the salicylaldiminato dimeric complexes.

The substituent effect in the pyridine *N*-oxide dimers is directly transmitted to bridging oxygen atom in the superexchange pathway and changes in the copper-bridging oxygen distance will directly effect the μ_{eff} and the λ_{max}.

In the substituted salicylaldiminato-complexes, on the other hand, it is proposed that the alcohol oxygen bridges and is in the superexchange pathway. Under these conditions the substitution on the benzene ring effects primarily the phenolic oxygen or imino nitrogen *not* in the superexchange pathway. The effect on the alcoholic oxygen should only be secondary and opposite in divertion as shown below.

If a methyl group is substituted into the benzene ring of the parent compound the inductive character of this group would increase the σ electron donor capacities of the phenolic oxygen and the imino nitrogen atoms. This would enhance the ligand field around the copper(II) ion and shift the d-d band toward shorter wavelengths. However, simultaneously by the increase in σ electron density in the copper(II) orbitals would decrease its electron affinity. This in turn leads to a weakening of the σ bond of the bridging alcoholic oxygen atoms trans to the phenolic oxygen or the imino nitrogen bond. Such a decrease in the covalent bond character in the superexchange pathway will in turn result in a decrease in the superexchange itself. This should produce an increase in the magnetic moment which indeed was observed as shown in Table 3.

The chloro and benzo groups in this series seem to act in the same manner. The nitro group, on the other hand, being a strong electron withdrawing enhances markedly the π backbonding capacities of the aromatic π-electron system from the copper(II) ion. As a result, compared to the parent compound

(X=H), the splitting of the d-d levels of the nitro compound will be increased.[39] Such was indeed observed by Sacconi[37] who reported the greatest "blue shift" in λ_{max} for the monomeric nitro substituted salicylaldimine-copper(II) complexes.

The mechanism of the "blue shift" seems to be the same for these monomeric and dimeric complexes. Backbonding from the copper(II) d-orbitals into the aromatic π-electron system increases the electron affinity of the copper(II) ion. This will increase the covalency of the bond from the copper(II) ion to the alcoholic oxygen atom. This, in turn, will increase its superexchange capacity and will lower the value of μ_{eff}.

The data reported in this study indeed indicate that in these complexes the alcoholic oxygen atoms are the bridging atom rather than the phenolic oxygen attached to the benzene ring.

Fruitful discussions with Dr. L. C. Cusachs are gratefully acknowledged.

Intramolecular Hydrogen Bonds. XII.[1] The Dipolar-field and the Hydrogen-bonding Effects of the Hydroxyl Group on the Carbonyl Frequencies of Aliphatic Hydroxy-carboxylates

Nobuo Mori, Yuzuru Asano and Yojiro Tsuzuki

Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received September 25, 1967)

The infrared carbonyl-stretching absorption bands of several methoxy- and hydroxy-alkanoates have been measured in dilute carbon tetrachloride solutions, and their frequency shifts from the normal bands of ethyl alkanoates have been explained in terms of the dipolar-field and the hydrogen-bonding effects of the substituents. Further, as regards the direction of hydrogen bonding, the spectral data of the hydroxy-esters lead to essentially the same conclusion as that based on their hydroxyl spectra. However, the magnitudes of the carbonyl-frequency shifts due to hydrogen bonding can not be related to those of the corresponding hydroxyl shifts.

In general, the hydrogen bonding of an alkoxycarbonyl group with a hydroxyl preferably involves the carbonyl group, rather than the alkoxy group, as the proton acceptor; the most striking spectral evidence for this is the lowering in carbonyl frequency which results from the formation of a hydrogen bond,[2,3] this lowering usually being of the order of about 10—20 cm^{-1}. In unusual cases where the alkoxy group participates in the hydrogen bonding, however, the carbonyl frequency rises about 10 cm^{-1} above the usual value.[4] This can be a criterion for deciding which of the two proton-acceptors is involved in the hydrogen bonding.

This spectroscopic method of determination has hitherto been used in elucidating similar problems in several intramolecularly hydrogen-bonded systems, such as alicyclic diol-monoacetates,[5] alicyclic hydroxy-carboxylates,[6] and pyrrole-carboxylates.[7] In their own previous papers[8-10] the present authors reported, on the basis of the hydroxyl spectra exclusively, that the intramolecular hydrogen bonding in aliphatic hydroxy-carboxylates involved predominantly the carbonyl group as the proton acceptor. In the cases of ethyl *d,l*-lactate and *d*-tartrate, the carbonyl frequencies were about 4 cm^{-1} lower in carbon tetrachloride than in ether.[8] However, the extent of frequency-lowering in the former solution did not provide any reliable evidence for the above type of hydrogen bonding. In order to elucidate this problem, the carbonyl spectra in dilute carbon tetrachloride solutions have now been measured, together with those of corresponding methylated-hydroxy compounds selected for purposes of comparison.

Experimental

Samples. All the esters examined were known compounds, some of them were commercial products and others, prepared by known methods. They were purified through several fractional distillations; their physical constants were equal or very close

to the literature values. The carbon tetrachloride was fractionally distilled over phosphorus pentoxide.

Infrared Measurement. The carbonyl-stretching spectra were measured at *ca.* 25°C, using a Hitachi EPI-2 double-beam spectrophotometer equipped with a sodium chloride prism. The measurement was carried out both in the neat state and in solutions of such low concentrations (of about 1—2 mmol/*l*) that any intermolecular hydrogen bonding, as revealed by the hydroxyl spectra,[8-10] was negligible. For the solution measurement, both the reference- and the sample-cell used had a path length of 1.0 cm. The observed frequencies were calibrated against the spectrum of a standard polystyrene film.

Results and Discussion

For purposes of comparison, a series of alkyl alkanoates (1—8) also were examined under the same conditions, since there have been no descriptions of their carbonyl data being measured in concentrations as low as 1 mmol/*l*; the spectra in solutions were almost equal to those in the neat state and they were essentially symmetric with respect to the ordinate at the apparent maximum. The peak frequencies are equal to, or very close to, the

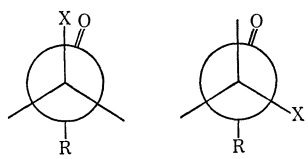
*[1] Unless otherwise noted, the esters are of the racemic form.
*[2] The frequencies are those of the apparent band-peaks described in the literature.
*[3] I, II and III denote the types of hydrogen bonding : I = C=O···HO; II = >O···HO; III = Unbonded. w = weak; sh = shoulder.
*[4] This is the bonded β-OH frequency to be associated with the OH(β)-to-OH(α) bonding.[11]

reported values, and they depend on both the type of the alcohol part and the type of the acid part, as is shown in Table 1. According to the generally-accepted explanation, this dependence can be attributed predominantly to the electronic effects, operating along the bonds, of both parts on the double-bond character of the carbonyl group. Therefore, the ethyl esters of methoxy- and hydroxy-alkanoic acids, which are the most popular, have been examined in the present study. Some typical spectra are shown in Figs. 1 and 2, while the carbonyl data are summarized, together with the hydroxyl data, in Tables 1 and 2.

Ethyl Methoxy-alkanoates. In solutions, each of the α-methoxy-esters (9—11) shows two bands; one of them appears at the normal frequency characteristic of the corresponding ester with a methyl group instead of a methoxy group, and the other, at a higher (by *ca.* 10—20 cm^{-1}) frequency. The appearance of such a boublet band has hitherto been observed in many α-halo-carbonyl compounds,[12-14] such as some α-halogenated ketones, alkanoates, aldehyds, acid halides, and amides, and, further, in several α-alkoxy-ketones[15] and in some phenoxy- and ethoxy-acetates.[13,16] The doublet has been attributed to the existence of rotational isomers showing two carbonyl frequencies, such as the forms I and II, which can be represented by Newman's projection along the C_1–C_2 bond:



cis Form (I) gauche Form (II)

where X is a highly polar group or atom. The nature of the effects causing the frequency shift has been discussed by Bellamy and Williams,[14] who attributed it primarily to the dipolar field effect operating across the space. When the negatively-charged atom or group X is close in space to the readily polarisable, negatively-charged oxygen atom of the carbonyl group, as in the form I, such a geometry results in a mutual induction of opposite charges; consequently, the carbonyl group becomes less polar, and its vibrational frequency rises above the frequency of the carbonyl group, which is twisted away from X, as in the form II. This mechanism can conveniently explain the present case; the higher frequency band can be associated with the cis form, and the lower frequency band, with the gauche form. Further, the α-methoxy group in the gauche form does not lead to any appreciable carbonyl-frequency shift (*i. e.*, the lower frequency is almost equal to the normal carbonyl frequency of the corresponding ester with a methyl group instead of a methoxy group). This does not necessarily suggest, however, that all inductive effects are absent; rather, it could be due to the cancellation of the inductive effects by small residual field effects, which in that form would be expected to operate in the opposite direction. Such a cancellation has been suggested in accounting for a similar behavior of α-halogens observed in several carbonyl compounds.[14]

Ethyl β-methoxypropionate (12) shows a single band that is identical in both shape and frequency with that of ethyl propionate (5). This indicates that the methoxy group in the β-position, and probably also in a more separated position, has no influence on the carbonyl double-bond character.

Diethyl mono- and di-methoxysuccinate (13 and 14) each shows a doublet band the peak-frequency and relative intensity of which agree with that would be expected from their structures; the monomethoxy-ester shows the overlapped spectra of ethyl α- and β-methoxypropionates (10 and 12), while the dimethoxy-ester shows nearly the same spectrum as that of ethyl α-methoxypropionate.

Ethyl Hydroxy-alkanoates. The α-hydroxy-esters (15—19) show, in solutions, a single, almost symmetric band at nearly the same frequency as the lower-frequency band of the corresponding α-methoxy-esters. This suggests that the hydroxy-esters exist predominantly in an internally-bonded cis-geometry. If the carbonyl and the hydroxyl group (X) are in the cis-relationship, as in the form I,

the dipolar electrical forces operating across the space between the groups would raise the carbonyl frequency, much as in the case of the α-methoxy-esters, while the possible hydrogen bonding between them should have the effect of decreasing the carbonyl frequency. On the other hand, if the groups are situated as in the form II, the carbonyl frequency may be expected to be nearly equal to the lower frequency of the corresponding α-methoxy-esters, while the possible hydrogen bonding between the hydroxyl and the ethoxy group (R) should raise the carbonyl frequency. The observed frequencies indicate the preferential existence of the internally-bonded cis-form or the internally-unbonded gauche-form. In reality, however, the latter can not be considered. Nevertheless, this does not obviate the existence of the internally-bonded gauche-form, *i. e.*, another type of hydrogen bonding which involves the ethoxy group as a proton acceptor, because the resolution power of the instrument used is not strong enough to detect a weaker band which may appear at a slightly separated position. The above indication is in good agreement with the conclusion, previously reported on the basis of the hydroxyl spectra,[8-10] that the hydrogen bond is predominantly formed on to the carbonyl group, the ethoxy group being involved to only a minor extent.

In solutions, the β-hydroxy-esters (20 and 21) show, apart from the normal-frequency band appearing as a shoulder, a stronger band at a lower (by *ca.* 20 cm^{-1}) frequency. Since the β-hydroxyl group is expected to have no field and electronic effects, like the β-methoxy group, the strong band can reasonably be assigned to the bonded carbonyl group,*1 and the shoulder, to the free carbonyl group. This provides other striking evidence for the conclusion, previously deduced from their hydroxyl spectra,[10] that the hydrogen bonding in these esters involves the carbonyl group predominantly, while their unbonded molecules are much lower in proportion.

The other higher ω-hydroxy-esters (22—24) show no bonded-carbonyl band, although their hydroxyl spectra indicated that only one of them, ethyl ε-hydroxycaproate (22), was internally bonded to a very small extent.[10] Accordingly, a very weak band due to the bonded carbonyl group in the ester (22) probably overlaps the observed free-carbonyl band.

Diethyl malate (25) and tartrates (26 and 27) show a single band, whose frequency is close to the lower frequency of the corresponding mono- or di-methoxysuccinate (13 or 14). Therefore, the type of hydrogen bonding in these esters is essentially the same as in the α-hydroxy-esters, as was previously concluded on the basis of their hydroxyl spectra.[8,9] Similarly, ethyl α,β-dihydroxybutyrates (28 and 29) form a hydrogen bond between the α-hydroxyl and the carbonyl group, as is indicated by their having the same carbonyl data as the α-hydroxy-esters and as was previously conjectured on the basis of their hydroxyl spectra.[11]

In the neat state, the spectra of all the mono- and di-hydroxy-esters are interesting in comparison with their spectra in solutions. Although the hydroxyl bands in the neat state are very broad and shift greatly towards the lower-frequency side as compared with the spectral bands in solutions, the carbonyl bands, except for those of the β- and the higher ω-hydroxy-esters, remain nearly unchanged in both frequency and band shape. In the β-hydroxy-esters (20 and 21), the relative intensities of the higher-frequency bands to the lower ones are reversed, while in the higher ω-hydroxy-esters (22—24) a new band appears as a shoulder on the lower-frequency side. The authors can not give any decisive explanation for this observation, because more complex, unknown intermolecular interactions are probably involved in the liquid state.

The authors wish to thank Mr. Yutaka Kikuchi of this University for his infrared measurements. Their thanks are also due to the Ministry of Education for its grant-in-aid for Fundamental Scientific Research.

*1 Note Added in Proof : We have recently been informed by Professor P. von R. Schleyer of Princeton University of his study of intramolecular hydrogen bonding between the π-electrons on a carbonyl oxygen atom and a hydroxyl group in hydroxy-carbonyl compounds. He regards, exclusively on the basis of a comparison of $\Delta\nu_{OH}$'s and possible conformations, that the hydrogen bonding in β-hydroxy-ketones involves the π-electrons as the predominant proton acceptor, while in α-hydroxy-ketones the n-electrons on the oxygen atom is the proton acceptor. The same may be suggested in the cases of the α- and β-hydroxy-esters examined, since they have essentially the same $\Delta\nu_{OH}$ values and possible conformations as have the corresponding hydroxy-ketones.

The Cobalt Carbonyl-catalyzed Intramolecular Hydroesterification of Allyl Alcohol with Carbon Monoxide

Akio MATSUDA

Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo

(Received November 1, 1967)

The intramolecular hydroesterification of allyl alcohol with carbon monoxide to give γ-butyrolactone occurred in the presence of cobalt carbonyl under the pressure of carbon monoxide containing a small amount of hydrogen; propionaldehyde and isobutyraldehyde were produced as by-products. The selectivity toward γ-butyrolactone increased with the use of acetonitrile or its derivatives as the solvent. The addition of pyridine, in the absence of these solvents, was effective only in increasing the reaction rate, not in increasing the selectivity toward γ-butyrolactone. On the other hand, in the presence of acetonitrile as a solvent, the selectivity toward γ-butyrolactone increased together with the reaction rate when a catalytic amount of an organic base such as pyridine was added. The higher the reaction temperature, the higher the pressure necessary to attain a maximum selectivity toward γ-butyrolactone; the best yield of γ-butyrolactone was *ca.* 60%. The effect of the partial pressures of hydrogen and carbon monoxide on the initial rate of the formation of each product was made clear. The experimental results were explained by a mechanism involving two different paths for the formation of an alkylcobalt carbonyl-intermediate. The order of effectiveness of acetonitrile and its derivatives as solvents has been interpreted in terms of the HSAB principle by Pearson *et al.*

In a preceding paper on the cobalt carbonyl-catalyzed hydroesterification of acrylonitrile with carbon monoxide and methanol, it was reported that the reaction carried out in the presence of a small amount of hydrogen proceeded rapidly upon the addition of as little pyridine (Py) as 1—4 in terms of the Py/$Co_2(CO)_8$ mole ratio, and that the reaction resulted in a high yield of methyl cyanopropionate, while in the absence of Py the reaction proceeded very little.[1]

In the present study, the possibility of using this method for the synthesis of hydroxymethylbutyrate from allyl alcohol, carbon monoxide, and methanol was first tested. As a result, the intramolecular hydroesterification of allyl alcohol with carbon monoxide to give γ-butyrolactone, the isomerization of allyl alcohol to give propionaldehyde, and the hydroformylation of allyl alcohol with carbon monoxide and hydrogen to give β-hydroxyisobutyraldehyde, which can then be readily dehydrated and hydrogenated into isobutyraldehyde, were found to occur, but not the expected hydroesterification of allyl alcohol with carbon monoxide and methanol to give hydroxy-methylbutyraet.

Adkins and Kresk tested the hydroformylation of allyl alcohol with carbon monoxide and hydrogen and obtained γ-hydroxy-butyraldehyde.[2]

Goetz and Orchin studied the isomerization of allyl alcohol with cobalt hydrocarbonyl, which gave propionaldehyde.[3]

The report by Falbe concerning the ring-closure reactions with carbon monoxide describes the reaction between allyl alcohol and carbon monoxide in the presence of dicobalt octacarbonyl, but the yield of the resulting γ-butyrolactone is reported to be as little as 2%.[4]

The aim of the present investigation, in this connection, is directed at obtaining γ-butyrolactone in as good an yield as possible by the intramolecular hydroesterification of allyl alcohol with carbon monoxide. The synthesis of γ-butyrolactone from allyl alcohol and carbon monoxide may be interesting from

an industrial point of view. Moreover, the present reaction may be convenient for determining the factors governing the rate of double-bond isomerization and the factors governing the rate of carbonylation, because, as was pointed out by Goetz *et al.*,[3] if the double-bond isomerization of allyl alcohol should occur, the isomerized product would tautomerize rapidly to propionaldehyde, so equilibrium reactions are unlikely.

Experimental

Such reagents as allyl alcohol, acetonitrile, and pyridine were obtained commercially and rectified before use, except for nicotine and nicotinic acid, which were used without rectification. The synthesis gas was prepared by mixing carbon monoxide with an appropriate amount of hydrogen so that the desired percentage of hydrogen could be obtained. Carbon monoxide and dicobalt octacarbonyl were prepared by the procedure described previously.[5]

The reactions were carried out in a 100-cc stainless-steel autoclave equipped with a magnetic up-and-down stirrer, using essentially the same procedure as was described previously.[1] The reaction temperature was controlled within a range of ±1°C. In the case of the constant-pressure experiment, the synthesis gas was automatically supplied by means of a pressure regulator from a pressure storage vessel in order to keep the total pressure constant throughout the reaction. The amount of gas supplied during the reaction was calculated from the pressure drop in the pressure storage. Experiments at pressures over 300 kg/cm² were carried out with another apparatus, one which had been designed for use at pressures of 1000 kg/cm², but the method of the experiments was essentially the same as in the case of experiments at pressures lower than 300 kg/cm², except that the pressure level in the pressure storage was recorded during the reaction by means of a Strain gauge for the sake of accuracy.

The product composition was quantitatively determined by the gas chromatographical method: the γ-butyrolactone was analyzed with a 3-m column of ethyleneglycol-adipic acid polyester by adding octylacetate, as an internal standard, to the reaction product at the temperature of 200°C, while lower-boiling components, such as propionaldehyde, isobutyraldehyde, and allylalcohol, were analyzed with a 3-m column of ethyleneglycol-adipic acid polyester plus a 2-m column of dioctylphthalate by adding toluene as an internal standard at the temperature of 100°C.

Results

The Effect of Solvents. Preliminary experiments carried out under conditions similar to those of Table 1 showed that the yield of γ-butyrolactone was larger in the absence of a solvent than in the presence of such a solvent as methanol and benzene; they thus suggested that a solvent might have some effect, whether positive or negative, on the selectivity of the reaction. Experiments were, therefore, carried out with various kinds of solvents in order to test their effects, the Py/$Co_2(CO)_8$ mole ratio being kept constant at the optimum value of 1. The results are summarized in Tables 1 and 2.

Solvents such as acetonitrile and its derivatives, as can be seen from Tables 1 and 2,

a) The amount of gas supplied during the initial 10 min is listed in Tables 2—6 as a rough measure of the initial rate.

are effective in increasing the selectivity toward γ-butyrolactone and in decreasing the selectivity toward propionaldehyde and the residue, but the reaction rate is decreased by these solvents; these effects are apt to be enhanced by the use of a larger amount of such a solvent. Benzonitrile, unlike acetonitrile or its derivatives, has no effect on the selectivity toward γ-butyrolactone.

The effectiveness of such acetonitrile derivatives as $HOCH_2CN$, CH_3OCH_2CN, and $C_6H_5CH_2CN$ in increasing the selectivity toward γ-butyrolactone decreases in the order $HOCH_2CN > CH_3OCH_2CN > C_6H_5CH_2CN$. When methyl-substituted acetonitriles are used as solvents, the above effectiveness decreases as the number of methyl-substitution increases, *i.e.*, in the order $CH_3CN > CH_3CH_2CN > (CH_3)_2CHCN$.

Aldehyde and formic esters as solvents have almost no effect on the selectivity toward γ-butyrolactone. Such ethers as diethyl ether and dioxane, however, when used as solvents increase the selectivity toward propionaldehyde and decrease the selectivity toward γ-butyrolactone. Methanol and benzene also increase the selectivity toward propionaldehyde and decrease the selectivity toward γ-butyrolactone, but their effects are smaller than those of ethers.

The Effect of Acetonitrile as a Solvent and the Effect of the Addition of Py and Other Organic Bases. The selectivity toward γ-butyrolactone has thus been found to increase remarkably with the use of acetonitrile as a solvent and with the use of an amount of Py equimolar to $Co_2(CO)_8$. Experiments were then carried out in the absence of both acetonitrile and Py, in the presence of acetonitrile and no Py, in the presence of Py and no acetonitrile, in the presence of acetonitrile with various amounts of Py, and in the presence of acetonitrile with various kinds of bases other than Py. The results are shown in Table 3.

Evidently, the addition of Py increases the reaction rate, it but does not by itself affect the selectivity, while acetonitrile, when used as a solvent, is, even in the absence of Py, effective in increasing the selectivity toward γ-butyrolactone and in decreasing the selectivity toward propionaldehyde and the residue. Clearly, acetonitrile is effective in increasing the selectivity toward γ-butyrolactone simply because it retards the formation of propionaldehyde and the residue, not because it accelerates the formation of γ-butyrolactone, for Tables 2 and 3 indicate that the reaction rate rather decreases upon the use of acetonitrile as a solvent. Both the reaction rate and the selectivity toward γ-butyrolactone, in the presence of acetonitrile as a solvent, increase as the amount of Py is increased, reach maxima when the $Py/Co_2(CO)_8$ mole ratio is

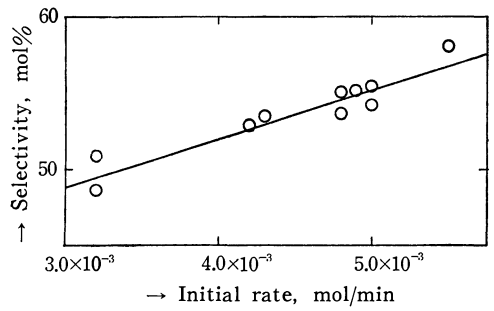

Fig. 1. The relation between the selectivity toward γ-butyrolactone and the initial rate.

1, and then decline. In fact, from the results of experiments carried out with acetonitrile as a solvent in the presence of various amounts of Py or other organic bases, an almost linear relation between the reaction rate and the selectivity toward γ-butyrolactone was obtained, as is shown in Fig. 1. This means that the intramolecular hydroesterification, in the presence of acetonitrile as a solvent, is fairly selectively accelerated by the addition of Py or other organic bases.

The Effect of Pressure and Temperature. The results of experiments which were carried out under various pressures at the constant temperatures of 100, 120, and 130°C are shown in Tables 4 and 5. Clearly the selectivity toward propionaldehyde decreases as the pressure increases, while that toward isobutyraldehye increases. The selectivity toward γ-butyrolactone reaches its maximum at a certain pressure, which increases along with the temperature; the pressure for the best selectivity is 100 kg/cm² at 100°C, 300 kg/cm² at 120°C, and 500 kg/cm² at 130°C.

The results of the experiments carried out under the constant pressures of 400, 600, and 800 kg/cm² at various temperatures are shown in Table 6. Clearly the selectivity toward propionaldehyde increases along with the temperature. The higher the pressure, the higher the optimum temperature for attaining the best selectivity toward γ-butyrolactone; it is 130°C under 400 kg/cm², 140°C under 600 kg/cm², and in the 150—160°C range under 800 kg/cm².

The Effects of the Partial Pressures of Hydrogen and Carbon Monoxide. In order to understand the effect of the total pressure on the rate of the formation of each product, the effects of the partial pressures of hydrogen and carbon monoxide must be examined.

Constant-pressure experiments were carried out at 120°C with 1/4 mol of allyl alcohol, 1/2 mol of acetonitrile, 2 mmol of $Co_2(CO)_8$, and 2 mmol of Py, the composition of the synthesis gas used and the total pressure being varied so that the desired initial partial pressures of hydrogen and carbon monoxide could be attained. Aliquots of the reacting solution were withdrawn from the autoclave at definite intervals of time from the beginning of the reaction and were analyzed in order to

determine the individual products. Examples of the plot of the yields of individual products against the reaction time are shown in Fig. 2. In Table 7 are summarized the initial rates calculated on the basis of results of analyses of samples withdrawn at the reaction time of 20 min; the initial rates of the formation of γ-butyrolactone, propionaldehyde, and isobutyraldehyde are denoted by v_1, v_2, and v_3 respectively. The specific increments of the initial rates of the formation of individual products caused by a unit increase in the hydrogen partial pressure, $\Delta v_{1,2,3}/v_{2,2,3}\Delta P_{H_2}$, and those caused by a unit increase in the carbon monoxide partial pressure, $\Delta v_{1,2,3}/v_{1,2,3}\Delta P_{CO}$, were calculated from Table 7. Table 8 lists the specific increment of v caused by a 10 kg/cm² increase in $P_{H_2}(10\Delta v_{1,2,3}/v_{1,2,3}\cdot\Delta P_{H_2})$, and the specific increment of v caused by a 100 kg/cm² increase in P_{CO} $(100\Delta v_{1,2,3}/v_{1,2,3}\Delta P_{CO})$. It is clear from Table 8 that v_1, v_2, and v_3 all increase along with increases in the hydrogen partial pressure, v_3 increasing most conspicuously; that v_1 and v_2 decrease with increases in the carbon monoxide partial pressure, v_2 decreasing more than v_1, and that v_3 is essentially independent of the carbon monoxide partial pressure.

Discussion

Since the rates of the formation of γ-butyrolactone, propionaldehyde, and isobutyraldehyde all increase with increases in the hydrogen partial pressure, cobalt hydrocarbonyl evidently plays a part in each of these formations. The cobalt hydrocarbonyl-catalyzed isomerization of allyl alcohol is assumed to take place through the hydrogen-shift in an intermediate π-complex, which is formed between coordinately-unsaturated cobalt hydrotricarbonyl and allyl alcohol, just as is usually assumed in the case of the metal carbonyl-catalyzed isomerization of olefins.[6,7]

Since the overall reaction rate in the present experiment decreases with an increase in the carbon monoxide partial pressure, the first step of the reaction would involve, at least partially, the formation of cobalt hydrotricarbonyl, as was proposed by Heck *et al.* to

explain the inhibition by CO of the reaction of cobalt hydrotetracarbonyl with olefins.[8]

In a preceding paper on the hydroesterification of acrylonitrile,[1] two separate paths were proposed for the formation of alkylcobalt tetracarbonyl; one was the direct addition of $HCo(CO)_4$ to acrylonitrile, while the other was the path which goes through an acrylonitrile π-complex. In the present paper, also, the reaction mechanism will be discussed taking into account the possibility of the two separate above-mentioned paths.

The catalytic mechanism shown below can explain the experimental results; S denotes a solvent such as acetonitrile, while L denotes a basic ligand such as Py. The intermediate cobalt hydrotricarbonyl is assumed to form a complex with a solvent molecule before it reacts with allyl alcohol, since it is coordinately unsaturated and can, therefore, easily be attacked by surrounding molecules. A basic ligand such as Py (L) is assumed to take part in the reaction by forming complexes (VI) and (VII), since it was proved in a previous study that Py was necessary for the formation of acylcobalt carbonyls.[1]

Acetonitrile forms a complex with metal carbonyls, and, according to Cotton,[9] it possesses a small but real ability to accept π-electrons in competition with CO groups. Accordingly, the complex (I), when S is acetonitrile, will be comparatively stable as a result of π-bonding. The concentration of the complex (II) will, therefore, decrease with an increase in the concentration of acetonitrile as a solvent according to the equilibrium relation (2). Hence, the isomerization, which proceeds *via* the complex (II), will be retarded when acetonitrile is used as a solvent, and the selectivity toward the intramolecular hydroesterification, which can proceed *via* another path, will, relatively, increase; this is in good agreement with the results shown in Table 1. The residue of the analysis shown in Table 1—6, which is an aldolic polymer with a molecular weight of 290,[10] seems to be formed, at least in part, *via* the complex (II), since the selectivity toward the residue decreases together with the selectivity toward propionaldehyde as the amount of acetonitrile increases; however, the exact mechanism of its formation is not known.

The facts that, in the presence of acetonitrile as a solvent, the initial rate increases upon the addition of a small amount of pyridine or another organic base as a ligand (L), and that the selectivity toward γ-butyrolactone in this case increases in proportion to the initial rate (Fig. 2), can be understood by this scheme, for when the step (IV)→(VI) is accelerated by the addition of L, the extent of the isomerization and the polymerization, which are assumed to be independent of the concentration of L, will relatively decrease, and consequently the selectivity toward γ-butyrolactone

will increase. The retarding effect of Py on the overall reaction when the $Py/Co_2(CO)_8$ mole ratio exceeds 1 may be due to the formation of pyridinium salt of cobalt hydrocarbonyl, as was proposed in a previous study.[1)]

The fact that the selectivity toward isobutyraldehyde increases with an increase in the hydrogen partial pressure is reasonable, since the rate of the hydrogenolysis of VII by hydrogen or $HCo(CO)_4$ will increase with an increase in the hydrogen partial pressure.[11)] The hydrogenolysis of VII, therefore, should be the rate-determining step in the isobutyraldehyde formation; this well accounts for the other experimental fact that the rate of isobutyraldehyde formation is essentially independent of the carbon monoxide partial pressure.

Considering the two equilibrium relations, (1) and (2), it is clear that the larger the carbon monoxide partial pressure, the smaller the concentration of the complex (II) becomes. Hence, the rate of propionaldehyde formation *via* the complex (II) must decrease with an increase in the carbon monoxide partial pressure, while the rate of γ-butyrolactone formation, if it can proceed *via* another path, as is assumed in the scheme, must not be so much retarded by the increase in the carbon monoxide partial pressure. In fact, the results in Table 8 shows that the rate of propionaldehyde formation is retarded by the increase in the carbon monoxide partial pressure to a larger extent than that of γ-butyrolactone formation. Thus, the presence of the two different paths, assumed in the scheme is supported by this fact.

11) Neither γ-hydroxybutyraldehyde, which may be formed by the hydrogenolysis of VI, nor β-isobutyrolactone, which may be formed by the intramolecular alcoholysis of VII, could be detected in the reaction products; this may be because the intramolecular alcoholysis of VI is very fast, and that of VII, very slow.

Although it is conceivable that the more stable the complex (II) is made by the choice of the solvent (S), the larger the selectivity toward γ-butyrolactone becomes, no better solvent than acetonitrile has yet been found.

The fact that the effectiveness of solvents in increasing the selectivity toward γ-butyrolactone decreases in the order $CH_3CN > CH_3CH_2CN > (CH_3)_2CHCN > C_6H_5CN$ seems to be related to the concept of HSAB by Pearson *et al.*[12,13)] They pointed out that the hardness and, consequently, the electronegativity of the carbonium ion decreases in the order $C_6H_5^+ > (CH_3)_3C^+ > (CH_3)_2CH^+ > CH_3CH_2^+ > CH_3^+$.[13)] Accordingly, the softness of the above-mentioned solvents must decrease in the order $CH_3CN > CH_3CH_2CN > (CH_3)_2CHCN > C_6H_5CN$. Hence, according to the principle of HSAB, the complexing ability of these solvents with regard to zero-valent cobalt, which is classified as in the group of soft acids,[12)] must decrease in this order. Thus the ability of these solvents (S) to decrease the concentration of complex (II) by means of the equilibrium relation (2) shown in the above scheme and, therefore, their ability to increase the selectivity toward γ-butyrolactone by reducing the rate of isomerization, should decrease in that order also.

A similar effect of nitriles in reducing the isomerization was observed by Roos *et al.*, who studied the effect of nucleophiles on the stoichiometric hydroformylation of 1-pentene.[14)]

The author is indebted to Mr. Toshiro Minegishi for his aid in constructing the high-pressure apparatus and to Dr. Ken-ichiro Bando for his discussions.

Solvolysis of *cis* and *trans* 2-Cyclohexylcyclohexyl, 2-Phenylcyclohexyl and 2-*p*-Anisylcyclohexyl *p*-Toluenesulfonate

Shun-Ichi MURAHASHI and Ichiro MORITANI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received December 21, 1967)

trans-2-*p*-Phenylcyclohexyl *p*-toluenesulfonate acetolyzes (75°C), at one-eighth of the rate of cyclohexyl *p*-toluenesulfonate, and one-sixteenth times smaller than that of the *cis* isomer. *trans*-2-*p*-Anisylcyclohexyl *p*-toluenesulfonate acetolyzes (75°C) much the same as cyclohexyl *p*-toluenesulfonate, and one-third times smaller than that of the *cis* isomer. Thus, the slow rate of the trans isomers cannot be interpreted in term of significant phenyl and *p*-anisylparticipation. This may be due to high cost in energy required to place the aryl group in the axial position where it would be in a favorable position to participate. However, it is noteworthy that the acetolysis of *trans*-2-*p*-anisylcyclohexyl *p*-toluenesulfonate gave *trans*-2-*p*-anisylcyclohexyl acetate in 70% yield, which had retention of configuration. The mechanism of this reaction is discussed. The greater reactivities of *cis* isomers are interpreted in terms of E_2 type elimination involving nucleophilic participation by the solvent as well as 2-alkylcyclohexyl *p*-toluenesulfonate.

On the cyclohexyl system the conformation of substituent might be consider to be fixed because the chair form is by far stable.[1] Thus it is very suitable to investigate the cyclohexyl system stereochemically or kinetically. Since the acceleration of rate or the stereochemistry of the reaction of aliphatic compounds is usually interpreted in terms of neighbouring participation or bridged nonclassical carbonium ion,[2] it is interesting to investigate these concepts in cyclohexyl system. The neighbouring participation of acetoxy,[3] halogen[4] and methoxy[5] groups are already investigated. In the acetolysis of *trans*-2-acetoxycyclohexyl *p*-toluenesulfonate the reactivity of *cis* isomer is 630 times greater than that of the *trans* one, and *trans* acetate which has retention of configuration is obtained. Furthermore, the acetate which is obtained from optically active *p*-toluenesulfonate is found to be racemic. These results are reasonably explained by assuming that symmetrical bridged ion is involved as an intermediate.[3]

We have investigated on behavior of the neighboring participation of cyclohexyl, phenyl and anisyl groups in cyclohexyl system.

Results

Preparation of Materials and Infrared Spectra. The *cis* and *trans* isomers of 2-cyclohexylcyclohexanol (Ia), (IIa) and 2-phenylcyclohexanol (IIIa), (IVa) were prepared with the usual manner.[6,7] *trans*-2-*p*-Anisylcyclohexanol (VIa) was prepared by the reduction of the corresponding ketone with lithium aluminum hydride or hydrogenation-oxidation of 1-*p*-anisylcyclohexene. The latter reaction is better than the former one. On the other hand the hydrogenation of 2-*p*-anisylcyclohexanone in the presence of platinum black catalyst gave the *cis* isomer (Va).

The infrared spectra of these isomeric alcohols obtained above are consistent with the conformational assignment. It has been pointed out that alkyl substituted cyclohexanol with an equatorial hydroxyl can be distinguished from the epimers with an axial hydroxyl by the position of C–O stretching frequency.[8] The *cis* isomer (axial) of 2-cyclohexyl, 2-phenyl and 2-*p*-anisylcyclohexanol showed absorption at 968, 964 and 965 cm^{-1} (KBr) respectively, the *trans* isomers (equatorial) at 1044, 1057 and 1056 cm^{-1}.

p-Methoxybenzalcyclopentane (XIV) which might be formed as the ring contraction product was obtained through the path A as shown in Scheme I. On the other hand, from the path B the alcohol XIII was not obtained, since the alcohol XV was easily dehydrated to give *p*-methoxybenzalcyclopent-1-ene (XVI).

Kinetic Experiments. The results of the kinetic measurements are listed in Table 1. Acetolyses of the isomeric *p*-toluenesulfonates in the presence of pottasium acetate are first order and the rates are increased only slightly over that observed in the absence of added acetate ion except *trans*-2-*p*-anisylcyclohexyl *p*-toluenesulfonate.[9]

The *cis* isomers are solvolyzed faster than the *trans* isomers respectively. However, the

8) W. Hückel and Y. Riad, *Ann.*, **637**, 33 (1960); W. Hückel and J. Kunze, *ibid.*, **645**, 194 (1961).

9) Special salts effect has been observed about *trans*-2-*p*-anisylcyclohexyl *p*-bromobenzenesulfonate (A. N. Fainberg, G. C. Robinson and S. Winstein, *J. Am. Chem. Soc.*, **78**, 2278 (1956)).

acetolysis rate of *trans*-2-*p*-anisylcyclohexyl *p*-toluenesulfonate is smaller than that of *cis* isomer, and the value of $\Delta H^{\neq}$ of *trans* isomer is larger than that of *cis* isomer. In the system without lyate ion, the rate is approximately half of that containing lyate ion, and showes $\Delta H^{\neq}=30.7$ kcal/mol and $\Delta S^{\neq}=6.7$ e.u.

Products. The lyate ion salt was present in slightly excess and the products were isolated after the reaction proceeded to ten half lives. The results are shown in Table 2. The solvolysis products were extracted followed by injecting to preparative v. p. c. The control experiments showed that the products were stable under the condition of the reactions, and fractionation during the isolation process was found to be slight and probably not significant. The analytical data by means of v. p. c. were suported by another method shown in Table 2. The acetolysis products of *trans*-2-*p*-anisylcyclohexyl *p*-toluenesulfonate were separated by column chromatography followed by reduction with lithium aluminum hydride, and it was ascertained the main product was *trans*-2-*p*-anisylcyclohexanol. It is noted that the main product is *trans*-2-*p*-anisylcyclohexyl acetate, which has the retention of configuration. Furthermore, the formation of *p*-methoxybenzalcyclopentane (2%) was detected by means of v. p. c.

Discussion of Results. The data on all of the compounds are summarized in Table 3, giving extrapolated or interpolated rate constants at 75°C. In addition, relative rates for cyclohexyl *p*-toluenesulfonate[10] are given for reference. As shown in Table 3 *cis* isomer (axial) solvolyzes faster than the *trans* isomer (equatorial) respectively.

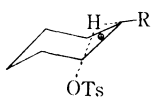
In these substances the sizes of cyclohexyl, phenyl and *p*-anisyl groups are sterically large enough to suppose these groups occupy the equatorial position ; in other words tosyl group occupies the axial position in the *cis* isomer, on the other hand the equatorial position in the *trans* isomer.

It appears that the greater reactivity of 2-cyclohexylcyclohexyl *p*-toluenesulfonate is due to steric acceleration. Scale model indicates that the 2-cyclohexylcyclohexyl system, unlike the 2-phenyl and 2-*p*-anisylcyclohexyl system, is quite congested and rotation of cyclohexyl and tosyl groups is restricted.

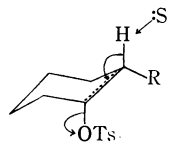
The axial-equatorial ratio of cyclohexyl *p*-toluenesulfonate is three owing to the 1,3-diaxial interaction.[11] In the case of 2-cyclohexyl and 2-phenylcyclohexyl *p*-toluenesulfonate the *cis*/*trans* ratio is respectively 16 and 17, so the *cis* isomers are more accelerated than the trans isomers. Inspection of these relative reactivities shows that in both isomers, there may be some factors to be account for the acceleration except that of 1,3-diaxial interaction. In order to aspect this factor, the products of acetolysis were investigated. As shown in Table 2 *cis* isomers gave mainly 1-olefin accompanied with a small amount of 3-olefin and acetate, although *trans* isomers gave 1-olefin and considerable large amounts of 3-olefin and *cis* acetate. Thus the formation of different products from the two

10) H. C. Brown and G. Ham, *ibid.*, **78**, 2735 (1956).
11) I. Moritani, S. Nishida and M. Murakami, *ibid.*, **81**, 3420 (1959).

isomers shows that the products are not derived entirely from a dissociated 2-substituted cyclohexyl cation, since this intermediate would be common to both isomers. These results suggest that in the case of *trans* isomer, the transition state involves the classical carbonium ion. On the other hand in the *cis* isomer two explanations may offer themselves to rationalize these results; (a) E_1 type elimination involving the bridged ion XVIII or (b) E_2 type elimination by the solvent as illustrated by XIX.



XVIII



XIX

The high solvolysis rate of vicinally *cis* alkylcyclohexyl *p*-toluenesulfonates is due to participation of the adjacent hydrogen atom, though no details of the reaction products are given.[12] Recently this was supported by the study of β-deuterium isotope effect in solvolytic reaction.[13] However, by the systematic study of 2-alkylsubstituted cyclohexyl *p*-toluenesulfonate, it was revealed that the reaction was E_2 type elimination involving nucleophilic participation by the solvent.[14]

The acetolysis rates of *trans*-2-alkylcyclohexyl *p*-toluenesulfonates increase as the bulk of the substituent becomes larger, $CH_3 < i\text{-}C_3H_7 < C_6H_{11} < t\text{-}C_4H_9$. This may be also interpreted in terms of increasing steric effect by substituent. Nevertheless, the order of the rate ratio of *cis*/*trans* for each *p*-toluenesulfonate is found to $t\text{-}C_4H_9 < C_6H_{11} < i\text{-}C_3H_7 < CH_3$. This tendency may not be due to inductive effect but hyperconjugation. Therefore in the transition state of acetolysis of *cis* isomers the reaction may proceed through the *trans* elimination. Furthermore, it has been reported that the hydrogen participation is not effective in the solvolysis of neomenthyl,[15] 3-cyclohexyl-2-butyl[16] and 2-*t*-butylcyclohexyl *p*-toluenesulfonate.[17] Thus the accelerated rate of *cis*-2-cyclohexylcyclohexyl *p*-toluenesulfonate is considered to be arised from a predominating bimolecular solvolysis (*trans*-elimination).

TABLE 4. RATES AND RELATIVE RATES FOR ACETOLYSIS OF 2-ALKYLCYCLOHEXYL *p*-TOLUENESULFONATES (75°C)

2-Alkyl substituted cyclohexyl *p*-toluenesulfonate	CH_3	$i\text{-}C_3H_7$-	C_6H_{11}-	$t\text{-}C_4H_9$-
k_1^{trans} (10^5)	1.56	9.22	16.5	352
k_1^{trans}/k_0^{trans}	1.00	5.91	10.6	226
k_1^{cis} (10^5)	79.5	221	278	634
k_1^{cis}/k_0^{cis}	1.00	2.78	3.50	7.98
cis(a)/*trans*(e)	51	24	17	1.8

Turing to the π-electron neighbouring system, the similar result was obtained concerning to 2-phenylcyclohexyl *p*-toluenesulfonate as shown in Tables 2 and 3. The data suggest that the reaction mechanism of acetolysis of this *p*-toluenesulfonate is same as that of 2-alkylcyclohexyl *p*-toluenesulfonate. The rate retardation observed is presumably due to the inductive effect of phenyl group.

The *trans* isomer solvolyzes not faster but slower, at one-eighth of the rate of cyclohexyl *p*-toluenesulfonate, and one-sixteenth times smaller than that of the *cis* isomer. The slow rate of the *trans* isomer cannot be interpreted in terms of significant phenyl participation. In the present case we can rationalize the failure to observe participation to the high cost in energy required to place the phenyl group in the axial position where it would be a favourable position to participate.

For the sake of comparison, rate and products of acetolysis were studied on 2-*p*-anisylcyclohexyl *p*-toluenesulfonate. In the case of *cis* isomer, the results shown in Tables 3 and 4 are similar to that of *cis*-2-phenylcyclohexyl *p*-toluenesulfonate. This indicates that *cis* isomer proceeds through *trans* elimination. On the contrary, *trans*-2-*p*-anisylcyclohexyl *p*-toluenesulfonate gave different products from those obtained from 2-alkylcyclohexyl *p*-toluenesulfonate, *viz.* the main product was not 1-olefin but acetate (70 %), which was produced by retention of configuration, *trans* acetate.

The products of retention of configuration might be obtained from double inversion, that is, phenyl participation. It leads to the

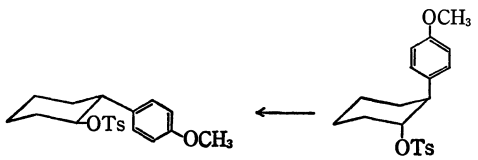
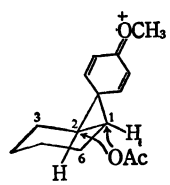
17) K. Okamoto and K. Saito, The Abstract of the 18th Conference on the Reaction Mechanism of Organic Reaction at Kyoto 1967, page 81.

rate enhancement and retention of configuration through bridging of phenyl group. The powerful participation effect of *p*-anisyl group[18] and the formation of bridged *p*-anisonium ion in strong acid[19] have been observed. However, since the *trans* isomer VI solvolyzes slower than cyclohexyl *p*-toluenesulfonate, it seems likely that *p*-anisyl participation is not important in the reaction of this compound. This may be due to high cost in energy required to place the *p*-anisyl group in the axial position where it would be in a favourable position to participate.



XX XXI

We therefore propose the following mechanism. The rate determining step is the formation of classical carbonium ion. *p*-Anisyl group can migrate just before carbonium ion is formed at C_1, then the intermediate XXII may be formed. The newly formed bridged ion XXII may be a considerable stable intermediate of so called dienon type.[20]



XXII

When the bridged ion is opened by acetate ion, the products, which possess the same configuration as the starting materials, are obtained. Olefins might be obtained through abstraction of proton by solvent. The fact that 3-*p*-anisylcyclohexene is mainly obtained may be rationalized by suspecting the easy abstraction of proton at C_3 or C_6.

It is noteworthy that *p*-methoxybenzal cyclopentane, the rearranged ring contracted product, was detected only as low as 2% yield. The migration of methylene group may be far less than that of *p*-anisyl group in this compound.

Experimental

All melting points ware uncorrected. The IR spectrum was recorded by the use of an EPI-S2 apparatus. The UV spectrum was recorded by the use of an EPS-2U apparatus.

Materials. *2-Cyclohexylcyclohexanone.* 1-Chlorocyclohexylcyclohexanone was prepared by condensation of cyclohexanone by the method of Kunze,[21] in 70% yield, bp 115°C/6 mmHg (lit.[22] bp 140°C/18 mmHg), semicarbazone, mp 182—183°C (lit.[22] mp 182—183°C). This ketone was converted to 2-cyclohexylidenecyclohexanon by treatment with sodium methoxide in 82% yield, mp 57°C (methanol) (lit.[23] mp 57°C), semicarbazone mp 186.5—188°C. Moreover hydrogenation of 2-cyclohexylidenecyclohexanone over PdO_2-$CaCO_3$ catalysts gave 2-cyclohexylcyclohexanone in 98% yield, bp 126°C/8 mmHg (lit.[23] bp 135°C/11mmHg), n_D^{20} 1.4913 (lit.[23] n_D^{20} 1.4915).

cis-2-Cyclohexylcyclohexanol (*Ia*). This material was prepared by hydrogenation of 2-cyclohexylcyclohexanone over platinum black in acetic acid in 74% yield, mp 59—60°C (petroleum ether, bp 40—50°C) (lit.[6] mp 60.8°C).

trans-2-Cyclohexylcyclohexanol (*IIa*). This material was prepared by reduction with lithium aluminum hydride of 2-cyclohexanone at 0°C, bp 106—107°C/6 mmHg, n_D^{20} 1.5010. This alcohol was esterificated with phthalic acid and recrystallized several times with chloroform followed by hydrolysis, and pure alcohol was obtained, mp 53—54°C (lit.[6] 52.8°C).

1-Cyclohexylcylohexene (*VII*). 1-Cyclohexylcylohexanol, mp 53-54°C (lit.[24] mp 51°C), bp 114—115 °C/7 mmHg was dehydrated by iodine at 150°C in 50% yield, bp 64—66°C/7 mmHg, n_D^{20} 1.4965 (lit.[25] n_D^{20} 1.4949).

3-Cyclohexylcyclohexene (*VIII*). This material was prepared from cyclohexylmagnesium bromide and 3-cyclohexenyl bromide, bp 73—74°C/7 mmHg, n_D^{20} 1.4964 (lit.[25] n_D^{20} 1.4941).

cis-2-Phenylcyclohexanol (*IIIa*). *o*-Phenylphenol was hydrogenated using Raney nickel as catalyst in ethanol.[7] The oily mixture of alcohol (6.5 g) obtained was chromatographed over 100 g of activated alumina. Elution with petroleum ether (bp 40—50 °C) gave 4.1 g of *cis* alcohol, mp 40—42°C (petroleum ether, bp 40—50°C) (lit.[7] mp 40—42°C).

Found: C, 81.54; H, 9.16%. Calcd for $C_{12}H_{16}O$:

C, 81.77; H, 9.14%. *cis*-2-phenylcyclohexyl phthalate, mp 174—175°C. Further elution with the petroleum ether (bp 40—60°C) gave small amount of *trans* isomer (IVa).

trans-2-Phenylcyclohexanol (*IVa*). This material was prepared from 2-phenylcyclohexanone[7] by lithium aluminum hydride reduction, mp 52—54°C (petroleum ether, bp 40—50°C) (lit.[7] mp 52—53°C).

Found: C, 81.60; H, 9.04%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.14%.

1-Phenylcyclohexene (*IX*). 1-Phenylcyclohexanol was dehydrated by heating with potassium acid sulfate,[26] bp 125—127°C/15 mmHg, n_D^{20} 1.5692.

3-Phenylcyclohexene. This material prepared from 3-bromocyclohexene and phenylmagnesium bromide, bp 114—115°C/15 mmHg, n_D^{20} 1.5448 (lit.[26] n_D^{20} 1.5448).

2-p-Anisylcyclohexanone. This ketone was prepared by the reaction of *p*-anisylmagnesium bromide with 2-chlorocyclohexanone in 46% yield, mp 88.0—88.5°C (lit.[27] mp 89°C).

Found: C, 76.61; H, 7.90%. Calcd for $C_{13}H_{16}O$: C, 76.44; H, 7.90%.

1-p-Anisylcyclohexene(*XI*). 1-*p*-Anisylcyclhexanol prepared from cyclohexanone and *p*-anisylmagnesium bromide was easily dehydrated during distillation, bp 138—139°C/6 mmHg. Completely dehydration by heating with potassium acid sulfate gave the pure 1-*p*-anisylcyclohexene in 52% yield, mp 32—33°C.

Found : C, 82.94 ; H, 8.60%. Calcd for $C_{13}H_{16}O_2$: C, 82.93 ; H, 8.57%. This olefin was hydrogenated with paladium black in alcohol at atmospheric pressure. After absorbing theoretical amount of hydrogen, crystalline material was obtained, which was ascertained to be *p*-anisylcyclohexene by comparison with IR spetrum and mixed melting point of the authentic sample, mp 57—58°C (lit.[27] 57—58°C).

Found: C, 81.60; H, 9.30%. Calcd for $C_{13}H_{18}O$: C, 82.08: H, 9.53%.

trans-2-p-Anisylcyclohexanol (*VIa*). This material was prepared by two methods. First, 2-*p*-anisylcyclohexanone (14 g) in dry ether (100 m*l*) was added with stirring to the ethereal solution (100 m*l*) of lithium aluminum hydride (1.5 g) below 10°C. After treatment with the usual manner, alcohol VIa (12.6 g) was obtained, mp 70—71°C (petroleum ether, bp 40—50°C).

Found: C, 75.47; H, 8.85%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%. On the other hand, 1-*p*-anisylcyclohexene (30 g) in tetrahydrofuran (100 m*l*) was treated with diborane generated from 30 mmol of boron trifluoride ethelate.[28] After destroying excess diborane the organoborane was treated with 18.5 m*l* of 3N sodium hydroxide followed by addition of 18.5 m*l* of 30% hydrogen peroxide at 30—50°C. The reaction mixture was stirred for an additional hour, then extrated with ether. After treatment with the usual manner recrystallization by petroleum ether (bp 50—70°C) gave *trans-2-p*-ansylcyclohexanol (29 g), mp 70.8—71.2°C.

Found: C, 75.77; H, 8.88%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%. These two alcohols obtained above showed the same IR spectra and mixed melting points.

cis-2-p-Anisylcyclohexanol (*Va*). A mixture of 2-*p*-anisylcyclohexanone (6.7 g), acetic acid (70 m*l*) and conc. hydrochloric acid (1 m*l*) was hydrogenated over platin-mohr catalysis at atmospheric pressure until the theoretical amount of hydrogen had been absorved. After treatment with the usual manner *cis*-2-*p*-anisylcyclohexyl acetate (Vb) was obtained, mp 81—82°C.

Found: C, 72.49; H, 8.05%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%. *cis-p*-Anisylcyclohexanol was prepared by hydrolysis of the acetate in 66% yield (from ketone), mp 53—54°C (petroleum ether, bp 40—50°C).

Found: C, 75.82; H, 8.73%, Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%. This alcohol was identical with the one obtained from the reduction of 2-*p*-anisylcyclohexanone by aluminum isopropoxide.[27]

trans-2-p-Anisylcyclohexyl Acetate (*VIb*). This material was prepared from *trans*-2-*p*-anisylcyclohexanol and acetic acid anhydride in dry pyridine in 98% yield, mp 58—59°C (petroleum ether, bp 40—50°C).

Found: C, 71, 94; H, 8.00%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

3-p-Anisylcylohexene (*XII*). This material was obtained from 3-bromocyclohexene and *p*-anisylmagnesium bromide in 40% yield, n_D^{25} 1.5498 (lit.[29] 1.5500).

Cyclopentyl Aldehyde. 1-Cyclopent-1-ene aldehyde[30] was prepared from oxidation of *trans*-cyclohexane-1,2-diol by sodium paraperiodate followed by condensation by potassium hydroxide solution at pH 4, bp 57°C/25 mmHg, ν 1640 (C=C), 1679 cm^{-1} (C=O), λ_{max}^{EtOH} 234.5 mμ. A solution of this aldehyde (40 g) in ether (50 m*l*) was hydrogenated over 8% paradium-charcoal catalyst (8 g). After absorption of the theoretical amount of hydrogen (10 *l*), the catalysts were filtered off, and the distillation of the filtrate gave cyclopentyl aldehyde[31] (20 g), bp 34°C/24 mmHg, ν 1720 cm^{-1}.

p-Anisylcylopentylcarbinol (*XIII*). To a solution of *p*-anisylmagnesium bromide (0.23 mol) in ether (400 m l) was added a solution of cyclopentyl aldehyde (20 g) in ether (200 m*l*) with reflux. After treatment with the usual manner *p*-anisylcyclopentylcarbinol (20 g) was obtained. Phenyl urethane, mp 237—238°C.

p-Methoxybenzalcyclopentane (*XIV*). *p*-Anisylcyclopentylcarbinol was dehydrated by heating with aqueous oxalic acid, bp 82—84°C/0.001 mmHg, n_D^{20} 1.5710.

Found: C, 82.94; H, 8.54%. Calcd for $C_{13}H_{16}O$:

C, 82.93; H, 8.57%.

p-Methoxybenzalcyclopentene (*XVI*). To a solution of *p*-anisylmagnesium bromide (0.42 mole) in ether (350 m*l*) a solution of 1-cyclopent-1-ene aldehyde (38 g) in ether (100 m*l*) was added slowly with stirring at 0°C. After reflux for additional half of hour, the mixture was poured into a cold saturated aqueous solution of ammonium chloride. The organic layer was washed with water and dried over magnesium sulfate, and the ether was removed. The residual oil was distilled, bp 118—119°C/0.15 mmHg, mp 70—71°C (ethanol) (56%).

Found: C, 83.35; H, 7.40%. Calcd for $C_{13}H_{14}O$: C, 83.83; H, 7.58%. ν_{Nujol} 1255, 1247 ($-OCH_3$), 1606, 1537, 1510, 1179, 814 (phenyl), 1306 cm^{-1}, λ_{max}^{EtOH} 297.5 mμ. The olefin (mp 70—71°C) above obtained was hydrogenated by absorbing two moles of hydrogen, and *p*-anisylcyclopentylmethane was obtained, n_D^{20} 1.5238.

Found: C, 81.86; H, 9.49%. Calcd for $C_{13}H_{18}O$: C, 82.06; H, 9.54%. This material was also obtained by hydrogenation of *p*-methoxybenzal cyclopentane by the absorption of one mole of hydrogen.

Kinetic Measurements. Solvolysis kinetics were measured by our previous methods.[11] In the solvolysis of the *p*-toluenesulfonates, no unusual feature was noted in the kinetic behavior except *trans*-2-*p*-anisylcyclohexyl *p*-toluenesulfonate. In this case special salt effect was found.[32]

Acetolysis products. *Acetolysis of cis and trans-2-Cyclohexylcyclohexyl p-Toluenesulfonate. a) Vapor Phase Chromatography.* The mixture of *trans*-2-cyclohexylcyclohexyl *p*-toluenesulfonate (4.95 g) and potassium acetate (2.25 g) was acetolyzed at 99.8°C until the reaction proceeded to ten-half lives. The reaction mixture was poured into cold water followed by continuous extraction by petroleum ether (bp 40—50°C). After washing with sodium bicarbonate solution and water, the petroleum ether solution was dried, concentrated and injected to v. p. c. (Carbowax 6000, 3m, 150°C). The data obtained is shown in Table 2. For the acetolysis of *cis*-2-cyclohexylcyclohexyl *p*-toluenesulfonate the data was obtained by the same treatment.

b) Product Isolation. A solution of *trans*-2-cyclohexylcyclohexyl *p*-toluenesulfonate (3.36 g) and potassium acetate (1.10 g) in acetic acid (100 m*l*) was acetolyzed and treated similarly as described above. The concentrated petroleum ether solution was chromatographed over alumina. Elution with petroleum ether gave olefins (1.99 g) selectively and further elution with benzene gave acetate (0.32 g). Treatment of the acetate with lithium aluminum hydride gave an alcohol, which was identified to be *cis*-2-cyclohexylcyclohexanol by comparison of IR spectrum with that of an authentic sample.

Acetolysis of cis and trans-2-Phenylcyclohexyl p-Toluenesulfonates. The acetolysis products were determined by v. p. c. (Carbowax 6000, 3m, 200°C).

Acetolysis of cis and trans-2-p-Anisylcyclohexyl p-Toluenesulfonates. a) Vapor Phase Chromatography. A solution of *trans*-2-*p*-anisylcyclohexyl *p*-toluenesulfonate (5.02 g) in acetic acid (140 m*l*) and potassium acetate (2.20 g) was heated at 99.8 °C until the reaction proceeded to ten-half lives. Further work up essentially as above for the *cis*-2-cyclohexyl *p*-toluenesulfonate yielded oily liquid (3.81 g), this was submitted to v. p. c. (Apiezon L, 2m, 250°C, and Carbowax 6000, 2m, 200°C, biphenyl was used as an internal standard substance). *p*-Methoxybenzalcyclopentane which was formed through ring contraction was identified, but *p*-anisylcyclopentylcarbinyl acetate and *p*-anisylmethylcyclopentene-1 were not detected.

A solution of *cis*-2-*p*-anisylcyclohexyl *p*-toluenesulfonate (0.788 g) in acetic acid (140 m*l*) and potassiun acetate (0.457 g) was solvolyzed. The reaction products (0.408 g) was analyzed by v. p. c.

b) Product Isolation. A solution of *trans*-2-*p*-anisylcyclohexyl *p*-toluenesulfonate (250g) in acetic acid (100 m*l*) potassium acetate (1.02 g) were heated at 99.8°C until ten half lives. After treatment as described above the oily reation products (1.42 g) obtained were dissolved in petroleum ether and submited to v. p. c. Elution with benzene gave olefins and further elution with benzene-methanol gave acetate. Treatment of the acetate with lithium aluminum hydride gave alcohol (mp 70—71°C), which was identified to be *trans*-2-*p*-anisylcyclohexanol by comparison with IR spectrum and mixed mp. The ratio of olefin and *trans* acetate is 12/88.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1891—1896 (1968)

Condensation Reaction of Ferrocene with Carbonyl Compounds

Mikio SHIGA, Izumi MOTOYAMA and Kazuo HATA

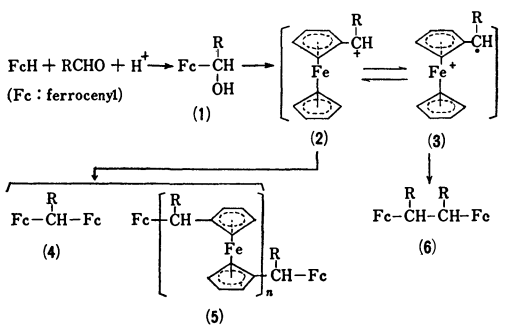
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received December 27, 1967)

The condensation reactions of ferrocene with various ketones and with trichloroacetaldehyde in the presence of aluminum chloride were investigated. The formation of carbinol (**7**) as an intermediate was postulated in these reactions. In the reaction of acetone with ferrocene, the intermediate carbinol underwent further condensation with other ferrocene molecules to give oligomers (**9**). On the other hand, in the cases of methyl ethyl ketone, acetophenone, propiophenone, cyclohexanone, and trichloroacetaldehyde, the condensation reactions produced olefinic compounds *via* the intermediate carbinols. The intermediate carbinol was isolated together with the olefin in the reaction with trichloroacetaldehyde.

The codensation reactions of ferrocene with aldehydes catalyzed by Lewis acid have already been reported by several workers.[1—5] In the reaction of formaldehyde with ferrocene, Rinehart *et al.* isolated 1,2-diferrocenylethane (**6**, R=H) as the main product,[3,4] whereas Pauson *et al.* obtained diferrocenylmethane (**4**, R=H) by the same reaction under different conditions.[1] These facts have been reasonably interpreted by postulating a ferrocenylmethyl radical (**3**,R=H) derived from the ferrocenylmethyl cation (**2**,R=H) by internal electron-migration from the iron to the α-carbon atom.[1]

It is expected that the substituent on the α-carbon of the intermediate carbinol (or carbonium ion) will electronically affect such an electron-migration process. To date, however, few papers have been published on the reaction of ferrocene with ketone and polyhaloaldehyde. This paper will report on the condensation reactions of ferrocene with various ketones and with trichloroacetaldehyde in the presence of aluminum chloride.



Results and Discussion

The reaction of ferrocene with acetone in the presence of aluminum chloride in anhydrous chloroform under an atmosphere of nitrogen at room temperature gave a mixture of oligomers (**9**). The formation of such polycondensation products suggests that the reaction proceeded through a carbonium ion (**8**), derived from carbinol (**7**), as is shown in the scheme.

In the case of the reaction with methyl ethyl ketone, only 2,4-diferrocenyl-3,4-dimethyl-2-hexene (**12**) (mp 47—52°C) was isolated. The structure of **12** was supported by the IR spectrum. An absorption band at the 1625 cm^{-1} of **12** due to the ethylenic bond disappeared upon its catalytic hydrogenation to the alkane **13**, mp 41—49°C. It is most likely that the product **12** was produced as a result of the dimerization of an olefin **10a**, which was expected to arise upon the dehydration of the carbinol **7**, although it could not be isolated in this experiment. An alternative structure **14** for **12** was excluded by its IR spectrum.

Acetophenone also gave a dimerized product, 1,3-diferrocenyl-1,3-diphenyl-1-butene (**15**), mp 137.5—138.5°C. The NMR spectrum of **15** shows the integrated intensity ratio of the protons in ferrocenyl : phenyl and olefinic (overlapped) : methyl to be 18.3 : 11.2 : 3.0, which is nearly equal to that calculated on the basis of the formula **15**. An alkane **16**, mp 118—126°C, was obtained quantitatively by the hydrogenation of the dimer **15**. The formation of the dimer **15** may be interpreted through a mechanism analogous to that for the dimer **12**.

Neither of these reactions gave any oligomeric product, unlike the reaction of acetone with ferrocene. The absence of oligomeric products in these reactions strongly suggests that no electrophilic attack of the carbonium ion **8**, which might be created from the carbinol **7**, occurred on the other ferrocene nuclei during these reactions. Therefore, the carbinol or the carbonium ion might, upon the elimination of the water molecule or the α-proton, be converted into the two olefins, **10a** and **10b**, which would be immediately dimerized to **12** and **15** respectively by the action of aluminum chloride and a trace of water.

The condensation reaction of propiophenone with ferrocene gave only an olefinic product, 1-ferrocenyl-1-phenylpropene **10c**, a part of which was oxidized, when chromatographed on alumina, to give benzoylferrocene (**18**), mp 111—112°C. When it was refluxed with a Raney nickel catalyst in methanol,[6] the olefin **10c** was converted almost quantitatively into the hydrogenated product **17** (mp 59—60°C), which was identified by comparing it with the authentic sample prepared from the reaction of benzoylferrocene with ethylmagnesium bromide, followed by treatment with zinc dust and hydrochloric acid.[7] The NMR

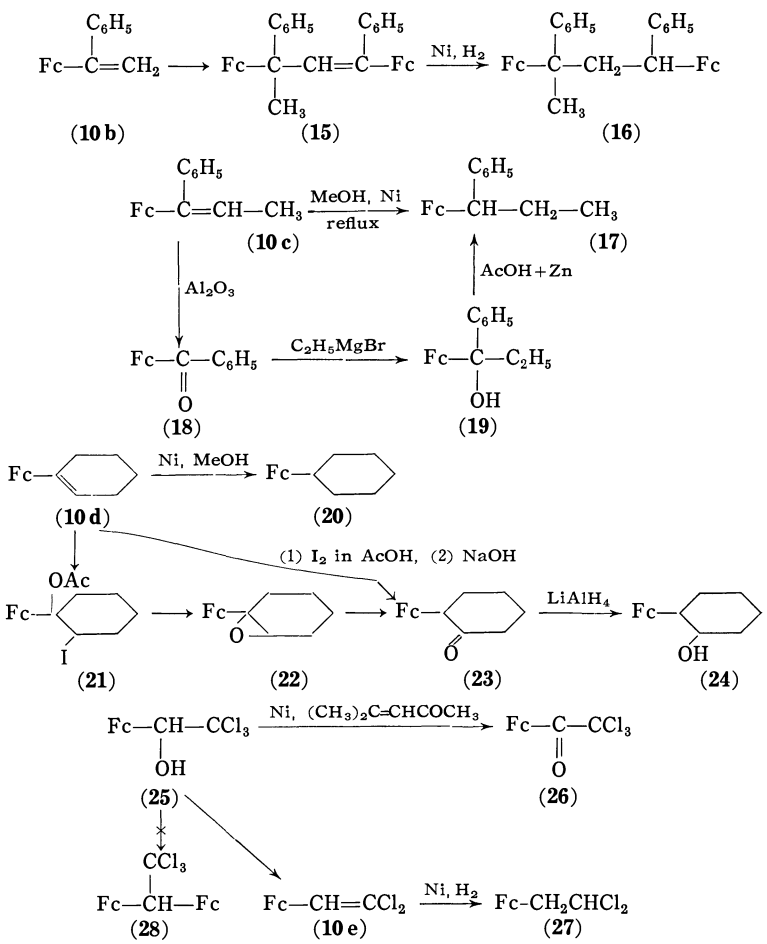
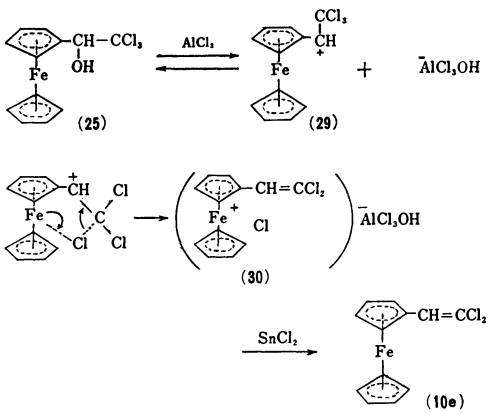
a) The observed methylene proton signals at $C_{4,5}$, C_3 and C_6 in compound **10d** were 3.9 : 2.2 : 2.1.
* The figures in parentheses shown below each τ-value indicate the corresponding integrated intensity ratios.
The figures shown between ····· indicate those for overlapped peaks.



spectrum of **10c** had a doublet peak at τ 8.49 for methyl protons and two singlets, at τ 5.93 and τ 6.02, for the substituted cyclopentadienyl ring protons and the unsubstituted ones respectively, as is shown in Table 1 and Fig. 1-(1). The NMR signal due to the methyl protons of **17** showed a higher τ-value (τ 9.2, triplet) than that of **10c**. An analogous tendency was observed also in the resonance peaks of ring protons between these two compounds.

The reaction of cyclohexanone with ferrocene afforded cyclohexenylferrocene (**10d**), mp 67—68°C, in a good yield (96%). The olefin **10d** was quantitatively converted to cyclohexylferrocene (**20**), mp 40—41°C, when it was refluxed with a Raney nickel catalyst in methanol. The NMR spectrum of **10d** showed three triplets assignable to the 2,5- and 3,4-protons of the substituted cyclopentadienyl ring and the five protons of the unsubstituted ring respectively, whereas in the hydrogenated product **20** these three triplets changed into two singlets, at τ 6.06 and τ 6.01, corresponding to those of the substituted and the unsubstituted rings respectively, as is shown in Figs. 1-(3) and 1-(4). Cyclohexenylferrocene (**10d**) was transformed into 2-ferrocenylcyclohexanone (**23**), mp 99—101°C, probably through the intermediates **21** and **22**, when treated with iodine in glacial acetic acid and then with aqueous alkali. The reduction of the product **23** with lithium aluminum hydride gave 2-ferrocenylcyclohexanol (**24**), mp 88—90°C.

Trichloroacetaldehyde condensed with ferrocene to give 1,1-dichloro-2-ferrocenylethylene (**10e**), mp 55.5—56.5°C, and trichloromethylferrocenylcarbinol (**25**). The IR spectrum of the latter showed that the OH stretching band shifted toward a lower-frequency region (3430 cm^{-1}), suggesting the presence of intramolecular hydrogen-bonding between the hydroxyl group and the iron atom. The integrated intensity ratios in the NMR spectra of the olefin **10e** and the carbinol **25** were found to be as shown in Table 1. They are nearly equal to the values calculated on the basis of the formulas **10e** and **25**. When the carbinol **25** was heated with mesityl oxide in the presence of a Raney nickel catalyst, a mild redox reaction[6] afforded the corresponding ketone **26**, which sublimes easily. The olefin **10e** was catalytically hydrogenated in methanol to 1,1-dichloro-2-ferrocenylethane (**27**). The fact that the expected product **28** could not be isolated in the reaction of trichloroacetaldehyde with ferrocene can not simply be explained in terms of the steric effect of substituents on the



also-expected carbonium ion **29**. On the other hand, it has been suggested that the participation of the iron atom may facilitate the formation of the olefin from the carbonium ion **29** through the ferricinium ion **30**, as is shown in the scheme.[8]

The fact that the intermediate carbinol was isolated only in the case of trichloroacetaldehyde indicates that the formation of the carbonium ion was retarded by the strong electron-withdrawing nature of the trichloromethyl group in the carbinol **25**. The extraordinary stability of the ferrocenylmethyl carbonium ion (**2**, R=CH_3) over the phenyl analog has previously been demonstrated in many cases,[9,10] and it is considered that the carbonium ion can be an important intermediate in the condensation reaction of ferrocene with a carbonyl compound, although there is no positive evidence that the carbonium ion was produced during any reaction except in that with acetone.

The results described above indicate that the presence of a substituent on the α-carbon of the intermediate carbonium ion facilitates the formation of olefin and seems to prevent the formation of a radical from the carbonium ion by electron-migration.

Experimental

General Procedure. The reaction conditions and the products of the condensation reactions of ferrocene and carbonyl compounds are summarized in Table 2. A typical reaction procedure was as follows: To 0.16 mol (24 g) of anhydrous aluminum chloride in 20 *ml* of chloroform at 0°C, under an atmosphere of nitrogen, there was slowly added

		Trichloromethylferrocenylcarbinol (**25**)	140—141	0.85	5

In each reaction, 10 g (0.054 mol) of ferrocene was treated with 0.16 mol of carbonyl compounds in the presence of 24 g (0.16 mol) of $AlCl_3$ at 0°C.

0.16 mol of the respective carbonyl compound. Subsequently, 0.054 mol (10 g) of ferrocene, dissolved in 30 m*l* of chloroform, was added dropwise to the mixture with good stirring. After it had been stirred for several hours at room temperature, the reaction mixture was poured into 200 m*l* of water containing 5 g of stannous chloride, and then stirred for another 30 min. Finally, the chloroform layer which separated from the aqueous layer was washed three times with 50-m*l* portions of water and dried over anhydrous magnesium sulfate. Then, the chloroform and the unreacted carbonyl compound were removed by distillation to give a crude reaction product. The subsequent treatment and purification were conducted in different ways for the different products, as will be described below.

Isolation of Oligomers 9′ and 9″. The red brown oil (11.5 g), obtained from the reaction of acetone (9.3 g) with ferrocene (10 g) was dissolved in 2 m*l* of chloroform, and then the solution was poured into 200 m*l* of methanol. After the mixture had been kept standing overnight, 2.5 g of a yellow solid separated as a precipitate. The recrystallization of the precipitate from $CHCl_3$-CH_3OH gave 2.2 g of a yellow solid, mp 162—168°C.

Found: C, 68.95; H, 5.98%; mol wt(Rast), 2010. Calcd for the formula **9″**: C, 68.60; H, 6.11%; mol wt, 1944.

By the evaporation of the solvent from the filtrate, 6.5 g of an amber liquid was obtained.

Neither of these compounds showed any olefinic absorption band in its IR spectrum. The amber liquid was assumed to be a mixture of oligomers (**9′**) with lower molecular weights.

2,4-Diferrocenyl-3,4-dimethyl-2-hexene (12). The condensation product of the reaction of methyl ethyl ketone (11.6 g) with ferrocene (10 g) was extracted with methanol in a Soxhlet extractor for three hours. Then, the residual, insoluble part in methanol was dissolved in 2 m*l* of chloroform and the solution was poured into 200 m*l* of methanol. A yellow solid (8.1 g) was thus obtained as a precipitate. It was recrystallized from $CHCl_3$-CH_3OH. Yield 7.9 g (62%), mp 47—52°C.

Found: C, 70.21; H, 5.48%; mol wt, 496. Calcd for $C_{28}H_{32}Fe$: C, 70.05; H, 6.67%; mol wt, 481.

2,4-Diferrocenyl-3,4-dimethylhexane (13). A solution of 2 g of 2,4-diferrocenyl-3,4-dimethyl-2-hexene (**12**) in 30 m*l* of methanol was refluxed for 3 hr in the presence of Raney Ni (1 g).[6] The reaction mixture was then allowed to cool to room temperature and filtered in order to remove the catalyst. The methanol solution was poured into 200 m*l* of water and extracted with chloroform. The extract was concentrated to a small volume and poured into 100 m*l* of methanol. Another treatment of the mixture in the way described above gave a solid. It was recrystallized from $CHCl_3$-CH_3OH to yield 1.98 g (98% yield) of a yellow product, mp 41—48°C. Its IR spectrum had no absorption band at 1625 cm^{-1}, a band which had been assigned in **12** to the ethylenic bond.

Found : C, 69.85; H, 7.10%; mol wt, 499. Calcd for $C_{28}H_{34}Fe$: C, 69.56; H, 7.03%; mol wt, 483.

1,3-Diferrocenyl-1,3-diphenyl-1-butene (15). The condensation of acetophenone with ferrocene gave **15**. The procedure was similar to that employed for the isolation of **12**. The crude product was recrystallized from ether after the removal of the unreacted ferrocene by sublimation to give 8.5 g (55% yield) of orange yellow crystals, mp 137.5—138°C.

Found: C, 74.87; H, 5.50%; mol wt, 570. Calcd for $C_{26}H_{32}Fe$: C, 74.79; H, 5.55%; mol wt, 577.

The reduction[6] of **15** was carried out in the way which has been described for **12**. Yellow crystals of 1,3-diferrocenyl-1,3-diphenylbutane (**16**), mp 118—126°C; (1.9 g, 98% yield) were obtained from 2 g of **15**.

Found: C, 74.12; H, 5.84%; mol wt, 582. Calcd for $C_{26}H_{34}Fe$: C, 74.53; H, 5.86%; mol wt, 579.

1-Ferroceny-1-phenylpropene (10c). The crude product (11.6 g), obtained from the condensation reaction of ferrocene (10 g) with propiophenone (21.6 g) was distilled under reduced pressure to give 7.1 g (44% yield) of **10c** as a reddish-brown liquid (bp 105—110°C/0.4 mmHg) ; this liquid partially decomposed when chromatographed on alumina to give benzoylferrocene (**18**), mp 111.5—112°C. This anomalous behavior of **10c** toward alumina was confirmed by repeated experiments, and the benzoylferrocene obtained in this reaction was identified by comparing it with an authentic sample.

Found: C, 75.41; H, 6.02%; mol wt, 305. Calcd

for $C_{19}H_{18}Fe$ (**10c**): C, 75.49; H, 5.96%; mol wt, 302.

1-Ferrocenyl-1-phenylpropane (**17**). The olefinic compound **10c** was hydrogenated by the procedure described above, and the crude product was chromatographed on alumina to give 1.92 g (98%) of yellow needles, mp 59—60°C.

Found: C, 74.92; H, 6.67%; mol wt, 309. Calcd for $C_{19}H_{20}Fe$: C, 75.04; H, 6.58%; mol wt, 304.

1-Ferrocenyl-1-phenylpropane (**17**) was also prepared[7] from benzoylferrocene (**18**) by the Grignard reaction with ethylmagnesium bromide and by the successive reduction of the product with zinc dust and hydrochloric acid.

Cyclohexenylferrocene (**10d**). The crude condensation product obtained from cyclohexanone (15.6 g) and ferrocene (10 g) was chromatographed on alumina to give 13.7 g (96%) of golden yellow crystals, mp 67—68°C. The IR spectrum of **10d** showed an olefinic absorption band at 1630 cm^{-1}.

Found: C, 72.06; H, 6.89%; mol wt, 264. Calcd for $C_{16}H_{18}Fe$: C, 72.23; H, 6.77%; mol wt, 266.

Cyclohexenylferrocene (**10d**) was treated with Raney Ni in the way described above, and the crude product was purified by chromatography on alumina to yield 1.19 g (79%) of cyclohexylferrocene (**20**) as yellow crystals (mp 40—41°C).

Found: C, 71.69; H, 7.34%; mol wt, 265. Calcd for $C_{16}H_{20}Fe$: C, 71.69; H, 7.46%; mol wt, 268.

2-Ferrocenylcyclohexanone (**23**). A solution of 2 g of cyclohexenylferrocene and 0.4 g of iodine in 40 m*l* of glacial acetic acid was heated to 95°C for 1.5 hr. After it had been cooled, the reaction mixture was added, drop by drop, to 200 m*l* of a 30% aqueous potassium hydroxide solution. The solution was stirred for 1 hr and then extracted with benzene. The extract was washed once with water and dried over anhydrous magnesium sulfate. After the drying agent had been removed, the solvent was distilled off. The residue was chromatographed on alumina, using benzene as a solvent, to yield 0.44 g (21%) of orange yellow crystals, mp 99—101°C. The IR spectrum of this compound showed a sharp carbonyl band at 1685 cm^{-1}.

Found: C, 67.89; H, 6.19%; mol wt, 299. Calcd for $C_{16}H_{18}FeO$: C, 68.13; H, 6.38%; mol wt, 282.

2-Ferrocenylcyclohexanol (**24**). 2-Ferrocenylcyclohexanone (**23**) (0.5 g), dissolved in 20 m*l* of anhydrous ether, was treated with lithium aluminum hydride in the usual way to afford a yellow solid (0.42 g). Recrystallization from *n*-hexane gave 0.24 g (48%) of yellow crystals, mp 88—90°C. Its IR spectrum showed a hydroxyl band at 3380 cm^{-1}.

Found: C, 68.33; H, 6.70%; mol wt, 262. Calcd for $C_{16}H_{20}FeO$: C, 67.60; H, 6.33%; mol wt, 284.

1,1-Dichloro-2-ferrocenylethylene (**10e**) **and Trichloromethylferrocenylcarbinol** (**25**). The dark orange solid product, obtained by the condensation of trichloroacetaldehyde (23.5 g) with ferrocene (10 g), was chromatographed on alumina with chloroform. The first fraction afforded a mixture of 1,1-dichloro-2-ferrocenylethylene (**10e**) and unreacted ferrocene. After the removal of the ferrocene by sublimation, 4.2 g of dark orange crystals were obtained. These crystals were purified by chromatography on alumina using benzene - *n*-hexane to give 3.1 g (21%) of dark orange crystals, mp 55.5—56.5°C.

Found: C, 51.77; H, 3.72%; mol wt, 284. Calcd for $C_{12}H_{10}FeCl_2$: C, 51.46; H, 3.57%; mol wt, 280.

The second fraction of the chromatography yielded 0.91 g of yellow crystals. Recrystallization from *n*-hexane gave 0.85 g (5%) of yellow crystals, decomp. at 140—141°C, whose IR spectrum had a hydroxyl band at 3420 cm^{-1}.

Found: C, 43.48; H, 3.21%; mol wt, 329. Calcd for $C_{12}H_{11}FeOCl_3$: C, 43.24; H, 3.33%; mol wt, 332.

Trichloromethyl Ferrocenyl Ketone (**26**). A solution of 1 g of trichloromethylferrocenylcarbinol (**25**) and 0.5 g of a Raney nickel catalyst in 15 m*l* of mesityl oxide was heated at 95°C for 5 hr.[6] After cooling, the catalyst was filtered off and the filtrate was distilled under reduced pressure to remove the mesityl oxide. Subsequently, the residue was chromatographed on alumina with benzene to obtain 0.41 g of red crystals from the first fraction. Purification by sublimation then gave 0.38 g (38%) of red crystals, mp 84—86°C.

Found: C, 44.21; H, 2.93%; mol wt, 335. Calcd for $C_{12}H_9FeOCl_3$: C, 43.66; H, 2.72%: mol wt, 330.

1,1-Dichloro-2-ferrocenylethane (**27**). 1,1-Dichloro-2-ferrocenylethylene (**10e**) was treated by the same procedure as has been described for the reduction of **12**. The crude product was purified by chromatography on alumina with *n*-hexane to give 1.84 g (92%) of an amber liquid product **27**.

Found: C, 52.11; H, 4.87%; mol wt, 278. Calcd for $C_{12}H_{12}FeCl_2$: C, 51.06; H, 4.25%; mol wt, 282.

The authors wish to express their hearty thanks to the Ministry of Education for a grant-in-aid for fundamental scientific research.

Nitroalkenylferrocene. I. Preparation of 2-Nitro-1-ferrocenylalkenes

Mikio SHIGA, Hiromichi KONO, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received December 27, 1967)

A wide variety of nitroalkenylferrocenes and their derivatives were synthesized by the condensation of formylferrocene and nitroalkanes. As a condensing agent, either sodium methoxide or a cyclic amine, such as piperidine, pyrrolidine and morpholine, was employed. Condensation using a cyclic amine, which is analogous to the Mannich reaction in nature, gave better results than that using sodium methoxide. The mechanism of the Mannich-type reaction has been discussed, and the formation of a molecular complex between formylferrocene and piperidine has been proposed as an intermediacy.

Many condensation reactions involving formylferrocene have been appeared in the literature. However, the reaction of the aldehyde with nitroalkane has not yet been studied except with nitromethane.

The present paper will report the preparation of several kinds of nitroalkenylferrocenes by two different methods; one is a method using sodium alkoxide[1,2] as a condensing agent, while the other uses a cyclic amine.[3-5] The reaction mechanism of the latter method, which is analogous to that of the Mannich reaction in nature, will also be discussed.

The Condensation Using Sodium Methoxide. The condensation of formylferrocene with nitroalkane by sodium methoxide was carried out as follows: A methanolic solution of sodium methoxide was gradually added to a cooled mixture of formylferrocene (**1**) and nitromethane in methanol. At the end of the reaction, an insoluble sodium salt of nitroalcohol (**2**) separated out as a yellow solid; this solid was apt to decompose to the starting materials in the presence of water. Dark violet crystals of 2-nitro-1-ferrocenylethylene (**3a**) (mp 139—140 ℃), which has been reported on as an oil by Flores *et al.*,[6] were isolated in an excellent yield by acidifying the salt with dilute hydrochloric acid. The NMR spectrum of **3a** exhibits two singlet peaks, at τ 5.46 and τ 5.81, corresponding to protons in the substituted and in the unsubstituted cyclopentadienyl ring respectively, and two doublets, centered at τ 2.03 and τ 2.80 ($J_{\alpha\beta}$= 12.5 cps), assignable to the vinyl α-proton and the vinyl β-proton*1 respectively. The IR spectrum of the nitroolefin showed absorption peaks at 1290 and 950 cm^{-1}; these peaks are indicative of *trans*-olefin.

In the reaction of formylferrocene with nitroethane, 2-nitro-1-ferrocenylpropene (**3b**), (mp 57—58℃), obtained in a low yield (12%), was the only isolated product; no salt intermediate **2** was isolated. The NMR spectrum of **3b** exhibits two singlet peaks, at τ 5.49 and τ 5.83, corresponding to the ring protons, and two singlets, at τ 2.08 and τ 7.70, assignable to the vinyl α-proton and the methyl proton respectively (Table 3).

The Condensation Using Cyclic Amines. This condensation was conducted by using a cyclic amine, such as piperidine, pyrrolidine, or morpholine, as the condensing agent in a way similar to that using sodium methoxide. The nature of this condensation seems to be analogous to the Mannich reaction; in fact, the reaction afforded a Mannich-type product,[7] aminonitroalkane (**4**), which could eventually converted into a nitroolefin (**3**) if the right conditions were employed. The condensation

of nitromethane, nitroethane, and 1-nitropropane with formylferrocene in the presence of piperidine gave only aminonitroalkanes (**4**) as yellow crystals. The reduction of these products with $LiAlH_4$ afforded reddish-orange crystals (mp 84—86℃), along with the original aldehyde **1**; the expected amino compounds **7** were not obtained. The reddish-orange substance was identified as piperidinomethylferrocene (**6**)[8] by means of elementary analysis and a study of the IR spectrum and the NMR spectrum. Accordingly, it appears that the reaction proceeds through a cationic intermediate **5**, as is shown in the scheme.

On the other hand, nitromethane condensed with formylferrocene in the presence of pyrrolidine to form nitroolefin **3a** exclusively, while nitroethane and 1-nitropropane gave only aminonitroalkanes, **4d** and **4e** respectively. Furthermore, in the presence of morpholine, which is a weaker base than the others, the condensation of nitromethane and nitroethane with formylferrocene gave exclusively nitroolefin **3a** and **3b** respectively, whereas 1-nitropropane gave only aminoalkane **4f** as is shown in Table 1. When the Mannich bases, **4c** and **4e**, were converted to sodium salt by sodium methoxide and then treated with hydrochloric acid, the basic group on α-carbon was readily eliminated to afford quantitatively 2-nitro-1-ferrocenyl-1-butene **3c**, mp 77—78℃, whose NMR spectrum is shown in Table 3. A characteristic color change from yellow to violet was observed when a Mannich base **4** was converted into a nitroolefin **3**.

Discussion of the Mechanism of the Condensation Reaction. As the mechanism of the Mannich-type reaction[9] affording an aminonitroalkane **4**, the three courses shown in Fig. 1 can be considered. Course A involves the nucleophilic substitution of cyclic amine on the nitroalcohol **8** formed by the nucleo-

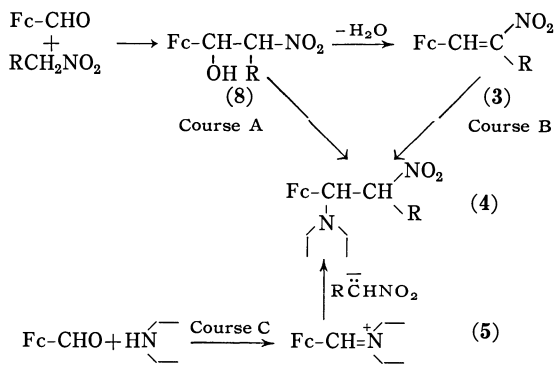

Fig. 1. Eventual mechanism of the Mannich-type condensation.

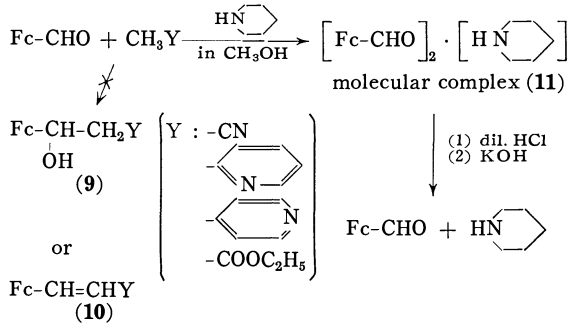
philic attack of nitroalkane on formylferrocene. Course B involves the addition of amine to the nitroolefin **3** produced by the dehydration of the nitroalcohol 8. Course C involves the intermediacy of the enamine **5**,[10] which is subjected to attack by a carbanion derived from nitroalkane. Of these three possibilities, Course A may be eliminated because of the fact that no alcoholic product was isolated from the reaction. In addition, Courses A and B can both be ruled out by the fact that the formation of aminonitroalkane **4** is not retarded, but even accelerated, when the nitroalkane with a bulkier alkyl substituent is used.

In order to obtain further information, condensation reactions of formylferrocene with compounds less acidic than nitroalkane, such as acetonitrile, α- and γ-picoline, and ethyl acetate, were attempted in the presence of piperidine in methanol. Neither the expected alcohol **9** nor the olefin **10** was thus formed; the only product isolated was a yellow, crystalline substance. When an ethereal solution of the yellow substance was shaken with dilute hydrochloric acid, the substance easily transferred to the aqueous layer to give a red solution. The neutralization of the aqueous layer with alkali gave the original aldehyde and amine. Moreover, the yellow substance was not isolated in the absence of a nucleophile, such as acetonitrile and the like, under the same conditions as above. This substance, therefore, seems to be something like a molecular complex; its elementary analysis suggests a structure corresponding to the formula **11**. The proposed structure is consistent with the following observations. The IR spectrum showed the characteristic absorption band of the carbonyl group of

10) S.P. Makarov, *J. Prakt. Chem.*, **141**, (2), 77 (1934).



formylferrocene and that of the methylene group of piperidine, but no peak in the region of ν_{NH}. The UV spectrum of this compound is almost identical with that of formylferrocene. The complex **11** gradually decomposed into formylferrocene and piperidine when left standing in the air. Furthermore, the aminonitroalkane **4** was produced when the complex was dissolved in nitroalkane.

On the basis of these experimental results, it seems reasonable to conclude that Course C is the most likely, although there is no direct evidence for the formation of the enamine **5**.

For the preparation of 2-nitro-1-ferrocenylalkanes, piperidine is the most effective condensing agent among the cyclic amines employed in those reactions. The reactions of the nitroalkenes and the aminonitroalkanes will be reported in the following papers.

Experimental

Materials. Commercial cyclic amines and nitroalkanes were used without any further purification. Formylferrocene was prepared by the modified Vilsmeier reaction previously reported.[11]

TABLE 2. THE IR SPECTRA OF 1-FERROCENYL-2-NITROALKENES (KBr disk)

Compound	Mp(°C)	Frequency (cm^{-1})	
		$\nu_{C=C}$	ν_{NO_2}
FcCH=CHNO$_2$ (**3a**)	139—140	1630	1503 1328
FcCH=C(CH$_3$)NO$_2$ (**3b**)	57—58	1655	1499 1303
FcCH=C(C$_2$H$_5$)NO$_2$ (**3c**)	77—78	1639	1509 1298

Identification of the Reaction Products. The reaction products were identified by means of the NMR spectra, the IR spectra, and the results of elementary analyses. These results are tabulated in Tables 2, 3, and 4 respectively.

2-Nitro-1-ferrocenylethylene (3a). To an ice-cooled solution of formylferrocene (21.4 g, 0.1 mol) and nitromethane (12.2 g, 0.2 mol) in 60 m*l* of absolute methanol, there was gradually added a methanolic solution of sodium methoxide (10.8 g, 0.2 mol). Within a few minutes, about 30 g of a yellow-brown solid separated out. The solid salt was collected and washed with dry ether. Treating the solid with dilute hydrochloric acid gave 19.5 g (76% yield) of 2-nitro-1-ferrocenylethylene (**3a**) as violet crystals, mp 139—140 °C. The analytical sample was prepared by recrystallization from ethanol.

The nitroolefin **3a** was also well prepared as

follows: (a) Pyrrolidine (1.42 g, 0.02 mol) or morpholine (1.74 g, 0.02 mol) was gradually added to an ice-cooled solution of formylferrocene (2.14 g, 0.01 mol) and nitromethane (1.22 g, 0.02 mol) in 10 m*l* of absolute methanol. After standing for a few hours, the reaction mixtue was poured into dilute hydrochloric acid in order to be acidified, and then extracted with chloroform. The extract was washed with water, and then dried over anhydrous magnesium sulfate. After the removal of the solvent, the residue was chromatographed on alumina, using benzene as a solvent, to give the olefin **3a** in an excellent yield (Table 1).

(b) Aminonitroalkane (**4a**) (1.7 g, 0.005 mol), to be described below, was added to 10 m*l* of absolute methanol containing 1.08 g (0.02 mol) of sodium methoxide. The reaction mixture was stirred for an hour on an ice bath and then acidified with dilute hydrochloric acid to give the olefin **3a** quantitatively.

2-Nitro-1-ferrocenylpropene (**3b**). Sodium methoxide (3.6 g, 0.07 mol) in methanol was gradually added with cooling to a solution of formylferrocene (4.00 g, 0.02 mol) and nitroethane (3.0 g, 0.04 mol) in 20 m*l* of absolute methanol. After it had then been let stand for four days at room temperature, the reaction mixture was poured into 70 m*l* of 15% hydrochloric acid and extracted with chloroform. The organic layer was separated, washed with water, and dried over anhydrous magnesium sulfate. After the evaporation of the solvent, the crude product was chromatographed on alumina, using dry benzene as a solvent. From the first fraction, 2-nitro-1-ferrocenylpropene was obtained as violet crystals, mp 57—58 °C. From the following fractions 2.26 g (57%) formylferrocene were recovered.

For the preparation of nitroolefin **3b**, pyrrolidine and piperidine gave much better results than sodium methoxide, but morpholine gave only a low yield.

Aminonitroalkane, **4b** (1.78 g, 0.005 mol) and **4d** (1.71 g, 0.005 mol), prepared in excellent yields by the procedure to be described below, were quantitatively converted to the nitroolefin **3b** by treating them for an hour with 10 m*l* of a methanolic solution containing 1.08 g (0.02 mol) of sodium methoxide, followed by acidification with dilute hydrochloric acid.

2-Nitro-1-ferrocenyl-1-butene (**3c**). By the same procedure as has been described above, 2-nitro-1-ferrocenyl-1-butene was quantitatively prepared from the aminoalkanes **4c**, **4e**, and **4f** as violet crystals, mp 77—78 °C.

1-Ferrocenyl-1-piperidino-2-nitroethane (**4a**). Formylferrocene (2.14 g, 0.01 mol), nitromethane (1.22 g, 0.02 mol), and piperidine (1.70 g, 0.02 mol) were dissolved in 20 m*l* of absolute methanol. The solution was let stand at room temperature for a few hours to give 1-ferrocenyl-1-piperidino-2-nitroethane as yellow-brown crystals (2.9 g, 86%). It was filtered and washed with water and then with a small portion of ether. The pale yellow crystals obtained by recrystallization from dichloromethane - *n*-hexane melted at 116°C (dec.).

1-Ferrocenyl-1-piperidino-2-nitropropane (**4b**). Following the procedure described above, 1-ferrocenyl-1-piperidino-2-nitropropane was prepared from formylferrocene, nitroethane, and piperidine in a 94% yield. The pale yellow crystals obtained by recrystallization from dichloromethane - *n*-hexane melted at 121—122°C (dec.).

1-Ferrocenyl-1-piperidino-2-nitrobutane (**4c**). Yellow crystals of 1-ferrocenyl-1-piperidino-2-nitrobutane, mp 132°C (dec.), were similarly obtained.

Piperidinomethylferrocene (**6**). A mixture of 1-ferrocenyl-1-piperidino-2-nitropropane (**4b**) (1 g, 0.003 mol) and lithium aluminum hydride (0.8 g, 0.02 mol) in 50 m*l* of dry ether was stirred for 3 hr on an ice bath, and then 30 m*l* of methanol was gradually poured into the reaction mixture, followed by 100 m*l* of water. The mixture was then extracted with ether, and the extract was washed with water and dried over anhydrous magnesium sulfate. After the removal of the solvent, the residue was chromatographed on alumina, using benzene - *n*-hexane as a solvent. Reddish-orange crystals of piperidinomethylferrocene (**6**), mp 84—86°C, were obtained from the second fraction; yield 0.13 g (17%). The same compound **6** was obtained in a 15—17% yield from 1-ferrocenyl-1-piperidino-2-nitroethane (**4a**) by a similar procedure. The NMR spectrum of **6** exhibits two broad peaks, at τ 8.58 and τ 7.67, due to the methylene protons of the piperidine ring, and two singlets, at τ 6.66 and τ 5.93, due to α-methylene protons and ferrocene ring protons respectively.

1-Ferrocenyl-1-pyrrolidino-2-nitropropane (**4d**). By a procedure, using pyrrolidine as a condensing agent, similar to that used for the preparation of **4a**, **4d** was prepared in an 89% yield. The analytical sample, recrystallized from dichloromethane-*n*-hexane, melted at 75°C (dec.).

1-Ferrocenyl-1-pyrrolidino-2-nitrobutane (**4e**). From formylferrocene, 1-nitropropane, and pyrolidine, **4e** was obtained in a 88% yield as pale yellow crystals, mp 101—102°C, after recrystallization from dichloromethane - *n*-hexane.

1-Ferrocenyl-1-morpholino-2-nitrobutane (**4f**). A similar reaction of formylferrocene with 1-nitropropane and morpholine afforded **4f** as yellow-brown crystals, mp 139—140°C, in a 72% yield.

Molecular Complex (11) of Formylferrocene and Piperidine. Formylferrocene (1 g) was added to an ice-cooled solution of piperidine (1 g) and acetonitrile (0.5 g) in 5 m*l* of absolute methanol. After half an hour, the complex **11** separated from the solution as yellow crystals, which were then filtered and washed with methanol (yield, 0.7 g). Some discrepancies in the analytical data shown in Table 4 may be due to its instability in the air.

When 0.2 g of the complex **11** was dissolved in 2 g of nitromethane with stirring under ice cooling, the reaction mixture immediately turned to a brownish-violet. From the solution, 0.1 g of 1-ferrocenyl-1-piperidino-2-nitroethane (**4a**) was obtained as yellow crystals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1902—1908 (1968)

Novel Reduction of Various Organic Compounds with Water in the Presence of Precipitated Metals[1)]

Koji SAKAI, Masayoshi ISHIGE, Hiromichi KONO, Izumi MOTOYAMA, Ken-ichi WATANABE and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received December 27, 1967)

It was found that various organic compounds were reduced in good yields by refluxing them with precipitated metals in water. Water was proved to be indispensable as a hydrogen donor. The reduction of compounds which are insoluble in water was facilitated by using a mixture of dioxane and water. It is of interest that the reduction of nitriles with this catalyst afforded the hydrochlorides of the corresponding primary amines. The results imply the participation of the chloride ion on the ppt-metal catalyst. A selective reduction of C=C was observed in some α,β-unsaturated ketones, such as mesityl oxide and 1,3-diferrocenyl-2-buten-1-one. The relative activity of the various precipitated metals depends not only upon the kinds of the metals but also upon their combination. It is assumed that the surface of the ppt-Ni is acidic as a result of the coexisting chloride ion, which might participate in the catalytic reaction.

In 1952, Urushibara and Chuman discovered a new nickel catalyst[2)] and named it Urushibara nickel (abbreviated as U-Ni). It is prepared by the acid- or base-treatment of precipitated nickel (ppt-Ni in abbreviation), which is itself obtained by an ion-exchange reaction between a nickel chloride solution and zinc dust. This new nickel catalyst was proved to be useful for the catalytic hydrogenation of various organic compounds[3)] and also for other organic catalytic reactions[4)]; it has also been found that the catalytic activity of U-Ni is comparable to that of Raney-Ni. However, the nature of ppt-Ni as a precursor of the U-Ni had not yet been well studied. In a previous communication,[1)] it was reported that some organic compounds, such as olefins, ketones and nitro compounds, were catalytically reduced by refluxing them with water in the presence of ppt-Ni. It is noticeable that this reduction is performed by a simple procedure without any hydrogen gas, and that the ppt-Ni is generally useful for the reduction of various organic compounds. The present paper will deal with an extended investigation of reduction with water in the presence of ppt-Ni, and will discuss the function of ppt-Ni as a catalyst.

Results

The Reduction of Organic Compounds in the Presence of Ppt-Ni. The ppt-Ni is easily prepared by adding a hot aqueous solution of nickel chloride to zinc dust. After it has been dried under reduced pressure, it is so stable that it can be preserved in the air for a long time. Various organic compounds involving C=C, NO_2, C≡N, and C=O groups were reduced in satisfactory yields when refluxed with water in the presence of ppt-Ni; the results are summarized in Table 1.

In these reactions, it is noteworthy that water plays a dual role, serving both as a solvent and as a hydrogen donor. Indeed, while water was proved to be effective enough as a hydrogen donor,*1 methanol and ethanol are

*1 According to a private communication from Y. Urushibara and H. Tomoda, an effective reaction occurs without refluxing when an aqueous solution of acids or bases, such as HCl or NaOH, is added, drop by drop and in admixture with the sample to be reduced, into a stirred mixture of ppt-Ni and water.

a) The yields were calculated from the results of gas chromatographic analysis, except for Exp. No. 5. b) The reaction time was 16 hr. c) The reaction time was 20 hr. d) The amine was obtained as hydrochloride from the reaction mixture by evaporation. e) The composition of the nickel chelate was found to be $[Ni_2(2\text{-pyridylmethylamine})_5(2\text{-pyridinecarboxylic acid})(H_2O)_3Cl]$. f) More than 90% even when refluxed for 5 hr. g) Each product was identified by infrared spectra after the isolation by gas chromatography.

unsatisfactory. Whereas compounds insoluble in water were reduced only in poor yields, the use of a mixture of dioxane and water facilitated the reaction.

As may be seen in Table 1, ethylenic double bonds were easily hydrogenated in high yields; for example, ethylbenzene was obtained in an 81.4% yield from styrene, and isobutyl methyl ketone, in a 95% yield from mesityl oxide. In the reduction of unsaturated ketones, such as mesityl oxide and 1,3-diferrocenyl-2-buten-1-one,[5] the ethylenic double bonds were preferentially hydrogenated, while the carbonyl groups were unaffected.

Ketones were generally reduced to the corresponding secondary alcohols. In some cases a reduction of the carbonyl group to the methylene group was observed, as in the Clemmensen reduction.[6] Thus, dypnone, acetylferrocene, and benzoylferrocene[7] were mainly converted to 1,3-diphenylbutane, ethylferrocene, and benzylferrocene respectively. The reduction of acetophenone yielded a mixture containing 1-phenylethanol and ethylbenzene, while benzophenone similarly gave benzhydrol and diphenylmethane. Benzylideneacetone gave a more complicated product consisting of 4-phenyl-2-butanol, 4-phenyl-2-butanone, and *n*-butylbenzene. Menthone and camphor were respectively 96% and 97% recovered unchanged, while only a small amount of the corresponding alcohols were obtained.

Nitriles were predominantly converted to primary amines without the formation of secondary amines, which are often produced as by-products in ordinary catalytic hydrogenations. It is noteworthy that the amines were obtained as their hydrochlorides, the chloride anion presumably being supplied from ppt-Ni. 2-Cyanopyridine characteristically afforded a metal complex of the amine when treated with water in the presence of ppt-Ni or ppt-Cu, while 3- and 4-cyanopyridine gave only the corresponding amine hydrochlorides. *m*-Nitrobenzaldehyde was converted to *m*-methylaniline by a Clemmensen-type reduction, whereas benzaldehyde afforded only benzyl alcohol, no appreciable amount of the expected formation of toluene being observed.

The Reduction of Organic Compounds in the Presence of Ppt-Ni, Al. Another type of ppt-Ni (denoted as ppt-Ni,Al) was prepared using aluminum grains of 40—80 meshes instead of zinc dust. The U-Ni-BA,[8] prepared from the ppt-Ni,Al, has already been reported to be a good catalyst for the hydrogenation of aromatic nuclei. The X-ray diffraction pattern of ppt-Ni,Al showed sharp, proper peaks of nickel at 38.7°, 44.7°, 51.7°, and 76.5° in 2θ, whereas in ppt-Ni the peaks of nickel were little observed.

The results of the reduction in the presence of ppt-Ni,Al are given in Table 2. The activity of the ppt-Ni,Al was found to be high enough to reduce phenol to cyclohexanone and cyclohexanol. However, in the reduction of *o*- and *m*-cresol, most of the

phenols were recovered unchanged. The results of the reduction of acetophenone, benzophenone, styrene, and benzaldehyde were very similar to those obtained with the ordinary ppt-Ni.

Features of the Precipitated Metals. It has been reported[9,10] that ppt-Ni contains Ni, Zn, ZnO, Zn(OH)Cl, and $Zn(OH)_2$, and that the zinc in ppt-Ni is gradually oxidized to zinc oxide with the progress of the catalytic reaction in the presence of ppt-Ni; thus, the zinc not only acts as a carrier, but also protects the nickel from oxidation.

Since the behavior of zinc might be assumed to contribute greatly to the function of ppt-Ni, we tried to determine to what extent a variation in the Zn/Ni ratio in ppt-Ni affects the reaction. In Fig. 1 the correlation is expressed in terms of the yield of cyclohexanol obtained by the reduction of cyclohexanone. As Fig. 1 shows, the maximum yield of cyclohexanol was attained by a catalyst whose Zn/Ni ratio was 10. This ratio coincides with that of the ppt-Ni, from which the U-Ni catalyst with the highest activity was prepared. It might be concluded from this finding that zinc participates in the reaction by interacting with nickel as well as with water.

From these considerations, some other precipitated metals produced by treating a certain metal chloride with zinc may be

6	Ppt-Ni-Cu	5.5	94.5
7	Ppt-Ni-Fe	15.2	84.8

a) Products were determined by gas chromatography; column 1.5 m, silicone grease DC 550 on Celite 30—40 meshes; temp., *ca.* 150°C; flow rate, 60 cc/min; carrier gas, H_2.

expected to be more reactive than the ppt-Ni. Thus, the following precipitated metals were prepared: ppt-Co, ppt-Cu, ppt-Fe, and mixed precipitated metals, such as ppt-Ni-Co, ppt-Ni-Cu, and ppt-Ni-Fe. The relative activities of these precipitated metals were then examined in the reduction of cyclohexanone. The results of representative experiments, shown in Table 3, exhibit the relative activities in the following order: ppt-Ni-Co > ppt-Ni > ppt-Ni-Fe > ppt-Co > ppt-Ni-Cu > ppt-Cu > ppt-Fe. This indicates that the activity of precipitated metal may be increased by a proper combination of metals.

The behavior of ppt-Ni contrasts with that of ordinary hydrogenation catalysts. Thus, a rapid decomposition of hydrogen peroxide was observed in the presence of U-Ni, "Stabilized nickel," copper chromite, or zinc chromite, but it could not be observed with ppt-Ni. On the other hand, the effective reduction of the cited compounds by water was observed only in the presence of the "precipitated metals," whereas U-Ni, Raney-Ni, and other hydrogenation catalysts were very feeble. The difference between them is reflected in the X-ray diffraction diagrams. The results of X-ray diffraction analysis, suggest[11] that the surface of ppt-Ni never consists of nickel itself, but rather is convered with alloy-like layers composed of nickel and zinc, contaminated with OH^- and Cl^-.

Some of the experimental results are compatible with this view. Thus, it was found that the reduction of nitriles in the presence

11) S. Taira, "Shokubai Kogaku Koza (Catalytic Engineering)," Vol. 10, Chijinshokan & Co., Tokyo (1967), p. 498.

of ppt-Ni produced amine hydrochlorides, while scarcely any free amines were detectable. When the ppt-Ni was soaked in water, a silver nitrate test for chloride anion was negative after 24 hr and only slightly positive after 72 hr. However, when the ppt-Ni was digested in hot water for 72 hr, a distinct deposit of silver chloride was observed in a silver nitrate test of the solution. Consequently, the surface of the ppt-Ni may be assumed to be relatively acidic as a result of coexisting chloride ions, which might participate in the catalytic reaction.

The Acidity and Acid Strength[12] of the Surface of Ppt-Ni. To measure the acidity and acid strength of the surface of ppt-Ni, *n*-butylamine titration was applied to the ppt-Ni in benzene, using Methyl Red as an indicator (pK_a 4.8). Though Methyl Red generally turns into a red acidic form when it reacts with an acidic solid, the dark gray color of the ppt-Ni makes it impossible to detect any color change in the adsorbed indicator on the solid surface. Therefore, the point of neutralization was determined by noting the change in color on anhydrous magnesium sulfate, which had previously been mixed with the ppt-Ni. The relation between the weight of the ppt-Ni used and the amounts of the *n*-butylamine adsorbed is shown in Fig. 2. From the slope of the line in Fig 2, the acidity of ppt-Ni was calculated to be 1.05×10^{-5} (eq/g) at pK_a 4.8. On the other hand, the acidity of ppt-Ni was nearly zero when Methyl Yellow was used as an indicator (pK_a 3.3). These results imply that the acid strength of the surface is at least more acidic than pK_a 4.8, while the number of acid sites is comparatively small.

Discussion

It is well known that both zinc amalgam[6] and zinc itself[13] can be used for reduction in acidic, basic, or neutral solutions. However, the reduction generally requires the cooperation of acid to increase the yield of the reaction product, and subsequent undesirable side-reactions due to the acid are inevitable. A unique characteristic of the reduction with ppt-Ni is the use of water as a hydrogen donor, thus making the use of any acid generally unnecessary. Consequently, the reduction can be performed under practically neutral conditions.

The results shown in Table 1 suggest that the reduction may proceed in a manner somewhat similar to that in the Clemmensen reduction. However, there are some differences between these two reduction reactions. The Clemmensen reduction of a ketone often results in the formation of alcohol, saturated hydrocarbon, olefin, and a dimerization or rearrangement product; for example, benzophenone yields benzhydrol, diphenylmethane, tetraphenylethylene, and benzopinacol. In regard to the formation of the pinacol, a radical intermediate has been proposed for the mechanism of the Clemmensen reduction.[14] On the other hand, the reduction of benzophenone in the presence of the ppt-Ni affords only benzhydrol and diphenylmethane. A radical mechanism may be excluded on the base of the fact that no formation of the pinacol was observed. The presence of a large quantity of water as a solvent also supports this presumption.

Among three analogous α,β-unsaturated ketones $RC(CH_3)=CHCOR$ ($R=CH_3$, C_6H_5, ferrocenyl), the reduction of carbonyl to methylene was observed only in dypnone ($R=C_6H_5$). It has been reported[15] that the carbonyl group in mesityl oxide also remains unaffected by the Clemmensen reduction, the reason being discussed by postulating the intermediacy of a cyclopropanol form. On the other hand, Rinehart *et al.*[16] have pointed out the differ-

16) L. Rinehart, Jr., J. Curby, Jr., H. Gustafson, K.G.Harrison, R.E. Bozak and D.E.Bublity, *J. Am. Chem. Soc.*, **84**, 3263 (1962).

ence in behavior between 1,3-diferrocenyl-2-buten-1-one and dypnone toward reaction with methylmagnesium bromide, the former not bringing about either the 1,4- or 1,2-addition of the Grignard reagent, whereas the latter does so. The present results on the reduction in the presence of ppt-Ni are compatible with these observations.

Bradlow *et al.*[17] have examined the substituent effect in the Clemmensen reduction of benzophenone derivatives; they found that substituents in the ortho position or electron-withdrawing substituents facilitate the formation of diphenylmethanes, whereas electron-donating substituents promote the formation of pinacols. In the present reduction of carbonyl groups, the trend of the reaction must be affected not only by the electronic factor but also by the steric factor. A molecule of dypnone can take a planar conformation in which the C=C, C=O, and two phenyl groups lie on a common plane, as is indicated by a molecular model. The planar conformation may facilitate the approach of the molecule toward the catalyst metal, resulting in the reduction of both ethylenic and carbonyl groups. On the other hand, a voluminous ferrocenyl group is assumed to hinder the approach of the carbonyl group toward the catalyst metal, thus preventing the catalytic reduction.

At any rate, the ppt-metal catalyzed reaction has been found to be relatively complex, and it is difficult to explain the function of ppt-metal in terms of the electrode potential of the metals. It was found that the ppt-Ni prepared with a 0.25 M sodium chloride solution instead of water increased the yield of the product, and the X-ray diffraction analysis has indicated an increase in the amount of Zn(OH)Cl in this particular ppt-Ni.

Though the mechanism of the ppt-metal-catalyzed reaction has not yet been sufficiently elucidated, the reaction may be assumed to involve at least two processes—the decomposition of water and the reduction of substrates, and the reduction may follow a course similar to that in an ordinary hydrogenation reaction. A more detailed discussion of the mechanism of this reaction will, however, be reported in a subsequent paper.

Experimental

Catalysts. *Precipitated Metals.* Zinc dust (10 g) and distilled water (3 m*l*) were placed in an Erlenmeyer flask and heated on a water bath. An aqueous solution (10 m*l*) containing either 4.04 g of nickel(II) chloride ($NiCl_2 \cdot 6H_2O$),[2] 4.04 g of cobalt(II) chloride ($CoCl_2 \cdot 6H_2O$), 2.69 g of copper(II) chloride ($CuCl_2 \cdot 2H_2O$), or 4.84 g of iron(III) chloride (anhydrous), previously heated to 60°C, was added to the heated zinc dust mud with vigorous shaking. A violent exchange reaction took place, depositing nickel on the surface of the zink dust. The whole solid was collected on a glass filter by suction, washed with water three times and then with methanol and ether, and dried under reduced pressure. The precipitated metal thus obtained contains about 1 g of each metal, supported on the zinc dust.

Mixed Precipitated Metals. Ppt-Ni-Co, ppt-Ni-Cu, and ppt-Ni-Fe were prepared by the same procedure using a mixture of 2 g of nickel(II) chloride and either 2 g of $CoCl_2 \cdot 6H_2O$, 1.5 g of $CuCl_2 \cdot 2H_2O$, or 1.4 g of $FeCl_3$, instead of 4.04 g of nickel chloride alone.

Ppt-Ni,Al. Aluminum grains of 40—80 meshes (50 g) were washed with 250 m*l* of a 3% sodium hydroxide solution and then with water. The aluminum grains were placed in a 300-m*l* Erlenmeyer flask along with a small quantity of water, and were heated on a water bath. An aqueous solution of nickel chloride (100 m*l*) containing 40 g of $NiCl_2 \cdot 6H_2O$, previously heated to 80°C, was poured on the aluminum grains. Occasional stirring with a glass rod was continued until the slushy reaction mixture became nearly solid. The solid was then washed three times with water and then with methanol and ether, and dried under reduced pressure.

The Reduction of Styrene. A suspension of styrene (10 g) in 100 m*l* of water was refluxed vigorously in the presence of the ppt-Ni containing 4 g of nickel. After the solution had been refluxed for 12 hr, the ppt-Ni was separated by filtration while hot, and washed with water and with ether. The filtrate and the washings were combined and extracted with ether. The extract was dried over anhydrous magnesium sulfate, and the ether was carefully evaporated away on a water bath. The residue was analyzed by gas chromatography (column, 30% Carbowax 1500 on Celite 30—40 meshes; length, 2 m; column temp., *ca.* 180°C; flow rate, 14—20 cm/sec; carrier gas, H_2). The yield of ethylbenzene was 81.4%. The ethylbenzene (bp 129—131°C) was identified by infrared spectrum analysis.

The Reduction of Benzonitrile. The reaction procedure was almost the same as that described above. After the reaction, the ppt-Ni was filtered off. The filtrate was carefully evaporated to dryness under reduced pressure, and the residue was extracted with ether. The evaporation of the ether extract gave a small quantity of a white solid which was identified as benzamide. A major part of the product, which consisted of a white solid insoluble in ether, was recrystallized from hot water (mp >240°C). It was identified as benzylamine hydrochloride by IR analysis (ν_{max}^{KBr} 3012, 1520, 1500, 750, and 695 cm^{-1}) and by NMR analysis (benzene ring protons τ 2.55, methylene protons τ 5.8 in D_2O). The hydrochloride (yield, *ca.* 90%) liberated benzyl-

17) H. L. Bradlow and C. A. van der Werf, *J. Am. Chem. Soc.*, **69**, 1254 (1948).

amine when treated with sodium hydroxide.

The Reduction of Formylferrocene.[18] After the reaction had been conducted in a similar manner, the ppt-Ni was separated and the product was obtained by extraction with ether. The gas chromatographic analysis (column, 20% APL on Celite 30—40 meshes; length, 2 m; column temp., *ca.* 180°C; flow rate, 20—15 cm/sec; carrier gas, H_2) indicated a sole compound as the reduction product. The crude product was dissolved in benzene and separated by column chromatography on active alumina (*ca.* 100—200 meshes), using *n*-hexane for elution. A careful evaporation of the yellow elute afforded yellow crystals of methylferrocene (yield, *ca.* 80%), mp 34.9—35.2°C (lit. 35.5—36.5 °C). This substance was identified by comparing its infrared spectrum with that of an authentic specimen. A successive elution of the column chromatography exhibited a small quantity of a yellow crystalline product, which could not be detected on gas chromatography and which was assumed to be 1-methyl-2-(ferrocenylmethyl)ferrocene on the basis of its NMR spectrum.

The Reduction of 2-Cyanopyridine. 2-Cyanopyridine (0.3 g) and water (10 m*l*) were refluxed vigorously in the presence of ppt-Ni or ppt-Cu (containing 0.4 g of the catalyst metal) for 10 hr. After the ppt-Ni or ppt-Cu had then been filtered off, the filtrate was carefully evaporated to dryness on a water bath; a green solid was thus obtained. The solid was washed with ether, dissolved in ethanol, and separated by column chromatography on active alumina. The evaporation of the solvent from the elute gave a greenish-blue solid. Recrystallization from hot water afforded a nickel or copper chelate in the form of greenish-blue (nickel) or pale blue (copper) needles. Elementary analyses were carried out with samples dried at 56°C under reduced pressure for 1 hr.

Nickel complex, Found: C, 49.67; H, 5.52; N, 17.68%. Calcd for $C_{36}H_{50}O_5N_{11}ClNi_2$: C, 49.7; H, 5.75; N, 17.7%.

Copper complex, Found: C, 31.09; H, 3.91; N, 12.42%. Calcd for $C_6H_8N_2Cl_2Cu$: C, 29.7; H, 3.30, N, 11.5%.

These metal complexes were confirmed to be metal chelates of 2-pyridylmethylamine by means of their infrared and ultraviolet spectra.[19] The composition of the nickel chelate corresponds to the formula. $Ni_2(C_5H_5NCH_2NH_2)_5(C_5H_5NCO_2H)(H_2O)_3Cl$ Nickel complex: IR, ν_{max}^{KBr} 3220,2924,1670(s), 1608 cm^{-1} UV, $\lambda_{max}^{H_2O}$ 267,261,254 mμ. Copper complex: IR, ν_{max}^{KBr} 3220, 2924, 1604 cm^{-1}. UV, $\lambda_{max}^{H_2O}$ 253, 247, 240 mμ.

Acid Strength Measurement[12] **of Ppt-Ni.** The ppt-N powder was completely dried for an hour at 80°C under reduced pressure. A sample of the ppt-Ni (0.0215 g) was then placed in a 50-m*l* Erlenmeyer flask, together with 0.500 g of anhydrous magnesium sulfate. Dry benzene (5 m*l*) and a drop of a 0.1% benzene solution of Methyl Red (pK_a 4.8) were added to the mixture. The indicator immediately gave a red color on the magnesium sulfate. Then, a 0.0999 N benzene solution of *n*-butylamine was added, drop by drop, through a micropipet until a color change from red to yellow was observed on the surface of the magnesium sulfate. Referring to a blank test in order to evaluate the acid strength of the magnesium sulfate itself, the amount of *n*-butylamine adsorbed on the acid sites of the ppt-Ni was then calculated. Similar titrations were made with 0.0516 g and 0.0817 g of ppt-Ni; the results are plotted on Fig. 2.

Using Methyl Yellow as an indicator, the same titration method was applied to measure the acid strength of ppt-Ni in pK_a 3.3. In order to ensure that no excess of amine was present on the solid at the end point, a drop of 0.05 N trichloroacetic acid in benzene was added; the red color then reappeared.

The authors wish to express their hearty thanks to Professor Dr. Michio Kobayashi for his helpful advice, and also to Mr. Yasuharu Nakaido and Mr. Satoshi Kobayashi of Gunma University and Dr. Masami Ichikuni of this University for their X-ray analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1909—1916 (1968)

Studies of Peptide Antibiotics. XIII. Synthesis of Retrogramicidin S[1]

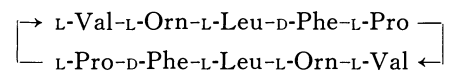
Michinori WAKI and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received January 22, 1968)

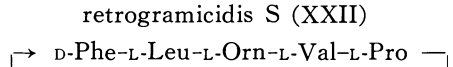
In order to investigate a contribution for an antibacterial activity of a direction of the peptide bonds in gramicidin S molecule, retrogramicidin S with the reverse peptide sequence was prepared through a cyclization reaction of linear decapeptide active ester in pyridine. The cyclization of linear pentapeptide active ester yielded a mixture of retrocyclosemigramicidin S and retrogramicidin S. Retrogramicidin S thus obtained exhibited a weak activity against *Bacillus subtilis* and *Staphylococcus aureus*, whereas retrocyclosemigramicidin S showed no activity against any of microorganisms tested.

In studies of the relationship between chemical structure and biological activity of gramicidin S, various analogs wherein several amino acid residues are replaced by other amino acids have been synthesized in this laboratory.[2] For example, it was found that [5,5′-glycine]-gramicidin S[3,4] possessed a stronger activity in several-fold than natural gramicidin S. As a different type of synthetic analogs of gramicidin S, we have designed the synthesis of retrogramicidin S in order to determine what degree the direction of the peptide bonds contributes to a biological activity. The retrogramicidin S can be regarded as a cyclodiastereomer, which has been called by Prelog,[5] of gramicidin S.



gramicidin S

retrogramicidis S (XXII)



retrocyclosemigramicidin S (XXIII)

In the studies of synthetic analogs of linear biologically active peptides, a retro-analog of bradykinin has been synthesized by two groups,[6] they observed that the retrobradykinin was completely inactive in the rat uterus assay. As an analog of cyclic active peptides, Shemyakin *et al.* demonstrated that the retroenantio-[5,5′-glycine]-gramicidin S was highly active as the parent compound, [5,5′-glycine]-gramicidin S.[7]

For the conformation of gramicidin S in the solid- and solution-state, several models have been proposed.[8] A possible model (Fig. 1) is the intramolecular antiparallel β form with four hydrogen bond which has been suggested by Hodgkin and Oughton with the results of X-ray crystallographic investigation.[9] Schwyzer also suggested the same model with the occurrence of dimerization reaction on the

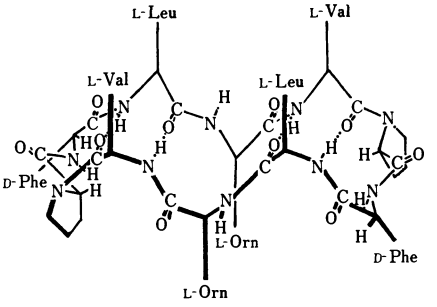

Fig. 2. A possible structure of retrogramicidin S.

occasion of gramicidin S synthesis.[10] In this model, the hydrophilic ornithyl side chains are on one side of the pleated sheet, thus the model appears to be a cationic detergent. Rothen's surface studies on gramicidin S, quoted in Craig's article,[11] also seem to support this model. We attempted to construct the retrogramicidin S model (Fig. 2) with the antiparallel β form, which has been suggested by Hodgkin and Oughton, as a principal frame by molecular model study. It is observed that the hydrophobic proline residues are directed to the side where the ornithyl side chains are located on. Since the character as a specific cationic detergent for gramicidin S is an important factor for the antibacterial activ-

11) L.C. Craig, *Science*, **144**, 1093 (1964).

ity,[12] two proline residues in retrogramicidin S may disturb an interaction of the compound and a microorganism. Thus, we tended to surmise that retrogramicidin S would possess weaker or no activity compared with gramicidin S.

The sequence of reaction employed for the synthesis of retrogramicidin S (XXII) from a linear decapeptide nitrophenyl ester is shown in Fig. 3. The sequence of steps was chosen specifically to preclude racemization. The tripeptide ester (X) was obtained by treatment of hydrogen chloride on either VIII or IX. In this step, the use of *o*-nitrophenylsulfenyl group seemed more advantageous than that of *p*-methoxybenzyloxycarbonyl; *o*-nitrophenylsulfenyl chloride,[13] which was used for VI synthesis, was prepared more easily than *p*-methoxybenzyloxycarbonyl azide,[14] and the selective removal of nitrophenylsulfenyl group from VIII or XIII was easier than that of methoxybenzyloxycarbonyl group from IX or XIV. The condensation of the azide derived from acyldipeptide hydrazide (III) with X gave acylpentapeptide ester (XI).

To obtain an acylpentapeptide acid (XVI), the acylpentapeptide ester (XI) was subjected to saponification. When XI was treated with dilute alkali (Fig. 4), there was formed a crude product which was composed of two compounds. The mixture was separated into two pure components by use of a Sephadex LH-20 column; the desired acylpeptide acid (XVI) was obtained from the faster eluting fraction, and a compound with mp 121—123 ℃ was obtained from the slower fraction. The elemental analysis of the latter compound and the neutral equivalent by quantitative titration procedure favored the dibasic acid of structure

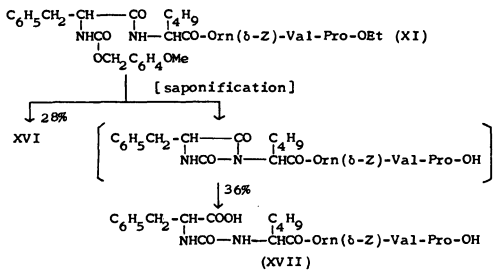

Fig. 4. Saponification of acylpentapeptide ethyl ester (XI).

XVII. It appeared that the cyclization with loss of *p*-methoxybenzyl alcohol, followed by hydrolytic opening of the hydantoin intermediate, had occurred in addition to the desired hydrolysis reaction. Such rearrangements have been observed already by Maclaren[15] and Bodanszky *et al.*,[16] the latter group demonstrated that alkaline treatment of *α*-benzyloxycarbonyl-*ω*-nitroarginyl-tetraglycine ethyl ester yielded a dibasic acid, 5-[1-carboxy-4(3-nitroguanidino)butyl]-hydantoyl-triglycine.

The acylpentapeptide acid (XVI) was prepared more efficiently as follows. Saponification of acyltripeptide ester (VIII or IX) gave the acyltripeptide acid (XIII or XIV) without appreciable side reactions, then either XIII or XIV was transformed to the free tripeptide (XV). The condensation of the azide from III with XV afforded the acylpentapeptide acid (XVI) in a good yield. Then, the condensation of the azide from XII with free pentapeptide (XVIII), which had been obtained from XVI, gave the acyldecapeptide acid(XIX). The successive treatments of XIX with di-*p*-nitrophenyl sulfite, trifluoroacetic acid and excess pyridine afforded the benzyloxycarbonyl-substituted cyclic decapeptide (XX) in a good yield (49% from XIX). The hydrogenation of XX in the presence of two equivalents of hydrogen chloride yielded the desired retrogramicidin S dihydrochloride as colorless crystals containing water of crystallization.

The synthesis of the protected cyclic decapeptide (XX) was also attempted by possibe dimerization reaction of the pentapeptide active ester (XXIV) (Fig. 5). The compound XXIV was treated with excess pyridine, and after evaporation the reaction mixture was passed through Dowex 1 and 50 columns; the subsequent evaporation of the effluent yielded a semisolid residue. This

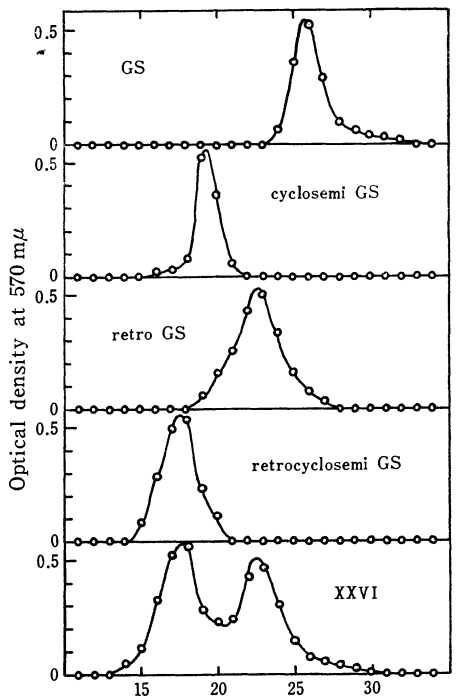

Fig. 7. Carboxymethylcellulose column chromatography of the compounds.

residue was found to be a mixture of two components by analyses with a hydrogenated material of a small part of the residue (see, Figs. 6 and 7). The residue was applied with a Sephadex LH-20 column to be separated into the components; dimer (XX) was obtained in a yield of 22.6% and the monomer (XXI) obtained in 25.3%. Thus, the weight ratio of XXI and XX is calculated as 53 : 47; the result indicates that an appreciable portion of the active ester (XXIV) is present in a transition state favored for the formation of the cyclic dimer even though some active esters are directed to the intramolecular cyclization reaction. We reported already that the cyclization reaction of H-Val-Orn(δ-Z)-Leu-D-Phe-Pro-ONp (XXVII) had afforded a mixture of the protected cyclosemigramicidin S and the protected gramicidin S with a weight ratio of 32 : 68.[16] In spite of the profound difference of the amino acid sequences between XXIV and XXVII, the formation of the protected cyclic decapeptides in considerable amount by the dimerization reaction in both cases favors for the stable comformation of a XX and protected gramicidin S molecule.

The antibacterial activity of gramicidin S, retrogramicidin S (XXII) and retrocyclosemigramicidin S (XXIII) toward several microorganisms was examined. The monomer XXIII showed no activity for any of the microorganisms even at 100 μg/ml of the assay medium.[17] Gramicidin S and XXII showed also no activity for the Gram negative microorganisms (*E. coli* and other), whereas minimum concentrations of growth-inhibition for the Gram positive microorganisms (*B. Subtilis* and other) were found to be 5 μg/ml with gramicidin S and 50 μg/ml with XXII. Since this results agree in some extent with the surmise described already, the proposed structure (Fig. 2) for a retrogramicidin S molecular as a possible conformation will be useful for understanding the mode of antibacterial activities of gramicidin S and its analogs.

Experimental

All the melting points are uncorrected. Prior to analysis, the compounds were dried over phosphorus pentoxide to a constant weight at 80°C and 2 mmHg, except for the cyclic peptide hydrochlorides.

Z(OMe)-D-Phe-OH·DCHA(I·DCHA).[18] A solution of dicyclohexylamine (6 ml) in ether (10 ml) was added to *p*-methoxybenzyloxycarbonyl-D-phenylalanine which was prepared from D-phenylalanine (0.03 mol).[19] Ether was evaporated *in vacuo*, and the residual oil was crystallized by the addition of petroleum ether. It was recrystallized from ethyl acetate-petroleum ether; yield, 9.85 g (64% from

D-phenylalanine); mp 154—155°C; $[\alpha]_D^{20}$ −23.6° (*c* 1, methanol); R_f 0.77.[20]

Found: C, 70.36; H, 8.27; N, 5.22%. Calcd for $C_{30}H_{42}O_5N_2$: C, 70.56; H, 8.29; N, 5.49%.

Z(OMe)-D-Phe-Leu-OEt (II). To a solution of I·DCHA (10.21 g, 20 mmol), L-leucine ethyl ester *p*-toluenesulfonate[21] (6.63 g, 20 mmol) in chloroform (120 ml) was added dicyclohexylcarbodiimide[22] (4.13 g, 20 mmol) at 0 °C. The reaction mixture was stirred for 1 hr at 0 °C, and then kept overnight in a refrigerator. The mixture was evaporated *in vacuo*, and ethyl acetate (150 ml) was added to the residue. After the dicyclohexylurea was filtered off, the filtrate was washed successively with 0.5 M citric acid, 4% sodium bicarbonate and water, and dried over sodium sulfate. The filtrate was evaporated *in vacuo*, and the residue was crystallized by the addition of ether and petroleum ether. It was recrystallized from methanol-ether-petroleum ether; yield, 7.25 g (77%); mp 108—109°C; $[\alpha]_D^{25}$ −0.6° (*c* 1, DMF); R_f 0.97.[20]

Found: C, 66.31; H, 7.35; N, 6.01%. Calcd for $C_{26}H_{34}O_6N_2$: C, 66.36; H, 7.28; N, 5.95%.

Z(OMe)-D-Phe-Leu-NHNH$_2$ (III). A solution of II (7.06 g, 15 mmol) and hydrazine hydrate (14.6 ml, 300 mmol) in dimethylformamide (20 ml) was allowed to stand at room temperature for 2 days. The hydrazine was evaporated *in vacuo*, and then water (250 ml) was added to the residue. The resulting crystals were collected by filtration; yield, 6.51 g (95%); mp 176—177°C; $[\alpha]_D^{20}$ −7.5° (*c* 1, DMF); R_f 0.87.[20]

Found: C, 63.23; H, 7.05; N, 12.18%. Calcd for $C_{24}H_{32}O_5N_4$: C, 63.14; H, 7.07; N, 12.27%.

Z-Val-Pro-OEt (IV). To a chilled solution of benzyloxycarbonyl-L-valine (10.05 g, 50 mmol) and triethylamime (5.6 ml, 40 mmol) in tetrahydrofuran (60 ml), isobutylchloroformate (5.24 ml, 40 mmol) was added. After 15 min, a mixture of L-proline ethyl ester *p*-toluenesulfonate[21] (12.61 g, 40 mmol), triethylamine (5.6 ml, 40 mmol) and chloroform (60 ml) was added to the solution. The reaction mixture was allowed to stand overnight and then evaporated to dryness *in vacuo*. After the residual oil was dissolved in ethyl acetate, the solution was washed successively with 3% hydrochloric acid, 4% sodium bicarbonate and water, dried over sodium sulfate, and then the filtrate was evaporated. The product was obtained as an oil; yield, 10.36 g (69%); R_f 0.94.[20]

HCl·H-Val-Pro-OEt (V·HCl). A solution of IV (7.53 g, 20 mmol) dissolved in a mixture of 3.97 N ethanolic hydrogen chloride (5.04 ml) and ethanol (100 ml) was hydrogenated in the presence of palladium black. After 3 hr, the filtrate from the catalyst was evaporated to dryness *in vacuo*. The oil weighed 5.35 g (96%); R_f 0.79.[20]

Nps-Orn(δ-Z)-OH·DCHA(VI·DCHA). δ-Benzyloxycarbonyl-L-ornithine (10.65 g, 40 mmol) was dissolved in a mixture of 2 N sodium hydroxide (40 ml, 80 mmol) and dioxane (160 ml). To the solution, *o*-nitrophenysulfenyl chloride[13] (7.59 g, 40 mmol) and 2 N sodium hydroxide (15 ml, 30 mmol) was added 5 portions over a period of 30 min under vigorous stirring. The reaction mixture was diluted with water (600 ml), a small amount of the insoluble material was filtered off and the filtrate was acidified with 0.5 M citric acid at 0 °C. The solution was extracted with ethyl acetate, and the extract was washed with water and dried over sodium sulfate. The filtrate from the salt was evaporated *in vacuo*. To the residue the solution of dicyclohexylamine (8 ml) in ether (10 ml) was added. This solution was treated following the same procedure described for the preparation of I·DCHA. The crude product was recrystallized from methanol-ether-petroleum ether; yield, 17.06 g (71%); mp 167—169 °C; $[\alpha]_D^{25}$ −25.0° (*c* 1, DMF); R_f 0.85.[20]

Found: C, 61.81; H, 7.38; N, 9.06%. Calcd for $C_{31}H_{44}O_6N_4S$: C, 61.97; H, 7.38; N, 9.33%.

Z(OMe)-Orn(δ-Z)-OH·DCHA (VII·DCHA). *p*-Methoxybenzyloxycarbonyl-δ-benzyloxycarbonyl-L-ornithine[23] was prepared from δ-benzyloxycarbonyl-ornithine (0.05 mol) and then changed to VII·DCHA as described for the preparation of I·DCHA; yield, 20.56 g (67%), mp 121—122 °C; $[\alpha]_D^{20}$ −4.0° (*c* 1, methanol); R_f 0.81.[20]

Found: C, 66.80; H, 8.15; N, 6.77%. Calcd for $C_{34}H_{49}O_7N_3$: C, 66.75; H, 8.09; N, 6.87%.

Nps-Orn(δ-Z)-Val-Pro-OEt (VIII). To a suspension of VI·DCHA (6.01 g, 10 mmol) in ethyl acetate (100 ml) at 0 °C, 0.5 M citric acid (40 ml) was added under stirring. After 1 hr, the organic layer was separated and washed with water. It was then dried over sodium sulfate and evaporated to dryness to give an oily product (4.20 g) of VI. To a solution of the oily VI in chloroform (60 ml) was added V·HCl (3.07 g, 11 mmol) and triethylamine (1.54 ml, 11 mmol). Dicyclohexylcarbodiimide (2.06 g, 10 mmol) was added to the solution at 0 °C, and then the reaction mixture was treated in the same manner as that used for the preparation of II. The residual oil weighed 6.37 g (99%); R_f 0.98.[20]

Z(OMe)-Orn(δ-Z)-Val-Pro-OEt (IX). A crystalline product VII (4.35 g) from VII·DCHA (6.12 g, 10 mmol) was coupled with V·HCl (3.07 g, 11 mmol) by dicyclohexylcarbodiimide (2.06 g, 10 mmol) following essentially the same procedure described above. The oily residue obtained weighed 6.29 g (96%); R_f 0.94.[20]

HCl·H-Orn(δ-Z)-Val-Pro-OEt (X·HCl). From VIII. To a solution of VIII (5.15 g, 8 mmol) in

20) The R_f value of the thin-layer chromatography with Merck silica gel refers to a solvent system of *n*-butanol-acetic acid-pyridine-water (4 : 1 : 1 : 2, v/v). Spots of materials possessing a free amino group on a thin-layer plate were detected by spraying ninhydrin, and those of the amino group-blocked materials, by spraying 47% hydrobromic acid and then ninhydrin.

dioxane (16 ml), 2 N hydrogen chloride in dioxane (16 ml) was added. After the solution was allowed to stand at room temperature for 30 min, the solution was evaporated *in vacuo*. The residual oil was washed several times with ether by the way of decantation ; yield of the oily X·HCl, 5.11 g (97 %); R_f 0.82.[20]

From IX. A solution of IX (5.24 g, 8 mmol) and anisole (2 ml) in dioxane (20 ml) was treated with 3 N hydrogen chloride in dioxane (53 ml) for 3 hr; yield of the oily X·HCl, 5.27 g (100%); R_f 0.82.[20]

Z(OMe)-D-Phe-Leu-Orn(δ-Z)-Val-Pro-OEt (XI). To a chilled solution of III (4.57 g, 10 mmol) in glacial acetic acid (140 ml) and dimethylformamide (70 ml), there were stirred 1 N hydrochloric acid (22 ml), sodium nitrite (0.76 g) in water (2 ml). After 10 min, cold water (500 ml) was added. The azide which thereupon precipitated was collected by filtration, washed with water, a saturated sodium bicarbonate solution and water, and then dried in a desiccator. The azide was added to a solution of X·HCl (5.27 g, 10 mmol) and triethylamine (14 ml) in dimethylformamide (50 ml). The mixture was then stirred for 3 days at 0 °C and evaporated *in vacuo*. The precipitate which was formed upon the addition of water (400 ml) was collected, and then washed with 4 % sodium bicarbonate, 0.5 M citric acid and water. It was recrystallized from dioxane-ether-petroleum ether. Yield, 6.26 g (68%); mp 158—159 °C; $[\alpha]_D^{20}$ −31.0° (*c* 1, DMF); R_f 0.98[20]

Found: C, 64.38; H, 7.31; N, 9.00 %. Calcd for $C_{49}H_{66}O_{11}N_6$: C, 64.31; H, 7.27; N, 9.19 %.

Z(OMe)-D-Phe-Leu-Orn(δ-Z)-Val-Pro-NHNH$_2$ (XII). To a solution of XI (0.92 g, 1 mmol) in dimethylformamide (8 ml), hydrazine hydrate (1.21 ml, 25 mmol) was added and the solution was allowed to stand for 7 days at room temperature. The reaction mixture was then evaporated *in vacuo*. The hydrazide which precipitated upon the addition of water was collected by filtration and dried. The product was recrystallized from methanol-ether; yield, 0.75 g (83 %); mp 160—161 °C; $[\alpha]_D^{20}$ −29.4° (*c* 0.5, DMF); R_f 0.88[20].

Found: C, 62.14; H, 7.27; N, 12.12 %. Calcd for $C_{47}H_{64}O_{10}N_8 \cdot 1/2H_2O$: C, 62.03; H, 7.20; N, 12.31 %.

Nps-Orn(δ-Z)-Val-Pro-OH (XIII). To a solution of VIII (5.31 g 8 mmol) in methanol (40 ml) and dioxane (40 ml), N sodium hydroxide (32 ml) was added; the solution then was allowed to stand for 24 hr at room temperature. After the addition of water (40 ml), the solution was evaporated *in vacuo* to remove organic solvents. After the solution was extracted with ether, it was acidified with 0.5 M citric acid at 0 °C. The solution was extracted with ethyl acetate and the organic layer was dried over sodium sulfate. The filtrate was evaporated to dryness *in vacuo* to afford an oily product; yield, 3.05 g (62%); R_f 0.86.[20]

Z(OMe)-Orn(δ-Z)-Val-Pro-OH (XIV). To a solution of IX (3.27 g, 5 mmol) in methanol (50 ml), 1 N sodium hydroxide (10 ml) was added. The solution was treated following the same procedure described above. The residual oil weighed 1.89 g (60 %); R_f 0.84.[20]

HCl·H-Orn(δ-Z)-Val-Pro-OH (XV·HCl). From XIII. To a solution of XIII (3.08 g, 5 mmol) in dioxane (20 ml), 2 N hydrogen chloride in dioxane (15 ml) was added at room temperature. After 30 min the solution was evaporated to dryness, and the residue was washed repeatedly with ether by decantation. The remaining hygroscopic crystals were collected by filtration with the aid of ether; yield, 1.90 g (76 %); mp 135—140 °C (decomp.); $[\alpha]_D^{20}$ −18.0° (*c* 0.5, DMF); R_f 0.71.[20]

Found: C, 53.60; H, 7.19; N, 10.57 %. Calcd for $C_{23}H_{34}O_6N_4 \cdot HCl \cdot H_2O$: C, 53.43; H, 7.21; N, 10.84%.

From XIV. XV·HCl was also prepared from XIV (1.88 g, 3 mmol), anisole (0.9 ml) and 2.53 N hydrogen chloride in dioxane (23.7 ml) for 2 hr following the same procedure described above; yield, 1.03 g (69 %); $[\alpha]_D^{25}$ −17.9° (*c* 0.4, DMF); R_f 0.71.[20]

H-Orn(δ-Z)-Val-Pro-OH (XV). XV·HCl (998 mg, 2 mmol) was dissolved in small volume of a mixture of water and methanol. After triethylamine (0.28 ml) had been added, the solution was evaporated to dryness *in vacuo*. The crystalline product was collected by filtration with the aid of water ; yield, 898 mg (97 %); mp 174—176 °C (decomp.); $[\alpha]_D^{25}$ −34.0° (*c* 0.4, acetic acid); R_f 0.71.[20]

Found: C, 53.34; H, 7.68; N, 10.91 %. Calcd for $C_{23}H_{34}O_6N_4 \cdot 2H_2O$: C, 55.41; H, 7.68; N, 11.24 %.

Z(OMe)-D-Phe-Leu-Orn(δ-Z)-Val-Pro-OH (XVI). From III and XV. The azide derived from III (2.15 g, 4.7 mmol) was added to a solution of XV·HCl (2.50 g, 5 mmol) and triethylamine (1.4 ml, 10 mmol) in dimethylformamide (25 ml), and the mixture was stirred for 3 days at 0 °C. The mixture was evaporated *in vacuo*, and the residue was added to ethyl acetate (300 ml). The mixture was washed successively with water, 0.5 M citric acid, and water, and then dried over sodium sulfate. After the filtrate was evaporated, the residual crystals were collected with the aid of a mixture of ether and petroleum ether. It was recrystallized from methanol-ether-petroleum ether; yield, 2.92 g (70 %); mp 137—138°C; $[\alpha]_D^{25}$ −29.5° (*c* 0.5, DMF); R_f 0.82,[20] 0.68.[24]

Found: C, 63.53; H, 6.75; N, 9.66 %. Calcd for $C_{47}H_{62}O_{11}N_6$: C, 63.64; H, 7.65; N, 9.48 %.

From XI. To a solution of XI (275 mg, 0.3 mmol) in ethanol (4 ml) and dioxane (2 ml), 1 N sodium hydroxide (0.6 ml) was added at room temperature. The hydrolysis was almost complete after 4 hr. The solution was concentrated *in vacuo* to small volume, and acidified with 0.5 M citric acid under cooling. The separated crystalline solid was taken up with ethyl acetate, and the ethyl acetate solution was washed with water, dried over sodium sulfate. The filtrate was evaporated, and the residual crystals were collected by filtration with the aid of a mixture of ether and petroleum ether; yield of the crude product, 208 mg. The crude product was separated into the two pure components as follows. A solution of the crude product (200 mg) in dioxane (0.6 ml)

24) The R_f value of the thin-layer chromatography refers to a solvent system of chloroform-methanol (5 : 1, v/v).

was applied to a column (0.9×48 cm) with Sephadex LH-20, and the development continued with dioxane. Elution was carried out at room temperature, the flow rate 7 ml per hr, and 1.5 ml fraction collected. When the peptide content in the fractions was determined on a thin-layer plate, two compounds appeared separately in tube numbers 10 to 13 and 14 to 20. The fractions of 10—13 were combined, evaporated and the crystals of XVI were obtained. Yield, 73 mg (28 % from XI); mp 136—137 °C; $[\alpha]_D^{25}$ −30.6° (*c* 0.2, DMF); R_f 0.82[20], 0.68.[24]

2-Isobutyl-5-[1-carboxy-2-(phenyl)-ethyl]-hydantoyl-Orn(∂-Z)-Val-Pro-OH (XVII). The fractions of 14—20 obtained in above was evaporated *in vacuo*, and the residual product was recrystallized from methanol-water; yield, 80 mg (36 % from XI); mp 121—123 °C; $[\alpha]_D^{25}$ −23.3° (*c* 0.3, DMF); R_f 0.65.[24]

Found: C, 61.21; H, 7.49; N, 10.55 %; neut equiv, 784. Calcd for $C_{39}H_{54}O_{10}N_6$: C, 61.08; H, 7.10; N, 10.96 %; neut equiv, 767.

HCl·H-D-Phe-Leu-Orn(∂-Z)-Val-Pro-OH (XVIII·HCl). To a solution of XVI (1.06 g, 1.2 mmol) and anisole (0.3 ml) in dioxane (6 ml), 2.57 N hydrogen chloride in dioxane (9.3 ml) was added at room temperature. After 4 hr, the solution was treated following the same procedure for the preparation of XV·HCl. Yield, 0.82 g (90 %); mp 201—203 °C (decomp.); $[\alpha]_D^{25}$ −53.6° (*c* 0.3, DMF); R_f 0.77.[20]

Found: C, 58.72; H, 7.25; N, 10.75 %. Calcd for $C_{38}H_{54}O_8N_6 \cdot HCl \cdot H_2O$: C, 58.71; H, 7.39; N, 10.81 %.

H-D-Phe-Leu-Orn(∂-Z)-Val-Pro-OH (XVIII). XVIII·HCl (152 mg, 0.2 mmol) was dissolved in a mixture of water and methanol. After triethylamine (0.06 ml) had been addded, the solution was evaporated to dryness *in vacuo*. The crystalline product was collected by filtration with the aid of methanol. It was recrystallized from hot methanol-ether, and washed with a small amount of water; yield, 105 mg (72 %); mp 199—201°C (decomp.); $[\alpha]_D^{20}$ −84.3° (*c* 0.3, acetic acid); R_f 0.77.[20]

Found: C, 60.35; H, 7.50; N, 11.04 %. Calcd for $C_{38}H_{54}O_8N_6 \cdot 2H_2O$: C, 60.14; H, 7.70; N, 11.08 %.

Z(OMe)-D-Phe-Leu-Orn(∂-Z)-Val-Pro-D-Phe-Leu-Orn(∂-Z)-Val-Pro-OH (XIX). The azide was prepared from XII (451 mg, 0.5 mmol), 1N hydrochloric acid (1.1 ml), and sodium nitrite (38 mg) in a mixture of acetic acid (6 ml) and dimethylformamide (3 ml) as in the case of the preparation of XI. Then the azide dried was added to a solution of XVIII·HCl (380 mg, 0.5 mmol) and triethylamine (0.14 ml, 1 mmol) in dimethylformamide (10 ml). After the reaction mixture was stirred for 3 days at 0°C, it was treated following the same procedure that employed for the preparation of XVI. The crude product was recrystallized from hot dioxane-methanol-ether; yield, 600 mg (75 %); mp 174—175 °C; $[\alpha]_D^{25}$ −31.4° (*c* 0.5, DMF); R_f 0.94,[20] 0.45.[24]

Found: C, 62.78; H, 7.24; N, 10.58 %. Calcd for $C_{85}H_{114}O_{18}N_{12} \cdot 2H_2O$: C, 62.71; H, 7.31; N, 10.33 %.

***cyclo*-(D-Phe-Leu-Orn(∂-Z)-Val-Pro-)$_2$ (XX).** **From XIX.** To a solution of XIX (557 mg, 0.35 mmol) in pyridine (10 ml), di-*p*-nitrophenyl sulfite[25] (2.27 g, 7 mmol) was added. After the mixture had been allowed to stand for 24 hr at room temperature, it was evaporated *in vacuo*. The residual solid was collected by filtration with the aid of a mixture of ether-petroleumether (1 : 1, v/v); 589 mg. The *p*-nitrophenyl ester content for this product was estimated to be 85 % by measuring the optical density of the compound at 412 mμ.[26] To the acyldecapeptide *p*-nitrophenyl ester (585 mg) thus obtained, anisole (0.5 ml) and trifluoroacetic acid (3.5 ml) were added at 0 °C. After the solution was evaporated *in vacuo*, the residual powder was collected by filtration with the aid of ether. The decapeptide *p*-nitrophenyl ester trifluoroacetate thus obtained was dissolved in dimethylformamide (10 ml) and acetic acid (0.1 ml). The solution was then stirred, drop by drop and over a period of 4 hr, into pyridine (170 ml) which had been kept at 60 °C; the stirring was then continued for an additional 2 hr at the same temperature. After the solvent had been removed, the residue was dissolved in a mixture of methanol (40 ml) and water (10 ml). After the insoluble substance was removed, the filtrate was passed successively through columns (1.8×10 cm, each) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (200 ml), and the combined effluent was evaporated *in vacuo* to yield a crystalline product. The product was collected by filtration with the aid of water, and recrystallized from methanol-ether-petroleum ether; yield, 242 mg (49 % from XIX); mp 250—251°C (decomp.); $[\alpha]_D^{20}$ −41.3° (*c* 0.3, acetic acid).

Found: C, 64.44; H, 7.46; N, 11.73 %; mol wt, 1413.[27] Calcd for $C_{76}H_{104}O_{14}N_{12} \cdot 1/2H_2O$: C, 64.34; H, 7.46; N, 11.85 %; mol wt, 1419.

From XVI. The acylpentapeptide XVI (2.22 g, 2.5 mmol) was converted to the pentapeptide *p*-nitrophenyl ester trifluoroacetate (XXIV·CF_3COOH) following the same procedure as described above. XXIV·CF_3COOH (2.39 g) thus obtained was added to pyridine (800 ml). After the filtrate was passed through columns of Dowex 1 and Dowex 50 as described above, the effluent was evaporated to dryness, the residual product was collected by filtration with the aid of water; yield of the crude product (XXV), 830 mg. The solution of XXV (50 mg) in methanol (1 ml) was applied to a column (2.7×50 cm) with Sephadex LH-20, and the development continued with methanol. Elution was carried out at room temperature, the flow rate 30 ml per hr, and 3 ml fraction collected.

When the peptide content in the fractions was determined on a thin-layer plate, the peak of XX appeared from the test tube numbers 45 to 52 and the peak of XXI from 54 to 65. The same chromatography was repeated further nine times; thus, 500 mg of XXV was separated into two component. The ten fractions of 45—52 were combined, evapo-

Retrocyclosemigramicidin S, *cyclo*-D-Phe-Leu-Orn-Val-Pro (XXIII). XXI (42 mg, 0.06 mmol) was treated as described for the preparation of XXII·2HCl; yield, 31 mg (84 %); mp 252—253 °C (decomp.); $[\alpha]_D^{20}$ −60.0° (*c* 0.5, ethanol); R_f 0.92,[28)] 0.61; [20)] amino acid ratios in acid hydrolysate, $Phe_{0.9}Leu_{1.0}Orn_{1.0}Val_{0.9}Pro_{1.1}$.

Found: C, 54.27; H, 7.77; N, 12.85 %. Calcd for $C_{30}H_{46}O_5N_6 \cdot HCl \cdot 3H_2O$: C, 54.49; H, 8.08; N, 12.71%. The air-dried product lost 8.7 % of its weight after drided for 3 hr at 80 °C and 2 mmHg. Calcd for $3H_2O$: 8.2 %.

Electrophoresis and Carboxymethylcellulose (CMC) Chromatography. These experiments were carried out as has been described before.[16)] A part of the crude product (XXV), which was obtained after the cyclization reaction of the pentapeptide *p*-nitrophenyl ester (XXIV), was hydrogenated, and the hydrogenated product thus obtained was designated as XXVI. As shown in Figs. 6 and 7, retro GS and retrocyclosemi GS was clearly separated in the electrophoresis, whereas these compounds could be only partially separated with a column (0.9×50 cm) of CMC.

Microbiological Assays.[29)] The microorganisms employed are listed in Table 1. The minimum amount of the compound necessary for the complete inhibition of growth was determined by a dilution method using a bouillon agar medium and a synthetic medium. As is shown in Table 1, retrogramicidin S (XXII) was found to exhibit weak antibacterial activity against *Bacillus subtilis* and *Staphylococcus aureus*. Whereas retrocyclosemigramicidin S (XXIII) exhibited no antibacterial activity against the microorganisms tested.

28) The R_f value of the paper chromatography refers to the same solvent system described.[20)]

29) We are indebted to Dr. M. Shibata of Takeda Chemical Industries, Ltd. for the assay.

The Chemiluminescence of Indole Derivatives. IV. Correlation between Chemiluminescence and Structure of 2,3-Dimethylindoles

Noboru SUGIYAMA, Hiroshi YAMAMOTO and Yoshimori OMOTE

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

and Masamoto AKUTAGAWA

Department of Chemistry, Faculty of Education, Kumamoto University, Kurokamicho, Kumamoto

(Received January 30, 1968)

Four 5-substituted and three 6-substituted 2,3-dimethylindoles and unsubstituted 2,3-dimethylindole were synthesized and their light emission was measured in the presence of atmospheric oxygen and potassium *t*-butoxide in dimethyl sulfoxide. It was found that the Hammett equation was applicable to their chemiluminescent reaction with ρ value of -1.24. For the 6-position of indole nucleus σ_p was used, and for the 5-position σ_m was used. Also, four hydroperoxides of 2,3-dimethylindole bearing substituents at the 5- or 6-position, which emitted light in the presence of potassium *t*-butoxide in dimethyl sulfoxide, gave linear Hammett plots with ρ value of -2.04. The relationship between the Hammett equation and the chemiluminescence of these inole derivatives has been discussed further.

Previously we found that forty-one of substituted indoles were chemiluminescent in the presence of atmospheric oxygen and potassium hydroxide in dimethyl sulfoxide.[1] Also, we proposed the mechanism of the chemiluminescence of 2,3-dimethylindole (I) involving the hydroperoxide anion (II) as an intermediate.[2] McCapra *et al.*[3,4] independently suggested the same intermediate and discussed the mechanism of the chemiluminescence from the standpoint of the decomposition of the hydroperoxide.

Scheme 2

Furthermore, we speculated the mechanism of the chemiluminescent reaction of I as shown in Scheme 1.[5] The compound I changes to hydroperoxide anion (II), with oxygen and base, while the hydroperoxide (V) requires only base for conversion to II. Then II is converted to four-membered cyclic peroxide (III) which decomposes to an excited *o*-acetamidoacetophenone anion (IV*). And IV* falls to the ground state with an emission of light.

Recently we have prepared some substituted 2,3-dimethylindoles, measured their chemiluminescence, and found that the Hammett equation was applicable to their chemiluminescent reaction. The Hammett relationship was first found to apply to the chemiluminescent reaction of lophine by Philbrook *et al.*[6] There is, however, no example of the application of the Hammett equation to the chemiluminescence of indoles. It is interesting to examine the relationship between the Hammett equation and the chemiluminescence of indole derivatives.

Results and Discussion

We prepared eight 2,3-dimethylindoles, four of which had substituents at the 5-position of indole ring (Ib, Ic, Id and Ie), and three of which had substituents at the 6-position (If, Ig and Ih). Also we synthesized four hydroperoxides of 2,3-dimethylindoles (Va, Vb, Vd and Vf). The chemiluminescence maxima are shown in Table 1 and the fluorescence maxima after the chemiluminescent reaction are shown in Table 2. It can be concluded that the emitting species of the chemiluminescent reaction of I and V are the same and might be *o*-acetamidoacetophenone anion (VI*) in an excited singlet state, because the maxima of the fluorescence spectra of VI under the same condition as the chemiluminescence agreed closely with the maxima of the chemiluminescence spectra of I and V and also with the maxima of their fluorescence spectra after the chemiluminescent reaction.

+ synthesized product under the same condition as the chemiluminescent reaction.

We found that σ values of para and meta substitution in benzene ring were favorably used for the 6- and 5-positions of indole nucleus respectively. In the cases of eight indoles, Ia, Ib, Ic, Id, Ie, If, Ig and Ih, the plot of $\log A/A_0$ against σ given by McDaniel and Brown,[7] was a straight line, where A and A_0 are the amount of light emitted during the chemiluminescent reaction of substituted 2,3-dimethylindoles and that of 2,3-dimethyl-

indole, respectively. (Fig. 1) The value of the reaction constant ρ determined by least squares method is -1.24. Also we proved the Hammett relationship in the chemiluminescent reaction of four indole hydroperoxides, Va, Vb, Vd and Vf. The value of ρ is -2.04. (Fig. 2).

The negative values of ρ indicate that these chemiluminescent reactions are facilitated by a high electron density at the reaction site. Both Fig. 1 and Fig. 2 show that an electron-releasing substituent favors the chemiluminescent reaction and the negative slope is consistent with the interpretation described above.

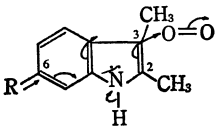
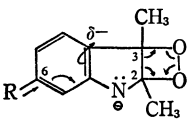
From intensity of chemiluminescence-time curves, decay constants were calculated by the equation $I=I_0\exp(-t/\alpha)$, where I and I_0 are the intensity at time t and zero respectively, and $1/\alpha$ is a decay constant. A plot of $\log I$ *vs.* time t gave α. The half-lives of chemiluminescence calculated by the equation $t_{1/2}=2.303\times\alpha\times\log 2$ for indoles and hydroperoxides are shown in Table 4. The hydroperoxides (V) emitted light instantaneously, the duration being a few seconds, $t_{1/2}=1.5-1.9$ sec, while the parent indoles (I) emitted light more slowly, the duration being from 40 to 170 seconds, $t_{1/2}=9.8-82$ sec. Considering the facts that the reaction rate of the chemiluminescence of V is very fast, and that the amount of the light is different with different substituents, it is tentatively assumed that the quantum yield of the chemiluminescence of V is correlated with the Hammett σ function.

Finally, we attempt to show a reasonable explanation for the slope of the curve in Fig. 1 or in Fig. 2, which is consistent with the reaction mechanism shown in Scheme 1. In the intermediate III an electron-releasing substituent R at the 6-position contributes to an increase of an electron density on the para



position to R. This negative charge will facilitate the homolytic fission of the bond between C-2 and C-3. This is the reason why the reaction from V to IV or from I to II is favored by high electron availability.

Also, we can explain the fact that the absolute value of ρ, 1.24, for the reaction from I to IV is less than that of ρ, 2.04, for the reaction from V to IV. If we assume that the rate from I to II in the reaction from I to IV is slow, the substituent R at the 6-position increases an electron density on the para position to R and it is probably unfavorable for the increase of the electron density at the 3-position of indole nucleus. Then the electron-releasing substituent in the 6-position retards the reaction from I to III, and this makes the absolute value of ρ decrease from 2.04 to 1.24.



Now, we can conclude that the Hammett relationship may be applied to interpret the influence of a substituent on an indole ring upon the quantum yield of the chemiluminescent reaction of 5- or 6-substituted 2,3-dimethylindole hydroperoxides as well as upon the light emission of the parent 2,3-dimethylindoles.

Experimental

5-Acetamido-2,3-dimethylindole (Ic). Powdered 5-amino-2,3-dimethylindole,[8] 0.5 g, was dissolved in 4.7 m*l* of acetic anhydride and kept for 3 hr at room temperature. Then the solution was poured onto crushed ice. White precipitates, 0.52 g, were collected and recrystallized from ethanol-water to give colorless long plates, mp 171.0—171.5 °C.

Found: C, 71.26; H, 6.71; N, 13.95 %. Calcd for $C_{12}H_{14}ON_2$: C, 71.26; H, 6.98; N, 13.85 %.

UV: λ_{max}^{EtOH} mμ (log ε), 245(4.45), 298(3.68, sh.), 310(3.44). IR: ν^{KBr} cm^{-1} 3370, 3250, 1650, 1550, 860, 810.

6-Acetamido-2, 3-dimethylindole (Ig). By the same method as Ic, 6-amino-2,3-dimethylindole was acetylated. Colorless leaflets from ethanol, mp 204—206°C.

Found: C, 71.08; H, 7.08; N, 13.97 %. Calcd for $C_{12}H_{14}ON_2$: C, 71.26; H, 6.98; N, 13.58 %.

UV: λ_{max}^{EtOH} mμ (log ε), 218(4.24), 248(4.37), 294 (4.01). IR: ν^{KBr} cm^{-1} 3290, 3210, 1625, 1525, 860, 810.

2, 3, 6-Trimethylindole (If).[9] White leaflets from ethanol-water, mp 119.5—121.0 °C.

UV: λ_{max}^{EtOH} mμ (log ε), 230(4.55), 280(3.79), 295 (3.69, sh.). IR: ν^{KBr} cm^{-1} 3360, 2950, 2890, 2840, 853, 802.

6-Chloro-2,3-dimethylindole (Ih).[9] White leaflets, from ether-petroleum ether, mp 164.5—165.5 °C.

UV: λ_{max}^{EtOH} mμ (log ε), 235(4.57), 286(3.83), 296 (3.78, sh.). IR: ν^{BKr} cm^{-1} 3360, 848, 804, 740.

2,3,6-Trimethylindolenyl-3-hydroperoxide (Vf). 1f, 200 mg, was dissolved in warm light petroleum (bp 60—80 °C, 30 m*l*) and a trace of benzoyl peroxide was added to the solution in the presence of atmospheric oxygen. After an hour the solution began to deposit the hydroperoxide, 110 mg, as white crystals, mp 112.5—113.0 °C (decomp.).

Found: C, 69.09; H, 6.79; N, 7.24 %. Calcd for $C_{11}H_{13}O_2N$: C, 69.05; H, 6.85; N, 7.33 %.

UV: λ_{max}^{EtOH} mμ (log ε), 218(4.31, sh.), 223(4.37), 230(4.26, sh.), 274(3.43). IR: ν^{KBr} cm^{-1} 3410, 3050, 2920, 2770, 878, 820.

Preparation of 2-Acetamidoacetophenone Derivatives (VI). Corresponding substituted indoles were dissolved in acetic acid and treated with ozonized oxygen at room temperature until the indole spot had disappeared on thin-layer chromatography. The products were isolated by neutralization followed by extraction with ether.

2,4-Diacetamidoacetophenone (VIg). Colorless leaflets from ethanol-water, mp 217—218 °C.

UV: λ_{max}^{EtOH} mμ (log ε), 254(4.42), 296(4.27). IR: ν^{KBr} cm^{-1} 3260, 3180, 1692, 1665, 1640, 1545, 883, 825.

2-Acetamido-4-methylacetophenone (VIf).[10] Colorless crystals, mp 75—76 °C.

UV: λ_{max}^{EtOH} mμ (log ε), 235(4.43), 239(4.44), 266 (4.04), 274(4.02), 325(3.58). IR: ν^{KBr} cm^{-1} 3200, 1680, 1640, 1525, 880, 810.

2-Acetamido-4-chloroacetophenone (VIh).[9] White plates from methanol, mp 146.5—148.0 °C.

UV: λ_{max}^{EtOH} mμ (log ε), 236(4.53, sh.), 240(4.57), 266(4.15), 274(4.11), 323(3.67). IR: ν^{KBr} cm^{-1} 3160, 1680, 1640, 875, 810, 750.

2,5-Diacetamidoacetophenone (VIc).[11] White needles from ethanol, mp 190—191 °C.

UV: λ_{max}^{EtOH} mμ (log ε), 243(4.43), 276(4.18), 351 (3.40). IR: ν^{KBr} cm^{-1} 3190, 1680, 1650, 882, 820.

Chemiluminescence. In the case of the chemiluminescence of I, 1 m*l* of potassium *t*-butoxide DMSO solution (10^{-2} mol/*l*) was at once added to 1 m*l* of the sample DMSO solution (10^{-3} mol/*l*), continuous tiny bubbles of oxygen being passed through the solution. The change in the intensity of light with time was recorded and total light emission

(A) was determined by the area of emission curve. Then relative total light emission (A/A_0) was calculated. A_0 is the area of Ia which was taken as the reference substance. In the case of V, continuous bubbles of argon was passed through the DMSO solution and the area of emission curve of Va was taken as the reference area. (Table 3).

Chemiluminescence Spectra and Fluorescence Spectra. Chemiluminescence spectra of I and V were measured by the same method as described in the preceeding paper.[5] Fluorescence spectra of substituted 2-acetamidoacetophenone (VI) were measured under the same condition as chemiluminescent reaction of I. Chemiluminescence and fluorescence maxima are shown in Table 1 and Table 2.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1921—1924 (1968)

Electrochemical Fluorination of Glycols and Esters of Dicarboxylic Acids*1

Shunji NAGASE, Takashi ABE and Hajime BABA

Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya

(Received February 1, 1968)

The electrochemical fluorination of glycols (1,3-propanediol and 1,4-butanediol), and dimethyl or diethyl esters of dicarboxylic acids (malonic, succinic, and maleic acids) was carried out. Difluoromalonic acid from esters of malonic acid, and perfluorosuccinic acid from esters of succinic acid or maleic acid, were obtained in reasonable yields, while 1,3-propanediol and 1,4-butanediol were cleaved or underwent ring formation and yielded only small amounts of perfluoro-dicarboxylic acids. Perfluoromonocarboxylic acids and fluorocarbons were among the by-products of these esters and glycols.

Alcohols and esters have been known to give perfluoro-carboxylic acid fluorides upon electrochemical fluorination.[1,2] The perfluorocarboxylic acid fluorides can be converted into the parent acids by hydrolysis. The present paper will deal with the syntheses of difluoromalonic acid and perfluorosuccinic acid by the use of this method.

Perfluoro-dicarboxylic acids have commonly been prepared by the oxidation of fluorinated cycloölefins[3-5] or diolefins.[6,7]

The oxidation of unsaturated fluoro-carboxylic acid[8] and the hydrolysis of chlorofluoro-carboxylic acid[9] have also been reported to yield perfluoro-dicarboxylic acids. The preparation of perfluorosuccinic acid from succinic acid and anhydride,[10,11] maleic acid and anhydride,[11] or from succinoyl fluoride[12] by the electrochemical process has been described.

Accordingly, glycols (1,3-propanediol and 1,4-butanediol), and dimethyl or diethyl esters of dicarboxylic acids (malonic, succinic, and

maleic acids) were subjected to electrochemical fluorination. No work had previously been reported on the electrochemical fluorination of these compounds.

It was found that the esters of dicarboxylic acids afforded the expected perfluoro-dicarboxylic acids in a reasonable yield, along with degraded products, while glycols were cleaved extensively or underwent cyclization, yielding smaller amounts of perfluoro-dicarboxylic acids. Perfluoro-monocarboxylic acids and fluorocarbons, including perfluoro-ethers and bis(trifluoromethyl) peroxide, were among the by-products in these fluorination reactions.

Experimental

Materials and Apparatus. The samples subjected to fluorination were commercial-grade chemicals. Their purities were confirmed by gas chromatography.

All the features of the apparatus used for this fluorination reaction were essentially the same as those of the apparatus diagrammed in a previous paper,[11] except that a part of the electrolytic cell used was that described in another paper.[13]

Procedures. As a typical example, the procedures for the fluorination of diethyl succinate (Run 6 in Table 1) will be described. Diethyl succinate (31.4 g, 0.18 mol) was introduced into anhydrous hydrogen fluoride (1 *l*) which had been purified by electrolysis, and then the electrolysis of the solution was carried out with an anodic current density of 2.9 A/dm^2, at a cell voltage of 5—6 V and at a cell temperature of 5—6°C. The electrolysis was continued until the voltage rose to 6.8 V. The amount of electricity required for this fluorination was 191 A hr. To aid agitation, helium was introduced into the hydrogen fluoride solution at the flow rate of 15 m*l*/min from the bottom of the cell through a bubbler.

The outgoing gases, such as hydrogen, hydrogen fluoride, monobasic and dibasic perfluoro-acid fluorides, oxygen difluoride, and fluorocarbons, from the electrolytic cell were passed through the reflux condenser (kept at −15°C) into the hydrogen fluoride absorber (A), an iron tube containing sodium fluoride pellets, and the perfluoro-acid fluoride absorber (B), a pair of polyethylene bottles containing water. The gases were then led into gas-washing bottles (C), an Ichinose bottle containing an aqueous solution of sodium sulfite and sodium hydroxide with a small amount of potassium iodide, and then finally conducted into traps (D) kept in ice and liquid nitrogen.

The hydrogen fluoride in the gas stream was removed in A, perfluoro-acid fluorides were converted into the parent acids in B, oxygen difluoride and carbon dioxide were removed in C, and fluorocarbons were collected in D. The hydrogen was allowed to escape into the air.

The products in B were worked up as usual[11] to give an ether extract of perfluoro-carboxylic acids. This ether extract was dried and, after the removal of the ether, distilled under reduced pressure (20 mmHg) at a bath temperature of below 100°C. The distillate was a mixture of trifluoroacetic acid and perfluoropropionic acid, which were converted into their sodium salts (23.8 g). These were analyzed quantitatively by the base-line technique of the IR spectrum, as has previously been described in detail.[1] The composition (wt%) of the product was $CF_3COONa : C_2F_5COONa = 64 : 36$. A trace of sodium perfluorobutyrate was also present. The residue was crude perfluorosuccinic acid, which was dissolved into hot benzene; a small amount of inorganic impurity was filtered off, and the filtrate was allowed to stand overnight. The crystalline precipitate which was thus separated was recrystallized from benzene, giving white needles of perfluorosuccinic acid (5.8 g, 17.0% yield), mp 116—116.5°C (lit.[4] mp 116—116.5°C). The IR spectrum of this product was identical with that of an authentic specimen prepared by another method.[4]

Fluorocarbons (18.0 g) trapped in D were analyzed quantitatively by low-temperature distillation, gas chromatography, and IR spectroscopy, much the same methods as had been used in a series of electrochemical fluorinations of gaseous organic compounds.[14] The composition (mol%) of the fluorocarbons was as follows: carbon tetrafluoride (45.3%), fluoroform (24.2%), perfluoroethane (19.2%), perfluoropropane (3.7%), perfluorodiethyl ether (2.6%) perfluorodimethyl ether (2.2%), pentafluoroethane (1.9%), and 1,1,1,2-tetrafluoroethane (0.9%). A small quantity of unidentified compounds (0.9 g) was also found.

The experimental procedures for all the other runs, including those giving difluoromalonic acid, were similar to the one illustrated above. Difluoromalonic acid was obtained as very hygroscopic white needles, mp 117—118°C (lit.[5] mp 117—118°C) (Found: C, 25.25; H, 1.64; F, 27.0%).

Results and Discussion

The reaction conditions and the results obtained are summarized in Table 1. The product distribution of the fluorocarbon by-products obtained from five representative samples are shown in Table 2.

1,3-Propanediol was cleaved extensively into fluorocarbons and perfluoro-monocarboxylic acids, and difluoromalonic acid was produced in only a low yield. The main components of fluorocarbons were carbon tetrafluoride, perfluoroethane, and fluoroform, but perfluoropropane, perfluorodiethyl ether, perfluorodimethyl ether, perfluoro-*n*-butane, and pentafluoroethane were also formed.

a) A small amount of unidentified products was not considered.

These compounds appeared to be derived by the fluorination reaction *via* a free-radical mechanism on the anode surface; the progressive replacement of hydrogen and some oxygen of the glycol by fluorine atoms occurred, with accompanying extensive fragmentation of the carbon skeleton due to the high reaction heat. The combination of the fragment radicals yielded perfluorodimethyl ether, perfluorodiethyl ether, and perfluoro-*n*-butane. Difluoromalonyl fluoride, which yields difluoromalonic acid by hydrolysis, may be formed through the malonyl fluoride produced by the mechanism involving fluorination, followed by dehydrofluorination at the α-carbon atoms of the glycol, much as with that of monohydric alcohols.[1)]

The electrochemical fluorination of 1,4-butanediol produced perfluorotetrahydrofuran as the principal product (23.7% yield).*2 Perfluorosuccinic acid, perfluoro-monocarboxylic acids, and fluorocarbons were also obtained. Such cyclization reactions are often observed in the electrochemical fluorination of some oxygen-containing compounds.[15,16)] In this case, cyclization could have occurred at an early stage of the process, since the ring formation of this glycol takes place easily in acid media, and even the cyclic skeleton thus formed may be further ruptured into straight-chain fluorinated products in the fluorination. The results of the electrochemical fluorination of tetrahydrofuran (0.18 mol), which was found to afford perfluorotetrahydrofuran in a 34.7% yield, may be consistent with this interpretation.

The electrochemical fluorination of 1,2-ethanediol (0.3 mol) was examined under similar conditions. Trifluoroacetic acid was formed in a 6.1% yield, together with fluorocarbons. The fluorocarbons*3 contained mainly carbon tetrafluoride and fluoroform. Bis(trifluoromethyl) peroxide, perfluoroethane, and perfluorodimethyl ether were also among the products.

The esters of malonic acid afforded difluoro-

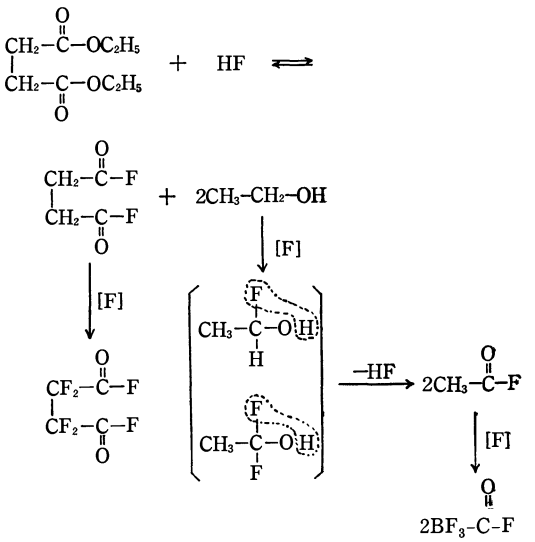
*3 The amount of the fluorocarbon mixture was 16.5 g, but a considerable portion (4.0 g) of it went unidentified.

malonic acid in a fair yield. Perfluoropropionic acid was produced in addition to trifluoroacetic acid from these esters; both the carbonyl carbons were incorporated into the perfluoropropionic acid. The formation of a large amount of trifluoroacetic acid from the ethyl esters indicates its additional formation from the two ethoxyl groups of the ester.

For the sake of comparison, the electrochemical fluorination of free acid, malonic acid, was also performed; only traces of difluoromalonic acid and trifluoroacetic acid were yielded. The free acid was cleaved almost completely into fluorocarbons (carbon tetrafluoride, fluoroform, and methylene fluoride) and carbon dioxide in the course of the fluorination.

The esters of succinic acid and even those of maleic acid gave perfluorosuccinic acid in reasonable yields, yields which were greater than the yields from the free acids and their anhydrides.[11] Perfluoro-monocarboxylic acids and fluorocarbons, exemplified by those obtained from the methyl esters of the acids shown in Table 2, were common by-products in these fluorination reactions.

The sequence of the formation of dibasic perfluoro-acid fluorides from the esters may involve the hydrofluorolysis of the esters in hydrogen fluoride to form dibasic acid fluorides and alcohols. The alcohols formed in this way would be converted into acid fluorides through the mechanism involving fluorination, followed by dehydrofluorination, at the oxygen-bonded carbon atom.[1] Both the acid fluorides thus produced would then be fluorinated further to the corresponding perfluoro-acid fluorides. For example, in the case of diethyl succinate, this reaction would be represented by the following formulae:



Although fragmentation or cyclization prevailed in the fluorination of glycols, dibasic perfluoro-acid fluorides were produced. The mechanism of the formation of dibasic perfluoro-acid fluorides from glycols could be considered to be similar to that of monohydric alcohols.[1] The production of a considerable amount of perfluorotetrahydrofuran from 1,4-butanediol shows the ease of five-membered-ring formation and the stability of an ether linkage in the fluorination reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1925—1928 (1968)

The Reactions of Esters of Amidosulfurous Acid

Hisashi TAKEI, Hideo SHIMIZU, Moriaki HIGO and Teruaki MUKAIYAMA

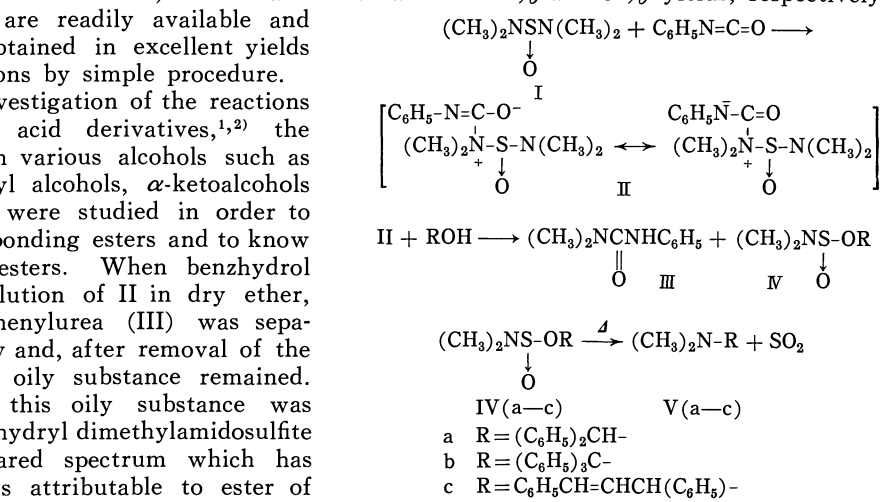
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 6, 1968)

It was found that benzhydryl dimethylamidosulfite, obtained from *N,N,N',N'*-tetramethylsulfurous diamide-phenyl isocyanate adduct and benzhydrol, decomposed to give benzhydryldimethylamine and sulfur dioxide. Similarly, triphenylmethyl and 1,3-diphenylallyl dimethylamidosulfite gave corresponding tertiary amines when these esters were refluxed in benzene. On the other hand, benzoin dimethylamidosulfite gave benzil, the oxidized product of benzoin. When β-anilinoethyl and β-*N*-methylaminoethyl dimethylamidosulfite were heated at 120—130℃ for 10 min, cyclic esters of amidosulfurous acid, 3-phenyl- and 3-methyl-1,2,3-oxathiazolidine-2-oxide, were obtained along with evolution of dimethylamine. Further, the thermal decomposition of the cyclic compounds was studied.

In the preceding paper, it has been shown that tetraalkylsulfurous diamides(I) and phenyl isocyanate gave 1 : 1 adducts (II), which react readily with active hydrogen compounds such as alcohols, carboxylic acids and mercaptans to give *N,N*-dialkyl-*N'*-phenylureas (III), and alkyl dialkylamidosulfites, *N,N*-dialkylcarboxylic amides and *S*-alkyl dialkylamidothiosulfites, respectively.[1] This reaction is considered to be a convenient route for the synthesis of amidosulfurous acid derivatives, since I and phenyl isocyanate are readily available and the products are obtained in excellent yields under mild conditions by simple procedure.

As part of the investigation of the reactions of amidosulfurous acid derivatives,[1,2] the reactions of II with various alcohols such as α-substituted benzyl alcohols, α-ketoalcohols and aminoalcohols were studied in order to prepare the corresponding esters and to know the nature of the esters. When benzhydrol was added to a solution of II in dry ether, *N,N*-dimethyl-*N'*-phenylurea (III) was separated quantitatively and, after removal of the solvent, a viscous oily substance remained. The structure of this oily substance was assigned to be benzhydryl dimethylamidosulfite (IVa) by its infrared spectrum which has characteristic bands attributable to ester of amidosulfrous acid (1150 and 900 cm^{-1}). However, an attempt to purify this oily substance by vaccum distillation resulted in decomposition with evolution of sulfur dioxide. From the residue, benzhydryldimethylamine (Va) was isolated in a 50 % yield. Similar decomposition was observed when triphenylmethyl and 1,3-diphenylallyl dimethylamidosulfites (IVb and IVc), obtained as viscous oily substance by the above mentioned procedure, were refluxed in dry benzene, and corresponding tertiary amines (Vb and Vc) were obtained in 50% and 59% yields, respectively.



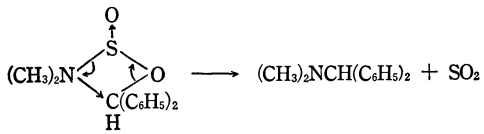
While, ethyl, allyl, cyclohexyl and benzyl dimethylamidosulfites are fairly stable and are able to be distilled under reduced pressure without decomposition.[1] Concerning the above results, Zinner[3] has reported that attempts to

1) T. Mukaiyama, H. Shimizu and H. Takei, *J. Org. Chem.*, **32**, 3475 (1967).

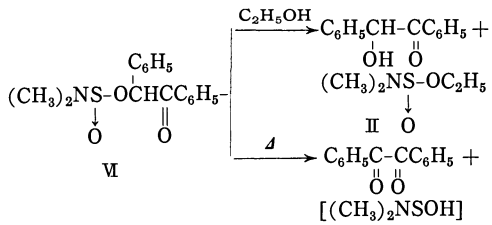
2) T. Mukaiyama, H. Shimizu and H.Takei, This Bulletin, 40, 939 (1967).

3) G. Zinner, *Angew. Chem.*, **69**, 93 (1959).

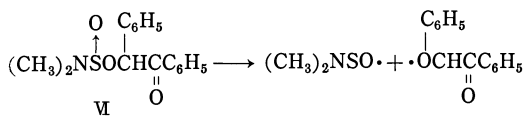
distill ethyl dialkylamidosulfites at atmospheric pressure resulted in decomposition with evolution of sulfur dioxide, but the corresponding tertiary amines could not be isolated. It can be noted that electron-withdrawing substituents, *e. g.* two phenyl groups, on α-carbon atom of the esters favor the reaction to afford tertiary amines probably proceeding through an internal nucleophilic attack by the amino group on α-carbon atom (S_Ni Mechanism).

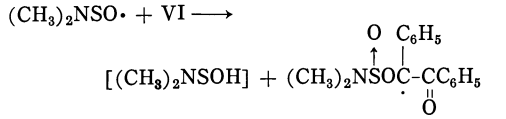


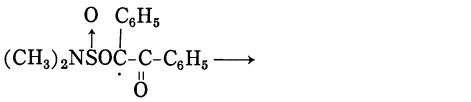
Next, it was established that the reaction of II with benzoin afforded benzoin dimethylamidosulfite (VI) as a viscous oily substance along with III. The structure of VI was confirmed by its infrared spectrum and the fact that treatment of VI with ethanol gave benzoin and ethyl dimethylamidosulfite (VII), transesterification products, in good yields. When VI was refluxed in dry benzene for an hour, the expected products, dimethylaminodeoxybenzoin and sulfur dioxide, could not be detected, instead, benzil, the oxidized product of benzoin, was obtained in a 74 % yield.



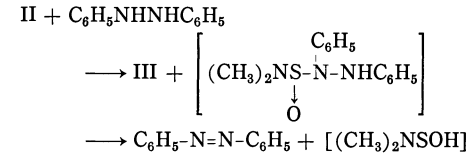
It seemed reasonable to assume that benzil may be produced through radical intermediates based on the following results: When VI was heated in benzene in the presence of diphenylpicrylhydrazyl, violet color of the radical disappeared soon. In addition, it was found that addition of diethylaniline, which is known to be a radical scavenger, inhibit the decomposition of VI. Based on these results, the oxidation reaction can be explained by assuming the following radical chain mechanism.





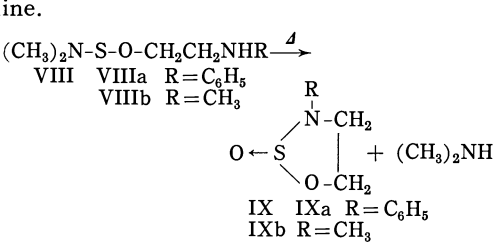


In a similar fashion, when hydrazobenzene was treated with II in benzene at room temperature, azobenzene was obtained in a 78 % yield along with III.



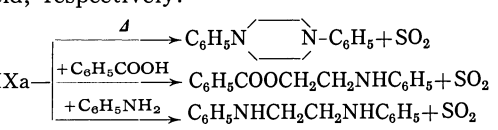
In the case of the reaction of II with α-hydroxycarboxylic esters such as ethyl lactate and ethyl mandelate, however, the thermal decomposition of the corresponsing esters of dimethylamidosulfurous acid obtained as undistillable oily substance did not afford the expected products, α-ketocarboxylic esters, but a large amount of dark colored tarry product and a small amount of unpleasant smelling, low-boiling substances resulted.

Finally, the reaction of II with aminoalcohol was examined. When *N*-phenylethanolamine was added to II in dry ether, III was obtained in a quantitative yield and, after removal of the solvent under reduced pressure, a viscous oily substance remained. The structure of the oily substance was assigned to be β-anilinoethyl dimethylamidosulfite (VIIIa) by its infrared spectrum which has characteristic bands of nitrogen-hydrogen linkage (3200 cm^{-1}) and of ester of amidosulfurous acid (1180 and 900 cm^{-1}). When IXa was heated at 120—130 ℃ for 10 min, evolution of dimethylamine was observed and vacuum distillation of the residue gave cyclic ester of amidosulfurous acid, 3-phenyl-1,2,3-oxathizolidine-2-oxide(IXa), in an 81 % yield. In a similar way, 3-methyl-1,2,3-oxathiazolidine-2-oxide(IXb) was prepared by the reaction of II with *N*-methylethanolamine.



These cyclic compounds were unstable to prolonged heating. For example, when IXa was refluxed in dry xylene for 5 hr, evolution of sulfur dioxide was observed and a large

amount of dark colored tarry material was deposited in the flask. From the hot xylene layer, a small amount (6 %) of *N,N'*-diphenylpiperazine was obtained. Further, it was found that when IXa was refluxed in xylene in the presence of benzoic acid or aniline, β-anilinoethyl benzoate or *N,N'*-diphenylethylenediamine was obtained in a 54% or 33% yield, respectively.



Experimental

All melting points and boiling points are uncorrected.

Reaction of *N,N,N',N'*-Tetramethylsulfurous Diamid-Phenyl Isocyanate Adduct (II) with Benzhydrol. To an ice-cooled solution of *N,N,N',N'*-tetramethylsulfurous diamide (I) (1.36 g, 10 mmol) in 5 m*l* of dry ether, a solution of phenyl isocyanate (1.19 g, 10 mmol) in 10 m*l* of dry ether was added dropwise with stirring. The mixture was kept standing at room temperature for an hour, and then a solution of benzhydrol (1.84 g, 10 mmol) in ether was added. An exothermic reaction took place and *N,N*-dimethyl-*N'*-phenylurea (III) was precipitated soon. The III was collected and recrystallized from water: yield 1.6 g, mp 134 °C. The filtrate was evaporated at room temperature under reduced pressure, and a viscous oily substance remained. The infrared spectrum of this colorless oily substance shows characteristic bands attributable to ester of amidosulfurous acid (1150 and 900 cm^{-1}). An attempt to purify the oily substance by vacuum distillation led to the decomposition giving 1.05 g (50 %) of benzhydryldimethylamine (Va), bp 130°C/8 mmHg, which solidified soon. It was recrystallized from aqueous ethanol, mp 70.5—71 °C (lit. mp 68.5—70°C).[4]

Found: C, 85.27; H, 8.05; N, 6.67 %. Calcd for $C_{15}H_{17}N$: C, 85.26; H, 8.11; N, 6.63 %.

Similarly, the reaction of II (10 mmol) with 1,3-diphenylallyl alcohol (2.10 g, 10 mmol) gave the corresponding ester of dimethylamidosulfurous acid (IVc) as an oily substance. Its infrared spectrum shows characteristic bands attributable to ester of amidosulfurous acid (1170 and 960 cm^{-1}). When this oily substance was refluxed in benzene for an hour, evolution of sulfur dioxide was observed. After removal of the solvent, the residual liquid was distilled to give 1.40 g (59 %) of 1-dimethylamino-1,3-diphenyl-2-propene (Vc), bp 120—122 °C/0.1 mmHg.

Found: C, 85.87; H, 8.27; N, 6.12 %. Calcd for $C_{17}H_{19}N$: C, 86.03; H, 8.07; N, 5.90 %.

Picrate, mp 175—177 °C (decomp).

Found: C, 59.46; H, 4.96; N, 11.99 %. Calcd for $C_{23}H_{22}N_4O_7$: C, 59.22; H, 4.75; N, 12.01 %.

4) M.M.Sommelet, *Compt. rend.*, **175**, 1150 (1922).

The reaction of II (10 mmol) with triphenylcarbinol (2.60 g, 10 mmol) gave 1.44 g (50 %) of dimethyl(triphenylmethyl) amine (Vb), mp 93—95 °C (lit. mp 97°C).[5]

Reaction of II with Benzoin. To a solution of 10 mmol of II in dry benzene, a solution of benzoin (2.12 g, 10 mmol) in dry tetrahydrofuran was added dropwise with stirring. After stirring for half an hour at room temperature, the solvent was removed under reduced pressure. Precipitated urea (III) (quantitative yield) was filtered off and the residual liquid (VI) was dissolved in dry benzene. Then the solution was refluxed for an hour, cooled and concentrated under reduced pressure. After standing the residue overnight, precipitated benzil was collected, washed with a small amount of ethanol and recrystallized from ethanol: yield 1.56 g (74%), mp and mixed mp 95—96°C.

Reaction of VI with Ethanol. Ethanol (5 m*l*) was added to the VI prepared by the procedure described above, and the mixture was refluxed for half an hour, cooled and concentrated under reduced pressure. Precipitated benzoin was collected, washed with a small amount of ethanol and recrystallized from ethanol: yield 1.40 g (70 %), mp and mixed mp 134 °C. The filtrate was distilled to give ethyl dimethylamidosulfite (VII): yield 0.8 g (60 %), bp 65—67°C/18 mmHg[1].

Thermal Decomposition of VI in the Presence of *N,N*-Diethylaniline. A solution of VI (10 mmol) and *N,N*-diethylaniline (1.5 g, 10 mmol) in dry benzene was refluxed for an hour. Then 2 m*l* of ethanol was added and the mixture was refluxed for 15 min, cooled and concentrated under reduced pressure. Precipitated benzoin (1.60 g, 76 %), mp and mixed mp 134 °C, was filtered off and the filtrate was distilled to give VII (0.9 g, 66 %), bp 66—68°C/18 mmHg.[1]

Reaction of II with Hydrazobenzene. To a solution of 10 mmol of II in dry ether, 1.84 g (10 mmol) of hydrazobenzene in dry benzene was added dropwise with stirring at room temperature. Precipitated urea (quantitative yield) was filtered off and the orange-red filtrate was concentrated under reduced pressure. The residual liquid was distilled to give azobenzene (1.42 g, 78 %), bp 145—150°C/12 mmHg, which solidified soon. It was recrystallized from aqueous ethanol, mp and mixid mp 67—68°C.

Reaction of II with *N*-Phenylethamine. To an ice-cooled solution of 10 mmol of II in dry ether, a solution of *N*-phenylethanolamine (1.37 g, 10 mmol) in dry ether was added dropwise with stirring. Precipitated urea (III) (quantitative yield) was filtered off and the filtrate was concentrated under reduced pressure. The infrared spectrum of the oily residue shows characteristic bands attributable to nitrogen-hydrogen linkage (3200 cm^{-1}) and ester of amidosulfurous acid (1180 and 900 cm^{-1}). When this oily substance was heated at 120—130°C for 10 min, evolution of dimethylamine was observed. The residual liquid was distilled to give 3-phenyl-1,2,3-oxathiazolidine-2-oxide (IXa), which solidified

5) E. Hemilian and H. Silberstein, *Ber.*, **17**, 746 (1884).

immediately: yield 1.48 g (81 %), bp 144 °C/0.07 mmHg.

Found: C, 53.18; H, 5.36; N, 8.37 %. Calcd for $C_8H_9NO_2S$: C, 52.45; H, 4.95; N, 7.65 %.

In a similar manner, 3-methyl-1,2,3-oxathiazolidine-2-oxide (IXb) was obtained in a 21 % yield by treating II with *N*-methylethanolamine, bp 100—102°C/23 mmHg.

Found: C, 30.15; H, 6.56; N, 11.31 %. Calcd for $C_3H_7NO_2S$: C, 29.74; H, 5.82; N, 11.57 %.

Attempts to prepare 3-unsubstituted. oxathiazolidine or benzoxathiazoline by treating II with ethanolamine or *o*-aminophenol were unsuccessful though the urea was obtained in a quantitative yield.

Thermal Decomposition of IXa. When a solution of IXa (1.83 g, 10 mmol) in dry xylene was refluxed for 5 hr, evolution of sulfur dioxide was observed and a large amount of dark colored tarry product was deposited. The hot xylene layer was decanted and the residue was heated with benzene. The hot benzene layer was decanted and combined with the xylene solution. After removal of the benzene and xylene under reduced pressure, the residue solidified. It was recrystallized from ethanol to give *N,N'*-diphenylpiperazine: yield 0.07 g (6 %), mp 164 °C. (lit. mp 164—165 °C).[6]

When the thermal decomposition of IXa was carried out in the presence of *N*-phenylethanolamine, *N,N'*-diphenylpiperazine was obtained in a 25 % yield.

Reaction of IXa with Benzoic Acid. When a solution of IXa (1.83 g, 10 mmol) and benzoic acid (1.22 g, 10 mmol) in xylene was refluxed for 7 hr, vigorous evolution of sulfur dioxide was observed. After removal of the solvent under reduced pressure, colorless crystalline product was obtained. It was recrystallized from ethanol to give β-anilinoethyl benzoate: yield 1.30 g (54 %), mp 73.5—76 °C (lit. mp 77 °C).[7]

In a similar manner, the reaction of IXa with aniline gave *N,N'*-diphenylethylenediamine. It was recrystallized from aqueous ethanol: yield 0.73 g (33%), mp 65.5—67 °C (lit. mp 65 °C).[8]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1928—1937 (1968)

Hydrogen Abstraction Reaction of α-Heteroatom Substituted Compounds by *t*-Butoxy Radical*1

Kenji UNEYAMA, Hiroshi NAMBA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received February 19, 1968)

Hydrogen abstraction reactions of various α-substituted compounds were examined in chlorobenzene using di-*t*-butyl peroxide. The reactivities are not satisfactorily correlated with σ^* values of the substituents. The relative rates of substituted anisoles, *N,N*-dimethylanilines and phenyl methyl sulfones give good correlations with Hammett σ values with ρ values of -0.39, -0.42 and -0.2 respectively, but those of thioanisoles requires an additional term due to conjugative effect as described in $\log k/k_0 = -0.11(\sigma + 0.75\Delta\sigma_{R^+})$ in order to get a good Hammett correlation. These results were discussed in terms of a combination of an inductive effect, an electron-releasing and an electron-sharing conjugation.

In connection with our recent work on the 3d orbital resonance in divalent sulfides, we have extended our investigation to the hydrogen abstraction reaction of various sulfur compounds and related α-heteroatom substituted compounds by *t*-butoxyl radical. In the carbanion forming reaction such as the base catalyzed hydrogen-deuterium exchange reaction of various mercaptoles,[1] the base catalyzed decarboxylation reactions of various α-alkyl- and arylmercaptoacetic acids,[2] the E_2 reaction of β-chloroethyl phenyl sulfides[3] and also the acid dissociation equilibria of phenols

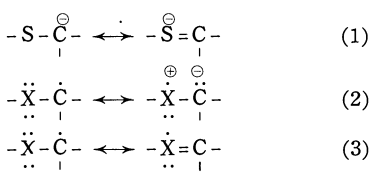
which bear either mercapto or other related sulfur substituents in the benzene rings,[4] all the mercapto groups showed rate enhancing effect, while the corresponding oxygen counterparts showed rate retardation and these results are explained on the basis of the stabilization of carbanion incipiently formed in the transition state by the 3d orbital resonance effect of divalent sulfur atom as shown in Eq. (1).[5] Meanwhile in the carbonium ion forming reaction such as the solvolyses of α-substituted methyl chlorides, alkoxyl group is known to give greater rate enhancement than mercapto group[6] due to the more effective electron-releasing conjugative effect of alkoxy group than that of the sulfur counterpart. The effects of divalent sulfur and alkoxy group in the radical forming reaction have not been investigated quantitatively and hence are quite interesting subjects for investigation in connection with these conjugative effects, namely electron-releasing conjugation[7] like (2) and electron-sharing conjugation like (3), since the electric environment of the radical reaction is vastly different from these of the ionic reactions and other factor may become important.



(1)

(2)

(3)

Russell *et al.* investigated the hydrogen abstraction from α-methyl or methylene group attached to heteroatoms by phenyl radical and found that alkoxyl, mercapto and amino groups have substantial rate enhancing effects as compared with phenyl group and explained these rate-enhancements in terms of the stabilization of the incipient radicals by electron-releasing conjugative effect of α-substituents as shown in Eq. (2). Meanwhile, the electron-sharing conjugation[8,9] like (3) has been proposed on the basis of the remarkably large Q values of alkyl vinyl sulfides and vinylidene mercaptals as compared with those of the oxygen analogs, methyl vinyl sulfone and trimethylvinylsilane in the copolymerization with styrene. The stabilization of the radicals, namely the large Q values, has been proposed to be due to the delocalization of an odd electron into the hybridized orbital between 2p-orbital on α-carbon atom and 3d-orbital on sulfur atoms, and this type of conjugative effect can display only with those groups of the 2nd row elements bearing at least one lone electron pair and not with these without any lone-pair or with those of the lst row elements. The electron-sharing conjugation also can satisfactorily explain the orientation of the thiyl radical to mercapto- and alkoxyacetylenes.[10] However, the hypothesis of the electron-sharing conjugation effect has to be tested with more critical and quantitative experiments. With these background thoughts, we have studied the hydrogen abstraction reaction of various α-substituted compounds by *t*-butoxy radical and this paper will discribe the detailed account of the results and discussion especially as to what extent, electron-releasing or/and electron-sharing conjugative effects would control the reactivities and also change the mechanism of the reaction.

Results and Discussion

Kinetics. The decomposition of di-*t*-butyl peroxide was carried out in chlorobenzene at 130℃ ±0.5℃, for 42 hr during which the peroxide was completely decomposed.[11] The *t*-butoxy radical formed by the thermal decomposition of the peroxide is mainly consumed through the following two processes. The one is the β-scission of *t*-butoxy radical into acetone and methyl radical as shown by Eq. (4) and the other is the hydrogen abstraction from a hydrogen donor compound (RH) giving *t*-butanol Eq. (5). In these experiments, the total yields of acetone and *t*-butanol combined were always more than 95 % with all the substrates examined; therefore, the hydrogen abstraction and the β-scission consist of the main portion of the reaction. Thus, the relative reactivity of reactions (4) to (5) is given by Eq. (6),[12]

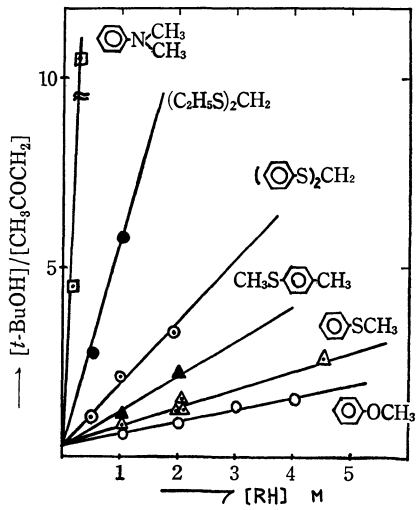

Fig. 1. Plot of [t-BuOH]/[CH_3COCH_3] against [RH].

$$t\text{-BuO}\cdot \xrightarrow{k_d} CH_3COCH_3 + CH_3\cdot \quad (4)$$

$$t\text{-BuO}\cdot + RH \xrightarrow{k_a} t\text{-BuOH} + R\cdot \quad (5)$$

$$t\text{-BuOH}/CH_3COCH_3 = k_a/k_d \times [RH] \quad (6)$$

where k_d and k_a are the rate constants of the decomposition and the hydrogen abstraction respectively, while [RH] is the concentration of a substrate. Applicability of this Eq. (6) to all the substrates can be tested by plotting their t-BuOH/CH_3COCH_3 values againt [RH] and we got a straight line, from whose slope k_a/k_d was able to be calculated. Applications for a few substrates are illustrated in Fig. 1.

Influence of α-Substituent. The relative reactivities k_a/k_d of all the substrates and those of hydrogen abstraction relative to toluene are summarized along with the σ^* values of all the substituents in Table 1. Inspection of the data reveals a few interesting points worthy to be noted in the following paragraphs. 1) Anisole, thioanisole and *N,N*-dimethylaniline react much faster than

toluene, while *N,N*-dimethylaniline is the fastest reacting substrate among all of the substrates examined and thioanisole has a slightly larger rate than anisole, whereas very little hydrogen abstraction takes place with phenyl methyl sulfone. This markedly slow rate of phenyl methyl sulfone is quite contrary to the case of the carbanion forming reaction as seen in the decarboxylation reaction,[2] in which phenylsulfonyl group accelerates the reaction more than phenylmercapto group. 2) The ring compound (ethanedithioformal) reacts faster than the corresponding acyclic compound (diethylmercaptoformal). 3) Successive substitution of either phenylmercapto or phenoxyl group at α-carbon atom of either thioanisole or anisole respectively leads to a gradual rate increment (see Table 2). 4) No reasonable correlation between reactivities of substrates (XCH_3) and σ^* values of substituents (X) is found and only scattered points are obtained when one plots $\log k_a/k_d$ against σ^* values as shown in Fig. 2. These observations reveal that the reactivities of α-hydrogen are not determined simply by inductive effect of α-substituents and that those substituents that have heteroatoms bearing at least one lone electron pair at α-position enhance the rate of hydrogen absotraction. The successive substitution of phenylmercapto and phenoxyl groups at α-position appears to increase the relative rate considerably. Thus diphenylmercaptoformal is 5 times as reactive as thioanisole, while tris (phenylmercapto) methane has rate 7 times larger than that of thioanisole. This gradual rate enhancement with additional substitution of same substituent on α-carbon atom can be seen with all the substituents, however, the amount of the rate enhancement by one additional substituent seems to be nearly identical independently of the nature of substituent in spite of the different induc-

a) All the values of k_a/k_d are the averages of more than two runs.
b) 2.00 M in chlorobenzene with 0.107 M of di-*t*-butyl peroxide.
c) 1.00 M.
d) 0.1 M solution with 0.043 M of $(t\text{-BuO})_2$.
e) The reactivity of hydrogen of methoxyl group was subtracted from the total reactivity (3.76) as follows. Substituted anisole gave a satisfactory Hammett σ correlation and σ value of para-methylmercapto group is 0.00, therefore, the reactivity of hydrogen of methylmercapto group in para methoxythioanisole is 3.76—1.36 (reactivity of anisole) = 2.40.
f) Substituted toluene is known to give σ^+ correlation (see Ref. 22) and ρ is −0.38 (σ^+) at 125 °C with di-*t*-butyl peroxide.
The reactivity of para-methyl group is

$$\log k = -0.38(-0.604) + \log 0.944 = 0.205,\ k = 1.60.$$

Therefore, the reactivity of hydrogen of methylmercapto group is

$$3.70(\text{total reactivity}) - 1.60 = 2.10.$$

tive effects of these substituents, if one carefully examines the data in Table 2, which includes other reported data on methyl[13] and phenyl[14] groups. This fact suggests that all the substituents including methyl, phenyl, phenoxyl and phenylmercapto groups when they are substituted additionally at α-position give some additional stabilization to the incipiently developing radicals by the conjugative effect of the respective groups.

Hamett Relationship. The relative reactivities found for these substituted anisole, thioanisole, *N,N*-dimethylaniline, and phenyl methyl sulfone derivatives are treated with the Hammett equation. The results are shown in Figs. 3 and 4, and Tables 3 and 4, while the Hammett ρ values of these reactions are listed in Table 4. Table 4 shows that the logarithms of the relative rates of the substituted anisoles and *N,N*-dimethylanilines can be satisfactorily correlated with normal Hammett σ values with ρ values of -0.39 and -0.42 respectively and the sulfones also give σ correlation with $\rho=-0.2$ although reproducibility of k_a/k_d values is by no means excellent for the sulfonyl compounds. The substituted thioanisoles show somewhat different pattern of substituent effect. While *p*-CN, *p*-Cl, *m*-Cl, H and *p*-CH_3 groups are well correlated with σ values, *p*-CH_3O and *p*-PhO groups give slight deviations from the linearity of correlation line with the value of $\rho=-0.15$ and the correlation coefficient of 0.956. Yukawa-Tsuno's treatment[15] gave the best line with $r=0.75$, to give an equation $\log k/k_0=-0.11(\sigma+0.75\,\Delta\sigma_R^+)$ with correlation coefficient of 0.986, while Brown-Okamoto's σ^+[16] correlation gave $\rho=-0.11$, correlation coefficient of 0.970. Yamamoto's treatment[17] of E_R value also gave a relatively good correlation with $\rho=-0.12$, and the correlation coefficient of 0.980, but methoxyl group falls off substantiallyl.

We used Yukawa-Tsuno'st reatment because of the following reasons. 1) calculated r value, which is a rough measure of resonance contribution[17] is very small, namely, 0.1, in this free radical reaction of hydrogen abstraction of thioanisole when one compares the value with those observed in many other examples.[18] 2) The carbon atom of the reacting center is considered to bear a partial positive charge in the transition state because the hydrogen abstracting agent in this reacton is *t*-butoxyl radical. 3) The trend of the α-substituent effects in this hydrogen abstraction reaction is similar to that found in the solvolyses of α-substituted methyl chlorides, but not to that in the carbanion-forming reactions as seen in Table 5. 4) The kinetic isotope effect of the reaction measured with both α-deuterated and undeuterated thioanisoles, *i.e.* 3.2 at 130℃, which is considered to be a relatively large as compared to the others[19] listed in Table 6, indicates that C–H bond of thioanisole

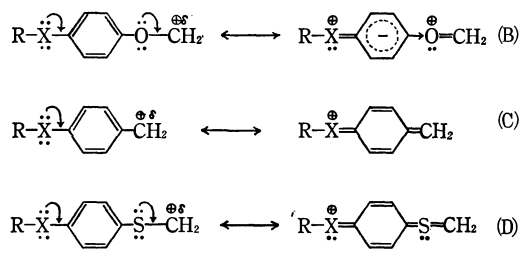
is broken at the transition state sufficiently enough to receive a noticeable assistance of the conjugative effect of the ring substituents *via* the divalent sulfur atom.

Therefore, electron-releasing conjugative effect of substituent must be responsible. Alkoxyl, mercapto and amino groups are known to be markedly electron-releasing in the electron-donating reactions, and the order of the effect is the following, $R_2N- \gg R-O- > R-S- > Ph- \gg PhSO_2-$.*2 This order of electron-releasing effect can explain the sequence of the relative reactivities of the heteroatom-substituted compounds. This is quite understandable in view of the fact that *t*-butoxyl radical is highly electronegative and the transition state of this hydrogen abstraction reaction would be of somewhat polar nature as was postulated previously by Russell in the similar hydrogen abstraction reaction with phenyl radical. The slightly larger reactivity of thioanisole as compared with anisole may be due to the stronger inductive effect of phenoxyl group than that of phenylmercapto group and/or a possible electron-releasing effect from aryl group additionally transmitted to the reaction center through the divalent sulfur atom. Russell *et al.* also reported that thioanisole is three times as reactive as anisole in hydrogen abstraction by phenyl radical. Taking into account the less electronegativity of phenyl radical and the larger kinetic isotope effect (k_H/k_D), (which means the greater bond breaking in the transition state) than that with *t*-butoxy radical, this rather large rate difference is considered to be due to the greater stabilization of thiophenylmethyl radical ($PhSCH_2\cdot$) by the electron-sharing conjugation. Such an effect which we call electron-sharing conjugation is not conceivable in the case of anisole because of the lack of available 3d-orbitals. Though the effect is small, this conjugative effect by divalent sulfur atom is playing a definite role in the reaction of thioanisole derivatives as will be discussed.

In the previous paragraph it was shown that both anisole*3 and *N,N*-dimethylaniline give good correlations with Hammett σ constants. This successful σ-correlation for both substituted anisoles and *N,N*-dimethylanilines indicates that electron-releasing π-inductive effects of these *p*-substituents like *p*-methoxyl and *p*-phenoxyl groups are transmitted inductively to the terminal carbon atom through the chain as illustrated by (B).



Meanwhile, thioanisole derivatives apparently display an additional conjugative effect of substituents and its Hammett relationship is described in Eq. (7),

$$\log k/k_0 = -0.11\ (\sigma + 0.75\Delta\sigma_R^+) \qquad (7)$$

although the degree of the additional conjugative effect is somewhat smaller ($r=0.75$) than benzyl radical ($r=1.0$), in which σ^+ plot is known to give a satisfactory correlation.[22] The successful σ^+ correlation suggests that a direct conjugative interaction between the reacting carbon center and the substituents is operative and such a conjugation is possible only through the 3d-orbital resonance of divalent sulfur atom shown by (D). Sulfonyl group, having no electron pair available for such a conjugation retards the rate of hydrogen abstraction by *t*-butoxyl radical and σ correlation gives a better fit than σ^+ correlation for the rates of substituted sulfonyl compounds.

As a final remark, we may conclude that the rate enhancement by α-heteroatoms in this reaction is mainly due to the electron-releasing conjugative effect and both substituted anisoles and *N,N*-dimethylanilines give good Hammett σ correlations, while in the

*2 ($\sigma_p^+ - \sigma_m^+$) values of $(CH_3)_2N$, CH_3O, CH_3S, C_6H_5, and CH_3SO_2- are -1.49, -0.83, (-0.75 for Ph-O), -0.76, -0.29 and 0.12 respectively from H. C. Brown and Y. Okamoto, *J. Am. Chem. Soc.*, **80**, 4979 (1958) ; H.H. Jaffe, *Chem. Revs.*, **53**, 222 (1953). σ_m^+s of phenyl, *N,N*-dimethyl and phenoxy are not available, hence σ_m values were used for σ_m^+. σ^+ of sulfonyl group is not available, therefore ($\sigma_p - \sigma_m$) was used instead of $\sigma_p^+ - \sigma_m^+$. This treatment is reasonable when one recalls the similarity of σ_p^+ values with σ_p values of electron-withdrawing group.

*3 Sakurai and Hosomi reported also $\rho = -0.41$ in the hydrogen abstraction of substituted anisoles by *t*-butoxyl radical at 45°C[20] ,and the thermal decomposition of ring substituted *t*-butyl perphenoxyacetate in ethylbenzene is known to give σ correlation with ρ value of -1.18.[21]

case of substituted thioanisoles, an additional conjugative effect of substituents such as *p*-methoxyl and *p*-phenoxyl group, appears to be transmitted *via* sulfur atom perhaps using 3d-orbitals of divalent sulfur atom and the rates are correlated better with σ^+ values. More clear evidence of electron-sharing conjugation of divalent sulfur atom may be obtained in the hydrogen abstraction reaction with more neutral phenyl radical and the work on this line is in progress in these laboratories.

Experimental

Preparations of Materials. *Substituted Anisoles.* *p*-Chloro-, *m*-chloro-, *p*-methoxy- and *m*-methoxyanisoles were synthesized by methylation of the corresponding phenols with dimethyl sulfate in alkaline methanol solution. *p*-Cyanoanisole was prepared by Sandmeyer reaction of diazonium salt of *p*-anisidine.

Substituted Thioanisoles. The methylation of thiophenol, *p*-chloro- and *p*-methylthiopheno land *p*-methylmercaptophenol by dimethyl sulfate gave the corresponding thioanisole derivatives in good yields. *p*-Methylmercaptobenzonitrile was prepared from Sandmeyer reaction of *p*-methylmercaptoaniline in 23% yield and recrystallized from methanol as colorless crystals melting at 63—64°C. *p*-Methylmercaptoaniline was obtained by the usual methylation of *p*-aminothiophenol, which was prepared by the treatment of *p*-chloronitrobenzene with sodium sulfide nonanhydrate as described by Gilman.[23] *m*-Chlorothioanisole was prepared by allowing to react sodium methylmercaptide with diazonium salt of *m*-chloroaniline in an aqueous alkaline solution.[24] *p*-Methylmercaptophenyl phenyl ether was prepared by heating the mixture of *p*-methylmercaptophenol[25] and bromobenzene in a concentrated aqueous potassium hydroxide solution in the presence of a small amount of copper powder at 150°C as described by Brewster.[26]

Preparation of Substituted N,N-Dimethylaniline Derivatives. *p*-Dimethylaminobenzonitrile was prepared by Sandmeyer reaction of *p*-amino-*N,N*-dimethylaniline and purified by recrystallization from methanol as colorless crystals melting at 73—74°C. 4-*N,N*-dimethylaminodiphenyl ether was prepared by methylation of 4-aminodiphenyl ether with dimethyl sulfate in aqueous $NaHCO_3$ solution as described by Evans[27]. 4-Aminodiphenyl ether was prepared by the reduction of 4-nitrodiphenyl ether with zinc dust as described by Suter.[28] 4-Chloro-*N,N*-dimethylaniline and 3-chloro-*N,N*-dimethylaniline were prepared by the usual methylation of *p*-chloro- and *m*-chloroanilines with dimethyl sulfate in dioxane. Distillation gave crude products, which were then purified through an alumina column chromatography with *n*-hexane in order to remove trace amount of secondary and primary amines and finally distilled. *N,N,N',N'*-tetramethyl-*p*-phenylenediamine was prepared as follows.[29] A mixture of 8 g of hydrochloric acid and 8 g of methanol was placed in a sealed tube and heated at 180—200°C for 3 hr. After breaking the tube, the reaction mixture was poured into a sufficient amount of 10% aqueous sodium hydroxide solution to afford a precipitate, which was then filtered and washed several times with water, dried and finally recrystallized from *n*-hexane. Mp 49—50. Yield 50%.

Substituted Phenyl Methyl Sulfones. *p*-Chloro-, *m*-chloro-, *p*-phenoxyphenyl methyl sulfones and unsubstituted phenyl methyl sulfone were prepared by the oxidation of the corresponding sulfides with an execess amount of hydrogen peroxide in acetic acid and recrystallized twice from benzene-*n*-hexane.

Other α-Substituted Compounds. Ethanedithioformal, diethylthioformal, diphenylthioformal and diphenylformal were prepared by the substitution reaction of methylene chloride with corresponding sodium mercaptides and phenoxide in ethanol. After the usual work-up, ethanedithioformal, diethylthioformal, and diphenylformal were distilled under reduced pressure through an efficient column. Diphenylthioformal was recrystallized from petroleum ether. Tris(phenylmercapto) methane was prepared by the substitution reaction of ethyl orthoformate with thiophenol in benzene using boron trifluoride as a catalyst and recrystallized from methanol to give colorless crystals melting at 39—40 °C.

Di-t-butyl peroxide. Di-*t*-butyl peroxide was prepared by Milas and Surgenor's method.[30] This peroxide was distilled to give distillate boiling at 109—110 °C. No detectable amount of *t*-butyl hydroperoxide was found to be contained from the IR and NMR spectra.

Elemental analysis. Found: C, 65.35; H, 12.30%. Calcd: C, 65.70, H, 12.40%.

Deuterated Thioanisole. Thioanisole 2.0 g (*ca.* 0.016 mol) was poured into 12.5 g (*ca.* 0.12 mol) of *t*-BuOD (70% deuterated) containing 0.6 g (*ca.* 0.012 mol) of metal potassium and the mixture was sealed into an ampoule *in vacuo*, which was kept at 90°C for 48 hr. The usual work-up gave 1.8 g of 33% deuterated thioanisole by NMR measurement.

Chlorobenzene. Chlorobezene used for solvent was purified by washing commercial grade of chlorobenzene with concentrated sulfuric acid, and then distillation over phosphorus pentoxide. The distillate was distilled again through an efficient column. Bp 130.5—131.0°C. Purities of all the substrates used in this experiment were carefully checked by IR, NMR, Gas chromatography and elemental analyses. Properties of all these compounds used

a) In 10% CCl_4, TMS was used as an internal standard.

for kinetics are listed in Table 7.

Kinetic Procedure. Each sample substrate was weighed in a 5 m*l* volumetric flask and diluted with chlorobenzene to make the total volume of the solution exactly 5 m*l*. The solution, 2 m*l* was pipetted out into a glass tube (*ca.* 10 m*l* volume), into which 2 m*l* of 0.214 M of di-*t*-butyl peroxide-chlorobenzene solution was pipetted to make the total volume of 4 m*l*. The tube was cooled with dry ice-acetone, evacuated three times and sealed. The tubes were set in a paraffin bath kept at 130 ±0.5°C for 42 hr.

The cooled tube was opened, into which 1 m*l* of toluene solution containing 0.74 mmol of benzene

per 1 m*l* was added for the internal standard of gas chromatography. The mixture in the tube was placed in a distilling flask and distilled. The distillate below 130°C was collected and the amounts of acetone and *t*-butanol were analyzed by gas chromatography using PEG 6000 4 m column at 81°C using hydrogen as a carrier gas. From the relative areas of two peaks, the moles of acetone and *t*-butanol produced in the reaction were calculated using the calibration line.

Values of k_a/k_d were calculated by Eq. (6).

Macrocyclic Dilactone. II. The General Synthesis of Macrocyclic Dilactone

Noboru SUGIYAMA, Hiroaki MARUYAMA,
Taketoshi GASHA and Choji KASHIMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

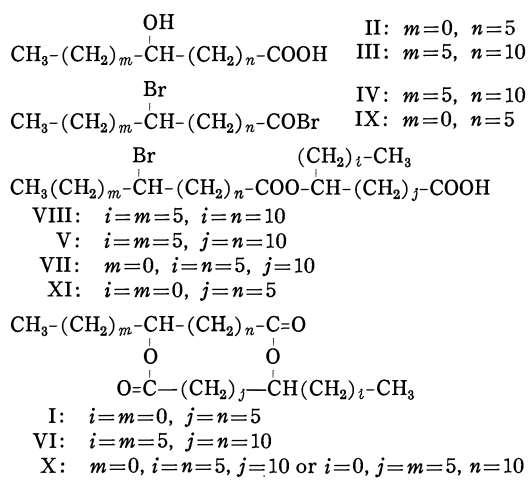
(Received February 19, 1968)

One previous papar reported the synthesis of 7-hydroxyoctanoic acid dilactone through the dimeric ester. This paper will describe how the dilactone of 12-hydroxystearic acid is synthesized by this method. The dilactone from two kinds of hydroxy alkanoic acid, 7-hydroxyoctanoic acid and 12-hydroxystearic acid, is also otained. From these results, it seems that this new method can be of general use in the synthesis of various kinds of dilactones.

Previously, the present authors reported on the preparation of the dilactone of 7-hydroxyoctanoic acid by two methods, the pyrolytic depolymerization of the polyester and the cyclization of the dimeric ester.[1] The latter method was found to be superior for the synthesis of 7-hydroxyoctanoic acid dilactone (I).

This paper will describe the synthesis of dilactone from 12-hydroxystearic acid (III), which can cyclize to a thirteen-membered monolactones from 12-hydroxystearic acid (III).

As a result of the action of thionyl bromide, III gave 12-bromostearoyl bromide (IV), which was then treated with the original acid III to produce the dimeric ester, 1′-carboxy-11′-heptadecyl 12-bromostearate (V). The infrared absorption spectrum of V showed absorption bands at 1730 and 1180 cm^{-1} of the ester carbonyl group. The NMR spectrum of V is shown in Table 1. These spectral data and the molecular weight measurment support the structure of V. By means of the high-dilution method in methyl ethyl ketone,[2] V



was cyclized to 12-hydroxystearic acid dilactone, 1,14-dioxa-2,15-dioxo-13,26-dihexylcyclohexacosane (VI). The structre of VI was comfirmed as follows. The infrared absorption spectrum showed the ester carbonyl bands at 1730 and 1180 cm^{-1}, and no absorption in the region of carboxyl bands. The NMR spectrum, listed in Table 2, showed the multiplet at τ 5.16 of the methine protons at C-13 and C-26, the triplet at τ 7.79 of the methylene protones

TABLE 1. THE NMR SPECTRAL DATA OF V, VII, VIII AND XI (τ)

	V	VII	VIII	XI
Carboxyl	−0.05	1.50	−0.43	0.05
Methine (CH-O)	5.21	5.40	5.21	5.18
Methine (CH-Br)	5.91	6.02	6.00	6.57
Methylene (CH_2-C=O)	7.78	7.75	7.80	7.78
Methylene (CH_2-CBr)	8.10	8.34	8.10	—*
Methyl (CH_3CBr)	—	8.30	—	8.29
Methyl (CH_3-C-O)	—	—	8.85	8.83
Methyl (CH_3-CH_2)	9.11	9.12	9.09	—
Other methylenes	8.72	8.71	8.68	8.56

* The methylene (CH_2-CBr) signal was indistinguishable from the multiplet of other methylenes.

TABLE 2. THE IR AND THE NMR SPECTRAL DATA OF I, VII, AND X

	I	VI	X
$\nu_{C=H}$	1730	1730	1730
τ_{CH} (CH-O)	5.24	5.16	5.21
τ_{CH_2} (CH_2-C=O)	7.83	7.79	7.79
τ_{CH_3} (CH_3-C-O)	8.85	—	8.86
τ_{CH_3} (CH_3-CH_2)	—	9.12	9.14
τ_{CH_2} (other methylenes)	8.62	8.73	8.73

at C-3 and C-16, the triplet at τ 9.21 of the methyl protons, and multiplet centered at τ 8.73 of the methylene protons. The molecular weights and the results of the elemental analysis supported the structure of VI.

Using this new method, it is effected that a dilactone can be obtained from two kinds of hydroxy alkanoic acids. The dilactone which is formed from two kinds of hydroxy carboxylic acids can be called a mixed dilactone. The preparation of a mixed dilactone has not been found described in the literature except for the heating a miture of two kinds of acids; by this method the corresponding dilactone can not be selectively obtained. The present authors succeded in synthesizing the dilactone selectively from two kinds of acids, II and III. Since two kinds of ester are expected as the intermediates in the synthesis of the mixed dilactone, two synthetic routes were examined for obtaining the mixed dilactone from II and III. One route was the cyclization of 1′-carboxy-11′-heptadecyl 7-bromooctanoate (VII), and the other, that of 1′-carboxy-6′-heptyl 12-bromostearate (VIII).

The dimeric ester VII was obtained from 7-bromooctanoyl bromide (IX) by treatment with III. The structure of VII was confirmed as follows. The infrared absorption spectrum was similar to that of V; the NMR srectrum was as shown in Table 1. The molecular weight measurements and the elemental analysis supported the structure of VII. Similarly, the dimeric ester VIII was obtained from 12-bromostearoyl bromide (IV) by treatment of 7-hydroxyoctanoic acid (II). The infrared absorption spectrum was similar to that of VII, while the NMR spectrum was as listed in Table 1. The spectral data, the molecula weight measurements, and the elemental analysis showed the structure of the dimeric ester VIII.

By the high-dilution method,[2] VII was cyclized in the presence of potassium carbonate. The infrared absorption spectrum of this cyclized product showed ester carbonyl bands at 1730 and 1180 cm^{-1}, and no band characteristic of the carboxyl group. The NMR spectrum, listed in Table 2, showed the multiplet at τ 5.21 assigned to methine protons, the triplet at τ 7.79 of methylene protons, and the signals at τ 8.86 and 9.14 of methyl protons, while other protons appeared at τ 8.73 as a multiplet. The spectral data, the molecular weight measurements, and the elemental analysis confirmed this cyclized product to be the mixed dilactone, 1,14-dioxa-2,15-dioxo-13-hexyl-21-methylcycloheneicosane (X). Under the same conditions, catalyzed by potassium carbonate, VIII was cyclized, and the cyclized product was identified with X by the spectral data and by the R_f value on silicagel thin-layer chromatograpy.

In conclusion, these results suggest that the new synthetic method is generally applicable to the preparation of the dilactone from hydroxy alkanoic acids. Moreover, the mixed dilactones can be obtained from two different kinds of hydroxy alkanoic acids by this methods.

Experimental

1′-Carboxy-11′-heptadecyl 12-bromostearate (V). A mixture of 10 g of III and 10 m*l* of thionyl bromide in 100 m*l* of dry chloroform was refluxed for 3 hr with stirring. After the removal of the solvent and the excess thionyl bromide, the residue was dissolved in 100 m*l* of dry benzene, and then 9 g of III was added. The mixture was refluxed for 4 hr with stirring, and then washed with water and dried over anhydrous sodium sulfate. After the evaporation of the solvent, the residue, which showed three spots on silica-gel thin-layer chromatography, was passed through a silica-gel (Merck 7734) column with a benzene - chloroform (7 : 3 v/v) mixture. When the second fraction was then collected, 8.5 g of V were obtained, mp 55°C.

Found: C, 66.95; H, 10.68%; mol wt (titration), 625. Calcd for $C_{36}H_6O_4Br$: C, 66.93; H, 10.79%; mol wt, 645.97. IR (liquid film): 3500—2400, 1730,

1710, 1180 and 970 cm^{-1}.

1,14-Dioxa-2,15-dioxo-13,26-dihexylcyclohexacosane (VI). Over a 28 hr-period, a solution of 2.5 g of V in 50 m*l* of methyl ethyl ketone was added, through a reflux condenser, to 600 m*l* of methyl ethyl ketone containing 15 g of anhydrous potassium carbonate under vigorous stirring and refluxing. After the additon of V, the stirring and refluxing were continued for 8 more hours. The reaction mixture was concentrated after the removal of potassium carbonate, and the residue was dissolved in ether. The ethereal solution was washed with water and dried over anhydrous sodium sulfate. The solvent was removed, and the residue was passed through a silica-gel (Merck 7729) column with a benzene-ethyl acetate (4 : 1 v/v) mixture. The first fraction was then collected, and the solvent was removed. The first fraction was then collected, and the solvent was removed. The residue was chromatographed on an alumina (Wako alumina) column with a benzene-ethyl acetate (20 : 1 v/v) mixture. A fraction which showed a R_f value of 0.60 on silica-gel (Wakogel B-5) thin-layer chromatograph with a benzene-ethyl acetate (10 : 1 v/v) mixture was then collected; yield 1 g.

Found: C, 76.92; H, 12.27%; mol wt (Rast), 619. Calcd for $C_{36}H_{68}O_4$: C, 76.54; H, 12.13%; mol wt, 564.90. IR (liquid film): 2940, 2860, 1730, 1460, 1180 and 1110 cm^{-1}.

1'-Carboxy-11'-heptadecyl 7-Bromooctanoate (VII). A mixture of 4 g of II and 6 m*l* of thionyl bromide in 100 m*l* of dry benzene was refluxed for 3.5 hr with stirring. After the removal of the solvent and the excess thionyl bromide, the residue was distilled under reduced pressure, bp 146—150°C/10 mmHg, 2.1 g of IX were thus obtained. IR (liquid film): 2940, 2860, 1800, 1460 and 970 cm^{-1}. The mixture of 2.1 g IX and 3 g of III in 50 m*l* of dry chloroform was refluxed for 3 hr with stirring. The reaction mixture was then treated by the same procedure as V. Four grams of VII were then obtained by recrystallization from chloroform; mp 65°C.

Found: C, 61.84; H, 9.88%; mol wt (titration), 494. Calcd for $C_{26}H_{49}O_4Br$: C, 61.81; H, 9.72%; mol wt, 505.67. IR (liquid film): 3500—2400, 1730, 1710, 1470, 1190 and 970 cm^{-1}.

1'-Carboxy-6'-heptyl 12-Bromostearate (VIII). 12-Bromostearoyl bromide, which had been obtained from 10 g of III and 10 m*l* of thionyl bromide, was added to a solution of 3.5 g of II in 100 m*l* of dry benzene, after which the mixture was refluxed for 4.5 hr with stirring. The reaction mixture was then treated by the same procedure as were V and VII; 1.5 g of VIII were thus obtained.

Found: C, 61.59; H, 10.14%; mol wt (titration), 594. Calcd for $C_{26}H_{49}O_4Br$: C, 61.81; H, 9.72%; mol wt, 505.67. IR (liquid film): 3500—2400, 1730, 1710, 1460, 1180 and 970 cm^{-1}.

1,14-Dioxa-2,15-dioxo-13-hexyl-21-methylcycloheneicosane (X). For 20 hr, a solution of 1 g of VII in 50 m*l* of methyl ethyl ketone was slowly added, under vigorous stirring and refluxing, through a reflux condenser to 600 m*l* of methyl ethyl ketone containing 15 g of anhydrous potassium carbonate. After continuous stirring and refluxing for 4 hr, the reaction mixture was treated by the same procedure as VI. The yield of X was 0.5 g; the R_f value on silica-gel (Wokogel B-5) thin-layer chromatography with a benzene-ethyl acetate (10 : 1 v/v) mixture was 0.53.

Found: C, 72.68; H, 11.19%; mol wt (Rast), 422. Calcd for $C_{26}H_{48}O_4$: C, 73.53; H, 11.39%; mol wt, 424.64. IR (liquid film); 2940, 1730, 1460, 1180 and 1110 cm^{-1}.

X was also obtained by the cyclization of VIII by the same procedure; it was identified by means of the infrared absorption, the NMR spectra, and the R_f value of thin-layer chromatography.

NMR Spectra. The NMR spectra were measured on a Hitachi H-60 High resolution Nuclear Magnetic Resonance Spectrometer. The solvent was carbon tetrachloride, while tetramethylsilane was used as the internal standard.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1940—1944 (1968)

Anionic Copolymerization of Styrene and *trans*-Stilbene with *n*-Butyllithium

Heimei YUKI, Masahiko KATO and Yoshio OKAMOTO

Department of Chemistry, Faculy of Engineering Science, Osaka University, Toyonaka, Osaka

(Received February 19, 1968)

The anionic copolymerization of styrene (M_1) and *trans*-stilbene (M_2) by *n*-butyllithium was investigated. *trans*-stilbene, which can not homopolymerized by itself, could be copolymerized with styrene in tetrahydrofuran and in benzene by an anionic catalyst. The copolymerization in tetrahydrofuran proceeded with a chain transfer to *trans*-stilbene, while that in benzene seemed to proceed without the chain transfer. The monomer reactivity ratio, r_1, was obtained from the copolymer composition at the complete consumption of M_1, assuming that the rate constant, k_{22}, is zero. The r_1 values were 2.3 in tetrahydrofuran at 0°C and 18 in benzene at 30°C. The color of the solution changed from red to purple in tetrahydrofuran, while in benzene no change occurred.

The present authors have found that, if a suitable combination of monomers is chosen, an alternating copolymer can be obtained by an anionic mechanism.[1] In the previous paper, an investigation of the anionic copolymerization of styrene (M_1) and 1,1-diphenylethylene (M_2) was reported in detail.[2] The copolymerization proceeded in a living system, and monomer reactivity ratios, r_1, were obtained as 0.2 in tetrahydrofuran(THF) at 30°C and as 0.4 in benzene at 30°C, assuming that a 1,1-diphenylethylene anion does not add to 1,1-diphenylethylene.

In this paper, a detailed study of the copolymerization of styrene (M_1) and *trans*-stilbene (M_2) will be described, and the results will be correlated with the results of the copolymerization of styrene and 1,1-diphenylethylene.

Experimental

Materials. *Styrene.* This was purified by the usual method and was distilled on a vacuum line from calcium hydride.

trans-Stilbene. The monomer synthesized from benzoin[3] was recrystallized from methanol and then twice from *n*-hexane.

Tetrahydrofuran (THF). The solvent, refluxed over metallic sodium and then over lithium aluminum hydride, was distilled onto sodium-potassium alloy and naphthalene. From the characteristic green solution, it was then distilled on a vacuum line to a reaction vessel.

Benzene. Benzene was purified by the standard method[4] and was stored over sodium. Before use, it was transferred to a flask containing *n*-butyllithium, and then it was distilled on a vacuum system to a reaction vessel.

n-Butyllithium (n-BuLi). According to the method of Ziegler,[5] *n*-BuLi was prepared in *n*-heptane and the concentration was determined by double titration.[6]

Polymerization. *trans*-Stilbene was first placed in a glass ampoule and dried *in vacuo*. Then, the solvent and styrene were transferred into the ampoule by vacuum distillation. The solution was immersed in a bath at a constant temperature, and *n*-BuLi was added under dry argon with a syringe. The reaction was terminated by adding methanol, after which the contents of the ampoule were poured into a large amount of methanol. The precipitated polymer was collected by filtration, washed with methanol, dried, and weighed. The mother liquor and the washings of the polymer precipitation were then combined and evaporated at reduced pressure, and the residual unchanged monomer and lithium compound were weighed.

Measurement. *Viscosity.* The viscosity of the polymer was measured in a benzene solution (C= 1.0 g/d*l*) at 30.0°C.

Electronic Spectrum. The spectrum of a living anion was measured in THF with a Cary 15 Spectrophotometer.

Results

Polymerization in THF. The copolymerization of styrene (M_1) and *trans*-stilbene (M_2) with *n*-BuLi was carried out in THF at 0°C, the initial molar ratio of styrene to *trans*-stilbene, $[M_1]_0/[M_2]_0$, being 1.0/1.5. The results are shown in Fig. 1. The reaction came instantaneously to an end, always giving a copolymer in a 68% yield against the total amount of monomers, regardless of the reaction time measured.

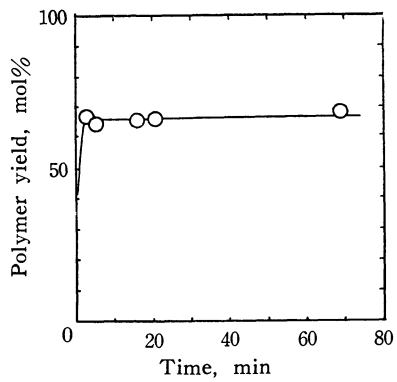

Fig. 1. Anionic copolymerization of styrene (M_1) and *trans*-stilbene (M_2) in THF.—Time *vs.* polymer yield.
$[M_1]_0+[M_2]_0$ 7.0 mmol, $[M_1]_0/[M_2]_0$ 1/1.5, THF 15 m*l*, Temp. 0°C, *n*-BuLi 5.8×10^{-2} mmol.

The copolymerization was carried out by varying the ratio, $[M_1]_0/[M_2]_0$, the total amounts of monomers, $[M_1]_0+[M_2]_0$, being kept constant. The results are summarized in Table 1. Attempts to determine the copolymer composition were made with elementary analysis, UV and NMR spectroscopies, but no satisfactory results were obtained because these monomers all have similar structures. On the other hand, the residues recovered from the mother liquor of polymer precipitates were solid and were found to be a mixture of lithium compounds, mainly carbonate, and unchanged *trans*-stilbene, which was identified by IR and UV spectroscopies. The sum of the amounts of the polymer and the unchanged monomer, $P+M_r$, just balanced the total amounts (weight) of the monomers, M_1+M_2, indicating the complete incorporation of the charged styrene into the copolymer. The amount of unchanged *trans*-stilbene was also determined by studying the UV spectrum of a part of the reaction mixture; it was found to be nearly equal to the value obtained by gravimetry. Thus, the copolymer composition can be determined from the polymer yield as $M_1/P-M_1$; this value is converted into the molar ratio of the monomers in the copolymer, $[m_1]/[m_2]$, in Table 1. Below, the composition of the copolymer is always calculated from the polymer yield on the assumption that the charged styrene is completely consumed by the copolymerization. We have found that the polymer yield and the $[m_1]/[m_2]$ ratio decrease with a decrease in the $[M_1]_0/[M_2]_0$ ratio.

The copolymerization at 0°C in THF was investigated by varying the ratio, $[M_1]_0/[M_2]_0$, while the amount of the M_1 monomer was kept constant. The results are listed in Table

2. The polymer yield against the total amount of the monomers, the copolymer composition expressed in the $[m_1]/[m_2]$ ratio, and the viscosity of the polymer all decreased with an increase in the amount of M_2 in the monomers charged, while the softening point rose. The data in Table 2 suggest that a lower monomer composition, $[M_1]_0/[M_2]_0$, than 0.4 may give an essentially alternating copolymer of M_1 and M_2 monomers with a very low molecular weight.

If, in the copolymerization, the M_2 monomer can not add to the $\sim M_2^-$ anion, and if the M_1 comonomer is completely incorporated into the copolymer, the monomer reactivity ratio, r_1, can easily be obtained from the polymer yield by assuming that $k_{22}=0$ and $[M_1]=0$ in the Mayo-Lewis copolymer composition equation.[2] The copolymerization in THF at 0°C gave the value, $r_1=2.3$, as is show in Fig. 2, the plots in which were obtained from the data in Tables 1 and 2.

Polymerization in Benzene. The reaction rate was investigated in the copolymerization in benzene with *n*-BuLi at 30°C; the molar ratio of the initial monomer concentrations, $[M_1]_0/[M_2]_0$, was 1.0/3.0. The results are shown in Fig. 3. The reaction proceeded slowly in comparison with that in THF, a constant yield (24%) being obtained after about 24 hr. It was confirmed that, in this case, styrene was also completely incorporated into the copolymer after a sufficient reaction time.

The effects of the initial molar ratio, $[M_1]_0/[M_2]_0$, on the copolymerizaton in

benzene were investigated with a constant concentration of the M_1 monomer. The results are listed in Table 3. The relative reactivity of styrene against *trans*-stilbene was much greater in benzene than in THF. The solution viscosity of the polymer was constant regardless of $[M_1]_0/[M_2]_0$.

The monomer reactivity ratio, r_1, was calculated from the polymer yield as has been described above. As Fig. 4 shows, r_1 is 18 in the copolymerization in benzene at 30°C.

Electronic Spectrum of the Reaction Mixture. In the copolymerization of styrene and *trans*-stilbene by *n*-BuLi in THF, the red color gradually turned purple, even at 0°C. The change in the electronic spectra of the solution was followed; it is shown in Fig. 5. The red color of the solution diminished gradually and an absorption appeared at 555 mμ after about 30 min, by which time the copolymerization reaction had already finished. In the homopolymerization of styrene carried out under the same conditions, the red color of the reaction mixture did not change when it stood for a prolonged period. Therefore, this change in spectra may be attributed to the anion of *trans*-stilbene. The same spectral change was also observed in the reaction of *trans*-stilbene with *n*-BuLi in THF.[7] The purple solution initiated the polymerization of styrene to give a polymer quantitatively. On the other hand, in the copolymerization in benzene the orange color of the solution did not change in several hours, even at 30°C.

Discussion

Reactivity of Monomers. The monomer reactivity ratios, r, in the copolymerization of styrene (M_1) and *trans*-stilbene (M_2) or 1,1-diphenylethylene (M_2)[2] with *n*-BuLi are summarized in Table 4. The r_1 values obtained in the copolymerization with 1,1-diphenylethylene were less than unity in THF and also in benzene, while the ratios in the copolymerization with *trans*-stilbene were more than unity in both the solvents. These results show that, in the following reactions, the order of the rate constants is $k_{12D}>k_{11}>k_{12S}$.

$$\sim CH_2-\underset{\underset{Ph}{|}}{CH^-}+CH_2=\underset{\underset{Ph}{|}}{CH} \xrightarrow{k_{11}} \sim CH_2-\underset{\underset{Ph}{|}}{CH^-} \qquad (1)$$

$$\sim CH_2-\underset{\underset{Ph}{|}}{CH^-}+CH_2=\underset{\underset{Ph}{|}}{\overset{\overset{Ph}{|}}{C}} \xrightarrow{k_{12D}} \sim CH_2-\underset{\underset{Ph}{|}}{\overset{\overset{Ph}{|}}{C^-}} \qquad (2)$$

$$\sim CH_2-\underset{\underset{Ph}{|}}{CH^-}+\underset{\underset{Ph}{|}}{\overset{\overset{Ph}{|}}{CH}}=CH \xrightarrow{k_{12S}} \sim \underset{\underset{Ph}{|}}{\overset{\overset{Ph}{|}}{CH}}-CH^- \qquad (3)$$

1,1-Diphenylethylene is the most reactive monomer to a styryl anion, for the monomer reacts with the anion to give a more stable anion conjugating with two benzene rings. On the other hand, *trans*-stilbene is the least reactive monomer because of its steric hindrance. The copolymerization of styrene and *trans*-stilbene in THF proceeded rapidly, while the copolymerization of styrene and 1,1-diphenylethylene proceeded so slowly that the reaction finished in 24 hr, even in THF at 0°C.[2] This may have been because the *trans*-stilbene anion produced in the reaction (3) has the same structure as the styryl anion, which is reactive enough to end instantaneously the homopolymerization of styrene, while the 1,1-diphenylethylene anion is very stable and has a big steric hindrance, therefore giving a very small k_{21}.

As Figs. 1 and 3 show, the overall rate of the copolymerization is greater in THF than in benzene. This may be becanse in THF a free ion plays a great part in the chain growth,[8] while in benzene living chain ends form ion pairs to associate themselves.[9] The

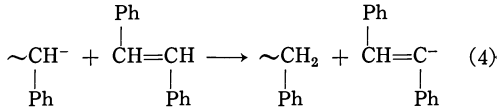
TABLE 4. MONOMER REACTIVITY RATIO, r_1, IN ANIONIC COPOLYMERIZATION OF STYRENE (M_1) AND 1,1-DIPHENYLETHYLENE (M_2)[2] OR *trans*-STILBENE (M_2) WITH *n*-BULI

Monomer		r_1 value	
M_1	M_2	in THF	in Benzeen
Styrene	1,1-Diphenyl-ethylene	0.13[a]	0.71[a]
Styrene	*trans*-Stilbene	2.3[b]	18[a]

a) At 30°C. b) At 0°C.

$1/r_1$ value (k_{12}/k_{11}) is smaller in benzene than in THF, as is shown in Table 4; this suggests that the relative reactivity of a M_2 monomer toward a $\sim St^-Li^+$ ion pair is smaller than that toward a styryl free anion, when the reactivities of styrene toward its chain ends are taken as standards.

Chain Transfer and Electronic Spectrum of the Living Anion. The viscosity of the copolymer decreased with an increase in the *trans*-stilbene, as is shown in Table 2. This indicates that a chain transfer to the *trans*-stilbene occurred in THF. This transfer may proceed as follows:



(4)

The production of the anion with a λ_{max} at 555 mμ may be connected with the chain transfer reaction shown by the process (4). On the other hand, the copolymerization in benzene (Table 3) seemed to proceed without the chain transfer, for no change in the red color of the reaction mixture was observed and the solution viscosity of the copolymer did not decrease with an increase in the *trans*-stilbene charged, although the exact molecular weight of the copolymer could not be determined.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1945—1950 (1968)

Constituents of Fruit Oil from Japanese Pepper

Tsutomu SAKAI, Kazuo YOSHIHARA and Yoshio HIROSE

The Institute of Food Chemistry, Dojimanaka, Kita-ku, Osaka

(Received February 19, 1968)

The steam-volatile constituents from ripe fruits of Japanese pepper have been studied using column and gas chromatographic separations, followed by characterization on the basis of infrared, nuclear magnetic resonance, and mass spectrometry. The capillary gas chromatography of the volatile oil from ripe fruits of Japanese pepper revealed the presence of approximately 130 components. Among the components identified were the following: 19 hydrocarbons (α-pinene, camphene, β-pinene, sabinene, myrcene, α-phellandrene, limonene, β-phellandrene, *p*-cymene, terpinolene, α-copaene, β-caryophyllene, humulene, γ_2-cadinene, α-muurolene, δ-cadinene, γ-cadinene calamenene, and α-calacorene), 15 alcohols (linalool, isopulegol, *trans*- and *cis*-2,8-*p*-menthadien-1-ol, terpinen-4-ol, limonen-4-ol, α-terpineol, 1(7), 8-*p*-menthadien-*trans*-2-ol, citronellol, *trans*- and *cis*-carveol, geraniol, cuminalcohol, β-caryophyllene alcohol, and nerolidol), 9 aldehydes and ketones (citronellal, dihydrocarvone, cryptone, carvone, piperitone, phellandral, cuminaldehyde, perillaldehyde, and piperitenone), 7 esters (isobutyl isovarelate, isobutyl caproate, linalyl acetate, citronellyl acetate, terpinyl acetate, geranyl acetate, and methyl cinnamate), and 6 oxides (1,8-cineol, β-terpinen-3,4-oxide, *trans*- and *cis*-limonen-1,2-oxide, terpinolen-4,8-oxide, and methyl chavicol).

Japanese pepper (*Zanthoxylum piperitum* DC., in Japanese, "Sansho," and its variety *Z. piperitum var. inerme* Makino, "Asakura-sansho") is a popular spicy plant in our country. The young leaves and fruits of Japanese pepper, possessing a pleasant odor and a strong pungent taste, are widely used as spice.

The essential oil from fruits of Japanese pepper have been studied by several authors. Earlier work on the volatile oil has been reviewed by Guenther.[1] Later, Katayama[2] reported the identification of several terpenes on the basis of the R_f value on a chromatostrip. The compounds reported on hitherto were 1,8-cineol, limonene, β-phellandrene, terpinolene, citronellal, linalool, α-terpineol, citronellyl acetate, geraniol, geranyl acetate, and cuminalcohol.

This paper will present the results of our investigation of the volatile oil isolated from ripe fruits of "Asakura-sansho."

Experimental

Apparatus. *Gas Chromatography.* The components were separated on a Varian Aerograph Model 90-P. The columns were : (1) a 25 ft-by-1/4 inch stainless steel column packed with 20% Triton X 305; (2) a 10 ft-by-3/8 inch aluminum column, 20% Carbowax 20 M ; and (3) the same column as (2), 20% SF-96; solid support, 60—80 mesh chromosorb W. These runs were isothermal or programmed. The flow rate of the helium carrier gas was 30—60 ml/min. The separated components were trapped in thin-walled glass capillaries following the method developed by Jennings and his co-workers.[3]

For analytical chromatography we used a Hitachi Perkin-Elmer Model F-6D gas chromatograph equipped with a flame-ionization detector. 45 m-by-0.25 mm stainless steel capillary columns coated with HB-2000, with FS-45, and with Q-45 were used. The column temperature was programmed from 70 to 150 °C (HB-2000), and was held isothermally at 80, 130, 150, and 200°C. The nitrogen carrier-gas inlet pressure was 1.0 kg/cm^2.

Infrared Spectroscopy. The infrared spectra were taken as thin films between sodium chloride plates on a Hitachi EPI-G2 spectrometer, equipped with a custom-made beam condenser.

Nuclear Magnetic Resonance Spectrometry. The NMR spectra were measured on a JEOL Model C-60 spectrometer at 60 MHz in carbon tetrachloride, using tetramethylsilane as an internal reference. The microcell technique was adopted.[4]

Mass Spectrometry. Mass spectra were obtained

Stored ripe fruit oil 45 m×0.25 mm HB-2000 column; temperature isothermal at 70°C for 3 min then programmed at 2.5°C per minute to 150°C and run isothermal thereafter; sample 1.0—2.0 μl ; range 1×1 except as indicated.

on a Hitachi RMU-6 mass spectrometer. The operating conditions were as follows: ionization voltage, 80 eV; ion-accelerating voltage, 2000 V; temperatures of ionization chamber and sample injection block, 250 and 150°C respectively.

Preparation and Separation of the Volatile Oil. Ripe fruits of "Asakura-sansho," cultivated in the Yoshino district, Nara Prefecture, were crushed and steam-distilled. The yield of the volatile oil was 0.96 per cent of the raw material.

The neutral volatile oil (104 m*l*), freed from acids and bases, was fractionated into sixteen fractions by distillation under reduced pressure, utilizing a Podbielniak 13 mm-by-24 inch Heli-Grid column. Each fraction was further fractionated by means of silica gel column chromatography and preparative gas chromatography. The individual components were then purified by reinjection into various columns.

Results and Discussion

Figure 1 shows the comparative capillary chromatograms of ripe fruit oil (top of Fig. 1), unripe fruit oil*[1] (middle), and ripe fruit oil stored for a long time at room temperature (bottom). Each chromatogram was obtained by using a flame-ionization detector and by injecting 1.0 μl of the raw volatile oil into a HB-2000 capillary column. The column temperature was held initially at 70°C for 3

*[1] The oleoresin was obtained by extraction with hexane from unripe fruits of "Asakura-sansho" which were cultivated in Minô, Osaka Prefecture. By steam-distillation of oleoresin, the volatile oil was isolated.

min, then programmed at 2.5℃ per minute to 150℃, and run isothermally at 150℃ until all the components had emerged. For the determination of the location of a particular peak, an authentic sample or a purified component was mixed with the original oil and chromatographed using the same analytical conditions as above. The location was confirmed by an appreciable increase in the particular peak.

Among the more than 130 component peaks observed in the chromatogram of fruits oils, fifty-six compounds were isolated and determined. Table 1 lists the components which were confirmed by a comparison of their infrared, nuclear magnetic resonance, and mass spectra with those of authentic samples and the literature data. Authentic samples were obtained from reliable commercial sources or synthesized by well-established methods, and were purified by gas chromatographic separation before use. In a few cases authentic samples were not available.

The mono- and sesqui-terpenic hydrocarbons were identified by direct comparison with authentic samples, except for β-phellandrene and γ_2-cadinene. The main components were limonene and β-phellandrene. Most of the hydrocarbons in the fruit oil of Japanese pepper are commonly found also in other oils of the same family (*Rutaceae*)-citrus oils, orange oil,[5,6] lemon oil[7,8] and natsudaidai oil.[9]

Among the oxygenated components, geranyl acetate, linalool, cryptone, and citronellal were present in quite large amounts. The two isobutyl esters were supposed to be related by a poignant principle, sanshool.[10]

It is most interesting that almost all of the auto- and photo-oxidation products from limonene[11-13] were isolated from fruits of Japanese pepper. These were *trans*- and *cis*-limonen-1,2-oxide, *trans*- and *cis*-2,8-*p*-menthadien-1-ol, *trans*- and *cis*-carveol, 1(7),8-*p*-menthadien-*trans*-2-ol, carvone, and perillaldehyde. Some of them were also found in citrus oils, orange oil,[5,14,15] and grapefruit oil.[16] Cryptone was also derived from the autoxidation of β-phellandrene.[17] These facts are indicated in Fig. 1.

The three monoterpenic oxygenated compounds, β-terpinen-3,4-oxide, terpinolen-4,8-oxide, and limonen-4-ol, had not previously been found in natural products. Besides, it seems that this is the first report on the isolation of β-caryophyllene alcohol from natural sources.

β-Terpinen-3,4-oxide. The IR (Fig. 2) and NMR spectra of this substance showed the presence of an isopropyl group (ν_{max}^{film} 1380, 1360 cm^{-1}; δ 0.92, 0.94 ppm, each 3H d. *J* 7 Hz), an exocyclic methylene group (ν_{max}^{film} 3060, 1640, 880 cm^{-1}; δ 4.62 ppm, 2H s.), and a proton linked to an epoxide ring (ν_{max}^{film} 850 cm^{-1}, 1,2-epoxide; δ 2.87 ppm, 1H unresolved). Its mass spectrum showed a molecular ion peak at *m/e*

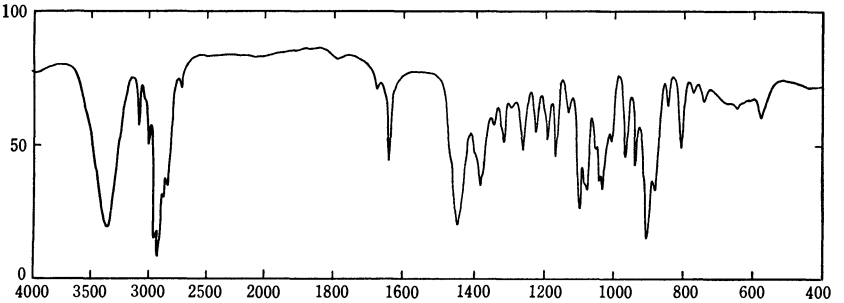

Fig. 4. IR spectrum of limonen-4-ol.

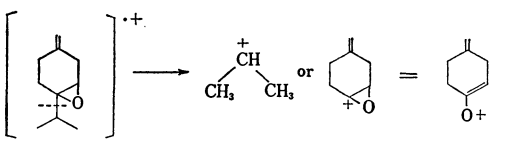
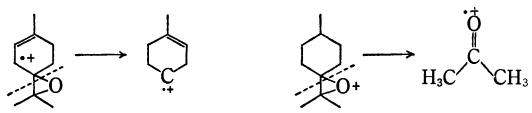
152 ($C_{10}H_{16}O$, 6%), a base peak at *m/e* 43, and conspicuous peaks at *m/e* 109 (48%), and 81 (83%).



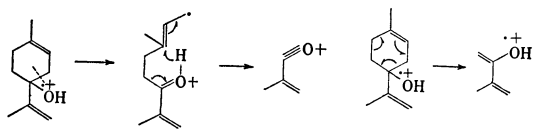
m/e 152 *m/e* 43 *m/e* 109

Terpinolen-4,8-oxide. The mass spectrum of this substance showed a molecular ion peak at *m/e* 152 ($C_{10}H_{16}O$, 3%) and a base peak at *m/e* 94 ($M^+-CH_3COCH_3$). The mass spectrum of the dihydro-oxide showed a molecular ion peak at *m/e* 154 and a base peak at *m/e* 58 (CH_3COCH_3). According to the NMR spectrum, two methyl groups were assigned to the *gem*-dimethyl group attached to a carbon-bearing oxygen (δ 1.20 ppm, 6 H s.) and one methyl group to $-CH=C-CH_3$ (ν_{max}^{film} 1685, 790 cm^{-1}; δ 1.62 ppm, 3H s., 5.34, 1H unresolved). Its IR spectrum (Fig. 3) showed an absorption peak at 840 cm^{-1} due to an 1,2-epoxide ring.



Limonen-4-ol. From the IR (Fig. 4) and NMR spectra of this substance the presence of a hydroxyl group (ν_{max}^{film} 3370 cm^{-1}), an isopropenyl group (ν_{max}^{film} 3100, 1640, 900 cm^{-1}; δ 1.75 ppm, 3H s., 4.74, 4.92, each 1H broad s.), and a methyl group attached to a trisubstituted double bond (δ 1.65 ppm, 3H s., 5.20, 1H unresolved) were inferred. This alcohol was hydrogenated with platinium oxide in methanol to give a tetrahydro-derivative, which was identified with the known tetrahydroterpinen-4-ol.[18] Its mass spectrum showed a molecular ion peak at *m/e* 152 ($C_{10}H_{16}O$, 11%), a base peak at *m/e* 69, and strong peaks at *m/e* 84 (85%) and 41 (60%), which were explained by the following fission mode:

From these facts the structure of this alcohol was deduced to be 1,8-*p*-menthadien-4-ol.



m/e 152 *m/e* 69 *m/e* 152 *m/e* 84

As is shown in Fig. 1, the amounts of citronellal and β-phellandrene decreased when the fruit oil stood at room temperature. On the contrary, the amounts of isopulegol and cryptone increased. Citronellal was also isomerized to isopulegol by distillation and by column

18) B.M. Mitzner and S. Lemberg, *Amer. Perf. & Cosm.*, **81**, June 80 (1966).

chromatographic separation. Schulte-Elte and Ohloff[19] reported that the thermal isomerization of citronellal yielded a mixture of isopulegol and neoisopulegol.

During the study of the chemical characteristics of the fruit oil, we attempted to identify the principal flavor components other than citronellal in Japanese pepper, but we were not able to reach any conclusions. Its seems that the characteristic aroma of Japanese pepper is chiefly attributable to citronellal after all.

A comparison of the constituents of volatile oils of unripe fruit oil and ripe fruit oil stored for a long time is in progress. Our results will be reported later.

The authors thank Dr. C. S. Foote, University of California, Los Angels, for supplying authentic samples and IR and NMR spectra of 1(7),8-*p*-menthadien-*trans*-2-ol, *trans*- and *cis*-2,8-*p*-menthadien-1-ol, *etc.*, which led to its identification. The authors are also grateful to Dr.S. Shimizu, The Shinshu Uniersity, Ina, for samples of piperitone and piperitenone, and to Dr. M. Romanuk, Czechoslovak Academy of Science, Prague, for authentic α-muurolene. Thanks are also due to Mr. M. Shiga, Shiono Koryo Kaisha Ltd., Osaka, who kindly provided oleoresin from unripe fruits of "Asakura-sansho."

BULLETIN OF THE CHEMICAL SOCIETY OY JAPAN VOL. 41 1950—1953 (1968)

Constituents of Leaf Oil from Japanese Pepper

Shoichi KUSUMOTO, Akio OHSUKA and Munio KOTAKE

Institute of Organic Chemistry, Faculty of Science, Osaka City University, Kita-ku, Osaka

and Tsutomu SAKAI

Institute of Food Chemistry, Kita-ku, Osaka

(Received February 20, 1968)

The steam-volatile constituents from leaves of Japanese pepper were separated by column chromatography and GLC, and their chemical structures were studied by IR, NMR, and mass spectrometry. The volatile oil was found to be composed of about 100 components; those identified were as follows: 15 hydrocarbons (α- and β-pinene, camphene, sabinene, myrcene, α- and β-phellandrene, limonene, *p*-cymene, terpinolene, α-copaene, caryophyllene, humulene, α-muurolene, and γ-cadinene), 16 alcohols (2-penten-1-ol, *n*-hexanol, 3-hexen-1-ol, *trans*- and *cis*-sabinene hydrate, *cis*-linalool oxide, linalool, isopulegol, neoisopulegol, terpinen-4-ol, α- and δ-terpineol, limonen-4-ol, benzyl alcohol, β-phenylethyl alcohol, and nerolidol), 2 aldehydes (2-hexenal and citronellal), 1 ketone (cryptone), 7 esters (isobutyl caproate, linalyl acetate, citronellyl acetate, terpinyl acetate, geranyl acetate, methyl salicylate, and methyl cinnamate) and 2 ethers (1,8-cineol and methyl chavicol).

The fruits and the young leaves of Japanese pepper (*Xanthoxylum piperitum* DC. (Japanese name, "Sanshoo"), and a variety of it, *X. piperitum var. inerme* Makino ("Asakura-sanshoo")) are widely used as spice in our country because of their characteristic odor and burning taste.

The essential oil of the fruits has been studied by several investigators, and recently almost all the components of the oil were identified by one of the present authors, Tsutomu Sakai.[1] The components responsible for its pungent taste have been shown to be α- and β-sanshool by Crombie and Tayler.[2] However, the constitution of the leaves has not yet been studied. Therefore, the study of the composition of the volatile oil isolated from the young leaves of "Asakura-sanshoo"

2) L. Crombie and J. L. Tayler, *J. Chem. Soc.* **1957**, 2760.

was undertaken.

Experimental

Extraction and Steam Distillation. 1) Twenty-six kilograms of fresh young leaves of *X. piperitum* DC. *var. inerme* Makino (collected at the beginning of June in Kyoto Prefecture) were extracted three times with redistilled petroleum ether (bp below 50 °C) at room temperature. The residue obtained by the evaporation of the solvent was steam-distilled under reduced pressure (30—40 mmHg). The distillate was saturated with sodium chloride and extracted with petroleum ether. The solvent was evaporated after the removal of acids to give a colorless oil (about 37 g).

2) Twelve kilograms of the leaves (see above) were extracted with ether instead of petroleum ether. About 11 g of a pale yellow oil was obtained.

Silica-gel Chromatography of the Essential Oil. The essential oils obtained in 1) and 2) were combined and placed in a column packed with 300 g of silica-gel (Merck 0.05—0.2 mm). This mixture was eluted first with petroleum ether, and then with petroleum ether containing various concentrations of ether (from 2 to 50%). The fractions obtained are summarized in Table 1.

The Isolation of the Components by Preparative Gas-liquid Chromatography (GLC). Each fraction obtained by silica-gel chromatography was distilled under reduced pressure, and the components of the distillate were isolated by preparative GLC under suitable conditions. A Shimadzu GC-2B-type gas chromatograph with a copper spiral column (4 mm in diameter, 5 m in length) was used in the preparation. Glass capillaries were employed as receivers, and hydrogen, as the carrier gas. The conditions employed are shown in Table 2.

The Identification of the Isolated Components. The isolated components were identified by means of IR, NMR,*1 and mass spectrometry, and by a direct comparison of the retention times in an analytical GLC with those of authentic samples. The analytical GLC was carried out using a Hitachi Perkin-Elmer Model F-6D gas chromatograph provided with a flame-ionization detecter. Stainless-steel capillary columns (0.25 mm in diameter and 45 m in length) were coated with HB-2000 and FS-45. The column temperature was programmed from 70 to 150°C, or was held isothermally at 80, 110, and 130°C. The nitrogen-carrier gas-inlet pressure was 1.0 kg/cm^2.

* Diethyleneglycol succinate polyester

Synthesis of *trans*- and *cis*-Sabinene Hydrate. A mixture of sabinene (1.05 g), potassium permanganate (0.21 g), potassium periodate (7.35 g), and potassium carbonate (0.52 g) in 200 m*l* of water was stirred continuously for 39 hr at room temperature. After the manganese dioxide precipitated had been removed by filtration, the aqueous layer was extracted with ether; this ether extract was then washed with water, dried, and concentraed under reduced pressure to give 0.6 g of a colorless oil; ν_{max}^{film} 1720 cm^{-1}. The oil was found by its gas chromatogram to be composed of almost pure sabinaketone.

A solution of this product in 3 m*l* of absolute ether was added, drop by drop, to a solution of methylmagnesium bromide (which had been prepared from 0.21 g of magnesium) in 10 m*l* of absolute ether; the mixture was refluxed for 40 min with occasional shaking, and then, after cooling, the excess reagent was decomposed with crushed ice. The product was isolated by steam distillation and by the extraction of the distillate with ether. *trans*- and *cis*-Sabinene hydrate were isolated from this crude product (0.53 g) by preparative GLC (PEG 20M, 170°C); the *trans*-isomer, mp 59—60°C (Lit.[4] 60—61°C), and the *cis*-isomer, mp 36—37.5 °C (Lit.[4] 38—39°C).

Results and Discussion

Since the essential oils prepared from fresh leaves of "Asakura-sanshoo" by extraction with either ether or petroleum ether were found through their gas chromatograms to be composed of almost identical substances, the

*1 NMR spectra were measured in carbon tetrachloride using TMS as internal reference at 60 Mc on a JEOL model C-60 spectrometer.

(L) The essential oil of the leaves
(F) The essential oil of the fruits

two oils were combined for further study. Figure 1 shows the gas chromatograms of the whole essential oil obtained from young leaves by ether extraction and the whole volatile oil of the fruits.[1] These chromatograms were obtained by injecting 1.0 μl of each oil into an HB-2000 capillary column. The column temperature was initially held at 70°C for 3 min, then programmed at 2.5°C/min to 150°C and ran isothermally at 150°C until all the components had emerged. Table 3 lists the components, which were identified by means of spectral studies.

The compounds responsible for the characteristic odor of Japanese pepper, however, were not obtained in this instance, just as in the earlier work.[1] Therefore, the natural odor may be attributed to a mixed effect of many components.

Limonene and β-phellandrene were the main constituents of the monoterpene hydrocarbons, accounting for about 60% of the total volatile oil.

The major components of the oxygenated compounds were 1,8-cineol, citronellal, linalool, and methyl cinnamate, followed by terpinen-4-ol, α-terpineol, terpinyl acetate, and geranyl acetate.

Although citronellal could be isolated directly from the essential oil by preparative GLC, it disappeared completely after the oil had been subjected to silica-gel column chromatography, and the amounts of isopulegol and neoisopulegol were more than those found to be present in the original oil. Therefore, these alcohols may partly be formed as a result of the isomerization of citronellal on the silica-gel column.

One compound, which was masked by the peak (53) due to linalool in Fig. 1, was isolated from fractions E and F by preparative GLC. Its IR spectrum showed the presence of the tertiary hydroxyl group (ν_{max}^{film} 3370, 1135 cm^{-1}), the isopropyl group (1380, 1364 cm^{-1}), and the methylene group in a cyclopropane ring (3050 cm^{-1}). Its NMR spectrum also suggested the presence of an isopropyl group (δ=0.88, 0.93 ppm, each 3H d, J=6 cps), two protons of a cyclopropane ring (δ=0.23 ppm, 1 H dd, J=9, 5.3 cps and δ=0.70 ppm, 1H dd, J=4.5, 5.3 cps), and a methyl group on a carbon atom bearing an oxygene function(δ= 1.28 ppm, 3H s). No sign of a double bond was found in either of the spectra. The mass spectrum showed a molecular-ion peak at m/e 154 ($C_{10}H_{18}O$, 4%) and a base peak at m/e 93. Furthermore, its mass spectrum lower than m/e 136 ($M-H_2O$) was similar in every respect to that of sabinene. These results suggest that this alcohol is sabinene hydrate (4-thujanol). In order to confirm this, *cis*- and

* These were not isolated but identified by analytical GLC in comparison with the retention times of the components of fruits.
** These were not isolated from the fruit oil.

trans-sabinene hydrate were synthesized according to the method of Daly.[4] The alcohol thus isolated was found to be identical with the synthetic *cis*-isomer with respect to the IR, NMR, and GLC spectra. On the other hand, the *trans*-isomer was isolated in an impure state, as was indicated by an analytical gas chromatogram.

The IR spectrum of peak (24) in Fig. 1 indicates the presence of the primary hydroxyl group (ν_{max}^{film} 3350, 1040, 1000 cm^{-1}) and the double bond (1650 cm^{-1}). Its mass spectrum showed a molecular-ion peak at *m/e* 86 ($C_5H_{10}O$, 9%), a base peak at *m/e* 57, and strong peaks at *m/e* 68 ($M-H_2O$, 16%), 44 (33%), 41 (41%), and 29 (38%). These results suggest that this alcohol is a primary pentenol possessing no terminal methylene group. There are four possible structures consistent with the data given above, 2-methyl-2-buten-1-ol, 3-methyl-2-buten-1-ol, 3-penten-1-ol, and 2-penten-1-ol. The isolated alcohol was found not to be identical with the former two when examined by IR and mass spectra. It was considered to be the last one because of the fact that its mass spectrum showed a strong base peak at *m/e* 57, suggesting the presence of the $-CH=CH-CH_2OH$ group. The configuration of the double bond is probably the cis form, judging from its IR spectrum.

In addition to the compounds listed in Table 3, several esters, monoterpenic alcohols, and sesquiterpenic hydrocarbons were isolated, but their structures could not be deduced because of the small quantities present.

It is apparent from Fig. 1 that the main components of the leaves mentioned above are also present in high concentrations in the oil obtained from the fruit. However, their relative quantities varied considerably from case to case. For instance, cryptone, a relatively large amount of which was found in the fruit oil, was shown to exist in a much smaller amount in the leaf oil. Other carbonyl compounds, such as carvone, piperitenone, phellandral, and cuminaldehyde, isolated from fruit oil were not isolated from the leaf oil. In the leaf oil, on the other hand, caryophyllene was found in greater quantities than in the fruit oil.

Moreover, the aliphatic compounds, such as 2-hexenal (leaf aldehyde), 2-penten-1-ol, *n*-hexanol, and *cis*-3-hexen-1-ol (leaf alcohol), had the characteristic odor of the leaves.

It is still impossible at the present time to show the differences between the leaf and fruit oil, since they were not collected in the same localities and seasons and since different methods were used to obtain the oils.

The authors are grateful to Dr. Yoshio Hirose of the Institute of Food Chemistry for his suggestions and helpful discussions during the course of this work.

Organic Syntheses by Means of Noble Metal Compounds. XXXVII.[1] Carbonylation of Allene-Palladium Chloride Complexes

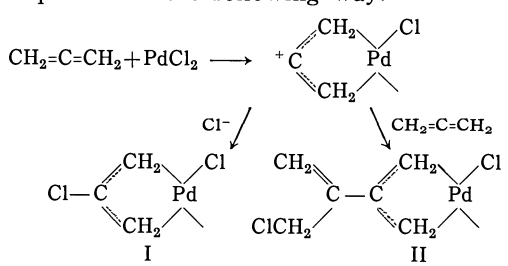
Tosaku SUSUKI and Jiro TSUJI

Basic Research Laboratories, Toyo Rayon Co., Kamakura

(Received February 22, 1968)

The reaction of allene with palladium chloride and a carboxylate anion gave di-μ-chloro-bis(2-acyloxy-π-allyl) dipalladium which was converted into an acetoacetate by carbonylation. Carbonylation of allene in ethanol in the presence of palladium chloride produced ethyl itaconate. The carbonylation of di-μ-chloro-bis(2-chloro-π-allyl) dipalladium in ethanol formed 3-chloro-3-butenoate. 4-Hydroxy-3,4-dimethyl-2-pentenoic acid γ-lactone, 3-isopropylideneglutarate and 3-(ethoxycarbonylmethyl)-4-methyl-3-hexenedioate were isolated by the carbonylation of di-μ-chloro-bis[2-(1-(chloromethyl)vinyl)-π-allyl] dipalladium. The mechanisms of these reactions are discussed.

Olefinic double bonds react with palladium chloride easily to form π-complexes or π-allyl complexes.[2] Of particular interest is the complex formation with dienes. Thus 1 3-butadiene reacts with palladium chloride to form 1-(chloromethyl)-π-allylpalladium chloride.[3] Allene is a 1,2-diene and its reaction with palladium chloride gives either complex I or II, depending on the reaction conditions.[4,5] The formation of the complexes I and II can be explained in the following way.



By the displacement of a chlorine atom of palladium chloride by one of the double bonds of allene, the center carbon atom of allene becomes cationic and a nucleophilic attack at this carbon is expected. When the displaced chloride anion attacks the carbon, the complex I is formed and this reaction proceeds in a benzene solution. In other words, this reaction is the insertion of the double bond of allene between the Pd–Cl bond. When the reaction is carried out in methanol, the cationic center is somewhat stabilized and another molecule of allene attacks the carbon to give the complex II. The consideration of this mechanism led us to expect that the attack of other nucleophiles at the center carbon of allene in the presence of palladium chloride should give π-allylic complexes substituted at the center carbon. From these considerations, the π-allylic complex formation from allene in the presence of a carboxylate anion and carbon monoxide was studied.

The carbonylation of π-allylic palladium complexes to form β,γ-unsaturated carboxylic acid derivatives is a well established reaction.[6,7] Therefore, it is expected that the carbonylation of the allene complexes should give 3-substituted 3-butenoic acid derivatives. A part of these studies has already been reported.[8]

Results

At first the reaction of allene with palladium chloride in the presence of carboxylate anions

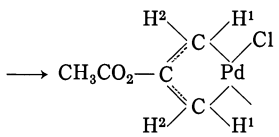
was studied. When allene was bubbled into acetic acid solution of sodium chloropalladate and sodium acetate, di-μ-chloro-bis(2-acetoxy-π-allyl) dipalladium (complex III) was isolated. Similarly, the reaction in propionic acid gave a propionyl substituted π-allyl complex. Although the reaction was carried out in protic solvents, a complex corresponding to II was not isolated.

$$CH_2{=}C{=}CH_2 + PdCl_2 + CH_3CO_2^- \longrightarrow$$



III

The structure of the complex III was proved by its NMR spectrum (Fig. 1), which showed

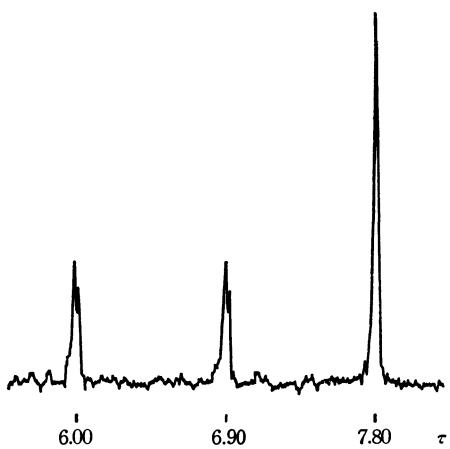


Fig. 1. NMR spectrum of di-μ-chloro-bi (2-acetoxy-π-allyl) dipalladium.

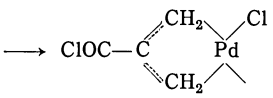
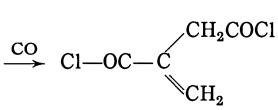
a pattern typical of π-allylpalladium chloride. In this spectrum, the peaks at τ 6.90 and 6.00 assignable to H^1 and H^2 appeared as doublets and their coupling constant ($J_{1,2}$) was found to be 2.4 cps. The coupling of H^1 and H^2 is not observed with most of π-allylic complexes and the only exception so far reported is the complex I, which has $J_{1,2}=2.0$.[5] Thus it seems likely that only the π-allyl complexes substituted with electronegative groups at the center carbon show the coupling of H^1 and H^2.

The attack of carbon monoxide on olefins coordinated to palladium to form acid derivatives is well known.[9] It is expected that the attack of carbon monoxide on the center carbon of allene should form a carbonyl substituted π-allyl complex which is further attacked by carbon monoxide to give itaconate as shown below. Based on this assumption, the reaction of allene, carbon monoxide and palladium chloride in ethanol was carried out, and actually itaconate was isolated, although the yield was poor.

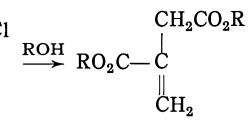
$$CH_2{=}C{=}CH_2 + CO + PdCl_2 \longrightarrow$$



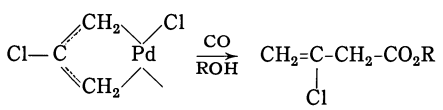
$$\xrightarrow{CO}$$



$$\xrightarrow{ROH}$$

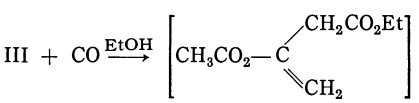


Then the carbonylation of the complexes I, II and III was studied. The product of the carbonylation of the complex I was 3-chloro-3-butenoate as expected.



I

The carbonylation of the complex III was carried out in benzene and the product was treated with ethanol. An ester was isolated by distillation and identified as ethyl acetoacetate (V), which was presumably formed by ethanolysis of ethyl 3-acetoxy-3-butenoate (IV) formed initially.



IV

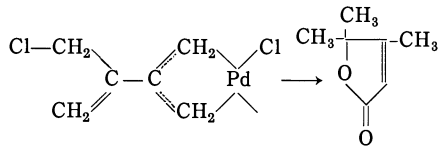
$$\longrightarrow CH_3COCH_2CO_2Et$$

V

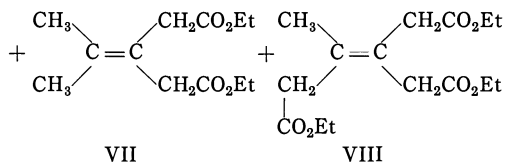
Different from the complexes I and III, which gave 3-substituted 3-butenoates, the carbonylation of the complex II seems to be complicated. In addition to the π-allylic structure, this complex contains allylic chloride and conjugated diene structures, both of which are expected to be carbonylated. Actually the carbonylation of the complex II in ethanol produced three products, which were formed by the stepwise attack of one, two and three molecules of carbon monoxide. The first product was an unsaturated lactone (IR 1750 cm^{-1}) and identified as 4-hydroxy-3,4-dimethyl-2-pentenoic acid γ-lactone (VI) by

9) J. Tsuji, M. Morikawa and J. Kiji, *J. Am. Chem. Soc.*, **86**, 4851 (1964).

NMR and IR spectra and mixed melting point measurement with an authentic sample.



II VI



VII VIII

The second one was an unsaturated diester. The NMR spectrum showed two singlets due to two methyl groups (6H at τ 8.26) and two methylene groups (4 H at τ 6.94). The ozonization, followed by the treatment with dinitrophenylhydrazine produced two hydrazones. They were the hydrazones of acetone and ethyl 3-oxoglutarate. From these evidences, the ester is determined as ethyl 3-isopropylideneglutarate (VII). The third, higher boiling fraction was a triester. The ozonization gave ethyl acetoacetate and ethyl 3-oxoglutarate, which suggests that the triester is ethyl 3-(ethoxycarbonylmethyl)-4-methyl-3-hexenedioate (VIII). The NMR spectrum supports the structure (Fig. 2).

The formation of these three esters can be explained by the following mechanism. At first carbon monoxide attacks the π-allylic system to form IX, which is converted into the lactone VI by double bond isomerization and hydrogenolysis of the chlorine as shown below. The intermediate lactone X is an allylic lactone and can react with palladium by oxidative addition to form another π-allylic complex XI. The carbonylation of this complex leads to the formation of a diester (XII), which gives VII by hydrogenolysis.

The intermediate diester XII has an allylic chloride structure and can be converted into another π-allylic complex XIII by the reaction with palladium. The carbonylation of this complex gives the triester VIII.

Experimental

Materials. Allene was purchased from the Matheson Co. It was distilled from a cylinder into a glass vessel and its volume was measured. Then it was redistilled into a stainless steel autoclave. The NMR specptra were determined with high resolution spectrometer, models DP 60 and HR 100, the peak positions are expressed in terms of τ values. The molecular weights were determined in benzene using a Mechrolab vapor pressure osmometer, or by mass spectrometer.

Formation of the Complex III. Sodium chloropalladate (9.0 g) and sodium acetate (2 g) were dissolved in acetic acid (220 m*l*) and allene was bubbled into the solution at room temperature with stirring. The deep brown solution turned gradually to pale brown, and the complex began to precipitate slowly. After one hour, the complex was collected by filtration (6.7 g) and recrystallized from a mixture of chloroform and methanol, mp 178.5—179.5°C (decomp).

Found; C, 24.96 ; H, 3.09 ; Cl, 15.15%, mol wt, 478.7. Calcd for $(C_5H_7O_2PdCl)_2$; C, 24.84 ; H, 2.90; Cl, 14.70%, mol wt, 481.8. NMR. Fig. 1.

By the similar procedure, the propionyl complex

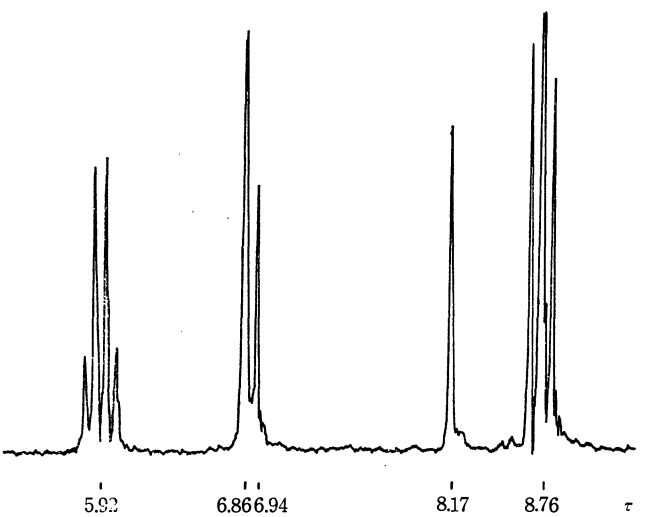


Fig. 2. NMR spectrum of ethyl 3-(ethoxycarbonylmethyl) 4-methyl-3-hexenedioate.

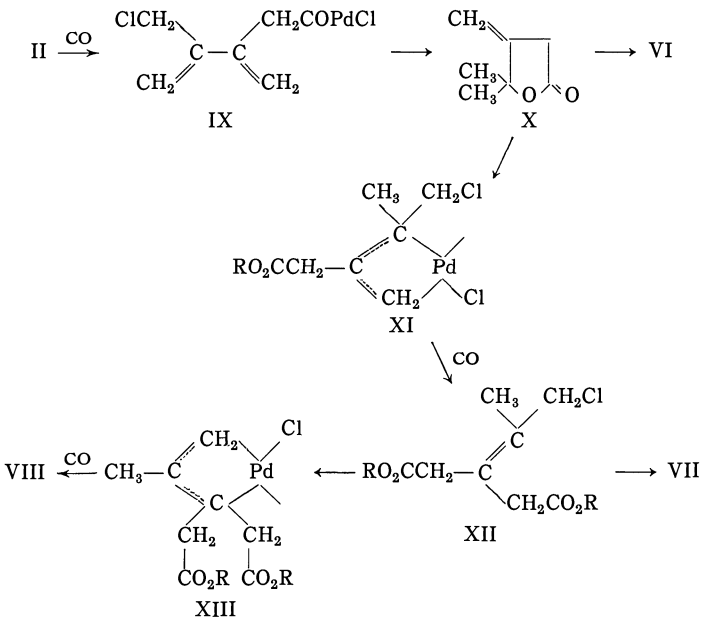

(3.9 g) was obtained from sodium chloropalladate (6.0 g) and sodium propionate in propionic acid (200 m*l*) and methanol (100 m*l*). The complex was recrystallized from chloroform-methanol mixture, mp 169—170°C (decomp).

Found: C, 28.30; H, 3.53; Cl, 14.38%, mol wt, 516. Calcd for $(C_6H_9O_2PdCl)_2$: C, 28.26; H, 3.56; Cl, 13.90%, mol wt, 510. NMR. 8.80 (triplet, CH_3-), 7.51 (quartet, -CH_2-CO-), 6.88, and 5.96 (doublets), $J_{1,2}=2.4$ cps.

Carbonylation of the Complex I. The complex I (9.5 g) in methanol (60 m*l*) was carbonylated at 100°C under carbon monoxide pressure (100 atm) for 15 hr. After the usual work-up, 4.0 g of the product was isolated by distillation at 145—146°C. It was identified as methyl 3-chloro-3-butenoate by the following evidences. IR, 1750 and 1640 cm^{-1}, NMR spectrum, 6.55 (-CH_2-), 6.11 (CH_3), 4.44 (=CH_2).

Found: C, 44.81; H, 5.31; Cl, 26.24%, mol wt, 134. Calcd for $C_5H_7O_2Cl$: C, 44.63; H, 5.24; Cl, 26.35%, mol wt, 134.5.

Carbonylation of the Complex III. The complex (2.5 g) and benzene (40 m*l*) were placed in a glass vessel with a gas inlet capillary, and then the vessel was placed in an autoclave. The carbonylation was carried out at 100°C under carbon monoxide pressure (100 atm) for 16 hr with shaking. The product was heated with 10 m*l* of ethanol and the solvents were removed by distillation. The residue was distilled under reduced pressure (50°C/14 mmHg) to give 0.3 g of the product, which was identified as ethyl acetoacetate by gas chromatography, IR spectrum and the mixed melting point determination of its dinitrophenylhydrazone (mp 95—96°C).

Carbonylation of Allene. Ethanol (50 m*l*) and palladium chloride (3 g) were placed in the glass vessel which was placed in the autoclave. Allene (10 m*l*) was distilled into the autoclave and then carbon monoxide was charged (100 atm). The autoclave was shaken at 150°C for 20 hr. The precipitated palladium was removed by filtration and ethanol was removed by distillaton. The residue was subjected to the distillation under reduced pressure (103°C/9 mmHg) to give 0.5 g of ethyl itaconate. The structure was determined by IR and NMR spectra. IR 1730, 1640 cm^{-1}, NMR 3.76, 4.35 (=CH_2), 5.85 (-CH_2-), 6.76(CH_2) 8.73 (CH_3).

Found: C, 58.32; H, 7.68%, mol wt, 189. Calcd for $C_9H_{14}O_4$: C, 58.05; H, 7.58%, mol wt, 186.2.

Carbonylation of the Complex II. The complex (10 g) was carbonylated in ethanol (60 m*l*) at 110°C under carbon monoxide pressure (110 atm) for 15 hr with shaking, and pressure drop of 13 atm was observed. After the usual work-up, the residue was distilled under reduced pressure to give the following two fractions. The first fraction (80—110°C/3 mmHg, 4.6 g) was found to be a mixture of two compounds and they were separated by preparative gas chromatography. One of them solidified on standing and was recrystallized from ether-hexane mixture, mp 43.5—45°C (reported mp 44.5—46.5°C[10]), yield 24.4%. This compound was identified as 4-hydroxy-3,4-dimethyl-2-pentenoic acid γ-lactone by the following evidence. IR, 1750, 1630 cm^{-1}, NMR 8.53(CH_3), 7.94(CH_3), 4.40 (=CH-).

Found: C, 66.54; H, 7.97%, mol wt, 130. Calcd for $C_7H_{10}O_2$: C, 66.64; H, 7.99%, mol wot, 126.

The compound was identified by the comparison with the authentic sample which was prepared by

10) J. M. Stewart and D. W. Wooley, *J. Am. Chem. Soc.*, **81**, 4951 (1959).

11) S. G. Matsoyan, G. A. Chukhadzhyan and S. A. Vartanyan, *Zhur. Obshchei. Khim.*, **30**, 1202 (1960); *Chem. Abstr.*, **55**, 374 (1961).

the known method.[10,11] The other one was redistilled (132℃/10 mmHg, 20.2%) and found to be ethyl 3-isopropylideneglutarate by the following evidence. IR, 1740 cm^{-1} NMR, 8.75 (6H, $-CH_3$), 8.26 (6H, $-CH_3$), 6.94 (4H $-CH_2-$), 5.98 (4H, $O-CH_2-$).

Found : C, 63.01 ; H, 8.79%, mol wt, 220. Calcd for $C_{12}H_{20}O_4$: C, 63.13 ; H, 8.83%, mol wt, 228.

The ester was ozonized in ethyl acetate containing tetracyanoethylene and the ozonide was treated with dinitrophenylhydrazine. The hydrazone was separated by passing through a silica column using benzene as an eluate to give two hydrazones. One of them was recrystallized from ethanol and identified as the hydrazone of acetone, mp 125—126℃. The other was recrystallized from aqueous ethanol, mp 85—86 ℃. The hydrazone was identified as that of ethyl 3-oxoglutarate by mixed melting point determination with an authentic sample.

Found: C, 47.20; H, 4.77; N, 14.64%. Calcd for $C_{15}H_{18}N_4O_8$: C, 47.12; H, 4.75; N, 14.66%.

The second fraction was redistilled (125—127℃/3 mmHg) to give 1.1 g of a triester which was identified as ethyl 3-(ethoxycarbonylmethy)-4-methyl-3-hexenedioate by the following evidences. IR, 1735 cm^{-1}, NMR (Fig. 2) 8.76 and 5.92 (3 ethyl groups), 8.17 (methyl), 6.94 and 6.86 (3 methylene groups).

Found : C, 59.84 ; H, 8.04%, mol wt, 306. Calcd for $C_{15}H_{24}O_6$: C, 59.98 ; H, 8.05%, mol wt, 300.

The ester was ozonized as before and the product was converted into dinitrophenylhydrazones, which were separated into two fractions by column chromatography through silica gel using benzene as an eluate. One of them was identified as the hydrazone of ethyl acetoacetate by IR and mixed melting determination (95—96℃) with an authentic sample.

Found : C, 46.51 ; H, 4.45 ; N, 18.07%. Calcd for $C_{12}H_{14}N_4O_6$: C, 46.45 ; H, 4.55 ; N, 18.06%.

The other hydrazone was identified as that of ethyl 3-oxoglutarate (mp 85—86℃).

NOTES

Studies on the Thin Layer Chromatography of Condensed Phosphates

Takeo YAMABE, Takaya IIDA and Nobuharu TAKAI

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received January 12, 1968)

It is said that the chemistry of phosphates has been developed through the improvement of the techniques of the separation and the analysis of phosphates. The separation and the analysis of phosphates with various degrees of condensation have been tried by many methods.[1-3] Among them, the thin layer chromatography is one of the most effective, because a relatively short time of running and a small amount of samples are required and the separation is fairly good.

Thin layers are usually made by fixing silica gels or alumina powders with gypsum, but gypsum cannot be used for substances such as phosphates which react with it. Accordingly, the present authors have improved the method and the result will be presented.

Experimental

Silica gel (Wakogel B-O, 10 g) or cellulose powder (Toyo-Roshi >300 mesh, 10 g) was suspended in a 0.05% aqueous sodium polyacrylate (30 m*l*) or a 1% cellulose acetate solution in *N, N*-dimethylformamide (35 m*l*). The thin layers with the following combinations were prepared as usual; silica gel-sodium polyacrylate, silica gel-cellulose acetate, cellulose powder-sodium polyacrylate, and cellulose powder-cellulose acetate. As samples of phosphates with various degrees of condensation, sodium salts of orthophosphate, pyrophosphate, tripolyphosphate, trimetaphosphate, and tetrametaphosphate were used.

On the thin layer plates, 1 μl of 0.2% aqueous solution of each phosphate was spotted with a microsyringe, and developed in a closed chamber at room temperature. When the solvent was developed up to 10 cm from the spotting point, the plates were taken out and dried in air. Then the phosphates were hydrolyzed with an aqueous nitric acid solution (1 : 1) and colored with ammonium molybdate and stannous chloride.[4,5] The developing solvents are shown in Table 1.

and when basic solvents are used, the order of R_f values is

metaphosphate > orthophosphate > polyphosphate.

These orders agree with those in the paper chromatography.[3] It was proved that the thin layer chromatography by the method proposed in this report was very useful for the separation and the analysis of condensed phosphates. The cellulose acetate, used as the binder, gave almost the same results for all the solvents, but when the system of silica gel, sodium polyacrylate, and acidic solvent was used, it is apt to take much time of running and caused tailing of spots.

The authors wish to express thanks to Dr. S. Hayano and Dr. M. Seno in our Institute for their kind advices.

Quenching of Fluorescence of Pyrene and Anthracene by Electron-accepting Substances

Akira NAKAJIMA*[1] and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received January 22, 1968)

In despite of many investigations,[1] the inner mechanism of fluorescence quenching is not clearly understood. It has been pointed out that fluorescence quenching by foreign substances might be closely related to the electron transfer reaction or the charge-transfer interaction between an excited fluorescent molecule and a quencher molecule.[2-8] If such a reaction or an interaction plays an important role in the mechanism of fluorescence quenching, the quenching ability of a quencher molecule may be connected with its electron-affinity or ionization potential.[9] As far as we know, however, only a few works[9-11] have been done along this line.

In this investigation, the electron-accepting substances were employed for quenching the fluorescence of pyrene and anthracene, and a study was attempted on the relation between the quenching constants and the electron-affinities of the quencher molecules, on the basis of the quenching mechanism involving the charge-transfer interaction between the fluorescent hydrocarbons and the quenchers.

Experimental

Pyrene and anthracene were purified by recrystallization, zone-refining and sublimation in vacuum. The substances employed as quenchers were repeatedly recrystallized and then sublimed in vacuum. The solvents used were dried and distilled benzene for the pyrene solution and G. R. grade acetone for the anthracene solution.

The measurements of the fluorescence spectra and the fluorescence intensities were made with a Hitachi EPS-2U recording spectrophotometer mounted with an attachment for fluorescence measurement. The light source for fluorescence excitation was a super-high pressure mercury lamp with a suitable UV filter (mainly 365 mμ). The measurements were made at room temperature for the benzene solution of pyrene and the acetone solution of anthracene, the concentrations of which were 2.52×10^{-3} and 1.00×10^{-3} (mol/l), respectively. These solutions were not degassed, but it is usually assumed that the quenching action of a quencher is independent of dissolved oxygen.[8b]

Since the shape of the fluorescence spectra of these aromatic hydrocarbons did not practically change in the presence of a quencher, the relative fluorescence intensities were obtained from the heights at a given wavelength for the various quencher concentrations. At higher quencher concentrations, however, the absorption of exciting light by the quencher as well as the reabsorption of fluorescence gave rise to serious errors in the observed fluorescence intensities. They were appropriately corrected by taking account of the optical geometry of excitation and observation and of the quencher concetrations.[12]

From a plot of the relative fluorescence intensities against the logarithms of quencher concentrations, the quenching constant was obtained as the reciprocal of the half-value-concentration, where the value of the relative fluorescence intensity was reduced to half the value in the absence of the quencher.

12) The observed fluorescence intensities, I_f^{obs}, were corrected by the following formula:

$$I_f^{cor} = \frac{D_Q+D_A}{1-10^{-(D_Q+D_A)}} \frac{1-10^{-D_A}}{D_A} \frac{1-10^{-D_F}}{2.303 D_F} I_f^{obs}$$

where D_A and D_Q are the absorbances at the exciting wavelength of a fluorescer and a quencher, respectively, and D_F is the absorbance of the solution at the wavelength where the fluorescence intensities were measured.

For the pyrene solution, the quenching constants were estimated for both monomer and excimer fluorescence bands with the peaks at 396 mμ and 480 mμ, respectively.[13]

Results and Discussion

The quenching constants obtained for a series of electron-accepting substances are shown in Table 1 together with the values of their electron affinities. For the pyrene solution the equilibrium constants, K, for charge transfer complex formation with these electron-accepting substances, are also given.

In studies on fluorescence quenching, it is important to know the type of the molecular process and the nature of the inner mechanism of fluorescence quenching. Two types of quenching processes, static and dynamical ones, can be assumed.[1,14] In a static quenching process, the non-fluorescent molecular complex, (AQ), is formed between a fluorescer, A, and a quencher, Q, in the ground state and only the uncomplexed fraction of the fluorescer contributes to the observed emission. This is given by the following scheme:

$$\begin{array}{ccc} A + Q & \rightleftharpoons & (AQ) \\ {\scriptstyle h\nu_a}\downarrow\uparrow{\scriptstyle h\nu_f} & {\scriptstyle K} & {\scriptstyle h\nu_a}\downarrow\uparrow{\scriptstyle \text{heat}} \\ A^* & & (AQ)^* \end{array}$$

The equilibrium constant, K, is expressed as

$$K = \frac{[(AQ)]}{[A][Q]}.$$

If a static quenching process can be assumed, the quenching constant, k, may be approximately given by the following form:

$$k = \frac{K}{KC+1}$$

where C is the initial concentration of fluorescer. This equation can easily be derived for 1 : 1 complex formation, if the complexed fraction is sufficiently small, as is usually the case. For the pyrene solutions, as is seen from Table 1, $C = 2.52 \times 10^{-3}$ (mol/l) and K= 0.1—20 (l/mol); therefore, k should be 0.1—20, which is, however, inconsistent with the observed k-values, *i.e.*, 10^2—10^3.

The fact that the observed k-values are much larger than those estimated on the assumption of a static quenching process, leads to the predominance of the dynamical quenching process.[10,11,13,14] in which a quencher molecule encounters an excited fluorescer molecule by diffusion through the solution, forming an excited complex in which deactiva-

b) Estimated by the Benesi-Hildebrand's method.
c) The charge transfer spectra were not separably observed.
d) This large value may have resulted from the insufficient correction for the reabsorption of fluorescence by the quencher.
e) The observed small value is probably due to the Diels-Alder reaction.

tion of energy is effective. That the absorption spectra of the aromatic hydrocarbon were not affected by the addition of a quencher, is also favorable to a dynamical quenching process.

As for the inner mechanism, the possibility of the electronic energy transfer can be eliminated because of the small overlap of the fluorescence spectra of the fluorescers with the absorption spectra of the quenchers. Further, it can be seen from Table 1 that the quenching abilities of these quenchers can not consistently be explained by the heavy atom effect, which enhances the intersystem-crossing from the excited singlet state to the triplet state in the fluorescer molecule.

Comparing the k-values with the electron-affinities enables one to find a fairly good correlation between them. This parallelism between the quenching constants[15] and the electron-affinities suggests that the charge transfer interaction should play an important role in the fluorescence quenching mechanism for these systems.

The charge transfer mechanism of fluorescence quenching may be interpreted in terms of the formation of excited-state charge transfer complex due to the increased mixing of the locally excited (A*Q) and the charge transfer (A^+Q^-) configurations on the mutual approach of A* and Q.[6,7]

For the systems of pyrene-phthalic anhydride and pyrene-tetrachlorophthalic anhydride, the complex emissions were observed at 510 mμ and 550 mμ,[16] respectively, in benzene solution at room temperature. The intensity of these complex emissions increased with the rise of temperature. Since the viscosity of the solvent decreases at higher temperatures, the molecules diffuse in solution more easily to form the excited complexes, resulting in the complex emission. This phenomenon will also support a diffusional process in excited complex formation.

Since the observed 'apparent' quenching constants for excimer fluorescence, k_e, are larger than the quenching constants for monomer fluorescence, k_m, it can safely be said that the quenching of pyrene excimer by these quenchers does occur.[17] Furthermore, the fact that $k_e < 2.4\,k_m$ shows that the excimer is less sensitive to the quenching action of these quenchers,[13] indicating that the electron-donating ability of excimer is smaller than that of the excited monomer.

The authors are indebted to Professor Hiroaki Baba of Hokkaido University for his valuable advices.

15) Strictly speaking, the k-value for a quencher depends on its diffusion constant in solution. However, the differences among the diffusion constants of these quenchers are too small to change the order of k-values.

16) The complex emission of pyrene-tetrachlorophthalic anhydride was the mirror image of the corresponding charge transfer complex absorption.

17) A kinetic analysis gives the following relation:

$$k_e \geqq k_m + k_{te}$$

where k_{te} is the 'true' quenching constant for excimer fluorescence, defined as an analogous expression to k_m.

In the case where no 'true' quenching of excimer occurs, $k_e = k_m$; otherwise holds the inequality. It can also be shown that when the quenching of excimer occurs to the same extent as the quenching of excited monomer,

$$k_e = (1+\sqrt{2})k_m = 2.4\,k_m.$$

Zinc 2,2,2-Trichloroethoxide. A Soluble Zinc Alcoholate

Takeo SAEGUSA and Takashi UESHIMA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received January 24, 1968)

In our previous studies,[1-3] aluminum 2,2,2-trichloroethoxide (I) was prepared and its properties were compared with those of such usual aluminum alcoholates as aluminum isopropoxide and *t*-butoxide. I is distinguished from usual aluminum alcoholates by the following properties: i) I dissociates to a monomer in donor solvents, whereas usual aluminum alcoholates are in associated form even in donor solvents. ii) I is a strong

1) T. Saegusa and T. Ueshima, *Inorg. Chem.*, **6**, 1679 (1967).

2) T. Saegusa and T. Ueshima, to be published in This Bulletin.

3) T. Saegusa, S. Tomita and T. Ueshima, *J. Organometal. Chem.*, **10**, 360 (1967).

Lewis acid and causes the cationic polymerization of vinyl monomers and cyclic ethers. iii) The insertion reaction of methylene into the Al-OR linkage in the reaction with diazomethane is observed in I, but not in usual aluminum alcoholates. The present study deals with the preparation and the properties of zinc 2,2,2-trichloroethoxide (II).

Experimental

Synthesis of II. Under a nitrogen atmosphere, 0.1 mol of diethylzinc in 20 m*l* of ethyl ether was added slowly with vigorous stirring into a mixture of CCl_3CH_2OH (0.2 mol) and ethyl ether (50 m*l*) at −50—−20°C. Then the reaction system was allowed to warm to room temperature and finally heated to reflux for 2 hr. A white precipitate separated from the solution; this was washed repeatedly with tetrahydrofuran to remove C_2H_5Zn-OCH_2CCl_3[4] and the starting materials. Reprecipitation was performed by the solvent-precipitant combination of pyridine and *n*-heptane. The yield was about 75%. Found: Zn, 18.08%. Calcd for $C_4H_4Cl_6O_2Zn$: Zn, 18.02%. The trichloroethoxy group was quantitatively determined by the v.p.c. analysis of trichloroethanol in the acid hydrolysis mixture. The CCl_3CH_2OH/Zn ratio was 1.94 (Calcd 2.00). II was decomposed without subliming under reduced pressure (0.08 mmHg) at *ca.* 120°C.

Results and Discussion

Zinc dialcoholates of unsubstituted alcohols, such as methanol and ethanol are known to be insoluble in organic solvents as a result of the strong tendency of the association through the oxygen atom of an alkoxy group.[5] The II prepared in the present study, however, was found to be soluble in the systems containing strong donor solvents, such as pyridine, quinoline, dimethylaniline, morpholine, piperidine, *N*-ethylpiperidine, and dimethyl sulfoxide. Ethers, ketones, esters, and trialkylamines were not effective in solubilizing II. In the present study, reference experiments showed that $Zn(OEt)_2$ was not soluble in any solvents which solubilized II. The specific solubility character of II may be due to the three chlorine atoms of the Cl_3CCH_2O-group, which have an electron-withdrawing effect to decrease the nucleophilicity of the oxygen of the Cl_3CCH_2O-group. The coordination of a donor molecule of a solvent onto zinc prevails over that of the oxygen of the Cl_3CCH_2O-group of another molecule of II. Thus, the coordination of a donor to zinc breaks the association through the oxygen-zinc bond and, hence, solubilizes II. On the contrary, the oxygen atom in usual zinc dialcoholates has a stronger nucleophilicity and a donor molecule does not break the association.

This explanation has been supported by the IR spectrum study. Three bands, at 1605, 1580, and 1572 cm^{-1} of the IR spectrum of the II-pyridine system (in Nujol), were due to the stretching vibration ($\nu_{C=N}$ or $\nu_{C=C}$) of pyridine. The first band, at 1605 cm^{-1}, can reasonably be ascribed to the pyridine which is coordinating onto the zinc atom,[1,6] whereas the latter two bands are due to free pyridine. On the other hand, the IR spectrum of the $Zn(OCH_2CH_3)_2$-pyridine system (in Nujol) showed only the two bands of free pyridine. Thus, the IR study has indicated that pyridine coordinates onto the zinc of II, but not onto the zinc of $Zn(OCH_2CH_3)_2$.

The coordination of pyridine to II, however, was not so strong that the pyridine-II complex could not be isolated. The recrystallization and evaporation of the excess pyridine-II mixture was attempted to isolate the pyridine-II complex. Pyridine was easily removed from the complex, and II was always left in these trials. A rather weak coordination of pyridine to II was further indicated by the finding that more than 10 mol of pyridine were required in order to dissolve 1 mol of II in a large amount of benzene. The IR spectrum indicated that a large portion of pyridine existed in a free, non-coordinating form.

The NMR spectrum of the solution of II in the benzene-pyridine mixture showed a sharp singlet at 4.70 ppm (δ) at temperatures from −30 to 23°C. This observation is taken to indicate that II is in a monomeric form in the solvent system containing pyridine. The effect of the CCl_3 group in II corresponds to that in $Al(OCH_2CCl_3)_3$.[1] These two halo-alcoholates differ from each other in acid strength. The shift of the $\nu_{C=N(or\ C=C)}$ of pyridine by coordination was 30 cm^{-1} in the pyridine-$Al(OCH_2CCl_3)_3$ complex; this shift was larger than that of 25 cm^{-1} in the pyridine-II complex (not isolated). In addition, the 1 : 1 complex of $Al(OCH_2CCl_3)_3$ with pyridine was isolated,[1] whereas no complex of II was isolated.

Studies of Thin-layer Chromatography of Inorganic Salts. I. The Separation of Inert Metallic Complexes by Means of Thin-layer Chromatography on Silica Gel[1]

Tetsuo BABA,[2] Hayami YONEDA[3] and Masayuki MUTO

Department of Chemistry, Wakayama University, Masagocho, Wakayama

(Received February 5, 1968)

Two kinds of equilibrium, partition and adsorption, can be considered as the main types of retention of solutes onto adsorbing material during development. In paper chromatography, partition mechanism has been widely accepted because adsorption sites of paper are covered with water or hydrophilic solvent, so that the direct adsorption of solute molecules is considered to be negligible. However, one of the present authors[4] studied the paper chromatography of inert cobalt(III) complexes having different ionic charges using an aqueous ethylamine solution as a developer and found that the R_f values of the complexes increase with the decrease of their positive ionic charge to reach nearly unity in the case of complex anions. Thus an adsorption mechanism was established at least in the case where inorganic salts are developed with an aqueous solution.

A similar kind of adsorption mechanism is expected in thin-layer chromatography. In this case, one can select adsorbents as well as developers so that one can carry out the development under much wider range of conditions than in paper chromatography. Therefore much more informations can be expected from the study of thin-layer chromatography. The present paper will discribe the results obtained in thin-layer chromatography, in which inert metallic complexes were developed on silica gel with aqueous solutions of simple inorganic salts.

Experimental

As an adsorbent, Merck's silica gel H, prepared for thin-layer chromatography according to Stahl's method was used without further purification.

The compounds developed in this investigation were inert metallic complexes having various ionic charges: $[Co(NH_3)_6](ClO_4)_3$, $[CoCH_3CO_2(NH_3)_5](ClO_4)_2$, *cis*-$[Co(CHCO_3)_2en_2]NO_3$, α-$[Cogly_3]$, Na-$[Co(S_2O_3)_2en_2]$, $Na_3[Co(NO_2)_6]$ and $K_3[Crox_3]$, where *en*, *gly* and *ox* denote ethylenediamine, glycinate anion and bivalent oxalate anion, respectively. The development was carried out at room temperatures of 22—25°C. The spots of the cobalt complexes were detected by spraying a potassium sulfide solution, while the spot of the chromium complex could be easily identified by its characteristic blue color.

Results and Discussion

Figure 1 shows the chromatogram developed with distilled water. A marked contrast can be seen between the behavior of the anionic and the neutral complexes and that of the complex cations; $[Crox_3]^{3-}$, $[Co(NO_2)_6]^{3-}$, $[Co(S_2O_3)_2en_2]^-$ and $[Co\,gly_3]^0$ show large R_f values, while $[Co(NH_3)_6]^{3+}$, $[CoCH_3CO_2(NH_3)_5]^{2+}$ and $[Co(CH_3CO_2)_2en_2]^+$ remained near the origin. This fact indicates that the adsorptive power of silica gel is acting selectively upon the complex cations but not upon the complex anions and the neutral complex.

Next, in order to palliate the strong adsorption of the complex cations and to see the effect of the different ionic charges, the

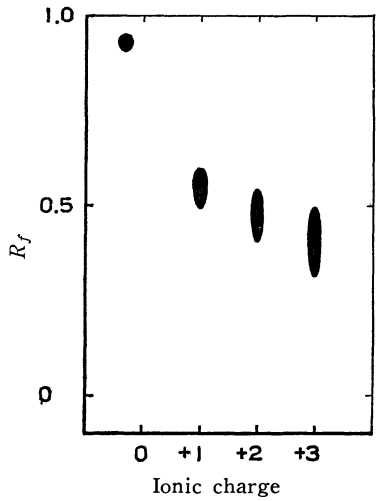

Fig. 2a Chromatogram for 0.1M KCl system.

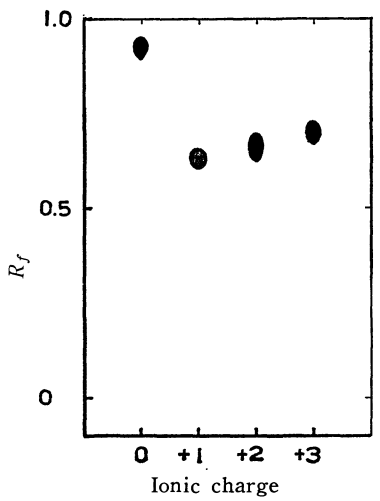

Fig. 2b Chromatogram for 0.2M KCl system.

development was carried out with several potassium chloride solutions of stepwisely varied concentration. Thus the complex cations moved from the origin, and their R_f values increased with the increase of the salt concentration. At low concentrations up to 0.1M, the R_f values of the complex cations showed a regular increase with the decrease of the ionic charge as can be seen in Fig. 2a (+1> +2>+3). However, this regular trend in variation of R_f values became irregular above 0.1M, and at 0.2M the order of the R_f values was completely reversed as is seen in Fig. 2b (+3>+2>+1). This order of the R_f values (+3>+2>+1) was maintained above 0.2M and at 0.5M all the R_f values became near 0.9. A similar variation of R_f value was also observed in the case of ammonium chloride

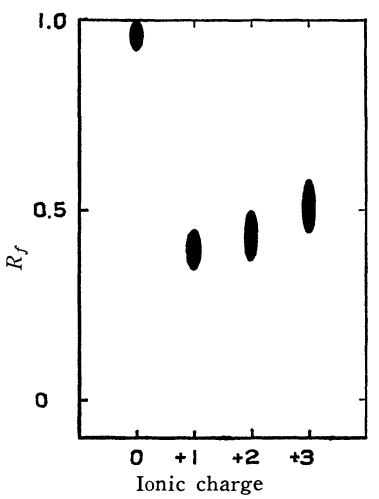

Fig. 3. Chromatogram for 0.05M Na_2SO_4 system.

solution.

When sodium sulfate solutions were used as developer, the above-mentioned phenomena were observed at much lower concentrations; at 0.01M the complex cations moved from the origin, and the order of the R_f values was +1>+2>+3, and at 0.05M this order was completely reversed as is seen in Fig. 3.

The R_f value of the neutral $[Cogly_3]^0$ complex was always about 0.9 and did not show the salt effect.

These results can be explained as follows. Since silica gel is charged negatively in contact with water, it adsorbs strongly the complex cations. This kind of electrostatic attraction can be reduced by the addition of an electrolyte such as potassium chloride or sodium sulfate. The R_f value of the complex cation increases with the decrease of positive ionic charge, which reflects decrease of the electrostatic attraction. As the electrolyte concentration increases, association of anions around the complex cation takes place to a considerable extent to result in appreciable decrease of the apparent charge of the complex cation. Since such association proceeds to a greater extent at higher concentrations of the salt anions and for higher positive ionic charges of the complex cation, the order of the apparent charges of the complex cations $[Co(NH_3)_6]^{3+}$, $[CoCH_3CO_2(NH_3)_5]^{2+}$ and $[Co(CH_3CO_2)_2en_2]^+$ becomes reverse to their ionic charges. Thus the electrostatic adsorption onto silica gel is in the order of $[Co(CH_3CO_2)_2en_2]^+$-anions > $[CoCH_3CO_2(NH_3)_5]^{2+}$-anions > $[Co(NH_3)_6]^{3+}$-anions, and the reverse of the R_f value order can be understood.

Studies on Heteroaromaticity. XVII.[1] Photorearrangement of *N*-(2-Oxo-3-indolylidene)-aniline *N*-Oxides

Tadashi SASAKI and Masahiko TAKAHASHI

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received February 7, 1968)

It is well known that the photochemical rearrangement of heterocyclic *N*-oxides is followed by ring-enlargement or -contraction,[2] but little has been reported on the similar reactions of exocyclic nitrones, though there are several papers published concerning their photochemical reactions.[3,4]

The present note deals with the experimental results of photochemical ring-enlargement of *N*-(2-oxo-3-indolylidene)-aniline *N*-oxide[5] (I), its 5,7-dibromo- (IV) and 5-nitro analog (VI), exocyclic ketonitrones of isatin and its analogs. The photochemical reactions of isatin itself[6] and isatin ylid[7] have been reported.

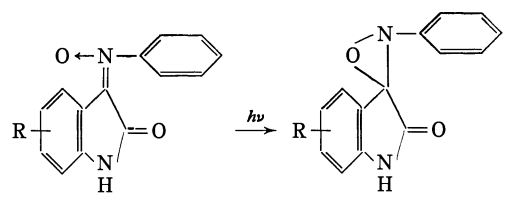
I was irradiated in tetrahydrofuran at room temperature with a 100 watt high pressure mercury lamp to afford III as colorless needles, which was identical with an authentic sample of 3-phenyl-2,4-(1*H*,3*H*)-quinazolinedione[8] in every respect.

Irradiation of some nitrones leads to the formation of the isomeric oxaziridines which are convertible to the corresponding amides[3] by further thermal or photochemical rearrangement and thermal rearrangement of some spiro-oxaziridines often gives the ring-enlarged lactams.[9] Considering above facts, it may be reasonably assumed that a spiro-type oxaziridine intermediate (II) might be involved in the present reaction, but several attempts to isolate II were unsuccessful.

Similar treatment of *N*-(5,7-dibromo-2-oxo-3-indolylidene)-aniline *N*-oxide (IV) afforded expected 6,8-dibromo-3-phenyl-2,4-(1*H*,3*H*)-quinazolinedione (V) in 13% yield, accompanied with III in 23% yield; other products were intractable tars.

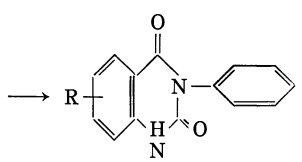
It should be noteworthy that the formation of III from IV in this reaction has revealed occurrence of the photochemical elimination of two aromatic bromine atoms under the above reaction conditions; similar photochemical behaviors have been observed quite seldom,[10] except in some iodine-substituted aromatic compounds.[11]

Photolysis of *N*-(5-nitro-2-oxo-3-indolylidene)-aniline *N*-oxide (VI) only resulted in the formation of intractable tars under the same reaction conditions as described above.



(I) R=H
(IV) R=5,7-dibromo
(VI) R=5-nitro

(II)



(III) R=H
(V) R=6,8-dibromo

Experimental[12]

Starting Materials. *N-(2-Oxo-3-indolylidene)-aniline N-Oxide (I).* This was prepared by the known method,[8] mp 218—220°C (decomp).

N-(5,7-Dibromo-2-oxy-3-indolylidene)-aniline N-Oxide (IV). To a solution of 2g of 5,7-dibromoisatin[13] in 50m*l* of ethanol was added 0.88g of phenylhydroxylamine and the reaction mixture was refluxed on a water bath for 1 hr. After cooling, the precipitated crystals were collected and recrystallized from dioxane to afford 2.5g (96%) of IV, mp 283—284°C.

Found: C, 42.62; H, 1.82; N, 7.27%. Calcd for $C_{14}H_8O_2N_2Br_2$: C, 42.44; H, 2.04; N, 7.07%.

N-(5-Nitro-2-oxo-3-indolylidene)-aniline N-Oxide (VI). This was prepared from 5-nitroisatin[14] and phenylhydroxylamine in the similar way as IV in 40% yield, mp 229—231°C.

Found: C, 59.60; H, 2.87; N, 14.92%. Calcd for $C_{14}H_9O_4N_3$: C, 59.38; H, 3.20; N, 14.84%.

Irradiation of I. A solution of 0.5g of I in 80 m*l* of tetrahydrofuran was irradiated for 17 hr. After removing the solvent, the residue was treated with a small amount of ethanol and the insoluble products were recrystallized from ethanol to afford 0.255g of white crystals, mp 287—289°C, which was identified to be III by infrared-spectroscopic comparison with a specimen prepared by the known method.[8]

Irradiation of IV. A solution of 0.5g of IV in 100m*l* of tetrahydrofuran was irradiated for 15hr. After removing the solvent, the residual oil was dissolved in chloroform and chromatographed on a silica-gel column (17g), using chloroform as an eluent. From the first fraction, 0.067g (13%) of white needles, mp 238—241°C from methanol, was obtained; this was identified to be V from the elemental analysis and by comparison with a specimen prepared by the reported method[15] infrared-spectroscopically. From the second fraction, 0.13g (23%) of III was isolated.

12) All melting points reported in this note were determined on a microhot stage and are not corrected. Microanalyses were carried out with a Yanagimoto C, H, N-Corder, MT-1 type.

Room-Temperature Polycondensation of β-Amino Acid Derivatives. IV.*1 Solvent Effect on the Michael Reaction of Acrylates

Kohei SANUI and Naoya OGATA

Chemistry Department, Sophia University, Chiyoda-Ku, Tokyo

(Received February 17, 1968)

It was previously shown[1,2] that acrylates add with amino alcohols, followed by polycondensation at room temperature to form polyamide in alcohol solution in the presence of basic catalysts. When ethanolamine and acrylate are mixed in a solvent, an addition reaction of ethanolamine with acrylate takes place at the amino group and *N*-(hydroxyethyl) β-alanine ester is formed.

In this addition reaction, it was found that amino alcohol has a much higher reaction rate than amine itself and the addition of amine to acrylate is accelerated to a large extent in the presence of alcohol.[3] Also, it was found[4] that solvent has a great influence on the course of the polycondensation in the presence of basic catalysts, and polyamide is formed in methanol solution *via* route I, while polyamide ether is mainly formed in tetrahydrofuran *via* route II through rearrangement.

These results suggest that the nucleophilicity of amino and hydroxyl groups may depend on solvent, hence the variation of the solvent results in the change in the course of the polycondensation.

Therefore, the solvent effect on the course of the competitive addition reaction of acrylate with aliphatic amine and alcohol was investigated in the presence of alkali metal alkoxide.

$$CH_2{=}CHCOOR + R\text{-}OH + R\text{-}NH_2 \xrightarrow{\text{base}} R\text{-}NHCH_2CH_2COOR + R\text{-}OCH_2CH_2COOR$$

The reaction was carried out as follows: methyl or ethyl acrylate, *n*-butylamine and methanol or ethanol were dissolved in various solvents each in the concentration of 1 mol/*l* in the presence of 5 mol% of potassium methoxide or ethoxide, and the amount of each reactants and also products in the solution were determined by gas chromatographic analysis using a dioctyl phthalate column.

Figure 1 shows the rate of the addition reaction of acrylate in methanol and tetrahydrofuran solutions, where it is seen that the addition of alcohol to acrylate takes place mainly in tetrahydrofuran and the ratio of the addition products of alcohol and amine is 7/3, while acrylate adds almost exclusively with amine in methanol without the addition of methanol.

Table 1 shows results of the competitive addition reaction in various solvents. Solvents in which the addition takes place almost exclusively with amine were cyclohexanone, methanol and dioxane. Methyl acrylate is more reactive than ethyl acrylate. Ethyl acrylate adds with both amine and ethanol in the ethanol solution, although the addition with amine still predominated. In a mixed solvent of ethanol and tetrahydrofuran, the addition reaction with both amine and alcohol took place as can be seen in Table 1. In all other solvents except acetone the addition reaction of acrylate proceeded almost quantitatively, leaving very small amount of unchanged acrylate in the solution. In the acetone solution, almost half amount of ethyl acrylate remained unchanged and the addition reaction did not further proceed even after several days. Several unidentified peaks were detected in the gas chromatographic analysis of the acetone solution after the reaction occurred. When only *n*-butylamine was dissolved in acetone, the amount of *n*-butylamine in the

(Concn., 1 mol/*l*, at 25°C., Catalyst, CH_3OK=5 mol%)
○ : *n*-BuNHCH$_2$CH$_2$COOCH$_3$
× : CH$_3$OCH$_2$CH$_2$COOCH$_3$

solution decreased very rapidly to a trace after 30 min, and a new peak appeared in the gas chromatograph which coincided with one of the unidentified peaks.

The dielectric constant of solvent does not necessarily affect the course of the competitive addition reaction as can be seen in Table 1, whereas the rate of the addition reaction increased generally in a solvent with a higher dielectric constant.

The observed solvent effect on the Michael-type reaction of acrylate might be due to the change of the nucleophilicity of amine and alcohol in different solvents.

In the tetrahydrofuran solution, the rate of the simple addition of acrylate with alcohol alone in the presence of potassium alkoxide is much faster than that with amine alone.[2] However, when an acrylate and an amine are dissolved in an alcohol, the addition reaction of the acrylate takes place almost exclusively with the amine, and the alcohol does not react at all. Dioxane and cyclohexanone had the same solvent effect on the addition reaction of acrylates. Therefore, amines are more nucleophilic than alkoxide ions in such solvents as alcohol, dioxane and cyclohexanone.

Thus, the formation of polyamide through the polycondensation between amino and ester groups in an alcohol solution is explained from the increase in the nucleophilicity of the amino group in alcohol, while the formation of polyamide ether in tetrahydrofuran is attributed to the increase in the nucleophilicity of the hydroxyl group in this solvent.

It is known that the interfacial polycondensation of aromatic amine and dicarboxylic acid chloride in ordinary organic solvents resulted in a low molecular weight polyamide, because of low basicity of aromatic diamine. However, a very high molecular weight polyamide is formed[5] when cyclohexanone is used as the solvent for the aromatic amine. This might be correlated with the present results that the nucleophilicity of amine is greater in cyclohexanone solutin.

The above-mentioned results on the course of the addition reaction of acrylates offer a cue to obtain a high molecular weight polymer by the room-temperature polycondensation of the β-alanine derivatives.

SHORT COMMUNICATIONS

New Cyano-Ammine Cobalt(III) Complexes

Nobufumi MAKI, Masaharu MOCHIZUKI and Shukichi SAKURABA
Depertment of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received March 15, 1968)

Shibata *et al.*[1] reported the synthesis of $[Co(CN)(NH_3)_5]Cl_2$ and $[Co(CN)_3(NH_3)_3]$, while Siebert[2] independently published the preparation of the former-type of complex, $[Co(CN)(NH_3)_5]X_2$ (X=Cl, Br, NO_3, ClO_4, or 1/2 SO_4). Several years ago, Cambi *et al.*[3] reported the preparation of $K_2[Co(CN)_5(NH_3)]$.

In the cyano-ammine series, however, the complexes of cis- and trans-isomers described below are now still missing members: $[Co(CN)_2(NH_3)_4]X$ and $M[Co(CN)_4(NH_3)_2]$.

In the present communication, the preparation of complexes *cis*-$[Co(CN)_2(NH_3)_4]NO_3 \cdot H_2O$, *cis*-$[Co(CN)_2en(NH_3)_2]NO_3$ and $[Co(CN)_3en(NH_3)] \cdot H_2O$ are reported.

Preparation of *cis*-$[Co(CN)_2(NH_3)_4]NO_3 \cdot H_2O$.[4] Forty grams of *trans*-$[Co(CN)Cl(NH_3)_4]NO_3$[5] were mixed with 29 g of AgCN in 400 m*l* of water at room temperature and heated on a water bath (40—50°C) for three hours. Special care was taken to warm gently, because the complex solution tends to decompose above 50°C. No smell of ammonia should be present. The mixture was filtered and the residue repeatedly extracted with hot water (50°C).

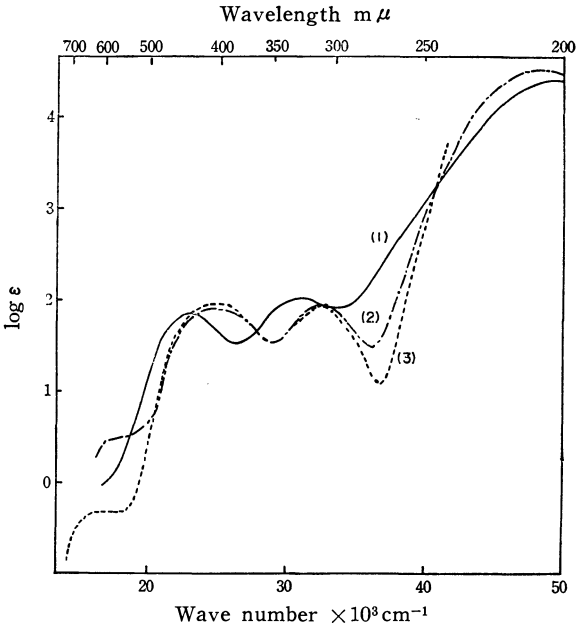

Fig. 1. The absorption spectra of dicyano cobalt (III) complexes: (1) —— *cis*-$[Co(CN)_2(NH_3)_4]NO_3 \cdot H_2O$; (2) —·— *cis*-$[Co(CN)_2en(NH_3)_2]NO_3$; (3) ------ *cis*-$[Co(CN)_2en_2]NO_3$.

A New Series of Chromium(III) Complexes of Schiff Bases obtained from Substituted Salicylaldehydes and Amines

Shoichiro YAMADA and Katsumoto IWASAKI
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received June 4, 1968)

Schiff base complexes of various transition elements have been reported in the literature.[1,2] However, synthesis of chromium(III) complexes of *C*, *N*-disubstituted salicylideneimines has been considered to be very difficult, and the complexes of the $Cr(X\text{-sal. }R)_3$ type, for example, have never been isolated (Fig. 1). The present paper deals with successful preparation of a series of these chromium (III) complexes.

The new chromium(III) complexes, which are given in Table 1, were prepared by the following general method. To a suspension of chromium(III) acetate hydrate (0.01 mol) in ethylene glycol were added salicylaldehyde or 5,6-benzosalicylaldehyde (0.03 mol), an alkyl or an aryl amine (0.03 mol) and an aqueous solution of sodium carbonate (0.01 mol, 67% of the theoretical amount), and the resulting solution was heated on an oil-bath at about 120°C for two or three hours. After the red solution was cooled to room temperature, the precipitate was filtered off, washed with ethanol and recrystallized from ethanol. Brown-purple to orange-red crystals of the compound, the colour depending appreciably upon the size of the particles, were obtained in good yield. The crystals are soluble in common organic solvents.

TABLE 1. ANALYTICAL DATA OF CHROMIUM(III) COMPLEXES OF THE $Cr(X\text{-sal. }R)_3$ TYPE

X	R	Calcd, % C	H	N	Found, % C	H	N

	n-C_3H_7	73.23	6.15	6.10	72.67	6.10	6.03
	iso-C_3H_7	73.23	6.15	6.10	72.98	6.06	6.10
	Ph	77.45	4.59	5.31	77.69	4.20	5.04

* The notation Ph denotes a phenyl group.

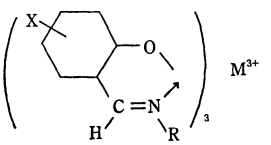

Fig. 1. $M(X\text{-sal. }R)_3$.

Elemental analyses, as shown in Table 1, indicate that these complexes have the formulae of $Cr(X\text{-sal. }R)_3$, in agreement with the formulae expected on the basis of the magnetic moments, which were determined to be about 3.79 to 3.86 B.M. at room temperature corresponding to three unpaired electrons. Infrared spectra of these complexes show an absorption band at about 1530 to 1540 cm^{-1} due to the C=N stretching vibration, indicating the formation of the Schiff bases.

Although the two types of configuration, a *mer*- and a *fac*-form, are possible for these complexes, only one form of the two was isolated as crystals in the present work. In any case, it is likely that all the chromium-(III) complexes so far prepared take the same type of configuration, since they show nearly identical electronic absorption spectra having a d-d band maximum at about 18000 cm^{-1}.

It is interesting to note that the complexes of the $Cr(X\text{-sal. }iso\text{-}C_3H_7)_3$ type, X being H and 5,6-benzo, have been prepared in the present work, since it was believed to be very difficult due to the steric hindrance to synthesize the corresponding complexes of cobalt(III), which have only recently been isolated.[3]

The details of this work will be reported elsewhere later.

Thermal Racemization of the Optically Active Chlorosilane

Hideki SAKURAI, Masashi MURAKAMI and Makoto KUMADA
Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Receivd June 10, 1968)

Incidentally to studies on chlorination of an optically active hydrosilane, (+)-α-naphthylphenylmethylsilane (I),[1] to the corresponding chlorosilane, (−)-α-naphthylphenylmethylchlorosilane (II), we have found that II was configurationally unstable at moderately high temperature (200—300°C) and recemized rather rapidly in the vapor phase as well as in the liquid state. Interestingly, I was configurationally more stable than II.

The optically active chlorosilane, II, mp 63.8°C, $[\alpha]_D$ −6.00(*c* 10.68, cyclohexane)[lit.,[1] mp 63.5—64°C, $[\alpha]_D$ −6.28 (*c* 10.5, cyclohexane)] was passed through a preparative g.l.c. (3m column of Apiezon L grease on Celite 545) at 300°C with retention time of 35—50 min and recovered. Contrary to our expectation, the recovered II exhibited no optical rotation. However, I, mp 63.7—64.3°C, $[\alpha]_D$ +33.7 (*c* 10.9, cyclohexne) [lit.,[1] mp 63.5—64.5°C, $[\alpha]_D$ +34.3 (*c* 10.9, cyclohexane)], did not racemize under the same condition. Thus, I passed through the preparative g.l.c. at 300°C (retention time of 30—35 min) showed an optical activity, $[\alpha]_D$ +30.5 (*c* 1.40, cyclohexane). Accordingly, this figure indicates at least 95% retention of configuration of I.

To test that racemization of II proceeds non-catalytically, reactions were carried out in clean small sealed tubes. The results are listed in Table 1.

Obviously, II racemizes thermally even in the liquid state. Several possibilities responsible to racemization may be considered and elucidation of the mechanism is now in progress.

TABLE 1. THERMAL RACEMIZATION OF OPTICALLY ACTIVE CHLOROSILANE

No.	Wt. of II (g)	Temp. (°C)	Reaction time (min)	$[\alpha]_D$	Optical purity (%)
1	1.085	200	65	−5.54	92.3
2	1.054	250	65	−4.74	79.0
3	1.136	300[a]	67	−1.06	17.7

a) After the reaction, the sample colorized slightly, but an examination by g.l.c. showed that no detectable chemical change had occurred.

Molecular Complex between Two Free Radicals. A Complex between the *p*-Phenylenediamine Cation Radical and the *N,N,N′,N′*-Tetramethyl-*p*-phenylenediamine Cation Radical

Katsuo TAKEMOTO, Shigeki NAKAYAMA, Keisuke SUZUKI and Yuzuru OOSHIKA

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received June 11, 1968)

Dimerizations of the cation radicals of *p*-phenylenediamine and its analogues[1-6] have already been studied by spectroscopic[1-4,6] and ESR[5] techniques. In the present communication, a spectroscopic study of a molecular complex formed between the cation radical of *p*-phenylenediamine (PD^+) and that of *N, N, N′, N′*-tetramethyl-*p*-phenylenediamine ($TMPD^+$) will be reported.

The temperature and the concentration dependence of the UV and visible spectra of solutions containing PD^+ and $TMPD^+$*1 were determined by using a Cary Model 14 recording spectrophotometer. From the analyses of these results, it was concluded that a (1 : 1) molecular complex $(PD^+)_1(TMPD^+)_1$ is formed below −80°C. A typical run is shown in Fig. 1. The spectrum at room temperature is only a weighted sum of the spectra of PD^+ and $TMPD^+$. The spectrum at −195°C consists of three new bands (C, R′, and Y′) which are characteristic of the complex. The spectra in the intermediate-temperature range may be explained as sums of the absorption bands of PD^+, $TMPD^+$, $(PD^+)_2$, and the complex.*2

The spectrum of the present complex closely resembles those of the dimers of PD^+ and its methyl-derivatives.[1] The ν_{max} and the heat of complex formation (which was obtained from the temperature dependence of the equilibrium constant determined from the above spectra) of the present complex are compared with those for the above dimers in Table 1.

From these results, it may be considered that the present complex is formed by the pairing action of odd electrons in the PD^+ and the $TMPD^+$, and that the C band is due to a charge-transfer transition[7] between the covalent (PD^+-$TMPD^+$) and charge-transferred states (resonance between PD^{2+}-TMPD and PD-$TMPD^{2+}$).

More detailed research is now progress at this laboratory.

TABLE 1

Substance	ν_{max} (kK) of absorption C	R′	Y′	Heat of complex formation (or dimerization)
$(PD^+)_1(TMPD^+)_1$	14.7	24.0	34.8	*ca.* 6.0 kcal/mol

Determination of Optical Constants of Single Crystal by ATR*1

Koji Tsuji and Haruka Yamada
Department of Chemistry, Kwansei Gakuin University, Nishinomiya

(Received June 13, 1968)

Very few measurements of absolute absorption intensities have been made on the infrared spectra of single crystals, because the thin layers of single crystals required are quite difficult to prepare, and it is also difficult to measure the thickness. It is, however, desirable to measure the intensities for single crystals, as they provide important knowledge related to the intermolecular forces when compared with those for the polycrystalline films.[1] Recently the infrared spectra of a single crystal, an anisotropic medium, have been successfully obtained by applying the ATR technique.[2] The determination of the infrared intensities of single crystals will also be possible if the optical constants can be obtained by the same method.[3] No attempt to do so has, however, yet been made, because there is an inevitable difficulty in making a good contact between the crystal sample and the high-index material.

We are developing a method of measuring optical constants of single molecular crystals by the ATR technique. The method is based on the determination of the true reflectivity for the perpendicular polarization, R_s. The reflecting surface of the sample is polished, and it is fixed firmly to the KRS-5 hemicylinder. After the R_s curve is recorded, we correct the R_s for the incompleteness of the contact as follows: A) The reflectivity for parallel polarization, R_p, goes down to zero at the principal angle, θ_p, in non-absorbing regions. If the optical contact is not complete, then the appreciable energy at θ_p, which is due to the lack of optical contact, is detected as R_p. Measuring the minimum R_p at θ_p, we obtain $R_s(\text{true}) = R_s\ (\text{observed}) - R_p$ (at $\theta = \theta_p, k = 0$). B) In non-absorbing regions the R_s is observed at a small angle of incidence, one where the total reflection does not occur. Then it is compared with the R_s calculated theoretically at the same incident angle. The difference between observed and calculated R_s values may be attributed to the energy resulting from the incompleteness of the contact. After the true R_s curves are thus obtained with two different incident angles, the n and k values are calculated on the basis of Frenel's formulae.

To illustrate the results obtainable with this method, we have measured the ATR spectra of an iodoform single crystal for the ν_4(E) CH bending band. Using a hexagonal bipyramidal iodoform, and taking the reflecting surface as the (0001) plane, the R_s (true) curves have been obtained. Then the n, k and α have been calculated by following Fahrenfort's method,[4] with some modifications suggested by Hansen,[5] using a FACOM 270—20 computer.

The calculated n and α values are shown in Fig. 1. The intensity $A_{\text{crystal}(0001)}$ is

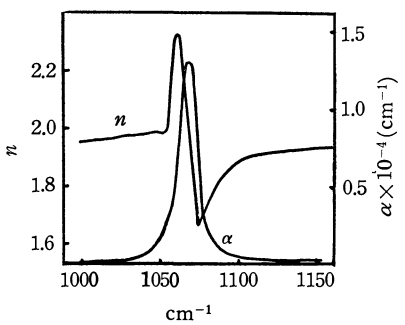

Fig. 1. Refractive index, n, and absorption coefficient, α, of CHI_3 single crystal in (0001) plane.

19.4 ± 4 cm/μmol, which is compared with the value 9.9 ± 0.5 cm/μmol for $A_{CS_2\,\text{soln.}}$. Iodoform belongs to the C_6^6 space group and the molecular axes of CHI_3 lie perpendicular to the (0001) plane, so that the ν_4 has all the intensity in this plane if the oriented gas model is assumed. $A_{\text{crystal}(0001)} = (3/2) A_{\text{soln.}} \times$ (field parameter). The details and a discussion will be published in the near future.

Energy Difference between Rotational Isomers of Methyl Ethyl Ether

Teizo KITAGAWA and Tatsuo MIYAZAWA
Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received June 18, 1968)

Raman lines due to skeletal bending modes of methyl ethyl ether were observed at 381 (weak) and 471 cm^{-1} (strong) for the liquid phase.[1-3] Corresponding infrared bands were observed at 370 and 464 cm^{-1} for the vapor phase at room temperature.[2,3] However, the band at 370 cm^{-1} was not observed in the solid state and was assigned to the gauche isomer, whereas the band of the solid phase at 472 cm^{-1} was assigned to the trans isomer.[4] The molecular structure of the trans isomer was determined by microwave analysis.[5] Measurement of the energy difference between the rotational isomers of methyl ethyl ether is also important for studying conformations of polymers, *e.g.*, polyethyleneglycol[6] in solution.

In the present study, the infrared spectra of methyl ethyl ether in the gaseous, liquid and solid states were measured in the region 550—200 cm^{-1}. The length of the gas cell used was 105 mm and the sample pressure was 660 mmHg at 303°K. The liquid cell (about 0.2 mm thick) was connected to a vacuum line and was kept at 204°K. The ether sample was distilled into the cell. For preparing a solid film, vapor was condensed on a cesium iodide window at 98°K and the solid was then annealed at 145°K. Typical spectra of the vapor, liquid, and solid phases are shown in Fig. 1. Temperature dependence of the intensities of liquid bands was observed and the bands at 258 and 300 cm^{-1} were found to become stronger as temperature was lowered. Accordingly, the area intensities of

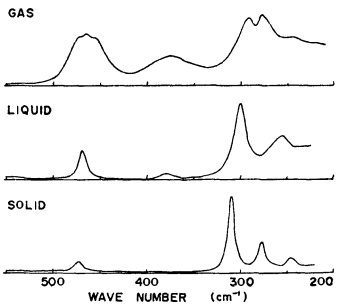

Fig. 1. Infrared absorption (optical density) curves of methyl ethyl ether.

the bands at 380 cm^{-1} (gauche) and 300 cm^{-1} (trans) were measured at 259, 248, 237, 228, 223, 216, 210, 204, and 198°K, and the energy difference between the rotational isomers was found as $\Delta H = H(\text{gauche}) - H(\text{trans}) = 1.5 \pm 0.1$ kcal/mol for the liquid phase. Temperature dependence of the vapor bands at 465, 375, and 280 cm^{-1} was also observed. After making corrections for emission from the cell at elevated temperatures, area-intensity ratios were measured at 303, 333, 375, and 423°K and the energy difference was found as $\Delta H = 1.5 \pm 0.2$ kcal/mol for the vapor phase. (From this value, the population of the gauche isomer is calculated to be as small as ~5% at ~200°K where microwave absorption lines of the gauche isomer were not identified.[5]) Thus, the ΔH values for the vapor and liquid phases of methyl ethyl ether are like, as expected from small dipole-moment difference between the two isomers.

The band of the liquid and vapor phase at ~465 cm^{-1} was previously assigned to the trans isomer, because the corresponding band was also observed in the solid phase. However, apparent relative intensities of the bands at 375 cm^{-1} (gauche) and 465 cm^{-1} were found to be independent of temperature, indicating that the bands of the trans and gauche isomers overlap at 465 cm^{-1} and the intensity of the composite band is largely due to the gauche isomer.

Studies of Photosensitive Resins. IV. Photosensitization Mechanism of Polyvinyl Cinnamate

Kenichiro NAKAMURA and Shinichi KIKUCHI

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received October 3, 1967)

The photosensitization mechanism of polyvinyl cinnamate was investigated by measuring the phosphorescence spectra of cinnamic acid and sensitizers. The peak of phosphorescence for *trans*-cinnamic acid was found to be 20100 cm^{-1}, and the triplet energies of the effective sensitizers were found to be situated near or higher than that of cinnamic acid. It was established that the phosphorescences of sensitizers were exceedingly quenched when cinnamic acid was introduced into their solutions. This finding can be understood if it is assumed that the excitation energy is transferred from the triplet state of the sensitizer to that of cinnamic acid. The critical separation of donor and acceptor and the configuration of the triplet state for cinnamic acid are also discussed.

Polyvinyl cinnamate is one of the most common photosensitive resins which become insoluble upon irradiation with light. The sensitized polyvinyl cinnamate is sensitive to visible light, while the non-sensitized resin is sensitive only to ultraviolet light. Many sensitizers, such as aromatic nitro and keto compounds, are reported to have this effect.

The photo-crosslinking mechanism of polyvinyl cinnamate has been made fairly clear. However, the sensitization mechanism of the resin is still the subject of frequent discussion. Tsuda[1,2] measured the photosensitivities of resins sensitized by mixtures of aromatic compounds, and showed that the mixing effect of a sensitizer can be fairly well understood by assuming a triplet energy transfer. He also measured the phosphorescence spectra of cinnamic acid, and reported that the limit of the spectral sensitization of polyvinyl cinnamate coincided with the wavelength of phosphorescence emitted from cinnamic acid. However, the triplet energy transfer mechanism has not been reported more definitely. Studies of the quenching of sensitizers' phosphorescence would seem to make the mechanism clearer. Therefore, the authors have measured the phosphorescence spectra of various sensitizers and have studied the quenching effect on a sensitizer's phosphorescence of the addition of cinnamic acid.

The photo-crosslinking of polyvinyl cinnamate is a reaction similar to the photo-dimerization of cinnamic acid in a solid phase. Therefore, the authors also studied the photochemistry of cinnamic acid. When cinnamic acid is irradiated with ultraviolet light in a solution, a photoisomerization reaction occurs. The quantum yields of the cis→trans and trans→cis isomerization of cinnamic acid were found by Vaidya[3] to be 0.21 and 0.61 respectively. The sum of the two quantum yields was about unity. This fact suggests that the excited states of *cis*- and *trans*-cinnamic acid concerned are the same.

Hammond *et al.*[4] discussed the cis-trans isomerization of stilbene in detail, and emphasized that a phantom triplet exists in the lowest triplet state of stilbene. There has, however, been no report which gives information about phantom triplet of cinnamic acid. Therefore, the authors intended to investigate the configuration of the triplet state by measuring the phosphorescence spectra of *cis*- and *trans*-cinnamic acid. The phosphorescence spectrum of trans-cinnamic acid was measured by Tsuda,[5] but that of cis isomer has not yet been measured.

Energy transfer from the triplet state has been observed between a number of donor-acceptor pairs.[6,7] Hammond *et al.*[8] have shown that the photosensitized cis-trans isomerization of stilbene is caused by the transfer of the triplet excitation. Porter *et al.*[9] have studied the quenching of the triplet state by measuring the triplet-triplet absorption spectra; they reported that there is no evidence for long-range resonance transfer of the kind found

in the anlogous singlet energy transfer process. In this paper, the distance of the energy transfer between the acceptor and donor molecules will also be discussed.

Experimental

The phosphorescence spectra of sensitizers were measured in an EPA solution at 77°K. The concentration of the sensitizer was 10^{-3} M, and 0.01—0.2 M *trans*-cinnamic acid was added to the sensitizer's solution. In the quenching measurements, the concentration of the sensitizer was kept at a constant value.

cis-Cinnamic acid was prepared from phenyl propiolic acid by the hydrogen reduction method described by Paal.[10] Colloidal palladium[11] was used as a catalyst in the reduction. The synthesized product was slightly colored, but the product recrystallized three times from ligroin was white, mp 68°C. *trans*-Cinnamic acid, guaranteed reagent, was purified two times by recrystallization from ethanol. The phosphorescence spectra were measured by an Aminco-Bowman spectrophotofluorometer.

Results and Discussion

Phosphorescence Spectra of Cinnamic Acid. The phosphorescence spectrum of *trans*-cinnamic acid in an EPA solution is shown in Fig. 1. The 0–0 band (20100 cm^{-1}) and the 0–2 band (18600 cm^{-1}) are strong in this phosphorescence spectrum, while 0–1 band is rather weak. The excitation wavelength was 280 mμ; it corresponds to the K-absorption band of cinnamic acid.

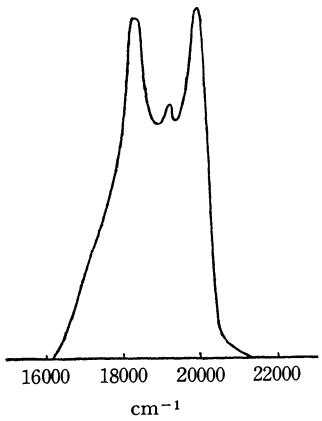

Fig. 1. Phosphorescence spectrum of *trans*-cinnamic acid.

In order to study the solvent effect on the phosphorescence, the authors also measured it in petroleum ether. However, no change in spectra could be found between EPA and petroleum ether. It may, therefore, be concluded that the phosphorescence of cinnamic acid is not affected by the solvent.

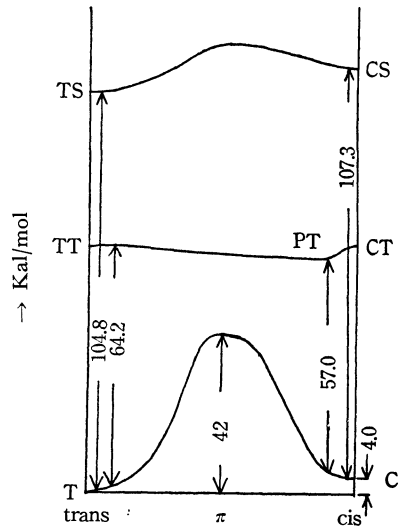

Fig. 2. Possible potential function for rotation in cinnamic acid.

The phosphorescence spectra of *cis*-cinnamic acid in EPA and in petroleum ether were also measured; They were the same as those of *trans*-cinnamic acid. This fact suggests that the triplet state of *trans*-cinnamic acid is the same as that of *cis*-cinnamic acid, and that the phantom triplet state proposed by Hammond *et al.*[4] exists in the triplet state of cinnamic acid. Therefore, the configuration of the potential function for rotation in cinnamic acid may be as is shown in Fig. 2.

The energies necessary for exciting *trans*- and *cis*-cinnamic acid are 104.8 kcal/mol (273 mμ) and 107.3 kcal/mol (266 mμ) respectively. The energy difference between the ground state of *trans*-cinnamic acid and that of *cis*-cinnamic acid was estimated to be 4.0 kcal/mol from the difference in hydrogenation energy between the two compounds.[12]

The activation energy for the thermal isomerization of cinnamic acid has not been measured, because the decomposition reaction takes precedence over the isomerization reaction at higher temperatures. However, its esters are stable for heat and they thermally isomerize. The activation energy for the thermal isomerization of methyl cinnamate has been reported to be 41.6 kcal/mol. A similar activation energy, about 41.6 kcal/mol, is necessary to cause the isomerization of styryl compounds.[13] Consequently, the activation energy of cinnamic acid may not be very different from that of cinnamic acid.

At a photostationary state, the ratio of the cis product to the trans product is about 3.0.[3] The

irradiated solution contains more of the cis isomer than that of the trans isomer. Therefore, the phantom triplet state may be located near the cis position, as is shown in Fig. 2. It may be seen in this figure that, when cinnamic acid at the phantom triplet is degraded to the ground state, the cis isomer may be mainly produced.

In a previous paper,[14] the present authors calculated the electronic structure and energy levels of *trans*-cinnamic acid by the LCAO-SCF-MO method. The calculated energy of the first triplet, 2.79 eV, corresponds to the T-TT energy in Fig. 2. In Fig. 3, all the energy levels are the calculated values.

The flourescence of cinnamic acid was measured, but no fluorescence could be detected. This may be due to the intersystem-crossing from the singlet state to the triplet state. The intersystem-crossing from the first excited singlet state to the second triplet state is probable, because the second triplet state is located near the first excited singlet state, as is shown in Fig. 3.

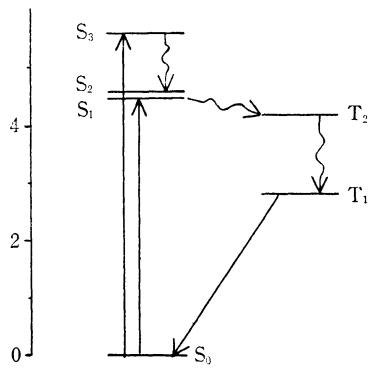

Fig. 3. State diagram for cinnamic acid.

Phosphorescence Spectra of Sensitizers. All the effective sensitizers for polyvinyl cinnamate emit phosphorescence near the 20000 cm^{-1} region, as is shown in Table 1. In this table, the wavelengths for the phosphorescence and absorption peaks and the values of the photosensitivities of the sensitized resins are shown. The triplet state energy of phenol is larger than that of cinnamic acid, but it is not an effective sensitizer for the resin. In photosensitization, phosphorescence is not the only important factor; the absorption of a sensitizer is also essential. For the irradiation of the resin, a mercury lamp is generally used. The photosensitivities shown in Table 1 are those obtained by irradiation with a mercury lamp. The wavelength of the emission peak of a mercury lamp is about 350 mμ. Therefore, the effective sensitizers must have absorption peaks near this region. In this table the intersystem-crossing efficiency from the singlet state to the triplet state is also shown. The efficiencies of 5-nitroacenaphthene and *p*-nitroaniline have not yet been reported. However, their efficiency may be about 1 because their absorptions are caused by n–π^* and the efficiency for the n–π^* compound is generally large. The efficiency of Michler's ketone is about 1, and its photosensitivity is very large. These results can be understood if the excitation energy is transferred from the triplet state of the sensitizer's molecule to that of the resin.

In order to make the triplet energy transfer more clear, the quenching of a sensitizer's phosphorescence was studied. The phosphorescence spectra of 2-nitrofluorene are shown in Fig. 4. The spectrum was measured at 77°K in a 10^{-3} M EPA solution. The uppermost curve in this figure is the spectrum of 2-nitrofluorene alone. The other curves are the spectra of 2-nitrofluorene, which includes 0.01—0.2 M cinnamic acid. It may be seen in this figure

Table 1. Photosensitivities of sensitized resins

Sensitizer	Abs. cm^{-1}	Phos. cm^{-1}	Intersystem[16] crossing efficiency	Photosensitive[1,17] value
Naphthalene	36400	22000	0.39	2.6
Phenanthrene	26700	19000		7.7
Chrysene	27800	19800	0.67	18
Phenol	37000	28600		1.8
2-Nitrofluorene	30300	20600		113*
5-Nitroacenaphthene	27000	19800		84*
p-Nitroaniline	27000	19700		110
Michler's ketone	25600	21300	1.01	650

* The method employed for these two values is different from that for other values. 5-Nitroacenaphthene is about 10 times more sensitive than *p*-nitroaniline.

the fifth curve: added 0.15 M cinnamic acid
the lowest curve: added 0.2 M cinnamic acid

that the phosphorescence of 2-nitrofluorene is remarkably quenched by the addition of cinnamic acid. The solutions were irradiated by a 350-mμ light. There is no absorption of cinnamic acid in this region, while 2-nitrofluorene has an intensive absorption band there. Therefore, the addition of cinnamic acid does not affect the phosphorescence spectrum. The quenching of the phosphorescence is considered to be due to the energy transfer from the triplet state of 2-nitrofluorene to cinnamic acid.

In Fig. 5, the intensities of the 0–0 bands of the sensitizers' phosphorescence are plotted against the concentrations of cinnamic acid. The quenching curves of other bands of 2-nitrofluorene are uniformly quenched. The concentration of the acceptor molecule, $[A]_{1/2}$, is estimated when the decay of the donor's phosphorescence, in the presence of the acceptor, is equal to one-half of its value in the absence of the acceptor. Thus, it is found from this

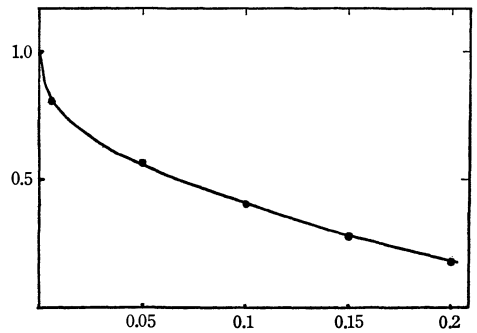

Fig. 5. The decay curve of phosphorescence of 2-nitrofluorene with addition of cinnamic acid.

the lowest curve: added 0.2 M cinnamic acid

figure that the concentration of $[A]_{1/2}$ is 0.063 M.

The phosphorescence spectra of *p*-nitroaniline are shown in Fig. 6. The samples were irradiated with a 350 mμ light. The remarkable quenching of the phosphorescence occurs just as in the case of 2-nitrofluorene. The 0–0 band of *p*-nitroaniline was found to be 19700 cm^{-1}. Therefore, the triplet state of *p*-nitroaniline is also an effective sensitizer of polyvinyl cinnamate. However, *o*-nitroaniline is not effective for sensitizing the resin. The intensity of the phosphorescence of *o*-nitroaniline was found

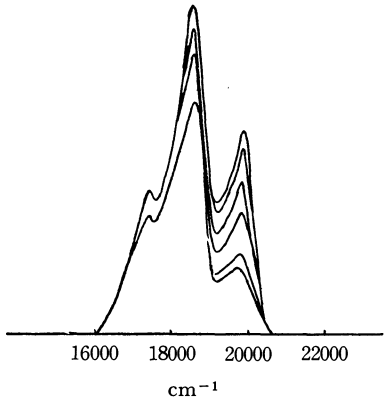

Fig. 7. Phosphorescence spectra of 5-nitroacenaphthene.
the uppermost curve: added 0 M cinnamic acid
the second curve: added 0.01 M cinnamic acid
the third curve: added 0.05 M cinnamic acid
the fourth curve: added 0.1 M cinnamic acid
the fifth curve: added 0.15 M cinnamic acid
the lowest curve: added 0.2 M cinnamic acid

to be very weak, in comparison with that of the *p*-isomer, although the phosphorescences of the two compounds are quite similar in shape and are equally quenched by the addition of cinnamic acid. In the case of *o*-nitroaniline, the same energy transfer could be found as in the *p* isomer. This suggests that the structural effect on the triplet transfer is small, and that the smaller sensitization effect of *o*-nitroaniline can be correlated with the weak intensity of the phosphorescence in comparison with that of *p*-nitroaniline.

The phosphorescence spectra of 5-nitroacenaphthene are shown in Fig. 7. The exciting light was 350 mμ. The remarkable quenching by cinnamic acid could also be observed. The triplet state of 5-nitroacenaphthene is situated near that of cinnamic acid, and the effect of the sensitization on the resin is very large.

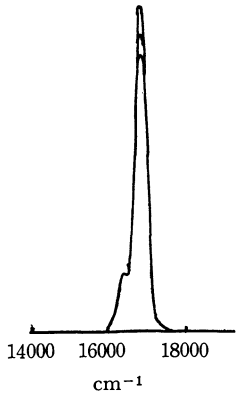

Fig. 8. Phosphorescence spectra of 1,2-benzanthracene.
the uppermost curve: added 0 M and 0.01 M cinnamic acid
the second curve: added 0.05 M and 0.1 M cinnamic acid
the lowest curve: added 0.15 M and 0.2 M cinnamic acid

The phosphorescence spectra of acenaphthene were also measured. It was found that its phosphorescence is greatly quenched by the addition of cinnamic acid. However, this compound is not an effective sensitizer. This lack of effectiveness is attributable to the absorption wavelength. The wavelength of the absorption peak for 5-nitroacenaphthene is about 320 mμ.

As is shown in Fig. 8, the phosphorescence of 1,2-benzanthracene is not quenched by the addition of cinnamic acid. The triplet energy of this compound is 16700 cm^{-1}, much smaller than that of cinnamic acid. Therefore, it is impossible for the triplet energy of 1,2-benzanthracene to be transferred to cinnamic acid.

The above quenching measurements make it clear that sensitization is due to the triplet-energy-transfer mechanism. The authors also tried to detect the sensitized phosphorescence of cinnamic acid. However, it could not be detected. The strength of the phosphorescence of cinnamic acid is smaller than that of the sensitizer, and the wavelengths of the two phosphorescence peaks are similar. Therefore, it seems reasonable to say that it is covered by that of the sensitizer.

In the measurement of the quenching of the sensitizer's phosphorescence, the authors could estimate $[A]_{1/2}$. Once $[A]_{1/2}$ is known, the experimental value of R_0 may be calculated by the equation:[15]

$$R_0 = \frac{7.35}{\sqrt[3]{[A]_{1/2}}} \quad (Å)$$

The critical separation estimated from the above equation is shown in Table 2. There is no evidence for a long-range resonance transfer of the kind found in the analogous singlet-energy-transfer process. Therefore, the exchange transfer mechanism may be applied to the triplet energy transfer from the sensitizer molecule to cinnamic acid.

The rate of the production of the triplet state can be written by:

$$\frac{d[T]}{dt} = \phi I_{abs} - (k_1[T] + k_q[Q][T]) \qquad (1)$$

where I_{abs} is the number of the absorbed photons, ϕ is the quantum yield which represents the efficiency of the absorbed photon in creating the triplet state, k_1 is the first-odrer rate constant of the decay of the triplet donor T, k_q is the bimolecular-quenching rate constant, and [Q] is the concentration of the quencher, cinnamic acid.

Table 2. Critical separation of sensitizer

Sensitizer	Phos. energy cm^{-1}	$[A]_{1/2}$ M	R_0 Å	α mol^{-1}
5-Nitroacenaphthene	19800	0.12	14.9	9
Acenaphthene	20900	0.019	17.5	52

—×— 5-nitroacenaphthene --□— 1,2-benzanthracene

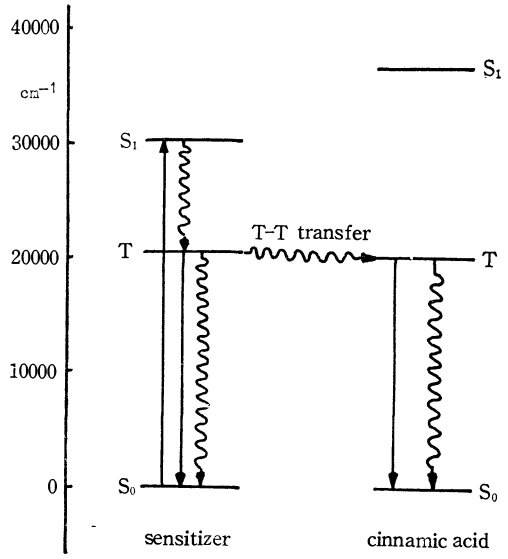

Fig. 10. The electronic levels of the sensitizer, 2-nitrofluorene, and cinnamic acid in the phenomenon of sensitization.

At the stationary state, the following equation can be derived:

$$[T]_Q = \frac{\phi I_{abs}}{k_1 + k_Q[Q]} \tag{2}$$

The emission strength of the donor phosphorescence is proportional to the triplet concentration [T]. Therefore, the ratio of phosphorescences, P_Q/P_0, can be estimated by:

$$\frac{P_Q}{P_0} = \frac{1}{1 + \alpha[Q]} \tag{3}$$

where P_0 and P_Q are the emission strengths of the phosphorescences of the donor and the quenched donor, and α is k_Q/k_1. From the above equation, the following relation can be derived:

$$x = \alpha[Q] \tag{4}$$

where $x=(P_0/P_Q-1)$.

In Fig. 9, the relations obtained experimentally are shown. The linear relation between them is fairly satisfactory. The inclination of the line shows the value of α. In Table 2 the obtained values of α are presented in the last column.

Finally, the electronic levels of the energy donor and acceptor in the phenomenon of sensitization can be expressed as is shown in Fig. 10. The energy difference in the donor between the lowest singlet and the triplet is much smaller than that in the acceptor, and the phosphorescence of the donor is quenched by the addition of an acceptor.

On the basis of the above results, it can be concluded that the photosensitization of polyvinyl cinnamate is caused by the triplet-state mechanism.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1983—1989 (1968)

Hydrolysis of Uranium Monocarbide and Oxidation Potentials

Yoshio HORI and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received February 6, 1968)

The hydrolysis of UC with 1 N H_2SO_4 was carried out in the presence of various oxidants at 80°C. The amount of gaseous products was measured by means of a gas chromatograph; the dissolved, carbon-containing compounds, and the insoluble residues produced in the reaction were analyzed for carbon. Analyses of the uranium and oxidants consumed were also made by volumetric and gravimetric methods. The results may be summarized: (1) The hydrolysis of UC with 1 N H_2SO_4 proceeds by an electro-chemical mechanism. (2) The hydrolysis products fundamentally depend upon the oxidation potential of the oxidants in the solution. (3) The oxidation potential at which the hydrolysis of UC with 1 N H_2SO_4 proceeds can be explained in terms of the partial ionic character of UC. (4) The application of this experimental method to other carbides would serve to clarify the chemical reaction and the bond character of the carbides.

Reactions between carbides and aqueous solutions containing oxidants have been studied by several authors. According to these studies, the hydrolyses of some carbides, such as uranium and actinides with nitric acid, yield products with different compositions from those obtained from aqueous solutions without any oxidants.[1-5] Others, such as CaC_2, give rise to products of the same composition whether containing nitric acid or not.[6] The present study seeks to clarify the mechanism of the hydrolysis of uranium monocarbide, which has not been discussed by previous authors.

Experimental

Experimental Procedure. About 250—500 mg of a UC sample was placed in a reactor. The reactor (volume: *ca.* 200 m*l*) consists of a glass tube 40 mm in diameter, connected with two vacuum stop cocks. After evacuation through one of the stop cocks, 35 m*l* of an aqueous reagent solution was introduced into the reactor as fast as possible in order to prevent air dissolution. Then it was immersed in a thermostated water bath at 80±0.1°C or placed in an air bath at the same temperature; in the latter case the reaction had to continue for more than ten hours. After the reaction, the reactor was cooled to room temperature, and the products were analyzed as will be described below.

Materials (1) Uranium Monocarbide. The same powdered sample as had been used in a previous work[7] was employed in this study.

Materials (2) Aqueous Reagent Solution. The solutions were prepared by dissolving oxidizing reagents into 1.1 N H_2SO_4, which had been flushed with purified nitrogen before the reaction. In order to control the oxidation potentials of the reactant solutions, the following reagents were employed (the standard oxidation potentials at 25°C are shown in parentheses): $FeSO_4 \cdot 7H_2O$(Fe^{2+}/Fe −0.44 V), JIS GR grade reagent. $CoSO_4 \cdot 7H_2O$(Co^{2+}/Co −0.277 V), JIS GR grade reagent. $NiSO_4 \cdot 7H_2O$(Ni^{2+}/Ni −0.250 V), JIS GR grade reagent. $SnSO_4$ (Sn^{2+}/Sn −0.140 V), the reagent solution of Sn^{2+}, was prepared by dissolving a ten-fold excess of Sn metal, 99.9% purity, into GR grade $CuSO_4$ and an H_2SO_4 aqueous solution in a purified nitrogen atmosphere. The resultant solution was analyzed to ascertain the absence of Cu^{2+} and Sn^{4+} concentrations. By the use of a KI and starch solution, Cu^{2+} was not detectable. The concentration of Sn^{2+} was equal to the total concentration of Sn ions within 1%; this indicates the absence of Sn^{4+} in the solution. $CuSO_4 \cdot 5H_2O$ (Cu^{2+}/Cu +0.377 V), JIS GR grade reagent. Ag_2SO_4 (Ag^+/Ag +0.799 V), the Ag_2SO_4 was obtained as a precipitate by the addition of H_2SO_4 to a GR grade $AgNO_3$ solution. The precipitate was filtered and then washed with alcohol and ethyl ether. NO_3^- was not detectable in the compound. $Fe_2(SO_4)_3 \cdot xH_2O$ (Fe^{3+}/Fe^{2+} +0.771 V), JIS GR grade reagent.

Chemical Analysis (1). The aqueous systems which involved Fe^{2+} and Co^{2+} were not analyzed for the corresponding metal after the reaction, because no metal deposit was found in these systems after the reaction had been completed. Ni^{2+} was weighed as nickel dimethyl glyoxime.[8] Sn^{2+} was determined as follows. A known amount of $FeCl_3$ solution was added to the test solution, and the Fe^{2+} reduced by Sn^{2+} was titrated

by 0.05 N $K_2Cr_2O_7$ using sodium diphenyl amine sulfonate as an indicator. An Sn metal, precipitated during the hydrolysis of UC, was dissolved into a mixed solution of HCl and H_2SO_4; after conversion to Sn^{4+} by chlorine gas, Sn^{2+} was precipitated as SnS_2 by H_2S. It was weighed as SnO_2 after vigorous heating. The concentration of Cu^{2+} was determined by iodometry.[8] The Fe^{2+} concentration in the solutions was determined by titration with 0.05 N $K_2Cr_2O_7$, and the total Fe was treated similarly after having been passed through a Jones reductor. Ag^+ was weighed as AgCl as usual.[8] The uranium test solution was reduced by a Jones reductor after appropriate separations, and was titrated by 0.05 N $K_2Cr_2O_7$ after air-bubbling for 10 min.[9]

Chemical Analysis (2). The carbon which was initially included in the UC powder was found in the gaseous products, in the reactant solution, and in the solid products after the reaction. The total pressure of the gaseous products was measured by a conventional mercury manometer, and the volume at STP was obtained by the correction of the water vapor pressures at room temperatures. The analysis of the gaseous products was made for N_2, H_2, CO, CO_2, CH_4, C_2H_6, C_3H_8, C_3H_6, i-C_4H_{10}, 1-C_4H_8, and unidentified C_4 and C_5 products by means of a gas chromatography equipped with a thermal conductivity detector. They were separated by means of a 4 m-long column containing 38% dimethyl formamide - activated alumina with H_2 carrier gas, a 2.5 m-long column containing 2.5% squarene-silica gel, with H_2 carrier gas, and a 1 m-long column containing a 13X molecular sieve, with H_2 and N_2 carrier gas. All these four operations were carried out at room temperature, and all gave accurate and reproducible results concerning the composition of the gaseous products. The carbon - containing compounds in the solutions were analyzed for carbon by persulfate oxidation.[10] The solid products were treated in warm hydrochloric acid in order to dissolve the deposited metals, and the insoluble residues were burned to CO_2, which was then weighed in a usual way.

Results

Table 1 presents the products of reactions between UC and various aqueous systems.

Aqueous Systems Which Contain Fe^{2+}, Co^{2+}, Ni^{2+}. Apparently from Table 1, the products and the compositions obtained for the systems containing Fe^{2+}, Co^{2+}, and Ni^{2+} (columns 4 to 6) are virtually equal to those without any oxidant (column 2). No metal deposition was observed for any of these systems. For comparison a reaction between UC powder mixed with *ca.* 20 mg of Ni powder and Ni^{2+} solution was also carried out. The result (column 7) differs a little from that obtained for the system without Ni powder (column 6). The difference between the solutions with and without nickel metal (columns 6 and 7) may be attributed mainly to the nucleation overpotential of nickel. It indicates that the hydrolysis of UC is influenced by the oxidant at the oxidation potential of -0.26 V for $Ni^{2+}+2\,e \rightarrow Ni$ (concentration 0.10 M and at 80°C). The uranium ion was found to exist as U^{4+} in all the solutions.

Sn^{2+} Systems. The reaction proceeded as readily as in the non-oxidant solution. The gaseous products decreased with the Sn^{2+} concentration. The amount of hydrogen and methane considerably decreased. Ethane and the other higher hydrocarbons, the dissolved carbon-containing compounds, and the greenish-black insoluble residues increased. It is also significant that the quantity of the unsaturated hydrocarbons (C_3H_6 and 1-C_4H_8) became

more than that of the saturated hydrocarbons (C_3H_8 and C_4H_{10}, respectively). A gray sponge identified as metallic tin was produced.

Cu^{2+} Solution. The reaction was so slow that after 69 hr only 20% of the UC has reacted. Thus, the precision of the analysis of the products was lower than in the other systems. Though traces of hydrogen and methane were produced, the main products were dissolved, carbon-containing compounds and insoluble black residues. A small amount of CO_2 was also detected. A grain-like copper metal was produced, and some of the copper deposit was found to adhere to he carbide surface. The valence of uranium in the product solution was +6.

Ag^+ Solution. The reaction proceeded rather readily. Virtually no hydrogen and no methane were produced. The insoluble residues and carbon dioxide were obtained dominantly. Dendritic silver was deposited, and the uranium in the solution was in the +6 state.

Fe^{3+} and Fe^{2+} Solution. Although the reaction rate was not high, the reaction was completed after 69 hr. Virtually no hydrocarbons evolved. A large amount of an insoluble powder and/or sponge-like residue was found. The quantity of the dissolved carbon-containing compounds decreased. The evolution of CO_2 increased. A trace of CO was detected, but no quantitative analysis was made. After the reaction, Fe^{3+} was found to be reduced to Fe^{2+} quantitatively.*1

Au Powder System. The reaction between UC and 1.1 N H_2SO_4 in the presence of Au powder was studied in order to determine whether or not the reaction products differ when UC came into contact with non-reactive metal. About 250 mg of UC and 3 g of 325 mesh under Au powder were mixed in a mortar, and then charged into a reactor. There were more hydrogen and more insoluble residues, and less methane, compared with the non-oxidant solution (Table 1, columns 2 and 3). These results will be discussed in the following section.

Discussion

The Relation between the Oxidation Potentials and the Hydrolysis Reaction of UC. The hydrolysis of UC with 1 N H_2SO_4 is considered, on the basis of the experiment with Au powder to be discussed below, to proceed by the electrochemical mechanism:

* UC contained 0.968 mg atom/mmol of carbon, initially.

*1 The valence of uranium was not determined. Titration with a $K_2Cr_2O_7$ solution is employed as a conventional volumetric analysis of uranium. As the direct oxidation of U^{4+} to UO_2^{2+} by $Cr_2O_7^{2-}$ proceeds slowly, it is recommended to add a Fe^{3+} solution first, then oxidize U^{4+} to UO_2^{2+}, and finally determine the resultant Fe^{2+} by titration. Therefore, uranium ions coexisting with Fe^{3+} can be regarded as UO_2^{2+}.

* Oxidation potentials were calculated from thermochemical data (at 80°C).[11,12]

$$UC \rightarrow U^{4+} + (C + 4e)_{carbide}$$

$$(C + 4e)_{carbide} + 4H^+ \rightarrow CH_4$$

As UC is a good electric conductor, a part of the electrons liberated by the dissolution of U are able to migrate to Au powder, which is in contact with UC. Then the electrons will reduce protons to hydrogen radicals on Au particles.

Partially, $H^+ + e \rightarrow H\cdot$ (on Au particles)

Since there is no carbon atom available for the formation of methane on Au particles, these radicals will react with each other and will result in hydrogen molecules:

$$H\cdot + H\cdot \rightarrow H_2 \text{ (on Au particles)}$$

11) W. Latimer, "Oxidation Potentials," Prentice Hall, Englewood Cliffs, N. J. (1952).
12) A. J. deBethune, T. S. Licht and N. Swendeman, *J. Electrochem. Soc.*, **106**, 616 (1959).

As a result, carbon atoms which failed to react with hydrogen atoms would polymerize and precipitate, because the overall ratio of H to C remains 4.0.

$$C \rightarrow \text{insoluble residues}$$

Evidently the composition of the reaction products changes with the oxidation potential, as may be seen from Tables 1, 2, and 3. In solutions without any oxidant, the overall reaction will proceed as below:

$$(UC)_{carbide} \rightarrow U^{4+} + (C + 4e)_{carbide}$$

$$(C + 4e)_{carbide} + 4H^+ \rightarrow CH_4 + \text{a small quantity of higher hydrocarbons, and hydrogen.}$$

The same discussion holds also in the solution containing Fe^{2+} and Co^{2+}. At a potential higher than about -0.26 V of the oxidation potential (*i.e.*, Ni^{2+}/Ni solution), the composition of the reaction products is found to change with the potential. The overall reaction in the Sn^{2+}/Sn solution can be written:

$$UC + xH^+ + (4-x)/2\ Sn^{2+} \rightarrow U^{4+} + (4-x)/2\ Sn + CH_x$$

where x is the average ratio of H to C in the products. From Table 2, x is found to be $2.23/0.867=2.57$ in the 0.1 M solution of Sn^{2+}. The value of x decreases with the concentration of Sn^{2+}.

As is shown in Table 2 concerning the material balance, the total carbon exceeds 0.968 in the Cu^{2+}/Cu system, and the material balance for oxidation and reduction (Table 3) is not matched. The reason for this will be explained below. After the reaction, the insoluble residue was treated with warm hydrochloric acid in order to dissolve the unchanged UC. In this procedure, hydrogen probably evolved on copper metal adherent to the unchanged UC, and carbon atoms in UC were polymerized and precipitated by the mechanism described in connection with the Au powder system. The insoluble residues containing carbon which resulted from this procedure entered the product of the reaction in the Cu^{2+}/Cu system.

In the system of Ag^+/Ag and Fe^{3+}/Fe^{2+}, the overall reaction can be expressed:

$$UC + 2H_2O + 6Ag^+ \rightarrow UO_2^{2+} + 4H^+ + 6Ag + C^{*2}$$

Carbon atoms result in the insoluble residue, the dissolved compounds, and carbon dioxide in the above reaction.

The Production of CO_2. When the reactant solution did not include any oxidant, a substantial number of the carbon atoms in UC were converted to CH_4. As the oxidation potential becomes higher, C_2H_6, C_3H_8, C_3H_6, the soluble compounds, the insoluble residues, and CO_2 increase. Figure 1 presents the average oxidation number of the carbon atom. In its calculation a hydrogen atom bonded to a carbon atom is estimated at -1, and an oxygen, at $+2$. Obviously CH_4 is produced when no oxidation occurs, and the increase of C_2H_6, C_3H_8, C_3H_6, the soluble compounds, and the insoluble residues corresponds to partial oxidation, while CO_2 evolves as a result of full oxidation.

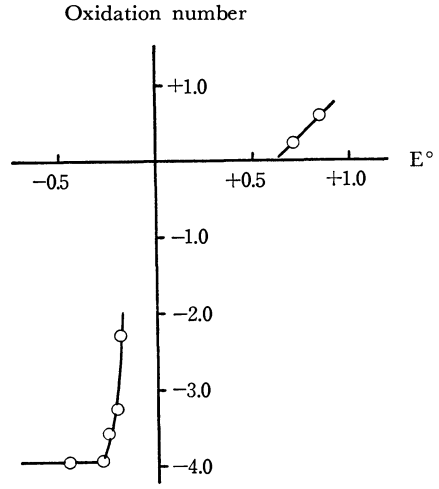

Fig. 1. Oxidation number of carbon *versus* oxidation potential.

The formation of CO_2 is interesting, since the oxidation potential for the reaction:

$$2H_2O = O_2 + 4H^+ + 4e$$

is about $+1.2$ V at 80°C.[11,12] It is impossible that CO_2 evolves through the oxygen molecules or atoms that come from the oxidation of water by such oxidants as ferric ions. CO_2 would be formed from the direct reduction of H_2O with the carbon atom which is recovered from the carbide lattice. Without presence of oxidants, the carbon atom will not react with H_2O to produce CO_2, because Coulombic repulsion will be caused between $^{\delta+}H\diagdown\diagup O^{\delta-}\diagup H^{\delta+}$: and the partially-ionic carbon atom, as will be discussed below. Accordingly, the carbon atom can reduce H_2O after losing some fraction of its electrons.

Comparison with Other Studies. Damiens[13] studied the hydrolysis of cerium carbide with HCl solution which contained $FeCl_3$; the found that the products differed considerably from those obtained in a solution not containing an oxidant. The reaction between UC and HNO_3 has been studied by many authors in connection with the reprocessing of nuclear fuel.[1-5] Except for the report by Pollard

*2 The oxidation-reduction potential for the reaction

$$U^{4+} + 2H_2O \rightarrow UO_2^{2+} + 4H^+ + 2e$$

is $+0.264$ V at 80°C.[11]

13) A. Damiens, *Ann. chim.*, **10**, 137 (1918).

et al.,[4] most of their studies are in general agreement, showing that carbide carbon is converted to CO_2, oxalic acid, mellitic acid, other aromatic compounds, and free carbon in some papers. Pollard *et al.*, however, reported that most of the carbide carbon was found in hydrocarbons, the composition of which was virtually equal to that obtained in dilute acid not containing nitric acid. This discrepancy has not been explained. The formation of CO_2 and other organic compounds is consistent with the present experimental results, since the oxidation-reduction potential for the reaction:

$$NO_3^- + 4H^+ + 3e \rightarrow NO + 2H_2O \qquad E^\circ_{25^\circ} = 0.96\ V$$

$$2NO_3^- + 4H^+ + 2e \rightarrow N_2O_4 + 2H_2O \qquad E^\circ_{25^\circ} = 0.80\ V$$

Baudin[14] *et al.* reported the hydrolysis of UC with 3 N HCl - 0.25 N $K_2Cr_2O_7$. According to them, hydrogen decreased markedly (11.2%→1.1% of total gases), compared with a non-oxidant solution, and C_3, C_4 ethylenics evolved (C_3H_6 1.65%, C_4H_8 1%). Their report, however, indicates that the composition of products of a 0.25 N $K_2Cr_2O_7$ solution is rather equal to that for the nonoxidant solution, since more than 90% of the carbide carbon is converted to methane. In our preliminary 1 N HCl-0.25 N $K_2Cr_2O_7$ experiment, the reaction rate was rather low; about half of the reacted carbide carbon was found in CO_2, and the other half in insoluble residues. A more critical comparison of these marked differences between the two cannot be made since their experimental procedures were not reported in detail by Baudin *et al.* Greenwood and Osborn[15] described the hydrolysis of LaC_2 and La_2C_3 with 4 N H_2SO_4 and 2 N HNO_3. According to them, hydrogen was markedly lessened in 2 N HNO_3, but most of the carbide carbon was converted into C_2H_2, C_2H_4, and free carbon in both 2 N HNO_3 and 4 N H_2SO_4. Pollard *et al.*[16] reported the hydrolysis of LaC_2, CeC_2, NdC_2, GdC_2, and $YC_{1.6}$ with 4 N HNO_3. The hydrolysis of carbides with 4 N HNO_3 gave results virtually equal to those for water and 4 N H_3SO_4, in spite of the considerable evolution of nitric oxides. This problem cannot be further discussed critically, however, since the experimental details were not described.

Sears and Ferris[6] studied the reactions of CaC_2 and BaC_2 with different concentrations of nitric acid. The reactions of CaC_2 with 0—16 M HNO_3 and BaC_2 with 0—8 N HNO_3 yielded C_2H_2 as the only carbon-containing product, but when reacted with 10—16 M HNO_3, BaC_2 gave rise to free carbon and carbon oxides by the partial oxidation of carbide carbon simultaneously with the production of acetylene.

The Potential at Which UC Reacts with Aqueous Acid. On the basis of the present experiment, E_H, the oxidation potential at which the hydrolysis of UC proceeds really may be said to be near −0.26 V since the Ni^{2+} ion has the basest oxidation potential among any oxidants that show the oxidant effect. As an extreme case, the reaction:

$$UC = U^{4+} + 4e + C(\beta\text{-graphite}) \qquad E^\circ = -1.2\ V \qquad (1)$$

can be interestingly compared with the present one. In this case the reaction:

$$4H^+ + 4e + C(\beta\text{-graphite}) = CH_4 \qquad E^\circ = 0.13\ V \qquad (2)$$

would correspond to the cathodic one. The oxidation potentials for these two reactions, (1) and (2), can readily be calculated to be −1.2 V and +0.13 V, respectively from the thermochemical data.[11,17] E_H will depend upon the overpotentials for the evolution of methane and the dissolution of uranium. In general, the anodic dissolution of metals occurs at a rather low polarization; the cathodic evolution of gases, such as H_2 and O_2, is accompanied by rather high overpotentials. Accordingly, if it is assumed that the Reactions (1) and (2) actually proceeds in the hydrolysis of UC, E_H may be observed to be roughly equal to E_R,*3 the oxidation potential for (1), that is −1.2 V. Thus, the difference between the experimental E_H values near −0.26 V and E_R, −1.2 V would indicate the variation in the reactivity of the carbon in the carbide lattice from that in the graphite lattice.

From the behavior of CaC_2 and BaC_2 reported by Sears and Ferris,[6] the E_H value is estimated to be about 1.0 V for BaC_2 and higher than 1.0 V for CaC_2. The oxidation potential, E_R, for the (1)-type reaction.

$$BaC_2 = Ba^{2+} + 2e + 2C(\beta\text{-graphite})$$

may be said to be −2.62 V and that for CaC_2 −2.56 V on the basis of the thermochemical data.[11,18,19] $E_H - E_R$ is then, rather a large value of 3.6 V. CaC_2 is reported to be an ionic crystal, $Ca^{2+}C_2^{2-}$, on the basis of the neutron diffraction.[20] If it is tentatively assumed that the $E_H - E_R$ value becomes larger as the ionic character of carbides increases, the $E_H - E_R$ value of 0.9 V for UC may be

said to be due to the partially ionic character of UC, *i.e.*, $U^{n+}C^{n-}$. The partial ionic character is also confirmed by the fact that the work function for U is about 3.5 eV,[21,22] while that for graphite is about 4.4 eV.[23] This suggests that electrons will be transferred from U atoms to C atoms in the UC crystal lattice. The reaction between UC and an acid aqueous solution would proceed as below:

$$U^{n+}C^{n-} \rightarrow U^{4+} + C^{n-} + (4-n)e_{\text{in crystal}}$$

$$C^{n-} + (4-n)e_{\text{in crystal}} + 4H^{+} \rightarrow CH_4$$

As has been discussed above, the $E_H - E_R$ value would reflect the bond nature of carbide and could be employed as a parameter for the reactivity of various carbides.

Conclusion

1) The reaction between UC and 1 N H_2SO_4 proceeds by an electrochemical mechanism.

2) The hydrolysis products of UC with aqueous acid solution depend fundamentally upon the oxidation potential of the oxidant in the solution.

3) The potential, E_H, where the hydrolysis proceeds is about -0.26 V for UC, and UC would be partial ionic crystal.

4) E_H can be employed as a parameter which expresses the reactivity of carbides.

The authors are grateful to Dr. K. Fueki for his valuable discussions during the course of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1989—1997 (1968)

An MO-theoretical Interpretation of the Nature of Chemical Reactions. I. Partitioning Analysis of the Interaction Energy*[1]

Kenichi FUKUI and Hiroshi FUJIMOTO

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received February 20, 1968)

The molecular interaction energy, without considering the nuclear configuration change, is discussed by partitioning it into the Coulomb, exchange, delocalization, and polarization terms. A succinct approximate expression for each term is derived, and its magnitude is discussed. The expressions obtained as the second-order perturbation terms for the delocalization and the polarization energies are in accord with those of the well-established reactivity indices, the delocalizability, and the self-atom polarizability respectively. The chemical reactivity can thus be measured by the combined sum of these four terms. In usual ionic reactions the Coulomb and the delocalization terms are more important than the exchange and the polarization terms respectively.

The molecular orbital (MO) approach can be used to interpret the chemical reactivity of organic molecules, both saturated[1)] and unsaturated.[2)] Most of these MO criteria for the chemical reactivity are based on the use of various reactivity indices defined as the theoretical quantities of isolated reactant molecules, each based on an appropriately-assumed model for the chemical reaction. The classification of these indices has tentatively been made by dividing them into three groups, the static, the localization, and the delocalization approaches.[3)] The comparison of these approaches appeared promising for acquiring knowledge of the reaction mechanism.[2)] However, the semiempirical character of calculation made an absolute comparison of the various methods difficult. In addition, as a result of the existence of several theoretical correlations among the reactivity indices,[4)] no unequivocal conclusion has yet been obtained. Although the formal introduction of

*1 The basic idea of this paper was presented by one of the present authors (K.F.) at the International Summer School of Quantum Chemistry, Istanbul, August, 1964, while a skeletal presentation was made in K. Fukui, *Kogyo Kagaku Zasshi* (*J. Chem. Soc. Japan, Ind. Chem. Sect.*), **69**, 794 (1966).

the "transition-state" concept in the absolute-rate theory has doubtless been illuminating, the basic principle of the activated complex formation is not yet clear. The nature of chemical reactions, therefore, still remains obscure in many details from the quantum-mechanical point of view.

It is the aim of the present approach to make a contribution to this problem through a formulation of the energy of chemical interaction, to derive at the same time a prototype of several reactivity indices in a unified manner, and also to discuss the characteristic features of the reaction path on the potential energy surface. The method is based chiefly on the Roothaan-type linear combination of atomic orbitals (LCAO) MO approach, with some use of the configuration interaction (CI) procedure.[5]

Electron Delocalization in the Chemical Interaction. Since 1933[6] several theories were proposed one after another to explain the chemical reactivity of conjugated molecules along the static[6-8] and the localization approaches.[9] In 1952 the "frontier electron" concept[10] was put forth; it pointed out that the electrophilic aromatic substitution should take place at the carbon atom of the largest density of the highest energy electrons. Similarly, the nucleophilic replacement was later shown to occur at the position of the largest density of the lowest unoccupied MO. In comparison with the theoretically well-established character of the other reactivity theories then existing, the lack of a solid physical foundation for the infant frontier electron theory suggested instead the possibility of the involvement of a new principle for the mode of chemical interaction.

It was coincidentally in the same year that the elegant theory of the charge-transfer interaction was developed by Mulliken with regard to the molecular complex formation between a donor and an acceptor.[11] In this connection, the "overlap and orientation" principle was proposed;[12] it considered only the overlap interaction between the highest energy occupied MO of the donor and the lowest energy unoccupied MO of the acceptor.

Since the behavior of the frontier electrons was attributed to some type of electron delocalization between the reactant and the reagent,[13] it was natural for the charge-transfer mechanism and the overlap and orientation principle to be connected to the problem of ionic reactions. Brown combined the charge-transfer theory with the frontier electron concept to derive a consistent theory of chemical reactivity.[14] All of these treatments[10-15] together may be termed the "delocalization approach" to chemical reactivity theory.

Applying the donor and acceptor concept to the substitution reactions in conjugated molecules, the electrophilic and the nucleophilic reactions were discussed from a unified point of view. Thus, the highest occupied (HO) MO of the donor molecule and the lowest unoccupied (LU) MO of the acceptor molecule were considered to behave as frontier orbitals in ionic reactions,[10] not only in substitutions but also in additions, and even in multicentric reactions.[8] When the overlap and orientation principle was applied to odd-electron molecules or radicals, the half-occupied nonbonding (NB) MO was responsible for the reactive interaction. A similar behavior of these particular MO's has also been pointed out in nonplanar saturated molecules.[1] In addition, the conspicuous property of HO and LU in determining the steric course of organic reactions has been discovered and has attracted much attention.[3,16]

In this view, it may be of interest to discuss the energy of reacting systems by dividing it into various kinds of interactions. Such a treatment will be useful in helping us to understand what factor is really important in the chemical reaction.

Interaction with No Nuclear Configuration Change

The energy of the interaction between two independent systems, in which, tentatively, no nuclear configuration change is considered, is defined by the following equation:

$$\Delta W = W - (W_{A0} + W_{B0}) \quad (1)$$

where ΔW is the interaction energy, W_{A0} and W_{B0} being the energies of the initial stationary states of two isolated systems, A and B, and W, the lowest total energy of the two mutually-interacting systems. The energies of all the systems were calculated in the frame of the Born-Oppenheimer approximation[17] and obtained in the form of the adiabatic potential.

The Hamiltonian operator of the combined system in atomic units is:

$$H = \sum_{\lambda} H(\lambda) + \sum_{\lambda<\lambda'} \frac{1}{r_{\lambda\lambda'}} + \sum_{\gamma<\gamma'} \frac{Z_\gamma Z_{\gamma'}}{R_{\gamma\gamma'}}$$

$$H(\lambda) = -\frac{1}{2}\Delta(\lambda) + V(\lambda)$$

$$V(\lambda) = V_A(\lambda) + V_B(\lambda)$$

$$V_A(\lambda) = -\sum_{\alpha} \frac{Z_\alpha}{r_{\lambda\alpha}}, \quad V_B(\lambda) = -\sum_{\beta} \frac{Z_\beta}{r_{\lambda\beta}} \quad (2)$$

in which:

$H(\lambda)$:	One-electron Hamiltonian operator of the electron λ.
$Z_\alpha, Z_\beta, Z_\gamma$:	The positive charges of the nuclei α, β, and γ, which specify their belonging to the system A, the system B, and the combined system, AB, respectively.
$r_{\lambda\lambda'}$:	The distance between the two electrons λ and λ'.
$r_{\lambda\alpha}$, *etc.*:	The distance of the electron λ from the nucleus α, *etc.*
$R_{\alpha\alpha'}$, *etc.*:	The distance between the nuclei α and α', *etc.*

The unperturbed normalized wave-functions of the A and B systems are assumed to be represented in terms of Slater determinants composed of orthonormal spin-orbitals with LCAO MO spatial functions, which are Roothaan-type SCF (self-consistent-field) MO's with respect to the *ground state* of each isolated system.[18] The wave-functions of an excited or charge-transferred configuration may be made up of the MO's associated with the realistic and non-realistic roots of the Fock equation for the ground state. Therefore, all of the MO's are definite and fixed, with a given nuclear configuration in each isolated system.

The spatial parts of LCAO MO are represented by:

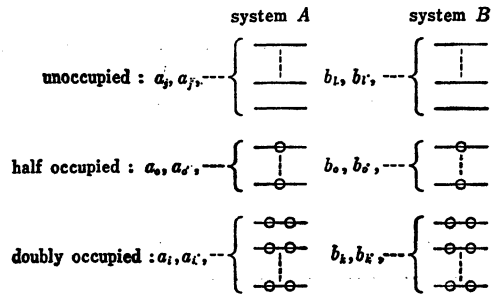
$$a(1) = \sum_{t} C_t t(1) \quad \text{for the system } A \quad (3a)$$

and

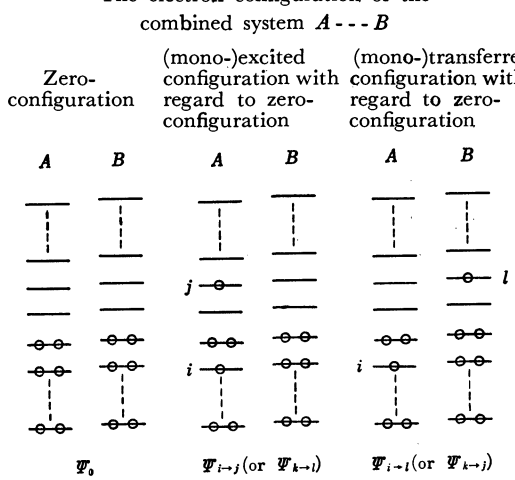
$$b(1) = \sum_{u} C_u u(1) \quad \text{for the system } B \quad (3b)$$

where t and u are the AO's belonging to the nuclei of A and B respectively. No particular restriction is placed on the type of these AO's. Usually they may be taken to be Slater-type or Gaussian AO's. However, it is often convenient for the later discussion of reactivity criteria to employ the valence atomic orbitals (VAO's).[19] Our present purpose allows us to take all functions as real.

The occupied and unoccupied MO's in the ground state are distinguished in the following way:[20]



The configurations to be taken into account are as follows:



The perturbed normalized wave-functions of the combined-system Ψ_J's are constructed by means of

17) M. Born and J. R. Oppenheimer, *Ann. Physik*, **84**, 457 (1927).

18) Either A and B, or both, may be an odd-electron system. For such a system the "restricted" open-shell SCF MO theory (*e.g.*, see G. Berthier, "Molecular Orbitals in Chemistry, Physics, and Biology," ed. by P.-O. Löwdin and B. Pullman, Academic Press, New York (1964), p. 57) should be applied to compose the wave-function. A calculation similar to the present one was early made by Mori (Y. Mori, This Bulletin, **35**, 1584 (1962)) with respect to the interaction between a molecule and a radical.

19) K. Ruedenberg, *Rev. Mod. Phys.*, **34**, 326 (1962); compare R. McWeeny, *ibid.*, **32**, 335 (1960).

20) For the presentation of an "unoccupied" MO to interact with another molecule, the Roothaan LCAO MO approach, with a basis set of a limited number of AO's chosen so as to be suitable for describing the occupied MO's is not necessarily appropriate.

the Slater determinants, composed of a_i's, a_j's, b_k's, and b_l's according to each electron configuration. The subscript J stands for all configurations, 0, $i\to j$, $k\to l$, $i\to l$, $k\to j$, and other highly-excited or transferred ones, such as $(i\to j, i'\to j')$, $(i\to j, i'\to l)$, $(i\to l, i'\to l')$, and so on.[21] The wave-function Ψ_J may further be specified by the superscript $(2S+1)$ and the subscript M_S as represented by ${}^{2S+1}_{M_S}\Psi_J$, where S and M_S designate the usual total spin quantum numbers. For instance, ${}^{3}_{0}\Psi_{i\to l}$ is represented by:

$$\frac{1}{\sqrt{2}}[NA\,|a_1\bar{a}_1a_2\bar{a}_2\cdots a_{i-1}\bar{a}_{i-1}a_ia_{i+1}\bar{a}_{i+1}\cdots a_n\bar{a}_nb_1\bar{b}_1\cdots b_m\bar{b}_m\bar{b}_l| + NA\,|a_1\bar{a}_1a_2\bar{a}_2\cdots a_{i-1}\bar{a}_{i-1}\bar{a}_ia_{i+1}\bar{a}_{i+1}\cdots a_n\bar{a}_nb_1\bar{b}_1\cdots b_m\bar{b}_mb_l|]$$

where NA signifies the normalization-antisymmetrization operator; the nonbarred and barred MO's represent the spin-orbitals with spin-functions of α and β respectively, and n and m indicate the number of doubly-occupied MO's of A and B respectively in the zero-configuration.

The secular determinant is represented by:

$$\begin{vmatrix} H_{I,I}-E & H_{I,J}-S_{I,J}E\cdots \\ H_{J,I}-S_{J,I}E & H_{J,J}-E\cdots \\ \cdots\cdots & \end{vmatrix} = 0 \quad (4)$$

where the subscript I signifies the initial J, and where:

$$H_{J,J'} = \int \Psi_J^* H \Psi_{J'} d\tau$$

$$S_{J,J'} = \int \Psi_J^* \Psi_{J'} d\tau$$

The orders of magnitude of the overlap integrals are estimated as:

$$S_{0,i\to l} = S_{0,k\to j} = O(s_{ab})$$

$$S_{0,i\to j} = S_{0,k\to l} = S_{i\to l,\,k\to j} = S_{i\to j,\,k\to l} = O(s_{ab}^2)$$

$$S_{i\to j,i'\to l} = S_{i\to j,k\to j'} = S_{i\to l,k\to l'} = S_{k\to j,k'\to l} = O\ (s_{ab}^3)$$

$$S_{i\to j,i'\to j'} = S_{k\to l,k'\to l'} = O\ (s_{ab}^4)$$

$$S_{i\to j,(i\to j,i'\to l)} = S_{i\to j,(i\to j,k\to j')} = S_{i\to j,i\to l} = S_{i\to j,k\to j} = O(s_{ab})$$

$$S_{i\to j,(i\to j,i'\to j')} = S_{i\to j,(i\to j,k\to l)} = S_{i\to j,i'\to j} = O(s_{ab}^2)$$

and so forth, where s_{ab} represents an overlap integral of an MO of the system A and an MO of the system B. The general relation is given by:

$$S_{J,J'} = O\ (s_{ab}^{\nu}) \quad (5)$$

in which ν is the minimum number of electron transfers between A and B required to shift the electron configuration from J to J'.

In order to calculate W in Eq. (1), which is given by the lowest root of the secular equation (4), it is assumed that the lowest $H_{J,J}$ is $H_{I,I}$ and that no others are equal to $H_{I,I}$.[22] On the basis of the second assumption, that $S_{J,J'}$ and $H_{J,J'}$ $(J\neq J')$ are small, W can be expanded in approximately the following form:

$$W = H_{I,I} - \left(\sum_p^{\text{monotr.}} + \sum_p^{\text{monoex.}} + \sum_p^{\text{ditr.}} + \sum_p^{\text{monotr.-monoex.}} + \sum_p^{\text{diex.}} + \cdots\right)\frac{|H_{I,p}-S_{I,p}H_{I,I}|^2}{H_{p,p}-H_{I,I}} + \cdots \quad (6)$$

where monotr., diex., *etc.* imply monotransferred, diexcited, *etc.* configurations with respect to the initial configuration, I.[23] The third term $(+\cdots)$ designates the remaining terms, which cover the difference from the exact root of Eq. (4).

If it is assumed[12] that the interaction between A and B is not yet very strong and that $H_{I,p}$ is almost linear with $S_{I,p}$, it follows that, in light of Eq. (5), the terms from monotransferred configurations will possess magnitudes of the order of s_{ab}^2, and that the monoex. and the ditr. terms are of s_{ab}^4, the monotr.-monoex. term is of s_{ab}^6, and so on. In addition to this, if SCF MO's are employed, the well-known Brillouin theorem[24] makes the $H_{I,p}$ values of monoex. terms small. Moreover, the denominator of the second term, $H_{p,p}-H_{I,I}$, can usually not be small in excited configuration terms, while in transferred configuration terms it can be, and sometimes, as in Eq. (7'), even a first-order term appears in place of the second-order transferred configuration terms of Eq. (6). In these circumstances the monotransferred term will become uniquely important.

21) The wave-functions for these electron configurations should be regarded as those adopted to describe the perturbed wave-function in terms of that of the isolated reactant molecules, and not necessarily as corresponding to any realistic " excited " or " transferred " states.

22) This assumption reflects the adiabaticity requirement for the interaction. There are two other possibilities. In one the lowest $H_{J,J}$ is $H_{I,I}$ and the other $pH_{J,J}$'s ($H_{1,1}$, $H_{2,2}\cdots$, $H_{q,q}\cdots$, $H_{p,p}$) are equal to $H_{I,I}$, where the suffix q stands for one of the monotransferred configurations with reference to I. In this case the equation corresponding to Eq. (7) becomes:

$$W = H_{I,I} - \left\{\sum_{q=1}^{p}|H_{I,q}-S_{I,q}H_{I,I}|^2\right\}^{1/2} + \cdots \quad (7')$$

The other is the case in which the lowest $H_{J,J}$ is not $H_{I,I}$ but $pH_{C,C}$'s ($H_{C1,C1}$, $H_{C2,C2}\cdots$, $H_{Cq,Cq}\cdots$, $H_{Cp,Cp}\cdots$) of an equal energy, where C_q stands for one of the monotransferred configurations of I. In this case

$$W = H_{C,C} - \frac{\sum_{q=1}^{p}|H_{I,C_q}-S_{I,C_q}H_{C,C}|^2}{H_{I,I}-H_{C,C}} + \cdots \quad (7'')$$

23) When the initial configuration is an excited one, the term " excited " configuration should include "di"-excited configurations, too.

24) L. Brillouin, *Actualités sci. et ind.*, **71** (1933); **159** (1934).

Thus, if we take only the terms not smaller than s_{ab}^2, namely, the monotransferred terms in the second term of Eq. (6), we get:

$$W = H_{I,I} - \sum_{p=1}^{N} \frac{|H_{I,p} - S_{I,p}H_{I,I}|^2}{H_{p,p} - H_{I,I}} \tag{7}$$

where p stands for the pth monotransferred configuration with reference to I, and where N is the number of monotransferred configurations.

Combined Reactivity Index

The interaction energy, ΔW, in Eq. (1), appropriately calculated with respect to a given nuclear configuration, will serve as a reasonable measure of the stability of that configuration. A comparisen of ΔW with the various nuclear configurations which are possible in a given chemical interaction will make it possible to discuss the preferred orientation theoretically. Thus, ΔW can be a general scale of reactivity. The singlet interaction energy,[25] ΔW, of Eq. (1), which has reference to the initial state, with a zero-configuration composed of two even-electron ground-state systems, is written by Eq. (6) as:

$$\Delta W = \varepsilon_0 - D - \Pi \tag{8}$$

where:

$$\varepsilon_0 = H_{0,0} - (W_{A0} + W_{B0}) \tag{8a}$$

$$D = \sum_{i}^{\text{occ}} \sum_{l}^{\text{uno}} \frac{|H_{0,i\to l} - S_{0,i\to l}H_{0,0}|^2}{H_{i\to l,i\to l} - H_{0,0}} + \sum_{k}^{\text{occ}} \sum_{j}^{\text{uno}} \frac{|H_{0,k\to j} - S_{0,k\to j}H_{0,0}|^2}{H_{k\to j,k\to j} - H_{0,0}} \tag{8b}$$

$$\Pi = \sum_{i}^{\text{occ}} \sum_{j}^{\text{uno}} \frac{|H_{0,i\to j} - S_{0,i\to j}H_{0,0}|^2}{H_{i\to j,i\to j} - H_{0,0}} + \sum_{k}^{\text{occ}} \sum_{l}^{\text{uno}} \frac{|H_{0,k\to l} - S_{0,k\to l}H_{0,0}|^2}{H_{k\to l,k\to l} - H_{0,0}} \tag{8c}$$

Coulomb and Exchange Interaction Terms. Among the three terms on the right side of Eq. (8), ε_0 is a first order term which arises from the Coulomb and the exchange interaction terms between A and B: it can be calculated easily as:

$$\varepsilon_0 = \varepsilon_Q + \varepsilon_K \tag{9}$$

where the Coulomb interaction energy, ε_Q, is:

$$\varepsilon_Q = 2\sum_i V_{Bii} + 2\sum_k V_{Akk} + 4\sum_i \sum_k (ii|kk) + \sum_\alpha \sum_\beta \frac{Z_\alpha Z_\beta}{R_{\alpha\beta}} \tag{10}$$

and where the exchange interaction energy, ε_K, is:

$$\varepsilon_K = -2\sum_i \sum_k [(ik|ki) + s_{ik}[V_{ik} + \sum_{i'} \{2(ik|i'i') - (ii'|i'k)\} + \sum_{k'} \{2(ik|k'k') - (ik'|k'k)\}]] \tag{11}$$

in which:

$$V_{Bii} = \int a_i(1)V_B(1)a_i(1)\mathrm{d}v(1), \text{ etc.}$$

$$V_{ik} = \int a_i(1)V(1)b_k(1)\mathrm{d}v(1), \text{ etc.}$$

$$(ij|kl) = \int a_i(1)b_k(2)\frac{1}{r_{12}}a_j(1)b_l(2)\mathrm{d}v(1)\mathrm{d}v(2), \text{ etc.}$$

$$s_{ik} = \int a_i(1)b_k(1)\mathrm{d}v(1), \text{ etc.}$$

If we here employ the Mulliken approximation:[26]

$$\int \cdots \int t(1)t'(1)f\cdots \mathrm{d}v(1)\cdots \cong \frac{1}{2}s_{tt'}\left\{\int \cdots \int t(1)t(1)f\cdots \mathrm{d}v(1)\cdots + \int \cdots \int t'(1)t'(1)f\cdots \mathrm{d}v(1)\cdots\right\}$$

we can easily obtain:[27]

$$\varepsilon_Q \cong \sum_t N_{At}v_{Btt} + \sum_u N_{Bu}v_{Auu} + \sum_t \sum_u N_{At}N_{Bu}(tt|uu) + \sum_\alpha \sum_\beta \frac{Z_\alpha Z_\beta}{R_{\alpha\beta}} \tag{12}$$

25) The term "singlet interaction" signifies an interaction of two systems, A and B, with a conservation of the total spin zero. Similarly, "doublet interaction" and "triplet interaction" will later be used in the cases of the interaction of a radical with a molecule or with a radical.

26) R. S. Mulliken, *J. chim. phys.*, **46**, 497 (1949).

27) In the doublet interaction between an even-electron system (A) and an odd-electron system (B), a similar equation is obtained:

$$\varepsilon_Q = 2\sum_i V_{Bii} + 2\sum_k V_{Akk} + V_{Ao'o'} + 4\sum_i \sum_k (ii|kk) + 2\sum_i (ii|o'o') + \sum_\alpha \sum_\beta \frac{Z_\alpha Z_\beta}{R_{\alpha\beta}} \cong \sum_\alpha \sum_\beta \frac{(Z_\alpha - N_\alpha)(Z_\beta - N_\beta)}{R_{\alpha\beta}} \tag{12'}$$

The singlet and the triplet interactions between two odd-electron systems give an analogous relation.

where N_{At} is the population of the tth AO of the isolated system, A, and is given by:

$$N_{At} = 2\sum_{i}^{occ}\sum_{t'} C_t^{(i)}C_{t'}^{(i)}s_{tt'}$$

and:

$$v_{Btt} = \int t(1)V_B(1)t(1)\mathrm{d}v(1) = \sum_{\beta} v_{\beta tt},\ etc.,$$

in which $C_t^{(i)}$ means the coefficient of Eq. (3a) for MO a_i, and in which

$$s_{tt'} = \int t(1)t'(1)\mathrm{d}v(1)$$

$$v_{\beta tt} = -\int t(1)\frac{Z_\beta}{r_{1\beta}}t(1)\mathrm{d}v(1),\ etc.$$

Further approximation which puts

$$v_{\beta tt} \cong -\frac{Z_\beta}{R_{\alpha\beta}}$$

etc., where α denotes the nucleus to which the tth AO belongs, may be possible if the distance between A and B is not very short. This approximation at once gives rise to the succinct expression:

$$\varepsilon_Q \cong \sum_{\alpha}\sum_{\beta}\frac{(Z_\alpha - N_\alpha)(Z_\beta - N_\beta)}{R_{\alpha\beta}} \qquad (13)$$

where N_α is the population of the atom α, that is, it is equal to $\sum_{t}^{(\alpha)} N_{At}$.[28] This equation is very convenient for grasping the meaning of the Coulomb interaction term, since $(Z_\alpha - N_\alpha)$ and $(Z_\beta - N_\beta)$ represent the net plus charge of the atom α of A and of the atom β of B respectively. In neutral nonpolar molecules, therefore, ε_Q is not very important.

The exchange interaction term, ε_K, is almost solely responsible for the multiplet separation. In the ground-state interactions it is usually repulsive except for the singlet interaction of two ground-state odd-electron systems.[29]

The case of single-site overlapping, namely, when overlapping between only one AO (say r) of A and one AO (say r') of B is appreciable, may often be important. This is nearly the case in the aromatic substitution by a reagent with essentially one AO. If VAO's are employed as the basis AO's, the MO overlapping with reagent orbitals becomes single-sited in many cases.

In the case of single-site overlapping, Eq. (11) becomes, by the use of the Mulliken approximation:

$$\varepsilon_K \cong -\frac{1}{8}s_{rr'}{}^2P_{rr}P_{r'r'}[2v_{rr} + 2v_{r'r'} + (rr|rr) + (r'r'|r'r') + 2(rr|r'r') + P_{rr}\{(rr|rr) + (rr|r'r')\} + P_{r'r'}\{(r'r'|r'r') + (rr|r'r')\}] \qquad (14)$$

in which:

$$v_{rr} = v_{Arr} + v_{Brr},\ etc.,$$

$$P_{rr} = 2\sum_{i}^{occ} C_r^{(i)}C_r^{(i)},\ etc.$$

indicating that the exchange interaction varies with the square of the overlap integrals and is, accordingly, less important than the Coulomb interaction at the initial stage of interaction in polar reactions.

Charge-transfer Interaction Term. The second term appearing on the right side of Eq. (8) comes from the electron-delocalization interaction due to the mixing of monotransferred configurations. The calculation of the matrix elements and overlap integrals gives:

$$H_{i\to l,i\to l} - H_{0,0} = -(E_{Bl} + \Delta E_{Bl}) + (I_{Ai} + \Delta I_{Ai}) + a_{il} \qquad (15)$$

in which:[30]

$$E_{Bl} = -[H_{Bll} + \sum_{k}\{2(ll|kk) - (lk|kl)\}]$$

$$I_{Ai} = -[H_{Aii} + \sum_{i'}\{2(ii|i'i') - (ii'|i'i)\}]$$

---

28) If we put $s_{tt'}$'s and $s_{uu'}$'s equal to zero, Eq. (13) becomes identical to the equation obtained by Rein and Pollak (R. Rein and M. Pollak, *J. Chem. Phys.*, **47**, 2039 (1967)). They also assumed $s_{ab}=0$ in obtaining the exchange interaction energy. See also G. Klopman and R. F. Hudson, *Theoret. chim. Acta (Berl.)*, **8**, 165 (1967).

29) In this case

$$\varepsilon_K = -2\sum_i\sum_k[(ik|ki) + s_{ik}[V_{ik} + \sum_{i'}\{2(ik|i'i') - (ii'|i'k)\} + \sum_{k'}\{2(ik|k'k') - (ik'|k'k)\}]] - \sum_i\sum_k s_{ik}[\{2(ik|oo) - (io|ok)\} + \{2(ik|o'o') - (io'|o'k)\}] - \sum_i[(io'|o'i) + s_{io'}[V_{io'} + \sum_{i'}\{2(io'|i'i') - (ii'|i'o')\} + \sum_k\{2(io'|kk) - (ik|ko')\} + (io'|oo) + (io|oo')]] - \sum_k[(ok|ko) + s_{ok}[V_{ok} + \sum_i\{2(ok|ii) - (oi|ik)\} + \sum_{k'}\{2(ok|k'k') - (ok'|k'k)\} + (ok|o'o') + (oo'|o'k)]] + \delta_{oo'}$$

where:

$$\delta_{oo'} = (oo'|o'o) + s_{oo'}[V_{oo'} + \sum_i\{2(oo'|ii) - (oi|io')\} + \sum_k\{2(oo'|kk) - (ok|ko')\}]$$

Since the magnitude of ε_K is essentially determined by the orbital overlapping between the two systems, the attractive term, $\delta_{oo'}$, is in this case dominant, as is the case of hydrogen molecule formation from two hydrogen atoms.

30) The terms of the s_{ab} $(cd|ef)$ type are omitted in order to avoid intricacy of expression in the subsequent equations, where a, b,··· denote MO's. These are obtainable in a manner similar to that of 29). The terms of $s_{ab}{}^2$ are all neglected.

$$\Delta E_{Bl} = -\{V_{All} + 2\sum_{i'}(ll|i'i')\} + \sum_{i'}\{V_{li'}s_{li'} + (li'|i'l)\}$$

$$\Delta I_{Ai} = -\{V_{Bii} + 2\sum_{k}(ii|kk)\} + \sum_{k}\{V_{ik}s_{ik} + (ik|ki)\}$$

$$a_{il} = -(ii|ll) + 2\{V_{il}s_{il} + (il|li)\}$$

$$H_{Aii} = \int a_i(1)H_A(1)a_i(1)\mathrm{d}v(1), \text{ etc.}$$

$$H_A(\lambda) = -\frac{1}{2}\Delta(\lambda) + V_A(\lambda), \text{ etc.}$$

and:

$$H_{0,i\to l} - S_{0,i\to l}H_{0,0} = \sqrt{2}\,[Q_{il} + K_{il}] \quad (16)^{31}$$

where

$$Q_{il} = \{V_{Bil} + 2\sum_{k}(il|kk)\} - s_{il}\{V_{Bii} + 2\sum_{k}(ii|kk)\}$$

is the Coulomb interaction part, and where

$$K_{il} = -\sum_{k}\{(ik|kl) - s_{il}(ik|ki)\}$$

is the exchange interaction part.

The Koopmans theorem[32] makes a possible physical interpretation of the quantities in Eq. (15). The quantity I_{Ai} is the vertical ionization potential, with no rearrangement of the nuclear configuration, of the isolated system A with respect to the electron in the ith MO; similarly, E_{Bl} is the vertical "electron affinity"[33] of the isolated system B with respect to the lth MO, while ΔI_{Ai} is the change in I_{Ai} due to the approach of the system B, and ΔE_{Bl} is the change in E_{Bl} due to the approach of the system A. With regard to a_{il}, the following relations hold:

$$a_{il} = I_{Ai}^{(B+l)} - I_{Ai}^{(B)} = E_{Bl}^{(A)} - E_{Bl}^{(A-i)}$$

where:

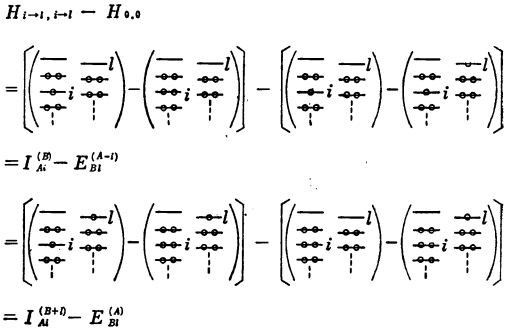
$$I_{Ai}^{(B)} = I_{Ai} + \Delta I_{Ai}$$
$$E_{Bl}^{(A)} = E_{Bl} + \Delta E_{Bl}$$

where $I_{Ai}^{(B+l)}$ is the value of I_{Ai} in the case of the approach of the system B with an additional electron occupying the lth unoccupied MO, and where $E_{Bl}^{(A-i)}$ is the value of E_{Bl} in the case of the approach of the system A in which one electron occupying the ith MO is subtracted.

Then, we derive the useful equation:

$$H_{i\to l,i\to l} - H_{0,0} = I_{Ai}^{(B)} - E_{Bl}^{(A-i)} = I_{Ai}^{(B+l)} - E_{Bl}^{(A)} \quad (17)$$

which shows that this quantity is not simply written as $(I_{Ai}-E_{Bl})$. As a matter of fact, Eq. (17) is self-evident, as is directly elucidated by the following diagram:



Relations of such a kind are completely general in character (*cf.* Eq. (21)).

Equation (16) indicates that the numerator of each term on the right side of Eq. (8b) consists of two parts, the Coulomb interaction part and the exchange interaction part. Since the latter is small compared with the former except in a perfectly nonpolar case, we will consider only the case in which the exchange part can be neglected.

The approximation of *multiple-site overlapping*, in which the paired AO's are denoted by the r of A and the r' of B, leads to the expression:

$$H_{0,i\to l} - S_{0,i\to l}H_{0,0} \cong \sqrt{2}\sum_{r} C_r^{(i)}C_{r'}^{(l)}\gamma_{rr'}^{(i)} \quad (18)$$

where:

$$\gamma_{rr'}^{(i)} \cong s_{rr'}\left[\frac{1}{2}(v_{Brr} + v_{Br'r'}) + \frac{1}{2}\sum_{u}N_{Bu}\{(rr|uu) + (r'r'|uu)\} + \sum_{\alpha}\sum_{\beta}\frac{n_\alpha^{(ii)}(Z_\beta - N_\beta)}{R_{\alpha\beta}}\right] \quad (19)$$

in which:

$$n_\alpha^{(ii)} = \sum_{t}^{(\alpha)}\sum_{t'}C_t^{(i)}C_{t'}^{(i)}s_{tt'}$$

Eq. (19) indicates a linear relationship of the right side of Eq. (16) with orbital overlapping. Equation (19) can also be written:

$$\gamma_{rr'}^{(i)} \cong -\int r(1)\left(\sum_{\beta}\frac{Z_\beta - N_\beta}{r_{1\beta}}\right)r'(1)\mathrm{d}v(1) + s_{rr'}\sum_{\alpha}\sum_{\beta}\frac{n_\alpha^{(ii)}(Z_\beta - N_\beta)}{R_{\alpha\beta}} \quad (19')$$

which shows the remarkable characteristic that the charge-transfer interaction is large with the local net

31) To derive this equation, it must be remembered that the MO's are assumed to satisfy the Fock equation for the isolated system.

32) T. Koopmans, *Physica*, **1**, 104 (1933).

33) With respect to the physical significance of the energy level of a Fock-Roothaan unoccupied MO, one should in any event be cautious. To connect E_{Bl} with any experimental value, it is recommended that one adopts an extended-basis set of AO's in the Roothaan LCAO. This point will be discussed in a subsequent paper.

charge near the reaction center of the acceptor molecule.

Thus, we can obtain this approximate expression of D:

$$D \cong 2\left\{\sum_{i}^{\text{occ}}\sum_{l}^{\text{uno}} \frac{(\sum_r C_r^{(i)} C_{r'}^{(l)} \gamma_{rr'}^{(i)})^2}{I_{Ai}^{(B)} - E_{Bl}^{(A-i)}} + \sum_{k}^{\text{occ}}\sum_{j}^{\text{uno}} \frac{(\sum_r C_r^{(j)} C_{r'}^{(k)} \gamma_{rr'}^{(k)})^2}{I_{Bk}^{(A)} - E_{Aj}^{(B-k)}}\right\} \quad (20)$$

in which:

$$\gamma_{rr'}^{(k)} \cong -\int r(1)\left(\sum_\alpha \frac{Z_\alpha - N_\alpha}{r_{1\alpha}}\right) r'(1)\mathrm{d}v(1) + s_{rr'}\sum_\alpha\sum_\beta \frac{n_{\alpha\beta}^{(kk)}(Z_\alpha - N_\alpha)}{R_{\alpha\beta}}$$

If we consider the special case of a single-site interaction between the rth AO of the reactant, A, and a reagent, B, assuming that the reagent possesses only one AO (designated as r') and, accordingly, only one MO to be taken into account, and that $C_{r'}^{(l)}\gamma_{rr'}^{(i)}(=\gamma_r)$ and $C_{r'}^{(k)}\gamma_{rr'}^{(k)}(=\gamma_{r'})$ are constant with respect to a given reagent, then it follows that:

$$D \cong \begin{cases} 2\sum_{i}^{\text{occ}} \dfrac{C_r^{(i)2}}{\varepsilon_B - \varepsilon_{Ai}}\gamma_r^2 & \text{when the reagent orbital is unoccupied} \\ 2\sum_{j}^{\text{uno}} \dfrac{C_r^{(j)2}}{\varepsilon_{Aj} - \varepsilon_B}\gamma'^2_r & \text{when the reagent orbital is occupied,} \end{cases} \quad (20')$$

in which:

$$\varepsilon_{Ai} = -I_{Ai}^{(B)}, \quad \varepsilon_{Aj} = -E_{Aj}^{(B-k)}$$

and

$$\varepsilon_B = \begin{cases} -E_B^{(A-i)} & \text{when the reagent orbital is unoccupied} \\ -I_B^{(A)} & \text{when the reagent orbital is occupied} \end{cases}$$

The quantity on the right side of Eq. (20′) is nothing but *superdelocalizability*[13] and *delocalizability*[34] previously defined by one of the present authors in discussing the reactivity of unsaturated and saturated compounds. These relations are useful for estimating the value of the quantities employed in semi-empirical reactivity theories.

The same equations as in Eqs. (17)—(19′) hold in the interaction of an even-electron system and an odd-electron system. In this case, however, Eq. (20) becomes:

$$D \cong 2\left\{\sum_{i}^{\text{occ}}\sum_{l}^{\text{uno}} \frac{(\sum_r C_r^{(i)} C_{r'}^{(l)} \gamma_{rr'}^{(i)})^2}{I_{Ai}^{(B)} - E_{Bl}^{(A-i)}} + \sum_{k}^{\text{occ}}\sum_{j}^{\text{uno}} \frac{(\sum_r C_r^{(j)} C_{r'}^{(k)} \gamma_{rr'}^{(k)})^2}{I_{Bk}^{(A)} - E_{Aj}^{(B-k)}}\right\} + \left\{\sum_{i}^{\text{occ}} \frac{(\sum_r C_r^{(i)} C_{r'}^{(o')} \gamma_{rr'}^{(i)})^2}{I_{Ai}^{(B)} - E_{Bo'}^{(A-i)}} + \sum_{j}^{\text{uno}} \frac{(\sum_r C_r^{(j)} C_{r'}^{(o')} \gamma_{rr'}^{(o')})^2}{I_{Bo'}^{(A)} - E_{Aj}^{(B-o')}}\right\} \quad (21)$$

and, corresponding to Eq. (20′), we obtain:

$$D \cong \sum_{i}^{\text{occ}} \frac{C_r^{(i)2}}{\varepsilon_B - \varepsilon_{Ai}}\gamma_r^2 + \sum_{j}^{\text{uno}} \frac{C_r^{(j)2}}{\varepsilon_{Aj} - \varepsilon_{B'}}\gamma_{r'}^2 \quad (21')$$

in which ε_B is equal to $(-E_{Bo'}^{(A-i)}$ and $\varepsilon_{B'}$ is equal to $(-I_{Bo'}^{(A)})$. This equation is similar to the form of superdelocalizability and that of delocalizability for this case of interaction. It is noteworthy that, even in the interaction of a neutral molecule with a neutral radical, the local charge of atoms determines the magnitude of D.[35]

Polarization Term. The third interaction term corresponds to the polarization due to the mutual approach of A and B. The necessary matrix elements to calculate are as follows:

$$H_{i\to j, i\to j} - H_{0,0} = I_{A+j,i}^{(B)} - E_{Aj}^{(B)} = I_{Ai}^{(B)} - E_{A-i,j}^{(B)} \quad (22)$$

where $I_{A+j,i}^{(B)}$ is the ionization potential of an electron of the ith MO of the system A, with one additional electron occupying the jth MO, in the approach of the system B, and $E_{A-i,j}^{(B)}$ is the electron affinity with respect to the jth unoccupied MO of the system A, with one electron of the ith MO subtracted, in the approach of the system B. Moreover,

$$H_{0,i\to j} - S_{0,i\to j}H_{0,0} = \sqrt{2}[V_{Bij} + 2\sum_k (ij|kk)] + O(s_{ab}^2) \quad (23)$$

This reduces, by the aid of the Mulliken approximation, to:

$$H_{0,i\to j} - S_{0,i\to j}H_{0,0} \cong -\sqrt{2}\zeta_{AB}^{(ij)} \quad (23')$$

in which:

$$\zeta_{AB}^{(ij)} = \sum_\alpha\sum_\beta \frac{n_\alpha^{(ij)} + n_\alpha^{(ji)}}{2} \cdot \frac{Z_\beta - N_\beta}{R_{\alpha\beta}} \quad (24)$$

where:

$$n_\alpha^{(ij)} = \sum_t^{(\alpha)}\sum_{t'} C_t^{(i)} C_{t'}^{(j)} s_{tt'}$$

The case of a single-site interaction between the atom α of A and the atom β of B is taken for the

34) K. Fukui, H. Kato and T. Yonezawa, This Bulletin, **34**, 1111 (1961).

35) This fact does not imply that the term D is not important in the radical interaction of a molecule. One must note that a majority of radicals involve a polar character, so the Coulomb interaction part of Eq. (16) still remains important.

sake of simplicity, in which the overlap integrals are neglected. This is a case of aromatic substitution in which only the 2 pπ AO's are taken into account. Then, we have:

$$\zeta_{AB}^{(ij)} \cong C_r^{(i)} C_r^{(j)} \frac{Z_\beta - N_\beta}{R_{r\beta}} \tag{24'}$$

which is proportional to the net charge of the atom β of the system B. This equation is useful for understanding the physical meaning of Eq. (23). The approximate formula of Π can be obtained by using Eq. (23'):

$$\Pi \cong 2\left\{ \sum_i^{\text{occ}} \sum_j^{\text{uno}} \frac{(\zeta_{AB}^{(ij)})^2}{I_{Ai}^{(B)} - E_{A-i,j}^{(B)}} + \sum_k^{\text{occ}} \sum_l^{\text{uno}} \frac{(\zeta_{BA}^{(kl)})^2}{I_{Bk}^{(A)} - E_{B-k,l}^{(A)}} \right\} \tag{25}$$

If we consider that the quantity $(Z_\beta - N_\beta)/R_{r\beta}$ in Eq. (24') for a definite distance of approach is consant with regard to a given reagent, B, and denote it by δ_r, we obtain as the first half of Π:

$$\Pi \sim \frac{1}{2} \pi_{Arr} (\delta_r)^2$$

in which:

$$\pi_{Arr} = 4 \sum_i^{\text{occ}} \sum_j^{\text{uno}} \frac{C_r^{(i)2} C_r^{(j)2}}{\varepsilon_{Aj} - \varepsilon_{Ai}} \overline{\beta} \tag{26}$$

($\varepsilon_{Aj} = -E_{A-i,j}^{(B)}$, $\varepsilon_{Ai} = -I_{Ai}^{(B)}$; $\overline{\beta}$ is an appropriately-chosen energy unit)

is of the same form as the well-known *self-atom polarizability* defined by Coulson and Longuet-Higgins in discussing the property of conjugated molecules.[8a]

In this way, it has been demonstrated that the generalized scale of reactivity for an interaction between two chemical systems breaks up into the Coulomb interaction term of the atomic charge, the exchange interaction term, the delocalizability term, and the polarizability term. In some chemical reactions, some of these terms may be less important than the others. As has been discussed earlier, the polarizability term is usually less important than the delocalizability term in ionic reactions, and the exchange interaction term is not important except in special cases. In a case in which one of the charge-transfer configurations possesses nearly the same energy as the initial one, the corresponding term becomes particularly important, whereas none of excited configurations can be important since none of them can possess the same energy as the initial one. The Coulomb interaction of the atomic charge is appreciable in a long-range interaction, but it will become less and less important as the reaction proceeds and as an appreciable amount of charge is transferred from the donor to the acceptor, which thus " neutralize " each other.

The nuclear configuration change which is caused by the interaction described above and which is left out of account in the present paper will be discussed in a forth coming paper with reference to the general features of the chemical reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1998—2004 (1968)

Electronic Properties of Some Complexes of Tetracyanoquinodimethan with Aromatic Diamines

Masatake OHMASA, Minoru KINOSHITA, Mizuka SANO and Hideo AKAMATU

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Tokyo

(Received February 23, 1968)

Complexes of tetracyanoquinodimethan have been prepared with a number of aromatic diamines which are varied in their molecular shape and ionization potential. Infrared absorption spectra have revealed most of the complexes to be ionic in character. They showed a strong ESR absorption; in regard to its temperature dependence, however, three modes of variation were observed for these solid complexes. The complexes with *N,N'*-diphenyl-*p*-phenylenediamine and *N,N'*-di-β-naphthyl-*p*-phenylenediamine were considered to be of non-bonding type and showed no ESR absorption. However, no appreciable difference in semiconductive properties has been found between the ionic type and the non-bonding type complexes, except the complex of diaminodurene-TCNQ (1 : 2). The latter showed a high electrical conductivity and a paramagnetic behavior which was nearly independent of temperature.

In recent years, Weiss' idea[1] that some organic molecular complexes are ionic in their ground state has been proved by studies of their visible[2] and infrared[3,4] absorption spectra. Usually, as expected, such ionic complexes are formed by an electron transfer from a good electron-donor to a good electron-acceptor, provided that the resulting ion radicals are sufficiently stable.

Although these ion radicals are themselves paramagnetic, it is of interest to see how their paramagnetism is modified upon aggregation. This was studied by Kainer *et al.*[5-8] in 1950's for the complexes formed between aromatic diamines and halogenated benzoquinones. They discussed three possible modes of variation of the paramagnetism with temperature. One is a normal magnetic behavior of Curie type, and others are paramagnetism controlled by thermal equilibration between magnetic and non-magnetic states.

Most complexes studied by Kainer *et al.*[5-8] showed the paramagnetism of Curie type in their temperature range. In these years, however, the complexes of *p*-chloranil with diaminodurene[9] and *p*-phenylenediamine,[10,11] and the complexes of iodine with perylene,[12] pyrene[12] and benzidine[11] have been shown to be of the other type having a magnetic state at thermally accessible position. We have also found a similar magnetic property with the complex obtained from *N,N,N',N'*-tetrametyl-*p*-phenylenediamine and 7,7,8,8-tetracyano-*p*-quinodimethan (TCNQ).[13]

Our study has been extended to a number of complexes based on TCNQ as an acceptor, using various aromatic diamines as a donor. Tetracyanoquinodimethan is known to possess a marked acceptor ability, and furthermore, it shows remarkable stability in its anion radical form, which is an important property suited to our systematic study. The complexes studied are tabulated in Table 1, in which the corresponding abbreviations are also given.

Experimental

Chemicals. 7,7,8,8-Tetracyano-*p*-quinodimethan was synthesized from 1,4-cyclohexanedione by the method described by Acker and Hertler,[14] and purified by recrystallization from acetonitrile. Diaminodurene was synthesized from durene by nitration followed by reduction, and purified by sublimation in a vacuum. Other aromatic amines were obtained from commercial sources,

	(400)	(200)[b]			
DNPD·TCNQ	319	26000	3300	1 : 0.82	1 : 1

a) The concentration of TCNQ was first determined from the absorbance at 400 mμ; its extinction coefficient at 400 mμ was taken to be 67600 *l*/mol·cm.
b) The contribution at 400 mμ was neglected in determining the TCNQ concentration.

and used after purification by recrystallization, sublimation or distillation under a reduced pressure. All solvents used for complex formation were commercial ones, and were used without further purification.

Complex Preparation *p*-PD·TCNQ. Deep purple polycrystals were obtained by mixing a solution of 25 mg of TCNQ in 60 m*l* of chloroform with a solution of 14 mg of *p*-phenylenediamine in 20 m*l* of chloroform at room temperature.

TMPD·TCNQ. To a saturated solution of Würster's blue perchlorate in methanol was added a saturated solution of lithium salt of TCNQ in methanol at room temperature, and dark green crystals thus formed were collected.

DAD·TCNQ (1:2). To a solution of 95 mg of diaminodurene in 70 m*l* of ethanol was introduced hydrogen iodide and then added 150 m*l* of diethyl ether. White precipitate was obtained. To a solution of 101 mg of the precipitate in 25 m*l* of ethanol was added a solution of 102 mg of TCNQ in 150 m*l* of chloroform, and the mixture was allowed to stand overnight at room temperature. Black rod crystals were obtained.

Other complexes were prepared from neutral components in a similar manner to that adopted in the preparation of *p*-PD·TCNQ. Solvents used are given in Table 1. In some cases, a complex was prepared under a nitrogen atmosphere and sealed into a sample tube without being exposed to air. Its ESR absorption was found to be identical, in every way, with that of the corresponding complex prepared in air.

Visible Absorption Measurement. To determine composition of a complex, visible absorption spectrum was examined for a dilute solution of the complex in dichloromethane, in which the complex dissociated into components of their neutral form. Their extinction coefficients at the relevant wavelengths were determined separately, as shown in Table 2. Using these values, the composition of a complex was estimated from the observed absorption spectra. In some cases, an elementary analysis was also adopted for comparison.

Infrared Absorption Measurement. Absorption spectra in the infrared region were measured using the method of Nujol mulls to determine whether the complexes were ionic or not. Lithium salt of TCNQ and bromide of the amines, as well as neutral TCNQ and amines, were used as references.

ESR Absorption Measurement. Electron spin resonance (ESR) measurements were made with a Hitachi X-band spectrometer. To control temperature, nitrogen gas at various temperatures was introduced into a cavity through a quartz dewar and blown toward a sample tube. The temperature was measured by means of a thermocouple attached to a sample. The relative spin concentrations at various temperatures were obtained by integration of derivative curves recorded. The absolute number of spins was determined at room temperature by comparing the integrated absorption intensity of a sample with that of a standard specimen

of 1,1-diphenyl-2-picrylhydrazyl, which was calibrated by a static susceptibility measurement.

Electrical Resistivity. Electrical resistivity of a complex was measured in a form of compressed pellet by a DC-method.

Results and Discussion

Composition of the Complexes. Chemical composition (donor to acceptor ratio) obtained from an analysis of visible absorption spectra is given in Table 2. To a molecular complex, however, it is quite reasonable to assume the stoichiometric ratio as is given in the last column of Table 2. The composition of the complex of DEPD·TCNQ was found to be 2 : 3. The ratio was different from the one determined by Melby *et al.*[15] They have given the ratio of 1 : 2 to the complex obtained in the same manner on the basis of an elementary analysis. An elementary analysis, however, was not sensitive enough to distinguish the ratios in question. We thus tentatively adopted the ratio of 2 : 3.

Characterization of the Complexes. Recently, Matsunaga[4] has shown that infrared absorption spectra can be used successfully in characterization of charge transfer complexes of halogenated *p*-benzoquinones. This method is also applicable to TCNQ complexes. The key band in the latter case is that of the C≡N stretching vibration located around 2200 cm^{-1}. For neutral TCNQ, the band is located at 2223 cm^{-1}, and it shifts to 2203 cm^{-1} and becomes somewhat broadened for a typical ion radical salt of TCNQ with lithium.*1

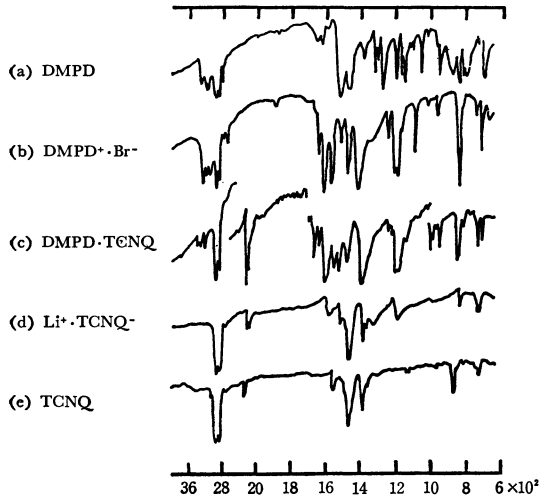

Fig. 1. Infrared absorption spectrum of the complex of DMPD·TCNQ is compared with that of related compounds; (a) DMPD, (b) its bromide, (c) the complex, (d) Li^+TCNQ^- and (e) TCNQ.

15) L. R. Melby, R. J. Harder, W. R. Hertler, W. Mahler, R. E. Benson and W. E. Mochel, *J. Am. Chem. Soc.*, **84**, 3374 (1962).

In Fig. 1 are shown,*2 as an example, the infrared absorption spectra of DMPD, its bromide, DMPD·TCNQ, lithium salt of TCNQ, and TCNQ. The C≡N stretching band is broadened and shifted to 2200 cm^{-1} for the complex. These features are identical to those of lithium salt of TCNQ, and suggest the complex is primarily ionic in its ground state. Further supports are obtained from a comparison of the spectra in Fig. 1. For instance, the C-N stretching vibration band at 1275 cm^{-1} in DMPD disappears and, instead, a new band appears at 1385 cm^{-1} by the formation of the complex. The latter band is considered to correspond to that of the bromide at 1410 cm^{-1}. It is thus concluded that the complex of DMPD·TCNQ is of ionic type.

In a similar way, the complexes of *p*-PD·TCNQ, and DAD·TCNQ (1 : 1) were characterized as essentially of ionic type. The complex of TMPD·TCNQ was also shown to be ionic.[18] In these complexes, therefore, both donor and acceptor are considered to exist as paramagnetic ion radicals. The complex of *o*-PD·TCNQ (2 : 1) belongs almost certainly to this group because of an observed shift and broadening in the C≡N stretching vibration band, but we are not certain about the structure of the amine part.

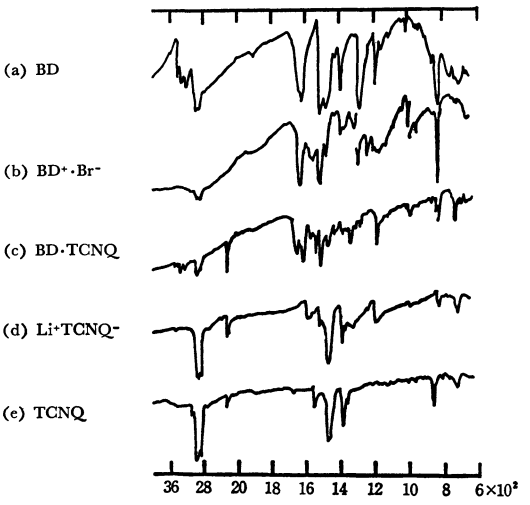

Fig. 2. Infrared absorption spectra of (a) BD, (b) its bromide, (c) the complex of BD·TCNQ, (d) Li^+TCNQ^- and (e) TCNQ.

On the other hand, the infrared absorption spectra of DNPD·TCNQ and DϕPD·TCNQ were found to be quite in accord with a superposition of spectra of neutral components. These complexes are thus

*1 Actually, the band consists of three lines at 2171, 2189 and 2203 cm^{-1} for the anion radical salt. The absorption at 2203 cm^{-1} is the most intense one.

*2 Note that the absorption bands due to Nujol are not deleted from the spectra in Figs. 1, 2 and 3.

considered to be of non-bonding type. The complex of BD·TCNQ may also fall into this group, for which the C≡N stretching vibration band was found to be sharp and located closely to that of neutral TCNQ. As is compared in Fig. 2, however, the entire spectrum of this complex is not explained either by a superposition of ionic components or by a superposition of neutral components. At this moment, therefore, we are not conclusive, but we are of opinion that the complex may also be of non-bonding type.

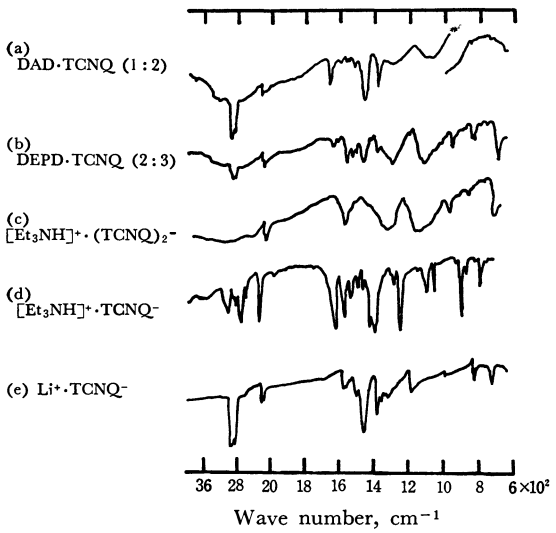

Fig. 3. Infrared absorption spectra of (a) DAD·TCNQ (1 : 2), (b) DEPD·TCNQ (2 : 3), (c) $[Et_3NH]^+(TCNQ)_2^-$, (d) $[Et_3NH]^+(TCNQ)^-$ and (e) Li^+TCNQ^-.

The infrared absorption spectra of DAD·TCNQ (1 : 2) and DEPD·TCNQ (2 : 3) are shown in Fig. 3, together with those of $[Et_3NH]^+(TCNQ)_2^-$, $[Et_3NH]^+(TCNQ)^-$ and lithium salt of TCNQ. In these complexes, it was found that the key band around 2200 cm^{-1} was broadened, and that two new broad absorptions appeared at 1100 and 1300 cm^{-1}. These features are quite in accordance with the spectrum of $[Et_3NH]^+(TCNQ)_2^-$.[15] Therefore, the TCNQ part of the complexes was considered to possess a similar character to that of the latter salt. The amine part of DAD·TCNQ (1 : 2) and the 1 : 2 complex of DEPD·TCNQ, on the other hand, has been assigned to an onium type cation by Melby *et al.*[15] This is very likely for the complex of DAD·TCNQ (1 : 2) because of its preparation procedure. From an infrared absorption, we could not determine whether the amine part in our 2 : 3 complex of DEPD·TCNQ takes an onium form or a positive ion radical form. When it was dissolved in acetonitrile, the complex showed a visible absorption spectrum characteristic of a positive ion radical of Würster's blue type. We thus concluded that DEPD exists as an ion radical form in the complex.

Magnetic and Electrical Properties. The magnetic and electrical properties observed for the complexes are summarized in Table 3, in which the complexes are divided into four groups, A, B, C and D for convenience, according to differences observed in the temperature dependence of ESR absorption intensities. The complexes in group A show a rapid intensity drop with the decrease in temperature, while the complex in group B shows a very slow descent. Group C includes the complexes for which the paramagnetism is of Curie type, and group D stands for the complexes of no ESR absorption.

The complexes of *p*-PD·TCNQ, DMPD·TCNQ, DAD·TCNQ (1 : 1) and *o*-PD·TCNQ (2 : 1), as well as TMPD·TCNQ,[13] fall into group A. The intensity-temperature curves are shown in Figs. 4 and 5. A common feature of this group is that the ESR absorption loses its intensity rather sharply in the higher temperature region when the temperature is lowered. In the lower temperature region, however, these complexes behave differently. For *p*-PD·TCNQ and TMPD·TCNQ, the intensity reaches to its minimum and then increases as the

Table 3. Magnetic and electrical properties of the complexes

Complex	Spin concentration[a]	J (eV)	$\rho_{15°C}$, Ω·cm	E (eV)	Type
p-PD·TCNQ	3×10^{22}	0.15	4.2×10^{3}	0.17	A
DMPD·TCNQ	3×10^{22}	0.21	4.0×10^{7}	0.48	A
TMPD·TCNQ	2×10^{23}	0.08	6.8×10^{5}	0.36	A
o-PD·TCNQ (2 : 1)	7×10^{21}	0.07	1.4×10^{7}	0.45	A
DAD·TCNQ (1 : 1)	1×10^{22}	0.13	1.5×10^{6}	0.27	A
DAD·TCNQ (1 : 2)	3×10^{23}	—[b]	1.5×10^{1}	0.04	B
DEPD·TCNQ (2 : 3)	8×10^{23}	0	3.3×10^{3}	0.08	C
BD·TCNQ	5×10^{21}	0	5.1×10^{3}	0.08	C
DϕPD·TCNQ	No signal	—	4.9×10^{5}	0.33	D
DNPD·TCNQ	No signal	—	6.7×10^{7}	0.67	D

a) Number of spins per one mole of a complex at room temperature, 296°K.
b) Slight change in intensity; about 20% decrease from 300 to 120°K.

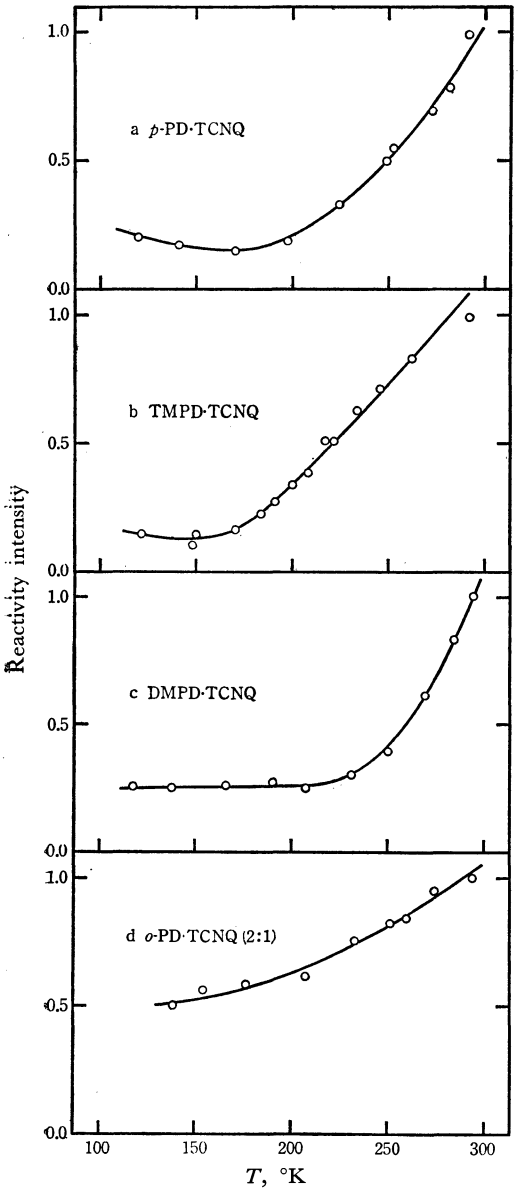

Fig. 4. Relative ESR absorption intensities of the complexes of (a) *p*-PD·TCNQ, (b) TMPD·TCNQ, (c) DMPD·TCNQ and (d) *o*-PD·TCNQ (2 : 1) are plotted against temperature. The intensities are arbitrarily normalized to unity at room temperature.

temperature decreases, while the other complexes show no minimum and their intensity traces a plateau. For these complexes, the ESR absorption intensity I in the higher temperature region was analysed by an equation

$$I = C\exp(-J/kT)/T$$

where C is a constant and J is an activation energy for generation of a magnetic state. A plot of $\ln(IT)$ *vs.* $1/T$ yielded a straight line, whence the J-values

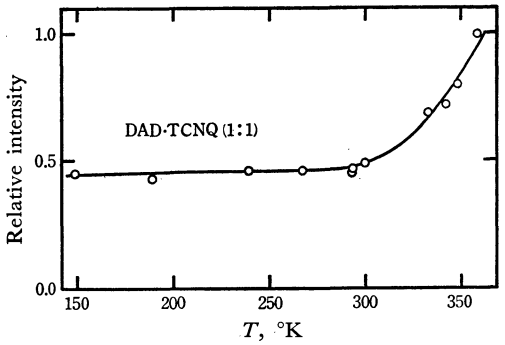

Fig. 5. Plot of relative ESR absorption intensities as a function of temperature for complex of DAD·TCNQ (1 : 1).

in Table 3 were obtained.*3

For the complex of DAD·TCNQ (1 : 1), there was only a slight decrease in its ESR absorption intensity below room temperature. As shown in Fig. 5, however, we observed a sharp increase in intensity when the temperature was raised above room temperature. This change was found to be completely reversible, and the J-value listed was determined from this part of temperature dependence.

Other ESR behaviors of the complexes in group A are more or less identical with each other. The line width was found to change with temperature with a single exception of *p*-PD·TCNQ. The line width was, in general, very sharp at room temperature, but it was broadened by factors of 2—5 by lowering the temperature. The complex of *p*-PD·TCNQ showed virtually no broadening effect over the whole temperature range. The absorption for the complexes of DAD·TCNQ (1 : 1), *o*-PD·TCNQ (2 : 1) and DMPD·TCNQ consisted of a single line, while the other complexes showed a structure characteristic of *g*-factor anisotropy. The line shape was not affected by an introduction of air for all complexes in group A.

It should be noted that the spin concentrations at room temperature are not consistent with the order of the J-values. Higher concentration may be expected for a complex with smaller J-value. The complex of *o*-PD·TCNQ (2 : 1) is of the smallest J-value, but it has the lowest concentration.

Electrical resistivity of these complexes was found to be rather high at room temperature compared to that of groups B and C. The activation energy E for electrical conduction in the equation of $\sigma = \sigma_0 \exp(-E/kT)$ was also relatively large, and always larger than that for spin excitation (J). For the complex of *p*-PD·TCNQ, however, both activation energies were found to be virtually coincident within

*3 A correction was made for the intensities in the higher temperature region of the complexes, *p*-PD·TCNQ and TMPD·TCNQ, by subtracting the intensities obtained by an extrapolation from the lower temperature side to the high temperature side.

a range of experimental accuracy, which would have some significance in a sense that a similar observation[12] was reported for the complexes of iodine with perylene and pyrene. In the latter complexes, the parallelism in both activation energies has strongly supported a prediction that conduction electrons (or holes) are responsible for the observed paramagnetism. However, it seems rather hasty to draw the same conclusion for the complex of *p*-PD·TCNQ by reason of the general tendency of $E > J$ in this group of complexes.

Group B consists of only one member, DAD·TCNQ (1 : 2). It should be, however, noted that this salt is different structurally from other complexes studied here. It has, as shown in Fig. 6, a

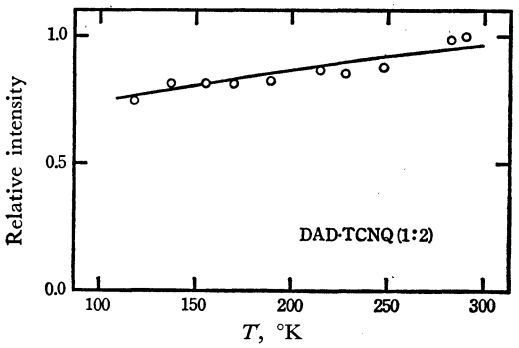

Fig. 6. Temperature dependence of relative ESR absorption intensities for DAD·TCNQ (1 : 2).

unique paramagnetism similar to that found with the salts of (quinolinium)$^+$(TCNQ)$_2^-$ type.[16,17] The intensity-temperature curve was very similar to that of the lower temperature portion of DAD·TCNQ (1 : 1). To check the behavior at higher temperatures, we raised the temperature above room temperature, but we could not observe any steep rise of its ESR absorption intensity. Furthermore, in contrast to the complexes in group A, the absorption width was found to be very sensitive to air. In a vacuum, it gave a sharp absorption with a structure due to *g*-factor anisotropy. An introduction of air caused a remarkable broadening in the width and the structure was smeared out. The effect of air on line width is given in Table 4.

Table 4. Effect of air on the ESR absorption line width

Complex	Line width* (in gauss)	
	in a vacuum	in air
DAD·TCNQ (1 : 2)	1.4_4	2.2_7
BD·TCNQ	1.1_4	3.1_2

* The line width was measured at the half height of an integrated absorption curve.

16) R. G. Kepler, P. E. Bierstedt and R. E. Merrifield, *Phys. Rev. Letters*, **5**, 503 (1960).
17) R. G. Kepler, *J. Chem. Phys.*, **39**, 3528 (1963).

The electrical resistivity of DAD·TCNQ (1 : 2) was found to be very low and the activation energy was also small. These are again a similar feature of the salt of quinolinium-TCNQ type.[16,18] The ESR line shape of DAD·TCNQ (1 : 2) was sometimes distorted by skin-effect because of its low resistivity. Therefore, a possibility that the observed ESR absorption is due to conduction electrons may be considered. In the case of the salt of (quinolinium)$^+$(TCNQ)$_2^-$, the magnetic susceptibility-temperature curve has been interpreted in terms of conduction electrons.[19]

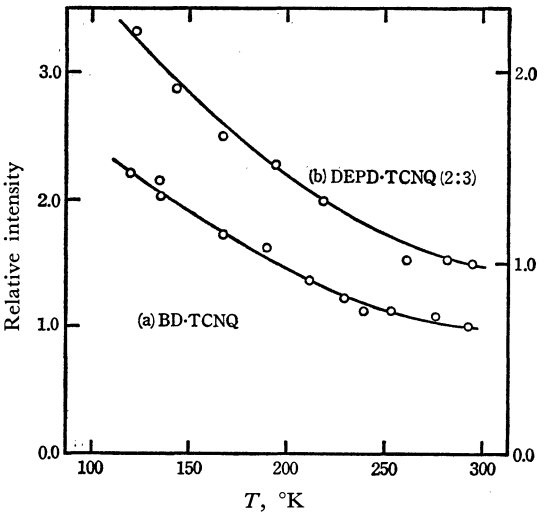

Fig. 7. The variations of ESR absorption intensities with temperature are illustrated in relative units for the complexes of (a) BD·TCNQ and (b) DEPD·TCNQ (2 : 3). The scale for (a) is shown on left, while for (b) on right. The actural intensity for (a) is smaller by a factor of about 10^2 than that for (b) at room temperature (see Table 3).

There are two complexes, DEPD·TCNQ (2 : 3) and BD·TCNQ, in group C. These complexes exhibited Curie type paramagnetism, as shown in Fig. 7, and they showed relatively low electrical resistivity and small activation energy. However, other properties of these complexes were found to differ remarkably from one another. The spin concentration of DEPD·TCNQ (2 : 3) was very high. The absorption line shape was not varied either by temperature or by air. On the other hand, the spin concentration of BD·TCNQ was found to be very low; indeed, there was only one unpaired electron over about 100 donor-acceptor pairs. The ESR absorption line shape and width of BD·TCNQ were found to be sensitive to air, whereas there was no temperature effect on them.

19) T. Kondow, K. Siratori and H. Inokuchi, *J. Phys. Soc. Japan*, **23**, 98 (1967).

A change of line width by air is indicated in Table 4.

A low spin concentration in the complex of BD·TCNQ suggests its non-bonding character, because, in complexes of non-bonding type, the spin concentration is usually very low and the ESR absorption intensity varies, in most cases, following Curie law. However, a relatively high conductivity and a small activation energy of BD·TCNQ suggest some difference in property from those of usual weak complexes. These features seem to be correlated to a difficulty found in characterizing the complex by the infrared absorption spectrum.

The complexes DφPD·TCNQ and DNPD·TCNQ were found to be diamagnetic and classified under group D. The diamagnetism is consistent with the results in their infrared absorption spectra.

Conclusion

The complexes studied are found to show a variety of properties, magnetically, electrically and optically, even though they are formed between chemically resembling donors and the same acceptor. An ionization potential of a donor, for example, is not a determining factor of a complex character by itself. To gauge the ionization potential of these donors, we used wavelengths of absorption maxima of charge-transfer bands for the complexes of *p*-bromanil with the amines in carbon tetrachloride.*4 The results are given in Table 5. The donors fall into two groups; most donors have the maxima in the range of 900—970 mμ, and only three donors have the maxima in 620—670 mμ. However, in the former group, for which the ionization potential is lower than that for the latter, the donors which give rise to a complex of non-bonding type are included, as well as those giving rise to an ionic complex. The donors in the latter group give also an ionic complex, although their ionization potentials are higher than those of DφPD and DNPD. Within our experimental range, therefore, it is concluded that a character, dative or non-bonding, of a complex with a particular acceptor is determined by a conflict between ionization potential of a donor and its steric factors. This can be easily seen in a comparison between a character of TMPD·TCNQ or *p*-PD·TCNQ and that of DφPD·TCNQ or DNPD·TCNQ.

Table 5. Charge transfer absorption maxima of the complexes of *p*-bromanil with the amines in carbon tetrachloride, as an indication of the ionization potentials

Donor	Absorption maximum
p-PD	672 mμ
DMPD	908
DEPD	950
TMPD	918
DAD	973
o-PD	646
BD	624
DφPD	942 (453)[a]
DNPD	931 (485)[a]

a) There are two charge transfer absorption bands for the complex.

*4 Since the complexes of TCNQ with some of the amines are scarcely soluble in a less polar solvent and since they dissociate into ions in a polar solvent, it is very difficult to observe a charge-transfer band of the TCNQ complexes itself.

Once an ionic character is obtained for a complex, its magnetic behavior is dominated by an electronic interaction between the unpaired electrons on donor and acceptor ion radicals. If there is no interaction, the complex will show the paramagnetism of the Curie type. However, an appreciable amount of interaction may result, as discussed by Kainer *et al.*,[8] in the paramagnetism of the other type. For such an interaction, charge-transfer stabilization of the non-magnetic ground state has been suggested to explain a somewhat large activation energy for spin excitation.[20,21]

All the ionic charge-transfer complexes studied except DEPD·TCNQ (2 : 3) exhibit the latter type of paramagnetism.*5 Therefore, the paramagnetic behavior of type in group A seems very common to the ionic complexes. In the case of DEPD·TCNQ (2 : 3), the interaction is, in our opinion, hindered by the large substituents and possibly by its anomalous composition.

Finally, it could be mentioned that the ESR behaviors of the complexes in group A are consistent, at least qualitatively, with a prediction for the ESR absorption of Wannier spin excitons.[22] The crystal structure of the 1 : 1 complexes in group A is very well considered to be similar to that of the complex of TMPD·TCNQ. In the latter complex, the donor and acceptor ions are stacked alternately and equidistantly in a face-to-face manner forming a linear chain.[23] For such a structure, it has been predicted that spin excitation produces Wannier type spin excitons, which are observable in ESR. The line width of the ESR absorption for Wannier type excitons is suggested to be approximately independent of temperature.[22]

The line width for *p*-PD·TCNQ did not change with temperature, and our attempts to observe any fine-structure and $\Delta m = \pm 2$ transition have failed for the complexes in group A. These observations may suggest the possibility of Wannier spin excitons in these solid complexes.

Hydrogen Produced by the Hot-Atom-Process in the Radiolysis of Ethane

Masao INOUE, Taiko UNO, Shin SATO and Shoji SHIDA

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 29, 1968)

The mechanism of the formation of " molecular " hydrogen in the ethane radiolysis at 300 Torr has been studied with ethane-ethane-d_6-ethylene mixtures. The *G*-value of the hydrogen has been found to be 3.3. The addition of electron and positive ion scavengers scarcely affected the formation of the hydrogen at all. From the isotopic composition of the hydrogen, it was demonstrated that most of the hydrogen is formed by molecular detachment from the ethane molecule, while the rest is formed by the abstraction of a hydrogen atom from the ethane molecule by a hot hydrogen atom, the *G*-value being estimated to be 0.6.

Hydrogen is one of the important products in the radiolysis of hydrocarbons; the mechanisms of its formation may be divided into two types, radical and " molecular " processes. The former is the abstraction of a hydrogen atom from a molecule by a thermal hydrogen atom which is scavengeable by the additives, the so-called radical scavengers. The latter may include different modes of hydrogen formation which cannot be inhibited by the radical scavengers.

The abstraction of a hydrogen atom from a molecule by a hot hydrogen atom, which has a kinetically or electronically excess energy due to the dissociation of a molecule in superexcited states, is a mode of " molecular " hydrogen formation suggested by several authors.[1-3] Recently, some experimental evidence for this mode of formation has been given by the radiolysis of several olefins in the liquid phase.[4,5] In this experiment, we attempted to study the mechanism of the formation of " molecular " hydrogen, especially the hydrogen formation by the hot-atom-process in the radiolysis of ethane in the gas phase.

It seems well established by previous studies of ethane radiolysis near atmospheric pressure[2,6,7] that the *G*-value of the total hydrogen is 8.3—8.8, and that about 60% of it is formed by radical process. These authors have also shown that the additives, such as ethylene, propylene, and nitric oxide, can completely suppress the hydrogen formation due to thermal hydrogen atoms.

In order not only to confine ourselves to " molecular " hydrogen but to discriminate the hydrogen formed by the hot-atom-process from that formed by the molecular detachment process, we irradiated mixtures of ethane and ethane-d_6 containing ethylene as a radical scavenger and examined the isotopic composition of the hydrogen formed. The effects of other types of additives, such as electron scavengers and positive-ion scavengers, were also investigated to see if electrons and/or ionic species were involved in the formation of " molecular " hydrogen. Furthermore, the variation in the isotopic composition of hydrogen as a function of the ratio of ethane to ethane-d_6 was studied; this permitted us to estimate tentatively the relative importance of the hydrogen formation due to the hot-atom-process in comparison with other processes.

Experimental

Research-grade ethane and ethylene purchased from the Takachiho Trading Co. were used after degassing and bulb-to-bulb distillations. The ethane-d_6 was synthesized from acetylend-d_2 which had been obtained by passing deuterium oxide vapor over purified carbide at room temperature. The addition of deuterium to acetylene-d_2 was carried out at 190°C over a palladium catalyst. The ethane-d_6 produced was used after gas-chromatographic purifications and bulb-to-bulb distillations. The isotopic purity was found by mass spectrometry to be 99.6 at% D.

Samples were irradiated in Pyrex-glass tubes (about 80 m*l* in volume) with a breakable seal attached. The sample pressure was 300 Torr, and each sample contained 8 mol% of ethylene as a radical scavenger. Irradiations were carried out by gamma-rays of 6000Ci ^{60}Co at a dose rate of 1.1×10^6 R/hr. After irradiation, the hydrogen and methane were separated off at −196°C. The yield of hydrogen was measured, and its isotopic composition was determined by mass spectrometry.

Results and Discussion

Table 1 shows a variation in the hydrogen yield as a function of the absorbed dose. The *G*-value of non-radical hydrogen was calculated to be 3.3, a value which is in good agreement with those obtained by previous investigations.[2,6,7] The linearity of the hydrogen yield with the absorbed dose, as well as the absence of any effect of the temperature on the hydrogen yield or on the isotopic composition between −78.5°C and 125°C, shown in Table 2, confirmed that hydrogen is not formed by a radical process.

TABLE 1. VARIATION OF HYDROGEN YIELD AS A FUNCTION OF ABSORBED DOSE. RADIOLYSIS OF 90 : 10 : 8 ETHANE - ETHANE-d_6 - ETHYLENE

Irradiation time hr	Absorbed dose eV/g	Yield μmol
5	2.5×10^{19}	1.6
10	5.0×10^{19}	2.8
15	7.5×10^{19}	4.5

125	2.77	90.8	2.3	6.9

* Contribution from ethylene to H_2 and HD% in the isotopic composition of hydrogen was found to be negligible from the study of ethane-ethylene-d_4 radiolysis.

Because of its large proton affinity and its weak reactivity towards electron and radicals, ammonia is considered to be an efficient proton acceptor and is often used in the study of hydrocarbon radiolysis to ascertain whether the cationic reactions are effective.[8,9] On the other hand, sulfur hexafluoride has been found to be an efficient scavenger of thermalized electrons, such as nitrous oxide and carbon tetrachloride.[10,11] In Table 3 it may be seen that the addition of ammonia and sulfur hexafluoride scarcely affects either the hydrogen yield or its isotopic composition at all. The results exclude the possible participation of a recombination of the positive ion with the electron and/or of an ion-molecule reaction in the formation of hydrogen in this system.

TABLE 3. EFFECTS OF POSITIVE ION SCAVENGER AND OF ELECTRON SCAVENGER ON THE HYDROGEN YIELD AND ISOTOPIC COMPOSITION. RADIOLYSIS OF 90 : 10 : 8 ETHANE - ETHANE-d_6 - ETHYLENE

90	10	8	90.8	1.5	6.7

The existence of HD in the isotopic composition of hydrogen, even though it is present in only a small amount, confirms that part of the "molecular" hydrogen is formed by a bimolecular process; on the basis of the above results, we can reasonably attribute its formation to the abstraction

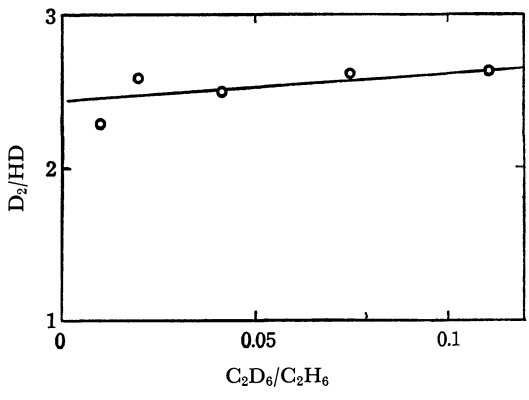

Fig. 1. D_2/HD as a function of ethane-d_6 concentration.

of a hydrogen atom from an ethane molecule by a hot hydrogen atom. Table 4 shows the variation in the isotopic composition of hydrogen as a function of the concentration of ethane-d_6. From a kinetic analysis of the reaction mechanisms in the radiolysis of butenes - butenes-d_8, Hatano and Shida[4] pointed out that the value of D_2/HD extrapolated to a zero concentration of butenes-d_8 is equal to one-half of the ratio of the unimolecular to the bimolecular process. Figure 1 shows the plots of D_2/HD as a function of the ethane-d_6 concentration. The application of the above method enables us to estimate the *G*-value of the formation of the hydrogen by the hot-atom-process to be 0.6.

In conclusion, the neutralization of ions and the ion-molecule reactions do not play significant roles in the hydrogen formation by the " molecular " process; the modes of the formation of all the hydrogen in the radiolysis of ethane may be classified as the radical process, the molecular detachment process and the hot-atom-process, whose *G*-values are, respectively, 5.0—5.5, 2.7, and 0.6.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2007—2017 (1967)

The Crystal Structure of the Copper(II) Chelate of *N,N'*-Ethylenebis(*l*-ephedrine)

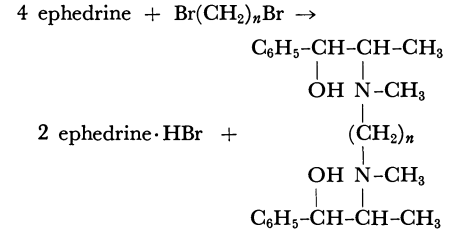
Michio MOTOHASHI, Yoshiharu AMANO and Toyozo UNO

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto

(Received March 4, 1968)

The crystal structure of the copper(II) chelate of *N,N'*-ethylenebis(*l*-ephedrine), where two molecules of *l*-ephedrine are connected through an ethylene group, has been determined by three dimensional X-ray analysis. The dimensions of the orthorhombic unit cell with the space group $P2_12_12_1$-D_2^4 are $a=8.431$, $b=15.92$, $c=16.70$ Å, $Z=4$ and $\rho_0=1.34$ g/cm^3. The intensity data were collected by multiple film technique, and the structure was determined by the heavy atom method. The positions of the copper atom simulated the symmetry of a higher space group than that of $P2_12_12_1$ and the phases calculated from them gave two pseudo mirrors in the Fourier map based on the copper atom only. The structural determination was made with the use of the methods of successive approximations and diagonal and block diagonal least-squares. The problems concerning the pseudo mirrors were solved mainly from the behaviors of the thermal parameters. The final results were obtained by correcting some unsuitable positional and thermal parameters found by the block diagonal least-squares refinement. The final *R*-factor is 13.0%. The structure shows that two crystalline water molecules do not coordinate to the copper atom and that the N–C–C–N bridge causes distortion of the square planar coordination around the copper atom.

In a previous paper,[1] we reported that the *trans*-bis(*l*-ephedrine)copper(II)[2] chelate reacted with carbon tetrachloride and chloroform. Considering that this peculiar reaction might be concerned with the structure of the chelate, we attempted synthesis of some *N,N'*-polymethylenebis(ephedrine) by combining two molecules of ephedrine with a polymethylene group and preparation of their copper(II) chelates in order to investigate their properties from the structural point of view.



When *n* is equal to one, the corresponding substance could not be obtained, and oxazolidine was obtained instead.[3] When *n* is equal to three, neither *N,N'*-trimethylenebis(*l*-ephedrine) nor its hydrochloride was obtained in the pure state. *N,N'*-Hexamethylenebis(*l*-ephedrine) hydrochloride*1 with $n=6$ was isolated, but its copper(II) chelate could not be prepared because of its instability. When *n* is equal to two, the copper(II) chelate of

*1 Anal., Found: C, 64.22; H, 8.88; N, 5.99; Cl, 14.64%. Calcd for $C_{26}H_{42}O_2Cl_2$: C, 64,31; H, 8.72; N, 5.77; Cl, 14.60% mp: 249°C.

meso-*N*,*N*′-ethylenebis(ephedrine),[4] where one molecule of *l*-ephedrine is connected with one molecule of *d*-ephedrine through an ethylene group, was obtained as a green crystalline powder, but the purification was not feasible. On the other hand, *N*,*N*′-ethylenebis(*l*-ephedrine)[4] reacted with copper sulfate in the presence of sodium hydroxide to give *N*,*N*′-ethylenebis(*l*-ephedrinato) copper(II) chelate (abbreviated as EBECu hereafter). From the results of the elemental analysis and the continuous variations, it became clear that this chelate has a ligand in the ratio of 1 : 1 to copper(II) and that one molecule of this chelate has two water molecules.

The IR spectrum of this chelate shows two absorption bands at 1670 and 1710 cm^{-1}. On recrystallization from deuterium oxide, two new absorption bands appear at 1170 and 1210 cm^{-1} with the decrease of the intensities of the original bands, so we assigned the original two absorption bands to the bending vibrations of water, but there seemed to be some ambiguities about the assignment, because the frequency (1710 cm^{-1}) was higher than the frequencies found for ordinary H_2O bending vibrations. The existence of two different absorption bands was supposed to show either that there were two water molecules in the different states in the crystal or that two molecules of water approached so near that they had influence on each other with consequent splitting of the bands.

It was reported that the copper(II) chelate coordinated by oxygen and nitrogen were blue or blue violet (trans coordination)[5,6] or green (cis coordination).[7,8] From the chemical structure of the ligand, EBECu was presumed to have cis coordination structure for oxygen and nitrogen, but it was blue. When it was dissolved in acetone and some of acetone was distilled, the color turned green but changed to original blue on addition of water. From this fact it was presumed that the blue chelate had two molecules of water which coordinated to the copper atom and that the chelate had an octahedral structure around the copper atom. In order to make clear the state of the water molecules in the chelate and to compare the structure with that of *trans*-bis(*l*-ephedrine) copper(II) chelate, we carried out three dimensional X-ray crystal structure analysis.

Experimental

N,N′-Ethylenebis(*l*-ephedrianto) Copper(II) Chelate. Sixty milliliters of 20% aqueous solution of sodium hydroxide was slowly added under cooling in ice to a mixture of 3.6 g of *N*,*N*′-ethylene bis(*l*-ephedrine) in dilute hydrochloric acid and 2.4 g of $Cu(SO_4)_2 \cdot 5H_2O$ in water. At this time light blue precipitates were once formed and they turned deep blue gradually. The blue precipitates were filtered and washed with small volumes of water and diethyl ether and dried well in a desiccator under reduced pressure. The blue precipitates were dissolved in dry pyridine, and the blue solution was filtered, concentrated *in vacuo*, and water was added, when blue needles separated. This reprecipitation procedure was repeated two more times (mp 156—157°C, decomp.). Found: C, 58.45; H, 7.66; N, 6.19; Cu, 14.27%. Calcd for $C_{22}H_{30}O_2N_2Cu \cdot 2H_2O$: C, 58.19; H, 7.55; N, 6.17; Cu, 13.99%;

Continuous Variations. An aqueous solution of copper sulfate (10^{-2} M) was mixed at various ratios with a solution of *N*,*N*′-ethylenebis(*l*-ephedrine) in dilute hydrochloric acid (10^{-2} M) to make the total volume 10 m*l*. After 10 min the blue substance was extracted with 15 m*l* of isoamyl alcohol, dried with anhydrous sodium sulfate, and the absorbance was measured at 620 mμ. The results are shown in Fig. 1.

Intensity Data. From the precession and Weissenberg photographs of the crystals prepared by the method described above, the unit cell dimensions were determined and are shown in Table 1. The reflection data were collected by multiple film technique. They

were recorded on equi-inclination Weissenberg photographs around *a* axis ((0*kl*)—(5*kl*)) and 30° precession photographs ((*hk*0), (*hk*1), (*h*0*l*)). The copper $K\alpha$ radiation with a nickel filter was used for the Weissenberg and the precession photographs, and 1968 independent reflections were observed. For 1752 reflections the intensities were measured by visual comparison with the standard intensity scale prepared from the same crystal. The intensities ranged from 0.5 to 10^4 for 1752 reflections. The 216 reflections, which had too weak intensities, to be measured were given the intensities 0.2. The Lorentz and polarization corrections and calculations of Wilson's scaling were made in the usual way by the program which was written by the author. No corrections were made for the absorptions because the crystal size was small ($\mu R=0.166$). The overall thermal parameter of the crystal was 5.0 Å^2. The computations in the present study were carried on the electronic computer KDC-II (Hitachi, HITAC 5020) of the Kyoto University Computation Center and on the HITAC 5020E of the Tokyo University Computation Center.

Structure Determination

The ordinary heavy atom method was applied to phase determination. From Haker sections, the positional parameters of copper atom were determined: $x/a=0.250, y/b=0.075$ and $z/c=0.000$. The structure amplitudes were calculated on the basis

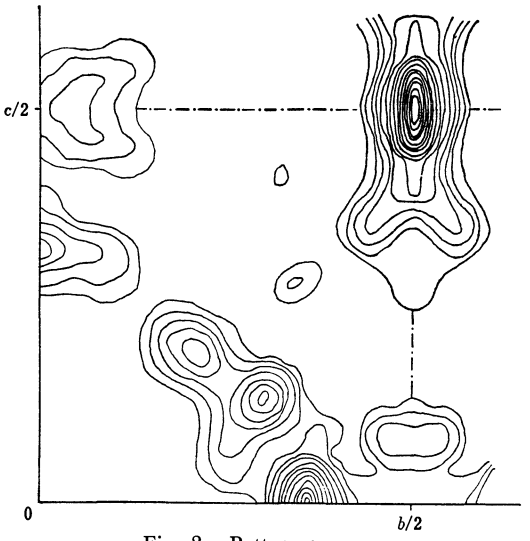

Fig. 2. Patterson map.

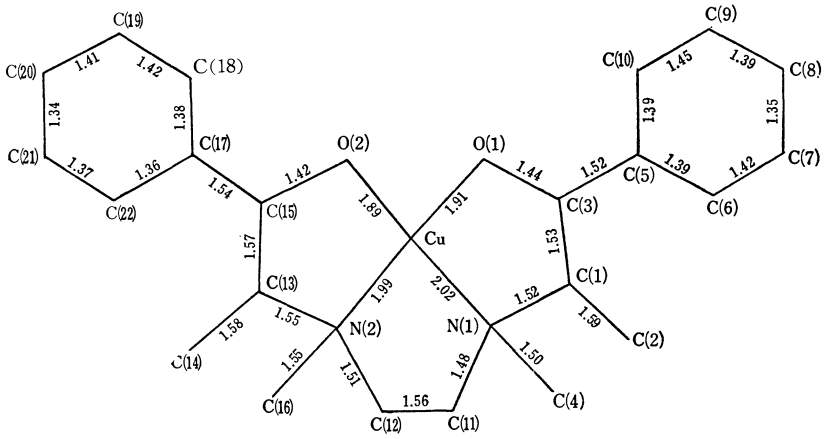

Fig. 3(a). Bond lengths of EBECu (in Å).

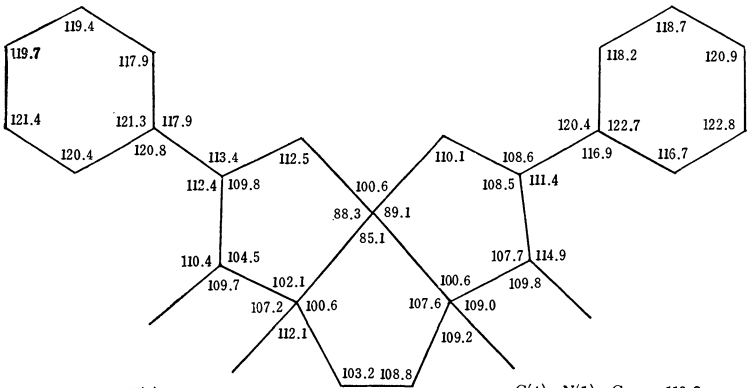

Fig. 3(b). Bond angles of EBECu (in °).

of this atom only, and the R-factor

$$R = \sum ||F_o| - |F_c|| / \sum |F_o|$$

was found to be 74%. The atomic scattering factors were taken from the International Tables for X-ray Crystallography, and no dispersion corrections for atomic scattering factors were applied. As the copper atom, the only heavy atom in an asymmetric unit, had the positional parameters $x/a=1/4$ and $z/c=0$, two pseudo mirrors were found in the Fourier synthesis using the phases calculated on the basis of the copper atom only, and there were four peaks having the same height for one atom. Accordingly it was very difficult to discriminate the correct peaks out of them. From the copper-copper peaks in the Haker sections somewhat extended along b axis as shown in Fig. 2 for example, it was supposed that two or more copper-copper peaks overlapped one another. Therefore, the positional parameters of copper atom x and z were shifted by 1/60 of the unit cell dimensions and the structure amplitudes were calculated. The R-factor was 45%. After the Fourier synthesis the four peaks, which had shown the same peak height when copper had the positional parameters $x/a=1/4$ and $z/c=0$, gained different positions and different peak heights. So the method of successive approximations was applied.

First, as the results of the Fourier synthesis with phases calculated on the basis of the copper atom only, 15 peaks of light atoms were found, and then the Fourier synthesis based on 16 atoms, namely, copper and 15 light atoms, gave additional six peaks. This process was repeated once more, giving

all 29 peaks except the peaks for hydrogen atoms. At this stage the *R*-factor was found to be 33%. The validity of the determined positional parameters of all the atoms except hydrogen atoms was examined by refining them by the method of diagonal least squares using 655 reflection data ($0.1 \leqq \sin\theta \leqq 0.6$). Only the real part of dispersion corrections were taken into account at this stage. After five cycles, there was one atom whose thermal parameter diverged, so that the new positional parameters were determined from the Fourier map obtained by the structure amplitude from 28 atoms except that atom with the use of all reflection data. After four cycles there was no atom with diverging thermal parameter. At this stage the thermal parameters of the atoms were generally small owing to the use of only a part of the observed reflection data in the least-squares treatment, but some of them were exceptionally small. By considering the bond lengths and angles, the positions of some atoms were found to be opposite to the correct ones with respect to the pseudo mirrors. We revised these erroneous positions and carried out five cycles of diagonal least-squares treatment using all reflection data. After this calculation, all the thermal parameters, bond lengths and angles were found to be nearly satisfactory, the *R*-factor being 16.4%. The data were then refined by the block diagonal least-squares method by using all the reflection data and the isotropic temperature factors for all the atoms. For this stage we used the computer program which was written by Dr. T. Ashida and is reserved at the Tokyo University Computation Center. As described in the diagonal least-squares method, only the real part of the dispersion corrections was considered. All reflection data were weighted equally. After four cycles, the *R*-factor was found to be 14.4%. However, two unreasonable results were obtained; the thermal factor of one crystal water W(2) was 12.3 Å^2 and the C(21)–C(22) bond length was 1.26 Å. Using the anisotropic temperature factor for the copper atom and excluding seven reflection data supposed to have the extinction effects, we attempted the refinement by the block diagonal least-squares method but failed to obtain better results. The *R*-factor was 12.8%. Considering the fact that the thermal parameter of W(2) remained large, we supposed that the correct position of this atom might be on the opposite side of the pseudo mirrors, and without changing the parameters of the other 28 atoms, we calculated the atomic distances by assuming the three positions on the opposite side of the pseudo mirrors. However, the results were not satisfactory because the three positions calculated were unreasonably close to the chelating molecules.

Taking account of these facts, we set thermal parameter of W(2) equal to that of W(1) and corrected the positional parameters of C(17) and of C(21) so as to have a reasonable atomic distance between C(21) and C(22). The final parameters thus obtained are shown in Table 2, where the values with asterisk refer to the corrected parameters. The bond lengths and angles calculated from these parameters are shown in Fig. 3. The *R*-factor calculated from these corrected parameters was found to be 13.0%. The observed and calculated structure factors computed from corrected parameters are listed in Table 3.

Results and Discussion

Figure 4 shows one molecule of the copper chelate and the two nearest crystallization water. As described in the previous section, the copper atom has the position near $x/a=1/4$ and $z/c=0$, and the distances from copper atom to this position along *a*

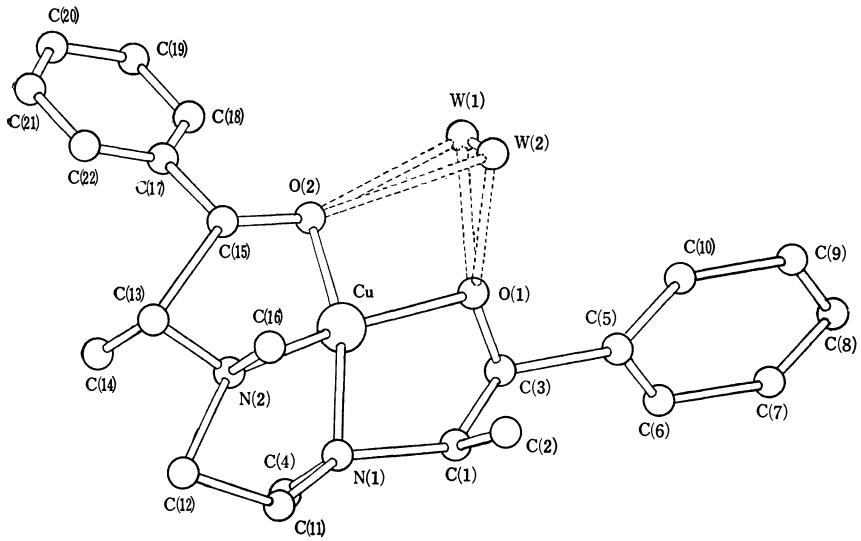

Fig. 4. The molecular structure of EBECu.

Table 4. Best plane

[a] Each plane is represented by $Z=AX+BY+D$, where X, Y and Z are coordinates in Å. For this calculation the positional parameters are translated from Table 2 by symmetric codes.

** shows corrected positional parameters (see Text).

and c axis are 0.028 (0.239 Å) and 0.021 (0.191 Å), respectively, whereas the distance along b axis is 0.072 (1.144 Å).

The copper atom is situated at the center of a distorted square plane where the two oxygen atoms O(1), O(2) and two nitrogen atoms N(1), N(2) assume the cis configuration. The bond lengths of Cu–O(1), Cu–O(2), Cu–N(1) and Cu–N(2) are 1.91, 1.89, 2.02 and 1.99 A, respectively, which are in good agreement with those of *trans*-bis(*l*-ephedrine)-copper(II) chelate (Cu–O: 1.88, Cu–N: 2.05 Å). These five-atom system is non-planar. The oxygen atom, O(1), is −0.516 Å from the plane through N(1), Cu and N(2), and O(2) is +0.423 Å from this plane. The fact that the O(1)–Cu–N(2) and O(2)–Cu–N(1) angles are 163.3 and 165.5°, respectively, indicates the probable distortion of the square-planar structure owing to the N(1)–C(11)–C(12)-N(2) bridge formation. This bridge is in the *gauche* form with the internal rotation angle of 53.8°, and C(11) is −0.354 Å from the plane through N(1), Cu and N(2), and C(12) is +0.392 Å from this plane (Table 4).

As to the five membered chelate ring formed by Cu, O(2), C(15), C(13) and N(2), the atom C(13) deviates from the least-square plane through the other four atoms; C(13) is 0.695 Å apart from this plane, while the distances between each of the four atoms and the plane is in the range 0.013—0.026 Å. Similary, in the system formed by Cu, O(1), C(3), C(1) and N(1), the atom C(1) is 0.657 Å apart from the least-square plane through the other four atoms, while the distances from this plane are between 0.013 and 0.032 Å with respect to the other four atoms. In these chelate rings the carbon atoms adjacent to the nitrogen atoms are far from the plane., These results also coincide well with the *trans*-bis(*l*-ephedrine)copper(II) chelate.

The thermal parameters of N(1) and N(2) are small as compared with those of the other atoms. This fact may be interpreted in terms of the distortion of the tetrahedral structure around the nitrogen atoms and the restriction of the movements caused by the N–C–C–N bridge. Some of C–N bond lengths, 1.55 Å for C(16)–N(2) or C(13)–N(2). appear to be somewhat longer than he mean value for C–N single bond (1.47 Å). We can find, however, the cases such as quaternary ammonium salts where C–N bonds are between 1.50 and 1.55 Å.[9] Therefore our results are not unreasonable.

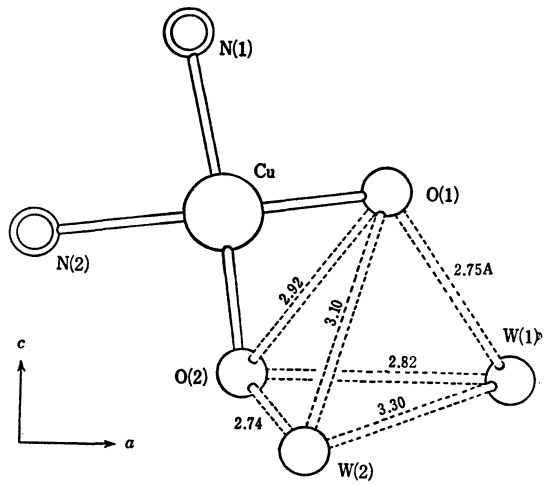

Fig. 5. Interatomic distances of oxygen atoms.

9) R. Eisenberg and J. A. Ibers, *Inorg. Chem.*, **4**, 605 (1965).

Four oxygen atoms projected on *ac* are shown in Fig. 5. As shown in the figure, the interatomic distances of these four atoms are between 2.74 and 3.30 Å, and the interatomic angles are 50—73° (Table 5). Accordingly the four atoms are nearly at the corners of a tetrahedron, and it is impossible to consider that one atom has the hydrogen bond with other special oxygen atom. However, because the thermal parameters of W(1) and W(2) are larger than the corresponding values of the other atoms, we consider that, as Bryan *et al.* reported about bis(β-aminobuthyrato)-copper(II) dihydrate,[6] a water molecule forms a hydrogen bond with each of the two oxygen atoms alternately. It is improbable that the two hydrogen atoms of a water molecule are hydrogen-bonded with the oxygen atoms at the same time. As there is no obvious difference between W(1) and W(2) and the two water molecules approach each other, the splitting of the absorption bands near 1700 cm^{-1} may be ascribed to the interaction between the two water molecules.

Table 5. Interatomic angles of oxygen atoms

O(2)-O(1)-W(1)	59.6°

O(1)-W(2)-O(2)	60.0
W(1)-W(2)-O(2)	54.8

About the reversible color change of EBECu, it was presumed first that the octahedral chelate of EBECu containing two molecules of water would be blue and that the anhydrous square planar chelate would be green, but on the contrary the present X-ray studies show that the blue chelate has the square planar structure. This phenomenon may be

explained as follows; on dissolving the chelate in acetone the hydrogen bonds connecting the crystal water with the oxygen atoms in the chelate are cleaved, affecting the coordinating abilities of the oxygen atoms of the chelate and consequently the color of the chelate. The orientation of molecules in the crystal projected on *bc* and *ac* are shown in Fig. 6. Table 6 shows the intermolecular atomic distances which are less than 3.9 Å from one of the carbon atoms of benzene ring and less than 4.0 Å from one of the other atoms. The distances are considered to be reasonable. The benzene rings in four different molecules fairly approach one another, and if this state is projected on *bc* the twofold screw

axis along *b* axis is found at the center of the four benzene rings. There are hydrogen bonds between the two water molecules and the nearest chelate molecule, but the atomic distances from these water molecules to the oxygen atoms of the other chelate molecules are more than 5.0 Å, so that there are no intermolecular hydrogen bonds.

For *trans*-bis(*l*-ephedrine)copper(II) chelate, we presumed in earlier publiciation[1] that the hydrogen bonds were cleaved in polar solvents and that halogenated hydrocarbons could easily approach the copper atom and react with it. There are active hydrogen atoms on the nitrogen coordinating to the copper atom, but it is not clear whether they are concerned with this reaction or not. EBECu chelate dissolved in ethyl alcohol also reacts with carbon tetrachloride. It is probable that the cleavage of the hydrogen bonds due to solvation results in the formation of a vacant space near the copper atom, allowing carbon tetrachloride molecules to approach the copper atom. Although EBECu has no active hydrogen, it reacts with carbon tetrachloride. It seems therefore that in the case of *trans*-bis(*l*-ephedrine)copper(II) chelate, the existence of active hydrogen is not an important factor for these reactions.

The authors are grateful to Professor K. Osaki and Mr. T. Taga, Faculty of Pharmaceutical Sciences, Kyoto University, for their kind advices and supplying some of the computer programs used in the present studies. We also thank Mr. T. Nishio for the synthesis of some *N*,*N*′-polymethylenebis(ephedrines).

ASMO-SCF-CI Calculation on the Electronic Structures of the Bases of Nucleic Acids with Special Emphasis on the Configuration Interaction

Hiroko FUJITA, Akira IMAMURA and Chikayoshi NAGATA

Biophysics Division, National Cancer Center Research Institute, Tsukiji, Chuo-ku, Tokyo

(Received March 14, 1968)

The calculation was carried out on the electronic structures of the bases of nucleic acids by means of semi-empirical self-consistent field configuration interaction (SCF-CI) method taking into account of the CI calculation. The effects of mixed configurations, *e.g.*, doubly excited ones, on the transition energies and oscillator strengths, were remarkable. On the other hand, the effects on the direction of the transition moments and the π-electron densities were small. The more configurations were involved, the better the calculated data agreed with the experimental result, but the change of the calculated values with increasing number of configurations from twenty to thirty was small. The agreement between the calculated singlet transition energies and the observed ones obtained by the vapor spectra of the bases was satisfactory, when twenty or thirty configurations including doubly excited ones were considered. The direction of the transition moment calculated by the present authors for thymine agreed well with the experimental result by Stewart and Davidson. For adenine, the calculated direction of transition moment of the main band was polarized parallel to long-axis and it coincided not with the result obtained by Stewart and Davidson, but with that proposed by Mason. Variation of the core resonance integral exerted the influence on the elcetronic structures, and K in Eq. (1), *viz.*, -0.49 was better than -0.431 when doubly excited configurations were taken into calculation.

The approximate calculations were already carried out on the electronic structures of the bases of nucleic acids by Hückel MO, semi-empirical SCF MO, or SCF-MO-CI (configuration interaction) methods. Pullman and Pullman,[1] and Ladik and Hoffman[2] used Hückel MO, while Berthod *et al.*,[3] Nagata *et al.*[4] and Veillard and Pullman[5] used SCF-MO. While, Nesbet,[6] Tanaka and Nagakura,[7] Ladik and Appel,[8] and Denis and Pullmen[9]

adopted the SCF-MO-CI method considering singly excited configurations. Imamura *et al.*[10] have included the doubly excited configurations as well as singly excited ones in the SCF-MO-CI calculation. However, in this paper transition energy and oscillator strength were not given.

Murrell and McEwen[11] carried out the calculation on the electronic structure of aromatic hydrocarbons and emphasized the importance of doubly excited configurations in CI calculation.

Similarly, Koutecký *et al.*,[12] on the basis of their calculation of the electronic structures of benzene, showed that tri-, tetra-, and hexa-excited configurations had practically no effect on the singlet energy levels. On the contrary, doubly excited configuration had remarkable effect on them irrespective of its dependence on the parametrization of the integrals.

It may be worthy to study afresh the effect of mixed configurations, excited singly and/or doubly, on the electronic structures of the bases of nucleic acids. The present paper deals with the systematic study of the effect of mixed configurations on the transition energy, oscillator strength, direction of the transition moment, and π-electron density of bases of nucleic acids. The importance of doubly excited configurations was stressed. Furthermore, the parametrization of core integral, in the CI calculation which included doubly excited configurations, was studied to verify the proposition of Anno and Sado,[13] *viz.*, -2.7217 eV for β_{cc} of benzene was better than -2.39 eV. The calculated transition energies were depend greatly on the values of β_{cc}, and, if β_{cc} was assumed to be -2.7217 eV, they agreed well with the experimental values derived from the vapor spectra of bases.

Method

We have used the semi-empirical ASMO-SCF-CI method. One center Coulomb repulsion integrals were evaluated in terms of $I-A$ according to the Pariser-Parr approximation,[14] where I and A were ionization potential and electron affinity, respectively. The values of I and A were the same as our previous papers.[4,10] For two center repulsion integrals, Mataga-Nishimoto's approximation[15] was used. The core resonance integral, different from our previous papers,[4,10] was represented by Wolfsberg-Helmhotz's approximate equation,[16]

$$\beta_{rs} = K\, S_{rs}(I_r+I_s), \qquad (1)$$

were K is a constant, *i.e.*, -0.431 or -0.490 when β_{cc} in benzene is -2.39 eV or -2.7217 eV, respectively, and S_{rs} is the overlap integral between the rth and sth atomic orbitals. As usual, the differential overlap integral and penetration integral were neglected.

The electron density was calculated by the equation used in our previous paper,[10],*1 and the expersions of the transition moment and oscillator strength were the same as our previous ones.[4,17]

The configurations taken into CI calculation contained the ground, singly excited and doubly excited ones. Doubly excited configurations were due to the excitations of electrons in the same occupied level from this to the another same unoccupied one. The four CI calculations were denoted by 2, 3, 4 and 5, respectively, and the SCF calculation was denoted by calculation 1. The classification of CI calculation and the configuration used are shown in Table 1.

Results and Discussion

Singlet Transition Energy and Oscillator Strength. The calculated singlet excited energies and oscillator strengths for adenine, guanine, thymine, cytosine, and uracil are shown in Tables 2 and 3. As is seen in Table 2, the lowest singlet excited energy or those near to it were reduced when the singly excited configurations were alone considered. This tendency can easily be explained in terms of that the ground configuration has zero matrix element when the singly excited configurations are considered in the SCF-CI calculation, but the excited levels with lower energies are depressed by interaction of singly excited configurations. On the other hand, CI calculation of singly and doubly excited configurations gave rather complicated results; *viz.*, some calculated results showed the states shifted to longer and others to shorter wavelength. The doubly excited configurations depress the ground state energy, which contributes to the blue shift. The tendency of this shift of the spectra is originated from the change of the energies of the ground and the excited states. The difference between the energy level of the ground state in CI calculation involving thirty configurations and that in SCF calculation was about 0.4 eV in all bases. This value was rather small as compared with that of benzene, *i.e.*, 1.5 eV.[11]

As shown in Tabl 2, the calculation including 5 singly excited configurations (calculation 2) showed little change on the SCF excitation energies, but those including several doubly excited configurations

* SCF without CI was denoted by Calculation 1. ** G: ground, S: singly excited, D: doubly excited configuration.

(calculation 3) exhibited remarkable changes. As was anticipated, the more the number of configurations increased, the better the calculated data agreed with the experimental results (calculation 4). But the inclusion of more than twenty configurations showd no better result (calculation 5). The results of calculation 5 are depicted in Fig. 1 together with the observed absorption curves obtained from the vapor,[18] liquid,[19] and solid film states,[20] respectively. The absorption maxima recorded in the liquid and solid states, occured at longer wavelengths than in the vapor state, and these shifts would be due to the hydrogen-bonding in the liquid and solid states. Therefore, the values obtained in the vapor state were the most preferable for comparing them with the calculated ones. Since we had a few data on the vapor state the comparison was mainly made with the data obtained from the liquid state, in this paper. As is seen in Fig. 1 and Table 2, the agreement between the calculated and the observed data in the liquid state was especially good for adenine. It is of interest that the two lowest absorption bands of adenine were interchangeable when doubly excited configurations were included in the CI calculation. In the SCF or in the CI calculation with 5 singly excited configurations and in the CI calculations involving doubly excited configurations, the (6—7) transition and the (6—8) transition were contained in the lowest energy transition, respectively. In order to know the contribution of the singly excited configurations and doubly excited ones to the change of transition energy of adenine, the calculation with singly excited configurations alone was carred out in claculation 3. No interchange of the transition energies resulted in this case showing an important contribution of

* (1—2) transition is mixed with (6—7) transition (45.6%) and (6—8) transition (35.8%) and (1—3) transition is mixed with (6—7) transition (46.8%) and (6—8) transition (36.1%)

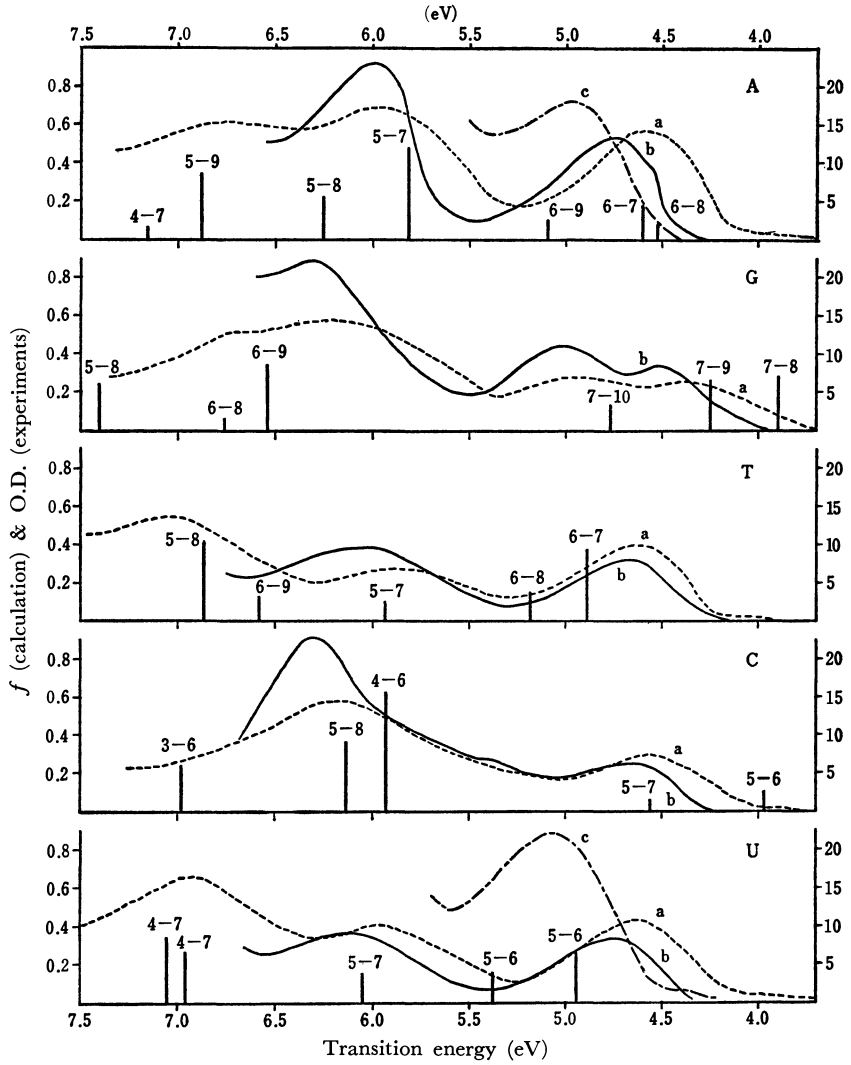

Fig. 1. The calculated singlet transition energies and oscillator strengths (f) in bases of nucleic acids in comparison with the observed absorption curves, measured (a) with evaporated film on puartz plate (Ref. 20) in O. D., (b) in aqueous solution (Ref. 19) in $\varepsilon \times 10^{-3}$ and (c) in vapor state (Ref. 18) in O. D., respectively. (Value of K in Eq. (1) is -0.431.)

doubly excited configurations to the transition energy, although some authors[6-8] calculated the structures of the bases including singly excited configurations alone, predicted the lowest energy transition with small oscillator strength.

In our previous report,[4] the (6—8) transition of adenine showed larger value of transition energy than the (6—7) transition, and its oscillator strength showed almost the same order with the (6—7) transition. On the basis of this, it was difficult to assign the shoulder band of adenine around 268 mμ to π–π^* transition. Recently, Tanaka and Nagakura,[7] on the basis of their experiments and theoretical considerations, have clearly shown that the shoulder band was π–π^* transition. Appearance of the lowest (6—8) transition with very small value of oscillator strength in our CI calculation of adenine would also be explained in terms of the appearance of shoulder band.

The calculated excitation energies of the lowest transition for thymine and uracil were larger than the observed ones. However, if we compared the calculated values with that obtained from vapor spectra of uracil,[18] the agreement became better. Although the vapor spectra of thymine have not yet been reported, the same may be true of this compound.

The calculated values of the lowest transitions for guanine and cytosine were too small to compare them with the observed ones. Especially agreement was not good for cytosine. But in these cases, if we took the vapor spectra of cytosine and guanine into

account, the circumstances were improved.

Expectedly, the magnitude of the calculated oscillator strengths for all bases were decreased with increasing number of the mixed configurations. However, this tendency was not seen when the number of configuration was increased from twenty to thirty (Table 2). The effect of CI calculation with doubly excited configurations was especially remarkable (calculation 3).

In the discussions stated above, K in Eq. (1) was equal to -0.431. If K was equal to -0.490, the coincidence of the calculated values with the observed ones was satisfactory: thus, the agreement of the calculated transition energies with the experimental ones was better than the above case (*cf.* Tables 2 and 3). This result was fairly consistent with the conclusion of Anno and Sado[13] who assigned -2.7217 eV for β_{cc} in benzene in the CI calculation including doubly excited configurations.

Triplet Excitation Energy. As shown in Table 4, the change in triplet transition energies against the numbers of mixed configurations was similar to that in singlet transition energies. The phosphorescence spectra of DNA or bases of nucleic acids have already been measured,[21-26] but phosphorescence spectra of DNA were not yet interpreted. Lamola

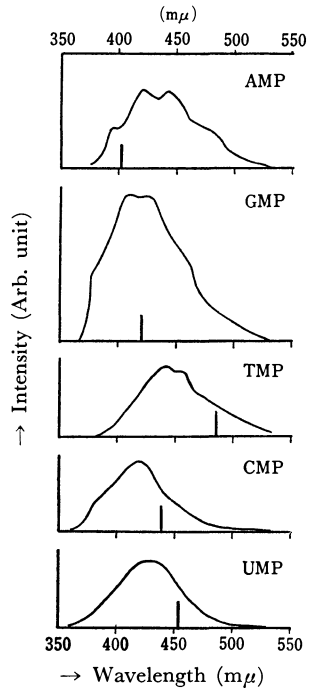

Fig. 2. The calculated triplet transition energies in bases of nucleic acids in comparison with the observed phosphorescence spectra. (Ref. 25) (K in Eq. (1) is -0.490)

et al.[26] have concluded that the triplet state in DNA was formed in the thymine residue, while Imakubo *et al.*[25] assumed that DNA phosphorescence spectra were not due to one base alone, but more than two bases. Both reports agreed with each other in that thymine had the lowest triplet energy among the five others. In agreement with this, our calculation

predicted the lowest triplet energy of thymine among five bases as seen in Table 4. (Fig. 2 and Table 4). Berthod *et al.*[3] predicted that the triplet energy of uracil whose structure is akin to thymine was the smallest among adenine, guanine, cytosine and uracil.

Direction of Transition Moment. The direction of transition moment of bases was not known. Thus, on the basis of their measurement of polarized absorption spectra of single crystal of 9-methyladenine, Stewart and Davidson,[27] have concluded that the intense band at 275 mμ which corresponded to the main band at 260 mμ of adenine in solution was polarized parallel to short-axis. This conclusion was not harmony with Mason's proposition that it was polarized parallel to long-axis,[28] although Mason has derived his conclusion from indirect measurement.

Therefore, it may be worthy to study the polarization of transition moment by means of MO calculation. As shown in Fig. 3, (a), in the SCF calculation without CI calculation, (6—7) and (6—8) transitions in adenine were neither polarized parallel to long-axis nor short-axis but parallel to the middle of both directions. But the effect of CI calculation on the direction of polarization and the oscillator strength was not small, especially on those of (6—7) and (6—8) transitions in adenine. Therefore, the SCF calculation without CI calculation was not fitted for discussing the direction of transition moment. A slight change in the direction of (6—7)

transition in adenine parallel to long-axis was brought about by the CI calculation (Fig. 3, (b)). This tendency was more remarkable if $-0.490(=K)$ was used (Fig. 3, (c)). As was discussed before, (1—3) transition in adenine was assigned to the main band at 260 mμ. This transition is rather long-axis polarized in contrast with the experimental result of Stewart and Davidson. This direction of the calculated lowest transition in adenine ((1—2) transition in Fig. 3, (b) or (1—2) transition in Fig. 3, (c)) which was assigned for the shoulder band around 268 mμ, could be determined to be polarized parallel to neither long-axis nor short-axis. However, we dare to think that it was polarized parallel to short-axis, as seen in Fig. 3, (c). But this lowest transition was difficult to be assigned to the observed short-axis polarized transition because of its small oscillator strength. As seen in Fig. 3 (b) and (c), the direction of this lowest transition was greatly influenced by the change of β_{cc}.

Stewart and Davidson[27] found that for 1-methylthymine, the first absorption band ($\lambda_{max}=275$ mμ) was polarized parallel to the N_1–C_4 axis, and the second band ($\lambda_{max}=230$ mμ) was polarized nearly perpendicular to the first. Upon comparison of the calculated electronic structures of uracil and thymine, it was clear that the effect of the substitution of methyl group for hydrogen was slight. Hence, the comparison of the calculated result for thymine with experimental one for 1-methylthymine was of interest. As shown in Fig. 3, the lowest transition was polarized parallel to the N_1–C_4 axis, and the second and third transitions were polarized nearly perpendicular to the first in agreement with the experiment. Since no available experimental data has been given for the bases except adenine and thymine, so far as the calculated results are shown in Fig. 3. The calculated directions of polarizations for these compounds were slightly changed by CI calculation.

Total π-Electron Density. As shown in Table 5, the effect of CI calculation on the total π-electron density was negligibly small. However, the CI calculation affected the SCF π-electron density in such a way that the carbon atom became less polar, and the electron density approached to the value of 1.0. It is well known that SCF method always overestimates the polar resonance structure of the molecule, and consequently, the effect of CI calculation seems to decrease the polarity of the molecule.

This investigation was partly supported by a grant of the Japanese Ministry of Education, and the calculations were performed on an IBM 7090 computer at the Japan IBM Co., with the permission of the UNICON Committee.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2026—2029 (1968)

Infrared Spectra of the Addition Compounds of Trimethylamine Oxide with Zinc, Cadmium and Mercuric Halides in the Range 1500—250 cm^{-1}

Masao KIMURA,*1 Yoko KURODA and Ikutoshi SHIBUYA*1

Department of Chemistry, Faculty of Science, Nagoya University, Nagoya

(Received March 18, 1968)

Infrared spectra were taken in the region 4000—250 cm^{-1} for trimethylamine oxide complexes of the type ZnX_2L_2 and Cd(or Hg)X_2L(L=$(CH_3)_3NO$ and X=Cl, Br or I). Two new bands at about 550 and 400 cm^{-1} were observed for all complexes. The zinc complexes gave rise to more bands at about 955 and 270 cm^{-1}. Except for these bands, no appreciable change was observed in the vibrational frequencies of trimethylamine oxide upon coordination. These results suggest that the complexes form a tetrahedral arrangement about a metal atom with weak coordinate bonds, and that the crystals of the zinc complexes consist of monomers and those of the cadmium and the mercury complexes of halogen bridged dimeric molecules $[MX_2L]_2$.
