(Received May, 4, 1967)

Liquid-liquid distribution behavior of sulfur(IV), selenium(IV) and tellurium(IV) in acid perchlorate media was studied at 25°C. The distribution of sulfur(IV) into carbon tetrachloride was determined by iodometry and that of selenium(IV) into methylisobutyl carbinol or of tellurium(IV) into hexane containing trioctylphosphine oxide was determined by radiometry. The changes in the distribution ratio caused by the changes in the hydrogen ion concentration were explained in terms of the distribution of sulfurous, selenious or tellurous acid as the noncharged form into the organic phase and the dissociation of these acids in the aqueous phase. The distribution constants as well as the dissociation constants of these acids were determined by a graphical method. In acid perchlorate media, sulfurous and selenious acids exist as neutral and mononegative species while tellurous acid exists as monopositive, neutral and mononegative species, and the neutral species exists only in a narrow hydrogen ion concentration range.

Although the dissociation constants of sulfurous and selenious acids have been reported by many authors,[1] very few has been known about the dissociation of tellurous acid in acid aqueous solutions.[1,2] This may be due to the insoluble nature of tellurous acid in weakly acid aqueous solutions.

In the present paper, the authors have studied the liquid-liquid distribution behavior of sulfur(IV) at low concentration and that of selenium(IV) and tellurium(IV) at tracer concentration in acid perchlorate media at 25°C. From the distribution data given as a function of the hydrogen ion concentration, the acid dissociation constants of sulfurous, selenious and tellurous acids in 0.1 and 3 M perchlorate media were determined by a graphical method.

Statistical Treatment

The dioxide of sulfur, selenium and tellurium in an aqueous solution may be hydrated with unknown number of water molecules. Accordingly the noncharged acids should be described as the general form, $QO_2(H_2O)_m$. Here, m represents zero or any positive integer, while Q represents one of these elements. In the present study, however, they will be always denoted by H_2QO_3. Further it is assumed that only this neutral species can be extracted into the organic phase in a liquid-liquid distribution system.

The stepwise dissociation constants of these acids are described as;

$$K_{a_n}=[H_{2-n}QO_3^{-n}][H^+]/[H_{3-n}QO_3^{-(n-1)}] \quad (1)$$

The distribution constant of the neutral species is described as;

$$K_D=[H_2QO_3]_{org}/[H_2QO_3] \quad (2)$$

The net distribution ratio, D, may be described as;

$$D=[Q]_{org,total}/[Q]_{total}$$
$$=[H_2QO_3]_{org}/\sum[H_nQO_3^{n-2}] \quad (3)$$

In a system where only H_2QO_3 and HQO_3^- species exist, Eq. (3) can be written

$$D = K_D/(1 + Ka_1[H^+]^{-1}) \quad (4)$$

On the other hand, in a system where the three species $H_3QO_3^+$, H_2QO_3 and HQO_3^- are found, Eq. (3) is transformed into;

$$D = K_D/(Ka_0^{-1}[H^+] + 1 + Ka_1[H^+]^{-1}) \quad (5)$$

The equilibrium constants in Eq. (4) or (5) can be determined graphically by a curve-fitting

*1 A part of this work was presented to the International Conference on Solvent Extraction Chemistry, Göteborg, Sweden (1966), "Solvent Extraction Chemistry", p. 32, North-Holland (1967).

method. As the details of the graphical treatments were given in the previous work,[3] only the final equations are given in this paper.

When the distribution ratio can be represented by Eq. (4), the log$D$ *vs.* $-\log[H^+]$ plot is fitted with the standard curve;

$$Y = \log(1 + v), \quad X = \log v \tag{6}$$

and when it is represented by Eq. (5), the log D *vs.* $-\log[H^+]$ plot is found to fit one of the following family of standard curves,

$$Y = \log(v^{-1} + p + v), \quad X = \log v \tag{7}$$

Experimental

Tracers. Selenium-75 was obtained from the Oak Ridge National Laboratory, U. S. A. as a hydrochloric acid solution. It was diluted in 0.1 M perchloric acid or a mixture of 0.1 M perchloric acid and 2.9 M sodium perchlorate and used as the stock tracer solution. Tellurium tracer (a mixture of various radioactive tellurium isotopes) was prepared as follows; tellurium powder (four nine grade) was irradiated with thermal neutrons in JRR-2 reactor at Japan Atomic Energy Research Institute, Tokai, Ibaragi. This was let stand about two weeks and dissolved in a hot 1 : 1 nitric acid. The solution was then shaken five times with 100% tributylphosphate in order to remove radioactive iodine[4] and washed with hexane. This aqueous solution was evaporated to dryness on a water bath and the residue was dissolved in 0.1 M perchloric acid or a mixture of 0.1 M perchloric acid and 2.9 M sodium perchlorate and stored as the stock tracer solution.

Reagents. All of the reagents were of analytical grade. Sodium perchlorate prepared from perchloric acid and sodium carbonate was recrystallized two times from water. Methylisobutyl carbinol was obtained from Tokyo Kasei Co. Trioctylphosphine oxide (TOPO) was obtained from Dijindo & Co. The methylisobutyl carbinol or 0.2 M TOPO hexane solution was washed with 0.1 M perchloric acid, water, 0.1 M sodium hydroxide solution and then several times with water respectively.

Procedures. All of the procedures were carried out in a thermostated room at 25 ± 0.5°C. Two liquid phases were equilibrated in a glass stoppered tube (volume 20 m*l*).

The Experiments for Sulfur(IV). Ten to twenty milligrams of sodium sulfite, various amounts of perchloric acid, sodium perchlorate solution and carbon tetrachloride were placed in the tubes. The two phases in the tubes were agitated vigorously with a mechanical shaker for 5 min and centrifuged. Two milliliter portion was pipetted from each phase and transferred into 120 m*l* Erlenmeyer flasks and the sulfur(IV) content was determined by iodometry.

The Experiments for Selenium(IV) and Tellurium(IV). One tenth milliliter portion of the tracer stock solution, various amounts of perchloric acid and sodium perchlorate solution and then the organic solution were placed in the tubes. The initial concentration of selenium in the aqueous phase was less than 10^{-6} M and that of tellurium was 1.0×10^{-4} M. In some experiments with tellurium(IV), a small amount of sodium sulfanilate or sodium acetate (initial concentration in the aqueous phase was 0.01 M) was added in order to buffer the aqueous phase. No buffer was added to the system containing selenium(IV). The two phases in the tubes containing selenium(IV) were agitated on a mechanical rotating framework usually for one week. The two phases containing tellurium(IV) were shaken 15 min by a mechanical shaker and were then centrifuged for 3 min at 2000 rpm. Two milliliter portion was pipetted from each phase and transferred into small test tubes. The γ-radioactivity of these samples was measured with a well-type (NaI) scintillation counter. Another small portion was also pipetted from the aqueous phase and the hydrogen ion concentration was determined potentiometrically by using a standard solution, 0.0100 M $HClO_4$ + 0.09 M $NaClO_4$ or 0.0100 M $HClO_4$ + 2.99 M $NaClO_4$ as the standard of $-\log[H^+] = 2.000$. A correction was made for the emf data by using a series of standard solutions when the aqueous phase contained more than 0.01 M hydrogen ion. The ionic media was 0.1 M (H, Na)ClO_4 or 3 M (H, Na)ClO_4 in all experiments. The initial volume of the aqueous phase was always 5.0 m*l* and that of the organic phase was 5.0, 5.0 and 3.0 m*l* respectively for the experiments with sulfur(IV), selenium(IV) and tellurium(IV). In some experiments with tellurium(IV), the tracer was first extracted into the organic phase by similar procedures as described above and then it was back extracted from this organic phase to a fresh aqueous solution and the distribution ratio was determined.

Results

Dependence of D on $-\log[H^+]$. Figures 1a and 2a give the distribution of sulfur(IV) between carbon tetrachloride and the aqueous phase whereas Figs. 1b and 2b give that of selenium(IV) between methylisobutyl carbinol and the aqueous phase as a function of the hydrogen ion concentration. In both cases it is seen that the plot has two asymptotes with a slope zero and minus one. The dependence of D on the $-\log[H^+]$ is explained by Eq. (4), that is, both of sulfurous and selenious acids exist as H_2QO_3 and HQO_3^- species in the aqueous phase of this $-\log[H^+]$ range. By the curve fitting with the standard curve given by Eq. (6), the distribution constant of the acids in the neutral form, K_D, and the dissociation constant, K_{a_1}, were determined as they are listed in Table 1.

Figures 1c and 2c give the distribution ratio of tellurium(IV) between hexane containing 0.2 M TOPO and the aqueous phase as a function of $-\log[H^+]$. No difference was observed between the results when the tracer initially added to the aqueous phase and those when the tracer was initially added to the organic phase. Figures 1c and 2c contain both kind of the results obtained by the extraction or by the back extraction. Except for the lowest $-\log[H^+]$ region in 0.1 M

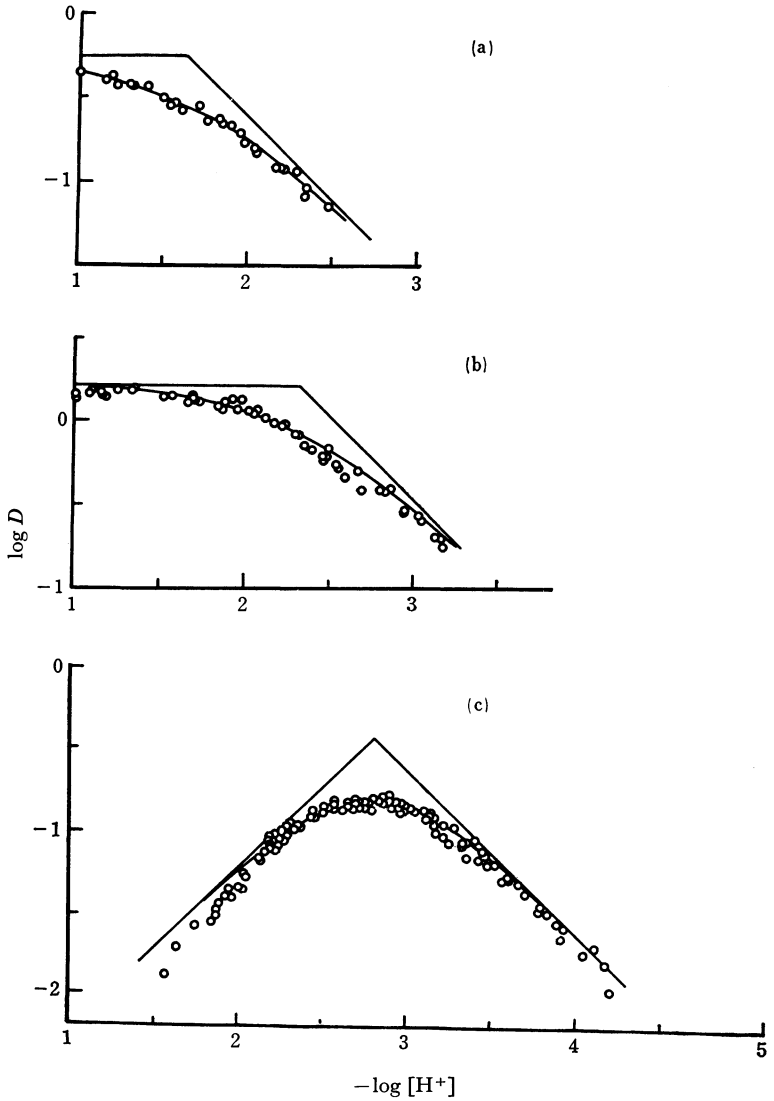

Fig. 1. Distribution of (a) sulfur(IV), (b) selenium(IV) and (c) tellurium(IV) in 0.1 M perchlorate media. The organic phases are described in Table 1. The two asymptotes and the distribution curve were obtained from the constants in Table 1.

TABLE 1. DISTRIBUTION AND DISSOCIATION CONSTANTS OF THE ACIDS AT 25°C (*cf.* Eqs. (1) and (2))

	Ionic media M, (H, Na)ClO_4	$\log K_D$	$-\log K_{a_0}$	$-\log K_{a_1}$
Sulfurous acid	0.1	−0.25	—	1.62
	3.0	−0.23	—	2.03
Selenious acid	0.1	0.21	—	2.33
	3.0	0.56	—	2.24
Tellurous acid	0.1	−0.08	3.16	2.46
	3.0	0.39	4.17	3.07

Organic phase sulfurous acid: carbon tetrachloride
Selenious acid: methylisobutyl carbinol
Tellurous acid: hexane containing 0.2 M trioctylphosphine oxide

perchlorate media, the plot has two asymptotes with a slope plus one and minus one and has a pronounced maximum between them and this indicates that the monopositive species, $H_3TeO_3^+$, is predominant in the lower $-\log[H^+]$ region while the mononegative species, $HTeO_3^-$, is predominant in the higher $-\log[H^+]$ region. Thus it is anticipated that the proportion of the neutral species, H_2TeO_3, is low all over the $-\log[H^+]$ region because if there were a region where the neutral species is predominant, an asymptote of a slope zero should be seen. The plot was fitted with one of the family of standard curves in Eq. (7) and the distribution constants and the dissociation constants for tellurous acid were determined from the parameters of the best-fit standard

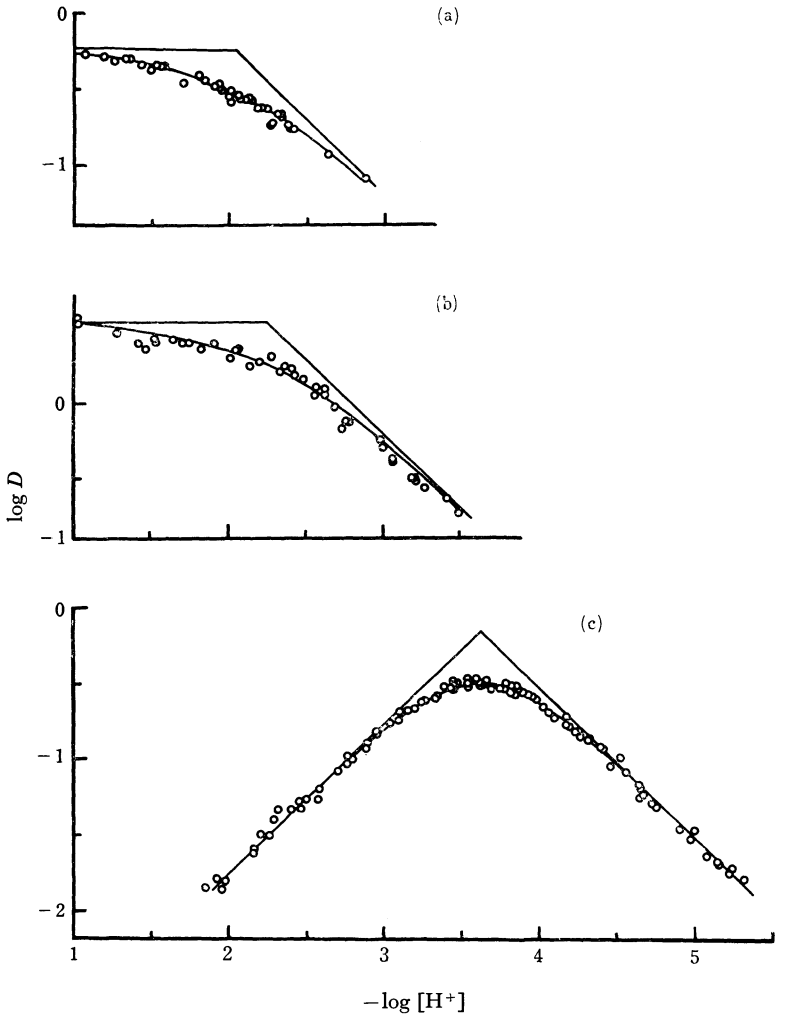

Fig. 2. Distribution of (a) sulfur(IV), (b) selenium(IV) and (c) tellurium(IV) in 3.0 M perchlorate media. The organic phases are described in Table 1. The two asymptotes and the distribution curve were obtained from the constants in Table 1.

curve as they are listed in Table 1.

Rate of the Extraction. The extraction of selenium(IV) in aqueous solutions into the methylisobutyl carbinol phase was a slow reaction. Figure 3 gives the increasing D with time when the tracer was initially added to the aqueous phase. The figure shows that the extraction rate is larger in the higher $-\log[H^+]$ range. It was observed that the rate of the back extraction of selenium-(IV) from the organic phase to the aqueous phase was very small. No appreciable amount was back extracted into the aqueous phase even after an agitation over one week. On the other hand, the rate of the extraction or the rate of the back extraction of sulfur(IV) and tellurium(IV) was much larger than that of selenium(IV) all over the $-\log[H^+]$ range studied. The distribution equilibrium of these species was attained by an agitation for five minutes.

Effect of the Concentration of the Acids. No change in the distribution ratio or the rate of the extraction of sulfur(IV) was observed when the amount of sodium sulfite initially added was changed from 5 to 20 mg. The distribution ratio of selenium(IV) decreased very much by adding 10^{-4} to 10^{-3} M selenium(IV) carrier to the aqueous phase. It was also observed that an organic solution of selenious acid at macro concentration was not stable. Namely, red precipitates which looked like elementary selenium were formed in methylisobutyl carbinol solutions containing macro amounts of selenious acid. Thus it was concluded that the distribution equilibrium of selenium(IV) is established only when the concentration is

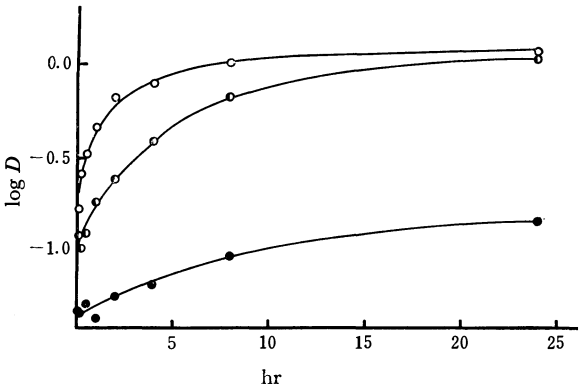

Fig. 3. Increase in the distribution ratio of selenium(IV) in 0.1 M perchlorate media at $-\log[H^+]$ 1.00 (open circles), 1.96 (half-closed circles) and 2.84 (closed cirles) into methylisobutylcarbinol as a function of time.

low and when the tracer is initially added to the aqueous phase. Practically no difference of the distribution ratio of tellurium(IV) was observed when the initial concentration in the aqueous phase was 5×10^{-5}, 1×10^{-4}, 2×10^{-4}, 3×10^{-4} and 4×10^{-4} M in 3 M perchlorate media at $-\log[H^+]$ 3.7 and 4.6. This seems to indicate that no polynuclear tellurium(IV) species are formed in the aqueous phase within the experimental accuracy.

Extraction by Using Other Solvents. The extraction of sulfur(IV) seems to be the lowest when non-polar solvents such as hexane or carbon tetrachloride are used. The distribution of sulfur(IV) increases with increasing the polarity of the solvent. The distribution of selenium(IV) between various organic solvents and an aqueous solution containing 0.1 M perchloric acid and 2.9 M sodium perchlorate was also studied. Most of the solvents like benzene, chloroform, carbon tetrachloride or hexane extracted selenium(IV) only poorly; the D value was 10^{-2} or less. Some polar solvents extracted selenium(IV) to some extent. For example, tributylphosphate or methyl isobutyl ketone extracted selenium(IV) with the D of arround 10^{-1}. Thus it was concluded that the extraction of selenium(IV) with methylisobutyl carbinol is exceptionally large among the solvents studied.

No organic solvent was found to extract tellurium(IV) to any appreciable amount without TOPO. Some experiments were carried out using different organic solvents as the diluent of TOPO. When the TOPO concentration was the same, the extraction of tellurium(IV) from an aqueous solution at a certain $-\log[H^+]$ into benzene or carbon tetrachloride was one third or one tenth of that into hexane and the extraction was negligibly small when chloroform was used as the diluent of TOPO.

Dependence of Tellurium(IV) Extraction on the TOPO Concentration. The dependence

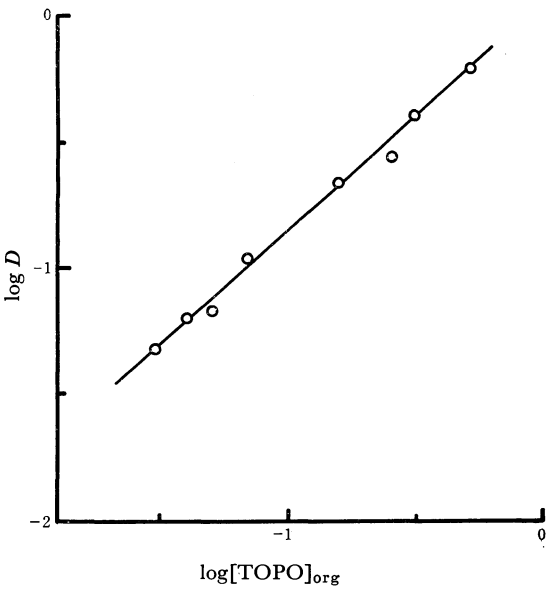

Fig. 4. Distribution of tellurium between hexane containing various amounts of TOPO and 3 M perchlorate media at $-\log[H^+]$ 3.9 as a function of TOPO concentration in the organic phase.

of tellurium(IV) extraction on the TOPO concentration in hexane has been studied. Figure 4 gives the plot log$D$ *vs.* $\log[TOPO]_{org}$ when the aqueous phase was 3 M perchlorate solution at $-\log[H^+]$ 3.9. The plot falls on a straight line with a slope plus one. This indicates that one molecule of TOPO combines with one molecule of H_2TeO_3 species in the organic phase. This can be described as follows;

$$H_2TeO_3+TOPO(org) \rightleftharpoons H_2TeO_3\cdot TOPO(org)$$

Reproducibility of the Results. The recovery of sulfur(IV) from the two phases was almost quantitative. The loss of sulfur(IV) from the two phases as sulfur dioxide after the phase separation was negligible. The recovery of selenium(IV) or tellurium(IV) from the both phases was also quantitative.

An addition of buffering agent such as sulfanilate or acetate to the aqueous phase increased the distribution ratio of selenium(IV) systematically. No effect of the buffer was, however, observed in the extraction of tellurium(IV) when the buffer concentration was less than 0.01 M.

It was necessary to purify the tellurium tracer by a preliminary extraction cycle in order to obtain reproducible results. No purification of the selenium tracer by the extraction method was carried out because the rate of the back extraction was very small. The results of selenium(IV) or of tellurium(IV) extraction seem to be affected by various factors such as the presence of dusts

more than many other solvent extraction experiments.

Discussion

It is difficult to compare the dissociation constants of these acids in the present study directly with the previous data which have been determined in ionic media at different concentration. Further, the dissociation constants were calculated by using the stoichiometric concentration ($-\log[H^+]$) in the present study while those have been calculated by using the activity of the hydrogen ion (pH) in most of the previous work.

The first dissociation constant of sulfurous acid, pK_{a_1}, in the previous papers are in the range 1.76 to 1.92[1] when the ionic concentration is low and the present pK_{a_1} values in 0.1 and 3 M perchlorate media is a little smaller and a little larger than those previous values.

The first dissociation constant of selenious acid, pK_{a_1}, in dilute ionic media in the previous papers[1] are in the range 2.46 to 2.62 which are a little higher than the present results in 0.1 and 3 M perchlorate media.

It was observed that the rate of the extraction of selenium(IV) is very small especially when some amounts of carrier was added, that the back extraction was not possible and that the quadrivalent state of selenium in methylisobutyl carbinol at macro concentrations was unstable. Still the distribution ratios of selenium(IV) at tracer concentration in Figs. 1b and 2b are well explained by Eq. (4) and the dissociation constants obtained look reasonable. Thus it may be concluded that selenium(IV) in such a distribution system is enough stable and the rate of the extraction is large enough to achieve the distribution equilibrium by an agitation for one week.

There were not many reports on the first dissociation constant of tellurous acid. This may be due to the insoluble nature of tellurous acid in aqueous solutions. The dissociation constants in the previous work were obtained from the analysis of the acid dependence of the solubility of tellurous acid.[1] The existence of the positive charged species of tellurous acid in acid aqueous solutions has been pointed out by some authors from the solubility data,[5-7] cation-exchange data[8] or by the dithizone extraction data.[9] However, none of them have determined the dissociation constant for the first proton in this positive charged species, $H_3TeO_3^+$ or $TeOOH^+$. Dutton and Cooper[2] recommended 3×10^{-3} as K_{a_1} ($=[HTeO_3^-]\,[H^+]/[H_2TeO_3]$) of tellurous acid in the recent review but they did not discuss the dissociation constant of this positive charged species. As is seen in Fig. 5, contribution of the non charged species to the whole tellurium concentration is small over all hydrogen ion concentration region (this corresponds to the fact that there is no region in Figs. 1c and 2c where the slope $d\log D/d\log[H^+]^{-1}$ is zero). It is indispensable to take the dissociation of the positive charged species into the account for the calculation of the K_{a_1} of tellurous acid. Thus although the value given by Blanc,[10] $K_{a_1}=2.7\times10^{-3}$, agrees with the present value in 0.1 M perchlorate media, $K_{a_1}=3.5\times10^{-3}$, still it is necessary to reexamine this previous value.

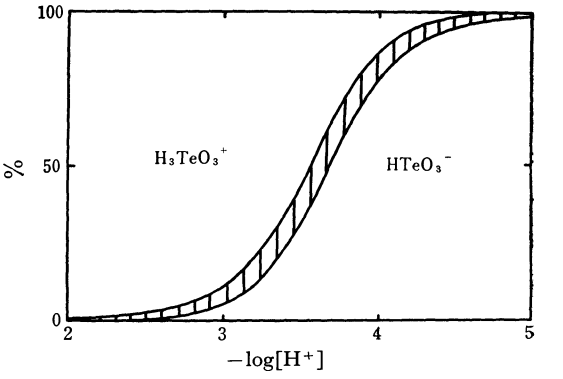

Fig. 5. Distribution of hydrolyzed species as a function of $-\log[H^+]$. The virtically liniated part represents the H_2TeO_3 species.

Figure 1c shows the plot deviates from the asymptote with a slope plus one. The same kind of deviation was also observed in the distribution of vanadium(V), HVO_3, between methylisobutyl carbinol and 0.5 M (H, Na)ClO_4[3] and Dyressen and Sekine explained this deviation as the change in K_D when sodium ions are replaced by hydrogen ions. The deviation in Fig. 1c seems to be also explained by this explanation, the fact that the deviation does not appear in the experiments in 3 M (H, Na)ClO_4 in Fig. 2c where the change in the cation is not large even in the lower $-\log[H^+]$ region may support the explanation.

Table 1 elucidates that the K_D value in 3 M perchlorate media is larger than that in 0.1 M media. This increase in the distribution constant, the salting-out effect, increases in the sequence sulfurous, selenious and tellurous acids. This sequence also agree with that of the basicity of the necessary extractant for these acid in aqueous solution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 7—17 (1968)

Condensation of Methylolmelamine

Kenji SATO*[1]

Tokyo Research Laboratory, Nippon Carbide Ind., Co., Inc., Ota-ku, Tokyo

(Received October 17, 1966)

The condensation of methylolmelamine in the range of *ca.* pH 8—1 was investigated. An aqueous-dimethylsulfoxide (DMSO) solution (*ca.* 1 : 2, vol. ratio) was mainly used as the solvent, because it was revealed that the condensate in the latter stage of the condensation is soluble in DMSO solvent, and also that in this solvent methylolmelamine scarcely decomposes into a lower methylolmelamine liberating formaldehyde; then, the condensation mechanism of that methylolmelamine whose composition corresponds approximately to di-, tri-, and hexa-methylolmelamine, was investigated, not only in the early stage but also in the latter stage. It was found that the condensation rates of di- and tri-methylolmelamines (low methylolmelamines) in the early stage show maxima at *ca.* [HCl]/[methylolmelamine]=0.5 (molar ratio), *i. e.*, at *ca.* pH=log$K$, where K is the equilibrium constant between the molecular form of the methylolmelamine and its conjugate acid, and that in hexa-methylolmelamine (high methylolmelamine) the above maximum appears at *ca.* [HCl]/[methylolmelamine]=0.5—1.0 (molar ratio). Also, the above maxima were found to shift toward smaller [HCl]/[methylolmelamine] (molar ratio) values as the condensation proceeded (the latter stage). From these results, a condensation mechanism was proposed for the early stage of the condensation.

Moldings and laminates are prepared by curing methylolmelamine with a composition corresponding approximately to di- or tri-methylolmelamine; an acid catalyst is usually added just prior to the cure because the condensation rate increases remarkably upon the addition of a small amount of an acid[1] (near the neutral range). However, there have been no reports on the condensation of methylolmelamines in a more strong acidic range. For this reason, the condensation of methylolmelamine in the range of *ca.* pH 8—1 was investigated in detail.

It has recently been revealed by the present author[2,3] that dimethylsulfoxide (DMSO) is a good solvent for melamine, methylolmelamine, and the condensate, and that neither the iodometric nor the sulfite method is affected by the presence of a small amount of DMSO.

Moreover, methylolmelamine was found by this study to decompose scarcely into a lower methylolmelamine liberating formaldehyde, in DMSO or even in an aqueous-DMSO solution (*ca.* 1 : 2, vol ratio); consequently, the condensation mechanism of a methylolmelamine with a different number of methylol groups can be investigated by the use of an aqueous-DMSO solution, even in the latter stage of the condensation.

There was another purpose of this study: In the reaction of melamine with formaldehyde, the hydroxymethylation and the condensation proceed almost simultaneously; also, the hydroxymethylation rate shows quite different values with the change in pH values.[4,5] Hence, a hydroxymethylation product prepared in the neutral range (see "Preparation of Methylolmelamine"), *i. e.*, methylolmelamine (monomer), was used as the starting substance for the study of the condensation mechanims.

The present report will summarize in detail our findings on the condensation rate *vs.* the acidity, some properties of the condensate, the rate of

decrease in the methylol group *vs.* the acidity, and the change in pH value during the reactions: samples with compositions approximating di-, tri-, and hexa-methylolmelamine were used (for they have different numbers of methylol groups); among these items, we will emphasize the condensation rate *vs.* the acidity. These studies may imply a probable mechanism for the early stage of the condensation. In addition, methylolmelamine was investigated by differential thermal analysis and by thermobalance measurements.

Experimental

Materials. Pure commercial melamine was recrystallized from water. The formaldehyde was the best grade formaline (*ca.* 37 wt%). Pure commercial DMSO was purified by a known method[6]; bp 47°C/3 mmHg.

Preparation[7] of Methylolmelamine. Formaline was added to 126 g (1 mol) of melamine in the formaldehyde/melamine molar ratios of 2, 3, and 8, and the pH was adjusted to 8.0 with 0.1 N sodium hydroxide. This mixture was dissolved by heating it at 70°C, and then heated for an additional 5 min after dissolution; the solution thus formed was quickly poured into a large amount of an ice-cooled methanol and left standing overnight. The precipitate thus formed (methylolmelamine) was collected on a Büchner funnel, washed with methanol, and then dried *in vacuo* (50°C). These products were analyzed by the conventional method[7,8]; the results obtained show that the molar ratios of the combined formaldehyde to melamine are 1.98, 2.68, and 5.65, and that scarcely any condensation takes place in any case, *i. e.*, only the monomer of methylolmelamine is formed since the reaction time is short.

Thus, samples with compositions approximating di-, tri-, and hexa-methylolmelamine were prepared. Henceforth, these will be represented as M1.98F, M2.68F, and M5.65F respectively.

Reaction and Measurement. A definite amount of an aqueous-DMSO solution containing an appropriate amount of M1.98F was prepared. Next, definit amounts of an aqueous solution containing various amounts of hydrochloric acid were prepared. Each solution was then introduced into a thermostat regulated to the operating temperature, and the above solutions were mixed to react them. The initial pH values were controled by [HCl]/[M1.98F] (molar ratio). Aliquots were taken out at appropriate intervals of time and were analyzed by the iodometric and sulfite methods after neutralization, the pH values being measured by means of a glass electrode pH meter; the iodometry was carried out after adding DMSO[3] to the aliquot. The condensation rate, *i. e.*, the rate of the formation of the methylene linkage, was directly computed iodometrically. The results are shown graphically in Fig. 1(1), where the "methylene linkage"/"melamine rest (remainning) in methylolmelamine" molar ratio *vs.* the pH is indicated in connection with the reaction times. The rate of decrease in the methylol group was computed from the difference between the two values obtained by the iodometric and sulfite methods. The results are shown in Fig. 1(2), where the "methylol group"/"melamine rest in methylolmelamine" molar ratio *vs.* the pH is indicated in connection with the reaction times.

Experiments concerning M2.68F and M5.65F were carried out similarly; these results are shown in Figs. 2(1), (2)—4(1), (2).

For comparison, an investigation was also carried out with regard to M1.98F in an aqueous solution instead of an aqueous-DMSO solution. The results are shown in Figs. 5(1) and (2).

Differential Thermal Analysis and Thermobalance Measurement. The investigations were carried out using a 100 mg portions of M2.68F and M5.65F. The temperature was raised at the rate of 5°C/min for the differential thermal analysis, and at the rate of 3°C/min for the thermobalance measurement. For comparison, a 100 mg portion of melamine was also used in these investigations. The results of the differential thermal analysis are shown in Fig. 6, and those of the thermobalance measurement, in Fig. 7.

Results and Discussion

Solvent. Penta- or hexa-methylolmelamine (high methylolmelamine) is almost insoluble in water; therefore, water cannot be used as a solvent in this case. With regard to di- or tri-methylolmelamine (low methylolmelamines) also, water is not suitable as a solvent, because, although these substances are slightly soluble in water, they easily decompose, liberating formaldehyde to become lower methylolmelamines.

However, it became clear from this study that the decomposition of methylolmelamine is almost suppressed in DMSO, even in an aqueous-DMSO solution (*ca.* 1 : 2 vol ratio). For example, an aqueous solution containing 0.040 mol/*l* of M1.98F and of M2.68F were prepared at 50°C, and the formaldehyde thus liberated was determined immediately by the sulfite method. These results indicate that the former decomposes into M1.51F, and the latter, into M1.83F. Then, DMSO solutions containing 0.040 mol/*l* of M1.98F, M2.68F, and M5.65F were similarly tested using the sulfite method. As a result, each of the methylolmelamines was revealed to decompose very little, even after 50 hr (50°C); the same was almost true in the case of aqueous-DMSO solutions (*ca.* 1 : 2, vol ratio) of M1.98F, M2.68F, and M5.65F. The above results suggest a facility of solvation between DMSO and methylolmelamine; such solvation must be associated with the fact that DMSO is a polar solvent and that it dissolves a large amount of methylolmelamine; *e. g.*, the solubilities of M1.98F in water and DMSO are *ca.* 0.9 wt% and 56 wt%[3] respectively at 30°C.

Moreover, when an aqueous-DMSO solution (*ca.* 1 : 2 vol ratio) of methylolmelamine is used,

no precipitate appears, even in the latter stage of the condensation shown in Figs. 1(1)—4(1), because DMSO is a good solvent for the condensate. However, when an aqueous solution is used instead of the above solution, it soon becomes turbid; then a precipitate is deposited as the condensation proceeds. Therefore, the aliquot was taken out in this case after the solution had been agitated vigorously with a glass rod. Thus, the value obtained using an aqueous solution is not as accurate as that obtained using an aqueous-DMSO solution; in particular, the values of (c) and (d), which correspond to a reaction time of 3.5 hr, shown in Fig. 5 could not be obtained, because the aliquot could not be taken out because the precipitate was deposited at the bottom of the vessel.

Consequently, the advantage of using an aqueous-DMSO solution is that the condensation mechanism of methylolmelamine with different numbers of methylol groups can be investigated not only in the early stage but also in the latter stage.

Relation between the Condensation Rate and the Acidity. The results obtained are shown in Figs. 1(1), 2(1), 3(1), 4(1), and 5(1).

As is well known, the condensation rate of methylolmelamine increases as a solution becomes

more acidic (near the neutral range: *ca.* pH 8*[2]→ 7).[1] However, there have been no reports on the condensation in a range more acidic than this.

It may be found from the above figures that the condensation rates of Ml.98F, M2.68F, and M5.65F show a maximum value in each curve. For example, with regard to M1.98F and M2.68F, *i. e.*, low methylolmelamines, the maximum appears at *ca.* [HCl]/[M]=0.5 (molar ratio)*[3] in the early stage, where [M] represents the concentration of the melamine rest in the starting methylolmelamine, and [HCl], that of hydrochloric acid. When an aqueous solution was used

*[2] Since methylolmelamine is basic, the pH value of a solution containing methylolmelamine is somewhat larger than 7.0.

*[3] In an acidic region, DMSO may form its conjugate acid ($(CH_3)_2SO \rightarrow H^+$), but the additional proton would be remarkably small. In the presence of some hydrochloric acid, the pH value of an aqueous-DMSO solution is somewhat different from that of an aqueous solution. For this reason, the maximum has been discussed in terms of [HCl]/[M] (molar ratio).

instead of an aqueous-DMSO solution, as has been stated above, no such accurate data can be obtained as in the case of an aqueous-DMSO solution, but the maximum appears at *ca.* [HCl]/[M]=0.5 (molar ratio) (Fig. 5(1)).

Furthermore, the maximum was found to shift toward smaller [HCl]/[M] (molar ratio) values as the condensation proceeds (the latter stage); *e. g.*, as is clear in Fig. 2(1), the maximum shifts from 0.5 to 0.4, and then to 0.2 (molar ratio). The above fact may be explained from the consideration that the melamine rest in the condensate is less basic than that of the starting methylolmelamine (see "Change in pH Value during Reaction" and "Condensation Mechanism for the Early Stage").

Next, the effect of the concentration of methylolmelamine and that of the temperature upon the maximum were studied. Investigations were carried out by adjusting the concentrations of M2.68F to twice the starting concentration shwon in Fig. 2, and also by adjusting the reaction temperature to 60°C and 40°C from the 45°C shown in Fig. 2. These results show that maxima in the early stage appear at *ca.* [HCl]/[M]=0.5 (molar ratio) in all cases, regardless of the concentration of methylolmelamine and the reaction temperature.

High methylolmelamines differ from low methylolmelamines in the following behavior. In M5.65 F, a high methylolmelamine, maxima in the early stage appear at *ca.* [HCl]/[M]=0.5 and 1.0 (mol ratio) at 65°C and 45°C respectively, as Figs. 3(1) and 4(1) show. The maximum of a high methylolmelamine, thus, shifts toward smaller [HCl]/[M] (molar ratio) values, and it approaches that of a low methylolmelamine, *i.e.*, [HCl]/[M]=0.5 (molar ratio), with an elevation in temperature. These results will be discussed below in connection with the condensation mechanism (see "Condensation Mechanism for the Early Stage").

Some Properties of the Condensate. According to Eqs. (3) and (4) (*cf.* "Condensation Mechanism for the Early Stage"), the "methylene linkage"/"melamine rest in methylolmelamine" ratio of the dimer is 0.5 (molar ratio). Kohler

et al.[9] stated that the above value of the molded product of the methylolmelamine prepared under the usual molding conditions is *ca.* 1.2 (molar ratio) and that it does not dissolve in solvents. From Figs. 1 (1) and 2 (1), it was found that the value of the condensate in the latter stage is *ca.* 1.2—1.6 (molar ratio), and also that this condensate is easily soluble in an aqueous-DMSO solution.

Thus, the above value of the condensate in the latter stage is almost the same or somewhat larger than that of the molded product; also, melamine resin is one of the thermosetting resins.

Therefore, this condensate (in the latter stage) may be predicted to show a three-dimensional structure with a remarkably large molecular weight, and to be insoluble in any solvent. However, the molecular weight of this condensate has been estimated by this research to be not as large as had been predicted, since the above condensate is soluble in an aqueous-DMSO solution.

Relation between the Rate of Decrease in the Methylol Groups in Methylolmelamine and the Acidity. The results obtained are shown in Figs. 1(2), 2(2), 3(2), 4(2), and 5(2).

First, it may be inferred that the methylol group is decreased by the formation of the methylene linkage and by the liberation of formaldehyde through the decomposition, which is mainly due to an acid.

Concerning M1.98F and M2.68F, Figs. 1(1), (2) and 2(1), (2) show that the maximum in the rate of decrease in the methylol group, *i. e.*, the minimum in the methylol group (present) *vs.* the pH, almost coincides with the maximum in the condensation rate; that is to say, it appears at *ca.* [HCl]/[M]=0.5 (molar ratio) in the early stage and shifts toward smaller [HCl]/[M] values as the condensation proceeds. Furthermore, regarding the early stage, from the above figures, it can be seen that the decrease in the methylol group is roughly the same as the increase in the methylene linkage formed in the range of *ca.* pH 7—3; therefore, the methylol group has been confirmed to be consumed mainly by the condensation within this pH range; however, within *ca.* pH 1—2, the decrease in the methylol group is considerably larger than the increase in the methylene linkage; this confirms that the methylol group is decreased by the decomposition due to a large amount of acid in this pH range.

On the other hand, as for M5.65F, the above mentioned minimum can scarcely be observed, and the decrease in the methylol group in the early stage is remarkably larger than the increase in the methylene linkage, even in a weak acidic range (Figs. 3(1), (2) and 4(1), (2)); this fact suggests that high methylolmelamines are unstable and easily liberate formaldehyde, even in the presence of a small amount of an acid.

Change in pH Value during Reaction. With regard to M1.98F and M2.68F, the pH values of the solution gradually shift toward smaller pH values as the reactions proceed, as Figs. 1(1), 2 (1) and 5(1) show, particularly at [HCl]/[M]= 0.5 (molar ratio). Thus, the change in pH value is observed, in particular, when the condensation rate is large. The melamine rest in the condensate is surely less basic than that of methylolmelamine; this effect accounts for the above fact.

On the contrary, with regard to M5.65F, the pH values were found to shift toward larger pH values (Figs. 3(1) and 4(1)). This fact may be explained as follows: During the course of reactions, high methylolmelamines easily decompose into lower methylolmelamines, liberating formaldehyde, as has been described above. Hence, the basicity of the solution increases as the decomposition proceeds, because the basicity increases in the order of M1.98F>M2.68F≫M5.65F (based on their neutralization curves). The observed change in the pH value is mainly affected by the above effect, only slightly by the opposing effect of the decrease in the basicity as the result of the formation of the condensate.

Differential Thermal Analysis and Thermobalance Measurement. As is shown in Fig. 6 (differential thermal analysis), the endothermic peaks, somewhat flattened, were observed at *ca.* 150°C in M2.68F and M5.65F.

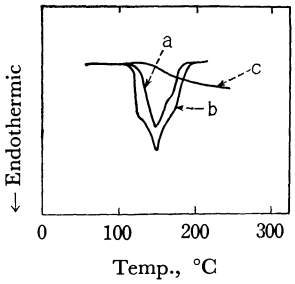

Fig. 6. Investigations by differential thermal analysis.
a: M2. 68F b: M5. 65F c: Melamine

General molding in methylolmelamine, irrespective of the type of molding, is carried out at *ca.* 150°C[10] in commercial practice; hence, the condensation must proceed considerably at this temperature. Since the temperature of endothermic peak closely coincides with that of the molding, this peak may be explicable from the considerations that the condensation proceeds upon

the discharge of a large amount of water (according to Eqs. (3) and (4), 1 mol of water is discharged for 1 mol of each methylene linkage), and that the heat of vaporization of water is large.*4

Next, Fig. 7 (thermobalance) shows the reduction in the weight of methylolmelamine that was observed during the rise in the temperature. This reduction may result from the liberation of formaldehyde by the thermal decomposition of methylolmelamine, and that of water by the condensation of methylolmelamine. Also, a more striking reduction in weight was observed in M5.65F than in M2.68F. This result may be explained from the thermal unstability of M5.65F, which easily liberates formaldehyde.

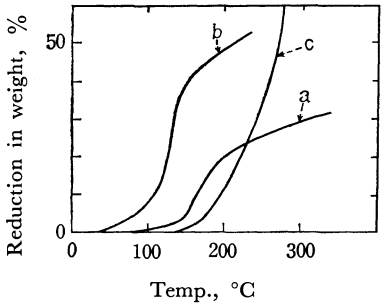

Fig. 7. Investigations by thermo-balance.
a: M2.68F b: M5.65F c: Melamine

Besides, melamine sublimes[12] easily. The observed endothermic behavior (Fig. 6(c)) and reduction in weight (Fig. 7(c)) may be due to this sublimation.

Condensation Mechanism for the Early Stage. Since the curve showing the condensation rate *vs.* the acidity for methylolmelamine resembles that of an acid-catalyzed semicarbazone formation,[13] and since a C–N linkage is formed in both reactions, a similarity in mechanism may be suggested.

Methylolmelamine and methylolurea are both amino resins. The condensation rate of methylolurea[14] increases with an increase in the acidity, but, contrarily, that of methylolmelamine passes through a maximum. This different behavior in the condensation rate *vs.* the acidity suggests a difference in their condensation mechanisms; it may be explained in brief in terms of the large difference in their basicities.

Let us discuss the condensation mechanisms of low and high methylolmelamines for the early stage.

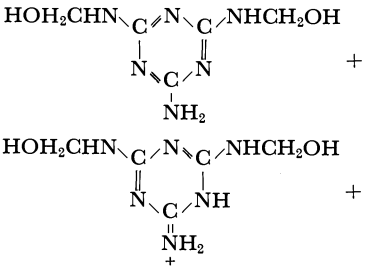
(1) Di- and Tri-methylolmelamine. Although low methylolmelamines such as di- and trimethylolmelamine are slightly less basic[15,16] (mono-acidic)[17] than melamine, these low methylolmelamines, unlike methylolurea, have sufficient basicity to combine with an equivalent amount of hydrochloric acid to form the conjugate acid. The relation between the molecular form of methylolmelamine, MCH_2OH, and its conjugate acid, $\overset{+}{H}MCH_2OH$, is shown in Eq. (1):

$$MCH_2OH + H_3O^+ \overset{K}{\rightleftarrows} \overset{+}{H}MCH_2OH + H_2O \quad (1)$$

$$K = \frac{[\overset{+}{H}MCH_2OH]}{[MCH_2OH][H_3O^+]} \quad (1')$$

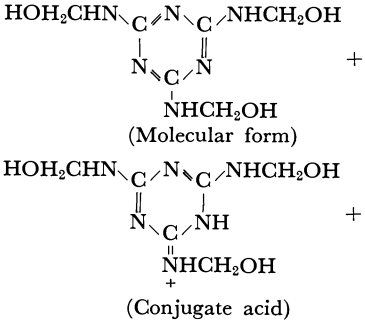
The structure of the conjugate acid has been demonstrated by Dixon *et al.*[15-18] on the basis of the ultraviolet absorption spectra (Eqs. (1a) and (1b)):

Di-methylolmelamine:



(1a)

Tri-methylolmelamine:



(1b)

(Conjugate acid)

Therefore, the condensation takes place between them, and Eq. (2) may be derived:

*4 In the case of hexa-methylolmelamine-hexamethylether,[11] scarcely no endothermic peak was observed at *ca.* 150°C (or even in the range of *ca.* 30—200°C). This result may be due to the fact that this condensation occurs with the liberation of methanol, as is well known, and that the heat of the vaporization of methanol is markedly small.

	MCH_2OH	$\overset{+}{H}MCH_2OH$
MCH_2OH	k_1	k_2
$\overset{+}{H}MCH_2OH$	k_2	k_3

$$\text{Rate} = k_1[MCH_2OH]^2 \quad \text{(molecular form, molecular form)} \quad \text{1st term}$$
$$+ k_2[MCH_2OH][\overset{+}{H}MCH_2OH] \quad \text{(molecular form, conjugate acid)} \quad \text{2nd term} \qquad (2)$$
$$+ k_3[\overset{+}{H}MCH_2OH]^2 \quad \text{(conjugate acid, conjugate acid)} \quad \text{3rd term}$$

where k_1, k_2, and k_3 are the respective rate constants of the elementary reaction in Eq. (2).

The condensation without an acid is evidently a reaction between the molecular forms themselves, *i. e.*, the first term of Eq. (2). This reaction is markedly slow because the condensation without an acid does not proceed even after a long time has elapsed, as is clear from (a) of Figs. 1(1), 2(1) and 5(1).

The condensation may occur by an attack of the electrophilic carbon of the amino-methylol group on the nitrogen of the amino group or on that of the amino-methylol group of methylolmelamine. In view of this, the carbon of the amino-methylol group of the conjugate acid is markedly more electrophilic, that is to say, conspicuously more reactive, than that of the molecular form of methylolmelamine; also, the amount of the conjugate acid (reactive) increases with an increase in the acidity. The enhancement of the rate with an increase in the acidity in the range of [HCl]/[M]< 0.5 (molar ratio) can be explained by this mechanism. This is expressed in Eqs. (3) and (4):

$$\overset{+}{H}\text{-MNHCH}_2\text{OH} + H_2NM \rightarrow \overset{+}{H}\text{-MNHCH}_2\text{NHM} + H_2O \qquad (3)$$

(the formation of the *methylene bisamide linkage*)

$$\overset{+}{H}\text{-MNHCH}_2\text{OH} + \text{HN}\overset{\text{CH}_2\text{OH}}{\overset{|}{\text{M}}} \rightarrow \overset{+}{H}\text{-MNHCH}_2\text{N}\overset{\text{CH}_2\text{OH}}{\overset{|}{\text{M}}} + H_2O \qquad (4)$$

(the formation of the *methylol methylene bisamide linkage*)

However, this effect is counteracted by the increasing removal of the molecular forms of methylolmelamines by the formation of the conjugate acid in the range of [HCl]/[M]>0.5 (molar ratio). The result of these opposing factors obviously is that a maximum appears at *ca.* [HCl]/[M]=0.5 (molar ratio); this 0.5 (molar ratio) value corresponds to pH=log$K$*5 where K is an equilibrium constant between the molecular form of methylolmelamine and its conjugate acid (see Eq. (1')).

In other words, the maximum can be explained from Eq. (2) as follows: According to the above electronic theory, k_2 is markedly larger than k_1 or k_3. (k_1 shows the smallest value because the smallest condensation rate is observed without an acid, as is shown in Fig. 1(1), 2(1) and 5(1).) Thus, k_2 is larger than k_1, and k_3 is smaller than k_2, thus accounting for the increase in the rate in the range of [HCl]/[M]<0.5 (molar ratio), and the decrease in the rate in the range of [HCl]/[M]> 0.5 (molar ratio). Also, the $[MCH_2OH][\overset{+}{H}MCH_2OH]$ (concentration product) of the second term in Eq. (2) shows a maximum at $[MCH_2OH]=[\overset{+}{H}MCH_2OH]$, as is clear from Eq. (1').*6 Consequently, a maximum in the rate appears at this point. In view of this, it may be considered that the main reaction in the condensation among the three reactions of Eq. (2) in the range of 0< [HCl]/[M]<1.0 (molar ratio) is that between the molecular form of methylolmelamine and its conjugate acid (the second term).

In this case, methylolmelamine is converted into its conjugate acid by the addition of the proton in an acidic region, as has been stated above (*cf.* Eqs. (1), (1a) and (1b)); hence, the proton is scarcely added to methylolmelamine to form carbonium ion (Eq. (5)). Therefore, the carbonium ion, $\overset{+}{M}CH_2$, must play a minor part in the condensation, unlike methylolurea.*7 On the assumptions that the carbonium ion is rapidly formed, *i. e.*, that the

*5 As is well known, the K (or the base constant of methylolmelamine, K_b) is obtained from the pH value of the solution at [HCl]/[methylolmelamine]= 0.5 (molar ratio). The pK_b[15] values of M1.99 F and M3.00F are 9.5 and 10.1 (25°C) respectively; hence, the K is amount to $10^{4.5}$ and $10^{3.9}$ respectively. Therefore, the pH value of the observed maximum agreed fairly well with that computed from the pK_b of the literature.

*6 From Eq. (1'), the following relation can be derived between pH and $\overset{+}{H}MCH_2OH$ (or MCH_2OH):

$$\text{pH} = \log K - \log \frac{\alpha}{1-\alpha}$$

($[\overset{+}{H}MCH_2OH] = \alpha$, $[MCH_2OH]=1-\alpha$)

*7 For example, the condensation of mono-methylolurea in an acidic range[19] is as follows:

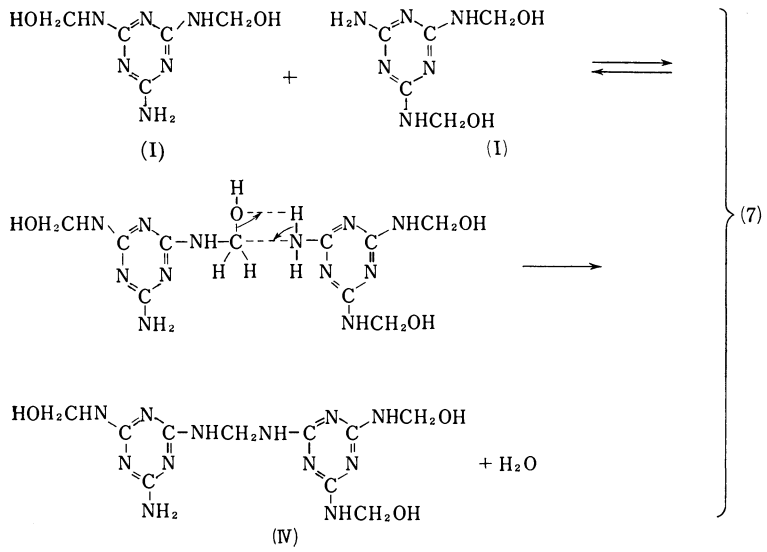
$$H_2NCONHCH_2OH + H_3O^+ \rightleftarrows H_2NCONHCH_2\overset{+}{O}H_2 + H_2O \rightleftarrows H_2NCONH\overset{+}{C}H_2 + 2H_2O$$
$$H_2NCONH\overset{+}{C}H_2 + H_2NCONHCH_2OH \rightarrow H_2NCONHCH_2NHCONHCH_2OH + H^+$$

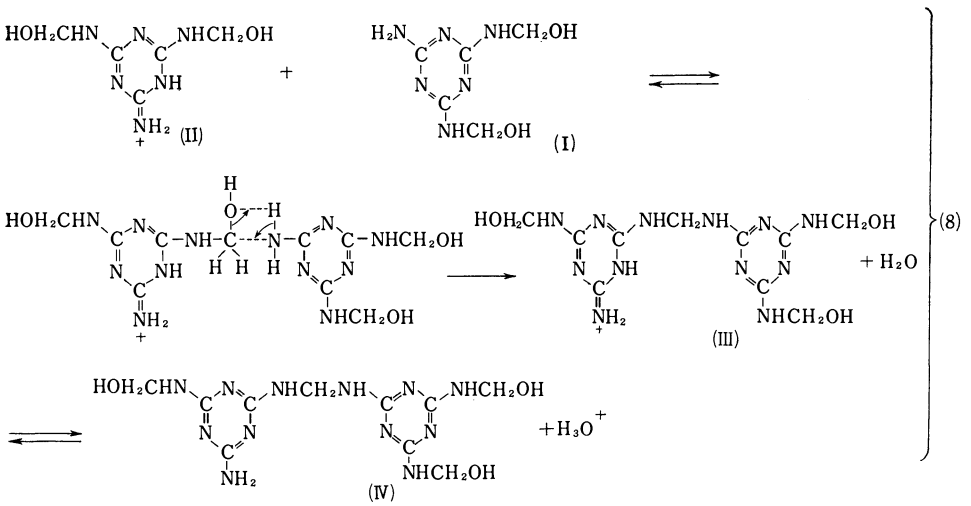
19) G. Smeth, *J. Poly. Sci.*, **8**, 371 (1952); L. E. Smythe, *J. Am. Chem. Soc.*, **75**, 574 (1953) and others.

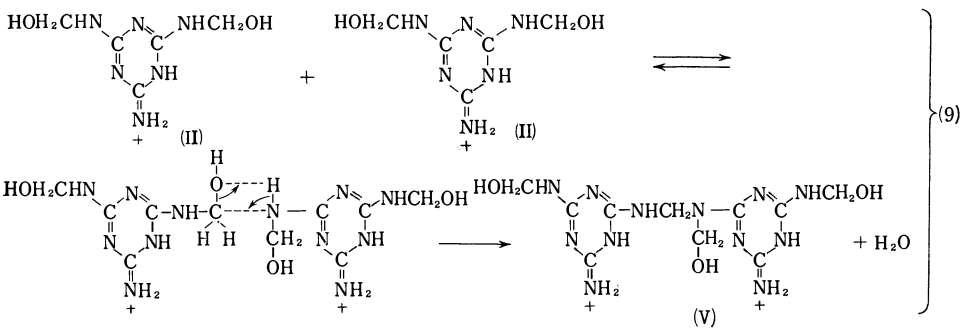
reaction of Eq. (5) is fast, and that the succeeding reaction of the carbonium ion with the molecular form of methylolmelamine (Eq. (6)) is the rate-determining step, the observed maximum may be explained on the basis of this mechanism because the carbonium ion is proportional to the conjugated acid formed (Eq. (1)) at the same pH values, as is clear from the relationship between Eqs. (1) and (5):

$$MCH_2OH + H_3O^+ \rightleftarrows MCH_2\overset{+}{O}H_2 + H_2O \rightleftarrows M\overset{+}{C}H_2 + 2H_2O \quad (5)$$

$$M\overset{+}{C}H_2 + MCH_2OH \rightarrow M\overset{+}{C}H_2MCH_2OH \quad (6)$$







However, it is not clear whether or not these assumptions are reasonable. On the other hand, *if the conjugate acid itself reacts as an active species,* the observed maximum can readily be accounted for without any assumption, as has been indicated above.

Furthermore, the main reaction for the condensation among the three reactions of Eq. (2) in the range of [HCl]/[M]>1.0 (molar ratio) may be considered to be that between the conjugate acids of methylolmelamine themselves, *i. e.,* the third term of Eq. (2), because the concentration of the molecular form of methylolmelamine is markedly small (methylolmelamine turns almost completely into its conjugate acid) and the observed rate (Figs. 1(1), 2(1) and 5(1)) is considerably larger than that of a reaction between the molecular form of methylolmelamine and its conjugate acid, both concentrations being computed from the base constant[15] of methylolmelamine. (That is, if the main reaction in this range is the second term of Eq. (2), the rate must be considerably smaller than the observed one; the same is true for the first term of Eq. (2). Consequently, the main reaction in this range is neither the first term nor the second term of Eq. (2).)

Previously[20] it has been speculated that the condensation of methylolmelamine in such a strong acidic range takes place between the conjugate acids themselves; but there has been no experimental evidence for this. Nevertheless, the present findings may support this speculation. In a strongly acidic range, reactions between conjugate acids themselves have often been reported.[21]

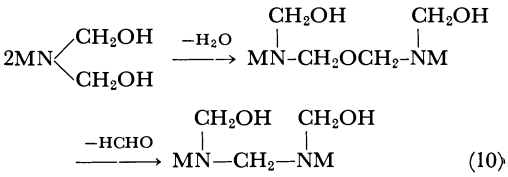
Next, in view of the above, let us propose some structural mechanisms of the reaction between the molecular forms (I) themselves, the conjugate acid (II) and the molecular form, and the conjugate acids themselves to form the dimer in the early stage. Those mechanisms are illustrated in relation to di-methylolmelamine in Eqs. (7), (8), and (9) respectively.

In Eq. (8), with the formation of the dimer with the conjugate acid form (III), this dimer converts into its molecular form (IV: triazine with the conjugate double bond) with the release of the proton, because the melamine rest of the dimer is less basic than that of the starting methylolmelamine; this probably takes place to a major extent with the molecular form of methylolmelamine and its coexisting conjugate acid (0<[HCl]/[M]<1.0 (molar ratio)). Hence, the proton thus released combines with ane quvalent amount of the molecular form of methylolmelamine to form its conjugate acid (reactive). The fact that the maximum shifts toward smaller [HCl]/[M] values as the condensation proceeds is thus obviously accounted for. Also, in the case of methylolmelamine, small changes in the acidity have a greater effect on the condensation rate than in the case of methylolurea (near the neutral region)[22]; this fact, which is well known from experience, may be explained by this mechanism.

With the further growth of the condensate, additional protons are released as the basicity decreases, so that in the case of the trimer a smaller proportion would exist in the charged form, *i. e.,* in the conjugate acid form, than in that of the dimer. (In Eq. (7), the release of the proton does not take place.)

On the other hand, the reaction of Eq. (9) takes place to a major extent in the range of [HCl]/[M]>1.0 (molar ratio), as has been stated above; hence, more hydrochloric acid than methylolmelamine is present in this range. Therefore, the release of the proton in the dimer with the conjugate acid form (V) seems to be markedly smaller than that in the reaction of Eq. (8) in this range. However, since the melamine rest of the condensate in the latter stage is markedly less basic, this condensate may easily release the proton more than in the case of the dimer.

(2) Hexa-methylolmelamine. Hexa-methylolmelamine has the terminal group $-(CH_2OH)_2$. Hence, it is assumed that a dimethylene ether linkage, $-CH_2OCH_2-$, is formed with the liberation of water, and then this linkage, completely or partially or not all, is converted into a methylene linkage with the liberating formaldehyde during the course of the condensation. This is shown in Eq. (10):



(10)

The reaction of Eq. (10) may play a minor part in the condensation under the conditions of Figs. (3) and (4), because no dimethylene ether linkage could be found by the conventional analytical method[23] during the course of the reactions; what is more, when the rate of the formation of the methylene linkage of M2.68F was compared with that of M5.65F under the same conditions (The investigation was carried out in the medium of an aqueous-DMSO solution without an acid.), the

rate of M5.65F was confirmed to be negligibly smaller than that of M2.68F.

Contrarily, in the polycondensation reaction of melamine-formaldehyde, Gam *et al.*[24] have attached particular importance to the dimethylene ether linkage and have assigned a minor role to the methylene linkage as a condensate—forming linkage. However, as has been demonstrated above, the reaction forming a dimethylene ether linkage is slow; this linkage would be formed if the temperature were higher and the solution more concentrated than in the present experiments.

From this evidence, the condensation mechanism of hexa-methylolmelamine may be considered to be that hexa-methylolmelamine first decomposes into a lower methylolmelamine such as tri- or tetra-methylolmelamine in the presence of an acid, and that then the condensation proceeds by the same mechanism as in the case of a low methylolmelamine. The observed results can be explained by this mechanism. The decomposition of hexa-methylolmelamine at a high temperature proceeds even in the presence of a small amount of an acid. Therefore, as the temperature is raised, the maximum shifts toward smaller [HCl]/[M] values and approaches to *ca.* [HCl]/[M]=0.5 (molar ratio), as has been stated above. On the other hand, with a lowering of the temperature, the maximum shifts toward larger [HCl]/[M] values, because the decomposition of hexa-methylolmelamine proceeds slowly and more acid is necessary for its decomposition with a lowering of the temperature.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 17—25 (1968)

Stability of Hydrosol of Arsenic Trisulphide in the Light of D. L. V. O. Theory

K. L. DALUJA and S. N. SRIVASTAVA

Department of Chemistry, Agra College, Agra, India

(Received May 1, 1967)

The stability of negative As_2S_3 sol of mean particle diameter 90 Å has been studied in presence of different valent cations *viz.* Na^+, Ba^{2+}, UO_2^{2+}, Al^{3+} and Th^{4+} using D. L. V. O. theory. The zeta potential (assumed to be equal to the surface potential) of the sol particles was calculated from the electrophoretic measurements as a function of ionic strength. The knowledge of zeta potential permitted the calculation of repulsive energy V_R, and the energy of attraction V_A was estimated from physico-chemical data. The stability ratio, W, was calculated from interaction profiles which were made from the combination of the two energies. Stability factor, F, was also estimated from the Derjaguin equation, but it was not satisfactory presumably owing to the exclusion of V_A. In general, the interaction between As_2S_3 particles could be interpreted in the light of D. L. V. O. theory. The flocculation powers of cations were in the order of $Al^{3+} > Th^{4+} > UO^{2+} > Ba^{2+} > Na^+$. The anomalous behaviour of thorium is perhaps due to its hydrolysis.

From the survey of literature it appears that sufficient data are available on As_2S_3 sol.[1-10] However, there is a lack of quantitative data especially in the light of some recent developments on the stability theory of lyophobic colloids. In the present work, therefore, an attempt has been made to apply the modern theory of the subsidence of lyophobic sols due to Derjaguin, Landau,[11,12]

Verwey and Overbeek[13] (D. L. V. O. theory) to the flocculation results of the hydrosol of arsenic trisulphide. The use of the three important variables namely particle radius a, surface potential ϕ_0 and Debye-Hückel reciprocal length κ has been made while applying the D. L. V. O. theory in order to calculate interaction energies, stability factor and flocculating concentrations.

Theoretical

The Stability Theory and Its Application to the Present System. According to the well known theory of the stability of lyophobic colloids the stability depends upon the total energy of interaction between two colloidal particles consisting of a long range electrical repulsion and van der Waals attraction. If the resultant potential energy barrier is high enough, *viz.* $V \geqslant 15\,\boldsymbol{k}T$, the colloidal system is stable, otherwise a portion of colliding colloidal particles can surmount it, leading to flocculation. The potential energies of repulsion and attraction and the total attraction are given below.

Potential Energy of Repulsion V_R. The potential energy of repulsion between two spherical particles of radius a, electrical potential ϕ_0, interparticle distance H_0 is given by a simple approximate equation (*loc. cit.*),

$$V_R = \frac{\varepsilon a \phi_0^2}{u+2} e^{-\tau u} \tag{1}$$

which is valid only for the small value of τ, where ε is the dielectric constant of the medium, $u = H_0/a$ and $\tau = \kappa a$.

Potential Energy of Attraction V_A. The potential energy of attraction can be put into the simple form[14]

$$V_A = \frac{-A}{12u} \qquad \text{(Provided } u \ll 1\text{)} \tag{2}$$

Here A is the van der Waals or Hamaker constant.

Total Potential Energy of Interaction V and the Stability Ratio W. The total energy of interaction V, for the present system where other energies can be neglected, is simply the sum of the repulsive and attractive energies. For slow flocculation, the theory is developed by Fuchs[15] who found that the effective collisions were reduced by a factor W which is termed the stability ratio. This ratio is related to the potential energy of interaction V as follows,

$$W = 2\int_2^\infty \exp \frac{1}{\boldsymbol{k}T}\left(\frac{\varepsilon a \phi_0^2}{u+2} e^{-\tau u} - \frac{A}{12u}\right) \times \frac{du}{(u+2)^2} \tag{3}$$

Here the value of W has to be obtained by graphical integration using the plots of $\exp(V/\boldsymbol{k}T)/s^2$ against s.

An approximate equation[16] as given below may also be used for the value of stability ratio of lyophobic colloid.

$$W = \exp\left(V_{max}/\boldsymbol{k}T\right)/2\kappa a \tag{4}$$

where V_{max} is the maximum in the potential energy curves.

Derjaguin (*loc. cit.*) has also described a formula for the stability of lyophobic sols as given below,

$$F = \frac{\varepsilon a \phi_0^2}{2\boldsymbol{k}T} \tag{5}$$

in which attraction force has been neglected. Here F is the stability factor and other terms have the usual significance.

Theoretical Calculation of van der Waals Constant A. To calculate London-van der Waals attraction constant A, Hamaker (*loc. cit.*) has given an equation (*cf.* Srivastava[17])

$$A = \pi^2 q^2 L \tag{6}$$

where q is the number of atoms (molecules) in 1 m*l* of the substance composing the particles and L is the London constant which is calculated from the following equations.

(i) The Slater-Kirkwood[18] (S-K) equation.

$$L_{\text{S-K}} = 11.25 \times 10^{-24}\, \nu^{1/2} P^{3/2} \tag{7}$$

(ii) The Slater-Kirkwood equation modified by Moelwyn-Hughes[19] (S–K–M)

$$L_{\text{S-K-M}} = 7.8 \times 10^{-24}\, \nu P^{3/2} \tag{8}$$

(iii) Neugebauer[20] (N) equation

$$L_{\text{N}} = -1.62 \times 10^{-6}\, \kappa P \tag{9}$$

where ν is the number of valency electrons in the outer shell, P is the polarizability and κ is the diamagnetic susceptibility. Polarizability is calculated from the classical Clausius-Mosotti equation.

However, the value of A obtained from Eq. (6) is for the interaction between two As_2S_3 solid particles in vacuum. Therefore, to calculate the interaction between As_2S_3 solid particles in water a correction has been made and interaction was calculated from the expression (*loc. cit.*)

$$A = \left(A^{1/2}_{As_2S_3\text{-}AS_2S_3} - A^{1/2}_{H_2O\text{-}H_2O}\right)^2 \tag{10}$$

Experimental Procedure

Materials. All the chemicals were of B. D. H. Analar grade. All glassware was of Pyrex and was thoroughly cleaned before use. Ordinary distilled

water redistilled from an all Pyrex apparatus and having the specific conductance $\approx 1\times10^{-6}$ ohm^{-1}cm^{-1} was used for all experimental work.

Preparation of the As_2S_3 Sol. To prepare the arsenic trisulphide sol a very slow stream of hydrogen sulphide gas was bubbled through 250 m*l* redistilled water in which 250 m*l* aqueous solution 0.4% arsenic trioxide was added dropwise. The speed of the drops and stream of hydrogen sulphide were adjusted in such a manner that the addition of each drop of aqueous solution of arsenic trioxide was followed by 3—4 bubbles of H_2S gas. The excess of H_2S gas was then removed by passing a current of purified hydrogen gas till the H_2S gas completely removed. The light yellow sol of As_2S_3 so obtained was then dialysed in a parchment paper bag against slow running distilled water for one and a half day. The conductance of the As_2S_3 sol thus obtained was 3.2×10^{-5} ohm^{-1} cm^{-1}.

Electrophoretic Mobility Measurements. The mobility measurements were made by moving boundary method. To measure the elcctrophoretic mobility of the sol, the experiments were carried out in a modified apparatus[21] of Burton tube fitted with two wide side tubes. Constant current was supplied to the platinum foil electrodes in wide tubes and the potential drop across the two Pt electrodes in U-tube was measured with a vacuum tube voltmeter. Measurements were made at sharp descending boundary between the colloidal solution and an equiconducting aqueous solution of acetic acid.

The zeta potential was calculated by the Overbeek[22,23] formulae for symmetrical and unsymmetrical electrolytes from the following equations (*cf.* Hückel[24])

$$U=\frac{\varepsilon\zeta}{6\pi\eta}\left[f_1(\kappa a)-v^2\left(\frac{e\zeta}{kT}\right)^2 f_3(\kappa a)-\frac{\rho_+ +\rho_-}{2e}\cdot\frac{\varepsilon kT}{6\pi\eta e}\left(\frac{e\zeta}{kT}\right)^2 f_4(\kappa a)\right] \quad (11)$$

$$U=\frac{\varepsilon\zeta}{6\pi\eta}\left[f_1(\kappa a)-(v_- - v_+)\left(\frac{e\zeta}{kT}\right)f_2(\kappa a)-\frac{\rho_+ v_+ -\rho_- v_-}{(v_+ +v_-)e}\cdot\frac{\varepsilon kT}{6\pi\eta e}\left(\frac{e\zeta}{kT}\right)^2 f_4(\kappa a)\right] \quad (12)$$

Here $f_1(\kappa a)$ is identical with the Henry function and the $f_2(\kappa a)$, $f_3(\kappa a)$ and $f_4(\kappa a)$ have been tabulated by Overbeek.[23] v_+ and v_- are the valencies of the cations and anions respectively. ρ_+ and ρ_- are the frictional constant of the cations and anions respectively of the used electrolyte. Other terms have their usual meaning.

Electron Microscopic Size of the Colloidal As_2S_3 Particles. A Sample of the colloidal solution under investigation was diluted 10 times. A specimen for electron microscopy was prepared by allowing a small drop of specimen in liquid suspension to dry on 200 mesh copper grid support which had earlier been covered with thin film of collodion. The electron photograph was taken on Siemens Elmiskop I electron microscope at 100kV (due to courtesy of Dr. K. Bahadur, Officer in-charge of electron microscopy Division, Defence Science Laboratory, Delhi).

Results and Discussion

Size of the Particles of As_2S_3 Sol. A typical electron micrograph of As_2S_3 sol particles is given in Fig. 1 and the particles size distribution curve obtained from this is given in Fig. 2. The mean particle radius was found to be 45 Å.

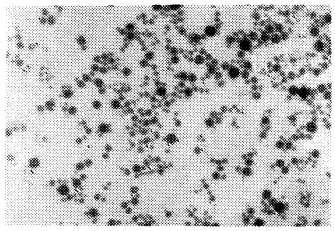

Fig. 1. Electron micrograph of negative As_2S_3 sol under the magnification of 1.2×10^5.

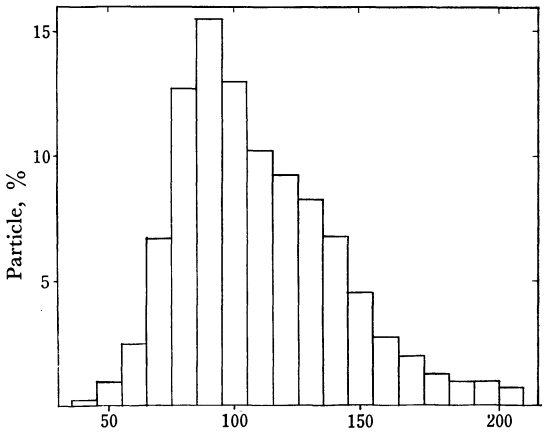

Fig. 2. Particle size distribution of negative arsenic trisulphide sol.
Number of particles counted=400
Mean diameter of the particles=90 Å

The Zeta Potentials. The concentration and pH of the 50% diluted sol were 1.2×10^{-3} g/m*l* and 4.0±0.05. The experimental value obtained for the mobility of the above arsenic trisulphide sol was 5.4 (μ/sec)/(V/cm) at 26°C. The zeta potential calculated from this value was 102.6 mV.

The mobility and zeta potential of As_2S_3 sol particles as a function of log molar concentration of different electrolytes are given in Figs. 3 and 4 respectively. In general, it is seen that the mobility and the zeta potential decrease as the concentration of electrolytes increases. With NaCl the fall of the zeta potential is almost linear throughout but with $BaCl_2$, $UO_2(NO_3)_2$, $AlCl_3$ and $Th(NO_3)_4$, it is comparatively slow in the initial stages and then becomes sharp. The minimum zeta potential that could be conveniently measured was about 60 mV below which there was visible flocculation of the sol particles.

Calculation of van der Waals Constant. The value of the London constant is required to calculate van der Waals constant which was calculated using the susceptibility of one gram formula wt.[25] $=-7.00\times10^{-5}$, $\nu=28$ and $P=2.16\times10^{-23}$ (calculated from Clausius-Mosotti equation using refractive index data of As_2S_3.[26] With the proper choice of units the London constant, calculated from Eqs. (7), (8) and (9) are as follows

$$L_{S\text{-}K}^{As_2S_3} = 6.0\times10^{-57}\ \text{erg cm}^6$$

$$L_{S\text{-}K\text{-}M}^{As_2S_3} = 22.02\times10^{-57}\ \text{erg cm}^6$$

and

$$L_N^{As_2S_3} = 4.08\times10^{-57}\ \text{erg cm}^6$$

Now the use of Eq. (6) permits the calculation of van der Waals constant for As_2S_3 from each of the three equations by finding $q(=8.4\times10^{21})$ and density (=3.43). Similarly, the corresponding constant for water is given by Verwey and Overbeek (*loc. cit.*) (see also Watillon[27]) and hence the net attraction constant of As_2S_3 particles in water can be estimated from Eq. (10). The results are summarized in Table 1.

It is found that the value of the van der Waals constant calculated from S-K-M formula yields comparatively high value. Therefore, in the

present calculations, the value of $A_{S\text{-}K\text{-}M}$ has been neglected and for further calculations the mean value of the remaining two ($=1.25\times10^{-12}$ erg) formulae has been used.

An Estimate of the Stability Factor *F*, from the Derjaguin Equation. The stability of the colloid has been first estimated by Derjaguin's Eq. (5) and results have been depicted in Fig. 5. According to theoretical expectation F should be higher than 10 for a colloid to be stable. But for the present system the value of F is not less than 15 even for a reasonably flocculated sol examined within 45 min after preparation. This is inconsistent with the Derjaguin theory. In the application of Derjaguin's Eq. (5) only one approximation ($\psi_0\approx\zeta$) is used which is not expected to effect the results so much. Therefore, the reason for this discrepancy seems to be in the neglect of the van der Waals attraction forces and Debye-Hückel parameter which also play an important part in the stability as discussed before.

Potential Energy. In Fig. 6, Curves I, II and III show the repulsive energy V_R, attractive energy V_A and net potential energy of interaction $V(=V_R+V_A)$ of the As_2S_3 sol corresponding to zeta potential=102.6 mV. This has an energy maximum, $V_{max}=33.4\,\boldsymbol{k}T$ (using van der Waals constant $A=1.25\times10^{-12}$ erg) which is a sufficiently high value to show that the sol is stable.

Potential energy curves of colloidal particles as

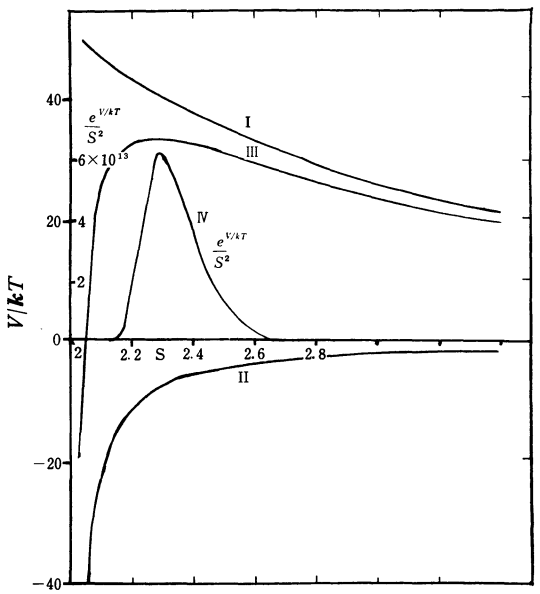

Fig. 6. Curves of potential energy of (I) repulsion, (II) attraction (III) interaction and (IV) of the quantity $\exp(V/\boldsymbol{k}T)/s^2$ *versus* s for the values of $a=45$ Å, $\kappa=4.52\times10^5$ cm^{-1}, $A=1.25\times10^{-12}$ erg and $\zeta=(\psi_0)=102.6$ mV of 50% diluted As_2S_3 sol.

a function of distances between their surfaces are shown in Figs. 7—10 respectively in the presence of NaCl, $UO_2(NO_3)_2$, $AlCl_3$ and $Th(NO_3)_4$ which are in good agreement with theoretical prediction. The value of V_{max} in each case shows the range of slow flocculation till V_{max} decreases to a sufficiently low value which is the threshold of rapid coagulation. In Fig. 8 a dotted curve without relaxation correction to zeta potential=98.8 mV (after correction zeta potential=95 mV) has also been given. This gives an idea of the magnitude of error likely to be introduced if relaxation is not taken into account.

Stability Factor *W*. Stability factor was calculated by graphical integration of Eq. (3), as well as from an approximate Eq. (4) and the results are reported in Table 2. In Fig. 6 a typical Curve IV of $\exp(V/\boldsymbol{kT})/s^2$ *versus* s has been shown to calculate the stability ratio in the absence of electrolytes, where $W=2.63\times10^{13}$, while the value of W calculated from approximate Eq. (4) is 7.4×10^{14}. In Figs. 11 and 12, the curves for log W against log C_e are given for varying concentration of the electrolytes which are of the similar shapes and the slope in the lower part of the slow coagulation range is also almost in the same range. It is found that the values of W obtained from the method of approximate equation are higher than

those calculated from graphical integration. The values of the stability ratio in the zone of slow coagulation are comparable with those obtained by Ottewill and co-workers[28,29] on AgI and arachidic acid systems. The general shape of the log W *versus* zeta potential curves given in Fig. 13 is in keeping with the theory. It is obvious from the curves that higher the value of τ higher is the zeta potential at which flocculation can occur.

To calculate the coagulation concentration of various salts which are used to coagulate As_2S_3 sol the extrapolation of the linear portion of log W against log C_e curve was made to log C_e axis (*loc.*

cit.) where log $W=0$ assuming the validity of the equation[30,31]

$$\log W = K_1 - K_2 \log C_e$$

The values obtained in this manner are given in Table 3. Comparison of the coagulation data given in Table 3 shows that the coagulating concentration is slightly higher in the case when the results were calculated by approximate Eq. (4) than for the results calculated by graphical integration. To confirm the flocculating concentrations so obtained, the turbidity work was carried out.[32]

From the view point of the Schulze-Hardy rule the flocculating concentrations of mono, bi, tri and tetra valent ions would be expected to be

in the ratio of 100 : 1.6 : 0.13 : 0.024 taking the monovalent ion as 100. Experimentally the ratio for Na^+, UO_2^{2+}, Ba^{2+}, Al^{3+} and Th^{4+} was found to be 100 : 1.12 : 1.23 : 0.100 : 0.311 taking Na^+ ions as 100. Thus a marked deviation from the Schulze-Hardy rule occurs particularly with thorium. It appears that the thorium ion present in the pH ranges about 4 was not a simple tetravalent species but contaminated with ions of different valencies as a result of hydrolysis.[33,34]

Reversal of charge with polyvalent ions as usually expected with colloids is absent in the present work. This is in conformity with the work of Troelstra[35,36] who showed that in acid solutions when pH is low the reversal of charge was absent or at least difficult. This was also pointed out by Matijevic and co-workers[37] who showed that the reversal of charge is obviated owing, in all probability, to the presence of the insoluble hydroxide of thorium formed as a result of hydrolysis.

It may be concluded that the D. L. V. O. theory seems to apply reasonably well to the present system for small spherical colloidal particles and high zeta potentials as it gives a satisfactory interpretation of the interactions between As_2S_3 sol particles.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 25—33 (1968)

The Nephelauxetic Effect in Praseodymium(III) and Neodymium(III) Complexes

Seizo Misumi, Sigeo KIDA,*1 Toshiyuki ISOBE and Akio INAZUMI

Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University Hakozaki, Fukuoka

(Received May 19, 1967)

The absorption spectra of praseodymium(III) and neodymium(III) complexes were measured in an aqueous alkaline solution with an excess of ligands. The experimental data being used, the Racah parameter, E^3, and the Landè parameter, ζ_{4f}, werc ealculated by the least-squares method on the assumption that the energy separation between J-levels of the $4f^n$-configuration is a function of E^3 and ζ_{4f}. The nephelauxetic effect in the Pr(III) and the Nd(III) complexes was then discussed by using the values of E^3 thus obtained.

It has been known that the radial integrals of the valence orbitals of a metal ion decrease when the free metal ion combines with ligands to form a metal complex.[1] This phenomenon is called the nephelauxetic effect, which means the expansion of electron clouds; it may be regarded as a measure of the covalency of coordination bands.[1] Although the nephelauxetic effect has been extensively investigated in d-transition metal complexes, the study of f-transition metal complexes has been rather limited because of the theoretical and experimental difficulties.

The absorption bands of lanthanide(III) ions, which are attributed to the electronic transitions within the $4f^n$-configuration ($n=2$—12), are shifted when the environment of the ion is changed. This is undoubtedly an indication of a change in the radical integrals.[2] However, in lanthanide(III) ions the spin-orbit interaction can not be neglected and the radial integrals should be treated by an intermediate coupling scheme.[3] The separation between J-levels of the $4f^n$-configuration may be expressed in terms of the radial integrals (f)[4] and the spin-orbit coupling parameter.

3) B. G. Wybourne, "Spectroscopic Properties of Rare Earth," Interscience, New York (1965), pp. 42—49.

4) The radial integral of the $4f$-orbital is usually expressed in terms of Slater-Condon Parameters, F^k's ($k=0$, 2, 4, and 6) or Racah parameters, E^k's ($k=0$, 1, 2, and 3). In this paper we used E^k for convenience.

Jørgensen and others[5-9] took the value of $1-\beta=\Delta\tilde{\nu}/\tilde{\nu}_{aquo}=(\tilde{\nu}_{aquo}-\tilde{\nu}_{complex})/\nu_{aquo}$ (where ν stands for the wave number of an absorption band of a lanthanide(III) ion) as a measure of the nephelauxetic effect, assuming that each J-level of a $4f^n$-configuration is linearly dependent only on the radial integrals. On this assumption, the $\Delta\tilde{\nu}/\tilde{\nu}_{aquo}$ of all bands of the same lanthanide(III) complex should be identical; however, an inspection of the experimental data[9] has revealed that the $\Delta\nu/\nu_{aquo}$ values for different J-bands of a lanthanide complex differ from each other considerably. Therefore, it is necessary to obtain the radial integrals or Racah parameters, E^k's (interelectronic repulsion parameters), and the spin-orbit coupling constant or Landè parameter, ζ_{4f}, simultaneously on the assumption that the energy of the J-levels is a function of E^k's and ζ_{4f}.

Calculation

In the intermediate coupling scheme, the energy separations between J-levels of an f^n configuration ($n=2-12$) are expressed approximately in terms of radial integrals, F_2, F_4 and F_6 (Slater-Condon parameter), or E^1, E^2, and E^3 (Racah parameter), and the spin-orbit coupling parameter, ζ_{nf} (Lande parameter).*2

According to Wybourne, if a hydrogenic wave function is assumed,[6] the ratios of the radial integrals are given by:

$$E^1 : E^2 : E^3 = 14.6817 : 0.0768463 : 1.48447 \quad (1)$$

This relation being used, the energy of a J-level can be expressed as a function of the two variables, E^3 and ζ_{4f}.

Applying Taylor's theorem and neglecting the higher order terms, one may obtain:

$$g_i(E^3, \zeta) = g_i(E_0{}^3, \zeta_0) + \left(\frac{\partial g_i}{\partial E^3}\right)_{E^3=E_0{}^3}\chi + \left(\frac{\partial g_i}{\partial \zeta_0}\right)_{\zeta=\zeta_0} y \quad (2)$$

where $g_i(E^3, \zeta)$ denotes the energy of the ith J-level from the ground state, $E^3=E_0{}^3+\chi$, $\zeta=\zeta_0+y$, $E_0{}^3 \gg \chi$ and $\zeta_0 \gg y$. The numerical values of the parameters of the trivalent lanthanide compounds, $E_0{}^3$ and ζ_0, may be taken from the literature,[10] then $g_i(E_0{}^3, \zeta_0)$, $(\Delta g_i/\Delta E^3)_\zeta$ and $(\Delta g_i/\Delta\zeta)_{E^3}$ can be calculated by solving the secular equation derived from the spin-orbit matrix and the LS term energies. Accordingly, $g_i(E^3, \zeta)$ is simplified to a linear function of χ and y, assuming that

$$(\Delta g_i/\Delta E^3)_\zeta = \partial g_i/\partial E^3 = a_i:$$
$$(\Delta g_i/\Delta\zeta)_{E^3} = \partial g_i/\partial\zeta = b_i.$$
$$g_i(E^3, \zeta) = k_i + a_i\chi + b_i y \quad (2')$$

where $k_i = g_i(E_0{}^3, \zeta_0)$.

Based on Eq. (2'), χ and y are obtainable by the least-squares method using the experimental values.

Pr(III). The LS term energies and the spin-orbit matrices were obtained by Condon and Shortley[11] and by Satten and Margolis[12] respectively. The calculation was carried out by putting $E_0{}^3=451.36\ cm^{-1}$ and $\zeta=729.5\ cm^{-1}$. Four experimental values were used for the least-squares calculation for each praseodymium(III) complex (*Cf.* Table 2).

Nd(III). Instead of doing laborious calculations, we have made use of the results of the detailed calculation of Carlson and Crosswhite.[13] Putting $E_0{}^3=492.00\ cm^{-1}$ and $\zeta=861.72\ cm^{-1}$, we obtained the numerical values of $g_i(E_0{}^3, \zeta_0)$, $(\partial g_i/\partial E^3)_{E^3=E_0{}^3}$ and $(\partial g_i/\partial\zeta)_{\zeta=\zeta_0}$ for each J_i-level; then we carried out the least-squares cal-

* *Cf.* the footnote of Table 1.

culation using eleven experimental values for each neodymium(III) complex (*Cf.* Table 2).

Experimental

Measurements. The absorption spectra were measured at room temperature (about 20°C) with a Hitachi EPS-2 spectrophotometer, a 10 mm quartz cell being used.

The concentration of the solution was 0.1 mol/*l* for the lanthanide(III) perchlorate. Enough excess ligand was used as to cause complex formation. Since the absorption spectra may be affected by the pH of the solution under some conditions, ammonia was added to the solution until the increase in pH did not affect the absorption bands any more. The pH values and the ratio of metal to ligand in the solution are listed in Table 1.

Materials. The lanthanide(III) perchlorate solutions were prepared by dissolving pure lanthanide

TABLE 4. THE NAPHLAUXETIC EFFECT OF $4f$- AND $3d$-TRANSITION METAL COMPLEXES

Metal ion	Co(III)	Ni(II)	Mn(II)	Pr(III)	Nd(III)
Ligand	3(oxalate)	EDTA	EDTA	EDTA	EDTA
β'	0.88	0.91	0.96	0.990	0.991
$1-\beta'$	0.12	0.09	0.04	0.010	0.009

oxides (purity: more than 99.99%) in perchloric acid. Since the absorption spectra of the aqueous solutions were completely in accord with the literature,[14] they were not purified further.

Results and Discussion

Since it was difficult to obtain the barricenter of the J-band experimentally, we had to be satisfied with taking the center of the band (not the peak).

The energies of the J-levels of each lanthanide(III) complex were obtained using the results of the least-squares calculations.

The accordance of the calculated values with the observed values was satisfactory. The calculated values of the aquo complexes are shown as examples in the second column of Table 2.

The values of E^3 and ζ_{4f} obtained are listed in Table 3. By using these data, the degree of the nephelauxetic effect of $4f$-transition metal complexes can be compared with that of d-transition metal complexes in terms of $1-\beta'$ (where $\beta'=F_k(\text{complex})/F_k(\text{aquo})$), as illustrated in Table 4.

Jørgensen[5] has made a similar comparison by regarding $(\tilde{\nu}_{\text{aquo}}-\tilde{\nu}_{\text{comp}})/\tilde{\nu}_{\text{aquo}} \fallingdotseq 1-\beta'$, assuming that the separation between J-levels is linearly dependent only on E^3. He studied several lanthanide(III) complexes with tartarate, citrate, EDTA, *etc.* in solution and obtained $1-\beta'=0.8$—1.2×10^{-2} for Pr(III) and 0.4—0.7×10^{-2} for Nd(III). In the present study, the values of $1-\beta'$ were 0.8—1.0×10^{-2} for Pr(III) and 0.7—0.9×10^{-2} for Nd(III). Jørgensen's values agree with ours fairly well, considering his simple method and the small differences in materials and conditions.

In connection with the above discussion, it should be noted that the absorption spectrum of a lanthanide(III) complex in an aqueous solution depends not only on the species of the metal ion and the ligand, but also on the metal-ligand ratio and the pH of the solution. The experimental conditions for the nephelauxetic effect, $1-\beta'$, obtained in this study are shown in Table 1. In spite of this limitation, however, the results of the present study are still useful for estimating the covalent character of the $4f$ electrons of the lanthanide(III) ion.

Furthermore, in some cases, the present data may serve to give some information on the configuration of the complex. For example, as may be seen in Table 3, the cysteine complex shows the smallest E^3 and is located on the bottom of the nephelauxetic series in either a praseodymium(III) or a neodymium(III) complex; on the other hand, the other α-amino acids, such as glycine, alanine, and serine, are placed on the upper positions of the series in both praseodymium(III) and neodymium(III) complexes. This fact suggests that the sulfur atom of cysteine takes part in the formation of the cysteine complex in the solution. Jørgensen[15] has already shown that the nephelauxetic effect of sulfur-coordinated metal ions is much stronger in covalency than that of oxygen- or nitrogen-coordinated metal ions.

This study was partly supported by grants from the Ministry of Education and the Japan Society for the Promotion of Science, to both of which organizations the authors wish to express their thanks.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 34—41 (1968)

Electronic Absorption and Emission Spectra of 9, 10-Dichloroanthracene and 9, 10-Dibromoanthracene Crystals

Jiro TANAKA and Masao SHIBATA

Department of Chemistry, Nagoya University, Chikusa, Nagoya

(Received June 12, 1967)

The electronic absorption spectra of three crystalline modifications of anthracene derivatives have been measured; they are the α and β form of 9, 10-dichloroanthracene and 9, 10-dibromoanthracene. The assignment has been presented for each absorption band. The charge transfer absorption which is regarded to the transition between two stacked molecules has been observed in the α-form of 9, 10-dichloroanthracene; also a Rydberg type transition which has an out of plane polarization is found in this crystal starting at 290 mμ. It is unusually broad and is regarded as a band to band transition. The emission band has been measured at different temperature; it is found that excimer type emission is most prominent in the β-form of 9, 10-dichloroanthracene, in which intermolecular approach in the excited state will occur with less difficulty. A criterion for strong, medium, and weak interactions in the excited state is presented by comparing the shift, and the shape of the emission band with the intermolecular vibrational spacing. These results show that the charge transfer interaction and excimer formation are greatly dependent on the relative orientation of molecules, the π-electron overlap, and the difficulty of intermolecular approach in the excited state, particularly with its correlation to the steric repulsion of the bulky substituent groups.

Recently a number of investigations have been published on the problem of excimer and the charge transfer state of aromatic hydrocarbon crystals. The absorption spectra of anthracene crystals have been studied by many people,[1-3] but spectroscopic evidence of the charge transfer state has not been obtained as yet. On the other hand, recent experiments on the photoconductivity of anthracene crystal by Castro and Hornig,[4] Geacintov and Pope,[5] and by Chaiken and Kearns[6] have shown that a band to band transition may exist in pure anthracene crystal in the 280 mμ region. As regards the excimer of anthracene derivatives, Chandross and Ferguson[7] have succeeded in observing excimer emission and absorption spectra at lower temperature in solution. Kuwano and Kondo[8] have found a new crystalline form of 9, 10-dichloroanthracene, and have discussed the anomalous emission characteristics of the new form. Trotter[9,10] has already analysed the crystal structure of the other form of 9, 10-dichloroanthracene, and 9, 10-dibromoanthracene. The comparison of absorption and emission spectra of different types of crystals will clarify the mechanism of excimer formation in the crystalline state, the charge transfer absorption, and the band to band transition of anthracene type crystals.

Experimental

9, 10-dichloroanthracene was synthesized by the method of Ware and Borchert.[11] Actually, the reactants were purified before starting the synthesis and after reaction the product was purified by repeated recrystallization from hexane and several passages of column chromatography. 9, 10-Dibromoanthracene was a product of the Tokyo Kasei Co., and was recrystallized for five to six times from hexane solution. The crystal for emission measurement was grown from hexane solution and the new crystal form of 9, 10-dichloroanthracene was made by heating the crystal in a sealed glass tube at 180°C for twenty hours. This temperature is reported to be the transition point from the α to the β-form. The crystals for the absorption measurement were made by three different methods: first, by the usual

recrystallization method, second, by dropping a solution onto a quartz plate and growing the crystals on the plate and, third, by sublimation in a small beaker onto cotton wool. All crystals were examined with a polarization microscope in order to find the orientation, and the crystalline axis of some crystals was confirmed by taking X-ray photographs.

The absorption of the crystals was measured using an ultraviolet microspectrophotometer, consisting of a Carl Zeiss monochromator and light detection system, an Olympus microscope with Ultrafluar lenses of Carl Zeiss, and a Rochon type polarizer made of quartz. This instrument is capable of measuring crystals as small in area as $10\,\mu \times 10\,\mu$; the wavelength region is from 220 mμ to 2.0 μ. The emission spectra were observed using a Carl Zeiss spectrophotometer PMQ II combined with a mercury excitation lamp and suitable filters, and were also photographed using a Shimadzu Spectrograph GE-100 with Kodak 103a-F plates. The polarization of emission spectra was measured using a specially designed microscope of the Olympus Optical Co.

Results and Discussion

1. Absorption Spectra of Crystals. *a) α-Form of 9,10-Dichloroanthracene.* The electronic absorption and fluorescence spectra of 9,10-dichloroanthracene (hereafter called DCA) in hexane solution are shown in Fig. 1. They resemble that of anthracene, and the lower excited state at 27000 cm^{-1} is regarded as the $^1B_{3u}$ (^1L_a) excited state, with the polarization being along the short-axis, and the second excited state at 34900 cm^{-1} is assigned to the $^1B_{2u}$ (^1B_b) excited state, the polarization being along the long axis. The crystalline structure analysis made by Trotter[9] on the α-form of DCA showed that the molecules are nearly parallel to the bc plane (Fig. 3).

The crystals grown from solution and by sublimation show a habit of developing the ac plane. The a-axis is nearly perpendicular to the plane of the benzene ring, therefore, it does not involve the component of the π-π transition. If we take the isolated-molecule approximation (oriented-gas model) in the crystal then molecular π-π

transition to both the $^1B_{3u}$ and $^1B_{2u}$ excited states may occur only along the c axis in the ac plane. The crystalline spectrum is shown in Fig. 2.

The first absorption band at 23800 cm^{-1} is in good agreement with this prediction, since the first 0–0 transition is much stronger along the c axis than the a axis, and the second peak at 25500 cm^{-1} is also stronger along the c axis. The third peak around 26600 —27000 cm^{-1} shows a significant deviation from this character, therefore this band should be regarded as being mixed with a band different origin than that of the first and second peaks. The measured plane is an ac plane of a monoclinic crystal, therefore the possibility of Davydov type band splitting can be eliminated since there is no difference in the crystalline selection rule between the a-axis and the c-axis. The most reasonable explanation for the appearance of the out of plane absorption band in this region can be based on a charge transfer mechanism between the molecules in the crystal. The direction of the transition moment for the charge transfer absorption band should be along the line connecting the center of the donor and acceptor molecules. Therefore in the region around 26000—28000 cm^{-1}, there might be two bands with different polarization character which are overlapping each other. The first is the in-plane band, which is the third vibrational progression of the transition to the $^1B_{3u}$ state, and the second is the charge transfer transition, which has a polarization vertical to the plane of the benzene rings in this crystal. Rice and his coworkers[12] have estimated the charge transfer level for the anthracene crystal to be 3.5±0.5 eV, while the present result shows that it is 3.36 eV in this crystal.

The next absorption band around the 34000 to 40000 cm^{-1} region also shows peculiar characteristics. The absorption band along the c-axis might be the transition to the $^1B_{2u}$ state, the polarization being along the long axis of the molecule, but the structure is blurred. The a-axis component shows again an exceptional out-of-plane polarization, therefore it should be regarded as a Rydberg type transition of $2p\pi$ to 3s or to higher Rydberg states in an isolated molecule. However, the 3s and 4s or higher s orbitals have larger radii than the $2p\pi$ orbital, therefore the Rydberg levels of 3s or *n*s will form broader energy bands in the crystal. The ionization continuum level may be lowered in the crystal, thereby causing mixing of the ns band with the continuum level. The position of this band starts at 34000 cm^{-1}, which is in good agreement with the energy threshold for the anthracene[4-6] band to band transition. The band shape of this transition shows a gradual increase up to the higher energy region; this characteristic is certainly different from the usual band shape of molecular transitions. Anyway, the so-called band to band transition found by photoelectric conductivity measurement should be regarded as due to the $2p\pi$ band - *n*s Rydberg band transition.

The c-axis polarized absorption band shows unusually smooth features, although the absorption peak of the $^1B_{2u}$ molecular excited state transition should be located in this region. A drastic change in the molecular $^1B_{2u}$ excited state might be resulted through the interaction of the $2p\pi$ excited state with the Rydberg *n*s and continuum states.

The developed plane of the α-form of DCA crystal presents a fortunate case for observing a charge transfer absorption and the band to band transition of a 2p→*n*s type. It is confirmed that a charge transfer absorption takes place even between the same molecules, one acting as a donor and the other as an acceptor. It should also be emphasized that spectroscopic evidence of the Rydberg and continuum states is obtained for the present crystal in which the molecules are stacked parallel to each other, but which are actually in a skewed sandwich configuration in an infinitely linear array. The intensity of the charge transfer absorption band is extraordinarily enhanced in the present crystal, which may mean that the charge transfer transition is borrowing intensity from the continuum level of the band to band transition.

b) β-Form of 9, 10-Dichloroanthracene. By sublimation both the α-form and the β-form of DCA crystal could be obtained; it was possible to distinguish between the two forms with a polarization microscope. The crystalline absorption of the β- form of DCA is presented in Fig. 4, in which spectra are shown for light polarized along the c- and the a-axis. The crystalline structure analysis of the β- form is now being carried out by Kuwano and Kondo,[13] and we present their preliminary results in Fig. 5.

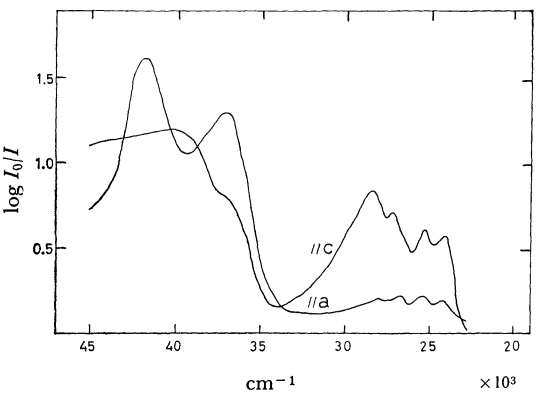

Fig. 4. Crystallin absorption spectra of β-form of 9, 10-dichloroanthracene crystal.

12) S. A. Rice, Private communication.

13) H. Kuwano and M. Kondo, private communication.

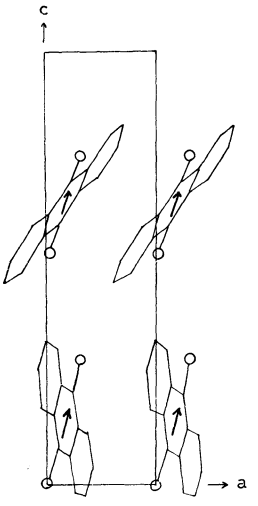

Fig. 5. Projection of 9,10-dichloroanthracene molecules onto ac plane in β-form crystal, where arrows means the direction of the short-axis polarized transition.

The first absorption band at 23800 cm^{-1} is assigned to the short axis polarized band of $^1B_{3u}$ character.

The molecular exciton state function for a triclinic crystal including two molecules in a unit cell is written as

$$\left.\begin{aligned}\Psi_+ &= \frac{1}{\sqrt{2N}}\left(\sum_{i=1}^{N}\phi_{1i}' + \sum_{j=1}^{N}\phi_{2j}'\right)\\ \Psi_- &= \frac{1}{\sqrt{2N}}\left(\sum_{i=1}^{N}\phi_{1i}' - \sum_{j=1}^{N}\phi_{2j}'\right)\end{aligned}\right\} \quad (1)$$

in which ϕ_{1i}' means that the molecule in the 1st site of the ith cell is excited and all other molecules are in the ground state. In the present case the (+) state of the $^1B_{3u}$ excited state has an additional contribution from the transition moments of both molecules, while in the (−) state two transition moments nearly cancel each other, with a slight residual moment along the c-axis.*2 The polarization ratio calculated for the (+) $^1B_{3u}$ excited state by using the assumption of the oriented-gas model is 12.6, while the observed value is 7.6.

The band splitting for each vibronic band is: the first peak is split by about 300 cm^{-1}, the c-axis is lower in energy, the splitting of the second peak is about 150 cm^{-1}. Around the third peak we found rather curious band shapes, and the c-axis band is much more separated from the 2nd peak and the splitting $(\nu_a - \nu_c)$ is −550 cm^{-1}. The splitting of the fourth peak is −450 cm^{-1}.

The next transition in the 37000—42000 cm^{-1} region is related to the $^1B_{2u}$ molecular excited state.

*2 Here the (+) state means in-phase combination of two transition moments shown in Fig. 5.

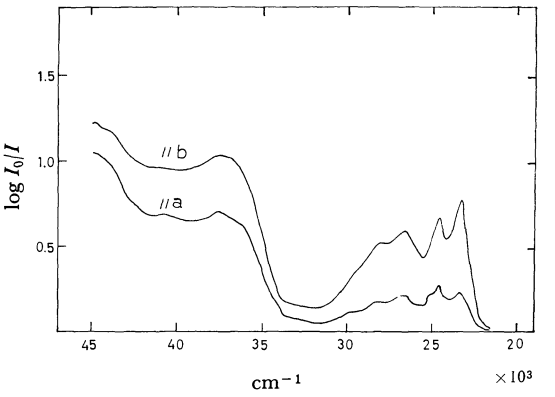

Fig. 6. Crystalline absorption spectra of 9,10-dibromoanthracene crystal.

The two peaks along the c-axis polarized band are separated by about 4800 cm^{-1}, and this might be correlated with the (+) and (−) states of Eq. (1) of the $^1B_{2u}$ molecular excited state.

The intensity ratio for (+) and (−) states is calculated to be 4 : 1, but the observed bands are overlapped, and it is difficult to separate into components and to discuss the intensity ratio for each transition. By combining those two transitions, the c-axis polarized band should have a much larger intensity than the a-axis polarized band, but it is actually smaller and broader. Following the result presented for the α-form of DCA, this could be the band to band transition in this region. It is expected that the mixing of the Rydberg or ionized continuum states with the molecular excited state will lead to such a complicated pattern of spectra.

c) 9,10-Dibromoanthracene. The crystalline absorption spectra of DBA are shown in Fig. 6, which is measured with the ab plane by the light polarized along the a- and b-axes. The projection of molecules onto the ab plane is shown in Fig. 7 following the result of Trotter.[10] The exciton state of the triclinic crystal is given by Eq. (1), and the band splitting and polarization ratio can be discussed in terms of these exciton state functions.

The first absorption band around the 32400 cm^{-1} region is regarded as the transition to the $^1B_{3u}$ excited state, but the vibrational progression is slightly distorted as compared with the solution spectra. By careful examination of the a- axis spectra, it is found that a little hump exists at 25300 cm^{-1} in the a-axis polarized spectrum. This small shoulder might be assigned to a transition of the charge transfer type between molecules in the same crystallographic position. The reason for the small intensity of this band might be due to the weak electron overlap between the molecules. The vibrational progressions of the apparent 0-0, 0-1 and 0-2 transitions are different from that in solution; this discrepancy may be attributed

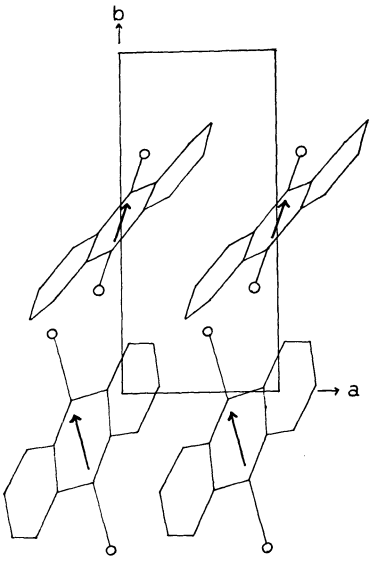

Fig. 7. Projection of 9, 10-dibromoanthracene molecules onto the ab plane, where arrows means the direction of the short-axis polarized transition.

to the interaction between the vibronic state and the charge transfer state.

The polarization ratio of the first 0-0 band (I_b/I_a) is 3.2, while the value calculated on the basis of the oriented gas model is 12.1. These values are not in good agreement, but this sort of discrepancy can be explained as due to crystal field mixing with higher excited states.

The second absorption band around the 37000 cm^{-1} region does not show any appreciable splitting. When we take the excition state function as given by Eq. (1) (see Fig. 7), transitions to the (+) state should occur both along the a- and b-axes, but transitions to the (−) state may cancel and will therefore not be seen in the crystal absorption.

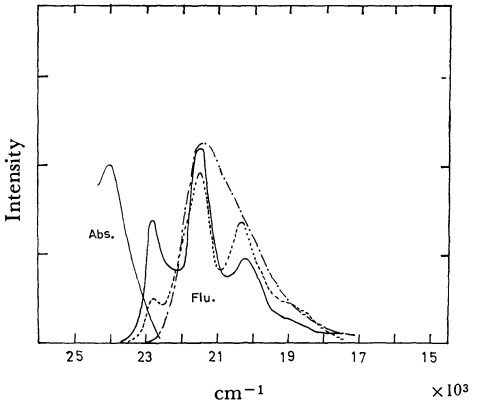

Fig. 8. Temperature dependence of crystalline flourescence spectrum of α-form of 9, 10-dichloroanthracene.
—— 4.2°K ····· 77°K ·—· 330°K

The polarization ratio (I_a/I_b) observed is 1.5 while the calculated value is 0.9. The third absorption band increases in intensity with increasing energy in the 45000 cm^{-1} region, and it may be related to the higher molecular excited states and the continuum state. Also a contribution from the band to band transition may occur in this region.

2. Fluorescence Spectra of Crystals. *a) α-Form of 9, 10-Dichloroanthracene.* The fluorescence spectra of the α-form of DCA is shown in Fig. 8 for different temperatures, the measurement being made with a Carl Zeiss monochromator with a slit width of less than 0.1 mm. The absorption edge at 300°K is also shown in order to illustrate the effect of reabsorption by the crystal. The absorption starts at 22500 cm^{-1} at 300°K, while emission begins at 23700 cm^{-1} at 4.2°K. The origin of the emission band is overlapped with the absorption at 300°K, therefore the effect of reabsorption will change the shape of the emission band at 300°K. At lower temperatures the absorption band edge moves to the shorter wavelength region, and therefore the first 0-0 emission band in the crystal can be clearly recognized. The fluorescence spectra of DCA thus far reported[7,14] are all different from the present result, and it may be that these spectra have been reported for crystals not as pure as the present one. The fluorescence spectra show a resolved vibrational progressions of about 1400 cm^{-1} at 4.2°K, while the solution value for emission is 1400 cm^{-1}.

The shift of the first 0-0 band from absorption to emission is about 860 cm^{-1} and it is almost certain that excimer formation does not take place in this crystal as judged from the shift and the shape of the emission band. This situation is illustrated in Fig. 9 together with cases of stronger interaction in the excited state. In this figure, the electronic energy level is correlated with the intermolecular distance R. The horizontal levels drawn in the potential curve denote the energy of the intramolecular vibrational mode, not the intermolecular vibration. The three potential

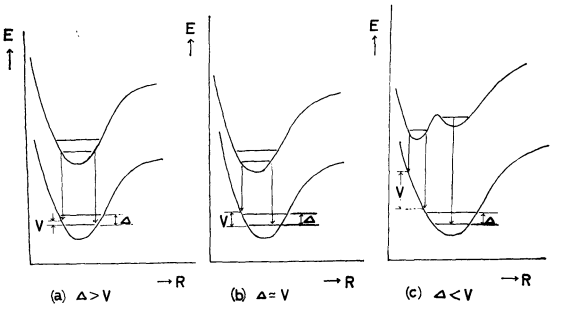

Fig. 9. Potential energy diagram of the excited and ground state of the dimer pair.

14) E. Bock, J. Ferguson and W. G. Schneider, *Can. J. Chem.*, **36**, 507 (1958).

curves illustrate the weak, medium and strong types of excited state interaction. It is thought that excimer formation will occur after excitation by the exciton and the charge transfer type interaction at a closer intermolecular distance than in the ground state. In this case the movement of molecules is considered to occur so as to avoid the steric repulsion between the bulky substituent groups. The magnitude of the stabilization will be dependent on the intermolecular distance and electron overlap between molecules.[15]

However, the energy of the emission band of the excimer is also dependent on the potential energy curve of the repulsive ground state, and this might be the reason why the excimer emission is always broad and structureless. In Fig. 9 the V-value shows the uncertainty in the ground state potential energy, and we assume that this value represents the width of the ground state potential energy. Therefore we will take this value as the uncertainty in the energy under the condition that emission is occurring at the bottom of the excited state potential curve. From this criterion, the α-form of DCA has a V-value smaller than the intramolecular vibrational spacing, Δ, implying that the center of the excited state potential function moves slightly to smaller intermolecular distances in the excited state.

This behavior may be explained on the basis of the steric repulsion between the two chlorine atoms, which have larger van der Waals radii than the carbon atoms. The present crystal has an unfavorable configuration to form the excimer, since intermolecular appoach in the excited state will be hindered by the overcrowding of the chlorine atoms.

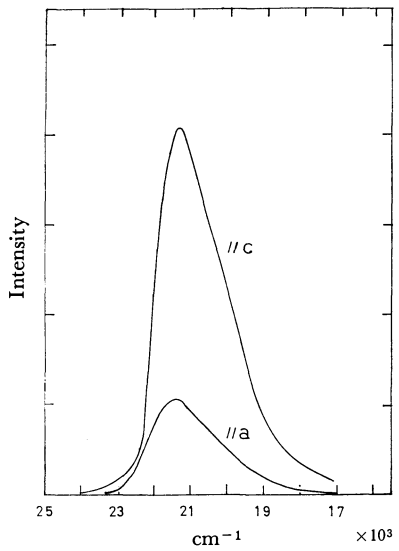

Fig. 10. Polarization of the fluorescence spectrum of α-form of 9,10-dichloroanthracene.

Further evidence for molecular characteristics in the emission of α-form type crystal is that the polarization ratio of the emission along the c-axis is much stronger than along the a-axis (*cf.* Fig. 10). The ratio is 4 : 1 ($I_c : I_a$), which is less than in the case of absorption (12 : 1), but still the high dichroic ratio indicates the molecular character of the $^1B_{3u}$ excited state in the emission.

b) β-Form of 9, 10-Dichloroanthracene. The emission spectra of the β-form of DCA at several different temperatures are shown in Fig. 11, and it is found that drastic change in emission spectra

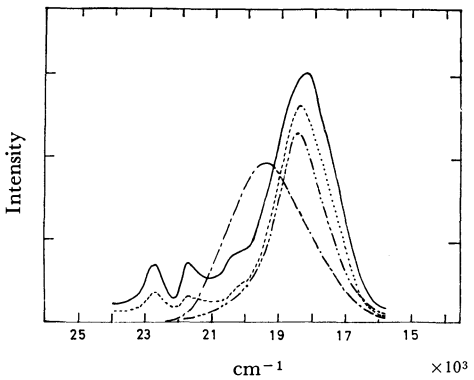

Fig. 11. Temperature dependence of the crystalline fluorescence spectra of β-form of 9,10-dichloroanthracene.
—— 4.2°K ····· 13°K —··— 77°K
—·— 300°K

occurs with the change of temperature. A broad emission band is observed at 19280 cm^{-1} at 300°K, which is 4700 cm^{-1} below the first crystalline absorption peak. This broad band moves to lower frequency at 77°K, the peak being at 18600 cm^{-1}, which is 5400 cm^{-1} below the crystal absorption. At liquid helium temperature the peak shifts to 18200 cm^{-1}, and in addition to this broad band, a monomer band with two or three vibrational bands has been observed starting at 22940 cm^{-1}. The appearance of two kinds of emissions, one, that of the excimer, and the other, that of the monomer, can be explained by assuming a hump in the potential energy curve in the excited state.*3 A similar situation has been recognized in the case of perylene excimer emission.[16] This mechanism will be explained by the energy diagram in

15) J. N. Murrell and J. Tanaka, *Mol. Phys.*, **7**, 363 (1964).

*3 The possibility of a phase transition from the β-form to the α-form at lower temperature is excluded since the change in the fluorescence spectra is reversibly observed with change of the temperature, in spite of the fact that a modification of the crystalline form was not observed. If the phase transition were taking place at lower temperature a significant change in the optical properties of the crystal should be detectable with a polarization microscope.

16) J. Tanaka, This Bulletin, **36**, 1237 (1963).

Fig. 9 (c) where the excited molecule will move to a shorter intermolecular distance to form the excimer, but the movement of the molecule will be hindered at lower temperatures due to the existence of the little hump in the potential curve and eventually will emit monomer type emission. The broader band character of the longer wavelength emission can be explained by assuming a V-value which is larger than the vibrational spacing. The relatively large temperature dependence of the longer wavelength band at higher temperature is typical of excimer emission. It is interesting that the so-called 6000 cm^{-1} rule[17] is nearly satisfied in the present crystal, the value at 4.2°K being 5800 cm^{-1}.

c) 9, 10-Dibromoanthracene. The fluorescence spectra of DBA have been measured at several different temperatures, and are shown in Fig. 12. They show relatively little temperature dependence, but the emission band as a whole shifts to lower frequency as compared with the α-form of DCA. The shift measured at the first 0-0 transition is 2150 cm^{-1}, which is larger than the α-form of DCA, but far less than the β-form of DCA. The potential energy levels based on these numbers are pictured in Fig. 9 (b), and it is estimated that the V-value is nearly the same order of magnitude as the Δ-value of the vibrational spacing. It is also interesting that the 0–0 emission band is clearly seen at 77°K rather than at 4.2K; this indicates that the equilibrium configuration of the excited state is shifted from the center of the ground state configuration, resulting in a small Franck-Condon overlap factor for the 0-0 transition at 4.2°K. Comparison with the cases of the α- and β-forms of DCA shows that both the shift of the emission band and the V-value are intermediate in the DBA crystal. The polarization ratio of the emission band measured along the b- and a-axes is 1.7,

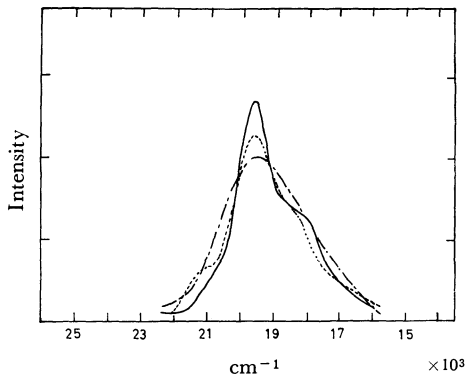

Fig. 12. Temperature dependence of the crystalline flourescence spectrum of 9, 10-dibromoanthracene.
—— 4.2°K ····· 77°K —·— 300°K

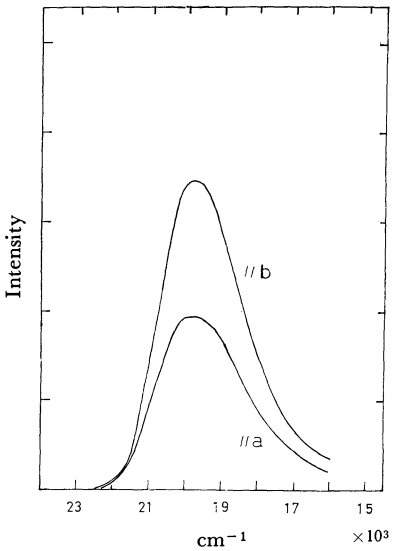

Fig. 13. Polarization of the fluorescence spectrum of 9, 10-dibromoanthracene.

while that of the absorption is 3.2 (*cf.* Fig. 13). The decrease in the dichroic ratio means that the charge transfer contribution to the emission component is increased in the DBA crystal.

The results obtained for the three different crystals indicate that excimer formation is most favorable when intermolecular approach in the excited state is not hindered by bulky substituent groups. The larger shift for β-DCA compared with DBA indicates that the π-electron overlap is more efficient for β-DCA than for DBA even in a similar crystallographic relationship, since the van der Waals radii are smaller for chlorine atoms than for bromine.

Conclusion

The electronic interaction of molecules in a crystal is primarily governed by the relative orientation and the interatomic distances between molecules. The charge transfer absorption band could be observed for the α-DCA crystal where the inter-molecular electron overlap in the ground state configuration is apparently larger than for other crystals. The excimer type emission is found most prominently in the β-DCA, and DBA crystals, where the molecules are stacked nearly parallel to each other but at relatively large distances. This configuration is most favorable for excimer formation, since the bulky substituent groups are located in such a way that the molecular movement to the shorter intermolecular distance in the excited state may be least hindered. The intermolecular electron overlap is essential for excimer formation, therefore it can be naturally concluded that the molecules will move to as short an intermolecular distance as possible in the excited state.

17) J. B. Birks, M. O. Lumb and I. H. Munro, *Proc. Roy. Soc., (London)*, **A280**, 289 (1964).

For the ground state configuration the intermolecular separation is larger for the β-DCA and DBA crystals than for the α-DCA crystal, therefore it is most probable that the excimer force should operate to bring the molecules into a closer position in the excitd state. The nature of the excimer force has not been fully discussed in the present text. It is conventionally divided into two parts: the exciton type and charge transfer type interactions will be most important; the former will be dominant at longer distances, and the latter is significant in the region of strong electron overlap. At the real excimer equilibrium distance, both forces will be strongly mixed and will be balanced by the potential of the exchange repulsion. The van der Waals radius of each atom in the ground state will be determined by this latter type of exchange repulsion between closed-shell atomic systems. For the excited state, however, an open-shell electron configuration will allow the molecules to approach each other, since the exchange repulsion between open-shell excited configuration and ground configuration will be smaller than that with closed shell ground electron configurations. It will mean that the van der Waals radius may be smaller for the excited state than the ground state configuration.

Finally, it should be emphasized again that the band to band transition of $2p\pi$ to ns type is found for the α-DCA crystal in the 34000 cm^{-1} region. This finding should throw some light on the mechanism of photoconductivity in organic crystals.

The authors wish to express their sincere thanks to Drs. H. Kuwano and M. Kondo of the Sankyo Pharmaceutical Co. for their kind communication of their X-ray crystal results prior to publication.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 41—44 (1968)

An NMR Study of Proton Exchange in Alcohols. II.*1 Proton Transfer in the Water-Isopropanol System

Toshio FUKUMI, Yuzuru FUJIWARA, Yoji ARATA and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received June 16, 1967)

Proton exchange has been investigated in the system of water and isopropanol by means of high-resolution nuclear magnetic resonance. The rates of proton transfer have been obtained at different hydrogen ion concentrations and at different ratios of water and isopropanol. It has been shown that the exchange reaction is of higher order with respect to water and isopropanol concentrations. Possible mechanisms of proton transfer have been discussed, and values for their respective rate constants given.

Proton transfer in systems of water and simple aliphatic alcohols has been studied by several workers.[1-3] In these studies the exchange reaction has been assumed to be of first order with respect to water and alcohol concentrations. However, this assumption has not been verified in all the cases which have been reported so far. In this note, we attempted to check the validity of this assumption using a water-isopropanol system. Several types of exchange reaction will be proposed to explain the rate of proton transfer obtained experimentally, and values for their respective rate constants will be given. For this purpose, the water-isopropanol system has the following advantages: (i) spectral analysis can always be done to a good approximation using first-order perturbation theory, and (ii) since the proton exchange is much slower than in the cases of methanol-water and ethanol-water systems, the proton transfer can be studied over a wide range of molar ratios of water and isopropanol, thus making it possible to determine the order of the exchange reactions in some cases.

Experimental

Commercial reagent-grade isopropanol was dried by treatment with magnesium and a trace of iodine,[4] and was then distilled several times at ordinary pressure. Water was deionized by passing it through a

column packed with a cation exchange resin, and was boiled just before use. In the following, the readings of a Toa Dempa Model HM-5A pH meter with micro glass and calomel electrodes will be cited as h.

A Varian HA-100 high-resolution NMR spectrometer operating at 100 Mc/sec was employed at 28°C under the condition of slow passage and negligible saturation. Several examples of the spectra are shown in Fig. 1. Chemical shift data for the protons of water and isopropanol are summarized in Fig. 2.

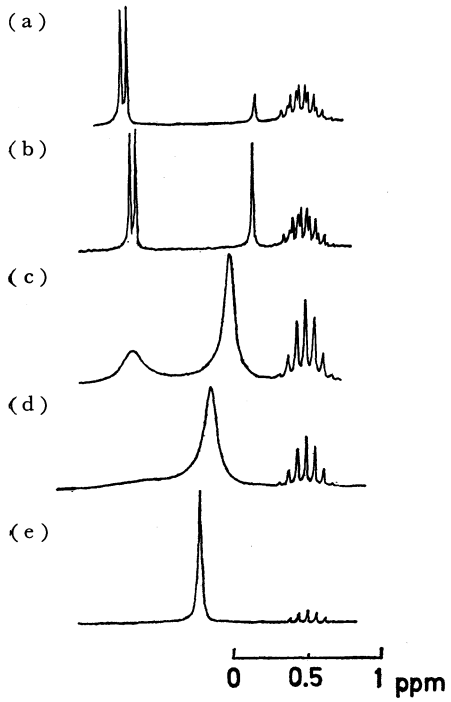

Fig. 1. NMR spectra of isopropanol containing water at various concentrations, $[H_2O]$ being (a) 2.78 M, (b) 5.56 M, (c) 11.1 M, (d) 22.2 M, and (e) 33.4 M.

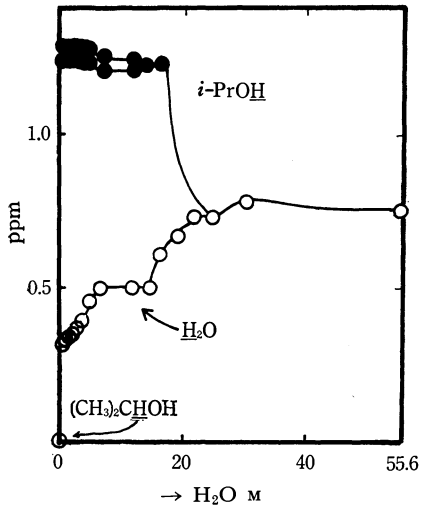

Fig. 2. The change in the chemical shifts of the OH protons of water and isopropanol in the water-isopropanol system. The CH proton signal of isopropanol is tentatively taken as a reference of the chemical shifts.

The average times a proton is bonded to a specific oxygen atom of isopropanol, and water are designated as τ_A, and τ_W, respectively. τ_A^{-1} may be expressed as:

$$\tau_A^{-1} = \tau_{AA}^{-1} + \tau_{AW}^{-1} \quad (1)$$

where τ_{AA}^{-1}, and τ_{AW}^{-1} refer to the proton transfer rate between isopropanol and isopropanol, and that between water and isopropanol, respectively. When the OH signals of water and isopropanol are observed separately, the full widths of the resonance line at half height (in cycles per second), Δ_A and Δ_W, are measured to obtain the specific rate of exchange. τ_A and τ_W are given by the relations:

$$\begin{aligned} \tau_W^{-1} &= \pi\Delta_W - \pi\Delta_W^0 \\ \tau_A^{-1} &= \pi\Delta_A - \pi\Delta_A^0 \end{aligned} \quad (2)$$

where Δ_W^0, and Δ_A^0 are full widths at half height for the OH protons of water, and isopropanol in the absence of exchange. When the two OH signals collapse into a singlet, the line-width, Δ, is given by[5]:

$$\Delta = p_A\Delta_A^0 + p_W\Delta_W^0 + \pi^{-1}p_A^2p_W^2(2\pi\delta)^2(\tau_{AW}+\tau_W) \quad (3)$$

where p_A, and p_W, are the fractional populations for the OH protons of isopropanol, and water, respectively, and δ is the chemical shift difference (in cycles per second) between the OH protons of water and isopropanol, which is dependent on the ratio of water and isopropanol. From Eq. (3), the sum $(\tau_{AW}+\tau_W)$ can be obtained, and using the relation

$$\frac{[i\text{-PrOH}]}{\tau_{AW}} = \frac{2[H_2O]}{\tau_W}, \quad (4)$$

which is valid for equilibrium, τ_{AW}, and τ_W can be obtained separately.

Results and Discussion

In Fig. 3, the line-widths for the OH protons of water and isopropanol at $h=6.5$ are plotted as a function of the molar concentration of water, $[H_2O]$. The line-widths, and therefore the exchange rates, are strongly dependent on h. For $[H_2O]=2.78$ M, the exchange is shown to be of first order with respect to h. In Figs. 4 and 5 $(\tau_W h)^{-1}$, $(\tau_{AW}h)^{-1}$, and $(\tau_{AA}h)^{-1}$ are plotted as a function of $[H_2O]$.

For the proton exchange between water and isopropanol, the following reaction schemes are assumed:

$$a\,i\text{-PrOH} + b\,H_2O + H_3O^+ \xrightarrow{k_1} \quad (I)$$

$$c\,i\text{-PrOH} + d\,H_2O + i\text{-PrOH}_2^+ \xrightarrow{k_2} \quad (II)$$

For these reactions, the following relation holds:

5) See *e. g.*, J. A. Pople, W. G. Schneider and H. J. Bernstein, "High-resolution Nuclear Magnetic Resonance," McGraw-Hill, New York (1959), p. 222.

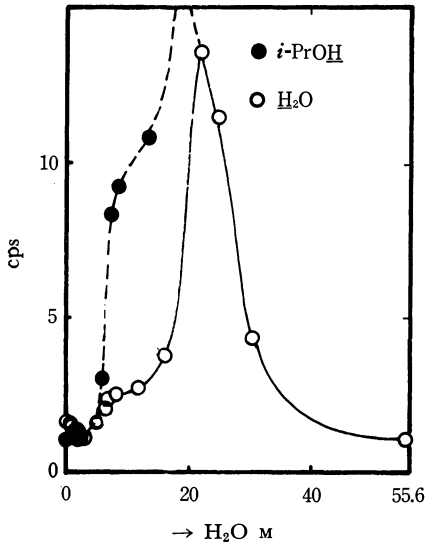

Fig. 3. The change in the line-widths of the OH protons of water and isopropanol in the water-isopropanol system.

$$-\frac{d}{dt}[H_2O] = \frac{2}{\tau_W}[H_2O] = k_1[i\text{-PrOH}]^a[H_2O]^b[H_3O^+] + k_2[i\text{-PrOH}]^c[H_2O]^d[i\text{-PrOH}_2^+] \quad (5)$$

It is assumed that the following equilibrium exists in the solution:

$$i\text{-PrOH} + H_3O^+ \overset{K}{\rightleftharpoons} i\text{-PrOH}_2^+ + H_2O$$

and that h is equal to $-\log([H_3O^+]+[i\text{-PrOH}_2^+])$.

$$(\tau_W h)^{-1} = \frac{1}{2}(k_1[i\text{-PrOH}]^a[H_2O]^{b-1} + k_2K[i\text{-PrOH}]^{c+1}[H_2O]^{d-2}) \times (1+K[i\text{-PrOH}][H_2O]^{-1})^{-1} \quad (6)$$

For $[H_2O] \lesssim 0.3$ M, $(\tau_W h)^{-1}$ decreases with increasing $[H_2O]$, as shown in Fig. 4. In this case, Eq. (6) can be approximated as:

$$(\tau_W h)^{-1} = \frac{1}{2}k_2K[i\text{-PrOH}]^{c+1}[H_2O]^{d-2} \times (1+K[i\text{-PrOH}][H_2O]^{-1})^{-1} \quad (7)$$

For $[H_2O] > 0.3$ M, $(\tau_W h)^{-1}$ increases with increasing $[H_2O]$. In this case, Eq. (6) can be approximated as:

$$(\tau_W h)^{-1} = \frac{1}{2}k_1[i\text{-PrOH}]^a[H_2O]^{b-1} \quad (8)$$

From Eqs. (7) and (8) and Fig. 4, it is found that $a=1$, $b=2$, and $d=1$. When $[H_2O]$ is small, $(\tau_W h)^{-1}$ changes greatly with a small change in $[H_2O]$. Since $[i\text{-PrOH}]$ changes only a little in this region of low concentration, c cannot be determined from this experiment. In the proton transfer reactions (I) and (II), the roles of water

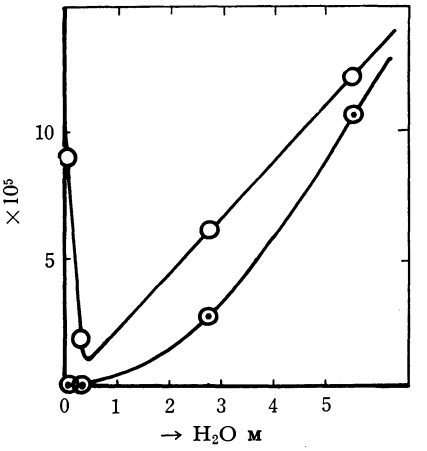

Fig. 4. The change in $(\tau_W h)^{-1}$ and $(\tau_{AW} h)^{-1}$ with the concentration of water in the water-isopropanol system. ○ and ⊙ refer to $(\tau_W h)^{-1}$ and $(\tau_{AW} h)^{-1}$, respectively.

and isopropanol molecules are interchanged, so that it is assumed that $c=2$. From these results, the constants k_1, k_2, and K can be determined. These constants can also be determined from the change in $(\tau_{AW}h)^{-1}$ in a similar way. The results are as follows:

$$k_1 = 2 \times 10^4 \quad l^3\,\text{mol}^{-3}\,\text{sec}^{-1}$$
$$k_2 = 5 \times 10^3 \quad l^3\,\text{mol}^{-3}\,\text{sec}^{-1}$$
$$K = 2 \times 10^{-4}$$

In order to explain the change in $(\tau_{AA}h)^{-1}$, the following reaction schemes are assumed:

$$e\,i\text{-PrOH} + f\,H_2O + H_3O^+ \xrightarrow{k_3} \quad \text{(III)}$$

$$g\,i\text{-PrOH} + i\text{-PrOH}_2^+ \xrightarrow{k_4} \quad \text{(IV)}$$

From Fig. 5, it is found that $f=1$. However, e and g cannot be determined for a reason similar

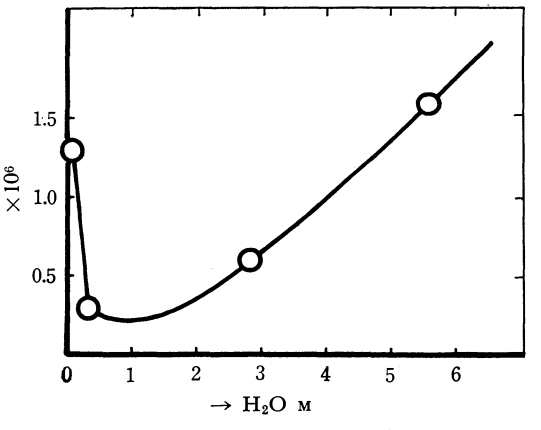

Fig. 5. The change in $(\tau_{AA} h)^{-1}$ with the concentration of water in the water-isopropanol system.

to that mentioned above for c in reaction (II). If both e and g are tentatively assumed to be unity, the constants k_3 and k_4 become:

$$k_3 = 2 \times 10^6 \quad l^2\,\mathrm{mol}^{-2}\,\mathrm{sec}^{-1}$$

$$k_4 = 3 \times 10^6 \quad l\,\mathrm{mol}^{-1}\,\mathrm{sec}^{-1}$$

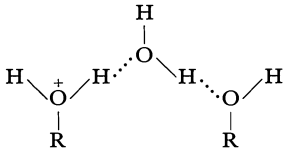
Another possible reaction for proton exchange between water and isopropanol is the following one, which is not catalyzed by acid:

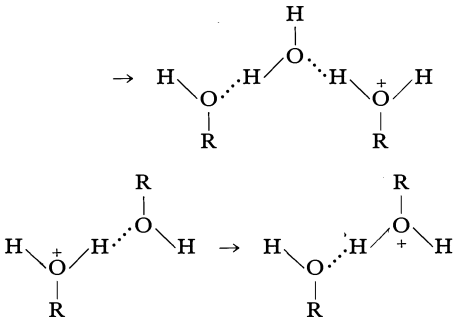
$$i\text{-PrOH} + H_2O \xrightarrow{k_5} \qquad \text{(V)}$$

From the values for τ_W^{-1} and τ_{AW}^{-1} obtained for the sample with no acid added externally, k_5 is found to be $2\,l\,\mathrm{mol}^{-1}\,\mathrm{sec}^{-1}$.

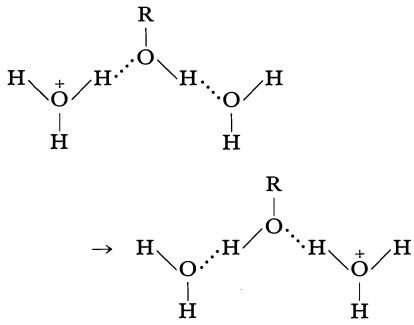
From the above results, it is clear that in the water-isopropanol system, proton exchange reactions are not of first order with respect to water and isopropanol concentrations, as has been assumed in previous works. Possible mechanisms for proton transfer will be discussed in the following.

Possible Mechanisms for Proton Transfer. At low water concentrations, the isopropyloxonium ion plays a majar role in proton transfer. Possible models for proton transfer are shown in the following:





At higher water concentrations, a possible model for proton exchange is:



The above mechanisms can be responsible for the proton transfer between water and isopropanol, and for that between isopropanol and isopropanol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 45—48 (1968)

The Dimerization of Propylene over a Nickel Oxide-Silica-Alumina Catalyst

Hisao IMAI, Touji HASEGAWA and Hiroshi UCHIDA*1

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received July 1, 1967)

The composition of hexene isomers produced by the dimerization of propylene over a nickel oxide-silica-alumina catalyst has been examined under the following experimental conditions: 10—300 kg/cm², 100 and 200°C. Under a typical set of experimental condition (50 kg/cm², 200°C), eight hexene isomers, *i. e.*, 4-methyl-*trans*-2-pentene, 4-methyl-*cis*-2-pentene, 2-methyl-1-pentene, *trans*-2-hexene, *cis*-2-hexene, 3-methyl-*trans*-2-pentene, 3-methyl-*cis*-2-pentene, and 3-methyl-1-pentene, have been found to be the primary products of the dimerization. Among these, more trans isomers are produced initially than the corresponding cis isomers for 4-methyl-2-pentenes and 2-hexenes, but the reverse is true for 3-methyl-2-pentenes. Under higher pressures, 2, 3-dimethylbutenes are also produced at 200°C. A reaction scheme assuming the intermediates of cyclobutane derivatives has been proposed to explain the above findings. The scheme may also explain the unique order of the activity of the present catalyst for a series of *n*-olefins.

The catalyst consisting of nickel oxide, silica, and alumina has been found to be an effective catalyst for the dimerization of olefins.[1-3] One of the remarkable features of this catalyst system is its activity in relation to a series of *n*-olefins. In contrast to usual acid-type catalysts, the nickel oxide-silica-alumina shows a higher activity for a lower olefin, *i. e.*, the highest activity for ethylene.[2,3] Although some efforts have previously been made to elucidate this feature of the catalyst,[2,4] the problem remains practically unsettled.

In the dimerization of ethylene over this catalyst system, the composition of butene isomers was examined in order to get an insight into the mechanism of the reaction.[5-7] It may be expected that more information on the mechanism can be obtained in the dimerization of propylene because of the more complex shape of a propylene molecule, and so the composition of the hexene isomers produced by the dimerization of propylene has been examined in order to determine the primary products of the reaction.*2 A reaction scheme assuming the intermediates of cyclobutane derivatives has been proposed; this scheme may also suffice to explain the above-mentioned feature of the nickel oxide-silica-alumina catalysts.

Experimental

Materials. A nickel oxide-silica-alumina catalyst composed of 3 atom% nickel, 3 atom% aluminum, and 94 atom% silicon was prepared by a co-precipitation method described elsewhere.[5] The structural characteristics of the catalyst are summarized in Table 1. The specific surface area (S) was obtained by applying the standard B. E. T. method to the adsorption isotherm of nitrogen at −196°C; the mean pore diameter (d) was estimated by the equation, $d=4V_g/S$, where the total pore volume (V_g) was obtained from the amount of nitrogen adsorbed at the relative pressure of 0.967 in the adsorption of nitrogen at −196°C; the acidity was measured by a quinoline chemisorption method at 300°C on the catalyst samples before and after the removal of nickel oxide, and the acidity after the removal was defined as the acidity due to alumina-silica, and the difference between the two, as the acidity due to nickel oxide-silica.[5]

Table 1. Structural characteristics of the catalyst

Composition (Ni : Al : Si)	3 : 3 : 94 by atom ratio
Specific surface area	342 m²/g
Mean pore diameter	48.1 Å
Acidity

*2 Recently, Schultz *et al.* have studied the product distribution in the dimerization of propylene over cobalt-oxide-on-carbon catalysts; R. G. Schultz, J. M. Schuck and B. S. Wildi, *J. Catalysis*, **6**, 385 (1966).

Polymerization-grade propylene (purity>99.9%) was obtained from the Nippon Petrochemicals Co., Ltd., and was further purified by passing it successively through alkaline silica gel, sodium hydroxide, a supported copper catalyst, and alkaline silica gel. The standard samples of hexene isomers were obtained from the Tokyo Kagaku Seiki Co., Ltd.

Apparatus and Procedures. The dimerization of propylene was carried out by using a high-pressure flow system. The reactor body consisted of 25 mm-I. D. (50 mm-O. D.) stainless steel tubing, 50 cm long. A 5-m*l* portion of the catalyst was placed after the 10 cm preheating section at the entrance of the reactor. A thermocouple junction for measuring the reaction temperature was located at the center of the catalyst bed in a 2 mm-I. D. (4 mm-O. D.) stainless steel tube inserted through the bottom of the reactor. The temperature of the reactor was controlled by fluidizing heated iron powder around the reactor. The purified propylene was fed to the reactor by a high-pressure plunger pump, and the reactor effluent was cooled to −20°C in order to condense the dimerization products. A correction was made for uncondensed products by analyzing the uncondensed effluent gas.

The total dimers, trimers, and tetramers were determined by gas chromatographic analysis with a 3% silicon oil on a diasolid column (1 m) at 200°C, a hydrogen flame ion detector being used. All the hexene isomers, except for the *cis*-3-hexene from *trans*-3-hexene, were separated from one another and analyzed by gas chromatography using a 75-m silicon oil-coated capillary coulmn.

Prior to the reaction, the catalyst was treated *in situ* in a stream of dried air for 16 hr at 500°C, and then in a stream of purified nitrogen for 4 hr at the same temperature. After the temperature of the catalyst had been lowered to a reaction temperature in the nitrogen atomosphere, the feeding in of propylene was started.

Results

The conversion of propylene and the composition of the hexene isomers obtained under typical experimental conditions (200°C, 50 kg/cm²) are plotted against the contact time*3 in Fig. 1. Under these experimental conditions more than 80% of the products were dimers. The figure shows that the contents of eight isomers, *i. e.*, 4-methyl-*trans*-2-pentene, 4-methyl-*cis*-2-pentene, 2-methyl-1-pentene, *trans*-2-hexene, *cis*-2-hexene, 3-methyl-*trans*-2-pentene, 3-methyl-*cis*-2-pentene, and 3-methyl-1-pentene, decrease as the contact time is increased, while those of the other isomers increase with an increase in the contact time.

As only three types of chain structure were found in the hexenes produced, the contents of the hexene isomers with the same chain structure were summed up to give the total amounts of *n*-hexenes, 2-methylpentenes, and 3-methylpentenes.

*3 Contact time is defined by $1/SV$, where the space velocity (SV) is expressed in terms of m*l* of propylene (at NTP) per hr per m*l* of the catalyst.

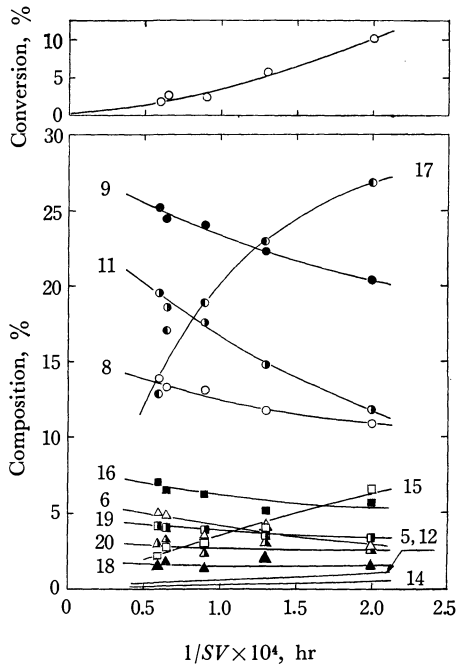

Fig. 1. Conversion of propylene as well as the composition of hexenes produced plotted against contact time.
Experimental condition: 200°C, 50 kg/cm²

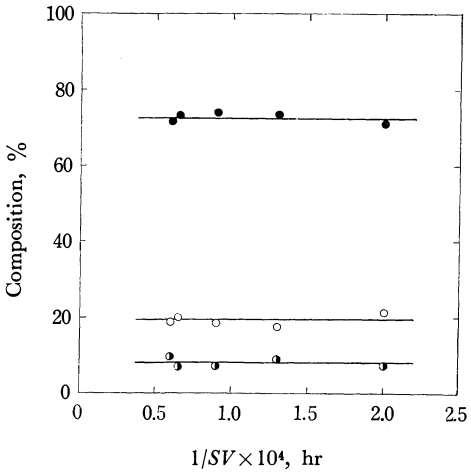

Fig. 2. Composition of hexenes expressed in terms of their chain structures as the function of contact time.
○: *n*-hexenes, ●: 2-methylpentenes, ◑: 3-methylpentenes

The composition of the product was classified in this way, and is plotted against the contact time in Fig. 2. The figure reveals that the content of the individual type remains constant with an increase in the contact time.

In Fig. 3, the ratios of trans- and cis-isomers are plotted against the contact time. The ratios of trans- and cis-isomers remain almost constant with an increase in the contact time; this is consistent with the results obtained in the dimerization of ethylene.[5] The figure also indicates the following fact; in the cases of 2-hexenes and 4-methyl-2-pentenes, more trans isomers are produced initially than the corresponding cis isomers, while in the case of 3-methyl-2-pentenes the reverse is true.

The composition of the products, expressed in terms of their chain structures, remained almost

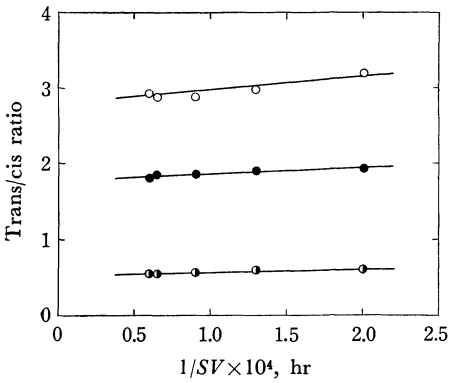

Fig. 3. Trans/cis ratios plotted against contact time.
○: 2-hexene, ●: 4-methyl-2-pentene,
◐: 3-methyl-2-pentene

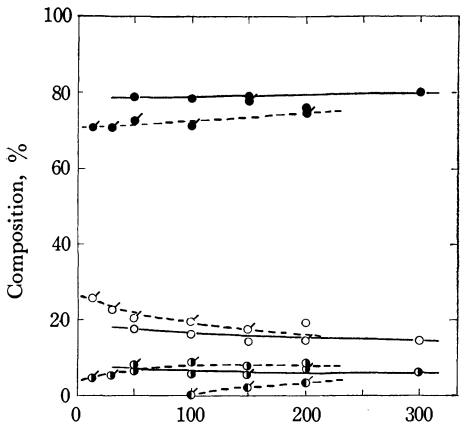

Fig. 4. Chain structures of hexenes produced at different experimental conditions.
n-hexenes at 100 (○) and 200°C (◌́)
2-methylpentenes at 100 (●) and 200°C (●́)

2, 3-dimethylbutenes at 200°C (◐́)

constant with an increase in the contact time under all the experimental conditions studied; in Fig. 4 the average values are plotted against the reaction pressures for the reactions carried out at 100 and at 200°C. The figure shows that *n*-hexenes, 2-methylpentenes, and 3-methylpentenes are produced under all the experimental conditions studied, and that, at 200°C, 2, 3-dimethylbutenes are produced at higher pressures. The 2, 3-dimethylbutene content was too small for us to determine the primary product of the dimerization.

Discussion

Figure 1 shows that eight hexene isomers, *i. e.*, 4-methyl-*trans*-2-pentene, 4-methyl-*cis*-2-pentene, 2-methyl-1-pentene, *trans*-2-hexene, *cis*-2-hexene, 3-methyl-*trans*-2-pentene, 3-methyl-*cis*-2-pentene, and 3-methyl-1-pentene, are the primary products of the dimerization. It should be noticed that the 3-methyl-pentenes are primary dimerization products. The presence of 3-methylpentenes in the products of propylene dimerization was previously reported by Wachter,[8] who attributed them to the products of the secondary rearrangement. Indeed, the 3-methylpentenes cannot be explained as the primary products of the dimerization by a carbonium-ion mechanism[9] nor by any other mechanisms which assume an open-chain hydrocarbon as the activated intermediate, but they can be explained as being produced by secondary skeletal isomerization. Figure 2 shows that the composition of the hexene isomers, as expressed by their chain structures, does not change with the contact time, remaining at a constant value which is far from the equilibrium.[10] This fact indicates that no skeletal isomerization occurs under the experimental conditions studied, although double-bond-shift reactions are taking place. Thus, it may be concluded that the 3-methylpentenes are not produced by the secondary skeletal isomerizations of *n*-hexenes or 2-methylpentenes, but are produced directly by the dimerization of propylene.

The above conclusion, as well as the facts shown in Figs. 3 and 4, cannot be explained by the carbonium-ion mechanism nor by any other cation polymerization mechanisms which assume an open-chain hydrocarbon as the activated intermediate, although the catalyst activity is proportional to the number of nickel acid sites, as determined by the chemisorption of a basic molecule.[5]

Schoepfle and Ryan[11] proposed a mechanism

of the dimerization of diphenylethylene which assumed an intermediate of a cyclobutane derivative. An examination of the present results has shown that the same mechanism may hold for the present reaction. A reaction scheme assuming the intermediates of cyclobutane derivatives can be described as follows:

$$C{=}C{-}C + S(Ni) \rightarrow C{=}C{-}C(ad) \quad (1)$$

(I)

$$I + C{=}C{-}C \rightarrow \underset{\text{(II)}}{\begin{array}{l} C_4\text{--}C_1 \\ \vert\ \ \vert \\ C_3\text{--}C_2 \end{array}}\!\!\begin{array}{l} \diagup C \\ \\ \diagdown C \end{array} + \underset{\text{(III)}}{\begin{array}{l} C_4\text{--}C_1 \\ \vert\ \ \vert \\ C_3\text{--}C_2 \end{array}}\!\!\begin{array}{l} \diagup C \\ \\ \diagdown C \end{array} \quad (2)$$

$$II \rightarrow C{-}C{=}C{-}C{-}C{-}C \quad (3)$$

$$II \rightarrow C{=}\overset{\overset{C}{\vert}}{C}{-}C{-}C + C{-}C{=}\overset{\overset{C}{\vert}}{C}{-}C{-}C \quad (4)$$

$$II \rightarrow C{=}\overset{\overset{C}{\vert}}{C}{-}\overset{\overset{C}{\vert}}{C}{-}C \quad (5)$$

$$III \rightarrow C{=}\overset{\overset{C}{\vert}}{C}{-}C{-}C{-}C + C{-}C{=}C{-}\overset{\overset{C}{\vert}}{C}{-}C \quad (6)$$

A propylene molecule is chemisorbed on a nickel acid site (Eq. (1)). The chemisorbed propylene molecule, I, then further reacts with a propylene molecule to form the intermediates of cyclobutane derivatives, II and III, on the nickel acid site (Eq. (2)). In the intermediate II, the breaking of the C_1-C_2, C_2-C_3, and C_3-C_4 bonds leads to the formation of 2-hexenes (Eq. (3)), 3-methylpentenes (Eq. (4)), and 2, 3-dimethylbutene (Eq. (5)) respectively. In the intermediate III, the same ring-opening processes lead to the formation of 2-methyl-1-pentene and 4-methyl-2-pentenes as the primary products (Eq. (6)). In this way, the reaction scheme can explain the presence of all the primary products found. Under the experimental conditions of 200°C and 50 kg/cm², no 2, 3-dimethylbutene was formed, and more *n*-hexenes than 3-methylpentenes were formed. This fact may be explained by assuming that the order of ease in the C–C bond breaking of the cyclobutane intermediate II is C_1-$C_2 > C_2$-C_3 $(= C_1$-$C_4) > C_3$-C_4. These cyclobutane intermediates, however, may not be the activated complexes which are at the top of the energy barrier, because the selectivity in the ring-opening reactions changes with the experimental conditions, as Fig. 4 shows.

Figure 3 shows that more of the trans isomers were produced initially than the corresponding cis isomers for 2-hexenes and 4-methyl-2-pentenes, and that the reverse was true for 3-methyl-2-pentenes. This fact can be explained on the reasonable assumptions that the two propylene molecules are chemisorbed on the catalyst surface so that the two methyl groups of the cyclobutane intermediate direct opposite to the catalyst surface (the cyclobutane ring lies horizontally on the catalyst surface), and that during the course of the ring-opening process on the catalyst surface the rotation of a C–C bond of the cyclobutane ring is retarded by the steric hindrance of the methyl groups.

Finally, we wish to refer to an interesting feature of the nickel oxide-silica-alumina catalysts. Unlike the usual acid-type catalysts over which the polymerization of olefins is considered to take place *via* a carbonium-ion mechanism, the nickel oxide-silica-alumina catalysts exhibit a higher activity for a lower olefin, *i. e.*, the highest activity for ethylene.[2,3] This fact cannot be explained by the carbonium-ion mechanism. The present mechanism may suffice to explain this fact, in view of the steric hindrance of the alkyl group in the formation of the intermediates of cyclobutane derivatives.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 49—52 (1968)

Mössbauer Effect of the ^{119}Sn in the Molecular Complexes of Tin Tetrachloride with Some Aliphatic Compounds

Sumio ICHIBA, Mitsuo MISHIMA, Hiroshi SAKAI and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received July 1, 1967)

Molecular complexes of tin tetrachloride with some aliphatic compounds, such as alcohols and esters, were investigated by means of the Mössbauer effect due to ^{119}Sn, irradiation being made by 23.8 keV γ-rays from the ^{119m}Sn in tin dioxide. Most of these complexes show quadrupole splittings resulting from the addition of organic molecules to tin tetrachloride, although broad absorption curves are observed in some cases. The isomer shifts range from 0.30 to 0.45 mm/sec. They are much smaller than that of tin tetrachloride itself. The results are interpreted by taking account of the electronic structures of the complexes.

A number of molecular complexes of tin tetrachloride with oxygen-containing aliphatic compounds, *i. e.*, Lewis bases, have been examined by means of the Mössbauer effect due to ^{119}Sn. Previous structural studies of these complexes have been made mostly by means of the infrared spectra, though sometimes, rarely, by X-ray analysis.[1-3] When tin tetrachloride complexes with such monofunctional donors as alcohols, esters, and ketones, 1 : 2 complexes are generally formed, and the molecular shape changes from a tetrahedron to a octahedron which has either a cis- or a trans-form. On the basis of the infrared spectra of several 1 : 2 complexes, it has been suggested[1,4] that small ligands tend to give cis-complexes. In the course of this work, however, both cis- and trans-complexes were examined.

The purpose of the present study is to clarify the changes in the electron density and the bond character in the $SnCl_4$-complexes. Some of the results obtained are similar to those obtained by Stukan *et al.*,[5] but they are slightly different from those obtained by Khristrov *et al.*[6] The Mössbauer spectra of most of the complexes are doublets. These doublets are caused by quadrupole splitting, 2ε, and are regarded as a direct measure of the electric-field gradient at a tin nucleus or, in qualitative terms, as a measure for the deviation from spherical symmetry of the electron cloud around the tin nucleus.

The difference between the center of the splitting and the zero Doppler velocity, δ, is the isomer shift, which is a relative value with respect to the source. It gives a measure of the s-electron density at the tin nucleus. The source in the present work was radioactive tin dioxide, $^{119m}SnO_2$, and was used at room temperature. Although a small quadrupole splitting is observed in tin dioxide,[7,8] it is preferable as a source because it has a large recoilless fraction of 23.8 keV γ-rays, even at room temperature.

All the δ-values of the molecular complexes fall in the range from 0.3 to 0.45 mm/sec with respect to tin dioxide and are smaller than that of tin tetrachloride. This means that the s-electron density at the nucleus decreases when tin tetrachloride complexes with oxygen-containing organic compounds.

Experimental

Preparation of Molecular Complexes. The $SnCl_4$-complexes were prepared by mixing reactants in benzene or petroleum ether, or by adding tin tetrachloride to ice-cold bases in suitable proportions. Generally the complexes precipitated immediately. They were then filtered off in a dry air stream, washed with a pure solvent, and recrystallized or sublimed under reduced pressure. The complexes with alcohols were prepared by a method previously reported in the literature.[9,10]

The 1 : 2 complexes were obtained by adding the tetrachloride (1/10 mol) to an ice-cold benzene solution of an alcohols (2/10 mol) except ethyl alcohols. The complexes were then purified by sublimation under reduced pressure. The complex of tin tetrachloride

with ethyl alcohol was prepared by adding tin tetrachloride to ice-cold ethyl alcohol directly. The crystalline tin trichloride monoethoxide ethanolate was obtained when the tetrachloride and ethyl alcohol were mixed in benzene. It was recrystallized from a benzene solution.

The 1 : 4 complex of tin tetrachloride with isopropyl alcohol was prepared by refluxing tin tetrachloride (27 g) and isopropyl alcohol (40 g) for several hours; it was crystallized spontaneously on cooling. A crop of cubic crystals was obtained.

The complexes of tin tetrachloride with ester, tetrahydrofuran (THF), dioxane, acetone, cyclohexanone, and acetonitrile were prepared by adding tin tetrachloride to a petroleum ether solution of the bases in accordance with the usual method.[4,11] The complexes were then purified by sublimation under reduced pressure.

The compound was identified by measuring its melting point. The results are summarized in Table 1, along with the literature values. They are in good agreement with each other.

Table 1. Melting points of $SnCl_4$-complexes

Complexes	Melting point, °C[a] obs.	lit.
$SnCl_4 \cdot 2CH_3OH$	99—106	98—103[b]
$SnCl_4 \cdot 2C_2H_5OH$	51— 58	53—56[b]
$SnCl_4 \cdot 2n\text{-}C_3H_7OH$	106—108	95—98[b]
$SnCl_4 \cdot 2(CH_3)_2CHOH$	112—113	104—106[b]
$SnCl_4 \cdot 4(CH_3)_2CHOH$	61— 68

Measurements. The isomer shift and the quadrupole splittings were observed by changing the Doppler-velocity of the absorber. An apparatus of this type was supplied by the Nuclear Science Engineering Company (NSEC, Model B).

The detector was a single channel γ-ray spectrometer made by the Nippon Musen Irigaku Kenkyusho Company. It was equipped with an NaI (1 mm in thickness) scintillation detector. The γ-ray radiation source was tin dioxide containing 2mCi ^{119m}Sn. The source was used at room temperature, while the absorber was cooled with liquid nitrogen. The thickness of the absorber was about 15 mg/cm^2 for Sn. X-Rays were cut off by a Palladium foil attached to the absorber. The activity at a given velocity was accumulated until it reached about 10^5 counts in order to reduce the statistical errors. The accuracy of the apparatus was checked by observing the Mössbauer spectrum of barium stannate, $BaSnO_3$. The isomer shift obtained by this apparatus was in good agreement with the literature value ($\delta < 0.1$ mm/sec).[12] The resonant absorption of the sample was not examined at room temperature.

Results and Discussion

The results of the Mössbauer effect measurement are summarized in Table 2. The isomer shift and quadrupole splitting in molecular complex are presented in the first and second columns of this table, while the third column gives the half-width of the absorption curve, $R_{1/2}$, which will be defined below. All the shifts are shown relative to that of tin dioxide; the positive values indicate the motion of the absorber toward the source. The quadrupole splittings were determined by a procedure to be described below. All the numerical values of δ and 2ε are given in mm/sec.

Table 2. Mössbauer parameters for $SnCl_4$-complexes

Complexes	δ mm/sec[a]	2ε mm/sec[b]	$R_{1/2}$ mm/sec[c]
$SnCl_4 \cdot 2CH_3OH$[d]	0.43	0.70	2.00
$SnCl_4 \cdot 2C_2H_5OH$[d]	0.33	0.70	2.00
$SnCl_4 \cdot 2n\text{-}C_3H_7OH$	0.43	0.50	1.80
$SnCl_4 \cdot 2(CH_3)_2CHOH$[d]	0.35	0.70	2.00
$SnCl_4 \cdot 4(CH_3)_2CHOH$	0.30	0	1.50
$SnCl_4 \cdot 2(C_2H_5)_2O$[d]	0.45	1.10	2.65
$SnCl_4 \cdot 2(CH_2)_4O$[e]	0.43	1.14	2.70
$SnCl_4 \cdot 2O(CH_2)_4O$	0.45	1.10	2.60
$SnCl_4 \cdot 2(CH_3)_2CO$[d]	0.40	small	1.70
$SnCl_4 \cdot 2(CH_2)_5CO$	0.35	0	1.50
$SnCl_4 \cdot 2CH_3CN$	0.43	0.70	2.00
$SnCl_3 \cdot OC_2H_5 \cdot C_2H_5OH$	0.33	small	1.65

a) δ is the isomer shift relative to the source of SnO_2 crystal. The accuracy in the measurement is $\pm 5\%$.
b) 2ε is the quadrupole splitting.
c) $R_{1/2}$ is the half-width.
d) D. Khristrov *et al.* (Ref. 6) obtained values of δ and 2ε different from those in this table.
e) δ-value obtained by Stukan *et al.* (Ref. 5) is 0.70 relative to SnO_2. They did not observe the quadrupole splitting.

Isomer Shift. The values for all the molecular complexes fall in a range from 0.30 to 0.45 mm/sec. It may be noted that these values are smaller than those of $SnCl_4$, 0.78 ± 0.07,[13] 0.9 ± 0.1,[14] $0.7 \pm$

14) M. Cordey-Hayes, *J. Inorg. Nucl. Chem.*, **26**, 915 (1963).

0.08,[5] and 0.8±0.05,[6] with respect to SnO_2. The isomer shift can be expressed as follows:

$$\delta = (4\pi Ze^2R^2c/5E_\gamma)[|\psi(0)_a|^2 - |\psi(0)_s|^2](\Delta R/R)$$

where $|\psi(0)_a|^2$, $|\psi(0)_s|^2$, Z, R and E_γ are the s-electron densities at the nucleus of the absorber and the source, the nuclear charge, the mean nuclear radius, and the energy of the γ-rays respectively. The value of $\Delta R/R$, which is the fractional change of the radius from the ground state to the excited state, was found to be 1.16×10^{-4} [15] (1.1×10^{-4} by Boyle *et al.*,[16] and 1.2×10^{-4} by Cordey-Hayes[14]). Thus, the fact that the complexes have a smaller isomer shift means that the s-electron density at the tin nucleus decreases when the complexes are formed.

The outer electron configuration of a tin atom in $SnCl_4$ is expressed by the tetrahedral sp^3 hybrid. If the Sn-Cl bond in $SnCl_4$ is completely covalent, its s-electron character is 0.25. The ionic character of the Sn-Cl bond in $SnCl_4$ was estimated to be 0.38 by the pure quadrupole resonance (PQR) resulting from chlorine atom,[17] while it was deduced to be 0.42 or 0.50 from the isomer shift of the Mōssbauer effect.[14,15] If the ionic character is approximated by 0.40, the 5s-electron character of the tin atom will amount of $0.25\times(1-0.40)=0.15$, since a quadrivalent tin ion has the $(4d)^{10}$ configuration outside the krypton core. Accordingly, the value of $|\psi(0)_a|^2$ is smaller for $SnCl_4$ than for β-Sn, in which tin networks are formed by sp^3 hybrid orbitals, and the isomer shift is diminished.

When tin tetrachloride forms molecular complexes with oxygen-containing organic compounds, atoms around the tin atom in the $SnCl_4\cdot2D$ complex (D : donor) occupy the corners of a distorted octahedron formed approximately by sp^3d^2 hybrid orbitals. The lone-pair electrons of oxygen atoms serve as the 5d-electrons, and one of the 5s-electron of the tin atom is promoted to the 5p-orbital, as in the complexes of $SnCl_4\cdot2(CH_2)_4S$[1] and $SnCl_4\cdot2SeOCl_2$.[3] If each of the bonds is formed by the sp^3d^2 hybrid, its s-character would be 0.17. From the PQR data in the $SnCl_4\cdot2(C_2H_5)_2O$ complex,[18] it may be seen that the ionic character of the Sn-Cl bond is about 10 percent larger than that for $SnCl_4$ itself. That is, the ionic character may be assumed to be 0.44. Therefore, the 5s-electron character of the tin atom may be estimated to be $0.17\times(1-0.44)=0.09$. However, it should be kept in mind that the pure sp^3d^2 hybrid bonds are not formed in the complexes with nonequivalent ligands, as listed in Table 2. Furthermore, the 5s-electron will be shielded, especially by the 5d-electron. When the results of tin tetrachloride are compared with those of its complexes with oxygen-containing organic compounds, it is expected that the $|\psi(0)_a|^2$ of the tin atom will decrease and that the isomer shift will be reduced in forming the complex. This is the case in the present work.

It is difficult to understand why the isomer shift for the $SnCl_4\cdot2C_2H_5OH$ complex is small in comparison with those of other alcohol complexes. For the 1 : 4 complex $SnCl_4\cdot4(CH_3)_2CHOH$, in which the quadrupole splitting has not been observed, it is not evident how four isopropyl alcohol molecules coordinate to a tin atom. Its structural analysis has not been performed as yet, but it seems plausible that two of them coordinate to a tin atom through oxygen atoms of the donors.

As for the isomer shift of $SnCl_4\cdot2(CH_2)_4O$, the present value (0.43 mm/sec) differs from that of Stukan *et al.* (0.70 mm/sec).[5] According to them, both $SnCl_4$ and $SnCl_4\cdot2(CH_2)_4O$ have the same isomer shift. This seems unreasonable in light of the s-electron density described above.

Quadrupole Splitting. The quadrupole splitting was observed for almost all the compounds. The observed values of the splitting are given in the second column of Table 2. The quadrupole

splittings were clearly observed only in complexes with esters, while broad absorption curves were found in the other complexes. A few examples of the spectra are shown in Fig. 1. The minimum value of the observed width, 1.5 mm/sec, is almost equal to that of $BaSnO_3$, which shows no splitting. In the example of the $SnCl_4 \cdot 2CH_3CN$ complex shown in Fig. 1(b), the observed spectrum seems to have a single peak. However, the half-width, $R_{1/2}$, is larger than 1.5 mm/sec, so that there must be some quadrupole splitting. Here $R_{1/2}$ was used to distinguish it from the notation, $\Gamma_{1/2}$, usually used for natural half-widths.

Assuming that the observed curve is composed of Lorentzian curves with the half-width of 1.5 mm/sec, the magnitude of the quadrupole splitting can be deduced easily. The component curves obtained in this way reproduce the original when they are combined. If the components have a width other than 1.5 mm/sec, *e. g.*, 1.4 or 1.6 mm/sec, the combined curves deviate from the experimental curves at the tail part or at the peak. However, this procedure for the derivation of the quadrupole splitting cannot be free from some small errors, since various factors may affect the line width.

In general, the electric field gradient may be caused by two sources, *i. e.*, the charges of the distant ion and the nonspherically distributed electrons around the nucleus. In ionic crystals, the latter effect vanishes, and only the former appears. On the contrary, in covalent crystals the electric field gradient arises mostly from the latter.

In the $SnCl_4$-complexes, both cis- and trans-forms exist, as may be seen in Fig. 2. Among the complexes examined in the present study, both $SnCl_4 \cdot 2CH_3CN$ and $SnCl_4 \cdot 2(CH_3)_2CO$ are known to exist in the cis-form in a benzene solution,[4] but their crystal structures have not yet been determined. If each of these complexes preserves the cis-form in the solid, a twofold axis exists, as in the $SnCl_4 \cdot 2SeOCl_2$ complex shown in Fig. 2(a). Thus the field gradient will appear at tin nuclei, and the quadrupole splitting will be observed to some extent. This is confirmed in Table 2.

The quadrupole splitting of the $SnCl_4 \cdot 2(CH_2)_4O$ complex has been observed, contrary to the results reported by Stukan *et al.*,[5] though its crystal structure has not yet been determined. Beattie *et al.*[1] indicated that a similar molecular complex, $SnCl_4 \cdot 2(CH_2)_4S$, is a centrosymmetric molecule with a trans-form; they ascertained this by studying the X-ray diffraction as well as the Raman and infrared spectra (*cf.* Fig. 2(b)). The infrared investigations[19,20] of the $SnCl_4 \cdot 2(CH_2)_4O$ complex show that the two donor molecules coordinate to a tin atom to yield a trans-form. Thus, the shape of the $SnCl_4 \cdot 2(CH_2)_4O$ complex may be almost the same as that of the $SnCl_4 \cdot 2(CH_2)_4S$ complex, which has a twisted form. Consequently, the distribution of the electric charge around the tin nucleus in the $SnCl_4 \cdot 2(CH_2)_4O$ deviates from spherical symmetry, and the quadrupole coupling arises. An interesting fact is that the magnitude of the quadrupole splitting is larger for a trans-complex than for a cis-complex.

The complex compound $SnCl_3OC_2H_5 \cdot C_2H_5OH$ was investigated by means of measurements of the vapor pressure of a benzene solution and the infrared absorption of the solid by Laubengayer *et al.*,[10] as well as by means of the dipole moment in a benzene solution by Osipov *et al.*[21] From these results the dimer structure shown in Fig. 3 was proposed. According to the Mössbauer effect on this compound, the quadrupole splitting is very small, although the value was not determined. Therefore, it seems likely that the compound exists as a cis-form in the solid state.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 53—60 (1968)

Thermal Decomposition of Ketene in Shock Waves

Morizo TSUDA*1 and Kenji KURATANI

Space and Aeronautical Research Institute, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received July 12, 1967)

With the use of a single pulse shock tube of a magic hole type, the thermal decomposition of ketene was studied at temperatures from 1140 to 1530°K. The formation of carbon monoxide, that is, the disappearance of ketene, followed a kinetic order of 1.5 with respect to ketene and its rate constant was represented by

$$k = 10^{14.2} \exp[(-65600 \pm 1100)/\boldsymbol{R}T] l^{1/2} \text{ mol}^{-1/2} \text{ sec}^{-1}.$$

The thermal decomposition of mixtures of ketene and ethylene in argon was also studied, and the formation of methylene radicals during the pyrolysis of ketene is deduced from the presence of propylene and cyclo-propane in the products of these three component reactants. The rate of ketene disappearance was not affected by the addition of ethylene, or nitric oxide. A chain mechanism in which methylene radicals play a principal part, and a combined molecular mechanism of first, and second orders were proposed tentatively to explain the observed 1.5th order reaction rate.

Methylene is formed in the thermal decomposition of diazomethane, as well as in the photochemical decomposition of diazomethane and ketene.[1] However, there have been few studies of the thermal decomposition of ketene at high temperatures, and one cannot presume the formation of methylene radicals in the pyrolysis of ketene.

In the rather lower temperature range from 400 to 600°C, Young,[2] and Guenther and Walters[3] studied the thermal decomposition of ketene and found that the main products in the initial stages were allene and carbon dioxide. On the other hand, data available at higher temperatures are only those of Muller and Peytral,[4] and they found carbon monoxide and ethylene as the major products at 1150°C. According to these studies, it seems that there is clear difference between the results obtained at different temperatures.

To confirm the formation of methylene radicals in the thermal decomposition of ketene, we have studied the pyrolysis of ketene by the use of a single pulse shock tube. A shock-heating procedure is suitable to generate high temperature, and we were able to investigate the decomposition of ketene in the higher temperature range, and to know whether the mechanism of decomposition at high temperature is different from that at low temperature of not.

Experimental

Materials. Ketene was prepared according to a modification of Back's method.[5] Vapor of G. R. grade acetic anhydride in nitrogen carrier gas was heated at 510+5°C in a quartz tube. Unreacted anhydride was removed by passage through a dry ice-acetone trap, and the pyrolyzed products were collected at −196°C. Crude ketene was degassed at −196°C, and purified by repeated distillations at about −120°C (an *n*-propyl alcohol bath was used). Usually purified ketene contains 0.1—0.3% carbon dioxide.*2

One lot of ketene was introduced into a 7 cm long cell at 150 mmHg, and surveyed by an infrared spectrometer. No absorption band was observed except those belonging to ketene. Immediately after purification, ketene was diluted with a large excess of argon to a concentration of 4% or 5%, and the mixture was stored in a 5 *l* flask at room temperature. At a total pressure of less than 600 mmHg, there was no change in composition during the storage period.

High quality argon, supplied by Tomoe Co. (oxygen content less than 0.2 ppm), and 99.7% ethylene obtained from Takachiho Co. were used without further purification.

Apparatus and Procedure. A single pulse shock tube of a new design, developed at Cornell University,[6]

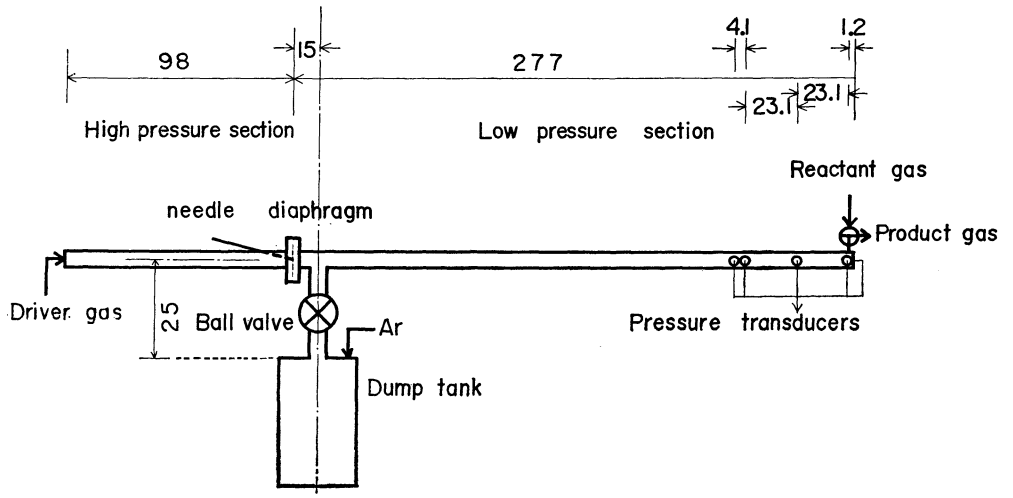

Fig. 1. Single pulse shock tube.

has a dump tank at the upstream end of a driven section. Using this device, it is not necessary to burst out two diaphragms at the preset time interval, and the whole system becomes very simple. We were greatly interested in this new design, and made a tube of this type as shown in Fig. 1. The inner diameter of our tube was 4 cm, and the length of the driver, and the driven sections were 98 and 277 cm, respectively. A dump tank of 19 *l* volume was attached to the driven section 15 cm downstream from the diaphragm through a branch tube and a ball valve of the same diameter. The main portion of the driven section was made of "Terex" glass, and the driver section of steel tubing, and was equipped with a needle to burst the diaphragms.

Four barium titanate-lead zirconate pressure transducers were mounted on the wall, flush with the inner surface, 51.5, 47.4, 24.3, and 1.2 cm from the end plate. The signals produced by the passage of an incident shock wave over these transducers were fed into amplifiers and converted into pulses by thyratrons. The pulsed output of the first transducer was used to trigger both a raster circuit, and an oscilloscope, to measure the shock velocity, and to show the pressure profile at the downstream end, respectively. Amplified pulses from the remaining three gauges were recorded on a raster synchroscope system having ten-microsecond marks. The incident shock wave velocity and its mean attenuation at the positions of these gauges were determined by measuring the time interval of the pulses shown on the pictures of the synchroscope display. The observed values of attenuation extended to nearly 0.4% when the incident shock wave travelled the distance of 23.1 cm, and they were taken into account to evaluate the incident shock wave velocity at the downstream end.

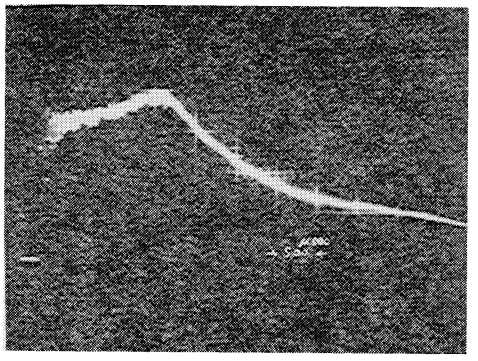

Fig. 2. A typical pressure profile at the end plate. In ordinary cases, pressure behind a reflected shock wave rises gradually, but the slope in Fig. 2 is too high. This disagreement may be derived from the narrowness of our shock tube.

One more piezo-electric pressure transducer was embedded in the end plate and was used to measure the pressure profile at the downstream end. The signal from this gauge was displayed on an oscilloscope, and the length of the plateau of the pressure profile was taken as the dwell time of the reaction.

A typical record of this pressure profile is illustrated in Fig. 2.

Prior to an experimental run, both the driver and the driven sections (including the dump tank) were evacuated, the latter especially, attaining a pressure of less than 0.2 μHg. Then the valve located between the dump tank and the main driven section was closed, and the former was filled with pure argon, and the latter with the sample gas highly diluted in argon. The pressure of both parts was kept at the same level, and just before pressurization of the driver section, the above valve was again opened.

The sample gas is heated only once by an incident and reflected shock wave in the shock tube. However, the former heating process is ignored, and the temperature behind the reflected shock wave, T_5, is taken to be the reaction temperature. The temperature T_5, and the density behind the reflected shock wave were calculated as functions of incident shock wave velocities at the downstream end, assuming that there was no chemical change behind the shock waves. The necessary enthalpy values for ketene at higher temperatures were taken from the table given by Moore and Pimentel,[7] or calculated using the same

molecular parameters adopted by them. To minimize the error in T_5, caused by neglecting the heat of reaction, most of the kinetic studies were carried out with mixtures of 0.5—2.0% ketene in argon.

"Lumirror" (trade name of poly-ethylene terephthalate, a product of Toyo Rayon Co.) sheets of various thickness were used as diaphragms to separate the higher and lower pressure section. When the pressure and composition of the driver gas were brought to previously determined values, diaphragms were pierced manually with a needle.

To achieve the highest cooling rate with a rarefaction wave, the tube should be tuned so that the head of the wave reflected from the end of the high pressure section, meets the reflected shock wave and the gas interface at approximately the same point. Since the length of the driver section of our tube is fixed at 98 cm, this adjustment was performed by the proper choice of the driver gas composition. A satisfactory composition was obtained according to the shock wave diagram calculation as shown in Fig. 3. Actually, it takes a finite time to rupture the diaphragms, and the calculated composition is regarded as an approximation. Fortunately, however, this estimate was proved to be accurate enough for our purpose, judging from the pressure profile at the end plate. A mixture of hydrogen and nitrogen was mainly used as the driver gas, and occasionally when it was planned to carry out a complete analysis of the products, a helium-argon mixture was used.

Analytical. The shock heated gas was rapidly cooled by a rarefaction wave, and immediately after the rupture of the diaphragms the reaction mixture was withdrawn to an evacuated vessel of 130 cc volume and analyzed by gas chromatography. A Yanagimoto G. C. G.-3DH gas chromatograph with a flame ionization attachment G. C. F.-103 was used for hydrocarbon analysis. Analyses of inorganic gaseous products were carried out with a usual thermal conductivity cell. In the latter case, in order to raise sensitivity, the output was recorded on a Sanei "Galvanograph", having a sensitivity of 0.25 mV full scale. For the determination of the small amount of hydrogen produced by pyrolysis, a helium-arogn mixture was used as the driver gas, since, even if we took extreme care to avoid migration of the driver gas into the sampling vessel, it was almost impossible to keep the reaction products completely free of the driver gas. Therefore, the

contents of the driver gas components were also analyzed for every run, and yields of product gases were corrected in accordance with the amount of driver gas migration.

For the separation of cyclopropane from propylene, a 5 m long column, at room temperature, packed with 7% $\beta\beta'$-oxy-dipropionitrile and 93% dibutylmaleate on chromosorb was connected in front of an alumina column 2 m in length at 150°C. With the use of this combined column, the relative retention volumes of propane, propylene, acetylene, cyclopropane, and allene to *n*-butane were found to be 0.32, 0.48, 0.56, 0.71, and 0.97, respectively.*3 Columns, and the experimental conditions used by us are shown in Table 1.

Results

On the Products. In several experimental runs we have measured the amount of unreacted ketene through absorption at 2163 and 2135 cm^{-1}, and confirmed that almost all oxygen atoms derived from pyrolyzed ketene are detected as carbon monoxide, and dioxide. This conclusion is consistent with the finding of Young,[2] and hereafter we assume that the amount of decomposed ketene is equal to the sum of $[CO]+2[CO_2]$ produced.

674	0.065	0.064	0.063	0.98	0.97

*3 These values shifted from 0.29, 0.51, 0.77, 0.67, and 1.04 to 0.33, 0.48, 0.50, 0.73, and 0.94 as the alumina column temperature was raised from 120°C to 170°C. 150°C was the best choice with respect to the separation of acetylene from the other components.

The product distributions of some typical runs are shown in Tables 2 and 3. In these tables, corrected values of $[CO_2]$, reducing the amounts contained in the original reactant mixtures from the values obtained by the product analyses, are listed, but since the amount of CO_2 in the reactant was comparable to that produced, the values of $[CO_2]$ shown in these tables are rather erroneous. However, as illustrated in Fig. 4, the ratio of

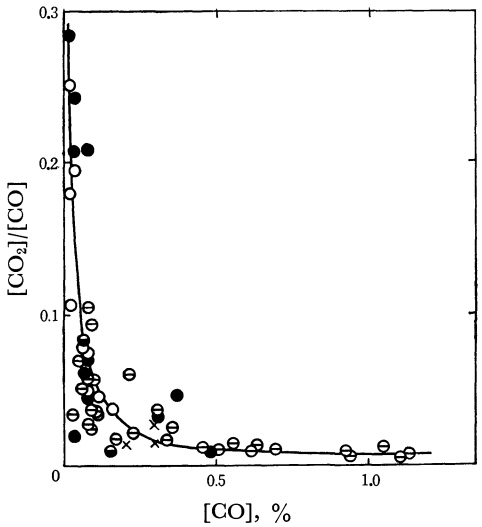

Fig. 4. Relationship between yields of carbon dioxide and carbon monoxide.
× 0.5% mixture ○ 1.0% mixture
⊖ 2.0% mixture ◒ 4.0% mixture
● 5.0% mixture

$[CO_2]/[CO]$ decreases rapidly with increase in the amount of CO produced. Furthermore, the yield of CO_2 itself is extremely small. Therefore, it seems a good approximation to take the rate of CO formation in place of the pyrolysis rate of ketene itself, especially in the higher temperature range studied by us.

The deficiencies of mass balances of carbon and hydrogen atoms compared with that of the oxygen atom, extend in some cases to 10—20%, and they may be attributable to the formation of a small amount of hydrocarbon polymers and carbon soot. However, when the yields of methane and acetylene are plotted against that of CO, as shown in Fig. 5, linear relationships among the yields of products are revealed, independent of the reaction temperatures and initial concentrations of ketene. That is, the ratios $[CH_4]/[CO]$, and $[C_2H_2]/[CO]$ are almost constant and equal to 0.15, and 0.13, respectively, throughout the experimental runs. As for ethylene, the ratio $[C_2H_4]/[CO]$ is held constant at 0.28 as long as the extent of reaction is less than 10%, but when the reaction proceeds further, this ratio decreases gradually.*4 Yields of hydrogen, ethane, and C_3-hydrocarbons are relatively small and considered to be minor products.

On the Rate Constant. According to the aforementioned assumption, the initial rate of the thermal decomposition of ketene is transformed to the following equation,

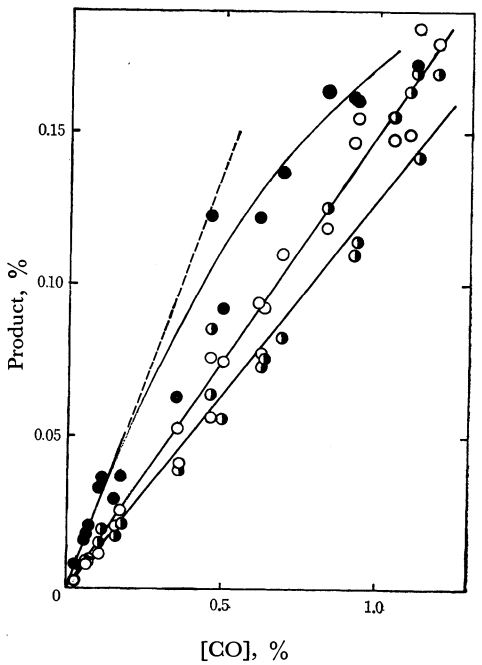

Fig. 5. Yields of methane, acetylene and ethylene.
○ methane ◑ acetylene ● ethylene

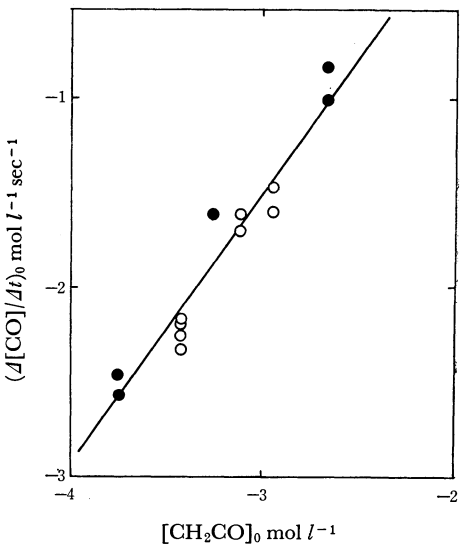

Fig. 6. Determination of reaction order at 1290°K.

*4 Contrary to the formation of ethylene, only small amounts of hydrogen are formed at the lower levels of reaction, but the ratio $[H_2]/[CO]$ increases rapidly at higher levels of reaction.

$$(-\mathrm{d[ketene]}/\mathrm{d}t)_0 = (\mathrm{d[CO]}/\mathrm{d}t)_0 = \Delta[\mathrm{CO}]/\Delta\tau \quad (1)$$

where $\Delta\tau$ represents the dwell time measured at the downstream end. Succeeding this, we assume that the reaction rate is expressed by the formula,

$$\Delta[\mathrm{CO}]/\Delta\tau = k[\mathrm{ketene}]^n[\mathrm{argon}]^m \quad (2)$$

where exponents n and m represent the order with respect to each reactant component.

However, to determine the reaction orders with respect to the initial concentrations of the reactants from Eq. (2), it is necessary to keep the extent of reaction less than 10%, and a reaction temperature of 1290°K was adopted for this reason. The observed rates at 1290°K with the various compositions of ketene and the total pressures are plotted in Fig. 6.

At first, assuming argon to be ineffective, Eq. (2) becomes

$$\Delta[\mathrm{CO}]/\Delta\tau = k'[\mathrm{ketene}]_0^n \quad (3)$$

According to formula (3), the exponent n was determined as the slope of Fig. 6 by a least squares method and found to be

$$n = 1.46 \pm 0.04.$$

In Fig. 6, open circles show the rates obtained with reaction mixtures of the same initial composition. Therefore, in these runs the following relations will hold,

$$[\mathrm{ketene}]_0 \propto [\mathrm{argon}]_0 \propto [\text{total concentration}]_0,$$

and

$$\text{rate} \propto [\text{total concentration}]_0^{n+m}.$$

When attention is paid to only these runs, the abscissa in Fig. 6 can be read as showing total concentrations in arbitrary units. That is, the slope obtained from these experimental points must show the exponent $n+m$. Thus, the total order of the reaction was calculated in a similar manner as

$$n + m = 1.64 \pm 0.08$$

Although the value of $n+m$ is slightly different from that of n, the total order of the reaction is regarded as the same as the order with respect to ketene, and a value of 1.5 was adopted. This conclusion derives the zeroth order with respect to argon, and the assumption made at the begining may be appreciated.

From the integral formula in the case of a three-halves order reaction, the rate constant is expressed as

$$k = 2\{(C_0/C)^{1/2} - 1\}/C_0^{1/2} \cdot \Delta\tau, \quad (4)$$

where $C_0 = [\mathrm{ketene}]_0$, and $C = [\mathrm{ketene}]_t = C_0 - \Delta[\mathrm{CO}]$. Rate constants at different temperatures from 1140° to 1530°K were calculated by means of Eq. (4) and plotted against the reciprocal of the reaction temperatures. From the Arrhenius plot

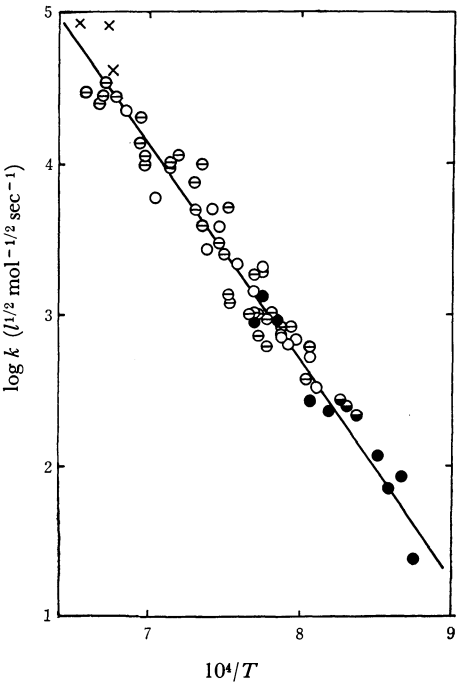

Fig. 7. Arrhenius plot of reaction rate.
× 0.5% ○ 1.0% ⊖ 2.0% ◒ 4.0% ● 5.0%

in Fig. 7, the apparent activation energy was evaluated as 65.6—1.1 kcal/mol, and finally the rate constant was given by

$$k = 10^{14.15} \exp\{(-65600 \pm 1100)/\boldsymbol{RT}\}$$

$$l^{1/2}\,\mathrm{mol}^{-1/2}\,\mathrm{sec}^{-1}$$

Discussion

In the thermal decomposition of ketene at higher temperatures above 1140°K, a small amount of carbon dioxide is found in the final products. For example, when 50% ketene was decomposed, the relative conversion of ketene into carbon dioxide, $2[CO_2]/([CO]+2[CO_2])$, is only about 1.6%. This fact is in remarkable contrast with the results obtained at temperatures below 900°K, where the relative conversion into carbon dioxide exceeds 50% at the corresponding extent of reaction. Accordingly, we might tentatively ignore the formation of carbon dioxide in the following discussion.

The product distributions of photo-decomposition of ketene at room temperature, which have been studied by Knox[8] and Chanmugan[9], are similar to our results. Since it has been established that methylene is an important radical in the photolysis of ketene, the similarity of the product

8) K. Knox, R. G. W. Norrish and G. Porter, *J. Chem. Soc.*, **1952**, 1477.
9) J. Chanmugan and M. Burton, *J. Am. Chem. Soc.*, **78**, 509 (1956).

646	2.0	0	98.0	0.036	1290	1.60	0	3	0	15

distributions between the thermal- and photo-decomposition of ketene suggests a resemblance of both reaction schemes. These facts may be interpreted as circumstantial evidence of the formation of methylene radical by the pyrolysis of ketene.

To prove the existence of methylene radicals, the thermal decomposition of ketene containing considerable amounts of ethylene was studied, and a small but not ignorable amount of propylene and a trace of cyclopropane were detected as shown in Table 4. The existence of these molecules in pyrolyzed products supports our aforementioned interpretation, since cyclopropane and propylene may be produced by the reactions

$$CH_2 + C_2H_4 \rightarrow \text{cyclo-}C_3H_6 \rightarrow \text{propylene.}$$
(fast isomerization)

We found another important result from these experiments. That is, the addition of ethylene or NO to ketene scarcely alters the rate of carbon monoxide production.*5 The rate constants of these mixtures calculated with the 1.5th order rate equation are plotted in Fig. 8 and these rate constants coincide with those obtained from a ketene-argon mixture.*6 This result excludes a chain reaction mechanism in which a mono-radical plays a main role, and suggests the dominance of a molecular reaction scheme, or the contribution of a bi-radical to the ketene pyrolysis.

We assume further that the small amounts of hydrogen and higher hydrocarbons are obtained as secondary products, and propose the following reaction schemes for the early stage of the thermal decomposition of ketene.

The first of these schemes assumes the following chain reaction mechanism,

$$CH_2CO \rightarrow CH_2 + CO \quad (5)$$

$$CH_2 + CH_2CO \rightarrow C_2H_4 + CO \quad (6)$$

$$CH_2 + CH_2CO \rightarrow CH_3 + CHCO \quad (7)$$

$$CH_3 + CH_2CO \rightarrow CH_4 + CHCO \quad (8)$$

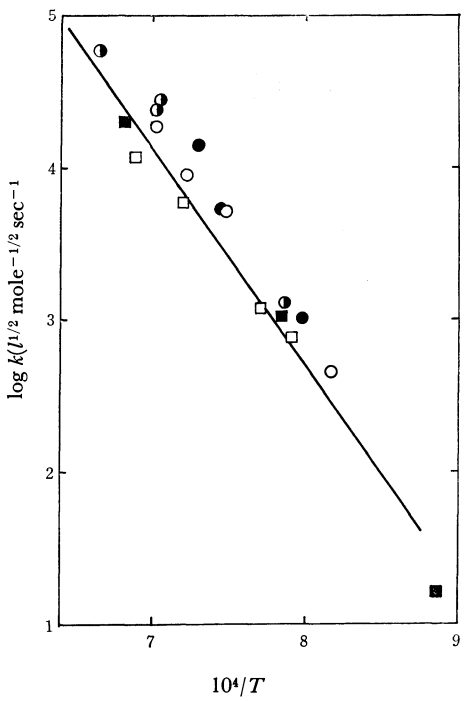

Fig. 8. Effect of ethylene and nitric oxide on the decomposition rate.
- □ 2% ethylene + 4% ketene
- ■ 4% ethylene + 4% ketene
- ○ 0.2% nitric oxide + 2.0% ketene
- ◑ 0.4% nitric oxide + 2.0% ketene
- ● 0.54% nitric oxide + 2.0% ketene

$$CHCO \rightarrow CH + CO \quad (9)$$

$$CH + CH_2CO \rightarrow CH_2 + CHCO \quad (10)$$

$$CHCO + CHCO \rightarrow C_2H_2 + 2CO \quad (11)$$

$$CH_2 + CH_2 \rightarrow C_2H_4 \quad (12)$$

In this scheme, we omit the reaction path to ethane,*7 since the yield of this substance is very small. Then, the rate of carbon monoxide formation or the thermal decomposition rate of ketene will be expressed as

$$\left.\begin{aligned} -R(\text{ketene}) &= R_5 + R_6 + R_7 + R_8 + R_{10} \\ &= R_5 + R_6 + R_9 + 2R_{11} \end{aligned}\right\} \quad (13)$$

*5 No inhibition of NO to ketene photolysis was already pointed out by Burton *et al.* M. Burton, T. W. Davis, A. Gordon and H. A. Taylor, *J. Am. Chem. Soc.*, **63**, 1956 (1941).

*6 In fact, the presence of NO rather accelerates the rate of ketene decomposition, as shown in Fig. 8.

*7 Ethane will be obtained by $CH_3 + CH_3 \rightarrow C_2H_6$.

where R denotes the rate of an individual step. If one assumes steady state concentrations of radicals, the following relations will be obtained:

$$R_9 = R_{10},$$
$$R_5 + R_{10} = R_6 + R_7 + 2R_{12},$$
$$R_7 = R_8,$$
$$R_7 + R_8 + R_{10} = R_9 + 2R_{11}$$

The second of these equations is rewritten as

$$[CH_2] = \{-(k_6+k_7-k_{10}) + [(k_6+k_7-k_{10})^2 + 8k_5k_{12}/[K]]^{1/2}[K]\}/4k_{12}$$

where [K] denotes the concentration of ketene, and if we assume $(k_6+k_7-k_{10})^2$ $[K]^2$ is very small compared with $8k_5k_{12}[K]$,*8 it follows that

$$[CH_2] = (k_5[K]/2k_{12})^{1/2} \quad (14)$$

and the reaction rate is represented by

$$-R(\text{ketene}) = R_5+2R_6+3R_7 = \{k_5+2k_6[K]^{1/2}+3k_7[K]^{1/2}\}[K]. \quad (15)$$

This expression is consistent with the observed order of the reaction if we ignore the first term. In a similar way, the ratios of methane, acetylene, and ethylene yields against that of CO are given by

$$[CH_4]/[CO] = R_7/(2R_6 + 3R_7),$$
$$[C_2H_2]/[CO] = R_7/(2R_6 + 3R_7),$$
$$[C_2H_4]/[CO] = R_6/(2R_6 + 3R_7).$$

Since the yield of ethylene at the lower extent of conversion was about twice as large as that of methane, as shown in Fig. 5, one might assume

$$R_6 = 2R_7,$$

and one can obtain numerical values for these ratios:

$$[CH_4]/[CO] = 0.14,$$
$$[C_2H_2]/[CO] = 0.14,$$

and

$$[C_2H_4]/[CO] = 0.28.$$

These results are also in excellent agreement with our observations.

The second proposal assumes the simultaneous decomposition of ketene by first and second order reactions, that is, the first order reactions

$$CH_2CO \rightarrow CH_2 + CO \quad (5)$$

and

$$CH_2 + CH_2CO \rightarrow C_2H_4 + CO \quad (6)$$

are combined with the second order reaction

$$2CH_2CO \rightarrow C_2H_4 + 2CO \quad (16)$$

With this tentative frame work, the rate of the carbon monoxide formation will be represented as

$$d[CO]/dt = k[\text{ketene}]^{1-2}.$$

The other products, such as methane and acetylene, will be derived through processes (7)—(11). This scheme is also in agreement with the observed relative yields of methane and acetylene, because

$$[CH_4]/[C_2H_2] = R_8/R_{11} = 2R_8/(R_7 + R_8) = 1.$$

Although experimental results concerning the yield of CO_2 are rather unreliable as already indicated in previous sections, the reaction rate of CO_2 formation in our experiment was found to be roughly proportional to the square of the initial ketene concentration. Moreover, a small amount of allene was detected in the products. These findings are in accord with the reaction path,

$$2CH_2CO \rightarrow CH_2{=}C{=}CH_2 + CO_2,$$

proposed by Young,[2] and Guenther and Walters.[3] Young suggested that allene splits into methylene and acetylene,

$$CH_2{=}C{=}CH_2 \rightarrow CH_2 + C_2H_2.$$

This step might be a secondary source of methylene radicals in addition to step (5).

At any rate, in our reaction scheme, methylene radicals may be formed, but it is not certain whether they play a leading role in the reaction sequence or not. The presence of methyl radicals is also demonstrated by the formation of a small amount of ethane as shown in Tables 2 and 3.

The authors wish to thank Messrs. Takuji Sakai and Shiro Hasumi for their assistance in construction of a single pulse shock tube.

*8 In order to derive an expression consistent with the observed order of our reaction rate, this assumption is very useful as shown in the text. But it seems rather artificial and the scheme proposed here should be regarded as a tentative one.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 61—64 (1968)

Structural Study of the Molecular Complex of Antimony Trichloride with Benzene by Means of the Pure Quadrupole Resonance

Tsutomu OKUDA, Akira NAKAO, Masaharu SHIROYAMA and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received July 17, 1967)

The Zeeman effect of ^{35}Cl pure quadrupole resonance was studied on a single crystal of the $2SbCl_3 \cdot C_6H_6$ molecular complex at room temperature; it was found that the Cl-Sb-Cl bond angles of two nonequivalent $SbCl_3$ molecules are 96.2°, 94.7°, 92.2°; 94.5°, 92.8°, and 95.2°, with an uncertainty of 1°. The asymmetry parameters for the six chlorine atoms were found to be 0.085 ± 0.001, 0.055 ± 0.004, 0.117 ± 0.005, 0.119 ± 0.005, 0.112 ± 0.005, and 0.160 ± 0.007, listed in the order of decreasing resonance frequencies. The bond character of the Sb-Cl bond was also calculated from the quadrupole coupling constant. It was found that the Sb-Cl bond corresponding to the lowest resonance lines in each nonequivalent $SbCl_3$ molecule has a larger ionicity than the remainder. Moreover, the former has less of a temperature dependence than the latter. Finally, this complex may be assigned to the C_i or C_1 symmetry class from the patterns of zero-splitting and from the intensity ratios of the multiplet of the spectrum.

It is well known that antimony trichloride forms 2 : 1 or 1 : 1 molecular complexes with a number of aromatic compounds. These complexes have been studied by various methods, but their crystal structures are still unknown. Studies of the pure quadrupole resonance on these complexes have been performed by several authors.[1-3] All of them, however, used polycrystalline samples, and their information was limited to the bond nature of the component. The aim of the present work is to deduce the asymmetry parameters of the electric-field gradient at the relevant nuclei, the nature of the Sb-Cl bond, and the bond angles of Cl-Sb-Cl, as well as to assign the resonance lines and find the crystallographic symmetry. The 2 : 1 molecular complex of antimony trichloride with benzene was chosen as the sample for the basic research in order to see how the molecular shape and the bond character of antimony trichloride change in forming the complex.

The study of antimony trichloride itself was performed prior to that of the complex. Fortunately, its crystal structure had already been established by X-ray analysis[4,5] as well as by the pure quadrupole resonance.[4,6]

Experimental

The molecular complex was prepared in the following way.[7] One mole of pure benzene and two moles of pure antimony trichloride were dissolved in carbon disulfide individually, and then these solutions were mixed together. After the solution had been concentrated, the crystal was filtered and dried *in vacuo*. The complex was identified by determining the melting point and the chlorine content. The single crystal of the complex was obtained by a melting method described previously.[8] It was 10 mm in diameter and 25 mm long.

The spectrometer consisted of a super-regenerative oscillator, an amplifier, and a detector. The absorption lines were displayed on an oscilloscope. A Zeeman field of about 200 gauss was applied by a Helmholtz coil. The crystal could be rotated about a fixed axis of the crystal, and its angle Φ could be measured to within $\pm0.1°$. On the other hand, the magnetic field could be rotated on a horizontal plane, and its angle Θ could be measured to within $\pm1'$. The patterns of zero-splitting were observed at about 21°C.

Results and Discussion

The $2SbCl_3 \cdot C_6H_6$ molecular complex has six resonance lines of the same intensity, all due to ^{35}Cl, at room temperature as well as at the temperature of liquid nitrogen,[3] as is shown in Table 1. Let us now label the six resonance lines $\nu_1, \nu_2, \cdots, \nu_6$ from the lower to the higher, and the chlorine atoms contributing to $\nu_1, \nu_2, \cdots \nu_6$, $Cl_1, Cl_2 \cdots, Cl_6$.

The pattern of the zero-splitting was obtained by measuring the Zeeman effect on the resonance

	ν'_2	20.419	20.912	480

a) $\Delta\nu$ is the difference between the resonance frequencies at 21 and −196°C.

line; it is reproduced in Fig. 1. Although the Zeeman patterns of six resonance lines are shown in Fig. 1, one of them was missing in the original sample because the principal z axis of the field gradient at the chlorine atom contributing to the missing line was nearly parallel to the rf coil axis, thus reducing its intensity considerably. In order to observe the pattern, we had to use another sample, a single crystal in which the crystal axes were oriented differently. For this sample, however, another resonance line was missing. Combining both results, the six patterns shown in Fig. 1 were obtained.

The direction of the principal z axis of the field gradient of the chlorine atom can be determined by the zero-splitting pattern.[9] Generally the z axis is parallel to the direction of the Sb-Cl bond in the complex. Consequently, the angle between any two Sb-Cl bonds can be deduced; these angles are listed in Table 2. It should be remarked here that the z axis may deviate slightly from the direction of the bond which is bound to the benzene ring. As has been stated above,

TABLE 2. THE ANGLES BETWEEN THE Sb-Cl BONDS[a]

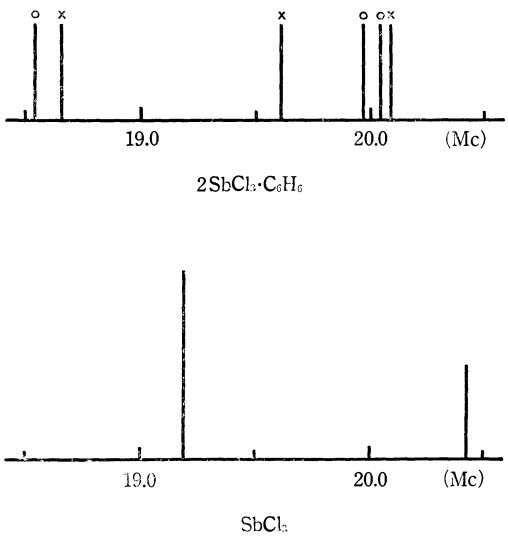

Fig. 2. Pure quadrupole resonance spectra of antimony trichloride and its complex with benzene. Resonance lines with the same mark, circle or cross come from the same antimony trichloride molecule.

9) K. Shimomura, *J. Phys. Soc. Japan*, **12**, 657 (1957).

six resonance lines of the same intensity are observed in a polycrystalline sample, but they can not be grouped into any sets. This problem can, however, be solved easily when the Zeeman effect on the resonance lines is examined. The results are shown in Fig. 2, in which those lines labeled by the same mark, a circle or a cross, come from the same molecule. The ν_1 and ν_2 resonance frequencies are considerably lower than the remainder. These lowering must be caused by some factors other than the crystal field. One possibility is that they correspond to the bonds which reside on the benzene ring.

The values of the asymmetry parameter are determined from the distortion of zero-splitting loci by the following equation:[10]

$$\eta = 3(\sin^2\theta_{max} - \sin^2\theta_{min})/(\sin^2\theta_{max} + \sin^2\theta_{min}) \quad (1)$$

where θ_{max} and θ_{min} are maximum and minimum zero-splitting angles, corresponding to $\phi=0°$ and 90° respectively. Consequently, the quadrupole coupling constants are calculated by this equation, substituing the value of η:

$$\nu = (eQq_{zz}/2h)(1 + \eta^2/3)^{1/2} \quad (2)$$

The values of η and eQq_{zz} derived in this way are listed in Table 3.

The bond character of the Sb-Cl bond can be determined from η and eQq_{zz}. The resonance structures are considered to be as shown in Fig. 3 in general. There is no doubt about the existence of covalent (1) and ionic (2) structures, but there must be a double-bond structure (3) as well.

Table 3. The nature of Sb-Cl bonds in $SbCl_3$ Molecule

Compound	Species	eQq_{zz} Mc/sec	U_p %	η %	i %

10) C. Dean, *Phys. Rev.*, **96**, 1053 (1954).

Since the ground state of antimony is $5s^25p^3$, the sp^3 hybrid orbital seems to occur in $SbCl_3$ to some extent. Kimball[11] discussed the possibilities of double-bond formation by treating the problem of direct valence from the viewpoint of the group theory. According to him, the sp^3 hybrid orbital is capable of forming a strong π bond with d^2 and a weak π bond with d^3. However, Gordy[12] proposed that the tendency to form a double bond by using d orbitals falls off rapidly in descending rows in the periodic table, essentially vanishing for such fifth-row elements as Sn and Sb. The Sb-Cl bond length of $SbCl_3$, as claculated by the equation of Schomaker and Stevenson,[13] is in good agreement with the observed value if the Sb-Cl bond has a little double-bond character in $SbCl_3$. If the double-bond character of the Sb-Cl bond can be neglected, the bond character can be derived as follows.

The number of the unbalanced p-electron is given by:

$$U_p = (1 - i)(1 - s) \quad (3)$$

where i is the ionic character and s is the s electron character, which is assumed to be equal to 0.15.[14] On the other hand, the value of U_p is evaluated from the observed quadrupole coupling constant:

$$U_p = (eQq_{zz})_{obs}/(eQq_{zz})_{atom} \quad (4)$$

where $(eQq_{zz})_{atom}$ is 109.7 Mc/sec.[15] The ionic character, i, can be calculated from Eqs. (3) and (4). The results are listed in Table 3. It may be noted that the Sb-Cl_1 and Sb-Cl_2 bonds have a larger ionic character than do the other bonds, which have nearly the same ionic character as those of $SbCl_3$ in its pure state. Thus it seems likely that the π electron of the benzene is transferred to the chlorine atom through the Sb-Cl_1 or Sb-Cl_2 bond.

The molecular shape of the $SbCl_3$ in the complex and its pure crystal are shown in Fig. 4, the bond angles being taken from Table 2. Two nonequivalent $SbCl_3$ molecules in the complex crystal have almost the same shape, but show differently-spaced resonance frequencies. That is, in the $Sb-Cl_3$ molecule (A) the smallest angle is between $Sb-Cl_3$ and $Sb-Cl_6$, which correspond to the middle and the highest frequencies respectively, whereas in the other molecule, $SbCl_3$ (B), the smallest angle is between Sb-Cl_1 and Sb-Cl_4, the lowest and the middle frequencies. The shape

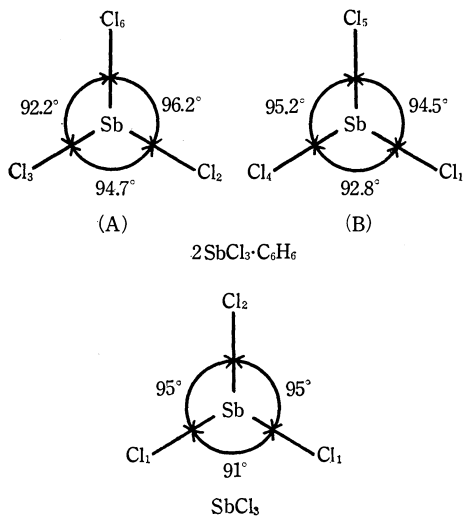

Fig. 4. Shapes of antimony trichloride molecule in the pure state[4] and its complex with benzene.

of $SbCl_3$ (B) is similar to that of $SbCl_3$ in its pure crystal; accordingly, the asymmetry parameter of Sb in the former should be equal to that in the latter. This is really the case; the findings on the ^{123}Sb resonance will be reported elsewhere. In this complex, benzene may combine with the chlorine atom to form the complex; that is, some charge may be transferred to the chlorine atom from benzene. Therefore, the bond angles of $SbCl_3$ in the complex may be expected to increase as a result of the stronger coulombic repulsion between chlorine atoms; however, only a little change may be seen, as is shown in Fig. 4.

We will now discuss the structure of $SbCl_3$ in the complex further. Daasch[16] assumed, from its infrared spectrum, that the $2SbCl_3 \cdot C_6H_6$ molecular complex has C_{2v} symmetry in the solid state and C_{3v} symmetry in the liquid state. Perkampus and Baumgarten[17] proposed, from the infrared spectrum, that the possible symmetry of the complex crystal was C_{2v}, C_s, or C. From the present Zeeman analysis it may be concluded that this complex has C_i or C_1 symmetry in the solid state; there is only one kind of pattern for each resonance line, as is shown in Fig. 1, and the intensities of all the resonance lines are equal.[18] If the structure of this complex has C_{2v} or C_s symmetry, at least one resonance line has two kinds of patterns. However, it is impossible to distinguish C_i from C_1 by the Zeeman analysis, because both positive and negative directions of the z axis of the field gradient give the same result.

Ashkanaji *et al.*[19] and Raskin[20] have reported on the Raman spectrum of a solution of antimony trichloride in benzene. The former authors observed two new lines which Raskin could not observe; they attributed these lines to the bending and stretching vibrations of the bond between antimony and benzene. On the contrary, it seems more probable, for the following reasons, that benzene combines with the chlorine atom. First, the lowest resonance frequency, ν_1, or ν_2, in each $SbCl_3$ molecule has the least temperature dependence, as may be seen in Table 1. This runs parallel to the more restricted motion of the chlorine atom bound to benzene. Second, the chlorine, Cl_1 or Cl_2, corresponding to the lowest line has the largest ionic character, which may be interpreted as having been brought about by the charge transfer from benzene. A somewhat similar situation arises in the molecular complex of carbon tetrabromide with *p*-xylene.[21] Two bromine atoms of the carbon tetrabromide in this complex are bound to benzene rings, while the other two bromine atoms are free from complexing. Hooper[22] tentatively assigned the lower frequency to the complexing bromine atoms. These results may support our conclusion, although the final decision should be made on the basis of X-ray analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 65—70 (1968)

Reactivity of Solid Acids with Methylene Chloride

Isao MOCHIDA, Jun-ichiro TAKE, Yasukazu SAITO and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received July 20, 1967)

In order to discriminate the natures of solid acids, the reactivity of methylene chloride with solid acids like alumina, silica-alumina and alumina-boria to give carbon monoxide and methyl chloride was studied with a pulse technique. The reactivities varied about ten thousandfold among these solid acids. The methyl chloride formation was predominant on alumina particularly at low reaction temperatures, with a distinctly small activation energy in comparison with that on silica-alumina or alumina-boria. The nature of the active sites for this reaction was discussed in connection with the effect of the calcination temperature as well as of the sodium ion-poisoning on activity. Furthermore, it was found that the feature of this reaction was in marked contrast with the typical solid acid catalysis such as the dealkylation reaction of alkylbenzenes. The reaction of methylene chloride with a set of the surface hydroxyl group and the oxidizing site is assumed to give methyl chloride through a radical mechanism.

It is well known that alumina and silica-alumina are in remarkable contrast with each other as solid acid catalysts. Silica-alumina has about one thousand times or even more higher catalytic activity than alumina has in such typical catalytic reactions as dealkylation of alkylbenzenes,[1] isomerization of xylene or cyclohexene[1] and oligomerization of propylene.[2] It is also to be noted that the ethylene/ether selectivities in dehydration of ethanol at 325°C on alumina and silica-alumina are quite different, although both give nearly the same activity.[3]

Alumina is known to exhibit exceedingly higher catalytic activities than silica-alumina does for the H-D exchange reaction between hydrogen and deuterium or between the surface hydroxyl groups and either deuterium or deuterated methane.[4] For example, the activation energy of the exchange reaction of the hydroxyl groups with deuterated methane was 5.7 kcal/mol for alumina, but 33.4 for silica-alumina.[4]

Many works have already been published concerning the triphenylcarbonium ion formation from triphenyl methane on solid acids.[5] Lately, Arai *et al.*[6] reported an interesting contrast between alumina and silica-alumina for the triphenyl methane chemisorption; a considerable amount of triphenyl methyl radical alone was formed on alumina, whereas both triphenylcarbonium ion and triphenyl methyl radical were formed on silica-alumina.

As well as silica-alumina, all of alumina-boria-(10% B_2O_3)[1] and aluminas treated with boron trifluoride, hydrogen fluoride or ammonium fluoride[1,7] gave higher catalytic activities for the dealkylation and other acid-catalyzed reactions.

The present authors have found that methylene chloride reacts with solid acids to give methyl chloride and carbon monoxide as the gaseous products and that the rate and the selectivity of methyl chloride/carbon monoxide varied extermely with the kind of the solid acid.[8] In other words, this reaction can characterize the specific nature of alumina as the solid acid in comparison with silica-alumina. The specific nature of alumina may be due to the cooperation of both the surface hydroxyl group and the oxidizing site for the radical reaction, as is previously concluded by the LFER (Linear Free Energy Relationships) approach with the aid of the simple molecular orbital theory.[8]

Experimental

Reagents. Methylene chloride and *n*-butylamine of G. R. grade (Tokyo Kasei Co.) were used without any purification. No impurities were detected by gas chromatography.

Solid Acids. Solid acids are listed in Table 1. They were calcined for 8 hr in air. All acids in Table 1 except for 13, 14, and 15 were used also in the previous work[1] as catalysts.

Apparatus and Procedure. An ordinary pulse technique was adopted.[9] Hydrogen as the carrier gas was purified by removing water and oxygen with a dry ice - ethanol cold trap and activated copper on kieselguhr, respectively. No difference in the reactivity or the selectivity was observed even if helium was used as the carrier gas. Tricresyl phosphate (Japan Chromato Co.) was used in the analytical column (4 m) at the room temperature. The identification of the products, *i. e.* carbon monoxide and methyl chloride was made by gas chromatography with an analytical column of silica gel and Molecular sieve 5A at the room temperature for the former and by mass spectrometry for the latter. By-products such as chloroform or formaldehyde were not detected at all by gas chromatography.

The reaction temperature was set between 250 and 420°C. After the solid acid was pretreated for 1 hr in a hydrogen gas flow at 450°C, 2 μl of methylene chloride was injected into the gas flow at the top of the reactor through a silicon serum cap with a microsyringe. The reaction was nearly first order under experimental conditions and the conversion was proportional to the reciprocal space velocity under low conversions, so that the initial rate constant, k (ml/g·min), was obtained directly from the slope.[9] This unit of the rate constant is converted into the usual one, mol/min·atm·g-cat, by the multiplication of a factor, 4.16×10^{-5}. The reactivity decreased remarkably pulse by pulse. Owing to the prevailing poisoning for the carbon monoxide formation, the ratio of CH_3Cl/CO increased pulse by pulse. Therefore, the rate constant was obtained from the conversion of the first pulse for a fresh catalyst. The rate and the selectivity of the first pulse were satisfactorily reproducible. The initial selectivities were constant under 30% conversion.

Results and Discussion

The reactivities of the fifteen solid acids were summerized in Fig. 1. The maximum reactivity was 8.2×10^{2} ml/g·min for H-10X and the minimum, 9.9×10^{-2} for S-1. All the solid acids have nearly equal surface areas (170—600 m^2/g) with a few exceptions. Therefore, the difference in the reactivity should be attributed to their surface nature.

The activation energies for methyl chloride and carbon monoxide formation were different from each others. On alumina, the former was smaller than the latter, with the reverse trend on alumina-boria, as shown in Table 2, It is unlikely that the trend in the adsorption strengths of the two

* Calculated from the rates at two reaction temperatures.

products on alumina is opposite to that on alumina-boria. The addition of *n*-butylamine before the reaction caused a severe posioning for both formations, especially for methyl chloride, as will be discussed later. Hence, different routes for each product should be postulated.

By the titration with silver nitrate in aqueous solution, nearly all chlorine atoms lost during the reaction were found to remain on alumina. This reaction may be analogous to that of alumina with carbon tetrachloride to synthesize anhydrous aluminum chloride.[10]

The Carbon Monoxide Formation. The temperature dependence of the rate constant of the carbon monoxide formation, together with the values of activation energies is shown in Fig. 2 and Table 2. The activation energy was nearly the same for all solid acids that contained alumina, although the rate constants themselves varied

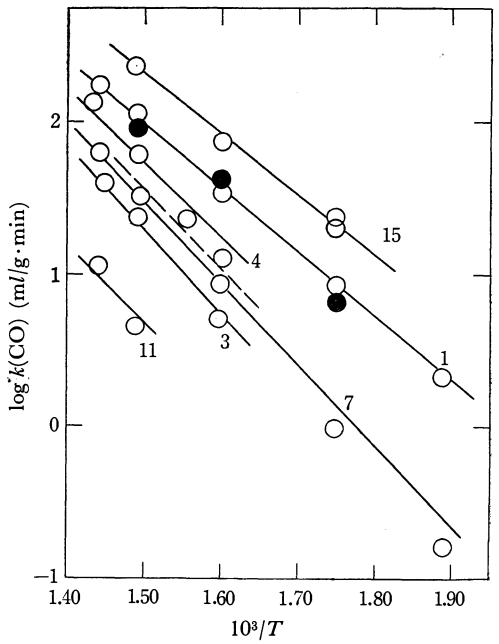

Fig. 2. Arrhenius plots of carbon monoxide formation on various solid acids containing alumina as a component.
Numbers refer to Table 1. The closed circles are for A-B and the dotted line is for SA-2.

greatly among them. The rate constant per unit surface area was large for the solid acid of high alumina content. At 400°C alumina had larger reactivity per unit surface area by five thousands times than silica had, as shown in Fig. 1. The correlation between the reactivity per unit weight of the component alumina and the surface area is

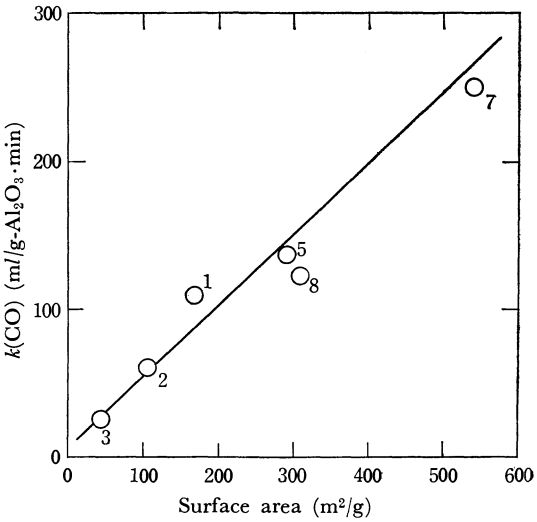

Fig. 3. Rate constants of carbon monoxide formation *vs.* the surface area of various solid acids containing alumina.
Numbers refer to Table 1.

10) K. Knox, R. D. Srivanstava, V. Norman, J. Y. Basserr and J. H. Hollowing, *J. Am. Chem. Soc.*, **79**, 3358 (1957).

shown in Fig. 3. Several solid acids, appearing in Fig. 3, were prepared by coprecipitation so that the aluminum atoms may be distributed throughout the surface and the bulk. The average rate constant of the carbon monoxide formation per unit surface area of the component alumina was 0.5 ml/min. From this close correlation, the "surface aluminate group," a group of a surface aluminum ion and its surrounding oxygen ions, which disperses on the surface as mentioned above, is proposed to participate in the carbon monoxide formation on these solid acids.

A series of the sodium ion-poisoned silica-alumina catalysts (SA-1, SA-1-Na-1, SA-1-Na-2, and SA-1-Na-3) gave the declining reactivities linearly with the increasing extent of sodium ion-poisoning, as shown in Fig. 4, with the activation energy uninfluenced (Table 2). These facts suggest the decrease in the amount of the active sites. Because the surface hydroxyl groups existing on silica-alumina are only silanols that are reportedly not influenced by this poisoning,[11] sodium ions

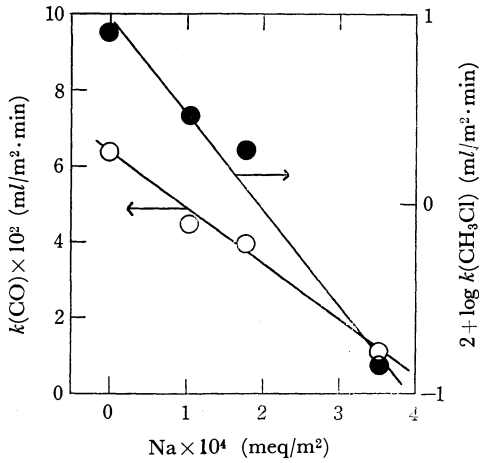

Fig. 4. Rate constants of carbon monoxide and methyl chloride formation *vs.* the amount of sodium ion. Catalyst, SA-1.

impregnated to SA-1 are possibly coordinated to the surface aluminate groups.

The Methyl Chloride Formation. The activation energy for the methyl chloride formation depends largely on the kind of the solid acids, which is in remarkable contrast to the case of the carbon monoxide formation. The temperature dependence and the activation energy are shown in Fig. 5 and Table 2, respectively. The alumina catalyst, A-3-550, had a markedly large activity of 1.2 ml/m^2·min at 400°C and a small activation energy of 6.1 kcal/mol whereas the silica-alumina catalyst, SA-1, had 7.8×10^{-2} ml/m^2·min and

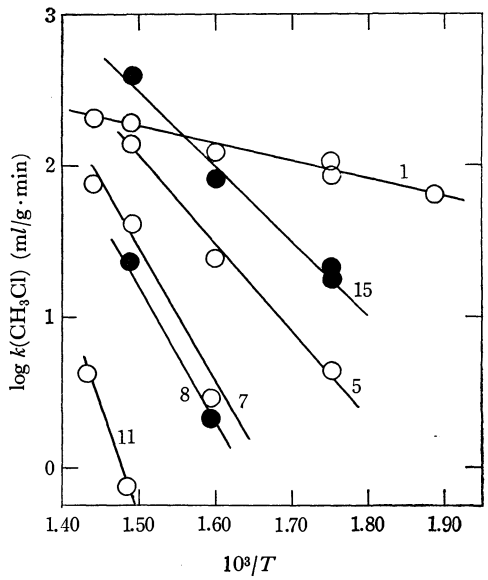

Fig. 5. Arrhenius plots of methyl chloride formation on various solid acids.
Numbers refer to Table 1.

40 kcal/mol, respectively. The difference of the activation energies for the methyl chloride formation between alumina and silica-alumina thus resembles the case of the H-D exchange reaction between deuterated methane and the surface hydroxyl groups on these solid acids.[4]

The surface hydroxyl groups, throughout these solid acids including alumina, should be concluded to participate in the methyl chloride formation from the following experimental results.

(1) This reaction resembles the H-D exchange reaction between deutereated methane and the surface hydroxyl groups of alumina or silica-alumina, as mentioned above.

(2) Each pulse of the reactant decreased largely and irreversively the reactivity of the solid acid.

(3) Any product of the disproportionation reaction, *e. g.* chloroform, was not detected.

(4) The reaction rate was not changed by the carrier gas of hydrogen or helium.

(5) The active hydroxyl groups on alumina surface with the highest wave number in the infrared spectroscopy were found to react with carbon tetrachloride at 200°C by Peri and Hannan.[12]

The reactivities of alumina calcined at various temperatures, as well as the sodium ion-poisoned alumina, are shown in Fig. 6 and Table 3. The impregnation of sodium ion and the calcination at high temperatures decreased the reactivity of alumina to a great extent. Analogus poisoning effects of sodium ion to alumina were reported for

Table 3. The calcination temperature effect on the methyl chloride formation activity of alumina

Alumina	Calcination temp. °C	Activity of the unit surface area at 400°C ml/m²·min
A-3-550	550	1.2
A-3-700	700	1.2
A-3-900	900	0.85
A-3-Na-550	550	0.48

the H_2-D_2 exchange reaction.[13] These deactivation may be due to the decrease in both the reactivity and the amounts of the hydroxyl groups and the oxidizing sites. Peri[14] reported by infrared spectroscopy the decrease of the surface hydroxyl groups of alumina by the calcination.

A linear relationship between the logarithms of the reaction rate constants and the amounts of sodium ion added was observed in the series of the sodium ion-posioned silica-alumina catalysts, as shown in Fig. 4. The activation energy also increased with sodium ion-poisoning, as shown in Table 2. These facts resemble the case of the typical solid acid catalysis. Sodium ion is coordinated to the surface aluminate group, as was discussed for the carbon monoxide formation. The hydroxyl groups on silica-alumina have been identified as the silanol groups and no Al-OH has been detected by either IR or NMR.[11] Silica-alumina had larger activity by about three thousands times than silica gel for the methyl chloride formation at 400°C, as shown in Fig. 1, in spite of the fact that the same amount of the hydroxyl groups was present on silica-alumina and silica gel both calcined at 550°C.[11] With sodium ions coordinated to the surface aluminate groups, the cooperation of the exposed aluminum ion with the neighboring silanol groups will be lost according to the decrease in the reactivity of the both sites. Therefore, the methyl chloride formation may be largely retarded by the sodium ion-poisoning, as is the case for the typical solid acid catalysis. It is also reasonable that the two silica-alumina catalysts of different alumina content (SA-1 and SA-2) exhibited nearly the same activation energy for the methyl chloride formation.

Alumina-boria (10% B_2O_3) has higher activity for the typical solid acid catalysis such as dealkylation,[1] but it was less reactive than alumina for the methyl chloride formation. The activation energy of alumina-boria for this reaction was about 20 kcal/mole larger than alumina (Table 2) and the reactivity per unit surface area at 400°C was 4.6×10^{-1} ml/m²·min for alumina-boria, whereas 1.2 for alumina. These results are understandable, if the hydroxyl groups are assumed not preferably to be bound to aluminum but rather to boron on the alumina-boria surface.

The Effect of the *n*-Butylamine Addition before the Reaction. The effect of the *n*-butylamine addition before the reaction is shown in Table 4. Both the reaction temperature and the addition temperature were 350°C. The addition of *n*-butylamine hindered strikingly both the methyl chloride and the carbon monoxide formations with alumina as well as alumina-boria, probably because of its strong coordination to the active sites. By exposing the amine-poisoned solid acids in the hydrogen gas flow at the reaction temperature for a certain period, the reactivity was gradually recovered presumably in accordance with the desorption of *n*-butylamine. The recovery from the *n*-butylamine poisoning of alumina was much faster than that of alumina-boria for the methyl chloride formation, as shown in Table 4. The reactivity was recovered up to 79% of the fresh alumina after 60 min, but only up to 11% for alumina-boria after 75 min. This slow recovery may be due to the stronger acidity of alumina-boria than alumina. The fresh alumina, however, was more active than alumina-boria for the methyl chloride formation, as described previously.

For the recovery of the reactivity for the carbon monoxide formation, it was also slower for alumina-boria than for alumina; the recovery of 71% for alumina after 60 min and of 13% for alumina-boria after 75 min. The active sites for the carbon monoxide formation on alumina-boria should be

more acidic than on alumina, since *n*-butylamine interacts more strongly with the former than the latter. But the difference in their acidities may be unrelated to their oxidizing abilities.

Proposed Reaction Mechanism. In aspect to the reactivities of alumina, silica-alumina or alumina-boria, the methyl chloride formation is similar to the H-D exchange reaction between their surface hydroxyl groups and deuterated methane, that may proceed through the radical mechanism, but is different from the typical solid acid catalysts that have been confirmed to be caused by the Bronsted acid sites. This reaction was unrelated to the strength of *n*-butylamine adsorption on these solid acids. Furthermore, alumina was found to have a lot of triphenyl methyl radical-forming sites.[6] These facts strongly suggest a radical mechanism to form methyl chloride from methylene chloride with these solid acids, and also that alumina is more reactive in some radical reactions than silica-alumina or alumina-boria, which is more acidic. The radical mechanism of the methyl chloride formation is consistent with the previous conclusion deduced from the reactant effects with the utilization of the simple LCAO-MO reactivity indexes.[8]

Our thanks are due to Mr. Masao Maruyama of the Engineering Research Institute of our Faculty for his analysis by a mass spectrometer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 71—75 (1968)

Solubility of Chlorine in Hydrochloric Acid*1

Fumio HINE and Shusei INUTA

Kyoto University, Uji, Kyoto

(Received July 20, 1967)

The solubility of chlorine in a concentrated HCl solution at various conditions of concentration, partial pressure, and temperature was determined. The concentration of chlorine in a solution as the sum of Cl_2 and Cl_3^- was found to be proportional to the partial pressure of chlorine in the gas phase, and its slope was a function of the HCl concentration and the temperature. Empirical equations representing these relations and the solubility of chlorine were obtained. It was confirmed that the results agreed with the experimental data in the 2—10 N HCl concentration range at partial pressures of chlorine lower than 1 atm and at 30—90°C. Such physicochemical properties as the Gibbs free-energy change were considered by using the data of solubility, and the behavior of the system consisting of Cl^-, Cl_2, and Cl_3^- was discussed.

The solubility of chlorine in water or in an aqueous solution of sodium chloride under various conditions has been studied by several authors previously,[1-3] but only a few results in an HCl solution at room temperature have been obtained.[4,5]

Today, many chlorine engineers are concerned with the recovery of chlorine from by-products or waste HCl, and they require more information and data on such properties of chlorine in an HCl solution as solubility.[6]

Experimental work was carried out at various conditions of temperature, concentrations and partial pressure, then some characteristic values, such as the Henry coefficient and the free energy, were evaluated from the solubility data thus obtained.

Experimental Procedure

The apparatus employed was essentially the same as that of Whitney and his collaborator,[2] who determined the solubility of chlorine in water with well-designed equipment, though we made some modifications for our own convenience.

The flow diagram is shown in Fig. 1. The absorption chamber and the gas pre-treatment system were set in a water bath so as to keep it at a constant temperature of ±0.1°C during the experiment.

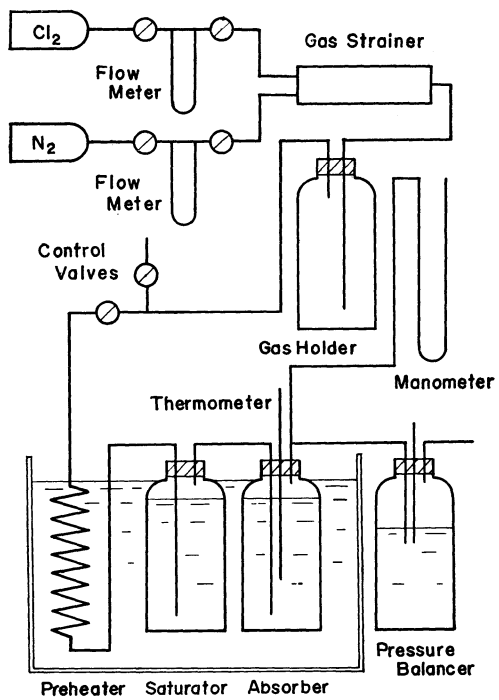

Fig. 1. Apparatus for experiment.

Chlorine and nitrogen from the cylinders were delivered to the gas strainer, which was packed with glass wool in order to mix the two gases thoroughly. The flow rate of chlorine and nitrogen was separately measured with a capillary-type flow meter.

The moisture and temperature of the gas were brought to equilibrium before it was introduced into the absorption chamber. The partial pressure of chlorine was maintained by mixing it with nitrogen, and was determined by chemical analysis. The total pressure of gas in the absorption chamber was assumed to be

the sum of the partial pressures of chlorine, nitrogen, hydrogen chloride, and water vapor, and was determined by means of a manometer. The partial pressure of water vapor was mostly obtained from Reference 7, though some data were confirmed empirically.

The sample gas was passed through the absorption chamber for an hour in order to gain an equilibrium state prior to measurement.

A certain amount of the solution at the equilibrium was pipetted out quickly, added to a 10% solution of potassium iodide, and diluted with water until its pH reached about 1. Its solution was then titrated by iodometry to measure the chlorine dissolved.

Results and Discussion

Sherrill and Izard[5] and Jokowkin[8] have studied the effects of HCl on the solubility of chlorine in water. They concluded that while the solubility of chlorine decreased upon the addition of a small amount of HCl, it increased in relatively concentrated HCl solutions because of the formation of tri-chloride ions by the combination of Cl_2 and Cl^- as follows:

$$Cl_2 + Cl^- = Cl_3^- \quad (1)$$

Furthermore, HClO may form in a weak acid solution when the pH of the solution is larger than 2. However, no such formation occurs in the present experiment because the concentration of hydrochloric acid is as high as 2—10 N. The results of titration show the sum of chlorine dissolved physically, or "free chlorine," and tri-chloride ions, it also shows the solubility of chlorine in a solution, that is:

$$S = (Cl_2) + (Cl_3^-) \quad (2)$$

where S is the solubility of chlorine, and where (Cl_2) and (Cl_3^-) are the concentrations of free chlorine and tri-chloride ions, respectively.

Experiment was carried out in a 2—12 N HCl solution at 30—90°C. The solubility obtained was plotted as a function of the partial pressure of chlorine under given conditions of HCl concentration and temperature, and the straight lines shown in Figs. 2—6 were thus obtained. The solubility of chlorine in HCl, then, follows Henry's Law; that is,

$$S = Hp \quad (3)$$

where p is the partial pressure of chlorine, and H is Henry's coefficient, which is a function of the temperature and HCl concentration.

Figure 7 shows the relationship between H and the HCl concentration at various temperatures.

Henry's coefficient is a function of the concentration as follows:

$$H = \alpha C + \beta \quad (4)$$

where C is the concentration of HCl, and where

8) A. A. Jakowkin, *Z. Physik. Chem.*, 29, 613 (1899).

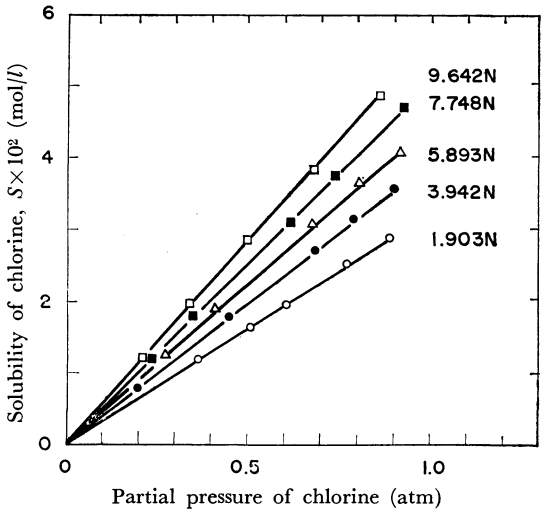

Fig. 4. Solubility of chlorine as a function of its partial pressure at 50°C.

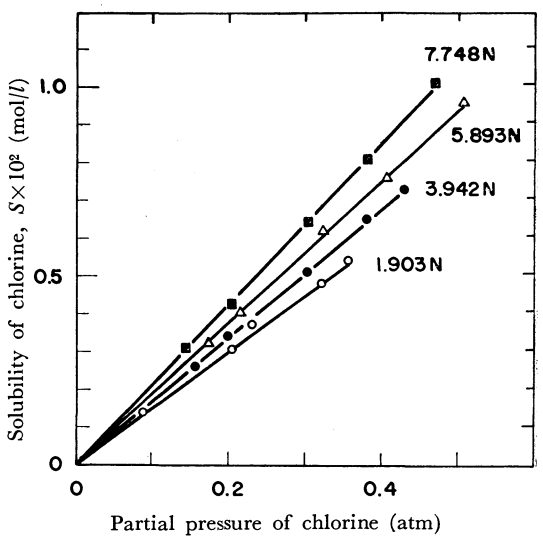

Fig. 6. Solubility of chlorine as a function of its partial pressure at 90°C.

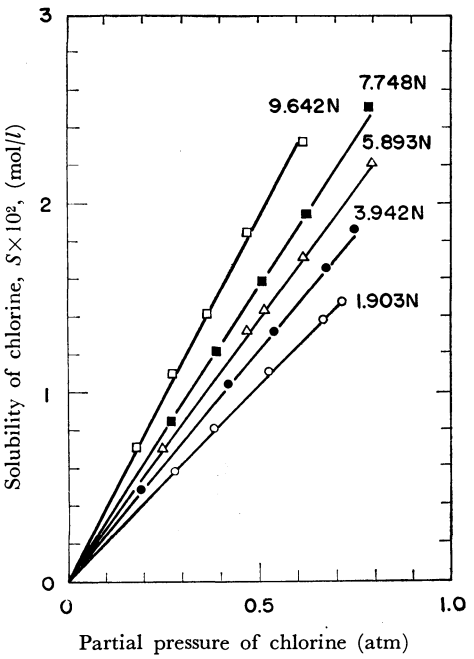

Fig. 5. Solubility of chlorine as a function of its partial pressure at 70°C.

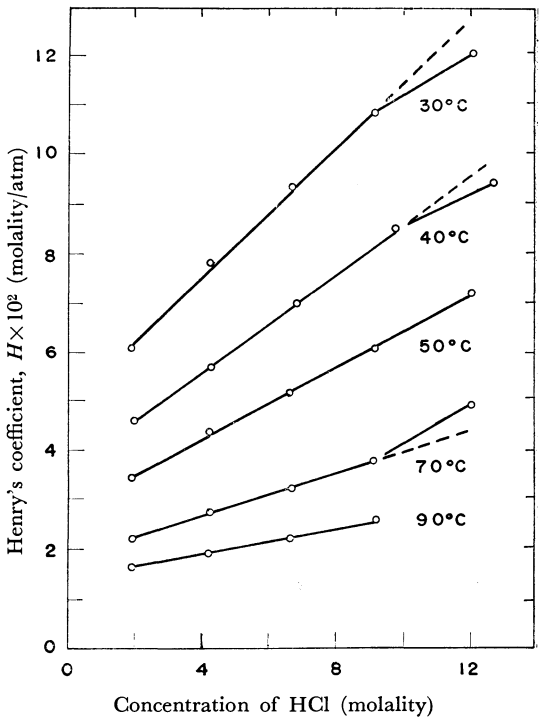

Fig. 7. Henry's coefficient at various temperatures as a function of HCl concentration.

α and β are constants. The substitution of H into Eq. (3) gives the following expression:

$$S = (\alpha C + \beta)p \qquad (5)$$

While the concentration of chlorine and HCl are represented in "molality" in these figures, relations similar to those above, also expressed in "grams per liter," were obtained.

As shown in Fig. 7, Henry's coefficient, and hence both α and β, could easily be derived as functions of the temperature. Figure 8 shows the relationship between α and the temperature: the logarithm of α is proportional to t°C. On the other hand, the logarithm of β *vs.* the logarithm of the temperature is linear, as shown in Fig. 9. Therefore, the empirical equations for α and β be written as follows:

$$\log \alpha = -1.21\times10^{-2}t - 1.603 \qquad (6)$$

and:

$$\beta = 2.14\times10^2 t^{-1.21} \qquad (7)$$

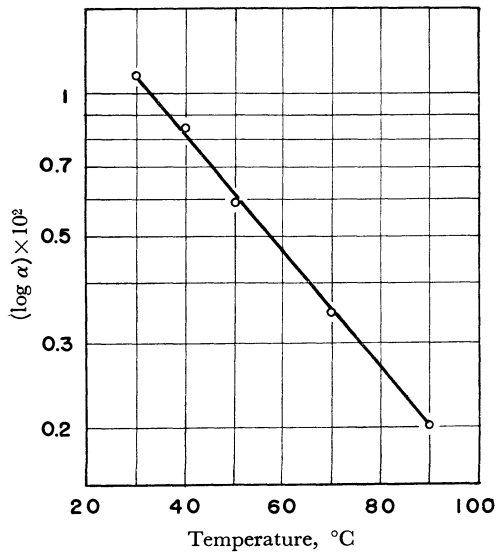

Fig. 8. Logarithm of α *vs.* temperature curve.

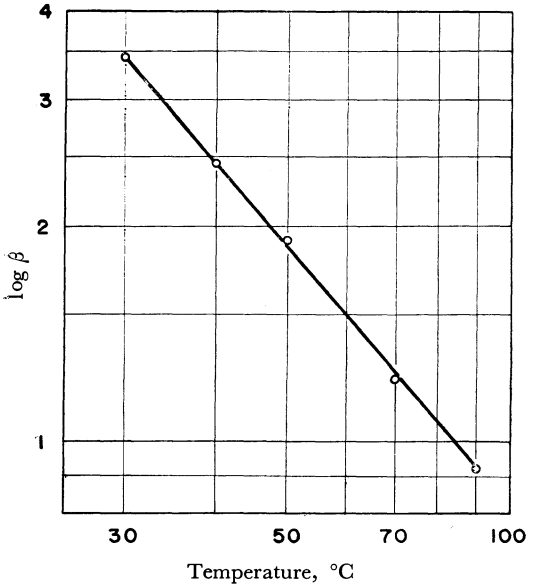

Fig. 9. Logarithm of β *vs.* logarithm of temperature.

where α and β are expressed in grams per liter-chlorine/grams per liter-HCl·atm and grams per liter-chlorine/atm respectively, and the temperature, in degrees centigrade.

Figure 10 shows the values calculated by Eqs. (5), (6), and (7) in comparison with the observed values. A good agreement was obtained between them at 30—90°C in HCl solutions of concentrations less than 10 N under partial pressures of chlorine lower than 1 atm.

It is well known that the equilibrium constant, K, for the reaction (1) may be represented as follows:

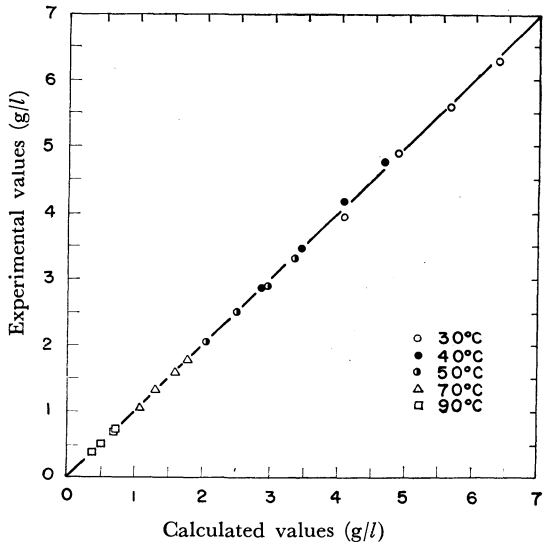

Fig. 10. Solubility of chlorine calculated by the empirical equation in comparison with the data determined.

$$K = \frac{a_{Cl_3^-}}{p \cdot a_{Cl^-}} = \frac{\gamma_{Cl_3^-} \cdot (Cl_3^-)}{p \cdot \gamma_{Cl^-} \cdot (Cl^-)} \tag{8}$$

where:

$a_{Cl_3^-}$	Activity of Cl_3^-	mol/l
a_{Cl^-}	Activity of Cl^-	mol/l
$\gamma_{Cl_3^-}$	Activity coefficient of Cl_3^-	
γ_{Cl^-}	Activity coefficient of Cl^-	

The unit of concentration of chlorine and trichloride ions, (Cl^-) and (Cl_3^-), is mol/l in this case.

Although the activity coefficient of Cl^- in aqueous solutions has been determined,[6] meagre data are available on the activity of Cl_3^-. Assuming that $\gamma_{Cl_3^-} = \gamma_{Cl^-}$, as Sherrill and Izard did,[5] the following equation was obtained:

$$K = \frac{(Cl_3^-)}{p \cdot (Cl^-)} = \frac{(Cl_3^-)}{p \cdot C} \tag{9}$$

where C is the concentration of Cl^- in mol/l.

On the other hand, we may assume that the concentration of chlorine dissolved, or "free chlorine," in a solution, is proportional to the partial pressure of chlorine in the gas phase, such as,

$$(Cl_2) = hp \tag{10}$$

where h is a constant.

By substituting Eqs. (9) and (10) into Eq. (3), we obtain the equation:

$$S = (KC + h)p \tag{11}$$

Therefore, it is evident that K and h should correspond to the two constants, α and β, in Eq. (4) or (5) respectively, if the same units of concentration, pressure, and temperature are used. Table 1 shows these values obtained at various temperatures: the values of α and β using conventional

TABLE 1. THE COEFFICIENTS, α and β, IN HENRY'S EQUATION (5)

Temperature		α		β	
°C	1/(°K)	mol/mol·atm	gpl/gpl·atm	mol/atm	gpl/atm
30	3.300×10^{-3}	6.57×10^{-3}	1.08×10^{-2}	4.85×10^{-2}	3.42
40	3.195	5.11	0.844	3.49	2.46
50	3.096	3.65	0.592	2.72	1.92
70	2.915	2.20	0.350	1.76	1.22
90	2.755	1.38	0.204	1.32	0.916

units are also listed in the table.

According to the van't Hoff Law, we may obtain the following equation:

$$\frac{d(\ln K)}{d(1/T)} = -\frac{\Delta H^\circ}{R} \qquad (12)$$

where T is the temperature in °K; R, the gas constant, and ΔH°, the standard enthalpy change for Reaction (1). The logarithm of K was plotted as a function of the reciprocal temperature, $1/T$, as shown in Fig. 11. That is, ΔH° is independent of the temperature. The enthalpy change, ΔH°, was calculated, from the slope of this curve, to be -5.77 kcal/mol.

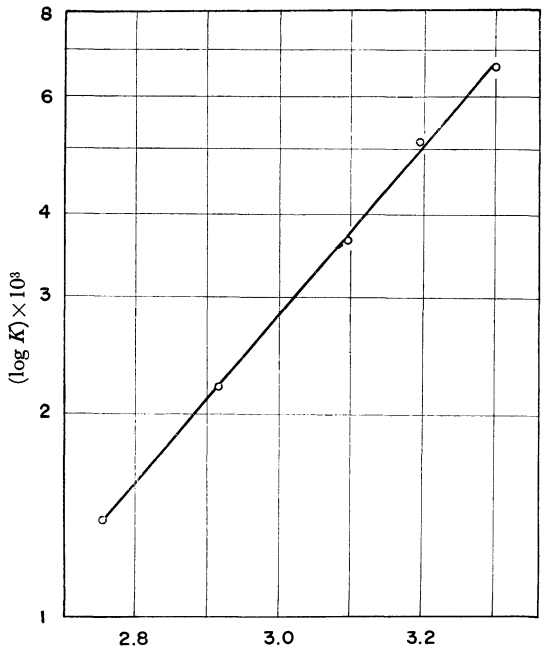

Fig. 11. Logarithm of K *vs.* reciprocal temperature curve.

The Gibbs free energy change, ΔG°, has the following relations with K:

$$\Delta G^\circ = -RT\ln K \qquad (13)$$

and:

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ \qquad (14)$$

where ΔS° is the entropy change. The free energy change, ΔG°, was plotted against the temperature; it was completely linear, as shown in Fig. 12. The empirical equation for ΔG° is as follows:

$$\Delta G^\circ = 2.147 + 0.0290t \quad \text{(kcal/mol)} \qquad (15)$$

The entropy change, ΔS°, was then evaluated to be 29.0 cal/mol·°K, which was independent of the temperature.

The equation for K is as follows:

$$\log K = \frac{1.26\times10^3}{T} - 6.34 \qquad (16)$$

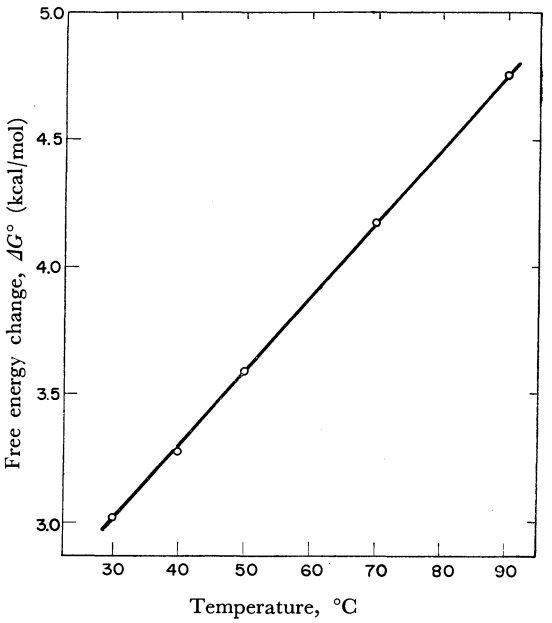

Fig. 12. Free energy change *vs.* temperature.

Summary

The solubility of chlorine in hydrochloric acid solutions of 2—12 N at partial pressures of chlorine lower than 1 atm and at 30—90°C was determined. Henry's Law was found to hold good in this range. Some thermodynamic characteristics of the system consisting of Cl_2, Cl^-, and Cl_3^- were also discussed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 76—82 (1968)

Scission Probabilities of the Skeletal Bond of Aliphatic Ethers by Electron Impact*1

Kozo HIROTA and Jun'ichi TAKEZAKI*2

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka and Osaka Laboratory, Japanese Association for Radiation Research on Polymers (JARRP), Neyagawa, Osaka

(Received July 28, 1967)

Mass spectra of eight aliphatic mono- and di-ethers have been measured with apparatuses of both ordinary and high resolution type, and scission probability of their skeletal bonds has been determined. By application of the molecular orbital theory on bond-scission by electron impact, the scission probability of the skeletal bonds has been evaluated, using only a few constants peculiar to the C–O bond so as to determine the molecular orbital. Comparison between theory and experiment has been found satisfactory on such ethers, even though they have lone-pair electrons in the inner part of the molecules. Thereby, scission of the skeletal bond has been shown explainable quite well by the primary processes in most ethers, except highly symmetric or large ethers.

Mass spectra of alkyl ethers were extensively studied by McLafferty,[1] and several characteristic rules were recognized on the fragmentation by electron impact. Recently, the rules were investigated in more details by Gjerassi and Fenslau.[2] Their discussion on the fragmentation processes, however, seems to remain in qualitative explanation and to lack in its molecular-theoretical derivation.

In the present report, probabilities of the skeletal bond-scission of several aliphatic ethers are investigated by determining the ions produced by use of apparatuses of both ordinary and high resolution type, and the molecular orbital (MO) theory is applied to explain the results quantitatively, generalizing the theory if necessary. The ethers to be investigated are methyl ethyl ether (MEE), methyl propyl ether (MPE), methyl butyl ether (MBE), diethyl ether (DEE), di-isopropyl ether (DIPE), methylal, ethyleneglyccl dimethyl ether (EGDME), and ethyleneglycol diethyl ether (EGDEE). Their structures are shown in Table 1, where the numerals attached to the bonds will become necessary in the following paragraphs.

Theory

In the previous reports on chain compounds,[3] it was assumed that the scission probability of skeletal bonds of the parent ion produced by electron impact is proportional to the positive charge density of the highest occupied (HO) molecular orbital (MO) localized at the bonds. This assumption on the initial fragmentation, though imcompatible with the widely accepted scheme of competitive and successive fragmentation,[4] will be understood, if the parent ion is a kind of super-excited ion of a short life[5] which is less than the time of a molecular vibration, so that it dissociates immediately into ion and radical, being followed by secondary fragmentation. A part of the theoretical basis on the above scheme was proposed in details elsewhere, making cycloalkanes as examples. In the present report, theoretical investigation will not be carried out so far, regarding the MO theory just as a semiempirical "tool" of investigating mass spectra of complex organic molecules.

Calculation

In actual calculation, the charge density is assumed to be equal in amount of the electron density of the corresponding neutral molecule, and it will, therefore, be evaluated approximately by the following LCBO*-MO-method. The MO belonging to the skeletal bond, φ, is expressed by Eq. (1),[6]

$$\Phi = \sum_{i=1}^{n} c_i \varphi_i \qquad (1)$$

(8)	Ethyleneglycol diethyl ether	EGDEE	$CH_3^{1}-CH_2^{2}-O^{3}-CH_2^{4}-CH_2^{5}-O^{6}-CH_2^{7}-CH_3$

where, φ_i is the bond-orbital of the ith skeletal bond, and summation is carried out on all the bonds, adopting united atom approximation.[7] Hence, the electron density in problem may be given by square of the expansion coefficient C_i of the HO molecular orbital. By the calculus variation, the energy levels can be determined by the secular equation (2), as usually done in the LCAO-MO method.

$$|e_{ij} - \delta_{ij}E| = 0 \qquad (2)$$

In Eq. (2), e_{ij} denotes the matrix elements given by Eq. (3), and is to be called coulombic or exchange integral, according as $i=j$ or $i=j\pm1$.

$$e_{ij}=\int \varphi_i H \varphi_j d\tau \qquad (3)$$

where H denotes the hamiltonian for an electron in the field of bare nuclei and inner shells of electrons. Both integrals concerning hydrocarbons will be denoted by α and β, respectively, hereafter.

Since the so-called Hückel approximation is adopted, all the e_{ij} in Eq. (2) becomes coulombic integral α_i or exchange integral β_{ij}. However, coulombic integral at the terminal CH_3-C bond α_t is equated to $\alpha+2\beta$. As an exceptional case, $\alpha+1.5\beta$ is used for α_t of MEE, improvement ought to be understood as empirical, but not due to the inductive effect at the terminal methyl group of neutral molecules.[8]

The coulombic and exchange integrals of the C–O bond are equated preliminarily to $\alpha+2\beta$ and β, respectively, but coulombic integrals of the terminal CH_3–O bond are equated to $\alpha+3\beta$. Such a selection of constants for the C–O bond is qualitatively allowable if the effect of lone-pair electrons at the oxygen atom be considered.

Using the α_i and β_{ij} defined above, the energy values of the HO orbital E_h and expansion coefficients at the orbital were calculated. Thereby, it was found sufficient only to determine the value of $\lambda_h=(\alpha-E_h)/\beta$ instead of E_h itself. At the same time, it was found not necessary to know the absolute values of α_i and β_{ij}, but sufficient to know their relative values to α and β.

* Estimated value

resolution apparatus as well as on ordinary one. In order to check the discrimination due to apparatus, the mass spectra obtained on MEE and DEE are compared with those of literature (Table 2), making total sum of the peaks to be 100. Column A is the one run on an apparatus of ordinary type (Hitachi RUM-5A) installed at JARRP, and column B on an apparatus of high resolution type (Hitachi RMU-7hr) installed at Osaka University, its resolution being *ca.* 5000. Both are of a magnetic scanning type, but their normal operating conditions are different as follows:

	Ionizing voltage, V	Accelerating voltage	Electron current, μA
RMU-5A:	90	1500	80
RMU-7hr:	80	2000	100

Column C is the spectra recalculated from the API mass spectral catalog (CEC Model 21-103). In column B, multiplet peaks appearing practically at the same *m/e* are summed up. Discrepancies among these spectra are not large, in spite of the measurement of different apparatuses and operating conditions. Similar tendency was obtained on other six ethers, so that the present data are assumed sufficient to be utilized in discussion.

In order to meet the requirement to be explained, MEE-d_3, $CD_3OCH_2CH_3$ was synthesized and its spectrum was measured and used mainly in discussion.

Results

Assignment of Peaks and Allotment of Ions. By combining the results of ordinary and high resolution spectra, multiplet peaks were allotted to each composite ions; *e. g.*, in the case of MPE, ratio of $C_2H_5^+$ to CHO^+ ions was estimated to be 22.5%/77.5% from the doublet peaks at *m/e* 29. Thus, ratio of the doublet peaks was determined and the results are summarized in Table 3, which indicates that some major peaks consist of two ions. Taking this point into consideration, spectral peaks with their assigned ions are shown in Table 4, where sums of the total ions including parents ions are made 100%. Details of the assignment of each peak to corresponding ions are described in the next paragraph as well as number of the ruptured bond to produce the corresponding ions.

Table 3. Allotment of multiplet peaks to ions in MEE, MPE, DEE and methylal

	m/e	MEE	MPE	DEE	Methylal

Ruptured Bond. It is easy for most of the ions to estimate the ruptured bond, if their chemical formula is known, but it is still difficult for several ions. For instance, the *m/e* 15 peak can be assigned to be CH_3^+ ion without ambiguity by high resolution spectra, but the ruptured bond cannot be determined uniquely as shown by the following example:

$$CH_3\overset{1}{\underset{\alpha}{|}}O\overset{2}{|}CH_2\overset{3}{|}CH_2\overset{4}{\underset{\beta}{|}}CH_3 \longrightarrow \begin{cases} \overset{\alpha}{\rightarrow} CH_3^+ + \dot{O}CH_2CH_2CH_3 \\ \overset{\beta}{\rightarrow} CH_3OCH_2\dot{C}H_2 + CH_3^+ \end{cases} \quad (4)$$

However, both processes could be discriminated in the case of MEE by comparing the spectrum of $CD_3OCH_2CH_3$ with that of $CH_3OCH_2CH_3$, and ratio of α and β bond-scission could be determined, if the isotopic effect be neglected. Such procedure was not taken up in other ethers, because amount of the CH_3^+ ions was always so small that their origin is not important in order to discuss the degree of agreement between theory and experiment entirely.

There are several ions, however, whose ruptured bond is difficult to be determined. Among them, estimation of the origin of the $(CHO)^+$ ion is comparatively easy. In the case of MEE, this ion can be produced from the $(CH_3O)^+$ ion either by successive scission of the second bond with 2H detachment,

$$(CH_3O\overset{2}{|}CH_2CH_3)^+ \rightarrow (CH_3O)^+ + \dot{C}H_2CH_3$$
$$\xrightarrow{-2H} (CHO)^+ + \dot{C}H_2CH_3 + 2H \quad (5)$$

or by double scissions of the first and third bonds with H detachment.

$$(CH_3\overset{1}{|}O\overset{2}{|}CH_2\overset{3}{|}CH_3)^+ \rightarrow$$
$$(OCH_2)^+ + 2\dot{C}H_3 \rightarrow (OCH)^+ + 2\dot{C}H_3 + H \quad (6)$$

However, the process (5) was considered reasonable, because scission probability of the second bond is theoretically large, besides the simpleness of the process. This conclusion is supported by the mass spectrum of MEE-d_3, where CH_3O^+ and CH_2O^+ are shown negligible few in Table 4. In the cases of other ethers, (MPE, MBE and EGDME), the same allotment was adopted, because the situation may be the same.

Of all the ethers, DIPE includes the largest

number of ambiguous ions, *i. e.*, only 38% of the total ions could be allotted without ambiguity. Of the remaining ions, 51.9% requires at least two bond scissions, and it is difficult to estimate which scission is the first of the two, as explained on the orgin of the CH_3^+ ions. Therefore, determination of scission-probability of DIPE was more difficult than that of other ethers. DEE was also

difficult, though of lesser degree in allotment of ions, because 57% of the total ions would be allotted without ambiguity. Similar difficulty exists in the largest ethers (EGDEE). The reason of bringing about such results will be explained afterwards.

After the above procedure, scission probability of each bond can mostly be evaluated on all the ethers. For instance, the probability at the second bond of DEE is given by the sum of $C_2H_5^+$ and $(C_2H_5O)^+$ ions. Summarized result on eight ethers is shown in Table 4, where u and p in the column of the ruptured bonds denote undeterminable ions and parent ions (M and M-1), respectively, and i in the same column denotes the ions produced by multiple scissions.

a) Values in parenthesis are calculated by allotting u peaks equally to both kinds of scissions.

Scission Probability. Scission probability thus determined from the data of Table 4 is summarized in Table 5. Thereby, only the ions whose ruptured bonds were determinable are considered and the probability is expressed in %. In Table 5, calculated probability is compared with the observed and the HO energy level in λ_h unit on each ether is shown, in addition to the $x_i=(\alpha-\alpha_i)/\beta$ used in the calculation.

Among the eight ethers, DIPE is the worst in coincidence between theory and experiment, because of the particular situation of this ether, whose determinable ions were less than 40% of the total. Similar tendency, though of less degree, is shown in the case of DEE. Other ethers especially, if MBE and EGDEE are excluded, show a good coincidence between theory and experiment.

Before entering into the paragraphs of discussion, it might be noted that the above probability obtained is the one at normal operating condition of the mass spectrometer.

Discussion

First, the peculiarity of ethers might be noted in comparison with the compounds hitherto investigated in the present series of study; *i. e.*, an atom containing lone-pair electrons exists in the inner skeletal bond of each ether. Considering this situation, such a degree of agreement of the theory with the experiment is quite good. Taking it into account, several points will be discussed.

TABLE 6. MAIN PEAKS IN THE SPECTRA OF DEE AND MBE *vs.* IONIZING POTENTIAL

a) Absolute values are not so exact.

Secondary Scissions. Among the three unsymmetric ethers, MPE is the best in coincidence, followed by MEE-d_3 and MBE. Concerning MBE, the result may be partly due to improper selection of integral values. Another important cause would be occurrence of multiple scissions which ought to be expected. Even though this process cannot be recognized in the procedure of determining the ruptured bond, this possibility exists, as will be discussed again. Comparatively large disagreement in MEE-d_3 may be due to the same reason rather than the isotopic effect of bond scission.

Similar cause of disagreement may occur in the cases of symmetric ethers, and EGDEE is the typical example, because many ions (about 20%) cannot be explained without assuming multiple scissions, besides the unassignable ions reaching *ca.* 8%. Concerning other symmetric ethers, secondary scissions also seem to occur with high probability, as already mentioned, though the assignment to definite ions was easy.

For the sake of confirmation of the secondary scission, the effect of ionizing potential on bond-scission was investigated on several ethers. The result on DEE is shown in Table 6A.

Though the *m/e* 59 peaks may be produced from DEE by the primary scission of bond 1 or 4, the highest *m/e* 31 peaks can be ascribed to a secondary scission from the *m/e* 59 ion.

$$CH_3\overset{1}{-}CH_2\overset{2}{-}O\overset{3}{-}CH_2\overset{4}{-}CH_3$$

$$\rightarrow CH_3CH_2\text{-}O^+\text{-}CH_2 \quad (m/e\ 59)$$

$$\rightarrow CH_2{=}CH_2 + HO^+{=}CH_2 \quad (m/e\ 31) \qquad (7a)$$

$$\rightarrow CH_3\text{-}CH_2^+ + O{=}CH_2 \quad (m/e\ 29) \qquad (7b)$$

If the above mechanism be true, the *m/e* 31 ion will be smaller at lower ionizing voltage, because excess energy which is necessary for the secondary processes would decrease. At the same time, the *m/e* 59 ion would increase on the contrary. This expectation is supported by comparing the ratio of the *m/e* 31 ion to the *m/e* 59 ion in Table 6A. The effect of ionizing potential on the *m/e* 29 peak can be explained similarly. *Cf.* Eq. (7b).

Another example of the effect of ionizing potential on the bond-scission is shown on MBE. Table 6B indicates that the *m/e* 56 ion increases and *m/e* 29 ion decreases with the decrease of ionizing potential. This finding denotes apparently increase of scission at bond 4 and decrease of scission at bond 2, suggesting that the observed scission probability has to increase at bond 4 and to decrease at bond 2, as compared with the data in Table 5. Thus the agreement of the calculated result of MBE with the observed would be improved.

It was found also that the discrepancy in MEE-d_3 decreased markedly by lowering the ionizing potentil; *i. e.*, scission probability at bond 2 becomes apparently larger than the theoretical due to secondary scission. The worst result of DIPE may be explained similarly, if the effect of ionization potential be studied.

Lone-pair Electrons and Fragmentation. In connection to the above discussion, the behavior of the lone-pair electrons at oxygen atom against the electron bombardment will be discussed, taking DEE as an example. The HO level of this ether is calculated to be -14.43 V from $\lambda_h = -0.38$ (*cf.* Table 5), assuming α and β of C-C bond to be -13.75 V and -1.80 V, respectively. The value is lower by four volts than its ionization energy (10.2 V).[9] This result indicates that at lower ionizing potential the lone-pair electrons would be expelled out, producing parent ions. However, as the ionizing potential is increased, electrons at the skeletal bonds are also expelled out, because the difference of the energy level of both electrons is so small that the ionizing potential of normal operating condition of mass spectrometers is sufficiently large. This reasoning can be explained by the fact that relative amount of the parent ion decreases according to the increase of the ionizing potential, as Table 6 indicates.

Concerning the role of lone-pair electrons, the difference of the C-C bond and C-O bond might be mentioned. In the present treatment, the MO of the skeletal bond was constructed from both kinds of bond, putting aside the presence of lone-pair electrons. However, some interaction may exist between the positive hole at the C-O bond and lone-pair electrons. The effect would appear to decrease the positive hole formed at the C-O bond. The reason why proper coulombic integral at the C-O bond may be $\alpha+2\beta$ can be explained.

Conclusion

It has been shown possible to apply the MO method of mass spectra to alkyl ethers which include lone-pair electrons in the inner part of the molecules.

The authors wish to express their sincere thanks to Dr. Motoyoshi Hatada (JARRP) of his discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 83—87 (1968)

The Polarized Absorption Spectra of Solid Molecular Compounds of Chloranil and Aromatic Amines

Takako AMANO, Haruo KURODA and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received August 3, 1967)

The polarized absorption spectra of the single crystal were observed for six molecular compounds which involve chloranil as the electron acceptor and aromatic amines as the electron donor. The molecular compounds of *N*, *N*-dimethylaniline, 1-naphthylamine, and *N*, *N*-dimethyl-2-naphthylamine have a non-ionic ground state. In these cases, the locations of the charge-transfer bands in the crystal spectra are similar to those of the corresponding bands of the 1 : 1 molecular complexes formed in the solution. The solid molecular compounds of *p*-phenylenediamine, *N*, *N*, *N'*, *N'*-tetramethyl-*p*-phenylenediamine, and diaminodurene can be regarded as ionic crystals composed of the positive ion of the donor and the negative ion of the acceptor. In these cases, the absorption bands associated with the component ions are observed in the crystal spectra, but they are broadened and appreciably shifted to a higher energy as compared with the case of the solution spectra of the ions. The absorption band associated with the charge transfer between ions is observed in the near-infrared region of the crystal spectra of these molecular compounds.

In most solid molecular compounds, the charge transfer from the electron donor to the electron acceptor is quite small in their ground states. It has been suggested, however, that a molecular compound composed of a strong electron donor and a strong electron acceptor may have an ionic ground state. Such an example can actually be found among the solid molecular compounds which involve aromatic amines as the electron donor, and *p*-chloranil or another quinone derivative as the electron acceptor.[1-5] These molecular compounds are also interesting from the view point of organic semiconductors, since they often exhibit a relatively good electronic conduction.[6-8]

The optical absorption spectra of the solid molecular compounds formed between aromatic amines and chloranil have been studied by several workers in an attempt to elucidate the electronic structures of these molecular compounds.[3-7,9,10] In most cases, however, the spectra were measured on powder samples by means of the KBr-pellet method or by the diffuse reflection method. Consequently, the absorption bands were usually not well resolved in the observed spectra, and their assignments were often quite ambiguous. As is well known, it is of great significance to study the polarized absorption spectra of the single crystal in order to examine the nature of the transition associated with an absorption band. No single crystal spectrum has been reported on the aromatic amine-chloranil compounds except the specular reflection spectra of the compound composed of tetramethyl-*p*-phenylenediamine and chloranil, which spectra have been recently reported by Anex and Hill.[11] Therefore, we have studied the polarized absorption spectra of the single crystals of various aromatic amine-chloranil compounds, including the ones with non-ionic ground states as well as those with ionic ground states.

In the present paper, we shall report on the crystal spectra obtained for the six molecular compounds which involve *N*, *N*-dimethylaniline, 1-naphthylamine, *N*, *N*-dimethyl-2-naphthylamine, *N*, *N*, *N'*, *N'* - tetramethyl - *p* - phenylenediamine (TMPD), *p*-phenylenediamine, and diaminodurene as the electron donors.

Experimental

The polarized absorption spectra of the single crystals were measured with a microspectrophotometer. The

details of the apparatus and the procedures of measurement have been described in a previous paper.[12] Minute crystals of the molecular compounds were prepared by crystallization from solutions containing an appropriate amount of each component. The crystals thus obtained were usually in the form of a needle or a lath elongated along one of the crystal axes. The absorption spectra were measured from the direction normal to the developed face of the crystal with the polarizations, both parallel and perpendicular, to the elongated axis. In the present paper, we shall denote the elongated axis as the "l-axis." In most cases, this is the direction along which donor and acceptor molecules are alternately stacked on each other. All the measurements were carried out at room temperature. The infrared absorption spectra of the solid molecular compounds were also examined in order to ascertain the ionic character of the ground state.

Results and Discussion

***N*, *N*-Dimethylaniline-Chloranil (1 : 1) Compound.** Deep blue needle crystals of this compound can be obtained from a dimethylaniline solution of chloranil. This compound has a non-ionic ground state. The crystal spectrum observed with the light polarized parallel to the l-axis, "the $//l$ spectrum", and that observed with the light polarized perpendicular to the l-axis, "the $\perp l$ spectrum", are shown in Fig. 1. There is a relatively strong absorption band with a maximum located at 15.3 kK in the $//l$ spectrum, but no corresponding band can be found in the $\perp l$ spectrum. Seemingly the 15.3kK band is exclusively polarized along the l-axis. The second absorption band, located at about 32.8 kK, is different from the first band as regards the direction of the transition moment: its intensity is stronger in the $\perp l$ spectrum that in the $//l$ spectrum.

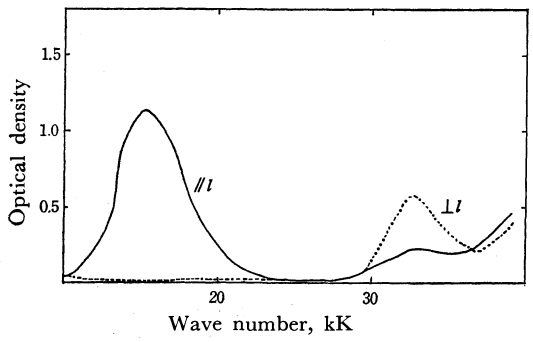

Fig. 1. Absorption spectra of *N*, *N*-dimethylaniline-chloranil compound.

Neither dimethylaniline nor chloranil exhibits any absorption in the 10—25 kK region. The lowest π–π^* transition of dimethylaniline is located at 33.9 kK ($\log \varepsilon = 3.2$), while that of chloranil is at 27 kK ($\log \varepsilon = 2.5$).[13] Therefore, the 15.3 kK band of the $//l$ spectrum can not be attributed to any intramolecular excitation of the component molecules. It must be a band associated with the intermolecular charge-transfer. In the spectrum of the 1 : 1 complex formed between dimethylaniline and chloranil in a carbon tetrachloride solution, the chrage-transfer band appears at 15.4 kK, a value which is associated with the charge transfer from the highest occupied molecular orbital of dimethylaniline to the lowest vacant molecular orbital of chloranil. Apparently the 15.3 kK band of the crystal spectrum corresponds to this charge-transfer band of the 1 : 1 complex. Therefore, we assign it to the charge transfer from the highest occupied orbital of a dimethylaniline molecule to the lowest vacant orbital of the nearest chloranil molecules in the crystal lattice. On the other hand, the polarization of the 32.8 kK band is that expected for a band associated with intramolecular transitions of the component molecules; also, the location of the band nearly corresponds to the lowest π–π^* transition of dimethylaniline or the 34.3 kK π–π^* transition of chloranil. We thus consider that this band of the molecular compound is a local excitation band associated with these transitions of the component molecules.

1 - Naphthylamine - Chloranil (1 : 1) Compound. This molecular compound is obtainable as green needles from a carbon tetrachloride solution. The ground state seems to be non-ionic. The $//l$ spectrum and the $\perp l$ spectrum are shown in Fig. 2. There are two absorption bands which appear more strongly in the $//l$ spectrum than in the $\perp l$ spectrum. Their maxima are located at 15 kK and at 24 kK. Evidently the 15 kK band can not be assigned to a local excitation, since neither component molecule has any transition in the corresponding region. The 1 : 1 complex of 1-naphthylamine and chloranil

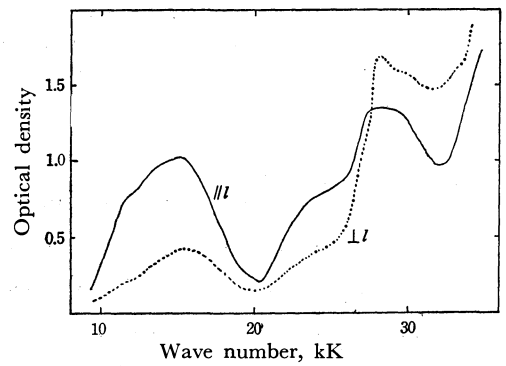

Fig. 2. Absorption spectra of 1-naphthylamine-chloranil compound.

12) H. Kuroda, T. Kunii, S. Hiroma and H. Akamatu, *J. Mol. Spectry.*, **22**, 60 (1967).

formed in the carbon tetrachloride solution shows a charge-transfer band with a maximum at 15.9 kK. Therefore, we shall assign the 15 kK band of the crystal spectra to the lowest charge-transfer excitation.

The orbital energies of the highest and second-highest occupied molecular orbitals of 1-naphthylamine are, respectively, −8.37 and −9.88 eV according to the SCF MO calculations.*1 Therefore, we can expect that the band associated with the charge-transfer from the second-highest occupied orbital of a naphthylamine molecule to the lowest vacant orbital of the nearest chloranil molecules will be located, if it appears at all, at a wave number separated by about 12 kK from the first charge-transfer band. This means that the location of its absorption maximum will be at about 27 kK. Seemingly the 24 kK band observed with $//l$ polarization corresponds to this absorption band. The charge-transfer band corresponding to this band of the crystal spectra may also be expected to appear in the spectrum of the 1 : 1 complex formed in solution, but it should be hardly observed since it overlaps with the tail of the absorption band of naphthylamine. The π–π^* transitions of 1-naphthylamine are located at 29.9 kK ($\log \varepsilon = 3.8$), 31.3 kK ($\log \varepsilon = 3.9$), and 32.8 kK ($\log \varepsilon = 3.9$) according to the spectrum observed for the cyclohexane solution.[13] The absorption in the 28—35 kK region of the crystal spectra is probably associated with these transitions of naphthylamine or with the π–π^* transitions of chloranil.

N, N-Dimethyl-2-naphthylamine - Chloranil (1 : 1) Compound. The crystals of this compound were obtained from a carbon tetrachloride solution as blue-green needles. The $//l$ and $\perp l$ spectra are shown in Fig. 3. The 11.9 kK band is exclusively polarized along the l-axis. We assign it to the lowest charge-transfer excitation. In the spectrum of the 1 : 1 complex in the carbon tetrachloride solution, two charge-transfer bands are observed; their absorption maxima are located at 13 and at 21.8 kK. Apparently the 11.9 kK band in the $//l$ spectrum of the crystal corresponds to the first charge-transfer band of the 1 : 1 complex. The band corresponding to the second charge-transfer band of the 1 : 1 complex, however, is hardly observed in the crystal spectra. Probably the overlap between the second-highest occupied orbital of the donor and the lowest vacant orbital of the acceptor is quite small for the relative orientation of the donor and acceptor in the crystal of this compound.

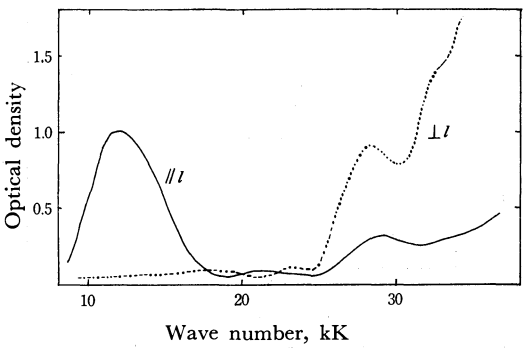

Fig. 3. Absorption spectra of *N*, *N*-dimethyl-2-naphthylamine-chloranil compound.

The absorption in the 25—35 kK region is stronger in the $\perp l$ spectrum than in the $//l$ spectrum. This indicates that the local excitations are responsible for the absorption in this region. In the ethanol-solution spectrum of the dimethyl-2-naphthylamine, the absorption maxima are found at 29 kK ($\log \varepsilon = 3.35$) and 35.5 kK ($\log \varepsilon = 3.86$).[13] It seems that the 28.3 kK band of the crystal spectra is associated with the 29 kK π–π^* transition of dimethyl-2-naphthylamine. The shoulder at about 32.4 kK could be a band associated with the 35.5 kK π–π^* transition of the amine or with the 34.3 kK π–π^* transition of chloranil.

N, N, N', N'-Tetramethyl-p-phenylenediamine-Chloranil (1 : 1) Compound. A reddish-brown crystalline powder of this molecular compound was prepared from a benzene solution. The crystal is either a needle or a thin plate elongated in one direction. This molecular compound

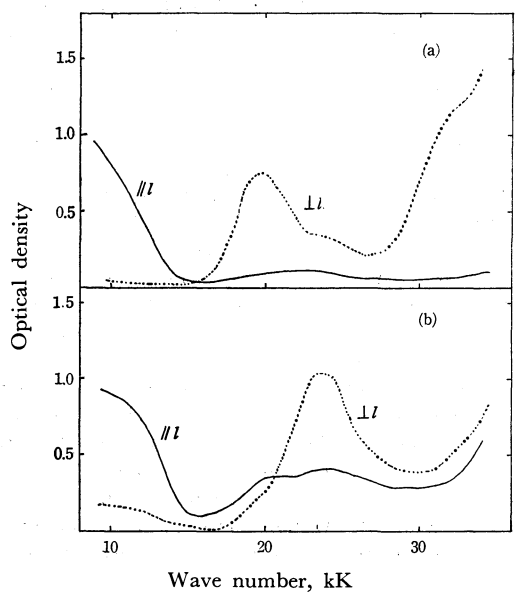

Fig. 4. Absorption spectra of *N*, *N*, *N'*, *N'*-tetramethyl-*p*-phenylenediamine-chloranil compound.
(a) needle crystal
(b) plate crystal

*1 The calculations were made by T. Kunii of our laboratory (Thesis, The University of Tokyo, 1967).

is known to have an ionic ground state.[7,14,15] The spectra observed for a needle crystal and those observed for a plate crystal are shown in Fig. 4a and Fig. 4b respectively. An appreciable difference is found between these two cases. This is probably due to the fact that the developed face of a needle crystal is crystallographically different from that of a plate crystal.

Both Fig. 4a and Fig. 4b indicate the presence of a strong absorption band in the near-infrared region. It is polarized along the *l*-axis, which is the direction of the alternate stacking of donors and acceptors. The band maximum seems to be located at a wave number appreciably lower than 10 kK, but we were not able to determine its location exactly since the spectral region measurable with our microspectrophotometer is limited to the area above 9 kK. This band seemingly corresponds to the 8 kK band found by Kainer and Überle[3] in the powder spectrum observed by means of the KBr-pellet method.

The absorption in the 20—35 kK region is different as regards the polarization from the near-infrared band described above. This can be most clearly seen in Fig. 4a. The absorption is stronger in the $\perp l$ spectrum than in the $//l$ spectrum. There seem to be three absorption bands, located at 19.4, 23.5, and 32 kK. In the $\perp l$ spectrum of Fig. 4a, a strong absorption maximum is found at 19.4 kK, accompanied by a weak shoulder located at about 24 kK. On the other hand, the 23.5 kK band is much stronger than the 19.4 kK band in the $\perp l$ spectrum of Fig. 4b. These facts clearly indicate that the direction of the transition moment is different in the 19.4 kK band and in the 23.5 kK band. From a comparison between Fig. 4a and Fig. 4b, we may also conclude that the polarization of the 32 kK band is the same as that of the 19.4 kK band. These conclusions are in good agreement with the observations reported by Anex and Hill.[11]

The absorption spectrum of the TMPD monopositive ion has been studied by Albrecht and Simpson,[16] who have shown that the π-π^* transitions located at 17.7 kK and at 30.8 kK are polarized along the long axis of TMPD, whereas the weak π-π^* transition at 25.3 kK is of the short-axis polarization. We consider that the 19.4 kK band and the 32 kK band of the molecular compound are associated, respectively, with the 17.7 kK band and the 30.8 kK band of the TMPD ion. There is a possibility that the 23.5 kK band of the molecular compound is due to the 25.3 kK band of the TMPD ion. However, the 23.5 kK band seems to be too strong for this assignment to be acceptable. An alternate assignement is to attribute it to the lowest π-π^* transition of the chloranil ion, located at about 22.2 kK, a transition which has been identified as a transition polarized perpendicular to the molecular axis that passes through the two oxygen atoms of chloranil.[17] It has been reported by Wallwork[18] that, in the crystal of the TMPD-chloranil compound, the component molecules are alternately stacked, face-to-face, on each other along a crystal axis, and that the molecular axis of chloranil mentioned above is parallel to the long axis of TMPD. Therefore, we can predict that the polarization of the local excitation band associated with the 22.2 kK band of the chloranil ion will be perpendicular to those of the bands assocaited with the long-axis polarized transitions of the TMPD ion. This is in agreement with the observed polarization of the 23.5 kK band of the molecular compound.

In conclusion, let us assign the near-infrared absorption band of the molecular compound to the charge transfer from the chloranil ion to the TMPD ion; the 19.4 and 32 kK bands, to the local excitation associated with the TMPD ion, and the 23.5 kK band, to the lowest π-π^* transition of the chloranil ion. It should be noticed, however, that the local excitation bands are considerably broadened and are shifted to a higher energy as compared with the corresponding bands observed in the solution spectrum of each component. These facts, as well as the high intensity of the charge-transfer band, suggest the presence of a relatively strong electronic interaction between the TMPD and chloranil ions.

***p*-Phenylenediamine - Chloranil (1 : 1) Compound.** A greenish-black crystalline powder of this compound was obtained from a benzene solution. This is also known as an ionic compound.[7,15] The observed crystal spectra, shown in Fig. 5, are very similar to the spectra observed

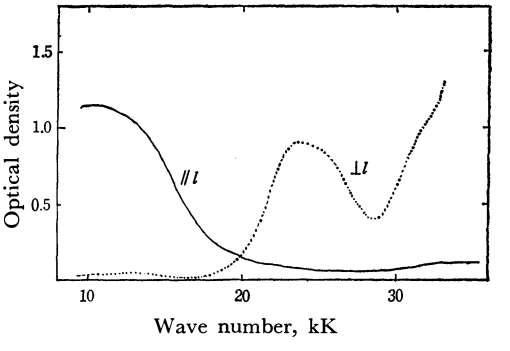

Fig. 5. Absorption spectra of *p*-phenylenediamine-chloranil compound.

14) H. Kainer and W. Otting, *Chem. Ber.*, **88**, 1921 (1955).

for the TMPD-chloranil compound. There is a strong absorption band in the near-infrared region; this band is exclusively polarized along the *l*-axis. We assign this band to the charge transfer between the *p*-phenylenediamine mono-positive ion and the chloranil mono-negative ion. The absorption maximum of this band is located at about 10 kK.

The broad absorption band located at 23.5 kK and polarized perpendicular to the *l*-axis can be regarded as a local excitation band. The p-phenylenediamine ion has the lowest π-π^* transition at 21.6 kK, while the chloranil ion has its at 22.2 kK. The 23.5 kK band of the molecular compound seems to be due to either of these transitions of the ions. In the present study, we were not able to determine which of these two transitions is actually responsible for the 23.5 kK band. In any case, however, we should consider that the local excitation band in the crystal spectra is shifted to a considerably higher energy as compared with the corresponding absorption band of the free ions.

Diaminodurene-Chloranil (1 : 1) Compound. A black crystalline powder of this compound was prepared from a benzene solution. This compound has an ionic ground state.[7,15] The crystal spectra are shown in Fig. 6. The general features of the crystal spectra are again quite similar to those of the TMPD-chloranil compound. The strong absorption band in the near-infrared region is polarized along the *l*-axis. This band can be assigned to the charge transfer from the chloranil mono-negative ion to the diaminodurene mono-positive ion. The absorption maximum of this charge-transfer band is located at about 10 kK.

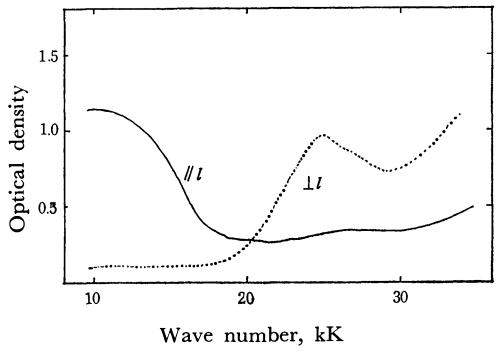

Fig. 6. Absorption spectra of diaminodurene-chloranil compound.

The 25 kK band in the $\perp l$ spectrum must be a local excitation band. The diaminodurene ion has its lowest π-π^* transition at 20.8 kK. We can not tell whether the 25 kK band is associated with this transition of the diaminodurene ion or with the 22.2 kK transition of the chloranil ion. At any rate, though, we can conclude that the local excitation band is shifted to a higher energy than the corresponding bands of the component ions.

Conclusion

We have studied the polarized absorption spectra of solid molecular compounds composed of aromatic amines and chloranil. The observed spectra can be classified into two types: the spectra of the non-ionic molecular compounds, and the spectra of the ionic molecular compounds. In the spectra of a non-ionic compound, the charge-transfer band appears at a wave number similar to that of the corresponding charge-transfer band of the (1 : 1) complex formed in the solution, and the locations of the local excitation bands also are not very different, or are shifted to an energy only a little lower, from those of the absorption bands in the solution spectrum of each component. In most cases the charge-transfer band is definitely polarized in the direction of the alternate stack of donors and acceptors. These general features of the crystal spectra are quite similar to those of the spectra of the molecular compounds formed between polycyclic aromatic hydrocarbons and tetracyanoethylene, which have been reported on in a previous paper.[12]

In the case of the ionic compounds, an absorption band associated with the charge transfer between ions is observed in the near-infrared region with a relatively high intensity. The band associated with the intra-molecular transitions of the component ions are appreciably broadened and are shifted to considerably higher energies compared with the corresponding bands in the solution spectra of the free ions. These phenomena suggest the presence of a relatively strong charge-transfer interaction between the radical ions in the solid molecular compounds.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 88—93 (1968)

The Mössbauer Spectra of Various Natural Minerals

Yoshimasa TAKASHIMA and Shigeru OHASHI

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received February 16, 1967)

The Mössbauer spectra have been measured for sixteen samples of natural minerals, including siderite, vivianite, garnets, olivines, pyroxenes, and other silicate minerals, The spectra were analyzed for the isomer shifts and quadrupole splittings, and the information thus obtained was correlated with the oxidation states of irons and the crystal structure of minerals. The relative abundances of the various sites present in a given mineral were also estimated by measuring the relative intensities of the absorption peaks in the resolved spectrum of the mineral. All the basic Mössbauer spectral patterns observed for the natural minerals are presented in graphic form.

In recent years considerable attention has been paid to the chemical application of the Mössbauer effect. There are a number of papers that allow one to evaluate the usefulness of Mössbauer spectroscopy as a tool for studying chemical bonding. Although a number of works have dealt with synthetic chemical compounds, however, comparatively little work has been done in measuring the Mössbauer spectra of naturally-occurring substances. The suggestion that Mössbauer spectroscopy can be well applied to a study of natural minerals was first made by Pollak[1] (1962). More recently, a similar studies of different types of minerals have been done successfully by Herzenberg *et al.*[2] and Sprenkel-Segel *et al.*[3] The chief application of Mössbauer spectroscopy to minerals has thus far been associated with the mineral structure as well as the oxidation states of iron atoms. In practice, the characteristic features of the spectra are well related to the chemical environment around the Mössbauer nucleus.

The present work on natureal minerals was performed with emphasis on the mineral structure. However, the possibilities of identifying the oxidation states and of determining their ratios were also discussed. It seems that we may expect the Mössbauer spectroscopic technique to be applied to many other areas of mineralogy in the futrue.

Experimental

Apparatus and Procedure. The apparatus and procedure employed were essentially the same as those described in a previous paper.[4] A part of the instrument, however, was altered so that the measurements could be made more easily and accurately. Namely, γ rays were detected with a thin NaI(Tl) crystal coupled to a 400-channel pulse-height analyzer.

All measurements were made at room temperature. In general, runs were made with total counts in excess of 10^4 per Doppler velocity. Statistical error was taken into account in drawing the spectral lines. The isomer shifts are all expressed in mm/sec relative to stainless steel.

Mineral Samples. Most of the mineral samples used were bought from the Japan Earth Science Company, Kyoto. The vivianites, axinite, and biotite were obtained from our own collection. Some olivines and pyroxenes were provided by Mr. Kiyoshi Ishibashi of Kyushu University, Department of Geology. The sixteen minerals studied are summarized in Table 1.

The bulk of the mineral was first crushed into small pieces. Then the sample was carefully selected through a microscope so as to exclude any impurity. Finally, the sample was pulverized in an agate mortar. The powder (*ca.* 100 meshes) was mounted as uniformly

as possible on an absorber disk. The samples ranged in thickness from 10 to 24 mg Fe/cm², depending on the iron content in the minerals.

Chemical Analysis of Iron. The determination of the iron(II) and iron(III) in minerals was carried out by means of the permanganate titration technique. The pulverized mineral was brought into the solution by treating it with sulfuric acid and hydrofluoric acid, with special care taken to prevent the oxidation of iron(II) in the process. The solution in a platinum crucible was transferred without removing the cover to 80 ml of a cold, saturated boric acid solution. The sample solution thus obtained was titrated at once with a 0.1 N potassium permanganate standard solution. Then the total iron content was determined in the same way by using the same solution after the iron in the solution had been reduced to the bivalent state with a zinc-amalgam reductant. The iron(III) content can be found by deducting the iron(II) content from the total iron content. This method is sufficiently accurate to be useful.

Results and Discussion

It is well known that there are three basic Mössbauer spectral patterns, *i. e.*, a single absorption line, double absorption lines, and six-splitted absorption lines. The last one is produced by a Zeeman splitting resulting from the interaction of the nuclear magnetic dipole with the magnetic field produced at the nuclear site by the electrons. Such spectra were observed in the cases of iron oxides[5] and sulfides.[6,7] In our measurements, however, such samples were intentionally avoided because they have already been extensively studied and our instrument is not suited for the measurement of such a wide range of velocity. Most of the samples studied were of a silicate form, but some were of phosphate and carbonate forms.

The spectra were analyzed for the isomer shifts and quadrupole splittings, and the information thus obtained was correlated with the oxidation states of iron and the crystal structures of the minerals. In principle, however, numerous difficulties are inherent in any detailed analysis of the Mössbauer spectrum. The trial-and-error method is necessary to make possible a reasonable analysis of the spectrum. The absorption peak intensity was roughly evaluated in order to obtain an estimate of the iron content in any particular crystal site. To eliminate the saturation effect in the absorption, the absorbers were made thin ranging, from 10 mgFe/cm² to 15 mgFe/cm². In some cases, however, thicker absorbers were used because of the difficulty inherent in the preparation technique. The saturation was observed in samples with thicknesses of >15 mgFe/cm².

Siderite ($FeCO_3$). The siderite exhibits only a sharp doublet Mössbauer pattern similar to a typical ionic ferrous compound. The isomer shift (δ) and the quadrupole splitting (ε) observed were $\delta = 1.38$ mm/sec and $\varepsilon = 0.94$ mm/sec respectively. The former value is typical of the ferrous ion, while the latter is somewhat small for the ferrous ion in ferrous compounds. This means that the binding of iron atoms in the siderite is similar to that of a typical ionic ferrous salt, but that the iron is in a nonspherical environment.

Vivianite [$Fe_3(PO_4)_2 \cdot 8H_2O$]. The spectrum of vivianite shows three absorption lines. The authors have resolved the spectrum into two doublets. The spectra of two vivianites are reproduced in Fig. 1. The first two bands are due to trivalent-state iron, and the second two bands, to bivalent-state iron. The spectrum of Himeshima vivianite was compared with that of Kobe vivianite by measuring each absorber with the same areal iron density. A difference in the intensity of the trivalent iron peak between the two vivianites was observed. On the contrary, the general trends of the X-ray powder patterns of the two minerals

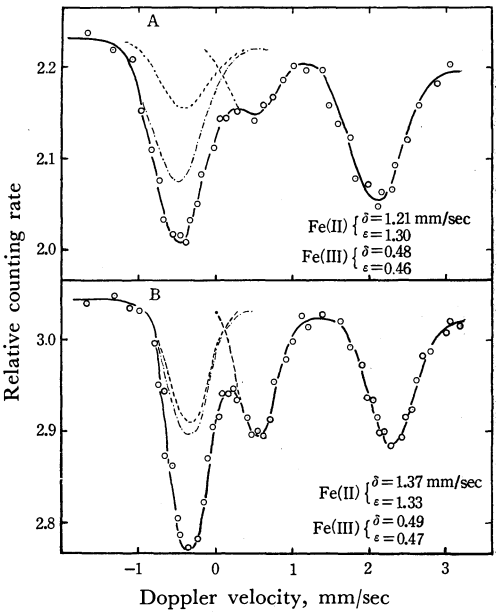

Fig. 1. Mössbauer spectra of vivianites.
Thickness=15 mg Fe/cm²
A: Himeshima vivianite, B: Kobe vivianite

are very similar. The above facts suggest that, *in some cases*, the Mössbauer absorption pattern can be used in the locality identification of minerals.

The presence of the trivalent iron in these minerals may be attributed to the erosive oxidation in the light of the δ and ε values, *i. e.*, the isomer shift and the quadrupole splitting of Fe_2O_3 are similar to those of the vivianites.

Garnets. The garnet group is repersented by the general formula, $A_3B_2Si_3O_{12}$, where A=Fe, Ca, Mg, Mn, *etc.*, and where B=Al, Fe, Cr, *etc.* As is shown in Fig. 2, the silicon-oxygen tetrahedra exist as independent groups linked to the octahedra of the trivalent ions, while the bivalent metal ions are situated in the center of the oxygen dodecahedra. Of the many kinds of garnets, andradite and almandite were chosen as samples. The Mössbauer spectra of these two minerals are compared with each other in Fig. 3. In this case, the absorbers were so prepared that the areal iron density was approximately 10 mgFe/cm^2. The andradite spectrum can be resolved into a single line with a high intensity and a doublet with a weak intensity. The intense single line may be an unresolved doublet, for its half-width is a little larger than that of stainless steel. The values of both the isomer shifts lie in the range characteristic of the trivalent state iron. The intense line indicates a more covalent nature in bonding than the weak one. This supports the assumptions that there are two different iron sites in the crystal, and that most of the iron atoms are at the B site and only a few, at the A site.

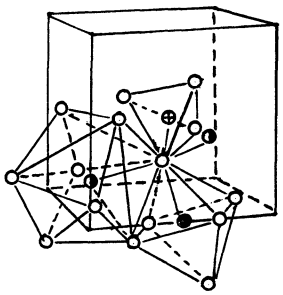

Fig. 2. Crystal structure of garnet ($A_3B_2Si_3O_{12}$).

◑: Fe, Ca, Mg, Mn,··· (A)
⊕: Si

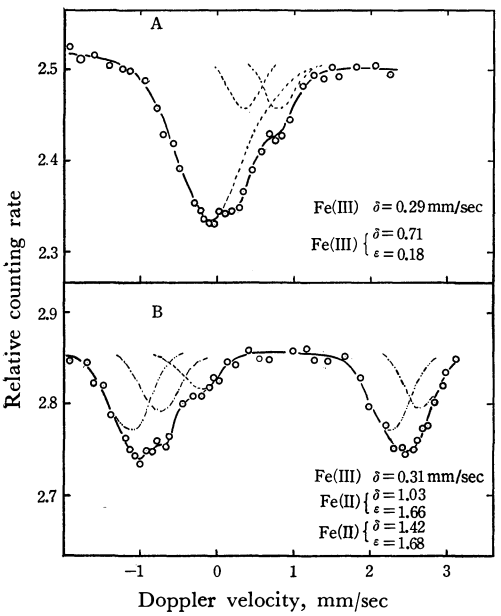

Fig. 3. Mössbauer spectra of garnets.
Thickness=10 mg Fe/cm^2.
A: Andradite, B: Almandite

The spectrum of almandite showed a relatively complex structure. It is resolved into two doublets characteristic of bivalent iron and a single line characteristic of trivalent iron. Since the isomer shift of the trivalent iron in the almandite is close to that of the covalently-bonded iron atoms, the trivalent iron must be located at the B site, together with a large amount of bivalent iron. Accordingly, the other bivalent iron, of about an equal amount, must be located at the A site.

Olivines. The Mössbauer spectra of two kinds of olivine, forsterite and fayalite, are shown in Fig. 4. The isomer shift and quadrupole splitting were of the same order as for almandite, showing the ionic nature of the iron bonding present.

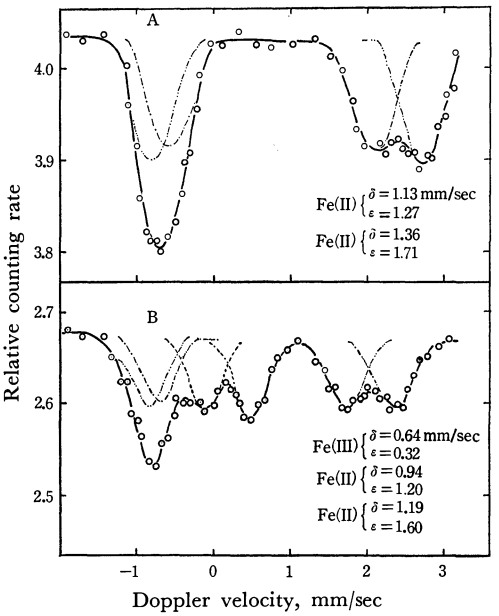

Fig. 4. Mössbauer spectra of olivines.
Thickness=24 mg Fe/cm^2.
A: Forsterite, B: Fayalite

The compositions of olivines vary from that of forsterite, Mg_2SiO_4, to that of fayalite, Fe_2SiO_4, there being a complete diadocky between manganese and iron atoms. The crystal structure parallel to the (100) plane is shown in Fig. 5. In Fig. 5, the silicon atoms at the center of the tetrahedra are not shown. Small open circles (Mg or Fe atoms) are at $x=0$, while small solid circles (Mg or Fe atoms) are at $x=1/2$. The fact that the Mössbauer spectrum has resolved into two

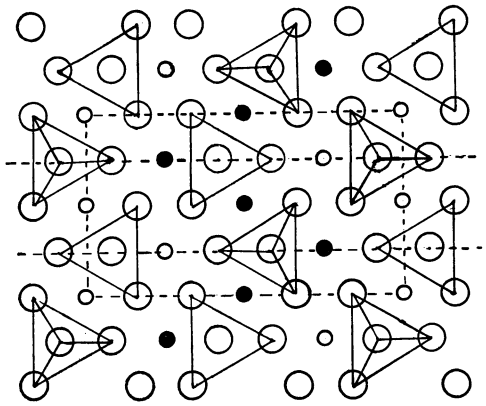

Fig. 5. Crystal structure of olivine.
○: O; ○ ●: Mg, Fe

doublets of equal intensities is consistent with the crystal structure. Namely, half of the metal (Mg or Fe) is located at the site having as nearest neighbors two oxygen atoms from two adjacent

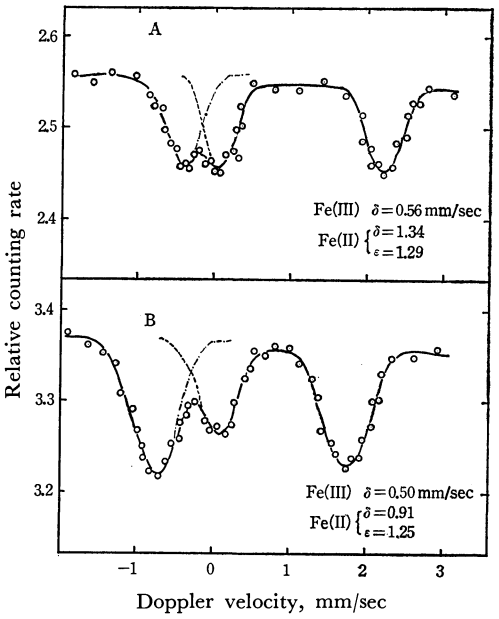

Fig. 6. Mössbauer spectra of pyroxenes.
Thickness=14 mg Fe/cm².
A: Nishigadake augite, B: Karatsu augite

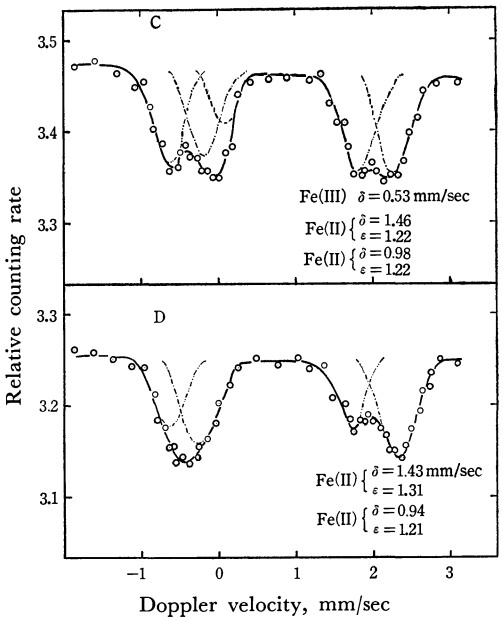

Fig. 7. Mössbauer spectra of pyroxenes.
Thickness=15 mg Fe/cm².
C: Diopside, D: Hedenbergite

tetrahedra, but the other half is located at the other site, having two oxygens from one adjacent trahedron. In these two Mössbauer spectra the predominant absorption patterns correspond to that of bivalent state iron. Only fayalite gave a weak absorption pattern corresponding to that of trivalent state iron.

Pyroxenes. The pyroxenes include varieties which have orthorhombic and monoclinic symmetries. The authors used four monoclinic samples, *i. e.*, two augites, a diopside, and a hedenbergite, for the measurement. The Mössbauer spectra obtained are shown in Figs. 6 and 7. The locality difference in the Mössbauer patterns was observed between the two augites as for the vivianites. The resolution of the spectra is shown by the dotted curves. The results indicate that the single site is available to the bivalent iron in the crystal structure of augite, while two sorts of sites are available in the cases of diopside and hedenbergite. No peak attributable to trivalent state iron was observed in the hedenbergite spectrum.

Table 2. Isomer shifts and quadrupole splittings of several silicate minerals

	Fe(II)		Fe(II)		Fe(III)	
	δ(mm/sec)	ε(mm/sec)	δ(mm/sec)	ε(mm/sec)	δ(mm/sec)	ε(mm/sec)
Axinite	1.39	1.2			0.60	0.14
Biotite	1.18	1.32	1.46	1.60	0.48	0
Tourmaline	1.06	0.98	1.42	1.34	0.89	0
Hornblende	0.98	1.13	1.38	1.62	0.66	0.20
Lievrite	1.30	1.37	1.25	0.89	0.54	0.32

Other Silicate Minerals. As has been discussed above, the Mössbauer spectrum measured for each mineral can be interpreted in terms of valency state, lattice sites, the covalency of bonding, and crystal distortion. Among the number of silicate minerals, axinite, biotite, tourmaline, hornblende, and lievrite were investigated by the present authors. Some of the same sort of minerals had already been measured by other people.[1,2] The silicate minerals generally give complicated Mössbauer spectra, the most complicated patterns being obtained in the cases of the hornblende and lievrite. They both consist of three doublets, our analysis shows. The values of the isomer shift and of the quadrupole splitting for these minerals are summarized in Table 2.

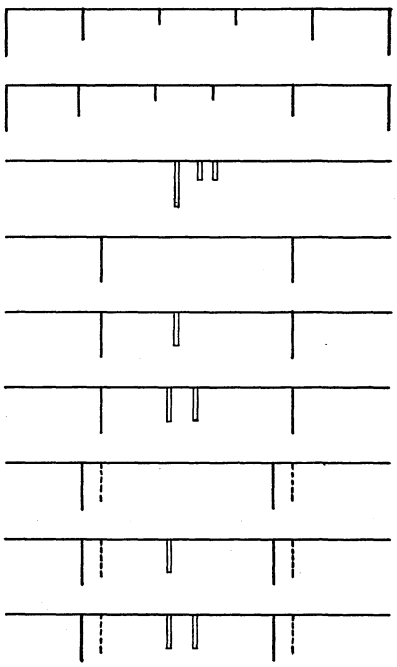

Fig. 8. Basic Mössbauer patterns observed in the natural minerals.
Solid and dotted lines represent bivalent iron.
Open lines represent tivalent iron.

Summary of the Mössbauer Spectra of Minerals. The absorption of resonant gamma rays produces various patterns characteristic of the various minerals. Nine basic patterns and their modifications have so far been observed for the natural minerals. Of these patterns, seven were observed in the wide variety of minerals examined here. The other two resulted from such ferromagnetic iron minerals as iron sulfides. The basic patterns are illustrated in Fig. 8, where the absorption peaks are abbreviated by the single lines, and where the intensity, peak position, and splitting scales are arbitrarily chosen.

Relationship between Peak Intensity and Iron Content. The amount of iron in a sample can be determined from the intensity of the Mössbauer spectrum if the nuclei are located in fairly identical environments. The correlation between the peak intensity (peak area) and the iron content was examined by using a stainless steel and a vivianite mineral of varying thicknesses. As the thickness was increased, the intensity increased, as is shown in Table 3.

TABLE 3. COMPARISON OF ABSORBER THICKNESS AND PEAK INTENSITY

Sample	Stainless steel	Vivianite
Ratio of iron content taken	1* : 4 : 12	1** : 2 : 3
Ratio of absorption peak area observed	1 : 2.1 : 4.5	1 : 1.6 : 1.9

* Thickness=6 mg Fe/cm^2
** Thickness=15 mg Fe/cm^2

The next point examined was the relation between the Fe(II)/Fe(III) ratios and their peak

TABLE 4. RELATION BETWEEN Fe(II)/Fe(III) RATIO AND RATIO OF ABSORPTION PEAK

Sample	Absorber thickness (mgFe/cm^2)	From chemical analysis data			From the Mössbauer spectrum
		Fe(II) %	Fe(III) %	Fe(II)/Fe(III)	Ratio of absorption peak area due to Fe(II) and Fe(III)
Vivianite (Himeshima)	15	22.7	9.1	2.49	2.49
Vivianite (Kobe)	15	13.2	12.6	1.05	1.12
Almandite	10	18.3	2.0	9.15	8.81
Fayalite	24	31.1	15.1	2.06	2.10
Augite (Nishigadake)	14	4.5	2.1	2.14	2.21
Augite (Karatsu)	14	5.4	2.0	2.70	2.96
Diopside	15	6.5	1.4	4.64	8.60
Axinite	10	4.4	1.5	2.93	2.96
Biotite	15	19.0	1.9	10.00	9.80
Tourmaline	10	5.2	1.4	3.64	5.11
Hornblende	12	7.1	4.2	1.69	1.73
Lievrite	20	27.4	12.2	2.28	2.15

intensity ratios. The results obtained are summarized in Table 4. It may be seen from Table 4 that there is in most cases a fairly good agreement between the ratios of the iron content determined by chemical analysis and the ratios of peak intensity obtained from the Mössbauer spectrum. The apparent discrepancies observed in several cases could result from several causes: 1) drift of the pulse-height analyzer, 2) nonidentical environment around the iron nuclei, 3) counting error, 4) effect of higher energy γ rays on 14.4 keV γ rays, and 5) saturation effect in the absorption. In view of the spectrometer employed, further discussion of the subject is premature. Experiments to elucidate this subject would need to be conducted with a better spectrometer.

The Mössbauer absorption peak does not appear when the iron content in the mineral is less than 1%. This would seem to be the limit of detection in this experiment.

The authors wish to thank Mr. Kiyoshi Ishibashi for contributing several mineral specimens, and Mr. Terumasa Nakamura for providing the X-ray powder pattern measurements. We also wish to extend our thanks to Mr. Toyoaki Kusaba who assisted in the experiments.

This study has been supported in part by a grant-in-aid for Scientific Research from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 93—99 (1968)

On the Structures of Alkali Polyaluminates

Goro YAMAGUCHI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

and Kazutaka SUZUKI

Nagoya Institute of Technology, Syowa-ku, Nagoya

(Received March 27, 1967)

Besides the so-called β-Al_2O_3 ($R_2O\cdot 11Al_2O_3$; R=Na or K), there have been found two kindred compounds with approximate formulas, $R_2O\cdot 7Al_2O_3$ (β'-Al_2O_3) and $R_2O\cdot 5Al_2O_3$ (β''-Al_2O_3). The structure determination of the latter two compounds was undertaken; the results are compared with the structure of β-Al_2O_3 in the present paper. These three structures are composed of spinel layers of the same configuration. The structures of β and β' are very similar to each other, both equally bearing a layer-stacking according to a two-fold screw symmetry, while β'' differs from these two in exhibiting another way of layer-stacking, according to a three-fold screw symmetry.

It has been established that the so-called β-Al_2O_3 is in fact an alkali polyaluminate with the chemical formula of $Na_2O\cdot 11Al_2O_3$ or $K_2O\cdot 11Al_2O_3$. In 1943 one of the present authors (G. Y.)[1] studied its formation during a sintering reaction between Al_2O_3 and alkali carbonate; he thus found a new substance whose X-ray powder diffraction pattern displayed a close resemblance to that of β-Al_2O_3. However, a few lines in the pattern, such as the strong 1.954A and 1.382A lines, failed to be properly indexed unless the c-axis of the crystal was assumed to be 3/2 or 3 times as long as that of β-Al_2O_3. He also pointed out that the above two lines coincide in spacings with the 400 and 440 reflections, respectively, from the spinel structure.

About ten years later, Yamaguchi[2] reinvestigated the material by chemical as well as X-ray methods. and reported that two phases were revealed, one with the approximate composition, $Na_2O\cdot 8Al_2O_3$ or $K_2O\cdot 8Al_2O_3$, and the other, with $Na_2O\cdot 5A_2O_3$ or $K_2O\cdot 5Al_2O_3$. The former was designated β'-Al_2O_3 (β'_{Na}, β'_{K}), and the latter, β''-Al_2O_3 (β''_{Na}, β''_{K}). He then reported in another paper[3] that the experimental formulas were $Na_2O\cdot 8.1Al_2O_3$ for β'_{Na}, $Na_2O\cdot 5.8Al_2O_3$ for β''_{Na}, and $K_2O\cdot 5.6Al_2O_3$ for β'_{K}, and that the way of oxygen packing in the β' structure might be similar to that in β, both being reflection-symmetrical across planes perpendicular to the c-axis, while that in

2) G. Yamaguchi, Preprint for the 7th Annual Meeting of the Chemical Socity of Japan (April, 1954), p. 192.

3) G. Yamaguchi, Doctor Thesis, University of Tokyo (1954).

β'' was after the manner of cubic closest-packing, with some layers replaced by those bearing less oxygen and some alkali ions. He thus explained the fact that the two lines characteristic of β'' coincide in spacings with the 400 and 440 lines from spinel, and gave the lattice parameters reproduced in Table 1.

c or 2c	22.56	67.86	68.01

Recently, Théry *et al.*[4] have published a report on substances which are probably the same as the alkali polyaluminates under consideration; one is $Na_2O{\cdot}5Al_2O$ with the lattice parameters of $a=5.61$ Å and $c=33.95$Å, and the other, $Na_2O{\cdot}7.02Al_2O_3$, with $a=5.595$Å and $c=34.02$Å.

In the present paper, the authors will describe the structures of these alkali polyaluminates.

Since no single crystal had yet been obtained for any of these materials, we were obliged to carry out this work using their powder data only. Therefore, we cannot claim that the results we deduce here are highly accurate, but we still believe them to be essentially correct.

Experimental

Mixtures of aluminum hydroxide and alkali carbonate in appropriate ratios were heated. The products were then washed with dilute HCl and water, and their chemical compositions and densities examined. The results, together with the suitable conditions for their preparations, are listed in Table 2. Though both sodium and potassium are capable of forming β' and β'', the former tends to favor the production of β', while the latter favors β''. The X-ray powder diffraction patterns shown in Figs. 1 and 2 were obtained with β'_{Na} and β''_{K} respectively. The observed lines were indexed with the aid of the lattice parameters given in Table 1, and their peak intensities were measured for a fixed exposure time. The results are tabulated in Tables 3 and 4, where the relative values of intensities have been put onto such a scale as to minimize the R-factors and where the calculated values for the strongest lines are taken to be 100. The lattice parameters newly derived from these two sets of data are given in Table 5.

Structure Analysis

At the onset of the structure determination of these two crystals, the diffraction pattern of β-Al_2O_3 was produced for comparison; the results are given in Fig. 3 and Table 6. On the base of the structure of this material as worked out by Beevers and Ross[5] and reproduced here in Fig. 4 and Table 7, the calculated intensities were deduced and compared with the observed intensities, shown in Table 6. The R-factor was found to be 0.30. It may be noted in Fig. 4 that the structure is composed of layers of the spinel structure, and that each layer is flanked by a pair of planes perpendicular to the c-axis and containing alkali ions (R in

the figure). These planes shall hereafter be called "alkali layers," and the part, within a unit cell, of a spinel layer, a "spinel block."

Structure of β'-Al_2O_3. The powder pattern of β'_{Na} was used for this purpose. As will be recognized upon comparisons of Fig. 4 with Fig. 3 and of Table 3 with Table 6, the powder pattern of β'-Al_2O_3 closely resembles that of β-Al_2O_3. This fact, together with the similarity in lattice parameters between these two substances, strongly suggests that both structures have the same principle. In fact, the pattern of β'-Al_2O_3 is completely in harmony with the space group of β-Al_2O_3, $P6_3/mmc$; namely, the $hh\bar{2}hl$ reflections are missing when l is odd. Therefore, it was assumed at the beginning of the analysis that the structure of β'-Al_2O_3 consists of spinel blocks which have the same configuration and mode of arrangement as in the structure of β-Al_2O_3.

Next, if we compare the experimental formula of the substance, shown in Table 2, with the composition of β-Al_2O_3, we shall find that the former

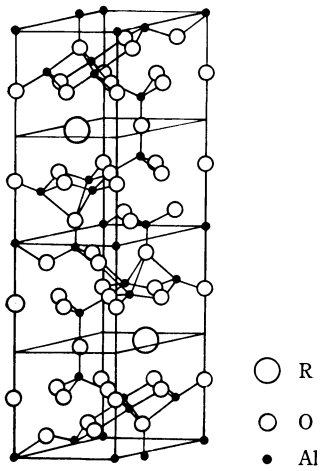

Fig. 4. Structure of β-Al_2O_3.

contains one and a half times as much alkali as the latter, both against a certain amount of oxygen. Therefore, $R_{1.50}Al_{10.83}O_{17}$ or $R_2O{\cdot}7.22Al_2O_3$ was tentatively adopted as the ideal formula for this phase. The theoretical values of density from this formula are 3.26 for β'_{Na} and 3.38 for β'_{K}, in good agreement with the observed values, 3.22 and 3.35 respectively.

Then, taking into account the fact that the spinel block is so densely constituted that no alkali ion is admitted into it, we could restrict the probable positions for excessive alkali ions in or near the alkali layers. Trial-and-error procedures carried out with the aid of an electronic computer then led us to the final structure, shown in Fig. 5.

In this structure, two sites for alkali ions per spinel block are statistically occupied by 1.5 ions, while the positions for Al ions (two per block) nearest the alkali layers are occupied by 1.83 such ions. The atomic coordinates are listed in Table 8, while the calculated intensities for the structure are given in Table 3. The *R*-factor for I deduced from this table is 0.26. It has also been confirmed that the intensities calculated for unobserved reflections are all less than 1 on the intensity scale of the table.

Structure of β''-Al_2O_3. Potassium-bearing β''-Al_2O_3 was chosen for this study; its powder data are given in Table 4. Since in every observed reflection there holds, between its indices, a $-h+k+l\equiv 0$ (mod 3) relation, no other condition being associated, the only conclusion deducible is that the crystal lattice is rhombohedral. However, there are five space groups altogether, each based upon the rhombohedral lattice and satisfying the above relation, so from the powder data alone it is impossible to identify the space group of the crystal further. Accordingly, we had to search for the structure on the base of the knowledge of the crystal lattice and by assuming the structure also to be built up of spinel blocks.

Next, a comparison of the experimental formula of this phase with the composition of β-Al_2O_3 suggests that a spinel block contains nearly two alkali ions in the present case. Therefore, $R_2Al_{10.67}O_{17}$ or $R_2O{\cdot}5.34Al_2O_3$ was considered as the ideal formula, for which the calculated density was 3.45.

The procedures described above were then employed for the derivation of the probable solution; the final result obtained is a structure based upon the $R\bar{3}m$ space group and illustrated in Fig. 6.

In this structure, a statistical distribution is observed only over the positions of the Al ions, two per block, nearest the alkali layers; they are occupied by 1.67 such ions. The coordinates are tabulated in Table 9, and the calculated intensities, in Table 4. The R-factor for **I** is 0.28; the statement given above concerning the unobserved reflections of β'-Al_2O_3 also applies in this case.

Discussion

According to the results of analysis so far described, some conclusions may now be reached. The three phases, β, β', and β'', are all composed of spinel layers of the same configuration. The former two are almost identical structurally, but are different in the amounts of alkali and aluminum present. On the other hand, the last one has its own way of layer-stacking. Thus, the former two structures may be looked upon as characterized by layer-stacking according to a two-fold screw symmetry, shown in Fig. 7, while the

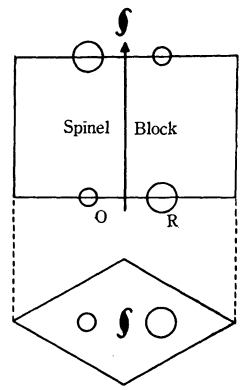

Fig. 7. Mode of stacking of spinel blocks in the β and β'-Al_2O_3 structures.

last, by that according to a three-fold screw symmetry, given in Fig. 8. These findings, together with the fact previously mentioned that sodium and potassium favor the formation of β' and β'' respectively, seem to suggest that the mode of layer-stacking in this series of structures depends upon the amount and kind of alkali.

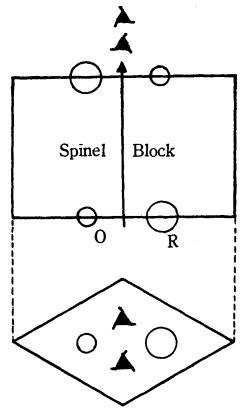

Fig. 8. Probable mode of stacking of spinel blocks in the β''-Al_2O_3 structure.

From the view-point of ionic distribution, β-Al_2O_3 may be considered an ordered phase, while β' and β'' are disordered phases, exhibiting a

statistical distribution of cations over sites in and near the alkali layers. An example of such a distribution has been found in an imperfect spinel, $RO \cdot nAl_2O_3$.[6]

Finally, it should be noted that, because of the restriction imposed upon the present work, namely, the difficulty of obtaining a single crystal for any of the substances under investigation, our results are liable to be some what inaccurate with regard to the atomic coordinates. For example, a position for excess alkali given above to β' or β'' in all probability indicates only the center of gravity of a more dispersed statistical distribution of the ion. However, the authors believe that, in spite of such minute uncertainties, the structural principles of this series of compounds have now been established satisfactorily.

The Extraction of Uranium(VI) from Sulphuric Acid Solutions by Di-*n*-octylamine

Taichi SATO

Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu, Shizuoka

(Received May 11, 1967)

The partition of uranium(VI) between sulphuric acid solutions and solutions of di-*n*-octylamine (DOA) in benzene has been investigated at different concentrations of sulphuric acid, solvent and aqueous uranium, and at different temperatures. The acidity and the water content of the organic phase, and the effect of the organic solvent on the extraction have also been examined. An infrared spectral study has been made of the organic solutions. The mechanism of the extraction of uranium from sulphuric acid solutions by DOA is discussed on the basis of the results obtained, and a composition is proposed for the complex formed in this extraction system.

The extraction of uranium(VI) from sulphuric acid solutions by high molecular-weight amines in organic solvents has been investigated by many researchers.[1] The present author has also studied these extraction systems,[2] and this paper constitutes the work extended to the extraction with di-*n*-octylamine (DOA).

Experimental

Reagents. The DOA (the Kao Soap Co., Ltd.) was of a high purity and was used without further purification. It was diluted with various organic solvents, but was not pre-equilibrated with sulphuric acid solutions. The other chemicals were of analytical reagent grade. The uranyl sulphate solution was prepared by dissolving the uranyl sulphate tri hydrate in sulphuric acid of selected concentration, and its concentration is generally indicated in g/*l* for UO_2SO_4.

Extraction and Analytical Procedures. Equal volumes (20 m*l*) of DOA solution and uranyl sulphate solution were shaken for 10 min in 50 m*l* stoppered conical flasks in a water bath thermostatted at the required temperature (preliminary experiments showed that equilibration is established in 10 min). After the separation of the aqueous and organic phases by centrifugation, uranium in the organic phase was back-extracted with 1 N hydrochloric acid, and then the partition coefficient (the ratio of the equilibrium concentration of uranium in the organic phase to that in the aqueous phase) was determined. Uranium was determined gravimetrically: precipitated as ammonium diuranate and ignited to U_3O_8. The water content of the organic solution was determined by the Karl Fischer titration method.

Infrared Spectral Measurement. The infrared spectra were measured by a Shimadzu Model IR-27C recording spectrophotometer equipped with sodium chloride prisms. The spectra of organic extracts were determined with benzene as reference liquid, in a matched pair cell of fixed path length 0.1 mm, with thallium halide window.

Results and Discussion

Dependence on Acid Concentration and Extraction in Presence of Sodium Sulphate. The extraction of uranyl sulphate solutions (5 g/*l*) containing sulphuric acid at various concentrations

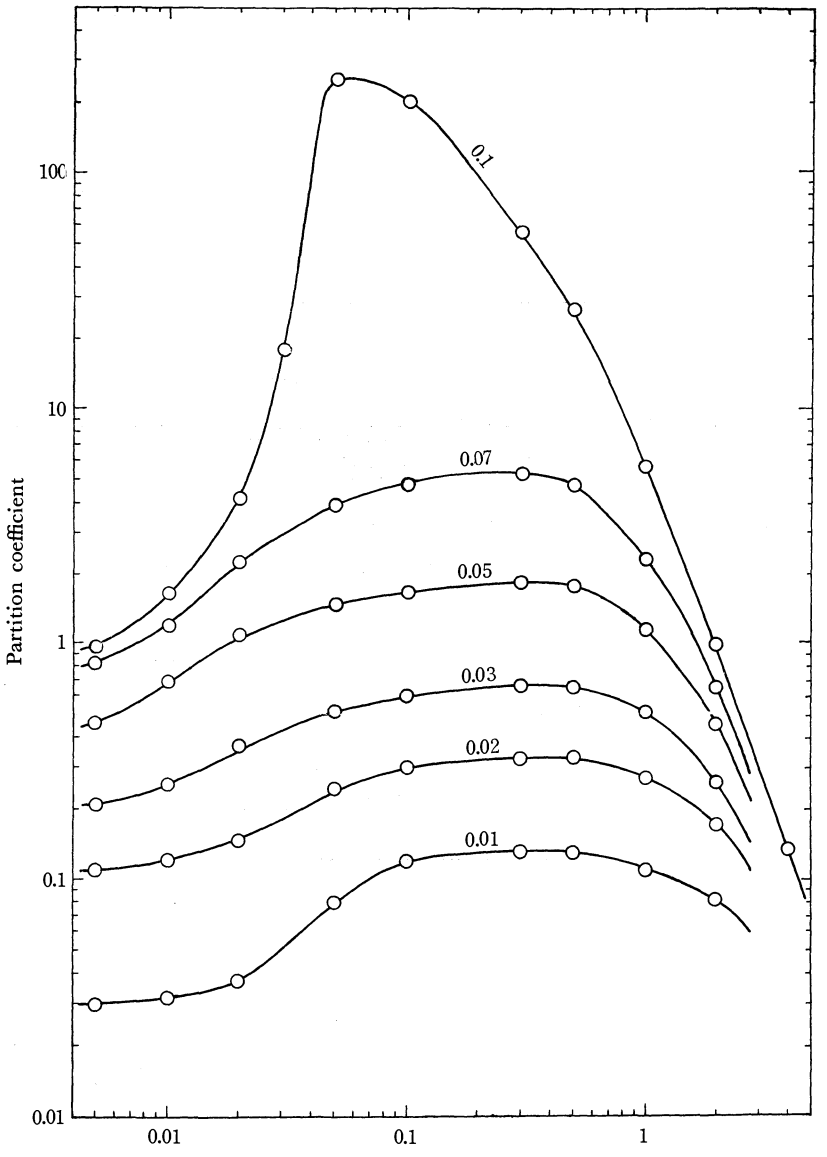

Fig. 1. Extraction of uranium(VI) from sulphuric acid solutions by solutions of DOA in benzene. numerals on curves are DOA concentrations, M.

with solutions of DOA in benzene at 20°C gave the results shown in Fig. 1.

The maximum partition coefficient appears at 0.05 M initial aqueous sulphuric acid concentration for the extraction with 0.1 M DOA and becomes indeterminate for the extraction below 0.07 M DOA, but the shape of the extraction curve resembles the forms of the curves with other amines.[2] It is thus postulated that at low aqueous acidities the increase in the partition coefficient arises from the formation of DOA-uranyl sulphate complex; at higher aqueous acidities the decrease in the partition coefficient is attributed either to competition between uranium and sulphuric acid for association with the amine or to the formation of less readily extractable complexes. This interpretation is confirmed with the result in Fig. 2, illustrating the data for the extraction of uranyl sulphate solutions (5 g/*l*) containing sulphuric acid and sodium sulphate with 0.1 M DOA in benzene at 20°C. This shows that when the sulphuric acid in the aqueous phase is partly replaced by sodium sulphate, the decrease in the partition coefficient is checked because of the removal of competition for uranium between sulphuric acid and the amine. The gradual decrease in the partition coefficient with

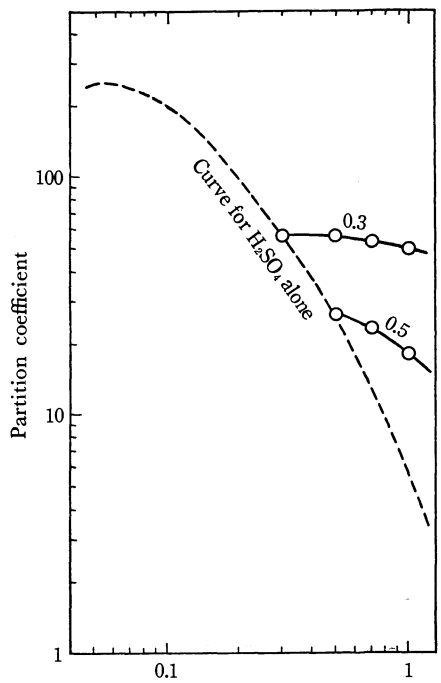

Fig. 2. Extraction of uranium(VI) from sulphuric acid solutions containing sodium sulphate by 0.1 M DOA in benzene.
(Numerals on curves are initial aqueous sulphuric acid concentrations, M).

increasing the sulphate concentration may be explained as being due to the formation of the inextractable species $UO_2(SO_4)_2^{2-}$, since the species UO_2SO_4 and $UO_2(SO_4)_2^{2-}$ exist in the aqueous uranyl sulphate solution containing sulphate ion.[3]

Dependence on Uranium and DOA Concentrations. The variation in the uranium concentration of organic phase with the initial aqueous uranium concentration at 0.05 M aqueous acidity was examined with 0.1 M DOA in benzene at 20°C. The result in Fig. 3 shows that the uranium concentration of organic phase approaches a limiting value (~0.025 M) with increasing the initial aqueous uranium concentration, indicating that four amine molecules are associated with each uranium ion. This is supported by the dependence of the partition coefficient on the DOA concentration at higher aqueous acidities. In the extraction of uranyl sulphate solutions (5 g/*l*) containing sulphuric acid with the solutions of DOA in benzene at 20°C, log-log plots of E_a° *vs.* (C_A-4C_U), in which E_a° is the partition coefficient, C_A the total DOA concentration and C_U the uranium concentration of organic phase, gave straight lines whose slopes are 2.0, 1.5 and 1.0 at 0.5, 1.0 and 2.1 M sulphuric acid concentrations respectively. At low aqueous acidities, on the other hand, it is considered that the value of the association number is apparently not always four, but approaches four in 0.05 M initial aqueous sulphuric acid as the aqueous acidity is increased.

Extraction of Sulphuric Acid. The acidity and water content of the organic phase from the extraction of uranyl sulphate solutions (5 g/*l*) containing sulphuric acid at various concentrations with 0.1 M DOA in benzene at 20°C are shown in Figs. 4 and 5, compared with the data for the similar extraction of sulphuric acid solutions alone. In the extraction of sulphuric acid from

aqueous solutions with solutions of DOA in benzene, the slope of log-log plots of the sulphuric acid distribution ratio *vs.* the initial DOA concentration was nearly two in 0.05 M H_2SO_4 and unity in 0.5 and 2.0 M H_2SO_4 respectively.

By analogy with the case of TOA (tri-*n*-octylamine),[4] it is considered that the equilibrium between DOA and sulphuric acid is expressed as follows: at low acidities

$$H_2SO_4(a) + 2R_2NH(o) \rightleftarrows (R_2NH_2)_2SO_4(o) \quad (1)$$

and at higher acidities

$$(R_2NH_2)_2SO_4(o) + H_2SO_4(a) \rightleftarrows 2(R_2NH_2)HSO_4(o) \quad (2)$$

4) T. Sato, *J. Appl. Chem.*, **15**, 10 (1965).

in which (a) and (o) denote aqueous and organic phases respectively, and R is C_8H_{17}.

The acidity of the organic phase in the presence of uranium is higher than that in the absence of uranium, but this difference is remarkably decreased above 0.1 M initial aqueous acidity. This probably implies that the reaction of the extraction at low acidities is different from that at higher acidities. From Fig. 5 it is deduced that the hydrated amine sulphate is gradually replaced by the unhydrated amine bisulphate as the aqueous acidity is further increased, and the water content of the organic phase is diminished by the formation of the DOA - uranyl sulphate complex. Further it is inferred that the DOA not associated with uranium is present in the bisulphate form at higher aqueous acidities, and is likely to be present as the free amine form at low aqueous acidities since the concentration of the amine sulphate present as the available amine is restricted by the aqueous acidity.

Infrared Spectral Study. The organic phases from the extraction of uranyl sulphate solutions (5 and 25 g/*l*) containing sulphuric acid of various concentrations by 0.1 M DOA in benzene at 20°C were examined by infrared spectroscopy. Similar measurements were also made of the organic solutions from the extraction of sulphuric acid solutions alone. The spectra are presented in Fig. 6.

In the extraction of sulphuric acid, the following results are observed as the aqueous acidity is increased: for 0.02 M sulphuric acid, the bands of

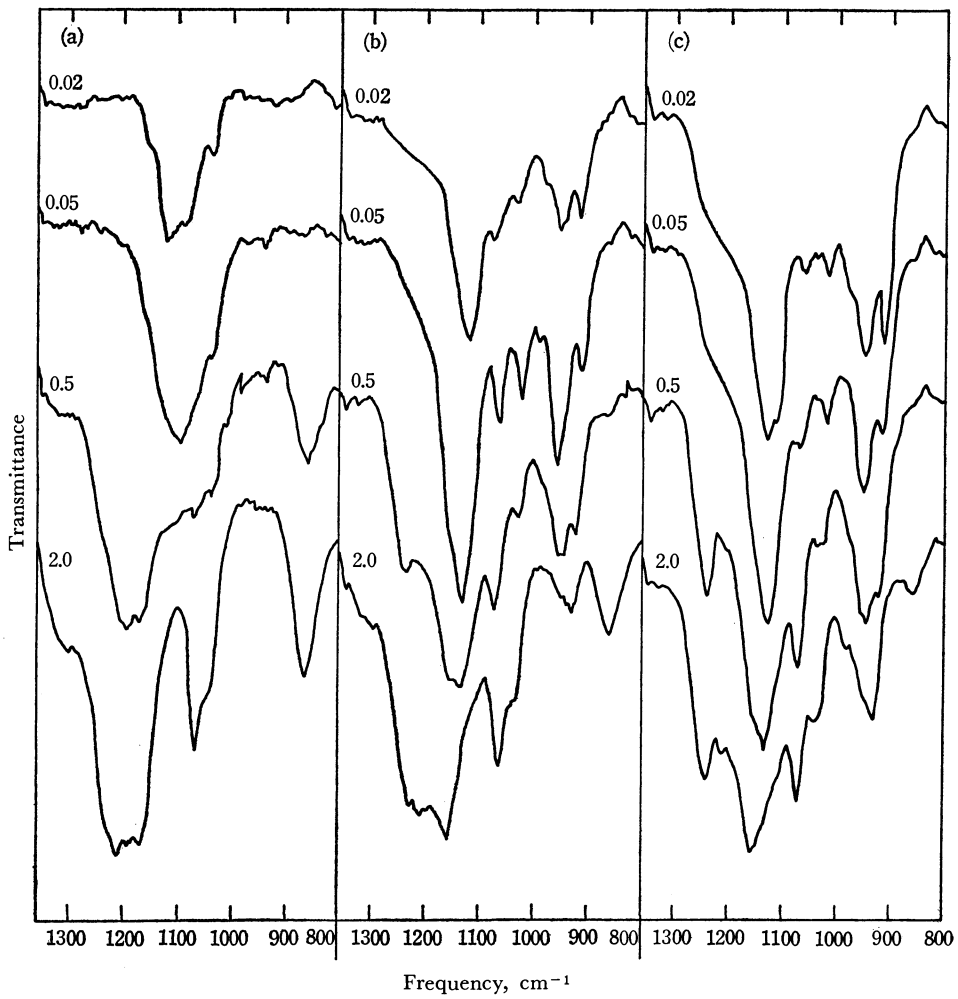

Fig. 6. Infrared spectra of the organic solutions from the extraction of uranium(VI) from sulphuric acid solutions at various concentrations by 0.1 M DOA in benzene.

(c) uranyl sulphate solutions at 25 g/*l*.

sulphate ion[5-7] appear at 1120—1080 and 1038 cm^{-1}, the NH_2^+ stretching vibration[8,9] which indicates the presence of hydrogen-bonding in the broad band centred at 3100 cm^{-1}, and the OH stretching and bending bands at 3560—3380 and 1635 cm^{-1} respectively; for 0.05 M sulphuric acid, the above absorption bands were more intense; for 0.5 M sulphuric acid, the absorptions due to the bisulphate ion[6,7] at 1210—1165, 1070, and 860 cm^{-1} were accompanied, whereas those of the sulphate ion become weaker; for 2.0 M sulphuric acid, the bands of the bisulphate ion show a progressive increase in intensity, and the intensities of the OH bands decrease, corresponding to the result in Fig. 5.

For the spectra in the presence of uranium, the band at 955 cm^{-1} is assigned to the asymmetric stretching frequency of the uranyl group,[10] and the bands at 1130, 1070, 1020 and 915 cm^{-1} to the vibrational frequencies of the sulphato group,[11] indicating a lower symmetry (point group C_{2v} symmetry) than the sulphate ion (point group T_d symmetry), due to covalent bonding to the uranyl ion. At the same time the absorption assigned to the NH_2^+ stretching vibration, which probably indicates the formation of the hydrogen bond in the complex, is observed at 2830 cm^{-1}. These are stronger in the extraction of uranyl sulphate solutions at 25 g/*l*, since the uranium concentration of organic phase is higher than those at 5 g/*l*. At low acidities the absorptions due to the amine-uranyl sulphate complex become stronger with increasing the aqueous acidity because of the increase in the concentration of amine sulphate formed by the extraction of acid, while at higher acidities the absorption bands due to the bisulphate ion appear in addition to the weaker bands of the amine - uranyl sulphate complex. These results closely resemble those for cyclohexyl- and benzyl-alkylamines,[2a,c] and is basically analogous to the cases of TOA and TDA (tri-*n*-dodecylamine).[2b]

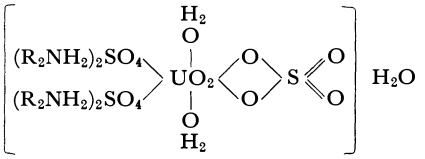
Consequently the following mechanism is proposed for the extraction of uranium(VI) from sulphuric acid solutions by DOA:
at low acidities

$$UO_2SO_4(a) + 2(R_2NH_2)_2SO_4(o) \rightleftarrows [(R_2NH_2)_2SO_4]_2UO_2SO_4(o) \quad (3)$$

and at higher acidities

$$UO_2SO_4(a) + 4(R_2NH_2)HSO_4(o) \rightleftarrows [(R_2NH_2)_2SO_4]_2UO_2SO_4(o) + 2H_2SO_4\ (a)\ . \quad (4)$$

As reported previously,[12] the TOA or TDA-uranyl sulphate complex further shows the absorption assigned to the stretching vibration of the sulphate ion. For the spectrum of the DOA - uranyl sulphate complex, this point is not distinct since the strong band due to the vibration of the sulphato group, co-ordinated to the uranyl ion, at 1130 cm^{-1} overlaps to the absorption assigned to the sulphate ion. However, the organic solution from the extraction of aqueous solution containing 250 g/*l* of uranyl sulphate in 0.05 M sulphuric acid solution with 0.1 M DOA in benzene at 20°C was found to contain uranium: sulphate : amine : water in the mole ratio 1 : 3 : 4 : 3, indicating the stoichiometry to be $(R_2NH_2)_4UO_2(SO_4)_3(OH_2)_3$, *i. e.* $[(R_2NH_2)_2SO_4]_2UO_2SO_4(OH_2)_3$. As this composition resembles the cases of TOA or TDA, it is assumed that the structure similar to the TOA or TDA - uranyl sulphate complex[12] may be given for the DOA - uranyl sulphate complex:



Dependence on Temperature. The extraction of uranyl sulphate solution (5 g/*l*) containing 0.02 and 1.0 M sulphuric acid with 0.1 M DOA in benzene at temperatures between 10 and 50°C gave the result shown in Fig. 7, where the logarithm of the partition coefficient is plotted against the reciprocal of the absolute temperature. This shows that the partition coefficient decreases with rising temperature, and accordingly the heat of reaction (change in enthalpy, kcal/mol) is 4.3 in 0.02 M H_2SO_4 and 4.5 in 1.0 M H_2SO_4.

Effect of Organic Solvent. Table 1 shows the results for various DOA - organic solvent systems in the extraction of uranyl sulphate solutions (5 g/*l*) containing 0.02 and 1.0 M sulphuric acid at 20°C, together with some properties of the solvent (dielectric constant and dipole moment).[13] It is

seen that although the partition coefficient depends markedly on the nature of the diluent, no simple relationship holds between the extraction efficiency of DOA and the physical parameter of organic solvent in these systems. It is presumed, however, that at low aqueous acidity, the extraction efficiency of DOA is enhanced with the diluents which have relative a large dielectric constant such as nitrobenzene and 1, 2-dichloroethane, and contrarily, at high aqueous acidity, these solvents reduce the extraction; at high acidity, carbon tetrachloride gives high extraction efficiency, but chloroform which solvates the amine relatively strongly, presumably through hydrogen-bonding, is not always good extraction medium; halogen substituted aromatic hydrocarbon exhibits considerable good extraction. Similar effect is also observed in the extraction by TOA.[14]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 106—110 (1968)

Diphenyl Sulphoxide Complexes of Lanthanide and Yttrium Perchlorates

S. K. RAMALINGAM and S. SOUNDARARAJAN

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-12, India

(Received May 10, 1967)

Diphenyl sulphoxide complexes of nine lanthanide perchlorates of the general composition $[Ln(DPSO)_6](ClO_4)_3$ where Ln=La, Ce, Pr, Nd, Sm, Gd, Ho and Yb and Y have been synthesised and characterized. Infrared studies indicate coordination through the oxygen atom of the ligand and the retention of the Td symmetry of the perchlorate group. The molar conductance and cryoscopic studies suggest a coordination number of six for the metal ions. Cryoscopic studies in DMSO indicate that DMSO is a better donor than DPSO. DTA and UV data are also presented.

The number of complexes of diphenyl sulphoxide (DPSO) reported in the literature is meagre compared with that of its alkyl analogue *viz.*, dimethyl sulphoxide (DMSO). Apart from the hydrogen-bonding[1,2] and the charge-transfer[3,4] studies involving complexes of DPSO in solution, the solid isolable complexes reported include the Lewis adducts with CdI_2,[5] BCl_3, tin halides,[6] BF_3, antimony halides,[7] Re_3Cl_9[8] and UCl_4,[9] the oxyhalide adducts of Nb and Ta[10]; and some transition and non-transition metal compounds.[11] An attempt to prepare $Hg(ClO_4)_2$ complex failed.[12] We have previously reported the DMSO complexes of some lanthanides.[13,14] It was of interest to investigate the DPSO complexes for two reasons: (i) due to its greater bulk than DMSO, DPSO can restrict the coordination number of the metal ion and (ii) DPSO may present a crystal field different from DMSO on account of the conjugation of its phenyl rings with the sulphoxide group. The present paper describes the isolation and characterization of nine new complexes of DPSO with lanthanide and yttrium perchlorates and the structural studies on them. The perchlorate salts were chosen due to their low anionic contribution to complexation.

Experimental

Materials. DPSO was prepared by the reaction of $SOCl_2$ with dry benzene in presence of anhydrous $AlCl_3$, as described by Shriner, Struck and Jorison.[15] The product was recrystallized from petroleum ether. Mp 71°C.

The hydrated lanthanide perchlorates were prepared from the respective oxides (Lindsey Chemical Co., U. S. A.) by treatment with aqueous perchloric acid (E. Merck).

The solvents, dimethyl formamide (DMF), nitrobenzene, nitromethane and acetonitrile were purified by standard methods.[16] DMSO was dried over CaO and fractionated under reduced pressure.

Preparation of the Complexes. All the complexes were prepared by the following general method. A solution of about 2.3 g of DPSO in 5 m*l* of dry methanol was added dropwise with stirring, to a solution of 1 g of the hydrated metal perchlorate in about 5 m*l* of methanol. The complex precipitated as fine crystals. It was filtered, washed with 2 m*l* of ice-cold methanol and then repeatedly shaken with small amounts of dry CCl_4. The product was filtered and dried in vacuum over P_2O_5 at room temperature. In some cases the complexes were recrystallized from acetonitrile.

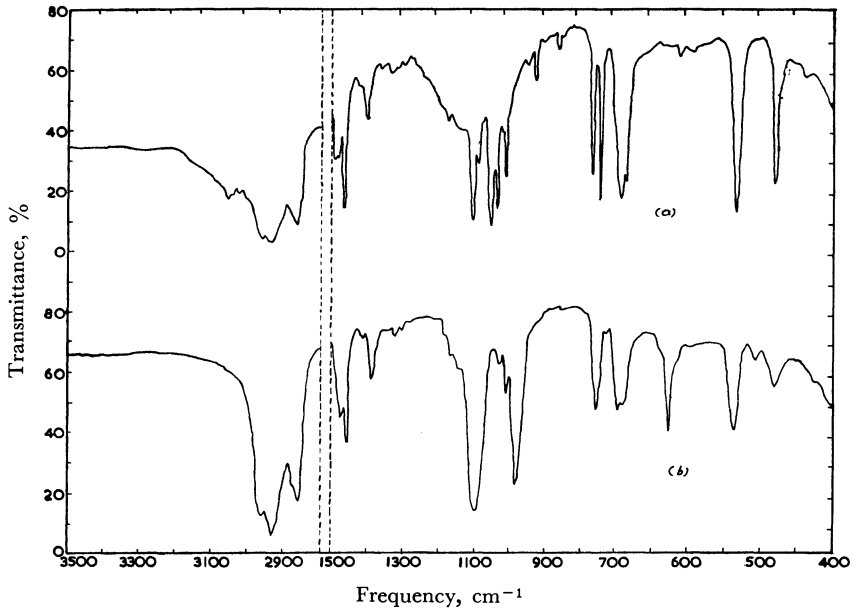

Fig. 1. Infrared spectra of (a) DPSO and (b) $Pr(DPSO)_6(ClO_4)_3$ in Nujol mull.

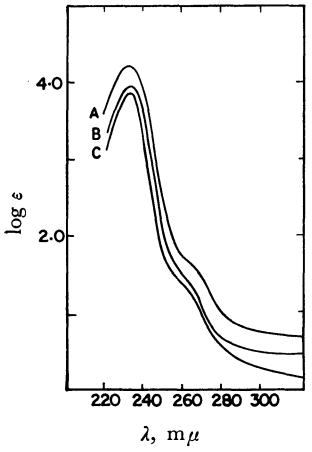

Fig. 2. UV spectra of DPSO (A) and its Pr (B) and Yb (C) complexes in CH_3CN.

Analyses. In the case of the lighter lanthanide complexes, the metal was estimated gravimetrically by the oxalate-oxide method. Y, Ho and Yb were estimated volumetrically by EDTA tritrations using xylenol orange as the indicator.[17] Perchlorate was estimated by the Kurz method.[18] Micro analyses of C, H and S were carried out for some representative complexes through the courtesy of the CIBA Research centre, Bombay. The analytical results along with some physical data are listed in Table 1.

Instrumentation. *Thermal Studies.* Owing to the explosive nature of the complexes, the differential thermal analysis (DTA) was carried out by diluting the complexes with alumina (~1 : 10 by weight). The apparatus employed was of a manual type provided with chromel-alumel thermocouples. The heating rate was 8°±1°C/min. The decomposition temperature is characterized by a sharp exotherm in the DTA profile. The DTA curves for three representative complexes are presented in Fig. 3.

Spectral Studies. The IR spectra of the complexes and of pure DPSO were measured in Nujol mulls in the region 4000—400 cm^{-1} employing Carl Zeiss UR-10 spectrophotometer. Spectral data for a typical case are presented in Table 2. The UV spectra were taken with a Beckman DB-10 recording spectrophotometer. Acetonitrile was used as the solvent and the concentration of the solutions was 10^{-5} M (*vide* Fig. 2).

Conductometric Measurements. The molar conductances of the complexes in various solvents were determined at 30°C in a Siemen's conductivity bridge with an immersion cell (Type LTA), previously calibrated with standard KCl solutions. It had a cell constant of 0.665. The data are given in Table 3.

Molecular Weight Data. These were obtained in nitrobenzene and DMSO using a crysocopic apparatus fitted with a Beckmann thermometer and a mercury-seal stirrer to exclude moistrure. The data are listed in Table 3.

Properties of the Complexes. In contrast to the high deliquescent nature of the lanthanide perchlorates, the complexes are non-hygroscopic. They are insoluble in solvents like CCl_4 and C_6H_6 but are appreciably soluble in acetone, acetonitrile, methanol, nitrobenzene, nitromethane, DMF and DMSO. In water they decompose to precipitate the insoluble ligand part. The colours of the complexes closely resemble those of their parent salts but are less in intensity. Some of the complexes under conditions of continuous evacuation over P_2O_5 develop a brown colour. Many of the physical and chemical data for all the complexes are very similar.

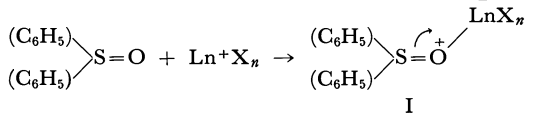
Note: The spectra of the different complexes (in Mulls) are quite similar (within $\pm 2\ cm^{-1}$). Except for the perchlorate bands the other assignments are based on the work of Lappert and Smith.[6]

Discussion

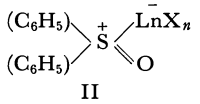
Single-crystal studies on diphenyl sulphoxide[19] have confirmed a pyramidal arrangement of the three bonds about the sulphur atom. With a semipolar S→O linkage and with unshared pairs of electrons on both S and O, it is possible that DPSO can form complexes with metal ions either through O or S atom. Hence it is of interest to determine the site of coordination.

Infrared studies of the complexes (Table 2 and Fig. 1) indicate that the DPSO molecules are bonded through their oxygen atom. This is evidenced by a considerable decrease in the S–O stretching frequency in the complexes ($\sim 60\ cm^{-1}$) compared to that in the free ligand. Such an inference stems from a consideration of the following structures for the complexes, where I represents O bonding and II, S bonding.



I

or



II

Ln is the lanthanide metal ion and X is the anion.

The S–O bond in the sulphoxide may be regarded as substantially, a double bond, with p_π-d_π $(\overset{-}{S}\text{-}\overset{+}{O})$ bonding from oxygen to sulphur, superimposed on the SO σ bond $(\overset{+}{S}\text{-}\overset{-}{O})$. Structure I implies a lengthening of the S–O bond accompanied by a decrease in the p_π-d_π back bonding in the complexes compared with the free ligand. Hence a decrease in S–O stretching frequency would be expected. On the other hand structure II requires an increase in the S–O stretching fundamental. Also the fact that the sulphoxide shift is nearly the same for all the lanthanide complexes studied, indicates that they all have nearly the same stability.

The unsplit IR band at 1096 (vs, bd) and the one at 625 (m) cm^{-1} suggest that the Td symmetry of the ionic perchlorate[20] is retained in the complexes. (Fig. 1)

Note: 10^{-3} M solutions were used for conductance measurements. Λ for 1 : 1 electrolytes in nitromethane (NM),[21] nitrobenzene (NB)[21] and DMSO[22] lie in the range 70—100, 20—30 and ~40 mhos $cm^2 mol^{-1}$ respectively.

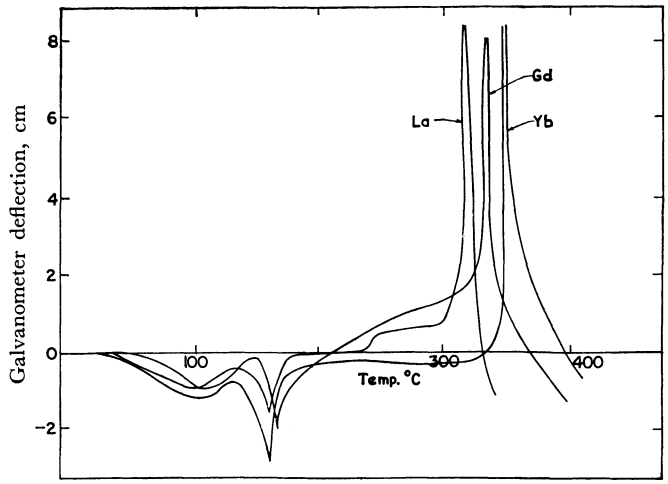

Fig. 3. DTA studies.

donor strengths such as nitromethane, nitrobenzene, acetonitrile and DMSO reveal a uni-trivalent structure for the complexes (see Table 3). Cryoscopic studies in nitrobenzene, a solvent of poor donor properties, show the presence of four species only, suggesting that the DPSO molecules bonded to the metal are not dissociated in solution. In accordance with these observations the complexes

21) M. Cox, J. Lewis and R. S. Nyholm, *J. Chem. Soc.*, **1962**, 2177.
22) P. G. Sears, G. R. Lester and L. R. Dawson, *J. Phys. Chem.*, **60**, 1433 (1956).

can be formulated as $[Ln(DPSO)_6]^{3+}$ $3(ClO_4)^-$, giving a coordination number six for the metal.

However, molecular weight studies of the complexes in DMSO show the presence of ten species, indicating that all the DPSO molecules are displaced from the coordination sphere by the solvent molecules. This implies that of the two ligands DMSO and DPSO, the former is a more powerful donor than the latter with respect to the lanthanide ions. This is probably a consequence of conjugation between the aromatic rings and the sulphoxide group. Hydrogen bonding[1,2] and charge-transfer[4] studies of some complexes of these ligands in solution, have also revealed a similar order of donor strengths for the two ligands.

The UV spectrum of DPSO in acetonitrile exhibits two maxima, one at 228mμ($\log \varepsilon = 4.2$) and the other at 265mμ(inflection) (see Fig. 2). Presumably, the former band is attributable to the absorption arising from the S–O group and the latter to the benzanoid chromophore. In the spectra of the complexes there is no significant shift in the position of either band. In the visible region the complexes were transparent throughout. The limited solubility of the complexes in suitable solvents restricted work on this line.

The DTA studies suggest that the complexes have nearly the same thermal stability. The decomposition temperatures for the different complexes, characterized by sharp exothermic peaks, lie in a close range (315—360°C) (Fig. 3). The small endothermic peak at ~100°C represents the exclusion of any absorbed moisture and the one at 160—190°C represents the melting point of the complexes. The Yb complex heated separately at 350°C, on infrared analysis showed the absence of any perchlorate ion or DPSO.

The physical data, thus suggest a coordination number of six for the lanthanides and yttrium. In many DMSO complexes of the lanthanides[13,14,23] the coordination number has been shown to be eight. Thisreduction in the coordination capacity of the metal ions in the DPSO complexes is presumably due to steric factors.

The authors thank Professor M. R. A. Rao for his keen interest in the work and Professor T. R. Govindachari, Director, CIBA Research Center for microanalytical data.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 110—114 (1968)

Manganese(II) and Mercury(II) Complexes Containing a Thio Derivative of Acetylacetone*1

Akiko FURUHASHI, Kunihiko WATANUKI*2 and Akira OUCHI*2

Department of Chemistry, College of Engineering and Science, Aoyama Gakuin University, Megurisawa Setagaya, Tokyo

(Received June 12, 1967)

New compounds of the type $M(C_5H_7S_2)_2Cl_4$, where M is Mn(II) or Hg(II), were obtained by passing hydrogen chloride and hydrogen sulfide through ethanol solutions containing acetylacetone and metal chlorides. Such adducts seem to be isostructural to iron compounds, and are stable in the solid state. They seem to decompose when brought into contact with such solvents as water, methanol and dimethylformamide. Their magnetic susceptibilities show that these compounds are all bivalent. The infrared spectra and electronic spectra resemble those of the dithioacetylacetonato iron compound.

The dithio derivatives of acetylacetonato complexes are expected to have many interesting properties, but their syntheses were not successful until only recently.

Martin and Stewart[1] have succeeded in synthesizing dithioacetylacetonate of nickel(II), cobalt(II), palladium(II) and platinum(II).

The present authors have investigated the syntheses of the dithioacetylacetonato complex of various other metals, and have come to synthesize

*1 A part of this paper was presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, March, 1967.

*2 College of General Education, University of Tokyo, Komaba, Meguro-ku, Tokyo.

1) L. Martin and I. M. Stewart, *Nature*, **210**, 522 (1966).

a series of $M(C_5H_7S_2)_2Cl_4$ type complexes where M is manganese(II), mercury(II) or iron(II). These compounds are mutually very similar in properties as well as in IR spectra but are a little different from the group of $M(C_5H_7S_2)_2$ complexes where M is nickel(II) or cobalt(II).

Recently Knauer, Hemerich and Van Voorst have published[2] a note about the synthesis of $Fe(C_5H_7S_2)_2Cl_4$. Although we have accomplished our synthesis of the iron complex independently, the compound is exactly the same properties as the one reported by Knauer and others. In this paper, therefore, the syntheses and the properties of the manganese(II) and mercury(II) complexes are mainly reported.

Knauer and others reported in their paper[2] that iron complexes dissociated in aqueous solution into dithiolium ion, ferrous ion and chloride ion. In fact, it is only by assuming the presence of dithiolium unit ($C_5H_7S_2^+$), instead of the usual dithioacetylacetonato unit ($C_5H_7S_2^-$), that the bivalency of iron and the above formula can be reconciled. The merucry and manganese compounds reported in this paper are considered to have similar constitutions.

Experimental

Materials and Instruments. The starting materials were of GR grade and were used without further purification. IR spectra were obtained by the KBr disc procedure using a DS 403G infrared spectrophotometer of the Japan Spectroscopic Co., Ltd. Electronic spectra were obtained with an Hitachi EPS-2 type automatic spectrophotometer.

Syntheses of Dithioacetylacetonato Manganese(II). Three grams of manganese(II) dichloride tetrahydrate (0.015 mol) was dehydrized by direct heating. The anhydrous salt and 3.1 m*l* of acetylacetone (0.030 mol) were dissolved into 30.0 m*l* of absolute ethanol. Hydrogen chloride and then hydrogen sulfide were passed through it. The solution thus obtained was mixed with an equivolume of petroleum ether and kept overnight. Fine yellow crystals were obtained. Yield was about 30%.

The same method as for manganese(II) compounds was effective for the synthesis of the mercury(II) compound from mercury(II) chloride, and for the synthesis of the iron(II) compound from iron(III) chloride hexahydrate. Yields were about 25% and 45% respectively.

All these three compounds are only very slightly soluble in usual organic solvents such as benzene, chloroform and acetone. On the other hand, they are soluble in water, methanol dimethylformamide and dimethylsulfoxide, with probable decomposition. Because of this, their recrystallization has not yet been successful.

Results and Discussion

Analytical data of these compounds are summarized in Table 1. Significant features of the infrared spectra are shown in Table 2, and those of the visible reflection spectra in Fig. 1, both including the data on the iron compound for comparison.

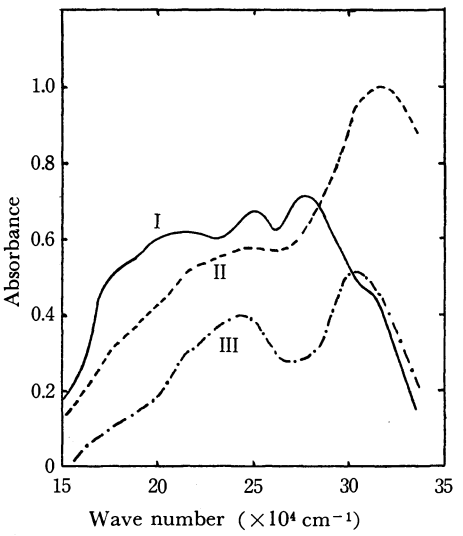

Fig. 1. Reflection spectra of the complexes.
Solid samples were diluted ten times with calcium carbonate (in weight). Reference was calcium carbonate.

* The oxydation of sulfur in this compound is very difficult and alway smaller values were obtained.

The magnetic moment of the manganese compound measured by Gouy's balance is 5.92 B. M. per one mole of metal indicating the existence of 5 unpaired electrons, while the mercury compound is diamagnetic, indicating the absence of any unpaired electron. The iron(II) compound seems to have 4 unpaired electrons, as it shows 4.99 B. M.

per iron atom. These facts show that these compounds have high spin octahedral or tetrahedral structures and not planar or distorted tetragonal ones. This supports the assumption proposed by Knauer and others.[2]

The infrared spectra data for the above compounds are summarized in Table 2 together with those of acetylacetonato-[3] and dithioacetylacetonatonickel(II)[4]. The general feature of the former resembles those of acetylacetonates except some additional special bands. The tentative assignments of many bands were given from the comparison with the acetylacetonates as shown in Table 2.

These compounds show no ν(C=O) band near 1570 cm^{-1} and this fact shows that they do not have any carbonyl oxygens. The ν(C=S) bands of these compounds, containing two dithioacetylacetonate ligand per one metal ion, appear near 1200 and 862 cm^{-1}, but on the other hand those of bisdithioacetylacetonate of nickel(II) and cobalt(II) appear near 1160 and 844 cm^{-1}. In other words, ν(C=S) has about 40—20cm^{-1} higher wave numbers in these tetrachloro compounds. This fact seems to indicate that the C–S bond in these tetrachloro compounds has a more covalent character and the metal-sulfur bond may not be as strong as in nickel or cobalt bisdithioacetylacetonate.

Reflection spectra of these compounds are shown in Fig. 1. Since usual Hg(II), Mn(II), as well as Fe(II) compounds have no marked d–d absorption in this region, the peaks in these spectra should be due to charge transfer, or to π-π transfer bands.

When these compounds are dissolved, they seem to be decomposed, and the spectra of the solutions are not the same as those in the solid state. But the solutions of these compounds, after staying about one hour at room temperature (20°C),

* These spectra should be those of some reaction products of complexes with solvents and may not be the spectra of the complex itself.

show reproducible spectra; the ε in appearance almost follows Beer's law in the concentration region of 10^{-3}—10^{-4} mol/l in the case of visible spectra, and 10^{-4}—10^{-5} mol/l in the case of ultraviolet region. From this fact, decomposition seems to be almost complete in solutions. The maxima and ε's (in appearance) of the main peaks are shown in Table 3.

In aqueous solution these complexes seems to be decomposed into M^{2+}, $(C_5H_7S_2)^+$ and Cl^- (where $M^{2+}=Fe^{2+}$, Mn^{2+} or Hg^{2+}). The color of the aqueous solution is weaker than that of solid or dimethylformamide solution. In the case of the iron complex, the existence of Fe^{2+} was recognized by the formation of bipyridine complex by Knauer and others,[2] and by the formation of *O*-phenanthroline complex in our study. The existence of Cl^- was found by the immediate precipitation of silver chloride by the addition of silver nitrate in our research. The existence of $[C_5H_7S_2]^+$ was proved by Knauer *et al.*[2] by the formation of picrate $C_{11}H_9O_7N_3S_2$. They also assigned the 280 mμ and 265 mμ peaks in aqueous solution to the π-π transition in the dithiolium ring.

The existence of the free dithiolium ion in aqueous solutions of the complex is very interesting, although the dithiolium ions were already reported in many papers.[5-8] They are the planar, benzenoid, heterocyclic, monopositive ions. Such salts as perchlorate or chloride are colorless and stable.

The aqueous solution of Mn(II) and Hg(II) compounds also reacts with silver nitrate and precipitates silver chloride immediately. Moreover, the wave numbers and ε's of the absorption in maxima in the ultraviolet region are very similar to that of the Fe(II) compounds. This fact shows that the aqueous solution of Mn(II) and Hg(II) compounds also contains dithiolium ion.

A complicated solvation phenomenon was found when Mn(II), Hg(II) and Fe(II) complexes are dissolved in dimethylformamide; the solution was violet immediately after the dissolution, but in a few minutes, the color turned yellow at room temperature. If the fresh yellow solution is diluted by more dimethylformamide the color turns blue, but the blue color is very unstable, turning yellow after a while. The old yellow solution does not change its color upon dilution. The values given in Table 3 are those of the final yellow solution.

5) E. Klingsberg, *J. Am. Chem. Soc.*, **83**, 2934 (1961).
6) E. Klingsberg, *J. Org. Chem.*, **31**, 3489 (1966).
7) G. Barinkow and H. Kunzeh, *Z. Chem.*, **6**, 343 (1966).
8) D. Leaver and W. A. H. Robertson, *Proc. Chem. Soc.*, **1960**, 252.

The kinetic approach of the above change has not yet been successful. The mean molecular weight of the species in the dimethylformamide solution of the iron complex was 110 as found by vapor pressure depression measurement, and this fact shows that the iron complex should be split into four or more parts in the solution. By analogy, the Mn(II) and Hg(II) complexes should also be split into several pieces in the solution.

The ultraviolet spectra of all of these compounds in water, methanol and dimethylformamide show two characteristic peaks (Table 3), and they are assigned to the π-π transition of the dithiolium ion ring as in the case of dithiolium derivatives.[5-8]

In the case of the dimethylformamide solution, the maxima of the two peaks in the ultraviolet region shift to lower wave number; 36000, and 28000 cm^{-1}, respectively. This fact may show that in dimethylformamide solution a part of the metal-sulfur bonding structure is kept, although it is not the same as that in the solid state.

It should be noted that a dimer of dithioacetylacetone is also very easily produced when acetylacetone is treated with hydrogen sulfide. This dimer is very stable, not decomposing easily. However, the infrared spectra of the dimer is very different from those of the complexes mentioned above.

In the case of dithioacetylacetonato nickel(II), or cobalt(II), the complexes are easily soluble in a non-polar solvent, but not in water. On the other hand, the complexes of iron, manganese and mercury are hardly soluble in non-polar solvents, and soluble in water (though accompanied by some decomposition). Infrared spectra of complexes of these two types are also different from each other.

From these data it is concluded that the dithioacetylacetone in these complexes does not exist in dimer form, nor in the usual dithioacetylacetonato $[C_5H_7S_2]^-$ form (as found in the nickel complex). Knauer and other's assumption[2] of the existence of dithiolium ion in it thus seems to be the most reasonable one. They have suggested two hypothetical formulae; (a) $FeCl_2(C_5H_7S_2)^{2+}Cl_2^-$, (b) $FeCl_2[CH_3(Cl)CS\,CH\,CS\,CH_3(Cl)]_2^0$ to explain the intense color of the solid iron complex. However, there seems to be still several other possibilities. The X-ray study which is going on by the present authors is expected to clarify this point. The manganese, and mercury complexes probably have the same type of structure.

The authors wish to thank to the Analytical Division of the Department of Pharmacy, The University of Tokyo for their elemental analyses of these compounds as well as for the measurement of infrared spectra; we also acknowledge Professor Yukichi Yoshino and the colleagues of our laboratory for helpful discussions.

A part of this research was carried out with a Scientific Research Grant from the Ministry of Education to which the authors' thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 115—119 (1968)

The Chemistry of Protactinium. VI. A Study of the Sulfato-Complex of Pa(IV) by Means of TTA-Benzene Extraction

Toshikazu MITSUJI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira-cho, Sendai

(Received July 4, 1967)

The behavior of Pa(IV) during extraction with TTA was investigated in perchlorate, chloride, and sulfate solutions (pH 0.4—1.1). In perchlorate and chloride solutions, the extraction equilibrium may be written as:

$$Pa(OH)_2^{2+} + 4HT \rightleftharpoons PaT_4 + 2H_2O + 2H^+$$

On the other hand, the extraction by TTA from the sulfate solution may be described as:

$$Pa(SO_4)(OH)^+ + 4HT \rightleftharpoons PaT_4 + HSO_4^- + H_2O + 2H^+$$

Therefore, the formation of the sulfato-complex of Pa(IV) is considered to occur as follows:

$$Pa(OH)_2^{2+} + HSO_4^- \rightleftharpoons Pa(SO_4)(OH)^+ + H_2O$$

The equilibrium constant for the above reaction has been determined to be 320 at the ionic strength of 0.50 (temperature: 10±0.5°C).

Guillaumont investigated the distribution of Pa(IV) between the perchlorate solution with the ionic strength of 3 and the TTA-benzene solution, and reported that Pa^{4+} gradually hydrolyzed to $Pa(OH)_3^+$ over the pH range from −0.5 to 3.0.[1] The same author also studied chloro-, sulfato-, and fluoro-complexes in aqueous solutions and calculated their stability constants at the ionic strength of 3.[2] In these papers, however, the experimental data were not reported in detail.

Two points have chiefly prevented the investigators from studying the behavior of Pa(IV) by using the ^{233}Pa tracer. One is the difficult reduction of Pa(V) in microquantities, and the other is the lack of a method to identify Pa(IV) in microquantities. In the foregoing paper, however, the present author showed that the ^{233}Pa(V) tracer was readily reduced by means of a liquid zinc amalgam in the presence of more than 10^{-4} M of Cr(III) and proposed that the co-precipitation with thorium fluoride gave an excellent method identifing of Pa(IV) in microquantities.[3]

The present author has also investigated the absorption spectra of Pa(IV) and inferred that the sulfato-complexes of Pa(IV) exist even in a dilute sulfuric acid solution, but that Pa(IV) is then reluctant to form chloro-complexes.[4] In this study, the sulfato-complex of Pa(IV) was investigated in detail by means of TTA-benzene extraction, after confirming the valency state of protactinium by the thorium fluoride co-precipitation method.

Experimental

Reagents. ^{231}Pa and ^{233}Pa were prepared by the method reported by Suzuki and Inoue.[5] All the reagents used were of the highest purity. Water was purified by distillation, followed by ion exchange treatment. Benzene was purified by distillation.

Apparatus. A reduction apparatus described earlier[4] was used for both reduction and extraction. The solvent extraction was carried out on a Iwaki universal mechanical shaker, Model V-S. The radioactivity was measured by means of a Kobe Kogyo well-type scintillation counter.

Procedure. The experimental procedures were as follows, unless otherwise noted. Pa(V) was reduced by means of a liquid zinc amalgam in the presence of 10^{-2} M Cr(III), as has been described in a previous report.[4] After the liquid zinc amalgam has been removed from the cell, the solvent extraction was carried out on a mechanical shaker for 25 min. The initial volumes of both the organic and the aqueous phases were 5.0 *ml*. The organic phase was pre-equilibrated by contact with its opposite. After the two phases had completely separated, an aliquot of each phase was transferred into a polyethylene test tube and its γ-radioactivity counted. The distribution ratio (D) was calculated by the following equation:

$$D = \frac{\gamma\text{-activity per ml of the organic phase}}{\gamma\text{-activity per ml of the aqeous phase}}$$

The concentration of protactinium was 10^{-7} M, and the ionic strength was kept constant at 0.50 throughout this experiment. The hydrogen ion concentration of

the aqueous phase in equilibrium was determined by titration with the standard sodium hydroxide solution.

Results

The Confirmation of the Valency State of Protactinium. The protactinium which had been extracted into the benzene phase was back-extracted into the aqueous phase and then subjected to the thorium fluoride method described in a foregoing paper.[3] More than 95% of protactinium was always co-precipitated with thorium fluoride. This means that protactinium remains tetravalent during solvent extraction.

Solvent Extraction from Perchlorate and Chloride Solutions. The TTA extraction of Pa(IV) was first carried out in a perchlorate solution as a non-complexing solvent. The relationship between the TTA concentration and the distribution ratio was examined in 0.37 M perchloric acid. As is shown in Fig. 1, the log-log plot of the distribution ratio and the TTA concentration shows a good linearity, with a slope of 4.

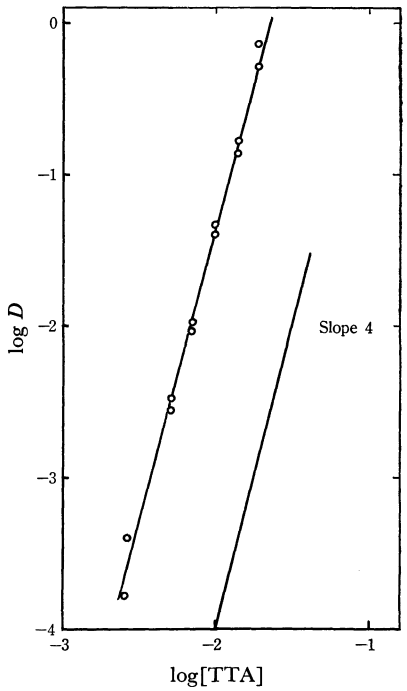

Fig. 1. Relationship between log D and log[TTA], 0.37 M $HClO_4$.

The effect of the hydrogen ion concentration on the extraction was examined by using a 10^{-2} M TTA-benzene solution. As Fig. 2 shows, the relationship between log D and $-\log[H^+]$ is linear, with a slope of 2, over the $-\log[H^+]$ range from 0.4 to 1.1.

The same experiments were also carried out in a chloride solution. The acid dependency of the distribution ratio was found to be second-power, as Fig. 3 shows.

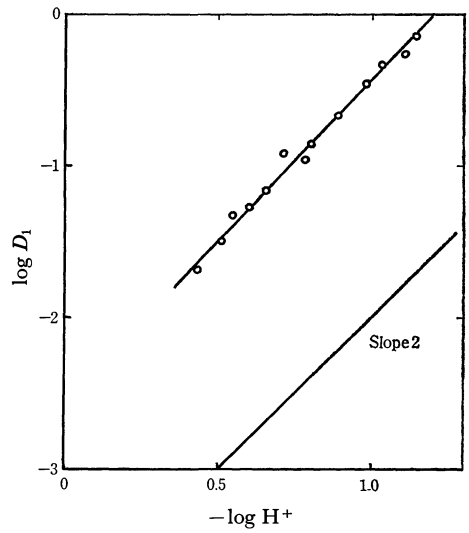

Fig. 2. Dependence of log D_1 on $-\log[H^+]$ in the extraction from perchlorate solution.

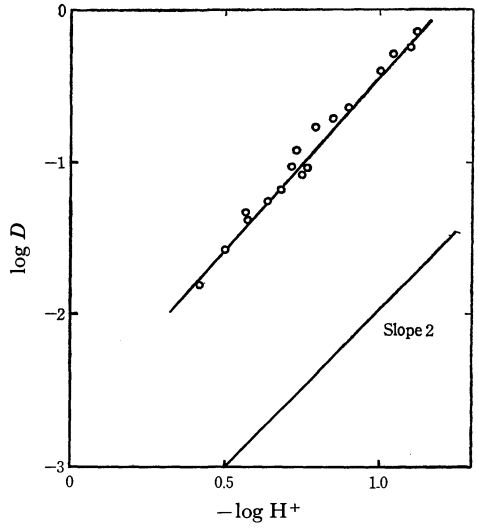

Fig. 3. Dependence of log D on $-\log[H^+]$ in the extraction from chloride solution.

Solvent Extraction from Sulfate Solution. To confirm the existence of sulfato-complexes of Pa(IV), solvent extraction was performed in a sulfate solution. The relationship between the TTA concentration and the distribution ratio was examined in 0.24 M sulfuric acid. The plot of the logarithm of the distribution ratio against the logarithm of the TTA concentration shows a linear relationship, with a slope of 4 (Fig. 4).

The relation of log D *versus* $-\log[H^+]$ was also investigated at a TTA concentration of 10^{-2} M. Figure 5 shows the linear relationship between them, with a slope of 2.

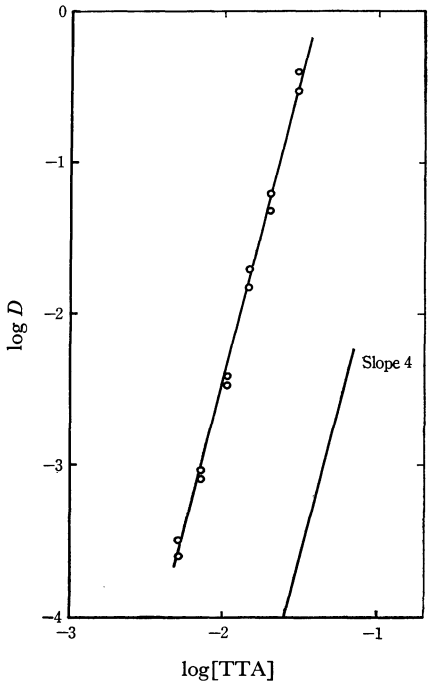

Fig. 4. Relationship between log D and log[TTA], 0.24 M H_2SO_4.

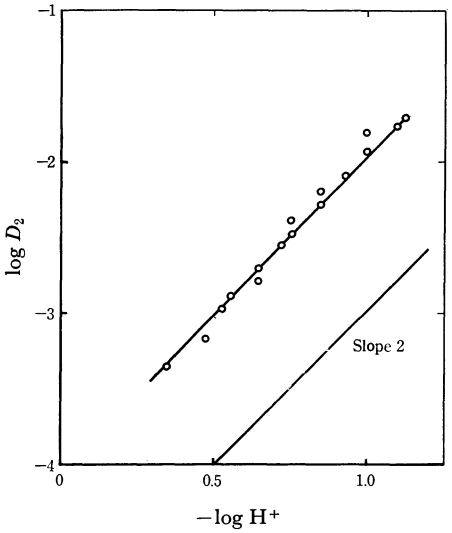

Fig. 5. Dependence of log D_2 on $-\log[H^+]$ in the extraction from sulfate solution.

Discussion

If the species extractable into the organic phase are considered to be non-charged, the general equation for the TTA extraction of Pa(IV) from the perchlorate solution can be written as follows:

$$Pa(OH)_m^{(4-m)+} + 4HT \rightleftharpoons PaT_4 + mH_2O + (4-m)H^+ \quad (1)$$

where HT represents the TTA molecule and T, the enolate ion of TTA.

If the activity coefficients of all the species are assumed to be constant, the equilibrium constant, k_1, can be defined as:

$$k_1 = \frac{[PaT_4][H_2O]^m[H^+]^{(4-m)}}{[Pa(OH)_m^{(4-m)+}][HT]^4} \quad (2)$$

where square brackets are used to represent the concentration of the relevant species.

Supposing only one kind of protactinium species exists in the aqueous solution, the distribution ratio can be defined as follows:

$$D_1 = \frac{[PaT_4]}{[Pa(OH)_m^{(4-m)+}]} \quad (3)$$

As the solvent extraction was performed at a constant temperature and with a constant TTA concentration, both k_1 and HT are constant. Under these conditions, the following equation is obtained by substituting Eq. (2) into Eq. (3) and taking the logarithm:

$$\log D_1 = -(4-m)\log[H^+] + \text{const.} \quad (4)$$

As may be seen in Fig. 2, the slope of the log-D_1—log $[H^+]$ plot is minus 2; that is, $(4-m)$ is equal to 2. Therefore, the protactinium species in the perchlorate solution may be in the form of $Pa(OH)_2^{2+}$ over the $-\log[H^+]$ range studied; one can then describe the extraction reaction as:

$$Pa(OH)_2^{2+} + 4HT \rightleftharpoons PaT_4 + 2H_2O + 2H^+ \quad (1')$$

This finding is in agreement with the finding of Guillaumont.[1]

On the other hand, the D-values in the extraction from the chloride solution were almost equal to the corresponding D-values in the extraction from the perchlorate solution. Therefore, Pa(IV) is probably reluctant to form chloro-complexes in dilute hydrochloric acid and may be predominantly in the form of $Pa(OH)_2^{2+}$ in the acidity range studied. This finding is in good agreement with the finding of the absorption spectroscopy undertaken by the present author.[3]

The general equation for the TTA extraction of Pa(IV) from a sulfate solution can be expressed as:

$$Pa(SO_4)_n(OH)_m^{(4-2n-m)+} + 4HT \rightleftharpoons PaT_4 + nHSO_4^- + mH_2O + (4-m-n)H^+ \quad (5)$$

The extraction constant k_2 equals:

$$\frac{[PaT_4][HSO_4^-]^n[H_2O]^m[H^+]^{(4-m-n)}}{[Pa(SO_4)_n(OH)_m^{(4-2n-m)+}][HT]^4} \quad (6)$$

On the assumption that only one kind of protactinium species is predominant in dilute sulfuric acid, the distribution ratio can be expressed as:

$$D_2 = \frac{[PaT_4]}{[Pa(SO_4)_n(OH)_m^{(4-2n-m)+}]} \quad (7)$$

By substituting Eq. (6) into Eq. (7), and by taking the logarithm, the following equation is obtained, provided both k_2 and HT are constant:

$$\log D_2 = -n\log [HSO_4^-] - (4-m-n)\log [H^+] + \text{cost.} \quad (8)$$

Let us now consider the dissociation of H_2SO_4. As H_2SO_4 is a strong acid, it is completely dissociated to HSO_4^- or SO_4^{2-} in a dilute aqueous solution.

$$HSO_4^- \rightleftharpoons SO_4^{2-} + H^+ \quad (9)$$

$$K = \frac{[SO_4^{2-}][H^+]}{[HSO_4^-]} \quad (10)$$

As pK is equal to 2.0,[6] Eq. (10) may be rewritten as follows:

$$\log \frac{[HSO_4^-]}{[SO_4^{2-}]} = 2 + \log [H^+] \quad (11)$$

When $-\log [H^+]$ is varied from 0.5 to 1.0, the ratio of $[HSO_4^-]$ to $[SO_4^{2-}]$ changes from about 32 to 10. Therefore, all the sulfuric acid is considered to be present as HSO_4^- over the entire $-\log [H^+]$ range studied. This, in turn, results in a constant concentration of HSO_4^-, regardless of the acidity. Hence, Eq. 8 may be rewritten as follows:

$$\log D_2 = -(4-m-n)\log [H^+] + \text{const.} \quad (8')$$

The coefficient of the first term of this equation, $-(4-m-n)$, should be 2, as is shown in Fig. 5; that is, $m+n=2$. Therefore, the possible protactinium species in a sulfuric acid solution are:

1) $m=0$, $n=2$, $Pa(SO_4)_2$
2) $m=1$, $n=1$, $Pa(SO_4)(OH)^+$
3) $m=2$, $n=0$, $Pa(OH)_2^{2+}$

It is unlikely that no change species such as $Pa(SO_4)_2$ is extracted into the benzene phase by TTA. It is also clear from Fig. 5 and Fig. 2 that the sulfato-complex of Pa(IV) exists. Therefore, the most probable ionic species may be considered to be $Pa(SO_4)(OH)^+$; Eq. (5) then becomes:

$$Pa(SO_4)(OH)^+ + 4HT \rightleftharpoons PaT_4 + HSO_4^- + H_2O + 2H^+ \quad (5')$$

The formation of the sulfato-complex of Pa(IV) can be expressed as:

$$Pa(OH)_2^{2+} + HSO_4^- \rightleftharpoons Pa(SO_4)(OH)^+ + H_2O \quad (12)$$

In the above equation, the equilibrium constant, k_3, may be defined as:

$$k_3 = \frac{[Pa(SO_4)(OH)^+][H_2O]}{[Pa(OH)_2^{2+}][HSO_4^-]} \quad (13)$$

6) G. Charlot, "L'analyse qualitative et les reactions en solution," Masson et Cie, Parris (1957).

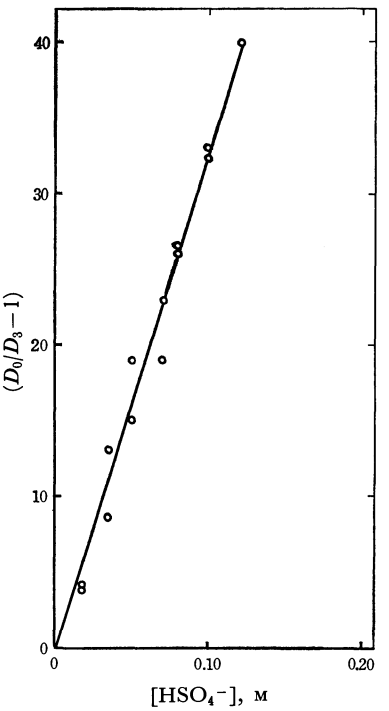

Fig. 6. Relationship between (D_0/D_3-1) and $[HSO_4^-]$ at pH of 0.50.

Since the extracted species from both the perchlorate solution and the sulfate solution is PaT_4, and since the protactinium species in the perchlorate solution and the sulfate solution are $Pa(OH)_2^{2+}$ and $Pa(SO_4)(OH)^+$ at a pH value of 0.5, the distribution ratio in various mixtures of perchlorate solutions and sulfate solutions at a constant pH can be defined as:

$$D_3 = \frac{[PaT_4]}{[Pa(OH)_2^{2+}] + [Pa(SO_4)(OH)^+]} \quad (14)$$

By substituting Eq. (13) into Eq. (14) and by rearranging, the following equation is introduced:

$$D_0/D_3 - 1 = k_3[HSO_4^-] \quad (15)$$

where D_0 represents the distribution ratio in the absence of the complexing anion, HSO_4^-. The relationship between (D_0/D_3-1) and $[HSO_4^-]$ was examined at the pH value of 0.50 and at 10°C. As is shown in Fig. 6, the plot of (D_0/D_3-1) *versus* the concentration of sulfate ions has a straight line, with a slope of 320. This supports finding that $Pa(SO_4)(OH)^+$ exists; the equilibrium constant, k_3, was determined to be 320 from the slope of the straight line.

Summary

1) The TTA extraction behavior of Pa(IV) was investigated in perchloric, hydrochloric, and sulfuric acid solutions (pH 0.4—1.1).

2) $Pa(OH)_2^{2+}$ was the most probable ionic species in the perchlorate solution, and the extraction reaction was considered tobe:

$$Pa(OH)_2^{2+} + 4HT \leftrightharpoons PaT_4 + 2H_2O + 2H^+$$

3) Pa(IV) was reluctant to form the chlorocomplexes and was considered to be in the form of $Pa(OH)_2^{2+}$ in the dilute hydrochloric acid solution.

4) $Pa(SO_4)(OH)^+$ was the most probable ionic species in the sulfuric acid solution. The extraction reaction into the benzene phase was considered to proceed as follows:

$$Pa(SO_4)(OH)^+ + 4HT \rightleftharpoons PaT_4 + HSO_4^- + H_2O + 2H^+$$

5) In the sulfuric acid solution used as a complexing agent, the following complexing reaction was considered to take place:

$$Pa(OH)_2^{2+} + HSO_4^- \rightleftharpoons Pa(SO_4)(OH)^+ + H_2O$$

and its equilibrium constant was determined to be 320 at the ionic strength of 0.50 (temperature 10 ± 0.5°C).

This author wishes to thank Professor Hidehiro Goto, Professor Shin Suzuki, and Dr. Yasushi Inoue for their kind and valuable advice throughout this study. A part of the expense has been defrayed by a grant-in-aid from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 119—126 (1968)

Effect of the Counter-Electrode Material on the Emission Spectrochemical Determination of Silicon and Manganese in Steel

Takanori SUZUKI*1 and Tomihito KAMBARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 10, 1967)

The line intensities of Si and Mn appear much more strongly in the spectrochemical analysis of high-carbon low-alloy steels when a low-voltage spark is employed. Considering the change in the line intensity with the time under various excitation conditions with graphite and zinc counter-electrodes, the present authors have established an improved method for the spectrochemical determination of Si and Mn. The effect of the heat-treatment on the metallurgical structure has been investigated by means of an electron-probe microanalyzer, and the results compared with the spectrochemical data.

The accuracy of an emission spectrochemical determination is influenced by many factors, such as the fractional distillation, the excitation conditions, self-absorption, and third-element effects. These complicated factors are generally called the matrix effect, which has been discussed in many articles.[1-5] In the analysis of iron and steel, one must also take metallurgical hysteresis and the structure of the specimen into consideration. Several investigations dealing with the matrix effects in special steels[6-11] have been reported, and solution methods[12-13] and powder

methods[14-16] have both been proposed in order to overcome the above-mentioned difficulties.

The results of the spectrochemical determination of silicon and manganese in high-carbon low-alloy steel have now been found to depend remarkably on the metallurgical structure. In the present study the excitation conditions for a more accurate determination will be examined.

Experimental

Apparatus. A direct-reading Quantorecorder (GQ-220) and an Ebert-mounting grating spectrograph (GE-340), both made by Shimadzu, were employed. The spark was generated by means of a multisource Feussner equipment. In the photographic measurement of line intensities, a microphotometer was used. The electron-probe microanalyzer was a product of the Japan Electron Optics Laboratory (Nihon Denshi), type JXA-304.

Electrodes. The steel specimens were used as the plane self-electrodes. As the counter-electrodes we employed graphite rods, 6 mm in diameter and 120° in cone angle, and zinc rods, 5 mm in diameter and 80° in cone angle, prepared by casting metal 99.9% pure.

Excitation Conditions. Six conditions were chosen for the determination of silicon and manganese; they are listed in Table 1.

Analytical Lines. The characteristics of the spectral lines utilized for the quantitative analysis are listed in Table 2. All the manipulations were done according to the Japanese Industrial Standards.[17]

Table 2. Analytical lines

Results and Discussion

Results Obtained with the Direct-reading Quantorecorder. Quenched and annealed specimens of five steel samples were analyzed spectrochemically for several elements by means of the working curves prepared for routine analysis with a series of BCS standard steels. The results are tabulated in Table 3. The results of the standard chemical analysis are given in Table 4 for comparison.

It can be seen that the spectrochemical results for nickel, chromium, copper, and molybdenum agree well with the values obtained by the standard chemical analysis. However, remarkable positive deviations were found for silicon and manganese, especially with the quenched specimens. In the LVS excitation with a graphite counter-electrode it was found that the spark did not focus well. The change in the line intensities with the time was measured by changing the presparking time, as is shown in Fig. 1. Both silicon and manganese always showed stronger intensities than the theoretical values throughout the 360-sec presparking time. When a zinc rod was used as the counter-electrode, the intensities of not only silicon and

manganese but also of iron decreased considerably.

Since the annealed specimen behaves differently from the quenched specimen, it may be supposed that the change in metallurgical structure has caused a matrix effect.

Figures 2, 3, and 4 show the changes in the spectral line intensities with the time under the excitation conditions of HVS 1 and 2, listed in Table 1. With HVS 1 the Fe 2714 Å line intensity is stable, but the lines of silicon and manganese fluctuate, as Fig. 2 shows. Figures 3 and 4 obviously show that the spectral lines of the three elements show stable intensities after 3 min. Thus, it may be safe to say that the interference by the metallurgical structure can well be eliminated under the HVS 2 excitation condition.

Results Obtained with the Ebert-mounting Spectrograph. The intensity ratios for iron-silicon and iron-manganese couples were measured, with varying presparking times, under the excitation conditions of HVS 3, 4, and 5. The results are illustrated in Figs. 5, 6, and 7 respectively. With a graphite counter-electrode, the stabilization of the line intensity ratio takes about 3 min, while with a zinc electrode the persistent and stable intensity ratio can be attained within 2 min.

Measurement of the Spark Temperature. Let us now discuss the ionization equilibrium in the gas phase on the basis of the famous Saha equation.[18] Provided that the light source is thermally equilibrated, one has for the radiation intensity, I, of a spectral line the following expression:[1-5]

$$I = A\boldsymbol{h}\nu N_0 \cdot \frac{g}{g_0} \cdot \exp\left(\frac{-E}{\boldsymbol{k}T}\right) \qquad (1)$$

Here, A is the transition probability; ν, the frequency of the spectral line; N_0, the number of atoms or ions in the ground state; g and g_0, the statistical weights for the activated and ground states respectively and E, the excitation potential, while $\boldsymbol{h}$, $\boldsymbol{k}$, and T have their usual significances. In the Gerlach internal standard method, therefore, the two line intensities, I_1 and I_2, of two elements are related by:

TABLE 4. RESULTS OBTAINED BY THE STANDARD CHEMICAL ANALYSES

Sample No.	Si, %	Mn, %	Ni, %	Cr, %	Cu, %	Mo, %	C, %
1	0.40	0.95	0.15	1.05	0.19	0.38	1.20
2	0.41	0.76	0.29	1.10	0.12	0.32	1.21
3	0.55	0.99	0.15	1.05	0.14	0.38	1.42
4	0.36	0.88	0.10	1.00	0.14	0.34	1.17
5	0.54	0.96	0.13	0.97	0.12	0.33	1.37

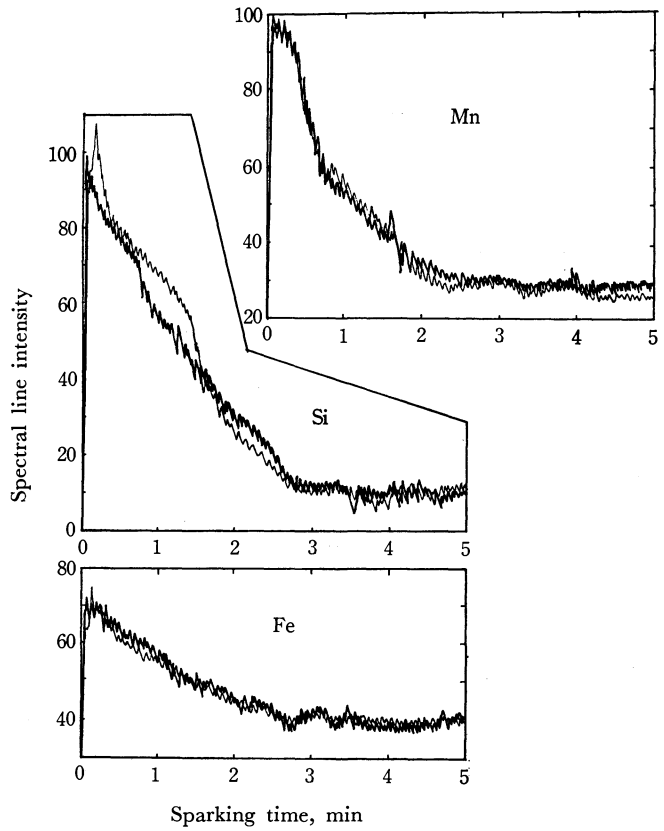

Fig. 3. Change of line intensity. Excitation condition HVS 2 with a graphite counter-electrode. Others are the same as in Fig. 2.

$$\frac{I_1}{I_2} = \text{const} \cdot \frac{N_1}{N_2} \cdot \exp\left\{\frac{-(E_1-E_2)}{kT}\right\} \qquad (2)$$

If the two excitation potentials, E_1 and E_2, differ a little, the ratio of line intensities should be proportional to the ratio of the amounts of the two elements.

Several authors[19-21] have reported on the spark temperature as measured by the intensity ratio method. As Ornstein[21] has shown, by taking the logarithm of Eq. (1), one derives:

$$\log \frac{I}{\nu g A} = \log \frac{N_0 h}{g_0} - \frac{0.625}{T} E' \qquad (3)$$

Here E' is the excitation energy expressed in cm^{-1}. From the slope of the plot of $\log (I/\nu g A)$ against E', we can estimate the light source temperature, as is shown in Fig. 8. The numerical values utilized are listed in Table 5.

A small deviation from linearity is seen in Fig. 8, but such a tendency has already been reported by Shimazu.[19] The estimated temperatures are listed in Table 1.

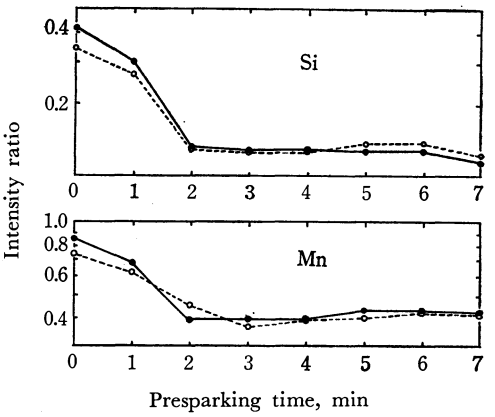

Fig. 6. Change of intensity ratio with time. Excitation condition HVS 4. Others are the same as in Fig. 5.

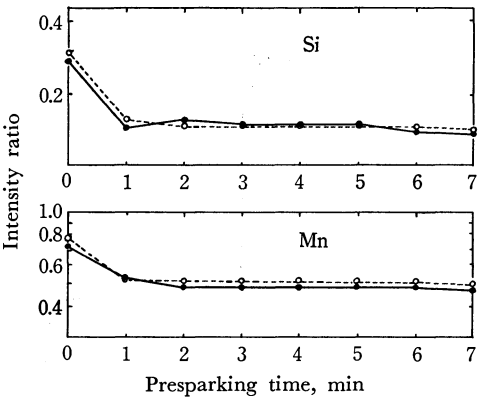

Fig. 7. Change of intensity ratio with time. Excitation condition HVS 5. Others are the same as in Fig. 5.

Metallurgical Structure. The structure of high-carbon low-alloy steel varies with different heat treatments. Figure 9 shows microscopic pictures of this. In many cases cementite appears in a net-structure at the boundaries of the austenite and surrounds the pearlite. Whether silicon and manganese are distributed uniformly or locally was investigated with the aid of an X-ray micro-analyzer. As Fig. 10 shows, it can be concluded that manganese is enriched a little in the cementite phase (from 0.95 to 1.06%) but is depleted in pearlite (from 0.95 to 0.71%). As to the other elements, such as silicon, nickel, chromium, and molybdenum, no appreciable segregation is observed.

Discharge Crater. The property of a spark may be judged by the discharge crater remaining on the iron plane electrode surface. The craters observed on the various counter-electrode materials are shown in Fig. 11. It was found that, with the

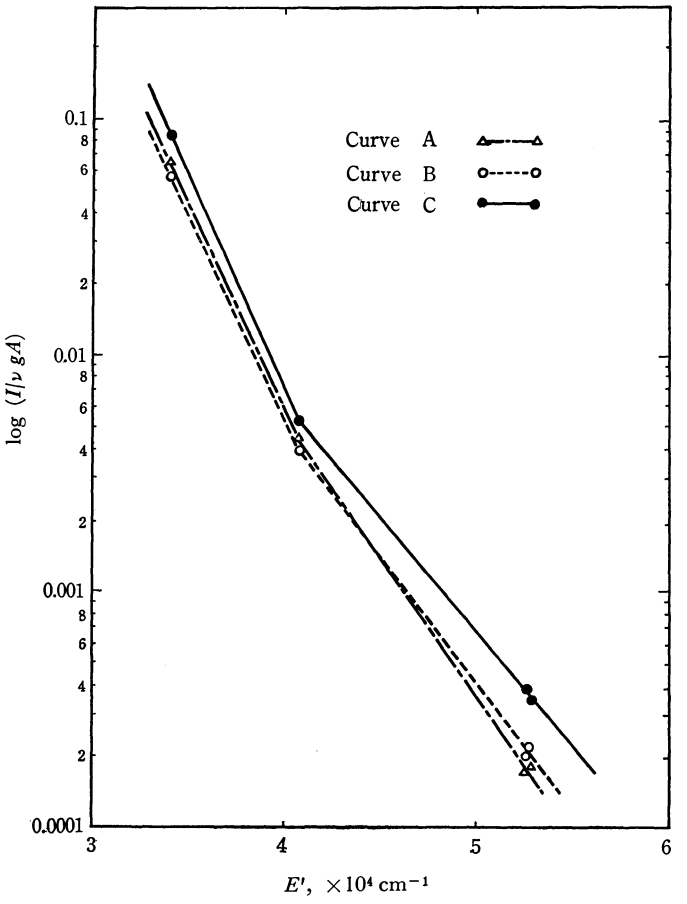

Fig. 8. log $(I/\nu gA)$ plotted against E'. Curve A HVS 3, B HVS 4 and C HVS 5.

zinc electrode, the spark plasma was stable and well-focused. With the graphite electrode, however, the spark tended to dance and to be diffuse. As Table 1 shows, with the zinc electrode the temperature became about 800°K higher than with graphite (HVS 4 and 5).

As for the other electrode materials, with silver the spark does not focus well in the atmospheric environment, while with magnesium, as Fig. 11 shows, although a well-focused and stable spark is attained, the strong lines of Mg 2802, 2928, 2936, and 3092 Å strongly interfere with the determination.

Improved Method of Determination. From the above experimental results, it can be expected that, under the excitation conditions of HVS 2 and 5, one may obtain better determination data than under the conditions of LVS, HVS 1, 3, and 4. Utilizing the series of BCS standard steels, the calibration curves for HVS 2 and 5 were prepared, with which the determination of silicon and manganese was then carried out. The results are tabulated in Tables 6 and 7.

The deviation of the results of the analysis by

the spectrochemical method from the results obtained by the standard chemical analysis is treated statistically. The familiar Student t test has already been applied to test the difference between the means obtained by the two methods in a number of analyses of specimens differing in their composition.[22]

The results of the t tests are tabulated in Table 8. The distinct deviations of the silicon and manganese determinations by LVS from the data obtained by the standard chemical analyses are obviously much improved by applying HVS 5, only the silicon determination still showing a significant difference. Under the strong excitation conditions with HVS 2, the observed t_0-value being less than the t-value in the table, no difference between the means can be seen at the significant level of 5%.

TABLE 8. THE t TESTS

Conclusion

The remarkable positive deviation in the determination data of silicon and manganese in high-carbon low-alloy steel when analyses are carried out under low-voltage excitation conditions is due to the matrix effect caused by the differences in the volatilization rate and the degree of ionization or excitation in the spark plasma, *etc.* The metallurgical structure of the sample steel clearly affects the analytical results. The application of the high-voltage spark with a zinc counter-electrode results in a much stronger excitation and permits an accurate determination to be made, that is not interferred with by the metallurgical structure.

The authors wish to express their heartfelt thanks to Drs. Shimoda and Maekawa of the Japan Steel Works, Muroran, Dr. Matsumae of the Government Industrial Development Laboratory-Hokkaido, and Professors Niwa and Matsubara and Dr. Kasamatsu of Hokkaido University for their kind help and support throughout this study.

Spectrophotometric Study of Metal Chelates of Eriochrom Black T (BT). II. Solution Equilibria between BT and Lead(II)-Nitrilotriacetate (NTA) or Cadmium(II)-*N'*-(Hydroxyethyl)-ethylenediamine-*N*, *N*, *N'*-triacetate (EDTA-OH)

Mutsuo KODAMA and Chifumi SASAKI

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received July 12, 1967)

The solution equilibria between BT and lead(II)-NTA or cadmium(II)-EDTA-OH chelates were studied spectrophotometrically, and the composition and the stability constants of the BT chelates of these metal ions were determined. In the presence of an excess amount of NTA or EDTA-OH, lead(II) and cadmium(II) ions join with BT to form a chelate with a 1-to-1 composition. The magnitude of the stability constants ($10^{13.19}$ and $10^{12.74}$ respectively, $\mu=0.30$) can explain satisfactorily the well-known experimental fact that BT can be used as a metallochromic indicator in Pb(II)- and Cd(II)-EDTA titrations.

In a previous paper,[1] the stability constants of the zinc(II)- and copper(II)-BT chelates with a 1-to-1 composition were determined by measuring spectrophotometrically the concentration of uncomplexed and complexed BT, which are in equilibrium with the chelon (NTA or EDTA-OH) and its metal chelates in the solution.

In this paper, the results of a spectrophotometric study of the solution equilibria between BT and the lead(II)-nitrilotriacetate or cadmium(II)-EDTA-OH chelate and of a determination of the compositions and the stability constants of the BT chelates of these metal ions will be presented.

From the viewpoint of the chemical equilibrium, a theoretical consideration of the use of BT as a metallochromic indicator in the EDTA titrations of lead(II)[2] and cadmium(II)[3] will also be presented.

Lead(II) and cadmium(II) ions were found to form exclusively chelates with a 1-to-1 composition with BT in the presence of an excess of NTA or EDTA-OH, the magnitude of their stability constants can successfully explain the well-known fact that BT dye is a useful indicator in the EDTA titrations of lead(II) and cadmium(II) and fulfills the titrimetric requirements theoretically expected.

Experimental

Apparatus and Procedure. The apparatus (spectrophotometer and pH meter) and the experimental procedure employed were the same as have been described previously.[1]

Reagents. Commercial Eriochrom Black T (BT) was purified by the procedure proposed by Diehl and Lindstrom.[4] The way of preparing the standard solution of cadmium(II) perchlorate was described in the previous paper.[1] The concentration of the cadmium(II) solution was determined by EDTA titration, using BT as an indicator.[3] A standard solution of lead(II) was prepared by dissolving a known amount of pure lead(II) nitrate (analytical-reagent grade) into redistilled water. The concentration was standardized against a standard CyDTA solution.[5] The preparation and the standardization of nitrilotriacetic acid (NTA) have been described previously.[1] Reagent grade *N'*-(hydroxyethyl)ethylenediamine-*N*, *N*, *N'*-triacetic acid (EDTA-OH) recrystallized from water was used. The concentration of its solution was standardized against a standard copper(II) solution by titration using murexide as an indicator.

All the other chemicals used were of an analytical-reagent grade, and all the absorption and pH measurements were conducted on solution with an ionic strength of 0.30 with sodium perchlorate.

Results and Discussion

Determination of Stability Constants of Lead(II)- and Cadmium(II) Chelates of BT. The solution equilibria between BT and the lead(II)-NTA or cadmium(II)-EDTA-OH chelate were studied over the pH range from 8.50 to 10.50. In this pH range, the solution containing free NTA or EDTA-OH is considered to have a buffer capacity sufficient to keep the pH value

** The complete displacement of NTA from its chelate by BT and the formation of CdD^- were confirmed by the present authors.

of the solution constant. For this reason, no other buffer reagent was used in this study.

The absorption spectra of uncomplexed and complexed BT were given in Fig. 1. These absorption spectra clearly suggest that the concentrations of BT and its chelates can be determined successfully by measuring the absorbancy at the wavelength of either 630 or 640 mμ.

Lead(II) ion has been reported to form only a 1-to-1 chelate, PbZ^-, with NTA under usual experimental conditions.[6] The cadmium(II) ion also forms exclusively chelate with a 1-to-1 composition with EDTA-OH.[7] Therefore, under the present pH conditions, the chemical equilibrium between BT and lead(II)-NTA or cadmium(II)-EDTA-OH can be written as follows:

$$HD^{2-} + MZ^{2-n} = MD^- + Z^{n-} + H^+ \quad (1)$$

where Z^{n-} refers to completely-dissociated chelon species.

For this equilibrium, thermodynamically Eq. (2) can be derived as in the case of the Cu(II)-CyDTA-BT system.[1]

$$\log\frac{A_D - A}{A - A_{MD}} = \log\frac{K_{MD}\cdot(\alpha_H)_z}{K_{MZ}\cdot(\alpha_H)_{BT}} + \log\frac{[MZ]_t}{[Z]_f} \quad (2)$$

The symbols used in Eq. (2) have the same meanings as those used in the previous paper.[1]

When the following equilibrium becomes important;

$$HD^{2-} + MZ^{2-n} = MDZ^{2-(n+3)} + H^+ \quad (3)$$

the (4) relation can be assumed in place of (2).

$$\log\frac{A_D - A}{A - A_{MD}} = \log\frac{K^{MZ}_{MDZ}}{(\alpha_H)_{BT}} + \log[MZ]_t \quad (4)$$

The above relations indicate that when MD^- is formed, only the plot of $\log(A_D-A)/(A-A_{MD})$ against $\log([MZ]_t/[Z]_f)$ can give a straight line with a slope of unity, but when the chemical equilibrium (3) becomes important, the plot of $\log(A_D-A)/(A-A_{MD})$ *vs.* $\log[MZ]_t$ yields a straight line with a slope of unity.

The experimental data obtained for lead(II)-NTA and cadmium(II)-EDTA-OH systems under the conditions where uncomplexed and complexed chelons are present in a large excess over BT were analyzed with the aid of Eqs. (2) and (4). Typical examples are shown in Figs. 2 and 3. In both systems, under the experimental conditions employed, only the plot of $\log(A_D-A)/(A-A_{MD})$ against $\log([MZ]_t/[Z]_f)$ gave a straight line with a slope of unity, indicating the formation of the normal chelate, MD^-.

$[Z]_f$) is zero. The numerical values for EDTA-OH,[8] its cadmium(II) chelate,[7] and the lead(II)-NTA chelate[6] used in the calclations are listed in Table 1, along with the dissociation constants of BT.[9] These values were calculated in ways which have been described previously.[1] The dissociation constants of NTA used in the calculation have also been given previously.[1]

Theoretical Considerations of the Use of BT as an Indicator in the Lead(II)- and Cadmium(II)-EDTA Titrations. Reilley and Schmid[10] have proposed a simple but quantitative method for the rapid prediction of the optimum titration conditions. Provided that the concentration of the indicator is negligibly small and the degree of contrast between the colors of the indicator before and after the end point is large enough, the sharpness of an end point can be characterized simply by two numbers, Δ_1 and Δ_2, defined as follows.

$$\Delta_1 = \log K_{MD} - \log(\alpha_H)_{BT} + \log C_M - \log \beta_{MX} \quad (5)$$

$$\Delta_2 = \log K_{MY} + \log(\alpha_H)_{BT} - \log K_{MD} - \log(\alpha_H)_Y \quad (6)$$

Here, Δ_1 is a measure of the tightness of the metal-indicator complex and Δ_2, of the extent to which the chelon displaces the indicator fromithe metal-indicator complex.

To obtain the end point exactly, it is necessary that both Δ_1 and Δ_2 are greater than 3.0. Here, however, Δ values larger than 4.0 gives no practical improvement.

BT has been reported to have been used successfully as an indicator in the EDTA titrations of lead(II) ion in solutions of tartrate[2] and of cadmium(II) ions in an ammonia buffer[3] at pH values from 8.0 to 10.0. In the EDTA titration of lead(II), when the initial concentration of lead(II) is 1.00×10^{-2} M, the Δ_1 and Δ_2 values defined by Eqs. (5) and (6) were calculated to be 7.07 and 5.28 respectively, using the K_{PbD} value, the dissociation constants of BT[4] and tartaric acid,[11] and the stability constants of lead(II)-tartrate[12] and of the lead(II)-EDTA chelate.[13] Although the

Table 3. The titration of Pb(II) ion in the alanine solution of pH 8.50 with EDTA

The concentration of alanine is 0.10 M.

i) The concentrations of EDTA and Pb(II) are 10.0 mM.

V_{Pb}, m*l*	V_{EDTA} added, m*l*
5.00	5.02
10.00	10.00

ii) The concentrations of EDTA and Pb(II) are 1.00 mM.

V_{Pb}, m*l*	V_{EDTA} added, m*l*
5.00	4.96
10.00	9.90

stability and dissociation constants under varying titration conditions differ by several tenths of the pK unit from the literature values, the above results of the calculations can satisfactorily explain the well-known observations reported by Flaschka *et al.*[2]

For 1.00×10^{-2} M Pb(II) ions in a 0.10 M alanine solution of pH 8.50, the Δ_1 and Δ_2 values can be calculated as 4.82 and 5.55 respectively, using the numerical values for alanine and its complexes[14] given in Table 2. This clearly suggests that Pb(II) ions in a 0.10 M alanine solution of pH 8.50 can be successfully titrated with EDTA, using BT as a metallochromic indicator. The demonstrative results of the titrations shown in Table 3 can be regarded as satisfactory.

In the case of Cd(II)-EDTA titration, the Δ_1 and Δ_2 values (5.87 and 4.15 respectively) calculated for 1.00×10^{-2} M cadmium(II) and 0.10 M ammonia by using the above-determined K_{CdD} value and the numerical values[13,16] given in Table 2 can be considered to have a magnitude which can explain well the facts given by Schwarzenbach *et al.*[13]

From the facts obtained and the theoretical discussion given above, it can be safely concluded that reasonable K_{PbD} and K_{CdD} values have been determined.

The present authors wish to thank the Ministry of Education for the financial support given to this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 130—135 (1968)

The Partial Resolution of Racemic α-Alanine through the Cobalt(III) Complexes of Optically Active Aspartic or Glutamic Acid*1

Muraji SHIBATA, Hiroaki NISHIKAWA and Kinya HOSAKA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received July 20, 1967)

When a hundred per cent excess of racemic α-alanine was reacted, in the presence of activated charcoal, with a reaction mixture of tricarbonatocobaltate(III) and L-asparate, water-insoluble β-tris(alaninato)cobalt(III) was precipitated. The recovery of alanine from this triscomplex showed a partial resolution; the D form of alanine was preferentially complexed, and the optical purity of the alanine recovered was about 38%. Spectroscopic measurements (absorption, ORD and CD) showed that the predominantly-existing species in the above reaction mixture was the (−)-$[Co\ CO_3(L\text{-asp})_2]^{3-}$ anion, and that the reaction of this complex anion with racemic alanine led to the predominant formation of β(−)-$[Co(D\text{-ala})_2(L\text{-ala})]$ (the (−) sign refers to the sign of the Cotton effect in the first absorption band region). Similar experiments were carried out with D-aspartate and L-glutamate in place of L-aspartate. Through all the experiments, we have found that the complexes which are effective for the resolution of racemic alanine and the product or tris(alaninato)cobalt(III) have the same sign of the Cotton effect in their first-band regions.

Gott and Bailar[1] first reported that when the carbonatobis(levo-propylenediamine)cobalt(III) cation was treated with a racemic organic acid, the dextro form of the acid entered the coordination sphere of the complex more readily than the levo form. By means of this preferential coordina-

*1 Presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.

1) A. D. Gott and J. C. Bailar, Jr., *J. Am. Chem. Soc.*, **74**, 4820 (1952).

tion of one of the active forms, Sarma and Bailar[2] resolved propylenedimaine, tartaric acid, and α-alanine; the resolutions of racemic alanine attained through the L-tartratocopper(II) complex and copper(II) L-glutamate were 3.8 and 3.3% respectively.

Later, we reported in a short paper[3] that the same amino acid was more effectively resolved by the use of a cobalt(III) complex with L-aspartate (about 30%). Incidentally, the resolution of DL-aspartic acid by the utilization of copper(II) chelates of D- or L-alanine, *etc.*, has been reported by Harada.[4] The present paper is an augmentation of the previous one;[3] it will report further investigations of the partial resolution of α-alanine. In addition to the cobalt(III) complexes of L- or D-aspartic acid, those of L-glutamic acid were also used as a material that effects the resolution. We found a correlation between the active form of alanine preferentially coordinated and the configuration of the cobalt(III) complexes.

Experimental

Resolution through the Complexes of L(or D)-Aspartic Acid. *Procedure 1.* Throughout the procedures described below, "the green solution" of tricarbonatocobaltate(III) was first prepared as a stock for the preparation of aspartato or glutamato complexes. A cold mixture of an aqueous solution (about 20 m*l*) containing cobalt chloride hexahydrate (6.0 g, 0.025 mol) and 30% hydrogen peroxide (10 m*l*, excess) was added, drop by drop, to an ice-cooled slurry of potassium bicarbonate (17.5 g, 0.175 mol) in water (18 m*l*); the resulting green solution was then stirred for a few minutes further in the cold.

Monopotassium L(or D)-aspartate (8.6 g, 0.050 mol) was added to the green solution, and the mixture was stirred at 60°C for 5 hr, whereupon the color of the solution became red-violet. A hundred per sent excess of racemic α-alanine (13.5 g, 0.150 mol) was added to the above solution, and the mixture was adjusted to pH 9.5—10 with an aqueous solution of potassium hydroxide. After the addition of activated charcoal (2 g), the solution was stirred at about 50°C for 2 hr, whereby the β(cis-cis)-complex of tris(alaninato)-cobalt(III) was precipitated. The complex was collected with the charcoal and washed thoroughly with hot water and ethanol, and then ether. After dyring, this material was suspended in hot dilute aqueous ammonia and treated with hydrogen sulfide to decompose the complex. After the removal of the cobalt sulfide by filtration, the filtrate was concentrated to a small volume under reduced pressure. When the concentrate became turbid, it was clarified by filtering it with a small amount of activated charcoal. Acetone was added in the cold to the final clear concentrate to recover alanine. A 5% solution of this alanine in 1 N hydrochloric acid was used for the measurement of the optical rotation at the sodium-D line. The percentage of the resolution or the "optical purity" was represented by the quotient of the observed specific rotation divided by the value for pure L-alanine ($[\alpha]_D=14.47$).

Alanine recovered in the case of the L-aspartato complex, 3.0 g, 3.0 g; $[\alpha]_D=-5.62$, -5.52; optical purity, 38.8%, 38.1%.

Alanine recovered in the case of the D-aspartato complex, 2.8 g; $[\alpha]_D=5.60$; optical purity, 38.7%.

In order to isolate the complex existing in the reaction mixture of tricarbonatocobaltate(III) and L-aspartate, we prepared the same solution, neutralized it with dilute acetic acid, and then added a large amount of methanol. A red-violet material precipitated, but it was very hygroscopic (it probably was potassium salt). Therefore, it was treated with an aqueous solution of silver nitrate to produce a less soluble silver salt.

Found: C, 13.65; H, 1.94; N, 3.65%. Calcd for $Ag_3[CoCO_3(C_4H_5NO_4)_2]\cdot 4H_2O$; C, 13.91; H, 2.33; N, 3.60%.

Thus, it was assumed that the predominant complex in the reaction mixture was the carbonatobis(L-aspartato)cobaltate(III) anion.

Procedure 2. The reaction mixture mentioned above was prepared with L-aspartate, and the mixture was once acidified with dilute acetic acid in order to decompose all of its carbonate ions. The resulting solution was then adjusted to pH 10 with dilute potassium hydroxide. This was treated with racemic alanine under the same conditions as have been described in Procedure 1.

Alanine recovered, 2.6 g; $[\alpha]_D=-5.91$; optical purity, 40.8%.

Procedure 3. A little higher resolution was attained by a slight alteration of Procedure 1, *i. e.*, the amount of L-aspartate was increased (12.1 g, 0.075 mol). Tricarbonatocobaltate(III) was reacted with aspartate in the presence of activated charcoal (0.5 g) at room temperature for 2 hr. Thereafter, the process was the same as has been described in Procedure 1.

Alanine recovered, 1.9 g, 1.8 g; $[\alpha]_D=-6.45$, -6.34; optical purity, 44.5%, 43.8%.

Procedure 4. Recently, we reported the isolation of the four isomers of trihydrogen tris(L-aspartato)-cobaltate(III).[5] By the use of solubility differences depending on the pH values, the α(+)-, α(−)-, β(+)- and β(−)-isomers were obtained from a reaction mixture of tricarbonatocobaltate(III) and L-aspartate. The fourth procedure concerns these isomers.

A certain amount (0.025 mol) of each isomer was dissolved in a very diluted aqueous solution of potassium hydroxide. Racemic alanine was then added to this solution, and the mixture was adjusted to pH 9.5—10. In the presence of activated charcoal (2 g), the mixture was stirred at 50°C for 2 hr. It was found that only one isomer of the four, α(−), produced a precipitate of water-insoluble β-tris(alaninato)cobalt(III).

Alanine recovered, 4.3 g; $[\alpha]_D=-4.47$; optical purity, 30.0%.

Resolution through the Cobalt(III) Complexes of L-Glutamic Acid. Except for the use of L-glutamate in place of L (or D)-aspartate, the same procedure was followed. Monopotassium L-glutamate (9.3 g,

5) M. Shibata, H. Nishikawa and K. Hosaka, This Bulletin, **40**, 236 (1967).

0.05 mol) was added to a tricarbonatocobaltate(III) solution, and the mixture was stirred at 60°C for 5 hr. The resulting red-violet solution was treated with racemic alanine.

Alanine recovered, 4.3 g, 4.3 g; $[\alpha]_D = -2.60$, -2.75; optical purity, 18.0%, 19.0%.

In the manner of Procedure 1, a carbonato complex was isolated as a silver salt.

Found: C, 15.97; H, 2.48; N, 3.83%. Calcd for $Ag_3[CoCO_3(C_5H_7NO_4)_2]\cdot 4H_2O$: C, 16.42; H, 2.73; N, 3.48%.

A higher percentage of resolution was obtained by a procedure similar to Procedure 2.

Alanine recovered, 3.6 g, 3.0 g; $[\alpha]_D = -4.33$, -4.38; optical purity, 29.9%, 30.3%.

Instrumental Measurements. Optical rotations at the Na-D line were measured with a Yanagimoto Model OR-20 photo-magnetic direct-reading polarimeter at room temperature. The absorption, optical rotatory dispersion (ORD), and circular dichroism (CD) spectra were all measured on a Jasco Model UV-5 optical rotatory dispersion recorder with a CD attachment. X-Ray powder patterns were taken with a Rigaku-denki Geigerflex, using a Co-target.

Results and Discussion

On the Reaction. A distinctive feature of the reactions which we adopted for the partial resolution of alanine is that the water-insoluble β-tris(alaninato)cobalt(III) precipitates from the reaction mixture of the asparatato (or glutamato) complex and racemic alanine. For this precipitation reaction, the presence of activated charcoal is an indispensable condition. The amount of charcoal influenced the yield and the optical purity of the recovered alanine. A series of experiments were carried out according to the previously-described procedure;[3] when the amounts of the charcoal were 0.4, 2.0, 4.0 and 6.0 g, the yields of alanine were 2.3, 3.4, 2.9 and 2.4 g, and the optical purities were 13.8, 33.5, 38.0 and 34.1%, respectively. Consequently, it may be assumed that activated charcoal is necessary for both the reactions of ligand exchange and preferential coordination. In the present experiments, 2.0 g of charcoal were used for easier handling and for a higher recovery of alanine. In our previous paper,[3] we reported that the co-existence of cellulose powder with activated charcoal increases the percentage of resolution. We now believe that not only the cellulose, but also the charcoal plays an effective role in the preferential coordination of one active form of racemic alanine.

On the Mechanism. Although the mechanism of the present reaction has not yet been clarified, there seems to be a certain correlation between the active form of alanine preferentially complexed and the configuration of the cobalt(III) complex that effects this resolution. Recently, several workers reported the isolation of the possible geometrical-optical isomers of tris(L- or D-alaninato)-cobalt(III).[6-8] They stated that one of the four isomers of [Co(L or D-ala)$_3$], the β(+)- or the β(−)-isomer, was completely insoluble in water (the (+) and (−) signs refer to the sign of the Cotton effect in the first absorption band region). If this solubility property holds in our reaction product, it must be a non-equimolar mixture of the β(−) and β(+) isomers. In this respect, the CD spectrum of the product obtained by Procedure 1 is compared with that of β(+)-[Co(L-ala)$_3$] under the same conditions (in 50% H_2SO_4) (Fig. 1). The two spectra differ considerably in the intensity of the first CD peaks, $\Delta\varepsilon = -1.27$ (or $+1.27$) for the product and $\Delta\varepsilon = -1.00$ for the [Co(L-ala)$_3$]. This fact suggests that the product concerned is not a mixture of the β(−) and β(+) isomers, and that the formation

of such a mixed-ligand isomer as β(− or +)-[Co(D- or L-ala)$_2$(L- or D-ala)] must be considered. In order to ascertain whether or not the product is such a mixture, the X-ray powder patterns of the reaction product and of β(+)-[Co(L-ala)$_3$] were compared (Fig. 2). The two patterns are

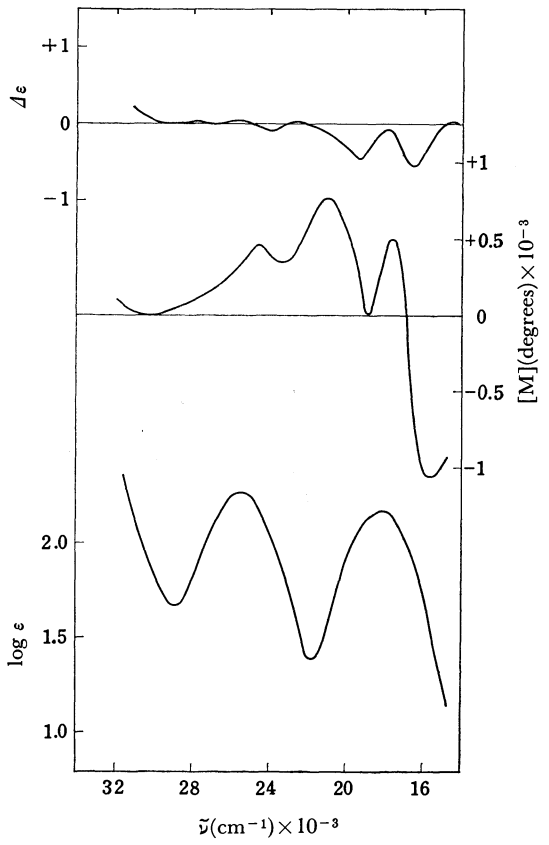

Fig. 5. Absorption, ORD and CD curves for $[CoCO_3(L\text{-glu})_2]^{3-}$ in N NaCl.

similar, but are not identical with each other. By the way, the pattern for the reaction product obtained by the use of D-asparatate was identical with that for the product obtained by the use of L-aspartate (Fig. 2(a)). Very recently, we[9] have prepared $\beta(+)$-$[Co(L\text{-ala})_2(D\text{-ala})]$ by the reaction of $[Co(L\text{-ala})_2CO_3]^-$ with D-alanine; the $\Delta\varepsilon$ value was found to be 1.33.

Next, let us discuss the configuration of the complexes containing optically active aspartate or glutamate anions. The absorption, ORD, and CD spectra for carbonatobis(L- or D-aspartato)-cobaltate(III) are given in Figs. 3 and 4, while Fig. 5 gives the data for the corresponding glutamato complex. For these complexes, three geometrical isomers are possible, *i. e.*, (a) *cis(N)-cis(O)*, (b) *cis(N)-trans(O)* and (c) *trans(N)-cis(O)*. Among these, the possibility of (c) may be excluded because of the non-splitting of the first absorption band. Matsuoka *et al.*[10] have recently reported that the *trans(N)* isomer of the oxalatobis(glycinato) cobaltate(III) complex shows a splitting of the first band.

The carbonato complex with L-aspartate anions shows a distinctive negative Cotton effect in the region of the first band. The complex with D-aspartate anions shows a distinctive positive Cotton effect. These facts indicate the predominance of the (−)- or (+)-isomer in the reaction mixture of tricarbonatocobaltate(III) and L- or D-aspartate. On the other hand, the corresponding carbonato complex with L-glutamate ions has a somewhat complicated ORD and CD spectra, although the sign of the CD is unchanged (negative).

Figure 6 shows the absorption, ORD, and CD spectra of $\alpha(-)$-$[Co(L\text{-asp})_3]^{3-}$ in water. The ORD and CD spectra show a distinctive negative Cotton effect in the region of the first band. Thus, we may generalize that the complexes which are effective for the resolution of racemic alanine and the reaction product have the same sign of the Cotton effect in the first band region. An X-ray study[11] has shown that the absolute configuration of $\alpha(+)$-$[Co(L\text{-ala})_3]$ is

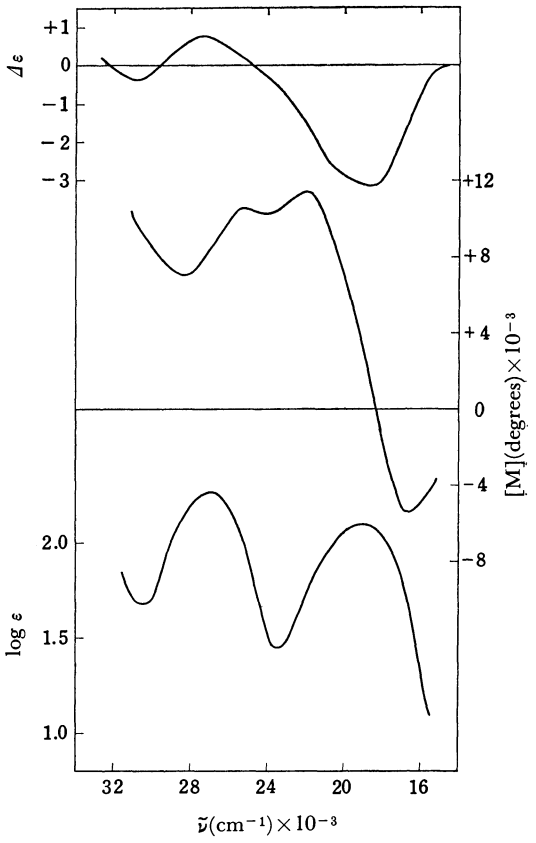

Fig. 6. Absorption, ORD and CD curves for $\alpha(-)$-$[Co(L\text{-asp})_3]^{3-}$ in water.

9) M. Shibata, H. Nishikawa and Y. Nishida, *Inorg. Chem.*, in contribution.

11) M. G. B. Drew, J. H. Dunlop, R. D. Gillard and D. Rogers, *Chem. Commun.*, 42 (1966).

$\Delta(C_2)$; hence, that of the corresponding $\alpha(-)$-isomer is $\Lambda(C_2)$. From this the present $\alpha(-)$-$[Co(L\text{-asp})_3]^{3-}$ may be identified as $\Lambda(C_2)$. The configuration of the carbonato complex of L or D-aspartic acid would also be Λ or $\Delta(C_2)$. Thus, it may be concluded that the Λ(or Δ) (C_2)-complex reacts with racemic alanine to produce the predominant formation of the β-Λ (or Δ)-isomer of DDL(or LLD)-tris(alaninato)cobalt(III). The fact that the $\alpha(+)$-isomer of tris(L-aspartato)cobaltate-(III) does not participate in the formation of the insoluble product may be due to the inertness of the isomer for a ligand-exchange reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 135—139 (1968)

Glass Transition Temperature and Isothermal Volume Change of Selenium

Shuichi HAMADA, Tadao SATO and Toshiaki SHIRAI

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received July 14, 1967)

The viscoelastic behavior of selenium and of partially-chlorinated selenium was studied by the dilatometric method. The glass transition temperature, T_g, of selenium was determined to be 32.0°C at a cooling rate of 0.2°C/min. The glass transition temperature decreased linearly with the reciprocal of the average chain length of selenium. The chain length was calculated using the degree of chlorination. An abrupt increase in T_g was observed at a chlorine content of about 0.013%. The volume-time curves obtained by the determination of the volume of selenium in the neighborhood of T_g were superposed on each other by sliding them along the abscissa. The values of the shift factor and of T_g fit well in Williams, Landel and Ferry's equation. The parameters in the WLF equation, C_1^g and C_2^g, of selenium were calculated to be 6.86 and 28.6 respectively. Both the parameters increased with an increase in the chlorine content up to 0.0125%, and reached the values of usual polymers above 0.0125%. The WLF f_g value of selenium was calculated to be 6.33×10^{-2}. This value decreased with an increase in the chlorine content, and reached the universal value of usual polymers (2.5×10^{-2}) when the chlorine content was more than 0.0125%. The chlorine content corresponds to 0.0125% when all the radicals at both ends of the linear chain molecules of selenium have been used in forming bonds with chlorine atoms. Therefore, it may be concluded that the existence of radicals at the molecular ends of selenium chains brings about an augmentation of the fraction of the free volume at T_g.

Amorphous selenium is considered to be a mixture of Se_8 ring molecules and long chains.[1] The properties of amorphous selenium should be governed by those of the long-chain molecules, since the content of the ring molecules in amorphous selenium has been estimated to be only 0.22 wt% at 230°C.[2] The number of selenium atoms in a chain of average length was calculated to be 7200 at 230°C by the thermodynamic theory developed by Eisenberg and Tobolsky.[1] This result agreed with that obtained by Shirai and Hamada by means of measurements of the viscosity of molten selenium.[3] The linear chains may be considered to be diradical molecules with an unpaired electron at each end of the chains. The presence of radicals in amorphous selenium was reported by Abdullaev *et al.*[4] and by Sampath *et al.*[5] on the basis of their ESR studies. Sampath[6] reported that the results obtained by Eisenberg and Tobolsky, and by Shirai and Hamada were supported by the value of the spin concentration in amorphous selenium.

In our work, the viscoelastic behavior of amorphous selenium was investigated by the method of isothermal volume contraction, similar to Kovacs' measurments of organic polymers.[7] Moreover,

the effect of radicals on the viscoelastic behavior of amorphous selenium was studied.

Experimental

Materials. The selenium was obtained from the Yokozawa Chemical Company; the guaranteed purity was more than 99.999%. The sample of amorphous selenium was prepared by quenching the molten selenium; the selenium was heated in an electric furnace at 230°C for 1 hr, then dropped in cold water and dried in a cooled vacuum dessicator. Chlorinated selenium was prepared by the method described in a previous paper.[8] The sample of chlorinated selenium was prepared by the same method which was used in preparing the amorphous selenium. The chlorine content in the chlorinated selenium was determined by the colorimetric method described in the previous paper.

Procedure. The glass transition temperatures, T_g, of the selenium and of the chlorinated selenium were estimated by the dilatometric method. A specimen of about 7 g of the amorphous selenium was sealed in a dilatometer containing about 62 g of mercury. The capillary was 0.726 mm in diameter and about 250 mm long. The height of the meniscus of mercury in the capillary was measured, using a measuring microscope, to the accuracy of 1/100 mm. The dilatometer was kept at 50°C for 30 min to establish the thermal equilibrium; then it was allowed to cool slowly at a cooling rate of 0.2°C/min. The glass transition temperature of the amorphous selenium was estimated graphically from the specific volume-temperature relationship.

The isothermal volume contraction phenomena of the amorphous selenium were also studied by the dilatometric method. The dilatometer was first kept at 50°C for 30 min; then it was quickly immersed into a water bath kept at a specified temperature in the neighborhood of T_g. The accuracy of the temperature was about ±0.1°C. The change in the height of the mercury column in the capillary was followed against the time in which the dilatometer had been immersed in the water bath.

Results

The Glass Transition Temperature of the Selenium. Figure 1 shows the specific volume-temperature relationship of the selenium when the specimen was cooled at a rate of 0.2°C/min. This relation was similar to those of usual organic polymers. The glass transition temperature of the selenium was estimated graphically to be 32.0°C at the cooling rate studied. This value was nearly equal to that obtained by Tammann and Kohlhaas (31°C).[9] The value of T_g was reproducible. It is well known that T_g depends on the rate of cooling. The glass transition temperature of selenium was also governed by the time scale of the measurement.[10,11] In the present work, therefore, the cooling rate of the specimen was kept at 0.2°C/min.

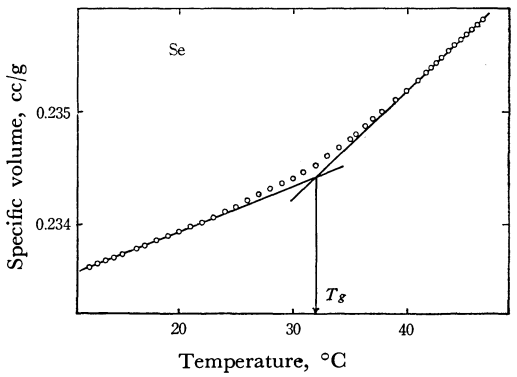

Fig. 1. Plot of specific volume against temperature.

The Glass Transition Temperature of the Chlorinated Selenium. The specific volume-temperature relationships of the chlorinated selenium specimens were similar to that of the selenium. Figure 2 shows the relationship between the T_g of the chlorinated selenium and the chlorine content. The glass transition temperature of selenium decreased as the chlorine content increased up to about 0.013%, while an abrupt increase in T_g was observed at about 0.013%.

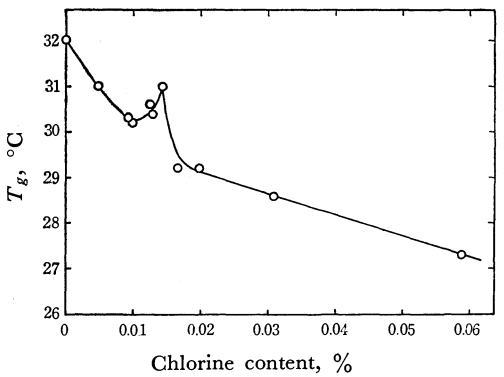

Fig. 2. Plot of T_g against chlorine content.

It is well known that an elevation of the T_g of organic polymer is observed when the polar group is introduced into the chain molecules. The abrupt increase in the T_g of the chlorinated selenium at a chlorine content of about 0.013% probably arose because of the large electronegative character of the introduced chlorine atoms, which terminated the radicals at the chain ends of the selenium molecules. The glass transition temperature of the chlorinated selenium with a chlorine

8) S. Hamada, T. Sato and T. Shirai, This Bulletin, **40**, 864 (1967).
9) G. Tammann and A. Kohlhaas, *Z. anorg. Chem.*, **182**, 49 (1929).
10) E. Jenckel, *Z. Elektrochem.*, **43**, 796 (1947).
11) T. Sekiguchi, *Sci. Papers I. P. C. R.*, **54**, 281 (1960).

content above 0.013% decreased linearly with an increase in the chlorine content. Fox and Flory[12] reported that the T_g of polystyrene decreased linearly with the reciprocal of the molecular weight when the molecular weight was not very large. The relation between the number of selnium atoms in an average-length chain of chlorinated selenium, Z_n, and the chlorine content, p, is shown as follows, after the chain ends have been terminated by chlorine atoms:

$$Z_n = 2\times 35.5(100-p)/78.96p$$

If the chlorine content is very small, Z_n is expressed as follows:

$$Z_n = 89.92/p$$

That is, the chlorine content is proportional to the reciprocal of the number of selenium atoms in an average-length chain of chlorinated selenium. The glass transition temperature of the chlorinated selenium decreased linearly with an increase in the chlorine content, as is shown in Fig. 2. This result agrees with that obtained by Fox and Flory.

The Isothermal Volume Change of the Selenium. A retardation of the volume change of the selenium was observed as in the case of organic polymers. Figure 3 shows the relation between the volume change of the selenium and the time, when the specimen kept at 50°C for 30 min was quickly immersed into a water bath kept at a specified temperature in the neighborhood of T_g. The volume changes, which were the differences between the equilibrium volume, $V_{T(\infty)}$, and the volume at the time $(t-a)$, $V_{T(t-a)}$, at several temperatures, are shown as the readings of the mercury meniscus in the capillary. The time which the dilatometer had been immersed in the water bath was expressed as $t-a$. The corrective factor, a, is a half of the time needed to attain the thermal equilibrium from 50°C to a specified temperature. The value of a was estimated to be 25 sec by a measurement made when the dilatometer containing mercury alone was quickly cooled in the same manner.

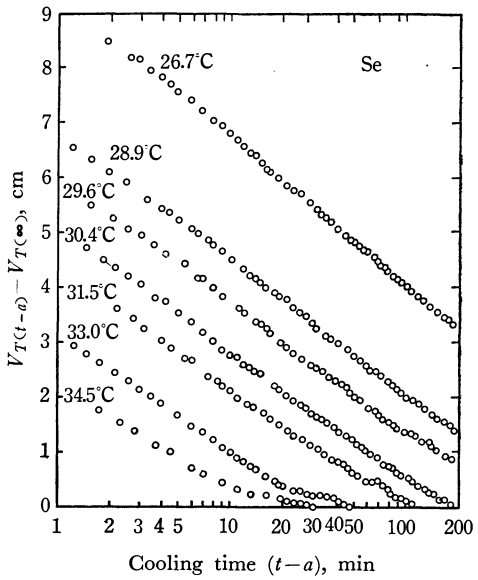

Fig. 3. Relationship between volume change and cooling time.

In order to study the volume relaxation phenomena of the selenium, the time-temperature superposition principle was applied.[7,13] The values of the shift factor, a_T, were estimated, since the volume-time curves could superpose upon each other by sliding along the abscissa. From

Usual polymers		17.4	51.6	2.5±0.3		(4.8)		11.3

12) T. G. Fox and P. J. Flory, *J. Polymer Sci.*, **14**, 315 (1954).

13) T. Sekiguchi, *Sci. Papers I. P. C. R.*, **55**, 148 (1961).

the estimated a_T and T_g values, the parameters, C_1^g and C_2^g, in the WLF equation,[14] $\log a_T = -C_1^g(T-T_g)/(C_2^g+T-T_g)$, were calculated to be 6.86 and 28.6 respectively. These values were small compared with those of usual organic polymers (17.4 and 51.6 respectively).

The Isothermal Volume Change of the Chlorinated Selenium. The volume relaxation phenomena of the chlorinated selenium were similar to that of the selenium. The volume-time curves of the chlorinated selenium could superpose upon each other as in the case of the selenium. The values of the C_1^g and C_2^g of the chlorinated selenium were estimated from a_T and T_g.

The glass transition temperatures and the values of C_1^g and C_2^g are listed in Table 1.

Though both the values of C_1^g and C_2^g were small and increased only with an increase in the chlorine content, they were nearly equal to those of usual polymers (17.4 and 51.6 respectively) at chlorine contents above 0.0125%.

Discussion

The retardation phenomena of the volume contractions of the selenium and of the chlorinated selenium were observed as viscoelastic behavior. As the relation between T_g and a_T was shown as the WLF equation, the fraction of the free volume at T_g, f_g, of the selenium can be discussed using the values of the WLF parameters, C_1^g and C_2^g.

Williams, Landel, and Ferry[14] expressed f_g and the expansion coefficient of the free volume, α_f, on the basis of their empirical equation and Doolittle's free space equation for viscosity[15] as follows:

$$f_g = B/2.303C_1^g \qquad \alpha_f = B/2.303C_1^gC_2^g$$

where B is the constant in Doolittle's equation. Therefore, α_f corresponds to the difference, $\Delta\alpha$, between the expansion coefficient of the supercooled liquid state of the polymer, α_l, in the temperature range above T_g and the expansion coefficient of the glassy state, α_g, in the temperature range below T_g. The constant, B, can be ragarded as unity.[15] Bueche[16] supported this assumption by his theoretical treatment. Therefore, f_g and α_f are represented as $1/2.303C_1^g$ and $1/2.303C_1^gC_2^g$ respectively.

The calculated values of f_g and α_f and the empirical values of $\Delta\alpha$ are listed in Table 1.

Kovacs[7] expressed f_g on the basis of the WLF equation as follows:

$$f_g = (\alpha_f[\beta]_g/2.303\Delta\alpha v_g)^{1/2}$$

where $[\beta]_g$ is the slope of the volume-time curve at T_g in Fig. 2, and where v_g is the specific volume at T_g.

The calculated values of f_g, as defined by Kovacs, are listed in Table 1. Because both the values of f_g, that defined by WLF and that defined by Kovacs, were in good agreement with each other, they are likely to be reasonable values. Figure 4 shows the relationship between f_g and the chlorine content. The fraction of the free volume decreased with an increase in the chlorine content, and then reached about a constant value at chlorine contents above 0.0125%, as in the case of usual polymers (2.5×10^{-2}).

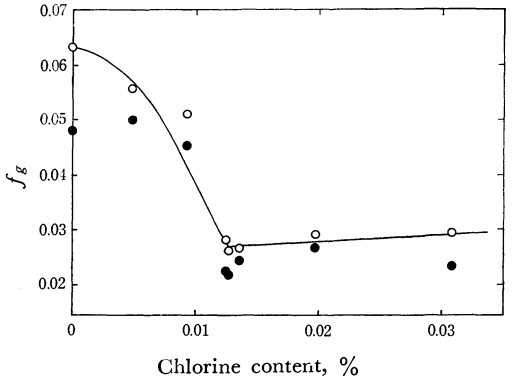

Fig. 4. Plot of f_g against chlorine content.
○: WLF's f_g ●: Kovacs' f_g

The calculated values of α_f, however, were about ten times larger than the empirical $\Delta\alpha$ values of the selenium and of the chlorinated selenium with chlorine contents of less than about 0.0125%, while the order of α_f values were the same as those of $\Delta\alpha$ at chlorine contents above 0.0125%. This notable disagreement of the values of α_f and $\Delta\alpha$ under these conditions may be caused by an abnormal value of B in Doolittle's equation. This has often been observed in usual polymers.[17] Therefore, the values of f_g defined by WLF and by Kovacs under these conditions can not be readily appraised as to their reasonableness.

Simha and Boyer[18] defined the fraction of the free volume at T_g to be $\Delta\alpha T_g$. The calculated values of $\Delta\alpha T_g$ are listed in Table 1. Though the value of $\Delta\alpha T_g$ increased with a decrease in the chlorine content at chlorine contents of less than about 0.0125%, nearly constant values of $\Delta\alpha T_g$ were observed above 0.0125%, as is shown in Fig. 5. The values of $\Delta\alpha T_g$, defined as the fraction of the free volume by Simha and Boyer, gave a curve with the same appearance as that

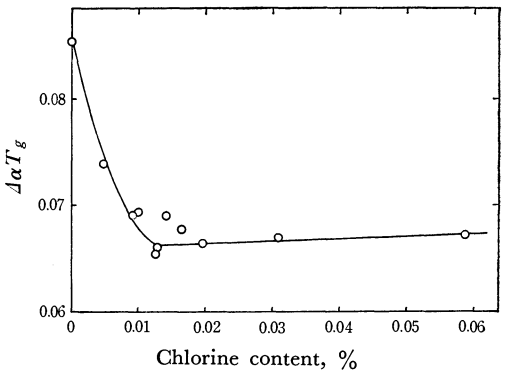

Fig. 5. Plot of $\Delta\alpha T_g$ against chlorine content.

obtained by WLF. This suggests that the f_g values of the selenium and of the chlorinated selenium with chlorine contents of less than 0.125% are larger than that of usual polymers (2.5×10^{-2}) in spite of an uncertainty regarding the values of the WLF f_g under these conditions.

As the number of selenium atoms in an average-length chain of the selenium at 230°C is 7200, the chlorine content corresponds to 0.0125% when all the radicals at both ends of linear chain molecules of the selenium have been dispensed in forming bonds with chlorine atoms. Thus, it may be concluded that the existence of radicals at the molecular ends of selenium chains brings about an augmentation of the fraction of the free volume at T_g. Though the mechanism of the augmentation of the fraction of the free volume at T_g by the existence of radicals has not been established, it may be considered to be due to bond interchange between neighboring selenium chains,[19] or to repulsion between radicals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 139—141 (1968)

The Viscosities of Aqueous Solutions Containing Metal Complexes. I. Luteo-type Co(II) and Co(III) Complexes and Ethylenediaminetetraacetato Complexes*[1]

Motoo YASUDA

Department of General Education, Nagoya University, Chikusa-ku, Nagoya

(Received July 21, 1967)

The viscosities of aqueous solutions containing cobalt complexes formed with ammonia, ethylenediamine (en), propylenediamine (pn), 2, 2'-bipyridine (bip), 1, 10-phenanthroline (phen), and ethylenediaminetetraacetic acid (H_4edta) were determined with a Cannon-Fenske capillary viscometer. Measurements were made in a Shibata viscosity bath maintained at 25± 0.01°C. The Jones-Dole viscosity *B*-coefficients of Co(III) complex cations formed with NH_3, en, pn, bip, and phen increase in that order. There is no significant difference between the *B*-coefficients of $[Cobip_3]^{3+}$ and $[Cobip_3]^{2+}$, or $[Cophen_3]^{3+}$ and $[Cophen_3]^{2+}$. On the other hand, a pronounced difference is found between the *B*-coefficients of $[Coedta]^-$ and $[Coedta]^{2-}$. This might suggest that there is a marked difference in the structure of $[Coedta]^-$ and $[Coedta]^{2-}$ anions.

The viscosities of aqueous electrolyte solutions have been accurately measured by many authors, but very few data are available for the metal complexes. Charles,[1] who measured the viscosities of the ethylenediaminetetraacetic acid and Schiff base chelates, showed that significant information concerning the configuration and the degree of solvation of the metal chelates could be obtained by viscosity measurements. It was felt that a thorough study on the viscosity of the metal complexes might supply useful information regarding the structure of the complexes. A study was therefore made of the viscosities of aqueous solutions containing cobalt complexes.

*1 Presented at the Symposium on Coordination Chemistry of the Chemical Society of Japan, Tokyo, Dec., 1966.

Experimental

Complexes. Co(III) complexes such as $[Co(NH_3)_6]Cl_3$,[2] $[Coen_3]Cl_3 \cdot 3H_2O$,[3] $[Copn_3]Cl_3$,[4] $K[Coedta] \cdot 2H_2O$,[5] and $[Cophen_3]Cl_3 \cdot 7H_2O$,[6] were prepared following the literature method. The first four complexes were obtained by oxidizing a solution of a mixture of cobalt(II) chloride and ligand with hydrogen peroxide; the last one, by oxidizing with chlorine. An analogous procedure (*i. e.* oxidization with chlorine) was used for the preparation of $[Cobip_3]Cl_3 \cdot 3H_2O$, which was originally obtained from cobalt(III) sulfate and bipyridine.[7] All these well-known complexes were checked by analysis of chloride ion and/or water contents. But Co(II) complexes such as $[Cobip_3]Cl_2$, $[Cophen_3]Cl_2$ and $Na_2[Coedta]$, were not isolated as crystals. Instead, solutions of these chelates were made up with the standard $CoCl_2$ solution, the weighed amount of ligand and distilled water. The concentration of the $CoCl_2$ stock solution was determined by the chelatometric titration.

Measurements. Viscosities were determined with a Cannon-Fenske capillary viscometer having efflex time *ca.* 240 sec for distilled water. Measurements were made in a Shibata viscosity bath maintained at 25± 0.01°. Efflex times, measured with a stopwatch to the 0.1 sec, were easily reproducible to 0.2 sec. Densities of the solutions were also determined in the same constant temperature bath used for the viscosities.

Calculations. According to Jones and Dole,[8] the viscosities of aqueous electrolyte solutions have the following relation with the solute molarity, C:

$$\frac{\eta}{\eta_0} = 1 + A\sqrt{C} + BC$$

where η and η_0 are viscosities of solution and water, respectively; A and B are constants characterestic of the solute. The square-root term was attributed to the interionic electrostatic forces and the experimental values of A were found to be positive in every case studied. The coefficient B of the electrolytes is composed additively of contributions from each of the solute species present in the solution. And Gurney[9] divided the B-coefficient of -0.014 for KCl equally between K^+ and Cl^- ions (thus $B_{K^+} = B_{Cl^-} = -0.007$). Although his division of the B-coefficient of KCl into individual ionic values is a rather arbitrary process, it is regarded as a good approximation. The contributions depend on the size of the ions and on the interaction between the ions and the surrounding solvent.

When $((\eta/\eta_0)-1)/\sqrt{C}$ was plotted against $\sqrt{C}$, a straight line was obtained for each of the complexes studied. The slope of the resulting straight line gives the value of B-coefficient and the intercept gives the value of A-coefficient. The B-value of the complex ions is obtained by subtracting a relatively small correction for the ions present in the solution.

Results and Discussion

A part of the viscosity and density data for $[Coen_3]Cl_3$ and $CoCl_2$ are listed in Tables 1 and 2. Table 3 contains the B-values of the complex ions at 25°C obtained in this study, together with those reported by Kaminsky[10] and by Charles[1]. The trivalent $[Co(NH_3)_6]^{3+}$ ion, having a much smaller radius than that of any of the other complex ions studied, is expected to form an ion pair much more easily with the anion, chloride ion. Accordingly, the B-value of this complex ion is the least accurate.

Table 1. Viscosity and density data for $[Coen_3]Cl_3$

C	d	η/η_0
0.01500	0.99924	1.01009
0.03981	1.00317	1.02484
0.07606	1.00798	1.04427
0.1305	1.01630	1.07536
0.1858	1.02426	1.10700

C	d	η/η_0
0.02302	0.99953	1.01216
0.06906	1.00526	1.03146
0.1381	1.01312	1.05885
0.2302	1.02374	1.09683

Table 3. The B-values of cobalt complexes (25°C)

Complex	B	Complex	B
$[Co(NH_3)_6]^{3+}$	0.17	$[Co(H_2O)_6]^{2+}$	0.38 (0.36*)
$[Coen_3]^{3+}$	0.56	$[Cobip_3]^{2+}$	1.37
$[Copn_3]^{3+}$	0.88	$[Cophen_3]^{2+}$	1.61
$[Cobip_3]^{3+}$	1.31	$[Coedta]^{2-}$	0.85 (0.88**)
$[Cophen_3]^{3+}$	1.53	$[Coedta]^-$	0.41

* Ref. 10 (at 35°C)
** Ref. 1 (at 30°C)

According to Kaminsky, the temperature coefficient of B is negative for the strongly hydrated ions such as Li^+, Be^{2+}, Mg^{2+}, Fe^{2+}, and Ce^{3+}, as seen from Table 4. Therefore, the B-value of 0.38 obtained for $[Co(H_2O)_6]^{2+}$ ion at 25° is very reasonable, compared with the Kaminsky's value of 0.36 at 35°.

The B-value for $[Co(NH_3)_6]^{3+}$ ion is much smaller than that for $[Co(H_2O)_6]^{2+}$ ion, as seen

from Table 3. This might suggest that the water molecules coordinated to the metal ion have a greater interaction with the surrounding molecules of solvent than the ammonia molecules, much more tightly bound to the metal ion, have.

The *B*-values of Co(III) complex cations formed with NH_3, en, pn, bip, and phen, all of which might be called as the luteo-Co(III) ions, increase considerably in that order, as may be expected. The *B*-value of Co(II) chelate of bip (or phen) is almost the same to that of corresponding Co(III) chelate. Moreover, the chelate derived from the bulky ligand, such as bip or phen has a rather large ionic radius, so it may be assumed that such a chelate ion has no large interaction with the solvent molecules. Accordingly, it might be considered that the Co(II) and Co(III) chelates of bip or phen have the similar structure one another.

TABLE 4. *B*-VALUES AND DEPENDENCE ON TEMPERATURE[10]

t°C	Be^{2+}	Mg^{2+}	Fe^{2+}	Co^{2+}	Ce^{3+}
15	0.4345	0.4091	—	—	0.5841
25	0.3923	0.3852	0.4160	—	0.5765
35	0.3444	0.3625	0.3955	0.360	0.5573
42.5	0.3105	0.3472	—	—	0.5427

On the other hand, as seen from Table 3, the *B*-value of the $[Coedta]^-$ chelate is only 0.41, much smaller than the *B*-value of 0.85 of $[Coedta]^{2-}$. In this connection, it is especially interesting to compare these *B*-values with those of EDTA-complexes reported by Charles (Table 5). The *B*-value of the $[Coedta]^-$ is much smaller than that of any other divalent metal chelates given in Table 5. Further, it is easily seen from Table 5, which contains also the values of stability constants reported by Schwarzenbach *et al.*,[11] that metals with a greater affinity for the ligand generally form chelates with smaller *B*-values. These facts might suggest that Co(III) chelate has a stable hexa-coordinated structure, but that divalent metal chelates, having not so stable hexa-coordinated structure as the Co(III) chelate, are present as a penta-coordinated structure or as a mixture of the penta- and hexa-coordinated structures.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 142—149 (1968)

Studies of Phosphorylation. II. Reaction of 2′, 3′-*O*-Isopropylideneinosine and -guanosine with Phosphoryl Chloride[1]

Koji KUSASHIO and Masaharu YOSHIKAWA

Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki

(Received March 20, 1967)

Several reactions accompanied by the phosphorylation of 2′, 3′-*O*-isopropylidene nucleosides with phosphoryl chloride in the absence of an organic solvent were investigated. When the reaction temperature exceeded 30°C, 2′, 3′-*O*-isopropylideneinosine gave 5′-chloro-5′-deoxy-2′, 3′-*O*-isopropylideneinosine and 5′-deoxy-2′, 3′-*O*-isopropylidene-3, 5′-cycloinosine. This cycloinosine, was then further subjected to rapid cleavage in a pyrimidine ring to give 5-amino-4-carbamoyl-N^5, 5′-cyclo-1-β-D-(5′-deoxy-2′, 3′ - *O* - isopropylideneribofuranosyl) - imidazole, 5-amino-4-cyano-N^5, 5′-cyclo-1-β-D-(5′-deoxy-2′, 3′-*O*-isopropylideneribofuranosyl)-imidazole, and the N^5-formyl derivative of the latter. Similar sequences of the chlorination at the 5′-position and the cyclization between 3 and 5′-positions were observed in the case of 2′, 3′-*O*-isopropylideneguanosine, but the resulting 5′-deoxy-2′, 3′-*O*-isopropylidene-3, 5′-cycloguanosine was not susceptible to ring cleavage under the conditions used. The factors affecting these reactions were described, and possible mechanisms were proposed.

A previous paper[2] reported a successful method for the preparation of 5′-nucleotides by a simple procedure. This method, involving the reaction of 2′, 3′-*O*-isopropylidene nucleosides with a large excess of phosphoryl chloride in the absence of any organic solvent, has given the maximum yields of the corresponding 5′-nucleotides at 0—15°C. A slight elevation of the reaction temperature or a prolongation of the reaction time, however, resulted in a gradual decrease in the yield as a result of several side reactions and the glycosidic cleavage. The present paper deals with the identification of all of the side products obtained by the reactions of 2′, 3′-*O*-isopropylideneinosine and -guanosine with phosphoryl chloride, and discuss possible mechanisms.

Results and Discussion

Identification of the Products. The reaction mixtures were treated with ether to precipitate the products, which were then hydrolyzed under mild acidic conditions. The two-dimensional paper chromatographies of the hydrolyzates using solvent 1 and then solvent 2 are shown in Figs. 1 and 2. The products, named H-1, H-2,··· and H-6, and G-1, G-2,··· and G-4, are represented in the figures. The R_f values of the products with three kinds of solvents are summarized in Table 1.

The spots of H-1 and G-1 were positive to the Hanes-Isherwood reagent[3] and negative to the periodate-benzidine test.[4] These properties indicate that both products are nucleotides substituted at one or both hydroxyl groups at 2′ and 3′-positions. Their R_f values and electrophoretic mobilities were in good agreement with those of authentic 2′(or 3′), 5′-diphosphoric esters of inosine and guanosine.

All spots of the other side-products were negative to the Hanes-Isherwood reagent.

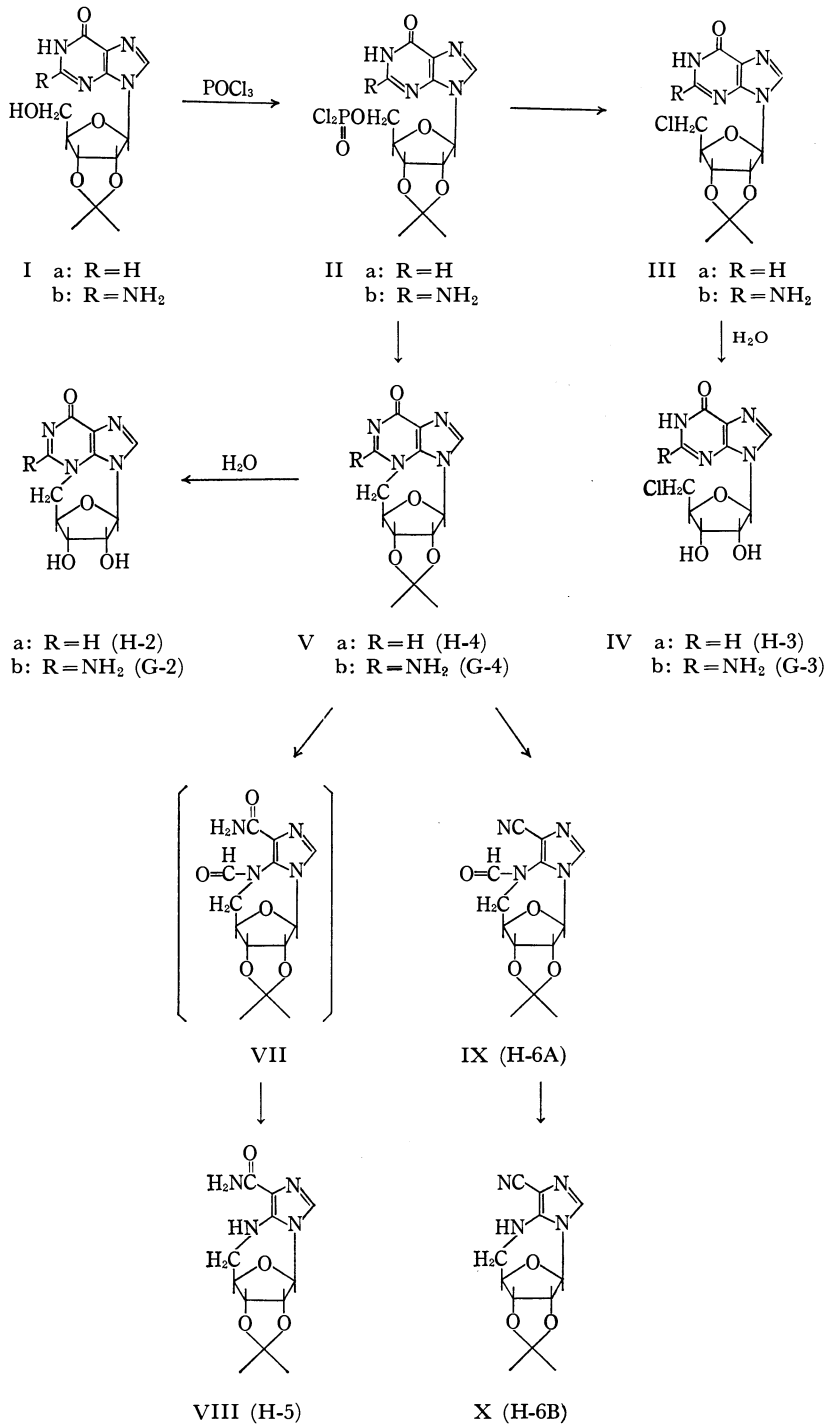
4) M. Viscontini, D. Hoch and P. Karrer, *Helv. Chim. Acta*, **38**, 642 (1955).



The spot of H-3 gave a positive periodate-benzidine test, and the ultraviolet absorption spectra proved to be similar to those of inosine. These results show the absence of the isopropylidene group and the presence of the unchanged base. The treatment of H-3 in 0.1 N sodium hydroxide under reflux afforded inosine. 5′-Chloro-5′-deoxy-2′, 3′-*O*-isopropylideneinosine (IIIa) was isolated from the chloroform extract of the reaction products and was entirely identical with the compound synthesized by the nucleophilic replacement of 2′, 3′-*O*-isopropylidene-5′-methane-sulfonylinosine with lithium chloride. The R_f values of its acid hydrolyzate were in good agreement with those

of H-3. In view of the above facts, it may be concluded that H-3 is 5′-chloro-5′-deoxyinosine (IVa).

The isopropylidene derivative of G-3 was readily separated from the aqueous solution of the reaction products. The acidic removal of the protective group gave G-3. The composition of G-3 satisfied $C_{10}H_{12}O_4N_5Cl$, corresponding to formula IVa. G-3 gave a positive periodate-benzidine test and the same ultraviolet absorption spectra as those of guanosine. After refluxing in 0.1 N sodium hydroxide, G-3 afforded guanosine. From these observations, G-3 was identified as 5′-chloro-5′-deoxyguanosine (IVb).

The infrared and ultraviolet spectra, melting point, and R_f values of H-4 proved to be the same as those[5] of the 5′-deoxy-2,′ 3′-*O*-isopropylidene-3, 5′-cycloinosine (Va) prepared *via* 2′, 3′-*O*-isopropylidene-5′-*O*-(*p*-toluenesulfonyl)-inosine according to the Robins method.[6] The structure was characterized by a single peak at 3.64 τ assigned to a proton at the 1′-position in the NMR spectrum.[7]

Such a characteristic peak of a proton at the 1′-position was also observed in the other 3, 5′-cyclonucleoside derivatives described below, which are summarized in Table 2.

The yield of G-4 was increased nearly 50% by elevating the reaction temperature to 40°C. The ultraviolet absorption spectra were very similar to those of 5′-deoxy-2′, 3′-*O*-isopropylidene-3, 5′-cycloguanosine reported by Chambers *et al.*[8] 3, 5′-(5′-Deoxy-D-ribofuranosyl)-guanine and 5′-deoxy-2′, 3′-*O*-isopropylidene-3, 5′-cycloxanthosine were formed when G-4 was refluxed in 1 N hydrochloric acid and in 1 N sodium hydroxide respectively. These compounds were confirmed by the ultraviolet spectra measurement of the spots on a paper chromatogram according to the Robins method.[6] Also, the NMR spectrum of G-4 supported the 2′, 3′-*O*-isopropylidene cyclonucleoside structure. On the basis of these results, G-4 was concluded to be 5′-deoxy-2′, 3′-*O*-isopropylidene-3, 5′-cycloguanosine (Vb).

The compound Vb could also be prepared directly by the reaction of Ib with methanesulfonyl chloride in pyridine.

The minor products, H-2 and G-2, gave positive periodate-benzidine tests. Their respective ultraviolet spectra were identical with those of Va and Vb, convincing evidence that they were 5′-deoxy-3, 5′-cycloinosine (VIa) and -guanosine (VIb). In fact, the R_f values of the acid hydrolyzates of Va and Vb were in complete agreement with those of H-2 and G-2 respectively.

The ultraviolet absorption spectra of H-5 were very different from those of the starting nucleoside. The NMR spectrum showed a single peak at 3.65 τ due to –NH–, in addition to the peaks indicating a 2′, 3′-*O*-isopropylidene cyclonucleoside structure, and the infrared spectrum exhibited an amide band at 1647 cm^{-1}. These spectral results and the composition supported the theory that H-5 was 5-amino-4-carbamoyl-N^5, 5′-cyclo-1-β-D-(5′-deoxy-2′, 3′-*O*-isopropylideneribofuranosyl)-imidazole (VIII).

5) The absorption maximum at pH 1 was in disagreement with their description.

6) R. E. Holmers and R. K. Robins, *J. Org. Chem.*, **28**, 3483 (1963).

7) The dihedral angle between the $H_1'C_1'C_2'$ plane and the $H_2'C_2'C_1'$ plane becomes nearly 90° upon the 3, 5′-cyclization in purine nucleoside.

8) R. W. Chambers, J. G. Moffatt and H. G. Khorana, *J. Am. Chem. Soc.*, **79**, 3747 (1957).

Table 2. Properties of the products

Compound	max (mμ) pH 1	max (mμ) pH 11	Solvent	NMR (τ) $H_{1'}$	$J_{1'2'}$ (cps)	Isopropylidene group		Characteristic group
IIIa	252	254	DMSO	3.78	2.5	8.48	8.65	
Va	258—263	271	C_5H_5N	3.64	0	8.50	8.76	
IIIb	258	258—267	DMSO	3.93	2.5	8.46	8.65	
Vb	251—257	218, 267	D_2O	3.51	0	8.42	8.68	
VIII	255—264	273	$CDCl_3$	4.24	0	8.49	8.69	3.65(-NH-)
IX	251	252	$CDCl_3$	4.11	0	8.49	8.70	1.52(-CHO)
X	251	252	DMSO	3.90	0	8.57	8.72	3.24(-NH-)

The compound H-6 was too small to isolate, but it was increased in the reaction with a mixture of phosphoryl chloride and pyrophosphoryl tetrachloride. Two compounds (named H-6A and H-6B, as is shown in Table 1) were separated by the careful treatment of the crude H-6 precipitates on an alumina column. From the assignment of the NMR spectra, both H-6A and H-6B were found to be isopropylidene cyclonucleosides.

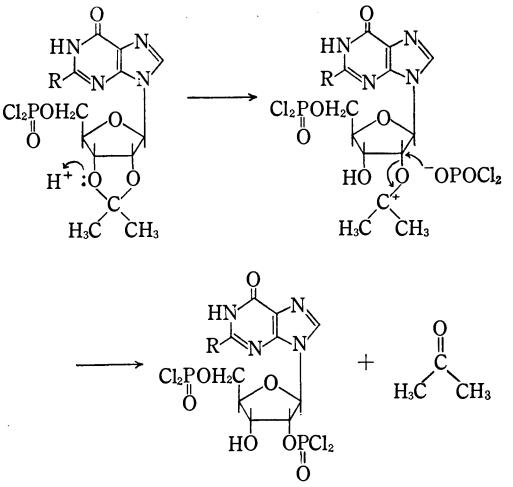
H-6B had a sharp band due to a conjugated cyano group at 2225 cm^{-1} in the infrared spectrum and a broad peak due to –NH– at 3.24 τ in the NMR spectrum. These spectral observations and the composition led us to conclude that H-6B was 5-amino-4-cyano-N^5, 5′-cyclo-1-β-D-(5′-deoxy-2′,3′-*O*-isopropylideneribofuranosyl)-imidazole (X).

The infrared spectrum of H-6A showed a new band due to a formyl group at 1705 cm^{-1} in addition to a cyano group at 2230 cm^{-1}. The NMR spectrum showed the presence of a formyl proton at 1.52 τ and the absence of the –NH– group. These results indicate that H-6A is the N^5-formyl derivative of X (IX).

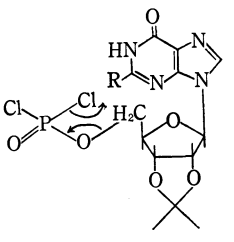
Discussion of the Mechanism. One possible mechanism for the formation of the nucleoside 2′(or 3′), 5′-diphosphoric ester from 2′,3′-*O*- isopropylidene nucleoside is illustrated by the reaction of the intermediate, 2′,3′-*O*-isopropylidenenucleoside 5′-phosphorodichloridate (II), with dichlorophosphoric acid according to the following equation:

Table 3. Influence of water for preparation of IVa

Molar ratio H_2O/Ia	Time hr	Yield of product (mol%) IVa	5′-IMP
0	2	7	75
0	16	22	42
0.5	2	2	76
0.5	16	10	53
1.0	2	trace	77
1.0	16	4	67
2.0	2	nothing	52
2.0	16	nothing	46



The 5′-chloro derivative IVa, which was a major side product from Ia, decreased with an increase in the amount of water added to the reaction mixture, as is shown in Table 3. This fact indicates that the formation of 5′-chloro-5′-deoxy-2′,3′-*O*-isopropylideneinosine (IIIa) is not due to the reaction of 2′,3′-*O*-isopropylideneinosine (Ia) with the hydrogen chloride produced. In the reaction without the addition of water, the amount of IVa increased with a decrease in 2′,3′-*O*-isopropylideneinosine 5′-phosphorodichloridate (IIa) (analyzed as inosine 5′-phosphate) even after the starting nucleoside Ia (analyzed as inosine) had phosphorylated, as is shown in Fig. 3. From these results, it seems reasonable to assume that the compound III is formed by the intramolecular rearrangement of the compound II.



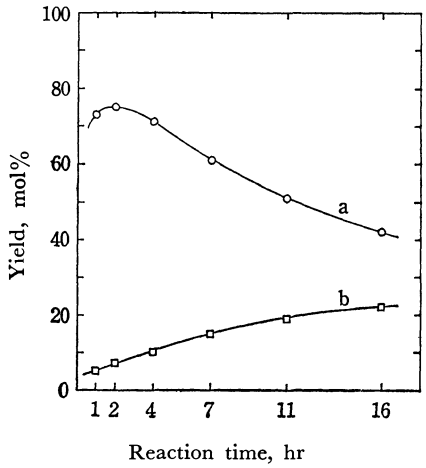


Fig. 3. Influence of reaction time for preparation of IVa.

Experimental condition; Ia: 10 mmol, $POCl_3$: 170 mmol, 20°C
a: 5'-IMP, b: IVa

The formation of the 3, 5'-cyclonucleoside derivative V is considered to be caused by the elimination of the dichlorophosphoryl group from the compound II. The possibility of this mechanism is supported by the increase in the cycloguanosine derivative Vb and the concurrent decrease in the compound IIb with the prolongation of the reaction period, as is shown in Fig. 4.

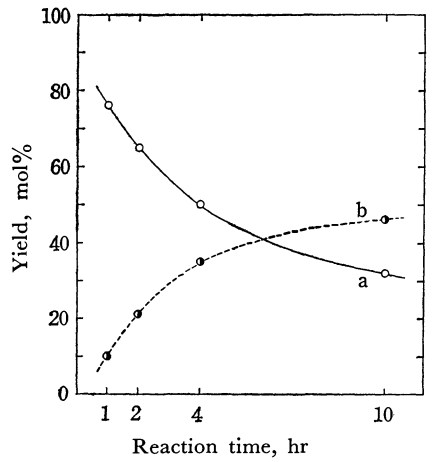

Fig. 4. Influence of reaction time for the preparation of Vb.

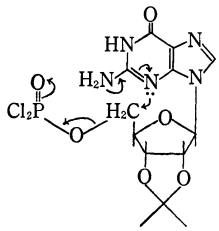
Experimental condition; Ib: 10 mmol, $POCl_3$: 170 mmol, H_2O: 5 mmol, 40°C
a: 5'-GMP, b: Vb

3, 5'-Cyclonucleoside has been synthesized *via* 2', 3'-*O*-isopropylidene-5'-*O*-(*p*-toluenesulfonyl)-nucleoside.[6,9] It can be considered that the reaction is dependent on the inductive effect of the tosyl group, and a similar effect can also be expected for the dichlorophosphoryl group. The 3, 5'-cyclization of 2', 3'-*O*-isopropylidene-5'-*O*-(*p*-toluenesulfonyl)-inosine has been more difficult than that of the same guanosine derivative, and the ease of the formation of such cyclonucleosides has been reported to be a function of the basicity of their purine bases.[9] A similar tendency was observed in the present studies. The cycloderivative Vb was more easily produced than the chloroderivative IIIb in the reaction of Ib, in contrast to the case of Ia. The ease of the cyclization of the compound IIb seems to be due to an increase in the electron density of the nitrogen atom at the 3-position because of the electromeric effect of the 2-amino group in the guanine base in addition to the decrease in the electron density of the carbon atom at the 5'-position because of the inductive effect of the dichlorophosphoryl group.



The isopropylidene group of Vb resisted mild acidic hydrolysis, as is shown in Fig. 5, which also exhibits the difference in the elimination rate from those of Ib and Vb. The increase in the stability of the dioxolane ring in cyclonucleoside seems to be due to a decrease in the strain as a result of the cyclization between the ribose and the purine base.

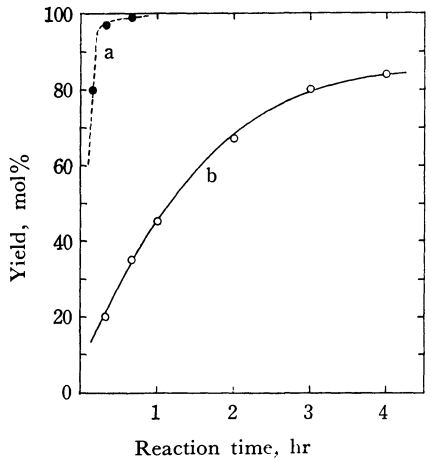


Fig. 5. Elimination rate of isopropylidene groups of Ib and Vb.

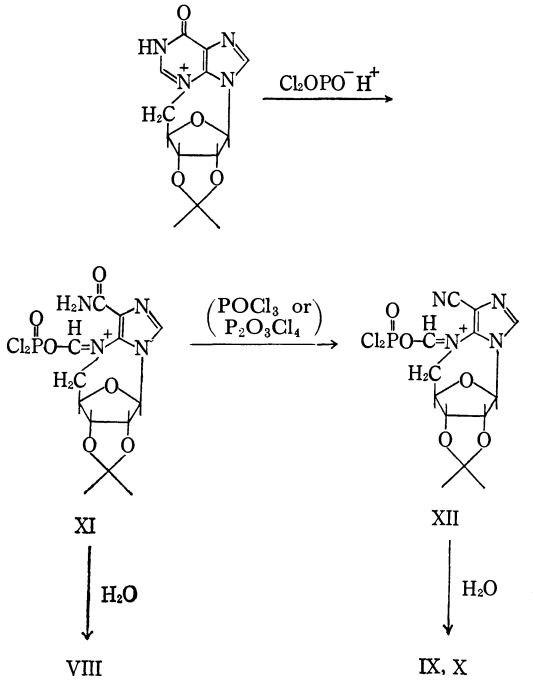
Experimental condition; pH 1.5, 70°C
a: guanosine produced, b: VIb produced

9) V. M. Clark, A. R. Todd and J. Zussman, *J. Chem. Soc.*, **1951**, 2952.

The degradation of 3, 5′-cyclopurinenucleoside involving ring cleavage has been studied by Baker[10] and by Todd.[11] It has been illustrated that the degradation is due to the attack of the hydroxyl anion on the carbon atom at the 2-position of the original cyclonucleoside. A similar explanation is acceptable in the present case, since the cleaved compounds, VIII and IX, were given when the cycloinosine derivative Va was heated with phosphoryl chloride hydrolized partially by a small amount of water. The ring cleavage of Va to VIII during the phosphorylation can be attributable to the nucleophilic attack of the dichlorophosphate anion on the 2-position, as is illustrated in following equation:



The labile intermediate XI is subjected to the rapid hydrolysis to give VIII.

The dehydration of the intermediate XI by phosphoryl chloride seems to form the compound IX. The addition of a more powerful dehydrating agent, pyrophosphoryl tetrachloride, promoted the formation of IX, as had been expected.

The corresponding ring-opening products of 5′-deoxy-2′, 3′-*O*-isopropylidene-3, 5′-cycloguanosine are not found in the reaction mixture under similar conditions. This may be attributable to the decrease in the positivity of the carbon atom at the 2-position because of the electromeric effect of the amino group. The formyl groups of the compounds VII and IX must be eliminated during the mild acidic hydrolysis.

Experimental

The melting points were determined on a Mitamura Riken hot stage and are uncorrected. The ultraviolet spectra were recorded on Hitachi EPS-2U spectrophotometer, and the infrared spectra on Hitachi EPI-2 and Perkin-Elmer 221 spectrophotometers. The NMR spectra were run on Varian A60 spectrometer, using tetramethylsilane as the internal standard. The paper chromatographies were carried out by the ascending technique on Toyo Roshi No. 51 (40×40 cm), using the following solvent system: Solv. 1, *n*-propyl alcohol - concentrated ammonium hydroxide - water, 20 : 12 : 3; Solv. 2, *n*-butyl alcohol - acetic acid - water, 4 : 1 : 1; Solv. 3, isopropyl alcohol - saturated ammonium sulfate - water, 2 : 79 : 19.

The Isolation of 5′-Chloro-5′-deoxy-2′, 3′-*O*-isopropylideneinosine (IIIa). To phosphoryl chloride (100 m*l*) 2.0 g of 2′, 3′-*O*-isopropylideneinosine (Ia) were added, after which the solution was warmed while being stirred for 5 hr at 40°C. After cooling, the reaction mixture was poured into 500 m*l* of petroleum ether in order to precipitate a syrupy product. The precipitate was centrifuged, washed with petroleum ether, and suspended in 50 m*l* of chloroform, and the solution was poured into an aqueous sodium hydrogen carbonate. After the separated aqueous layer had been extracted with four 50 m*l* portions of chloroform, all the chloroform solutions were collected, dried over anhydrous sodium sulfate, and evaporated to dryness under reduced pressure. The residue was recrystallized from methyl alcohol to give 1.0 g (47%) of IIIa, mp 195—196°C.

Found: C, 47.40; H, 4.79; N, 17.17; Cl, 10.70%. Calcd for $C_{13}H_{15}O_4N_4Cl$: C, 47.78; H, 4.59; N, 17.45; Cl, 10.87%.

The ultraviolet spectrum was similar to that of 2′, 3′-*O*-isopropylideneinosine. R_f values: 0.81 (Solv. 1), 0.94 (Solv. 2).

The Preparation of 2′, 3′-*O*-Isopropylidene-5′-*O*-methanesulfonylinosine. To a solution of Ia (3.08 g) in 50 m*l* of anhydrous pyridine, 1.25 g of methanesulfonyl chloride were added, after which the solution was stirred for 3 hr at 40°C. After it had stood overnight at room temperature, the reaction mixture was poured into 200 m*l* of water and the aqueous solution was extracted with 150 m*l* of chloroform. The chloroform layer was dried over anhydrous sodium sulfate and evaporated to dryness under reduced pressure. The recrystallization of the residue from ethyl alcohol gave 2.0 g of a pure product, mp 172—173°C.

Found: C, 43.67; H, 4.91; N, 14.70%. Calcd for $C_{14}H_{18}O_7N_4S$: C, 43.52; H, 4.66; N, 14.51%.

The Preparation of 5′-Chloro-5′-deoxy-2′, 3′-*O*-isopropylideneinosine (IIIa). 2′, 3′-*O*-Isopropylidene-5′-*O*-methanesulfonylinosine (10 g) and lithium chloride (2.2 g) were added to a mixture of 20 m*l* of acetone and 30 m*l* of ethyl alcohol, and the mixture was heated in a sealed tube for 5 hr at 100°C. The reaction mixture was then concentrated under reduced pressure and poured into ice water to precipitate a colloidal material. After being centrifuged, the product was dried under reduced pressure and recrystallized

from methyl alcohol to yield 1.5 g of an amorphous solid, mp 195—196°C.

Found: C, 47.53; H, 4.85; N, 17.80; Cl, 10.70%. Calcd for $C_{13}H_{15}O_4N_4Cl$: C, 47.78; H, 4.59; N, 17.45; Cl, 10.87%.

The melting point was not depressed on admixture with the IIIa isolated from the phosphorylation mixture; the infrared spectrum was also in complete agreement with that of the isolated IIIa.

The Preparation of 5'-Chloro-5'-deoxyinosine from IIIa. 5'-Chloro-5'-deoxy-2', 3'-*O*-isopropylideneinosine (IIIa) was dissolved in water and hydrolyzed for 1 hr at 70°C after the pH of the solution had been adjusted to 1.5. The hydrolyzed product did not crystallize after concentration owing to its strongly hygroscopic nature, but the product showed the same R_f values (Solv. 1, 0.53; Solv. 2, 0.35) as that of H-3 on paper chromatography. The concentrated residue obtained from the hydrolyzed solution after neutralization afforded hypoxanthine when refluxed in a 0.1 N hydrochloric acid solution and a small amount of inosine when refluxed in a 0.1 N sodium hydroxide solution.

The Preparation of 5'-Deoxy-2', 3'-*O*-isopropylidene-3,5'-cycloinosine (Va). 5'-Deoxy-2',3'-*O*-isopropylidene-3, 5'-cycloinosine was prepared *via* 2', 3'-isopropylidene-5'-*O*-(*p*-toluenesulfonyl)-inosine according to the directions of Holmers and Robins.[6] The melting point, 260—262°C, was slightly lower than their decription, 266—269°C.

The Isolation of 5'-Deoxy-2', 3'-*O*-isopropylidene-3, 5'-cycloinosine (Va). 2' 3'-*O*-Isopropylideneinosine (10 g) was added to a mixture of 46 m*l* of phosphoryl chloride and 0.3 m*l* of water, after which the solution was stirred for 18 hr at 40°C. The reaction mixture was then poured into ether to precipitate the reaction products. After the precipitate had been dissolved in water, the aqueous solution was adjusted to pH 1.5 with a sodium hydroxide solution, heated for 40 min at 70°C, and adjusted again to pH 3. The solution was passed through a Dowex 1-X8 (Cl^- form) (100—200 mesh) column with a bed volume of approximately 500 m*l*, and the ultraviolet absorbing effluent was divided into fraction I and fraction II, each 2 *l* in volume.

The fraction I was neutralized and concentrated to about 50 m*l* under reduced pressure to give a white precipitate. This precipitate was recrystallized twice from water to afford 327 mg (3.3%) of Va, mp 260—262°C, the melting point of which was not depressed by the addition of the authentic sample obtained in the preceding experiment.

Found: C, 50.60; H, 5.44; N, 18.10%. Calcd for $C_{13}H_{14}O_4N_4 \cdot H_2O$: C, 50.64; H, 5.23; N, 18.18%.

The ultraviolet and infrared spectra were entirely superimposable upon those of the corresponding spectra of Va synthesized above.

When this product was heated in an acidic solution of pH 1 for 3 hr at 70°C, the paper chromatography showed the same spot as those of H-2.

The Isolation of 5-Amino-4-carbamoyl-N^5, 5'-cyclo-1-β-D-(5'-deoxy-2', 3'-*O*-isopropylideneribofuranosyl)-imidazole (VIII). The fraction II obtained by the treatment with Dowex 1 in the preceding experiment was evaporated to dryness under reduced pressure, and the residue was extracted with chloroform. Paper chromatography revealed that the chloroform layer contained VIII, plus small amounts of Va, IX, and X. The chloroform layer was dried over anhydrous sodium sulfate and passed through a column (2×60 cm) of alumina (treated with concd. hydrochloric acid, washed with water, and dried at 100°C). The column was eluted with chloroform, and 50 m*l* fractions were collected. Fractions 12—22 were concentrated to give 550 mg (6%) of VIII as a colorless solid, mp 120—125°C (decomp.).

Found: C, 51.56; H, 5.87; N, 19.98%. Calcd for $C_{12}H_{16}O_4N_4$: C, 51.42; H, 5.75; N, 19.99%.

IR (KBr): ν_{max} 1647 ($-CONH_2$), 1598 (C=C) cm^{-1}.

The compounds IX and X were too small to be isolated in this experiment.

The Isolation of 5-Amino-4-cyano-N^5, 5'-cyclo-1-β-D-(5'-deoxy-2', 3'-*O*-isopropylideneribofuranosyl)-imidazole (X) and Its N^5-Formyl Derivative (IX). To a mixture of 27.6 m*l* of phosphoryl chloride and 10.9 m*l* of pyrophosphoryl tetrachloride, 10 g of Ia were added, after which the solution was worked up according to the method used in the case of the isolation of Va. The fraction II obtained by treatment with Dowex 1 was adjusted to pH 7, concentrated to 100 m*l* under reduced pressure, and extracted with chloroform. The chloroform solution was dried over anhydrous sodium sulfate and evaporated to dryness to give 400 mg of a white solid. Paper chromatography showed that the solid consisted almost entirely of IX (H-6A) and X(H-6B). The solid was dissolved in chloroform and passed through a column (1.5×20 cm) of alumina (treated by the preceding method). The column was then eluted with chloroform, and the eluate was fractionated into 50 m*l* portions. Fractions 3—4 were combined and evaporated to dryness under reduced pressure. The recrystallization of the residue from water gave 50 mg of IX, mp 211°C (decomp.).

Found: C, 54.14; H, 5.17; N, 19.20%. Calcd for $C_{13}H_{14}O_4N_4$: C, 53.79; H, 4.86; N, 19.31%.

IR (KBr): ν_{max} 2230 ($-C\equiv N$), 1705 (-CHO), 1596 (C=C) cm^{-1}.

When fractions 7—8 were also combined and evaporated to dryness under reduced pressure, 150 mg of a white powder were obtained. The powder was recrystallized from methyl alcohol to give white needles, mp 270—271.5°C.

Found: C, 54.80; H, 5.58; N, 20.89%. Calcd for $C_{12}H_{14}O_3N_4$: C, 54.96; H, 5.38; N, 21.36%.

IR (KBr): ν_{max} 2225 ($-C\equiv N$), 1614 (C=C) cm^{-1}.

The Isolation of 5'-Chloro-5'-deoxy-2', 3'-*O*-isopropylideneguanosine (IIIb). A solution of 2.0 g of Ib suspended in 150 m*l* of phosphoryl chloride was warmed for 3 hr at 50—55°C and then poured into ether after cooling. The precipitated product was slowly dissolved in 100 m*l* of water so that the pH of the aqueous solution was maintained at about 7 by the gradual addition of a sodium hydroxide solution, after which the insoluble material was collected on a filter. The insoluble material was then washed with hot water and dissolved in a dilute sodium hydroxide solution. The solution was treated with charcoal and neutralized with hydrochloric acid to precipitate 183 mg (8.7%) of IIIb, mp 275—280°C (decomp.).

Found: C, 45.07; H, 4.80; N, 19.76%. Calcd for $C_{13}H_{16}O_4N_5Cl \cdot \frac{1}{4}H_2O$: C, 45.16; H, 4.81; N, 20.26%.

R_f values: 0.80 (Solv. 1), 0.58 (Solv. 2). The

ultraviolet spectra were similar to those of Ib.

The Preparation of 5-′Chloro-5′-deoxyguanosine (IVb) from IIIb. A solution of 200 mg of IIIb suspended in 50 m*l* of water was adjusted to pH 1.5 and heated for 2 hr at 70°C. The solution was then neutralized with concentrated ammonium hydroxide, concentrated to 7 m*l* under reduced pressure, and cooled to afford a syrupy product. Recrystallization from water gave 120 mg of a white solid, mp 240°C, with a gradual decomposition.

Found: C, 39.18; H, 4.10; N, 22.85; Cl, 11.86%. Calcd for $C_{10}H_{12}O_4N_5Cl\cdot\frac{1}{4}H_2O$: C, 39.23; H, 4.11; N, 22.87; Cl, 11.58%.

This product consumed one equivalent mole of periodic acid per mole of the nucleoside as formula IVb upon oxidation by the Fleury-Lange method.[12] When refluxed in 0.1 N hydrochloric acid and 0.1 N sodium hydroxide solutions, this product gave guanine and a small amount of guanosine respectively. The treatment of this solid with acetone according to the method of Mori *et al.*[13] afforded 5′-chloro-5′-deoxy-2′,3′-*O*-isopropylideneguanosine (IIIb).

The Isolation of 5′-Deoxy-2′,3′-*O*-isopropylidene-3,5′-cycloguanosine (Vb). To a mixture of 27.6 m*l* of phosphoryl chloride and 10.9 m*l* of pyrophosphoryl tetrachloride, 10 g of Ib were added, after which the mixture was stirred for 7 hr at 40°C. Ether was added to the reaction mixture, and the precipitated product was collected on a filter and dissolved in 300 m*l* of ice water. The solution was adjusted to pH 5, and passed through a Dowex 1-X2 (Cl^- form) (100—200 mesh) column (200 m*l* bed volume), and the column was washed with water. The ultraviolet absorbing effluent was then collected, adjusted to pH 7, and concentrated under reduced pressure until the product began to precipitate, after which it was kept at room temperature. The precipitate was collected on a filter, washed with 10% ethyl alcohol, and dried to give 5.2 g of white crystals. Recrystallization from water afforded 4.25 g of white needles, mp 250—255°C (decomp., with a gradual coloring from 240°C).

Found: C, 50.70; H, 5.02; N, 22.55%. Calcd for $C_{13}H_{15}O_4N_5$: C, 51.14; H, 4.95; N, 22.94%.

When a part of the crystals were refluxed in 1N hydrochloric acid for 1 hr and the solution was developed on paper chromatography, a new spot was found at the R_f value of 0.09 by Solv. 1 and at 0.08 by Solv. 2. This spot was identified as 3,5′-(5′-deoxy-D-ribofuranosyl)-guanine by comparing its ultraviolet absorption maxima with the values of the literature.[6] When refluxed in a 1 N sodium hydroxide solution, Vb gave a new spot which showed R_f values of 0.68 (Solv. 1) and 0.58 (Solv. 2). This product was similarly identified as 5′-deoxy-2′,3′-*O*-isopropylidene-3,5′-cycloxanthosine.

The Preparation of 5′-Deoxy-2′,3′-*O*-isopropylidene-3,5′-cycloguanosine (Vb). A solution containing 3.4 g of Ib and 1.25 g of methanesulfonyl chloride in 50 m*l* of anhydrous pyridine was heated for 2 hr at 80°C. The resulting solution was then poured into 200 m*l* of water and evaporated to dryness under reduced pressure. After the residue had been dissolved in water, the pH of the solution was adjusted to 7 and ethyl alcohol was added to the solution. The precipitate was collected on a filter and recrystallized three times from water to give 1.3 g (40%) of white needles.

The crystal was indistinguishable spectrally (infrared and ultraviolet) from a sample of the Vb isolated in the preceding experiment.

The Preparation of 5′-Deoxy-3,5′-cycloguanosine (VIb). A solution of 2.0 g of Vb in 50 m*l* of water was adjusted to pH 1.5 with hydrochloric acid and then heated for 6 hr at 70°C. The resulting solution was neutralized with concentrated ammonium hydroxide, concentrated, and cooled to give a gelationous product. This product was changed to a powdery white precipitate with slight warming in ethyl alcohol. The precipitate was filtered, quickly dried, and reprecipitated from water-ethyl alcohol to give 0.2 g of a product. Although an attempt at elemental analysis failed due to its hygroscopic nature, it was confirmed by the ultraviolet spectra and R_f values that the product was G-2 itself.

The authors wish to express their deep gratitude to Dr. Tetsuya Kato of the Ajinomoto Co., Inc., for his unfailing guidance throughout the course of this work, and Dr. Akihiro Yamazaki for his help with the identification of some of the products.

(Received May 5, 1967)

A new catalyst consisting of a cobaltous chloride-ditertiary phosphine complex and an organoaluminum compound was found to be effective for the selective preparation of 1, 4-hexadiene by the reaction of butadiene with ethylene. The effects of the reaction variables on the activity and on the selectivity in 1, 4-hexadiene formation were studied. It is considered that a coordination of the ditertiary phosphine on the catalytically activated intermediate is essential for the selective catalysis. A reaction mechanism is proposed which involves an activated hydrido-cobalt complex as intermediate.

This investigation has been undertaken in order to find catalysts suitable for the highly-selective synthesis of 1, 4-hexadiene from butadiene and ethylene. The catalytic preparation of the diene has been reported by Hata[1] and by Alderson *et al.*[2] In Hata's process, the maximum selectivity[3] in 1, 4-hexadiene formation was, at most, 50%, and a fairly large amount of the charged butadiene was consumed in forming higher oligomers and polymeric substances. Binary catalysts containing various iron compounds gave similar results. In a previous paper,[4] however, we reported that a new catalyst consisting of an iron halide, an organoaluminum compound, and a ditertiary phosphine exerted an excellent selectivity (more than 80%) is the formation of the diene.

Since Wilke has opened a new field of cyclic butadiene oligomer formation, involving such substances as cyclododecatriene and cyclooctadiene, numerous patents and reports have been published in this field.[5] The formation of 1, 4-hexadiene is formally a 1, 4-addition of ethylene to butadiene; this type of oligomerization is found in the linear dimerization of butadiene catalyzed by cobalt-containing compounds.[6-9] A transfer of one hydrogen atom is involved in these reactions.

Table 1 summarizes the characteristic catalytic activities of iron, cobalt, and nickel compounds in the addition reactions of butadiene and butadiene-ethylene. It seems likely that the cobalt complex is one of the most suitable catalysts for the oligomerization of butadiene involving hydrogen transfer. The reaction of butadiene with ethylene catalyzed by a cobalt compound metal alkyl catalyst gave 1, 3-hexadiene as a 1 : 1 addition product.[9] A ternary iron catalyst consisting of ferric chloride, triphenylphosphine, and triethylaluminum acted similarly to the cobalt catalyst in the reaction of butadiene, while a different behavior was observed in the reaction of butadiene with ethylene.[10] By adding triphenylphosphine to a binary cobalt catalyst, *e.g.*, a cobalt tris-(acetylacetonate) and triethylaluminum catalyst, the activity with regard to the dimerization of butadiene disappeared.[8] In the reaction of butadiene with ethylene, however, no ternary cobalt catalyst containing a phosphorus compound has been investigated.

In this paper the results of our studies of the addition reaction of butadiene with ethylene catalyzed by a cobaltous halide-ditertiary phosphine complex and an organoaluminum compound will be described.

Results

As shown in Table 2, the dienylation reaction to yield 1, 3-hexadiene and linear dimers of butadiene was predominant, although the formation of 1, 4-hexadiene was slightly promoted by the cobaltous halide-triphenylphosphine complex catalyst. The results also suggest the possibility of modifying the catalytic properties of the cobalt compound by the addition of a proper ligand. It has been reported before that a ditertiary phosphine had an excellent effect in making the ternary iron catalyst highly selective for the preparation of 1, 4-hexadiene.[4]

The cobaltous chloride-1, 2-bis(diphenylphosphino)ethane complex, in which the ditertiary phosphine was coordinated as a chelate ligand to the cobaltous ion, was used as one component of the catalyst. The results are summarized in Table 3. At a relatively high concentration of the catalyst, a rapid exothermic reaction proceeded and the absorption of ethylene stopped in a short time. An almost exclusive formation of one product was found by gas chromatographic analysis; this product was identified by its boiling point, its retention volume in a gas chromatogram, the results of a mass analysis, and its infrared absorption spectrum, as 1, *cis*-4-hexadiene.

in the range from 80 to 100°C. At temperatures higher than 100°C, a considerable isomerization of 1, 4-hexadiene to conjugated dienes, mainly to 2, 4-hexadiene, was observed. The product obtained at 140°C contained 71.6% of the 2, 4-isomer in the C_6-fraction. When the reaction was carried out at 150°C or above, only the 2, 4-isomer appeared. The effect of the molar ratio of Al/Co on the reaction was also studied; the results are shown in Tables 4 and 5. The selectivity of 1, 4-hexadiene was not influenced by the molar ratio. In using this catalyst, a large amount of triethylaluminum was required for the activation, in particular at a low concentration of the cobalt complex, it is considered that the purity of the reactions and solvents also affects the molar ratio of Al/Co.

Although the cobalt complex is insoluble in common organic solvents, a homogeneous catalyst solution can be obtained by mixing the two components of the catalyst. The solution can be stored at room temperature without a decline in catalytic activity (Table 6). The cobalt complex is soluble in 1, 2-dichloroethane to give a dark green solution. A more rapid reaction occurred in the initial stage when 1, 2-dichloroethane was used as the solvent. In this case the control of the reaction temperature was impossible and side reactions occurred to a considerable extent to give the 2, 4-isomer and C_8-dienes. In Table 7 the results obtained by using a variety of solvents are shown. Although the reaction could be carried out smoothly without any solvent, a higher conversion was attained when a proper solvent was used. 1, 4-Hexadiene itself can also be used as a solvent.

In all the reactions described above, triethylaluminum was used as a reducing component. In addition, some other organometallic compounds were also used as reducing agents; the results are summarized in Table 8. It was found that triisobutylaluminum, diisobutylaluminum hydride, and diethylzinc were highly effective in making

the cobalt catalysts selective for 1, 4-hexadiene formation. Although the activity of the catalyst containing diethylaluminum chloride or ethylaluminum sesquichloride was fairly high, the selectivity of 1, 4-hexadiene was low and a considerable amount of polymeric substance was formed. Diethylaluminum ethoxide reacted with the cobalt complex to give a dark brown solution, but no catalytic activity was observed.

It was confirmed that butadiene did not react with isobutene and *n*-butene under the reaction conditions. Therefore, it is possible to use the B-B fraction as a source of butadiene instead of pure butadiene.

Discussion

In a previous paper,[4] the effect of the ditertiary phosphine in the iron ternary catalyst on the selective formation of 1, 4-hexadiene was discussed. It is expected that the ditertiary phosphine will occupy one or more coordination sites around the catalytically active metal atom and that, hence, the coordination of reactants will be suppressed. The ditertiary phosphine, having an apt structure for chelate coordination, was effective. In the preparation of a catalyst for the linear oligomerization of butadiene, the catalyst components should be mixed in the presence of butadiene in order to obtain a highly-active catalyst; otherwise, a black precipitate is separated and no active catalyst is obtained. On the other hand, the cobaltous chloride-ditertiary phosphine complex catalyst can be prepared in the absence of the reactants and kept without a decline in catalytic activity. This fact indicates that low-valent cobalt, formed by a reaction of the cobalt complex with triethylaluminum, is stabilized by the coordination of the ditertiary phosphine. The function of the phosphine in stabilizing a low-valent state of a metal atom is generally accepted.[11] It is known that a reaction of cobaltous chloride-1, 2-bis(diphenylphosphino)-ethane complex with lithium aluminum hydride or sodium borohydride gives a hydride-cobalt complex, $CoH((C_6H_5)_2PCH_2CH_2P(C_6H_5)_2)_2$.[12] A reaction of cobalt tris(acetylacetonate) with diethylaluminum ethoxide in the presence of the ditertiary phosphine also gives the hydride-cobalt complex.[13] However, these combinations of the cobalt complex with lithium aluminum hydride and diethylaluminum ethoxide are catalytically inactive; these facts suggest that the hydrido-cobalt complex itself is not an active species, because the hydrido-cobalt complex is coordinately saturated. It is considered that an organoaluminum compound in the catalyst acts in two ways, that is, as a reducing agent to form the hydrido-cobalt complex, and as an activating agent to place the hydrido-cobalt complex in a coordinately-unsaturated state.

It was found that 1, 2-bis(diphenylphosphino)-ethane formed a 2 : 1 complex with cobaltous chloride, whereas 1, 3-bis(diphenylphosphino)propane formed a 1 : 1 complex. The 1 : 1 complex combined with triethylaluminum revealed a selective activity for the preparation of 1, 4-dienes.[14] On the basis of these findings, it seems that a complete inhibition of the dienylation reaction can be realized by blocking one or two coordination sites around the catalytically active cobalt atom. The coordination of nitrogen-containing ligands to cobalt chloride was, however, ineffective in preparing the diene selectively (Table 9).

From these experimental results, the following mechanism may be proposed; first, the hydrido-cobalt complex is formed as a transient intermediate by the reaction of the cobaltous chloride-1, 2-bis(diphenylphosphino)ethane complex with triethylaluminum, and then the hydrido-cobalt complex is activated to a coordinately unsaturated state by the action of the organoaluminum compound. Butadiene reacts with the activated complex to

give a π-butenyl complex such as that derived from butadiene and cobalt hydrocarbonyl.[15] An ethylene molecule coordinated to the activated cobalt complex attacks the π-allyl part of the butenyl group to give a 4-hexenyl complex. This intermediate finally yields 1, *cis*-4-hexadiene, which is set free, while, at the same time, the hydrido-complex is regenerated for further reaction. The exclusive formation of the *cis*-isomer and the facile and selective reaction of butadiene with ethylene constitute strong evidence for the coordination mechanism.

Experimental

Reagents. The solvents were purified by conventional methods. The butadiene (Japan Synthetic Rubber Co.) was dried by passing it through columns of a sodium glycolate-ethylene glycol solution, potassium hydroxide, activated alumina, and a molecular sieve, and then condensed in a measuring vessel kept in a dry ice-acetone bath. The ethylene (Nihon Petrochemical Co.) was used without further purification. The organoaluminum compounds (Ethyl Corp.) were obtained commercially. The triphenylphosphine (Techno Chemie G. m. b. H.) was used without purification. The ditertiary phosphines were prepared according to the method described by Hewertson and Watson.[16] Commercially available ethylenediamine and α,α'-dipyridyl were used. The cobalt halide-triphenylphosphine complex was prepared according to the method of Venanzi.[17]

The cobalt halide-ditertiary phosphine complex was obtained by the reaction of anhydrous cobaltous halide with the ditertiary phosphine in ethanol. The hydrido-cobalt complex was prepared according to the method of Zingales.[12] The cobalt complexes with chelate ligands containing nitrogen atoms were prepared according to the method described in the literature.[18,19]

Reaction Procedure. The reaction was usually carried out in a 200-m*l* pressure vessel equipped with a magnetic stirrer. Under a nitrogen atmosphere, calculated amounts of the solvent, the cobalt complex, liquified butadiene, and the organoaluminum compound were charged in this order into the vessel. After the vessel had then been tightly closed, ethylene was injected directly from the cylinder until a given pressure was reached at a reaction temperature. The mixture was heated with agitation for a given time, cooled to room temperature, and vented to remove any unreacted ethylene. The catalyst was then deactivated by the addition of a small amount of methanol containing dilute hydrochloric acid. The reaction mixture was repeatedly washed with water, after which the organic layer was separated and dried with anhydrous sodium sulfate overnight. A distillate obtained at atmospheric pressure was analyzed by gas chromatography using a copper tube (3 mm in diameter and 3 m long) packed with Apiezon Grease L at 100°C. The yield was calculated by comparing the peak area with that of a substance added as an internal standard. The validity was confirmed by the analysis of a known mixture.

Effect of the Storage of the Catalyst Solution on the Activity. The catalyst solution was prepared by mixing 0.74 g (0.8 mmol) of the cobalt-ditertiary phosphine complex and 3.65 g (32 mmol) of triethylaluminum in 100 m*l* of toluene. The solution was then stored in a 300-m*l* Erlenmeyer flask equipped with a glass stopper under a nitrogen atmosphere at room temperature. After 2 days and 12 days, 20-m*l* portions of the solution were used as catalysts for the reaction of butadiene with ethylene, carried out at 80°C for 2 hr; the results are shown in Table 6.

B-B Fraction as a Source of Butadiene. A B-B fraction purchased from the Mitsubishi Petrochemical Co. was vaporized from a cylinder and condensed in a glass pressure vessel. The B-B fraction was purified by

passing it through the column system for butadiene purification described above. It was then again condensed in a measuring vessel. The content of butadiene in the purified B-B fraction was 42.4% while the remainder consisted of C_4-olefins and lower homologues. A 200-m*l* pressure vessle was charged with 10 m*l* of 1, 2-dichloroethane, 100 m*l* of the liquefied B-B fraction, 0.09 g of the cobalt complex, and 0.944 g of triethylaluminum. Under an ethylene pressure of 50 kg/cm^2, the reaction was then carried out for 2 hr at 100°C. Gas chromatographic analysis of the reaction mixture showed that 58.5 g of 1, 4-hexadiene and 2.2 g of 2, 4-hexadiene were produced.

The authors wish to express their appreciation to Mr. M. Taguchi and Mr. T. Aziki for their assistance in the experimental work, and to Toyo Rayon Company for permission to publish this work.

The Preparation of Optically Active Trimethylcyclododecatriene by the Resolution of Racemic Oligomers and the Asymmetric Oligomerization

Junji FURUKAWA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

and Tsuneo KAKUZEN, Hiroyuki MORIKAWA, Ryuzo YAMAMOTO and Osamu OKUNO

Institute for Chemical Research, Kyoto University, Takatsuki

(Received May 17, 1967)

Trimethylcyclododecatriene was prepared by the oligomerization of pentadiene, using the diethylaluminum chloride - titanium tetrabutoxide system as a catalyst. The resulting oligomer was fractionated by vapor-phase chromatography into geometrical (cis and trans) and structural (head-to-tail and head-to-head) isomers with respect to the pentadiene units involved. The structures of these isomers were proposed on the basis of infrared and NMR spectra of the oligomers and their hydrogenated products. The results of the oxidative degradation of the oligomers were compatible with the proposed structures. Further, the existence of stereoisomers was shown by resolution and asymmetric oligomerization. The resolution of *d*- and *l*-enantiomers was carried out through the asymmetric hydroboration of the oligomers, while the asymmetric oligomerization was achieved using the titanium menthoxide - diethylaluminum chloride system as a catalyst.

The cyclotrimers of butadiene[1] and pentadiene[2] have been known to be prepared by means of a transition metal catalyst. The geometrical isomers of the cyclotrimer of butadiene seem to be interesting in relation to the stereochemistry of oligomerization. Among possible isomers, *ttt*-, *ttc*-, and *tcc*-trimers have been reported by Wilke,[1] but little is known of the cyclotrimers of pentadiene-1, 3. In the latter there should exist stereoisomers as well as cis-trans and head-to-tail isomers, but no research has ever been undertaken on stereoisomers of this sort.[2] This paper will describe the separation of the geometrical isomers of the cyclotrimers of pentadiene-1, 3 by means of vapor-phase chromatography with a Gorey column, and the resolution of *d*- and *l*-enantiomers through asymmetric hydroboration. The asymmetric synthesis of optically active oligomers has also been successfully completed by using a titanium catalyst containing asymmetric component. The oligomers thus obtained are low in optical rotation and may, therefore, not be high in optical purity, but this report may have same value as the first one concerning the resolution of such oligomers and asymmetric oligomerization.

Trimethylcyclododecatriene was synthesized using titanium tetrabutoxide and diethylaluminum chloride as catalysts. The reaction was accompanied by the formation of a large amount of polymer of a low molecular weight, and the vacuum distillation afforded trimethylcyclododecatriene as a fraction with a boiling point of 80—100°C at 2 mmHg (whose yield was, however, as low as 15.7%). This compound showed the infrared absorptions for trans and cis unsaturations at 955 cm^{-1} and 735 cm^{-1} respectively. Its ultraviolet

spectrum showed no absorption peak corresponding to the conjugated diene structure (at 230 mμ). Its NMR spectrum contained an olefinic proton absorption at $\tau=4.7$—5.2, methine- and methylene-absorptions at $\tau=7.7$—8.2, and a methyl absorption at $\tau=8.8-9.3$, the intensity ratio being 6 : 9 : 9. In the hydrogenated product the ratio of methyl to methine and methylene was 9 : 21. These results accord with any of the cyclic structures, I—VII, in Fig. 1.

Of these, I and IV have all head-to-tail structures, while II, III, V, VI, and VII involve head-to-head and head-to-tail structures. Therefore, there should be two types of hydrogenated products. Hydrogenation with palladium black in ether yielded two products, which were then fractionated into two fractions (named H-1 and H-2) by vapor-phase chromatography using an Apiezone L column at 200°C. NMR study indicated that both H-1 and H-2 contained methyl and other protons in a ratio of 9 : 21, and that H-1 involved methyl absorption at 9.1 and 9.2, whereas H-2 involved such absorption at 9.15 and 9.25, together with that at 9.1 and 9.2. This fact may be accounted for by assuming that the H-1 fraction consists entirely of head-to-tail structures and involves three methyl groups located symmetrically to each other (structure VIII), while the H-2 fraction contains two types of methyl groups, resulting from both head-to-head and head-to-tail structures (structure IX).

Further fractionation by means of Gorey-column vapor-phase chromatography (Hitachi F6D-Q-45) at 180°C indicated that H-1 and H-2 consisted of two and three fractions respectively. This fact may be associated with the presence of cis and trans isomers of methyl groups.

The original trimethylcyclododecatriene was fractionated into five fractions, 1 through 5, forming 7, 13, 21, 15, and 44% of the total respectively. Their infrared spectra indicate that the fractions 1 and 2 correspond to the *ttt*-structure (I, II, or III), while the fractions 3, 4, and 5 correspond to the *ttc*-structure (IV, V, VI, or VII).

The hydrogenation of the fractions 1 and 3 gave H-1, whereas the fractions 2, 4, and 5 gave H-2. Furthermore, methylsuccinic acid was yielded exclusively from the fraction 1 by oxidative degradation with potassium permanganate, while the unfractionated oligomer gave a mixture of succinic, methylsuccinic, and α, α'-dimethylsuccinic acids. Thus, the fractions 1 and 3 must be symmetric in structure.

From these results we may conclude that the fractions 1, 2, and 3 correspond to the structures I, II (or III), and IV respectively. However, it

still remains uncertain to which structure (V, VI, or VII) the fractions 4 and 5 correspond.

The original trimethylcyclododecatriene was resolved by asymmetric hydroboration with diisopinocampheyl borane,[3] which had itself been prepared from BF_3 etherate, sodium borohydride and α-pinene $[\alpha]_D^{20}=+43.8°$, followed by hydroxylation with hydrogen peroxide. From the reaction product, the *ttt*- and *ttc*-oligomers remaining unreacted were fractionated by vapor-phase chromatography, these oligomers showed optical rotations of $-8.0°$ and $-15.7°$ respectively. The other products were hydroxylated products of the oligomer, $[\alpha]_D^{20}=-11.4°$, and isopinocampheol, $[\alpha]_D^{20}=-28.3°$. The optical rotations of unreacted and reacted oligomers are not high, but the resolution may take place to a significant extent.

Finally, we tried to synthesize the optically active oligomer by means of asymmetric oligomerization, using titanium tetramenthoxide or tetraamyloxide and diethylaluminum monochloride as catalysts. The fractions with boiling points of 80—100°C/2 mmHg (yield 10%) and of 100—120°C/2 mmHg (yield 4%) distilled from the reaction product were treated with triethylaluminum and phenylisocyanate in order to remove the menthol. The two fractions thus obtained, which were confirmed by vapor-phase chromatography and IR to contain no menthol, had optical rotations, $[\alpha]_D^{15}$, of $-8.6°$ and $-4.4°$. The distillation residue had $[\alpha]_D^{15}=-2.0°$.

In the case of the titanium tetraamyloxide-diethylaluminum chloride catalyst also, the optically active oligomer was obtained by the same method. The optical rotations were as follows: fraction 80—100°C/2 mmHg, $[\alpha]_D^{15}=-0.9°$ (yield 12%), and the distillation residue, $[\alpha]_D^{15}=-0.5°$.

In conclusion, we have succeeded in the resolution and asymmetric synthesis of trimethylcyclododecatriene.

Our success in the fractionation of geometrical isomers and in the resolution of the enantiomer shows the existence of such isomers. The success in asymmetric oligomerization suggests the possibility that the asymmetric ligand, if present, in titanium catalyst has an asymmetric steric effect on the formation of trimethylcyclododecatriene.

Experimental

Preparation of Trimethylcyclododecatriene. In a 50 m*l* test tube there were placed 10 m*l* (0.1 mol) of purified pentadiene-1, 3, 10 m*l* of purified benzene, and 1 mmol of purified titanium tetra-*n*-butoxide under a nitrogen atmosphere. After 6 mmol of diethylaluminum monochloride had then been added, the test tube was sealed and subjected to a reaction. After the reaction had continued for 48 hr at 40°C, the reaction product was treated with 2 m*l* of methanol and washed with diluted sulfuric acid. After drying with calcium chloride, fractional distillation under a vacuum yielded 1.2 g (15.7%) of trimethylcyclododecatriene (80—100°C/2 mmHg), together with a liquid polymer. The trimethylcyclododecatriene had a boiling point of 256—261°C/760 mmHg and a refractive index, n_D^{20}, of 1.4918.

Found: C, 87.97; H, 11.69%; mol wt (cryoscopic method), 204. Calcd for $C_{15}H_{24}$; C, 88.16; H, 11.84%; mol wt, 204.

The infrared spectrum showed trans- and cis-unsaturations at 955 cm^{-1} and 735 cm^{-1} respectively, but no vinyl unsaturation. The ultraviolet spectrum showed no peak at 230 mμ corresponding to that of the conjugated double bond. NMR study confirmed the presence of methine, methylene, and methyl groups in a 6 : 9 : 9 ratio.

Hydrogenation of Trimethylcyclododecatriene. Two hundred milligrams of purified trimethylcyclododecatriene were hydrogenated in 2 m*l* of ether with 200 mg of a Pd-black catalyst at 25°C under H_2-pressure (300 mmH_2O). The product was trimethylcyclododecane, which was a mixture of H-1 and H-2.

Oxidative Degradation of Trimethylcyclododecatriene. Trimethylcyclododecatriene was oxidized by the drop-by-drop addition of a potassium permanganate solution for 4 hr at 5°C. After the oxidation, sulfur dioxide was passed through until the solution became clear. After the product had then been extracted with ether, the ether was evaporated off and the residue esterified in a mixture of benzene and ethanol by the azeotropic method. The distillates (bp 104—110°C/18 mmHg) were identified as the ethyl esters of succinic, methylsuccinic, and α, α'-dimethylsuccinic acid by vapor-phase chromatography.

Resolution of Trimethylcyclododecatriene. 0.90 g of sodium borohydride was dissolved in 25 m*l* of the diethylene glycol dimethylester (diglyme) and then admixed with 9.8 g of α-pinene $[\alpha]_D^{20}=+43.8°$.

A solution of boron trifluoride-etherate (3.9 g in 5 m*l* of diglyme) was added, drop by drop, over a 15 min period at 0—5°C, after which the mixture was stirred for 4 hr. Furthermore, 4.2 g of trimethylcyclododecatriene were added, drop by drop, over a 15 min period, after which the reaction mixture was subjected to the reaction for 4 hr while being stirred under cooling with ice. One milliliter of water was added to decompose the residual hydride. The reaction mixture was then separated into two layers; the lower layer involved diglyme and water, while the upper layer contained organo-borane, coming from trimethylcyclododecatriene, and unreacted trimethylcyclododecatriene. The upper layer was treated with 30 m*l* of a 3 N sodium hydroxide solution and 30 m*l* of 30% hydrogen peroxide at room temperature and with stirring for one hour. The vacuum distillation of the reaction product yielded 7.2 g of the fraction of 80—100°C/2 mmHg, together with a solid residue. The former fraction contained trimethylcyclododecatriene (optically active), isopinocampheol, and a trace of α-pinene; the latter solid was a mixture of hydroxylated trimethylcyclododecatriene, a solid residue, and a trace of isopinocampheol. They were further fractionated by fractional vapor-phase

3) H. C. Brown, N. R. Ayyangar, G. Zweifel and T. Munekata, *J. Am. Chem. Soc.*, **86**, 397, 1071, 1076 (1964).

chromatography. Their optical rotations were as follows: *ttt*-trimethylcyclododecatriene, $[\alpha]_D^{20} = -8.0°$, *ttc*-trimethylcyclododecatriene, $[\alpha]_D^{20} = -15.7°$, isopinocampheol, $[\alpha]_D^{20} = -28.3°$ (literature[3] $-32.4°$), and hydroxylated trimethylcyclododecatriene, $[\alpha]_D^{20} = -11.4°$.

Asymmetric Synthesis of Optically Active Trimethylcyclododecatriene. Optically active trimethylcyclododecatriene was synthesized in a manner similar to that adopted for the optically inactive one, except for the use of an asymmetric titanium alkoxide catalyst, which was prepared in a way to be described later. In order to remove the menthol, 5 m*l* of the product oligomer was treated with 1.5 m*l* of triethylaluminum and 1.5 m*l* of phenyl isocyanate. In the oligomer thus treated, no trace of menthol was found by vapor-phase chromatography or by IR.

Preparation of Titanium Tetraamyloxide. One mol of titanium tetrachloride, purified by refluxing it in the presence of copper powder under nitrogen, was reacted with 5 mol of purified amylalcohol ($[\alpha]_D^{15} = -4.9°$) in *n*-hexane solution at room temperature for 4 hr under dehydrated ammonia vapor. The reaction product was then filtered and subjected to distillation; boiling point 150—152°C/1 mmHg (literature 154°C/0.5 mmHg[4]). The vapor-phase chromatography of the decomposition product obtained with methanol-water showed the presence of tetraamylalcoxide.

Preparation of Titanium Tetramenthoxide. Titanium tetramenthoxide (white powder, melting point over 200°C) was prepared from titanium tetrachloride and menthol ($[\alpha]_D^{15} = -48°$) by the same method.

Studies of the Organic Reactions of Metal Carbonyls. XIII.*1 The Reduction of Olefin Oxides with Potassium Iron Carbonylates

Yoshinobu TAKEGAMI, Yoshihisa WATANABE, Takeaki MITSUDO, Isao KANAYA and Hiromitsu MASADA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 27, 1967)

The reaction between potassium iron carbonylates ($KHFe(CO)_4$, $K_2Fe(CO)_4$, and $K_2Fe_2(CO)_8$) and olefin oxides has been studied. Styrene oxide reacts readily with these carbonylates and with carbon monoxide under an atmospheric pressure and at 30°C. As the reaction products, styrene, ethylbenzene, and α- and β-phenylethyl alcohol are obtained. The major product is styrene or β-phenylethyl alcohol for the reaction of $K_2Fe(CO)_4$ or $KHFe(CO)_4$ and $K_2Fe_2(CO)_8$ respectively. The effects of solvents and additives are examined. Further, propylene oxide and epichlorohydrin are found to react with $K_2Fe(CO)_4$ and carbon monoxide to give not only carbonylated products, but also propylene. The results indicate that olefin oxides are generally reduced with $K_2Fe(CO)_4$ and carbon monoxide to give the corresponding olefins and carbon dioxide.

$$R\text{-}CH\text{-}CH_2 + CO \xrightarrow{K_2Fe(CO)_4} R\text{-}CH{=}CH_2 + CO_2$$
(O)

Previous work in this laboratory has shown that propylene oxide and ethylene oxide react with potassium iron carbonylates ($KHFe(CO)_4$, $K_2Fe(CO)_4$ and $K_2Fe_2(CO)_8$) and carbon monoxide[1]; carbon monoxide is readily absorbed, and, as the carbonylated products, β-hydroxy esters*2 are obtained by the treatment of the reaction mixture with iodine and alcohol, indicating that the corresponding β-hydroxyacyliron carbonyls are formed. However, the yield of the esters is very low. This suggests that some reaction other than the carbonylation also occurs.

In the present investigation, the reaction of styrene oxide and epichlorohydrin with the iron carbonylates has been mainly studied in detail in examining for a reaction other than the carbonylation.

Experimental

The Preparation of Potassium Iron Carbonylates, $KHFe(CO)_4$, $K_2Fe(CO)_4$ and $K_2Fe_2(CO)_8$. These salt solutions in alcohols were prepared according to the method described in a previous paper[1]: A

*1 Part XII: Y. Takegami, Y. Watanabe and H. Masada, This Bulletin, **40**, 1459 (1967).

1) Y. Takegami, Y. Watanabe, H. Masada and I. Kanaya, This Bulletin, **40**, 1456 (1967).

*2 β-hydroxybutyrate and β-hydroxypropionate.

50-m*l* portion of 0.22 M $KHFe(CO)_4$, $K_2Fe(CO)_4$, or a 0.11 M $K_2Fe_2(CO)_8$ solution was used in each run.

When $K_2Fe(CO)_4$ is prepared, two equivalent moles of water are formed:[2]

$$Fe(CO)_5 + 4KOH \xrightarrow{\text{in alcohol}} K_2Fe(CO)_4 + K_2CO_3 + 2H_2O \quad (a)$$

Therefore, when a dry solution of $K_2Fe(CO)_4$ was required, the solvent of $K_2Fe(CO)_4$ was once distilled off under a vacuum and then 50-m*l* of a new dry solvent was added.

Materials. The styrene oxide, propylene oxide, epichlorohydrin, iron pentacarbonyl, and other compounds employed in this study were all commercial products.

Reaction Procedures. *Styrene Oxide.* To the solution of the potassium iron carbonylate described above, 3.2 g of styrene oxide were added; the mixture was then agitated vigorously for 3 to 8.5 hr at 30 to 50°C, under an atmosphere of carbon monoxide or nitrogen. The amount of carbon monoxide absorbed was determined by following the change in the readings of a buret. After a certain reaction time, the reaction mixture was poured into a separatory funnel, in which 100-m*l* of water had been placed, and extracted with two 100-m*l* portions of *n*-hexane. The *n*-hexane solution was concentrated to about 10-m*l*, and then submitted to analysis.

Propylene Oxide or Epichlorohydrin. The reaction of $K_2Fe(CO)_4$ with propylene oxide or epichlorohydrin was similarly carried out, and the gas over the reaction mixture was analyzed.

Analytical Procedures. The reaction products were analyzed by gas chromatography and by means of their infrared spectra, which had been taken on a Shimadzu model IR-27 infrared spectrophotometer. Further, styrene was confirmed by being converted to ethylbenzene; after hydrogenation with Raney nickel, the peak of styrene in the gas chromatogram vanished and a new peak of ethylbenzene appeared.

Results

The Reaction of $K_2Fe(CO)_4$ with Styrene Oxide. *The Relation between the Amount of Carbon Monoxide Absorbed and the Yield of the Products.* The results of the reactions are summarized in Table 1 and Fig. 1. All of the reactions were carried out at 30°C under an atmosphere of carbon monoxide, except for Exp. 4, which was carried out under nitrogen.

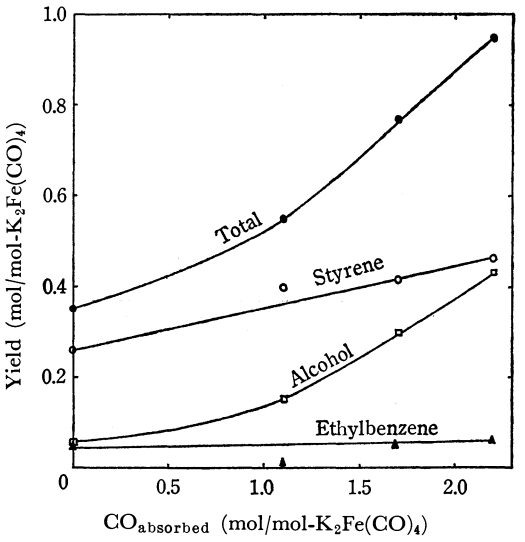

Fig. 1. The reaction of $K_2Fe(CO)_4$ with styrene oxide.

As Table 1 shows, styrene oxide readily reacts with $K_2Fe(CO)_4$ and carbon monoxide, while the reaction solution turns from light brown to dark red. As the reaction products, styrene, which is the major product, ethylbenzene, and α- and β-phenylethyl alcohol are obtained. However, no carbonylated product is obtained.*3 The gas absorption amounts to more than two moles,*4 therefore, the total yield of the products is almost equivalent to the $K_2Fe(CO)_4$ used (see Exp. 3). The plots of the yield of the products against the amount of carbon monoxide absorbed are illustrated in Fig. 1. As Fig. 1 shows, the yields of all products except ethylbenzene increase with the amount of carbon monoxide absorbed.

*1 At 30°C under one atmosphere. Reaction time: 4 hr. Solvent: EtOH.
*2 α- and β-Phenylethyl alcohol. About 2/3 of the alcohols is β.
*3 Fe exists as iron carbonylates.

Effects of Solvents and Additives. The effects of solvents and additives on reactions analogous to Exp. 2 were examined. The results are summarized in Table 2.

In the reaction in dry ethyl alcohol at 30 and 50°C (Exps. 5 and 6), the yield of styrene is better and that of phenylethyl alcohols is worse than those in Exp. 2, in which some of the water formed during the preparation of the iron carbonylate is present in the solvent. This fact indicates that a dry solvent is favorable to the production of styrene and that a relatively small amount of water has an effect on the distribution of the reduction products. In dry tetrahydrofuran solution, scarcely no reaction occurs (Exp. 7).

As additives, water and pyridine were used (Exps. 8 and 9). When 10 mol of water are added, the yield of styrene decreases to about half that in Exp. 2, but the yields of the alcohols increase slightly. When 10 mol of pyridine are added, scarcely no reduction product other than styrene is formed. These results show that the water added has an inhibitory effect on the formation of styrene, but that the pyridine added retards the production of phenylethyl alcohols completely.

The Reaction of $KHFe(CO)_4$ or $K_2Fe_2(CO)_8$ with Styrene Oxide. The results are summarized in Table 3. $KHFe(CO)_4$ and $K_2Fe_2(CO)_8$ also readily react with styrene oxide and carbon monoxide to give styrene and phenylethyl alcohols. As for the reaction of $KHFe(CO)_4$, the major product is not styrene, but β-phenylethyl alcohol (Exp. 10), the yield of which is about 1.7 times as much as that in the reaction of $K_2Fe(CO)_4$ (Exp. 2), indicating that $KHFe(CO)_4$ is very favorable for the production of the alcohol. As Exp. 12 shows, $K_2Fe_2(CO)_8$ is also more favorable for the production of the alcohol than for that of styrene.

The Reaction of $K_2Fe(CO)_4$ with Propylene Oxide or Epichlorohydrin. Propylene oxide and epichlorohydrin also readily react with $K_2Fe(CO)_4$ and carbon monoxide,*5 the reaction solution thus turning from light brown to red brown. Propylene was detected in the gas over both reaction mixtures, the amount being at least 0.2 mol in both cases.

Discussion

The results obtained here show that olefin oxides generally react with $K_2Fe(CO)_4$ and carbon monoxide to give the corresponding olefins. In the course of the reaction, carbon dioxide is definitely

*5 At 20°C, about 2 mol of carbon monoxide were absorbed in both cases.
*6 Analyzed by gas chromatography and by means of a mass spectrum taken on a JMS=OISG mass spectrometer (Japan Electron Optics Laboratory Co.).

produced.*7 Thus, the following reaction appears to occur:

$$R\text{-}\underset{\diagdown\,\diagup}{\underset{O}{CH}}\text{-}CH_2 + CO \xrightarrow{K_2Fe(CO)_4} R\text{-}CH{=}CH_2 + CO_2 \qquad (b)$$

This reaction is not considered to proceed *via* α- and β-phenylethyl alcohol, because they do not react with the iron carbonylate and carbon monoxide. The reaction mechanism, however, is not yet completely clear.

The yield of styrene is best when $K_2Fe(CO)_4$ and a dry ethanol solvent are used at 50°C. On the other hand, the reaction of $KHFe(CO)_4$ gives phenylethyl alcohols in the best yield. The addition of water to the $K_2Fe(CO)_4$ reaction system causes a significant decrease in the yield of styrene and a slight increase in the yield of the alcohols. This fact may be explained by assuming that an equilibrium between $K_2Fe(CO)_4$ and $KHFe(CO)_4$ exists in the reaction solution; the reaction of $K_2Fe(CO)_4$ gives styrene, and that of $KHFe(CO)_4$ gives phenylethyl alcohols.

$$K_2Fe(CO)_4 + H_2O \rightleftharpoons KHFe(CO)_4 + KOH \qquad (c)$$

The fact that pyridine used as an additive remarkably inhibits the formation of the alcohols suggests that the pyridine disturbs the reaction of $KHFe(CO)_4$ and styrene oxide by forming a kind of salt between $KHFe(CO)_4$ and the pyridine.

$K_2Fe_2(CO)_8$ shows a rather reduced reactivity in comparison with $K_2Fe(CO)_4$ and $KHFe(CO)_4$.

The reaction of epichlorohydrin with $K_2Fe(CO)_4$ involves another problem; in this reaction, allyl chloride, the corresponding olefin, was not detected by gas chromatography, but propylene was obtained. On the other hand, allyl chloride was found to react readily with $K_2Fe(CO)_4$ under the same conditions as in Exp. 2, with an evolution of propylene.*8 This suggests that the active halogen atom of allyl chloride is readily replaced by a hydrogen atom under these conditions. Therefore, epichlorohydrin may be reduced to allyl chloride in the first step, and then the allyl chloride is converted to propylene as follows:

$$H_2C\text{-}\underset{\diagdown\,\diagup}{\underset{O}{CH}}\text{-}CH_2Cl \rightleftharpoons H_2C{=}CH\text{-}CH_2\text{-}Cl \rightleftharpoons H_2C\text{-}\underset{\diagdown\,\diagup}{\underset{O}{CH}}\text{-}CH_3 \longrightarrow H_2C{=}CH\text{-}CH_3 \qquad (d)$$

This work was supported in part by The Kawakami Foundation, to which our thanks are due.

*7 Carbon dioxide was evolved when the reaction mixture was treated with concentrated hydrochloric acid. The amount of carbon dioxide evolved was almost equal to the sum of the carbon dioxide formed according to Eqs. (a) and (b).

*8 The absorption of carbon monoxide did not occur.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 161—165 (1968)

A New Synthesis of Pyridoxal-5-phosphate

Masaru IWANAMI, Toshiko NUMATA and Masuo MURAKAMI

Central Research Laboratory, Yamanouchi Pharmaceutical Co., Ltd., Azusawa-cho, Itabashi-ku, Tokyo

(Received June 5, 1967)

By the hydrolysis of pyridoxal-5-phosphate Schiff bases, pyridoxal-5-phosphate was prepared in a crystalline form without any further purification. Pyridoxal-5-phosphate Schiff bases were prepared in good yields by the phosphorylation of pyridoxal Schiff bases and were easily purified by alkali-acid reprecipitation. The pyridoxal-5-phosphate thus obtained was demonstrated to be identical with an authentic sample by a study of its UV, IR, and NMR spectra.

It is generally accepted that the biological activity of vitamin B_6 is due to the participation of a phosphorylated derivative, pyridoxal-5-phosphate[1,2] (I). The synthesis of I has been reported by many investigators. Peterson and Sober first obtained I in a crystalline form by the oxidation of pyridoxamine phosphate and by purification through chromatography on cation-exchange resin.[3] The Hoffman La Rosche Co. improved this method and obtained I by the transamination of pyridoxamine phosphate with pyruvic acid in the presence of a metal ion and by purification

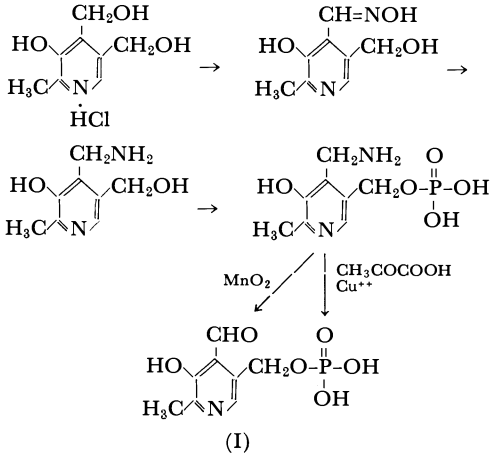

Fig. 1. Synthesis of pyridoxal-5-phosphate from pyridoxamine.

through chromatography on cation-exchange resin,[4] as shown in Fig. 1. In the present study it was established that I can be successfully prepared by the phosphorylation of pyridoxal Schiff bases followed by the hydrolysis of the phosphorylated products.[5]

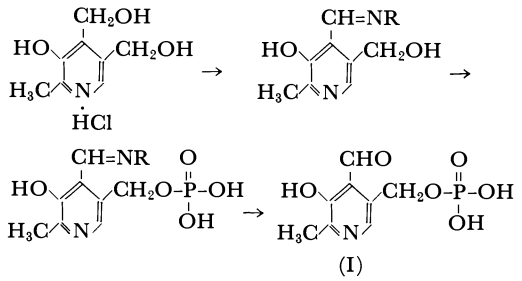

Fig. 2. A new synthesis of pyridoxal-5-phosphate from pyridoxal Schiff bases.

There have been few investigations concerning the synthesis of pyridoxal Schiff bases,[6] which were prepared in this paper from the three different substances described below. Pyridoxal (II) was used at first as the starting substance.[6] Pyridoxal Schiff bases were prepared from II by reaction with amines in methanol. Secondly, a pyridoxal sodium bisulfite addition compound (III), which could be obtained more easily than II from pyridoxine hydrochloride (IV), was used. Various pyridoxal Schiff bases were synthesized from III in yields varying from 30 to 95%, as Fig. 3 shows. Further, a more convenient method for the preparation of pyridoxal Schiff bases was established by the manganese dioxide oxidation of IV, followed by subsequent condensation with amines.

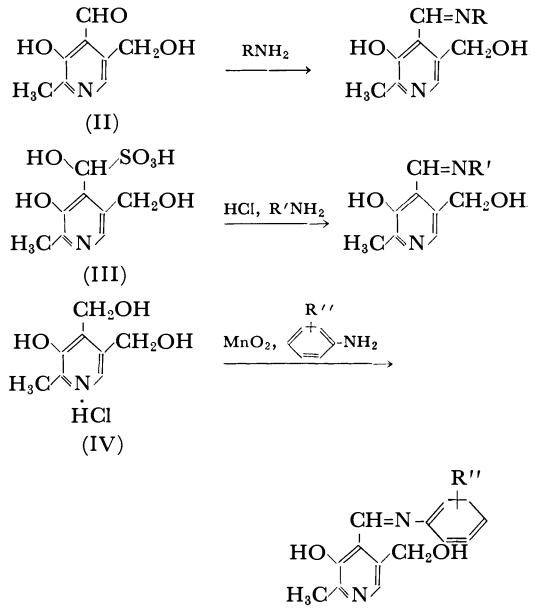

Fig. 3. Synthesis of pyridoxal Schiff bases.

This procedure is best suited to the synthesis of aromatic Schiff bases, since they are insoluble in water and therefore can be isolated as precipitates from the reaction mixture. For example, pyridoxal *p*-toluidine and pyridoxal *o*-phenetidine Schiff bases were obtained in good yields (80—85%) by this procedure.

Because of their instability, especially under acidic conditions, the Schiff bases have generally been considered to be unsuitable for the protection of the aldehyde group. Aromatic pyridoxal Schiff bases are unstable compared with pyridoxamine, which has been used for the starting material of I in a previous method.[3,4] On the other hand, it was found that pyridoxal Schiff bases were stable in a nonaqueous solution, and a mixture of 85% phosphoric acid and phosphorus pentoxide (1.1 : 1) was used for the phosphorylation of pyridoxal Schiff bases. In the case of pyridoxamine, the phosphorylation could be carried out at 60°C without decomposition, but aromatic pyridoxal Schiff bases decomposed almost completely at the same temperature and the yields of I were very low. However, aromatic pyridoxal Schiff bases gave I in good yields when the temperature for phosphorylation was fixed at 40—50°C, while the phosphorylation of aliphatic pyridoxal Schiff bases was effected at higher temperatures, such as at 60°C for 18 hr. The yields of I from various pyridoxal Schiff bases are shown in Table 1.

It can be noticed that aromatic pyridoxal Schiff bases react more rapidly than aliphatic Schiff bases with the phosphorylating agent, and that the presence of such an electron-repulsive substituent as a methoxy, ethoxy, or methyl group in the benzene rings of aromatic pyridoxal Schiff bases

b) Reaction condition: 60°C, 18 hr

increases the yields of the phosphorylated products.

Pyridoxal-5-phosphate was isolated in a crystalline form from pyridoxal phosphate Schiff bases obtained by the above-mentioned procedure by a simple treatment. Pyridoxal phosphate Schiff bases were precipitated from the reaction mixture by adjusting the pH to 3—4 and were purified by alkali-acid reprecipitation. Purified pyridoxal phosphate Schiff bases were converted to pure I and amines simply by making the solution strongly alkaline by the addition of sodium hydroxide at room temperature. After the amines had been extracted with organic solvents, I remained as its sodium salt in the water layer, I was isolated in a crystalline form by the adjusting pH to 3—4 by the addition of hydrochloric acid. All of the earlier methods for preparation of I required chromatography on cation-exchange resin and the condensation of the dilute eluate up to the crystalline form, the present method is unique in that it does not involve such a complicated procedure. In the case of *p*-toluidine and *p*-phenetidine Schiff bases, phosphorylated products were obtained in more than 90% yields.

Experimental

Pyridoxal Methylamine Schiff Base. To an aqueous solution of 1.5 g of II, 3 m*l* of 30% methylamine were added. The reaction mixture was then neutralized to pH 7 with a sodium carbonate solution, and extracted twice with 30 m*l* portions of chloroform. The evaporation of the solvent gave a crude pyridoxal methylamine Schiff base, which was then recrystallized from *n*-hexane, mp 148—150°C. Pyridoxal *n*-hexylamine and *n*-butylamine Schiff base were prepared similarly. (Table 2).

Pyridoxal *t*-Butylamine Schiff Base. To a mixture of 1.0 g of II and 0.36 g of *t*-butylamine in 3 m*l* of absolute ethanol, alcoholic potassium hydroxide was added and the solution was heated to reflux for 2 hr. After cooling, the evaporation of the solvent gave an oily residue which was taken up in ether. The evaporation of the ether gave a crude *t*-butylamine Schiff base which was recrystallized from benzene, mp 56—57°C.

Pyridoxal Schiff Base from III (General Procedure). A solution of 3.0 g of III in 10 m*l* of 25% hydrochloric acid was heated at 60°C for 10 min under a nitrogen atmosphere. After cooling, amine was added to the solution. The pyridoxal Schiff base was precipitated from the solution by neutralization with a potassium carbonate solution.

Pyridoxal' *p*-Toluidine Schiff Base from Pyridoxine Hydrochloride. To an aqueous solution of 10.0 g of pyridoxine hydrochloride, manganese dioxide which had been prepared from 8.0 g of potassium permanganate, 9.5 g of sodium bisulfite, and 10.0 g of 50% sulfuric acid were added. After the solution had then been stirred for 4—5 hr, 7.8 g of *p*-toluidine were added. The pyridoxal *p*-toluidine Schiff base was precipitated from the solution, mp 274—275°C. Yield 10.2 g (82%)

The pyridoxal *o*-phenetidine Schiff base, the pyridoxal

p-anisidine Schiff base, *etc.*, were prepared similarly (Table 2).

Pyridoxal Phosphate Schiff Base (General Procedure). To a mixture of 5.0 g of phosphorus pentoxide and 6.5 g of 85% phosphoric acid, 1.0 g of the pyridoxal Schiff base was added. The reaction mixture was then heated at 45°C for 6 hr. After cooling, 5 m*l* of 0.1 N hydrochloric acid was added and the solution was heated at 60°C for 10 min. The reaction mixture was then neutralized with a 50% sodium hydroxide solution. The pyridoxal phosphate Schiff base was precipitated from the solution. The pyridoxal phosphate Schiff bases thus obtained are summarized in Table 3.

Isolation of Pyridoxal-5-phosphate through Chromatography on Cation-exchange Resin (General Procedure) in the Case of Aliphatic Pyridoxal Schiff Bases. To a mixture of 5.0 g of phosphorus pentoxide and 6.5 g of 85% phosphoric acid, 1.0 g of pyridoxal Schiff base was dissolved. The mixture was then heated at 60°C for 18 hr. The resulting solution, after the addition of 5 m*l* of 0.1 N hydrochloric acid, was again heated at 60°C for 10 min and then carefully applied to a 70 m*l* Amberlite IR-120 (acid form) column and eluted with water. The eluate was collected in 10—20 m*l* fractions. As the ultraviolet absorption spectra of pyridoxal-5-phosphate have a maximum at 390 mμ in a neutral or alkaline solution, the absorption spectra of each fraction were measured at 320 and 390 mμ, and those in which $E390\,m\mu/E320\,m\mu = 2.4 \pm 0.1$ were mixed. The first fraction, containing inorganic acid, was subjected to the column again. All the fractions containing pure pyridoxal-5-phosphate were combined and evaporated under reduced pressure below 40°C. A representative elution curve is presented in Fig. 4.

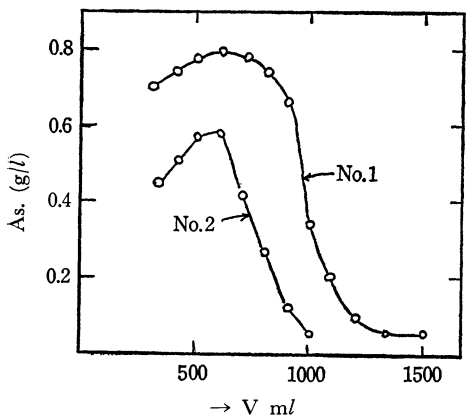

Fig. 4. A elution curve of pyridoxal-5-phosphate.

The curve No. 1 shows the elution pattern of pyridoxal-5-phosphate, while the curve No. 2 shows the elution pattern recovered from the acid part. The yields of pyridoxal-5-phosphate have been summarized in Table 1.

In the Case of Aromatic Pyridoxal Schiff Bases. In a mixture of 5.0 g of phosphorus pentoxide and 6.5 g of 85% phosphoric acid, 1.0 g of the pyridoxal Schiff base was dissolved. The solution was heated at 45°C for 4 hr, and to this 0.1 N hydrochloric acid was added after cooling. The resulting solution was heated again at 60°C for 10 min, carefully subjected to the column after cooling, and eluted with water. Pyridoxal-5-phosphate was obtained from the eluate by the method described above. The yields of pyridoxal-5-phosphate have been summarized in Table 1.

Schiff base in 5 m*l* of water, 10 m*l* of a 2 N sodium hydroxide solution was added. The reaction mixture was extracted twice with 20 m*l* portions of ether. To the water layer, 10 m*l* of 2 N hydrochloric acid was added. The solution was then cooled at 0—5°C overnight. Pure pyridoxal-5-phosphate was thus obtained in a crystalline form from the solution.

The yields of pyridoxal-5-phosphate are summarized in Table 4.

The pyridoxal-5-phosphate thus obtained was demonstrated to be identical with an authentic sample by a study of its UV, IR, and NMR spectra. The ultraviolet spectra data are summarized in Table 5.

The authors wish to express their gratitude to the staff of the analysis laboratory for their elementary analysis and infrared and ultraviolet spectra measurements

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 165—167 (1968)

The Cyclization of Ethyl Acetoacetate and Ketones by Ammonium Acetate

Akio SAKURAI and Hiroshi MIDORIKAWA

The Institute of Physical and Chemical Research, Komagome, Bunkyo-ku, Tokyo

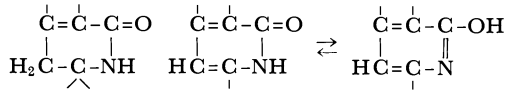
(Received June 16, 1967)

The reactions of ethyl acetoacetate with cyclic ketones and aromatic methyl ketones by using excessive ammonium acetate gave some heterocyclic compounds, such as 2-hydroxy-4-methyl-5, 6, 7, 8-tetrahydroquinoline (III), 2-hydroxy-4-methyl-6, 7-dihydro-5*H*-1-pyrindine (IV), and 2-hydroxy-4-methyl-6-alkyl-pyridines (VI). The structures of these compounds were investigated by means of their infrared and NMR spectra.

In a previous paper,[1] the synthesis of pyridone derivatives and related heterocyclic compounds by the condensation of ethyl cyanoacetate with various ketones in the presence of excessive ammonium acetate was reported.

The present paper will deal with the synthesis of hydroxyquinoline and hydroxypyridine derivatives by the reactions of ethyl acetoacetate and aromatic ketones or cyclic ketones with ammonium acetate. The cyclizations between ethyl acetoacetate and the ketones were quite limited compared with the case of ethyl cyanoacetate previously reported.

The cyclization reactions with a number of ketones were attempted; cyclic ketones, such as cyclohexanone and cyclopentanone, and aromatic methyl ketones, such as acetophenone and methyl α-naphthyl ketone, could be involved in this reaction, the hydroxyquinoline derivative (III) and the hydroxypyridine derivatives (IV) and (VI) being products. However, attempts to prepare the hydroxypyridine derivatives by reaction with aliphatic methyl ketones, such as acetone and methyl ethyl ketone, were unsuccessful under similar conditions. The infrared spectra of the dihydro-2-pyridone derivatives (I) described in the previous paper showed sharp bands at 3200 cm^{-1} and 1660 cm^{-1} attributed to the imino group and the carbonyl group of pyridone ring respectively. The NMR spectra of these compounds revealed a signal at 7.8—8.6 ppm due to the imino proton of the pyridone ring.



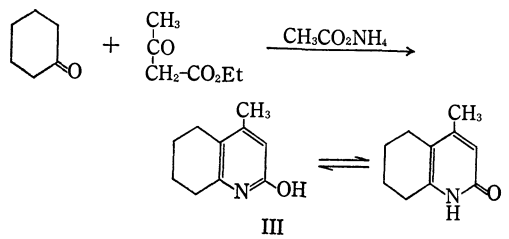
I II

On the other hand, 2-pyridone derivatives (II) gave no signal at 7.8—8.6 ppm and no infrared absorption band at 3200 cm^{-1}. The carbonyl band always appeared in the 1640—1660 cm^{-1} region. None of the infrared spectra of the compounds, III, IV and VI, in the present study exhibited a band at 3200 cm^{-1}, only a broad and weak band at 3370—3440 cm^{-1} and a strong band at 1640—1650 $cm.^{-1}$ Furthermore, the NMR

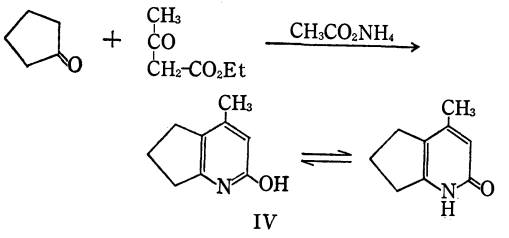
1) A. Sakurai and H. Midorikawa, This Bulletin, **40**, 1680 (1967).

spectra of these compounds showed no signal in the 7.8—8.6 ppm region, but they did show a signal at 10—12.5 ppm corresponding to one proton. Presumably, the infrared absorption at 3370—3440 cm^{-1} and the NMR signal at 10—12.5 ppm are due to the hydroxy group; dihydro-2-pyridone derivatives are predominantly in the -NH-CO- form, but the 2-quinolone derivatives (III) and the 2-pyridone derivatives (IV and VI) in both the -NH-CO- and -N=C(OH)- forms, as in the structure II. However, the NMR spectra seem to indicate that the -N-C(OH)- form rather than the -NH-CO- form is predominant.

The condensation between ethyl acetoacetate and cyclic ketones in a 1 : 1 molar ratio took place. The corresponding tetrahydroquinoline derivative (III) or dihydropyrindine derivative (IV) were obtained with the elimination of water and alcohol. The scheme of these reactions is



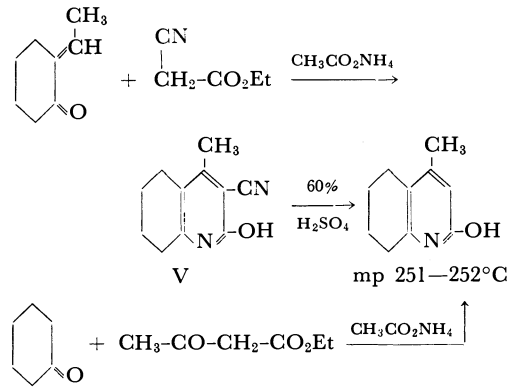
III



IV

indicated as follows. The dehydration takes place between the carbonyl group of ethyl acetoacetate and the methylene group adjacent to the carbonyl group of ketones.

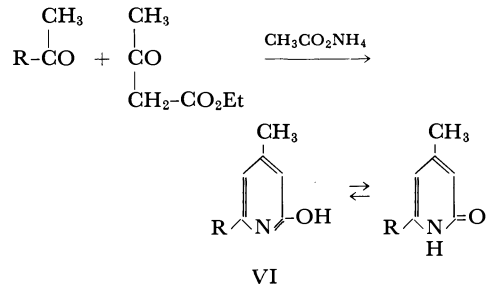
The condensation of ethyl cyanoacetate with ethylidenecyclohexanone[1] proceeds through a Michael reaction; 2-hydroxy-3-cyano-4-methyl-5, 6, 7, 8-tetrahydroquinoline (V) is thus obtained. On hydrolysis, the cyano group of V gave 2-hydroxy-4-methyl-5,6,7,8-tetrahydroquinoline (mp 251—252°C), as is illustrated below:



V mp 251—252°C

The compound III was identical with this tetrahydroquinoline (mp 251—252°C) in its melting point, infrared spectrum, and NMR spectrum. Therefore, the condensation products obtained from ethyl acetoacetate and cyclic ketones can be relied upon to have the structures indicated in the scheme A.

The condensations of aromatic methyl ketones with ethyl acetoacetate are considered to proceed similarly to those of cyclic ketones (molar ratio 1 : 1). The dehydration between the carbonyl group of ethyl acetoacetate and the methyl group of the ketones and the elimination of alcohol took place to form hydroxypyridine derivatives. The



VI

a R=C_6H_5
b R=$C_{10}H_7$

compound VIa was identical with the known 6-phenyl-4-methyl-2-pyridone[2] in its melting point.

All the compounds (III, IV, VIa, and VIb) were colored a reddish orange by alcoholic ferric chloride.

Experimental

All the melting points are uncorrected.

The infrared spectra were determined by means of pressed potassium bromide disks.

The NMR spectra were determined in deuteriochloroform or trifluoroacetic acid at a frequency of 60 Mc, using tetramethylsilane as the internal standard. The chemical shifts are given as ppm downfield from tetramethylsilane.

2-Hydroxy-4-methyl-5, 6, 7, 8-tetrahydroquinoline (III). A mixture of ethyl acetoacetate (13 g, 0.1 mol), cyclohexanone (9.8 g, 0.1 mol), and ammonium acetate (7.7 g, 0.1 mol) was refluxed for 12 hr. After cooling, and after water had been added the reaction mixture was allowed to stand overnight; a crystalline matter was thus precipitated. Recrystallization from alcohol gave colorless needles, mp 252—253°C (lit[3] mp 217—218°C and lit[4] mp 240—241°C); yield 1.9 g (12%).

Dehydrocyclization of 3-Methyl Heptatriene-1, 4, 6

Youji KOMATSU

Research Center, Chiba Office, Maruzen Oil Co., Ltd., 824, Konakadaicho, Chiba

(Received June 26, 1967)

Xylenes, mainly consisting of *p*-xylene and *o*-xylene, were selectively synthesized by the dehydrocyclization of 3-methyl heptatriene-1, 4, 6 (MHT) using a chromia-alumina catalyst. MHT was easily converted to xylenes in a good yield; this reaction proceeded even under mild conditions, as at 200°C. The effects of the catalyst composition, and the influence of the reaction temperature on the conversion of MHT, the xylene yield, the by-products, *etc.*, were studied.

The dehydrocyclization of 3-methyl heptatriene-1, 4, 6 (MHT), obtained by butadiene oligomerization,[1-4] was carried out using chromia-alumina, molybdena-alumina, and platforming catalysts.

Though many reports[5-13] have been presented regarding the dehydrocyclization of paraffins

and olefins, and investigating the catalyst, the mechanism of dehydrocyclization, *etc.*, the dehydrocyclization of trienes such as MHT has not yet been examined. It was found that MHT was converted to xylenes (including ethylbenzene) in a good yield with a trace of *m*-xylene.

Experimental

MHT. MHT was obtained through the oligomerization[2] of butadiene by a cobalt(III) acetylacetonate-triethyl aluminum catalyst. Bp 57—58°C/100 mmHg; purity, 98.6%.

Catalyst. All the catalysts except the platforming catalyst were prepared by the impregnation method; active alumina (8—14 mesh) was used as the support, and an aqueous solution of metal nitrates was used as the catalyst-metal source. Each catalyst was pretreated with oxygen at 500—550°C for 2 hr. The platforming R-7 catalyst was used as the platinum alumina catalyst.

Apparatus and Procedure. A conventional flow-type reactor was used as the experimental apparatus. After 50 cc of catalyst had been placed in it, the reactor (d. 15 mm, l. 100 cm) was kept at 500°C for 2 hr in a hydrogen stream; the reaction of MHT (LHSV 1.0—1.3 v/v/hr) was carried out at the reaction temperature and at a normal pressure of the hydrogene stream (H_2/MHT mol ratio 1.0—1.3). Beginning 5 min after the first drop of the product appeared, liquid and gas were collected during a 1-hr period as the reaction products. The liquid product was analyzed by gas chromatography (PEG column; d. 0.15 mm, l. 90 m, 90°C) and the gas was analyzed both by gas chromatography and using a mass spectrometer (Hitachi RMU-5). A typical gas chromatogram of the reaction product is shown in Fig. 4.

Results

Catalyst. Several kinds of catalysts were examined in order to compare the catalyst activity and the selectivity in the dehydrocyclization of MHT. The results are shown in Table 1. It was found that, except for the platforming catalyst, the catalysts used produced a xylene fraction which contained only a trace of *m*-xylene, and that the total aromatics yield decreased in the following order: chromia-alumina, molybdena-alumina, and the platforming catalyst. Under these experimental conditions, the K_2O-Ce_2O_3-Cr_2O_3-Al_2O_3 catalyst showed the best xylene yield, but even in the other catalysts, xylenes were obtained in 52—82 wt% yields per pass. It is very interesting that *m*-xylene were not formed when the chromia-alumina or molybdena-alumina catalysts were used, but when the platforming catalyst was used, *m*-xylene was formed at nearly the same level of equilibrium content.

Influence of Temperature. In the case of the chromia-alumina catalyst, the reaction conditions, the xylene yield, the by-products, *etc.* were investigated.

1) MHT Conversion and Xylene Yield. In the experimental reaction temperature range (150—540°C), the conversion of MHT reached 99—100 mol% (Fig. 1). In the case of the dehydrocyclization of *n*-heptane[8] and 3-methyl heptane[9], the conversion was 41.7% (*n*-heptane) under the same conditions as those used for MHT, and 31—41% (3-methyl heptane) at the temperature of 527°C and the contact time of 3 sec using a chromina-alumina catalyst. When these data were compared with those of MHT, it was considered that the conversion rate of MHT was faster than that of paraffins and olefins. At reaction temperatures higher than 200°C, the higher the temperature, the better the yield of xylenes. At 400—450°C the xylene yield reached maximum; at temperatures higher than 450°C much decomposition and coking began to occure, causing a decrease in the yield of xylenes. The maximum yield of xylenes was attained at the reaction temperature of 450°C, and the total yield of xylenes and *p*-xylene were 82.0 wt% and 48.4 wt% respectively. Akiyoshi and his co-workers[10] obtained a maximum aromatics yield of 53.0% in the dehydrocyclization of 3-methyl heptane with the chromia-alumina catalyst at 450—570°C, and Pines[9] reported that the xylene yield was 10—20 wt% in the aromatization of 3-methyl heptane with the chromia-alumina catalyst.

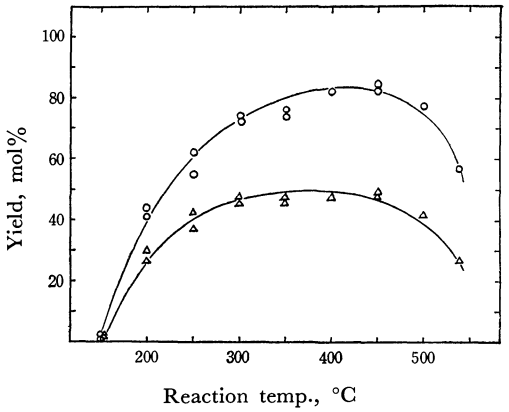

Fig. 1. Relation between xylenes yield and reaction temperature with K_2O-Ce_2O_3-Cr_2O_3-Al_2O_3 catalyst.
—○— Total xylenes —△— *p*-Xylene

In comparing these results, it should be noted that MHT has a higher reactivity than paraffinic hydrocarbons with the same carbon skeltone.

2) Xylene Composition. As shown in Fig. 2, the *p*-xylene content in the xylenes decreased slowly, while the *o*-xylene and ethylbenzene contents gradually increased with the temperature increase. It is remarkable that no *m*-xylene was found below 400°C, while at 400°C a trace of *m*-xylene appeared and at higher temperatures, *m*-xylene was formed in small amounts.

3) By-products. Many kinds of by-products, but in small amounts found in the products. Benzene

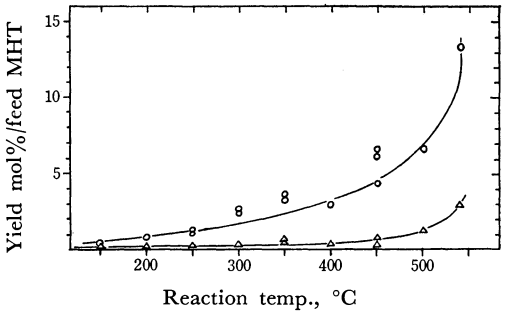

Fig. 3. Benzene and toluene yield.
—○— Toluene —△— Benzene

and toluene were produced in small amounts, but their yields showed a rapid increase above 500°C (Fig. 3)

In our discussion, the other by-products were classified into 2 groups, unknown group 1 (UK-1) and unknown group 2 (UK-2). The UK-1 group has a shorter retention time than toluene in the gas chromatogram (PEG Golay type column, 90°C), while the other has a longer one, as shown in Fig. 4. The boiling points of these unknown substances were determined by means of squalane column gas chromatography (Golay type, 90°C), caliburated by standard hydrocarbon smaples. UK-1 consisted of 9 main compounds; the boiling range assumed to be 85—111°C. UK-2 had 5 major compounds and a boiling range assumed to be 111—135°C. The relationship between the unknown-substance yields and the reaction temperature is shown in Fig. 5. A distinct difference in temperature dependency appeared between the amounts of UK-1 and of UK-2. The UK-1 yield almost does not change at all over the experimental-reaction temperature range. On the con-

—○— UK-1 —△— UK-2

trary, UK-2 was not detected above 400°C, and the UK-2 yield decreased along with the temperature increase, until at 150°C the yield reached about 90%. This reaction product, containing about 90% UK-2, was used instead of MHT as a reaction feed stock for the dehydrocyclization in order to ascertain the character of UK-2. The reaction of this feed stock, diluted with benzene, was carried out at 450°C using a K_2O-Ce_2O_3-Cr_2O_3-Al_2O_3 catalyst. The products of this reaction were analyzed, and the xylene yield calculated. It was found that, the xylene composition and yield were about the same as when MHT was used as the feed stock (Table 2).

4) Deposit on the Catalyst. The yields of the substances on the catalyst at 150—540°C are shown in Fig. 6. It is very interesting to see that deposit-material yield showed a minimum at 300°C. At 500°C, after the reaction, the catalyst surface was covered with a black material which looked like carbonaceous matter, but at 150°C and 200°C, the appearance of the catalyst did not change after the reaction. The reason for the different appearances between 150°C and 540°C was clarified by carbon and hydrogen analyses of these spent catalyst. At 150°C, 200°C, and 540°C the C/H ratios were 6.4, 6.5, and 19.2 respectively (8.0 in MHT). These results shown that, at higher

temperatures, the deposits on the catalyst were mainly coke, whereas at lower temperatures they seemed to be polymerization products of MHT.

5) Exit Gas. All the exit gas except that at 540°C consisted of 99—90% hydrogen. The mole ratios of evolved hydrogen/consumed MHT and evolved hydrogen/formed xylenes at 200—540°C are shown in Fig. 7. At the reaction temperature between 300—450°C, hydrogen was evolved about stoichiometrically to the xylenes formed, and the evolved hydrogen/consumed MHT mole ratio was about 0.8, which was helpful in estimating the reaction mechanism.

Discussion

Without a catalyst, only 2.5% and 8% of the MHT was converted, the rest was recovered as MHT at 300°C and 450°C respectively. This shows that thermal reaction can be neglected, and that the xylene-formation reaction is undoubtedly accelerated by these catalysts.

On the basis of the above results, let us suggest an alternative assumption regarding the route by which MHT is converted to aromatics:

(1) At first the cyclization of MHT takes place, followed by dehydrogenation.

(2) On the contrary, the dehydrogenation of MHT took place first, and then cyclization took place.

It was presumed, except in the case of the platforming catalyst, that this reaction was carried out *via* the route of assumption (1); this presumption is based on the fact that the amount of hydrogen evolved was about stoichimetrical to the xylenes. Though many dehydrocyclization mechanisms have been presented and discussed,[9-13] *m*-xylene was not formed from MHT; therefore, it seemed in the case of MHT that neither isomerization in its carbon skelton[13] nor the formation of a severn-membered ring took place[9] during this reaction.

* Composition was same as exp. No. X-151 (Table 1).
** Composition was same as exp. No. X-2 (Table 1).

In our experiments we could not ascertain what kind of intermediate was formed, but xylenes were formed from UK-2 as they were from MHT, and the fact that the catalyst deposit was about the same C-H ratio as that of MHT is very helpful in finding the intermediate.

In the case of the platforming catalyst, the products contained a lot of *m*-xylene. A mixture of *o*- and *p*-xylene was treated at 450°C with the platforming and K_2O-Ce_2O_3-Cr_2O_3-Al_2O_3 catalysts in order to ascertain the difference in these catalysts effects (Table 3). The resulting product composition was the same within the limit of experimental error; this showed that the platforming catalyst did not isomerize *o*- and *p*-xylene. Therefore, it could be understood that the *m*-xylene in the product was not the isomerization product of the *o*- and *p*-xylene which came from the dehydrocyclization of MHT. According to this finding, it could be estimated that, on the platforming catalyst, the dehydrocyclization mechanism of MHT was different from the cases of the chromia and molybdena catalyst.

The author wishes to thank Professor Ryozo Goto, Kyoto University, and Dr. H. Hasegawa for their many helpful discussions and suggestions during this work, and also the manager of the Maruzen Oil Co. Ltd., for permission to publish this work. Thanks are also due to Messrs. T. Tamura, M. Iriuchijima, H. Taniguchi and H. Okamoto for these experimental work and I. Koyabu for gas chromatographic analysis.

Copolymerization of *N*-Phenylethylenimine and β-Propiolactone

Tsutomu KAGIYA, Tomizo KONDO, Shizuo NARISAWA and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received June 30, 1967)

The copolymerization of *N*-phenylethylenimine and β-propiolactone was carried out at 0°C in an acetonitrile solution. *N*-Phenylethylenimine and β-propiolactone copolymerized without any catalyst to give a powdery or a resinous polymer. From the results of a study of the infrared spectrum, X-ray diffraction, differential thermal analysis, and hydrolyses of the copolymer, it was concluded that the homopolymerization of neither monomer took place, and that the copolymer contained the ester structure of —(–N(C$_6$H$_5$)–CH$_2$CH$_2$OC(=O)–CH$_2$CH$_2$–)$_n$– in the main chain. The monomer reactivity ratios of *N*-phenylethylenimine (r_1) and β-propiolactone (r_2) were estimated to be $r_1=7.5$ and $r_2=0.15$.

It is well known that aziridines polymerize to polyimines[1] with various cationic catalysts, and that β-propiolactone to the crystalline polyester with pyridine or other amines.[2,3] It has already been reported by the present authors[4] that ethylenimine and β-propiolactone serve as mutual polymerization catalysts, and that, when these two substances are mixed in bulk, the copolymerization takes place explosively and gives a polymer mainly with a branching structure of β-propiolactone to the polyethylenimine.

As a part of the investigation of the copolymerization of aziridines and cyclic ester, the copolymerization of *N*-phenylethylenimine and β-propiolactone was studied. It was found that the copolymerization took place without any catalyst and gave a white crystalline copolymer. The purpose of the present paper is to determine the structure and composition of the copolymer by means of a study of the infrared spectrum, X-ray diffraction, the differential thermal analysis, and an analytical study of the hydrolysis products of the copolymer.

Experimental

Copolymerization Procedure. Commercial β-propiolactone was distilled over calcium hydride under reduced pressure at 59°C/20 mmHg. The *N*-phenylethylenimine was prepared according to the literature[5] from β-bromoethylaniline hydrobromide. It was dried over sodium sulfate and fractionated twice before use; bp 70—70.5°C/13 mmHg. The acetonitrile was purified by the usual method.[6]

Measured amounts of β-propiolactone and a solvent were placed into a glass ampule under a nitrogen atmosphere, and then *N*-phenylethylenimine was added to this system at −78°C. After the ampule had been sealed and maintained at 0—1°C for a definite period of time, the products were washed with chloroform and diethyl ether, separated by a centrifuge, and dried *in vacuo*.

Physical Analyses of the Copolymer. The melting point of the copolymer was measured visually in a nitrogen atmosphere in a capillary on an electric heater. The reduced viscosity of a 0.25% solution of 90% formic acid was measured at 35°C with an Ostwald viscometer. The infrared spectrum was obtained with the use of the potassium bromide-pellet technique on a Shimadzu infrared spectrophotometer, Model IR-27. The X-ray diffraction diagram was recorded with a powder camera on a Shimadzu X-ray diffractometer, Model GX-3B. The differential thermogram was obtained with the use of a Rigaku Denki differential thermal apparatus, Model VIP-32.

Determination of the Composition of the Copolymer. The absorption peak of the infrared spectrum at 1740 cm^{-1} assigned to the ester group of β-propiolactone, and that at 1600 cm^{-1} assigned to the phenyl group of *N*-phenylethylenimine were used in order to determine the composition of the copolymer.

9	73.80	6.81	9.05	66.9	33.1	0.906

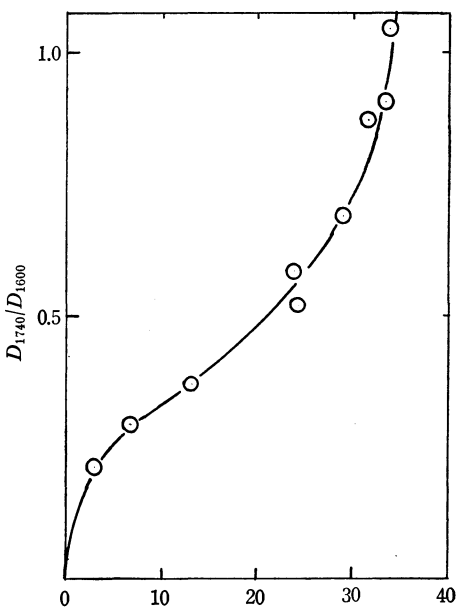

Fig. 1. Calibration curve of the copolymer of *N*-phenylethylenimine and β-propiolactone.

The calibration curve was obtained by plotting the optical density ratio, D_{1740}/D_{1600}, against the mole fraction of β-propiolactone, which was itself determined from the carbon and nitrogen contents by elementary analyses (Fig. 1 and Table 1).

Polymers of *N*-Phenylethylenimine and β-Propiolactone. A white crystalline polymer (mp 287—292°C) of *N*-phenylethylenimine was obtained by polymerization in water at 0°C without a catalyst, while the polymerization of β-propiolactone was carried out in acetonitrile at 0°C with a pyridine catalyst.

Hydrolysis of the Copolymer. In 5 m*l* of 1/10 N sodium hydroxide-ethanol, about 70 mg of the copolymer were hydrolyzed under reflux for 20 hr and then back-titrated with 1/20 N hydrochloric acid, using a 5% alcoholic solution of phenolphthalein as an indicator.

Reaction of Poly-*N*-phenylethylenimine with β-Propiolactone. A mixture of 0.293 g of poly-*N*-phenylethylenimine, 0.571 g of β-propiolactone, and 5 m*l* of acetonitrile was heated in a sealed tube at 35°C for 20 hr without a catalyst, the reaction product was then washed in chloroform and dried *in vacuo*. The amounts of carboxylic acid in these polymers were determined as follows. About a 70-mg portion of the polymer was added to 5 m*l* of 1/10 N sodium hydroxide-ethanol, and the solution was back-titrated with 1/20 N hydrochloric acid.

Results and Disscusion

The results of the copolymerization without a catalyst in acetonitrile at 0°C are summarized in Table 2. The copolymer obtained was a white powdery or a yellowish resinous solid polymer which was soluble in formic acid, but insoluble in chloroform, ethanol, dimethylformamide, and other organic solvents. The melting points of the copolymers were 245°C to 279°C, between those of poly-β-propiolactone (75°C) and poly-*N*-phenylethylenimine (287—292°C).

The infrared spectra of the resulting polymer showed the characteristic absorptions at 1740 cm^{-1} and 1600 cm^{-1} based on the ester linkage (β-propiolactone unit) and the benzene nucleus (*N*-phenylethylenimine unit) respectively (see Fig. 2). In order to determine whether the polymer obtained here was the copolymer or a mixture of the corresponding homopolymers, the resulting polymer was fractionated in chloroform, which is a solvent for only poly-β-propiolactone. The infrared spectrum of the fraction insoluble in chloroform is shown in Fig. 2. This infrared spectrum proves that the insoluble fraction of the resulting copolymer contained the β-propiolactone units. On the other hand, the infrared spectrum of the insoluble fraction of the mixture of the homopolymers does not show the peak of the ester linkage. These results indicate that the copolymer of *N*-phenylethylenimine with β-propiolactone was produced.

(1) Poly-*N*-phenylethylenimine (2) Poly-β-propiolactone (3) Copolymer of *N*-phenylethylenimine and β-propiolactone.

Structure of the Copolymer. X-Ray diffraction diagrams of the copolymer (β-propiolactone 31.8 mol%), the poly-β-propiolactone, and poly-*N*-phenylethylenimine are shown in Fig. 3. The characteristic peaks (2θ) of these polymers are listed in Table 3.

The peaks of the copolymer were similar to characteristic peaks of poly-*N*-phenylethylenimine, but not to those of poly-β-propiolactone. Although no attempt was made to determine the ratio of the crystallinity, it may be considered in view of the relative half-value widths, that the crystallinity of the copolymer is smaller than that of poly-*N*-phenylethylenimine. Figure 4 shows the differential thermogram of the copolymer (β-propiolactone 31.8 mol%) in comparison with those of both homopolymers. We observed the endothermic peak corresponding to the melting point of neither homopolymer, but a new peak of the copolymer was observed, as Fig. 4 shows.

From these results, it may be concluded that neither poly-β-propiolactone nor poly-*N*-phenylethylenimine is present in the copolymer.

It is well known that β-propiolactone polymerizes by opening the ring between acyl-oxygen or alkyl carbon-oxygen bonds. In the copolymerization of *N*-phenylethylenimine with β-propiolactone,

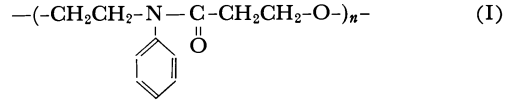
(2) Poly-*N*-phenylethylenimine
(3) Poly-β-propiolactone

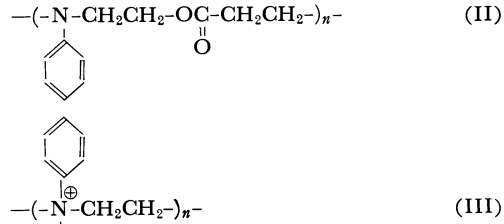
it is possible that the copolymer contains the following structures, according to the different modes of lactone-ring cleavage:

Cleavage of the acyl-oxygen bond:



(I)

Cleavage of the alkyl carbon-oxygen bond:



(II)

(III)

The absence of the characteristic peak of tertiary amide at 1650 cm^{-1} indicates that the copolymer does not contain the polyamide ether structure (I). Poly-*N*-phenylethylenimine and β-propiolactone could be reacted at 35°C to produce a branched polymer (III), but not at 0°C. The intrinsic viscosity and the carboxylic-group contents of the copolymer and the branched polymer are shown in Table 4.

The amount of the carboxyl group of the branched product was 5.90×10^{-4} g equivalent/g polymer, but no carboxylic group was present in the copolymer. This result indicates that the copolymer has not carboxyl group. It was observed that the amount of the carboxylic acid was equivalent to that of lactone present in the hydrolyzed product of the copolymer. The infrared spectrum of the hydrolyzed product displayed its peak at 1700 cm^{-1}, which was assigned to carboxyl bond, and the peak of the ester bond (1740 cm^{-1}) disappeared. The viscosity of the copolymer was depressed by the hydrolysis, whereas that of the branched copolymer was not changed. From these facts, it may be concluded that the copolymer contains the ester structure (II) in the main chain.

Monomer Reactivity Ratio. The relation

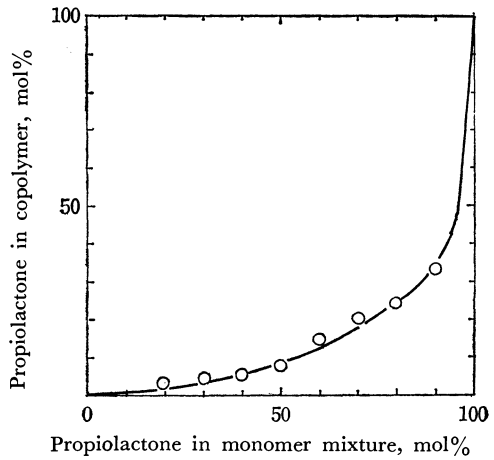


Fig. 5. Copolymerization of *N*-phenylethylenimine and β-propiolactone. Copolymer composition curve.

between the mole percentage of β-propiolactone in the copolymer and that in the monomer feed is shown in Fig. 5. From the curve, the monomer reactivity ratio of *N*-phenylethylenimine (r_1) and that of β-propiolactone (r_2) were estimated to be $r_1=7.5$ and $r_2=0.15$ respectively by the usual method.

The results show that *N*-phenylethylenimine reacted about 50 times as fast as β-propiolactone in this copolymerization, which gave a copolymer containing a small amount of the β-propiolactone. Further work on the mechanism of the initiation and propagation of this copolymerization will be reported in a subsequent paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 176—182 (1968)

Intramolecular Interaction between Hydroxyl Group and Carbonyl Moiety in Keto-alcohols[1)]

Michinori Ōki, Hiizu Iwamura, Jun-ichi Aihara and Hiroshi Iida

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received July 3, 1967)

The O–H stretching absorption (ν_{O-H}) spectra of some keto-alcohols have been examined. The ν_{O-H} shift to the lower frequency due to the intramolecular O–H···O bonding can roughly be correlated to the geometry of the hydroxyl group relative to the *n*-electrons on the carbonyl oxygen. When the bonding is forbidden because of the conformational restriction, a weaker interaction between the hydroxyl group and the π-electrons on the carbonyl group is observable as the lower shift of the ν_{O-H} by 10—30 cm^{-1} as far as the conformation is favorable for the interaction.

It has been well established by physico-chemical methods that the π-electrons on the olefinic and aromatic hydrocarbons function as a proton acceptor in the interaction with the hydroxyl group.[1,2)] As a nautral extension of the survey for a new type of the hydrogen bond acceptor, the π-electrons on the carbonyl double bond, a typical example of the multiple bonds carrying a hetero-atom, have now been taken into account. In addition to a pair of π-electrons, the carbonyl group has two lone-pairs of electrons, one of which can be regarded approximately of 2s character while the other of 2p character (n-electrons).[3)] The basicity or the donor ability of the carbonyl compounds in forming metallic and hydrogen bonded complexes has been ascribed entirely to the latter electrons, because these are more easily donated to an electron acceptor owing to the lower ionization potential (*ca.* 10 eV) and to the open nature to the attacking electrophile.[4)] The donor character of the carbonyl π-electrons which are assumed to have the ionization potential of *ca.* 12 eV, to the contrary, seems to have been less recognized.[5)] In order to observe the interaction of the carbonyl π-electrons with the hydroxyl group, some geometrical devices are necessary which exclude the preferential interaction involving the carbonyl n-electrons. In the present paper, the intramolecular interaction between the hydroxyl and the carbonyl groups in keto-alcohols has been investigated through the O–H stretching absorption (ν_{O-H}) spectra. In fulfilment of the above requirement, special emphasis has been laid on some conformationally-fixed keto-alcohols in which the hydroxyl group is so oriented as to approach the carbonyl group only from the upper side of the π-electrons clouds and perpendicularly to the n-electrons.

Results and Discussion

Typical ν_{O-H} absorption curves are shown in Figs. 1 to 3. In Tables 1 and 2 are summarized the spectral parameters of all the keto-alcohols

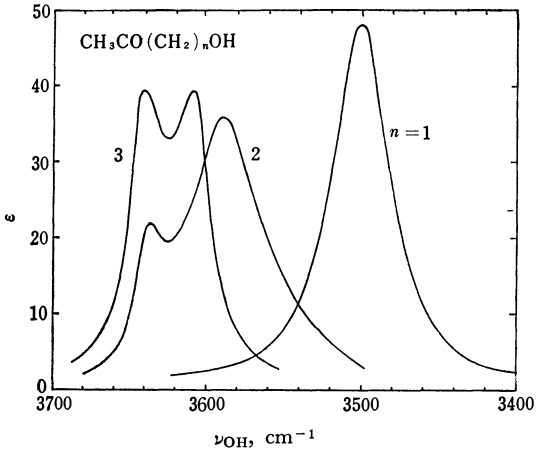

Fig. 1. ν_{O-H} absorptions of ω-hydroxy-2-alkanones.

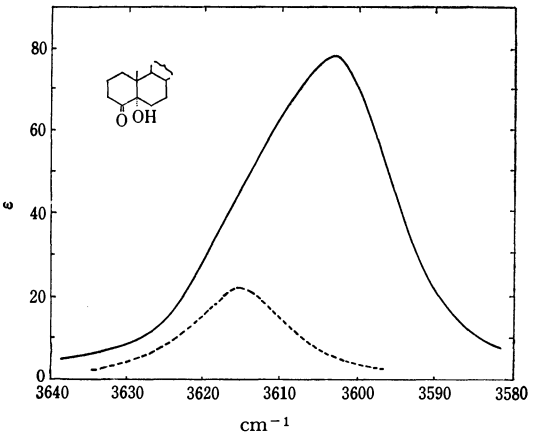

Fig. 2. ν_{O-H} absorption of 5α-cholestan-5α-ol-4-one (I).

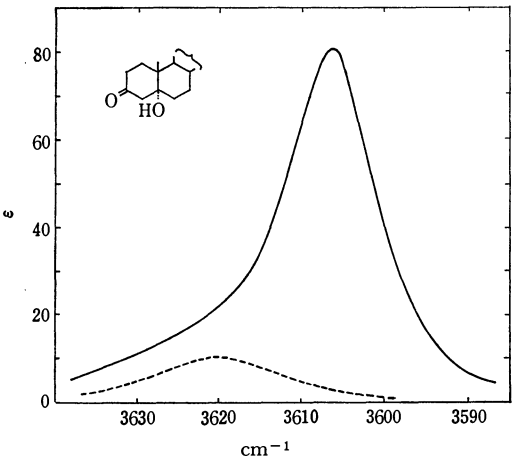

Fig. 3. ν_{O-H} absorption of 5α-cholestan-5α-ol-3-one (II).

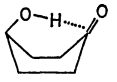
5) In this connection the following papers deserve mention. It had once been considered that the band at 3427 cm^{-1} of 4-hydroxycyclohexanone might be due to the hydroxyl group intramolecularly bonded (i) (W. von E. Doering and A. A.-R. Sayigh, *J. Org. Chem.*, **26**, 1365 (1961)). The possibility was, however, eliminated by observing the survival of the band when the OH group was transformed into an OD group by deuterium exchange, and thus the 3427 cm^{-1} absorption was reassigned to the first overtone of the carbonyl stretching vibration at 1725.5 cm^{-1} (R. D. Stolow, *J. Am. Chem. Soc.*, **84**, 686 (1962)). Dalton and coworkers[6] have reported the anomalously low O-H stretching maxima in 5α-cholestan-5α-ol-3-one, 5β-cholestan-5β-3-one and the decalone analogs, but did



i

not notice the role of the π-electrons of the carbonyl group. The shape of the broad band due to the O-H stretching vibration of the hydrogen bond complexes of phenol with ketonic proton acceptors has been studied (H. Fritzsche, *Z. phys. Chem.*, **43**, 154 (1964); *Spectrochim. Acta*, **21**, 799 (1965)). It deviates from the normal symmetric type. The phenomenon was interpreted by assuming the superposition of two symmetrical bands and ascribed to the presence of two types of the hydrogen bond, the model for the second band requiring the participation of the π-electrons. Lately, the O-H stretching maximum at 3588 cm^{-1} of 2-hydroxy-4, 6-di-*t*-butylbenzophenone has been assigned to the hydroxyl group interacting with the π-electrons of the carbonyl group (A. T. Shulgin and H. O. Kerlinger, *Chem. Commun.*, **1966**, 249). However, the possibility of the interaction with the π-electrons of the phenyl group may not be ruled out, since the phenomenon is observed also in the structurally analogous 2-benzylphenol, the ν_{O-H} being at 3560 cm^{-1} (M. Ōki and H. Iwamura, This Bulletin, **33**, 681 (1960)).

examined together with some of those reported in the literature.

O–H···O Hydrogen Bond. As has been pointed out,[7,8] α-, β- and γ-keto-alcohols whose molecules are not fixed have ν_{O-H} maxima shifted to the lower frequency, and it is clear that the ordinary O–H···O hydrogen bond to form five, six and seven membered rings is taking place to a certain extent. The apparent ν_{O-H} shifts ($\Delta\nu_{O-H}$) are 135, 48 and 31 cm^{-1} for 1-hydroxy-2-propanone, 4-hydroxy-2-butanone and 5-hydroxy-2-pentanone, respectively. The trend is in sharp contrast with that of the inetrnal O–H···O bonding in α, ω-alkanediols and ω-methoxyalkanols, in which the value of $\Delta\nu_{O-H}$ increases on going from

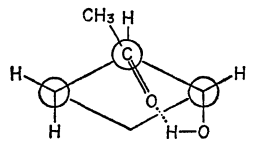
a) When the free ν_{O-H} is not observable, it is assumed to be 3636, 3627 and 3618 cm^{-1} for primary, secondary and tertiary alcohols, respectively.
b) ε

vicinal to 1, 4-difunctional derivatives, where it attains its maximum.[16] The difference between the two series may be due mainly to the different geometry around the proton accepting functions.



ii

Thus the carbonyl carbon atom is sp^2-hybridized and the α-carbon atom lies always on the same plane with the n-orbital of the oxygen atom. In 2-(hydroxymethyl)cyclohexanone and the derivatives, molecular models indicate even the hydroxylic oxygen atom is placed nearly on the very plane. The planar cyclic hydrogen bond is formed resulting in the ν_{O-H} shift of *ca.* 130 cm^{-1} which does not change materially over a whole range of examples.[8,9,11,17] Judging from the nearly equivalent $\Delta\nu_{O-H}$, the conformation of 1-hydroxy-2-propanone and other unfixed α-keto-alcohols may also be planar. Under the circumstances, the hydroxylic hydrogen atom participating in the hydrogen bond will be situated just on the extension line of the n-orbital of the carbonyl oxygen, as shown in

a), b) See footnotes of Table 1.

Fig. 4, effecting strong hydrogen bond formation.[18)] In contrast with the α-keto-alcohols, the conformation about the ethylene glycol and 2-methoxyethanol has been shown not to be eclipsed but staggered and not only the distance between the bonding groups but also the angle are not most favorable for the intramolecular hydrogen bond.[19)]

In β-keto-alcohols, the values of $\Delta\nu_{O-H}$ range from 30 to 120 cm^{-1}. The variety may be due to the difference in the conformation of the bonding species which has been considered to be unaltered in α-keto-alcohols. It may be argued that the bonding form of 4-hydroxy-2-butanone is planar because stabilization by hydrogen bond formation overwhelms the conformational energy. If it were the case, however, the distance between the hydroxylic hydrogen and the carbonyl oxygen would amount to 1.2 Å, and the stronger interaction which is reflected by greater shift to the lower frequency than those of α-keto-alcohols would have been observed. Therefore, in the bonding form of 2-(hydroxymethyl)cyclohexanone, the hydroxymethyl group is assumed to be equatorial with the hydroxyl group staggered between the axial hydrogen and the carbonyl carbon atoms. If the hydroxyl hydrogen is staggered between a methylene hydrogen and the ring carbon to which the hydroxymethyl group is attached, the distance between the hydroxyl hydrogen and the carbonyl oxygen atoms in this model becomes

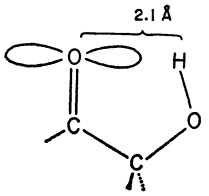

Fig. 4. Geometry of intramolecular hydrogen bond in α-keto-alcohols.

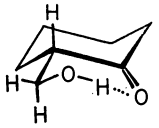

Fig. 5. Bonding conformation of 2-(hydroxymethyl)cyclohexanone.

18) When methanol and acetone are mixed in carbon tetrachloride to make a solution of 0.012 and 0.45 mol/l with respect to each component, a broad band due to the intermolecular hydrogen bond formation appears at 3534 cm^{-1}. Since there seems to be no geometrical restriction in the intermolecular association, the interacting groups are mutually so disposed that the greatest enthalpy of the interaction is attained. The fact that $\Delta\nu_{O-H}$ as a measure of the enthalpy of the interaction in α-keto-alcohols is greater even than those intermolecular bonding may suggest a factor which is advantageous to the intramolecular bonding. A possible electronic interaction through hyperconjugation of the intervening methylene group is excluded because α, α-disubstituted derivatives have similarly intensified hydrogen bond. It may be an explanation that the electrostatic field effect on the hydrogen bond is playing a great role, since the dipolar O–H and C=O groups are, as shown in Fig. 4, placed nearly anti-parallel with the result of some additional stabilization.

19) P. J. Krueger and H. D. Mettee, *J. Mol. Spectrys.*, **18**, 131 (1965); H. Matsuura and T. Miyazawa, This Bulletin, **40**, 85 (1967); P. Buckley and P. A. Giguere, *Can. J. Chem.*, **45**, 397 (1967).

nearly 2.1 Å coincident with those of α-keto-alcohols, but the angle made by the direction of the carbonyl n-orbital and the line connecting the hydroxyl hydrogen with the carbonyl oxygen atoms amounts to as high as 40° (see Fig. 5). It follows, therefore, that $\Delta\nu_{O-H}$ is reduced nearly to half of that in α-keto-alcohols.[20]

In an attempt to find correlation between the conformation and $\Delta\nu_{O-H}$ due to hydrogen bonding,

Table 3. The geometrical relation between hydroxyl and carbonyl groups in keto-alcohols as defined by Fig. 6

Compound	R, Å	θ
α-Keto-alcohols (1—3)	2.1	8
4-Hydroxy-2-butanones (4—6)	2.1	40
2-(Hydroxymethyl)cyclohexanone (7)	2.3	35
(+)-10-Nor-8-oxoneomenthol (8)	2.0	30[10]
(−)-10-Nor-8-oxomenthol (9)	2.3	55[10]

3β, 14β-Dihydroxy-12β-benzoyloxy-pregn-5-en-20-one (13)	1.6	20
3β-Acetoxy-14β, 15α-dihydroxypregn-5-en-20-one (14)	1.6	20
3β-Acetoxy-5α-hydroxy-9α-ergostan-11-one (15)	1.4	35

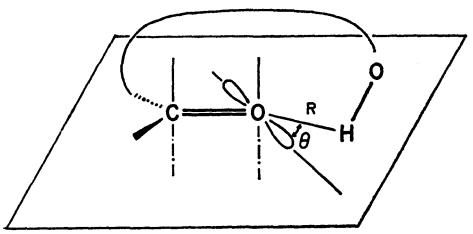

Fig. 6. Parameters representing the geometrical relation between hydroxyl and carbonyl groups.

the latter values have been plotted against $\cos\theta/R$, in which R and θ are defined as shown in Fig. 6, and estimated by examination of a Dreiding model (Table 3). The parameters were tentatively employed because it is easily expected that the enthalpy of the hydrogen bond increases as the distance between the interacting groups is shortened and the overlap between them becomes heavilier.

It is rather surprising that a smooth relationship has been obtained as shown in Fig. 7, when one considers that, to the hydrogen bond, several mechanisms such as electrostatic interaction, delocalization energy, repulsive force and dispersion force[22] are contributing which should be expressed in terms of a complex function of R and θ. It is beyond the purpose of the present authors to discuss the relative contribution of the above mechanisms from the relationship now obtained, but the atuhors would like to point out that $\Delta\nu_{O-H}$ due to the intramolecular hydrogen bond in keto-alcohols is dependent on the distance between the two groups and the direction of approach of the hydroxyl group to the head of the n-orbital on the carbonyl oxygen.[23] A few examples of γ-keto-alcohols and the higher homologs also conform to the same relationship and are included in Fig. 7.

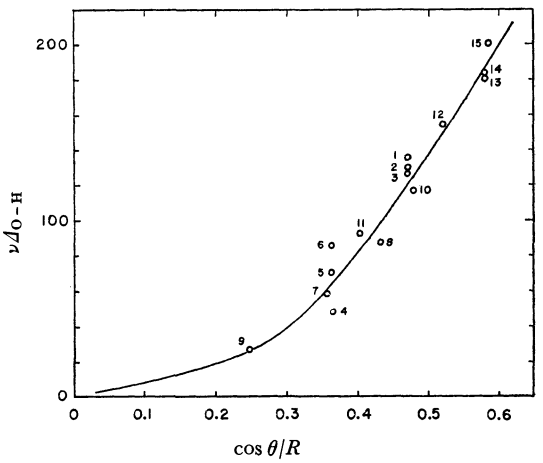

Fig. 7. Relation between the conformation and $\Delta\nu_{O-H}$ due to hydrogen bonding in keto-alcohols (numbers in Table 3).

O–H···π Interaction. In Table 2 are collected ν_{O-H} data of keto-alcohols in which R is not shorter than 3 Å, $\cos\theta/R$ parameter smaller than 0.9, and consequently the contribution to the hydrogen bond by n-electrons can be regarded geometrically

20) There seems to be a controversy as to the hybridization of the proton accepting n-orbital of the carbonyl group. W. G. Schneider (*J. Chem. Phys.*, **23**, 27 (1955)) regarded the hybridization of the carbonyl oxygen to be sp^2 in his electrostatic interpretation of the hydrogen bond, while a self-consistent field calculation of formaldehyde (P. L. Goodfriend, F. W. Birss and A. B. F. Duncan, *Rev. Mod. Phys.*, **32**, 307 (1960)) shows a clearly defined 2p-lone pair on the oxygen atom. Since trigonal sp^2 lone pair would have been more favorable geometrically for the hydrogen bond formation in β-keto-alcohols than for α-homologs, the above observations may provide another support for the 2p-character of the oxygen lone pair.

21) Contrary to the original authors,[11] the ring A of methyl icterogenin and methyl hederagonate was assumed to be a boat which has frequently been encountered in the lanostan-3-one derivatives (E. L. Eliel, N. L. Allinger, S. J. Angyal and G. A. Morrison, "Conformational Analysis," Interscience Publishers, New York (1965), p. 469).

22) C. A. Coulson, "Hydrogen Bonding," ed. by D. Hadzi and W. H. Thompson, Pergamon Press, London (1959), p. 339.

23) Kubota and co-workers[12] found an empirical relation, $\Delta\nu_{O-H}=-143R+412$ (cm^{-1}).

forbidden. According to the relationship found in Fig. 7, any low-frequency band may not be expected ($\Delta\nu_{O-H}<10\ cm^{-1}$). In these examples, however, the apparent ν_{O-H} maxima are always shifted to the lower frequency and a shoulder band is usually observed at the higher frequency side which is located at the normal position of the free ν_{O-H} (Figs. 2 and 3). Instead of the *n*-electrons, π-electrons on the carbonyl group are now situated favorably for accepting the hydroxyl hydrogen as depicted in Fig. 8, and it is postulated that the lower frequency bands are assigned to the ν_{O-H} due to the O-H···π interaction. The ν_{O-H} shifts range from 8 to 34 cm^{-1} and are roughly in accord with the degree of overlap between the orbitals of the hydroxyl group and π-electrons as estimated by the Dreiding model.[21,24] $\Delta\nu_{O-H}$ of 11, 14 and 34cm^{-1} in 5α-cholestan-5α-ol-4-one (I), 5α-cholestan-5α-ol-3-one (II) and methyl hederagonate (III), respectively, may be compared with those of structurally analogous 5-*trans*-*t*-butyl-2-methylenecyclohexanol ($\Delta\nu_{O-H}=9\ cm^{-1}$), epicholesterol (34 cm^{-1}) and 3β-acetoxychlolest-5-en-19-ol (52 cm^{-1}).[1] In these latter examples, the ethylenic π-electrons are playing the role of the proton acceptor. Near parallelism in the order of $\Delta\nu_{O-H}$'s between the keto-alcohols and the olefinic alcohols can be noted and, when structurally related alcohols in which only the C=O group is replaced by C=C are compared, $\Delta\nu_{O-H}$ in the former series is about half of the latter series. The trend is interpretable in terms of the reduced basicity of the carbonyl π-electrons compared to that of the ethylenic π-electrons as indicated by the higher ionization potential of the former.[3,4,25] Best illustration of the competition between the basicity of the carbonyl group and the ethylenic linkage is afforded by 5α-hydroxyergosta-7, 22-dien-3-one (V),[6] in which, under the nearly equivalent geometrical environment, $\Delta\nu_{O-H}$ is 10 and 24cm^{-1}, respectively. α-Axial keto-alcohols,[26] 5α-cholestan-5α-ol-4-one, -6-one and α-digiprogenin 3β-acetate, are rather exceptional in that $\Delta\nu_{O-H}$'s are even larger than those of the corresponding α-axial olefinic alcohols. This may be due to the strengthened interaction as a result of the enhanced acidity of the hydroxyl group which is located α

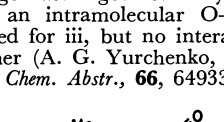
Table 4. $\nu_{C=O}$ data for keto-alcohols

Compound	ν_{max}	ε
CH_3COCH_2OH	1727	(406)
2-Hydroxycyclohexanone	1718	(—)
5β-Cholestan-5β-ol-4-one	1703	(650)
5β-Cholestan-5β-ol-6-one	1704	(598)
$CH_3COCH_2CH_2OH$	1716	(303)
$CH_3COCH_2CMe_2OH$	1712[30]	
2-(Hydroxymethyl)cyclohexanone	1705	(442)
$CH_3COCH_2CH_2CH_2OH$	1720	(293)
5α-Cholestan-5α-ol-4-one	1718	(597)
5α-Cholestan-5α-ol-6-one	1718	(528)
(−)-2-Hydroxyisopinocamphone	1721	(505)
5α-Cholestan-5α-ol-3-one	1721	(448)
5β-Cholestan-5β-ol-3-one	1720	(430)
5α-Hydroxyergosta-7, 22-dien-3-one	1722	(430)[6]

24) The similarity of the ν_{O-H} absorption spectra between 5α-cholestan-5α-ol-4-one (I) and 5α-cholestan-5α-ol-6-one, and 5α-cholestan-5α-ol-3-one and 5β-cholestan-5β-ol-3-one provides a support for the normal chair conformation of the ring-A cyclohexanone in I and 5β-3-keto-steroid (N. L. Allinger and C. L. Neumann, *Tetrahedron*, **23**, 1279 (1967)). The 3540 cm^{-1} absorption of methyl hederagonate (III) may be due to the O-H···O bonding in a ring-A chair conformation which is in equilibrium with the boat form.[21] The conformation of 4-hydroxycycloheptanone was regarded to be chair (IV) (N. L. Allinger, *J. Am. Chem. Soc.*, **81**, 5727 (1959)). For 2-hydroxyisopinocamphone see, R. L. Erskine and S. A. Knight, *Chem. & Ind.*, **1960**, 1160.

25) Polarization of the carbonyl π-electrons in the sense $C\overset{\delta+}{=}O\overset{\delta-}{}$ will also be contributing, because in the pertinent examples the hydroxyl group is interacting with the π-electrons on the carbon atom rather than that on the oxygen atom geometrically.

26) Recently an intramolecular O-H···O bonding has been reported for iii, but no interaction is noticed in the OH-epimer (A. G. Yurchenko, *Zh. Organokhim.*, **2**, 1604 (1966); *Chem. Abstr.*, **66**, 64933b (1967)).



iii

to the electron-attracting carbonyl function. A support for this inductive effect may be obtained by the relatively low free ν_{O-H}'s at 3614 cm^{-1} of these α-keto-alcohols which should otherwise be expected to occur at 3618—3620 cm^{-1}.

Experimental

All the samples were of analytical purity and the physical constants agreed well with those in the literature.[27]

Spectral measurement was carried out as described in the previous papers.[1,28] Special care was taken to employ a little more dilute solution ($c \leq 10^{-3}$ mol/l) in carbon tetrachloride than usual, because it has often been mentioned[6,29] that in keto-alcohols the association through intermolecular hydrogen bond survives rather tenaciously even in *ca.* 5×10^{-3} mol/l solution.

The C=O stretching bands were measured in a sodium chloride cell of 0.55 cm optical length, and the data are summarized in Table 4. As has been pointed out,[30] the effect of the hydroxyl group in shifting the $\nu_{C=O}$ is not clear especially in the O–H$\cdots\pi$ interaction.

27) 2-Hydroxycyclohexanone is notorious for its spontaneous formation of a dimer with the hemiacetal structure (J. C. Sheehan, R. C. O'Neill and M. A. White, *J. Am. Chem. Soc.*, **72**, 3376 (1950)), and so the freshly distilled (bp, 87°C/18 mmHg) sample was used within five minutes after distillation.

The Peptide Synthesis. II. Use of the Phenol Resin for the Peptide Synthesis*1

Noriyoshi INUKAI, Kohzi NAKANO and Masuo MURAKAMI

Central Research Laboratory, Yamanouchi Pharmaceutical Co., Ltd., Azusawa-cho, Itabashi-ku, Tokyo

(Received July 4, 1967)

The phenol resin is useful as support of the solid phase peptide synthesis. Its use is particularly advantageous for the synthesis of the *N*-protected peptide fragments, and those which have the intramolecular disulfide bond, such as oxytocin. In the latter case, the application of *S*-ethylmercapto group as the protector of thiol group of cysteine residue was combined successfully. Oxytocin and physalaemin derivatives were thus synthesized.

Recently, the solid phase peptide synthesis introduced by Merrifield[1,2] has provoked keenest interest. The essential feature of this method is protection of the carboxyl group of an amino acid by esterification with polymeric derivatives of benzyl alcohol; the products being insoluble in the usual solvents, they can be isolated and purified simply by washing with a series of appropriate solvents. Many active peptides, such as bradykinin,[3,4] angiotensin,[5] insulin[6] and others were thus synthesized simply, rapidly and automatically. Long chain peptides which were difficult to synthesize to date are further expected to be synthesized by this method. However, many problems still remain; (1) The introduction of the starting acyl amino acid to polymer requires rather drastic condition, which may give rise to racemization and other side reactions. It is difficult to introduce the acyl peptide direct to the polymer. (2) *C*-Terminal of many important active peptides is often amide, as in oxytocin, vasopressin, eledoisin, physalaemin and gastrin. Synthesis of these peptide amides as described by Bodanszky *et al.*[7] are troublesome and peptide hydrazide is also hard to prepare. (3) To obtain the acyl peptide fragments is impossible, for the removal of peptide from polymer is performed by hydrogen bromide in trifluoroacetic acid, or liquid hydrogen fluoride,[8] *etc.*

We found that the polyphenol resin is an useful

support. Conditions of its synthesis will be described in the present investigation. The phenol resin as support of the solid phase peptide synthesis has not only all the merits of Merrifield's method, but also it can solve some of the problems of Merrifield's method as described above.

The phenol resin was synthesized by reacting phenol and equimolar amount of *S*-trioxane in bis-(2-ethoxyethyl)-ether containing catalytic amount of *p*-toluenesulfonic acid at 150°C in a sealed tube for 24 hr. This phenol resin is insoluble in the usual solvents employed for the peptide synthesis but it swells in them.

The introduction of the first acyl amino acid, such as *N*-*t*-amyloxycarbonyl-,[9] *N*-*t*-butyloxycarbonyl-[10] or *N*-carbobenzoxy[11]-amino acid, to the phenol resin is carried out with *N*, *N'*-dicyclohexylcarbodiimide[12] in dimethylformamide. The resulting resinous derivative of acyl amino acid phenyl ester was isolated and purified simply by washing with a series of appropriate solvents. The acyl group was removed by hydrogen halide in suitable solvent. The resulting hydrogen halide salt was converted to the free base with triethylamine in dimethylformamide, and it was coupled with the next acyl amino acid or acyl peptide by active ester method,[13-17] or *N*, *N'*-dicyclohexylcarbodiimide method in dimethylformamide. Excess reagents and by-products were removed from the insoluble product by filtration and through washing with suitable solvents. Further elongation of peptide bond was carried out in the same way by alternate deprotecting and coupling with the appropriate acyl amino acid or acyl peptide.

Choice of solvent was important for the coupling reaction. Of the several solvents examined, dimethylformamide was the best one which had high dielectric constant and also swelled the resin. Pyridine was also satisfactory, whereas chloroform, benzene, ethyl acetate and dioxane were unfit not swelling the resin or having low dielectric constant.

Selection of the coupling methods for the formation of the peptide bond was also important. The several methods were examined, and the order of the coupling efficiency was as follows;

N, *N'*-Dicyclohexylcarbodiimide, *p*-Nitrophenyl ester[13] > 2, 4-Dinitrophenyl ester,[14] *N*-Hydroxysuccinimide ester,[15] > 2, 4, 5-Trichlorophenyl ester[16] > Pentachlorophenyl ester[17] ≫ Azide,[18] mixed anhydride.[19]

The yield was excellent, when the coupling was performed by *p*-nitrophenyl ester method and *N*, *N'*-dicyclohexylcarbodiimide method. In the active ester methods, the coupling potency depended on the bulkiness of the esters, *i. e.* the steric effect.

When the coupling was completed, the protected peptide was cleft from the resin by treatment with aqueous N sodium hydroxide in methanol, 25% ammonia in methanol or hydrazine hydrate in dimethylformamide as the corresponding acyl peptide, acyl peptide amide or acyl peptide hydrazide. The crude acyl peptide derivatives are easily purified by one or two recrystallizations, and column chromatography for the purposes of purification was not necessary. But this method was unfit to synthesize the acyl peptides which were unstable under the basic condition.*2

Some examples of acyl peptide derivatives synthesized are listed in the table.

Optical rotation of these acyl peptide derivatives nearly agreed with that of the standard samples synthesized by the usual method and racemization was scarcely observed.*3

The latter five peptides in the table are the active fragments of physalaemin and its analogues. The activities of these free peptides deprotected were compared with that of a synthetic bradykinin[20] by the hypotensive effect in rabbit.

Oxytocin was synthesized for two reasons. First, it was of interest as a further test of the applicability of the phenol resin, since oxytocin is an active peptide rather hard to prepare containing the comparatively unstable amino acids; cystine, asparagine and glutamine. Secondly, it may be expected that the two deprotected free thiol groups of cysteine residues are converted to an intramolecular disulfide bond on the phenol resin instead of forming an intermolecular disulfide bond which often occurs in usual synthetic method of oxytocin.

*2 For example, the cleavages of prolyl-proline-, seryl-proline- and arginyl-proline-bonds were often observed under the basic conditions.

*3 Racemization was about 3% in the following tests; (1) Many isoleucine derivatives were synthesized on the resin using L-isoleucine, and the ratio of L-isoleucine to allo-isoleucine was determined by amino acid analyzer. (2). *N*-Carbobenzoxy-glycyl-phenylalanyl-glycine which was synthesized stepwise on the resin using L-phenylalanine, was converted to ethyl ester and it was subjected to the Anderson's racemization test.

b) The standard samples were prepared by the usual synthetic methods.
c) The activity of the deprotected free peptide was compared with that of a synthetic Bradykinin.[20] Z=carbobenzoxy; AOC=t-amyloxycarbonyl; Bz=Benzyl; Tyr(Me)=p-methoxytyrosine residue; DMF=dimethylformamide.

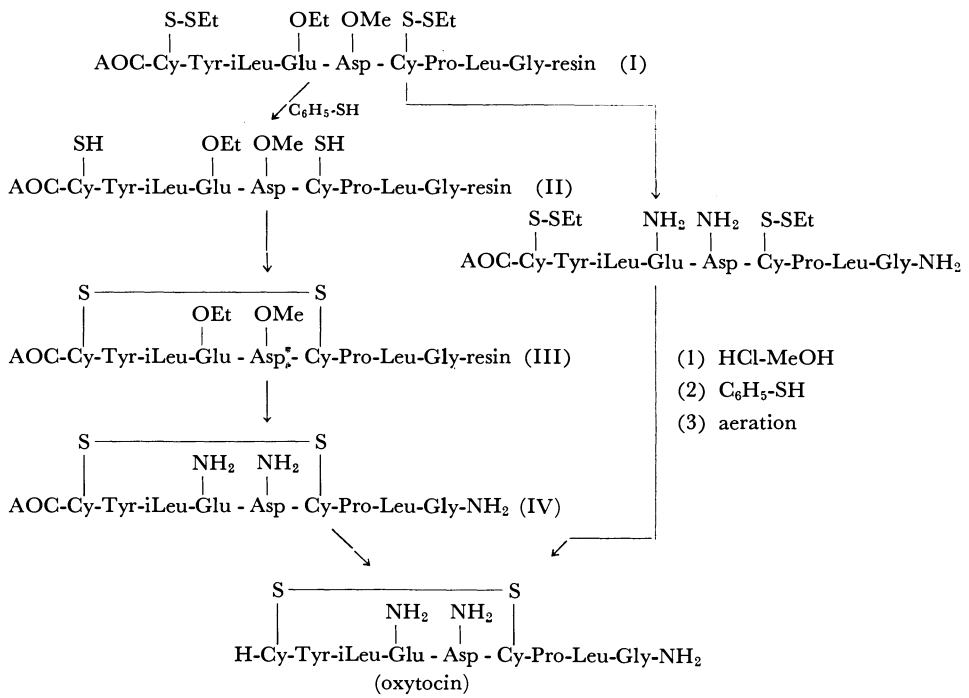

Fig. 1. The synthetic scheme of oxytocin.
AOC=t-amyloxycarbonyl; resin=polyphenol resin

The synthetic scheme of oxytocin was shown in the figure.

Peptide bonds were lengthened stepwise with the N-t-amyloxycarbonyl amino acids on the phenol resin. S-Ethylmercapto-L-cysteine which was reported in the proceeding paper[21] was used for this purpose, because the S-ethylmercapto group is

21) N. Inukai, K. Nakano and M. Murakami, This Bulletin, **40**, 2913 (1967).

easily removed by thiophenol.

From the completed *N-t*-amyloxycarbonyl-*S*-ethylmercapto-L-cysteinyl-L-tyrosyl-L-isoleucyl-γ-ethyl-L-glutamyl-β-methyl-L-aspartyl-*S*-ethylmercapto-L-cysteinyl-L-prolyl-L-leucylglycine phenol resin, *S*-ethylmercapto groups were removed by treating with thiophenol, the free two thiol groups of cysteine residues were converted to the intramolecular disulfide bond by aeration, and finally the peptides were cleft from the resin by treatment with 25% ammonia in methanol. By removing of the protecting group from the *N-t*-amyloxycarbonyl oxytocin thus obtained, the oxytocin could be synthesized. Its biological activity was found to be about two-thirds of that of a standard sample,[21] as determined by rat-uterine contractive activity. This result indicated that the stepwise synthesis of peptide bonds, the removal of *S*-ethylmercapto groups of cysteine residues and the formation of the intramolecular disulfide bond of cystine occured simply, rapidly and automatically on the resin without any complications.

In conclusion, the phenol resin as support of the solid phase peptide synthesis is very useful, especially so for the synthesis of the acyl peptide fragments which are stable under the basic condition. It could be employed successfully for the synthesis of the peptide derivatives which have the intramolecular disulfide bond, by the concomitant application of *S*-ethylmercapto group as protector of the thiol group of cysteine residue.

Experimental

Polyphenol Resin. The solution of phenol (18.8 g, 0.2 mol), *S*-trioxan (6.12 g, 0.068 mol) and *p*-toluenesulfonic acid (0.4 g) in bis-(2-ethoxyethyl)-ether (10 m*l*) was allowed to react at 150°C for 24 hr in the sealed tube in an oil bath. The tube is then permitted to cool to room temperature and is opened cautiously often wrapping in a towel. The amorphous solid product was repeatedly washed with acetone, dimethylformamide and ethanol and dried over phosphorus pentoxide *in vacuo*. Yield 13.8 g.

The Esterification Step. A solution of *t*-amyloxycarbonyl (AOC) amino acid or carbobenzoxyl (Z) amino acid (0.02 mol) and *N, N'*-dicyclohexylcarbodiimide (DCCD) (0.02 mol) in dimethylformamide (DMF) (20—30 m*l*) were added to the phenol resin (1 g) and the suspension was stirred at room temperature overnight. The resinous derivative was filtered and washed several times with DMF, ethanol and acetic acid to remove excess reagents and by-products, especially dicyclohexylurea was throughly removed by washing with acetic acid. 30—40% of phenolic hydroxyl group was esterified.*4 The phenolic hydroxyl group which remained was esterified with acetic anhydride.

The Deprotection Step. a) AOC-Amino acid phenol resin (containing 0.01 mol of AOC-amino aicd) was treated with 10% HCl in methanol or dioxane (20 m*l*) for 2 hr at room temperature. The suspension was filtered and washed with methanol, DMF and ethyl acetate. The resulting hydrogen chloride salt was then neutralized by shaking for 20 min in DMF (20 m*l*) containing triethylamine (0.04 mol). The solvent was removed by filtration and the resin was washed with methanol and DMF. The free base thus obtained was used to the coupling with the next acylamino acid or peptide.

b) Z-Amino acid phenol resin (containing 0.01 mol of Z-amino acid) was treated with 33% HBr in acetic acid (20 m*l*) shaking for 2 hr at room temperature. The suspension was diluted with 30 m*l* acetic acid, and filtered and washed with acetic acid, methanol and DMF. The resulting hydrogen bromide salt was neutralized with triethylamine in DMF as described above.

The Peptide-forming Step. *a) The DCCD Method.* AOC- or Z-Amino acid phenol resin (containing 0.01 mol of acylamino acid) was deprotected and neutralized as described above. The free base was suspended in DMF (20 m*l*) and the next AOC- or Z-amino acid or peptide (0.02 mol) was added and then a solution of DCCD (0.02 mol) in DMF (5 m*l*) was added. The suspension was shaken overnight. The resinous derivative was filtered and washed several times with DMF, acetic acid and methanol until dicyclohexylurea, excess reagents and byproducts are completely removed.

b) The p-Nitrophenyl Ester Method. AOC- or Z-Amino acid phenol resin (containing 0.01 mol of acylamino acid) was deprotected and neutralized as described above. The free base was suspended in DMF (20 m*l*) and the next AOC- or Z-amino acid or peptide *p*-nitrophenyl ester (0.02 mol) was added and then the suspension was shaken overnight. The resinous derivative was filtered and washed several times wiih DMF and methanol to remove excess reagents and by-products.

The Peptide Liberation Step. *a) AOC- or Z-Peptide.* The completed AOC- or Z-peptide resin (containing 0.001 mol of peptide) was saponified by shaking in a solution of 30 m*l* of ethanol-DMF (1 : 1) and 5 m*l* of aqueous N NaOH for 2 hr at room temperature. The phenol resin was removed by filtration and the filtrate was concentrated to a syrup. water (3 m*l*) was added to the syrup obtained and the solution was acidified with dilute aqueous HCl; the separated product was extracted with the suitable solvent and washed with water. The solvent was evaporated off and the crystal residue was recrystallized once or twice from the suitable solvents.

b) AOC- or Z-Peptide Amide. The completed AOC- or Z-peptide resin was treated with large excess of 25% ammonia in methanol for 2 days at room temperature in a sealed tube. The phenol resin was filtered off, the filtrate was concentrated, and the crystal residue was washed with dilute aqueous HCl, dilute aqueous sodium bicarbonate and water, and recrystallized once or twice from the suitable solvents.*5

*4 A fixed quantity of AOC- or Z-amino acid resin was saponified with aqueous N-NaOH in DMF and a ratio of the esterfication was calculated from the quantity of AOC- or Z-amino acid recovered.

*5 The rearrangement from the α-linkages of asparagine- and glutamine-residues to the β- and γ-linkages was 0—40%; it was checked by the methods of A. C. Chibnall *et al.* (*Biochem. J.*, **68**, 114 (1958)) and P. T. Lansbury (*J. Am. Chem. Soc.*, **83**, 429 (1961)).

c) AOC- or Z-Peptide Hydrazide. The completed AOC- or Z-peptide resin was treated with large excess of hydrazine hydrate in DMF overnight. The phenol resin was filtered off. Water was added to the filtrate and the precipitated crystal was collected by filtration and recrystallized from the suitable solvents.

***N-t*-AOC-*S*-Ethylmercapto-L-cysteinyl-L-tyrosyl-L-isoleucyl-γ-ethyl-L-glutamyl-β-methyl-L-aspartyl-*S*-ethylmercapto-L-cysteinyl-L-prol-yl-L-leucyl-glycine Resin (I).** Each peptide bonds were lengthened stepwise from the *C*-terminal with the AOC-amino acids by the DCCD method. These procedures were all carried out by the general method as described above.

***N-t*-AOC-L-Cysteinyl-L-tyrosyl-L-isoleucyl-γ-ethyl-L-glutamyl-β-methyl-L-asparatyl-L-cysteinyl-L-prolyl-L-leucyl-glycine resin (II) and Its Oxydated Derivative (III).** The compound I (0.5 g) was suspended in dioxane (10 m*l*) and thiophenol (0.1 m*l*) was added. The suspension was shaken for 10 hr at 45°C, and filtered and then washed with dioxane. II obtained was suspended in dioxane (5 m*l*) and methanol (5 m*l*) and CO_2 free air was bubbled for 4 hr. The oxidized derivative (III) was collected by filtration and washed with dioxane and methanol.

AOC-Oxytocin (IV). The compound III (0.4 g) was left for 2 days in 25% ammonia in methanol (20 m*l*) in a sealed tube. The phenol resin was removed by filtration and the filtrate was concentrated. The solid residue was dissolved in ethyl acetate and washed with 0.2 N aqueous HCl and water and dried over anhydrous sodium sulfate and then solvent was evaporated off. The crude amorphous solid (0.2 g) obtained was purified on a 2×30 cm Merck's silica gel G column by elution with chloroform - methanol - acetic acid (95 : 5 : 3 v/v); yield 0.1 g, mp 100—120°C, $[\alpha]_D^{23}$ −48.8 (*c* 0.5, DMF).

Found: C, 52.95; H, 6.94; N, 15.39%. Calcd for $C_{49}H_{76}N_{12}O_{14}S_2$: C, 52.48; H, 6.83; N, 14.99%.

Oxytocin. A fixed quantity of the AOC-oxytocin IV was treated with 7% aqueous HCl for 30 min, then the insoluble material was filtered off and pH of the filtrate was adjusted to 4 with dilute aqueous ammonia. The oxytocic activity of this final solution was found to be about two-thirds of that of a standard sample,[21] as determined by rat-uterine contractive activity.

The authors wish to express their thanks to Dr. Yuji Kawashima for his encouragement and valuable advice.

Reactive Monomers Derived from *p*-Vinylbenzoic Acid

Yoshio IWAKURA,* Keikichi UNO,* Nobuo NAKABAYASHI** and Takakazu KOJIMA*

**Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo*
***Institute for Medical and Dental Engineering, Tokyo Medical and Dental University, Chiyoda-ku, Tokyo*

(Received July 5, 1967)

Reactive monomers derived from *p*-vinylbenzoic acid have been prepared which have both a vinyl group and another functional group for addition reaction or condensation reaction. The radical polymerization of these monomers gives high polymers. Monomer reactivity ratios in relation to styrene were obtained for three of these monomers. Plots of Alfrey-Price's *e* value *vs.* Hammett's σ value show a linear relationship in the case of substituted styrenes. σ values are then estimated by this relation, using *e* values based on the monomer reactivity ratios. The σ constants assumed for the COCl, $COOCH_2CHCH_2$ (O), and NCO substituents are 0.71, 0.64, and 0.27 respectively. These σ values are confirmed by other supporting facts.

Wide investigations of reactive polymers have been carried out in our laboratory.[1-3] Generally speaking, there are two ways to introduce reactive functional groups into macromolecules. One way is the reaction of a polymer with some compound which has functional groups. The other is the polymerization of vinyl monomers which have functional groups for a polymer reaction. Such a vinyl monomer has been called a reactive monomer.[4] The latter way is rather more favorable than the former because of the uniform composition of the polymer obtained.

The present paper will describe the preparation of reactive monomers derived from *p*-vinylbenzoic acid. The reactive groups introduced are those for addition reaction or condensation reaction: epoxide, aziridine, isocyanate, acid chloride, and

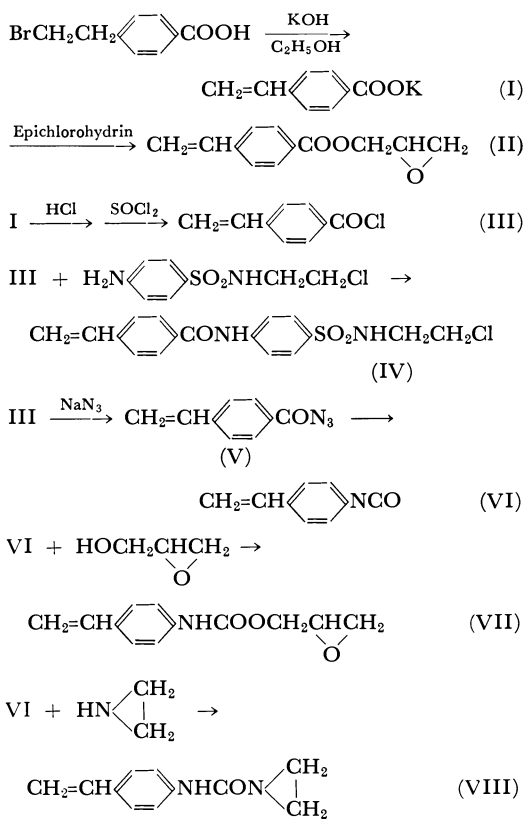
β-chloroethylsulfonamide. All of these monomers belong to *p*-substituted styrenes. The monomer reactivity ratios of these monomers in relation to styrene showed some correlation with the polar effect of the group.

Results and Discussion

Preparation of *p*-Substituted Styrenes. In the present study, *p*-substituted styrenes (II—VIII) were synthesized from *p*-vinylbenzoic acid[5-7] according to the following equations:



Potassium *p*-vinylbenzoate (I) was obtained according to Jäger's method. The glycidyl ester (II) was obtained in a good yield by the reaction of compound I with an excess amount of epichlorohydrin in the presence of quaternary ammonium salts serving as catalysts.

p-Vinylbenzoyl chloride (III) was prepared by Adrova.[8] In this reaction, the amount of thionyl chloride used must be carefully measured. Using an excess amount of thionyl chloride gives *p*-(α-chlorovinyl)benzoyl chloride, accompanied by a resinous polymer. The reaction of compound III with *N*-β-chloroethyl sulfanilamide[2] and sodium azide gave compound IV and compound V respectively.

A mixture of *o*- and *p*-isomers of vinylphenyl isocyanate is known to have been synthesized from *o*- and *p*-vinylaniline by phosgenation.[9] In the present study, *p*-vinylphenyl isocyanate (VI) was obtained by the Curtius rearrangement of the acid azide V. Furthermore, glycidyl urethane (VII) and *N*, *N*-ethylene urea (VIII) were derived through the reaction of VI with glycidol and aziridine respectively. The physical and infrared absorption data of these monomers are summarized in Table 1.

Polymerization of *p*-Substituted Styrenes. The radical polymerization of these monomers was carried out in a solution, using azo-bis-isobutyronitrile (AIBN) as an initiator. All of the monomers gave white powders soluble in such organic solvents as dioxane and dimethylformamide (DMF). The infrared spectra of these polymers give absorptions characteristic of the functional groups. The polymers from III and VI were very sensitive to moisture, and they became insoluble in an instant. The results of the homopolymerization of these reactive monomers are summarized in Table 2.

The isocyanates are known to undergo anionic polymerization easily even when sodium cyanide is used as an initiator.[10] On the other hand, styrene does not give any polymer in the presence of sodium cyanide. The compound VI has both vinyl and isocyanate groups; an anionic polymerization of it in DMF with sodium cyanide as an initiator was undertaken. The polymer thus obtained was soluble in DMF, and gave IR absorptions at 1630, 985, and 910 cm^{-1}, which are characteristic absorptions of vinyl group, and no absorptions around 2300 and 2900 cm^{-1}. These results indicate that the polymerization of VI proceeded exclusively through the isocyanate group. The further polymerization of the residual functional group in the polymer obtained from VI was then examined in order to get a ladder polymer. However, the radical polymerization of the pendant vinyl group in the isocyanate polymer failed, since the isocyanate polymer was readily degraded in DMF at room temperature. The anionic polymerization of the isocyanate group in the vinyl polymer could not be carried out either because of insolubility of the vinyl polymer.

Copolymerization. Compounds II, III, and VI were submitted to copolymerization with styrene. The monomer reactivity ratios of these compounds were obtained by the intersecting

method[11] from the compositions of the monomer feeds and copolymers obtained. The compositions of the copolymers were determined by analysis of the epoxy group for the copolymer from II, by analysis of chlorine for the copolymer of III, and by elemental analysis of nitrogen for VI. The monomer reactivity ratios and Alfrey-Price's Q and e values are shown in Table 3. The copolymer composition curves of styrene (M_1) with compounds II, III, and VI are shown in Fig. 1, where the mol% of m_1 in the copolymers is plotted against the mol% of M_1 in the monomer feeds.

The compounds II, III, and VI have electron-withdrawing groups, that is, $COOCH_2\underset{\diagdown O \diagup}{CH}CH_2$, COCl, and NCO. It has been reported that, on the copolymerization of styrene (M_1) with p-substituted styrenes, there is a good linear relation between $\log(1/r_1)$ and σ^-,[12] or between $\log(1/r_1)$ and σ, using a modification of Hammett's equation.[13] e values have also been said to show polarity, and to have some correlation with σ in substituted ethylenes.[14] When the e values of p-substituted styrenes were plotted against the σ values for substituents, a good linear correlation was observed, as is shown in Fig. 2. The e and σ values are taken from Perrin's and Young's

tables[15,16] respectively.

When the σ values for the substituents of compounds II, III, and VI were estimated from the e-σ map (Fig. 2). The following values were obtained for $-COOCH_2CHCH_2$, -COCl, and -NCO:

0.64, 0.71, and 0.27.

The σ value for *p*-NCO has been reported to be 0.24,[17] which is close to the estimated value of 0.27. The σ value for *p*-COCl can be estimated by Charton's method.[18] If X denotes a substituent with a known σ constant and Y an intervening group, the σ constant for the XY group can be estimated by the equation: $\sigma_{XY}=\alpha+\beta\sigma_X$. In this case, X=CO and Y=H, OCH_3, NH_2, and OH. The σ value given for *p*-COCl is 0.70, which is almost the same value as the estimated

value, 0.71. If the α and β values calculated by Charton are used, the σ value may be 0.60, but the Y groups used by him include substituent of a different type (COO^-), which deviates from the equation given above, and so the error must be much greater. The σ value for the glycidyl ester has not yet been obtained. The value obtained here is a little higher than the value for $-COOC_2H_5$, 0.45.[15] This can be attributed to the inductive effect of oxygen in a three-membered ring. The λ_{max} in UV and τ values in NMR for CH_2= (asterisked value) of these three monomers show an orderly correlation with the σ value assumed here (Table 4). The values of $\log(1/r_1)$ are plotted against σ in Fig. 3. This figure also shows that the σ values obtained here are reasonable, because the cubic points (our results) are almost on the plotted curve.

Experimental

Monomers. *Glycidyl p-Vinylbenzoate (II).* *p*-(β-Bromoethyl)benzoic acid was prepared from *p*-(β-bromoethyl)acetophenone by the procedure of Foreman,[19] using sodium hypochlorite (antiformine). Potassium *p*-vinylbenzoate (I) was obtained by heating *p*-(β-bromoethyl)benzoic acid with potassium hydroxide and hydroquinone in ethanol. Finely-powdered crude I (15.0 g), epichlorohydrin (120 m*l*), triethylbenzylammonium chloride (150 mg), and hydroquinone (80 mg) were heated while being stirred under reflux for 30 min. The resulting potassium chloride was filtered, and the excess epichlorohydrin was removed under reduced pressure. The fractional distillation of the residue gave 7.2 g (67%) of a colorless product; bp 115.5—116.5°C/0.1 mmHg. The epoxide content was over 99.0% (HCl-dioxane method[20]). $n_D^{20}=1.5622$.

Found: C, 70.63; H, 6.01%. Calcd for $C_{12}H_{12}O_2$: C, 70.57; H, 5.92%.

p-Vinylbenzoyl Chloride (III). To a mixture of *p*-vinylbenzoic acid (10.0 g) and *p-t*-butylpyrocathecol (10 mg), a 20 m*l* portion of thionyl chloride was added under cooling. The reaction mixture was kept below 10°C for 5 hr, and then gradually warmed to 40°C and maintained there for 1 hr. After the removal of the thionyl chloride, distillation gave 8.8 g (78%) of colorless liquid; bp 69.5—70.0°C/0.1 mmHg. $n_D^{20}=1.6020$.

The reaction of *p*-vinylbenzoic acid (10.0 g) with a large excess of thionyl chloride (60 m*l*) gave a product (bp 90—100°C/1 mmHg) which solidified on standing; recrystallization from *n*-hexane gave white needles which melted at 86.0—86.5°C.

IR: 1760, 1601, 1410, 1208, 1170, 933, 885, 847, 808 cm^{-1}

NMR: 2.04, 2.17, 2.62, 2.74 (quartet) and 3.15 (singlet)

Found: C, 53.65; H, 3.24; Cl, 34.57%. Calcd for $C_9H_6OCl_2$: C, 53.50; H, 3.00; Cl, 35.09%.

From these data, the product was identified as *p*-(α-chlorovinyl)benzyol chloride.[21]

p'-β-Chloroethylaminosulfonyl-p-vinylbenzanilide (IV). *N*-β-Chloroethylsulfoanilamide (2.6 g) and triethylamine (1.2 g) were dissolved in a mixture of acetone (3 m*l*) and ether (10 m*l*). To this solution acid chloride III (1.9 g) was added, drop by drop, on cooling in an ice-salt bath. In an hour of stirring a white precipitate appeared. The product was filtered, washed with water, and dried. It weighed 3.0 g (75%). Recrystallization from benzene-ethanol gave white crystals; mp 186.0—186.5°C.

Found: C, 56.14; H, 4.70; N, 7.62%. Calcd for $C_{17}H_{17}N_2O_3ClS$: C, 55.98; H, 4.70; N, 7.68%.

p-Vinylphenyl Isocyanate (VI). To a solution of sodium azide (10.0 g) in distilled water (26 m*l*), there was added, drop by drop, a solution of III (8.3 g) in ether (7 m*l*) at a temperature around 0°C. The mixture was then agitated for 30 hr at 0°C. The *p*-vinylbenzazide V thus deposited was filtered, washed thoroughly with water and then with a small amount of *n*-hexane, and dried. It weighed 8.0 g (93%); mp 54.0—54.5°C (recrystallized from *n*-hexane).

A solution of V (8.0 g) in toluene was gradually heated; gas evolved about 80°C. The solution was then refluxed for 30 min. After the removal of the toluene, the distillation of the residual liquid gave a colorless liquid, 4.4 g (66%); bp 40.5—41.5°C/0.1 mmHg. $n_D^{20}=1.5785$. This product gave methyl *p*-vinylcarbanilate by a reaction with methanol; mp 85.5—86.5°C (recrystallized from ether-petroleum ether).

Found: N, 7.68%. Calcd for $C_{10}H_{11}NO_2$: N, 7.91%.

Glycidyl p-Vinylcarbanilate (VII). This compound was obtained by the reaction of VI with glycidol in ether. The yield was 96%; mp 95.5—97.0°C (recrystallized from benzene-*n*-hexane).

Found: C, 65.42; H, 5.92; N, 6.32%. Calcd for $C_{12}H_{13}NO_3$: C, 65.74; H, 5.98; N, 6.39%.

N-p-Vinylphenyl-N', N'-ethyleneurea (VIII). This compound was obtained by the reaction of VI with aziridine in cooled ether. The yield was 70%; mp 108.0—108.5°C (recrystallized from aqueous methanol).

Found: C, 69.83; H, 6.17; N, 14.74%. Calcd for $C_{11}H_{12}N_2O$: C, 70.18; H, 6.43; N, 14.88%.

Polymerization. *Radical Polymerization.* The radical polymerization was carried out with an appropriate solvent in a sealed ampule using AIBN as the initiator. The polymer was obtained by pouring the reaction mixture into methanol (for II, IV, VII, and VIII) or into anhydrous *n*-hexane (for III and VI). The viscosities were measured in a DMF solution at 30.0°C.

Anionic Polymerization. The procedure for the anionic polymerization of VI was the same as that described by Shashoua.[10] The yield of the polymer was 32%. If the polymer obtained was dissolved in DMF at room temperature, it was degraded to a cyclic trimer and symmetrical urea. Therefore, the viscosity of the isocyanate polymer could not be obtained. Radical polymerization by the high dilution of this polymer in DMF failed for the same reason.

Copolymerization. Two grams of a pair of monomers and 10 mg of AIBN were mixed in a sealed tube under nitrogen. The polymerization was then carried out at a fixed temperature. The conversion of the copolymer was less than 8%. The resulting polymer was

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 191—197 (1968)

Proton Magnetic Resonance Studies of 2, 2'-Anhydro-2-*C*-hydroxymethyl-1, 3 : 4, 6-di-*O*-isopropylidene-L-sorbitol[1]

Takashi MAEDA, Kazuo TORI, Masako OHTSURU and Kanji TOKUYAMA

Shionogi Research Laboratorry, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received July 8, 1967)

The PMR spectra of 2,2'-anhydro-2-*C*-hydroxymethyl-1, 3:4, 6-di-*O*-isopropylidene-L-sorbitol were examined in several solvents to confirm its structure. The conformation of this molecule is also discussed.

In a recent paper,[2] we have reported that the treatment of 1, 3 : 4, 6-di-*O*-isopropylidene-β-L-sorbofuranose (I) with diazomethane in ether-methanol afforded a mixture of 2, 2'-anhydro-2-*C*-hydroxymethyl-1, 3 : 4, 6-di-*O*-isopropylidene-L-xylohexitol (II) and 2, 5-anhydro-2-*C*-hydroxymethyl-1, 3 : 4, 6-di-*O*-isopropylidene-L-iditol (III) accompanied with trace of methyl 1, 3 : 4, 6-di-*O*-isopropylidene-β-L-sorbofuranoside (IV), and that II was easily transformed to III even in the absence of an acid. Ring opening of an epoxide proceeds with inversion at that carbon atom which is attacked.[3,4] Therefore, it can be anticipated that the structure of II should be 2, 2'-anhydro-2-*C*-hydroxymethyl-1, 3 : 4, 6-di-*O*-isopropylidene-L-sorbitol but not 2, 2'-anhydro-2-*C*-hydroxymethyl-1, 3 : 4, 6-di-*O*-isopropylidene-L-iditol (V). This paper deals with the confirmation of the structure of II by means of PMR spectroscopy. Further the conformations of II in several solvents are discussed.

The 100 Mc PMR spectra of II were measured in carbon tetrachloride, chloroform-d, acetone-d_6, pyridine-d_5, and dimethylsulfoxide-d_6 in order to apply the solvent effects to the assignment of proton signals. The data obtained by the first-order approximation are shown in Table 1.

The spectrum of II in carbon tetrachloride shows the signal of epoxidic protons as an AB-type quartet at τ 7.06 and 7.45 ($J_{2'A,2'B}$=4.4 cps), as shown in Fig. 1a. The upfield-half of the quartet shows extra splittings of 0.8_5 cps. Double irradiation on this proton causes the collapse of the downfield-half of the quartet into a singlet and the change of a broad doublet due to H_3 at τ 5.90 ($J_{3,4}$= 3.0 cps) into a sharper doublet, but did not cause any changes to an AB-type quartet due to H_1 and $H_{1'}$ at τ 6.13 and 6.47 ($J_{1,1'}=(-)12.5$ cps) (Fig. 1b). Conversely, double irradiation at the resonance position of H_3 causes sharpning of the upfield-half of the quartet due to the epoxidic protons as well as the collapse of the multiplet arising from H_4 at τ 6.33 into a doublet ($J_{4,5}$= 2.0 cps) (Fig. 1c). Thus, the presence of a long-range spin coupling between only one of the epoxidic and C-3 protons was revealed. A doublet signal at τ 6.99 (J=7.0 cps) is thought to be due to the OH proton coupled to H_5. Decoupling of this proton by double irradiation (Fig. 1d) and by deuterium exchange by an addition of a small amount of deuterium oxide to the solution examined (Fig. 1f) made a broad multiplet at τ 6.58 narrower. Thus this multiplet was assignable to H_5 signal. The remaining AB-type quartet further split into doublets at τ 6.18 ($J=(-)12.2$ and 2.4 cps) and 6.38 ($J=(-)12.2$ and 2.5 cps) arises obviously from C-6 protons. Figures 1e and 1g show other examples of spin-decoupling experiments on II.

Similar decoupling experiments on II in chloroform-d (see Fig. 2) and acetone-d_6 (see Fig. 3) gave similar results. In these solutions the OH proton signals appear at positions so close to those

V

of H_5 signals that their patterns are much complicated, but the additions of deuterium oxide to the solutions examined make the signal patterns very clear with disappearing of the OH-signals. It is very interesting to note that decoupling of the OH proton in these solvents, particularly in chloroform-d, changes one of the C-6 methylene proton signals (at the lower field) into a sharp quartet. This observation implies the presence of long-range spin coupling between the OH- and the C-6 protons.

The infrared spectrum of II in a dilute solution of carbon tetrachloride shows two OH bands at 3539 and 3578 cm^{-1}; the former indicates the presence of a strong intramolecular hydrogen-bonding (the distance between OH–O is claculated about 1.76 Å) and the latter (shoulder) does a weak hydrogen-bonding (the distance is about 2.18 Å).[5]

The values for $J_{3,4}$ (2.7—3.6 cps) led us to determination of the dihedral anagle between H_3 and H_4 according to the well known Karplus correlation;[6] the angle is about 60° in a very rough estimation.[7] The values for $J_{4,5}$, $J_{5,6}$, and $J_{5,6'}$ (2—2.5 cps) are essentially unchanged with the change of solvents. Applying the Karplus equation to these values likewise in a rather qualitative

5) The distances were calculated according to Y. Matsui, M. Takasuka and T. Kubota, *Ann. Rept. Shionogi Res. Lab.*, **15**, 125 (1965), and T. Kubota, M. Takasuka and Y. Matsui, *ibid.*, **16**, 63 (1966), provided that the absorption band of an ordinary secondary OH group appears at 3630 cm^{-1}.

6) M. Karplus, *J. Chem. Phys.*, **30**, 11 (1959); *J. Am. Chem. Soc.*, **85**, 2870 (1963).

7) It is a well known fact that much caution should be exercised when deriving the dihedral angle between a set of protons from the Karplus equation. For example, see N. S. Bhacca and D. H. Williams, "Applications of NMR Spectroscopy in Organic Chemistry," Holden-Day, Inc., San Francisco (1964).

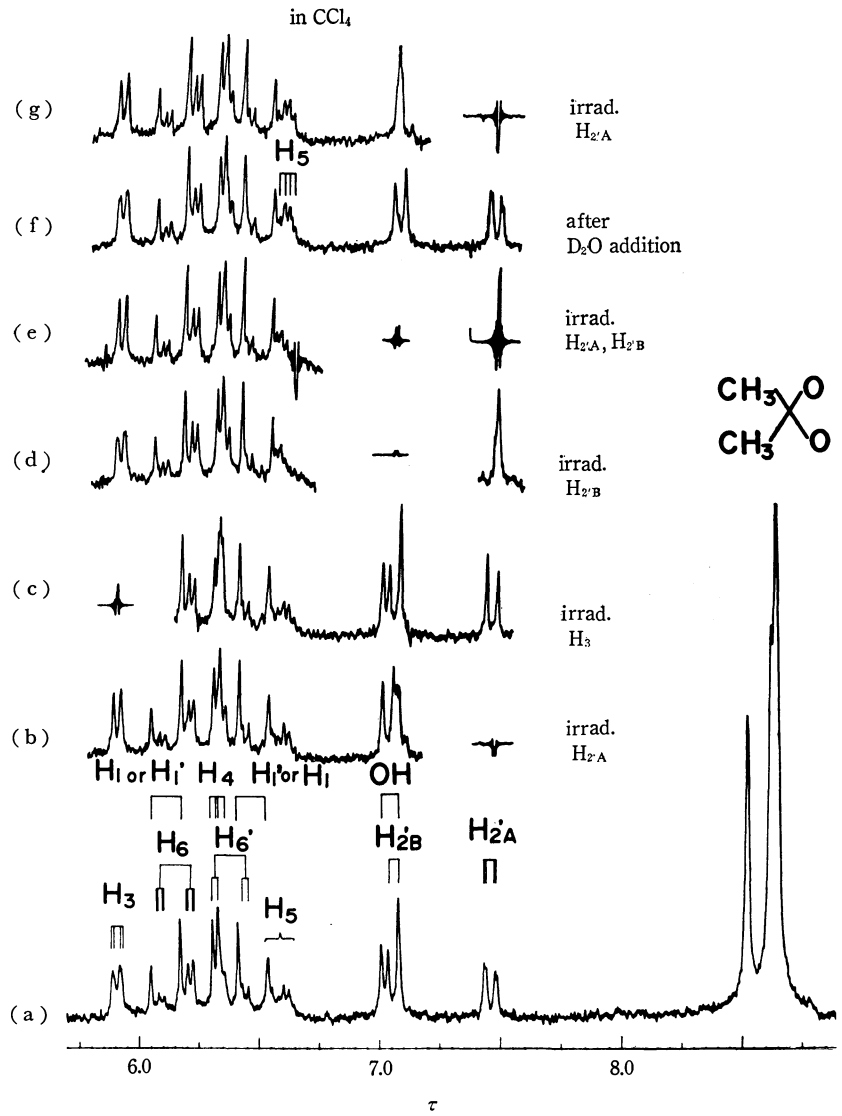

Fig. 1. PMR spectra of II in carbon tetrachloride at 100 Mc.

sense, we can conclude that the 4, 6-*O*-isopropylidene ring (ring B) has a chair form; the C-5 OH group has an axial conformation. Examination of Dreiding models shows that it is difficult to form the molecular conformation so as to enable the intramolecular hydrogen-bonding of this OH group toward the epoxide ring owing to strong steric hindrance. Therefore, the OH group should possibly, and perhaps dominantly, be hydrogen-bonded to the oxygen atom at C-3; but partly, as the infrared spectrum indicates, a weak hydrogen-bonding between the OH group and either of oxygen atoms in ring B is thought to be formed. The presence of the long-range spin couplings between one epoxidic and C-3 protons and between the OH- and one C-6 protons is useful for inferring the stereochemistry of II. The stereochemical relationship between these protons should obey the "W-letter" rule for the long-range spin coupling across four single bonds.[8] The "W-letter" arrangement between the OH- and the axial C-6 protons also explains the coupling constant between the OH- and C-5 protons in carbon tetrachloride; the dihedral angle between these two protons is

8) For example, see S. Sternhell, *Rev. Pure and Appl. Chem.*, **14**, 15 (1964); K. Tori, K. Aono, Y. Hata, R. Muneyuki, T. Tsuji and H. Tanida, *Tetrahedron Letters*, **1966**, 9, and references therein.

a) Obscured.

about 30—40°. The fact that in contrast to the general rule, the axial C-6 proton signal appears at a lower field than the equatorial C-6 proton is accounted for by the long-range shielding effects of the OH group in *trans*-diaxial relation to the axial C-6 proton and of the isopropylidene methyl group 1, 3-diaxial to this proton.[9] Provided that the OH group is strongly hydrogen-bonded to C-3 oxygen, only one skew-boat conformation of 1, 3-*O*-isopropylidene ring (ring A) in II can satisfy the "W-letter" relationship between $H_{2'A}$ and H_3, as Dreiding models indicate. However, any conformations of ring A in the structure V cannot explain the presence of the long-range spin coupling only between one epoxidic proton and H_3. Thus, we reached in the conclusion that the product II was confirmed to be 2, 2'-anhydro-2-*C*-hydroxymethyl-1, 3 : 4, 6-di-*O*-isopropylidene-L-sorbitol which has the molecular conformation shown in Fig. 4 in carbon tetrachloride, chloroform-d, and acetone-d_6. This conformation also well explains the appearance of the $H_{2'B}$ signal at a lower field than the $H_{2'A}$ signal because $H_{2'B}$

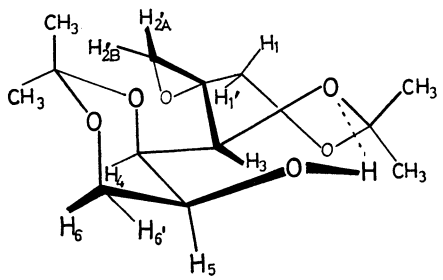

Fig. 4. The conformation of II.

is closely situated to one of the oxygen atom in ring B, which can exert deshielding effects on $H_{2'B}$.

This conclusion was further evidenced by the measurements of the spectra of II in pyridine-d_5 and dimethylsulfoxide-d_6; these solvents can be expected to remove the hydrogen-bonding owing to their strong basicity.[10-12] Seemingly, acetone

does not have sufficient basicity to remove such a strong intramolecular hydrogen-bonding between the C-5 OH and C-3 oxygen.

The spectrum of II in pyridine-d_5 shown in Fig. 5 exhibits well-separated signals, which were easily assigned. In the spectrum in dimethylsulfoxide-d_6 (Fig. 6a), the signals seemed somewhat complicated; but by an addition of deuterium oxide to the solution examined the lowest-field doublet ($J=5.4$ cps) disappears with the change of the H_5 signals (little changes in the chemical shift were caused as shown in Fig. 6b). This doublet is due to the C-5 OH proton. The signal assignment was made as indicated in Fig. 6. In these cases, the signals of $H_{2'A}$ appear as a clear doublet showing no further splittings. The larger values for $J_{3,4}$ obtained (5.5 and 6.4 cps) imply the increasing of population of the *trans*-conformation between H_3 and H_4 in these solvents. These observations can be due to the disappearance of the intramolecular hydrogen-bonding; instead, the intermolecular hydrogen-bondings between the OH group and the solvents were formed strongly. Thus, the above conclusion was amply justified by these facts also.

Experimental

The PMR spectra were taken with a Varian HA-100 spectrometer operating at 100 Mc by using about 5% solutions of the sample in carbon tetrachloride, chloroform-d, acetone-d_6, pyridine-d_5, and dimethylsulfoxide-d_6 in the frequency-swept and tetramethylsilane (TMS)-locked mode. Calibration of the spectrometer was checked by a Hewlett-Packard 5212A electronic counter. Spin-decoupling experiments were carried out by using two Hewlett-Packard 200ABR audiooscillators. Chemical shifts are expressed in τ unit (± 0.02) and coupling constants in cps (± 0.2 cps).

The infrared spectrum of II was measured with a Nippon Bunkō DS402G infrared spectrometer by using a 3.5 mg/8 cc (in 20 mm cell) solution in carbon tetrachloride.

We thank Dr. Ken'ichi Takeda, Director of this Laboratory, for his interest, and dedicate this paper to him in celebration of his sixtieth birthday.

Anionic Polymerization of *trans*-β-Methylstyrene

Yoshio OKAMOTO and Heimei YUKI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

and Shunsuke MURAHASHI

Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 17, 1967)

The anionic polymerization of *trans*-β-methylstyrene by *n*-butyllithium was carried out in hydrocarbon solvents and in tetrahydrofuran. In hydrocarbon solvents the monomer was consumed by *n*-butyllithium, but gave no polymer insoluble in methanol. In tetrahydrofuran the polymerization proceeded rapidly, giving a polymer insoluble in methanol. This polymer was produced by the normal addition polymerization of a C=C double bond. The relatively lower degree of polymerization of poly-β-methylstyrene indicated a chain transfer in the reaction. The chain transfer reaction due to the active hydrogen of a methyl group in this monomer was also observed by means of the electronic spectra of the reaction mixtures. The polymer anion was converted to inactive anions at high temperatures.

Staudinger[1] proposed that β-methylstyrene may be polymerized by a cationic initiator to give the so-called 1, 3-polymer by means of a hydrogen shift mechanism:

$$CH_3\text{-}CH{=}CH\text{-}C_6H_5 \rightarrow \left(\text{-}CH_2\text{-}CH_2\text{-}\underset{\displaystyle C_6H_5}{\underset{|}{CH}}\text{-}\right)_n$$

Recently, however, the reexamination of this cationic polymerization has proved that β-methylstyrene polymerizes only by means of the usual mechanism through the opening of a C=C double bond.[2,3]

On the other hand, regarding the anionic

polymerization of β-methylstyrene only a little information is available in the literature.[4,5] The present authors investigated the anionic polymerization of this monomer using *n*-butyllithium as a catalyst. It was found that in tetrahydrofuran the polymerization of this monomer took place by the normal addition of a C=C double bond, accompanied by the chain transfer to the monomer. The electronic spectra of the reaction mixtures were also investigated in order to correlate them with the reaction mechanism.

Experimental

***trans*-β-Methylstyrene (β-MeSt).** According to the method of Park,[6] β-methylstyrene was prepared by the dehydration of ethylphenylcarbinol with alumina at 300±10°C. The *trans*-isomer was collected by fractional distillation and was purified by redistillation under nitrogen from a flask containing lithium aluminum hydride. The purity was checked by gas chromatography. Bp 76—77°C/28 mmHg, n_D^{20} 1.5504: lit.,[7] n_D^{20} 1.5507.

Tetrahydrofuran (THF). Tetrahydrofuran which had been dried over sodium was refluxed over lithium aluminum hydride and then transferred by a vacuum system to a glass ampule before use.

Benzene and *n*-Hexane. Each solvent was purified by the usual method[8] and before use was transferred by the vacuum line from a flask containing a small amount of *n*-butyllithium to an ampule.

***n*-Butyllithium (*n*-BuLi).** *n*-Butyllithium was prepared in *n*-heptane according to the method of Ziegler.[9] The concentration was determined by the double-titration method of Gilman.[10]

Sodium Naphthalene (Na-Naph). Sodium naphthalene was prepared in tetrahydrofuran;[11] its concentration was determined by titration with 0.1 N hydrochloric acid, using phenolphthalein as an indicator.

Sodium-dispersion (Na-disp.). Sodium-dispersion in *n*-octane was used; the concentration was 30%.

Polymerization. The polymerization was carried out in a glass ampule which had been cleaned and dried completely. The solvent was first transferred into a glass ampule by means of a vacuum line, and then the monomer and initiator were added by syringes under an atomosphere of dried nitrogen. The solution was then allowed to stand in a constant temperature bath. The reaction was terminated by the addition of a trace of methanol. The concentration of unchanged *trans*-β-methylstyrene was determined spectrophotometrically by using a part of the solution. The optical density was measured at 293.5 mμ (ε_{max} 790), where it obeyed Beer's law. On the other hand, the residual solution was poured into a large amount of methanol and the precipitated polymer was separated by filtration, dried, and weighed.

In the following, the monomer consumption obtained by the spectrophotometric measurements and the yield of the methanol-insoluble polymer will be defined as "conversion" and "yield" respectively, while "polymer" will refer to the methanol-insoluble part otherwise stated.

Measurement. The molecular weight of the polymer was determined cryoscopically in a benzene solution. The infrared spectrum was measured on a Nihon Bunko DS-21 Spectrometer. The NMR spectrum was obtained in a carbon tetrachloride solution using a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.) at 100 Mc/sec, by using tetramethylsilane as an internal standard. The electronic spectrum was obtained with a Hitachi Perkin-Elmer 139 Spectrophotometer or a Hitachi EPS-2 Spectrophotometer. The spectrum of the living anion was measured in tetrahydrofuran according to the technique of Waack.[12]

Results

Polymerization in Hydrocarbon. Polymerizations were carried out in hydrocarbon solvents using *n*-BuLi, sodium-dispersion, and sodium naphthalene as initiators. The results are summarized in Table 1. A yellow color appeared two or three hours after the addition of an initiator, and its intensity gradually increased. When the reaction was performed for a prolonged time, it was observed that a considerable amount of the monomer was consumed, but no methanol-insoluble polymer was obtained. However, a small amount of the polymer was obtained in the polymerization where sodium naphthalene was used as an initiator and where a trace of tetrahydrofuran was present as the solvent of the initiator solution.

Polymerization in Tetrahydrofuran. The polymerization of *trans*-β-methylstyrene with *n*-BuLi was carried out in tetrahydrofuran. As soon as *n*-BuLi was added to the monomer solution, a red color appeared; the density of this color did not change during the reaction at room temperature.

The time dependencies of the conversion (obtained from the UV spectrum) and the yield (wt% of the methanol-insoluble polymer against the monomer charged) at 0 and 30°C are shown in Fig. 1. The monomer consumption was quantitative after 24 hr, but the yield of the methanolinsoluble polymer was much less than that. The molecular weights of the polymers obtained at 0 and 30°C were

about 1500 and 1300 respectively and were independent of the yield.

It was found that when the reaction ceased the monomer remained unchanged at high reaction temperatures. In order to investigate the effects of the temperature on the final conversion and the final yield, prolonged reactions were carried out at various temperatures between 0 and 100°C, using *n*-BuLi as an initiator. The results are shown in Fig. 2. The curves show that both the final conversion and the final yield gradually decreased at elevated temperatures. The color of the reaction mixture was red at 0 and 30°C, but turned purple above 60°C. A similar tendency was also observed in the polymerization initiated by sodium naphthalene.

The polymerization was carried out for 48 hr at 30°C, while varying the concentration of *n*-BuLi. As shown in Fig. 3, the final conversion, the final yield, and the molecular weight of the polymer were all independent of the concentration of *n*-BuLi.

The relationships between the final yield of the methanol-insoluble polymer and the initial monomer concentration are shown in Fig. 4. The yield increased with an increase in the initial monomer concentration independently of the reaction temperature. However, the yield at 30°C was less than that at 0°C with each initial monomer concentration. In this case the molecular weight of the polymer was also independent of the reaction conditions.

The data shown in Fig. 1 are plotted in Fig. 5 as if the reaction were first-order with respect to the monomer concentration. The reaction rates decreased with the reaction time and deviated from the first-order plots at the initial stage of the reaction, but later the relation between $\ln([M]_0/[M])$ and the reaction time became straight lines with the same slope at 0 and at 30°C.

The existence of an equilibrium in the polymerization of *trans*-β-methylstyrene at 60°C was checked. The monomer was polymerized at 60°C; after the reaction had ceased, (1) a fresh monomer was added to the reaction mixture, or (2) the reaction mixture was cooled to 0°C and left to stand 48 hr at this temperature. As shown in Table 2, the conversion did not change from that in the original reaction mixture, indicating that there is no equilibrium in the reaction at 60°C.

Electronic Spectra of Reaction Mixtures. The electronic spectra of the solutions are shown in Fig. 6. The reactions were carried out between *trans*-β-methylstyrene and *n*-BuLi, and between allylbenzene and *n*-BuLi, in tetrahydrofuran. Curve A, with an absorption maximum at 340 mμ in Fig. 6, is the spectrum of the reaction product of *trans*-β-methylstyrene with an excess of *n*-BuLi at room temperature. Curve B shows the spectrum of the reaction product after 48 hr in the polymerization of *trans*-β-methylstyrene with *n*-BuLi at 0°C. It has an absorption maximum at 398 mμ. A very similar spectrum (Curve B′) was obtained from the reaction product between allylbenzene and an equimolar amount of *n*-BuLi at room temperature. At 60°C this spectrum shifted to Curve D, which has an absorption maximum at 570 mμ. When *trans*-β-methylstyrene was polymerized with *n*-BuLi at 60°C, after 48 hr the reaction mixture

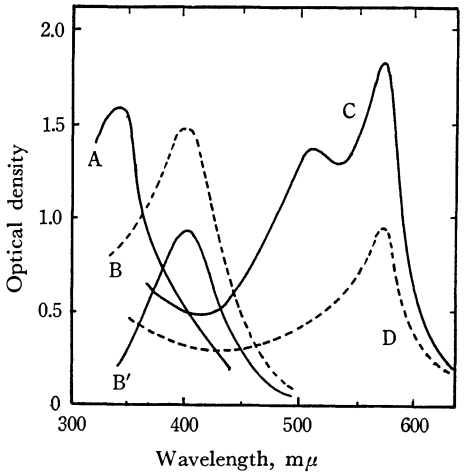

Fig. 6. Electronic spectra of anions in THF.

A: β-MeSt+excess *n*-BuLi, at room temp., after 5 min
B: Excess β-MeSt+*n*-BuLi, at 0°C, after 48 hr
B': Allylbenzene+*n*-BuLi, at room temp., after 5 min
C: Excess β-MeSt+*n*-BuLi, at 60°C, after 48 hr
D: Allylbenzene+*n*-BuLi, at 60°C, after 48 hr

gave the spectrum shown as Curve C in Fig. 6. This spectrum contains two absorption maxima, at 510 and 570 mμ.

Structure of Polymer. The infrared spectrum of the methanol-insoluble polymer obtained at 30°C is shown in Fig. 7. As a whole the spectrum was very similar to that of polystyrene, except for the strong absorption bands at 2960, 2875, and 1377 cm^{-1} due to methyl groups and the extremely weakened band at 2925 cm^{-1} due to methylene groups. The IR-spectrum of the methanol-soluble fraction, which has an average molecular weight of 360, was just the same as that of the methanol-insoluble fraction, but it showed a strong absorption at 2925 cm^{-1}

The ultraviolet spectrum of the methanol-soluble and insoluble fractions showed no C_6H_5–CH=CH– structure, which may be expected to have a strong absorption at about 292 mμ due to the conjugation between a phenyl group and a C=C double bond.

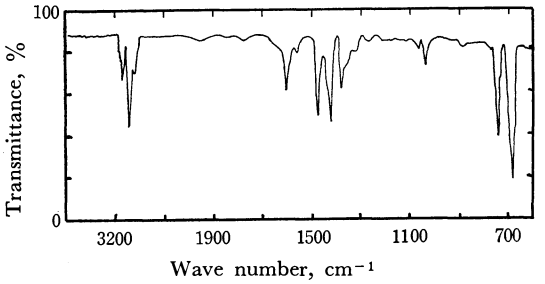

Fig. 7. Infrared spectrum of poly-β-methylstyrene (KBr).

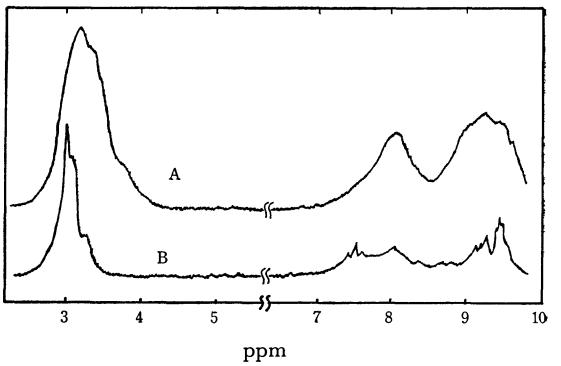

Fig. 8. NMR spectra of poly-β-methylstyrene.

A: Methanol-insoluble fraction
B: Methanol-soluble fraction

In Fig. 8 the NMR spectra of the methanol-insoluble and soluble polymers are shown. In neither the spectra was there any absorption at 3.5—5 ppm, where the signal of a proton attached to a C=C double bond appears. The spectrum of the methanol-insoluble polymer showed that the ratios of methyl to methylene protons and of phenyl to other protons were 3 : 2 and 5 : 5 respectively.

These results indicate that the polymer was formed by the usual addition polymerization at the C=C double bond, and that there is no essential difference between the structures of the methanol-soluble and -insoluble polymers.

Discussion

In spite of the long reaction time, the anionic polymerization of *trans*-β-methylstyrene in hydrocarbon solvents gave no polymer with a molecular weight high enough to be insoluble in methanol. However, the spectroscopic measurements showed that, compared with the amount of the initiator used, much of the monomer was consumed by the reaction, suggesting conversion to low-molecular-weight products.

Morton *et al.*[13] investigated the reaction between β-methylstyrene and *n*-amylsodium in *n*-pentane at room temperature. They reported that the carbonation of anions produced in the reaction gave mostly the I and II acids, but very small amounts of products with higher molecular weights.

C_6H_5–CH=CH–CH_2–COOH (I) C_6H_5–CH(COOH)–CH=CH_2 (II)

Pines *et al.*[14] also reported that the main product of the reaction between β-methylstyrene and metallic

13) A. A. Morton and E. Grovenstein, Jr., *J. Am. Chem. Soc.*, **74**, 5437 (1952).
14) H. Pines and J. Shabtai, *J. Org. Chem.*, **29**, 2408 (1964).

sodium in cyclohexane at 100°C was the following compound, III:

$$R^- + C_6H_5\text{-}CH{=}CH\text{-}CH_3 \longrightarrow RH + C_6H_5\text{-}CH{=}CH\text{-}CH_2^-$$

$$C_6H_5\text{-}CH{=}CH\text{-}CH_2^- + C_6H_5\text{-}CH{=}CH\text{-}CH_3 \xrightarrow{H^+} C_6H_5\text{-}CH{=}CH\text{-}CH_2\text{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}\text{-}CH_2\text{-}C_6H_5$$

III

These results indicate that, in hydrocarbon solvents, carbanion does not attack the C=C double bond, but abstracts a proton from the methyl group of the monomer.

In tetrahydrofuran, *trans*-β-methylstyrene polymerizes to give a methanol-insoluble polymer as well as a soluble one; even in a non-polar solvent it gave the same polymers, though the amounts were small, in the presence of a small quantity of tetrahydrofuran (Table 1). The two polymers, methanol-soluble and -insoluble, were the same in their structure (*i. e.*, the polymers were formed by the usual addition polymerization at the C=C double bond), but they were different in molecular weight.

The structure of the polymer shows that the propagation reaction in the polymerization of *trans*-β-methylstyrene proceeds through the addition of a benzyl-type anion, IV, to the monomer. It has been known that benzyl-type anions have their absorption maxima at around 340 mμ.[12,15] Therefore, the absorption band at 340 mμ (Fig. 6, A) shown by the fresh reaction mixture between *n*-BuLi and *trans*-β-methylstyrene must be due to the benzyl-type anion. Herbranderson *et al.*[4] obtained Compounds V and VI, plus a small amount of high-molecular-weight materials, as the main products of the reaction between equimolar amounts of β-methylstyrene and *n*-BuLi in diethyl ether. These results indicate that, in a polar solvent, carbanion adds to the C=C double bond of β-methylstyrene rather than abstracts a proton of a methyl group in this monomer. The polymerization of *trans*-β-methylstyrene is an extreme example of solvent effects on the polymerizability of a monomer by an anionic mechanism.

$$\sim\!\!\sim CH(CH_3)\text{-}CH(C_6H_5)^-$$

IV

$$n\text{-}C_4H_9\text{-}CH(CH_3)\text{-}CH_2\text{-}CH(C_6H_5)^-$$

V

$$n\text{-}C_4H_9\text{-}CH(CH_3)\text{-}CH(C_6H_5)\text{-}CH(CH_3)\text{-}CH_2\text{-}CH(C_6H_5)^-$$

VI

In the anionic polymerization of *trans*-β-methylstyrene in tetrahydrofuran, the monomer can be completely consumed during a long reaction period at 0—30°C, although the rate is very slow compared with the polymerization of styrene. Szwarc *et al.*[5,17] found that the rate constant of the addition of living sodium polystyrene to β-methylstyrene was *ca.* 20 *l* mol^{-1} sec^{-1} at 25°C in tetrahydrofuran, and that of the same anion to styrene, *ca.* 500 *l* mol^{-1}. sec^{-1}, suggesting a smaller reactivity of β-methylstyrene.

The molecular weight of the polymer was independent of the yield, and of the concentrations of the monomer and the initiator, indicating a controlled chain growth by chain transfer to the monomer.

The absorption at 398 mμ (Fig. 6, B) observed in the reaction mixture at the later stage was that of the allyl anion, VII, which was also obtained by Waack *et al.*[12] in the reaction between allylbenzene and *n*-BuLi in tetrahydrofuran:

$$R^- + C_6H_5\text{-}CH{=}CH\text{-}CH_3 \longrightarrow C_6H_5\text{-}CH{=}CH\text{-}CH_2^- + RH$$

VII

The VII anion was produced by chain transfer to the monomer in the anionic polymerization of *trans*-β-methylstyrene in tetrahydrofruan, as is shown above. It is fairly stable and can exist at a concentration sufficient to be observed in the solution. Szwarc *et al.*[5] also observed the abstraction of a proton of the methyl group of β-methylstyrene by a polystyryl anion. Figure 6 shows that the anion, IV, produced at the initial stage of the reaction diminished, while the VII anion gradually appeared with time.

The average degree of polymerization of the methanol-insoluble polymer obtained at 0°C was about 15. Therefore, the chain-transfer constant ($=k_p/k_{tr}$) may be smaller than 15 at this temperature because of the presence of lower-molecular-weight products soluble in methanol. The decrease in the methanol-insoluble polymer at elevated reaction temperatures shows that the rate of the chain transfer increases with the elevation of the temperature more than that of the propagation does. The re-initiation by the allyl anion produced by the chain transfer reaction is considered to be rather slow because of the stability of the allyl anion. This slow re-initiation may be the cause of the retardation of the polymerization observed after the initial stage of the reaction.

The polymerization of *trans*-β-methylstyrene at 60°C gave only a low final conversion and no polymer insoluble in methanol, in spite of the presence of living anions, recognized by means of

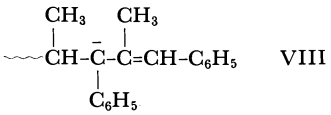
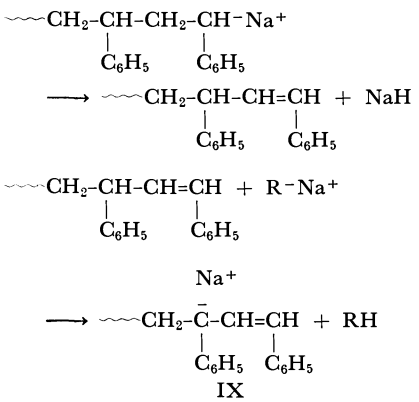
the color. As the cause of the lower final conversion at an elevated temperature two mechanisms are possible: the equilibrium polymerization due to a low ceiling temperature, and the conversion of an active chain end to an inactive carbanion. The possibility of equilibrium polymerization can, however, be eliminated in view of the results shown in Table 2.

On the other hand, the production of unreactive carbanions was supported by spectroscopic measurements. The absorption at 510 mμ observed in the reaction at 60°C in tetrahydrofuran may be considered to be due to the VIII anion as follows:



VIII

Szwarc *et al.*[16] have reported that the stable anion IX, with an absorption maximum at 535 mμ was produced in the polymerization of styrene by sodium in tetrahydrofuran:



IX

The anion VIII will be formed from poly-β-methylstyrene if a reaction similar to the above takes place. The anion will show then an absorption band at rather a lower wavelength than that of the anion IX. This may be caused by the lower conjugation between the C=C double bond and the benzene nuclei due to the steric hindrance of the methyl group. It is also known that a lithium counter ion lowers the λ_{max} of carbanion.[18] The structure of the other anion produced at 60°C and with a λ_{max} at 570 mμ is not certain at the present time, but it may be produced by the further change of the anion of allylbenzene VII. Both the anions with absorptions at 510 and 570 mμ are quite stable, as evidence by the fact that they could not initiate the polymerization of *trans*-β-methylstyrene. They could, however, cause the polymerizations of styrene and methyl methacrylate. The production of the anions is accelerated at higher temperatures.

The infrared and NMR spectra of the polymer showed that the monomer polymerizes by the normal addition polymerization mechanism. The chain transfer to the monomer produces the allyl anion VII, and so it may be expected that the polymer initiated by this anion will have a C=C double bond at the chain end. However, IR, UV, and NMR spectroscopies indicate that there is no aliphatic unsaturation, even in the low-molecular-weight polymer. The one possibility of the elimination of the double bond in the polymer is the following reaction:

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 204—207 (1968)

The Reactivities of Nuclear-Substituted Phenyl Methacrylates in Radical Copolymerization with Styrene

Takayuki Otsu, Toshio Ito, Yoshihiro Fujii and Minoru Imoto

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimotocho, Sumiyoshi-ku, Osaka

(Received July 18, 1967)

In order to clarify the effects of the alkyl substituents on the reactivities of methacrylate monomers toward the attack of a radical, the copolymerizations of a series of nuclear-substituted phenyl methacrylates with styrene were investigated. From the results, the monomer reactivity ratios and the Alfrey-Price Q and e values were determined. It was found that the relative reactivities toward the polystyryl radical were not correlated with the ordinary Hammett equation, but a linear relationship was obtained with a modified Hammett equation which contained a term of the resonance contribution by the substituents. Accordingly, it was considered that the reactivities of substituted phenyl methacrylates depend on both polar and resonance effects caused by the substituents.

In previous papers,[1-3] we have found that the relative reactivities ($1/r_1$) of alkyl methacrylates and acrylates (M_2) toward a polystyryl radical are dependent on the polar substituent constants (σ^*) of the alkyl groups, but not on their steric substituent constants (E_s) in the modified Taft equation (1):

$$\log (1/r_1) = \rho^*\sigma^* + \delta E_s$$

where ρ^* and δ are the constants which give the susceptibility of a given reaction series caused by polar and steric effects of the substituents respectively. In these cases, the findings indicate that the reactivities are subsject to the polar effect of the alkyl substituents, but not to their steric effects.

In order to evaluate the substituent effect, the correlation between the relative reactivities of nuclear-substituted phenyl methacrylates toward the polystyryl radical and Hammett's σ constants of the substituents were investigated in the present study. In the case of nuclear-substituted phenyl methacrylates, the steric effects by the substituents should be similar, because all of the substituents lie across the benzene ring.

The nuclear-substituted phenyl methacrylates used in this study have the following substituents (X): p-OCH_3, p-CH_3, H, p-Cl, m-Cl, p-$COCH_3$, m-NO_2, and p-NO_2.

Experimental

Preparation of Substituted Phenyl Methacrylates (X-PhMA). The Schotten-Baumann reaction of methacrylyl chloride with the corresponding phenols was used to prepare X-PhMA. Then the resulting monomers were purified by fractional distillation under reduced pressure (for PhMA, p-CH_3-PhMA,

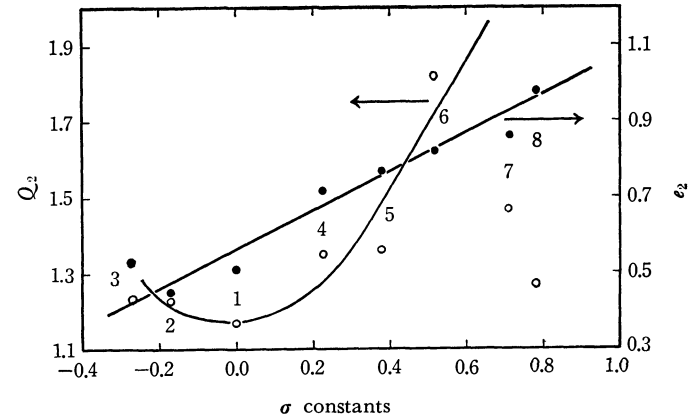

Fig. 2. Correlation between Q_2, e_2 values of X-PhMA and Hammett σ constants: the numbers are the same as those indicated in Fig. 1.

Copolymerization Procedure. The copolymerizations of X-PhMA (M_2) with styrene (M_1) were carried out in a glass tube with AIBN (6.1×10^{-3} mol/*l*) in bulk or in a benzene solution at 60°C. The resulting copolymers were precipitated in a large amount of methanol, and then reprecipitated from benzene and methanol. Most of the copolymerizations were continued up to 10% conversion. The composition of the copolymers was determined by nitrogen analysis for the copolymers of *p*- and *m*-NO_2-PhMA, by chlorine analysis for the copolymers of *p*- and *m*-Cl-PhMA, and by carbon analysis for the other copolymers. The monomer reactivity ratios were calculated by the method described by Fineman and Ross.[5]

Results and Discussion

The results of the copolymerization of X-PhMA (M_2) with styrene (M_1) at 60°C are shown in Table 2. From the results of this table, the monomer reactivity ratios (r_1 and r_2) and the Q_2 and e_2 values for X-PhMA were calculated to be as given in Table 3.

As can be seen from Table 3, the relative reactivities ($1/r_1$) of X-PhMA toward the attack of the polystyryl radical increase with the introduction of the substituents (X) in PhMA. The relation obtained is shown in Fig. 1, which the log ($1/r_1$) of X-PhMA is plotted *vs.* the σ-constants of the ordinary Hammett equation (2):

$$\log(1/r_1) = \rho\sigma \qquad (2)$$

where σ is the Hammett substituent constant and ρ is a reaction constant. As may be understood from this figure, no linear relationship between the log ($1/r_1$) and the σ constants is observed. Since the nitro group has been known to inhibit the radical polymerization, the values for NO_2-PhMA may include a rather large error. If these values are eliminated, the concave curve indicated by the dotted line is obtained. The value for *p*-OCH_3-PhMA was reconfirmed from a duplicate experiment.

It is well known that the resonance effect as well as the polar effect caused by the substituent is impotat in many radical reactions, as has already been pointed out by Alfrey and Price,[6] and Bamford and his co-workers.[7] Recently, one of the present authors proposed the following modified Hammett equation (3) for radical reactions:[8,9]

$$\log(1/r_1) = \rho\sigma + \gamma E_R \qquad (3)$$

where E_R is the resonance substituent constant (see Table 3) and γ is a reaction constant.

When Eq. (3) was applied in this case, a good linear relationship with $\rho=0.21$ and $\gamma=1.0$, except for the values for NO_2-PhMA, was obtained, as is also shown in Fig. 1. Accordingly, it may be expected that both polar and resonance effects of the substituents are important in considering the radical reactivities of X-PhMA.

Figure 2 shows the correlation of the Q_2 and e_2 values of X-PhMA with the σ-constants of their substituents. The Q_2 values are not linearly correlated with the σ-constants as well as in Fig. 1, but they are correlated with the resonance substituent constants (E_R), as Fig. 3 shows. Although the spectroscopic data of X-PhMA have been described in a previous paper,[10] no exact explanation of such a resonance effect is possible at the present time. From Fig. 2 it may be observed that the e_2 values show a straight-line relationship.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 208—211 (1968)

Structure and Properties of the Condensation Product of 2-Amino-3-ethoxycarbonyl-1-azaazulene and Formamide[1]

Tetsuo Nozoe, Shuichi Seto[2] and Takashi Toda

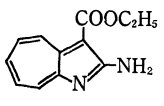
Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received July 18, 1967)

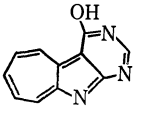
The structure of the condensation product of 2-amino-3-ethoxycarbonyl-1-azaazulene and formamide is proved not to be the expected cyclohepta[2, 3]pyrrolo[5, 4-*d*]pyrimidine derivative, but 5, 6-pentamethylene-7*H*-pyrrolo[2, 3-*d*]pyrimidin-4(3*H*)-one. The chemical properties of the obtained pyrrolo-pyrimidine are investigated, and then the tautomerism of the above compound is discussed.

Many heterocyclic compounds containing pyrimidines and purines are physiologically very important substances. Therefore, it is interesting to synthesize unsaturated seven-membered ring systems (such as tropolones and azulenes) which condensed with such heterocyclic nuclei, and to investigate the chemical and physiological properties of the resulting new heterocyclic compounds.

For this purpose, we attempted the condensation reaction of 2-amino-3-ethoxycarbonyl-1-azaazulene (I) with formamide, expecting to obtain a cyclohepta[2, 3]pyrrolo[5, 4-*d*]pyrimidine derivative such as (A). The condensation reaction was carried out in excess formamide by means of a modification of the method of Robins *et al.*[3,4]; this gave an almost colorless substance (II) in a



(I)



(A)

35—40% yield. II is hard to purify because of its insolubility in most organic solvents, and it can not be analyzed well. However, by a consideration of the results of the analysis of the its monoacetate (III)and monomethyl derivative (IV), the molecular formula of II is found to be not the expected $C_{11}H_7ON_3$, but $C_{11}H_{13}ON_3$. Neither the results of elemental analysis nor the ultraviolet spectra of II and IV show any absorption band longer than 320 mμ, as is shown in Fig. 1, even though the spectra of azaazulenes and their 2-hydroxy derivatives show strong absorption bands in the visible region.[5] The shape of the spectrum of II is analogous to those of 7-azaindole,[6] pyrrolo-[2, 3-*d*]pyrimidine,[7] and purines.[8] The IR spectrum of II (Fig. 2) shows strong bands at 2838

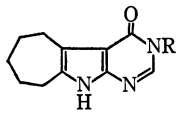
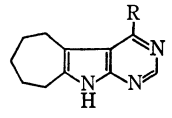
and 2920 cm^{-1} due to methylene CH stretching,[9] and at 1650 cm^{-1} a broad, strong bands correspond to the carbonyl band of pyrimidin-4-ones,[10] while the three bands at 1478, 1511 and 1588 cm^{-1} are assigned to the skeltal vibration of such heterocyclic compounds as pyrimidines.[11] It is known that 1-azaazulenes are sensitive to reducing reagents and that the reduction of the seven-membered ring of those compounds takes place easily to give perhydro-compounds.[12] The consideration of the above facts and of the properties of formamide as a reducing reagent leads to the conclusion that the seven-membered ring of I is reduced by formamide during the reaction; therefore, the structure of II is 5, 6-pentamethylene-7*H*-pyrrolo[2, 3-*d*]pyrimidin-4(3*H*)-one.





II: R=H
IV: Me

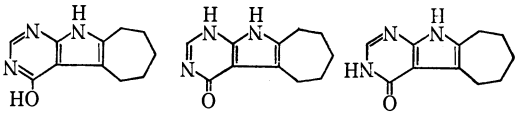
V: R=Cl
VI: OMe
VII: $NHNH_2$

Under milder conditions, however, the condensation reaction does not take place and I is recovered. The reason for the low yield of II is the formation of some intractable powder which is not soluble in most organic solvents. Although the molecular weight of the powder could not be measured because of its insolubility, this powder is presumably a mixture of the dimers or polymers formed by self-condensation during the reaction.

The treatment of II with phosphorous oxychloride afforded 4-chloro-5, 6-pentamethylene-7*H*-pyrrolo[2, 3-*d*]pyrimidine (V). 4-Methoxy (VI) and 4-hydrazino derivatives (VII) were derived when V was treated with sodium methoxide in methanol and with hydrazine respectively. VI was also obtained when V was treated with hydrazine in methanol, but VII was not obtained.

In order to obtain 5, 6-pentamethylene-7*H*-pyrrolo[2, 3-*d*]pyrimidine, a modified Stevenes-McFadyen decomposition reaction[13] was applied to VII, but the attempt was unsuccessful. The dehydrogenation of II by means of chloranil afforded a dark yellow, gummy substance (VIII) in a poor yield. Although it was hard to obtain in an analytically pure state, the ultraviolet and visible spectra of VIII are analogous to those of I, as is shown in Fig. 1; VIII is thus probably the expected cyclohepta[2, 3]pyrrolo[5, 4-*d*]pyrimidine derivative. However, VIII could not be investigated further because of the low yield of VIII and the lack of the starting material.

It is possible that II exists in such tautomeric forms as IIA, IIB and IIC. However, the ultraviolet spectra of II and IV differ from those of V and VI as Figs. 1 and 3 show, and the following investigation of their IR spectra leads to the conclusion that II is favorable to the IIA form.



IIA IIB IIC

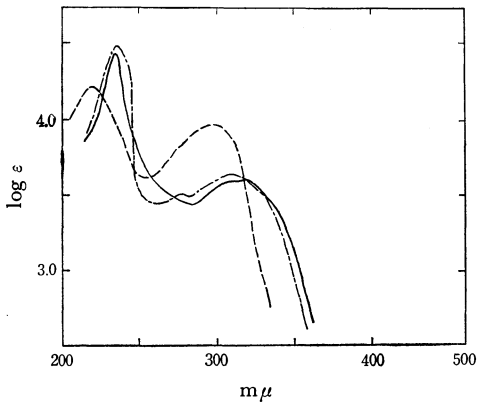


Fig. 3
V ——— VI —·—· VII ———

The strong band at 1650 cm^{-1} and several bands between 3100 and 3300 cm^{-1} of II in its IR spectrum can be reasonably explained on the basis of the IIA form which possess carbonyl and NH groups. α- or γ-Pyridone makes several different kinds of inter- and intramolecular hydrogen bonds between carbonyl and NH groups in the solid state; this is the reason why II shows a strong broad carbonyl band and several different kinds of NH stretching bands. IV shows a strong carbonyl band at 1655 cm^{-1} in its IR spectrum and so differs from VI, which does not show a carbonyl band. The problem of the α- or γ-pyrimidone form can be solved from the analogy with 4-hydroxypyrimidines; a consideration of their ultraviolet spectra and chemical properties shows the tautomeric form of those compounds to favor α-pyrimidones.[14] Thus the structures of II and IV are 5, 6-pentamethylene-7*H*-pyrrolo[2, 3-*d*]pyrimidin-4(3*H*)-one and 3*N*-methyl-5, 6-pentamethylene-7*H*-pyrrolo-[2, 3-*d*]pyrimidin-4(3*H*)-one respectively.

The ultraviolet spectrum of VII is rather analogous to that of II, but not to those of V and VI. VII presumably exists in its tautomeric (hydrazone) form. The IR spectrum of VII is not very helpful in determining its tautomeric form. Other evidence to support the tautomeric form of VII is as follows: the ultraviolet spectrum of VII is analogous to that of 4-pyrimidones, but not to that of 4-chloropyrimidines.[4] This relation is parallel with the relation of II, V, and VII, described above.

Experimental[15]

2-Amino-3-ethoxycarbonyl-1-azaazulene (I). In an autoclave, a solution of 5.0 g of 2-chloro-3-ethoxycarbonyl-1-azaazulene[5] in 50 m*l* of alcohol, which had been saturated with ammonia, was heated for 5 hr at 120°C. After cooling, the alcohol was removed and the residue was washed with water, dried, and chromatographed on alumina. From the benzene eluate, 4.5 g of yellow needles were obtained, while recrystallization from cyclohexane afforded yellow scales of I, mp 150—151°C.

Found: C, 66.89; H, 5.31; N, 13.27%. Calcd for $C_{12}H_{12}O_2N_2$: C, 66.65; H, 5.59; N, 12.96%.

5, 6-Pentamethylene-7*H*-pyrrolo[2, 3-*d*]pyrimidin-4(3*H*)-one (II). A solution of 3.20 g of I and 10.0 m*l* of formamide was heated for one and a half hours at 200°C. After the reaction, the solution was poured into 100 m*l* of cold water, and the precipitate thus formd was separated by filtration, washed with water and a small amount of ethyl acetate, and dried *in vacuo*. A pale brown powder, 2.40 g, was thus obtained. This powder decomposed near 280°C when heated. The powder is hardly soluble at all in benzene, ether, chloroform, ethyl acetate, acetone, and ethanol, but soluble in acetic acid and dioxane. It does not dissolve in aqueous sodium bicarbonate, but it does dissolve in dilute alkali. However, if the pH of the solution goes below 9, the precipitate forms immediately.

Finally, the reaction product (3.20 g) was dissolved in a large amount of methanol and chromatographed on alumina. The first eluate was recrystallized from methanol to give 1.20 g of micro prisms of II, mp 326—328°C (colored about 260°C, Koffler block).

Found: C, 62.92; 63.24; H, 6.14; 6.05; N, 20.16; 20.20%. Calcd for $C_{11}H_{13}ON_3$: C, 65.00: H, 6.45; N, 20.68%.

The methanol-water eluate of the chromatograph could not be obtained in a pure state and did not show any clear melting point but it gradually blackened between 250—300°C.

Acetylation of II (III). A solution of 0.10 g of II in 1.0 m*l* of acetic anhydrided was heated to reflux for 4 hr, and then the excess acetic anhydride was removed under reduced pressure to give pale yellow micro needles of III, mp 234—236°C. The recrystallization of this crude product from ethyl acetate and decolorizing charcoal afforded 0.08 g of pale yellow micro needles of III, mp 237—239°C.

Found: C, 63.24; H, 5.81; N, 17.26%. Calcd for $C_{13}H_{15}O_2N_3$: C, 63.66; H, 6.16; N, 17.13%.

λ_{max}^{MeOH} mμ (log ε); 237 (4.10), 265 (3.86) and 308 (3.82).

Methylation of II with Dimethyl Sulfate (IV). To a solution of 0.10 g of II and 0.04 g of sodium hydroxide in 1.0 m*l* of water, 0.07 g of dimethyl sulfate was added, and then the solution was shaken continuously for 5 hr. The pH of the solution was adjusted to about 6 with N hydrochloric acid to form resinous precipitate. This precipitate was separated by filtration, washed with water, extracted with ethyl acetate, and dried over sodium sulfate. After the sodium sulfate had been filtered off, the ethyl acetate was removed under reduced pressure to give a crystalline substance. The crude IV thus obtained was recrystallized from ethyl acetate with active charcoal to give 0.05 g of colorless scales of IV, mp 318—320°C (colored about 280°C, Koffler block).

Found: N, 18.91%. Calcd for $C_{12}H_{15}ON_3$: N, 19.34%.

λ_{max}^{MeOH} mμ (log ε); 220 (4.19) and 285 (4.00).

4-Chloro-5, 6-pentamethylene-7*H*-pyrrolo[2,3-*d*]pyrimidine (V). A solution of 0.30 g of II in 2.0 m*l* of phosphorous oxychloride in a sealed tube was heated for 3 hr at 100°C, and the excess phosphorous oxychloride was removed under reduced pressure. The pH of the residue was adjusted to about 8.5 with diluted aqueous ammonia, extracted with ethyl acetate, and dried over sodium sulfate. The sodium sulfate was then separated by filtration, and the residue was sublimed under reduced pressure (0.5 mmHg at 150°C). The sublimate was recrystallized from benzene to give 0.14 g of pale yellow prisms of V, mp 228°C.

Found: C, 59.63; H, 5.00; N, 19.00%. Calcd for $C_{11}H_{12}N_3Cl$: C, 59.59; H, 5.46; N, 18.96%.

λ_{max}^{MeOH} mμ (log ε); 234 (4.40) and 316 (3.60).

4-Methoxy-5, 6-pentamethylene-7*H*-pyrrolo[2, 3-*d*]pyrimidine (VI). A suspension of 0.20 g of V and 1.20 g of hydrazine hydrate (80%) in 5.0 m*l* of methanol was refluxed for 4 hr, after which the excess methanol was removed under reduced pressure. The residue was sublimed under reduced pressure (0.1 mmHg at 150°C), and the sublimate was recerystallized from acetone to give colorless scales of VI, mp 246—247°C; yield, 0.14 g.

Found: N, 19.16%. Calcd for $C_{12}H_{15}ON_3$: N, 19.34%.

λ_{max}^{MeOH} mμ (log ε); 234 (4.14), 275 (3.40) and 310 (3.53).

A mixed-melting-point determination of VI with IV clearly showed a depression. When sodium methoxide was used instead of hydrazine, VI was obtained in a quantitative yield.

4-Hydrazino-5, 6-pentamethylene-7*H*-pyrrolo-[2, 3-*d*]pyrimidine (VII). A mixture of 0.1 g of V and 1.0 m*l* of hydrazine hydrate (80%) was refluxed for 5 hr, thus the precipitate was formed. The formed precipitate was then recrystallized from methanol to give 0.07 g of colorless scales of VII, mp 233—235°C (decomp.).

Found: C, 60.86; H, 6.43; N, 31.81%. Calcd for $C_{11}H_{15}N_5$: C, 60.80; H, 6.96; N, 32.24%.

λ_{max}^{MeOH} mμ (log ε); 216 (4.22) and 294 (3.98).

The Decomposition of VII. A solution of 0.05 g of VII in 1 m*l* of acetic acid was poured into a boiling solution of 0.50 g of cupric sulfate in 1 m*l* of water.

15) All melting points are uncorrected.

The solution turned black with the evolution of gas; after it had cooled, 10 m*l* of water were added. The pH of the solution was then adjusted to about 8 by means of aqueous bicarbonate and extracted with ethyl acetate. The organic layer was dried over sodium sulfate, separated by filtration, and concentrated to give an intractable, gummy substance.

Dehydrogenation of II. To a solution of 0.50 g of II in 10 m*l* of refluxing isoamyl alcohol, 1.50 g of chloranil were added in five portions over a period of 2 hr; refluxing was then continued for 4 hr. The amyl alcohol was removed under reduced pressure, and the residue was dissolved in ethyl acetate. The ethyl acetate solution was then chromatographed on silica gel; a small amount of amorphous powder was thus obtained.

λ_{max}^{MeOH} mμ; 245, 300, 368 and 399.

The powder dissolved in benzene, ethyl acetate, and acetone, but it formed a gelly substance when concentrated. Further purification by means of recrystallization and other methods failed to produce a pure substance.

Ring-opening Polymerization of Norbornene and Its Derivatives by $MoCl_5$, WCl_6 and $ReCl_5$ Catalysts

Takao OSHIKA and Hiroyoshi TABUCHI

The Central Research Laboratory, Toa Nenryo Kogyo Co., Ohi-machi, Iruma-gun, Saitama

(Received July 21, 1967)

Norbornene and such of its derivatives as *exo*-5, 6-trimethylene norbornene (*exo*-TMN) and *endo*-dicyclopentadiene (*endo*-DCPD) have been polymerized ***via*** ring cleavage to high-molecular-weight polymers, soluble in aromatics, by the use of $MoCl_5$, WCl_6, and $ReCl_5$ catalysts in a carbon tetrachloride solvent. The ring-opening polymers obtained by $MoCl_5$ have a trans-structure almost exclusively, on the other hand the polymers obtained by $ReCl_5$ are rich in cis structures and those obtained by WCl_6 are mixtures of the two. The reactivities of the monomers on those catalysts have been found to have the order of decreasing reactivity: *exo*-TMN>NE> *endo*-DCPD. In the ring-opening polymerization of norbornene by $MoCl_5$, carbon disulfide and carbon tetrachloride have been found to be effective solvents. The yield increases with the rise in temperature and also upon the addition of a catalytic amount of tertiary amines in the midst of the polymerization procedure, while the structures of the polymers obtained do not change. The Co-catalyst H_2O is not necessary. Chlorine atoms are found in the polymers. Those results suggest that the ring-opening polymerization of norbornene over $MoCl_5$ occurs through a specific coordinated mechanism.

Three modes of reaction have been established for the polymerization of norbornene: a vinyl polymerization and two types of ring-opening polymerization, giving polymers with trans and cis double bonds. Ring-opening-type polymers have been obtained by Truett,[1] Sartori,[2] and Furukawa[3] using Ziegler-Natta catalysts, and by Michelotti[4] and Rinehart[5] using Ir^{3+}, Ru^{3+} and Os^{3+} in polar media. It has been concluded that the ring-opening polymerization proceeds through the coordinated anionic mechanism.[1,4] On the other hand, the vinyl-type polymer has been obtained using such cationic catalysts as $AlCl_3$, $TiCl_4$, and BF_3.[3] In a previous work in this series[6] it has been shown that the ring-opening polymer of norbornene can be obtained by the use of uni-component catalyst, $MoCl_5$, in carbon tetrachloride.

In this paper we wish to report on the ring-opening polymerization of norbornene, *exo*-TMN, and *endo*-DCPD by $MoCl_5$, WCl_6 and $ReCl_5$ catalysts and to discuss the polymerization mechanism from the point of view of the effects of the temperature, the solvents, and the co-catalysts.

Experimental

Materials. The Diels-Alder reaction of ethylene and dicyclopentadiene gave norbornene, bp 96.0—97.0°C (lit.[7] 94—97°C/740 mmHg). *exo*-5, 6-Trimethylene norbornene was prepared from dicyclopentadiene by hydration, hydrogenation, and esterification reactions, followed by pyrolysis; bp 54—56°C/8 mmHg, $n_D^{25}=1.4948$ (lit.[8] $n_{25}^{D}=1.4943$). An *endo*-dicyclopentadiene received from the Eastman Kodak Company was distilled prior to use; $n_D^{25}=1.5120$ (lit.[9] $n_D^{25}=1.5121$). The solvents were purified by conventional methods.

$NbCl_5$ and $SeCl_4$ were prepared from their respective metals by chlorination.[10] $MnCl_2$[11] was prepared from $MnCl_2 \cdot 2H_2O$; UCl_4[12] was prepared by refluxing UO_3 in disulfo dichloride. $MoCl_4$ was prepared according to the method of Larson.[13] Found: Cl, 55.1; Mo, 40.6%. Calcd for $MoCl_4$: Cl, 59.7; Mo, 40.4%. The other metal chlorides were commercially available in anhydrous pure grades and so were used without further purification.

Polymerization. Polymerization was carried out in a sealed glass tube under an argon atmosphere. The following is a typical example of the procedure employed. Into a 50 m*l* glass tube there was placed 0.682 g of $MoCl_5$; then were added 10 m*l* of CCl_4. After it had thus stood for ten minutes, the tube was immersed and chilled in a dry ice - methanol bath, after which a solution of 4.70 g of norbornene in CCl_4 (10 m*l*) was introduced into the tube; then the tube was sealed off. Polymerization was carried out with agitation in a water bath controlled thermostatically at 50°C. After 4 hr, the contents were poured into a large excess of methanol containing phenyl β-naphthyl amine as a stabilizer. The dark, crude polymer thus obtained was separated and dried at 40°C under vacuum; yield 2.40 g.

In 200 m*l* of hot benzene, 1.0 g of the crude polymer was dissolved and reprecipitated with methanol. There was thus obtained 0.59 g of a white, fibrous polymer, which was soluble in benzene, and 0.01 g of a black, insoluble polymer. Found (for the benzene soluble polymer): C, 88.98; H, 10.63%. Calcd for $(C_7H_{10})_n$: C, 89.29; H, 10.71%. The yields stated in this paper are the totals of the benzene-soluble and -insoluble polymers. The intrinsic viscosity was determined for *p*-xylene solutions at 100°C. The infrared spectrum was recorded using a Japan Spectroscopic Co. apparatus, Model DS 402G.

Results

Polymerization of Norbornene. Polymerization was carried out at 50°C using various metal chlorides in carbon tetrachloride. Table 1 shows that the low-molecular-weight vinyl-type polymers were obtained using such catalysts as $AlCl_3$, $ZrCl_4$, VCl_4, $NbCl_5$, and $TaCl_5$; of these $AlCl_3$ showed the highest activity.

The initially homogeneous system of norbornene polymerized by $MoCl_5$, WCl_6, or $ReCl_5$ becomes heterogeneous as the reaction progresses due to the insolubility of the polymer. The produced polymers are soluble in hot benzene and structurally similar to the products previously reported,[1,2] in which a major portion of the polymer chain consists of cyclopentane rings linked in a *cis*-1, 3 configuration with either trans- or cis double bonds.

In Table 1, $D_{965}/D_{740}/D_{1445}$ are the ratios of the optical densities at 965, 740, and 1445 cm^{-1} in the infrared spectra; these densities are assigned to the deformation of *trans* C=C, *cis* C=C, and CH_2 respectively. Furukawa[3] has found a linear correlation between the D_{965}/D_{1445} ratio and the amounts of trans double bonds in polymers. By the use of this correlation, the trans units can be calculated; then the cis units may be estimated from the difference between the total double bonds as determined by the Wijs method and the trans units as calculated above. By that calculation, it is found that the polynorbornene catalyzed by $MoCl_5$ is of trans units 80—95% and cis units 4—5%; the polymer catalyzed by WCl_6, of trans 50% and cis 39%, and the polymer catalyzed by $ReCl_5$, of trans 23% and cis 75%.

Under the same conditions described in Table 1, no polymer was found when those catalysts were used: $CdCl_2$, BF_3OEt_2, $TiCl_4$, $SnCl_4$, $AsCl_3$, $SbCl_5$, $CrCl_3$, $SeCl_4$, $MoCl_4$, UCl_4, $MnCl_2$, $FeCl_3$, $CoCl_3$, and $RuCl_3$.

Polymerization of *exo*-5, 6-Trimethylene Norbornene (TMN). A number of catalysts like Mo(V), W(VI), and Re(V) which were active in the polymerization of norbornene were found to be also active in the polymerization of TMN, giving benzene-soluble and high-molecular-weight polymers in a maximum total conversion of 75% as shown in Table 2. The polymer obtained by $MoCl_5$ had a strong absorption at 965 cm^{-1}, indicating substantial amounts of trans unsaturation along the polymer chain. On the other hand, the polymer obtained by $ReCl_5$ had strong absorptions at 2980, 1408, and 740 cm^{-1}, absorptions which were attributed to cis double bonds. Since the infrared absorptions of the polymers were similar to those of polynorbornenes obtained by the same catalysts, the structures of poly-TMN must be of a ring-opening trans- or cis-type similar to those of polynorbornenes.

The films or powders of poly-TMN prepared with $MOCl_5$, Ziegler, or $AlCl_3$ catalysts were all found by X-ray diffraction to be amorphous.

Polymerization of *endo*-Dicyclopentadiene (DCPD). Many examples have been known of the

polymerization[14] of DCPD as a third component in the ethylene-propylene-terpolymer. Recently Imoto[15] reported the homopolymerization of DCPD using Ziegler-type catalysts.

Independently, we also obtained the poly *endo*-DCPD by two kinds of catalysts: metal halides and Ziegler-type catalysts. The results of the polymerization are summarized in Table 3. The polymers had absorptions of a double bond on a cyclopentane ring at 1617 and 940 cm^{-1}, but had no absorption of the double bond on a bicyclic ring at 1575 cm^{-1}, as is shown in Fig. 1. These facts suggest that the latter double bond reacted in the polymerization, while the former one did not react. This is in accordance with the results of the addition reaction of H_2O, HX, ROH, and RCOOH to DCPD, in which only the double bond on the bicyclic ring can be attacked.[16] Since the poly-DCPD catalyzed by $MoCl_5$ had a strong absorption at 973 cm^{-1} (*trans* C=C), its structure must be of a ring-opening trans type (II):

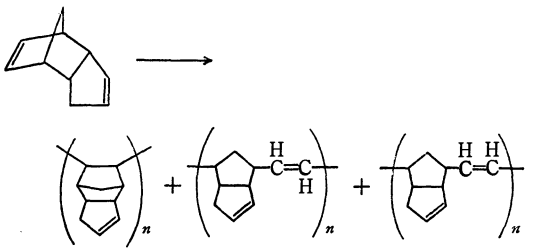
Cyclopentene	50	4	3	—	Double bond opening	19

Cat.: $MoCl_5$; 2—5 mol% of monomer; solvent: CCl_4



(I) (II) (III)

On the other hand, the polymer catalyzed by $ReCl_5$ was soluble in boiling benzene, and its IR spectrum showed sharp absorptions at 3000, 1408 and 755 cm^{-1}, absorptions which can be assigned to the cis double bond along the main chain. Thus, the structure is mainly of a ring-opening cis type (III).

The poly-DCPDs produced by Ziegler-type catalysts, $AlEt_3$-$TiCl_4$ or $AlEt_3$-$MoCl_5$, consisted mostly of ring-opening trans- or cis-type structures respectively. It was also possible to get the polymer with a vinyl-type structure (I) by using such Lewis acid catalysts as $AlCl_3$ and $TiCl_4$. Therefore, the effect of catalyst on the micro-structure of poly-DCPD was the same as that on the structures of polynorbornene and poly-TMN.

The polymerization rates of DCPD on various catalysts were smaller than those of norbornene and TMN, and none of the resultant poly-DCPD showed clear softening points, while they decomposed gradually at 150—400°C.

Polymerization of Olefins by $MoCl_5$. The microstructure of polynorbornene obtained by means of $MoCl_5$ was different from those obtained by usual cationic polymerization catalysts, *e.g.*, $AlCl_3$ and $TiCl_4$. To study this point further, it seemed of interest to carry out the polymerization of the other olefins over $MoCl_5$.

As is shown in Table 4, polyisobutylene, mol wt 4990, was obtained at −20°C, and the molecular weight increased with a decrease in the temperature. In the polymerization of isoprene, a low-molecular-weight polymer was obtained in a high yield, and the structure was not linear but of a bicyclic type, as has been reported by Golub.[17] Chloroprene was found poor in polymerizability. Cyclopentene, 4-vinylcyclohexene, and cyclohexadiene were somewhat polymerizable.

For these olefins, it was concluded that $MoCl_5$ catalyzes a normal cationic polymerization as well as typical Lewis acid catalysts.

	17.6	76/24	2.5/0.5/1.0	0.42
	38.0	—	2.5/0.5/1.0	—

Monomer: norbornene; cat.: $MoCl_5$, 5 mol% of monomer; 50°C; 4 hr

The copolymerization of norbornene with styrene was attempted in carbon disulfide using a $MoCl_5$ catalyst. The polymer thus obtained was only a mixture of two homopolymers. This suggests that the polymerization mechanism of norbornene is different from that of styrene.

The results of the copolymerization of norbornene with trioxane were complicated. When $MoCl_5$ was added to a carbon disulfide solution of norbornene and trioxane, no polymer was formed. There was the same result when trioxane was added to the brown-colored norbornene-$MoCl_5$ complex. However, when the norbornene was added to the light blue trioxane-$MoCl_5$ complex, only the homopolymer of trioxane was formed. In no case, did we found any evidence of the formation of a copolymer.

Mechanism of Ring-opening Polymerization of Norbornene by $MoCl_5$. *Solvent Effect.* Solvents greatly influenced the yield and the microstructure of the polymer. According to Table 5, the most effective solvents for the polymerization were halogenated hydrocarbons and carbon disulfide. Polymers were not formed in hydrocarbon solvents such as *n*-heptane. When such non-polar solvents as CCl_4 and CS_2 were used, the polymerization rates were large and the structures were predominantly of ring-opening types. In CH_2Cl_2 and $C_2H_4Cl_2$, which are more polar than the solvents mentioned above, the formation of ring-opening polymers decreased. In a very polar solvent such as CH_3NO_2, no polymer was formed.

It has been said that $MoCl_5$ is reduced to $MoCl_4$ in CCl_4 as follows.[20]

$$2\ MoCl_5 \xrightarrow{\text{in } CCl_4} 2\ MoCl_4 + Cl_2$$

Furthermore, it is known that the reaction of $MoCl_5$ with refluxing benzene gives $MoCl_4$ and chlorobenzene.[13] We found that $MoCl_4$ could not polymerize norbornene. From these results, it may be concluded that the true catalyst for polymerization is $MoCl_5$ and not the low valence molybdenum species ($Mo \leqq 4$), although $MoCl_5$ has a tendency to liberate its chlorine atom as an anion in CCl_4 and benzene.

Effect of Cocatalyst. It is well known that cationic polymerization by a Lewis acid generally needs a cocatalyst such as H_2O. If the polymerization over $MoCl_5$ proceeds through a cationic intermediate, therefore, it seems small amounts of water will be necessary, because the solvent, CCl_4, can not work as a cocatalyst.

The effect of the water on the polymerization was examined for dehydrated CCl_4 (water content 18 ppm) and water-saturated CCl_4 (water content 69 ppm). It is clear from Table 6 that the yield decreased with an increase in the water content. A detailed discussion is impossible at the present time, because a completely anhydrous solvent could not be prepared. Roughly, however, water may not be necessary for the polymerization. It is interesting that the structures of the polymers obtained were not influenced by the water content in the polymerization system.

Effect of Temperature. The rate of polymerization increased greatly with an increase in the polymerization temperature. For example, the yield

Table 6. Effect of co-catalyst

of polymers varied with the rise of temperatures in such a manner as: 1.9% (−15°C, 24 hr), 3.6% (0°C, 12 hr), 8.5% (30°C, 2 hr), and 19.6% (50°C, 0.5 hr). The microstructures and intrinsic viscosities of the polymers changed little within the range of polymerization temperature of −15°C—+50°C.

Elementary Analysis of Polymer. The results of carbon and hydrogen analysis of the polynorbornene have been shown in the Experimental section. The polymer produced by $MoCl_5$ in benzene was found to be 0.13% chlorine. Since the molecular weight of this polymer was 20900, one polymer should contain about one chlorine atom. The polymers prepared in carbon tetrachloride or carbon disulfide contained more chlorine atoms than those prepared in benzene.

Addition of t-Amines. The reaction between tertiary amines and $MoCl_5$ in a CCl_4 solution gives an insoluble black complex, R_3N-$MoCl_5$[21] This complex was inactive in the polymerization of norbornene. However, the tertiary amines were apparently active promoters of the polymerization only when the amines were added to a polymerization system in which an active growing chain of the polymer was present. Thus, norbornene was polymerized by $MoCl_5$ in a glass tube sealed with a stopper. Thirty minutes after the reaction had started, a mole of Et_3N equal to the catalyst was added; the contents then suddenly became viscous. As Table 7 and Fig. 2 show, the yield and the molecular weight increased remarkably upon the addition of Et_3N, but the microstructures remained unchanged. These results suggest that the addition of tertiary amine strongly increases the rate of propagation.

On the other hand, such primary amines as $EtNH_2$ and n-$BuNH_2$, and such secondary amines as n-Bu_2NH, pyridine, and α-picoline were all effective chain stoppers. There was no increase

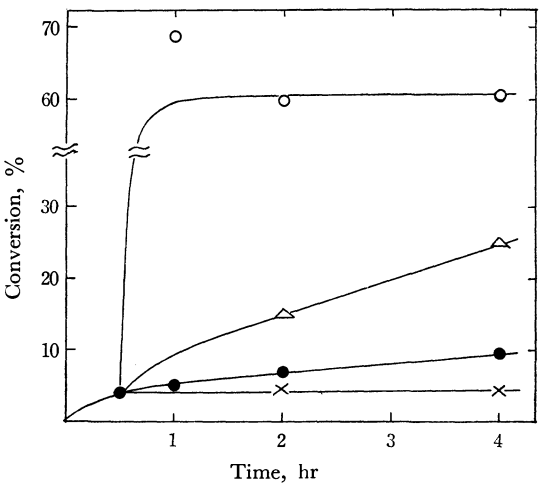

Fig. 2. Addition of amines to norbornene polymerization. Amine was added 30 min after reaction had started.
(○): Et_3N, (△): n-Bu_3N, (×): pyridine, (●): without amine. Polymerization conditions are the same as in Table 7.

in the yield upon the addition of such electron donors as triphenylphosphine, dioxane, trioxane, and tetrahydrofuran.

Discussion

Ring-opening-type polymers of norbornene, *exo*-TMN, and *endo*-DCPD can be prepared with unicomponent catalysts, $MoCl_5$, WCl_6, and $ReCl_5$. The microstructures of the polymers are influenced by the type of transition metals in the catalysts. The order of increase in the trans units is $MoCl_5 > WCl_6 > ReCl_5$. The reverse order is that of the increase of cis-type polymers. The polymerization activities of the monomers on these catalysts are; *exo*-TMN > norbornene > *endo*-DCPD.

It has been reported that Ziegler-type catalysts modified by the addition of several amines increase

21) D. A. Edward and G. W. A. Fowles, *J. Chem. Soc.*, **1961**, 24.

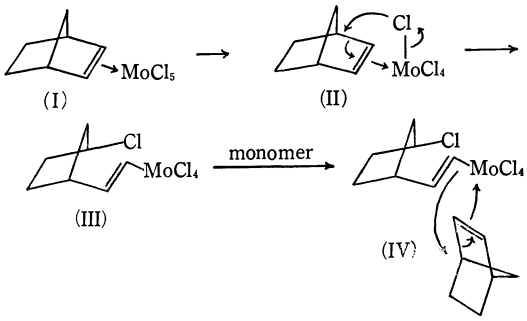
the activity in ring cleavage in the polymerization of norbornene.[3,22] In our study, it was found that the addition of a tertiary amine to the polymerization system remarkably increased the polymerization rate and the molecular weight, without making any change in the microstructures. In addition, several new facts were found in the polymerization of norbornene catalyzed by $MoCl_5$. Ring-opening polymers were produced by using such nonpolar solvents as CCl_4 and CS_2; on the other hand, vinyl-type polymers were predominant when a more polar solvents, like CH_2Cl_2 and $C_2H_4Cl_2$, were used. Water was not effective as a cocatalyst. The polymerization rate increased with the rise in the temperature. The polymers contained chlorine atoms which had been liberated from the catalyst. Molybdenum tetrachloride did not work as a catalyst. Copolymers with styrene or trioxane could not be formed.

There are two types of polynorbornene: a vinyl type and a ring-opening type. The former is prepared with typical Lewis acid catalysts, such as $AlCl_3$, $AlBr_3$, BF_3, and $TiCl_4$, through a usual cationic mechanism.[3] The latter is obtained only by those catalysts which act through an anionic coordination mechanism. Included in the latter group are LiAl $(C_7H_{15})_4$-$TiCl_4$ $(Al/Ti \geqq 2)$,[1] $AlEt_3$-$TiCl_4$ $(Al/Ti \geqq 2)$,[3] Al*iso*$(C_4H_9)_3$-$MoCl_5$ $(Al/Mo=2)$,[2] and $RuCl_3$ in alcohol.[4]

Judging from the general view that vinyl-type polymers are derived through cationic polymerization, and ring-opening-type polymers, through coordinated anionic polymerization, it may be concluded that the formation of ring-opening polynorbornene with $MoCl_5$ is through the coordinated anionic mechanism. Experimental findings on the effects of solvents, the temperature, and the addition of amines and water supported this mechanism.

At first sight it seems contradictory that $MoCl_5$ is an effective catalyst for Friedel-Crafts alkylation and acylation and also a cationic catalyst for α-olefins and dienes, while at the same time it acts as a coordinated catalyst for norbornene and its derivatives. However, this abnormal polymerization of norbornene by $MoCl_5$ may be due to the specific characteristics of both the monomer and the catalyst. Because of the great ring strain,[4,15] a bicyclic olefin like norbornene is attacked easily at the 1 and 2 carbon atoms by nucleophilic agents. Another important cause is that $MoCl_5$ is unstable enough to liberate its chlorine as an anion.[13]

The above evidence suggests the following mechanism, which is similar in nature to the ring-opening mechanism by Ziegler-type catalysts.[1]



The monomer is initially activated through π-complex formation (I), followed by a simultaneous, concerted, ring-opening displacement reaction on the bridgehead carbon by the Cl^- derived from the catalyst (II); this regenerates the active metal center (III) in a reduced oxidation state. The intermediate (III) may further activate another monomer. The repetition of this process leads to the propagation.

The chlorine atom introduced in the initiation step is found in the polymer. As soon as the same moles of norbornene as that of the catalyst are added to the carbon tetrachloride solution of $MoCl_5$, the red color due to Mo(V) disappears and a pale-colored precipitate is produced. This phenomenon suggests a complex formation between the monomer and the catalyst. Since molybdenum tetrachloride is catalytically inactive, it is considered that molybdenum is not reduced below Mo(IV).

Medium-Sized Cyclophanes. VI. High-Temperature NMR Spectra of [2. 2]Metacyclophane and Optical Resolution of 4, 14-Disubstituted Derivatives[1]

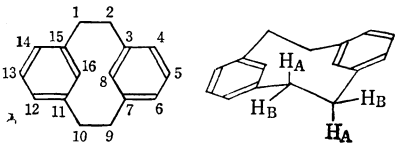
Takeo SATO,* Sadatoshi AKABORI,* Masatsune KAINOSHO** and Kazuo HATA*

* *Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo*
** *Ajinomoto Co., Inc., Kawasaki*

(Received July 25, 1967)

The NMR spectra of [2.2]metacyclophane have been shown to be held unchanged over a wide range of temperature, *ca.* −80 to 190°C, indicating that the ten-membered ring system undergoes no inversion and is frozen in a chair conformation. It may, then, be expected that suitably substituted derivatives of [2.2]metacyclophane would become disymmetric due to restricted inversion; such was proved to be the case by carrying out the optical resolution of the 4, 14-di-substituted derivatives. The 4, 14-dimethyl derivative was resolved by means of a complex formation with Newman's reagent, $[\alpha]_{578}^{26}=-3.4$ and $+4.2°$. 4, 14-Dicarboxylic acid was also resolved by converting it to the quinine salt, $[\alpha]_{D}^{22}=+5.0°$.

Among the medium-sized ring compounds [2.2]metacyclophane (I) is one of the few examples whose molecular geometry has been completely elucidated using the X-ray technique.[2] The compound has been shown to exist as a step-like molecule with two slightly distorted benzene rings, which are arranged on two parallel planes. As a consequence, the distance between C_8 and C_{16} has been found to be as short as 2.689 Å in spite of deformation in both the aryl and aliphatic bonds to relieve steric overcrowding. These structural features have been shown to be well reflected in the absorption spectra of I.[3] By comparing the UV spectrum of I with that of 3, 3'-dimethylbibenzyl, a corresponding open-chain compound, it has been noticed[4] that the absorption maximum of I at 270 mμ, devoid of any fine structure, shifts to a longer wavelength and a lower intensity, thus indicating an appreciable distortion in the aryl moiety. The absorption minimum of 3, 3'-dimethyl bibenzyl occurs at 236 mμ with a low intensity ($\varepsilon=75$,) whereas I has a higher extinction (log $\varepsilon=3.67$) at the same wavelength and the absorption minimum shifts to 260 mμ. The fact is explainable by assuming the presence of bands due to transannular interaction between the two benzene rings in this region.[4] Further, the examination of the NMR spectra of I has revealed the unusual nature of the 8, 16-protons and conformational details of the ten-membered ring. In addition to an AB_2-type absorption of the peripheral aryl protons at $C_{5,13}$ and $C_{4,6,12,14}$ at δ 7.18 and 6.97 respectively, a triplet assignable to intraannular aryl protons at $C_{8,16}$ appeared at δ 4.23 ($J=1.8$ cps). The up-field shift of almost 3 ppm is due to the diamagnetic ring current effect of the diametrical benzene rings, over which the intraannular protons are extended. Methylene protons appeared as A_2B_2-type absorptions, which were analyzed as $\delta_A=2.04$ and $\delta_B=3.05$, indicating the presence of nonequivalent protons. Since the ten-membered ring in I exists in a chair conformation, it is quite natural to assign these as arising from axial (H_A) and equatorial (H_B) protons, as is shown in structure II.



I II

The temperature dependence of NMR spectra has been proved to be a powerful tool for the detection of possible inversion in cyclic systems and has found wide application. Our interest in the conformational equilibrium of the ten-membered ring system in I led us to study the high-temperature NMR spectra of I.[5] The spectra were determined at *ca.* −80, 27, 67, 126, and 190°C; they are shown in Fig. 1. The assignments of the

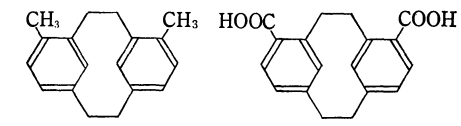
proton signals are summarized in Table 1. Except for a small shift due to solvent effect, no significant changes in the spectral pattern were observable. It was of special note that the A_2B_2 absorption was kept surprisingly unchanged even at 190°C, indicating that the molecule is frozen in the chair conformation II, thus eliminating the possibility of interconversion between the inverted isomers. It is also noteworthy, however, that 8, 16-protons experience a small yet definite down-field shift upon going to higher temperatures. At 190°C the signal occurred at 270.9 cps down-field from TMS, whereas at room temperature it appeared at 254.2 cps, both values being determined in a hexachlorobutadiene solution. An increase in the thermal motion at higher temperatures brings about distortions of bond angle and bond length, so that the distance of 8,16-protons from the center of the opposite benzene ring increases. This molecular deformation might be responsible for the slight down-field shift of the proton signal. Recently, Griffin and his co-worker[6] have demonstrated that the higher homolog, 2, 2-dicarbethoxy-[3.2]metacyclophane, experiences a ring inversion evidenced by the coalescence of the AB and A_2B_2 systems to two singlets above 125°C.

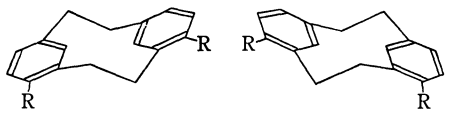
It is, then, to be expected that those [2.2]metacyclophane derivatives in which substituents are introduced unsymmetrically in relation to a plane of symmetry which bisects both of the benzene rings may become optically resolvable. As the

6) R. W. Griffin, Jr., and R. A. Coburn, *Tetrahedron Letters*, **1964**, 2571.

possible disymmetric molecules, two 4, 14-disubstituted derivatives III and IV, the optical antipodes of which are represented by Va and Vb, were prepared. The Wurtz dimerization reaction of 2, 4-bis(chloromethyl)toluene under high-dilution conditions using disodium tetraphenylethane as a condensing agent has been shown[5] to proceed stereospecifically to afford only the cis compound III, and not the possible trans isomer, the 4, 12-dimethyl derivative. The structural determination was achieved by the NMR spectral measurements. Dicarboxylic acid IV was obtained by the oxidation of [2.2]metacyclophane-4, 14-dicarbaldehyde, which had itself been prepared from III by bisbromination reaction with NBS, followed by the Sommelet reaction. Full accounts of the syntheses and a structural consideration based on the spectral data will be presented elsewhere.



III IV



Va Vb

The optical resolution of compound III, which is devoid of suitable functional grouping, was achieved by using (−)-α-(2, 4, 5, 7-tetranitro-9-fluorenylideneaminooxy)propionic acid[7] as a complex-forming reagent. When kept in a refrigerator, a benzene solution of the reagent and III deposited a crystalline complex, which, by column chromatography on alumina using benzene as an eluent, was found to decompose to afford (−)-III as colorless needles, mp 54—64°C, $[\alpha]_{578}^{26}=-3.4°$. By the chromatography of the material contained in the filtrate of the complex formation, a dextrorotatory isomer, mp 58—61°C, $[\alpha]_{578}^{26}=+4.2°$, was obtained. These two isomers showed negative and positive plain ORD curves respectively, and had infrared spectra identical with those of the racemic compound. Dicarboxylic acid IV was resolved by the aid of quinine. A solution of IV and quinine in ethanol was left to stand, thus producing a crystalline salt; on recrystallization from ethanol this salt melted at 150—160°C. A benzene solution of the optically active acid, after liberation by dilute hydrochloric acid, was evaporated to give a colorless powder, mp >300°C, $[\alpha]_{D}^{22}=+5.0°$.

Obviously these are the first examples which demonstrate that suitably substituted [2.2]metacyclophane derivatives become disymmetric due to the restricted inversion of the ten-membered ring system. After the completion of the present studies, two papers along similar lines have appeared. Lüttringhaus and his co-worker[8] have achieved a partial resolution of a cyclotriveratrylene derivative, the molecular disymmetry of which is due to a restricted inversion of the 9-membered ring, by passing its benzene solution through a column of cellulose-2 1/2-acetate, thus obtaining optical isomers with $[\alpha]_{405}^{22}=+7.5$ and $-5°$ As a new optically resolvable [mn]paracyclophane due to the restricted rotation of the aromatic rings, disymmetric tetramethyl[2.2]paracyclophane has been resolved into optical antipodes, $[\alpha]_{D}^{27}=-3.2$ and $+4.2°$, with the aid of Newman's reagent.[9]

Experimental

Physical Measurements. The measurements of NMR spectra at various temperatures were carried out using a Varian A-60 spectrometer equipped with a V-6040 variable temperature controller. Calibrations at high and low temperatures were performed by using ethylene glycol and methanol respectively; this method permitted an accuracy of ±1°C at higher temperatures. ORD curves were recorded with a Nihon Bunko ORD/UV-5 spectrometer. The optical rotations were measured by using a Carl Zeiss LEP A-2 or an Applied Electric Lab. Model MP-1T polarimeter.

Materials. 4, 14-Dimethyl[2.2]metacyclophane (III) was prepared[5] as colorless needles, mp 68—69°C, by the dimerization reaction of 2, 4-bis(chloromethyl)-toluene under high-dilution conditions realized by the slow addition (68 hr) of the latter compound to disodium tetraphenylethane in THF at −60 to −70°C. [2.2]-Metacyclophane-4, 14-dicarboxylic acid (IV), mp >300°C, was obtained either by the direct oxidation of III with potassium permanganate or *via* [2.2]metacyclophane-4, 14-dicarbaldehyde, which had itself been prepared from III by dibromination with NBS, followed by treatment with 2-nitropropane and sodium ethoxide in DMSO.[10]

Optical Resolution. a) A solution of 300 mg (1.0 mmol) of III and 300 mg (0.67 mmol) of (−)-α-(2, 4, 5, 7-tetranitro-9-fluorenylideneaminooxy)propionic acid in 2 m*l* of benzene was kept in a refrigerator for 4 days. Orange-red crystals of the complex were collected by filtration; a benzene solution of these was then submitted to column chromatography on alumina, using benzene as an eluent. There were thus obtained 49 mg of colorless needles which had a mp of 54—64°C and an $[\alpha]_{578}^{26}$ value of −3.4°(*c* 1.8, ethanol).

Similar treatment of the filtrate from the complex formation furnished 80 mg of colorless needles, mp 58—61°C, which showed $[\alpha]_{578}^{26}=+4.2°$ (*c* 3.3, ethanol).

The two compounds showed negative and positive

plain ORD curves respectively and had IR spectra identical with those of the racemic compound.

b) A solution of 330 mg (1.1 mmol) of IV and 730 mg (2.3 mmol) of quinine, which had been liberated from the hydrochloride, in 9 m*l* of hot ethanol was left to stand at room temperature for one day. Filtration then afforded 280 mg of a crystalline salt, which was recrystallized from ethanol, mp 150—160°C. Dicarboxylic acid was freed from the salt by shaking it with 20 m*l* of benzene and 10 m*l* of dilute hydrochloric acid. By the evaporation of the benzene solution, there were obtained 45 mg of a colorless powder, mp >300°C, with $[\alpha]_D^{22}=+5°$ (*c* 1.8, ethanol). It had IR spectra identical with those of the racemic compound.

The Reaction of Benzylic Alcohols with Dimethyl Sulfoxide-Polyphosphoric Acid

Takeo SATO, Akihiko TAKATSU, Yoshitaka SAITO, Takafumi TOHYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received July 25, 1967)

The reaction of dimethyl sulfoxide-polyphosphoric acid mixture with benzylic alcohols has been shown to afford a complex mixture of the products; this is in contrast to the case of aliphatic alcohols, which yield the corresponding acetal as the major product. By carrying out reactions using several benzylic alcohols and a series of benzyl alcohols, it was found that, in addition to the acetal formation reaction, dehydration and oxidation reactions, as well as a methyl thioether-formation reaction, were occurring. Possible pathways for the formation of these products are presented.

In continuing our work[1] aimed at the development of a new use of dimethyl sulfoxide (DMSO) in organic reactions, this paper will record the reactions of benzylic alcohols with DMSO, polyphosphoric acid (PPA), or a DMSO-PPA mixture.

In another study, a facile dehydration reaction of α-(bromomesityl)benzyl alcohol to give the corresponding ether has been achieved[2] by treatment with PPA. Current interest in DMSO as an efficient dehydrating agent[3] has led us to investigate the ether formation reaction of benzylic alcohols in DMSO.[2] By heating benzhydrol (IIId) in a DMSO solution, bis(diphenylmethyl) ether (IVd) was isolated in a 88% yield. Likewise, α-(bromomesityl)benzyl alcohol afforded an ether. Similar results have concurrently been reported by Traynelis and his co-worker.[4] In contrast, 9-hydroxyfluorene produced only a 14% yield of bis(9-fluorenyl) ether under similar conditions, the major product being 9-fluorenone, which was obtained in a yield of up to 56%. An attempted dehydration reaction of benzyl alcohol with either DMSO or PPA, however, resulted in the formation of only a small amount of benzaldehyde or of a polymeric material respectively.

Recently considerable interest has arisen in the reaction in which DMSO is used as a reactant as well as a solvent in acidic media. A novel oxidation method developed by Moffatt and his co-workers[5] utilizes DMSO-dicyclohexylcarbodiimide (DCC)-orthophosphoric acid for the selective oxidation of primary alcohols to aldehydes. It has also been reported from our laboratories[6] that a new reagent, a DMSO-PPA mixture, reacts even with aliphatic primary alcohols to form the corresponding acetal I in a 50—90% yield. These alcohols, which are inert toward DMSO, are known to produce only polymeric hydrocarbons on reaction with PPA.[6,7]

VIId			4.97(1)	1.91(3)	1325, 675

a) Determined on Varian A-60 spectrometer as a carbon tetrachloride solution except for Vb and VIIb (X=NO_2) which were dissolved in deuteriochloroform. All the signals, relative to TMS (δ=0.0 ppm), appeared as a singlet except for IVc, which were consisted of a pair of quartets. Numerals in parentheses denote the number of protons.

The treatment of benzylic alcohols with this DMSO-PPA mixture at a water-bath temperature for 2—5 hr produced a complex mixture of the ether IV, the acetal V, the carbonyl compound VI, and the methylthio compound VII. In contrast to the aliphatic series, acetal was no longer the main product, and no methylthiomethyl ether corresponding to II was detectable. Among the benzylic alcohols studied, 1-phenylethanol (IIIc) behaved differently and afforded only dehydration products, styrene and bis(1-phenylethyl) ether (IVc).[8] The results of representative examples are shown in Table 1. The reaction products were analyzed either by column chromatography on alumina or by gas chromatography. The carbonyl compounds were determined as 2, 4-dinitrophenylhydrazones. The pertinent NMR and IR data used for the identification of the materials are compiled in Table 2.

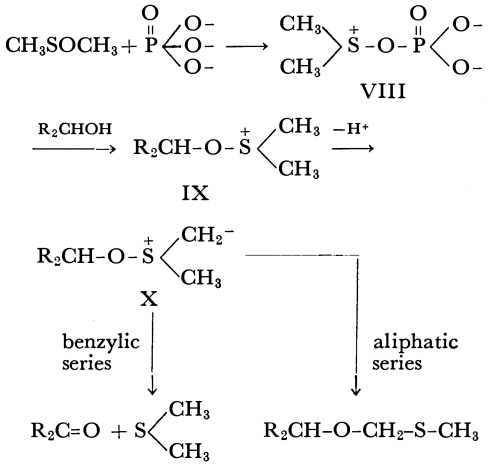
As a typical example, the reaction products from benzyl alcohol (IIIa) were analyzed in the following manner. By gas chromatographical analyses using Carbowax-1500 on celite column, benzaldehyde (VIa), benzyl methyl sulfide (VIIa), unreacted alcohol (IIIa), dibenzyl ether (IVa), and dibenzyloxymethane (Va) (listed in the order of the retention time) were identified. Column chromatography on alumina using *n*-hexane containing an increasing amount of ether as an eluent furnished VIIa, IVa, Va, and IIIa, in that order. The treatment of IIIa with DMSO-85% orthophosphoric acid resulted in the recovery of the starting material, while the mixture made from DMSO and phosphorus pentoxide decomposed

8) Dehydration of 1-phenylethanol to styrene required much drastic conditions when carried out in DMSO alone, see V. J. Traynelis, W. L. Hergenrother and J. A. Valicenti, *J. Org. Chem.*, **27**, 2377 (1962).

vigorously before it could be brought into the reaction.[9]

The formation of the ether IV, which is absent in the aliphatic series[6] but is formed in as high as a yield as 53% with IIId, is favored in benzylic alcohols, since the reaction proceeds through a carbonium ion mechanism. This may also explain the formation of VII, by assuming the reaction of benzylic carbonium ion either with methyl mercaptan, one of the possible decomposition products of DMSO in acidic media, or with any species capable of generating it.[10]

The yields of benzaldehydes derived from a series of *p*-substituted benzyl alcohols (IIIb) are shown in Table 4 (see the Experimental section). It is apparent that the presence of an electron-withdrawing group favors the formation of the oxidation products. The fact that aliphatic alcohols do not produce any oxidation product, but instead afford the methylthiomethyl ether II, which is absent in the benzyl series, suggests that the formation of VI from benzylic alcohols and that of II from aliphatic alcohols share a common intermediate X. The reaction of DMSO with PPA produces VIII, which, upon an attack from the back by an alcohol, is converted to the alkoxysulfonium compound IX. Further reactions of the ylide X derived from IX are dependent on the nature of the alkyl residues. In the case of aliphatic compounds, carbanion preferentially attacks oxygen to produce methylthiomethyl ether, while in the benzyl series the ylide decomposes into a carbonyl compound and dimethyl sulfide. The benzyl alcohol bearing an electron-withdrawing group is more easily oxidized, since the benzyl hydrogen becomes more acidic, thus facilitating the attack by the carbanion. The intermediacy of X in a number of reactions in which DMSO serves as an oxident has been well established.[5] Further, relevant examples found in recent papers include the formation of II by the reaction of alcohol with DMSO containing DCC,[11,12] or acid anhydride.[13,14]



Experimental

α-(Bromomesityl)benzyl Alcohol. Benzoylbromomesitylene[15] was reduced with lithium aluminum hydride in the usual manner. Colorless prisms, mp 65—67°C, were then obtained in a 95% yield by recrystallization from benzene - petroleum ether.

Found: C, 62.77; H, 5.51%. Calcd for $C_{16}H_{17}OBr$: C, 62.96; H, 5.61%.

IR (KBr): 3450 and 1150 cm^{-1}.

Acetylation with acetic anhydride containing pyridine afforded an acetate as colorless prisms, mp 99—100°C.

Found: C, 62.07; H, 5.21%. Cacld for $C_{18}H_{19}O_2Br$: C, 62.25; H, 5.51%.

Bis[α-(Bromomesityl)benzyl] Ether. To 32 g of PPA, 2.0 g (6.6 mmol) of the above alcohol was added, after which the mixture was heated on a water bath for 15 min. The reaction mixture was then diluted with water, and the crystalline material was recrystallized from benzene - ethanol to give 1.5 g (77% yield) of colorless prisms, mp 147—149°C. After five successive recrystallizations, the melting point was raised to 176—177°C.

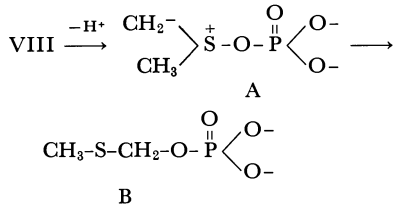
Found: C, 64.51; H, 5.51%. Calcd for $C_{32}H_{32}OBr_2$: C, 64.87; H, 5.45%.

The combined mother liquors were evaporated, and the residue was passed through an alumina column, using petroleum ether as an eluent; thereby we obtained another compound, mp 152—154°C which was assumed to be a structural isomer.

The Reaction with DMSO. *a) Bis(diphenylmethyl) Ether (IVd).* A mixture of IIId in DMSO was heated at 165—170°C under various conditions, summarized in Table 3. After the reaction was over, the mixture was diluted with water and the resulting IVd was recrystallized from ethanol; mp 108—109°C (lit. 108°C).

9) Recently, however, DMSO-P_2O_5 was used for the oxidation of carbohydrates, see K. Onodera, S. Hirano and N. Kashimura, *J. Am. Chem. Soc.*, **87**, 4651 (1965).

10) Compound B which arose *via* A may be responsible for the origin of methylthio group as well as formaldehyde.



11) J. B. Jones and R. C. Wigfield, *Tetrahedron Letters*, **1965**, 4103.

12) K. E. Pfitzner and J. G. Moffatt, *J. Am. Chem. Soc.*, **87**, 5670 (1965).

13) J. D. Albright and L. Goldman, *ibid.*, **87**, 4214 (1965).

14) An alternative mechanism[12,13] which postulates the intermediacy of $CH_3\overset{+}{S}=CH_2$ has also been advanced, see also K. E. Pfitzner and J. G. Moffatt, *J. Am. Chem. Soc.*, **87**, 5661 (1965).

15) J. F. Hyde and R. Adams, *ibid.*, **50**, 2503 (1928).

Table 3. Bis(diphenylmethyl) ether (IVd) formation reaction at 165—170°C

IIId mol	DMSO mol	Time hr	Yield of IVd, %
0.03	0.6	4	63
0.03	0.6	8	88
0.02	0.02	8	68
0.08	0.4	8	66
0.03	0.6	24	82

No ether formation was observed when IIId itself or a diethylene glycol solution was heated at 165—170°C for 11—18 hr.

b) Bis[α-(bromomesityl)benzyl] Ether. A mixture of 3.0 g (0.01 mol) of α-(bromomesityl)benzyl alcohol and 15.6 g (0.2 mol) of DMSO was heated at 165—170°C for 16 hr. Colorless prisms, mp 156.5—158°C, were thus obtained (0.6 g). The IR spectra agreed with the product obtained by the PPA dehydration reaction described above.

c) Bis(9-fluorenyl) Ether. A mixture of 3.6 g (0.02 mol) of 9-hydroxyfluorene and 31.2 g (0.4 mol) of DMSO was heated at 165—170°C for 24 hr. The recrystallization of the product from ethanol afforded 0.2 g of bis(9-fluorenyl) ether, mp 223—225°C (lit. 228°C). The rest of the material was analyzed by column chromatography on alumina, using benzene - chloroform - ethanol as an eluent; this afforded 0.2 g of an unidentified yellow solid, mp 232—237°C, 0.3 g of bis(9-fluorenyl) ether (total yield 14.3%), and 1.2 g (33.4%) of 9-fluorenone, mp 73—76°C, together with the starting material (14.3% recovery).

The same experiment carried out at 165—185°C for 25 hr afforded a 56% yield of 9-fluorenone.

d) Attempted Reaction of Benzyl Alcohol. A mixture of 5.4 g (0.05 mol) of benzyl alcohol and 78 g (1.0 mol) of DMSO was heated at 160—170°C for 20 hr. A part of the reaction mixture was then treated with a 2, 4-dinitrophenylhydrazine solution to give a 15.7% yield of the benzaldehyde hydrazone, mp 231.5—234°C. About 60% of the starting alcohol was recovered by simple distillation.

Methylthiomethyl Ether (II). *a) Cyclohexyl Methylthiomethyl Ether (II, R=Cyclohexyl).* The treatment of cyclohexanol with DMSO-PPA afforded,[6] in addition to a 44% yield of dicyclohexyloxymethane (I, R=cyclohexyl), a fraction which boiled at 97—99°C/15 mmHg. From its IR and NMR spectra it was identified as II (R=cyclohexyl), it was obtained in a 8.6% yield.

NMR (CCl_4): δ 4.58 (2H), 3.60 (1H), 2.08 (3H) and 1.1—1.8 (10H).

Found: C, 60.85; H, 10.10%. Calcd for $C_8H_{16}OS$: C, 59.98; H, 10.07%.

b) (−)-Menthyl Methylthiomethyl Ether (II, R=Menthyl). The same reaction as above but using (−)-menthol furnished a 28.9% yield of dimenthyloxymethane (I, R=menthyl), bp 207°C/23 mmHg, mp 58°C and a 4.5% yield of II (R=menthyl), bp 138—140°C/17 mmHg.

NMR (CCl_4): δ 4.62 (2H), 3.45 (1H), 2.08 (3H) and 0.7—2.3 (18H).

Found: C, 67.15; H, 11.26%. Calcd for $C_{12}H_{24}OS$: C, 66.63; H, 11.18%.

The Reaction with DMSO-PPA. *a) Benzyl Alcohol (IIIa).* To a mixture which had been prepared under cooling by adding 78 g (1.0 mol) of DMSO to 54 g of 80% PPA, 21.6 g (0.2 mol) of IIIa was added. After the reaction mixture had then been heated on a water bath for 5 hr, it was diluted with water and extracted with diisopropyl ether. A part of the extract was treated with a 2, 4-dinitrophenylhydrazine solution to give the benzaldehyde hydrazone in a 9.5% yield. The rest of the material was chromatographed through an alumina column, using *n*-hexane containing an increasing amount of ether; this eluted VIIa, IVa (10% yield), Va (16% yield), and unreacted IIIa successively. All the compounds had satisfactory NMR and IR spectra compared with the authentic specimens (Table 2). By gas chromatography using Carbowax-1500 on celite-408 column, VIa, VIIa, IIIa, IVa, and Va (in the order of the retention time) were identified. As VIIa tended to co-distill with *n*-hexane, the yield for this material (13% yield) was obtained from the gas chromatographical measurements.

b) p-Nitrobenzyl Alcohol (IIIb, X=NO_2). A mixture of 7.6 g (0.05 mol) of IIIb (X=NO_2), 19.5 g (0.25 mol) of DMSO, and 13.5 g of PPA was heated at water-bath temperature for 5 hr. A 20% yield of aldehyde VIb (X=NO_2) was then attained by converting it to 2, 4-dinitrophenylhydrazone.

Column chromatography on alumina using benzene as an eluent furnished sulfide VIIb (X=NO_2) in a yield of 4.9%.

Found: C, 52.51; H, 4.85; N, 7.28%. Calcd for $C_8H_9O_2NS$: C, 52.46; H, 4.95; N, 7.65%.

No ether formation was observed, and the next fraction contained acetal Vb (X=NO_2) as colorless needles mp 98—99°C; it was isolated in a 46% yield.

Found: N, 8.70%. Calcd for $C_{15}H_{14}O_6N_2$: N, 8.80%.

In one experiment, benzaldehyde bis(*p*-nitrobenzyloxy) acetal was isolated from the reaction mixture as a colorless, amorphous material, mp 202—206°C.

Found: N, 9.52%. Calcd for $C_{21}H_{17}O_8N_3$: N, 9.56%.

c) p-Substituted Benzyl Alcohols (IIIb). The same reaction was applied to a series of IIIb. The yields of the benzaldehydes formed are tabulated in Table 4.

Table 4. The formation of benzaldehydes (VIb) from *p*-substituted benzyl alcohols (IIIb)

IIIb	Yield of VIb, %
X: CH_3O	11
CH_3	9.4
H	8.5
Cl	39[a]
NO_2	20

a) Including *p*-chlorobenzoic acid.

d) 1-Phenylethanol (IIIc). A mixture of 24 g (0.2 mol) of IIIc, 120 g (1.5 mol) of DMSO, and 50 g of PPA was heated on a water bath for 5 hr. The diisopropyl ether extract was then distilled to give a 19% yield of styrene, bp 63—70°C/70 mmHg, and a 27% yield of the ether IVc, bp 158—162°C/70 mmHg,

n_D^{21} 1.5375. From the intermediate fraction, acetophenone (VIc) was isolated as 2, 4-dinitrophenylhydrazone (0.5% yield).

e) Benzhydrol (IIId). A mixture of 4.8 g (0.025 mol) of IIId, 9.8 g (0.125 mol) of DMSO, and 6.8 g of PPA was brought into the reaction as above. When water was then added to the reaction mixture, IVb was isolated as colorless plates, mp 102—104°C. From the filtrate, benzophenone was isolated as 2, 4-dinitrophenylhydrazone in a 13% yield. The diisopropyl ether extract of the filtrate was analyzed by alumina-column chromatography.

n-Hexane eluted VIId, mp 33—33.5°C, in a yield of 20%. The sulfide VIId was also isolated, together with benzophenone, by the direct distillation of the reaction mixture.

Found: C, 78.59; H, 6.34; S, 14.82%. Calcd for $C_{14}H_{14}S$: C, 78.48; H, 6.59; S, 15.00%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 225—229 (1968)

The Use of Carbon Monoxide in Low-temperature Sintering of High-density UO_2 Pellets*1

Kazuhide MIYAZAKI

Central Research Laboratories, Mitsui Mining & Smelting Co., Mitaka-shi, Tokyo

(Received May 27, 1967)

The fundamental effects of carbon monoxide on UO_2-pellet densification are described. A high density of more than 95% of the theoretical level is attained using carbon monoxide as the sintering atmosphere at a low sintering temperature of 1400°C for laboratory-processed UO_2 powders. An approximate prediction of the density for any given UO_2 powder may be made from the following two experimental criteria: (a) The experimental activation energy for the rate of dissolution of the material into nitric acid may be taken as a measure for the low-temperature sinterability. The density of sintered oxides rises to a maximum at a point where the value of the activation energy for dissolution is about 20 kcal/mol, which is actually very close to the value for the diffusion of oxygen in uranium oxides. (b) The relative intensity of the (220) peak of the X-ray diffraction pattern furnishes another foundation for judging the densification behavior of the UO_2 sample.

The present investigation is primarily concerned with basic data aimed at uncovering the role of carbon monoxide, which has seldom been used in uranium dioxide industries, in obtaining high-density UO_2 pellets at a low sintering temperature. The sinterabilities are, therefore, examined in the neighborhood of 1400°C instead of in the conventional 1600—1800°C range.

Various approaches have long been taken by many workers to lower the sintering temperature of uranium dioxide. For instance, non-stoichiometric uranium oxide containing an excess of oxygen[1] increases the degree of sintering. Small amounts of such additives as TiO_2 and CaO have been proposed[2,3] as binding materials between grains of sintered uranium dioxide. In some cases, uranium dioxide has been blended with U_3O_8 to prepare a non-stoichiometric uranium oxide mixture and the sintering temperature has been reduced to as low as 1300°C; however, the sintered product here was actually $UO_{2.30}$.[4] Moreover, an irradiation test elsewhere has indicated that the O/U ratio of the fuel should be less than 2.15 if we are to minimize cracking and fission gas release.[5]

In the present work, experimentation is carried out to examine the possibility of lowering the sintering temperature by using carbon monoxide to participate in a reduction-sintering schedule for a high-density pellet of more than 95% of the theoretical level. Also, we propose to describe the densification behavior in terms of the activation energy for the rate of dissolution in nitric acid and a specific X-ray diffraction peak of UO_2 powder as practical criteria for judging the feasibility of the material for use in low-temperature sintering.

Experimental

Materials. The materials were prepared at an elevated temperature by the simultaneous thermal decomposition and reduction of the ammonium diuranate

precipitate obtained from a purified nitrate solution. Commercially-available tank hydrogen and/or carbon monoxide were used as the reducing gas; the purities of these gases were graded as 99.9% H_2 and 99.5% CO respectively. Reducing gas was introduced into the inlet of the laboratory tube furnace with a static charge for several hours at an elevated temperature. The O/U ratio determinations were performed by the oxidation method, which involved igniting the original uranium dioxides to U_3O_8 in air and establishing the weight gain,[6,7] the composition of the starting materials was in the range of $UO_{2.07-2.11}$. The thermobalance technique was employed to simultaneously observe the thermogravimetric characteristics of the starting uranium dioxides in the course of the O/U ratio determinations. The UO_2 powders were stored in N_2-filled polyethylene containers.

Sintering Tests. The straight cold-press-and-sinter powder metallurgical technique was used. The granulations were performed by a method similar to that described by Langrod.[4] A high-chromium stainless steel-lined mold was designed to obtain an optimum lubrication of compact UO_2 under pressing as well as to eliminate the need for costly carbide dies. No additives were used to flux the grain boundaries of UO_2 at a low sintering temperature, the granulated powder was compacted into pellets 1.0 cm in diameter at a pressure of 3 tons/cm^2. The rather low compacting pressure of 3 tons/cm^2 was employed to insure a amooth release from the die and to minimize the cracking frequently incurred on green products under higher compacting pressures. The pellets were then sintered at 1400°C with an experimental furnace, either in an atmosphere of carbon monoxide or in hydrogen gas flowing through the furnace, and the densities were measured with the lapse of the sintering time. The density of the sintered UO_2 pellet was determined from the weight and geometrical dimensions of the pellet.[7] A dial-depth gauge was used to read the mean values of the diameter and length of the sintered UO_2 body.[8]

Characterization of UO_2 Powder in Relation to the Sintering Behavior. Two tests were performed in an attempt to devise a measure to characterize the sinterability of UO_2 powder. The various UO_2 powders used were prepared either by the pyrolysis of various precipitates of ammonium diuranate or by the partial air-oxidization of the reduced UO_2 samples. Oxide samples with O/U ratios in the range of 2.05—2.16 were thus obtained. In this paper a new experimental criterion will be proposed for judging the low-temperature sinterability of UO_2 in terms of another physico-chemical property rather than the well-known O/U ratio of the material.

(a) Determination of the Activation Energy for Nitric Acid Dissolution. One gram of the oxide was immersed in 100 m*l* of 1 N nitric acid. A test tube-type glass container was used as the dissolution cell, and the dissolution temperature was controlled to ±1°C throughout the run by means of a water-bath. After a given time has elapsed the cell was incorporated into a centrifugal machine and a 1-m*l* aliquot of the supernatant liquid was pipetted out, thus the dissolved amount of UO_2 milligrams could be determined over several time-intervals as measured in minutes. The total liquid volume consumed for the analysis of the dissolved UO_2 was not more than 5 m*l* per 100 m*l*. Arrhenius plots of the dissolution rate constant for the nitric acid solution were made at 15, 30, 40, and 60°C.

(b) Intensities of X-ray Diffraction Peaks. The deviation in relative intensities of the X-ray diffraction peaks of a given UO_2 powder was examined in terms of the density of the pellet when sintered. As a standard of the intensities, the ASTM Card listing the Swanson and Fuyat data[9] for $UO_{2.03}$ was used. An X-ray instrument was operated with the following set of conditions: Target, Cu; filter, Ni; voltage, 30 kV; current, 10 mA; divergency, 1°, and G. M. counting self-rocorder.

Results and Discussion

Figure 1 shows that, when a hydrogen atmosphere is used for sintering, the use of carbon monoxide in part or wholly as the reducing gas replacing the conventional H_2 reduction will be effective in obtaining more densified products in the relatively shorter period of sintering time of less than about 9 hr at 1400°C. However, the conventional hydrogen-reduced UO_2 powder gradually exceeds the pellet's density with the lapse of sintering time. The maximum density shown in Fig. 1 was still less than 95% as a fraction of the theoretical density, 10.97 g/cc, obtained by the use of carbon monoxide as the reducing gas.

On the other hand, the use of carbon monoxide as the sintering atmosphere densificates significantly higher when hydrogen-reduced UO_2 powder is provided for sintering, as is shown in Fig. 2. It is interesting to note that the combination of hydrogen reduction and carbon monoxide sintering is particularly beneficial for a low-temperature operation. In this case a density of more than 10.6 g/cc (*i. e.*, 96.6% of the theoretical level) is achieved in a firing time of 10 hr. Otherwise, however, the participation of carbon monoxide in the reduction gas will not appreciably contribute to the densification. It may be seen that carbon monoxide can more advantageously be employed as a sintering atmosphere than as a reducing gas.

A further comparison of carbon monoxide and hydrogen as a sintering atmosphere was made by two-stage sintering tests through the medium of nitrogen gas. At the firing temperature of 1400°C green compacts pressed with a hydrogen-reduced UO_2 sample were first sintered in an atmosphere of nitrogen, and then the atmosphere was successively switched over either to hydrogen or carbon monoxide. Figure 3 illustrates the surprising result that the successive introduction of hydrogen

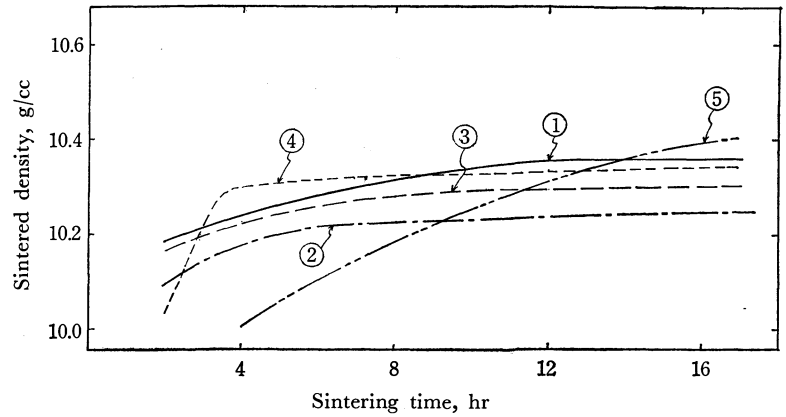

Fig. 1. Sintered density of carbon monoxide-reduced UO_2 pellets sintered in atmospheres of carbon monoxide in part or overall. (1): Sintered in CO, (2): in H_2+2CO, (3): in H_2+CO, (4): in $2H_2+CO$, and (5): in H_2, at 1400°C.

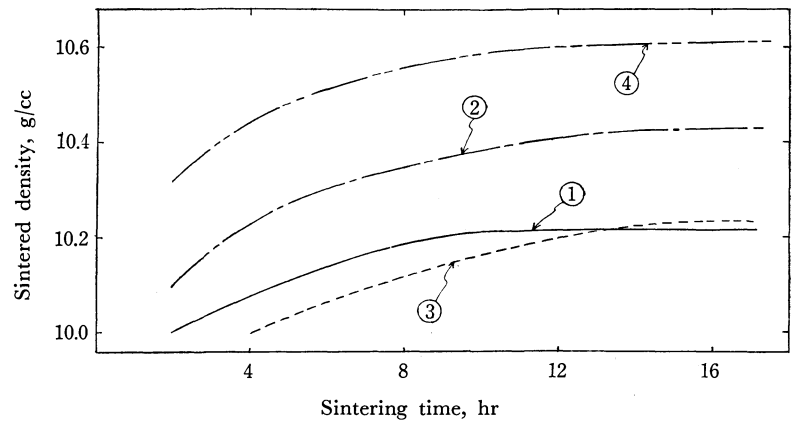

Fig 2. Sintered density of hydrogen-reduced UO_2 pellets sintered in atmospheres of carbon monoxide in part or overall. (1): Sintered in CO, (2): in H_2+2CO, (3): in $2H_2+CO$, and (4): in H_2, at 1400°C.

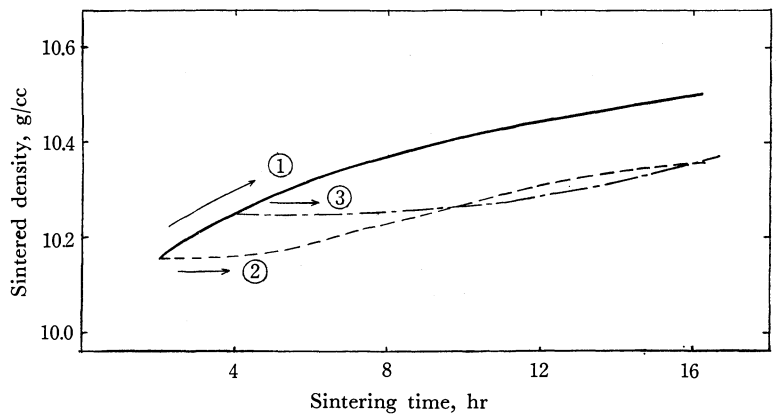

Fig. 3. Two-stage sintering in nitrogen followed by hydrogen atmosphere *versus* sintering time at 1400°C, with the use of hydrogen-reduced UO_2 pellets. (1): Sintered in N_2 only, (2): Sintering in H_2 after 2 hr sintering in N_2, and (3): Sintering in H_2 after 4 hr sintering in N_2.

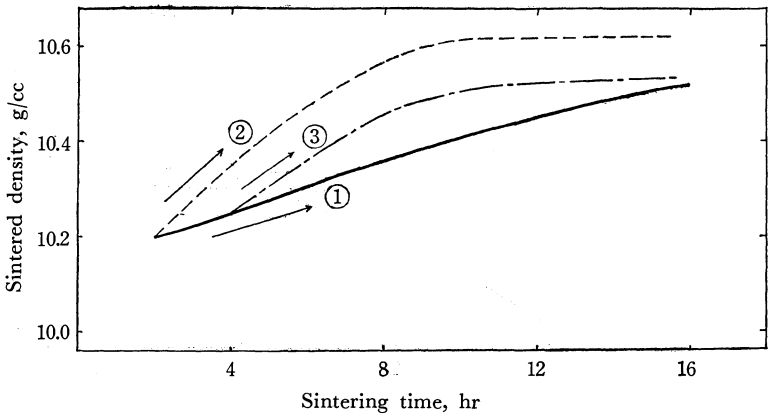

Fig. 4. Two-stage sintering in nitrogen followed by carbon monoxide atmosphere *versus* sintering time at 1400°C, with the use of hydrogen-reduced UO_2 pellets. (1): Sintered in N_2 only, (2): Sintering in CO after 2 hr sintering in N_2, and (3): Sintering in CO after 4 hr sintering in N_2.

hindered the densification of the pellets; *i. e.*, the density of the product, which would otherwise be increased along with the initial sintering atmosphere, was considerably decreased by admitting the hydrogen gas.

It is worth noting, on the other hand, that the nitrogen firing, followed by carbon monoxide-introduction, was remarkably effective in the densification of the product, as is shown in Fig. 4, where a density of 10.6 g/cc is obtained by a 2-hr nitrogen sintering plus a 7-hr carbon monoxide sintering. It is also interesting to observe in this case that the pellet which is treated longer with nitrogen (*e. g.*, 4 hr) emerges with a lower sintered density than that described above in spite of the successive carbon monoxide treatment.

The dissolution process into nitric acid as regards sintered pellets was undertaken by Taylor *et al.*[10] in an attempt to provide data for the design of a plant for the continuous dissolution of uranium oxide fuel in nitric acid; the sintered pellets exhibited activation energies of about 15 kcal/mol for much higher nitric acid concentrations.

However, the raw-material UO_2 has not yet been dissolved as a measure for describing the densification behavior. An examination of the Arrhenius plots for the nitric acid dissolution rates of the raw-material UO_2 powders has shown that the values of the activation energy vary from sample to sample, ranging from 12 to 24 kcal/mol; typical examples are illustrated in Fig. 5. Accordingly, it is clear from Fig. 6 that, with an increase in the activation energy up to about 20 kcal/mol, the pellet density sintered in carbon monoxide also increases up to a maximum of about 10.6 g/cc, while that with the higher activation energies, beyond 20 kcal/mol, shows an inferior densification

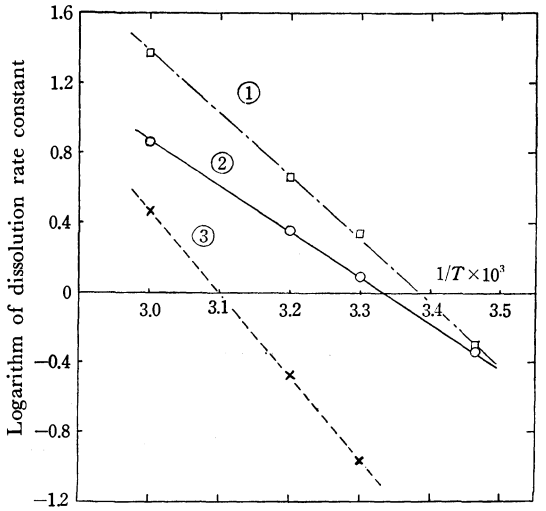

Fig. 5. Arrhenius plot of dissolution rates for typical UO_2 samples. (1): 10 g U/*l*, no-washed ADU, simultaneous decomposition and reduction by H_2; $E=16$ kcal/mol, (2): 100 g U/*l*, washed ADU, decomposition before reduction by H_2, $E=12$ kcal/mol, (3) 100 g U/*l*, no-washed ADU, with decomposition before reduction by H_2, $E=22$ kcal/mol.

behavior.

It is also of interest to survey several values of the activation energies for the diffusion of oxygen in uranium oxides investigated elsewhere and to compare these values with the value of 20 kcal/mol obtained for the maximum sinterability in terms of nitric acid dissolution. Ristic and Kostic[11] obtained 20.2 kcal/mol for the sintering of UO_2. Stamenkovic and Ristic[12] obtained 24.5

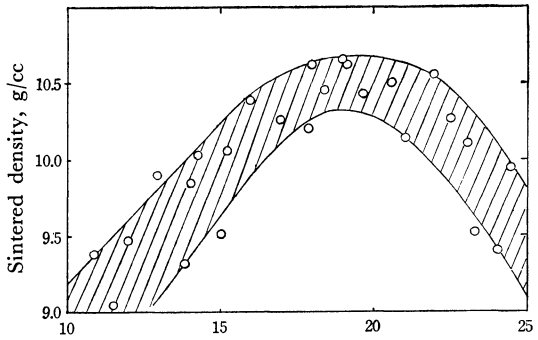

Fig. 6. Nitric acid dissolution activation energies of UO_2 powders *versus* sintered densities of the UO_2 pellets at 1400°C with carbon monoxide.

kcal/mol for the oxidation of UO_2 powders at 172—220°C. Walder[13] determined the value of activation energies for the oxidation of UO_2 at 120—360°C to be 20—27 kcal/mol. Therefore, it appears possible to say that the activation energies exhibited by the two independent phenomena, the dissolution of UO_2 into nitric acid and the self-diffusion of oxygen in solid UO_2, come very close to each other in magnitude, suggesting that the mechanism of the self-diffusion of oxygen which takes place in oxidation and the sintering of UO_2 powders can possibly be described by analogy with the behavior in the nitric acid dissolution of the material. At this early stage of investigation, however, it is impossible to extend say anything further about this problem.

Most importantly, however, it may be pointed out that the value of the activation energy for nitric acid dissolution will provide an approximate measure for judging the sinterability of a given UO_2 powder, being one of the outstanding characteristics inherited from the foregoing powder production process.

In parallel with this, the X-ray diffraction patterns of the prepared UO_2 samples were examined in order to obtain another convenient characteristic measure for dealing with their low-temperature sinterability. Figure 7 plots the deviations of the relative intensities of the (220) peak against the sintered densities at 1400°C obtained in an atmosphere of carbon monoxide. As a standard reference of the relative intensity of the (220) peak, the ASTM Card gives the value of 49 as the fraction of the intensity of (111), which is taken as 100.

The plots in Fig. 7 have been distributed around a well-defined convexity to the above; it may be seen that the sintered density rises to a maximum at the point where the relative intensity of (220) is slightly stronger than the standard value of 49, and then decreases. It can not yet be decided

13) D. B. Y. Walker, *J. Appl. Chem.*, **15**, 128 (1965).

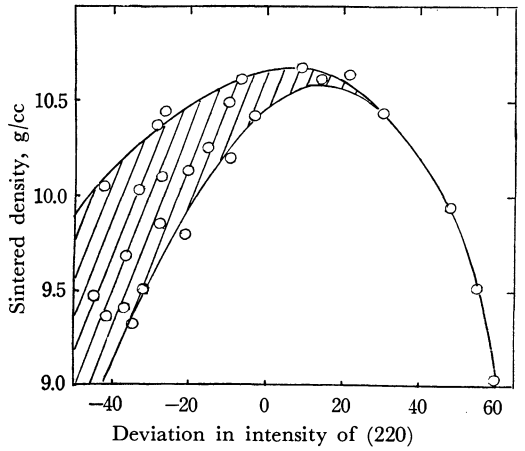

Fig. 7. Deviations in relative intensity of (220) X-ray diffraction peak of UO_2 powders *versus* the sintered densities at 1400°C with carbon monoxide.

whether this slight shift from neutral is substantially significant or whether it is a mere experimental discrepancy. Figure 7 implies, however, that a lattice disorder, if any, present in the UO_2 crystalline phase will possibly act as a resistance to the sound composition of UO_2 grains when sintered at a minimum sintering temperature such as 1400°C. At the same time, it is of interest to note that a UO_2 sample with a stronger intensity for the (220) peak was much less frequently encountered among the laboratory-produced UO_2 powders in comparison with one with a weaker intensity of the peak.

It should be noted that the examination of the relative intensity for a specific X-ray peak of UO_2 powder seems, particularly with an industrial point of view, to be a quite feasible criterion for making a quick estimation regarding the low-temperature sinterability.

Summary

The effect of carbon monoxide on the densification of UO_2 pellets was examined at around 1400°C instead of in the conventional 1600—1800°C range. A high density (above 95% of the theoretical level) was obtained using carbon monoxide as the sintering atmosphere.

The densities of the sintered UO_2 pellets were related to the activation energy of the dissolution rate for a nitric acid solution and a specific X-ray diffraction peak of UO_2 powder. The density showed a maximum for the UO_2 samples with an activation energy of about 20 kcal/mol. The densification behavior was inferior in a UO_2 powder with much deviations from the standard relative intensity of the (220) peak. The above two characteristics furnish experimental criteria for judging the low-temperature sinterability of UO_2 samples.

NOTES

Studies of Seven-membered Heterocyclic Compounds Containing Nitrogen. IX. The Synthesis of 5-Ethoxycarbonyl-1-azacycloheptan-4-one and Its Derivatives

Tamon MORIYA, Toichi OKI, Seiki YAMAGUCHI, Shiro MOROSAWA and Akira YOKOO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received February 22, 1967)

As an extension of our previous study[1] of the synthesis of the seven-membered ring ketone containing nitrogen through the reaction of 1-benzyl-1-azacyclohexan-4-one (I) with nitrosomethylurethane, the ring expansion of I and 1-ethoxycarbonyl-1-azacyclohexan-4-one (II) has been carried out using ethyl diazoacetate.

The ring expansion of I was examined first, using zinc chloride as a catalyst, according to the method of Eistert *et al.*,[2] the product, 1-benzyl-5-ethoxycarbonyl-1-azacycloheptan-4-one (III), was isolated as a hydrochloride. The yield of the reaction was 20%. This was improved to 34% by the use of boron trifluoride etherate as a catalyst, according to the method developed by Tal and Warnhoff.[3] In neither case, however, was it possible to isolate the free base (III) by the direct distillation of the reaction mixture, but III liberated from its hydrochloride was safely distilled. The decarboxylation of III by refluxing it with hydrochloric acid yielded the hydrochloride of 1-benzyl-1-azacycloheptan-4-one (V), which was found, by a mixed-melting-point determination and by a comparison of IR spectra, to be identical with an authentic sample.[1] The ring expansion of II, using boron trifluoride etherate, furnished 1, 5-diethoxycarbonyl-1-azacycloheptan-4-one (IV). IV was also derived from III by hydrogenolysis and subsequent ethoxycarbonylation.

III and IV gave the corresponding derivatives (VII—X) of a type of pyrazole or pyrazolone when treated with hydrazine or phenylhydrazine, while they gave normal 2, 4-dinitrophenylhydrazones. Debenzylation by the hydrogenolysis of VII in the presence of hydrochloric acid gave a hydrochloride of compound XI. A similar compound (XII) was obtained by the hydrogenolysis of VIII. XII was also derived from VI.

The methylation of III afforded 1-benzyl-5-ethoxycarbonyl-5-methyl-1-azacycloheptan-4-one (XIII). XIII was converted into 1-ethoxycarbonyl-5-methyl-1-azacycloheptan-4-one (XIV) by decarboxylation and debenzylation, followed by ethoxycarbonylation.

Experimental

Procedure for Ring Expansion of I and II. Into a solution of 0.28 mol of I or II in dry ether, maintained at −50——60°C, these were vigorously stirred, drop by drop, a solution of 0.26 mol of a freshly-distilled boron trifluoride etherate in 50 cc of dry ether and a solution of 0.85 mol of ethyl diazoacetate in 100 cc of dry ether were added. The addition of the two solutions was started simultaneously; it took 30 min for the addition of the former solution, and 100 min for the latter. After the reaction mixture had been stirred for an additional 30 min at the same temperature, the stirring was continued until the temperature of the mixture reached room temperature. The mixture was then shaken with a 20% aqueous potassium carbonate solution, and the ether layer was separated. The water layer was extracted with ether. The organic layer

1) S. Morosawa, This Bulletin, **31**, 418 (1958).

3) W. T. Tal and E. W. Warnhoff, *Can. J. Chem.*, **42**, 1333 (1964).

was dried over anhydrous potassium carbonate, and then treated in either of the ways shown below. (I): Dry hydrogen chloride was passed through to the organic layer, thus depositing a hydrochloride of III. This was recrystallized from ethanol. (II): After the solvent had been removed from the organic layer, IV was distilled under reduced pressure. The following results were obtained: III·HCl, yield, 34%, mp 164.5°C (dec.). Found: C, 61.68; H, 7.13; N, 4.55%. Calcd for $C_{16}H_{21}O_3N$·HCl: C, 61.63; H, 7.11; N, 4.49%; III, bp 160—162°C/0.4 mmHg. Found: C, 69.65; H, 7.50; N, 5.02%. Calcd for $C_{16}H_{21}O_3N$: C, 69.78; H, 7.68; N, 5.08%; Hydrochloride of 2, 4-dinitrophenylhydrazone, mp 179°C (dec.); IV, yield, 30.5%, bp 133—135°C/0.15 mmHg. Found: C, 56.33; H, 7.87; N, 5.45%. Calcd for $C_{12}H_{19}O_5N$: C, 56.02; H, 7.44; N, 5.42%; 2, 4-dinitrophenylhydrazone, mp 119.5°C.

The hydrochloride of VI was obtained by the hydrogenolysis of the hydrochloride of III in ethanol, using palladium as a catalyst. Yield, 81%, mp 133—134°C. Found: C, 49.03; H, 7.42; N, 6.44%. Calcd for $C_9H_{15}O_3N$·HCl: C, 48.75; H, 7.28; N, 6.32%; VI, bp 112—114°C/0.6 mmHg. Found: C, 58.01; H, 8.37; N, 7.39%. Calcd for $C_9H_{15}O_3N$: C, 58.36; H, 8.16; N, 7.55%.

The Preparation of VII—X. A mixture of III (1 equiv.), hydrazine hydrate (2 equiv.), and ether was warmed on a water bath for 15 min. In a similar method, each of the following mixtures was warmed for 1—3 hr; III·CHl (1 equiv.), hydrochloride of phenylhydrazine (1 equiv.), sodium acetate (2 equiv.), and water; IV (1 equiv.) and hydrazine hydrate (1 equiv.); IV (1 equiv.) and phenylhydrazine (1 equiv.). The following results were obtained: VII, yield, 95%, mp 220°C (dec.). Found: C, 69.61; H, 7.63; N, 17.03%. Calcd for $C_{14}H_{17}ON_3$: C, 69.20; H, 7.05; N, 17.29%; VIII, yield, 92%, mp 198°C (dec.). Found: C, 75.22; H, 6.61; N, 12.84%. Calcd for $C_{20}H_{21}ON_3$: C, 75.21; H, 6.63; N, 13.13%; IX, yield, 35%, mp 242—243°C (dec.). Found: C, 53.24; H, 6.65; N, 18.87%. Calcd for $C_{10}H_{15}O_3N_3$: C, 53.35; H, 6.72; N, 18.66%; X, yield, 76%, mp 144.5°C. Found: C, 63.93; H, 5.96; N, 13.58%. Calcd for $C_{16}H_{19}O_3N_3$: C, 63.77; H, 6.32; N, 13.95%.

XI and XII were prepared by the hydrogenolysis of VII and VIII in ethanol, (in the case of VII, the ethanol contained hydrochloric acid) by using palladium as a catalyst: XI·HCl, yield, 46%, mp 270°C (dec.). Found: C, 38.02; H, 6.54; N, 18.92%. Calcd for $C_7H_{11}ON_3$·2HCl: C, 37.71; H, 6.24; N, 18.58%. XII, yield, 41%, mp 203—204°C (dec.). Found: C, 63.34; H, 6.84; N, 16.70%. Calcd for $C_{13}H_{15}ON_3$·H_2O: C, 63.14; H, 6.93; N, 16.99%.

Preparation of XIII. To a solution of 1.2 g of metallic sodium in 20 cc of absolute ethanol, there was added a solution of 8 g of the hydrochloride of III in a small amount of absolute ethanol with stirring and ice-salt cooling. After 30 min of stirring, 3.7 g of methyl iodide was added, drop by drop, over a 10 min period, and then the stirring was continued for 2 more hours. After a large amount of water had been added to the reaction mixture, it was extracted with benzene. XIII was distilled under reduced pressure from the benzene layer; (yield 33%), colorless oil, bp 171—173°C/0.2 mmHg. Found: C, 70.69; H, 7.78; N, 4.48%. Calcd for $C_{17}H_{23}O_3N$: C, 70.95; H, 7.95; N, 4.83%.

Preparation of XIV. A mixture of 2.4 g of XIII and 70 cc of 4 N hydrochloric acid was refluxed for 2.5 hr, concentrated under reduced pressure, and made alkaline by adding solid potassium carbonate. The liberated oil was separated and hydrogenolized in 30 cc of water containing 0.1 cc of concentrated hydrochloric acid, in the presence of palladium chloride as a catalyst. After the removal of the catalyst, the solution was concentrated under reduced pressure. To the residue were added 7 cc of a 5% potassium hydroxide solution and 1.5 g of anhydrous potassium carbonate under ice-water cooling. Into the mixture was added 1.5 g of ethyl chloroformate under stirring. After 1 hr of stirring, XIV was extracted with ether. Colorless oil, bp 93—95°C/0.1 mmHg. Found: C, 60.17; H, 8.23; N, 6.51%. Calcd for $C_{10}H_{17}O_3N$: C, 60.35; H, 8.54; N, 7.03%. 2, 4-Dinitrophenylhydrazone, yellow plates (from ethanol), mp 145—146°C, Found: C, 50.54; H, 5.72; N, 18.46%. Calcd for $C_{16}H_{21}O_6N_5$: C, 50.65; H, 5.42; N, 18.46%.

Nuclear Magnetic Resonance Spectra of Carbanions. I. 1, 1-Diphenylethylene Dimer Dianion

Kensuke TAKAHASHI and Ryuzo ASAMI

Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya

(Received April 25, 1967)

Carbanions are of particular interest from the standpoint of their charge distribution, since the excess charges are substantially larger than in neutral molecules. Only a few NMR studies have been carried out on carbanions, particularly some organolithium compounds[1] and the cyclopentadienyl anion.[2] 1, 1-Diphenylethylene dissolved in

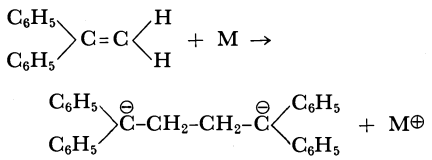
2) G. Fraenkel, R. E. Carter, A. McLachlan and J. H. Richards, *ibid.*, **82**, 5846 (1960).

THF gives colored solutions in contact with excess alkali metals at room temperature for about twenty-four hours. These colored solutions served as samples for the NMR measurements. The evolved reaction in THF might be expressed as follows:[3]



Typical spectra are shown in Fig. 1, representing a solution produced from 1, 1-diphenylethylene in contact with potassium sodium alloy in THF.[4] The peaks in the region of aromatic protons are clearly divided into three, appearing as a doublet, a triplet, and a triplet respectively from the lower to the higher field. Since their intensity ratios are 2 : 2 : 1, it seems that they can be assigned to the peaks of ortho-, meta-, and para-protons respectively, similar to those of triphenylmethyllithium in THF as assigned by Sandel and Freedman.[1] The chemical shifts are given in Table 1, in which the solvent peak serves as an internal reference (the higher-field peak of THF is taken to be at 1.79 ppm from TMS). The chemical shifts

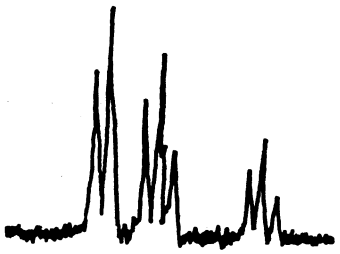


Fig. 1. The spectrum in the region of aromatic protons of the carbanion produced from 1, 1-diphenylethylene in contact with excess potassium sodium alloy in THF. Applied magnetic field increases from left to right, at 60 Mcps.

Table 1. The chemical shifts of aromatic protons of carbanions produced from 1, 1-diphenylethylene in contact with excess alkali metals in THF, in ppm at 60 Mcps

Metal used	Assignment		
	Ortho	Meta	Para
Potassium	7.01	6.55	5.67
Sodium	7.18	6.61	5.75
Lithium	7.03	6.49	5.66

between the ortho- and para-protons amount to about 1.4 ppm, but they are not sensitive to the kind of alkali metal. The chemical shift values shown in Table 1 exhibit shifts to a higher field as compared with that of benzene, which shows an absorption at 7.32 ppm in THF. Since the shift of about 10 ppm is assumed to be the contribution of one excess electron,[2] more than fifty per cent of the negative charge of the 1, 1-diphenylethylene dimer dianion might be located on the phenyl rings,[1] but this is only a rough estimate because we lack information on carbons with no protons and on methylene groups. In the solutions of these carbanions, a single peak is observed near 2.5 ppm, just between two large solvent peaks. The 1, 1, 4, 4-tetraphenylbutane which was prepared by treating these carbanions with water shows PMR signals at 2.00, 3.88, and 7.14 ppm in a carbon tetrachloride solution; these signals are identified as coming from the methylene, methine, and phenyl protons in this compound respectively. From this knowledge, the peak at 2.5 ppm mentioned above might be assigned as coming from the methylene protons in the carbanion. If this assignment is correct, one interesting point is the shift towards a lower field of the methylene protons of the carbanion as compared to those of the corresponding hydrocarbon; this shift can not be attributed to the charge, but it may be due to the change in the hybridization of the carbon atom from the hydrocarbon to the carbanion.

The carbanions produced from α-methylstyrene and cumyl methyl ether also showed large higher-field shifts in the aromatic regions of the spectra. These will be described later elsewhere.

The Reaction of Disulfides with Dinitrogen Tetroxide

Norio KUNIEDA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received May 4, 1967)

Dinitrogen tetroxide displays a unique feature in various oxidation processes. It can restrict a reaction to a single oxidation stage, when further oxidation still appears to be possible. Several workers have, therefore, used this reagent for the oxidation of alkyl,[1] aryl,[2] and alicyclic[3] sulfides to the corresponding sulfoxides.

In this note, we would like to report the oxidation of several disulfides with this reagent; this oxidation was carried out in a manner similar to the oxidation of sulfides.[2] We expected that the oxidation of disulfides with this reagent would proceed to yield, successively, thiolsulfinates (RSO·SR), thiolsulfonates (RSO_2SR), and disulfones (RSO_2SO_2R), since such a step-by-step oxidation is known to take place in the oxidation reaction of disulfides with hydrogen peroxide[4] or peroxy acids.[5] However, when alkyl or aryl disulfides were allowed to react with an excess of dinitrogen tetroxide in carbon tetrachloride, only the corresponding sulfonic anhydrides were obtained in good yields; neither thiolsulfinates nor thiolsulfonates were obtained. The yields and melting or boiling points of the products are listed in Table 1.

These products were allowed to react with aniline to afford the corresponding sulfonanilides quantitatively. In an attempt to isolate a possible intermediate of this reaction, diethyl disulfide (7.0 g, 0.057 mol) was treated with an equimolar amount of dinitrogen tetroxide (5.2 g, 0.057 mol), but only ethanesulfonic anhydride (4.7 g) was thus obtained, together with the recovered disulfide (2.8 g); no other intermediary products could be detected.

We have also found that *p*-toluenesulfonic anhydride was obtained in a 94% yield when *p*-toluenethiolsulfinate was treated with an excess of this reagent in a manner similar to that used for the disulfides, but *p*-tolyl *p*-toluenethiolsulfonate and *p*-tolyl disulfone did not react with this reagent, even without a solvent.

In view of these results, it is not probable that the oxidation of disulfides with this reagent proceeds through a step-by-step oxidation involving the successive formation of thiolsulfonate, sulfinylsulfone, and disulfone, such as is the case with peroxy acids; rather, it appears to proceed in a fashion similar to that which Barnard has postulated for the ozonolysis of disulfides.[6] However, further investigation is necessary before we can obtain any clear understanding of the dinitrogen tetroxide oxidation.

Experimental

Materials. *Disulfides* were prepared by the oxidation of the corresponding mercaptans with iodine by the method described by McAllan.[10]

p-Tolyl p-Toluenethiolsulfinate was prepared by the reaction of *p*-tolyl mercaptan with *p*-toluenesulfinyl chloride. Mp 94—94.5°C, yield 92%.

p-Tolyl p-Toluenethiolsulfonate was prepared by the oxidation of di-*p*-tolyl disulfide with hydrogen peroxide. Mp 77—78°C, yield 86%.

p-Tolyl Disulfone was prepared by the reaction of sodium *p*-toluenesulfinate with *p*-toluenesulfonyl chloride. Mp 206—206.5°C, yield 83%.

Dinitrogen Tetroxide was prepared by the pyrolysis of dinitrogen pentoxide.[11]

Reaction of Disulfides with Dinitrogen Tetroxide. The carbon tetrachloride solution of dinitrogen tetraoxide was cooled under 0°C, then a solution of disulfides, in which the mole ratio of the disulfide to the dinitrogen tetroxide was 1 : 3—5, was added slowly. The mixture was kept standing for 2 hr under 0°C, and then warmed at 30—50°C for 2 hr. Finally the mixture was distilled under reduced pressure to remove the excess reagent and solvent. The residual crude products were distilled or recrystallized. Methane-, benzene-, *p*-toluene-, and *p*-chlorobenzenesulfonic anhydrides were recrystallized from ether-benzene.

Sulfonanilides. The sulfonic anhydrides were dissolved or suspended in dry ether into which two molar equivalent of aniline had been added, then the anilinium sulfonate thus formed was filtered off. In this manner the sulfonanilides were obtained from the filtrate in good yields. ($C_6H_5NHSO_2R$); (R, mp(°C) (Lit)); (CH_3, 99(96)[12]), (C_2H_5, 59—60(55)[12]), (C_6H_5, 108.5 (112)[13]), (*p*-CH_3-C_6H_4, 101—102(101—102.5)[14]), (*p*-Cl-C_6H_4, 104.5 (105.5)[15]).

The Reaction of *p*-Tolyl *p*-Toluenethiolsulfinate with Dinitrogen Tetroxide. *p*-Tolyl *p*-toluenethiolsulfinate was reacted with 4.6 times the molar quantity of dinitrogen tetroxide in the same treatment as that used for disulfides. The anhydride was thus obtained in a 94% yield; mp 130—130.5°C.

Sesquiterpene Hydrocarbons of the Essential Oil of the Kusunoki (*Cinnamomum Camphora Sieb.*)

Shûichi HAYASHI, Nanao HAYASHI, Katsumi YANO, Masayoshi OKANO and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received May 9, 1967)

The investigation concerning sesquiterpene constituents of camphor oil was first undertaken by workers at Schimmel & Co., who detected bisabolene[1] and cadinene;[2] it was then continued by many workers. In this way, caryophyllene was identified by Simonsen,[3] α-santalene by Kato,[4] and α-humulene and nerolidol by Hirota,[5] while recently cadina-9, 11(12)-diene has been detected by Araki.[6] Further, Ono,[7] Komatsu[8] and Kafuku[9] have pointed out the presence of new sesquiterpene constituents characteristic of camphor oil.

The present study was made of a high-boiling fraction of camphor oil commercially obtained. Nine newly-found constituents, α-ylangene, β-elemene, β-santalene, δ-guaiene, δ-cadinene, calamenene, calacorene, 1, 6-dimethyl-4-isopropyl-7, 8-dihydronaphthalene, and γ-patchoulene, and four formerly-detected constituents, caryophyllene, α-santalene, α-humulene, cadina 9, 11(12)-diene, were identified. α-Santalene, α-ylangene, β-santalene, and δ-cadinene are the main constituents, each amounting to more than ten per cent, while cadina-9, 11(12)-diene, which was detected as a main constituent by Araki,[6] was very little in quantity. It was the first case of the detection of 1,6-dimethyl-4-isopropyl-7,8-dihydronaphthalene in a natural product. The bisabolene previously reported and the constituents whose structures were

Experimental

The high-boiling fraction (bp above 215°C, 6135 g) of camphor oil, after being treated with 3% aqueous solutions of sodium carbonate and of sodium hydroxide successively, was distilled under reduced pressure; the sesquiterpene hydrocarbon fraction (bp 85—145°C/2 mmHg) was thus obtained. By repeating the precise fractionation with a packed-type distillation column, and the adsorption chromatography on an alumina or silica gel column using *n*-hexane, the hydrocarbon fraction was separated into individual hydrocarbons; these hydrocarbons were identified as will be described below.

α-Ylangene (17.7%).*1 Found: C, 88.39; H, 11.61%. Calcd for $C_{15}H_{24}$: C, 88.16; H, 11.84%. The constituent consumed one equivalent of hydrogen in catalytic hydrogenation with platinum oxide in glacial acetic acid. The IR[10] and NMR[11] spectra of the original hydrocarbon coincided with those of α-ylangene; this spectrometric result was also supported by a gas chromatographic comparison with authentic α-ylangene.

β-Elemene (5.0%). The constituent ($[\alpha]_D^{25}$ −21.0°) showed IR[12] and NMR[13] spectra, and the gas chromatogram agreed with those of β-elemene.

α-Santalene (34.8%). Found: C, 87.85; H, 11.71%. Calcd for $C_{15}H_{24}$: C, 88.16; H, 11.84%. This hydrocarbon ($[\alpha]_D^{25}$ +11.1°) had a molecular weight of 204 (mass spectrometry, Fig. 1-A), and its IR[14] and NMR[15] spectra agreed with those of α-santalene. Besides, a nitrosochloride of colorless needles melted at 115—115.5°C, thus corresponding to α-santalene nitrosochloride.[16]

β-Santalene (12.0%). Found: C, 88.30; H, 11.70%. Calcd for $C_{15}H_{24}$: C, 88.16; H, 11.84%. The molecular weight of this hydrocarbon was 204 (mass spectrometry, Fig. 1-B). Its IR[14] and NMR[15] spectra showed a good agreement with those of β-santalene.

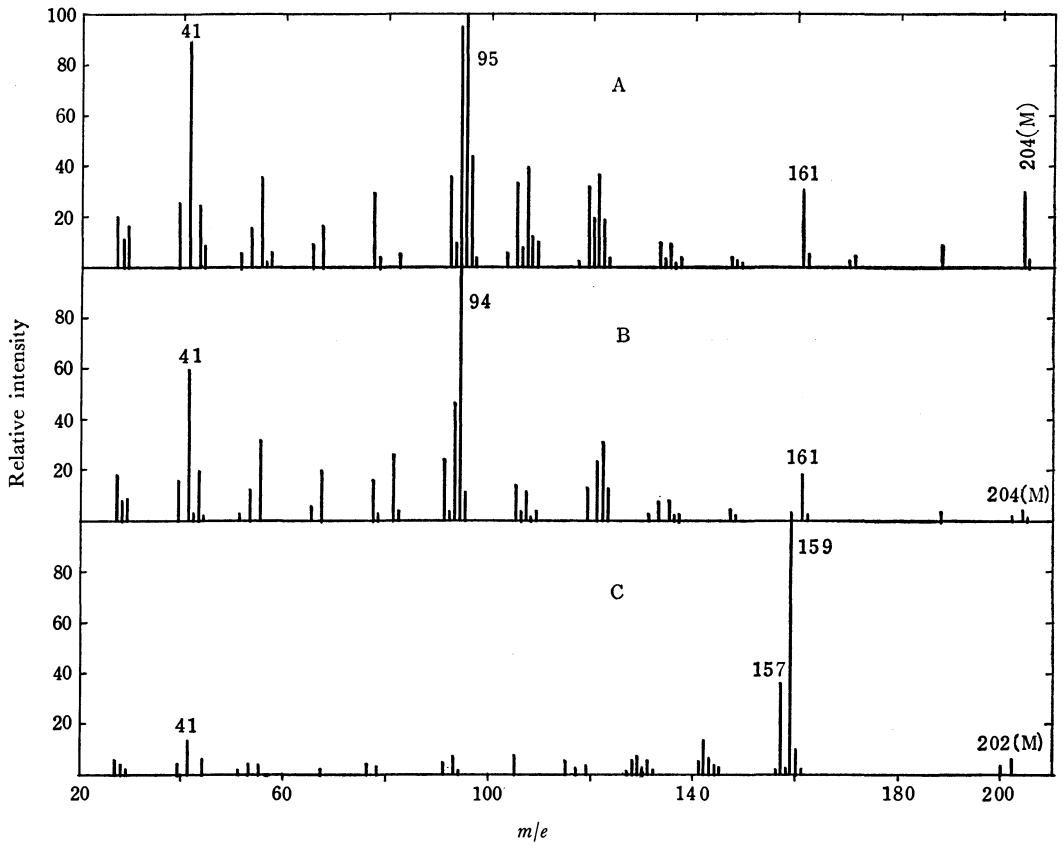

Fig. 1. Mass spectra of α-santalene (A), β-santalene (B) and calamenene (C).

*1 The content (%) of each constituent was calculated from the relative peak area of the gas chromatogram, which was obtained by use of a Golay Apiezon-L column at 150°C, and which showed 21 peaks, including 8 unidentified ones.

16) M. Guerbet, *Compt. Rend.*, **130**, 417, 1324 (1900).

α-Humulene (2.5%). The constituent had the same IR spectrum as that of α-humulene,[17] and the gas chromatograms of the constituent and α-humulene were identical.

δ-Guaiene (0.2%). The constituent was dehydrogenated by heating with sulfur and produced s-guaiazulene in a good yield. The IR spectrum and the gas chromatogram of the constituent agreed with those of δ-guaiene,[18] and the NMR spectrum, which has two broad singlets at 5.36—5.62 τ (2H, exocyclic methylene) and two near-singlets at 8.37 τ (6H, two methyl groups attached to double bonds,) supported the structure of δ-guaiene well.

δ-Cadinene (11.2%). Found: C, 88.35; H, 11.58%. Calcd for $C_{15}H_{24}$: C, 88.16; H, 11.84%. $[\alpha]_D^{25}$ +24.54°, molecular weight 204 (mass spectrometry). The IR,[19] NMR,[20] and mass spectra[21] agreed with those of δ-cadiene. This hydrocarbon produced cadinene dihydrochloride; 116—116.5°C, confirmed admixing.

Calamenene (2.5%). When the residue of the precise fractional distillation was chromatographed on a silica-gel adsorption column using petroleum ether as the solvent, calamenene, calacorene, and 1, 6-dimethyl-4-isopropyl-7, 8-dihydronaphthalene were eluted in this order. The first-eluted constituent ($[\alpha]_D^{25}$ −44.0°) had a molecular weight of 202 (mass spectrometry, Fig. 1-C). The IR[22] and NMR[23] spectra and the gas chromatogram were the same as calamenene.

Calacorene (0.4%). $[\alpha]_D^{25}$ +15.40°. The IR[19] and UV[19] spectra agreed with those of calacorene, and the NMR spectrum, which has a singlet at 7.74 τ (3H, a methyl group on a double bond conjugated with a benzene ring) and a doublet at 8.05 τ (3H, methyl group), fit the structure of calacorene well.

1, 6-Dimethyl-4-isopropyl-7, 8-dihydronaphthalene (0.3%). The IR and UV spectra of this constituent agreed with those of 1, 6-dimethyl-4-isopropyl-7, 8-dihydronaphthalene.[24]

Caryophyllene (3.0%), **γ-Patchoulene** (0.6%), **and Cadina-9, 11(12)-diene** (2.3%) were identified only by depending upon a gas chromatographic comparison with authentic specimens using a Golay Apiezon-L column.

The authors are indebted to Professor Shô Ito of Tohoku University for his measurement of the NMR spectra and Mr. Hiroshi Sato of the Hitachi Co., Ltd., for his measurement of the mass spectra.

Synthesis of Adamantane Derivatives. I. Application of the Ritter Reaction to 1-Bromoadamantane

Tadashi SASAKI, Shoji EGUCHI and Takeshi TORU

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received May 15, 1967)

The Ritter reaction is known to be an excellent method for the preparation of amides from tertiary alcohols, tertiary halides, or olefins.[1] Recently adamantane derivatives have attracted much attention, for the practical purpose of their pharmacological activity[2] and for their theoretical interest for organic chemists.[3] Stetter *et al.* have used the Ritter reaction to prepare *N*-1-adamantylacetamide from 1-bromoadamantane and acetonitrile[4]; more recently Haaf has reported a modified procedure, in which adamantane has been directly amidated in the presence of tertiary carbonium ions with hydrogen cyanide.[5] From our repetition of the above two methods, we found that Haaf's method always gave many by-products, which caused a lowering of the yield of the main product, and that, furthermore, the procedure of Haaf's method was more complicated than that of Stetter's. From these reasons we chose 1-bromoadamantane, easily obtainable from adamantane,[6] as the starting material.

Results and Discussion

The formation of amides by the Ritter reaction of 1-bromoadamantane can be explained by the following reaction scheme:

$$\underset{\text{I}}{\text{Ad-Br}} + H_2SO_4 \rightleftarrows \underset{\text{II}}{\text{Ad}^{\oplus}HSO_4^{\ominus}} + HBr \quad \text{(a)}$$

$$\underset{\text{II}}{\text{Ad}^{\oplus}HSO_4^{\ominus}} + RCN \rightleftarrows \underset{\text{III}}{\text{Ad-N=C}^{\oplus}\text{-R}\cdot HSO_4^{\ominus}} \quad \text{(b)}$$

$$\underset{\text{III}}{\text{Ad-N=C}^{\oplus}\text{-R}\cdot HSO_4^{\ominus}} + H_2O \rightarrow \underset{\text{IV}}{\text{AdNHCOR}} \quad \text{(c)}$$

Consequently, it might be expected that the formation of an intermediate adamantyl immonium ion complex, III, is a key factor in carrying

out the Ritter reaction successfully. However, it is known that 1-bromoadamantane is less reactive than other nonbridged tertiary halides because of the difficulty of forming the carbonium ion, II.[7] Since both reactions, (a) and (b), are thought to be reversible, the use of excess concentrated sulfuric acid and nitrile seems to favor the formation of II and, therefore, of III. In order to carry out the reaction homogeneously, liquid nitriles such as *n*-butyronitrile, isobutyronitrile, and benzonitrile were used as the solvents, but when nitriles could not be used as the solvents because of the solid state or low solubility of 1-bromoadamantane, *n*-butyl ether, glacial acetic acid or their mixture was used as the solvent. All of the results, including the products, are summarized in Table 1. From this table it may be seen that most amides were prepared in good yields, but the reactions with some nitriles which have strong electron-withdrawing groups, such as dicyandiamide, cyanoacetamide, and acetaminonitrile, were not successful. This fact can be explained by the lowered electron density of the nitrile group and, thus, the smaller affinity with the adamantyl carbonium ions. When 1-bromoadamantane was treated with acrylonitrile in concentrated sulfuric acid, many side reactions were observed involving polymerizations, from which none of the expected acrylamide derivatives could be separated. However, when the reaction was carried out in acetic acid by using a mixture of concentrated sulfuric acid and boron trifluoride etherate as a catalyst at 40°C, the desired *N*-1-adamantylacrylamide was obtained in a yield of 84%.

7) P. von R. Schleyer and R. Nicholas, *J. Am. Chem. Soc.*, **83**, 2700 (1961).

Experimental

The microanalyses were performed on a Yanagimoto C. H. N. Corder, Model MT-1, while the IR spectra were obtained on a JASCO Model IR-S infrared spectrophotometer. All the melting points were measured on a Yanagimoto micromelting-point apparatus and are uncorrected.

General Procedure of the Ritter Reaction. The reaction was carried out at room temperature by using an excess of nitrile and of concentrated sulfuric acid to 1-bromoadamantane. After making sure by the thin-layer chromatography that no more 1-bromoadamantane existed in the reaction mixture, the mixture was poured onto cracked ice-water and the product was extracted with ether. The ether layer was dried over anhydrous sodium sulfate and evaporated to dryness to give a crude amide. Crude amide was usually purified by recrystallization from aqueous methanol, and in some cases by chromatography on a silica-gel column. The results are summarized in Table 1. Table 2 shows the analytical and some physical properties of these products.

Synthesis of Adamantane Derivatives. II.[1] Preparation of Some Derivatives from Adamantylacetic Acid

Tadashi SASAKI, Shoji EGUCHI and Takeshi TORU

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received July 31, 1967)

Adamantylacetic acid (I) was prepared in 1959 for the first time by Stetter and his co-workers[2] through the Arndt-Eistert rearrangement of the corresponding diazoketone; recently Bott and Hellmann[3] have prepared it in good yields directly from vinylidene chloride and 1-bromoadamantane, which is now commercially available.*1 The present paper will deal with the syntheses of some derivatives starting from adamantylacetic acid (I). Acid chloride II was obtained by stirring a mixture of I and thionyl chloride diluted with petroleum ether at room temperature for two days, since heating I with thionyl chloride without a solvent lowered the yield of II and some decomposition products were observed. II was an oily material exhibiting an infrared band at 1810 cm^{-1} (ν_{CO}) and was used for the following reactions directly, without any further purification.

The treatment of this crude II with an excess amount of ethereal diazomethane gave adamantyl acetyl diazomethane III as an oil (ν_{N_2} at 2160 cm^{-1} and ν_{CO} at 1630 cm^{-1}), which was identified by the formation of adamantylpropionyl anilide IV, mp 154—155°C, after irradiation in the presence of aniline. The reaction of II with such amines as ammonia and aniline gave the corresponding amides, in those cases Va and Vb respectively, in good yields.

The Hofmann reaction of Va with bromine and alkali afforded crystalline solids with mps of

1) Part I: T. Sasaki, S. Eguchi and T. Toru, This Bulletin, **41**, 236 (1968).

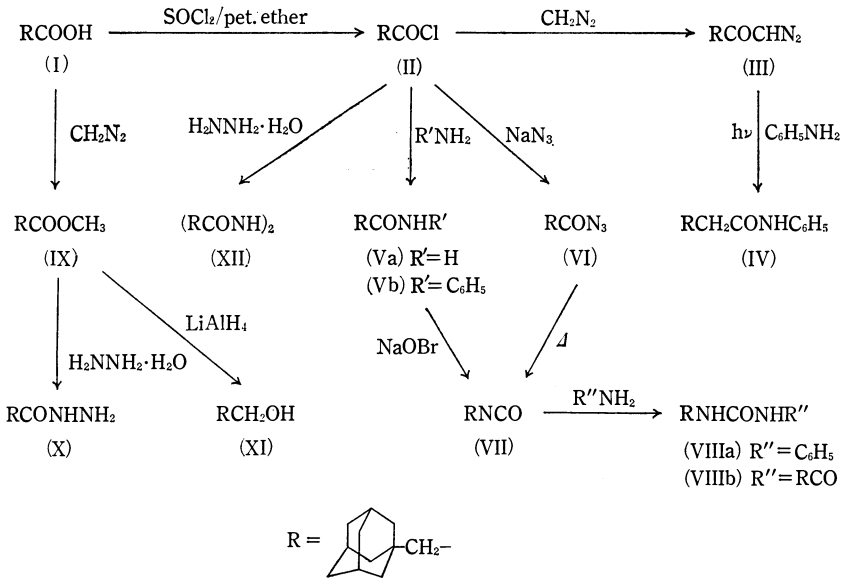
*1 Aldrich Cat. No. 967 (1967).



Scheme 1. Reactions of adamantylacetic acid.

254—255°C (dec.) in 76.5% yield based on I. The structure of this compound was identified as VIIIb on the basis of the results of the microanalysis and the infrared spectrum. The formation of the isocyanate (VII) as an intermediate was confirmed by the appearance in the course of the reaction of a band at 2280 cm^{-1} (ν_{NCO}) in the infrared spectrum of the reaction mixture, but it could not be isolated.

On the contrary, this isocyanate (VII) could be separated as an oil (ν_{NCO} at 2280 cm^{-1}) in a good yield by the Curtius rearrangement of acid azide VI, which was easily obtainable as an oil (ν_{N_3} at 2150 cm^{-1} and ν_{CO} at 1715 cm^{-1}) from II and sodium azide. The isocyanate structure of VII was confirmed by its conversion to the corresponding urea derivative, VIIIa, with aniline.

Acid chloride II and hydrazine hydrate afforded the corresponding bishydrazide XII, while methyl adamantylacetate IX and hydrazine hydrate gave monohydrazide X. The lithium aluminum hydride reduction of IX gave adamantylethanol XI with a mp of 73.5—75.0°C.

All of these results are summarized in Scheme 1.

Experimental

Microanalyses were performed on a Yanagimoto C. H. N. Corder Model MT-1, while the IR spectra were obtained on a JASCO Model IR-S infrared spectrophotometer. All the melting points were measured on a Yanagimoto micromelting-point apparatus and have not been corrected.

Adamantyl-1-acetamide (Va). Concentrated aqueous ammonia (11.0 m*l*) was, over a period of 30 min, stirred, drop by drop, into a stirred solution of II, prepared from 1.0 g of I, in 4.0 m*l* of dry tetrahydrofuran under cooling with ice-water. The stirring was continued for 6 hr, and then crystalline precipitates were filtered out. The addition of water to the filtrate gave the second crop. The combined precipitates were washed with water and dried to give 740 mg (74%*2) of Va. Repeated recrystallizations from aqueous methanol gave an analytical sample with a mp of 180°C.

ν_{max}^{KBr} 3360 (NH), 3200 (NH), 1660 (amide-I) and 1628 (amide-II) cm^{-1}.

Found: C, 72.00; H, 9.82; N, 6.85%. Calcd for $C_{12}H_{19}ON \cdot \frac{1}{2}H_2O$: C, 71.24; H, 9.97; N, 6.92%.

Hofmann Reaction of Va. Into an ice-cooled bromine-alkali reagent, freshly prepared from 1.0 g of bromine, 1.0 g of sodium hydroxide, and 10 m*l* of water, 0.5 g of Va was stirred. The temperature was then slowly raised to 80°C over a 3.5-hr period and kept there for 10 min. After cooling, the separated solids were filtered and washed with water. Recrystallization from chloroform-petroleum ether (bp 38—65°C) gave pure VIIIb, 380 mg (76.5%*2), mp 254—255°C.

ν_{max}^{KBr} 3300 (NH), 3240 (NH), 3120 (NH), 1685 (amide-I) and 1565 (amide-II) cm^{-1}.

Found: C, 74.82; H, 9.56; N, 7.34%. Calcd for $C_{24}H_{36}O_2N_2$: C, 74.96; H, 9.44; N, 7.29%.

Adamantyl-1-acetanilide (Vb). A mixture of II, prepared from 0.5 g of I, 0.5 g of aniline, and 20 m*l* of dry benzene, was refluxed for 15 min. The cooled reaction mixture was washed with 5% hydrochloric acid and then with water, and dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was recrystallized from methanol to give 0.4 g (71%*2) of Vb, mp 195—196°C.

ν_{max}^{KBr} 3280 (NH), 3050 (phenyl CH), 1660 (amide-I), 1605 (phenyl C=C) and 1548 (amide-II) cm^{-1}.

Found; C, 79.90; H, 8.22; N, 4.98%. Calcd for $C_{18}H_{23}ON$: C, 80.25; H, 8.61; N, 5.20%.

*2 All yields are based on I.

***N, N'* - Bisadamantyl - 1 - acetohydrazide (XII).** Into an ice-cooled solution of 1.6 g of 80% hydrazine hydrate in 1.0 m*l* of tetrahydrofuran was stirred and stirring was continued for 7 hr at room temperature, and then the mixture was allowed to stand in a refrigerator overnight. The deposited solids were then filtered and recrystallized from methanol to give pure XII, 380 mg (71%*[2]), mp 268—269°C.

ν_{max}^{KBr} 3200 (NH), 1680 (shoulder, CO), 1640 (shoulder, CO), 1610 (CO) and 1520 (NH) cm^{-1}.

Found: C, 74.51; H, 9.36; N, 7.20%. Calcd for $C_{24}H_{36}O_2N_2$: C, 74.96; H, 9.44; N, 7.29%.

Acid Azide VI and Its Curtius Rearrangement. Into a solution of II, prepared from 0.5 g of I, in 2 m*l* of acetone, a solution of 2.0 g of sodium azide in 5 m*l* of water was stirred. Stirring was continued for 2 hr at room temperature. The reaction mixture was then diluted with 15 m*l* of water and extracted with ether (30 m*l*×2). The combined ether extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated to give an oil which had an infrared band at 2290 cm^{-1} (weak, ν_{NCO}) as well as one at 2160 cm^{-1} (strong, ν_{N_3}); the appearance of the former band shows that the rearrangement had already occurred during the procedure. To complete the rearrangement, this crude azide was heated in dry benzene for 1 hr. The infrared spectrum of the oil after the removal of the solvent had a very strong band at 2290 cm^{-1} (ν_{NCO}), while the band at 2160 cm^{-1} (ν_{N_3}) had almost completely disappeared.

A half amount of this oil was treated with 0.15 m*l* of aniline in *n*-hexane at room temperature for 13 hr. The precipitates were then filtered to give 200 mg (55%*[2]) of crude VIIIa. Recrystallization from methanol gave an analytical sample, mp 172—173°C.

ν_{max}^{KBr} 3340 (NH), 3050 (phenyl CH), 1645 (amide-I) and 1570 (amide-II) cm^{-1}.

Found: C, 75.91; H, 8.78; N, 10.01%. Calcd for $C_{18}H_{24}ON_2$: C, 76.02; H, 8.51; N, 9.85%.

Adamantyl-1-propionanilide (IV). A solution of II, prepared from 0.5 g of I, in 10 m*l* of ether was added to a solution of diazomethane in 100 m*l* of ether under ice-water cooling, after which the reaction mixture was allowed to stand for two days at room temperature. The solvent was stripped off *in vacuo*, and the residual oil, III, was characterized as having a diazoketone structure on the basis of the infrared absorptions at 2100 (ν_{N_2}) and 1625 (ν_{CO}) cm^{-1}. III and 0.7 g of aniline were dissolved in 100 m*l* of anhydrous benzene, and the mixture was irradiated with a 100-W high-pressure mercury lamp (Ushio, UM-102) through a quartz cooler in a nitrogen stream at room temperature. After 9 hrs' irradiation, the solution was washed successively with 10% hydrochloric acid, 5% sodium hydroxide, and then water. The solution was dried over anhydrous sodium sulfate, and the benzene was distilled off *in vacuo*. The residual brown oil was triturated with 10 m*l* of *n*-hexane to give white crystals. The isolated solids were dissolved in 50 m*l* of ethanol, and the solution was treated with active charcoal. The solvent was distilled off *in vacuo*, and the residue was recrystallized from methanol to afford colorless needles, 100 mg (14%*[2]), mp 154—155°C.

ν_{max}^{KBr} 3240 (NH), 3029 (phenyl CH), 1655 (amide-I), 1600 (phenyl C–C) and 1555 (amide-II) cm^{-1}.

Found: C, 80.32; H, 8.74; N, 5.06%. Calcd for $C_{19}H_{25}ON$: C, 80.52; H, 8.89; N, 4.94%.

Adamantyl-1-ethanol (XI) from I *via* IX. To an ethereal solution of diazomethane, a solution of 0.5 g of I in 20 m*l* of ether was gradually added. The solution was allowed to stand overnight at room temperature, and then the ether was removed *in vacuo* to give a colorless oil, which was characterized as IX on the basis of the infrared band at 1730 (ν_{CO}) cm^{-1}. All of this oil was dissolved in 50 m*l* of dry ether, and then 1.1 g of lithium aluminum hydride was added to the solution. The reaction mixture was then stirred overnight at room temperature and diluted with 50 m*l* of water. The aqueous solution was acidified with concentrated hydrochloric acid and extracted with ether. The ether extract was washed with water and dried over anhydrous sodium sulfate. The ether was removed to give colorless crystals, 340 mg (73.2%*[2]). Recrystallization from *n*-hexane gave an analytical sample, mp 73.5—75.0°C.

ν_{max}^{KBr} 3300 (OH), and 1047 (CO) cm^{-1}.

Found: C, 79.91; H, 11.11%. Calcd for $C_{12}H_{20}O$: C, 79.94; H, 11.18%.

Adamantyl-1-acetohydrazide (X). A mixture of the crude methyl ester, prepared from 0.5 g of I, 0.2 m*l* of 80% hydrazine hydrate and 0.2 m*l* of water, was heated at 95—100°C for 9 hr and then at 110—120°C for 1 day in a sealed tube. After cooling, a 50 m*l* portion of water was added to the reaction mixture and the separared crystals were filtered and recrystallized from methanol to give white granular crystals of X, 390 mg (73%*[2]), mp 113—118°C.

ν_{max}^{KBr} 3280 (NH), 1640 (amide-I) and 1520 (amide-II) cm^{-1}.

Found: C, 68.85; H, 10.11; N, 13.04%. Calcd for $C_{12}H_{20}ON_2$: C, 69.19; H, 9.68; N, 13.45%.

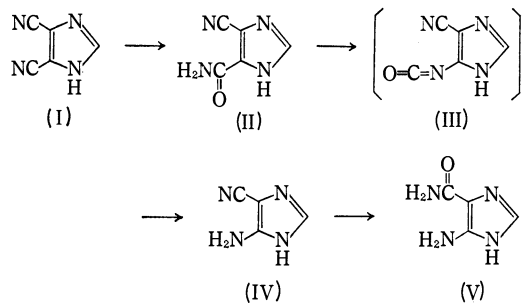
Synthesis of 4-Amino-5-imidazolecarbonitrile and 4-Amino-5-imidazolecarboxamide from 4, 5-Dicyanoimidazole[1]

Yoshitaka YAMADA, Izumi KUMASHIRO and Tadao TAKENISHI

Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki

(Received June 5, 1967)

In a previous communication,[2] we have reported that adenine and 4, 5-dicyanoimidazole were formed by heating anhydrous hydrogen cyanide, or an equivalent mixture of sodium cyanide and ammonium chloride, in excess liquid ammonia. In the present paper, the synthesis of 4-amino-5-imidazolecarbonitrile and 4-amino-5-imidazolecarboxamide (AICA) from 4, 5-dicyanoimidazole will be reported. AICA is a useful synthetic intermediate of purine derivatives. It has been prepared by various methods, from, for example, 4-nitro-5-imidazolecarboxylic acid[3] or ethyl aminocyanoacetate[4], however, these methods are complicated and the overall yields are unsatisfactory. It has now been found that 4-amino-5-imidazolecarbonitrile and AICA can be readily prepared from 4, 5-dicyanoimidazole by the use of Hofmann's rearrangement reaction:



(I) (II) (III) (IV) (V)

Since 4, 5-dicyanoimidazole were found to be resistant to a boiling dilute aqueous solution of ammonia or hydrogen chloride, the partial hydrolysis of I to 4-cyano-5-imidazolecarboxamide (II) has been accomplished with a 1 N sodium hydroxide solution. II was treated with a 0.1 N solution containing 1.25 equivalents of sodium hypochlorite at 0°C for 30 min. A concentrated sodium hydroxide solution was then added so as to make 4 equivalents based on II, after which the reaction mixture was warmed at 80°C for 3 hr. The infrared absorption spectra of 4-amino-5-imidazolecarbonitrile (IV), which was isolated by the ion-exchange resin treatment, agreed well with those of an authentic sample.[5,6] By hydrolysis in a strongly basic medium at a higher temperature, IV was converted to AICA (V). When the intermediate (III), probably isocyanate, was hydrolyzed directly under drastic conditions, AICA could not be obtained successfully, but a tarry substance was found to be formed.

Experimental[7]

4-Cyano-5-imidazolecarboxamide (II). After a solution of 4, 5-dicyanoimidazole (30 g) in 600 m*l* of 1 N sodium hydroxide had been kept at 40°C for 6 hr, it was neutralyzed to pH 6 with concentrated hydrochloric acid. The solid precipitates, which were formed immediately, were filtered, washed with ice water, and recrystallized from hot water to give colorless needles. Yield: 31 g (90%); mp 272—273°C; infrared (CN) 2240, (amide CO) 1695 cm^{-1}; ultraviolet $\lambda_{max}^{pH\ 1}$ 253 mμ (ε 8.32×10^3); $\lambda_{max}^{pH\ 13}$ 274 mμ (ε 10.10×10^3).

Found: C, 44.25; H, 3.05; N, 41.25%. Calcd for $C_5H_4N_4O$: C, 44.12; H, 2.96; N, 41.17%.

4-Amino-5-imidazolecarbonitrile (IV). To a solution of 600 m*l* of 0.22 N sodium hydroxide, chlorine gas (1.28 *l*) was dissolved at 0°C. To this solution, II (6 g) was added at 0°C; the resulting solution was stirred at the same temperature for 30 min, and then 1.5 N sodium hydroxide (120 m*l*) was added to the reaction mixture. After being heated at 80—85°C for further 3 hr, the reaction mixture was passed through a column of Amberlite IR-120 (H^+ form). Then the column was washed with water and eluted with 3 N ammonium hydroxide. The eluate was decolorized and evaporated under reduced pressure to give the crude IV. This crude substance was recrystallized twice from hot water. Yield: 3.2 g (67%); mp 129—129.5°C; ultraviolet $\lambda_{max}^{pH\ 1}$ 237 mμ (ε 9.57×10^3) and 252 mμ (ε 8.27×10^3); $\lambda_{max}^{pH\ 13}$ 255 mμ (ε 1.08×10^4).

Found: C, 44.57; H, 3.98; N, 52.15%. Calcd for $C_4H_4N_4$: C, 44.44; H, 3.73; N, 51.83%.

The ultraviolet and infrared absorption spectra were

7) All the melting points are uncorrected. The ultraviolet and infrared absorption spectra were measured with Hitachi EPS-2 and JASCO model IR-S recording spectrophotometers.

identical with those of an authentic sample.

4-Amino-5-imidazolecarboxamide (V). An alkaline reaction mixture of IV was heated at 125—130°C for 6 hr in a sealed vessel and then passed through a column of Amberlite IR-120 (H^+ form). By treating the eluate as in the case of IV, 5.0 g (70%) of crude V were obtained. By recrystallization from dilute hydrochloric acid, the hydrochloride of V was obtained as colorless crystals, mp 254.5—255°C. Ultraviolet $\lambda_{max}^{pH\ 1}$ 242 mμ (ε 6.30×10^3) and 269 mμ (ε 8.66×10^3); $\lambda_{max}^{pH\ 13}$ 278 mμ (ε 1.06×10^4).

Found: C, 29.58; H, 4.42; N, 34.68%. Calcd for $C_4H_6N_4O\cdot HCl$: C, 29.55; H, 4.34; N, 34.46%.

The product was identified with those of an authentic sample by a study of the spectral data, the paper chromatographic behavior, and the mixed melting point.

The authors wish to express their deep thanks to Mr. Shinichi Motozaki, Director of the Central Research Laboratories, for his kind encouragement. The assistance of Mr. Takashi Zama throughout this work is also gratefully acknowledged.

Oxidative Decarboxylation of Phenylacetic Acid[1)]

Takao WATANABE, Naomichi FURUKAWA and Shigeru OAE

Department of Applied Chemistry Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received June 12, 1967)

The cuprous ion catalyzed oxidative decarboxylation of benzoic acid to phenol is not only useful but also an interesting reaction which recently has been shown to proceed through a cyclic 6-membered transition state by use of ^{14}C and ^{18}O tracer techniques.[2,3)] Meanwhile this procedure has been used to prepare various aromatic phenolic compounds from the corresponding carboxylic acids; such as substituted benzoic, naphthoic, and heteroaromatic carboxylic acids.[4)] Recently Bigot and his co-workers[5)] have shown the oxidative decarboxylation reaction of cyclohexanecarboxylic acid. Phenylacetic acid has been known to undergo a facile decarboxylation to give toluene[6)] and hence an interesting compound to study the nature of this intriguing oxidative decarboxylation. We have carried out the oxidative decarboxylation of phenylacetic acid catalyzed by cuprous oxide, expecting to obtain either *o*-cresol, benzyl alcohol or diphenylethane. However we found that the reaction is more complicated and gives a variety of products. This paper will describe the detailed accounts of our investigation.

Results and Discussion

The apparatus used for the decarboxylation reaction was the same as the one described previously.[3)] The reaction was found to begin at around 180°C. The products isolated were characterized by comparing the IR and NMR spectra with those of the authentic samples. The products initially came out from the reaction vessel were benzaldehyde and carbon dioxide, both of which were trapped as the bisulfite adduct and barium carbonate, respectively. From the residue were isolated the following three neutral products I, II, III, the structures of which were characterized by IR and NMR spectra. The compounds I and II were actually synthesized by the procedures as was found to be identical,[7,8)] while the structure of the compound III was suggested based on the NMR spectrum and other evidences. However neither cresol nor other hydroxy compound could be isolated among the products. The products and yields are tabulated in Table 1.

The reaction is undoubtedly catalyzed by copper metal since most phenylacetic acid were recovered without copper catalyst. (Run 9). The presence of oxygen is also important because no products isolated when the reaction was carried out under nitrogen stream. (Run 7). Although benzaldehyde was isolated, diphenylethane and toluene were not found among the products, apparently suggesting that benzyl radical is not the intermediate in this reaction and that the reaction proceeds through ionic mechanism. Recently, Cohen *et al.*,[9)] have isolated I and II by the treatment of phenylacetic acid with pyridine-*N*-oxide

in addition to a few other products such as benzoylformic acid and benzaldehyde and suggested that benzoylformic acid might be the key intermediate, while, in this, the copper ion catalyzed decarboxylation, benzoylformic acid might be postulated as the key intermediate, the formation of which is

illustrated by either radical or ionic mechanism. The whole reaction may be schematically shown as below. (Fig. 1)

Experimental

The Decarboxylation. A typical example of the reaction is as follows.

Phenylacetic acid (8.98 g) was mixed with 0.16 g of cuprous oxide and 0.37 g of magnesium oxide and then the whole mixture was placed into the reactor and heated with an electric muffle heater with slowly introducing air while keeping the temperature at 195—205°C for 6.5 hr. Benzaldehyde and carbon dioxide eluted were trapped with sodium bisulfite and barium hydroxide, respectively. After the reaction, the residue remaining in the vessel was extracted with ether and washed with water. Ether extract was washed with dilute hydrochloric acid, and then with water and sodium carbonate solution. The ether layer was dried over magnesium sulfate. When ether was removed, red brownish oil (1.67 g) was obtained. Keeping the oil in cold, the crystals appeared. To this crystals ether was added and collected the crystals on a filter paper. Then the ether was removed from the mother liquor and the second crop of the crystals was obtained. Thus, by repeating this operation, three different products were isolated.

The weight and melting point of I, II, III, were, I, 0.03 g, mp 159—160°C (from benzene - *n*-hexane); II, 0.15 g mp 178—179°C (from benzene - *n*-hexane); III, 0.78 g, mp 211.5—212.5°C (from benzene or ethanol). The product I was identified from its mp and IR of that of the authentic 1, 2-diphenylmaleic anhydride which was prepared from benzaldehyde and phenylacetonitrile and sodium cyanide.[7] The product II, having slightly yellow color, IR absorption at 1765 cm^{-1} was identified as 5-oxo-3, 4-diphenyl-2-benzaldihydrofuran II which was prepared authentically from heating a mixture of I and phenylacetic acid with sodium acetate at 230°C for 2 hr.[8]

The product III, IR spectrum 1775, 1813 (doublet; lactone carbonyl) and 1150 cm^{-1} (anhydride); molecular weight determination. Calcd 342, Found, 336—343. Elemental analysis: Found: C, 81.04, H, 4.98%. Calcd: C, 80.68, H; 5.30%. The NMR spectrum of III has methylene quartet centered at 5.70 ppm and complex multiplet centered at 2.75 ppm in which benzene protons and highly deshielded methine proton are involved.

The pyrolysis of II led to 1, 2-diphenylmaleic anhydride which upon the treatment with phenylacetic acid in the presence of the catalyst at 200°C regenerating III. These experimental evidences showed that the products had a five membered lactone ring and three benzene ring involving methylene, thus III was suggested to have the structure of benzylsuccinic anhydride.

Studies of Poly-2-vinylpyridine. IV. Crystalline Bands in the Infrared Absorption Spectrum of Stereospecific Poly-2-vinylpyridine

Shizuo ARICHI

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received June 12, 1967)

In 1960, Natta and others[1,2] reported systematic studies of the method and mechanism of the stereospecific polymerization of 2-vinylpyridine, and also of some properties of the polymer. They made use of the diffraction of X-rays as a direct method for the characterization of the crystals of poly-2-vinylpyridine. They also confirmed that the crystallized polymers are insoluble in hot acetone. However so far as this polymer is concerned, no method in which the infrared absorption spectrum is used for the characterization of the crystals has yet been reported. The present author has recognized that there are distinct absorption bands in the infrared spectrum at the wave numbers of 928 and 1180 cm^{-1}, which are characteristic of crystallized poly-2-vinylpyridine.

The stereospecific polymerization of 2-vinylpyridine and the purification of the polymer were carried out according to the method of Natta and others.[2] In the polymerization, phenylmagnesium bromide was used for the catalyst, and toluene for the diluent. A series of isotactic poly-2-vinylpyridines was then obtained by the same procedure, but by varying the concentrations of the catalyst and the polymerization temperatures. The crystallization of the polymer was effected by first maintaining the amorphous polymer for seven hours at 155—157°C under a nitrogen atmosphere, and by then treating the whole polymer in hot acetone. The polymerization conditions and some properties of the polymer, S-3, which was mainly used in this study are summarized in Table 1. As for the atactic, noncrystallizable poly-2-vinylpyridine, which was used for comparison, the G-2 fraction, described in the preceding paper,[3] was used.

TABLE 1. THE POLYMERIZATION CONDITION AND THE PROPERTIES OF ACETONE INSOLUBLE FRACTION OF STEREOSPECIFIC POLY-2-VINYLPYRIDINE (SAMPLE No. S-3)

Monomer	C_6H_5MgBr	Toluene	Temp.	Time	Polymer	Yield	Acetone insoluble polymer				
							g/g of whole polymer %	Melting point °C	$[\eta]^{25°}_{benzene}$ dl/g	$[\eta]^{25°}_{methanol}$ dl/g	M_w by light scattering meas.
50 g	7.29 g	500 g	45°C	4 hr	45 g	90%	96.1	190—195	0.182	0.293	12.3×10^4

The Geiger-counter registration of the X-ray diffraction spectrum for the acetone-insoluble fraction of S-3 is shown in Fig. 1, and the photograph of the Debye-Scherrer ring for the same fraction, in Fig. 2. The crystal structure of S-3, characterized by an identity period of about 6.7 Å, which was estimated from Fig. 1, is essentially in accordance with the one reported by Natta and others.[2] When the same X-ray examination was carried out of the atactic poly-2-vinylpyridine, G-2, neither peak nor ring such as is seen in Fig. 1 and Fig. 2 was observed.

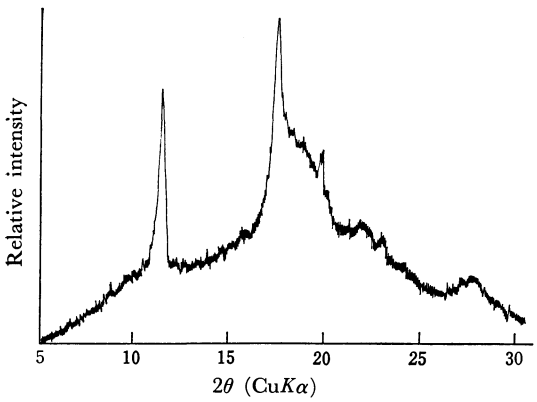

Fig. 1. Geiger counter registration of X-ray diffraction spectrum of the crystalline poly-2-vinylpyridine.

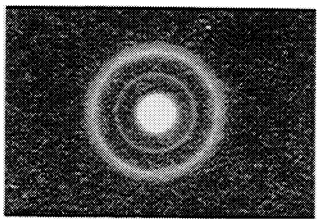

Fig. 2. Photograph of Debye-Scherrer ring for the crystalline poly-2-vinylpyridine.

The infrared absorption spectra of the crystallized poly-2-vinylpyridine, S-3, and the atactic poly-2-vinylpyridine, G-2, measured in the form of KBr pellets, are shown in Fig. 3. The characteristic absorption bands, shown in this figure, are observed in the spectrum of crystallized poly-2-vinylpyridine, S-3, at the wave numbers of 928 and 1180 cm^{-1}. These bands had been observed in the S-3 sample, neither before it was treated for crystallization nor when the acetone-soluble films which were prepared from a methanol or benzene solution of the S-3, sample, were examined without treatment for crystallization. The bands were, nevertheless, observed when the films had been treated in decalin at 120—130°C and proved to be acetone-insoluble.

The experimental results may allow us to conclude, at least qualitatively, that the characteristic absorption bands, especially the one at 928 cm^{-1},

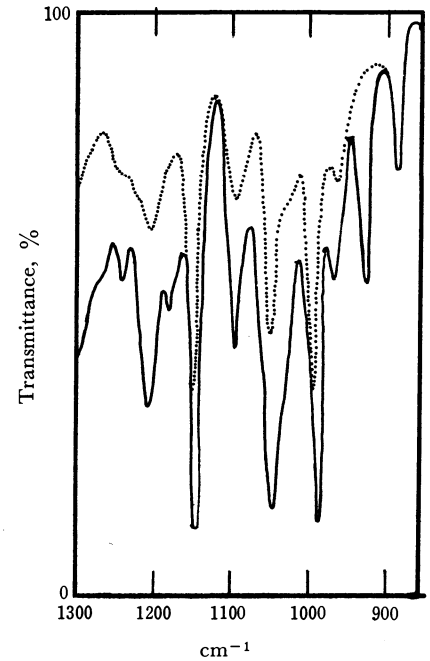

Fig. 3. Infrared absorption spectra of the crystalline (——), and atactic, (·····), poly-2-vinylpyridine.

can be used as an indicator of the degree of the crystallization of isotactic poly-2-vinylpyridine. The bands may even be useful in confirming the tacticity of poly-2-vinylpyridine.

In spite of various attempts, we have not yet been successful in detecting any dichroism in the infrared absorption spectrum of the stereospecific poly-2-vinylpyridine. Further investigations of the quantitative relationship between the degree of crystallization and the intensity of the bands at 928 cm^{-1} in the absorption spectrum are in progress.

An Analysis of Long-term Observations of ^{90}Sr Deposition*1

Takeshi SOTOBAYASHI, Toshio SUZUKI and Yukio KANDA

Department of Chemistry, Faculty of Science, Niigata University, Niigata

(Received June 19, 1967)

Measurements of the monthly deposition rate of ^{90}Sr and its time variation[1] have been made on a long-term scale of several years in our laboratory in order to estimate the cumulative deposition of ^{90}Sr per unit area and obtain more detailed information on its geochemical behavior in the atmosphere. We have recently discussed the ^{90}Sr fallout from surface and underground nuclear tests,[2] and, even more recently, the geochemical behavior of fresh nuclear debris of a known origin,[3] on the basis of radiochemical data for ^{89}Sr and ^{90}Sr. In the present paper we will make a brief analysis of our long-term observations of ^{90}Sr, a representative long-lived and hazardous fission product; further, we will estimate the cumulative deposition of ^{90}Sr per unit of area per unit of the activity produced by a series of atmospheric nuclear fission events.

Results and Discussion

More than 4 years after the termination of the atmospheric nuclear tests of 1961—62, measurable amounts of ^{90}Sr activity have been still detected in rain and ground-air samples at Niigata, although the yearly fall-rate had by 1966 lowered to one-eighth that of 1963. Table 1 shows the monthly deposition of ^{90}Sr per unit of area (mCi/km^2) and the monthly mean specific activity in precipitation (pCi/mm) during 1965—66. As can be seen in Table 1, a peak in the monthly deposition rate was observed in March for both years, while the peaks of the specific activity were in March for 1965 and in April for 1966; in 1966 the maximum values of the deposition rate and the specific activity decreased by 40 and 45 per cent respectively compared to those in 1965. The minimum deposition rates for both 1965 and 1966 were obviously found in August, but the 1966 rate dropped to 50 percent of that of 1965; the minimum specific activity in 1965 was clearly found in September, but in 1966 the specific activity ranged from 0.5 to 0.7 pCi/mm, with no definite trend observable during the period from July to December; it was difficult to determine which month of the year had a minimum value. Such a unique pattern of the specific activity remaining rather constant during the 4th quarter of a year was here observed for the first time since the beginning of our measurement of fallout activities.*2

Table 1. Monthly deposition of ^{90}Sr and its specific activity at Niigata during 1965—1966

Month of collection	1965		1966	
	Monthly deposition mCi/km^2	Specific activity pCi/mm	Monthly deposition mCi/km^2	Specific activity pCi/mm
Jan.	0.81	3.9	0.21	2.4
Feb.	0.60	5.9	0.27	2.5
Mar.	0.86	11.6	0.35	3.3
Apr.	0.21	3.9	0.33	5.2
May	0.74	6.0	0.29	2.5
June	0.38	2.4	0.26	2.4
July	0.43	1.2	0.19	0.5
Aug.	0.06	1.5	0.03	0.6
Sept.	0.11	0.8	0.11	0.5
Oct.	0.19	1.4	0.14	0.5
Nov.	0.24	1.2	0.15	0.7
Dec.	0.37	1.2	0.12	0.5

Table 2 shows the yearly total of ^{90}Sr deposition per unit of area and the ratio between the two yearly totals of two consecutive years, namely, the yearly decrease rate, during the periods of 1960—61 and 1964—66, together with the yearly amount of rainfall. The decrease rate for 1960—61, 2 to 3 years after the termination of the 1957—58 test series, showed almost the same value as those for 1964—1965 and 1965—1966, 2 to 4 years after the 1961—62 test series. This finding would suggest that the decrease rate seems to have shown a nearly constant value of 0.5 more than one year after the end of each test series in spite of a number of differences in the actual test conditions, *e. g.*, the total energy yields and the altitude at which the nuclear explosions took place. Meanwhile, during the 1964—66 period there were 6 instances of radioactive air contamination at Niigata, resulting from 5 Chinese nuclear tests and an

*1 Presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.

2) T. Sotobayashi and S. Koyama, *Science*, **152**, 1059 (1966).
3) T. Sotobayashi, S. Koyama and T. Suzuki, This Bulletin, **40**, 1269 (1967).

*2 According to our long-term ivnestigation of detailed seasonal variation in the monthly ^{90}Sr deposition at Niigata, the monthly value usually showed an increasing trend from October to December of any given year. *Nippon Kagaku Zassi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **89**, 206 (1968).

accidental release of nuclear debris due to a Russian underground test,[4] but the contribution to the total by the ^{90}Sr originating from these tests was small; the percentages of contributions by the ^{90}Sr fraction newly arising from each nuclear detonation to the yearly total were estimated to be 0.7, 3.0, and 2.4 per cent for 1964, 1965, and 1966 respectively. (In this estimation the two respective ^{90}Sr fractions resulting from the May 14, 1965, and the December 28, 1966, tests have not been taken into account, because data for the former were unavailable and the latter made no significant contribution to the yearly total of ^{90}Sr in 1966.)

TABLE 2. THE YEARLY TOTAL OF ^{90}Sr DEPOSITION AND THE YEARLY DECREASE RATE

Year of collection	Yearly total of ^{90}Sr mCi/km^2	Rain fall mm	Decrease rate %
1960	1.67	1780	53
1961	0.88*	2030	
1964	9.35	1880	54
1965	5.00	1880	50
1966	2.48	1950	

* This figure represents a value corrected for the contribution from the ^{90}Sr fraction originating from the 1961—1962 test series.

Table 3 gives two 10 year total depositions of ^{90}Sr per unit of area after the end of each test series; they were evaluated on the assumption that the yearly deposition of ^{90}Sr originating separately from the 1957—58 and the 1961—62 tests would independently continue to decrease at a decrease rate of 0.5 for 1962—68 and 1967—72 respectively.

4) S. Koyama, T. Sotobayashi and T. Suzuki, *Nature*, **209**, 239 (1966).

TABLE 3. ESTIMATED TEN-YEAR TOTAL OF ^{90}Sr DEPOSITION AND ITS RATIO TO TOTAL ^{90}Sr ACTIVITY PRODUCED

Test series	Estimated 10-year total of ^{90}Sr per unit area, mCi/km^2	Total ^{90}Sr activity produced* MCi	Total ^{90}Sr deposition/ ^{90}Sr produced mCi/km^2/MCi
1957—1958	26	4.0	6.5
1961—1962	55	9.6	5.7

* U.S. Federal Radiation Council Data (Ref. 5)

The values obtained are approximately equal to the expected total deposition at Niigata of ^{90}Sr which would be derived separately from each of the two test series. Thus, from these figures, the ratio of a 10 year total of ^{90}Sr deposition per unit of area to an estimated total of ^{90}Sr activity[5] produced by each of the two test series (Table 3) was estimated to be 6.5 and 5.7 mCi/km^2 per megacurie for the test series of 1957—58 and 1961—62 respectively. The fact that these ratios nearly equalled each other leads to the possible conclusion that a total deposition of ^{90}Sr per unit of area obtained at an observation site as a result of considerably long-term measurements would be proportional to the total ^{90}Sr activity produced, so long as nuclear tests have been performed in the atmosphere, in spite of the actual different test conditions. However, it should be noticed that this is not true for the case of a land-surface burst, such as the October 16, 1964, test by the Chinese; the corresponding ratio for the Chinese test[2] was estimated to be 32 mCi/km^2 per megacurie, about 5 times greater than those obtained above.

The authors wish to thank Professor Seitaro Koyama for his interest and encouragement.

5) Value taken from data in the Fourth Report of the U. S. Federal Radiation Council (July, 1963).

The Solid Complex Formation of Benzoic Acid with Piperidine

Setsuo KASHINO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received June 20, 1967)

A study of the carboxylic acids - amines system in benzene led Bruckenstein and Saito[1] to identify the 1 : 1, 2 : 1, and 3 : 1 acid-base adducts in solutions. Moreover, with regard to benzoic acid and piperidine, they identified the 1 : 1 and 2 : 1 acid-base adducts in benzene by infrared study.

The present study will deal with the formation and identification of solid complexes of benzoic acid (HA) with piperidine (B). It was found that the 1 : 1 and 2 : 1 benzoic acid - piperidine complexes exist in the solid state. The 1 : 1 complex (B·HA) was formed from a cyclohexane solution containing equimolar amounts of benzoic acid and piperidine. The complex is highly hygroscopic. When the complex is exposed to the atmosphere, it forms a complex ($B \cdot HA \cdot H_2O$) with a benzoic acid - piperidine - water ratio of 1 : 1 : 1. The infrared spectra in the KBr disks of the 1 : 1 and 1 : 1 : 1 complexes were very similar. As is shown in Table 1, however, their X-ray diffractions are apparently different.

The melting-point diagram for the benzoic acid-piperidine system is shown in Fig. 1. This shows the existence of a molecular compound with an acid-base ratio of 2 : 1. The complex (B·HA·HA) was isolated from a cyclohexane solution containing benzoic acid and piperidine in a mole ratio of 2 : 1. The X-ray diffraction data of the complex are given in Table 1.

The infrared data of these solid state complexes are given in Table 2, along with the data of

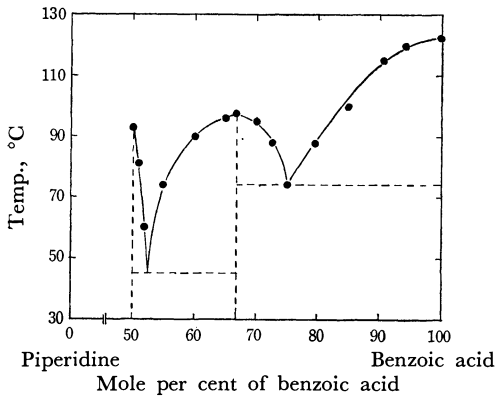

Fig. 1. The melting point diagram for the system benzoic acid - piperidine.

1) S. Bruckenstein and A. Saito, *J. Am. Chem. Soc.*, **87**, 698 (1965).

Bruckenstein and Saito[1] for a benzene solution. As may be seen in Table 2, the infrared absorptions of the 1 : 1 complex in the solid state are almost identical with the absorptions in a benzene solution, though the ν-CO_2^- absorptions in the solid state shift to slightly higher frequencies. The 1 : 1 complex shows ν-CO_2^- absorptions, but no absorptions of ν-C=O. This indicates that the 1 : 1 complex has an ionic structure in the solid state as well as in a solution.

The infrared data of the 2 : 1 complex suggest that the complex has both C=O and CO_2^- groups. The main absorptions of the 2 : 1 complex in the solid state are also observed in a solution, though some absorptions observed in a solution disappear in the solid state.

The facts presented above give clear evidence of the existence of solid complexes between benzoic acid and piperidine.

Experimental

Materials. The piperidine (E. P.-grade reagent) was used without further purification. The benzoic acid was recrystallized from cyclohexane and dried at 100°C for one hour. The cyclohexane was dried over metallic sodium and distilled.

The Complex Formation. The 1 : 1 complex was prepared as follows: To a warm (*ca.* 60°C),

TABLE 2. INFRARED DATA OF THE COMPLEXES BETWEEN BENZOIC ACID (HA) AND PIPERIDINE (B)

saturated solution of 2.9 g of benzoic acid in cyclohexane, an equimolar amount (2.0 g) of piperidine in the same solvent was added. After the solution had stood at room temperature for about one hour, colorless needles of the complex separated out. These needles were recrystallized repeatedly from cyclohexane, and then dried *in vacuo* over $CaCl_2$; mp 93—94°C. The complex was not subjected to elemental analysis, since it was highly hygroscopic. The complex was then exposed to the atmosphere overnight to form the 1 : 1 : 1 benzoic acid - piperidine - water complex; mp 51—52°C.

Found: C, 64.60; H, 8.61; N, 6.21%. Calcd for $C_{12}H_{17}NO_2(H_2O)$: C, 63.96; H, 8.50; N, 6.22%.

The 2 : 1 complex was prepared by a method virtually identical with that described for the 1 : 1 complex, but here the mole ratio of benzoic acid to piperidine was 2 : 1. Colorless needles, mp 97—98°C.

Found: C, 69.42; H, 7.31; N, 4.22%. Calcd for $C_{19}H_{23}NO_4$: C, 69.28; H, 7.08; N, 4.25%.

Identification. In all the experiments the 1 : 1 complex was treated in a dry box. The IR spectrum was obtained according to the usual KBr disk method. The X-ray powder-diffractometry was made with a Rigaku Denki diffractometer, Geigerflex, by the use of Cu$K\alpha$ radiation. For the melting-point diagram, a mixture of the 1 : 1 complex and benzoic acid in appropriate proportions was ground in a mortar and then sealed into capillaries. The melting point was obtained by the usual method.

The author wishes to express his thanks to Professor Shigeo Hasegawa and Dr. Norio Nishimura for their helpful discussions, and to Miss Sachiko Kusunoki for her experimental aid.

The Decomposition of *t*-Butylperoxy *o*-Phenylbenzoate

Hiroshi MINATO, Hisako MATSUZAKI and Kikuyo MIWA

Department of Chemistry, International Christian University, Mitaka, Tokyo

(Received July 1, 1967)

Bentrude and Martin[1] reported that the first-order thermal decompositions of some *o*-substituted *t*-butyl perbenzoates were very fast. Relative rates in chlorobenzene at 60°C varied with the *o*-substituents in the order:

$$PhS > MeS \gg I \gg (CH_3)_3C > H.$$

The tremendous rate enhancements observed with the first two of these peresters and the lesser effect accompanying the decomposition of the *o*-iodo perbenzoate were ascribed to the neighboring-group participation in a homolytic bond cleavage, the O-O bond cleavage being accompanied by simultaneous O-S (or O-I) bond formation.

It seems to be of great interest to investigate the decomposition of *t*-butylperoxy *o*-phenylbenzoate as to the possibility of the phenyl participation at the transition state of the decomposition, and this paper describes the results of the investigation of this perester.

Table 1 summarizes the kinetic data on *t*-butylperoxy *o*-phenylbenzoate together with those of *t*-butyl perbenzoate for comparison.

These very small acceleration of the decomposition (the ratio of the rate constants is 2.74 at 110°C and 2.56 at 130°C) seems to exclude the possibility of the *o*-phenyl participation at the transition state.

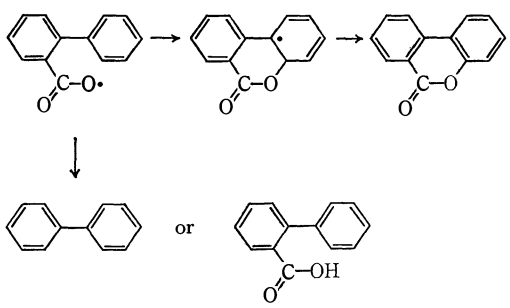
TABLE 2. PRODUCTS OF DECOMPOSITION OF t-BUTYL-PEROXY o-PHENYLBENZOATE IN CUMENE AT 125°C

	moles/mole of perester
Carbon dioxide	0.27
Acetone	0.23
t-Butyl alcohol	0.51
Fluorenone	0.11
o-Phenylbenzoic acid	0.22
3, 4-Benzcoumarin	0.32
Biphenyl	0.16
Bicumyl	0.20

The products of the decomposition of the perester in cumene at 125°C are listed in Table 2. It is interesting that about 32% of the perester was converted to 3, 4-benzcoumarin. This finding indicates that, even though the cleavage of the peroxide bond is not helped by the ortho phenyl π-system, the odd electron of the o-phenylbenzoyloxy radical formed reacts with the ortho phenyl π-system. The formation of fluorenone is rather difficult to explain. One speculation is that the perester decomposes to form fluorenone and t-butyl hydroperoxide, the latter being further decomposed to acetone and t-butyl alcohol.

The products of the decomposition of the perester indicate that the o-phenylbenzoyloxy radicals formed are converted into three products, namely, 3, 4-benzcoumarin, o-phenylbenzoic acid or biphenyl.



It is interesting to compare these findings with the studies on some of the peresters, the structures of which suggest the possibility of phenyl ring participation with the decomposition.

Greene *et al.*[2] studied the decomposition of o-phenylbenzoyl peroxide, and found that o-phenyl ring did not participate at the transition state but reacted with the carboxy radical to form 3, 4-benzcoumarin.

It seems worth commenting on the facile cyclization of o-phenylbenzoyl chloride to form fluorenone, the phenomenon observed when the acid was being converted into the acid chloride. Since a general method for preparation of an acid chloride is to reflux an acid with thionyl chloride, o-phenylbenzoic acid was refluxed with excess thionyl chloride for one hour. The product was fluorenone, not o-phenylbenzoyl chloride. Therefore, this reaction was further investigated at 30°C. Since the use of unpurified thionyl chloride resulted in the faster cyclization, hydrogen chloride was suspected to be the catalyst for this Friedel-Crafts reaction. When 0.02 g of water was carefully added into the mixture of 0.091 g of the acid and 0.331 m*l* of thionyl chloride in order to increase the content of hydrogen chloride in the mixture, the cyclization was faster. The reaction was followed by the changes of carbonyl absorptions in the infrared, and the results were shown in Fig. 1. Hydrogen chloride, though not reported as a catalyst for Friedel-Crafts reaction in literatures, could function as the catalyst.

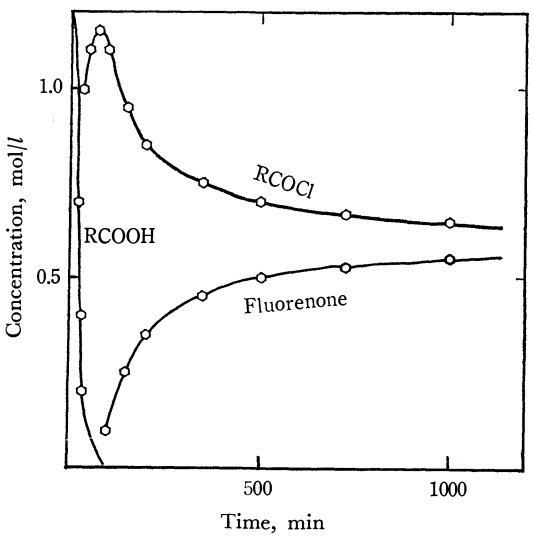


Fig. 1. Conversion of acid chloride to fluorenone. RCOOH=0.091 g, $SOCl_2$=0.331 m*l*, H_2O=0.02 g, 30.0°C

2) F. D. Greene, G. R. Van Norman, J. C. Cantrill and R. D. Gilliom, *J. Org. Chem.*, **25**, 1790 (1960).

The suppression of this Friedel-Crafts cyclization was investigated, and it was found that the addition of weak proton acceptor such as diethyl ether or diphenyl ether resulted in the almost complete suppression of the cyclization and the formation of the acid chloride in a good yield.

Experimental

o-Phenylbenzoic Acid. *o*-Phenylbenzoic acid was prepared from fluorenone by the method of Huntress and Seikel.[3]

Mp 114°C (lit[4] 114°C).

o-Phenylbenzoyl Chloride. Usually acid chlorides are prepared by heating acids with thionyl chloride. Greene *et al.*[2] reported that *o*-phenylbenzoyl chloride was prepared by the action of thionyl chloride on the acid and the distillation at 99.5—101°C/0.3 mmHg. They observed that some closure to fluorenone occurred during distillation (weak carbonyl absorption in the infrared at 1728 cm^{-1}).

However, when the acid was refluxed in thionyl chloride at 80°C for one hour almost all the acid was converted into fluorenone. After various attempts, the following method was found to be the best. A mixture of 1 g of the acid, 1 g of diethyl ether and 2.60 m*l* of thionyl chloride was let to react in an oil bath at 30°C for 120 min. Then the excess thionyl chloride was evaporated by aspirator. The residual oil was the acid chloride with a very small amount of fluorenone. The distillation at 99.5—101°C/0.3 mmHg yielded the pure acid chloride.

t-Butylperoxy o-Phenylbenzoate. A solution of 3.163 g (35.14 mmol) of *t*-butyl hydroperoxide in 10 m*l* of petroleum ether was added to a solution of 1 g (5.02 mmol) of the acid chloride in 10 m*l* of petroleum ether. 3.033 g (38.4 mmol) of pyridine in 10 m*l* of petroleum ether was then added slowly to this ice-cooled mixture. The solution was stirred at 0°C by a magnetic stirrer until the precipitation of pyridinium chloride was complete. The mixture was washed with a cold 10% sulfuric acid solution, a 5% sodium carbonate solution and water. The perester solution was then dried with anhydrous sodium sulfate. The evaporation of petroleum ether and other low-boiling impurities under vacuum yielded 1.13 g (83.4%) of the perester as a yellow oil. The infrared spectrum of this oil showed the strong absorption of the perester at 1765 cm^{-1}. When this oil in petroleum ether was passed down through a short chromatographic column packed with alumina, the decomposition of the perester occurred on the column. However, since the perester freed from low-boiling impurities was found to be of fair purity, this perester was used for kinetic and product studies. (Found: C, 76.03, H, 6.50%. Calcd for $C_{17}H_{18}O_3$, C, 75.53, H, 6.71%.).

Kinetic Procedure. A weighed quantity of perester was dissolved in cumene. The concentration of the solution was calculated to bring the concentration of the perester within the range of about 20 to 80% transmission as to the carbonyl absorption at the infrared.

The solution was transferred to about ten small test tubes. The tubes were then sealed at atmospheric pressure without degassing and placed in the thermostated oil bath at each decomposition temperature. The initial solution was taken as the zero time sample. At suitable intervals one of the tubes was subsequently withdrawn and cooled rapidly in ice. The infinity sample was left in the bath for about ten half lives. Each sample was stored at −5°C until the infrared analysis was carried out.

A Hitachi Infrared Spectrophotometer was used with cells of 0.1 mm thickness for the determination of the amount of the perester remaining.

The relative concentration at time t was calculated from the equation:

$$P/P_0 = \frac{\log T_\infty - \log T_t}{\log T_\infty - \log T_0}$$

Where T_∞ is the percentage transmission of the sample at infinite time against pure solvent, and T_0 is the percentage transmission of the initial sample.

Product Studies. 1.285 g (4.76 mmol) of the perester was dissolved in 10 m*l* of cumene in a decomposition flask and was attached onto a vacuum system. The solution was degassed three times by alternately freezing with dry ice - methanol mixture and evacuating the flask. The flask was sealed under vacuum and immersed in an oil bath at 125°C for about ten half lives until the perester decomposition was complete. The flask was again attached to the vacuum system. The amount of the gas not condensible with liquid nitrogen, which was presumably methane, was not determined. After the non-condensible gas was evacuated, the pressure of carbon dioxide released from the flask to the vacuum system was read on the manometer. The vacuum distillation of the solution yielded the liquid products and the non-distillable residue.

From the pressure of the gas and the known volume of the vacuum system, the number of moles of carbon dioxide formed was determined.

The volatile products in the solvent were identified to be acetone and *t*-butyl alcohol by the gas chromatography, and their amounts were quantitatively determined by a Shimadzu Gas Chromatograph Type GC-2B.

The infrared spectrum of the non-distillable residue indicated the presence of 3, 4-benzcoumarin (1747 cm^{-1}), *o*-phenylbenzoic acid (1690 cm^{-1}) and fluorenone (1717 cm^{-1}). The residue was chromatographed on alumina. The fractions were identified by the comparison of their infrared spectra and melting points with those of the authentic samples. The products found were biphenyl, bicumyl, fluorenone, 3, 4-benzcoumarin and *o*-phenylbenzoic acid.

Grateful acknowledgement is made to the donors of The Petroleum Research Fund, administered by the American Chemical Society, for support of this research.

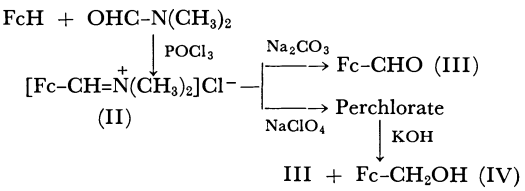
A Simple Modification of Vilsmeier Method for the Preparation of Formylferrocene

Masaru SATO, Hiromichi KONO, Mikio SHIGA, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received July 25, 1967)

Various routes to obtain formylferrocene (III), which serves as an important starting material for the synthesis of many ferrocene derivatives, have been reported.[1-6] The Vilsmeier reaction of ferrocene with *N*-methylformanilide and phosphoryl chloride was most conveniently utilized for the preparation of the aldehyde.[1-5] Graham and his coworkers[3] reported that the aldehyde could be prepared also with dimethylformamide and phosphoryl chloride as formylating reagent, but their method gave only 23% yield. In the course of synthetic investigation of ferrocene derivatives, the present authors found a modified Vilsmeier method using dimethylformamide instead of *N*-methylformanilide, in which the yield of the aldehyde was much improved and the separation of the product from the reaction mixture was much easier than the original method,[3] a troublesome chromatographic separation being unnecessary. In this modification, phosphoryl chloride was introduced into a chloroform solution of the mixture of ferrocene and dimethylformamide to form a Vilsmeier complex (II), which on careful neutralization by sodium carbonate afforded the aldehyde (III). The addition of ferrocene to the mixture of dimethylformamide and phosphoryl chloride also gave no unfavorable effect on the reaction. However, direct addition of phosphoryl chloride to ferrocene at the primary stage of the reaction decreased the yield of the product. This is probably due to the decomposition of ferrocene which is expected to occur to a certain extent by the action of phosphoryl chloride.



Fc = Ferrocenyl

When an aqueous solution of sodium perchlorate was added to the initial reaction mixture, followed by decomposition by water at the end of the reaction, violet crystals separated from the solution. Their IR spectrum showed the existence of $-C=\overset{+}{N}-$ group by the characteristic absorption band at 1668 cm^{-1}. Therefore, this substance is considered to be a perchlorate of the Vilsmeier complex (II) corresponding to that previously suggested by Jutz.[7] The perchlorate gave formylferrocene and hydroxymethylferrocene by treatment with 10% aqueous potassium hydroxide solution. Neither the Vilsmeier complex itself nor formylferrocene gave hydroxymethylferrocene by the action of aqueous alkali.

Experimental

A typical procedure for the modified Vilsmeier method was carried out as follows:

14.6 g (0.2 mol) of dimethylformamide was added to the solution of 18.6 g (0.1 mol) of ferrocene in 75 m*l* of dry chloroform and the resulting mixture was stirred in an ice-bath under nitrogen atmosphere for 10 min. Then, 30.6 g (0.2 mol) of phosphoryl chloride was added dropwise to the mixture over about half an hour. After the addition had been completed, the reaction mixture was kept stirring for 20 hr under heating at 55—60°C on a water-bath taking care that the temperature did not exceed 60°C. At the end of the reaction, chloroform was evaporated off under reduced pressure below 60°C,* and the residue was poured into the mixture of ice and water. Solid precipitates, most of which should be unreacted ferrocene, was filtered off. The filtrate, aqueous solution of the Vilsmeier complex, was neutralized carefully with sodium carbonate powder and then was extracted repeatedly with ether. All the extracts were combined together and dried over anhydrous magnesium sulfate after washing with water. The crude product obtained by evaporation of the solvent was pure enough for most synthetic purpose. Recrystallization from a mixed solvent (dichloromethane 3 : *n*-hexane 1) gave pure formylferrocene as reddish-brown crystals, mp 124.5°C. The yield was 15.2—15.7 g (71—74%).

A Correction Factor for Electrostatic Free Energy in Micelle Formation

Fumikatsu TOKIWA and Kenji OHKI

Research Laboratories, Kao Soap Company, Minato-Yakushubata, Wakayama-shi

(Received July 28, 1967)

It is well known that the critical micelle concentration (CMC) of a surfactant changes markedly with the concentration of counter-ions, c_i. There is in general a linear relation between log CMC and log c_i.[1-5] However, the log-log relation which we have obtained for straight-chain sodium decylbenzene sulfonate (SDBS) over a wide range of counter-ion concentrations is discrepant from the linear relation.*1 The present paper will discuss a correction factor for electrostatic free energy in micelle formation based on the dependence of CMC on the concentration of counter-ions.

Figure 1 shows the relation between log CMC and log c_i for SDBS.*2 The curves I and II are, respectively, the best-fitting straight and quadratic lines for the observed values in the sense of least squares. These two curves are written in the following forms:

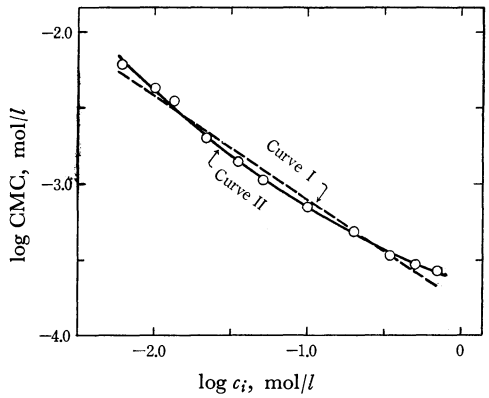

Fig. 1. The relation between log CMC and log c_i for SDBS at 25°C. The CMC values were taken from the sharp breaks in the solubilization curves for an oil-soluble dye, Yellow-OB, the method being described in previous papers.[7,8]

For the curve I,

$$\log \mathrm{CMC} = A + B \log c_i \qquad (1)$$

$$A = -3.77, \text{ and } B = -0.67$$

For the curve II,

$$\log \mathrm{CMC} = A' + B' \log c_i + C' (\log c_i)^2 \qquad (2)$$

$$A' = -3.66,\ B' = -0.40, \text{ and } C' = 0.12$$

Comparing the curves I and II, we may take the latter curve as the log CMC *vs.* log c_i relation for SDBS, since the curve II may be seen to be more fitting to the values experimentally determined than the curve I.

The micelle formation of ionic surfactants is generally governed by two energies: the cohesive energy among the hydrocarbon chains and the repulsive energy among the charged groups.[5,9,10] Thus, the CMC is expressed as:

$$\boldsymbol{k}T \ln \mathrm{CMC} = \Delta G_{\mathrm{HC}} + \lambda \varepsilon \phi_0 + K \qquad (3)$$

or:

$$\log \mathrm{CMC} = (0.434/\boldsymbol{k}T)(\Delta G_{\mathrm{HC}} + \lambda \varepsilon \phi_0 + K) \qquad (4)$$

where ΔG_{HC} is the free energy change in the hydrocarbon part by micelle formation; ϕ_0, the surface potential of the micelle; $\boldsymbol{k}$, the Boltzmann constant; T, the absolute temperature; ε, the elementary charge, and K, the constant which appears when the CMC value is expressed in moles per liter. The λ in Eq. (3) is the correction factor for the electrostatic free energy; that is, $\lambda \varepsilon \phi_0$ is the effective electrical energy.[7] If we assume a charged flat surface for the micelle, the surface potential of the micelle and the concentration of counter-ions are related by the Gouy-Chapman equation[11]:

$$\varepsilon \phi_0 / 2\boldsymbol{k}T = \sinh^{-1} \Theta c_i^{-1/2} = \ln\{\Theta c_i^{-1/2} + [1 + (\Theta c_i^{-1/2})^2]^{1/2}\} \qquad (5)$$

$$\Theta = (1000 \pi \sigma^2 / 2 \boldsymbol{N}_{\mathrm{A}} D \boldsymbol{k} T)^{1/2} \qquad (6)$$

where σ is the charge density; $\boldsymbol{N}_{\mathrm{A}}$, the Avogadro number, and D, the dielectric constant. The

*1 Such a deviation from the linear log-log relation has also been reported by Mysels.[6]

*2 The SDBS was prepared by the sulfonation of pure decylbenzene; it was neutralized with sodium hydroxide. The sample was purified by removing the unreacted material and inorganic salt.

quantity of $(\Theta c_i^{-1/2})^2$ is much greater than unity, as will be shown later; therefore, Eq. (5) may be reduced to:

$$\varepsilon\psi_0/2\boldsymbol{k}T \simeq \ln 2\Theta c_i^{-1/2} = 2.30(\log 2\Theta - \tfrac{1}{2}\log c_i) \quad (7)$$

or:

$$\log c_i \simeq 2\log 2\Theta - (0.434/\boldsymbol{k}T)\varepsilon\psi_0 \quad (8)$$

By inserting Eq. (8) into Eq. (2) and comparing Eq. (2) with Eq. (4), we obtain the relation:

$$\lambda = C'(0.434/\boldsymbol{k}T)\varepsilon\psi_0 - (B' + 4C'\log 2\Theta) \quad (9)$$

The λ in Eq. (3) or (4) is thus a linear function of ψ_0, as may be seen in Eq. (9). The value of λ can be calculated in terms of Eq. (9) when B', C', and Θ are known. The B' and C' constants have already been given in Eq. (2). The value of Θ is estimated to be 2.26 $(\mathrm{mol}/l)^{1/2}$ from Eq. (6) by assuming a reasonable value of 8.0×10^4 esu/cm^2 for σ. The area of the micellar surface in cm^2/molecule, S, is assumed to be approximately 6.0×10^{-15},[12] which gives the above σ value, since $\sigma=\varepsilon/S$.

Figure 2 shows the λ *vs.* ψ_0 plots, ψ_0 being calculated in terms of Eq. (7). The value of λ is not constant, but increases with an increasing ψ_0 value. A similar result has been obtained for a nonionic-cationic surfactant, dimethyldodecylamide oxide (DDAO), which is also shown in Fig. 2.[7] Figure 2 suggests that the extent of interaction among the charged heads changes with the surface potential of the micelle. The difference in the λ *vs.* ψ_0 plots between SDBS and DDAO may be attributed to different ways of interaction among the charged heads. Further, the molecular structure of these surfactants probably has some relation with the interaction.

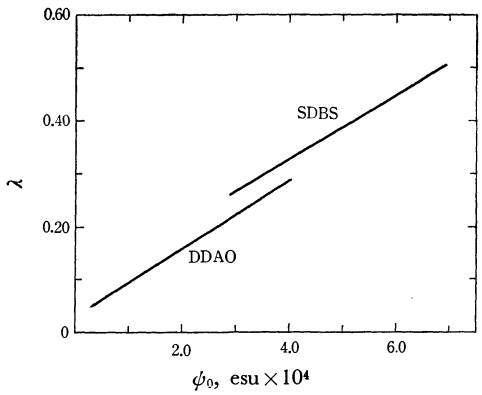

Fig. 2. The values of λ plotted against ψ_0. The plots for dimethyldodecylamine oxide is also shown for comparison.[7]

The Dimerization of Butadiene in Methanol by a Palladium Complex Catalyst

Shigetoshi TAKAHASHI, Hiroshi YAMAZAKI and Nobue HAGIHARA

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received July 29, 1967)

In a previous work[1] we have reported how palladium complexes catalyzed a dimerization of butadiene to form a linear dimer. The dimerization of butadiene in benzene, tetrahydrofuran, or acetone gave octatriene-1.3.7, while the reactions in alcohols proceeded more smoothly to give 1-alkoxyoctadiene-2.7 and/or octatriene-1.3.7, depending on the nature of the alcohols employed. We now wish to report in detail on studies of the products derived from the dimerization reaction in methanol. It was found that the dimerization of butadiene in methanol at 70°C in the presence of bis(triphenylphosphine)(maleic anhydride)palladium gave 1-methoxyoctadiene-2.7 (85%), plus small amounts of octatriene-1.3.7 (3%) and an isomer (I) (5%) of methoxyoctadiene. When tetrakis(triphenylphosphine)platinum was used as the catalyst, the reaction proceeded slowly, but the proportion of the isomer I in the products was relatively greater. The pure isomer I was isolated from this reaction mixture by preparative gas chromatography. The isomer I is a colorless liquid with a bp of 145—146°C, n_D^{20} 1.4321. (Found: C, 77.17; H, 11.51%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.) The infrared spectrum of the compound I showed the presence of terminal double bonds (994, 923, 910 cm^{-1}) and an ether group (1101 cm^{-1}). The NMR spectrum showed the presence of a methoxy group (6.88 τ), two $=CH_2$ and two =CH– groups, and a partial structure, $=CH-CH(OCH_3)-CH_2-$. These spectra indicate that the compound I is 3-methoxyoctadiene-1.7, $H_2C=CH-CH(OCH_3)-CH_2-CH_2-$

1) S. Takahashi, T. Shibano and N. Hagihara, *Tetrahedron Letters*, **1967**, 2451.

CH_2–CH=CH_2.*1

It is obvious that the formation of octatriene-1.3.7 in this catalytic dimerization in aprotic solvents involves hydrogen migration. Accordingly, the increasing rate of the reaction in protic solvents suggests the participation of the proton of the solvent. Because of our interest in the mechanism, therefore, the dimerization was carried out in CH_3OD. The main product, II (bp 164°C, n_D^{20} 1.4416), was recognized as monodeuterio-1-methoxyoctadiene-2.7 on the basis of its infrared (ν_{C-D} 2145 cm^{-1}) and NMR spectra. The position of the deuterium in the compound II could not be determined simply because the signals of the protons on C^4 and C^6 completely overlapped in its NMR spectrum. In order to distinguish them, the terminal double bond in the compound II was hydrogenated with $Ru(Ph_3P)_3Cl_2$ catalyst[2] in benzene-ethanol. It was confirmed that the compound II was 1-methoxy-6-deuteriooctadiene-2.7 because the hydrogenated product, III (bp 85—86°C/37 mmHg, n_D^{20} 1.4298), was found to be 1-methoxy-6-deuteriooctene-2 on the basis of a comparison of its NMR spectrum with that of 1-methoxyoctene-2 (bp 82—83°C/33 mmHg, n_D^{20} 1.4307).

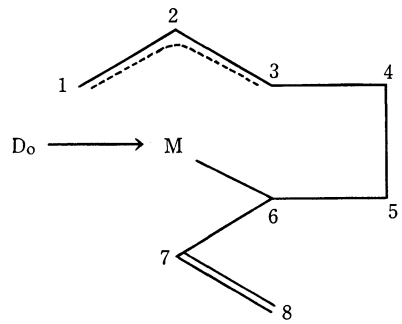
$$2H_2C{=}CH{-}CH{=}CH_2 + CH_3OD \rightarrow CH_3{-}O{-}CH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CHD{-}CH{=}CH_2$$

(II)

$$\xrightarrow{H_2} CH_3{-}O{-}CH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CHD{-}CH_2{-}CH_3$$

(III)

These results suggest the presence of a π-allyl intermediate (IV) similar to that proposed by Wilke *et al.*,[3] although attempts to isolate the intermediate have thus far been unsuccessful. Thus, octatriene-1.3.7 may be produced through a reaction course which involves the $C^4 \rightarrow C^6$ migration of hydrogen, and two isomers of the methanol adduct, through the two different modes of the addition of methanol to the intermediate (1, 6 addition and 3, 6 addition).



(IV) M=Pt or Pd

*1 The isomer of the acetic acid adduct, which was characterized as 4-acetoxyoctadiene-2.7 in our previous paper,[1] may really have the 3-acetoxyoctadiene-1.7 structure, similar to that of the isomer of the methanol adduct.

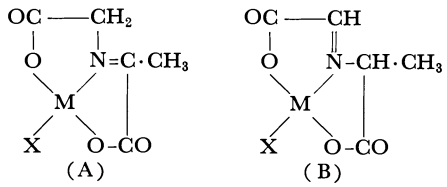
The Proton Magnetic Resonance Spectrum of the Palladium(II) Schiff Base Complex Derived from Glycine and Pyruvic Acid

Hayami YONEDA,* Yukiyoshi MORIMOTO,** Yasuo NAKAO*** and Akitsugu NAKAHARA***

*Chemistry Department, Wakayama University, Masagocho, Wakayama
**Research Laboratories, Fujisawa Pharmaceutical Company, Kashimacho, Higashiyodogawa-ku, Osaka
***Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received August 4, 1967)

Nakao, Sakurai, and Nakahara[1] prepared a pair of copper(II) complexes of Schiff bases derived from pyruvic acid and glycine, and from glyoxylic acid and α-alanine. Although they had been belived to have different structures, A and B, in the light of many results obtained by similar preparations earlier, it was disclosed that they were



(A) (B)

identical, both having the same structure, A. Since the A and B structures are different only in the relative positions of the double bond and the hydrogen atoms, the finding suggests that transamination reactions proceed *via* proton transfer. Therefore, in order to obtain deeper insight into the mechanism of transamination reactions, it is necessary to determine the behavior of the hydrogen atoms in the Schiff base complexes by some physicochemical means.

Proton magnetic resonance spectroscopy would seem to be a powerful tool for this purpose. As the copper(II) complexes were not suitable for PMR measurements, we prepared the corresponding palladium(II) complexes of Schiff bases derived from pyruvic acid and glycine, and from glyoxylic acid and α-alanine. Like the copper(II) complexes, the palladium(II) complexes proved to be identical with each other. Figure 1 shows the spectrum run in a D_2O solution. It exhibits only the signal due to the CH_3 group. This suggests that the CH_2 protons were completely exchanged for deuterium immediately after dissolution. Thus the lability of the CH_2 protons in the Schiff base complex was revealed. This kind of lability reminds us of the active methylene of the malonato chelate. Previously[2] we found that the signal due to the CH_2 protons in the malonato complexes dissolved in D_2O decreased in intensity with time. We interpreted the lability of the CH_2 protons as a result of the electron-withdrawing effect of the two adjacent carbonyl groups. In the Schiff base complex, the electron density of the CH_2 group may be expected to be reduced by the two unsaturated groups, $-C=O$ and $-N=C\langle$, and also through the coordination of the N atom to the metal ion. Therefore, the CH_2 protons may be expected to be highly active. Thus, it is not surprising to see the CH_2 protons more active than those in the malonato complex.

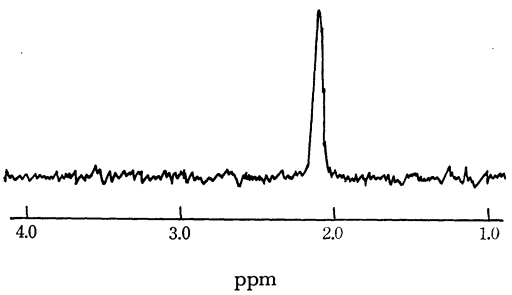

Fig. 1. The PMR spectrum of Na[Pd(pyv=gly)Cl] in D_2O.

The experimental details will be presented below.

Preparation of the Complex. Into 9 m*l* of a water : ethanol mixture (2 : 1 by volume) were stirred 0.62 g of sodium pyruvate and 0.42 g of glycine, and then 1 g of palladium chloride. After the solution had been kept at about 40°C for 2.5 hr under constant stirring, it was placed in an ice-bath. Yellow crystals thus came out. The crude product was recrystallized from a water : ethanol mixture (1 : 1 by volume). Found: C, 17.85; H, 2.53; N, 4.22%. Calcd for Na[Pd(CH_3·C(COO)=N·CH_2·COO)Cl]2H_2O: C, 17.45; H, 2.61; N, 4.08%. The same complex was obtained from glyoxylic acid and α-alanine.

NMR Measurements. The spectrum was recorded on a Varian A60 spectrometer. The chemical shift was measured relative to the sodium salt of trimethylsilyl propane sulfonic acid, taken as an internal standard.

Polycondensation of β-Amino Acid Derivatives

Kohei SANUI, Mitsuo ISHIDA and Naoya OGATA

Chemistry Department, Sophia University, Chiyoda-ku, Tokyo

(Received August 4, 1967)

It was previously shown[1-3] that acrylate adds to amino alcohol and then, polycondensation follows at room temperature in the presence of an alkoxide to form polyamide as described below:

$$CH_2{=}CHCOOR + NH_2R'OH \rightarrow$$

$$HOR'NHCH_2CH_2COOR \rightarrow$$

$$\left[\begin{array}{l} \quad R'OH \\ -[-\overset{|}{N}CH_2CH_2CO-]- \\ -[-NHR'OCH_2CH_2CO-]- \end{array}\right] + ROH$$

The reaction medium has an influence on the course of the polycondensation and *N*-(hydroxyalkyl) poly-β-alanine is mainly formed in alcohol solution and polyamide ether is obtained in other polar solvent such as tetrahydrofuran. However,

2) N. Ogata and T. Asahara, *J. Polymer Sci.*, **B-4**, 273 (1966).
3) N. Ogata and K. Sanui, This Bulletin, in press.

when diamines were used in place of amino alcohol, polycondensation did not occur at room temperature in tetrahydrofuran solution and only a low molecular weight polymer was obtained in methanol solution.

In this paper, several *N*-(amino alkyl) β-alanine esters were synthesized from diamines and ethyl acrylate and their thermal polycondensation has been carried out in the presence of various catalysts. Following diamines were used for the synthesis:

$$NH_2R'NH_2 + CH_2{=}CHCOOR \rightarrow$$
$$NH_2R'NHCH_2CH_2COOR \rightarrow$$
$$-[-NHR'NHCH_2CH_2CO-]- + ROH$$

R': $-(CH_2)_2-$, $-(CH_2)_4-$, $-(CH_2)_6-$, $-(CH_2)_8-$, $-(CH_2)_{10}-$, $-CH_2-C_6H_4-CH_2-$

Commercially available ethylenediamine and hexamethylenediamine were used and, tetramethylenediamine and octamethylenediamine were synthesized from adipamide and sebacamide through the Hoffmann's reaction. Decamethylenediamine and *p*-xylylenediamine were synthesized from dehydration of sebacamide and terephthalamide followed by hydrogenation of the nitriles.

When equal moles of diamine and acrylate were mixed together in a solvent, an addition reaction took place immediately at the vinyl group of acrylate at room temperature. Infrared spectrum of the product showed absorptions owing to amino and ester carbonyl groups as can be seen in Fig. 1. The acid titration curve exhibited two inflection points which corresponded with one amino and one imino groups. Color reactions of primary and secondary amine groups were also observed. Therefore, it is presumed that the addition product has a structure of *N*-(amino alkyl) β-alanine ester.

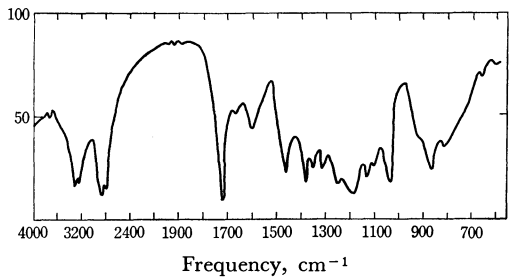

Fig. 1. Infrared spectrum of the reaction product of ethylene diamine and ethyl acrylate.

* Polymerization temperature, 153°C; time, 5 hr; vacuum, 2 mmHg.
** Measured a) in water, b) in methanol, at 30°C.

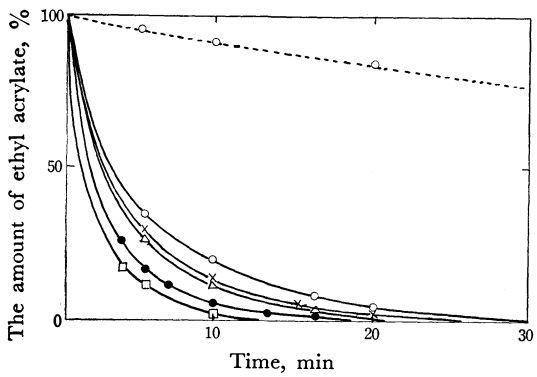

Fig. 2. The rate of reaction of diamines and ethyl acrylate (Concn., 1 mol/*l*, at 20°C).
----: in THF, ——: in methanol
○: $-(CH_2)_2-$, ×: $-(CH_2)_4-$, ●: $-(CH_2)_6-$
□: $-(CH_2)_8-$, $-(CH_2)_{10}-$,
△: $-CH_2-C_6H_4-CH_2-$

These esters were purified by a fractional distillation or recrystallization from alcohol and water.

The rates of the addition of several diamines to acrylate were determined in tetrahydrofuran or methanol solutions at 25°C by gas chromatographic analysis. The results in Fig. 2 show that the rate becomes faster with increasing carbon numbers of diamine and the rate in methanol solution is about 100 times as fast as in tetrahydrofuran solution. The accerelating effect of alcohol on the Michael reaction of acrylate was previously reported.[4]

The boiling or melting points of the esters is as follows; $NH_2(CH_2)_2NHCH_2CH_2COOC_2H_5$: bp 97°C/2 mmHg, $NH_2(CH_2)_4NHCH_2CH_2COOC_2H_5$: bp 140°C/7 mmHg, $NH_2(CH_2)_6NHCH_2CH_2COOC_2H_5$: bp 135°C/3 mmHg, $NH_2(CH_2)_{10}NHCH_2CH_2COOCH_3$: mp 92°C. *N*-(4-Aminomethyl benzyl) β-alanine ethyl ester polycondensated easily during distillation and it was used for polycondensation without distillation.

The thermal polycondensation of the esters was carried out by heating in vacuum in the presence of 1 mol% of basic or acidic catalysts. Results are shown in Tables 1 and 2. It is seen that acidic catalysts such as $SnCl_4$ or $TiCl_4$ are effective for the thermal polycondensation of *N*-(amino alkyl) β-alanine esters and the degree of crosslinking of polymers increases with increasing number of *N*-alkyl group.

the following order owing to crosslinking: *N*-amino alkyl group, $-CH_2-\langle\bigcirc\rangle-CH_2-$, $-(CH_2)_2-$ $>-(CH_2)_4->-(CH_2)_6->-(CH_2)_8-$, $-(CH_2)_{10}-$.

N-(2-Aminoethyl) β-alanine ethyl ester gave a polymer with a molecular weight of 1000, which had a greenish yellow fluorescence and was water-soluble, and *N*-(4-aminobutyl) β-alanine ethyl ester yielded a white solid with a molecular weight of 1800 which was also water-soluble. *N*-(4-Aminomethyl benzyl) β-alanine ethyl ester gave a water-insoluble but alcohol-soluble polymer. It is assumed from their solubility that linear polyamide imines were obtained in these cases. However, thermal polycondensation of higher *N*-alkyl esters resulted in a white, elastic and infusible polymer which had a crosslinked structure. It is assumed that the reactivity of imino group increases with increasing carbon number of *N*-alkyl group, resulting in a crosslinked polymer. The degree of crosslinking, which was determined by acid titration, was about 15 to 30%. The film from *N*-(6-aminohexyl) β-alanine ester could be elongated almost 300%.

In the case of thermal polycondensation of *N*-(6-aminohexyl) β-alanine ester, two-steps polycondensation is possible to obtain an elastic polymer film, that is, pre-polycondensation followed by secondary polycondensation in the presence of acidic catalyst. This method leads to the processing or the film casting. It might be possible to use these polymers as an anion exchange resin since basic imino group is placed in the polymer.

Asymmetric Synthesis with Sugar Derivatives. IV. Catalytic Hydrogenations of Phenylglyoxylic Esters of Sugar Derivatives

Masajiro KAWANA and Sakae EMOTO

Rikagaku Kenkyusho (The Institute of Physical and Chemical Research), Yamato-machi, Kita-Adachi-gun, Saitama

(Received August 9, 1967)

In connection with the studies[1] of asymmetric synthesis with sugar derivatives, the present work was undertaken to examine the effects of the sugars on the stereochemical course of the hydrogenations of phenylglyoxylic sugar-esters over the metal catalysts. The following sugar esters were employed: 1, 2; 5, 6-di-*O*-cyclohexylidene-3-*O*-phenylglyoxyl-α-D-glucofuranose (I), its isopropylidene derivative (II), 5-*O*-ethyl-1, 2-*O*-isopropylidene-3-*O*-phenylglyoxyl-α-D-xylofuranose (III), and its 5-deoxy derivative (IV). These esters were hydrogenated over Raney nickel or palladium in ethanol to the diastereomeric sugar mandelates, which were rapidly hydrolyzed under alkaline conditions[2] at room temperature to produce mandelic acid in 44.6% (maximum) optical yield (Table 1).

The easy removal of the sugar parts is of great advantage to asymmetric synthesis of optically unstable substances.

Mitsui *et al.*[3a] reported that (−)-menthyl phenylglyoxylate (V) was hydrogenated in the presence of various catalysts to diastereomeric (−)-menthyl mandelates, which gave either enatiomer of mandelic acid in excess after partial hydrolysis[4] with acid (Table 1). The direction of the asymmetric induction dependend on the natures of the catalysts used: 5% palladium on charcoal (Pd-C) prepared by the reduction of palladium chloride with hydrogen, or with formaldehyde in an alkaline solution contains extremely small quantities of acid (A) or base (B), respectively, and Raney nickel (Ni) has also trace amounts of alkali. They found that the acid or the base in the catalysts exerted influence on an equilibrium between (−)-menthyl ester (V) and its hemiketal in ethanol, and explained the steric course of the asymmetric hydrogenation according to Prelog's rule[5] as described below.[3a-d]

In the presence of Pd-C-A, *s*-cis (-COCO-) conformer of (−)-menthyl ester (V) will exist predominantly over *s*-trans one since the hemiketal of the former is more stabilized than that of the latter by the formation of intramolecular hydrogen bonding between the hydroxyl and the ester

	5% Pd-C-A	50	1.5	77.0	+20.2° (0.45) 25	12.8
V[d]	Raney Ni	1000 (wet)	1	—	−25.4° (4.6) 4	16.1
	5% Pd-C-B	500	10	—	−15.8° (3.2) 28	10.0
	5% Pd-C-A	100	5	—	+21.2° (5.1) 12	13.4

a) One mmol of the ester was hydrogenated except III and V, which were 0.67 and 10 mmol, respectively.
b) 5% Pd-C-B or -A means 5% palladium on charcoal contained base or acid, respectively; see Ref. 6. The catalysts from the same batch were used throughout the present experiments.
c) Calculated on the base of $[\alpha]_D$ 158° for optically pure mandelic acid.
d) Mitsui's data, see Ref. 3a.

carbonyl group. As a result of the reduction of the dominant *s*-cis conformer, L(+)-mandelic acid was produced in excess after the hydrolysis. In the presence of Pd-C-B or Ni, however, the *s*-trans conformer will be dominant since the formation of the hydrogen bonding of the hemiketal is prevented by the base contained in the catalyst. Therefore, preponderance of D(−)-mandelic acid was brougt about.

The data for the sign of rotation of mandelic acid from the sugar esters were in agreement with Mitsui's results except for 5-*O*-ethyl derivative (III), which afforded L(+)-acid in slightly excess by the reduction over Pd-C-B; such a specific property of Pd-C-B was observed in the asymmetric hydrogenation of (−)-menthyl α-naphtylglyoxylate.[3d] It seemed likely that the exposure of oxygen of the ethoxyl group in 5-*O*-ethyl derivative (III) played an important role for III being absorbed on Pd-C-B.

Regarding to the optical yields of mandelic acid, nickel gave better results than palladium did, and this trend appeared in the hydrogenation of (−)-menthyl ester (V). In the case of 5-deoxy derivative (IV), however, the difference of the optical yield between Ni and Pd was very small.

From these experiments it is concluded that in the asymmetric hydrogenation as well as the asymmetric Grignard addition[1] the sugar derivatives in the esters behaved like (−)-menthol in regard to determining the stereochemical course, one exception being included.

Experimental

Optical rotations were measured with a Perkin-Elmer Model 141 photoelectric polarimeter in a 1 dm tube.

Starting materials were prepared according to the procedure described earlier.[1]

Asymmetric Synthesis of Mandelic Acid. A solution of the sugar ester (1.0 mmol) in absolute ethanol (15 m*l*) was hydrogenated over 5% palladium on

charcoal[6] or Raney nickel (W-7)[7] catalyst at room temperature and ordinary pressure. Hydrogen absorption stopped or nearly stopped after the consumption of 1.0—1.2 mmol of hydrogen. The catalyst was removed by filtration and washed with ethanol. Evaporation of ethanol at 25°C and reduced pressure gave the crude sugar mandelate whose infrared spectrum did not showed the absorption of the keto carbonyl group. The reduction products were hydrolyzed without purification with a mixture of sodium hydroxide (80 mg) in water (3 m*l*) and methanol (10 m*l*) at room temperature for 30 min. After water (7 m*l*) had been added under cooling, the mixture was concentrated to about 10 m*l* at 25°C and reduced pressure, diluted with water (5 m*l*) and extracted several times with chloroform (70—140 m*l*, total volume) until the sugar in the last extract could not be detected by thin-layer chromatography of silica gel G (E. Merck, Darmstadt, Germaney) with ether-petroleum ether (3 : 7, v/v) solvent system.[8]

From the extract the crude sugar derivative was recovered in 84—99% yield. The complete hydrolysis of the reduction products was ascertained by the measurement of infrared spectrum of the extract.

The water layer was acidified with 6 N hydrochloric acid (1 m*l*) and extracted with ether (100 m*l*). The extract was washed twice with a small quantities of water and dried over sodium sulfate. Evaporation of ether afforded the crude acid, which, on treatment with charcoal (20 mg) in water (5 m*l*), gave mandelic acid. The infrared spectrum of the acid was identical with that of the commercially available one.

The results and other experimental conditions are summarized in Table 1.

6) R. Mozingo, "Organic Syntheses," Coll. Vol. III, ed. by E. C. Horning, p. 685 (1955); 5% Pd-C-B and Pd-C-A were prepared by the procedures B and C, respectively. Pd-C-A was used for the hydrogenation without washing with ethanol.

7) H. R. Billica and H. Adkins, "Organic Syntheses," Coll. Vol. III, ed. by E. C. Horning, p. 176 (1955); The catalyst was sufficiently washed with water.

8) The developed layer was visualized by spraying with a mixture of methanol, sulfuric acid, and *p*-anisaldehyde (17 : 2 : 1, v/v) and then heating.

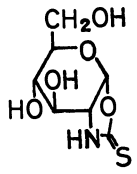
The Structure of the Oxazolidine-2-thione Derivative of D-Glucose*[1]

Juji YOSHIMURA and Hironobu HASHIMOTO

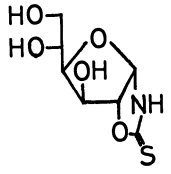
The Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 22, 1967)

Some reducing sugars[1-3] have been reported to give crystalline condensation products having an oxazolidine-2-thione ring by reaction with thiocyanic acid. The structural studies on the mode of condensation between oxazolidine-2-thione ring and sugar ring in these compounds have been mainly performed for the corresponding glucose derivative (I).



A



B

Zemplen *et al.*[1] gave the formula A for I, however, the formula B has generally been accepted from the following facts. Edward and Martlew[4] showed by paper chromatography the presence of 1-aminoglucose and diglucosylamine in the hydrolysate of I, but no glucosamine was demonstrated which was expected from the formula A. Wickström and Wold[5] also supported the formula B by comparison of the pK_a value of I with those of simple oxazolidine-2-thiones. As for the ring size of the sugar moiety in I, Schwarz[6] concluded the presence of a furanose ring from the facts that one mole of formaldehyde was liberated by periodate oxidation and orthoformate was formed by treatment with ethyl orthoformate.

Recently Jochims *et al.*[7] reported on the synthesis and the structure of I and its homologues in which I was proved to be D-glucofurano[1′, 2′: 4, 5]-oxazolidine-2-thione (formula B) from the NMR data in dimethylsulfoxide-d_6. H_1 (the proton attached to the C-1 of the sugar moiety) was found to be weakly coupled to NH and H_4 not to any hydroxyl protons. The authors have also obtained the same results by NMR studies of some derivatives of I.

It will be rationally expected that the *N*-acetylation of I should affect most strongly the chemical

shift of the proton on the carbon attached to the nitrogen atom. In comparison of the NMR spectra of the tri-*O*-acetate (II) and tetra-*N*, *O*-acetate (III) of I[1] (Figs. 1 and 2), it was observed that the chemical shift of H_1 was shifted far to the lower field, but that of H_2 was slightly to the higher field although those of other ring protons were almost identical (Table 1). This fact indicates that the nitrogen is attached to C-1 of the sugar ring. The unexpected shift of H_2 will be explained by the prevention of the contribution from the en-thiol structure in the *N*-acetyl derivative.

The dihedral angles in compounds II and III calculated from observed coupling constants by the modified Karplus equation of Abraham and coworkers[8] were 40° and 42° between H_1 and H_2, 80° and 80° between H_2 and H_3, and 53° and 53° between H_3 and H_4 respectively. These values imply that the furanose ring in these compounds has a "twist" conformation in which C-2 and C-3 are out of the plane containing the other ring members as shown in the case of 1, 2-*O*-isopropylidene-D-glucofuranose and its derivatives.[8]

The presence of the furanose ring in I was also ascertained by chemical methods. It is known

that the glucopyranose ring can not be isopropylidenated,[9] however, I gave a mono-isopropylidene derivative (IV), whose NMR spectrum measured in dimethyl sulfoxide-d_6 showed the hydroxyl signal at 4.28 (τ value) in doublet, indicating the presence of the secondary hydroxyl group. Therefore, IV should be 5′, 6′-*O*-isopropylidene-D-glucofurano[1′, 2′:4, 5]oxazolidine-2-thione, but not the corresponding 3′, 5′-*O*-isopropylidene derivative.

When I was benzylidenated with benzaldehyde and zinc chloride, two isomers which showed mp 232—233°C (V) and 186—188°C (VI) respectively were obtained. In the NMR spectra of these compounds also measured in dimethyl sulfoxide-d_6, each hydroxyl proton appears at 4.83 in triplet and at 4.20 in doublet, indicating the presence of a primary and a secondary hydroxyl group respectively. So V and VI were proved to be 3′, 5′-*O*-benzylidene- and 5′, 6′-*O*-benzylidene-D-glucofurano[1′, 2′: 4, 5]oxazolidine-2-thione respectively.

Experimental

NMR spectra were measured on JNM-3H-60 spectrometer at 60 Mc in deuterochloroform for II and III, and in dimethyl sulfoxide-d_6 for IV, V and VI respectively. Tetramethylsilane was used as an internal reference in each case.

5′, 6′-*O*-Isopropylidene-D-glucofurano[1′,2′ : 4,5]-oxazolidine-2-thione (IV). To a suspension of I (2.4 g) in dry acetone (60 m*l*) concentrated sulfuric acid (0.8 m*l*) was added dropwise with stirring in an ice-water bath, and the stirring was continued for a few hours. The reaction mixture was poured into ice-water containing sodium bicarbonate (5 g), and extracted with methylene chloride (100 m*l*). Methylene chloride layer was washed with water and dried over anhydrous sodium sulfate. Evaporation of methylene chloride gave white residue, which was recrystallized from ethanol, mp 220—221°C, $[\alpha]_D^{22}$ +33.0° (*c* 1.8, pyridine), yield 1.7 g.

Found: C, 46.05; H, 5.74; N, 5.48%. Calcd for $C_{10}H_{15}O_5NS$: C, 45.97; H, 5.79; N, 5.36%.

3′, 5′-*O*-Benzylidene- and 5′, 6′-*O*-Benzylidene-D-glucofurano[1′, 2′ : 4, 5]oxazolidine-2-thione (V and VI). A suspension of I (2.5 g) and anhydrous zinc chloride (3.0 g) in benzaldehyde (20 m*l*) was shaken for 1 hr to give a clear solution. The reaction mixture was poured into ice-water, stirred with petroleum ether, and the petroleum ether layer was decanted. It was repeated twice more to give a mixture of crystals and hard sirup. When this mixture was dissolved in hot ethanol (*ca.* 30 m*l*), a small amount of crystals was remained undissolved, which was filtered and recrystallized from a little larger amount of ethanol to give V as white crystals, mp 232—233°C, $[\alpha]_D^{22}$ +66.5° (*c* 1.0, pyridine), yield 0.2 g.

Found: C, 54.27; H, 4.84; N, 4.57%. Calcd for $C_{14}H_{15}O_5NS$: C, 54.36; H, 4.89; N, 4.53%.

From the filtrate, another crystals were separated and recrystallized from ethanol to give VI, mp 186—188°C, $[\alpha]_D^{22}$ +68.1° (*c* 1.0, pyridine), yield 0.6 g.

Found: C, 54.43; H, 4.92; N, 4.68%. Calcd for $C_{14}H_{15}O_5NS$: C, 54.36; H, 4.89; N, 4.53%.

The authors thank Mr. T. Tanaka of Science University of Tokyo for the oxazolidine-2-thione derivative of D-glucose.

SHORT COMMUNICATIONS

Studies of 2-Azabicyclo[3, 2, 2]nonanone-3. I. A New Synthesis of 2-Azabicyclo[3, 2, 2]nonanone-3

Masaaki TAKAHASHI and Shigeyuki SUZUKI

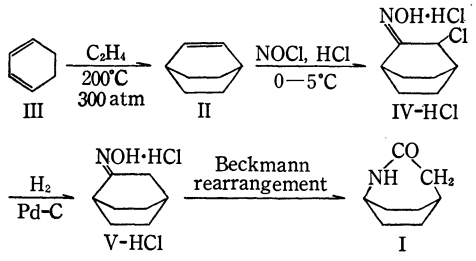
Tokyo Research Laboratory, Kureha Chemical Co., Ltd., Hyakunin-cho, Shinjuku-ku, Tokyo

(Received September 25, 1967)

Although 2-azabicyclo[3, 2, 2]nonanone-3 (I)[1-3] seems to be an interesting modifier for the polyamide obtained from ε-caprolactam, no detailed report has yet been published on the copolymerization of I with ε-caprolactam.

In the course of our studies of the copolymerization, we have achieved a new synthesis of I, starting from bicyclo[2, 2, 2]octene-2 (II). II has been obtained by the reaction of 1, 3-cyclohexadiene (III) with excess ethylene under pressure in an pressure vessel at 200°C.[4]

The addition of nitrosyl chloride to II in the presence of hydrogen chloride at 0—5°C in triclene



afforded 3-chlorobicyclo[2, 2, 2]octanone-2-oxime hydrochloride (IV-HCl), mp 127.5—130°C (dec.), in a 80% yield.

The treatment of IV-HCl with dilute NH_4OH gave the free chloroxime (IV), mp 106—106.5°C. The structures of IV-HCl and IV have been confirmed by elemental analysis, and by a study of their NMR and IR spectra.

The chlorine in the chloroxime was replaced with hydrogen under an atmospheric pressure, using Pd-C as the catalyst. Surprisingly enough, both IV and IV-HCl were smoothly hydrogenated at room temperature in ethanol. Bicyclo[2, 2, 2]octanone-2-oxime-hydrochloride (V-HCl) was obtained in an excellent yield, upon neutralization, this afforded the free oxime (V).

The Beckmann rearrangements of both V and V-HCl were carried out with benzenesulfonyl chloride in an alkaline solution. The product had a melting point identical with that of the lactam obtained from bicyclo[2, 2, 2]octanone-2 and hydroxylamine.[1]

The structure of the lactam was further confirmed by a study of the NMR spectrum and by the reduction of the carbonyl group with $LiAlH_4$.

Interesting polyamides have been obtained by the copolymerization of I with ε-caprolactam in various molar ratios. More detailed studies, including that of the copolymerization of I, will be published in the near future.

A New Route to Mellophanic Dianhydride

Masaaki TAKAHASHI

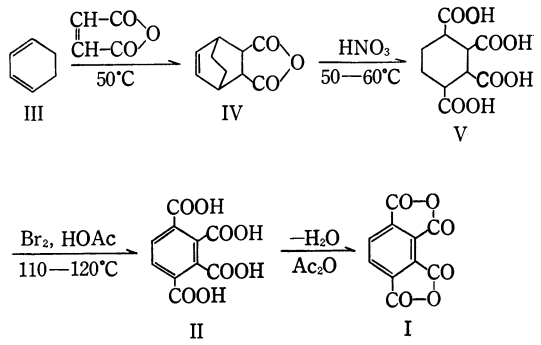
Tokyo Research Laboratory, Kureha Chemical Co., Ltd., Hyakunin-cho, Shinjuku-ku, Tokyo

(Received September 25, 1967)

Mellophanic dianhydride (I), the dianhydride of benzene 1, 2, 3, 4-tetracarboxylic acid (II), is thought to be an interesting raw material for high-temperature-resistant polyimide. Until the present time, however, there has been no satisfactory method for preparing I of a high purity in a large quantity, although convenient methods have been developed for the preparation of pyromellitic dianhydride.[1]

The present author wishes to report a new method of synthesizing I, starting from 1, 3-cyclohexadiene (III) and maleic anhydride.

The reaction sequence is shown below:



Bicyclo[2, 2, 2]-5-octene-2, 3-dicarboxylic anhydride (IV) was easily obtained by the Diels-Alder reaction of III with maleic anhydride.[2] The liquid-phase nitric acid oxidation of IV at 50—60°C, catalyzed by vanadium, afforded cyclohexane-1, 2, 3, 4-tetracarboxylic acid (V), mp 167°C (monohydrate), in a 70—80% yield.

The configurational relationship between the four carboxyl groups has been identified as 1, *cis*-2, *cis*-3, *cis*-4, by the fact that bicyclo[2, 2, 2]-octene-2 gave *cis*-1, 4-dicarboxycyclohexane in the nitric acid oxidation, and by examining the NMR spectrum of the V-tetramethyl ester. The dianhydride, mp 199—199.4°C, was obtained by treating V with excess acetic anhydride. The catalytic dehydrogenation of V using a Pd catalyst has been unsuccessful because of tar formation. II has been smoothly prepared by the oxidative dehydrogenation of V using bromine. The treatment of V with a three-fold equivalent of bromine in acetic acid at 110—120°C afforded II in an excellent yield.

The subsequent dehydration was carried out by treating II with excess acetic anhydride under reflux. The purification of the resultant dianhydride by sublimation, followed by recrystallization from benzene, afforded pure I mp 196—197°C (lit[3] 193—196°C). The structure was further confirmed by elemental analysis and by a study of the IR spectrum.

An interesting high-temperature-resistant polyimide has been obtained by the polycondensation of I with aromatic diamine. The thermal stability of polymellophanimide is similar to that of the corresponding polypyromellitimide.

A detailed discussion will be presented elswhere.

Copper Complexes of Heptan-2, 4, 6-triones*

Fumio SAGARA, Hiroshi KOBAYASHI and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka

(Received October 14, 1967)

Heptan-2, 4, 6-trione [H_2A] (I),[1] which was for the first characterized by Feist,[2] behaves as a bidentate or a terdentate ligand, depending upon the degree of enolization, to give a mononuclear 1 : 2 (metal : ligand) complex as well as a dinuclear 2 : 2 complex with a metal ion forming a square planer coordination. The degree of enolization of I seems to increase at a higher temperature in a less polar solvent.

Here we present some interesting behaviors of I upon complex formation with cupric ion. A blue mononuclear copper complex [$Cu(HA)_2 \cdot 2H_2O$] (II) precipitates when an aqueous cupric acetate is added into a methanolic solution of I at about 0°C. Found: C, 43.75; H, 6.09; Cu, 16.4%. Calcd: C, 43.80; H, 5.81; Cu, 16.6%. When the preparation is carried out at about 30°C, a green dinuclear complex [Cu_2A_2] (III) is obtained. Found: C, 41.41; H, 3.89; Cu, 31.0%; mol wt (Vapor Pressure Osmometer), 411.7. Calcd: C, 41.27; H, 3.96; Cu, 31.2%; mol wt, 407.4.

The complex III shows a multiplet absorption between 1500 and 1600 cm^{-1} ascribable to ethylenic bonds and coordinated carbonyl groups. In addition to those, in the case of II, a free carbonyl band at 1715 cm^{-1}, an enolic hydroxy band at 3530 cm^{-1} and a sharp absorption at 795 cm^{-1} of coordinated water are observed together with a broad band extending from 3200 to 3500 cm^{-1}.

The complex II dissolves in methanol, acetone and chloroform to some extent as long as the solution being kept at low temperature, while III dissolves only in pyridine, affording a pyridine adduct; two pyridine molecules bound to III [$Cu_2A_2 \cdot 2Py$].

The solid complex II transforms into III at about 80°C under reduced pressure, liberating an excess of the ligand. The same is observed when the methanolic solution of II is heated at its boiling point. On the other hand, the complex III in pyridine changes into II in the presence of a large excess of the ligand, when the solvent is removed at 0°C under reduced pressure. The observed transformations seem to indicate that III is stable at an elevated temperature, while II prefers a lowered temperature, and that the conversion from one to the other is reversible.

Alkylation of 3- and 5-carbon atoms of I affords the ligands which have the similar chelating tendencies for copper ion. Alkylation are carried out by treating a disodium salt of I with a little more than two moles of alkyl iodide in ethanol, to give a monomethyl- (IV) and a dimethyl triketone (V), mp 82.5—83.5°C (Found: C, 63.23; H, 8.54%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%), with methyl iodide, and with *n*-propyl iodide only a mono-*n*-propyl derivative (VI). The triketones IV and VI were characterized as copper complexes, which are best fractionated by column chromatography on silica gel. The copper complexes of the alkylated triketones are again 2 : 2 dinuclear as well as 1 : 2 mononuclear, and the latter structure seems to be enough stable even at room temperature; it gives usually a mononuclear complex alone at room temperature and, in order to obtain a dinuclear complex of V, the mononuclear complex once formed has to be heated at 60°C for a long time.

It is interesting to note that the mononuclear complexes of the alkylated ligands do not carry any coordinated water and that the uncoordinated carbonyl group takes a keto form and not an enol at all.

Syntheses of Some Substituted Heterocyclic Compounds from Propargyl Cyanide and Methylpropargyl Cyanide*[1]

Eiichi HARUKI, Yasuo HIRAI and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received October 25, 1967)

It has been well established that α, β-unsaturated nitriles condense with the nucleophilic reagents such as hydrazine derivatives and hydroxylamine to give heterocyclic compounds substituted by an amino group.[1] The first step of this cyclization reaction is the Michael addition of the nucleophiles to the α, β-unsaturated nitriles.

We wish to report that the reactions of β, γ-unsaturated nitriles such as propargyl cyanide with nucleophiles, *i. e.*, hydroxylamine and phenylhydrazine led also to heterocyclic compounds substituted by an amino group. However, it was found that the different type of heterocyclic compounds were produced from propargyl cyanide (I) and methylpropargyl cyanide (V). A typical example of the reaction was carried out as follows: a mixture of 2.0 g of I, 2.2 g of hydroxylamine hydrochloride and 0.7 g of sodium in 20 m*l* of methanol was refluxed for 10 hr. After reaction the solvent was removed. Distillation of the residue under reduced pressure gave a pale yellow liquid, bp 120—140°C/1 mmHg which was solidified by cooling and after recrystallization from ligroin afforded the pure methylisoxazole (III), mp 80—81°C. Compound III thus obtained was identified with the authentic sample synthesized from β-iminobutyronitrile and hydroxylamine by the mixed melting point and infrared spectrum. Similar treatment of I with phenylhydrazine afforded 5-amino-3-methyl-1-phenylpyrazole (IV), mp 110—111°C (from carbon tetrachloride) in 50% yield. These cyclization reactions would be rationalized in terms of the reaction scheme outlined in Chart 1.

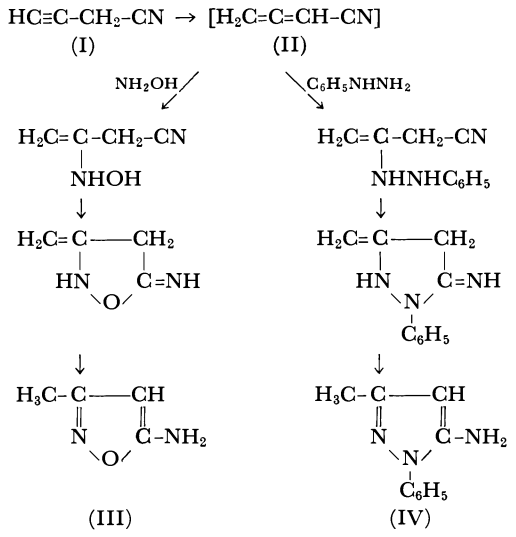

Chart 1

In the first step, I was converted to the allen type compound II, then, the nucleophiles attacked to form the heterocyclic compounds.

However, when methylpropargyl cyanide (V)*[2] was treated hydroxylamine by a similar way, 3-amino-5-ethylisoxazole (VI), mp 70—72°C, was obtained in 50% yield. By comparison of the melting points and the infrared spectra, VI was identified with the authentic sample.[2] This cyclization reaction of V may be interpreted as outlined in chart II. The reaction seems to proceed through the first attack of hydroxylamine toward the nitrile group.

The difference of the chemical behaviors of I and V for the nucleophilic attack can not be explained at present.

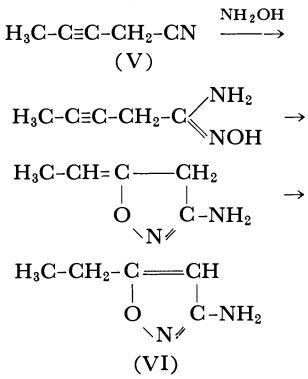

Chart II

The scope and mechanisms of the reported reactions are under investigation.

*1 This constitutes Part V of a series entitled "Studies on the Syntheses of Heterocyclic Compounds."

*2 Methylpropargyl cyanide was prepared by the reaction of methylpropargyl bromide[3] with cuprous cyanide in 75% yield.

Reduction of Cupric Ion to Zero Valent Metal by Benzophenone Ketyl Radical

Kenji TAKEDA and Yoshio IWAKURA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received October 30, 1967)

While photoreduction of benzophenone in hydrogen-donating solvent has been extensively studied,[1-3] not many works[1,3] have been carried out on the reactivity of benzophenone ketyl radical ($C_6H_5\dot{C}OH$–C_6H_5), the intermediate of photoreduction of benzophenone. The present communication deals with the reduction of metallic ions such as Cu^{2+} to zero valent metal by benzophenone ketyl radical.

Irradiation of 0.5 M benzophenone and 0.5 M cupric acetate in isopropyl alcohol by near ultraviolet rays from a high or low pressure mercury vapor lamp for a few minutes, led to form a metallic mirror of copper on the inner wall of the reaction vessel. The copper mirror was retained unchanged in the absence of oxygen, but it was oxidized into cupric oxide followed by the conversion to cupric acetate by the introduction of air.

Other metallic salts such as $Co(OCOCH_3)_2$, $Ni(OCOCH_3)_2$, $Pb(OCOCH_3)_2$, $Cd(OCOCH_3)_2$, $Hg(OCOCH_3)_2$, $PdCl_2$, Bi_2O_3 were also reduced to the metallic state in the same reaction system.

We have concluded that cupric ion was reduced to zero valent metal by the reaction with benzophenone ketyl radical *via* the following sequence of reactions.

$$(C_6H_5)_2C{=}O + (CH_3)_2CHOH \xrightarrow{h\nu}$$
$$(C_6H_5)_2\dot{C}{-}OH + (CH_3)_2\dot{C}{-}OH$$
$$(CH_3)_2\dot{C}{-}OH + (C_6H_5)_2C{=}O \rightarrow$$
$$(CH_3)_2C{=}O + (C_6H_5)_2\dot{C}{-}OH$$
$$2(C_6H_5)_2\dot{C}{-}OH \longrightarrow$$
$$(C_6H_5)_2C(OH)C(C_6H_5)_2OH$$
$$2(C_6H_5)_2\dot{C}{-}OH + Cu^{2+}(OCOCH_3)_2 \rightarrow$$
$$2(C_6H_5)_2C{=}O + Cu^0 + 2CH_3COOH$$

Benzophenone ketyl radical was reconverted to benzophenone by cupric acetate, while cupric acetate was converted to copper metal and acetic acid. Acetic acid was detected by gas chromatography. Acetylacetone was also detected by the same method when bisacetylacetonatocopper(II) was used in place of cupric acetate.

Support for the mechanism is based on the following experimental observations: (1) Both benzophenone and isopropyl alcohol were necessary for reduction of cupric ion to the metallic state by ultraviolet rays irradiation. Cupric ion was also reduced in the reaction system consisting of carbonyl compounds such as benzophenone, 4-methylbenzophenone, 4-methoxybenzophenone, acetophenone, propiophenone, *etc.* and of hydrogen-donating solvents such as methyl, ethyl, propyl, and butyl alcohols, ethanolamine and dicyclohexylamine, *etc.* On the other hand, carbonyl compounds such as 4-hydroxybenzophenone, 4-nitrobenzophenone, 4-phenylbenzophenone and benzoin, *etc.* which are not reduced to pinacol and solvents with no labile hydrogen such as benzene and carbon tetrachloride were ineffective reagents. For example, cupric ion in a reaction mixture consisting of 2-hydroxybenzophenone, cupric acetate and isopropyl alcohol was not reduced to the metallic state. In another reaction mixture consisting of benzophenone, 2-hydroxybenzophenonecopper chelate and isopropyl alcohol, cupric ion was reduced to zero valence. Other chelate compounds such as bisglycinatobisethylenediaminecopper(II) and bissalcilaldehydatocopper (II) were also reduced to metallic copper.

(2) Reduction to zero valence occurred in the reaction system involving only one intermediate radical, $(C_6H_5)_2\dot{C}$–OH, *i. e.*, benzophenone-benzhydrol system. Reduction of cupric ion by the radical $(CH_3)_2\dot{C}$–OH is still under investigation.

(3) Reduction of benzophenone to benzopinacol was retarded or inhibited by cupric ion. Irradiation of 0.5 M benzophenone in isopropyl alcohol for 12 hr led to 84.8% isolation of benzopinacol, however, 10^{-2} M of cupric acetate retarded the reduction of benzophenone and trace amount of benzopinacol were obtained.

(4) Studies by polarography supported the possibily of the reduction of cupric ion by benzophenone ketyl radical. The halfwave potentials of benzophenone and cupric acetate in isopropyl alcohol were -1.54 and -0.32 V (*vs.* Hg pool) respectively using 0.1 M LiCl as the supporting electrolyte.

Further investigations are desirable to elucidate the mechanism of the reaction between bezophenone ketyl radical and metallic ions.

Paramagnetic Susceptibilities of Para-substituted Hydrazyl Free Radicals

Noriko OHIGASHI and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received November 6, 1967)

The static magnetic susceptibilities of the stable free radicals, 2,2-diphenyl-1-picrylhydrazyl(DPPH) and 2,2-bis(*p*-chlorophenyl(*p*-bromophenyl, or *p*-methoxyphenyl))-1-picrylhydrazyl(abbreviated to DCl_2(DBr_2 or $D(CH_3O)_2$)*1, were measured in the temperature range from 10°K to 300°K. The measurements were made by the Faraday method. About 10 mg of the polycrystalline samples were placed in a cylindrical quartz cell (diameter 7mm, height 8mm) suspended by a quartz string from the arm of a vacuum balance. All the measurements were carried out in an oxygen-free helium atmosphere of 30 mmHg.

The paramagnetic susceptibility, χ_p, of DPPH followed the Curie-Weiss law, $\chi_p = Ng^2\beta^2S(S+1)/3k(T-\theta)$, with a Weiss constant, θ, of -24°K between 70°K and room temperature. DPPH is known to have several crystal modifications. Our sample is the one recrystallized from CS_2 and may belong to the DPPH (III) crystal modification, according to Weil *et al.*[1] The observed Curie constant corresponded to a spin concentration of 74%.

The susceptibility, χ_p, of DCl_2, recrystallized from benzene, followed the Curie law over the entire temperature range, and no co-operative phenomenon was observed. The spin concentration was estimated from the Curie constant to be 82%.

DBr_2, which was recrystallized from benzene, was found to have a susceptibility maximum at 15°K, while at higher temperatures it followed the Curie law, with a spin concentration of 82%. The magnetic susceptibility of $D(CH_3O)_2$ had its maximum at 21°K (Fig. 1). The numerical results were analyzed on the basis of the singlet-triplet model;

$$\chi_p = \frac{N/2g^2\beta^2S(S+1)}{3kT} \cdot \frac{3}{3+\exp(J/kT)} + \frac{C}{T} \qquad (1)$$

where J is the singlet-triplet energy separation and where the second term represents the contribution of an assumed isolated paramagnetic "impurity." If we take $J/k = 33.8$°K and assume the impurity concentration to be 8.7%, Eq. (1) reproduces fairly well the experimental results shown in Fig. 1. The electron spin resonance measurements were made on this sample between 77°K and room temperature. The absorption spectrum was very sharp, the ΔH_{msl} value being smaller than 1 gauss. As the absorption shape did not change with the temperature, the peak heights of the first derivative curves are thought to be proportional to the absorption intensity. These values are in good agreement with the static susceptibility data, as may be seen in Fig. 1. Of the four compounds, $D(CH_3O)_2$ has the smallest hyperfine coupling constants of the nitrogens,[2] showing that the unpaired electron in this compound delocalizes most extensively over the phenyl rings. The large intermolecular interaction observed in $D(CH_3O)_2$ can be attributed to this delocalization of the unpaired electron.

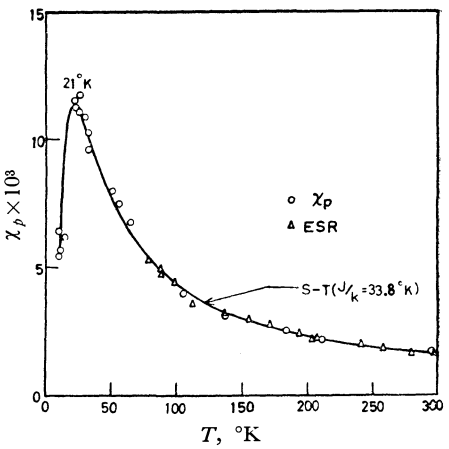

Fig. 1. Paramagnetic molar susceptibility of $D(CH_3O)_2$. The data have been corrected for an assumed impurity paramagnetism. The solid-line curve is the theoretical fit with $J/k = 33.8$°K. The ESR data (arbitrarily normalized at 300°K) are also plotted.

New Hydrido- and Oxygen-complexes of Rhodium

Masahiko TAKESADA, Hiroshi YAMAZAKI and Nobue HAGIHARA

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received November 18, 1967)

Hydrido- and oxygen-complexes of transition metals have found attention in connection with their catalytic behavior.[1] We now wish to report the preparations of new hydrido- and oxygen-complexes of rhodium which were obtained during studies on the hydrogenation of olefins, and the oxidation of triarylphosphines catalyzed by phenyl-(1, 5-cyclooctadiene)-(triphenylphosphine)-rhodium (I)*1.

During the treatment of a solution of I and triphenylphosphine (five molar equivalent to I) in toluene with hydrogen (1 atm) at room temperature for 30 min, approximately one mole of hydrogen was absorbed and yellow crystals were deposited. The reaction mixture was filtered and washed with toluene to give yellow crystals of hydrido-tetrakis-(triphenylphosphine)-rhodium, $HRh(PPh_3)_4$, (II) (Yield, 89%; mp 162—163°C (decomp). Found: C, 75.17; H, 5.31; P, 10.96%. Calcd for $RhC_{72}H_{61}P_4$: C, 75.00; H, 5.33; P, 10.74%.). II was unstable in air, especially in solution, and sparingly soluble in acetone, tetrahydrofuran, dichloromethane and benzene. II was diamagnetic and its infrared spectrum showed a sharp absorption at 2152 cm^{-1} (in Nujol mull; at 2140 cm^{-1} in KBr disk), which was assigned to the stretching vibration of the rhodium-hydrogen bond. The yellow deuterium analog was synthesized by a similar procedure with molecular deuterium, and its infrared spectrum showed an absorption at 1548 cm^{-1} (Nujol mull). Confirmation of the presence of a Rh-H bond in II by NMR was unsuccessful due to the low solubility. Yellow crystals of hydrido-(triphenylphosphine) - tris(triphenylarsine)-rhodium, $HRh(PPh_3)(AsPh_3)_3$,(III), were also obtained by a similar procedure (Yield, 20%; mp 168—169°C (decomp). Found: C, 67.18; H, 4.88%. Calcd for $RhC_{72}H_{61}As_3P$: C, 67.30; H, 4.79%. IR (Nujol mull): 2118 cm^{-1} with a shoulder at 2140 cm^{-1}). Hydrido-di(1, 2-bisdiphenylphosphinoethane)-rhodium[2] was also prepared by a similar treatment, obtaining a 67% yield.

Yellow crystals were obtained by a virtually similar method to that described for II except that molecular hydrogen was replaced with oxygen or air. Elemental analysis conformed to a composition, $Rh(PPh_3)_3O_2$, (IV) (Yield, 65%; mp 135—137°C (decomp). Found: C, 70.44; H, 4.96; P, 9.52%. Calcd for $RhC_{54}H_{45}O_2P_3$: C, 70.36; H, 4.92; P, 10.09%.). IV was explosive and sparingly soluble in common organic solvents. Its infrared spectrum showed an absorption at 815 cm^{-1} (KBr disk), assignable to the stretching vibration of the peroxy group. The diamagnetism of IV seems to suggest that the complex has a dimeric structure, but X-ray analysis should be carried out to determine the exact structure. By a similar procedure, $Rh(PPh_3)(AsPh_3)_2O_2$ was also prepared (Yield, 3%; mp 137—139°C. Found: C, 64.45; H, 4.51%. Calcd for $RhC_{54}H_{45}As_2O_2P$: C, 64.24; H, 4.49%. IR (KBr disk): 810 cm^{-1}.).

Detailed studies of these complexes will be published in the near future.

*1 This compound was prepared by the treatment of chloro-(1, 5-cyclooctadiene) - (triphenylphosphine)-rhodium with phenylmagnesium bromide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 271—274 (1968)

A Study of the Charge-Transfer Complexes. V. The Complexes of Tetracyanoethylene with *trans*-Stilbene and Related Compounds*1,*2

Taku MATSUO*3 and Hiroshi AIGA*4

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received August 11, 1967)

The charge-transfer (CT) absorptions of complexes of tetracyanoethylene with *trans*-stilbene and related compounds were measured both in solution and in solid media. The first and the second CT bands were found to be affected differently by the substituents on the donor molecule; thereupon they were assigned to the transitions of an electron from, respectively, the highest occupied and the second highest occupied orbitals of the donor to the lowest unoccupied orbital of the acceptor. Both the location and the intensity of the first CT band were found to be extremely sensitive to variation in media and temperature. The explanation was arrived at by the use of a model where an acceptor molecule was assumed to associate independently with several different sites of a donor molecule.

In contrast to the presence of abundant information on the charge-transfer (abbreviated to CT hereafter) complexes of condensed aromatic hydrocarbons, no paper has been devoted to the study of the donor properties of linear polyenes and their analogues. In this connection, it is very interesting to investigate the CT complexes of stilbene, the smallest α,ω-diphenylpolyene. In one of the preceding papers of this series, the CT complexes between methyl-substituted *trans*-stilbenes and chloranil or pyromellitic dianhydride have been reported on.[1] The donor strength of stilbene has been found, there, to be strongly dependent on the distortion of the molecular plane. In this paper, a study will be made of the interactions between stilbene derivatives and tetracyanoethylene (TCNE). In order to elucidate the nature of the second CT band, the donor properties of biphenyl, diphenyl ether, and other related compounds will also be investigated.

Experimental

Materials. The diphenyl ether, biphenyl, *p*-terphenyl, and naphthalene were reagent-grade chemicals supplied by the Tokyo Kasei Organic Chemicals Co., and were used after repeated purifications. The cyclohexane and methylene chloride were purchased from the Wako Pure Chemical Co., and were purified by the standard procedure for each solvent. All the other compounds were synthesized in the authors' laboratory by authentic processes, and were repeatedly and carefully purified. The melting points, results of CH analysis, IR and NMR spectra were used to identify the prepared compounds. The purity was checked by gas chromatography, if that was possible.

Spectroscopic Measurements. The solutions of CT complexes were prepared by mixing the respective components to suitable concentrations (donor, 0.01—0.1 mol/*l*; acceptor, 0.005—0.015 mol/*l*). The spectra were measured by a conventional method, using either a Hitachi model EPS-2U or a Shimazu-Bausch & Lomb model SP 505 recording spectrometer. The solid complexes were obtained from the cyclohexane solutions as sharp needles. The crystals were dispersed in starch, and their relative diffuse reflectance measured by a method described before.[2]

Results and Discussion

The wave numbers for the CT absorption bands of the complexes between TCNE and stilbene derivatives in methylene chloride are summarized in Table 1. As may be seen in the table, the two CT absorption bands behave differently upon the introduction of substituents. In the cases of the compounds II, III, and VII, the molecular planes are considered to be distorted due to the presence of steric hindrance. As to the complexes of the compounds in this group, the first CT bands are found at larger wave numbers than that for *trans*-stilbene, while the second bands are found at almost the same positions. The effect of methyl substitution on the benzene ring also gives very important information (compounds IV, V, VI,

Table 1. The charge-transfer absorption bands of TCNE complexes with *trans*-stilbene and the related compounds in methylene chloride

Donor	The first band (kK)	The second band (kK)
trans-Stilbene (I)	16.6±0.1	25.3±0.2
cis-Stilbene (II)	18.7±0.1	24.8±0.2
trans-α-Methylstilbene (III)	17.3±0.1	25.2±0.2
trans-2-Methylstilbene (IV)	16.7±0.1	23.9±0.2
trans-3-Methylstilbene (V)	16.5±0.1	24.5±0.2
trans-4-Methylstilbene (VI)	15.7±0.1	25.0±0.2
trans-α, α'-Dimethylstilbene (VII)	18.5±0.2	24.8±0.2
trans-4, 4'-Dimethylstilbene (VIII)	14.8±0.1	25.0±0.2
trans-4-Methoxystilbene (IX)	14.3±0.1	23.8±0.3
trans-4, 4'-Dimethoxystilbene (X)	12.8±0.1	21.9±0.2
trans-4, 4'-Dibromostilbene (XI)	16.9±0.1	25.4±0.2
trans-4, 4'-Diacetoxystilbene (XII)	16.8±0.1	25.9±0.3
Styrene (XIII)	20.6±0.1	25.1±0.2
trans-α, ω-Diphenylbutadiene (XIV)	14.9±0.1	24.2±0.3

and VIII). The second CT band shows an appreciable red shift if a methyl group is at 2- or 3-position. The first CT band, on the other hand, is affected by the methyl group at the 4-position. The effects of methyl substitutions, as has been described above, are well correlated to the first-order perturbation effects on the highest occupied and the second highest occupied π-orbitals, as calculated by simple LCAO MO theory. The highest occupied orbital mainly consists of the p-orbitals of the carbon atoms at the 1-, 4-, and α-positions. The second highest occupied orbital, on the other hand, does not involve the carbon atoms of the central double bond. In other words, the second highest occupied orbital is localized at the benzene rings. The methyl substitution at the 4-position and the decrease in conjugation in the C_1-C_α bond are, therefore, expected to have a much larger effect on the energy level of the highest occupied orbital than on that of the second highest occupied orbital. An exactly opposite situation is expected if the substituent is at either the 2- or 3-position. On the basis of the above facts, the first and the second CT bands may be assigned to the electronic transition originating from the highest occupied orbital and that from the second highest occupied orbital of stilbene respectively. By the use of the results of Beveridge and Jaffes' LCAO-SCF-CI computation,[3] the second highest occupied orbital of *trans*-stilbene is estimated to be 1.4 eV below the highest occupied orbital.*[5] In good agreement with this value, the separation between the first and the second CT bands in Table 1 is found to be 1.1 eV.

In the cases of methoxystilbenes, the second CT band, like the first band, is appreciably affected by the substituent at the 4-position. It may be suggested, then, that the effect of the methoxyl group is somewhat larger than a simple perturbation of the donor orbital. The minor effects of the bromine and acetoxyl groups may be due to the slightly electron-withdrawing natures of these substituents.

The effect of extended conjugation may be seen by examining the absorption bands of the complexes of TCNE with styrene, *trans*-stilbene, and *trans*-α, ω-diphenylbutadiene. The wave number for the first CT band rapidly decreases in the above order of donors. The second CT band, on the other hand, is affected to a much smaller extent.

In order to investigate the nature of these second

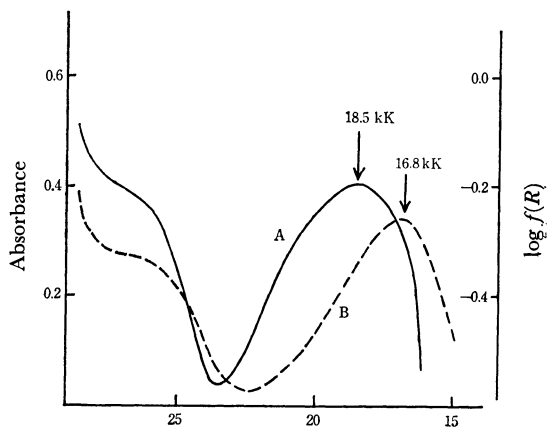

Fig. 1. The CT absorption spectra of TCNE complex with *trans*-stilbene.
A: The diffuse reflectance spectra (the complex, 6 mg; starch, 300 mg). The function $f(R)$ is the Kubelka-Munk function as defined as

$$f(R)=(R-1)^2/2R$$

where R is the relative diffuse reflectance (see Ref. 2 for further detail).

*5 The energy for the ^1G state, which corresponds to the excitation of an electron from the second highest occupied orbital to the lowest unoccupied orbital of *trans*-stilbene, was estimated by taking an arithmetic mean of those for the $^1G^-$ and $^1G^+$ states given in Ref. 3.

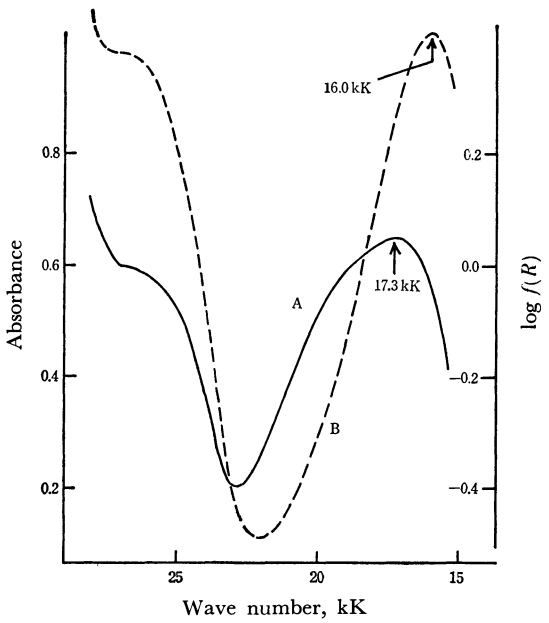

Fig. 2. The CT absorption spectra of TCNE complex with *trans*-4-methylstilbene.
A: The diffuse reflectance spectra (the complex, 9 mg; starch, 300 mg).
B: The absorption spectra in cyclohexane (the acceptor, 0.002 mol/*l*; the donor, 0.05 mol/*l*).

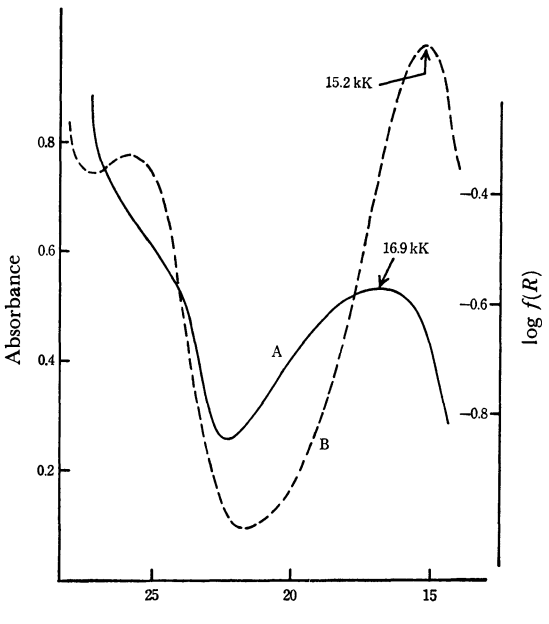

Fig. 3. The CT absorption spectra of TCNE complex with *trans*-4,4'-dimethylstilbene.
A: The diffuse reflectance spectra (the complex, 20 mg; starch, 400 mg).
B: The absorption spectra in cyclohexane (the acceptor, 0.002 mol/*l*; the donor, 0.05 mol/*l*).

CT bands further, the diffuse reflectance spectra of solid complexes have been measured (Figs. 1—3). In comparison with the absorptions in the solutions, the second CT bands of the solid complex appear in slightly lower wave-number regions. The first bands, on the other hand, shifts to considerably higher wave numbers. This blue shift of the CT band is extraordinary, since the frequencies of the absorption bands of crystals of TCNE complexes with polycyclic aromatic hydrocarbons are always lower than those observed with the solutions.[4] Even in the case of solid complexes, the CT absorption bands are almost entirely determined by the interactions between donor and acceptor molecules in contact each other. This suggests that the configuration of TCNE complexes of *trans*-stilbene in solid media may be quite different from that in solution.

Analogously to the case of stilbene, many donor molecules with two benzene rings connected by essential single bonds are expected to have second highest occupied orbitals which are localized on

Table 2. The charge-transfer absorption bands of TCNE complexes with biphenyl and the related compounds in methylene chloride

Donor	The first band (kK)	The second band (kK)
Biphenyl	19.9±0.1	25.2±0.2

D: *trans*-Stilbene-TCNE complex
E: Diphenylamine-TCNE complex
The absorbances at the absorption maxima of the first and the second CT bands are given by D_1 and D_2 respectively.

each benzene ring. The CT bands of TCNE complexes with such donors are summarized in Table 2. In contrast to the large variation in the first CT bands, the second CT bands remain relatively consistent throughout the complexes. In the case of the TCNE-*p*-terphenyl complex, it is also noticed that the intensity ratio between the first and the second CT bands is more than twice that in the TCNE-biphenyl complex (Fig. 4). Furthermore, the intensities of the two CT bands are found to show different temperature dependences, as Fig. 5 shows. The intensity ratio for the naphthalene complex, on the other hand, is independent of the temperature. Therefore, it is obvious that the CT complexes studied here can not be represented by the same single complex for each system and at various states. Briegleb, Czekalla, and Reuss have reported similar observations on the CT complexes of some condensed polycyclic aromatic hydrocarbons, and have suggested that the variation is due to the statistical fluctuation of the conformations.[5]

Here the authors would like to suggest a model for the CT complexes. In the case of a donor molecule with a long, conjugated π-electron system, as has been studied here, there are several sites which may be used for association with an acceptor molecule. The donor-acceptor pairs associated at the different sites will give different CT spectra. As the first CT band of the TCNE-stilbene complex shows a large blue shift in solid media, the conformation of the complex in crystal form seems to be less suited to the CT interaction than that in solution. In other words, intermolecular interaction other than CT force are very important in determining the conformations of the complex in solid media. This type of intermolecular interaction is naturally expected to be present even in the case of complex in solution. As a consequence, the relative importance of the sites for the complex formation is expected to be strongly dependent on the nature of the media and on the temperature. The CT spectra of the system may, then, be affected by the same factors.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 275—284 (1968)

Electron Spin Resonance of X-Irradiated Single Crystals of Zinc Acetate Dihydrate: Hindered Rotation of Methylene Group in a Free Radical CH_2COO^-*1

Hiroji OHIGASHI and Yukio KURITA

Basic Research Laboratories, Toyo Rayon Co., Ltd., Tebiro, Kamakura

(Received August 17, 1967)

Electron spin resonance spectra of X-irradiated single crystals of zinc acetate dihydrate have been studied at 9.2 Gc in the temperature range from 77°K to 380°K. The radicals trapped at 77°K are CH_3 and CH_2COO^-. The former disappears above 150°K. The latter is stable and persists up to 370°K. The principal values of hyperfine coupling constants for two indetical hydrogens of the radical CH_2COO^- have been found to be 10.5, 20.6 and 33.4G. The CH_2 group in the radical undergoes restricted rotation about the C–C bond. Analysis of the ESR spectra at different temperatures with a modified Bloch equation shows the activation energy and the frequency factor for the restricted rotation to be 5.8 ± 0.2 kcal/mol and $(4.4\pm2.7)\times10^{12}$ sec^{-1}, respectively.

Electron spin resonance (ESR) studies of free radicals have given valuable information on the structure of the radicals as well as their restricted motion. Changes in ESR spectra with temperature due to motion of free radicals have been found and analyzed in some irradiated organic substances. Methyl groups undergo restricted reorientation about a C–C bond in such radicals as CH_3-$CHCOOH$ trapped in alanine[1,2] and CH_3C-$(COOH)CH_2COOH$ trapped in itaconic acid[3]. Their rotation is nearly quenched below 100°K, but the methyl group of a radical $CH_3C(COOH)_2$ in irradiated malonic acid executes nearly free rotation even at 4.2°K.[4] Restricted torsional motion of a methylene group about a C–C bond has also been found in radicals trapped in an irradiated crystal of hexamethylenediammonium adipate,[5] in an irradiated mixed crystal of urea-fumaric acid[6] and in irradiated ethylmalonic acid and *n*-propylmalonic acid.[7] Reorientation of a terminal methylene group, however, has not been found in a radical of the type CH_2R within the knowledge of the present authors, except insufficient evidence for the reorientation motion in a radical CH_2COO^- trapped in an irradiated crystal of glycine.[8]

In this paper, the ESR studies of X-irradiated single crystals of zinc acetate dihydrate $Zn(CH_3COO)_2\cdot2H_2O$ are presented. The trapped radicals have been identified as CH_3 and CH_2COO^-. A marked temperature dependence has been found in the absorption spectra of the radical CH_2COO^-, from which it is concluded that the motion of the CH_2 group is quenched at low temperatures but undergoes rapid reorientation around the C–C bond above room temperatures. A quantitative analysis of the temperature dependence of the ESR spectra has been undertaken to give the activation energy and the frequency factor for the internal rotation of the radical in the crystal.

Experimental Procedures and Outline of the ESR Spectra

Single crystals of zinc acetate dihydrate were grown from the aqueous solution by slow evaporation. The crystal structure has been determined by Niekerk *et al.*[9]; the lattice is monoclinic with space group $C2/c$-C_{2h}^6, $a=14.5$, $b=5.32$, $c=11.02$ Å and $\beta=100.0°$ with four molecules per unit cell. The crystal axes were determined by comparing interfacial angles calculated from the lattice constants with those observed with an optical goniometer available from the Stoe Co. An orthogonal

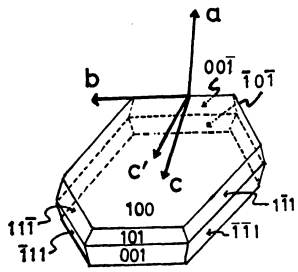

Fig. 1. The crystal form and the crystal axes of zinc acetate dihydrate. The orthogonal set of the *a*, *b* and *c'* axes are chosen for analysis of the ESR spectra.

set of the axes *a*, *b* and *c'* was chosen for the analysis of the spectra as shown in Fig. 1.

The crystals were exposed to X-rays (180 kV, 23 mA) to the extent of approximately 1 Mrad at 77°K. Second derivative ESR spectra were recorded with a Varian 4501 Spectrometer with 100 kc and 40 cps double field modulation. The spectra at 77°K were obtained for the irradiated crystal mounted in a quartz Dewar filled with liquid nitrogen for various orientations of the crystal. The spectra at various temperatures in the range from 77°K to 380°K were taken at two fixed field directions, parallel to the *c* axis and parallel to the direction which made an angle of +23° with the *a* axis in the *ac'* plane. The temperature control was achieved using a Varian V-4547 variable temperature equipment by passing heated or cooled nitrogen gas around the crystal. The temperature was measured with a copper-constantan thermocouple located near the crystal, with probable error of 3°C. ESR spectra of zinc acetate dihydrate powder irradiated at room temperature were also measured at various temperatures.

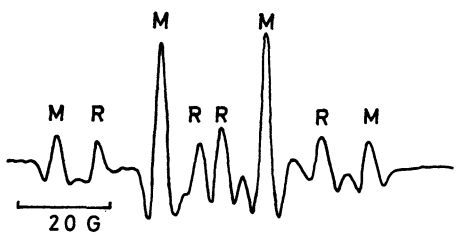

Fig. 2. Second derivative ESR spectra of a single crystal of zinc acetate dihydrate irradiated at 77°K. The spectra were obtained at 77°K for external magnetic field parallel to the *a* axis.

Figure 2 shows an ESR spectrum of the crystal irradiated at 77°K, which is measured immediately after the end of the irradiation, at the same temperature with magnetic field parallel to the *a* axis. The spectrum is composed of a quartet of peaks with equal spacings and with the intensity ratio of 1 : 3 : 3 : 1 (hereafter referred to as M for the sake of convenience), and a quartet (a doublet-doublet) of peaks with equal intensity (referred to as R). The integrated intensity of M is about twice as large as that of R. Above 150°K, the spectrum M disappears, while R persists up to 370°K where water of hydration is taken off. The pattern of R changes reversibly when the crystal is cooled or warmed in the temperature range from 77°K to 350°K. For the crystal irradiated at room temperature, only the spectrum R was observed at any temperature. The substitution of water of hydration by D_2O had no effect on the spectra except narrowing of the line width.

The spectrum M is essentially isotropic and its splitting is 23±1G. A paramagnetic species responsible for M is identified with no doubt as a methyl radical CH_3 which reorients rapidly. The same radical with coupling constants 21.8, 22.5, 22.5G was found in an X-irradiated sodium acetate trihydrate by Rogers and Kispert.[10] The spectrum R is highly anisotropic and its doublet splittings vary from 9 to 33G with the crystal orientation. It will be shown in the following section that the quartet R is attributable to a radical CH_2COO^-.

Analysis of ESR Spectra at Low Temperature and Structure of a Free Radical CH_2COO^-

Typical absorption spectra at 77°K are shown in Fig. 3 for the crystal irradiated at room temperature. In general, the spectra consist of two sets of quartets (doublet-doublet) with equal intensity, which coalesce into a quartet when the magnetic field

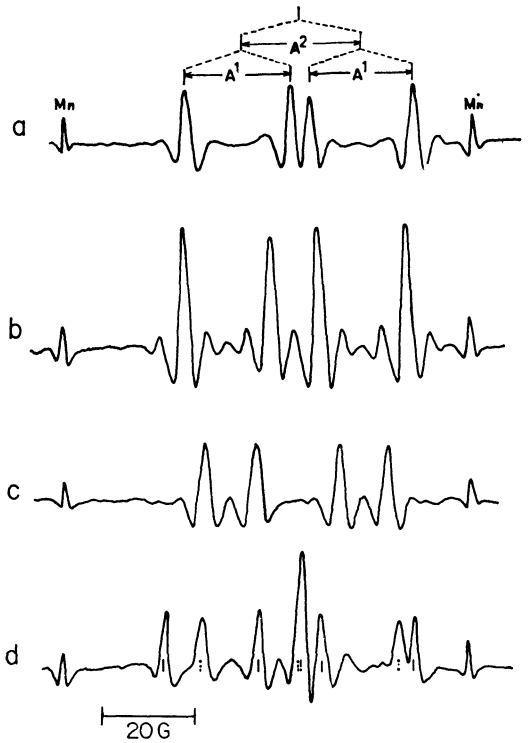

Fig. 3. Second derivative spectra of the crystal irradiated at room temperature and measured at 77°K with the magnetic field (a) parallel to the *a* axis, (b) parallel to the *b* axis, (c) parallel to the *c* axis and (d) at an angle of 30° from the *a* axis toward the *b* axis in the *ab* plane. The outermost lines are of Mn^{2+} in MgO powder which is used as field marker (spacing; 87.5 G).

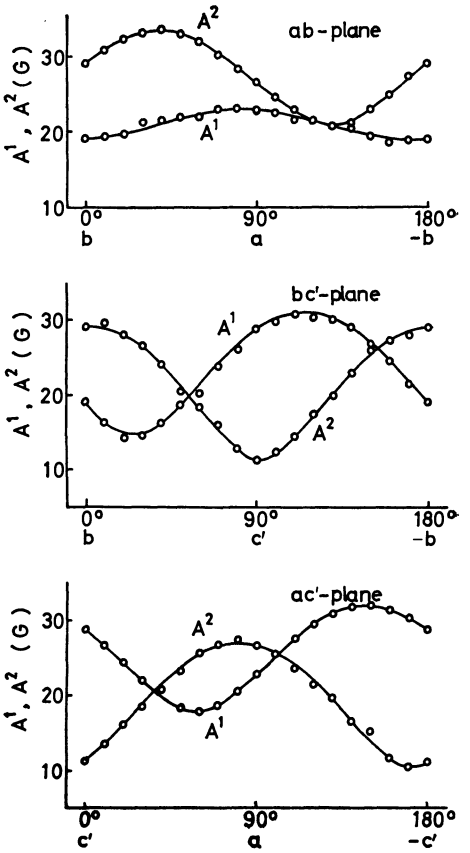

Fig. 4. Calculated (solid lines) and observed (circles) hyperfine splittings at low temperature with the magnetic field in the *ab*, *bc'* and *ac'* planes in a single crystal of zinc acetate dihydrate irradiated at room temperature. The angular dependences of A^1 and A^2 are illustrated for one of the two quartets observed with the magnetic field in the *ab* and *bc'* planes. A 180° rotation of the curves illustrated in the figure about the *b* axis gives the curves omitted.

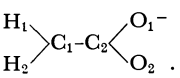
is parallel to the *b* axis or in the *ac'* plane. The same spectra were obtained when the direction of the field is (l, m, n) or $(l, -m, n)$, where l, m and n are the direction cosines of the magnetic field with respect to the *abc'* system. These facts are compatible with the expectation that the two chemically equivalent but magnetically different radicals are trapped in the crystal with monoclinic symmetry.

It is evident that each quartet arises from two protons with different nuclear hyperfine coupling constants which are referred to as A^1 and A^2 as shown in Fig. 3. Figure 4 shows angular dependences of A^1 and A^2 observed when the magnetic field is in the *ab*, *bc'* or *ac'* planes. The observed data were analyzed by means of least mean square method with the aid of the second-order equations. The calculation was performed by an electronic computer. Table 1 shows the values determined for the principal elements of the tensors $\boldsymbol{A}^1$ and $\boldsymbol{A}^2$, and those of the spectroscopic splitting tensor $\boldsymbol{g}$. The angular dependences of A^1 and A^2 calculated from the results given in Table 1 are shown graphically in Fig. 4. The principal values of $\boldsymbol{A}^1$ and $\boldsymbol{A}^2$ are identical within the limit of experimental error. Therefore, the radical responsible for the spectrum R must contain CH_2 and is most likely



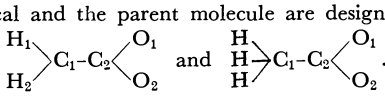
Further analysis confirms this identification. An unpaired electron is in the p_π orbital of the sp^2 configuration of C_1. In such a radical, it has been shown both theoretically and experimentally that the smallest g value ($\boldsymbol{g}_1$) should occur along the direction parallel to the symmetry axis of the p_π orbital (perpendicular to the radical plane) and the directions corresponding to the minimum, medium and maximum value of the principal elements of the hfs tensor are parallel to the C-H bond, parallel

TABLE 2. THE ORIENTATION OF THE RADICAL CH_2COO^- AND THE PARENT MOLECULE CH_3COO^- IN A CRYSTAL OF ZINC ACETATE DIHYDRATE[a)]

Direction	Vector[b)]	Direction cosine with respect to the *abc'* system[c,d)]			
C_1-C_2 (radical)	$(\boldsymbol{A}_1^1+\boldsymbol{A}_2^1)$	0.592	0.675	−0.443	$(\boldsymbol{n}_{r1})$
	$\boldsymbol{g}_3$	0.641	0.449	−0.583	$(\boldsymbol{n}'_{r1})$
C_1-C_2 (molecule)	From crystal structure[9)]	0.662	0.534	−0.531	$(\boldsymbol{n}_{m1})$
Normal to the plane of $H_1H_2O_1O_2$ (radical)	$(\boldsymbol{A}_1^1\times\boldsymbol{A}_1^2)$	0.792	−0.588	0.165	$(\boldsymbol{n}_{r2})$
	$\boldsymbol{g}_1$	0.726	−0.639	0.252	$(\boldsymbol{n}'_{r2})$
Normal to the plane of $O_1O_2C_1C_2$ (molecule)	From crystal structure[9)]	0.892	−0.446	0.115	$(\boldsymbol{n}_{m2})$

The angle between C_1-C_2 (radical) and C_1-C_2 (molecule) is 9° ($\angle\boldsymbol{n}_{m1}$, $\boldsymbol{n}_{r1}$) or 13° ($\angle\boldsymbol{n}_{m1}$, $\boldsymbol{n}'_{r1}$). The angle between the normal to the plane of $H_1H_2O_1O_2$ (radical) and that of $O_1O_2C_1C_2$ (molecule) is 9° ($\angle\boldsymbol{n}_{m2}$, $\boldsymbol{n}_{r2}$) or 16° ($\angle\boldsymbol{n}_{m2}$, $\boldsymbol{n}'_{r2}$).

a) The atoms in the radical and the parent molecule are designated as;



b) $\boldsymbol{A}_1^1$, $\boldsymbol{A}_1^2$, $\boldsymbol{g}_3$ and $\boldsymbol{g}_1$ represent the principal vectors shown in Table 1.

c) Of the two crystallographically unequivalent species, direction cosines are tabulated for one species.

d) Unit vectors having these direction cosines are designated as $\boldsymbol{n}_{r1}$, $\boldsymbol{n}'_{r1}$, *etc.*

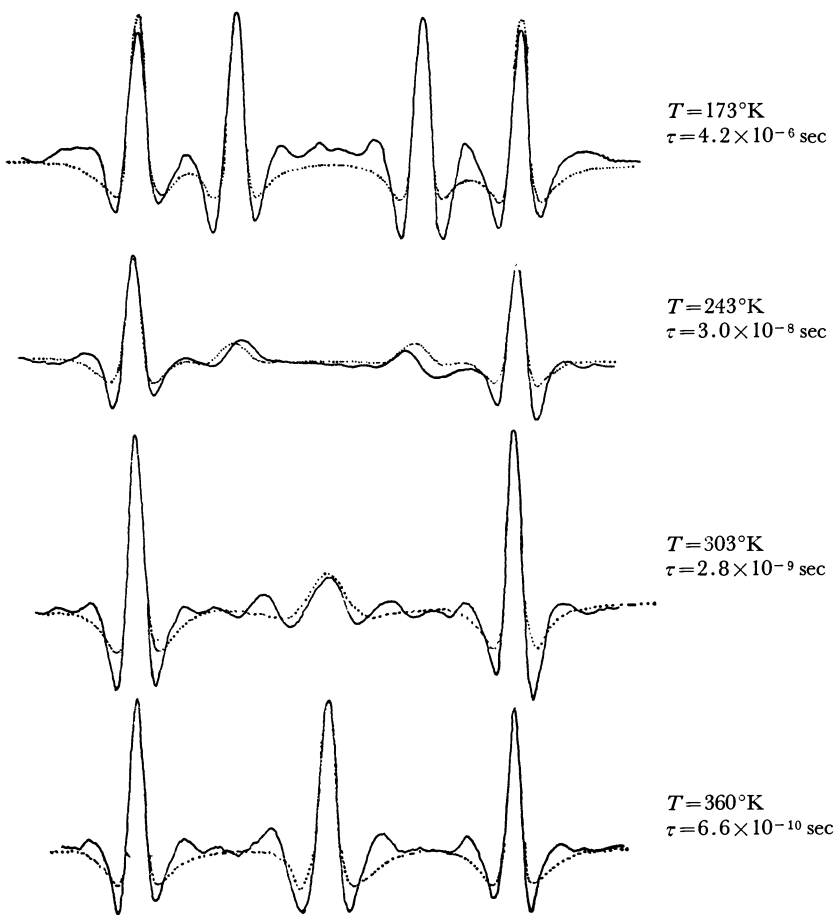


Fig. 5. Observed (solid lines) and calculated (dotted lines) second derivative ESR spectra of CH_2COO^- in the crystal for the magnetic field parallel to the *c* axis at different temperature *T*. The calculated spectra are obtained according to Eq. (2) together with Eq. (3) and the values of $\boldsymbol{E}$ and f_0 indicated in (4).

Fig. 6. Second derivative absorption curves of CH_2COO^- similar to Fig. 5, except that the applied magnetic field is in the ac' plane and makes an angle of 23° with the a axis toward the c' axis.

to the symmetry axis of the p_π orbital and perpendicular to these two directions, respectively.[11-13]

In addition, a symmetry consideration on the radical predicts that the direction of the C_1-C_2 bond is parallel to a bisector of the directions of the minimum principal values of $\boldsymbol{A}^1$ and $\boldsymbol{A}^2$ or is parallel to $\boldsymbol{g}_2$ or $\boldsymbol{g}_3$, where $\boldsymbol{g}_2$ and $\boldsymbol{g}_3$ are the medium and maximum principal elements of g tensor, respectively.

The direction of the C_1-C_2 bond and the normal to the plane $H_1C_1C_2H_2$ of the radical are determined from the values given in Table 1 and compared with the orientation of the parent molecule in the crystal which is determined by X-ray analysis.[9] The direction normal to the plane $H_1C_1C_2H_2$ (perpendicular to $\boldsymbol{A}_1^1$ and $\boldsymbol{A}_1^2$) agrees within 8° with the direction along the symmetry axis of p_π orbital (parallel to $\boldsymbol{g}_1$). The angle $\angle H_1C_1H_2$ (angle between $\boldsymbol{A}_1^1$ and $\boldsymbol{A}_1^2$) is obtained as 118°±3°. As shown in Table 2, the direction of the C_1-C_2 bond of the radical agrees with that of the parent molecule. Moreover, the plane $H_1C_1C_2H_2$ of the radical is parallel to the plane $O_1O_2C_1C_2$ of the parent molecule. These facts indicate that the free radical is formed from the parent molecule CH_3COO^- by loss of a hydrogen atom followed by a reorientation of the CH_2 group to make a planar radical. The orientation of $O_1O_2C_2$ is unchanged when the loss of hydrogen occurs. The principal values of the hfs tensor of the radical CH_2COO^- trapped in a zinc acetate dihydrate crystal (10.4, 20.8, 33.4G) are nearly equal to those of the radical CH_2COO^- produced in glycine (10.3, 21.8, 32.5G),[14] and to those of CH_2COOH produced in malonic acid (11.9, 20.5, 32.6G).[15] It is concluded that the spin density on the α-carbon atom in these radicals is

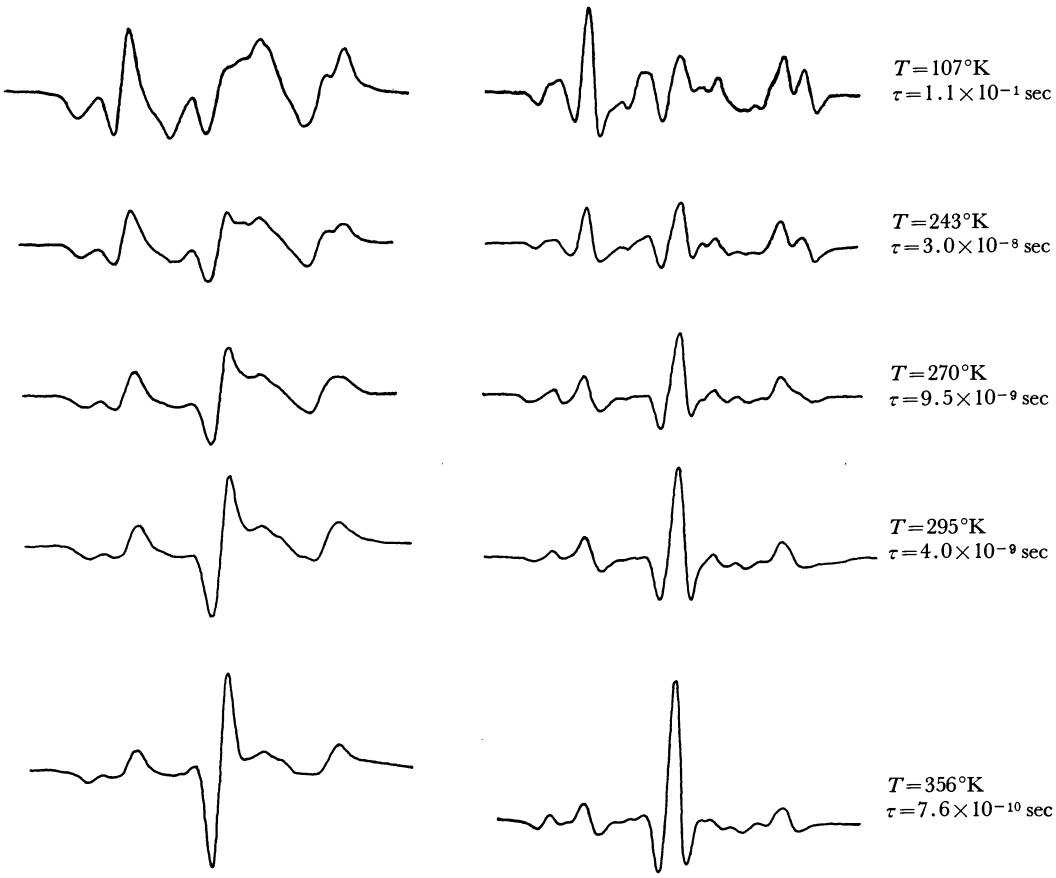

Fig. 7. Temperature dependences of the first (left side) and second (right side) derivative ESR spectra of CH_2COO^- trapped in X-irradiated zinc acetate dihydrate powder. The value of τ given in each spectrum is calculated from Eq. (3) with E and f_0 indicated in (4).

unaffected whether the COO group is linked with neighboring molecules by hydrogen bonds or makes ionic bonds with Zn^{2+}.

Temperature Dependence of ESR Spectra; The Hindered Rotation of CH_2 Group of CH_2COO^-

Figures 5 and 6 show the ESR spectra of CH_2COO^- recorded at various temperatures with the magnetic field in the *ac'* plane. In the temperature range from 77°K to 170°K the spectrum is composed of a quartet with equal intensity. At higher temperatures, the outer lines of the quartet are unchanged, whereas the inner lines become broadened, their peak heights decrease, and their separation also decreases. Near 270°K the inner lines practically disappear. At higher temperature a line appears at the center of outer lines and its intensity increases with increase of temperature and approaches twice the intensity of the outer lines. First and second derivative ESR spectra of CH_2COO^- trapped in zinc acetate dihydrate powder obtained at different temperatures are illustrated in Fig. 7 for comparison with the crystal ESR spectra.

The temperature dependence mentioned above is characteristic of the system in which the two hydrogen atoms exchange their sites with each other through a rotation of the CH_2 group about the C-C bond, the rate of the exchange increasing with increasing temperature. This is easily recognized qualitatively as illustrated in Fig. 8. If the reorientation rate, τ^{-1}, is much smaller than $|A^\alpha - A^\beta|$, the spectrum will be a quartet, where A^α and A^β are the hyperfine coupling constants in frequency unit of the protons located at equilibrium positions "α" and "β", respectively. The resonant frequencies of the quartet are $\nu_0 \pm |A^\alpha + A^\beta|/2$ (outer lines), corresponding to the nuclear spin states $(++)$ and $(--)$ of the two protons H_1 and H_2, and $\nu_0 \pm |A^\alpha - A^\beta|/2$ (inner lines), corresponding to $(+-)$ and $(-+)$, where ν_0 is the resonant frequency of the unpaired electron with no hfs and $(+-)$, for example, designates the state in which H_1 and H_2 have nuclear spin components of $+1/2$ and $-1/2$, respectively.

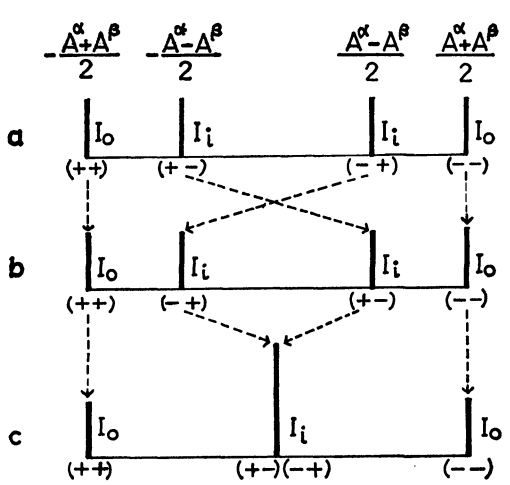

Fig. 8. Patterns of absorption spectra of CH_1H_2R.

(a) H_1 and H_2 are in the equilibrium positions "α" and "β", respectively.
(b) H_1 and H_2 exchanges their positions through rotation around the C-C bond. H_1 and H_2 are in "β" and "α", respectively.
(c) The methylene group undergoes rapid reorientation.

The relation $A^\alpha > A^\beta > 0$ is assumed.

When $\tau^{-1} \gg |A^\alpha - A^\beta|$, the spectrum is a triplet with the intensity ratio of 1 : 2 : 1, the resonant frequencies of which are $\nu_0 \pm |A^\alpha + A^\beta|/2$, corresponding to (++) and (−−), and ν_0 which corresponds to (+−) and (−+). If τ^{-1} is comparable to $|A^\alpha - A^\beta|$, the positions and intensities of the outer lines are the same as those in the two cases mentioned above but inner lines become broadened and its separation becomes smaller than $|A^\alpha - A^\beta|$. These changes of the spectra with change of τ^{-1} is caused by the fact that the nuclear spin state of the protons is unchanged during the reorientation and, then, the inner lines exchange their positions with each other but the outer lines do not through the reorientation. The exchange or reorientation effects of protons on NMR spectra have been analyzed by Gutowsky and Holm[16] with modified Bloch equations. The effects of rotation of methyl group in a radical CH_3CHR on ESR spectra have been investigated with a similar procedure by Miyagawa and Itoh.[1] After their procedure, we analyzed numerically the second derivative ESR spectra of a radical with two protons which transfer between two sites.

If the splitting of the inner lines H_{spl}($|A^\alpha - A^\beta|$ in gauss) and the maximum slope line width

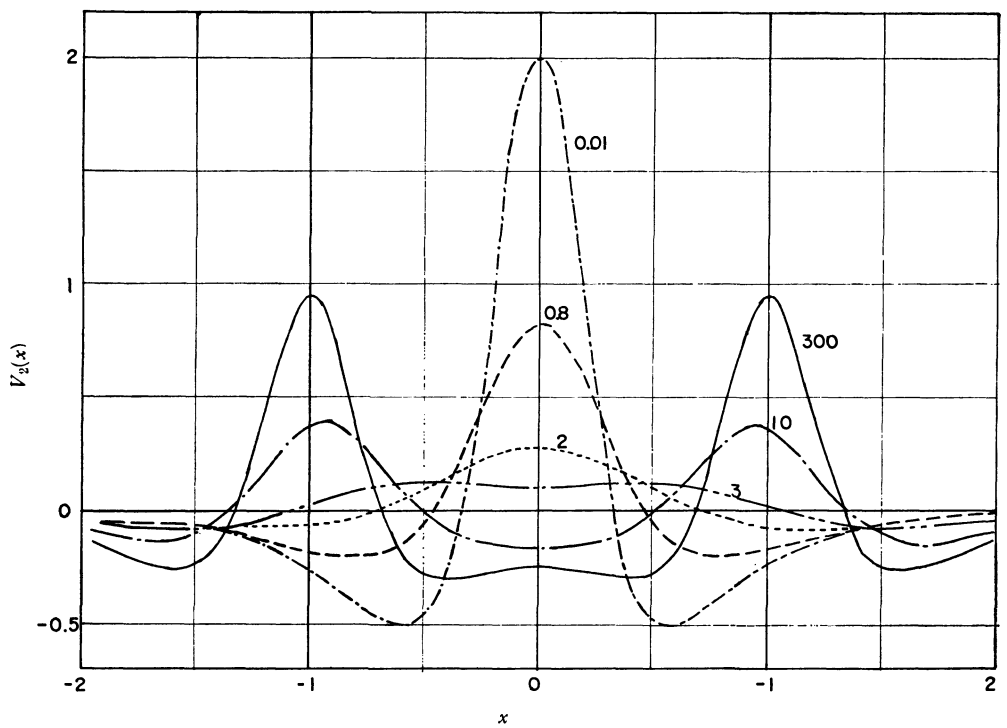

Fig. 9. Second derivative curves $V_2(x)$ for $r=0.33$ with different reduced exchange rates t. The values of t are given on each curves.

16) H. S. Gutowsky and C. H. Holm, *J. Chem. Phys.*, **25**, 1228 (1956); see also, J. A. Pople, W. G. Schneider and H. J. Bernstein, "High-Resolution Nuclear Magnetic Resonance," McGraw-Hill Book Company, Inc., New York (1959), Chapt. 10.

ΔH_{msl}, both in the absence of the reorientation, are known, the spectra of the inner lines can be calculated for any given life time of the reorientation, τ. The absorption curve, V_0, is given as a function of reduced magnetic field x by the expression

$$V_0(x) = \frac{\sqrt{3}}{2} rt \,\mathrm{Real}\left\{\frac{f_\alpha + f_\beta}{1 - f_\alpha - f_\beta}\right\}, \qquad (1)$$

and the second derivative of the absorption curves by

$$V_2(x) = \frac{3\sqrt{3}}{8} (rt)^3 \times \mathrm{Real}\left\{\frac{(f_\alpha - f_\beta)^2(f_\alpha + f_\beta - f_\alpha f_\beta) + f_\alpha f_\beta (f_\alpha + f_\beta)}{(1 - f_\alpha - f_\beta)^3}\right\} \qquad (2)$$

where f_α and f_β are complex functions expressed as

$$\left.\begin{aligned} f_\alpha &= \left\{\frac{\sqrt{3}}{2} rt + 2 - i\frac{t}{2}(1 - x)\right\}^{-1} \\ f_\beta &= \left\{\frac{\sqrt{3}}{2} rt + 2 + i\frac{t}{2}(1 + x)\right\}^{-1} \\ &\qquad (i = \sqrt{-1}) \end{aligned}\right\} \qquad (3)$$

where

$$x = \frac{2}{H_{spl}} (H - H_0),$$

$$r = \Delta H_{msl}/H_{spl},$$

and

$$t = \tau\gamma H_{spl}.$$

In the above expressions, H is applied magnetic field, H_0 is magnetic field at the center of the inner doublet and γ is electronic gyromagnetic ratio.

Line shape of each absorption line has been assumed to be Lorentzian and, therefore, $\Delta H_{msl} = 2/(\sqrt{3}\,\gamma T_2)$, where T_2 is spin-spin relaxation time. Equations (1) and (2) are normalized so as $V_0(\pm 1) = V_2(\pm 1) = 1$ when $\tau = \infty$. The maximum value of $V_2(x)$ is the ratio of the peak intensity of the inner line, I_i, to that of the outer line, I_o, which can be calculated from Eq. (2) as a function of τ for given r and H_{spl}.

At 77°K, τ is large enough to assume that the rotation of the CH_2 group of the radical CH_2COO^- does not take place practically and hence the linewidth and the separation between inner lines observed at this temperature can be taken as ΔH_{msl} and H_{spl}, respectively. The values of H_{spl} and ΔH_{msl} have been observed to be 20.1G and 2.52G (r=0.125), respectively, for H parallel to the c axis, and to be 8.1G and 2.67G (r=0.33), respectively, for the magnetic field parallel to a line which makes an angle of +23° with the a axis in the ac' plane. Figure 9 shows the calculated spectra of the inner lines for several values of t

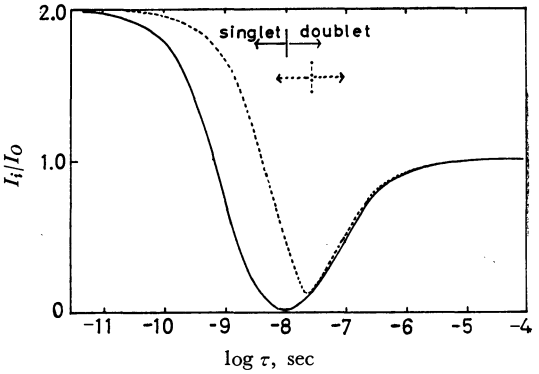

Fig. 10. Relation between τ and I_i/I_O for H_{spl}= 20.1 G and ΔH_{msl}=2.59 G (r=0.125) (solid line) and for H_{spl}=8.1 G and ΔH_{msl}=2.67 G (r=0.33) (dotted line).

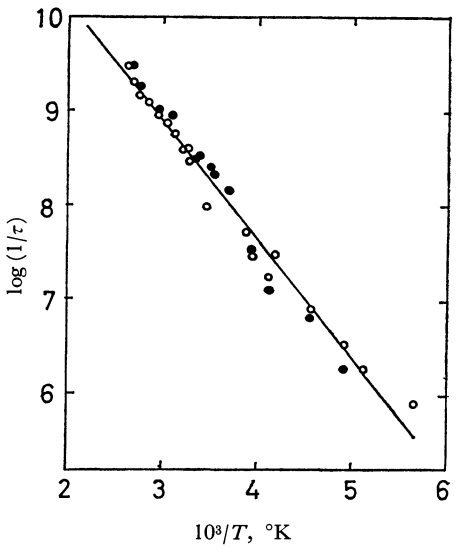

Fig. 11. Arrhenius plot of $1/\tau$ *versus* $1/T$. The straight line illustrates Eq. (3) with E=5.8 kcal/mol and $f_0 = 4.4 \times 10^{12}$ sec^{-1}. (○: H_{spl}=20.1 G, ΔH_{msl}=2.59 G, ●: H_{spl}= 8.1 G, ΔH_{msl}=2.67 G)

for the case of r=0.33. The ratios I_i/I_o calculated for r=0.125 and r=0.33 are shown in Fig. 10 as functions of τ. Comparing the quantities I_i/I_o observed at various temperatures with the calculated values, τ has been determined for the temperatures at which the spectra were obtained. The plots of $\log(1/\tau)$ *versus* $1/T$ are shown in Fig. 11. The linear relation between $\log(1/\tau)$ and $1/T$ indicates that τ follows the equation;

$$\frac{1}{\tau} = f_0 \exp(-E/RT), \qquad (3)$$

where f_0 and E are interpreted as the frequency factor and activation energy for the rotation of the CH_2 group about the C_1-C_2 bond, respectively.

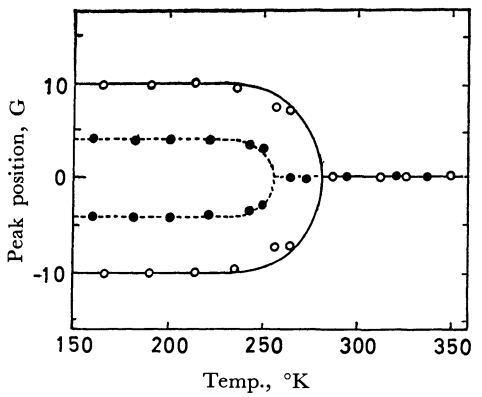

Fig. 12. Observed (dots) and calculated (lines) positions of the inner line peaks of the absorption spectra of CH_2COO^- in a zinc acetate dihydrate single crystal with varying temperature. The peak positions from the center of the spectra are measured in Gauss.
(○, ——: for $H_{spl}=20.1$ G and $\Delta H_{msl}=2.59$ G,
●, ----: for $H_{spl}=8.1$ G and $\Delta H_{msl}=2.67$ G)

The values for E and f_0 are found from Arrhenius plots in Fig. 11 as:

$$\left.\begin{aligned} E &= 5.8 \pm 0.2 \text{ kcal/mol} \\ f_0 &= (4.4 \pm 2.7) \times 10^{12} \text{ sec}^{-1}. \end{aligned}\right\} \quad (4)$$

In Figs. 5 and 6 the spectra calculated by Eqs. (2), (3) and (4) are illustrated with dotted lines for given temperatures. These figures show that the calculated spectra are in good agreement with the observed ones except tail parts of the absorption lines. The position of the inner line peaks has been calculated by the similar procedure as before and compared with the observation (Fig. 12). It is found in Fig. 12 that the observation is in good agreement with the calculation. The value of the frequency factor f_0 given in (4) is also in good agreement with 5.2×10^{12} sec^{-1} which is evaluated by the equation $f_0=kT/h$ based on the absolute rate theory,[17] where T is assumed to be 250°K. Lefebvre and Maruani[18] have calculated the absorption and first derivative spectra of randomly oriented CH_2COOH in which the methylene group rotate freely or is completely quenched arround the C-C bond (see Fig. 13 of their paper). It can be seen that Fig. 13 of their paper also reporduces the first derivative curves of the irradiated zinc acetate dihydrate powder (Fig. 7) in fair detail.

Disagreement of the calculated curves with the observed ones in the tail region (Figs. 5 and 6) arises from the following two reasons. Firstly, the calculation was carried out with an assumption that the shape function of each absorption line is Lorentzian but the real absorption line was nearly Gaussian. Secondly, the second-order effect or the "forbidden" transition was not taken into account, which was caused by a simultaneous transition of electronic and nuclear spins, though it was really observed in both sides of the absorption lines, as seen in Figs. 5 and 6.

For such radicals as $CH_2NHCONH_2$ (from methylurea),[19] CF_2CONH_2 (from trifluoroacetamide)[20] and CH_2COOH (from malonic acid),[15] the rotation of the CH_2 or CF_2 group does not occur even at room temperature. Activation energy of these groups is estimated to be higher than 9 kcal/mol. If it is assumed that $f_0=5\times10^{12}$ sec^{-1} and $H_{spl}=10$G, the lower energy than 9 kcal/mol would reveal the effect of the rotation on their ESR spectra. Therefore, it is of interest to examine, using a simple model, the cause of the fairly low activation energy for the CH_2 rotation in the case of CH_2COO^- in a crystal of zinc acetate dihydrate.

Now, we define θ as the angle between the plane $H_1C_1H_2$ and the plane $O_1O_2C_2$, and consider only an internal energy $V(\theta)$ of the radical which is a function of θ. $V(\theta)$ is a sum of the energies of five π-electrons $V_\pi(\theta)$ plus a repulsive energy $V_r(\theta)$ between the CH_2 and COO^- groups;

$$V(\theta) = V_\pi(\theta) + V_r(\theta). \quad (5)$$

$V_\pi(\theta)$ will be minimum at $\theta=0$ and π, and maximum at $\theta=\pi/2$ and $3\pi/2$, whereas $V_r(\theta)$ is maximum at $\theta=0$ and π, and minimum at $\theta=\pi/2$ and $3\pi/2$. The activation energy E for the rotation may be approximately $V(\pi/2)-V(0)$. With the simple Hückel MO method $V_\pi(\pi/2)-V_\pi(0)$ was calculated as follows.[21] Taking Coulomb energy for C_1, C_2, O_1 and O_2 to be α, $\alpha+0.2\beta$ $\alpha+2\beta$, and $\alpha+2\beta$, respectively, and taking the resonance energy for the C_1-C_2, C_2-O_1 and C_2-O_2 bonds to be $\beta\cos\theta$, $\sqrt{2\beta}$ and $\sqrt{2\beta}$, respectively, it is found that $V_\pi(\pi/2)-V_\pi(0)=-0.562\beta$. If β is taken as -18 kcal/mole,[21] which have been evaluated from the resonance energy for benzene, $V_\pi(\pi/2)-V_\pi(0)$ is 10.1 kcal/mol.

$V_r(\theta)$ is not known experimentally, but $V_r(0)-V_r(\pi/2)$ can be roughly evaluated as follows. Assuming the repulsive energy between a hydrogen atom and an oxygen atom is the same in CH_2COO^- and CH_3COOH, the activation energy for the hindered rotation of CH_2COO^- may be larger than that of the methyl group in CH_3COOH, which has been known to be 2.5 ± 0.7 kcal/mol.[22]

22) W. Weltner, Jr., *J. Am. Chem. Soc.*, **77**, 3941 (1955).

This is because the height of two fold potential barrier (in the case of CH_2COO^-) is larger than that of three fold potential barrier (in the case of CH_3COOH). Thus, $V_r(0)-V_r(\pi/2)$ may be estimated without serious error as twice the activation energy for CH_3COOH, *i. e.*, 5.0 ± 1.4 kcal/mol. Therefore, the activation energy for the rotation of CH_2 in CH_2COO^- is $V(\pi/2)-V(0)=10.1-(5.0\pm1.4)$kcal/mol$=5.1\pm1.4$ kcal/mol, which is in good agreement with the observed value 5.6 ± 0.2 kcal/mol.

The agreement of the calculated activation energy with the observation for CH_2COO^- in a crystal of zinc actetate dihydrate suggests that the contribution of the surrounding molecules to the hindered rotation of the CH_2 group is negligibly small and that the activation energy is essentially determined by the internal energy of the radical. For the radicals of the type CH_2R having a high activation energy, however, the rotation of the CH_2 group may be hindered by the force acting on the radicals from the surrounding molecules in the crystals.

The authors' thanks are due to Mr. H. Iguchi for his help in the experiment.

Reactions of *cis*- and *trans*-2-Butenes Photosensitized by $Hg(^3P_1)$ and $Cd(^3P_1)$

Shigeru TSUNASHIMA and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 31, 1967)

A comparative study has been made of the reactions of *cis*- and *trans*-2-butenes photosensitized by mercury($^3P_1$) at room temperature and by cadmium($^3P_1$) at temperatures ranging from 275 to 350°C. In both cases, the main reaction was cis-trans isomerization. The initial quantum yield of isomerization was the same for the two butenes. The rate of decomposition was about 10^{-2} and 10^{-3} times less than that of isomerization in the Hg- and Cd-photosensitizations, respectively. The ratio of *trans*- to *cis*-2-butene after prolonged irradiation was unity and did not vary with pressure in the Cd-photosensitization, while in the Hg-photosensitization it increased with decreasing initial pressure. This is probably due to the difference in the rates of decomposition of *trans*- and *cis*-2-butenes. It was found that the pressure dependence of Hg-photosensitized *cis-trans* isomerization could not be explained in terms of the simple mechanism proposed before. A possible mechanism is discussed.

The rate of photosensitized isomerization of an olefin depends upon three factors; (1) the electronic state of the excited sensitizer molecule and its lifetime, (2) the mechanism of energy transfer from sensitizer to olefin, and (3) the reactivity of the excited olefin molecules. Recent studies have uncovered many interesting features of photosensitized isomerizations and have indicated the importance of the above factors in determining the rate of isomerization.

Photosensitized isomerization of 2-butenes in the gas phase has been investigated with mercury,[1,2] benzene[3] and several organic compounds[4] as sensitizers, but no report has appeared yet with cadmium. LeRoy and Steacie reported only on the decomposition of 2-butene in Cd-photosensitization.[5]

This paper presents a detailed study of the reactions of 2-butenes photosensitized by $Hg(^3P_1)$ and $Cd(^3P_1)$. Some of the results are obviously at variance with the data reported previously.

temperature. Major impurities observed by gas-chromatography were *trans-cis* isomers, the amounts being at most below 0.5%. *trans*-2-Butene-d_8 was synthesized from butadiene-d_6[6] and was purified by gas-chromatography. The isotopic purity of *trans*-2-butene-d_8 was determined to be at least above 98%. Special grade nitrogen, nitrous oxide and sulfur hexafluoride supplied by Takachiho-Shoji Co. were used without further purification. Six 9's pure cadmium stick was used as supplied by Soekawa Chemical Co.

Quartz reaction cells were cylindrical (5 cm in diameter, 8, 5 and 3 cm long) and contained a drop of mercury or a few small pieces of cadmium.

Light sources were spiral low pressure mercury discharge lamps (filled with 4 mm Ne) and a cadmium discharge lamp of the same type (filled with 2 mm Ar).

To eliminate the $^1S_0$-$^1P_1$ resonance line, a Toshiba UV-25 filter which cuts off below 2000 Å or a Toshiba UV-29 filter which cuts off below 2500 Å, was inserted between the light source and the reaction cell.

For cadmium-photosensitization, the light source and the reaction cell were placed separately in two electric furnaces controlled by Toshiba Thermister Temperature Controllers to within ± 2°C and ± 1°C, respectively.

After each run, materials were transferred to a trap at liquid nitrogen temperature. The non-condensables were analyzed and measured with a combination of Toepler pump, gas buret and furnace (*ca.* 260°C) packed with cuprous oxide. The condensables were analyzed by gas-chromatography. The columns used were packed with a celite-dimethylsulpholane mixture (30 m long, supplied by Shimadzu Co.) and with activated alumina containing tailing reducer (7 m long, supplied by Nishio Kogyo Co.).

The isotopic distribution of hydrogen was determined by mass-spectroscopy.

In the experiments using mercury-photosensitization, the light intensity of the 2537 Å resonance line was determined by the amount of hydrogen produced from 13 mmHg of ethylene, assuming the quantum yield of hydrogen to be 0.35.[7]

Results

Cadmium-photosensitization. For cadmium photosensitization, it is necessary to elevate the temperature of the reaction cell in order to obtain a sufficiently high vapor pressure of cadmium. To check for the possibility of thermal isomerization of 2-butene, 10 mmHg of *cis*-2-butene was kept in the reaction cell at 350°C for two hours. However, after this period of time, neither isomerization nor decomposition products could be detected. After one hour irradiation of 9.8 mmHg of *cis*-2-butene at room temperature with a cadmium lamp, likewise no reaction product was found. These results show that isomerization of 2-butene is not effected by radiation of the 3261 Å resonance line since the 2288 Å line is filtered out and that the light source used is not contaminated by mercury lines.

In the presence of cadmium vapor, *cis*- or *trans*-2-butene were isomerized to *trans*- or *cis*-2-butene by the radiation from the cadmium lamp. The initial rates of isomerization were constant over the pressure range 2 to 100 mmHg. There was no

difference in rate between two isomers (Fig. 1).

After prolonged irradiation, hydrogen, methane and propylene were observed. Their rates of formation were very small, *ca.* 10^{-3} of that of isomerization (Table 1).

After prolonged irradiation, the concentration ratio of *trans*- to *cis*-2-butene approached a value (unity) which was independent of the temperature (Table 2). The reduction in the total amount of 2-butene during an irradiation was negligibly small.

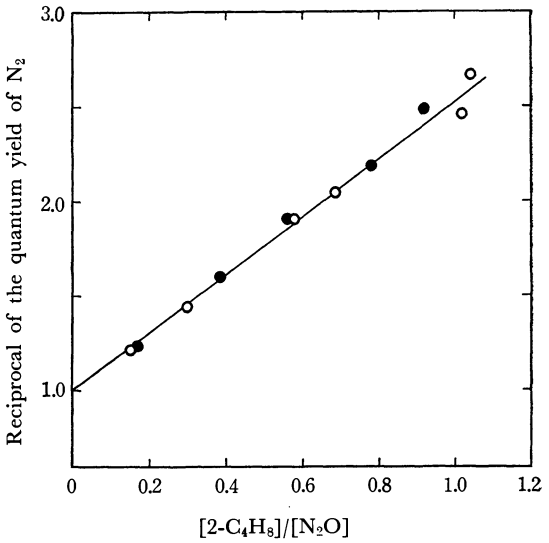

Fig. 4. Plots of the reciprocal of the quantum yield of nitrogen as a function of the ratio of the pressure of 2-butene to that of nitrous oxide. (○: *cis* → *trans*; ●: *trans* → *cis*)

Mercury-photosensitization. The products of the reaction of 2-butene photosensitized by $Hg(^3P_1)$ at room temperature were cis-trans isomer and small amounts of hydrogen, methane, propylene, *n*-butane and 1-butene. The rate of decomposition was *ca.* 10^{-2} of that of isomerization (Table 3).

The total amount of 2-butenes decreased with increasing reaction period and with decreasing initial pressure. After prolonged irradiation, the concentration ratio of *trans*- to *cis*-2-butene approached a constant value which was larger than unity and increased with decreasing pressure (Figs. 2 and 3).

Figure 4 shows the reciprocal of the quantum yield of nitrogen formation plotted against the ratio of the pressure of 2-butene to that of nitrous oxide, which is kept at 100 mmHg. The slope of the straight line in Fig. 4 obtained by the method of least squares was 1.6 ± 0.1 for both butenes.

yield of hydrogen decreased with increasing pressure and leveled off at 0.002 above 50 mmHg.

Table 4 shows the quantum yields of isomerization at 20 mmHg with various light intensities and lamps.

Figure 6 shows the effect of added gas; sulfur hexafluoride, nitrogen and nitrous oxide upon the quantum yield of isomerization at 20 mmHg of 2-butene. The quantum yield increased with sulfur hexafluoride, decreased with nitrous oxide and increased a little with nitrogen.

Discussion

Cadmium - photosensitization. *Decomposition Products.* The observed small amounts of decomposition products, hydrogen, methane and propylene, may be produced in the following mechanism;

$$Cd^* + C_4H_8 \rightarrow CdH + C_4H_7$$
$$CdH \rightarrow Cd + H$$
$$H + C_4H_8 \rightarrow \begin{cases} H_2 + C_4H_7 \\ CH_3 + C_3H_6 \\ C_4H_9 \end{cases}$$
$$CH_3 + C_4H_8 \rightarrow CH_4 + C_4H_7$$

Here, Cd* stands for $Cd(^3P_1)$. C_4H_7 and C_4H_9 radicals may produce stable molecules by disproportionation or recombination. The total amount of these decomposition products is about 10^{-3} of that of isomerization which is one order of magnitude less than that in the case of mercury-photosensitization. This result may be due to the smaller energy available for decomposition in the case of Cd-photosensitization.

Mechanism of Isomerization. Neglecting the small amount of decomposition, the following mechanism may be considered for cis-trans isomerization of 2-butene;

$$Cd + h\nu \rightarrow Cd^* \quad (I)$$
$$Cd^* \rightarrow Cd + h\nu \quad (0)$$
$$Cd^* + T \rightarrow Cd + B^* \quad (1t)$$
$$Cd^* + C \rightarrow Cd + B^* \quad (1c)$$
$$B^* + M \rightarrow \alpha T + (1-\alpha)C + M \quad (2)$$

Here, T and C are *trans-* and *cis*-2-butenes, respectively. B* is the triplet state of 2-butene. α is the fraction of trans isomer formed from B*. The steady-state treatment gives the following relations;

$$\left.\begin{aligned} d[C]/dt &= I((1-\alpha)k_{1t}[T] - \alpha k_{1c}[C])/ \\ &\quad (k_0 + k_{1t}[T] + k_{1c}[C]) \\ d[T]/dt &= I(\alpha k_{1c}[C] - (1-\alpha)k_{1t}[T])/ \\ &\quad (k_0 + k_{1t}[T] + k_{1c}[C]) \end{aligned}\right\} \quad (I)$$

Table 5. Isotopic distribution of hydrogen formed in the mercury-photosensitization of 1 : 1 mixture of *trans*-2-butene-d_0 and -d_8

Initial pressure mmHg	H_2	HD %	D_2	$[HD]^2/[H_2][D_2]$
6.5	46.6	30.7	22.7	0.89
32.0	65.8	25.7	8.5	1.2

When reaction starts from pure isomers, the initial rates of isomerization should be expressed as follows;

$$\left.\begin{aligned} R_{T\rightarrow C} &= (1-\alpha)Ik_{1t}[T]/(k_0 + k_{1t}[T]) \\ R_{C\rightarrow T} &= \alpha Ik_{1c}[C]/(k_0 + k_{1c}[C]) \end{aligned}\right\} \quad (II)$$

The relations, $k_0 \ll k_{1t}[T]$ or $k_{1c}[C]$ and $\alpha = 1-\alpha$, hold because, as Fig. 1 shows, $R_{T\rightarrow C} = R_{C\rightarrow T}$ and the rates of isomerization were not affected by the pressure change. Using the lifetime of $Cd(^3P_1)$ atom (2.4×10^{-6} sec[9]), k_0 and $k_{1t}(=k_{1c})$ were calculated to be 4.2×10^5 sec^{-1} and 9.4×10^6 $mm^{-1}sec^{-1}$, respectively, *i. e.*, $k_0 \ll k_{1t}[T]$ or $k_{1c}[C]$ at the pressure over 1 mmHg. This is consistent with the present result.

The ratio of *trans-* to *cis*-2-butene obtained after prolonged irradiation ($[T]_\infty/[C]_\infty$) can be derived by setting $(d[C]/dt)_\infty = (d[T]/dt)_\infty = 0$ as follows,

$$[T]_\infty/[C]_\infty = \alpha k_{1c}/(1-\alpha)k_{1t} \quad (III)$$

Because $[T]_\infty/[C]_\infty$ is unity for all temperature ranges (Table 1), k_{1t} should be equal to k_{1c}, *i. e.*, the quenching cross section of *cis*-2-butene for $Cd(^3P_1)$ is equal to that of *trans*-2-butene.

Mercury - photosensitization. *Mechanism of Hydrogen Formation.* Hydrogen formation from an olefin molecule in Hg-photosensitization has been ascribed to the C–H bond cleavage of an excited olefin molecule.[11] Accordingly, the quantum yield of hydrogen should approach zero at high pressures because of collisional deactivation. Figure 5, however, shows that the quantum yield of hydrogen does not approach zero even at 500 mmHg. This leads us to speculate that the following process plays a part in the mechanism;

$$Hg(^3P_1) + C_4H_8 \rightarrow (Hg\cdots H\cdots C_4H_7)^* \rightarrow Hg + H + C_4H_7 \quad (3)$$

This kind of quenching process was proposed by Gunning *et al.*[12] to account for the results of a study of the Hg-photosensitized decomposition of cyclohexene. Using the quantum yield of

hydrogen at the pressure higher than 50 mmHg and the ratio of the rate of abstraction to that of addition (0.023 and 0.076 for *cis*- and *trans*-2-butene,[13] respectively), the quantum yields of the complex formation were estimated to be 0.09 and 0.025 for *cis*- and *trans*-2-butenes, respectively.

The quantum yield of hydrogen decreased with increasing initial pressure (Fig. 5). This behavior may be explained in terms of C-H bond cleavage of excited 2-butene molecules. Mixtures of *trans*-2-butene-d_0 and -d_8 were decomposed by Hg-photosensitization, in order to investigate the mechanism of hydrogen formation. The results are listed in Table 5. Obviously, the molecular elimination reaction occurred. Although the result seems to show the decrease of the molecular elimination with increasing pressure, further discussions can not be made because of the small rate of hydrogen formation.

The Ratio of trans- to cis-2-Butene. As is shown in Figs. 2 and 3, the ratio $[T]_\infty/[C]_\infty$ increased with decreasing initial pressure and at the same time, some disappearance of total 2-butene was observed. Possible explanations for this observation are as follows; (1) *trans*- and *cis*-2-butenes have different quenching cross sections for $Hg(^3P_1)$, (2) the ratio of *trans*- to *cis*-2-butene formed from the excited olefin molecule is not unity, (3) the ratio is affected by the disproportionation reaction of butyl and butenyl radicals and (4) the ratio is affected by the reduction of total 2-butene, *i. e.*, the rates of decomposition of cis and trans are different. The possibility (1) may be eliminated in view of the identical quenching cross sections found for the two isomers (Fig. 4). The possibility (2) can be omitted because the quantum yields of isomer do not differ for the two reactant isomers (Fig. 5). (3) may be ruled out because the amounts of the products of the disproportionation reaction such as 1-butene and *n*-butane are too small to explain the change of the ratio with pressure. The most probable explanation is the possibility (4), because the rate of decomposition of *cis*-2-butene is faster than that of *trans*-isomer (Fig. 3).

The Pressure Dependence of Quantum Yield of Isomer. Cundall *et al.*[2] assumed only one precursor for the isomerization of 2-butene photosensitized by $Hg(^3P_1)$ and derived the following relation.

$$P/R_{iso} \propto P \qquad \text{(IV)}$$

Here, P and R_{iso} mean the initial pressure of 2-butene and the rate of isomerization, respectively. Equation (IV), however, explains the present results only approximately. We have attempted to establish a relationship which accounts for the pressure dependence of the quantum yield of isomerization. The following equation gives the relationship. The reaction mechanism which predicts the relationship will be discussed later.

$$\phi_{iso} = \frac{b+c[P]}{1+a[P]} \frac{d[P]}{1+d[P]} \qquad \text{(V)}$$

Here, [P] is the initial pressure of 2-butene in mmHg and ϕ_{iso} is the quantum yield of isomerization. The letters a, b, c and d are experimental parameters which are calculated to be 3×10^{-2} $mmHg^{-1}$, 0.1, 1.5×10^{-2} $mmHg^{-1}$ and 1.3 $mmHg^{-1}$, respectively.

As seen in Fig. 5, the sum of the quantum yield of precursor for isomerization which is equal to $2\phi_{iso}$ and that of C-H bond cleavage is almost unity above 300 mmHg. The quantum yield of C-H bond cleavage was estimated from that of hydrogen formed, using the ratio of the rate of abstraction to that of addition of a hydrogen atom.[13] In this estimation, the fraction of molecular elimination reaction was neglected, since it does not affect the present discussion. If the *cis-trans* isomerization and the cleavage of C-H bond are the only reactions induced by Hg-photosensitization, part of the absorbed light energy is lost at pressures below 300 mmHg of olefin. Incomplete quenching which can be estimated from the lifetime of $Hg(^3P_1)$ atoms (1.08×10^{-7} sec[14]) and from the quenching cross section of 2-butene (30 Å^2), is negligibly small above a pressure of 10 mmHg. A careful search was made for products other than *cis-trans* isomer, such as methyl cyclopropane (observed in the reaction of 1-butene photosensitized by $Hg(^3P_1)$[15]), cyclobutane, isobutene, 1-butene and C_8-compounds; but they were very small or not found at all. The disappearance of incident photons, therefore, remains unexplained.

The quantum yield of isomerization was unaffected by the light intensity. This suggests that the triplet-triplet anihilation of excited mercury atoms and of excited 2-butene, stepwise excitation processes and self reversal of the resonance line are negligible.

Cundall *et al.*[2] examined the effect of foreign gas on the isomerization and found that some compounds reduced the rate of isomerization with a competitive quenching for excited mercury atoms and some gave no effect because of the small quenching cross section of the foreign gas.

The effect of nitrous oxide, as is shown in Fig. 6, may be due to the competition for excited mercury atoms with 2-butene. The slight increase of the quantum yield of isomerization by adding nitrogen may be explained as the result of Lorentz

broadening. The apparent increase of the quantum yield can be estimated by using Kang Yang's data[16] under the assumption that collision broadening of 2-butene is the same as that of ethylene. The estimated values are consistent with the experimental values within experimental error. Although nitrogen is known to be a quencher for the process, $Hg(^3P_1 \rightarrow {}^3P_0)$, the pressure used is still not high enough to induce the participation of $Hg(^3P_0)$ in this system.[11] The effect of sulfur hexafluoride appears to be complex. The quantum yield of isomerization increases with increasing pressure of added sulfur hexafluoride. Clearly, this effect cannot be associated with the removal of vibrational energy from the precursor since sulfur hexafluoride is known to be an effective quencher of vibrational energy.

With these data in mind, the following reaction mechanism is tentatively considered to explain the pressure dependence of the isomerization.

$$Hg + h\nu \rightarrow Hg^* \quad (4)$$

$$Hg^* \rightarrow Hg + h\nu \quad (5)$$

$$Hg^* + C \text{ (or T)} \rightarrow HgC^* \text{ (or } HgT^*) \quad (6)$$

$$HgC^* \text{ (or } HgT^*) \rightarrow Hg + B^* \quad (7)$$

$$HgC^* \text{ (or } HgT^*) \rightarrow Hg + C^\dagger \text{ (or } T^\dagger) \quad (8)$$

$$HgC^* \text{ (or } HgT^*) + M \rightarrow Hg + B^* + M \quad (9)$$

$$B^* \rightarrow (1/2)C + (1/2)T \quad (10)$$

$$C^\dagger \text{ (or } T^\dagger) \rightarrow C \text{ (or T)} \quad (11)$$

Here, Hg*, C and T mean $Hg(^3P_1)$, *cis*- and *trans*-2-butene, respectively. B* may be the triplet state of 2-butene. HgC* or HgT* is a transient complex of *cis*- or *trans*-2-butene and excited mercury atom. $C^\dagger$ and $T^\dagger$ mean the vibrationally excited ground state of *cis*- and *trans*-2-butene which do not isomerize. The steady state treatment of the mechanism gives a relation of the type (V).

In this mechanism, the pressure dependence of the quantum yield of isomerization is explained by the competitive reactions, (7), (8) and (9). The effects of sulfur hexafluoride, nitrogen and nitrous oxide may be explained as follows; HgC* or HgT* is quenched efficiently by sulfur hexafluoride, but not by nitrogen and nitrous oxide. The reasoning of the mechanism, especially the reaction (8), must await further investigation.

The authors are indebted to Dr. K. F. Preston (National Research Council, Canada) for his assistance in correcting the manuscript.

Phase Transitions in Crystalline Divalent Metal Dicalcium Propionates. II. Proton Magnetic Resonance Investigation*[1]

Nobuo NAKAMURA, Hiroshi SUGA, Hideaki CHIHARA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received September 6, 1967)

The motions of the propionate anions in strontium-, lead-, and barium-dicalcium propionates were examined with the proton magnetic resonance method at low temperatures. It was found that the methyl groups rotate about the C_3-axes even at 20°K in the Sr-, and the Ba-salts. In the Sr-salt the gradual decrease of the second moment below the ferroelectric transition point was observed and this phenomenon was related to the large angle torsional oscillations of the ethyl groups about the C_3'-axes as introduced in Part I: Near the ferroelectric transition point the observed second moment shows the possibility of excitation of the C_3'-rotation which would make the crystal to be paraelectric above the transition point. It was expected that the C_3'-torsion is to some extent excited in the Pb-salt at liquid nitrogen temperature, a slight discrete change being observed at the lower transition point. A sharp line width transition was also observed in the Ba-salt and this fact resulted in the finding of a new λ-type phase transition with the peak at about 204°K by the differential thermal analysis. A slight decrease of the second moment was observed at the upper transition point and the C_3'-rotation was assumed to be fully excited above that point.

In 1955 calorimetric and dilatometric studies were carried out on $BaCa_2(C_2H_5CO_2)_6$ in the authors' laboratory, and a phase transition was found to occur at −8.5°C.[1] Calorimetric study was also performed on the mixed crystals between the Ba-salt and $PbCa_2(C_2H_5CO_2)_6$ and it was suggested that ordering effect of the orientations of the methyl groups in the propionate anions is responsible to the phase transition of the Ba-salt.

On the other hand, Matthias and Remeika have found in 1957 that $SrCa_2(C_2H_5CO_2)_6$ undergoes a ferroelectric phase transition at 8.5°C.[2]

In the previous paper[3] the present authors reported the results of the calorimetric study on the Sr-salt and suggested, on the basis of the crystal symmetry consideration and of the fact that the anomaly in the heat capacity is of typical λ-type, that the ferroelectric phase transition is closely related to an orientational ordering of the methyl groups in the propionate anions. An attempt was made to correlate the torsional oscillation of the ethyl group around the $C_{carboxyl}$-C_α axis to the temperature dependence of the spontaneous polarization near the Curie point. The X-ray analysis was performed later by Tomiie and others on the room temperature phase of this substance.[4] There was shown the possibility of the rotational motion of the ethyl groups about the $C_{carboxyl}$-C_α axes from extremely large temperature factors of C_α-carbons and also from the undeterminable positions of the methyl-carbon atoms. In addition, it was found a new phase transition takes place at 104.2°K by the calorimetric study and the features of this transition were already described in Part I.

In the case of $PbCa_2(C_2H_5CO_2)_6$ two phase transitions were found at 191.5°K and 333°K, respectively, and no existence of the ferroelectric phase was confirmed by a hysteresis bridge method as reported in Part I.

It has been suggested there that the proton magnetic resonance is a powerful method of obtaining further informations about the motions of the propionate anions in the Ba-, Sr-, and Pb-salts. In this paper, the results of the second moment measurement are reported. It will be shown that for the Sr-salt, the result of NMR experiment supports the assumptions on the motions of the propionate anions proposed in Part I: In the Pb-salt, the full account of the nature of the phase transitions remains still in difficulty even applying the NMR method. The line width transition observed in the proton resonance study of the

Ba-salt will be discussed based on the new transition phenomenon at 204°K found by the differential thermal analysis.

Experimental

The procedure of the sample preparation was already described in the previous papers.[1,3] Proton second moments were measured on the powdered specimens by a Robinson-type spectrometer at 20 MHz; the absence of the saturation effect was confirmed by changing the rf-levels especially at low temperatures; the correction of the modulation width was made after Andrew.[5] The temperature was left to increase very slowly and the resonance signals were recorded with measuring the temperatures by a chromel-constantan thermocouple; the temperature increase in each sweep is within 1°C above the liquid nitrogen temperature and at most 1.5°C near liquid hydrogen temperature.

Experimental Results and Discussion

Figures 1, 2 and 3 show the results of the second moment measurements on the Sr-, Pb- and Ba-salts, respectively, the heat capacity curves being illustrated for reference.

Calculation of the Second Moment. For a propionate anion the intra-ionic contribution to the second moment was calculated by the usual method[6] by using the values, $r_{CC}=1.54$ Å, $r_{CH}=1.10$ Å, $\angle HCH=\angle HCC=\angle CCC=109°28'$. The second moments were calculated for the typical four cases: 1) the rigid lattice (the *trans*-conformation was assumed); 2) the lattice in which only the rotation of the methyl group about the axis connecting α- and β-carbon atoms is excited (C_3-rotation); 3) both the C_3-rotation and the torsional oscillation of the methyl and ethyl groups about the $C_{carboxyl}$-C_α axis (C'-torsion) are excited; 4) both the C_3-rotation and the rotation of the methyl and ethyl groups about the $C_{carboxyl}$-C_α axis are

excited (C_3'-rotation). The results of the calculation are given in Table 1, where J_0's are the Bessel's functions of zeroth order, and θ_1 the mean amplitude of the C_3'-torsional oscillation.

The inter-ionic contribution was only estimated for the Ba-salt, by using the crystal structure data for the room temperature phase, and by assuming both the C_3- and the C_3'-rotations. The result of the calculation is also given in Table 1. In the case of the lower temperature phase of the Ba-salt, as well as of each phase of the Sr- and Pb-salts, no crystallographic data is available for the calculation of the inter-ionic contribution. In the following we proceed to the discussion of the temperature variation of the molecular motion in each salt, separately.

$SrCa_2(C_2H_5CO_2)_6$. The second moment at the liquid hydrogen temperature, *i. e.*, 19.1 gauss^2, as shown in Fig. 1, is smaller than the rigid lattice value which should somewhat be larger than 20.02 gauss^2 (See Table 1) if we add the inter-ionic contribution to this value. The C_3-rotation, therefore, may be excited to some extent already at this temperature. Above the liquid hydrogen temperature the second moment decreases down rapidly to the value 11.9 gauss^2 at 85°K. This value is only 0.3 gauss^2 larger than the value for the C_3-rotation. Accordingly it is reasonable to consider that the C_3-rotation is completely excited at 85°K. For the calculation of the contribution from the C_3-rotation, the following equation presented by Powles and Gutowsky may be applied:[7]

$$\ln\{(\langle\Delta H^2\rangle_r/\langle\Delta H^2\rangle)^{1/2}\tan(\pi/6\cdot\langle\Delta H^2\rangle/\langle\Delta H^2\rangle_r-1)\} = E_a/\boldsymbol{R}T + C,$$

$$C = \ln\{4\pi\mu\tau_0(\langle\Delta H^2\rangle_r)^{1/2}/\boldsymbol{h}\},$$

where $\langle\Delta H^2\rangle$ is the second moment at temperature T and $\langle\Delta H^2\rangle_r$ corresponding to the complete free rotation, E_a the activation energy for the C_3-rotation, and τ_0 the mean life-time at one of the three possible equilibrium positions for the methyl group. The experimental data were analysed with the aid of this equation, and the plot of $\ln\{\cdots\}$ against $1/T$ is shown in Fig. 4, where $\langle\Delta H^2\rangle_r$ was set to be 11.9 gauss^2 (at 85 °K): From the slope of this straight line, $E_a=1.5$ kcal/mol and $\tau_0=9.4\cdot10^{-8}$s were obtained, respectively.

A small but significant decrease in the second moment was found between 90°K and 100°K. This abrupt change of the second moment may be due to the change in the crystal structure accompanied with the phase transition found in Part I.

A gradual decrease of the value from 10.0 gauss^2 at 100°K to 7.8 gauss^2 at about 200°K may be attributed to the partial averaging out of the dipolar interactions caused by the gradual excitation of the large angle torsional oscillation of each ethyl group about the C_3'-axis: Such an assumption on the motion of the ethyl group was already introduced in Part I in order to explain the temperature dependence of the spontaneous polarization in the ferroelectric phase. In the case of the C_3'-torsion which is simultaneously accompanied with the C_3-rotation the following expression for the intra-ionic contribution to the second moment may be written by making a small modification of the Andrew's theory;[8] $\langle\Delta H^2\rangle=2.38+1.10\cdot J_0^2(\theta_1)+8.14\cdot J_0^2(2\theta_1)$, (in gauss^2), where θ_1 is the mean amplitude of the C_3'-torsion and $J_0(x)$ the Bessel function of zeroth order. If one assumes that the inter-ionic contributions to the second moment remain constant from 100°K to above the ferroelectric transition point, one can estimate the force constant for the C_3'-torsion by using the classical relationship: $\kappa\theta_1^2=\boldsymbol{k}T$, and by fitting the experimental data to the above relation. The analysis gives $\kappa=5\cdot10^{-3}$mdyn/Å and this value corresponds to the mean amplitude of torsional oscillation of $\pi/5$ at 150°K. This result does not agree exactly with the value of $\kappa=1.1$—$1.6\cdot10^{-3}$ mdyn/Å obtained in Part I from the P_s *vs.* T curve, but it seems to be reasonable to consider that the ethyl groups in the propionate anions librate with considerably large amplitudes below the ferroelectric transition point.

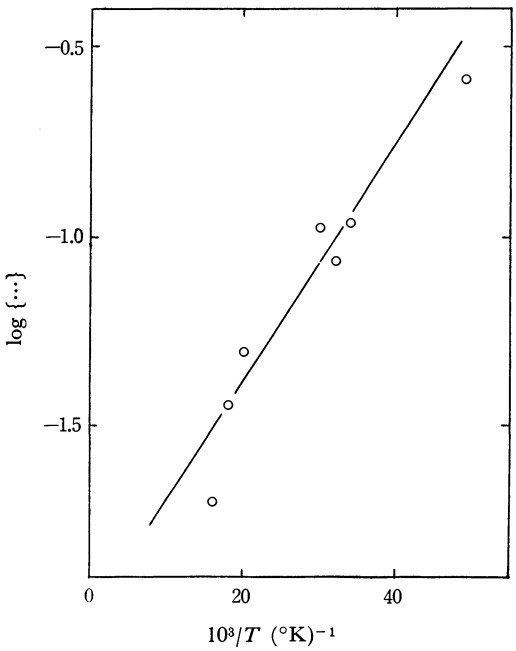

Fig. 4. The term $\ln\{\cdots\}$ plotted against $1/T$ for the experimental second moment of $SrCa_2(C_2H_5CO_2)_6$ between 20°K and 85°K.

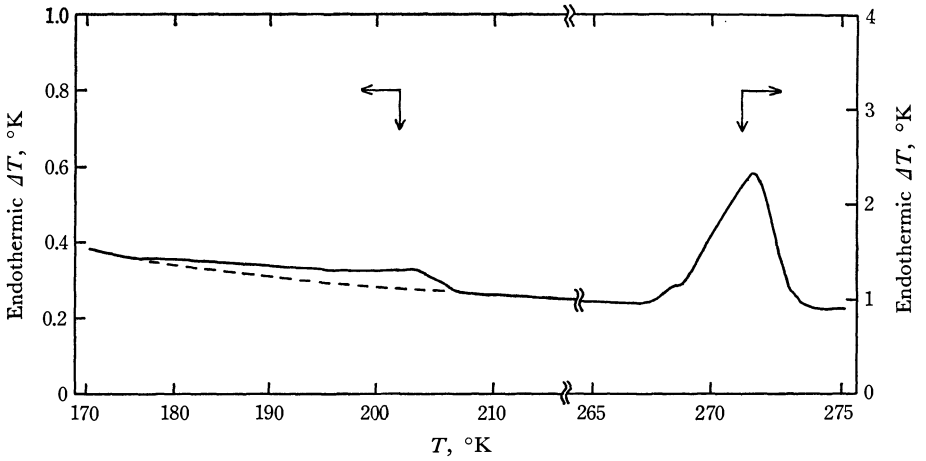

Fig. 5. Differential thermal analysis curve of $BaCa_2(C_2H_5CO_2)_6$. The plausible base line for the lower transition region is indicated by the broken line.

Further decrease of the second moment near the ferroelectric transition point may reflect the onset of the C_3'-rotation. In this case, some modification of Powles and Gutowsky's equation[7] gives the following expression:

$$\ln\{(\langle\Delta H^2\rangle_r/\langle\Delta H^2\rangle)^{1/2}\cdot\tan 0.128\pi\cdot(\langle\Delta H^2\rangle/\langle\Delta H^2\rangle_r-1)\} = E_a/\boldsymbol{R}T + C,$$

$$C = \ln 4\pi\mu\tau_0(\langle\Delta H^2\rangle_r)^{1/2}/\boldsymbol{h}$$

The meaning of the notations in this equation is the same as before. The analysis of the experimental data gives $E_a=630$ cal/mol and $\tau_0=1.2\cdot10^{-6}$s, and the latter seems to be somewhat unreasonable. Anyhow, it is possible to consider that the C_3'-rotation removes the polarization due to propionate anions which were originally aligned parallel to the crystalline c-axis and as the result the paraelectric phase appears. The continuous change from C_3'-torsion to C_3'-rotation may explain that the transition is of order-disorder type as assumed in Part I.

Above the transition point no distinct change was observed in the second moment, and 4.3 gauss^2 at room temperature may be the sum of the intra-ionic contributions of 2.38 gauss^2 and inter-ionic contribution of about 1.9 gauss^2.

$PbCa_2(C_2H_5CO_2)_6$. The second moment of 10.9 gauss^2 at liquid nitrogen temperature may be explained by the partial excitation of the C_3'-torsion in addition to the C_3-rotation. Near the transition temperature, 191.5°K, a slight discrete change was observed as shown in Fig. 2. This discontinuity in the second moment as well as the discontinuity in the dielectric constant described in Part I may be due to the change in the crystal structure accompanied with the phase transition.

Above the transition temperature the second moment decreases gradually and settled down to 4.0 gauss^2 above room temperature. The value of 4.0 gauss^2 is comparable to 4.3 gauss^2 for the room temperature phase of the Sr-salt. Therefore, it may be concluded that the C_3- and C_3'-rotations are completely excited in the Pb-salt above the room temperature.

No remarkable change in the second moment was observed through the transition at 333°K where the dielectric constant shows a large anomaly.

$BaCa_2(C_2H_5CO_2)_6$. The second moment decreases slightly from the liquid hydrogen temperature to about 100°K, and 12.0 gauss^2 at this temperature suggests the complete excitation of the C_3-rotation. The second moment falls further remarkably from 12.0 gauss^2 to about 6 gauss^2 at 160°K. This line width transition can be treated by the following theoretical expressions developed by Gutowsky and Pake;[9]

$$(\delta\nu)^2 = B^2 + C^2(2/\pi)\tan^{-1}(\alpha\cdot\delta\nu/\nu_c) \text{ and}$$

$$\nu_c = \nu_0\cdot\exp(-E_a/\boldsymbol{R}T),$$

where $A=(B^2+C^2)^{1/2}$ is the line width in the rigid lattice, B the narrowed line width characteristic to a motion, ν_c the correlation frequency, ν_0 the frequency factor and α a numerical factor characterized by the line shape. Form the activation plot the activation energy, $E_a=1.5$ kcal/mol, and the frequency factor $\nu_0=1.5\cdot10^7$ s^{-1} were obtained by assuming $\alpha=1$. Such a decrease of the second moment may be explained by assuming the C_3'-rotation of only four among six propionate anions in the unit cell, if we want to fit the magnitude of the second moment at 160°K (6.2 gauss^2) with the crystal model. The preliminary differential thermal analysis study shows the existence of a small λ-type anomaly with the

9) H. S. Gutowsky and G. E. Pake, *J. Chem. Phys.*, **18**, 162 (1950).

peak at about 204°K which is the evidence of a kind of phase transition (See Fig. 5). It is, therefore, considered that the phase transition may be related to some anisotropic motion of the propionate anions mentioned above.

Further remarkable decrease of the second moment occurs at 267°K which corresponds to the first order phase transition reported previously.[1]

Note Added in Proof

After the completion of this work, we noticed that the second moment of $BaCa_2(C_2H_5CO_2)_6$ has been measured by Chezeau, Dufourcq and Lemanceau in the temperature region from 100 to *ca.* 320°K:[10] Their second moment values are slightly larger than ours just below the upper transition point, but their model assumed for the motion of the ethyl group is essentially the same as that proposed by us.

As to the second moment of $SrCa_2(C_2H_5CO_2)_6$ Nakamura, Hikichi and Furuichi have reported also their data obtained between −190°C and +100°C;[11] their experimental second moments are quite consistent with our results.

Although we referred to the structural data on $SrCa_2(C_2H_5CO_2)_6$ as a private communication from Tomiie (Ref. 4), the short communications on the crystal structures of the para- and ferroelectric phases of $SrCa_2(C_2H_5CO_2)_6$ were published after this paper was submitted.[12]

The authors would like to express their thanks to Mr. Takuji Nakamura for his help in the measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 296—303 (1968)

Addition of Some Simple Molecules to Transition Metal-Phosphine Complex and the Crystal and Molecular Structure of $Pd\{(C_6H_5)_3P\}_2(CS_2)$

Toshihide KASHIWAGI, Noritake YASUOKA, Tatzuo UEKI, Nobutami KASAI and Masao KAKUDO

Department of Applied Chemistry, Osaka University, Higashinoda Miyakojima, Osaka

and Shigetoshi TAKAHASHI and Nobue HAGIHARA

Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received September 18, 1967)

From the reaction of $M\{(C_6H_5)_3P\}_4$ (M=Pd or Pt) with CS_2, $M\{(C_6H_5)_3P\}_2(CS_2)$ has been isolated. It has been found that $M\{(C_6H_5)_3P\}_2$ also reacts with sulfur dioxide to form a novel complex, $[M\{(C_6H_5)_3P\}_4(SO_2)_n]$. The structure of one of these compounds, $Pd\{(C_6H_5)_3P\}_2(CS_2)$, was determined by means of X-rays. $Pd\{(C_6H_5)_3P\}_2(CS_2)$ crystallizes in the monoclinic system, space group $P2_1/c$, with four molecules in a unit cell of dimensions: $a=11.55$, $b=19.52$, $c=18.38$ Å and $\beta=128°53'$. The most remarkable feature of the whole structure is the coordination of CS_2 to the Pd: only one of the S atoms, S(2), coordinates to the Pd, while the CS_2 ligand is bent at an angle of 140°. The Pd, two P's, S(2) and C(1) in CS_2 lie approximately on the same plane. The Pd-C(1) distance of 2.00 Å is slightly shorter than the sum of the covalent radii, 2.06 Å. But the S(2)-Pd-C(1) angle of 44° is very small.

Recently, the relationship between the catalytic activities of transition metal complexes and their structure has been widely discussed. Vaska and Diluzio[1] treated the catalyst, $IrCl(CO)\{(C_6H_5)_3P\}_2$, with molecular oxygen, or hydrogen, and obtained a complex in which O_2, or H_2 coordinates to the iridium atom. They considered those complexes to be intermediates in the oxygenation or hydrogenation, and discussed the relation between the catalytic mechanism and the structure of $IrCl(CO)\{(C_6H_5)_3P\}_2$. Successively, the structural studies of

1) L. Vaska and J. W. Diluzio, *J. Am. Chem. Soc.*, **84**, 679 (1962).

the complexes with simple molecules have been made by X-ray diffraction. LaPlaca and Ibers determined the structures of $IrO_2Cl(CO)\{(C_6H_5)_3P\}_2$[2a] and $IrSO_2Cl(CO)\{(C_6H_5)_3P\}_2$,[2b] and they gave some information about the catalytic activities of $IrCl(CO)\{(C_6H_5)_3P\}_2$.

Hagihara and his co-workers[3] recognized that the $M\{(C_6H_5)_3P\}_4$ (M=Pd or Pt) molecule catalyzes the following reactions.

$$2(C_6H_5)_3P + O_2 = 2(C_6H_5)_3PO$$

$$2(n\text{-}C_4H_9)_3P + O_2 = 2(n\text{-}C_4H_9)_3PO$$

$$2C_6H_{11}NC + O_2 = 2C_6H_{11}NCO$$

They obtained $M\{C_6H_5)_3P\}_nO_2$ as a reaction product of $M\{(C_6H_5)_3P\}_4$ and molecular oxygen.[4,5] $M\{(C_6H_5)_3P\}_nO_2$ is considered to be an active intermediate in the oxygenation.

The addition of the simple molecules, carbon disulfide or sulfur dioxide, to triphenylphosphine-palladium or -platinum complex is described in this paper.

The crystal and molecular structure of one of these compounds, $Pd\{(C_6H_5)_3P\}_2(CS_2)$, was determined to examine the coordination of CS_2 to $Pd\{(C_6H_5)_3P\}_2$ and to get some information about the catalytic mechanism.

Experimental

Materials. Tetrakis(triphenylphosphine)palladium, $Pd\{(C_6H_5)_3P\}_4$, and -piatinum, $Pt\{(C_6H_5)_3P\}_4$, were prepared according to a modified method of Malatesta.[3,6,7]

All the procedures mentioned below were performed under a nitrogen atmosphere.

Reaction of $M\{(C_6H_5)_3P\}_4$ with Carbon Disulfide. At room temperature 578 mg of $Pd\{(C_6H_5)_3P\}_4$ was dissolved in 20 m*l* of carbon disulfide. A small amount of orange crystalline -solid separated. After 30 min carbon disulfide was gradually removed under reduced pressure and the orange residue was recrystallized from hot carbon disulfide to give 220 mg (62% yield) of $Pd\{(C_6H_5)_3P\}_2(CS_2)$ (Ia): mp 130—133°C (decomp.).

Found: C, 63.00; H, 4.26; S, 9.33%. Calcd for $C_{37}H_{30}P_2S_2Pd$: C, 62.84; H, 4.28; S, 9.07%.

The platinum - carbon disulfide complex was prepared in a similar manner. In 15 m*l* carbon disulfide 622 mg of $Pt\{(C_6H_5)_3P\}_4$ was dissolved with stirring. After a few minutes the crystals of platinum - carbon disulfide complex began to separate. The crystals were filtered, washed with carbon disulfide, and dried. Pink crystals (350 mg, 88% yield) of $Pt\{(C_6H_5)_3P\}_2\cdot(CS_2)$ (Ib) were isolated, but further purification could not be attained because of its insolubility. Mp 151—154°C (decomp.)

Found: C, 55.65; H, 3.82; S, 8.15%. Calcd for $C_{37}H_{30}P_2S_2Pt$: C, 55.84; H, 3.80; S, 8.06%.

Preparation of $Pd\{(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2\}(CS_2)$. A solution of 200 mg (0.5 mmol) of 1, 2-bis-(diphenylphosphino)-ethane in 10 m*l* carbon disulfide was added dropwise with stirring to a suspension of $Pd\{(C_6H_5)_3P\}_2(CS_2)$ in 20 m*l* carbon disulfide prepared from 578 mg of $Pd\{(C_6H_5)_3P\}_4$ and carbon disulfide. The crystals of $Pd\{(C_6H_5)_3P\}_2(CS_2)$ then dissolved, and the solution gradually became orange red. After 1 hr the solvent was removed and the residue, on recrystallization from hot carbon disulfide (15 m*l*), afforded 190 mg (67% yield) of red brown crystals, $Pd\{(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2\}(CS_2)$ (II): mp 115—124°C (decomp.) in a sealed capillary filled with nitrogen.

Found: C, 55.80; H, 4.23; S, 11.28%; mol wt (cryoscopic in nitrobenzene), 596. Calcd for $C_{27}H_{24}P_2S_2Pd$: C, 55.82; H, 4.16; S, 11.04%; mol wt, 580.9.

Reaction of $M\{(C_6H_5)_3P\}_4$ with Sulfur Dioxide.[*1] Sulfur dioxide was bubbled through a solution of 578 mg (0.5 mmol) of $Pd\{(C_6H_5)_3P\}_4$ in 30 m*l* benzene at room temperature. The reaction mixture became dark red. After 1.5 hr the solvent was gradually removed in a water-aspirator vacuum, leaving a red purple solid. Recrystallization from hot benzene gave 285 mg (48% yield) of analytically pure red purple needles, $[Pd\{(C_6H_5)_3P\}_4(SO_2)]_n$ (IIIa). It decomposed at 84—85.5°C without melting in a sealed capillary filled with nitrogen.

Found: C, 70.76; H, 4.08; O, 2.88; S, 2.54; P, 10.07%. Calcd for $C_{72}H_{60}O_2P_4SPd$: C, 70.90; H, 4.96; O, 2.62; S, 2.63; P, 10.16%.

According to a similar procedure the reaction between 622 mg (0.5 mmol) of $Pd\{(C_6H_5)_3P\}_4$ and sulfur dioxide in 20 m*l* benzene gave 360 mg (55% yield) of red purple needles $[Pt\{(C_6H_5)_3P\}_4(SO_2)]_n$ (IIIb). They decomposed at 124—125°C without melting in a sealed capillary filled with nitrogen.

Found: C, 65.98; H, 4.74; O, 2.79; S, 2.69; P, 9.28%. Calcd for $C_{72}H_{60}O_2P_4SPt$: C, 66.10; H, 4.62; O, 2.45; S, 2.45; P, 9.47%.

Density Measurement of $Pd\{(C_6H_5)_3P\}_2(CS_2)$. The density, 1.457 g·cm^{-3}, was measured by the flotation method in carbon tetrachloride - dioxane solution at room temperature.

X-Ray Diffraction. $Pd\{(C_6H_5)_3P\}_2(CS_2)$ gives light orange needle-like (along the *c* axis) crystals, which were very stable in air during the X-ray work. The crystals belong to the monoclinic system and the unit cell dimensions are:

$a=11.55\pm0.03$, $b=19.52\pm0.02$, $c=18.38\pm0.03$ Å. and $\beta=128°53'\pm10'$. From the systematic absence of $0k0$ reflections for k odd and $h0l$ for l odd, the space

group was determined to be $P2_1/c$. The observed density, 1.457 g·cm^{-3}, suggested four molecules in a unit cell, the calculated density being 1.456 g·cm^{-3}.

A set of three-dimensional intensity data was collected on multifilm equi-inclination Weissenberg photographs with nickel-filtered Cu$K\alpha$ radiation. Layers 0 to 11 were recorded around the c axis. Intensities of 4079 independent reflections were measured.

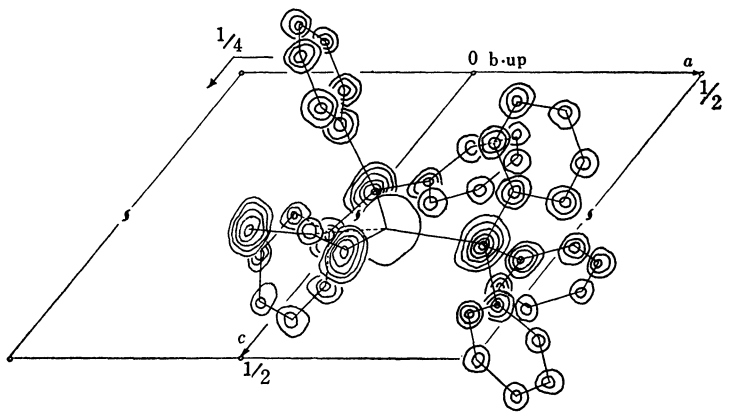

Fig. 1. A composite drawing of the final electron density map, viewed along the b axis. Contours are drawn at 3, 4 e.Å^{-3}... for carbon, and at 5, 8 e.Å^{-3}... for phosphorus and sulfur.

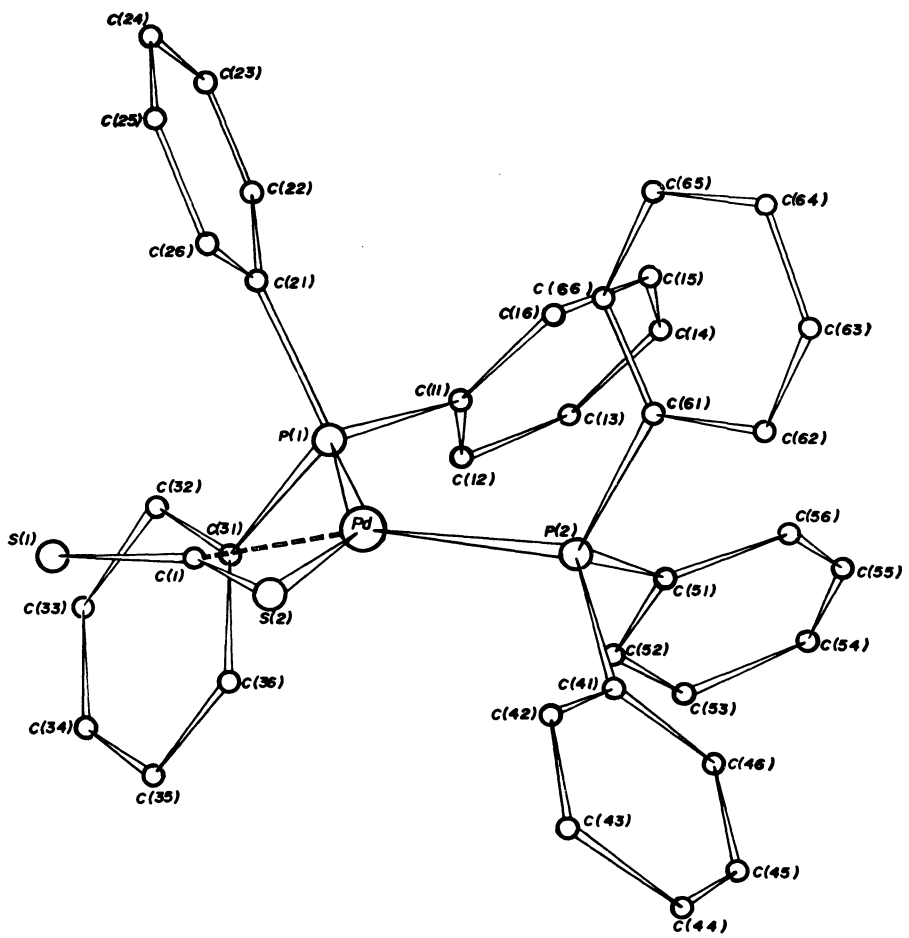

Fig. 2. View of molecule along the b axis.

visually. These intensities cover approximately 56% of possible reflections for Cu$K\alpha$. In order to get interlayer scale-factors, intensities around the a axis were also recorded. These intensities were corrected for the usual Lorentz and polarization factors, and spot-shape effects were also taken into account. As the dimensions of the crystal used in the experiment were about $0.09\times0.10\times0.27$ mm, the absorption correction was ignored in spite of the large absorption coefficient for Cu$K\alpha$, $\mu=70.81$ cm^{-1}.

Structure Determination and Refinement

The approximate position of Pd was deduced from the Patterson projections: P(U, V) and P(U,W). The Pd, S, P and twenty-seven C atoms were then obtained by inspection of the three-dimensional minimum function superposed by four equivalent positions of the Pd. The remaining ten C atoms were easily found in an electron density map based on the phases from the atoms which had already been determined. At this stage, the calculation of structure factors with a B of 3.0 Å^2 for all atoms gave a discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, of 0.34.

The least-squares refinement was done on a HITAC 5020-E computer at the University of Tokyo with the program written by T. Ashida. The refinement of overall and interlayer scale-factors, and positional and thermal parameters was undertaken by the block-diagonal least-squares method. Because of the limited capacity of the computer memories, the number of reflections used for the refinement was reduced to 3432 ($\sin\theta/\lambda=0.56$), in which 461 non-observed reflections were included. In the refinement, the minimized function used was $\sum w(\Delta F)^2$, and the weight w was taken as unity for all reflections. The atomic scattering factors used were taken from those of Hanson *et al.*[8] After three cycles of the refinement, the R factor reduced to 0.176 for non-zero reflections. Another five cycles with anisotropic thermal parameters for Pd, S, P, and C(1) gave $R=0.133$ for non-zero reflections ($R=0.146$ for all reflections).

The final atomic coordinates with their standard deviations and thermal parameters are listed in Table 1. Tables of the observed and calculated structure factors are deposited by the Chemical Society of Japan.*2 The final electron density map, and molecular structure viewed along the b axis are shown in Figs. 1 and 2, respectively.

Discussion

Synthetic Aspect. It has been found that $M\{(C_6H_5)_3P\}_4$ reacts readily with carbon disulfide to form novel complexes Ia and Ib (Eq. (1)).

$$M\{(C_6H_5)_3P\}_4 + CS_2 \longrightarrow M\{(C_6H_5)_3P\}_2(CS_2) \quad (1)$$
(Ia: M=Pd; Ib: M=Pt)

Independently, Baird and Wilkinson[9] also obtained complex I in a manner similar to that indicated by Eq. (1). These complexes are air-stable in the solid state. Complex I was treated with triphenylstibine in benzene to form the substituted product with the simultaneous liberation of carbon disulfide.

$$M\{(C_6H_5)_3P\}_2(CS_2) + 2(C_6H_5)_3Sb \longrightarrow \{M(C_6H_5)_3P\}_2\{(C_6H_5)_3Sb\}_2^{3)} + CS_2 \quad (2)$$

The quantitative determination of the carbon disulfide liberated in the above reaction by gas chromatographic analysis indicated that about one mole of carbon disulfide per one mole of complex was generated. This fact suggests that the complex I involves carbon disulfide attached directly to metal atom. Attempts to prepare the diphosphine-metal-carbon disulfide complexes by the direct reaction of $M\{(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2\}_2$ with carbon disulfide were not successful. However, complex II was prepared from the reaction of the phosphine complex Ia with equivalent diphosphine in carbon disulfide solution as shown in Eq. (3).

$$Pd\{(C_6H_5)_3P\}_2(CS_2) + (C_6H_5)_2PCH_2CH_2P(C_6H_5)_2 \longrightarrow Pd\{(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2\}(CS_2) + 2(C_6H_5)_3P \quad (3)$$

The infrared spectra of the complexes exhibit characteristic CS_2 bands as shown in Table 2. The bands appearing at $1200-1100$ cm^{-1} are probably to be assigned to the carbon-sulfur stretching vibration of the multiple bond of carbon disulfide. These absorption bands are shifted (*ca.* 300 cm^{-1}) toward lower frequencies by coordination to the metal atom in comparison with that of uncoordinated carbon disulfide.

a) The average value in benzene rings.

The complex $Pd\{(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2\}(CS_2)$ II was recognized to be mononuclear in nitrobenzene solution by means of molecular weight measurement. The similarity in the infrared absorption bands may imply that $M\{(C_6H_5)_3P\}_2(CS_2)$ has a structure analogous to that of II.

The sulfur dioxide complexes, IIIa and IIIb, are unstable in air, particulary in solution. When $[Pd\{(C_6H_5)_3P\}_4(SO_2)]_n$, IIIb was treated with triphenylstibine in benzene solution, bis(triphenylphosphine)bis(triphenylstibine)palladium, $Pd\{(C_6H_5)_3P\}_2\{(C_6H_5)_3Sb\}_2$, was quantitatively obtained and the simultaneous liberation of sulfur dioxide was verified by gas chromatographic analysis. Therefore it is evident that the complex (III) contains sulfur dioxide as a ligand (Eqs. (4) and (5)).

$$M\{(C_6H_5)_3P\}_4 + SO_2 \longrightarrow [M\{(C_6H_5)_3P\}_4(SO_2)]_n \quad (4)$$
(IIIa: M=Pd, IIIb: M=Pt)

$$[Pd\{(C_6H_5)_3P\}_4(SO_2)]_n + (C_6H_5)_3Sb \longrightarrow Pd\{(C_6H_5)_3P\}_2\{(C_6H_5)_3Sb\}_2 \quad (5)$$

The infrared spectra of the complex $[M\{(C_6H_5)_3P\}_4(SO_2)]_n$ exhibit characteristic strong bands near 1200 cm^{-1} and 1050 cm^{-1} (IIIa: 1206, 1051 cm^{-1}; IIIb: 1198, 1047 cm^{-1}; in Nujol mull) ascribed to the asymmetric, and symmetric stretching modes of the $-SO_2-$ group attached to the metal. Unfortunately, further detailed information about the structure was not obtained, because the molecular weight of the complex could not been measured owing to its low solubility. We have not, as yet, been able to comfirm whether complex III has a monomeric structure such as $IrCl(SO_2)(CO)\{(C_6H_5)_3P\}_2$,[11,2b] or a dimeric structure with a sulfur dioxide bridge such as the iron carbonyl-sulfur dioxide complex.[12]

Crystal and Molecular Structure of $Pd\{(C_6H_5)_3P\}_2(CS_2)$. Intramolecular distances and angles with their standard deviations are listed in Table 3.

The most remarkable feature of the whole structure is the coordination of CS_2 to the Pd atom. Figure 3 shows the geometry around the

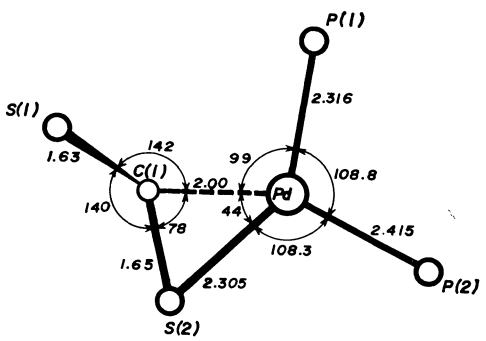

Fig. 3 Neighbors of the palladium atom in $Pd(Ph_3P)_2(CS_2)$, interatomic distances (Å) and bond angles (degree).

11) L. Vaska and S. S. Bath, *J. Am. Chem. Soc.*, **88**, 1333 (1966).
12) E. H. Braye and W. Hübel, *Angew. Chem.*, **75**, 345 (1963).

Pd atom. With only one of the S atoms, S(2), coordinated to the Pd, the CS_2 ligand, which is linear in a free molecule, is bent, the ∠S–C–S being 140°. The Pd atom and its neighboring atoms, P(1), P(2), S(2), and C(1) lie approximately on the same plane. The following is the equation of the least-squares plane;

$$0.11X + 0.73Y - 0.92Z + 3.12 = 0.0$$

where $X = ax + cx \cdot \sin\beta$, $Y = by$, and $Z = cz \cdot \sin\beta$.

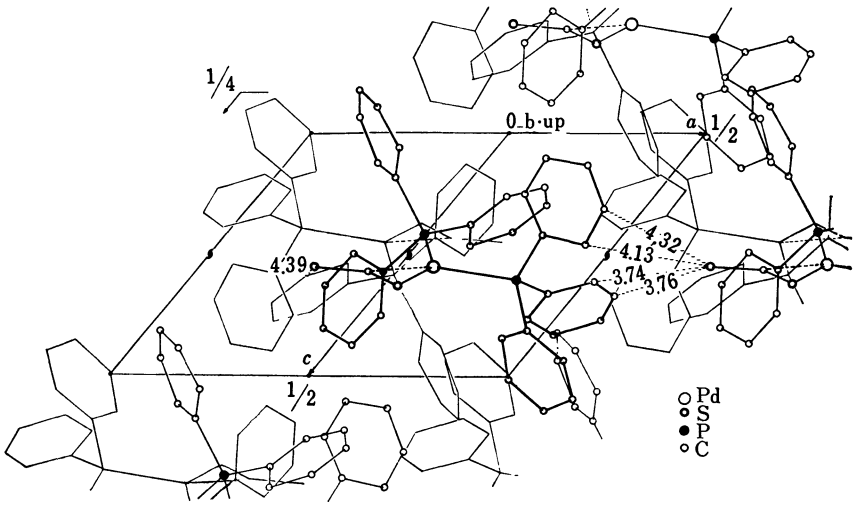

Fig. 4. The crystal structure viewed along the *b* axis.

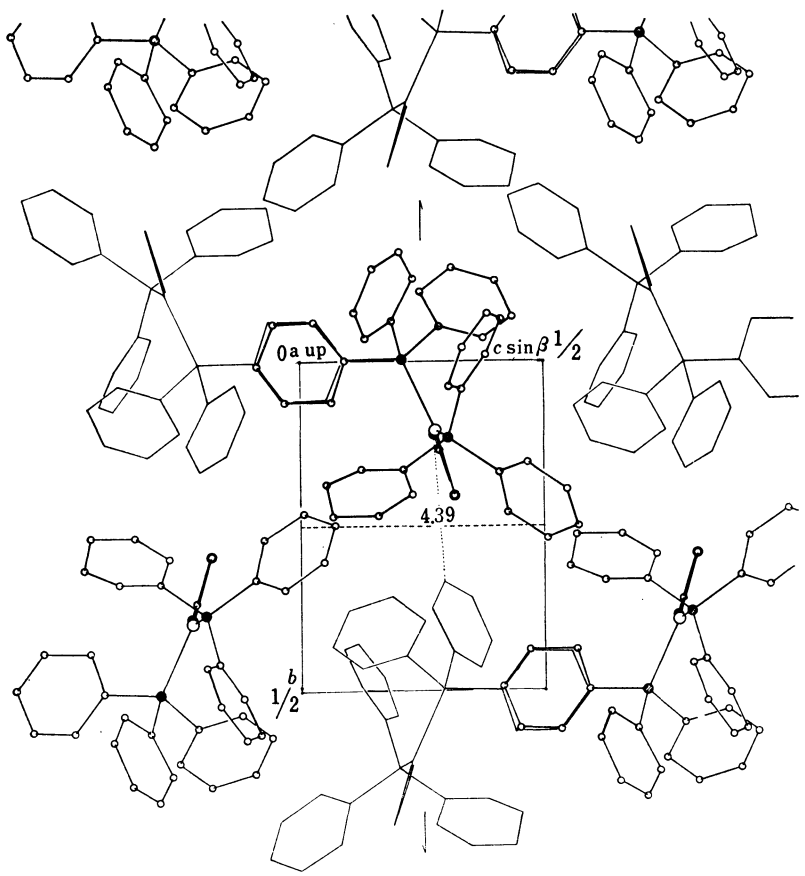

Fig. 5. The crystal structure viewed along the *a* axis.

Table 4. Deviations from the least-squares plane

Atom	Deviation
Pd	0.00Å
S(2)	0.08
P(1)	0.05
P(2)	−0.03
C(1)	−0.10
S(1)	−0.31

The angle between the S(1)–C(1) vector and this plane is 7°. The deviations of above-mentioned atoms from the best plane are listed in Table 4.

The Pd-S(2) distance is 2.305 Å, while Pd-S(1) is 3.441 Å (sum of the covalent radii, 2.36 Å). The S(1) atom is located far from any atoms of the surrounding molecules by over 3.74 Å as Figs. 4 and 5 show (sum of the van der Waals radii for S and benzenic C, 3.55 Å). The Pd-C(1) distance of 2.00 Å is slightly shorter than the sum of the covalent radii for Pd and trigonal hydridized C, 2.06 Å. But the ∠S(2)–Pd-C(1) of 44° is very small. One of the possible explanations for the C(1)-Pd bond is the bent-bond configuration. The two C-S distances in the CS_2 ligand are 1.63 Å and 1.65 Å (E. S. D., 0.034 Å), and they show no significant difference. However, these distances are longer than the ordinary C-S distance of 1.55 Å in a free molecule.[13] Recently, in Pt-$\{(C_6H_5)_3P\}_2(CS_2)$ a similar coordination of CS_2 to Pt (instead of Pd) as described above was found by Baird *et al.*[14] They also mentioned that $Pd\{(C_6H_5)_3P\}_2(CS_2)$ and $Pt\{(C_6H_5)_3P\}_2(CS_2)$ are isostructural. In this case, though, they reported preliminary results which indicated a big difference between the two C–S distances in the CS_2 ligand.

The Pd–P(1), and Pd–P(2) distances are 2.316, and 2.415 Å, respectively, and they differ significantly from each other. The longer Pd–P(2) distance may be interpreted as due to the trans-lengthening effect found in $(PdCl_2C_2H_4)_2$[15] and $(PdCl_2CH_2CHC_6H_5)_2$.[16] The Pd–P(1) distance of 2.316 Å is considerably shorter than the sum of the covalent radii (2.42 Å). This value corresponds to Pd–P=2.31 Å in $(C_4H_7)PdP(C_6H_5)_3$,[17] and also to Ir-P (av.)=2.34 Å in $IrO_2Cl(CO)\{(C_6H_5)_3P\}_2$.[2a] Such a shortening of the Pd–P distance may be a result of the partial double bond character acquired through back donation[18] of electrons from the Pd atom into the two P's.

Since the average angles of ∠C–P–C's, and ∠Pd–P–C's are 104°, and 115°, respectively, the geometry around the P atom is a distorted tetrahedral arrangement.

In benzene rings of $P(C_6H_5)_3$ groups the average bond distance, and angle are normal, 1.41 Å, and 120°C, respectively. Like a three-bladed propeller, the three planes of the benzene rings bonded to the P(1) rotate in the same direction, the average dihedral angle between these planes being 108°. However, this is not so in the case of benzene rings bonded to P(2), because these are in contact with the S(1) of the next molecule. An ordinary contact, 3.54 Å, is found as the shortest intermolecular benzene-benzene distance.

The present study was supported partly by a Scientific Research Grant from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 304—306 (1968)

Ionic Species in the Radiolysis of Cyclohexane

Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 23, 1967)

A diffusion model proposed in the previous paper (*Bull. Chem. Soc. Japan*, **40**, 1818 (1967)) has been applied to explain the ionic reactions occurring in the γ-radiolysis of cyclohexane. The effects of an electron scavenger (N_2O) and a positive ion detector (CH_3OD) were consistently interpreted. The ratio of the diffusion coefficient of electrons to that of parent positive ions has been estimated from the calculation to be in the range of 4 to 5. The calculating method has been compared with that recently published by Freeman (*J. Chem. Phys.*, **46**, 2822 (1967)).

γ-Radiolysis of liquid occurs through two processes; one, ionic, the other, non-ionic. The ratio probably depends upon the molecular structure of the liquid. In cyclohexane, roughly 1 to 1 has been estimated for the ratio of the two processes which contribute to the formation of hydrogen.[1]

Ionic species produced in cyclohexane by γ-ray irradiation are electrons and the parent positive ions. Their excess energies are dissipated in a short time, probably of the order of 10^{-13} sec, through many collisions with solvent molecules. Thus thermalized electrons and the parent positive ions are distributed in the solvent, but not homogeneously; each pair being attracted by the Coulombic interaction which depends on the dielectric property of the solvent. In the previous paper,[2] the function proportional to $r^2 \exp(-\alpha r^2)$ was proposed for the initial distribution of the pair and 50 Å was estimated for the average separation in cyclohexane. Thus ion pairs drift towards each other and neutralize. The heat of neutralization leads to the decomposition of a cyclohexane molecule, as follows.

$$c\text{-}C_6H_{12}^+ + e \rightarrow H \text{ or } H_2 + \text{residue} \quad (1)$$

$$H + c\text{-}C_6H_{12} \rightarrow H_2 + c\text{-}C_6H_{11} \quad (2)$$

One neutralization reaction corresponds to the formation of a hydrogen molecule.[1]

Since the average time interval for the neutralization is estimated to be 10^{-9} sec,[2] electrons can react with electron scavengers in the solution, if present. When nitrous oxide is used as the scavenger, the following reactions seem to occur.[1]

$$e + N_2O \rightarrow N_2 + O^- \quad (3)$$

$$O^- + N_2O \rightarrow N_2 + O_2^- \quad (4)$$

Neutralization reaction between O^- or O_2^- and $c\text{-}C_6H_{12}^+$ does not lead to the formation of hydrogen. The reactions may be as follows, but have not been studied thoroughly.

$$c\text{-}C_6H_{12}^+ + O^- \text{ or } O_2^- \rightarrow c\text{-}C_6H_{11} + OH \text{ or } HO_2 \quad (5)$$

Anyway, the yield of nitrogen can be used as an indicator for the reaction of electrons ejected from cyclohexane molecules.

If a positive ion detector such as CH_3OD is present in the system,*1 the following reaction occurs and produces a constant fraction of deuterated hydrogen.

$$c\text{-}C_6H_{12}^+ + CH_3OD \rightarrow c\text{-}C_6H_{11} + CH_3ODH^+ \quad (6)$$

The yield of deuterated hydrogen can be used as an indicator for the reaction of parent positive ions.[3]

Data is now available for the reactions described above. This paper reports that the diffusion model proposed in the previous paper can explain these data consistently.

Calculation

In the previous paper,[2] only electrons were treated as a diffusing species. Obviously, parent positive ions can also diffuse in the system. Therefore, a modification is needed in the formulation. When electrons and the parent positive ions diffuse in the system, the number of jumps which both entities make in the diffusion before the neutralization may be approximated as follows,[2]

$$n_{\pm} = \gamma_{\pm}(2r^3/\sigma^2 r_c)$$

Here, the subscripts + and − correspond to positive

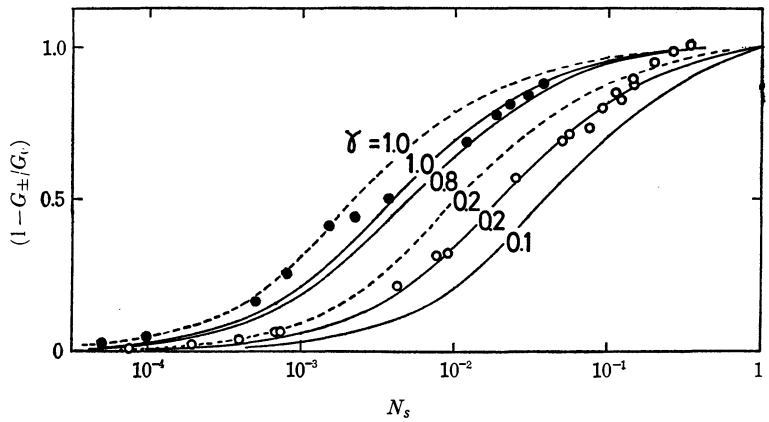

Fig. 1. Comparison of the calculated curves with the experimental data. ○: the fraction of positive ions scavenged by CH_3OD. ●: the fraction of electrons scavenged by N_2O. Full lines for $r_{av}=50$Å. Dashed lines for $r_{av}=60$Å.

ion and electron. r is an initial distance between the two entities. σ is the diameter of the solvent molecule. r_c is defined by the relation, $r_c=e^2/\varepsilon kT$. $\gamma_\pm$ is the fraction of the sum of two diffusion coefficients, D_+ and D_-.

Other formulations are the same as those in the previous paper,[2] except that the fraction $(1-N_s)^{zn\pm}$ is used in place of $(1-zN_s)^{n\pm}$, since, as Freeman stated,[5] the former expression is more exact than the latter. Thus, the G-values of positive ions (G_+) and electrons (G_-) which escape from scavenging are expressed by the relation,

$$G_\pm = G_0\frac{1}{N}\int_0^\infty \phi(r)(1-N_s)^{zn\pm}\mathrm{d}r$$

G_0 is the G-value of the initial ion pairs. z is the coordination number. N_s is the mole fraction of the scavenger. N is the normalization factor. $\phi(r)$ is the distribution function, for which we proposed the function, $r^2\exp(-\alpha r^2)$, in the previous paper.[2] As stated in the previous paper, G-value of electrons which escape geminate recombination in a non-polar solvent such as cyclohexane, is negligibly small compared with the total G-value of ejected electrons. In the case of a polar solvent, however, G-value of such electrons may be much larger. The function $\phi(r)$ should be modified as follows,

$$\phi(r) = r^2\exp(-\alpha r^2)(1-\exp(-r_c/r))$$

where, the fraction $\exp(-r_c/r)$ shows the probability of electrons which escape from the field of the parent positive ion.[6]

Figure 1 shows a typical result of the calculation, where $\gamma_\pm$ is used as a parameter. A pair of curves obtained for $\gamma_+ + \gamma_- = 1$ should be compared with the experimental data. Filled circles in Fig. 1 show the ratios, $G(N_2)/G_0(N_2)$. Here, $G_0(N_2)=6$ is assumed because the G-value of electrons has been estimated to be 3.[2] The data shown at the concentrations lower than 10^{-2} mol/l of nitrous oxide is newly obtained for this paper. Open circles are quoted from the data reported by Buchanan and Williams.[3],*2 Obviously, a pair of curves for $\gamma_+=0.8$ and $\gamma_-=0.2$ coincides best with the experimental results.

In Fig. 1, 50 and 60 Å are used as the average initial distances between a positive ion and the electron. Different distances can also be used for the calculation but the coincidence with the experimental results is never obtained unless r_{av} is in the range of 50 to 60 Å and the ratio of γ_-/γ_+ in the range of 4 to 5.

Discussion

The basic idea of the calculation presented here is the same as that proposed by Freeman.[5] The difference is in the assumption of the initial distribution of ion pairs produced in the system. Figure 2 compares the two distributions. Although the distribution used in the present calculation appears to be more plausible than that of Freeman, further examinations are needed to determine which is a better approximation.

Recently, Mozumder and Magee showed that,[7,8] in addition to isolated spurs, more densely charged spurs, namely, short tracks and blobs play important roles even in the γ-radiolysis of liquids. If this is taken into account in the calculation, the present formulation has to be modified, because, in this formulation, each ion pair is assumed to be independent from other pairs The modification

may be very much intricate.

In the present calculation, adjustable parameters are the distribution constant, α (or r_{av}) and the fraction, $\gamma_{\pm}$ from which the diffusion coefficient of electrons can be estimated if the diffusion coefficient for positive ions is known. This value is not known but may be equal to that of cyclohexane molecule itself, which is reported to be 1.38×10^{-5} cm^2 sec^{-1} at 25°C. According to the result calculated in the previous section, the diffusion coefficient of electrons in cyclohexane should be 4 or 5 times larger than that of the positive ions. This is very much smaller than that expected if the electron is not solvated and diffuses freely in the solution. Freeman assumed that $D_-/D_+\approx 5$ in his calculation.[5]

Using a photoelectronic technique to produce electrons in *n*-hexane, LeBlanc has measured the mobility of electrons at room temperature.[9] The value obtained was 1.4×10^{-3} cm^{2}V^{-1}sec^{-1}, which corresponds to a diffusion coefficient of 3.5×10^{-5} cm^2 sec^{-1}. Such a small value has led LeBlanc to conclude that electrons in *n*-hexane must be partially solvated by the solvent molecules. This is consistent with our present findings. Quantitatively, however, the ratio of $D_-/D_+=2.5$ $(=3.5\times 10^{-5}/1.38\times 10^{-5})$ calculated from LeBlanc's results, assuming that the diffusion coefficient for electrons in cyclohexane is equal to that in *n*-hexane, is about one half of that estimated in the present calculation. The discrepancy might arise from the speculations involved in the present treatment, but it is also possible that it may arise from the experimental error on D_-, although the recent measurement of conductivity of *n*-hexane irradiated by X-rays gave the value[10] consistent with that of LeBlanc.

In homogeneous systems, the rate of a reaction is proportional to the product of reactant concentrations, but this does not always hold in heterogeneous systems. Noyes has shown that the effect of a scavenger on a geminate recombination reaction is almost proportional to the square root of the scavenger concentration.[11] In the reaction of ND_3 with cyclohexane positive ion, Williams showed that this was the case.[4] However, when CH_3OD is used as a scavenger, Noyes' prediction does not fit well, probably because the range of the CH_3OD concentration is too wide to apply his approximation. This is shown in Fig. 3 along with the similar test for electron scavenging by nitrous oxide. Obviously, the proportionality to the square root of concentration holds only in a narrow range (from 0.002 to 0.02 mol/l for electrons and from 0.01 to 0.1 mol/l for positive ions) and a small negative intercept exists.

Even in a heterogeneous reaction, we are apt to assume that the rate of reaction with a scavenger is proportional to the concentration if it is very low. This was found to be correct even in the present case, but the maximum concentration used was quite low $\sim 10^{-3}$ mol/l. Therefore, we must be careful when we apply homogeneous kinetics to the radiolysis of a solution such as a liquid scintillator, where ionic species play an important role.[12]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 307—311 (1968)

Infrared and Raman Spectra of 2, 3-Dichloro-2, 3-dimethylbutane*1

Tsutomu KOIDE and Tsutomu ODA

Laboratory of Physical Chemistry, The Kyoiku Daigaku of Osaka, Tennoji, Osaka

and Kiyoshi EZUMI, Koji IWATANI and Tanekazu KUBOTA

Shionogi Research Laboratory, Shionogi and Co., Ltd., Fukushima-ku, Osaka

(Received September 27, 1967)

Infrared spectra of $Cl(CH_3)_2C$–$C(CH_3)_2Cl$ were obtained over the region from 400 cm^{-1} to 4000 cm^{-1} at room temperature in the gas phase, dilute solutions, and KBr-disk. In the KBr-disk case, spectra were also obtained at lower temperatures. In the gas phase, and in the disk at lower temperatures, spectral simplifications were obtained. Raman spectra at room temperature were photographed for the crystalline sample, and also for 17—25% solutions in several solvents. The coexistence of trans-gauche isomers in the high-temperature solid phase of this compound was verified by spectral comparison between trans- and gauche-isomers. The energy difference between two isomers was estimated to be about 1.5 kcal/mol from temperature changes in the infrared intensities.

The existence of an equilibrium mixture of two rotational isomers*2 for 1, 2-disubstituted-ethanes such as ClH_2C–CH_2Cl has been well established by spectroscopic studies.[1] For the case of 2, 3-dichloro-2, 3-dimethylbutane, $Cl(CH_3)_2C$–$C(CH_3)_2Cl$, and 2, 3-dibromo-2, 3-dimethylbutane, $Br(CH_3)_2C$–$C(CH_3)_2Br$, which have molecular structures analogous to ClH_2C–CH_2Cl, Morino *et al.* have reported the existence of trans-gauche equilibrium mixtures for the molecular system in carbon tetrachloride, heptane, and benzene solutions by dipole moment measurements.[2] Park *et al.*[3] observed the infrared and Raman spectra of $Br(CH_3)_2C$–$C(CH_3)_2Br$, and they reported that there is no evidence for the existence of an equilibrium mixture of trans- and gauche-rotational isomers in the solid state, while in the liquid, and in dilute solution the gauche form was found to exist. For $Cl(CH_3)_2C$–$C(CH_3)_2Cl$, our previous paper[4] revealed that in the high-temperature solid phase above −112°C, the molecule has some degree of rotational or reorientational freedom in the crystalline lattice. The analysis of the transition entropy of this compound has suggested the possibility of the existence of the rotational isomers in the high-temperature phase.[5]

Experimental

Sample. Pinacon was treated with an aqueous solution of hydrochloric acid saturated at about −20°C, and the mixture was allowed to stand for two weeks before filtration. The precipitate was purified by recrystallization from ethyl alcohol three times, and by fractional sublimation under a vacuum of about 10^{-5} mmHg. The melting point was found to be 158°C in a sealed tube.

Equipment. Infrared spectra were recorded with an infrared recording spectrometer Model DS-402 G of the Japan Spectroscopic Co., Ltd. The spectral region investigated was from 400 cm^{-1} to 4000 cm^{-1}. For the lower temperature measurements, the low-temperature cell of the Japan Spectroscopic Co., Ltd. was used. As the cooling material, a dry-ice - acetone solution was used for measurements at −80°C, and liquid nitrogen was used for measurement at −170°C.

Raman spectra were photographed with a model RL-II Raman Spectrograph (Yuki-Gosei-Yakuhin Co., Ltd.), which was modified for measurement of the crystalline sample, as reported in another paper.[6] The exciting light from a mercury lamp (4358 Å) was filtered through a layer of saturated aqueous solution of potassium nitrite. The mercury lamp was used with an electric current of 24—25 A. The slit width was 3—5×10^{-2} mm, and exposure time 3—5 hr. Neopan SSS

film of the Fuji Film Co., Ltd. was used. The usual Raman tube was not suitable for the present measurements because of the high volatility of the sample. For this reason, the sample was put into a flat-bottomed test tube. After evacuating the tube for two or three minutes, it was filled with nitrogen gas, and sealed-off 10 cm from the bottom.

Results

The infrared spectra at room temperature were observed for the gas phase, KBr-disk, Nujol, and dilute solutions with the solvents carbon tetrachloride, benzene, carbon disulfide, *N*, *N*-dimethylformamide, and acetonitrile. In the case of the KBr-disk, spectra were also obtained at temperatures of about −80°C and −170°C. Raman spectra were obtained for the crystalline state, and 17—25% solutions in carbon tetrachloride, *n*-heptane, and acetonitrile.

The results of the infrared measurements in the gas phase, KBr-disk, and the dilute benzene solution are collected in Fig. 1 and Table 1. In Table 1, the results of the Raman measurements are also summarized together with the previous results of Kahovec.[7] The present Raman spectra may be seen to be in accord with those of Kahovec *et al.*[7]

In Fig. 2, infrared spectra taken under various conditions are shown for the frequency range from

900 to 400 cm^{-1}. In Fig. 3, infrared spectra of the KBr-disk at lower temperatures are shown, for the frequency region 700—400 cm^{-1}. In this figure, the temperatures indicated for each curve are the averaged temperatures for the run of each measurement except for 25, −80, and −170°C; the apparatus used for the low temperature measurements was not temperature controlled during the interval of the measurement except for the above three temperatures. The temperature was maintained to within ±0.5°C at 25, −80, and −170°C, and at other temperatures, the change in temperature was about ten degrees for each interval of measurement.

The general pattern of the infrared spectra for each sample at room temperature was very close to each other except for those of the gas phase, in which spectral simplifications are observed, as shown in curve A of Fig. 1, and Fig. 2. Namely, the absorption bands at 443, 462, 565, and 648 cm^{-1} of the KBr-disk (Fig. 1 B) disappeared in the gas phase. The same simplifications stated above are also observed in the KBr-disk at lower-temperatures. (See Fig. 2B, and Table 1)

The spectral simplifications suggest the coexistence of rotationally isotropic forms in the molecular system of the KBr-disk sample, as compared with the case of 1, 2-disubstituted ethanes.[1] The problem of rotational isomerism in the present substance will be discussed in the next section.

Discussion

Rotational Isomerism. If we confine the problem to whether rotational isomers exist or not, it is sufficient to focus our attention on the C–Cl stretching band.

In general, the C–Cl stretching bands are said to appear in the region of 600—800 cm^{-1}. Actually, for the case of ClH_2C-CH_2Cl, the C–Cl stretching frequencies are observed at 665 (A), 675 (B), and 709 (Bu) cm^{-1}.[8] However, Mizushima *et al.*[9] have shown that the C–Cl stretching frequencies of the tertiary carbon atom such as $Cl(CH_3)_2C$– appeared in the regions of 610—640 cm^{-1} and 550—580 cm^{-1}. For instance, in the case of $Cl(CH_3)_2C$-CH_2Cl,[9] the C–Cl stretching appeared at 621 cm^{-1} (T_x*3) and 572 cm^{-1} (T_H*3), and in the case of $Cl(CH_3)_2C$-$CH_2(CH_3)$[9] at 613 cm^{-1} (T_x) and 558 cm^{-1} (T_H).

At room temperature, the KBr-disk of $Cl(CH_3)_2C$-$C(CH_3)_2Cl$ shows three frequency bands in this region, at 565, 604, and 648 cm^{-1}. Therefore, these bands seem to be the C–Cl stretching frequencies. This supposition may be ensured from the comparison of the Raman spectra with the infrared spectra.

The point groups of the molecular configurations and the types of vibrations expected for trans- and gauche-isomers of this compound are summarized in Table 2.[10] In the case of the gauche isomer, all the fundamental modes are active for both Raman and infrared spectra, while in the case of the trans-form the fundamental modes are mutually exclusive.

Inspection of Table 1 shows that the rule of mutual exclusion holds at 596 and 757 cm^{-1} for Raman spectra, and also at 604 cm^{-1} for infrared for the solid sample. Nevertheless, the band at 565 cm^{-1} is active for both Raman and infrared spectra. From the above considerations, the infrared band at 604 cm^{-1} be attributed to a may Bu-type vibration of C–Cl stretching, and that at 565 cm^{-1} is considered due to the gauche-form vibration.

TABLE 2. TYPES OF VIBRATION

Trans form (C_{2h}) Activity			Gauche form (C_2) Activity		
Type	Raman	IR	Type	Raman	IR
A_g	+	–	A	+	+
A_g	–	+			
B_g	+	–	B	+	+
B_u	–	+			

Furthermore, to confirm these assignments, the comparison of the intensity of these bands obtained under various conditions is also available. From Fig. 2, for the KBr-disk, and the benzene solution at room temperature, the bands (565, 604, 648, and 766 cm^{-1}) show patterns almost simillar to each other, and further their relative intensities show a similarity (see curves D and E in Fig. 2). On the other hand, for the dilute solutions of this compound with polar solvents of $HCON(CH_3)_2$*4 and CH_3CN,*4 the intensities at 565, 648 and 766 cm^{-1} increased more than that at 604 cm^{-1} as shown in curve F of Fig. 2.

The same increase in intensities in polar solvent is also observed in the Raman spectra; *i. e.*, as seen in Table 1, the relative intensity of the Raman bands at 568, 596, and 757 cm^{-1} is 1/6 : 1 : 1/2 for the KBr-disk, and 1/2 : 1 : 1 for the CH_3CN solution.

Concerning the effect of the polar solvents, Mizushima *et al.* have reported that the "gauche" molecule should be more stable in a continuous polar medium than in the gaseous state.[14] The increases in intensities observed in the polar solvent

for the 565, 648, and 766 cm^{-1} bands of the infrared, and for 596, and 755 cm^{-1} of the Raman indicate that these bands belong to vibrations of the "gauche" form. The Raman bands corresponding to 648 and 766 cm^{-1} of the infrared spectra are not observed even in the polar solvents; the reason is not known.

Turning to the solid state, the temperature dependence of the infrared spectra of the KBr-disk is shown in Fig. 3. Although the indicated temperatures in Fig. 3 are not equilibrium temperatures, except 25, −80, and −170°C, as described earlier, it is clearly shown that the bands at 565, 648, and 766 cm^{-1} show a decrease in their intensities with a lowering of the temperature. These bands disappeared below −120°C, and almost in the gas phase.

Contrary to this, the intensity of the 604 cm^{-1} band of the trans-form is not so dependent upon the experimental conditions. Therefore, these changes in intensity, along with the comparison of Raman and infrared spectra, indicate that the 604 cm^{-1} band belongs to the trans-form (C_{2h}), whereas the band at 565, 648, and 766 cm^{-1} are attributed to the gauche-form (C_2).

From the considerations of the Raman, and infrared spectra mentioned above, it is clearly seen that there is a coexistence of trans- and gauche-rotational isomers in the molecular system of the high-temperature solid phase as well as in the dilute solutions of $Cl(CH_3)_2C$-$C(CH_3)_2Cl$. For the dilute solution, the present conclusion is coincident with that of Morino *et al.*[2] In the gas phase, the majority of the molecular configurations will be trans-, together with a small number of the gauche-form.

Some comments are added here with regard to the infrared bands below −120°C for the KBr-disk sample. The band at 604 cm^{-1} for the KBr-disk observed at room temperature increases in width with decreasing temperature below −120°C, and split into two bands at 609, and 599 cm^{-1} at about −170°C. The splitting of the band may be due to a change in the crystal at the transition point (−112°C), as shown in the case of an other compound.[15]

The Energy Difference between Trans- and Gauche-form. From the temperature dependence of the infrared intensities, the energy difference, ΔE, between the trans- and gauche-positions may be calculated. The intensities of the trans-, and gauche-bands are approximately related to ΔE by the formula,[1a,1f,16]

$$I_{(g)}/I_{(t)} = A \exp(\Delta E/RT)$$

where $I_{(g)}/I_{(t)}$ is the ratio of the integrated intensities for the gauche- and trans-bands; A is a constant. Taking the 604 cm^{-1} band to be trans-, and the 565, and 648 cm^{-1} to be gauche-, we obtained

$$I_{565}/I_{604} = 0.10 \text{ at } 300°K$$
$$= 0.03 \text{ at } 190°K,$$

and

$$I_{648}/I_{604} = 0.13 \text{ at } 300°K$$
$$= 0.03 \text{ at } 190°K.$$

Then we have

$$\Delta E = 1.3 \text{ kcal/mol from } I_{565}/I_{604}$$
$$= 1.7 \text{ kcal/mol from } I_{648}/I_{604}.$$

The values of ΔE are of the same order as the results of Morino *et al.*, who have estimated ΔE= 1.6 kcal/mol for dilute solutions of this compound from dipole moment measurements.[2]

The values of ΔE indicate that in the high-temperature solid phase the trans-form has a lower energy than the gauche-form. In connection with the values given above, we should like to refer to the values of ΔE for 1, 2-disubstituted-ethanes. In the gas phase for ClH_2C–CH_2Cl and BrH_2C–CH_2Br, it was reported that the trans-form is the lower energy configuration.[1a] In contrast, for 1, 2-dicyanoethane (succinonitrile),[17] the gauche-form is the lower energy structure in the solid and liquid states, although the trans-form is the lower energy configuration in the gas phase. According to the discussion of Mizushima *et al.*,[14] the greater stability of the gauche-form in the solid and liquid phases of succinonitrile should be attributed to the high dielectric constant[18] and to the much greater dipole moment (5—6 D) of this structure compared with those of the dihaloethanes (2.23 D for dichloro-[19], and 2.62 D for Dibromo-[19] ethane). In the case of $Cl(CH_3)_2C$-$C(CH_3)_2Cl$, the dipole moment for the gauche-form is 3.1 D,[2] and further the dielectric constant for the high-temperature phase is not a high-value.[20] Therefore, the relation between the values of ΔE and the molecular configuration for the present compound seems to be similar to the case of the dihaloethanes.

The authors express their hearty thanks to Professor Hiroyuki Tadokoro of Osaka University for his interest during this study, and for his discussions. They also wish to express their thanks to Professor Tatsuo Miyazawa of Osaka University for his useful suggestions and discussions.

Thermal Properties of Alkali Halide Crystals with the CsCl-type Structure. I.*[1] Construction of a Calorimeter for the Temperature Region 1—20°K and Heat Capacities of Caesium Bromide and Caesium Iodide between 1.5 and 300°K

Michio SORAI, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received October 14, 1967)

An adiabatic low-temperature calorimeter, capable of measuring the heat capacities of solid or liquid between 1.4 and 21.0°K, was constructed. A mechanical thermal switch is used for cooling the sample cell, the temperature of which is measured with a doped germanium thermometer. The resistance-temperature calibration data for the resistor was fitted to a function of the form $\log_{10}R=A/T+B+CT+DT^2$. By using this formula the thermodynamic temperature scale is represented to within ±0.02°K and by combining the correction curves the final deviations of the calibration data from the thermodynamic temperature scale were within ±0.003°K in the whole temperature range investigated. The heat capacity measurements of CsBr and CsI crystals were made with two kinds of adiabatic calorimeter assemblies, one for the temperature range 1.4 to 21°K and the other for the range 12 to 300°K. Values of the heat capacity $C_p°$, entropy $S°$, enthalpy function $(H°-H_0°)/T$, and Gibbs energy function $-(G°-H_0°)/T$, at 298.15°K are: 12.441, 26.785, 10.415, and 16.370 for CsBr and 12.571, 29.127, 10.788, and 18.339 for CsI, respectively, in cal·mol^{-1}·°K^{-1}.

It is of some interest to note the fact that the alkali halides crystallize at standard temperature and pressure in the NaCl-type structure, with the exception of CsCl, CsBr, and CsI which crystallize in the CsCl-type structure, although polymorphic transitions between the NaCl and CsCl structure have been observed to occur for some of these crystals with increasing temperature or pressure. Although a great deal of work has been done on the alkali halides with the NaCl structure, theoretical and experimental studies of the alkali halide crystals with the CsCl structure seem to have received little attention in the past. Some theoretical investigations have been made to interpret which structure will be more stable under a given set of conditions. Among them Mayer[1] showed that van der Waals potential contributes to the stability of the CsCl-type lattice for CsCl, CsBr, and CsI at absolute zero. Tosi and Fumi[2] succeeded in establishing which phase has the lower free energy and is thus thermodynamically more stable under a given set of conditions. From the standpoint of lattice dynamics Hardy and Karo[3] accounted for the instability of the NaCl-type lattice under the condition just below the pressure-induced phase transition. Some experimental results[4-7] have been also reported in which the difference in the crystal structures seems to be reflected.

The purpose of the present investigation is to obtain detailed thermal data on CsBr and CsI crystals in the temperature range from 1.5 to 300°K, and, in particular, to study how the difference in structure is reflected in their thermal properties. An adiabatic calorimeter for the heat capacity measurements below 20°K is also described.

Experimental

Calorimeter and Cryostat. The main parts of the adiabatic calorimeter consist of calorimeter cell, cryostat, thermometer and electrical circuit. Figure 1 shows diagrammatically the cryostat assembly and its essential features are depicted in Fig. 2. There are two refrigerant compartments; an outer one (for the liquid nitrogen) consisting of a stainless-steel Dewar vessel and an inner one (for the liquid helium or liquid

hydrogen) consisting of a large glass Dewar of approximately 7 *l* capacity. Carbon resistors (Allen-Bradley, 47 Ω nominal resistance) positioned conveniently on the stainless-steel tube serve as useful refrigerant-level indicators. The third innermost compartment, which houses the high vacuum for the calorimeter cell, consists of a brass can apart from its bottom made of thick copper plate. All conduits are made of stainless-steel. To prevent that large amount of energy is imparted to a sample from room temperature radiation, two radiation traps are placed at the bottom of the central tube (E and G in Fig. 2). Styro-form plate located at the entrant of the glass Dewar also serves as a radiation shield from liquid nitrogen temperature.

The body of the calorimeter cell consists of a cylinder of copper. Thin copper fins project radially from a small tube which is centrally located along the vertical axis of the calorimeter (see Fig. 2). These fins are soldered with the tube and the calorimeter wall. The filling tube of the calorimeter cell is fitted with a small brass cap to the center of which is brazed a short piece of tubulation that permits evacuation of the sample in the calorimeter and filling helium gas for heat exchange. The diameter of the calorimeter cell is about 4.5 cm, the overall length (including cap) being approximately 9 cm and the volume about 110 cm^3.

A Minneapolis-Honeywell germanium resistor (Honeywell Series II) was used as a working thermometer. It was firmly embedded in a small copper pipe brazed to the top of the calorimeter. To further insure the good thermal contact it was varnished (GE adhesive # 7031). The current used for the measurements of resistance of the germanium resistor was selected as to render maximum accuracy; *i. e.* in the liquid helium region varied from 2.0 to 10.0 μA and in the liquid hydrogen region from 10 to 30 μA. The details of the calibrations of the thermometer will be described in the next section.

The heating element of the calorimeter is formed of about 1000 ohms of a strain-free constantan wire (Driver-Harris Co., #36). The wire was wound non-inductively around the calorimeter cell and varnished to insure good thermal contact. To minimize any exchange of energy between the calorimeter and the environment (refrigerant bath) the lead wires from the heating element and the thermometer were made thermal contact with the periphery of the calorimeter and coiled helically in the vacuum space. These wires entered the refrigerant compartments by means of hermetic seals (New Nippon Electric Co., Ltd., #A241). The electrical circuits for energy supply are the same as those for the calorimeter[8] previously described, which is operative in the temperature range 12 to 300°K. Determinations of the heat input and the resistances of the thermometer were all made on a Wenner-type potentiometer (Leeds & Northrup Co.). The heating time was read on a timer placed in the energy circuit.

The mechanical thermal switch consists of a "make and break" contact between the smoothly polished surface of the bottom of the calorimeter cell and the bottom of the vacuum jacket. The vertical movement of the cell is controlled by a winch mechanism located at the top of the cryostat. The connection between the winch and the calorimeter is accomplished by a fine nylon thread. The "making and breaking" of the contact is detected through a micro-ammeter by the "on and off" of the current controlled by the thermal switch. By means of this device the calorimeter cell may be cooled conveniently from room temperature down to about 1.4°K (lowest pumping temperature) in a vacuum better than 10^{-6} Torr without the use of any heat exchange gas.

Temperature Scales. The germanium resistance thermometer was calibrated in the temperature range from 1.4 to 4.4°K against the vapor pressure temperature scale (the T_{58} scale) compiled by Brickwedde *et al.*[9] In the temperature range between 11.8 and 21.0°K, on the other hand, the thermometer was calibrated against a Leeds & Northrup platinum resistance thermometer certified by the National Bureau of Standards (the NBS scale). These calibrations were performed by separate experiments before the germanium thermometer being fixed to the calorimeter. To complete the calibration of a germanium thermometer, some adequate functional relationships between resistance, R, and temperature, T, should be needed. Such attempts to find an empirical formula were made by, for examples, Lindenfeld,[10] Ahlers,[11] and Cataland and Plumb.[12] In the present case, however, a rather simple formula[13] of the form,

$$\log_{10} R = A/T + B + CT + DT^2, \qquad (1)$$

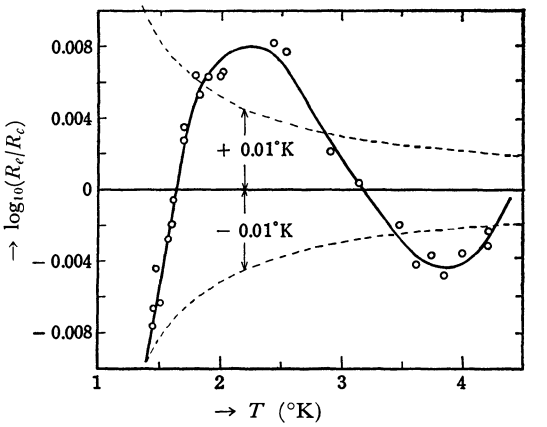

Fig. 3. Correction curve for the calibration of the germanium thermometer in the range 1.4 to 4.4°K.

was fitted to the experimental R_e and T_e calibration data of the germanium resistor by the method of least squares, where A, B, C, and D are numerical constants. A comparison between the R_e and the R_c (calculated value from formula (1)) is illustrated in Fig. 3 in the case of liquid helium temperature region. It is clear in the figure that formula (1) may reproduce the R_e and T_e relationship within ± 0.02°K. The same held well in the liquid hydrogen temperature region where the last term of the right-hand side of formula (1) was

omitted. To improve the effectiveness of formula (1), it is necessary to define a correction term as

$$\Delta = \log_{10} R_e - \log_{10} R_c. \quad (2)$$

Finally the smoothed values of resistance of the germanium resistor, R_s, were calculated by the following formula,

$$\log_{10} R_s = A/T + B + CT + DT^2 + \Delta, \quad (3)$$

and the tables of R_s *versus* T were made every interval of 0.01°K in the region 1.40 to 4.40°K and of 0.1°K in the region 11.8 to 21.0°K by the NEAC 2203 computer. Deviations of the calibration points, T_e, from formula (3) are shown in Fig. 6. In order to check the stability of thermometer after temperature cycling the calibrations were repeated six times and no significant changes were observed. This fact is consistent with the results by Kunzler *et al.*,[14] and Plumb *et al.*[15] The final deviations of the calculated curve by using formula (3) from the T_{58} scale and the NBS scale, respectively, are within ±0.003°K.

In general a commercially available germanium resistance thermometer had disadvantages such as that the resistance-temperature relation is complicated and should be established by calibration at many temperatures. Thus, without the use of a gas thermometer there is no method for evolving a "working" temperature scale between the liquid helium and the liquid hydrogen temperature region, *i. e.* 4.4—11.8°K, as far as a germanium resistor is used. For these reasons there is always an uncertainty in evaluating the thermodynamic temperature scale in this region, so the high-precision calorimetric investigations in this temperature region are rather scarce. An attempt has been made by DeSorbo and Nichols[16] to circumvent

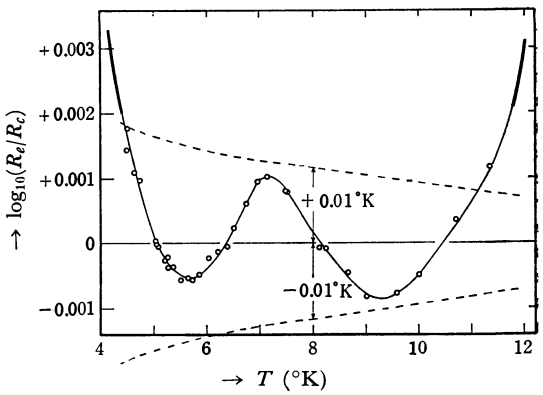

Fig. 5. Correction curve for the germanium thermometer in the temperature range 4.4 to 11.8°K.

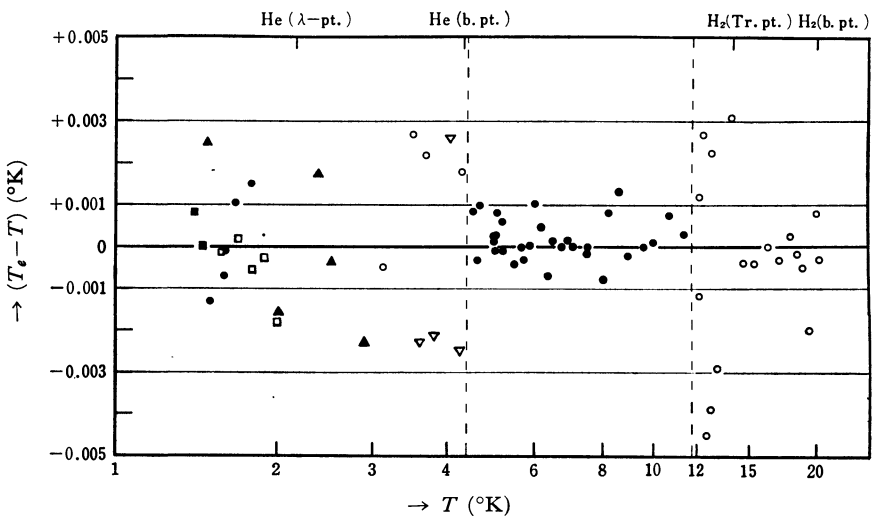

Fig. 6. Deviations of the calibration points for the germanium thermometer from the T_{58} scale (1.4—4.4°K), from "the Carbon scale" (4.4—11.8°K), and from the NBS scale (11.8—21.0°K). Various marks in the liquid helium region mean different runs of the calibration.

this problem, at least approximately, with a careful analysis of the carbon resistor data obtained both in the liquid helium and liquid hydrogen temperature regions. The working temperature scale adopted here between 4.4 and 11.8°K is based on this convenient method, that is to say "the Carbon scale". The procedure adopted is to evaluate the correction factor, α, for the region 1.4—4.4°K and 11.8—21.0°K, first by using the constants A and B evaluated from the R-T data for the liquid hydrogen region (see Fig. 4(a)) and secondly by using constants A and B determined for the liquid helium region (Fig. 4(b)). Here A and B are constants appeared in the formula, $\sqrt{(\log R)/T}=A\log R+B$, for the R-T relation of carbon resistor proposed by Clement and Quinnell.[17] By a method of successive approximation, the two interpolated segments of the curves shown in Figs. 4(a) and 4(b) by broken lines were determined to give a minimum discrepancy in $\Delta T(T(H_2\text{-formula})\text{-}T(\text{He-formula}))$. Uncertain deviations of "the Carbon scale" from the thermodynamic temperature scale will probably be introduced in the process of drawing the interpolated segments. An ambiguity in this procedure, however, does not seem to exceed ±0.02°K (see Figs. 4(a) and 4(b)). The working temperature scale for the germanium resistance thermometer was, thus, established by using both "the Carbon scale" and the formula (3).

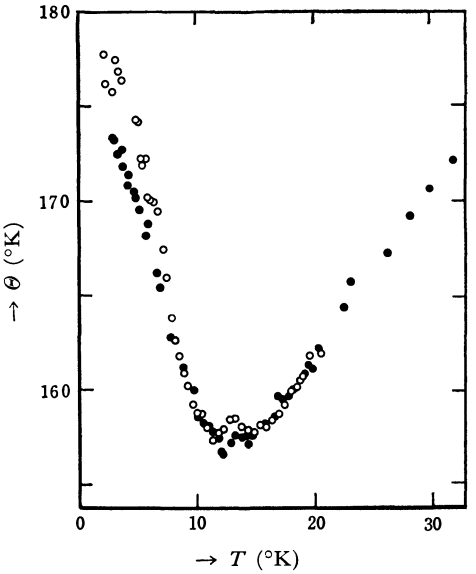

Fig. 7. Comparison of the heat capacity of KBr in terms of the Debye characteristic temperature below 21°K: ○, present work; ●, Berg and Morrison.[18]

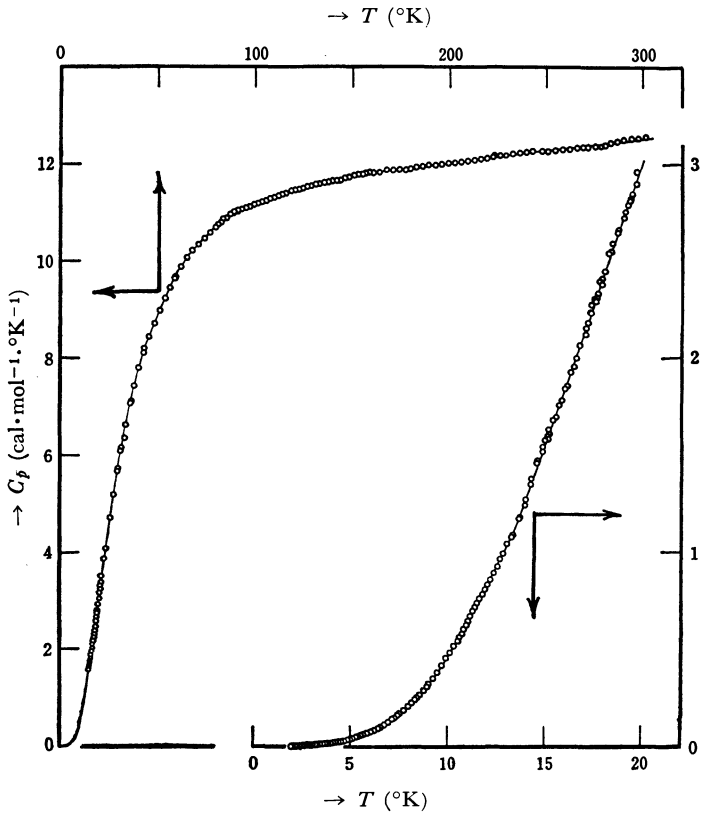

Fig. 8. Heat capacity of CsBr in the temperature region from 1.5 to 300°K.

18) W. T. Berg and J. A. Morrison, *Proc. Roy. Soc.*, **A242**, 467 (1957).

The correction curve in this region is illustrated in Fig. 5. Two thick solid lines in the vicinity of 4 and 12°K mean the T_{58} scale and the NBS scale, respectively. Final deviation plots of all the calibration points for the germanium resistor from "the Carbon scale" are shown in Fig. 6.

Materials. Powder crystals of CsBr and CsI of high purity optical grade were obtained from Mitsuwa's Pure Chemicals. The salts were recrystallized twice from distilled water and then dried at temperatures between 100 and 120°C in a vacuum for 15 hr. The results of spectrographic analysis of this purified samples are given in Table 1. Potassium bromide crystal of high purity optical grade was obtained from E. Merck AG. Procedure of purification was the same as mentioned above.

For the heat capacity measurements in the temperature range 1.5 to 21.0°K the calorimeter contained 104.743 g (0.49219 mol) of CsBr, 184.462 g (0.70999 mol) of CsI, and 150.582 g (1.2653 mol) of KBr, respectively, as well as a small amount of helium exchange gas. For the measurements at higher temperatures, on the other hand, the calorimeter contained 43.8972 g (0.20627 mol) of CsBr and 46.2041 g (0.17784 mol) of CsI, respectively, and helium gas as heat exchanger.

Heat Capacities of CsBr and CsI. The heat capacity measurements were made with the low-temperature adiabatic calorimeter (denoted as calorimeter-A hereafter) described above in the temperature region 1.5 to 21.0°K and with the automatic adiabatic calorimeter[8] (calorimeter-B) described previously in the range 15 to 300°K. Approximately 230 heat capacity data were determined for CsBr and CsI with various small temperature rise (0.05—0.5°K below 20°K and 1—3°K above 15°K).

The Precision and Accuracy of the Measurements. The scatter of the results obtained with the calorimeter-A is at worst ±3% at the lowest temperatures and ±1% for $T>4$°K. The precision of the calorimeter-B appears to be ±2% for $T<20$°K, ±1% for 20°K$<T<$50°K, and ±0.3% for $T>50$°K. The accuracy is more difficult to assess. It is likely that the most serious error arises from the uncertainty in temperature scales. The accuracy has therefore to be judged by comparison of results obtained from independent assemblies. A comparison of the two sets of results between 15 and 21°K provides a measure of accuracy in this range. For each of two salts the average deviation of one set from the other was within the experimental errors. The accuracy of the calorimeter-B had been checked previously[8] by using it to measure the heat capacity of the Calorimetry Conference sample of benzoic acid in the temperature range 13 to 300°K. Another comparison may also be made with the measurements of other workers. In order to check the accuracy of the calorimeter-A heat capacity of potassium bromide was also measured between 1.5 to 21°K. The results are compared with the data by Berg and Morrison[18] in Fig. 7 in terms of the Debye characteristic temperature. Agreement between them seems to be very satisfactory if the experimental errors are taken into account. For caesium iodide heat

capacity data have been reported by Taylor *et al.*[19] in the range 13 to 300°K. They agree with the present results to within ±1% above 60°K, but the systematic deviation appears with decreasing temperature to amount to +5% below 20°K. Heat capacities of CsBr and CsI above room temperature have been reported by Brönsted.[20] His value is 0.6% higher at 300°K for CsBr and 1.4% higher for CsI.

Experimental Results

The results of the heat capacity of CsBr and CsI in the region 1.5 to 300°K are plotted in Figs. 8 and 9, respectively. Tables 2 and 3 list their numerical values. The calorie defined as equal to 4.1840 absolute joules was used. The ice-point was taken as 273.15°K. The molecular weights are based on the 1966 IUPAC report on atomic weights.

Smoothed values of the heat capacity, entropy,

19) A. R. Taylor, Jr., T. E. Gardner and D. F. Smith, *U. S. Bur. Mines Rept. Invest.*, No. 6157 (1963).
20) J. N. Brönsted, *Z. Elektrochem.*, **20**, 554 (1914).

enthalpy function, and Gibbs energy function, and also of the standard thermodynamic values at 298.15°K, are listed in Tables 4 and 5, for CsBr and CsI, respectively. The differential heat capacity, $C_p°$, listed in the tables, which is obtained from the observed values of $\Delta H/\Delta T$, was not corrected for curvature because of the small rise in temperature, ΔT.

Other thermal properties of these crystals and significant differences between the alkali halide crystals with the NaCl-type structure and the CsCl-type one are fully described in part II.[21]

The authors wish to express their sincere thanks to Mr. Nobukatsu Fujino of Sumitomo Metal Industries, Ltd. for spectrographic analysis of the specimen for metal impurities. They are also indebted to Messrs. Takasuke Matsuo and Masayasu Sugisaki for their help in part of the measurements.

Studies on the Sol-Gel Transformation of Aluminium Hydroxide in the Presence of Dyes

Wahid U. MALIK and Iqbal A. KHAN

Chemical Laboratories, University of Roorkee, Roorkee, India

(Received April 9, 1966)

The influence of dyes on the gelation of aluminium hydroxide sol has been studied with the help of viscometric and pH metric methods. From these studies it is inferred that the behaviour of acid dyes towards alumina is different from that of basic dyes. The results have been interpreted in terms of various structural changes taking place in the dye molecule. Adsorption studies reveal that the data do not fit well into the Langmuir or Freundlich adsorption isotherm equation in the case of alizarin sulphoric acid, while in the cases of methyl orange, methylene blue, and malachite green, the data are found to fit well into the Langmuir adsorption equation.

A large amount of work has been done on the adsorption of dyes, especially of the alizarin class, on hydrous oxide sols. Mokuskin and Esin,[1] White and Gorden,[2] and Porter[3] have studied the association of several dyes with hydrous oxides. Weiser[4] has also made several studies in this direction. Other problems, however, for instance, the nature of the binding between sol and dye, the determination of the miceller size of hydrous oxide sols by dye interaction, and the influence of dyes on the gelation of sols, have not yet been comprehensively studied. In the present paper the results of the gelation of aluminium hydroxide in the presence of acid (alizarin sulfonic acid and methyl orange) and basic (methylene blue and malachite green) dyes are reported.

Experimental

Reagents. *(a) Aluminium Hydroxide Sol.* Positively-charged aluminum hydroxide sol was prepared by the method described by Weiser.[5] 10 g of aluminium chloride (E. Merck) was dissolved in 500 cc of doubly-distilled water, and the resulting solution was heated to boiling. Aluminium hydroxide was precipitated with a slight excess of ammonia, and the suspension was boiled for five minutes. The precipitate was then placed in a centrifuge tube and suspended in doubly-distilled water, after which the suspension was centrifuged for 15 min. The supernatant liquid was poured off, doubly-distilled water was again added, and the precipitate was washed. The process of washing was repeated many times. The precipitate was then transferred to a 500 cc Pyrex beaker and suspended with doubly-distilled water. The suspension was then heated to boiling. The precipitate of $Al_2O_3 \cdot xH_2O$ was peptized to alumina sol by gradually adding 0.2 N HCl in 1 cc portions and boiling the solution for ten minutes after each addition. The pH of the solution containing the alumina sol was lowered to the required value by the addition of the requisite amount of a 0.1 N HCl solution. The concentration of alumina in the colloidal solution was determined gravimetrically[6] by precipitating it

as $Al_2O_3 \cdot xH_2O$ in the pH range 7—7.5 and by then igniting the precipitate to Al_2O_3.

b) The dyes, alizarin sulphonic acid (sod. salt), methyl orange (sod. salt), methylene blue (chloride), and malachite green (chloride) were either B. D. H. or Merck products.

Apparatus and Technique. The viscosity measurements were carried out using a modification of Scarpa's method.[7] The pH measurements were made with a Cambridge bench pH-meter. Adsorption experiments were carried using the Bausch and Lomb "Spectronic 20."

Procedure. 2.0×10^{-2} M stock solutions of the dyes (alizarin sulphonic acid, methyl orange, methylene blue and malachite green) were prepared in doubly distilled water and kept in all-Pyrex glass vesseles. The following sets of mixtures were used for gelation measurements. (i) 20 cc sol + a varying amount of the dye (0, 0.5, 1.0, and 1.5 cc of 2.0×10^{-2} M methyl orange); (ii) 20 cc of sol + a varying amount of the dye (0.5, 1.0, and 1.5 cc of 2.0×10^{-2} M alizarin sulphonic acid); (iii) 20 cc sol + a varying amount of the dye (0.5, 1.0, and 1.5 cc of 2.0×10^{-2} M methylene blue); (iv) 20 cc sol + a varying amount of the dye (0.5, 1.0, and 1.5 cc of 2.0×10^{-2} M malachite green). In each case the total volume was made up to 30 cc with doubly-distilled water.

The viscometric and pH metric studies were carried out at 30±0.1°C during the dialysis of the above sets (i, ii, iii and iv in) different dialysing bags of the same size.

Dye Adsorption Measurements. The alumina gel (the adsorbent) was prepared by the continuous dialysis of the sol, and then dried between 50 and 80°C. The finely powdered gel was weighed and presoaked in a small quantity of doubly-distilled water prior to the addition of a dye solution. The following sets of mixtures were prepared: (i) 100 mg of alumina gel + a varying amount of the dye (1.0, 2.0, 3.0, 4.0, and 5.0 cc of 1.5×10^{-4} M alizarin sulphonic acid); (ii) 100 mg of alumina gel + a varying amount of the dye (1.0, 2.0, 3.0, 4.0, and 5.0 cc of 4.51×10^{-5} M methyl orange); (iii) 100 mg of alumina gel + a varying amount of the dye (1.0, 2.0, 3.0, 4.0, and 5.0 cc of 3.14×10^{-5} M methylene blue); (iv) 100 mg of alumina gel + a varying amount of the dye (1.0, 2.0, 3.0, 4.0, and 5.0 cc of 1.96×10^{-5} M malachite green). In each case the total volume was made up to 10 cc with doubly-distilled water.

Adsorption isotherms were run by making successive additions of 1.0, 2.0, 3.0, 4.0, and 5.0 cc of the dye solution to 100 mg of alumina gel. The adsorbent and the dye solution were agitated to equilibrium after each addition of dye prior to a colorimetric measurement of the dye solute. The volume of the solutions was 10 cc. The readings were made after a sufficient time of mixing, when the solution had attained equilibrium. The equilibrium solutions were then centrifuged for transmittance measurements.

Discussion

Before discussing the experimental findings on the sol-gel transformation of aluminium hydroxide in the presence of dyes, it is worthwhile considering the behaviour of the pure sol when converted into a gel by prolonged dialysis. A plot of the time of dialysis against the viscosity (Fig. 1) reveals that, after a certain stage of dialysis, there is an abrupt increase in the viscosity. This means that with a progressive dialysis the optimum conditions necessary to bring about gelation are realized, and that the time after which an abrupt increase in viscosity takes place may conveniently be termed the "gelation time"[8,9] (it is quite distinct from the time of the setting of a gel-forming mixture).

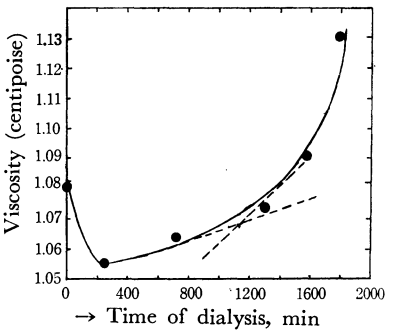

Fig. 1

The data (Table 1) show that, although the time of setting is different for samples subjected to dialysis for different time intervals (the minimum time being 4.5 hr), when samples are dialysed for 30 hr, the time required for all the samples of one mixture to attain the optimum conditions for gelation had the same value, ranging between 1040 and 1300 min.

Although an abrupt rise in viscosity in colloidal systems may be explained in the light of several factors, the solvation, the electroviscous effect, and adhesion of particles, *etc.*, in the case of pure sol, a forthright explanation is difficult in complex systems comprising mixtures of a sol and a foreign substance, or of two different sols. In such cases due consideration has to be given to structural changes accompanying the interaction of the different chemical entities involved besides the factors enumerated above.

Gelation of an Alumina Sol - Dye Mixture. With (acid or) anionic dyes the viscosity of the mixtures first decreases, and then increases near the gelation time, while with (basic or) cationic dyes the behaviour is quite different: the viscosity shows an initial decrease, followed by a gradual increase. These data may be discussed from the following two angles. (i) the variation in the viscosity with a progressive dialysis in the presence of a fixed amount of dye, and (ii) a change in the

viscosity with gradually increasing amounts of the dye in a sol dialysed for a fixed period of time. In (i) a continuous decrease in viscosity with dialysis is observed with acid dyes, the extent to which this change takes place being dependent on the nature of the dye employed. In the presence of a fixed concentration of the dye, 1.0 mmol/*l*, the following variations are observed.

On considering the viscosity data for samples dialysed for a period greater than the gelation time of the pure sol (say, 30 hr), it will be seen that there is considerable decrease in viscosity, 42.5% and 36.0% in the cases of methyl orange and alizarin sulphonic acid respectively, although there is an overall increase of 0.92% in the case of pure sol. With the basic dyes the results are different; the viscosity changes are very small, and only slight increases in viscosity are observed (0.18% for methylene blue and 3.4% for malachite green).

The decrease in viscosity on prolonged dialysis may be explained in terms of peptization. The

dye used may prevent agglomeration by the adsorption of the anionic part of the dye on the sol particles, which may keep the sol in the stable state and not allow it to undergo gelation. These data are supported by the work of Ghosh and his coworkers,[10] who observed that hydrous oxides, especially of the amphoteric type, develop a large adsorption capacity for anions. The findings on the changes in viscosity and pH with a variation in the concentrations of dyes after a fixed period of dialysis are worth considering.

Figure 2, indicates that the final viscosity increases with an increase in the concentration of the dye, in the cases, of both methyl orange (Curve 1) and alizarin sulphonic acid (Curve 2), although the natures of the two curves are different; in the case of alizarin sulphonic acid viscosity slightly decreases in the initial state (Table 3, Column 4), while in the case of methyl orange there is a continuous increase in viscosity. With basic dyes the behaviour is quite different; that is, the concentration-viscosity curve shows a decrease over a wide concentration range, followed by an abrupt increase in the case of malachite green (Curve 4), while there is an initial decrease, followed by an increase and then a slight decrease again, in the case of methylene blue (Curve 3). The difference in the nature of the products obtained with basic and acid dyes is also evident from the stability curves (a plot of the stability against C_e, where C_e is the concentration of the dye). That is, the stability of the sol increases slightly and then dedecreases rapidly with an increase in the concentration of the dye in the case of basic dyes, but in the case of acid dyes no such decrease is marked (Fig. 3, Curves 1 and 2).

Another factor worth taking into account in explaining the gelation tendency of alumina in the presence of dyes in the structure of the dyes and the molecular rearrangements in the different pH ranges. Since the alumina sol has a fairly low pH, the dye molecule may either undergo protonation or reorientation to give the quinoidal structure.

Preliminary experiments have shown that methylene blue does not change its colour in either an acidic or a basic medium. The addition of sol, however, brings about a slight fading of the coluor, indicating the possibisity of adsorption. The change in the pH of the sol upon addition of methylene blue supports this view (Fig. 4, Curve 3). The behaviour with malachite green can be explained on similar lines, except for the fact that there is nothing inherent in the structure of the molecule which may point towards some sort of interaction between the dye and the sol.

With acid dyes a lake formation takes place. The alizarin lakes of the hydrous oxides are ordinarily formed by an exchange adsorption process

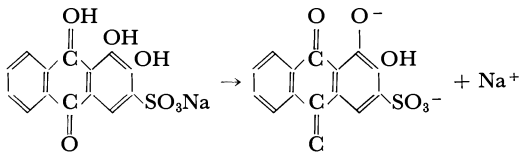
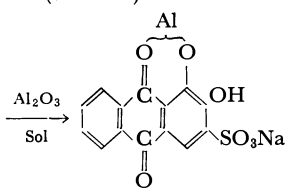
in which the relatively strongly-adsorbed alizarate ions displace such more weakly desorbed ions as chloride from the hydrous oxide. According to the view of Morgan,[11] the alizarin lakes are definite metal chelate compounds.

The various changes taking place can be represented by the following scheme:



alizarin sulphonic acid (sod. salt)



methyl orange

△ 4. Al_2O_3 gel + mal. green

In the case of alizarin sulphonic acid, the data on adsorption do not fit well into either the Langmuir or the Freundlich adsorption equation (Figs. 5 and 6, Curve 1). The extent of adsorption in this case is probably more closely related to the chemical nature of the substances than to their molecular size or molecular weight. In the case of methyl orange, methylene blue, and malachite green, the data are found to fit the Langmuir adsorption equation well (Figs. 5 and 6, Curves 2, 3, and 4 respectively).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 325—328 (1968)

Effect of the Dielectric Constant on the Reaction between the Iodide Ion and Hexacyanoferrate(III) in Acid Media

B. KRISHNA and H. S. SINGH

Department of Chemistry, University of Allahabad, Allahabad, India

(Received May 19, 1966)

In the reaction between the iodide ion and hexacyanoferrate(III), the order is unity with respect to the iodide ion and two with respect to the ferricyanide ion. It has been observed that the rate of the reaction increases with the increase in the dielectric constant of the medium. It has also been observed that the reaction occurred between trivalent and univalent negative ions.

The effect of the dielectric constant on the reaction between the iodide ion and ferricyanide in acid media has not yet been studied. The kinetic data show that the order with respect to ferricyanide is two, while that with respect to iodide is unity. By increasing the dielectric constant of the medium, the rate of the reaction is increased; this effect will be discussed in this paper, using the Brönsted-Christiansen-Scatchard[1] equation. The product of the ionic charges of the two reacting species will be calculated, and lastly we will come to the

1) E. S. Amis, "Kinetics of Chemical Change in Solution" (1949), 99.

conclusion that the reaction occurs between trivalent and univalent negative ions.

Experimental

Materials Employed. The solution of potassium ferricyanide was prepared by dissolving an ANALAR (B. D. H.)-grade reagent in distilled water.

The solution of potassium iodide was prepared by dissolving an approximate quantity of a G. R. (E. Merck)-grade reagent in water. The solution was then standardized by titrating it with a standard solution of silver nitrate, employing eosin[2] as an indicator.

ANALAR (B. D. H.)-grade hydrochloric acid was used throughout the experiments.

Absolute ethyl alcohol was redistilled in a quick-fit apparatus; the fraction boiling at 78.2°C was used.

Measurement of the Dielectric Constants. The dielectric constants were measured by a dielectrometer (Dielektrometer Type TRK No. 53015), working on the principle of the heterodyne-beat method. The null point was obtained with the help of a magic eye (Bridge Type). The values for the dielectric constant of absolute alcohol-water mixtures were obtained with a cell 1.68$\mu\mu$F in capacity. This cell had been previously brated with standard liquids of known dielectric constants.

A Study of the Progress of the Reaction. An excess of the potassium ferricyanide solution was placed in a conical flask and kept in a thermostat. The requisite quantities of potassium iodide, an alcohol-water mixture, and a hydrochloric acid solution were placed in a separate conical flask and kept in the same thermostat. When the solutions had attained the temperature of the bath, the requisite quantity of potassium ferricyanide was sucked in a pipette and poured into the solution containing potassium iodide and hydrochloric acid. The progress of the reaction was followed by sucking out an aliquot (10 m*l*) and pouring it into ice cold water in order to quench the reaction. The liberated iodine was then titrated with a standard solution of sodium thiosulphate, using starch as an indicator.

The following tables show the results at different concentrations of potassium ferricyanide and at a constant concentration of the other reactant.

A perusal of Tables 1 and 2 will show that the values of the second-order constant are fairly constant throughout the course of reaction. This proves that the order of reaction with respect to ferricyanide is two. The increase in the k_s value with the decrease in the concentration of ferricyanide is not clear at present, but the value of Z_AZ_B has been determined at a fixed concentration of ferricyanide. Therfore, the variation in ferricyanide will not affect the study of the dielectric constant. Similarly, Table 3 contains the results at different concentrations of potassium iodide.

Results and Discussion

In order to study the nature of the charge of the reacting ions, the above data were studied in the light of the Brönsted-Christiansen-Scatchard equation:

$$\ln k_s = \ln \underset{\substack{\chi=0 \\ D=\infty}}{k} - \frac{Z_A Z_B \varepsilon^2 N}{DRTr} + \frac{Z_A Z_B \varepsilon^2 N}{DRT}\chi \qquad (1)$$

This equation has been extensively employed by Amis[3-5] in his study of isodielectric and isocomposition activation energies. Here k_s is the observed velocity constant, while $\underset{\substack{\chi=0 \\ D=\infty}}{k}$ is the velocity at zero ionic strength and at an infinite dielectric constant. N is the Avogadro number, D is the dielectric constant of the medium, and r is the minimum distance of approach. χ is the constant which occurs in the Debye-Hückel theory of strong electrolytes; it can be calculated by the following equation:

$$\chi = \sqrt{\frac{8\pi\varepsilon^2 N^2 \mu}{1000DRT}} \qquad (2)$$

By substituting the value of χ into Eq. (1):

$$\log k_s = \log \underset{\substack{\chi=0 \\ D=\infty}}{k} - \frac{Z_A Z_B \varepsilon^2 N}{2.303RTr}\left[\frac{1}{D} - \frac{2\varepsilon Nr}{D^{3/2}}\sqrt{\frac{2\pi\mu}{1000RT}}\right] \qquad (3)$$

If in the above equation the quantity in square brackets is plotted against log k_s, a straight line is obtained the slope of which is equal to:

$$-\frac{Z_A Z_B \varepsilon^2 N}{2.303RTr}$$

The value of the velocity constant, k_s has been calculated in seconds.

The value of r taken here is quite in accordance with the value of r taken in the reaction between potassium persulphate[5] and the iodide ion. The reaction between persulphate and the iodide ion takes place between bivalent and univalent negative ions; the value of r which Amis and Pottes have taken is 1.76×10^{-8} cm. Therefore, the value of r which we have taken is quite reasonable. By substituting the values;

$\varepsilon=4.8025\times10^{-10}$ e. s. u.; $\boldsymbol{R}=8.31436\times10^{7}$ ergs/deg;

$\boldsymbol{N}=6.023\times10^{23}$ $r=2.65\times10^{-8}$ cm

$\mu=0.18$ $\pi=3.1416$

and $T=(273+30)$, $(273+35)$, and $(273+40)$ into Eq. (3), we obtain for three different temperatures the following equations:

$$\log k_s = \log k - \frac{Z_A Z_B \varepsilon^2 \boldsymbol{N}}{2.303\boldsymbol{R}Tr}\left[\frac{D^{1/2}-x}{D^{3/2}}\right] \qquad (4)$$

$(\chi=0,\ D=\infty)$

where the values of x at three different temperatures (*viz.* 303, 308 and 313) are 3.247, 3.221, and 3.194 respectively.

Table 5 has been reproduced in graphic form (Fig. 1) by employing Eq. (4). The measured slope of the curve and the value of $Z_A Z_B$ obtained therefrom are given in Table 6. From a perusal of Table 6 it is obvious that the product of Z_A and Z_B does not deviate very much from 3. Hence, we may conclude that the rate-determining step occurs between a univalent negative ion and a trivalent negative ion.

TABLE 6

Temperature t°C	Slope	$\frac{\varepsilon^2\boldsymbol{N}}{2.303\boldsymbol{R}Tr}$	$Z_A Z_B$

An Internal-Monitor Method for the Activation Analysis of Silver in Palladium with Thermal Neutrons

Yoshinaga OKA, Toyoaki KATO, Hui-Tuh TSAI and Koichi NOMURA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received May 10, 1967)

An internal-monitor method has been developed to eliminate many of the errors probable with activation analysis. This method involves the measurement of the composed radioactivity of the species to be analyzed and of an appropriate internal-monitor, and the estimation of the ratio of the induced activity of both the species. The present report will describe the principles and the applicability of the method to the determination of a trace amount of silver in palladium by means of thermal neutron irradiation. After the silver activity is chemically separated from the irradiated sample, the γ-ray spectrum corresponding to the mixture of ^{110m}Ag and ^{111}Ag formed by the β^- decay of ^{111}Pd is measured. Synthetic mixtures of silver and palladium with known weight ratios have been prepared to check the accuracy of the method. A good proportionality has been obtained between the ratios of the ^{110m}Ag to ^{111}Ag activities and the ratios of the concentrations. By using this relationship, silver analysis can easily be achieved. Contents of silver in a palladium sample down to about 1 ppm can be determined with a relative error of within $\pm 2\%$. By this method the errors which arise from neutron flux irregularities and self-shielding effects can be avoided, and no correction for chemical yield is necessary.

Although radioactivation analysis has been widely employed as one of the most sensitive analytical methods for the determination of many elements, the errors accompanying this method are usually significant. A comparative technique is used more frequently than the absolute determination method. An important source of errors can be due to a difference in neutron flux between the sample and the reference. Such differences are to be attributed to neutron flux irregularities and to different self-shielding effects in the substances. To correct for these differences, Leliaert *et al.*[1] have developed a method of activation analysis using an internal standard. This method involves the standard addition of the desired element to a portion of the sample. Both spiked and unspiked samples are irradiated, and the specific activity of the desired element is estimated by means of the activity difference. In activation analysis by charged particles or by high-energy photons, errors from the flux inhomogenuities become serious. When the comparative technique is used, therefore, it is difficult to get a good accuracy even when extreme care and effort are taken. To overcome these errors, Oka *et al.*[2] have developed a method using a matrix species as an internal-monitor in non-destructive activation analysis with bremsstrahlung γ-rays.

A second source of error which is likely to be important is the effect of competing reactions. Interferences may proceed either directly or through second-order nuclear reactions.[3] In addition to these nuclear factors, several additional factors can be expected to lead to serious inaccuracies. These are mainly connected with radiochemical and counting processes. The stage of yield correction can give rise to errors, and in the final stage of radioactivity measurement errors due to poor counting statistics can also be considerable. In ordinary activation analysis, thus, errors effected by these sources are accumulated to a significant extent, so that, in most cases, it is difficult to get an accuracy better than $\pm 5\%$. The use of an internal-monitor method can, however, eliminate many of the errors probable with activation analysis. This can be illustrated by the determination of trace silver in palladium by means of thermal neutron activation, with radiochemical separation and subsequent γ-ray spectrometry.

Illustration of the Method

The counting rate of the photopeak, A, due to any induced γ-ray emitter is given by:

1) G. Leliaert, J. Hoste and Z. Eeckhaut, *Nature*, **182**, 600 (1958); *Anal. Chim. Acta*, **19**, 100 (1958); *Talanta*, **2**, 115 (1959).

2) Y. Oka, T. Kato and M. Sasaki, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **84**, 588 (1963); *ibid.*, **86**, 612 (1965); Y. Oka and T. Kato, *ibid.*, **86**, 835 (1965); *ibid.*, **87**, 1057 (1966); Y. Oka, T. Kato and K. Nomura, *ibid.*, **87**, 147 (1966); Y. Oka, T. Kato and T. Saito, *ibid.*, **87**, 154 (1966); *ibid.*, **88**, 866 (1967); Y. Oka, T. Kato and I. Nagai, *ibid.*, **88**, 871 (1967).

3) R. C. Koch, "Activation Analysis Handbook," Academic Press, New York (1960), p. 10.

$$A = \varepsilon N \phi \sigma S \quad (1)$$

where N=the number of target nuclei, ϕ=flux of the bombarding particle, σ=a reaction cross section, ε=the photopeak efficiency of counting process, and S=the saturation factor.

For two species, I and II, in a homogeneous sample:

$$\frac{A_{\mathrm{I}}}{A_{\mathrm{II}}} = \frac{(\varepsilon N \phi \sigma S)_{\mathrm{I}}}{(\varepsilon' N' \phi \sigma' S')_{\mathrm{II}}} \quad (2)$$

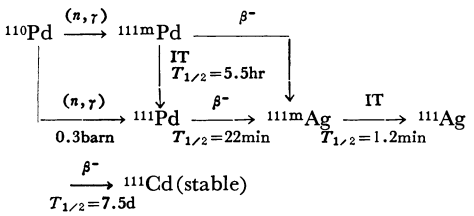
Accordingly,

$$\frac{W_{\mathrm{I}}}{W_{\mathrm{II}}} = K \frac{A_{\mathrm{I}}}{A_{\mathrm{II}}} \quad (3)$$

where the W's are the weights of the target elements and K is a constant.

The ratio of the photopeak activities attributed to these two species is a linear function of the ratio of the concentrations. Hence, the combination of an unknown (I) with a properly chosen internal-monitor (II) allows an accurate determination.

In the case of silver in palladium matrix, it can be assayed by γ-ray spectrometry through the induced ^{110m}Ag in an irradiated sample. Palladium, on the other hand, gives seven radionuclides as (n, γ) reaction products: ^{103}Pd, ^{107m}Pd, ^{107}Pd, ^{109m}Pd, ^{109}Pd, ^{111m}Pd, and ^{111}Pd. However, the major radionuclides are represented by the following sequences:



When the silver activity is separated from the irradiated sample, therefore, a composite γ-ray spectrum which corresponds to both the 253-day ^{110m}Ag and the 7.5-day ^{111}Ag as the β^--decay product of ^{111}Pd is measured. By detecting the photopeak activities of both nuclides at an identical time after each irradiation,[4] the following relationship can be obtained:

$$\frac{W_{\mathrm{Ag}}}{W_{\mathrm{Pd}}} = K' \frac{A_{\mathrm{Ag\text{-}110m}}}{A_{\mathrm{Ag\text{-}111}}} \quad (4)$$

Now if R_W is the ratio of concentrations and R_{A_0} is the ratio of the measured photopeak areas related at the end of the irradiation, Eq. (4) becomes:

$$R_W = K' R_{A_0} \quad (5)$$

The constant, K', can be determined by irradiating synthetic mixtures of silver and palladium with known compositions. By using this relationship, it is possible to determine the content of silver in a palladium sample provided that the irradiation period and the counting process are identical to those of the standard mixtures. It is obvious that this internal-monitor method offers several advantages with regard to accuracy and precision over ordinary activation analysis: i) Since results can be calculated on the basis of the activity ratios, the effects of flux irregularities and self-shielding are cancelled out. ii) Since the correction for yield is not necessarily taken into account, the errors arising in this stage can be avoided completely. iii) The effects of the (n, p) and the (n, α) reactions induced by fast neutrons give no trouble.

Experimental

Materials and Irradiation. A series of synthetic palladium-silver mixtures was prepared in the following manner. Fifty milligrams of palladium powder was weighed into a quartz tube with an internal diameter of 6 mm, and then known amounts of an aqueous silver nitrate solution were added. After evaporation to dryness, the tube was sealed. The palladium powder was processed from 99.99% palladium metal as follows. The metal was dissolved in aqua regia, evaporated nearly to dryness, repeatedly evaporated with additional conc. hydrochloric acid, and then subjected to anion exchange purification.[5] Palladium was eluted from a Dowex 1×8 column with an aqueous ammonium chloride-ammonia mixture. The metallic powder was precipitated from this eluate by reduction with formic acid, repeatedly washed with water, and dried in a vacuum. The aqueous silver nitrate solution was prepared by dissolving a reagent purified by repeated recrystallizations. Proper dilution with water was made from this just before use. The hydrochloric acid, nitric acid, and water were all redistilled. All the other chemicals were of a guaranteed grade.

Two kinds of electrolytic palladium plates were tested for their silver contents. From these samples, small pieces of approximately 30 mg were cut out and analyzed. The samples, a series of the synthetic mixtures, and 50 mg of the original palladium powder were put together in an aluminum capsule for pile irradiation. The irirradiation was performed for 72.8hr in the JRR-2 reactor of the Japan Atomic Energy Research Institute. The reactor was operated at 10 MW, providing a thermal neutron flux of 2.5×10^{13} $n/\mathrm{cm}^2/\mathrm{sec}$ at the irradiation site. After the irradiation, the samples were subjected to the radiochemical procedure for the isolation of the silver activities.

Radiochemical Procedure. The radiochemical procedure for the isolation of the silver activities is diagrammed in Table 1.

Separations were performed for each sample after ^{111}Pd had been allowed to decay to ^{111}Ag completely. The final aqueous layer was drained into a polyethylene tube for γ-ray spectrometric measurements.

γ-Ray Measurements. For the γ-ray spectrometric measurements, a $1^1/_2'' \phi \times 1^1/_2''$ NaI(Tl) crystal

4) For comparison, these activities were corrected for decay to the end of the irradiation, as will be described later.

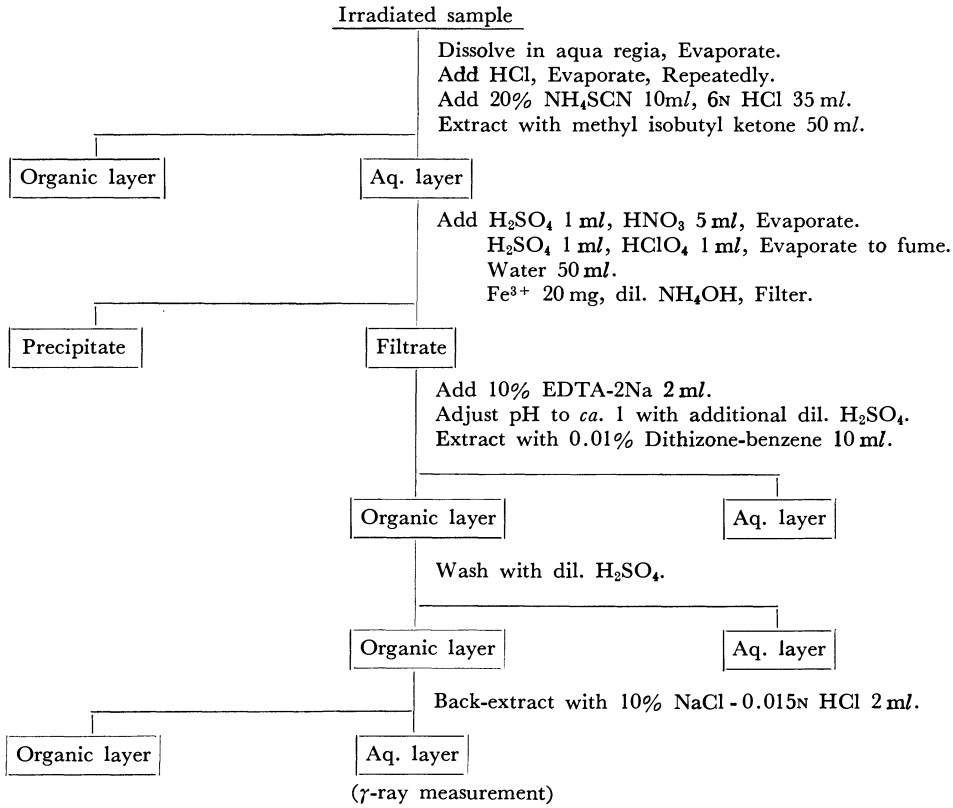
TABLE 1. SEPARATION SCHEME FOR RADIOSILVER FROM IRRADIATED PALLADIUM



coupled with a 800-channel pulse-height analyzer made by the Tokyo Shibaura Electric Co., Ltd., Japan, was used. The peeling-off method[6] was employed to determine the accurate photopeak areas from the γ-ray spectra obtained.

Results and Discussion

Radiochemical Process. The recovery of radiosilver in each step in Table 1 was studied using ^{110m}Ag as a tracer. The results are shown in Table 2. Although about 27.5% of the radiosilver was coprecipitated with ferric hydroxide, this scavenging technique made possible a successful decontamination from other radionuclides.[7]

TABLE 2. RECOVERY OF SILVER ACTIVITY IN SEPARATION STEP OF TABLE 1

Chemical step	^{110m}Ag recovery, %			
				Mean
Filtrate in ferric hydroxide scavenging	70.3	75.6	71.6	72.5
Dithizone extraction	98.8	99.7	99.4	99.7
Back extraction with chloride solution	97.5	97.3	96.8	97.2

6) W. S. Lyon, Jr., ed., "Guide to Activation Analysis," D. Van Nostrand Co., Princeton, N. J. (1964), p. 104.

The final recovery was about 70%. In the final chloride solution, a composite γ-ray spectrum which corresponded to the mixture of ^{110m}Ag and ^{111}Ag, as shown in Fig. 1-(1), was obtained. The decay curve followed on the 0.342 MeV photopeak area showed a half-life of 7.5 days, corresponding to the literature value of ^{111}Ag.[8]

R_W *vs.* R_{A_0}. The marked difference in the energy of γ-rays emitted from ^{110m}Ag and ^{111}Ag permits a γ-ray spectrometric determination of silver in palladium. From the composite spectra obtained from silver-palladium mixtures, photopeak areas were measured on the 0.342 MeV γ-rays for ^{111}Ag, and on the 0.656 and 0.885 MeV γ-rays for ^{110m}Ag.

These values were corrected for decay to the end of the irradiation,[9] and the R_{A_0}'s were computed on the basis of the illustration given earlier in this paper. At that time, the correction coefficient for silver in the original palladium, α,[10]

7) This technique was especially effective for the removal of ^{192}Ir .

8) Nuclear Data Sheets, Natl. Academy of Science-Natl. Research Council, Washington, D. C. (1961).

9) For convenience, the ^{111}Ag activities were determined by interpolating the counting rates to the end of the irradiation using a half-life of 7.5 days.

10) The α values obtained under the present conditions were 9.49×10^{-5} from the 0.656 MeV peak and 4.77×10^{-5} from the 0.885 MeV peak.

	1.55×10^{-4}	7.04×10^{-5}	13.3	13.1	13.2	
	1.56×10^{-4}	6.99×10^{-5}	13.4	13.0	13.2	

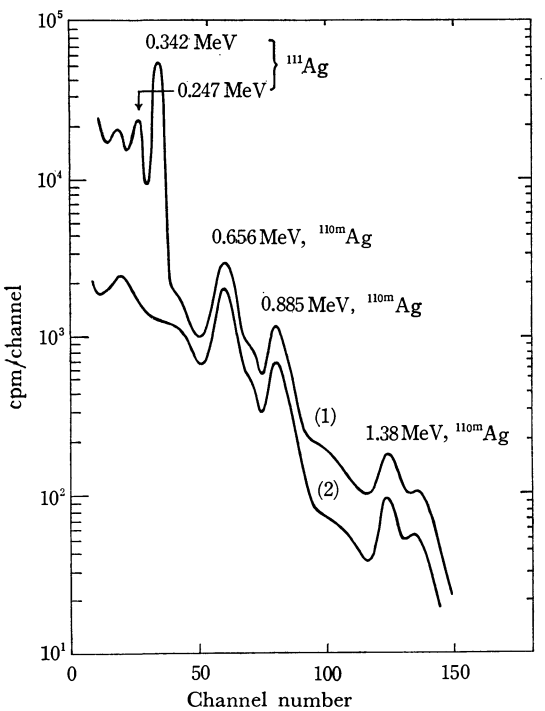

Fig. 1. γ-Ray spectra of radiosilver; (1) separated from irradiated silver-palladium mixture (Ag/Pd = 1.73×10^{-4}), 37 days after irradiation, and (2) standard ^{110m}Ag spectrum.

was introduced in Eq, (4); thus we obtained:

$$\frac{W_{Ag}}{W_{Pd}} = K'\left(\frac{A'_{Ag\text{-}110m}}{A_{Ag\text{-}111}} - \alpha\right)_{t=0} \qquad (6)$$

where:

$$\alpha = \left(\frac{A_{Ag\text{-}110m}}{A_{Ag\text{-}111}}\right)_{original}$$

On the standard series, the relation between the weight ratios and the corrected photopeak activity ratios was calculated. Table 3 shows these experimental results. In each case, a good proportionality was obtained between R_W and R_{A_0}. Relative standard deviations of $\pm1.4\%$ for the 0.656 MeV peak and $\pm1.6\%$ for the 0.885 MeV peak were obtained under the present conditions. The present results show that an accurate determination can be expected when using these relationships.

The separation procedure diagrammed in Table 1 can isolate the silver activity without any contamination of undesired activities; hence, the individual silver photopeak areas were measured with minimum relative errors. When a minimum photopeak area of 50 cpm is selected as the limit of detection, silver contents in palladium down to about 0.8 ppm (0.04 μg in a 50-mg sample) from the 0.656 MeV peak and down to about 2 ppm (0.1 μg in a 50-mg sample) from the 0.885 MeV

peak can be determined with relative errors of within $\pm 2\%$.

Silver Analysis. This method of silver analysis was tested on electrolytic palladium plates. After irradiation, samples were cooled for about 10 days, and then subjected to radiochemical procedure. As Table 4 shows, a good agreement in the silver contents was obtained, indicating satisfactory precision in the method.

Applicability of the Method. In general cases, where the atomic number of the element to be analyzed is higher by one unit than that of the matrix element, and where the nuclear characteristics of the (n, γ) reaction product of the former and the secondary β^--decay product from the latter are favorable for subsequent γ-ray spectrometric measurements, it is possible to use the present method in the determination. For example, the determinations of gold in platinum and of antimony in tin by the thermal neutron activation technique can be performed. Moreover, the technique of combining an unknown with an additional internal-monitor offers a general applicability.

Further application of this method would be found in the activation with high-energy photons by which the neutron defficient radionuclide is formed by the (γ, n) process. This primary product undergoes in the main β^+ and/or EC decay to produce a secondary nuclide. When this secondary activity is combined with the (γ, n) reaction product from the element to be analyzed, it is possible to determine the element in question with an atomic number smaller by one unit than that of the species chosen as the internal-monitor.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 333—342 (1968)

Synthetic Inorganic Ion-exchange Materials. X. Preparation and Properties of So-called Antimonic(V) Acid

Mitsuo ABE and Takuji ITO

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 2, 1967)

The preparation of so-called antimonic acid under various experimental conditions has been investigated in order to establish its usefulness as a chemically-stable cation-exchange material. In this experiment, the antimonic acid was mainly obtained by the hydrolysis of antimony pentachloride, and was rarely obtained from metallic antimony or potassium pyroantimonate. The hydrolyzed precipitate was amorphous at first, but it was gradually transformed into crystalline powder by keeping it in the mother liquor for a long time. The crystallization of the amorphous precipitate was facilitated by raising the temperature within a range of 0—80°C, and by increasing the concentration of strong mineral acid on aging, regardless of the kinds of starting antimony substances. The water-content of the air-dried samples is decreased by increasing the period of aging; the composition of the sample approximates $Sb_2O_5 \cdot 4H_2O$. The crystal of the antimonic acid is cubic and belong to the space group $O_h^7(Fd3m)$, with a lattice constant of 10.38_2 Å. The measurement of solubilities for the air-dried antimonic acid showed that both the amorphous and the glassy acids are soluble forms and that the crystalline is an insoluble form. The uptakes of potassium ions on these antimonic acids were little changed on the kinds of form; the uptake of lithium ions on the crystalline acid was very small as compared those on the amorphous and the glassy acids. This behavior may be attributed to the existence of different types of so-called antimonic acid, with different selectivities of their lithium ion adsorption, rather than to any difference in the size of the particle.

As was first shown in a previous paper,[1] the hydrous oxides of pentavalent metals, such as niobium, tantalum and antiomony, have useful cation adsorptive properties, including a high uptake of potassium ions. The so-called antimonic(V) acid has an especially large adsorption capacity, larger than that of any other metal hydrous oxides, which show a reasonable rate for adsorption and desorption when used in column operations. The adsorption and desorption of potassium ions on the antimonic acid have been found to be attributable to the exchange between the hydrogen ions in the acid and the potassium

1) M. Abe and T. Ito, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **86**, 1259 (1965).

ions in the external solution in contact with the acid.[2] Furthermore, the mutual separation of alkali metal ions has been completely achieved with a relatively small antimonic acid column ($0.8\phi \times 6.0$ cm).[3]

However, the antimonic acid obtained by the hydrolysis of antimony pentachloride is gradually peptized or dissolved by contact with pure water or with an alkaline solution for a long time.

In this experiment, the preparation of antimonic acid under various conditions is studied in order to obtain a chemically-stable material.

Much pertinent information regarding the antimonic acid or hydrous antimony pentoxide is to be found in the literature pertaining to inorganic chemistry. This information is well summarized in the standard works of Mellor[4] (1929) and Gmelin[5] (1949). Even here, however, some confusion is apparent, and contradictory statements are not hard to find. No comprehensive investigations of the so-called antimonic acid have yet been made. Fremy[6] and Senderens[7] showed that the water-content in the antimonic acid varies according to the kind of starting antimony salt. However, Conrad,[8] Daubrawa[9] and others showed opposite results, according to which a definite hydrate is obtained under the same drying conditions in spite of the different kinds of starting salt. In previous works, much attention had been devoted to determining whether or not several hydrates, such as ortho-($Sb_2O_3 \cdot 3H_2O$), pyro-($Sb_2O_5 \cdot 2H_2O$) and meta-($Sb_2O_5 \cdot H_2O$), well known in the case of hydrated P_2O_5, exist in so-called antimonic acid. Analysis made by Conrad[8], Fremy[6] and others of the air-dried product have given results ranging from 15.77 to 20.02 per cent of water, a figure corresponding with that of the tetrahydrate. The results of the analysis made by Conrad,[8] Daubrawa[9] and Senderens[7] of the product dried over concentrated sulfuric acid show 12.87—14.53 per cent of water, figures in agreement with that of the trihydrate, $Sb_2O_5 \cdot 3\,H_2O$. According to Daubrawa and others, products dried at 100°C and at 175—200°C possess water contents corresponding with dihydrate as pyro-antimonic acid and with monohydrate as meta-antimonic acid. Senderens[7] regarded the trihydrate as ortho-antimonic acid. However, the dehydration curves of the hydrate obtained by the hydrolysis of the pentachloride were found by Simon and Thaler[10] to be of the continuous type, with the characteristics of hydrated metal oxides of the hydrogel type. Therefore, they question the existence of the above-mentioned stoichiometrical composition shown by Daubrawa[9] and others. Fremy[6] found that the tetrahydrate obtained by the hydrolysis of antimony pentachloride, and that obtained by the action of mineral acid on a solution of the alkali antimonate, have different properties. The former was said to be dissolved in a large amount of water, and to be precipitated by acid from an aqueous solution. Its precipitate was dissolved in concentrated ammonia, whereas that obtained from the latter acid was not so dissolved. Conrad, Beilstein, and Bläse showed, however, that there is no real difference between the two products.[4] Senderens and Delacroix agreed that a soluble and an insoluble form of antimonic acid existed, and they called them ortho-antimonic acid and pyro-antimonic acid; however they differed as to which was which.[4] Simon and Thaler proved that hydrated antimony pentoxide crystallized when heated with water under pressure.[10] The product gave a definite indication of the existence of $3Sb_2O_5 \cdot 5H_2O$, which had a point of inflection.

It appears that such confusion as is indicated in the above information regarding the hydrous antimony pentoxides is mainly due to uncertainty concernig the preparation and the resulting properties of the oxides.

In the present experiment, much attention was given to the temperature of the hydrolysis, the effect of aging, and the concentration of acids.

Preparation

Hydrolysis of Antimony Pentachloride. When liquid antimony pentachloride is added to a large amount of water, an irregular precipitate is easily obtainable by means of a violent hydrolysis and a simultaneous exothermic reaction. Hence, a concentrated antimony pentachloride solution was prepared, liquid antimony pentachloride being dropped into the same volume of cold distilled water; the mixture was then hydrolyzed in a large amount of water at the prescribed temperature. The precipitate was aged by being kept in the mother liquor for some time at the said temperature. When 30 m*l* of the concentrated solution was hydrolyzed in 1 *l* of distilled water, the acid concentration of the supernatant liquid became a 0.5 N hydrochloric acid solution as a result of a by-product formed by the hydrolysis. The adjustment of the hydrochloric acid concentration to 0.25 or to 1.0 N was carried out, respectively, by dilution with water or by the addition of concentrated hydrochloric acid to the hydrolyzed solution. The precipitated antimonic acid was filtered under suction. When the hydrochloric acid in the

precipitate has almost all been washed away, the antimonic acid passed through fine filter-paper (such as Toyo filter paper 5C) by the peptization. Therefore, it was impossible to wash the antimonic acid until free from chloride ions by the filtration process. Very pure antimonic acid was obtained by washing the precipitate with cold water with the aid of a centrifuger operated at about 10000 rpm; as a result of this treatment, the metamorphosis of the precipitates was avoided. These products were dried at room temperature by the aid of a fan, then they were transformed into granular materials which were suitable for column operation.

Other Preparations. 1) S_{K-1}. A solution of 1.5 *l* of potassium pyroantimonate (32 g/*l*) was vigorously stirred, drop by drop, the same volume of 6 N nitric acid at 25—30°C. The precipitate was then kept in the mother liquor for 3 days at the same temperature. The potassium ions in the liquor were thus tenaciously adsorbed in the precipitate, they could not be removed only by washing with distilled water, though they could be remove by repeated washings with 2 N nitric acid. The precipitate was then washed with distilled water until it was free from nitric acid by means of a centrifuger, and dried in air using a fan.

2) S_{K-2}. A normal nitric acid was vigorously stirred into the above-mentioned potassium pyroantimonate solution at 25—30°C, and then the pH of the mother liquor was adjusted to 1 by dilution. The precipitate was kept in the mother liquor for 4 hr at 25—30°C, and then washed and dried in the same manner as S_{K-1}.

3) Sb-1 and Sb-2. The antimony metal (99.999%) (30 g) was dissolved in 150 m*l* of a mixed solution of $HCl+HNO_3$ (4 : 1). The solution was hydrolyzed and aged in 2 *l* of water at 20°C (Sb-1) or 60°C (Sb-2).

4) S_G. It has been known that freshly-prepared antimonic acid in a wet state can be dissolved in a large amount of water; the solution gradually becomes turbid when kept for a long time. To avoid such turbidity, the following treatment must be completed in a relatively short time; the amorphous precipitate in a wet state is rapidly dissolved in 300 m*l* of hot water. A glassly material was obtained by evaporating the moisture in the solution after cooling.

5) S_{200} *and* S_{300}. The above-mentioned fresh precipitate (10 g) was suspended in 100 m*l* of distilled water and then heated at 200 or 300°C for 4 hr under presure. The S_{200} sample was obtained as a fine crystalline powder, while the S_{300} sample was obtained as a thin hexagonal crystal.

Uptake of Lithium and Potassium Ions. Our previous report showed that when the antimonic acid was added to a neutral solution, hydrogen ions in the material were equivalently liberated as a result of exchange with the cation in the external solution. The measurement of the uptakes of lithium and potassium ions were made by both batch and column techniques, neutral solution of the corresponding salts being used. Each solution containing the liberated hydrogen ions was titrated with a standard 0.1 N sodium hydroxide solution.

Solubilities of Antimonic Acid. The solubilities of the antimonic acids were determined in various reagents. The procedure for determining the solubilities was as follows; the sample (0.4 g) of 100—200 mesh size was put into a 200-m*l* bottle equipped with a glass stopper, and then 100 m*l* of the reagent was added. The bottle was kept in a thermostated bath set at 25±0.05°C for a period of 1 to 10 days and shaken from time to time. The dissolved amount of the antimonic acid was measured by the polarographical method in 3 N hydrochloric acid, after the Sb^{5+} in the suppernatant liquor had been reduced to Sb^{3+} with a sodium sulfite solution.

X-Ray Examinations. The X-ray diffraction patterns of all the sample were measured with a Rigaku Denki Geiger Flex X-ray Diffractometer, filtered Cu$K\alpha$ being used.

Result and Discussion

Composition of So-called Antimonic Acid. The precipitates of the antimonic acid obtained by various preparations were dried in air with the aid of slow-moving electric fan. The time-composition curves of the antimonic acid samples are given in Fig. 1. The very rapid initial dehydration may be due to the evaporation of the adherent water in the precipitates, slow dehydration immediately follows, as in the case of the hydrous oxide gel of tin(IV), Zr and Ti. On the amorphous and glassy acid, the slow dehydration continued for a long time. These samples did not show a constant composition even if they were dried for a

period of about 6 months. In contrast, the samples aged over 7 days at 25—30°C showed an almost constant weight for a relatively short time of about 3 weeks.

The water-composition of the antimonic acids was determined gravimetrically on the assumption that Sb_2O_4 was formed by ignition at 900°C for 2—3 hr. As Table 1 shows, the water-composition (mole ratio of H_2O/Sb_2O_5) obtained by the various preparations was decreased by raising the temperature of hydrolysis and by lengthening the period of aging. The decrease in the H_2O/Sb_2O_5 ratio in antimonic acid was slightly facilitated by increasing the concentration of hydrochloric acid, even under the same aging conditions. These values of the water-compositions agree with those reported by Simon and Thaler. When the sample was obtained by hydrolysis at 20°C and then aged at 70°C for 4 hr, the water-composition was almost the same as that of the sample which was hydrolyzed at 70°C and aged for 4 hr at the same temperature.

The samples aged for a long period of more than 7 days had a definite composition of $Sb_2O_5 \cdot 4H_2O$. The results of other preparations, such as S_{K-1}, S_{K-2}, Sb-1 and Sb-2, showed phenomena similar to that of hydrolysis of antimony pentachloride.

In the hydrothermic treatment of the freshly-prepared antimonic acid at 300°C, Simon and Thaler showed the formation of a definite hydrate, $3Sb_2O_5 \cdot 5H_2O$.[10] In the present experiment, however, it was shown that a thin hexagonal crystal had a relatively small water-composition, that is, $Sb_2O_5 \cdot 0.49H_2O$. The composition of S_{200}

showed an intermediate value between those of S_{300} and the other dried samples.

X-Ray Examinations of Antimonic Acid. The X-ray diffraction paterns of the antimonic acids obtained by the hydrolysis of antimony pentachloride ranged from completely amorphous patterns to those containing a number of distinct reflections, as Figs. 2 and 3 show. The antimonic acids obtained by hydrolysis at 25°C began to crystallized after having been aged for a relatively long time at 25—30°C; the identical diffraction intensity was also shown after aging for a period of more than 10 days. The extent of the crystallization corresponded well with the change in the water-composition of the antimonic acid. Therefore, the results showed that the H_2O/Sb_2O_5 ratio of these acids decreased in proportion to the extent of crystallization.

The crystallization of the antimonic acids was facilitated by raising the temperature when the hydrolysis and the aging were carried out below 80°C. The extent of the crystallization of the sample obtained by hydrolysis at 60°C, followed by aging for 4 hr at the same temperature, was shown to be similar to that of another sample obtained by

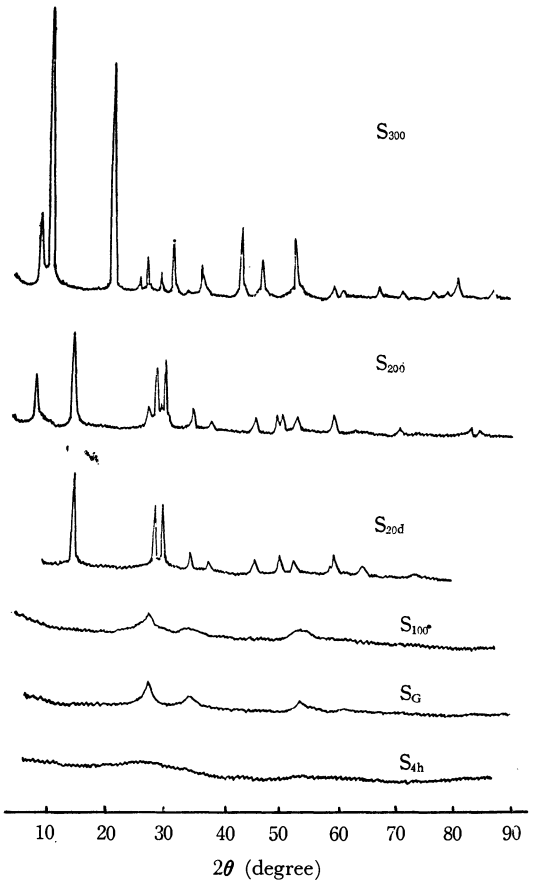

Fig. 3. X-Ray diffraction patterns of precipitated samples by various preparations.

hydrolysis at 25°C and by aging for 7 days at 30°C. Therefore, it seems that the crystallization of antimonic acid is facilitated by raising the temperature of the aging rather than that of the hydrolysis. The sample with a higher crystallization was shown to be a definite hydrate, $Sb_2O_5 \cdot 4\,H_2O$ (crystalline antimonic acid).

The comparison between 0.25 and 1.0 N portions of hydrochloric acid solutions on aging showed that the crystallization was facilitated by increasing the concentration of the acid. Similar results were observed in the samples obtained by other methods of preparation at temperature below 80°C.

The glassy sample produced by hydrolysis at 90—98°C was largely amorphous, except for the presence of five weak reflections (d: 3.28, 2.63, 1.72, 1.64 and 1.38 Å), indicating the presence of a new compound in a form different from the above-mentioned crystalline antimonic acid (Fig. 3).

The X-ray diffraction pattern of the S_G sample, which was made by treating prepared antimonic acid with hot water, was analogous to that of the glassy sample. The sample treated under a given pressure at 200°C showed a mixed pattern, composed of reflections indicating the crystalline antimonic acid and of reflections indicating an unknown material. The S_{300} sample showed a pattern different from that of any other prepared samples.

The X-ray diffraction data of the crystalline antimonic acid are compared in Table 2 with those of a number of antimony compounds indexed on the relevant cards published by the American Society for Testing Materials (A.S.T.M.). All of these substances belong to the same space group O_h^7 ($Fd3m$). The data relative to the crystalline antimonic acid are essentially similar to those of the Sb_2O_5 reported by Hanawalt and Rinn.[11] However, it seems that the conditions of

$\bar{a} = 10.38_2$ Å

a^*; lattice constant

preparing its antimony pentoxide were uncertain. According to Natta and Baccaredda,[12] hydrated antimony pentoxide prepared by the decomposition of potassium pyroantimonate with nitric acid was at first amorphous, but after 5 years it became a crystalline substance, $Sb_2O_5 \cdot 3H_2O$ and then after 10 years changed to another crystalline substance, $Sb_2O_5 \cdot H_2O$. The elementary cells of the hydrated Sb_2O_5 had lattice constants of 10.21—10.25 Å and belonged to the cubic system with the space group O_h^7, like cubic Sb_2O_3 (senarmontite).

The accurate lattice constant of the crystalline antimonic acid was determined by means of a Phillip X-ray diffractometer (Table 3). All the data were calibrated by standardized metallic silicon; they showed a lattice constant of 10.38_2 Å, which is larger than any other data listed in Table 2. The X-ray diffraction data of the crystalline antimonic acid were essentially identical in molecular crystal forms with the modification of Sb_2O_3 expressed by the mineral" senarmontite". The symmetry of the antimony trioxide is cubic, with a unit containing 16 molecules, and the structure consists of Sb_4O_6 molecules packed together in a unit cell in the same manner as the carbon atoms in a diamond.[14] The structure of the crystalline antimonic acid is probably similar to that of cubic antimony trioxide. The X-ray diffraction patterns of other crystalline powdered samples, such as S_{60}, $S_{K\text{-}1}$ and Sb-1, showed that in spite of different kinds of starting salt they were identical with that of the crystalline antimonic acid obtained by aging for a long time.

The freshly-prepared antimonic acid can be dissolved in pure water, but the solution becomes turbid and then a white precipitate appears. The X-ray investigation of the precipitate revealed the same compound as the crystalline antimonic acid.

Solubilities of Various Antimonic Acids in Water. As has been previously explained, there is contradictory information and confusion regarding the solubility of antimonic acid. The wet precipitate of pure antimonic acid is easily dissolved or peptized, but it becomes difficult to dissolve the acid dried for a long period. Such a phenomenon is similar to that observed in a number of hydrous oxide gels, such as stannic and zirconium hydrous oxide gel.

The physicochemical solubility must, in general, be determined in an equilibrium state. However, it is difficult to establish the conditions for determining the solubilities of the hydrous oxide because of the depolymerization or hydration which occurs in the oxides. In the present experiment, the solubilities of various antimonic acid sample were measured in order to examine the chemical stabilities with a view to their use as exchangers.

Three dried samples—a crystalline sample, S_{20d} aged for 20 days, an amorphous sample, S_{4h} aged for 4 hr at 25—30°C, and a dry sample, S_{4h}', dried S_{4h} in an air bath at 60°C for 24 hr—were studied in order to determine their time-solubility relationship. The S_{20d} and S_{4h} were dried more than 6 months in air at room temperature, just as in the case of the X-ray examinations. The sample S_{4h} was gradually dissolved in water; it took about 2 weeks to be completely dissolved. Such a slow dissolution of the amorphous samples in water may be due to depolymerization involving the hydration from a higher polymer of hydrous antimony pentoxide to a lower one (Fig. 4). The rate of the dissolution of S_{4h}' was slightly slower than that of S_{4h}, but S_{4h}' was completly dissolved after a long period. This is probably due to the fact that S_{4h} was changed to a higher polymer, S_{4h}', by drying at 60°C.

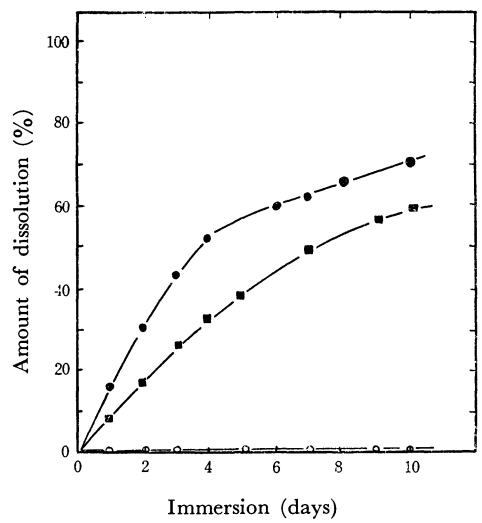

Fig. 4. Time-solubility curves for air-dried samples.
—●—; S_{4h} (amorphous)

—○—; S_{20d} (crystalline)
Condition; 0.40 g of 100—200 mesh in 100 ml of pure water at 25°C.

The extent of the solubility of the crystalline antimonic acid, S_{20d}, was extremely small as compared with those of amorphous substances; the amount dissolved increased little even when S_{20d} was immersed for a long time. On the semi-crystalline sample aged for 3 days, for example, dissolution and peptization were simultaneously observed. The solubilities of the sample obtained by other methods of preparation (except for that obtained by the hydrothermal teratment) were measured under the same condition. From these results, it is fairly conclusive that the other crystalline

sample, for example those aged for 4 hr at 60°C, have much smaller solubilities than an amorphous and glassy samples. The solubility of the glassy sample S_G was almost idential with that of the $S_{90°C}$ produced by hydrolysis at 90—98°C.

Consequently, it is evident that amorphous or glassy antimonic acid is a soluble form, while crystalline antimonic acid is an insoluble form. Such soluble and insoluble forms of antimonic acid can be formed by merely establishing suitable conditions for their preparation, regardless of the starting antimony substances.

It seems that the previous confusion regarding antimonic acid is due to the complex conditions of its preparation, such as temperature and the period of aging, the concentration of acid in the solution, and the temperature of the hydrolysis.

Chemical Stabilities. The chemical stabilities of the crystalline acid in common reagent are compared with those of amorphous substances in Table 4; the results are favorable. The soluble samples, both amorphous and glassy antimonic acid, are more stable in a dilute hydrochloric acid or in a neutral salt solution than in pure water or in an alkaline solution. Therefore, it is possible to use them as cation exchangers in these solutions. The crystalline antimonic acid is extremely stable against most reagents, and it is very difficult to dissolve it, even by heating it with concentrated hydrochloric acid; it is dissolved by the presence of potassium iodide. This high degree of stability of the crystalline antimonic acid is one of the important characteristics as an ion-exchange material.

Adsorptions of Lithium and Potassium Ions. Adsorptive properties of a number of hydrous oxides, as is well known, vary with the conditions of preparation, such as aging and hydrolysis.

Simon showed that the adsorptive amount of lithium ions on hydrated antimony pentoxide decreases with a rise in the temperature during the hydrolysis.[15] Our previous report showed that the uptake of potassium ions does not vary in spite of the changes in the temperature on hydrolysis.[2] To explain the difference between Simon's conclusion and ours, the uptake of lithium and potassium ions on various samples was determined by both column and batch techniques.

Form*: A, amorpous; C, crystalline; G, glassy; H, hexagonal.
Sample taken: 1.00 g of 100—200 mesh size; immersion: 25°C, 48 hr; Alkali metals solution: 0.1 M, 100 ml.

The uptake of lithium ions on the antimonic acid obtained by the hydrolysis of antimony pentachloride was related to the extent of the crystallization of its acid as well as to the solubility. The uptake decreased with the growth of the crystal, as illustrated in Figs. 6-1 and 6-2. In contrast, the uptake of potassium ions was little changed by the difference in the extent of the crystallization. Of the samples obtained by other methods of preparation, the adsorptive properties were similar to those of the hydrolyzed sample. The results are summarized in Table 5. In batch equilibration made by the addition of a neutral salt solution, the uptakes of lithium ions are 0.72—0.92 meq./g on the amorphous antimonic acids and 0.30—0.34 meq./g on the crystalline antimonic acids, while those of potassium ions are 1.23—1.25 meq./g on the former and 1.28—1.30 meq./g on the latter.

The previous investigators regarded a number of freshly-precipitated oxide gels as hydrates of orthohydroxides and thought that the aging process consisted of either a polymerization or a condensation involving the isolation of water from one or more molecules of orthohydroxide, thus producing polyhydroxide of a gradually increasing complexity. They showed that no definite hydrates were actually formed out of the several products composed of the corresponding oxides of various particle sizes with various amounts of adsorbed water, and that the larger particles obtained by aging frequently showed a lower adsorption capacity for ions, a lower capacity responding to the decrease in specific surface. It is very difficult to explain the differences in adsorptive properties between amorphous and crystalline antimonic aicd as being due simply to the variety of particle sizes in these materials. These differences suggest the presence of two types of antimonic acid, with different selectivities of the adsorption for lithium ions.

--○--, Li^+ uptake (Column)

The samples, S_{200} and S_{300}, obtained by hydrothermal treatment, have limited use as cation exchangers, as they show a very small uptake of lithium and potassium ions.

Summary

1) The very pure products obtained by the hydrolysis of antimony pentachloride exist as three different types, amorphous, glassy, and crystalline antimonic acids, according to the different experimental conditions prevailing at temperatures below 100°C.

2) The freshly-prepared precipitate is an amorphous mass at first; it is transformed to a crystalline powder upon aging in contact with the mother liquid for a long period at 25—30°C. The crystallization of the antimonic acid can be facilitated by raising the temperature and by increasing the concentration of the acid in the solution used for aging. The glassy material is obtained by hydrolysis at 80—100°C and by washing and drying.

3) The preparation of this crystalline antimonic acid is accomplished under suitable conditions of temperature, aging, and concentration of acid, regardless of the starting antimony substances.

4) The experiment on the solubilities of the samples in various reagents revealed the presence of two soluble forms and one insoluble form of antimonic acid. The soluble forms are the amorphous and glassy forms, whereas the insoluble form is crystalline.

5) The crystal of the antimonic acid, $Sb_2O_5 \cdot 4H_2O$, has a cubic lattice (space group; $O_h^7 = Fd3m$) with a unit-cell dimension (lattice constant) of 10.38_2 Å, a value which can be deduced from the data for all the diffractions at 25°C.

6) The uptake of potassium ions on the crystalline antimonic acid is scarcely different from those of amorphous and glassy acid, whereas the uptake of lithium ions in the former is very small as compared with those of the latter two acids. Therefore, these results show the presence of more than two types of antimonic acids with different selectivities for lithium adsorption.

7) It has been shown that the sample produced by hydrothermal treatment at 300°C has a smaller water content than the definite hydrate, $3\,Sb_2O_5 \cdot 5H_2O$, reported by Simon and Thaler.[10] A sample with an intermediate water content is easily obtainable at 200°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 342—347 (1968)

$Ca_3(PO_4)_2$ - $CaNaPO_4$ System

Jumpei ANDO and Seiichi MATSUNO

Department of Industrial Chemistry, Faculty of Science and Engineering, Chuo University, Bunkyo-ku, Tokyo

(Received June 30, 1967)

As a fundamental research of a calcined defluorinated phosphate containing a small amount of sodium, the system $Ca_3(PO_4)_2$(tricalcium phosphate, T) - $CaNaPO_4$(Rhenanite, R) was studied by high temperature X-ray diffraction, differential thermal analysis, *etc.*, and the phase diagram determined. During heating, T inverted from β to α at 1180°C, and then possibly from α to α' at 1280°C. R inverted from β to α at 690°C. In the composition range containing R from about 10 to 98% by weight, (βT+βR), the stable phase at room temperature, inverted to (βT+αR) at 650°C. The (βT+αR) changed at 980°C to form a compound "A" $Ca_5Na_2(PO_4)_4$ for the sample containing 50.5% R, and ("A"+βT) for samples containing a smaller amount of R. The ("A" +βT) then changed to "A" solid solution at elevated temperatures. The crystals of "A" consisted of a superlattice of αR. "A" and the solid solution changed to αR solid solution at higher temperature. By quenching the samples containing 35 to 50.5% R from 1400°C, a single phase "A" or "A" solid solution was obtained at room temperature. The "A" solid solution was the major phase of the calcined defluorinated phosphate. During heating of samples containing more than 50.5% R, (βT+αR) changed to αR solid solution at or below 980°C; during cooling of the solid solution ("A" + βR) formed at 650°C.

Recently in Japan, and in the United States of America, a large amount of defluorinated phosphate for fertilizer, as well as for animal food, has been produced by the calcination of phosphate ore blended with small amounts of phosphoric acid and sodium carbonate at 1350°C to 1400°C.

Ando[1,2] identified the principal mineral of the phosphate to be a solid solution of a new compound "A" $Ca_5Na_2(PO_4)_4$, and suggested that the crystals of "A" might consist of a superlattice of hexagonal α-$CaNaPO_4$.

The compound "A" is highly soulble in both 2% citric acid, and ammonium citrate. The products of the calcined defluorinated phosphate, however, contained not only "A", but also considerable amounts of β-$Ca_3(PO_4)_2$, which was less soluble.[3]

In the present study, the system $Ca_3(PO_4)_2$-$CaNaPO_4$ was investigated to determine the phase diagram, and to find the optimum condition to increase the "A" content of the calcined defluorinated phosphate.

Experimental

The samples of tricalcium phosphate and Rhenanite were prepared with refined calcium oxide, phosphoric acid, and sodium carbonate by blending and calcination at 1100°C. The samples, and their mixtures in various ratios, were submitted for differential thermal and high temperature X-ray diffraction analyses up to 1450°C. Some fusion tests were carried out in an effort to make a complete phase diagram; however, these tests, were not successful because of the high melting points of the samples (above 1700°C), and the volatilization of sodium at the high temperature.

In another series of tests, the mixtures were heated to 1400°C, cooled at different rates to room temperature, and tested by quantitative X-ray analysis to determine the amounts of the compounds in the products. The lattice constants of "A" and its solid solutions were also determined by X-ray diffraction.

Results and Discussion

Phase Changes. Differential thermal analysis curves taken during heating at a rate of 5°C/min are shown in Fig. 1. The temperatures at which thermal reactions started are plotted in Fig. 2. High temperature X-ray diffraction tests were made during heating and cooling for many compositions including all of those shown in Figs. 1 and 2. Some of the diffraction patterns are shown in Figs. 3 to 6.

Differential thermal analysis was also carried out during cooling. Four examples of the curves taken during cooling at a rate of 5°C/min are shown in Fig. 7, in which phases identified by X-ray tests are indicated. The phase diagram obtained from the above tests is shown in Fig. 8.

During heating, pure tricalcium phosphate (T) inverted from βT to αT at 1180°C, and then showed

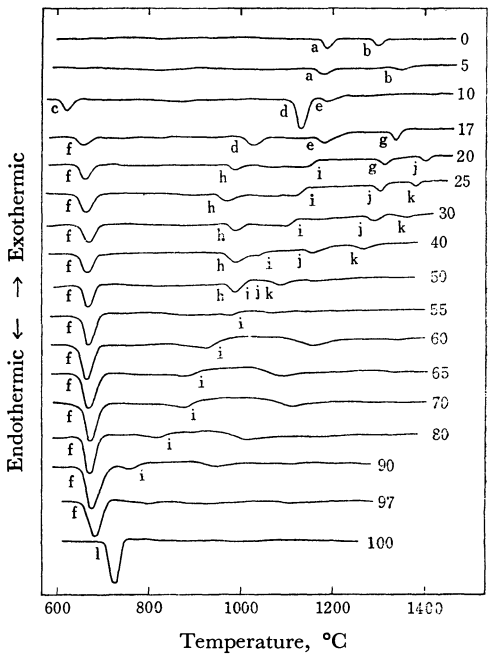

Fig. 1. DTA curves during heating (5°C/min). (Numbers in the figure indicate R content.)

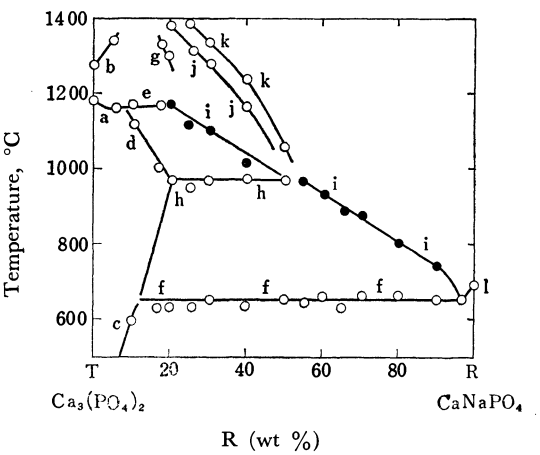

Fig. 2. Temperatures at which thermal reactions started during heating (5°C/min.).
○ endothermic reactions
● slow exothermic reactions

another thermal change around 1280°C. Nurse[4] recently reported the stable presence of α'T at above 1430°C. The present tests, however, did not show any appreciable change around 1430°C. In other tests with tricalcium phosphate produced from phosphate ore containing about 3% R_2O_3, a change occurred around 1430°C. For pure tricalcium phosphate, the inversion between αT and α'T might occur around 1280°C. Pure

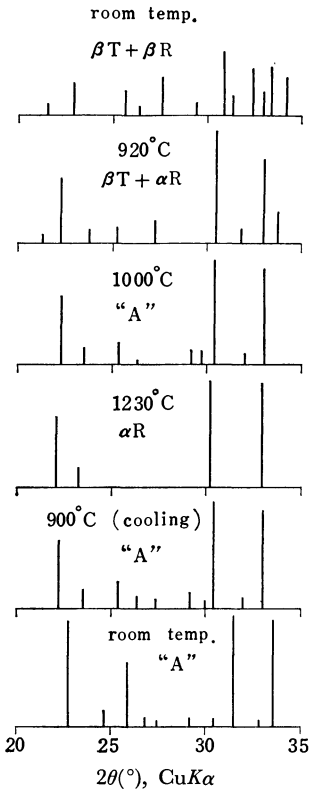

Fig. 5. High temperature X-ray diffraction patterns of the sample containing 50% R.

Rhenanite (R) inverted at 690°C from βR to αR during heating.

Complicated changes occurred for samples blended with T and R. When the R content was less than about 10% by weight, R dissolved during heating into βT to form βT solid solution which then inverted to αT a little below 1180°C. For samples containing 10 to 97% R, βR changed to αR at 650°C to give mixtures of βT and αR.

In the samples containing 20 to 50.5% R, mixtures of "A" and βT formed at 980°C. Larger amounts of "A" with smaller amounts of βT formed as the R content approched 50.5%, where single phase "A" with a stoichiometric composition of $Ca_5Na_2(PO_4)_4$ formed. At elevated temperatures, the βT dissolved into "A" to form "A" solid solution. At yet higher temperature, "A" and the solid solution inverted to αR solid solution.

When the αR solid solution was cooled, "A" solid solution formed again, βT separated during further cooling, and then "A" diminished at 980°C to form αR and βT. The decomposition of "A" occurred more slowly for solid solutions containing a larger amount of R. "A" with the stoichiometric composition, $Ca_5Na_2(PO_4)_4$, decomposed very slowly as will be described later in detail.

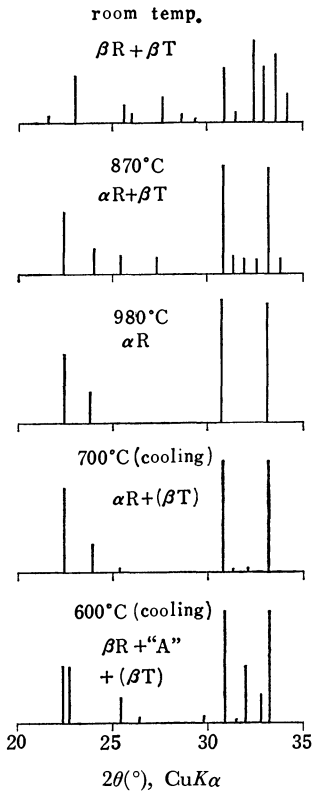

Fig. 6. High temperature X-ray diffraction patterns of the sample containing 70% R. (βT in the parentheses means very minor.)

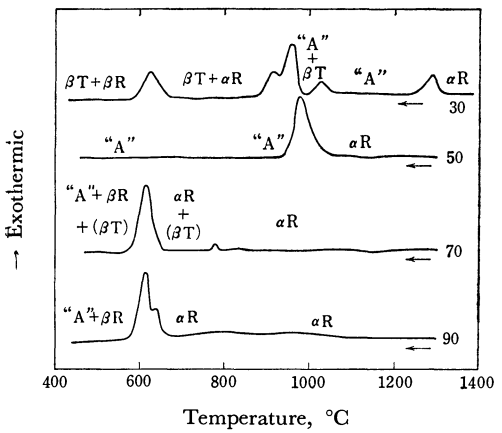

Fig. 7. DTA curves during cooling (5°C/min). (Numbers in the figure indicate R content. βT in the parentheses means very minor.)

In samples containing R from 50.5 to 97%, βT disappeared during heating between 650°C and 980°C to form αR solid solution. The formation of "A" was not detected by high temperature X-ray diffraction during heating.

The phase diagram shows that when the αR solid solution containing 55 to 97% R was cooled,

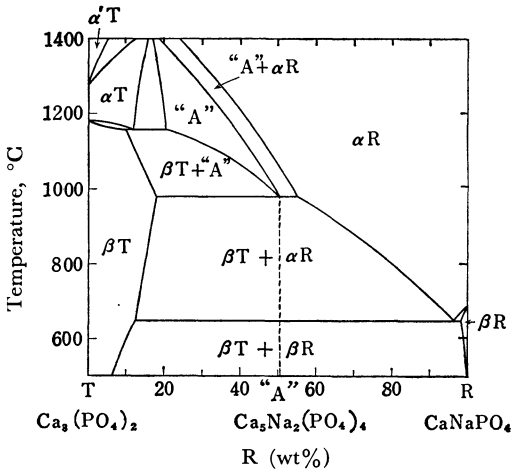

Fig. 8. Phase diagram of the system $Ca_3(PO_4)_2$-$CaNaPO_4$. (In the range containing 50.5 to 97% R, αR solid solution is easily supercooled to 650°C without forming βT, thereby "A" and βR form.)

βT should first form from the solid solution. The rate of formation of βT, however, was so small that appreciable amounts of βT did not form at the cooling rate of 5°C/min. The αR solid solution was thus supercooled down to 650°C, where βR and "A" formed simultaneously and rapidly as shown in Fig. 7.

Mineral Content of the Cooled Products. The mineral content of the samples cooled from 1400°C to room temperature at a rate of 10°C/min is given in Fig. 9.

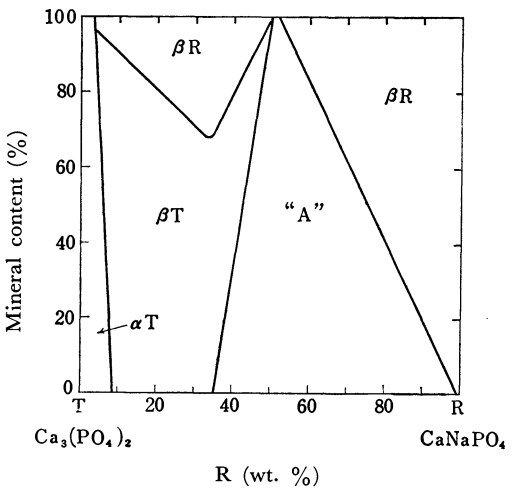

Fig. 9. Mineral content of the products cooled at a rate of 10°C/min.

For a pure sample of T, an α modification was obtained at room temperature because the inversion from α to β was very slow. When a small amount of R was present, the inversion was promoted and mixtures of βT and βR were obtained.

"A" was present in samples containing more than 35% R. The amount of "A" increased to 100% as the R content increased to 50.5%, indicating that the decomposition rate of "A" during cooling was decreased as the R content approached the stoichiometric amount. Samples containing more than 50.5% R consisted of "A" and βR.

Although "A" with the stoichiometric composition was fairly stable, decomposition occurred slowly below 980°C. When "A" was maintained at 850°C, decomposition occurred to the extent of 20% in 20 hr, and to the extent of 80% in 120 hr. The "A" solid solutions containing 35 to 40% R decomposed nearly completely at this temperature in 20 min, but the decomposition was very slow at 500°C.

In an other series of tests, the samples were quenched by air from 1400°C to 500°C in about 30 sec, and to room temperature in an additional 1 min. The mineral content of the quenched products is shown in Fig. 10.

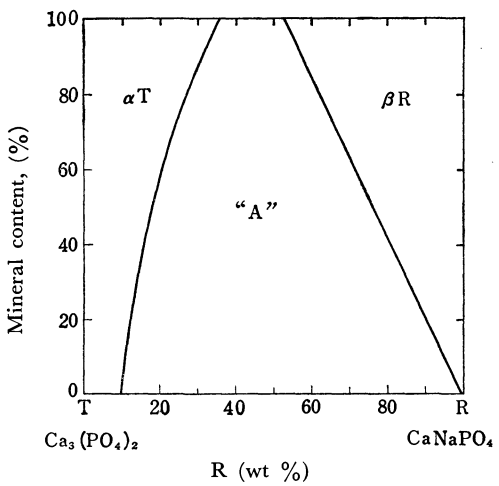

Fig. 10. Mineral content of the quenched products.

Single phase αT was obtained when the R content was less than 10%. Mixtures of αT and "A" were obtained in the range from 10 to 35% R although the phase diagram shows that αT should not form when the R content exceeds 20%. Presumably, the formation of αT in the samples containing 20 to 35% R was peculiar, and due to the rapid cooling from the high temperature at which the αR solid solution was present. Other tests showed that when samples containing 20 to 35% R were cooled rapidly after being kept for a while between 1200 and 1250°C, where "A" was stable, essentially no αT was present in the products while the main mineral "A" was accompanied by small amounts of βT which seemed to have formed from the "A" solid solution during cooling.

Single phase "A" was obtained in the 35 to 50.5% R range. Mixtures of "A" and βR were obtained when the R content exceeded 50.5% in the same manner as shown in Fig. 9.

These results show that to maximize the amount of "A" in the calcined defluorinated phosphate, the raw materials should be blended to maintain an R content of between 35 and 50.5%, and the calcined phosphate should be quenched to below 500°C from the temperature range in which single phase "A" is stable, or from a higher temperature.

Composition and Structure of "A". The X-ray diffraction data of "A" which has the stoichiometric composition, $Ca_5Na_2(PO_4)_4$, are shown in Table 1, and compared with those of pure α-$CaNaPO_4$.[5] The principal diffractions of "A" agree with those of αR, indicating that the structure of "A" is related to that of αR. "A" shows other minor diffractions which are not shown by αR.

The compound "A" contains a smaller number of cations in comparison with αR, $Ca_4Na_4(PO_4)_4$. Apparently "A" has lattice vacancies due to the lack of cations, and the vacant lattice points are arranged to form a superlattice of αR which is fourfold in *a* direction and threefold in *c* direction (Table 1).

At high temperature, the lattice vacancies are disordered by an endothermic reaction resulting in the formation of a lattice which is similar to that of αR except for the presence of the lattice vacancies which are distributed at random, and therefore do not give the typical diffraction lines of "A". When the αR solid solution was cooled, the lattice vacancies were again arranged to form "A" by an exothermic reaction.

It is also quite likely that Nagelschmidtite, $Ca_7Si_2P_2O_{16}$, which is isomorphic with "A", consists of a superlattice of α-Ca_2SiO_4 which is isomorphic with αR.[1,2]

Although the formation of "A" was not detected by X-ray during heating of samples containing more than 50.5% R, as was already mentioned, differential thermal analysis showed that considerable exothermic reactions occurred slowly after βT disappeared to form αR solid solution. For example, exothermic reactions occurred slowly between 930 and 1180°C for a sample with 60% R, and between 750 and 950°C for another sample with 90% R (Fig. 1).

The exothermic reactions may indicate the formation of "A" which has considerable disorder and do not give clearly the typical X-ray diffraction lines of "A". In those samples, the number of lattice vacancies is less than that required to form "A" because of the presence of an excessive R component. The formation of well-arranged "A" thus may not be easy.

During cooling, the imperfect "A", which is similar to the αR solid solution, was easily supercooled down to 650°C. The separation of βR

10	1.806	1.807	0012	004	1.77	40

from the solid solution at this temperature resulted in an increase in the number of lattice vacancies in the remaining component which resulted in the formation of "A". Presumably, if the αR solid solution was cooled so slowly that a sufficient amount of βT could first separate from the solid solution, the formation of "A" at 650°C would be depressed.

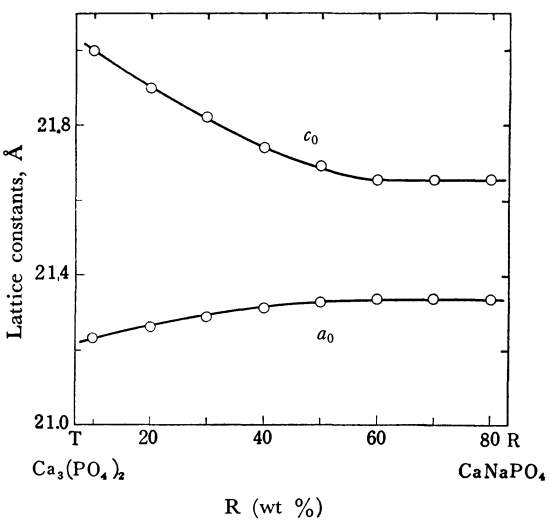

Fig. 11. Relation between R content and lattice constants of "A" and the solid solution present in the quenched products.

The relation between the R content and the lattice constants of "A" and "A" solid solution present in the products quenched from 1400°C is shown in Fig. 11.

The lattice constant a_0 increased slightly, and c_0 decreased remarkably as the R content increased from 10 to 50.5%. Essentially no change was observed when the R content exceeded 50.5%, indicating that the composition of "A" formed in the samples was close to the stoichiometric composition, $Ca_5Na_2(PO_4)_4$, due to the separation of the excessive R component at 650°C.

The "A" solid solution formed in samples containing less than 50.5% R includes more lattice vacancies than required to form "A", because tricalcium phosphate $Ca_6(PO_4)_4$ contains less cations than does $Ca_5Na_2(PO_4)_4$. The rate of the decomposition of the solid solution during the cooling thus increased with decrease in R content, due to the increase in the number of vacancies.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 348—353 (1968)

The Hydration and Crystallization of ρ-Alumina and Alumina-gel in Aqueous Solutions of Various Basic Reagents

Goro YAMAGUCHI and Wen-Chau CHIU

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received July 10, 1967)

Alumina gel, boehmite gel, ρ-alumina, η-alumina, and γ-alumina were treated with aqueous solutions of various inorganic and organic reagents at temperatures below 100°C. Boehmite gel, η-alumina and γ-alumina were found to show no change upon this treatment, while alumina gel and ρ-alumina either remained unchanged or changed into fairly well-crystallized boehmite, boehmite gel, gibbsite, bayerite, or nordstrandite, according to the treating conditions. It has been newly established that water-containing pyridine and aniline, the aqueous solution of hydrazine hydrate, and the aqueous solution of *o*, *m*-phenylenediamine are effective in forming fairly well-crystallized boehmite, nordstrandite, and gibbsite respectively.

A precipitate obtained from an aluminum salt aqueous solution by neutralization with ammonia and dried at a low temperature is found to be amorphous by X-ray analysis. The present authors have designated it as "alumina gel." Willstätter[1] had designated such an amorphous gel as C_α-gel; he also designated the precipitate which showed diffused boehmite-like X-ray diffractions as C_β-gel, and the one which showed X-ray diffractions of bayerite as C_γ-gel. He had described the occurrence of these gels as being dependent on the neutralization conditions and said that C_α-gel had a tendency to change into C_β-gel, and then gradually into C_γ-gel. These experimental results have been confirmed by several succeeding investigators. In this paper, C_β-gel will be called "boehmite gel."

Nordstrand[2] found a new aluminum trihydroxide, "nordstrandite," which was different from gibbsite and bayerite in the stacking sequence of its layer structure.[3] Afterward nordstrandite was found to occur in nature[4] and was also synthesized by treating alumina gel with an aqueous solution of ethylenediamine.[5]

Funaki *et al.*[6] studied the aging process of alumina gel and presented a mechanism whereby three crystalline hydrates and one gelatinous hydrate were formed independently. However, they did not describe the favorable conditions for each process.

alumina gel → gibbsite
alumina gel → bayerite
alumina gel → nordstrandite
alumina gel → boehmite gel

As for the aging of ρ-alumina, Tertian[7] reported that ρ-alumina had a tendency to change into bayerite upon rehydration.

In this experiment the present authors aged ρ-alumina and alumina gel with aqueous solutions of organic and inorganic basic reagents at temperatures below 100°C. Boehmite gel, η-alumina, and γ-alumina were also treated under the same conditions, but no reaction was observed with them.

Specimen

Alumina Gel. An $AlCl_3$ aqueous solution of 0.5 mol/*l* was treated with a 14% aqueous solution of ammonia in order to adjust the pH to 8.0. The alumina gel thus obtained was then thoroughly washed and used in the wet state. This gel is amorphous to X-rays and contains about 5 mol of adhered and combined water per mole of Al_2O_3.

ρ-Alumina. Gibbsite was heated at 600°C in a vacuum (below 3 mmHg). The dehydrated

alumina thus obtained gives the X-ray diffraction pattern shown in Fig. 1, a pattern which shows only one peak, at $d=1.40$ Å.

Experimental

Hydration. Alumina gel and ρ-alumina were treated with water, an NaOH aqueous solution, an NH_3 aqueous solution, various organic amines, and their aqueous solutions.

Identification. The identification was made by referring to the characteristic equistructural diffraction peaks of gibbsite and bayerite, shown in Fig. 2, and to the superstructural diffraction peaks of nordstrandite, shown in Fig. 3. Boehmite gel was identified from its three broad diffraction peaks, shown in Fig. 4.

Discussion and Conclusion

1) Boehmite gel, η-alumina, and γ-alumina did not change under any conditions, so it is clear that they are stable enough under treatment with basic reagents at temperatures below 100°C.

2) Alumina gel and ρ-alumina behaved almost the same under all conditions, but when treated with unhydrous reagents, the different water contents of alumina gel and ρ-alumina were found to cause some differences in their crystallization processes.

3) As for alumina gel and ρ-alumina, the observed phenomena can be classified into the following 6 types:

a. Starting material remains unchanged.
b. Starting material changes into fairly well-crystallized boehmite.
c. Starting material changes into boehmite gel.
d. Starting material changes into bayerite.
e. Starting material changes into gibbsite.

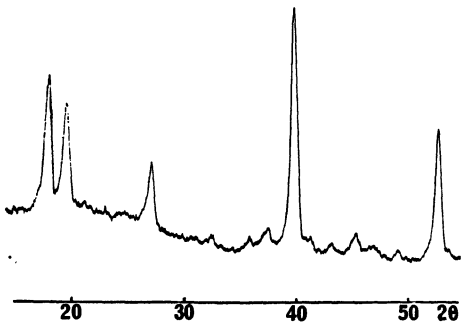

Fig. 8. X-Ray diffraction diagram of bayerite. (Condition: 10% Triethylenetetramine aq. soln., ρ-alumina, 15°C, 2 day. No. 83)

f. Starting material changes into nordstrandite.

4) ρ-Alumina remained unchanged when treated with unhydrous reagents, as in No. 34, No. 46, and No. 67; no similar phenomenon was observed in alumina gel, however since it contains a considerable amount of water. Alumina gel remained unchanged in No. 6 and No. 49. No. 6 shows that the crystallization of alumina gel does not proceed in such a sligtly acidic aqueous solution. The reason for No. 49 is not clear.

5) The "b" phenomena are caused by treating ρ-alumina at rather high temperatures with pyridine and aniline which contain a small amount of water, as in cases of No. 39, No. 40, No. 41, No. 43, and No. 47, and by treating alumina gel with a α, α'-diphenylamine aqueous solution and with aniline which are pure or which contain some water, as in cases of No. 18, No. 22, and No. 47.

From these results, the most favorable conditions for fairly well-crystallized boehmite formation seem to be a rather large solubility of the alumina and a low activity of the water.

6) The "c" phenomena are caused by treating alumina gel with pure water at any temperature and with slightly basic reagents at rather high temperatures, as in cases of No. 4, No. 5, No. 9, No. 31, and No. 35. However, the pure boehmite gel can not be obtained from ρ-alumina under the same treatment except in the cases of No. 1, No. 42, and No. 45.

These results can be attributed to the different solubilities of alumina gel and ρ-alumina. The solubility of ρ-alumina is larger than that of alumina gel. A favorable condition for forming boehmite gel is a rather small solubility. The solubility of ρ-alumina is too large and the temperature conditions of No. 42 and No. 45 are too low for forming fairly well-crystallized boehmite, so boehmite gel has been formed under these conditions.

7) The "d" phenomena are caused by conditions of large alumina solubility, high water activity, and comparatively low temperatures, as in the cases of No. 10, No. 11, No. 14, No. 15, No. 20, No. 21, No. 25, No. 50, No. 55, No. 56, No. 58, No. 59, No. 61, No. 66, No. 83, and No. 86.

The effect of low temperatures on bayerite formation can be sufficiently observed in the cases of No. 10, No. 20, No. 55, No. 66, No. 83, and No. 86. This effect is also observed in the Bayer process, in which gibbsite is formed at higher temperatures and bayerite, at lower temperatures.

The effect of solubility is confirmed from the fact that ρ-alumina changes more easily into bayerite than does alumina gel under the same conditions.

8) The "e" phenomena are found in the cases of No. 7, No. 30, No. 37, No. 53, and No. 64, but only in No. 64 are conditions sufficient for forming pure gibbsite. The conditions of No. 7 somewhat resemble those of the Bayer process; these conditions are a rather larger solubility and a high temperature. The conditions of No. 64, treating alumina gel with an *o, m*-phenylenediamine aqueous solution, constitute a new method for gibbsite formation.

9) The "f" phenomena are found in the cases of No. 69, No. 70, No. 72, and No. 78. The effect of an ethylenediamine aqueous solution had already been established,[5] but that of a hydrazine hydrate aqueous solution is first established by our experiment.

10) The reason why bayerite, gibbsite, or nordstrandite is formed selectively under treatment with a certain basic reagent is very interesting, but it can not be well explained now, remaining as a problem for furture study. This effect is possibly related to the molecular structures of the basic reagents.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 354—358 (1968)

D. C. and A. C. Polarographic Behavior of Thallium(I) Ions in Diethylenetriaminepentaacetate Solutions

Mutsuo KODAMA, Tomohiko NODA and Mitsuko MURATA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received July 12, 1967)

The reduction reaction of Tl(I) ions in DTPA solutions was studied d.c.- and a.c.-polarographically, and the composition and the stability constants of normal and hydrogen chelates of Tl(I) ions with DTPA, TlZ^{4-}, and $TlHZ^{3-}$ were determined. The reduction of Tl(I)-DTPA chelates at the DME proceeds reversibly in the polarographic sense according to this scheme:

$$\begin{array}{ccccc} TlZ^{4-} & + e^- + Hg & \rightleftharpoons & Tl(Hg) & + Z^{5-} \\ {\scriptstyle H^+}\downarrow\uparrow & & & & {\scriptstyle nH^+}\downarrow\uparrow \\ TlHZ^{3-} & & & & H_nZ^{n-5} \end{array}$$

The stability constants of TlZ^{4-} and $TlHZ^{3-}$ were found to be $10^{5.45}$ and $10^{4.24}$ ($\mu=0.40$). The determination of the a.c. summit-potentials, E_p, and the introduction of E_p into the Kolthoff and Lingane equation of polarographic waves of metal complexes were also discussed.

Trace quantities of surface-active substances can often exert a strong effect on the electrode process. In most cases, it has been shown that even minute amounts of surface-active substances present in the background solutions of analytical-grade-reagents are sufficient to change the measured rate of the electrode processes by a factor of 50 and to decrease the height of a. c. polarographic waves quite markedly.[1,2]

For this reason, an electrode reaction which proceeds reversibly in the d. c. polarographic sense cannot always be expected to be reversible under the influence of an alternating voltage.

Gupta and Chatterjee[3] have introduced a. c. polarographic summit-potentials in place of d. c. polarographic half-wave potentials into the Kolthoff-Lingane equation[4] for the reduction of a metal complex ion and have tried to determine the ligand number and the stability constants of the cadmium ammonia complex. However, the introduction they attempted can be safely undertaken only when the electrode reaction is reversible in both d. c. and a. c. polarography.

The theory of the a. c. polarography predicts that the plot of the d. c. potential, E, against $\log[(I_p/I)^{1/2}-((I_p-I)/I)^{1/2}]$ will give a straight line with a $\pm 0.118/n$ V slope for reversible electrode processes. Consequently, the reversibility of the electrode process can be tested by this log-plot, and the summit-potential can be determined to be the potential where the two linear portions intersect; *i. e.*, the $\log[(I_p/I)^{1/2}-((I_p-I)/I)^{1/2}]$ is equal to zero.

The a. c. polarographic behavior of a thallium-(I) ion and its complexes has been known to be apparently reversible, and exceptionally unaffected by the addition of such surface-active substances as gelatin.[5] In view of the fact that the rate constant of the reduction reaction of thallium(I) is markedly decreased by the addition of a surface-active substance, this may indicate that, even in the presence of surface-active substances, the rate constant of the reduction process remains so large that the process behaves reversibly. At the dropping mercury electrode, thallium(I)-DTPA chelate ions also give a single well-defined reversible wave both d. c. and a. c. polarographically. In this study, the electrode reaction of thallium(I)-DTPA chelates was investigated by d. c. and a. c. polarographic methods, and the stability constant of thallium(I)-DTPA chelate and the protolytic stability constant of its hydrogen chelate, $TlHZ^{3-}$, were determined.

Experimental

Reagents. The standard solution of thallium(I) perchlorate was prepared by dissolving a known amount of pure thallium metal in a reagent-grade perchloric acid.

Commercial reagent-grade diethylenetriaminepentaacetic acid (DTPA) was recrystallized from an aqueous

solution by adding hydrochloric acid, and then dissolved into a sodium hydroxide solution. The concentration of a DTPA solution was standardized against pure metallic zinc.

Apparatus. All d.c. current-voltage curves were measured by using a manual polarograph similar to that of Kolthoff and Lingane[4] and were corrected for the residual current and the *i-R* drop. The a.c. polarograms were recorded with a Yanagimoto PA-102 pen-recording polarograph operated manually. The d.c. potentials applied were accurately determined by using a Shimadzu K-2 potentiometer.

The rate of the flow of mercury, m, and the drop time, t_d, of the dropping mercury electrode (DME) were 1.24_8 mg/sec and 6.30 sec respectively, as measured in an air-free 0.1 M acetate buffer solution of pH 4.80 with an open circuit and at 60 cm of a mercury column at 25°C. A saturate calomel electrode (SCE) with a large area was used as the reference electrode; it was connected to the cell solution through a Hume and Harris-type salt bridge.[6] In the a.c. polarographic measurements, a 200 μF condenser was used to minimize the effect of the cell resistance.[7] The pH value of the solution was measured with a glass electrode pH meter (Hitachi-Horiba Model M4).

The dissolved oxygen in the solution was removed by bubbling pure nitrogen gas through the solution, and all the measurements were conducted on solutions with a constant ionic strength of 0.4 ($NaClO_4$).

Results and Discussion

Reversibility of the Electrode Reaction of Thallium(I) - Diethylenetriaminepentaacetate at the DME. The electrode reaction of thallium(I) ions in solutions containing an excess of DTPA was studied over the pH range from 7.30 to 10.20. In the present study, no other buffer reagent was used because in the pH range studied the system containing an excess of DTPA is considered to have enough buffer capacity to maintain the pH value of the solution constant.

A Tl(I)-DTPA chelate gives a single well-defined d. c. polarogram (Fig. 1); its limiting current was found to be proportional to the square root of the effective pressure of mercury applied to the DME (Table 1) and to the concentration of thallium(I) ions (Fig. 2). The relation between $\log[i/(i_l-i)]$ and E, where i, i_l and E have their usual meanings, gave exclusively a straight line with a slope of 60 mV, corresponding to a one-electron reduction (Fig. 3).

In a. c. polarography, also, typical polarograms were obtained; their summit potentials coincided with the half-wave potential of the d. c. polarogram (Fig. 1). This may mean that the electrode reaction of a Tl(I)-DTPA chelate proceeds reversibly in the a. c. polarographic sense. This conclusion can also be confirmed by the facts that the peak

C_{DTPA}=25.0 mM

height of the a. c. polarogram is exactly proportional to the concentration of the Tl(I)-DTPA chelate that the ratio of the peak height of a Tl(I)-DTPA chelate to that of a Tl(I) ion is nearly equal to the ratio of their limiting currents.

To be more exact, the reversibility of the electrode reaction at the electrode, which is polarized under the influence of an a. c. voltage of a small amplitude, should be tested by the a. c. log-plot method, *i. e.*, the plot of $\log[(I_p/I)^{1/2}-((I_p-I)/I)^{1/2}]$ against E, where I_p and I are the peak height and the height of a. c. polarogram at a given value of E, respectively.

The well-known relation (2) of the a. c. polarographic current derived for the following electrode reaction[8,9];

$$O + ne^- = R \qquad (1)$$

holds only when the reaction (1) proceeds reversibly in the polarographic sense:

$$I = (n^2F^2 \cdot A/4RT) \cdot D_0^{1/2} \cdot \omega^{1/2} \cdot C_0 \cdot \Delta E \times \mathrm{sech}^2[(nF/2RT)(E - E_{1/2})] \cdot \sin(\omega t + \pi/4) \qquad (2)$$

The notation definitions are as follows:

n=number of electrons involved in the electrode reaction
F=Faraday's constant, A=electrode area
R=ideal gas constant,
T=absolute temperature
D_0=diffusion coefficient of the species 0
C_0=bulk concentration of the species 0,
ω=frequency,
ΔE=amplitude of the applied alternating potential,
$E_{1/2}$=reversible polarographic half-wave potential for the electrode reaction (1)

Similarly, in the reduction of a metal complex,

$$MX_m^{n-mb} + ne^- + Hg = M(Hg) + mX^{b-} \qquad (3)$$

when the boundary condition (4), which shows conclusively that the electrode reaction (3) is reversible, is satisfied by the system under the a. c. polarographic conditions, the relation (5) can be obtained by the mathematical treatment employed by Matsuda,[8] Delmastro and Smith,[9] and Underkofler and Shain[10] to derive the relation (2):

$$(C_{MX_m}/C_{M(Hg)})_{x=0} = \theta \cdot \exp[-\nu \sin \omega t] \qquad (4)$$

where $\theta = \exp[nF/RT(E-(E_{1/2})_c)]$,

$\nu = nF \cdot \Delta E/RT$,

$(E_{1/2})_c = E^\circ_{M(Hg)} + RT/nF[\ln k_{M(Hg)} \cdot f_c/k_c - \ln K_c - m \cdot \ln C_x \cdot f_x]$[4],

E=d. c. potential applied,
$E^\circ_{M(Hg)}$=standard potential,
k's=diffusion current constants,
f's=activity constants,
C_x=the concentration of X^{b-} at the electrode surface, and

$K_c=[MX_m^{n-mb}]/[M^{n+}]\cdot[X^{b-}]^m$.

$$I = (n^2F^2 \cdot A/4RT) \cdot D^{1/2}{}_{MX_m} \cdot \omega^{1/2} \cdot C_{MX_m} \cdot \Delta E \times \mathrm{sech}^2[(nF/2RT)(E-(E_{1/2})_c)] \cdot \sin(\omega t + \pi/4) \qquad (5)$$

By casting the relation (5) into logarithmic form and by rearranging the resulting equation, one can obtain the following equation at 25°C;

$$E = (E_{1/2})_c + 2 \times 0.0591/n \log[(I_p/I)^{1/2}-(I_p-I/I)^{1/2}] \qquad (6)$$

Here I_p represents the peak height of the a. c. polarogram of MX_m^{n-mb}.

This relation, (6), clearly indicates that the summit potential in a. c. polarography can be safely equated with the half-wave potential in d. c. polarography when the electrode reaction is reversible, even under a. c. polarographic conditions, that the plot of E against $\log[(I_p/I)^{1/2}-((I_p-I)/I)^{1/2}]$ gives a straight line with a slop of $\pm$0.118/nV, and that the summit potential can be determined as the potential where the $\log[(I_p/I)^{1/2}-((I_p-I)/I)^{1/2}]$ is zero.

A typical example of an a. c. log-plot is shown in Fig. 4. The slopes found were +134 mV and −132 mV respectively, and the summit potential determined by the method described above agreed well with the half-wave potential (Table 2). Considering the effects of spherical diffusion,[10] of

the charging current[10] and of the incomplete compensation for the ohmic resistance of the cell circuit,[11] the above facts may be taken as conclusively indicating the reversible process.

The Mechanism of the Electrode Reduction of Tl(I)-DTPA Chelate at the DME. In view of the experimental facts that the half-wave potential or the summit potential is independent of the concentration of Tl(I) ions added (Tables 3a, 3b), but shifts with a change in the concentration of DTPA, C_{DTPA}, according to the relation;

$$\Delta E_{1/2}/\Delta \log C_{DTPA}$$
$$\text{or} \quad \Delta E_s/\Delta \log C_{DTPA} = -0.0591 \text{ V}$$

the following mechanism can be assumed for the reduction of the Tl(I)-DTPA chelate when the presence of a hydrogen chelate of Tl(I)-DTPA is taken into consideration, as in the case of other metal chelates of DTPA:[12]

$$\begin{array}{ccccc} TlZ^{4-} & + e^- + Hg = & Tl(Hg) & + Z^{5-} \\ \downarrow\uparrow H^+ & & & {}^{n}H^+ \downarrow\uparrow \\ TlHZ^{3-} & & & H_n\cdot Z^{n-5} \end{array} \qquad (7)$$

where Z^{5-} refers to the completely-dissociated DTPA.

Assuming that $a_{Hg}=1$ and $f_{Tl(Hg)}=1$, the relation (8) can be derived for the mechanism (7):

$$(E_{1/2})_{TlZ} = E^\circ_{Tl(Hg)} + 0.0591\left[\log\frac{f_{Tl^+}\cdot k_{Tl(Hg)}}{k_{TlZ}} - \log C_{DTPA} + \log\frac{\alpha_H}{K_{TlZ}\cdot(1+K^H_{TlHZ}[H^+])}\right] \qquad (8)$$

where $K_{TlZ} = [TlZ^{4-}]/[Tl^+]\cdot[Z^{5-}]$,
$K^H_{TlZ} = [TlHZ^{3-}]/[TlZ^{4-}]\cdot[H^+]$,
and $\alpha_H = [H^+]/k_5 + [H^+]^2/k_4\cdot k_5 + \cdots + [H^+]^5/k_1\cdot k_2\cdot k_3\cdot k_4\cdot k_5$.

Remembering the relation theoretically predicted for the half-wave potential of the reduction of a Tl(I) ion at the DME,[4,13] the shift of the half-wave potential of a Tl(I) ion, $\Delta E_{1/2}$, by the chelate formation with DTPA can be derived as:

$$\Delta E_{1/2} = 0.0591\left[\log\frac{k_{TlZ}}{k_{Tl^+}} + \log C_{DTPA} + \log\frac{K_{TlZ}(1+K^H_{TlHZ}[H^+])}{\alpha_H}\right] \qquad (9)$$

From the above theoretical consideration, it can be concluded that, for the reaction mechanism (7), the plot of antilog$[\Delta E_{1/2}/0.0591+\log\alpha_H+\log k_{Tl^+}/k_{TlZ}-\log C_{DTPA}]$ against $[H^+]$ can give a linear relation with a slope of $K^H_{TlHZ}\cdot K_{TlZ}$, and that the antilog value at $[H^+]=0$ corresponds to K_{TlZ}. Here, the shift of the summit-potential, ΔE_p,

by the chelate formation can be used in place of $\Delta E_{1/2}$.

The theoretical conclusion thus obtained was tested by using some of the typical data. The results are shown in Fig. 5. From the tangents of the linear relations and the antilog value at [H^+]=0 in Fig. 5, the K_{TlZ} and K^H_{TlHZ} values were determined; they are listed in Table 4, together with dissociation constants and diffusion current constants used in the calculations. The dissociation constants listed were calculated by using the value reported by Vandegaer *et al.*[14]; calculation was done in a manner similar to that described previously.[12]

* Obtained by the present authors
** Mixed constant

It is very interesting that the K^H_{TlHZ} value found is much greater than the K_{TlZ} value, making a marked contrast with that of the DTPA chelates of divalent or tervalent metal ions.

The complex formation reaction has been known to provide many useful polarographic methods for the analysis of metal ions. For instance, in a mixture of lead(II) and thallium(I) ions not containing a complex-forming reagent, it is very difficult to determine simultaneously those metal ions by the polarographic method, because the two metal ions are reduced at potentials so close togehter. However, in the solution containing a chelating reagent such as EDTA, the reduction wave of the lead(II) ion shifts to the negative potential, and so the resolutive determination of lead(II) and thallium(I) can be effected successfully. The resolution of the polarographic waves has generally been treated in an experimental manner, and few theoretical and quantitative discussions on it have appeared. In a. c. polarography, it has been reported[15] that, when the difference in the summit potential, ΔE_p, of a. c. polarograms is greater than 40 mV, the peak height of each polarogram can be determined accurately. However, this conclusion is somewhat experimental. From the foregoing discussion, it is very clear that the magnitude of the resolution of a. c. polarograms can be estimated quantitatively with the aid of Eq. (6). In the most favorable cases, a ΔE_p value greater than 117/n mV is theoretically required to determine the a. c. peak height within a 3.0% limit of error.

Spectroscopic Studies of Mixed Amine Carbonyl Complexes of d^6 Structure. I. Visible and Ultraviolet Absorption Spectra of Diamine-tetracarbonyl Complexes of Chromium(0), Molybdenum(0) and Tungsten(0)

Hide SAITO, Junnosuke FUJITA and KAZUO SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received July 17, 1967)

Chromium(0), molybdenum(0) and tungsten(0) complexes of $[M\cdot(CO)_4AA]^0$ type (AA= ethylenediamine (en), *l*-propylenediamine (*l*-pn), trimethylenediamine (tn), bipyridyl (bp), and phenanthroline (phen); *l*-pn and tn derivatives are new compounds) have been synthesized and their absorption spectra, rotatory dispersion (RD) and circular dichroism (CD) measured in methanol at room temperature. The nature of the absorption bands has been discussed by comparing them with one another and with those of hexacarbonyl- and piperidinepentacarbonyl complexes of these elements. The peaks in the region 23000 to 25000 cm^{-1} seem to be due to spin-allowed d–d transition. The bands at 30000 to 33000 cm^{-1} appears to correspond to the metal to carbonyl charge transfer band of hexacarbonyls at *ca.* 36000 cm^{-1}. Besides them, complexes of aromatic amines (bp and phen) show broad and strong bands at 21000 to 22000 cm^{-1} which seem to owe to metal to amine charge transfer.

Although many carbonyl compounds of VIB group elements of the periodic table have been studied,[1] little[2-5] is known of their optical properties except the infrared absorption spectra. Gray and Beach[2] measured the ultraviolet absorption spectra of hexacarbonyls of VIB group elements in the vapor state, and assigned the bands on a molecular orbital model. They gave thus several remarkable features of metal-carbonyl bonds. Strohmeier and Gerlach[4] measured the visible and ultraviolet absorption spectra of some mono- and diamine derivatives of metal carbonyls of group VIB elements and found that the patterns of spectra are all similar to one another. However, the character of each band was not made clear.

The bond between metal and carbon monoxide ligand has a significant π-character, whereas that between metal and amines is of almost pure σ-character. Hence studies of mixed complexes containing both kinds of ligand seem quite worthwhile. We have measured the absorption spectra of 15 kinds of mixed diamine carbonyls of the type $[M(CO)_4AA]$ ($M=Cr^0$, Mo^0, W^0; AA=ethylenediamine [en], *l*-propylenediamine [*l*-pn], trimethylenediamine [tn], bipyridyl [bp], phenanthroline [phen]) as well as their circular dichroism (CD) and rotatory dispersion (RD) and discussed the results in conjunction with those of hexacarbonyl complexes.

Experimental

Material. New compounds $[M(CO)_4$*l*-pn] and $[M(CO)_4$tn] were prepared by a similar method to Krainhanzel's,[6] which was useful for the preparation of $[M(CO)_4$en]. Bipyridyl and phenanthroline complexes, $[M(CO)_4$bp] and $[M(CO)_4$phen] were synthesized by Abel's method.[7] Each compound was identified by infrared spectra in the CO-stretching region and chemical analysis of carbon, hydrogen and nitrogen. The results of chemical analysis of the new compounds are shown in Table 1. Optically active *l*-pn was obtained by resolving commercial propylenediamine according to Dwyer.[8] The aqueous solution of *l*-isomer was acidified with hydrochloric acid and evaporated to dryness. Water was completely eliminated by adding ethanol and evaporating off ethanol together with water, twice. Anhydrous *l*-pn dihydrochloride was dissolved in absolute methanol containing an equivalent amount of sodium methylate, the sodium chloride decanted and the free *l*-pn distilled twice in the presence of metallic sodium. (yield after resolution, 26%) $[\alpha]_D^{25}$° −34.3° (2% in benzene, by Dwyer's method.[8]) The solvent methanol was purified by the usual method in nitrogen atmosphere.

Measurements. Visible and ultraviolet absorption spectra were measured with Hitachi EPS-3 Automatic Recording Spectrophotometer in the region where log ε is greater than 2. RD and CD were recorded with JASCO ORD/CD-5 Recorder in the wave number region below 35000 cm^{-1}. The measurements were all made in freshly prepared absolute methanol solution at room temperature. The mixed complexes tend to decompose in this solution, especially in the presence of dissolved oxygen.

Results and Discussion

Absorption curves of the diamine complexes are shown in Figs. 1 to 5, and the numerical data summarized in Tables 2 and 3. From these figures it is seen that the spectra depend on the ligand more remarkably than on the central metal atom. Especially, as seen from Fig. 5, bipyridyl and phenanthroline complexes give quite a different feature from those of aliphatic diamine complexes including ethylenediamine and trimethylenediamine derivatives. Such a difference can be expected from the aromaticity of ligand.

Bands at 23000 to 25000 cm^{-1}. All the complexes give bands in this wave number region, although bipyridyl and phenanthroline complexes give only shoulders. The wave numbers of the

peak of molybdenum and tungsten complexes are similar to each other and significantly greater than those of the chromium complex. The molar extinction coefficient ε increases slightly in the sequence chromium, tungsten and molybdenum. The absorption spectra of ethylenediamine and *l*-propylenediamine complexes are almost identical and their absorption maxima are at a higher wave number than those of trimethylenediamine complexes by *ca.* 500 cm^{-1}. Such a tendency is seen only for the bands in this region, and coincides with that expected from the spectrochemical series. Hence these bands are regarded to be mainly due to the spin-allowed d–d transition. The d–d transition of the cobalt(III) complexes, $[Co(CN)_4en)]^-$, and $[Co(CN)_4tn]^-$, which are isoelectronic with the mixed diamine carbonyls of chromium(0), shows the same trend.

This conclusion is further supported by the fact that the location and extinction coefficient seem to be compared to those of the d–d transition ($^1A_{1g} \rightarrow {}^1T_{1g}$) of hexacarbonyls at 31000 to 33000 cm^{-1}, which are regarded to be spin-allowed.[2] The apparent differences in transition energy between diamine-tetracarbonyl and hexacarbonyl complexes (in cyclohexane) are estimated to be 7800, 6100 and 7400 cm^{-1} for the chromium, the molybdenum and the tungsten complex, respectively. These bands are subject to significant solvent effect. The estimation should be modified to be 9000 and 6900 cm^{-1} for the chromium and the molydbenum complexes in cyclohexane, respectively, when McRae's theoretical equation is applied.[9] Contribution of the solvent effect cannot be appropriately estimated for the tungsten complex. The difference is only 3800 cm^{-1} for the corresponding hexa- and tetracyano cobalt(III) complexes. Such a remarkable difference between the carbonyl and the cyano complexes can be regarded as due to the greater destabilization of d_π levels on replacement of two carbonyls by diamine, as compared in case of the cyano cobalt(III) complexes. Such a view is also supported by infrared studies.[6,10]

Strohmeier[4] measured the absorption spectra of piperidinepentacarbonyl complexes of chromium(0), molybdenum(0) and tungsten(0) in cyclohexane and found that they also have absorption bands at 23000 to 26000 cm^{-1}. Their characteristics are very similar to those of the diamine-tetracarbonyl complexes given above, except for intensity. These bands are also considered to be mainly due to spin-allowed d–d transition.

Since these bands are considered to be a split component of d–d transitions which are triply degenerate in the hexacarbonyl complexes, it seems worthwhile, to examine whether their

The maximum frequency of the first band of $[Cr(CO)_6]$ is taken as zero.

locations are in accord with Yamatera's theory.[11] A similar trial was successful for the corresponding cyano complexes.[12] Ethylenediamine-tetracarbonylchromium(0) is insoluble in cyclohexane, but the location of maximum of d-d transition in cyclohexane is estimated to be at about 22170 cm^{-1} from the solvent effect.[9] The transition of piperidinepentacarbonylchromium(0) is observed at 23800 cm^{-1} in cyclohexane. We can estimate the wave numbers of the spin-allowed d-d transition of $[Cr(CO)_6]^0$, $[Cr(CO)_5pip]^0$ and $[Cr(CO)_4en]^0$ to be 31300, 23800, and 22170 cm^{-1}, respectively in cyclohexane. The ratio (31300—23800)/(31300—22170) is 3.3/4. According to Yamatera's theory, the expected shift of split componenets of the first bands of two mixed carbonyl complexes, $[MA_5B]$ and *cis*-$[MA_4B_2]$ type, are shown in Table 4. If the observed first bands of the two mixed carbonyl complexes were regarded as due to the three components averaged simply, the expected ratio mentioned above should be $(1/6\delta)/(1/3\delta)=1/2$, which is much smaller than the observed value. However, it would be possible to assign the observed band of $[Cr(CO)_5pip]$ as the E component of the first band, since the magnitude of shift seems to be extraordinarily remarkable, and further the theoretically forbidden A_2 component would have weaker intensity than the allowed E component has. The observed band of $[Cr(CO)_4en]$ shows no indication of splitting, on the other hand, and might consist of the three components mixed one another. Thus the magnitude of shift is $1/4\ \delta$ for $[Cr(CO)_5pip]$ and $1/3\delta$ for $[Cr(CO)_4en]$ and the ratio is 3/4. This value equals nearly to the observed value. However, the present case will be the first example, where Yamatera's theory applied to the band shifts of mixed carbonyl complexes involving low oxidation state metal and π-character ligand. More detailed study would be needed to elucidate the applicability of this theory to such complexes.

Bands at 21000 to 22000 cm^{-1}. Broad and strong bands are observed in this region only in the spectra of aromatic diamine tetracarbonyl complexes. Their characteristics are different from those of the spin-allowed d-d bands mentioned above. The wave number of the absorption maximum increases with almost equal differences (700 cm^{-1}) in the order chromium, molybdenum and tungsten, and the extinction co-efficient in the same order for a given diamine. Two low-spin d^6 type complexes $[Fe(bp)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$, have metal to ligand charge transfer bands at about 20000 cm^{-1} [13] and these seem to correspond to those of diamine-tetracarbonyl complexes in question.

Bands in Other Regions. The bands of diamine-tetracarbonylchromium(0) at 30000 and those of molybdenum and tungsten complex at 33000 cm^{-1} (shoulders for aromatic diamine complexes) would be metal to carbonyl charge transfer bands, because their extinction coefficients are very great and they would possibly correspond to the bands of hexacarbonyl complexes at 35000 cm^{-1} ($^1A_{1g}$ to $^1T_{1u}$[1]) charge transfer).[2] The remaining bands of aliphatic diamine complexes at 40000 cm^{-1} appear to correspond to those of hexacarbonyl complexes at 44000 cm^{-1}, which are assigned to metal to carbonyl transition band in molecular orbital sense[2] (see Fig. 6).

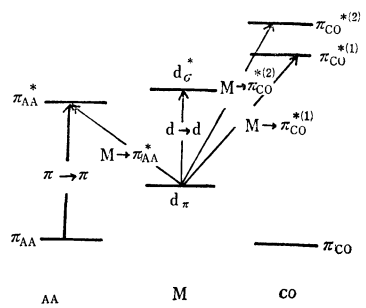

Fig. 6. Schematic energy level diagram for mixed carbonyls.

The sharp bands of bipyridyl-tetracarbonyl complexes at *ca.* 34000 cm^{-1} are little affected by the central metal and accompanied by shoulders

11) H. Yamatera, This Bulletin, **31**, 95 (1958).
12) K. Ohkawa, J. Fujita and Y. Shimura, *ibid.*, **38**, 66 (1965).
13) S. F. Mason, A. J. McCaffery and B. J. Norman, *Proc. Chem. Soc.*, **1964**, 259.

at a higher wave number by about 1000 cm^{-1}. They are likely due to intra-ligand transition ($\pi-\pi^*$), as exemplified by many bipyridyl complexes. The bands of phenanthroline-tetracarbonyl complexes at 37000 cm^{-1} seem also to be mainly due to the intra-ligand transition.

d_π-Levels. As seen from Figs. 3 and 4, the intra-ligand $\pi-\pi^*$ transition energy of the bipyridyl and the phenanthroline complexes is rather constant regardless of the kind of central metal. Hence the energy level of π_{AA}^* does not change significantly by complex formation with different metal atoms. Thus the shift of metal-to-diamine charge transfer bands would reflect the energy of metal d_π levels. This level is destabilized by 700 cm^{-1} each in going from molybdenum to tungsten and from tungsten to chromium.

On the other hand, the location of d-d band is rather independent of the kind of diamine for complexes of a given metal. The differences in d-d transition energies are estimated from the absorption spectra of ethylenediaminetetracarbonyl complexes of these metals: *i. e.* 1700 cm^{-1} between chromium and molybdenum, and 1600 cm^{-1} between chromium and tungsten complex. From these values and the d_π levels mentioned above, it is seen that the d_σ^* levels are destabilized in the order, chromium, molybdenum and tungsten, and the difference is 300 cm^{-1} between chromium and molybdenum, and 900 cm^{-1} between chromium and tungsten.

The difference of energy of π_{CO}^*[2] levels can be also calculated from the data in Table 3 and the relative height of the d_π levels. They are destabilized in the order, molybdenum, tungsten and chromium, and the difference is 100 cm^{-1} between molybdenum and tungsten, and 500 cm^{-1} between molybdenum and chromium. The order is the same as that for the d_π levels, to indicate that the antibonding levels of carbon monoxide in these complexes are stabilized as the d_π levels of the central metals are stabilized.

Rotatory Dispersion and Circular Dichroism of *l*-Propylenediaminetetracarbonyl Complexes. The curves are shown in Fig. 7. For the spin-allowed d-d transition of [$Cr(CO)_4$*l*-pn], negative and positive Cotton effect are observed from the lower wave number region. The RD curve has two inflection points, whose wave number coincides with the peaks of CD curve. *l*-Propylenediamine-tetracyanocobaltate(III) [$Co(CN)_4$*l*-pn]$^-$, isoelectronic to the chromium complex, also has such a CD pattern on the first d-d transition.[14] Although cyanide ions have weaker π-bonding character than carbonyl ligands has, the common pattern seems to support the assignment.

The splitting of d-d transition peak is not very great. The CD and the RD of molybdenum and tungsten complexes are very similar. They give only positive Cotton effect with large $\Delta\varepsilon$ values at the absorption maxima, and this feature is obviously different from that of the chromium complex. However, the reason cannot be appropriately accounted for at the present stage. Another positive Cotton effect seems to be in the $M\rightarrow\pi^*_{CO}$[1] C. T. region, but its detailed discussion cannot be made because of the difficulty in accurate measurement.

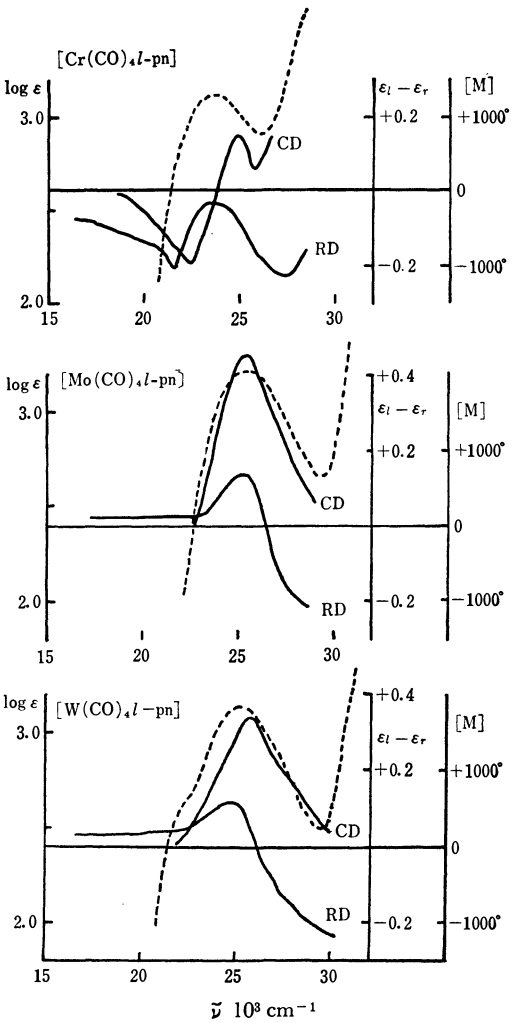

Fig. 7. Absorption spectra (····), CD and RD of the complexes [$Mo(CO)_4$ *l*-pn] (M=Cr, Mo, W) in methanol.

The authors thank Professor Muraji Shibata, Dr. Hiroaki Nishikawa and other members of Chemistry Department, Kanazawa University for their co-operation in measuring RD and CD of the complexes.

Electronic Structure of Tris(α-diimine)iron(II) Complexes

Tasuku Ito and Nobuyuki Tanaka

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

and Ichiro Hanazaki and Saburo Nagakura

The Institute of Physical and Chemical Research, Honkomagome, Bunkyo-ku, Tokyo and The Institute for Solid State Physics, The University of Tokyo, Azabu, Tokyo

(Received July 17, 1967)

The electronic structures of tris(α-diimine)iron(II) complexes have been investigated. The theoretical consideration has revealed that a considerable π-back donation takes place in the ground state and as a result unusually stable complexes of iron(II) are formed. The intense band which appears in the visible region has been proved to be due to the charge transfer transition from 3dπ AO (atomic orbital) of iron to the lowest vacant π MO (molecular orbital) of the ligand α-diimine. It was found both theoretically and experimentally that the π→π* transition with the lowest energy in α-diimine is polarized parallel to the nitrogen-nitrogen direction of the molecule, and that transition dipoles in the three ligands of tris(α-diimine)iron(II) ion interact to give resultant $A_1 \rightarrow A_2$ and $A_1 \rightarrow E$ transitions in the metal complex with D_3 symmetry. Details of the electronic structures, including the splitting energy and the intensity of the local excitation in α-diimine molecule and the nature of the charge transfer band, have been discussed.

It is well known that α-diimine, 2, 2'-bipyridine and 1, 10-phenanthroline form intensely colored stable complexes with iron(II) ions. The chromophoric nature and the unusual stability of such complexes have received a considerable attention and a number of experimental studies have been carried out.[1,2] Some researchers emphasized the importance of the π-bond formation between the ligands and the central metal ion.[3,4]

The aim of the present work is to extend the theoretical treatment previously developed for the acetylacetonato complexes[5] to tris(α-diimine)iron(II) ions and to study the electronic structures of the latter complexes as quantitatively as possible.*1 The absorption spectra, not only visible but also ultraviolet, of three kinds of tris(α-diimine)iron(II) complexes, namely tris(glyoxal-bis-*N*-methylimine)-, tris(biacetyl-bis-*N*-methylimine)- and tris(biacetyl-bis-*N*-butylimine)iron(II) ions, were measured to obtain the information on the electronic energy levels of the complexes.

Experimental

Materials. Tris(glyoxal-bis-*N*-methylimine)iron(II) iodide,[1] tris(biacetyl-bis-*N*-methylimine)iron(II) iodide[1] and tris(biacetyl-bis-*N*-butylimine)iron(II) tetrafluoroborate[6] were prepared by the methods described in the literatures. For the measurements of ultraviolet absorption spectra, the above iodides were converted to tetrafluoroborates. Among these three ligands, only biacetyl-bis-*N*-butylimine was able to be isolated by the method of Barany *et al.*[7]

Measurements. A Hitachi recording spectrophotometer Model EPS-3 was used for the measurements of the visible and the ultraviolet absorption spectra. The measurements in the vacuum ultarviolet region were made down to 182 mμ in aqueous solutions with 0.1 mm quartz cells using a vacuum ultraviolet spectrophotometer[8] at the Institute for Solid State Physics, the University of Tokyo.

Experimental Results

The absorption spectra of three kinds of tris(α-diimine)iron(II) complex were measured in aqueous solutions. As may be seen in Fig. 1, very similar spectra were obtained not only in the visible but also in the ultraviolet region, though a slight frequency shift was observed. A band

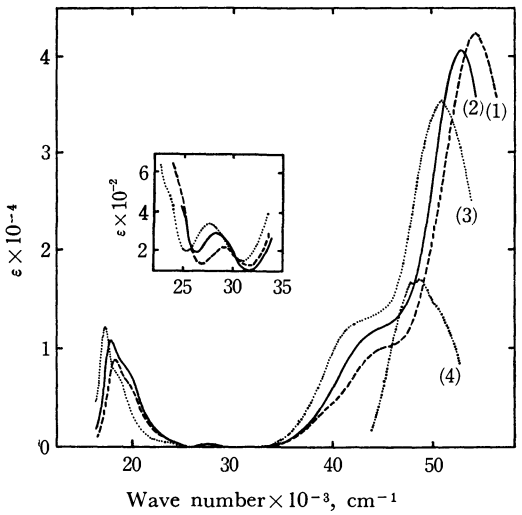

Fig. 1. The absorption spectra of (1) tris(glyoxal-bis-*N*-methylimine)iron(II) tetrafluoroborate, (2) tris(biacetyl-bis-*N*-methylimine)iron(II) tetrafluoroborate, (3) tris(biacetyl-bis-*N*-butylimine)iron-(II) tetrafluoroborate in an aqueous solution and (4) biacetyl-bis-*N*-butylimine in an ethanol solution.

appearing near 18000 cm^{-1}, which is the origin of the intense color, has received much attention. On the other hand, an intense band near 50000 cm^{-1} with a moderately intense shoulder has not attracted any attention, and nothing has been reported of it, probably because of the difficulty of the measurement. It should be noted that there are two shoulder bands which are difficult to observe. One appears in all cases near 25000 cm^{-1} with molar extinction coefficient of ~400, whereas the other is observed only with tris(glyoxal-bis-*N*-methylimine)iron(II) ion at ~38000 cm^{-1}.

The observed spectrum of the ligand, biacetyl-bis-*N*-butylimine, is also shown in Fig. 1. The spectrum of the free ligand was measured in an ethanol solution, which well accorded with the result of Barany *et al.*[7]

Theoretical Consideration and Calculation of Electronic Structure

The structures of an α-diimine molecule and a tris(α-diimine)iron(II) complex are shown in Figs. 2 and 3 together with the coordinate systems used. Since no experimental data of their geometrical structures were reported, it was assumed that the C–N and the C–C bond distance in the conjugated system were 1.37 and 1.46 Å, respectively, and also the angle between the C–N and the C–C bond was 120°.

The method of theoretical treatment was already described for the acetylacetonato complexes of transition metals.[5] The outline of the calculation will be given below. The integral values characteristic for the present complex ions, however, will be discussed in detail.*3

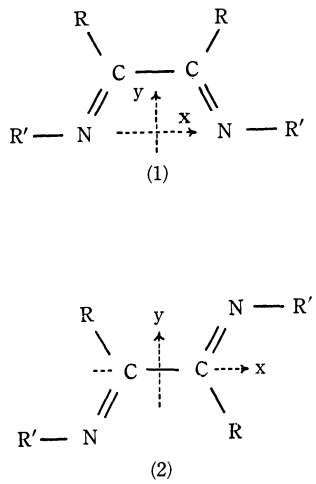

Fig. 2. Structure of α-diimine in cis form (1) and trans form (2). R=H, R′=CH_3, glyoxal-bis-*N*-methylimine; R=CH_3, R′=CH_3, biacetyl-bis-*N*-methylimine; R=CH_3, R′=C_4H_9, biacetyl-bis-*N*-butylimine.*2

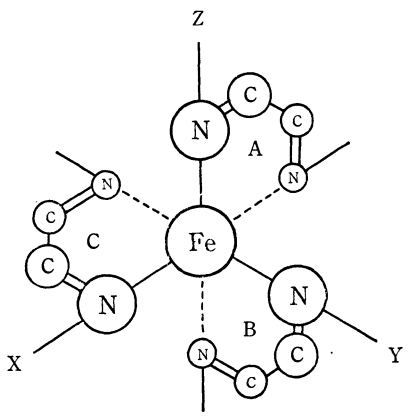

Fig. 3. The geometrical structure of tris(α-diimine)iron(II) complex and the coordinate system adopted. The Fe–N bond distance was assumed to be 2.00 Å. Only metal ion and chelate rings are shown.

SCF MO and the Lower Excited States of α-Diimine. α-Diimine molecule has four electrons in its π electron system which is made of two

*2 The IUPAC nomenclatures of glyoxal-bis-*N*-methylimine, biacetyl-bis-*N*-methylimine and biacetyl-bis-*N*-butylimine are *N*, *N*′-dimethyl-1, 2-ethanediimine, *N*, *N*′-dimethyl-2, 3-butanediimine and *N*, *N*′-dibutyl-2, 3-butanediimine, respectively.

*3 The numerical calculation was carried out by means of an OKITAC 5090H electronic computer at the Institute of Physical and Chemical Research, a NEAC 2230 at Tohoku University and a HITAC 5020E at the University of Tokyo.

TABLE 1. SCF MO AND ITS ORBITAL ENERGY (ε) OF α-DIIMINE IN CIS AND TRANS CONFORMATION

	Sym.	ε, eV	Coefficients of AO's

φ_4	b_g	0.513	0.3466	−0.6163	0.6163	−0.3466

carbon 2pπ AO's and two nitrogen 2pπ AO's. The nitrogen atom may be in an sp^2 hybrid valence state so that the lone-pair electrons in sp^2 hybrid AO's make a coordinate bond with a metal ion.

Following Pariser-Parr-Pople's treatment,[9,10] self-consistent field molecular orbitals (SCF MO's) were calculated. Then, the energies and the wave functions of lower excited states were determined by taking into consideration the configuration interaction (CI) between all singly-excited configurations. The valence state ionization potentials (I) and the electron affinities (A) were obtained from the table given by Pilcher and Skinner[11] as follows:

$I=11.22$ eV and $A=0.62$ eV for carbon, and

$I=14.51$ eV and $A=1.20$ eV for nitrogen.

On the zero-differential overlap approximation, the core resonance integrals between adjacent AO's were calculated with the relation,

$$\beta_{ij} = \frac{S_{ij}}{S_0}\beta_0 \qquad (1)$$

where S_0 (0.248) and β_0 (−2.39 eV) are the overlap integral and the core resonance integral for benzene molecule, respectively. Evaluating the overlap integral, S_{ij}, from the table of Mulliken *et al.*,[12] the core resonance integrals were determined to be

$$\beta_{CC} = -2.130 \text{ eV} \quad \text{and} \quad \beta_{CN} = -1.947 \text{ eV}.$$

α-Diimine molecule is considered to exist in preferred trans conformation in a free state, but in cis conformation when chelated in the metal complex. To examine the geometrical effect, the calculation of SCF-CI was carried out for both cis and trans conformations.

The calculated SCF MO's are shown in Table 1. The results of the calculation of the configuration interaction are summarized in Tables 2 and 3.

Barany *et al.*[7] reported that biacetyl-bis-*N*-butylimine showed the $\pi\rightarrow\pi^*$ absorption spectrum, at 207 mμ (5.99 eV) with the molar extinction coefficient of 17000. From the observed spectrum the oscillator strength of the band was determined to be ~0.5.

As can be seen from Tables 2 and 3, the excitation energy and the intensity calculated for the first excited state, especially, those of the trans conformation, are both in reasonable agreement with those of the observed band.*4 The lowest excited state is mainly composed of the $\varphi_2\rightarrow\varphi_3$ configuration in both conformation. The lowest transition is antisymmetric in cis conformation with respect to the symmetry plane perpendicular to the plane of the α-diimine molecule (x-polarization, see Fig. 2).*5

SCF Calculation of the Ligand in the Complex. The MO's of α-diimine obtained above are self-consistent with respect to the field of the free molecule. For the ligands in the complex ion, however, the effects of the electrostatic potential fields caused by the other ligands and the metal ion are considerably strong and must be taken into account in the SCF calculation, so that the MO's used for the calculation of the electronic

*4 Using the β_{CN} value larger than that evaluated by Eq. (1), the better agreement between the calculated and the observed results was obtained for the free ligand molecule but not for the ligand in the metal complex. It may be due to either the inaccuracy of the assumed interatomic distances or the essential difference of C–N bond character between in a free state and in a chelated state (see the discussions given in Refs. 4 and 13).

* Obtained for the case when the formal charge of iron is zero.

structure of the metal complex are self-consistent with the distribution of π-electrons in the other ligand, the electrostatic potential field of the central metal ion being taken into account.[5] Since the degree of σ-donation caused by the coordination was uncertain, the calculations were carried out for three cases in which the number of the formal charge of iron was assumed to be 0, +1 and +2. When the charge of the central metal ion is neutralized or partly neutralized, the σ-hole appears at the coordinated nitrogen atoms. The potential due to the σ-hole was also included in the core part of the Hartree-Fock operator. Its energy was calculated from Roothaan's table,[15] using Slater 2s and 2p AO of nitrogen and 2pπ AO of carbon. The parameters in the improved SCF calculation were determined similarly, but varied according to the degree of σ-donation.

Tables 4 and 5 show the results of the SCF-CI calculation obtained for the case when the formal charge of iron is zero. These results were used in the following calculation because of the reason discussed later.*6

15) C. C. J. Roothaan, "Tables of Two-Center Coulomb Integrals Between 1s, 2s and 2p Orbitals," Special Technical Report of the University Chicago (1955).

*6 The results for the other cases are reported elsewhere.[13] The parameters for nitrogen atom used in the calculation of the results given in Tables 4 and 5 are: I=18.68, A=4.52 and β_{CN}=−1.866 eV.

The Symmetries of the Electronic Configurations of Tirs(α-diimine)iron(II) Complex. It was found by the measurement of magnetic susceptibility that the electronic spin of tris(biacetyl-bis-*N*-methylimine)iron(II) iodide is singlet in its ground state.[3] Therefore, six electrons of iron(II) may be in $3d\pi$ AO, d_{xy}, d_{yz} and d_{zx} with antiparallel spins.

As we consider explicitly only π-electron systems, tris(α-diimine)iron(II) complexes can be divided into four components, namely, a π-electron system of metal ion and those of the three ligands. By placing π-electrons in the appropriate orbitals, the wave function for the ground configuration can be represented by the equation,

$$G = |(1\bar{1}2\bar{2})^{A}(1\bar{1}2\bar{2})^{B}(1\bar{1}2\bar{2})^{C}d_{xy}\overline{d_{xy}}d_{yz}\overline{d_{yz}}d_{zx}\overline{d_{zx}}|$$

where superscripts A, B and C denote the three coordinated α-diimine molecules shown in Fig. 3.

In addition to the ground configuration, eighteen charge transfer (CT) configurations and twelve locally excited (LE) configurations were taken into account, which are given in Table 6.

The CT configuration is constructed by transferring an electron from one of the $3d\pi$ AO's to the vacant MO φ_3 or φ_4 of one of the three ligands. The LE configuration is constructed by exciting an electron in an occupied MO of one of the three ligands to a vacant MO of the same ligand.

Table 6. Singly-excited configurations taken into account for the configuration interaction calculation

Configuration	Orbitals from	Orbitals to
CT	$\left\{\begin{matrix} d_{xy} \\ d_{yz} \\ d_{zx} \end{matrix}\right\}$	$\left\{\begin{matrix} \varphi_3^{A}, & \varphi_4^{A} \\ \varphi_3^{B}, & \varphi_4^{B} \\ \varphi_3^{C}, & \varphi_4^{C} \end{matrix}\right\}$
LE	φ_1^{A}	φ_3^{A} and φ_4^{A}
	φ_2^{A}	φ_3^{A} and φ_4^{A}
	Similar eight transitions in ligand B and C	

In a way similar to the ground configuration, the wave function for a CT configuration in which one electron is transferred from d_{xy} to φ_3^{A} is expressed as,

$$CT(d_{xy}\rightarrow\varphi_3^{A}) = \frac{1}{\sqrt{2}}\{|(1\bar{1}2\bar{2})^{A}(1\bar{1}2\bar{2})^{B}(1\bar{1}2\bar{2})^{C}\varphi_3^{A}\overline{d_{xy}}d_{yz}\overline{d_{yz}}d_{zx}\overline{d_{zx}}| + |(1\bar{1}2\bar{2})^{A}(1\bar{1}2\bar{2})^{B}(1\bar{1}2\bar{2})^{C}d_{xy}\overline{\varphi_3}^{A}d_{yz}\overline{d_{yz}}d_{zx}\overline{d_{zx}}|\}$$

Similarly, the wave function for a LE configuration in which one electron in φ_2^{A} is excited to φ_3^{A} is expressed as,

$$LE(\varphi_2^{A}\rightarrow\varphi_3^{A}) = \frac{1}{\sqrt{2}}\{|(1\bar{1}3\bar{2})^{A}(1\bar{1}2\bar{2})^{B}(1\bar{1}2\bar{2})^{C}d_{xy}\overline{d_{xy}}d_{yz}\overline{d_{yz}}d_{zx}\overline{d_{zx}}| + |(1\bar{1}2\bar{3})^{A}(1\bar{1}2\bar{2})^{B}(1\bar{1}2\bar{2})^{C}d_{xy}\overline{d_{xy}}d_{yz}\overline{d_{yz}}d_{zx}\overline{d_{zx}}|\}$$

Other CT and LE configurations are expressed in a similar way. By taking the linear combination of the above-mentioned wave functions, the ground, the CT and the LE configurations are classified into the irreducible representations of D_3 symmetry, which are given below.

A_1:

$$G = G$$

$$CT_1^{A_1} = \frac{1}{\sqrt{6}}\{CT(d_{xy}\rightarrow\varphi_3^{A}) - CT(d_{yz}\rightarrow\varphi_3^{A}) - CT(d_{xy}\rightarrow\varphi_3^{B}) + CT(d_{zx}\rightarrow\varphi_3^{B}) + CT(d_{yz}\rightarrow\varphi_3^{C}) - CT(d_{zx}\rightarrow\varphi_3^{C})\}$$

$$CT_2^{A_1} = \frac{1}{\sqrt{6}}\{CT(d_{xy}\rightarrow\varphi_4^{A}) + CT(d_{yz}\rightarrow\varphi_4^{A}) + CT(d_{xy}\rightarrow\varphi_4^{B}) + CT(d_{zx}\rightarrow\varphi_4^{B}) + CT(d_{yz}\rightarrow\varphi_4^{C}) + CT(d_{zx}\rightarrow\varphi_4^{C})\}$$

$$CT_3^{A_1} = \frac{1}{\sqrt{3}}\{CT(d_{zx}\rightarrow\varphi_4^{A}) + CT(d_{yz}\rightarrow\varphi_4^{B}) + CT(d_{xy}\rightarrow\varphi_4^{C})\}$$

$$LE_1^{A_1} = \frac{1}{\sqrt{3}}\{LE(\varphi_1^{A}\rightarrow\varphi_3^{A}) + LE(\varphi_1^{B}\rightarrow\varphi_3^{B}) + LE(\varphi_1^{C}\rightarrow\varphi_3^{C})\}$$

$$LE_2^{A_1} = \frac{1}{\sqrt{3}}\{LE(\varphi_2^{A}\rightarrow\varphi_4^{A}) + LE(\varphi_2^{B}\rightarrow\varphi_4^{B}) + LE(\varphi_2^{C}\rightarrow\varphi_4^{C})\}$$

A_2:

$$CT_1^{A_2} = \frac{1}{\sqrt{6}}\{CT(d_{xy}\rightarrow\varphi_3^{A}) + CT(d_{yz}\rightarrow\varphi_3^{A}) + CT(d_{xy}\rightarrow\varphi_3^{B}) + CT(d_{zx}\rightarrow\varphi_3^{B}) + CT(d_{yz}\rightarrow\varphi_3^{C}) + CT(d_{zx}\rightarrow\varphi_3^{C})\}$$

$$CT_2^{A_2} = \frac{1}{\sqrt{3}}\{CT(d_{zx}\rightarrow\varphi_3^{A}) + CT(d_{yz}\rightarrow\varphi_3^{B}) + CT(d_{xy}\rightarrow\varphi_3^{C})\}$$

$$CT_3^{A_2} = \frac{1}{\sqrt{6}}\{CT(d_{xy}\rightarrow\varphi_4^A) - CT(d_{yz}\rightarrow\varphi_4^A) - CT(d_{xy}\rightarrow\varphi_4^B) + CT(d_{zx}\rightarrow\varphi_4^B) + CT(d_{yz}\rightarrow\varphi_4^C) - CT(d_{zx}\rightarrow\varphi_4^C)\}$$

$$LE_1^{A_2} = \frac{1}{\sqrt{3}}\{LE(\varphi_2^A\rightarrow\varphi_3^A) + LE(\varphi_2^B\rightarrow\varphi_3^B) + LE(\varphi_2^C\rightarrow\varphi_3^C)\}$$

$$LE_2^{A_2} = \frac{1}{\sqrt{3}}\{LE(\varphi_1^A\rightarrow\varphi_4^A) + LE(\varphi_1^B\rightarrow\varphi_4^B) + LE(\varphi_1^C\rightarrow\varphi_4^C)\}$$

E:

$$CT_1^E = \frac{1}{2}\{CT(d_{xy}\rightarrow\varphi_3^B) + CT(d_{zx}\rightarrow\varphi_3^B) - CT(d_{yz}\rightarrow\varphi_3^C) - CT(d_{zx}\rightarrow\varphi_3^C)\}$$

$$CT_2^E = \frac{1}{\sqrt{12}}\{2CT(d_{xy}\rightarrow\varphi_3^A) - 2CT(d_{yz}\rightarrow\varphi_3^A) - CT(d_{zx}\rightarrow\varphi_3^B) + CT(d_{xy}\rightarrow\varphi_3^B) - CT(d_{yz}\rightarrow\varphi_3^C) + CT(d_{zx}\rightarrow\varphi_3^C)\}$$

$$CT_3^E = \frac{1}{\sqrt{2}}\{CT(d_{yz}\rightarrow\varphi_3^B) - CT(d_{xy}\rightarrow\varphi_3^C)\}$$

$$CT_4^E = \frac{1}{\sqrt{12}}\{2CT(d_{xy}\rightarrow\varphi_4^A) + 2CT(d_{yz}\rightarrow\varphi_4^A) - CT(d_{xy}\rightarrow\varphi_4^B) - CT(d_{zx}\rightarrow\varphi_4^B) - CT(d_{yz}\rightarrow\varphi_4^C) - CT(d_{zx}\rightarrow\varphi_4^C)\}$$

$$CT_5^E = \frac{1}{2}\{CT(d_{zx}\rightarrow\varphi_4^B) - CT(d_{xy}\rightarrow\varphi_4^B) - CT(d_{yz}\rightarrow\varphi_4^C) + CT(d_{zx}\rightarrow\varphi_4^C)\}$$

$$CT_6^E = \frac{1}{\sqrt{6}}\{2CT(d_{zx}\rightarrow\varphi_4^A) - CT(d_{yz}\rightarrow\varphi_4^B) - CT(d_{xy}\rightarrow\varphi_4^C)\}$$

$$LE_1^E = \frac{1}{\sqrt{6}}\{2LE(\varphi_1^A\rightarrow\varphi_3^A) - LE(\varphi_1^B\rightarrow\varphi_3^B) - LE(\varphi_1^C\rightarrow\varphi_3^C)\}$$

$$LE_2^E = \frac{1}{\sqrt{6}}\{2LE(\varphi_2^A\rightarrow\varphi_4^A) - LE(\varphi_2^B\rightarrow\varphi_4^B) - LE(\varphi_2^C\rightarrow\varphi_4^C)\}$$

$$LE_3^E = \frac{1}{\sqrt{2}}\{LE(\varphi_2^B\rightarrow\varphi_3^B) - LE(\varphi_2^C\rightarrow\varphi_3^C)\}$$

$$LE_4^E = \frac{1}{\sqrt{2}}\{LE(\varphi_1^B\rightarrow\varphi_4^B) - LE(\varphi_1^C\rightarrow\varphi_4^C)\}$$

There is another similar set of ten wave functions with E representation which are orthogonal to the above wave functions.

Configuration Interaction. The matrix elements of the total electronic Hamiltonian between the configurations were calculated in a way similar to the case of the acetylacetonato complex.*7 The diagonal element of the CT configuration, $E_{CT(i)}$, is represented by means of the equation,

$$E_{CT(i)} = I(\text{metal}) - A_{(i)}(\text{ligand}) + \Delta_{(i)} \qquad (2)$$

where, I(metal) is the valence state ionization potential of 3dπ AO of iron, $A_{(i)}$(ligand), the electron affinity to put an electron into the ith vacant MO of the ligand and $\Delta_{(i)}$, the electrostatic interaction energy between the electron donor and acceptor. $A_{(i)}$(ligand) may be equal to the orbital energy with sign reversed of the MO to which an electron is transferred. There remains difficulty in the actual evaluation of E_{CT}, because it is very sensitive to the σ-electron distribution and, also, because $A_{(i)}$(ligand) cannot be determined accurately (see the discussion given in Ref. 5).

Figure 4 shows the relation between $E_{CT(1)}$ and the formal charge of iron, which was roughly evaluated by the calculation of an appropriate two-center repulsion integral with the point charge approximation. Considering the fact that the CT band appears at about 2.2 eV ($\sim$18000 cm^{-1}), the formal charge of iron seems to be close to zero though there is some uncertainty in the estimated value of E_{CT}. Therefore, the MO's of the ligands used in the following calculation are those constructed with the condition that the formal charge of iron is zero.

As is evident from the above discussion, the accurate evaluation of E_{CT} is quite difficult. Therefore, in the present calculation, $E_{CT(1)}$, the diagonal element of CT configurations corresponding to d$\rightarrow\varphi_3$ transition, was treated as a parameter and set to be 1.0 eV. The value of $E_{CT(2)}$ corresponding to d$\rightarrow\varphi_4$ transition was determined to be $E_{CT(2)} = E_{CT(1)} + 3.87$ eV, considering the difference of $A_{(i)}$ and $\Delta_{(i)}$ between φ_3 and φ_4.

*7 The details of the matrix elements are shown in Ref. 13.

** Only main configurations are written.

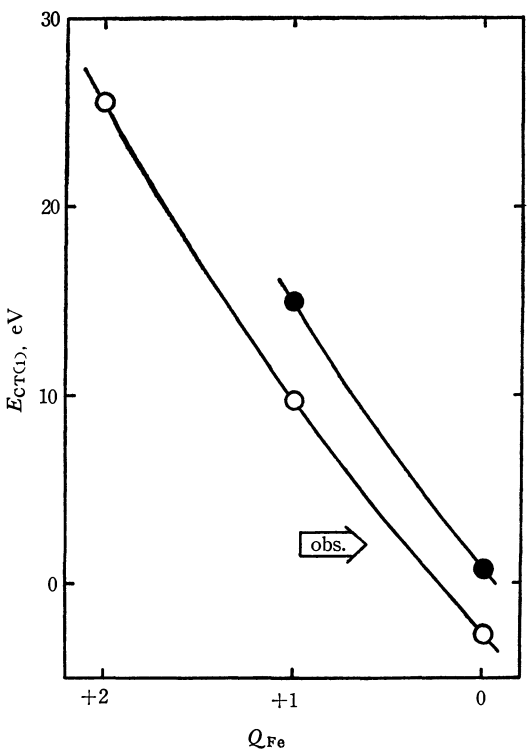

Fig. 4. The relation between $E_{CT(1)}$ and the formal charge of iron, Q_{Fe}, where $E_{CT(1)}$ is the diagonal element of the CT configuration with the lowest energy. ○ and ● correspond to d^n and $d^{n-1}s$ configuration, respectively.

The diagonal elements of LE configurations are expressed as the sum of the excitation energy of the chelated ligand molecule, $E_{LE}(\varphi_i\rightarrow\varphi_j)$, and the additional term including the integral K'_{ij}. The latter is the repulsion integral defined by

$$K'_{ij}=\int\varphi_i^{A}(1)\varphi_j^{A}(1)\frac{e^2}{r_{12}}\varphi_i^{B}(2)\varphi_j^{B}(2)d\tau_{12} \quad (3)$$

The K'_{ij}'s were calculated with the zero-differential overlap and the point charge approximation.*8

The off-diagonal matrix elements between G and CT and between CT and LE were accounted for only by means of β, the core resonance integral between the appropriate $3d\pi$ AO of iron and $2p\pi$ AO of nitrogen. It was evaluated with the relation,[16]

$$\beta=-S\frac{I_{Fe}+I_N}{2} \quad (4)$$

*8 In contrast with the treatment reported previoulsy,[5] the LE configuration is constructed with only one kind of singly-excited configuration. Therefore, $E_{LE}(\varphi_i\rightarrow\varphi_j)$'s appearing in the diagonal elements of the LE configurations correspond to the transition energies without CI. The interactions among the LE configurations were taken into account in the calculation of the CI for the whole complex.

16) R. S. Mulliken, *J. Phys. Chem.*, **56**, 295 (1952).

where S is the overlap integral, and I_{Fe} and I_N are the valence state ionization potentials of iron and nitrogen, respectively. The estimation of the overlap integral was made with the aid of the Slater AO of nitrogen and the two-term expanded AO of iron determined by Richardson *et al.*[17] It was calculated to be 0.084, using the table given by Jaffé.[18] I_{Fe} and I_N are 5.07 eV and 18.68 eV respectively and β amounts to -0.99 eV.

The results obtained by the configuration interaction calculation are shown in Table 7, and the calculated transition energy and oscillator strength are compared with the observed ones in Table 8.

Stabilization caused by the Charge Transfer. According to the present theoretical investigation, the energy of the ground state is lower than that of the ground configuration by 1.39 eV (32.0 kcal/mol). This stabilization is caused by the interaction between the ground and the CT configurations; the contribution of the CT configuration to the ground state amounts to about 30%. This means that the so-called π-back donation from the metal to the ligands is considerably large. This phenomenon may be responsible for the one of the origins of the unusual stability of tris(α-diimine)iron(II) complexes.

Interpretation of the Electronic Spectra

The spectra given in Fig. 1 exhibit a weak absorption band near 28000 cm^{-1} in all tris(α-diimine)iron(II) complexes investigated. The careful measurement also revealed a shoulder band with almost the same intensity near 25000 cm^{-1}. The shoulder and the peak may be assigned to the d→d transitions which correspond to the $^1A_{1g}\rightarrow {}^1T_{1g}$ and the $^1A_{1g}\rightarrow {}^1T_{2g}$ transition of the octahedral case, in view of their low intensities and also on the basis of the study reported by Shimura *et al.*[19] They found that the absorption frequencies of the iron(II) complex are smaller by 7×10^{13} sec^{-1} than those of the corresponding cobalt(III) complex independent of the kind of ligand, as far as the same kind of absorption bands are compared and both complexes assume the diamagnetic $(3d)^6$ configuration. Any further discussion on these bands is not given, because the authors were concerned with a parity-allowed transition of the π-electron system in the present study.

From the results given in Table 7, it can be concluded that the observed intense band at the visible region is reasonably assigned to the almost pure CT absorption accompanying the π-electron migration from $3d\pi$ AO of iron to the lowest vacant π MO, φ_3, of the ligands.

Since the α-diimine ligands has C_{2v} symmetry in the cis form, the $\pi\rightarrow\pi^*$ transition in the ligand has a transition moment either parallel (x) or perpendicular (y) to the nitrogen-nitrogen direction in the plane of the molecule (see Fig. 2). As has been disucssed by Larsen *et al.*,[20] the x-polarized transition in three ligands in the metal complex of D_3 symmetry gives rise to the $A_1\rightarrow A_2$ and the $A_1\rightarrow E$ transition, while y-polarized transition, the $A_1\rightarrow A_1$ and the $A_1\rightarrow E$ one, the $A_1\rightarrow A_1$ transition being symmetrically forbidden. Consequently, if the transition is y-polarized, there should appear a single band with its intensity three times as large as that of single α-diimine ligand. On the other hand, if the transition is x-polarized, the intensity ratio of the LE bands corresponding to the $A_1\rightarrow E$ and the $A_1\rightarrow A_2$ ought to be 1 : 2. Furthermore, the energy separation between these bands is $6K'_{ij}$ for $\varphi_i\rightarrow\varphi_j$ transition.

The observed spectrum in the ultraviolet region was composed of an intense peak and a moderately intense shoulder at the side of longer wavelengths. In view of their large intensities and energies and also in comparison with the absorption spectrum of the free ligand (see Fig. 1), both of them should be assigned to the lowest LE transitions. In fact, the calculated result predicts that the LE transitions corresponding to the x-polarized excitation $\varphi_2\rightarrow\varphi_3$ in the ligand appear in this region with splitting by 0.67 eV into the A_2 and E components. The observed spectra really show the splitting, which supports, at least qualitatively, the theoretical prediction. Quantitatively, however, the splitting was found to be nearly twice as large as the calculated value. This discrepancy seems to be explained by considering the mixing of the second CT transition d→φ_4 into the loewst LE transitions. The calculation has revealed that this second CT configuration appears in almost the same energy as the lowest LE configuration and that its mixing especially with the E component of the LE band is significant.*9

Therefore, it seems reasonable to conclude that the main peak results from the LE transition with $A_1\rightarrow A_2$ symmetry whereas the shoulder is due to the overlap of the d→φ_4 transition and the LE transition with $A_1\rightarrow E$ symmetry or their mixed states.

The replacement of the alkyl groups (R or R') attached to the conjugated system of the ligand with a larger alkyl group gives rise to a shift of absorption maxima of both the visible and the

*9 Another shoulder band is observed near 38000 cm^{-1} in the spectrum of tris(glyoxal-bis-*N*-methylimine)-iron(II) complex, which may be due to the interaction of CT(d→φ_4) and the E component of LE band.

ultraviolet bands toward longer wavelengths, as shown in Fig. 1. Such a frequency shift was also observed for alkyl derivatives of butadiene.[21] Although the sensitivity to the alkyl substitution is different between the visible and the ultraviolet band, the origin of the frequency shift may be the same. It is also said that the larger the substituent is, the lower the energy of the lowest vacant orbital may be.

The authors wish to express their hearty thanks to Dr. Koji Kaya of the Institute of Physical and Chemical Research, Tokyo, for measuring the vacuum ultraviolet spectra. They also thank the Ministry of Education for the financial support granted for this research.

Complexes of Copper Chlorides with Benzophenoneimine

Akira MISONO, Tetsuo OSA and Seiichiro KODA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received August 1, 1967)

We tried to prepare complexes of copper chlorides with benzophenoneimine. The complex $CuCl_2 \cdot 2Ph_2C{=}NH$ and the complex $CuCl \cdot Ph_2C{=}NH$ were newly prepared, and some of their properties were investigated by physico-chemical techniques. Besides these, two other complexes were obtained, but they were not completely stoichiometric compounds.

It is well known that aldimines and ketimines which can act as multi-dentate ligands form stable complexes with copper ions.[1] Several investigations have been published on the complexes of amines with copper halides.[2] However, there seems not yet to have been any report on the complex formation of benzophenoneimine with copper halides. The present authors have been interested in the cleavage of the bond between nitrogen and hydrogen[3] and have tried to prepare complexes of copper chlorides with benzophenoneimine in order to clarify the effect of complex formation on the oxidation of benzophenoneimine. In this paper, the authors wish to report on the preparation of such complexes.

Results and Discussion

It was observed that when benzophenoneimine was added to the acetonitrile solution of copper(II) chloride, some precipitates began to appear immediately. They were found to be complexes of copper(II) chloride with benzophenoneimine. From the precipitates, the complex, $CuCl_2 \cdot 2Ph_2C{=}NH$ (I) was isolated as a grey-purple powder. It became a green solution in chloroform. The curve of the absorption spectrum (Fig. 1, full line: ν_{max} ~13.7 kK, $\log \varepsilon = 2.3$) was similar to that of copper(II) dipyridine dichloride ($CuCl_2py_2$), though the absorption maximum of $CuCl_2py_2$ due to the d-d transition is at about 13.2 kK (in

pyridine).[4] This complex was slightly soluble in benzene and acetonitrile. The e. p. r. signal of this complex showed a typical resolution of the d^9 Cu(II) resonance according to the anisotropy in the g values (g_1=2.21, g_2=2.03), as shown in Fig. 2. The g values can be estimated approximately from the e. p. r. spectra of the complex in the

4) E. Ochiai, *Tetrahedron*, **20**, 1831 (1964); V. S. Sergeeva and S. V. Plyushcheva, *Zh. Neorgan. Khim.*, **7**, 2357 (1962).

powder state.[5] For a comparative study, the e. p. r. spectrum of $CuCl_2py_2$ in the powder state was observed under similar conditions (Fig. 2, dashed line). The observed g values ($g_1=2.23$, $g_2=2.07$) approximated the g values obtained in the vitreous state ($g_{\parallel}=2.241$, $g_{\perp}=2.079$).[6] The g values of the complex I were smaller than those of the triethylamine complex of copper(II) chloride, $CuCl_2\cdot 2Et_3N$ ($g_1=2.27$, $g_2=2.06$).[2a] Generally speaking, the g values decrease with an increase in the "covalency" between ligands and the central metal ion.[7] Therefore, smaller g values of the complex I in comparison with the complex $CuCl_2\cdot 2Et_3N$ may indicate a greater "covalency", which can be expected from the existence of a C=N double bond and the phenyl groups adjacent to it in the ligand, benzophenoneimine. The complex I was stable at room temperature in the solid state, as can be seen from the invariable results of the two elementary analyses, one of which was performed soon after the preparation, and the other, after 12 days. However, it was gradually decomposed at higher temperatures to yield a dark complicated mass, while the e. p. r. signal due to the divalent copper disappeared. This complex or its mixture with its decomposition products melted at about 180°C (Fig. 3, dashed line), at which time, the e. p. r. signal decreased rapidly (Fig. 4). The decomposition products seemed to be composed of various components, from which $CuCl\cdot Ph_2C{=}NH$ (*cf.* the next section) was isolated. The decomposition of the complex I may be a thermal-induced oxidation-reduction, similar to that of the triethylamine complex of copper(II) chloride, $CuCl_2\cdot 2Et_3N$.[2a] However, it is interesting to note that this complex, I, was considerably more stable than $CuCl_2\cdot 2Et_3N$, which has been reported to decompose completely at 20°C.[2a]

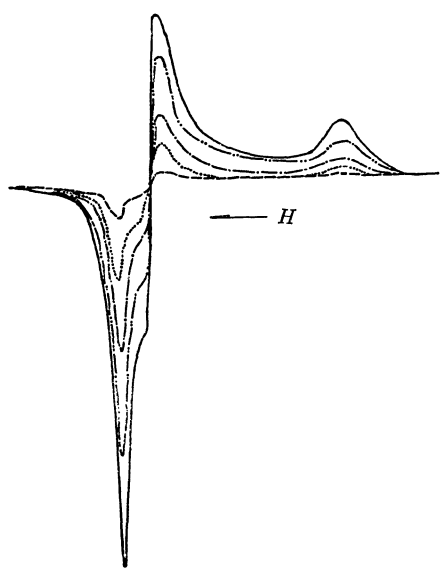

Fig. 4. The decrease of the e. p. r. signal according to the thermal decomposition.
———: Before heating and/or after 30 min (100°C)+10 min (130°C)
—··—: After additional 15 min (150°C)+20 min (160°C)+5 min (165°C)+5 min (170°C)
—·—·: After additional 5 min (177°C)
·····: After additional 5 min (180°C)
———: After additional 20 min (180°C)

Besides the complex I, another complex, II, was produced. It did not seem to be a simple species, but was perhaps mainly a 1 : 1 complex. This complex was produced as a yellow precipitate and as a by-product when the complex I was recrystallized from a hot chloroform solution. Besides, a similar yellow precipitate was formed when copper(II) chloride was stirred into a chloroform solution of the complex I. This complex, II, was insoluble in chloroform or in other ordinary solvents. It seemed probable that this complex was a binuclear (or sometimes polynuclear) complex bridged by chloride ions. The relation between the complex I and the complex II may correspond to that between the copper(II) chloride complexes of acetonitrile ($CuCl_2\cdot 2CH_3CN$ and $Cu_2Cl_4(CH_3CN)_2$, $Cu_3Cl_6(CH_3CN)_2$).[8]

The complex I was also produced in chloroform by mixing copper(II) chloride with benzophenoneimine.

A pale yellow complex, $CuCl\cdot Ph_2C{=}NH$ (III), and a red complex, $CuCl\cdot nPh_2C{=}NH$ (IV) (n is about two), were obtained by mixing benzophenoneimine with copper(I) chloride in benzene. The molecular weight of the complex III in benzene, obtainable from the vapor pressure osmometry at about 30°C, corresponded to 1.35 times the formula weight. Considering the facts[9] that the copper(I) halide complexes with phosphine derivatives were tetrameric in crystalline state and were in equilibrium with tetrameric and monomeric forms in solutions, this value seems not to be unreasonable. This complex was mostly transparent in the visible region (Fig. 1, dashed line). The complex III was quite stable against oxygen in the solid state, but the benzene solution of this complex absorbed oxygen rather easily and turned gradually greenish-brown. This complex melted at about 135°C. Correspondingly, the absorption of heat was observed to begin at about

140°C (Fig. 3, full line). The discrepancy in the temperatures may be caused by the faster elevating speed of the temperature in the differential thermal analysis.

The complex IV was unstable, judging from the fact that the *n* value often easily changed. For example,[2b] the complex $CuCl\cdot(C_2H_5)_2NH$ is known to be more stable than the complex, $CuCl\cdot 2(C_2H_5)_2NH$.

The coordinated benzophenoneimine showed, at different positions, absorption peaks corresponding to those at 3252 (N-H stretching), 1363, 1197, and 892 cm^{-1} in the free benzophenoneimine. The other peaks in the region from 4000 to 500 cm^{-1} shifted slightly in the coordinated benzophenoneimine (Fig. 5).

Experimental

Reagents. *Copper(II) Chloride.* Anhydrous copper(II) chloride was prepared through the dehydration by thionyl chloride from commercial copper(II) chloride dihydrate.[10]

Copper(I) Chloride. Commercial copper(I) chloride was treated by dilute sulfurous acid.[11]

Benzophenoneimine. Benzophenoneimine was prepared from phenyl magnesium bromide and benzonitrile[12] and was then distilled and stored under dried nitrogen (bp 146.5—148°C/7.5 mmHg). It contained a small amount of benzophenone as an impurity, judging from its infrared spectrum.

Benzene and n-Hexane. Commercial solvents were dried with sodium, distilled, and stored under dried nitrogen.

Acetonitrile. Commercial acetonitrile was dried with phosphorus pentoxide, distilled, and stored under dried nitrogen.

Chloroform. Commercial chloroform was passed through an alumina column, distilled, and stored under dried nitrogen.

Copper(II) Dipyridine Dichloride ($CuCl_2py_2$). This complex was precipitated by adding pyridine to a methanol solution of copper(II) chloride.

Found: C, 40.66; H, 3.36; N, 9.52%. Calcd. for $CuCl_2\cdot 2C_5H_5N$: C, 41.03; H, 3.45; N, 9.57%.

Procedure. All parts of the preparation of the complexes were carried out under dried nitrogen.

The e. p. r. spectra were observed with a Japan Electron Optics Laboratory Co., Ltd., e. p. r. spectrometer, Model JS-3BS-X. The value of field strength was calculated from the observed signal of the manganese marker. The estimation of the *g* values were based on accurate measurements of the changes in field strength from the point of approximate calibration.

The infrared spectra were measured with two Japan Spectroscopic Co., Ltd., infrared spectrometers, Model DS-402G and Model DS-301. The spectra of the complexes were measured in the KBr disk (sample 1 mg/KBr 150 mg).

The absorption spectra were observed with a Hitachi Co., Ltd., Hitachi spectrometer, Model ESP-2.

The thermal analyses were carried out with a Rigaku-Denki Co., Ltd., differential thermal and thermogravimetric analyzer.

The melting points were observed with a Yanagimoto Seisakusho Co., Ltd., micro-melting-point apparatus.

Copper(II) Chloride Complexes. a) To 150 m*l* of acetonitrile there were added 0.618 g (4.59 mmol) of copper(II) chloride and 1.701 g (9.40 mmol) of benzophenoneimine. The mixture was then stirred for 1 hr at room temperature, and the precipitates thus formed were separated (1.990 g). These precipitates were recrystallized from a chloroform solution. A grey-purple powder was thus obtained.

Found: C, 61.59; H, 4.30; N, 5.69%. Calcd for $CuCl_2\cdot 2Ph_2C{=}NH$: C, 62.85; H, 4.47; N, 5.64%.

After it had been stored for 12 days under nitrogen at room temperature, the powder was again analyzed.

Found: C, 61.54; H, 4.30; N, 5.67%.

A yellow-brown powder was also obtained as a by-product in the course of recrystallization. This was washed with sufficient amounts of acetonitrile and chloroform.

Found: C, 47.51; H, 3.43; N, 4.52%. Calcd for $CuCl_2\cdot Ph_2C{=}NH$: C, 49.46; H, 3.52; N, 4.44%.

b) In 90 m*l* of chloroform, 4.031 g (30.0 mmol) of copper(II) chloride and 3.567 g (19.7 mmol) of benzophenoneimine were stirred for 45 min at room temperature. The resulting mixture was then filtered. To the green filtrate 90 m*l* of acetonitrile were added, and the resulting precipitate was separated. A grey-purple powder was thus obtained; 0.820 g.

Found: C, 61.23; H, 4.43; N, 5.81; Cl, 15.11%. Calcd for $CuCl_2\cdot 2Ph_2C{=}NH$: C, 62.85; H, 4.47; N, 5.64; Cl, 14.27%.

Thermal Decomposition of the Copper(II) Chloride Complex, I, $CuCl_2 \cdot 2Ph_2C{=}NH$. The complex I was introduced into an e. p. r. sample tube under reduced pressure. This tube was heated in a thermostat at a certain temperature for a desired period. Then the e. p. r. spectrum was observed at room temperature. This procedure was repeated until the signal due to divalent copper disappeared (100°C, 30 min; 130°C, 10 min; 150°C, 15 min; 160°C, 20 min; 165°C, 5 min; 170°C, 5 min; 175°C, 5 min; 177°C, 5 min; 180°C, 5 min; 180°C, 20 min).

The complex I, in a sealed tube under dried nitrogen, was heated at 175°C for 30 min. A dark mass (viscous around 175°C) remained. This was washed with *n*-hexane, and then with hot benzene. From the benzene washing, a yellow powder was obtained after evaporating the benzene. This powder was again dissolved in benzene. By adding *n*-hexane to this benzene solution, a yellow powder was precipitated. The infrared spectrum of this powder was almost identical with that of the complex III.

Found: C, 55.84; H, 4.00; N, 5.53; Cl, 13.69%. Calcd for $CuCl \cdot Ph_2C{=}NH$: C, 55.71; H, 3.91; N, 5.00; Cl, 12.65%.

Copper(I) Chloride Complexes. In 25 m*l* of benzene, 1.064 g (10.7 mmol) of copper(I) chloride and 5.874 g (32.4 mmol) of benzophenoneimine were mixed and then stirred for 140 min at room temperature; this resulted in a red solution. To this solution were added 50 m*l* of *n*-hexane. A red viscous liquid was then separated. This liquid was dried under reduced pressure (about 20 mmHg) for 90 min. To the residue there were then added 25 m*l* of benzene. Some insoluble pale yellow needles were obtained after filtration; 2.160 g.

Found: C, 56.02; H, 4.23; N, 4.98; Cl, 12.58%. Calcd for $CuCl \cdot Ph_2C{=}NH$: C, 55.71; H, 3.96; N, 5.00; Cl, 12.65%.

From the benzene solution, there remained a red viscous mass after the benzene had been stripped off. This mass gradually crystallized to yield a red, needle-like powder. The powder was then washed with a small amount of *n*-hexane, and analyzed.

Found: C, 68.77; H, 4.93; N, 6.03%. Calcd for $CuCl \cdot 2Ph_2C{=}NH$: C, 67.66; H, 4.81; N, 6.07; Cl, 7.68%.

In another case, however, the powder was washed with a larger amount of *n*-hexane and then analyzed.

Found: C, 61.42; H, 4.36; N, 5.81; Cl, 10.23%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 377—380 (1968)

Electrometric Studies on the Reaction between Pb(II) and Alkali Meta-Vanadate

R. S. SAXENA and C. P. SHARMA

Department of Chemistry, Malaviya Regional Engineering College, Jaipur, India

The reaction between Pb^{2+} and VO_3^- was investigated by means of electrometric techniques involving potentiometric, pH-metric and conductometric titrations between $Pb(NO_3)_2$ and $NaVO_3$ at several concentrations, with each of the reagents alternately used as titrant. The sharp breaks and inflections obtained in titration curves evidenced the formation of lead meta-vanadate having the molecular composition $PbO \cdot V_2O_5$ at pH range 4.25—5.25. The precipitation of the compound has been found to be almost quantitative and the titration results are very accurate and reproducible.

Meagre references are available in the literature on the study of lead vanadates and most of the workers have based their conclusions on the analytical studies of the products formed by double decomposition. Berzelius, Roscoe and Carnot[1] obtained lead meta-vanadate by treating ammonium or alkali meta-vanadate with lead salts. Zolotavin[2] made a study of sparingly soluble vanadates of some metals including lead from the point of law of series by analysis and reported that precipitation of lead meta-vanadate was complete and instantaneous. The lowest pH at which such precipitation took place was determined. Henriguiter[3] reported the formation of lead meta-vanadate as a function of the pH and obtained $PbO \cdot V_2O_5$ by double decomposition and recommended it as a gravimetric method for determination of lead. In view of the insufficient details of the reports of earlier workers on analytical studies and in the absence of any available electrometric data on the subject it was considered desirable and necessary to investigate precisely the reaction between lead salts and alkali meta-vanadate, employing recent electrometric techniques which

have provided more conclusive information on the formation and composition of such compounds.[4-8]

Experimental

Merck's guaranteed extra pure reagents, V_2O_5, NaOH and lead nitrate were used and their solutions prepared in air free conductivity water. The standard solution of sodium meta-vanadate was prepared by adding four moles of HNO_3 to a solution containing one mole of ortho-vanadate at 100°C. The latter was prepared by dissolving one mole of V_2O_5 in boiling solution of NaOH containing six moles of it.

E. M. F., pH and Conductometric Titrations. The pH and E. M. F. of the solutions were measured on a Cambridge (null-deflection type) pH-meter by means of a glass electrode and a bright platinum foil as an indicator electrode respectively, in conjunction with saturated calomel electrode. The observed values of e.m.f. and pH during the course of titrations were plotted as a function of milliliter of titrant added. The end points were located graphically and checked further by calculating maximum values of dE/dV and dpH/dV. Twenty m*l* of the titre was taken in the cell each time thermostated at 25±0.1°C. Conductance measurements were carried out by a LBR type conductometer (W. T. W. Germany) taking 20 m*l* of solution in the cell.

Using different concentrations of the reactants, a series of direct and reverse e.m.f., glass electrode and conductometric titrations were performed in aqueous and aqueous-alcoholic media. Similar strengths of solutions were employed in these titrations for the sake of comparison of results. Only three diagrams illustrating direct and reverse e.m.f. (Fig. 1), pH (Fig. 2) and conductometric (Fig. 3) titrations have been given. The results have been summarised in Table 1.

Discussion

The vanadate anion (VO_4^{3-}) in acid medium shows anomalous behaviour and forms different isopoly anions of varying compositions through a series of intermediate steps. The systematic electrometric investigations carried out by the authors[9-11] on such systems have shown the formation of three different poly anions *viz.* pyro$(V_2O_7)^{4-}$,

meta (VO_3^-) and $(V_{10}O_{27})^{4-}$ in the vicinity of pH 10, 7 and 4.5 respectively. With a view to ascertaining whether these polyanions form the corresponding heavy metal derivatives, the reaction between VO_3^- and Pb(II) has been investigated electrometrically.

Figure 1 illustrates the direct and reverse e.m.f. titrations between $Pb(NO_3)_2$ and $Na_2O{\cdot}V_2O_5$ using a bright platinum foil as an indicator electrode. In direct titrations (Fig. 1, curves I—II) when $Pb(NO_3)_2$ solution was added from a micro-burette to sodium meta-vanadate solution, a gradual rise in e.m.f. was observed from the start of the reaction with a sharp jump in potential obtained at the end point corresponding to the formation and precipitation of lead meta-vanadate $PbO{\cdot}V_2O_5$. Beyond the stoichiometric end-point the e.m.f. attains almost a constant value. In the case of reverse titration (Fig. 1, curves III and IV), when sodium meta-vanadate was used as titrant, the first addition of the latter causes a sharp rise in e.m.f. which continues upto the addition of about 0.5 mol of $Na_2O{\cdot}V_2O_5$ per mole of $Pb(NO_3)_2$ but on further addition, the e.m.f. value starts decreasing, resulting in the occurrence of sharp inflection or maxima in dE/dV at the endpoint indicating the precipitation of the same compound $PbO{\cdot}V_2O_5$. The inverse titration curves are peculiar in form but provide accurate and reproducible results.

The pH of the $Pb(NO_3)_2$ and $Na_2O{\cdot}V_2O_5$ was measured by means of glass electrode and found to be about 4.60 and 7.40 respectively. The titration curves (Fig. 2, curves I and II) represent the changes occurring in H^+ ion concentrations when $Pb(NO_3)_2$ solution was treated with alkali-vanadate solution.

The direct glass electrode titration curves are regular in form and yield one break corresponding to the formation of lead meta-vanadate. Reverse titrations, however, are found to yield sharp upward jump at the same stoichiometric endpoint but are peculiar in form. Although the pH of the sodium meta-vanadate is about three units higher than that of $Pb(NO_3)_2$, but the first addition of the former causes an appreciable fall in pH and this decrease continues even upto the addition of about half the amount of alkali vanadate per mole of lead nitrate. Beyond this position pH begins to increase and a sharp upward jump is

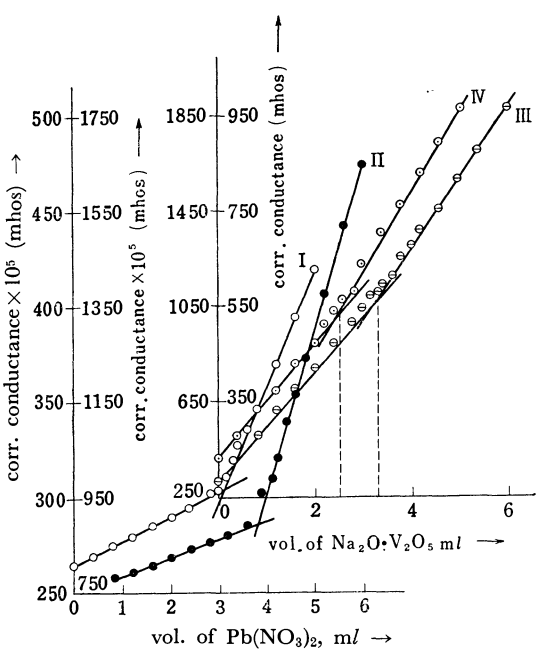

Fig. 3. Direct (I and II) and reverse (III and IV) conductometric titrations between $Pb(NO_3)_2$ and $Na_2O{\cdot}V_2O_5$.
Curve I: m*l* of M/10 $Pb(NO_3)_2$ added to 20 ml of M/60 $Na_2O{\cdot}V_2O_5$
Curve II: m*l* of M/30 $Pb(NO_3)_2$ added to 20 m*l* of M/150 $Na_2O{\cdot}V_2O_5$
Curve III: m*l* of M/5 $Na_2O{\cdot}V_2O_5$ added to 20 m*l* of M/30 $Pb(NO_3)_2$
Curve IV: m*l* of M/25 $Na_2O{\cdot}V_2O_5$ added to 20 m*l* of M/200 $Pb(NO_3)_2$

obtained at stoichiometric end-point (Fig. 2, curves III and IV).

This initial fall in pH, which continues upto the addition of half mole of alkali meta-vanadate per mole of lead nitrate (Fig. 2, curves III—IV) indicate the liberation of free acid during the course of reaction due to hydrolysis and the formation of basic lead-vanadate which on further addition of alkali vanadate gradually changes into lead meta-vanadate, simultaneously liberating equivalent amount of NaOH, which consequently results in the increase of pH. Finally a sharp upward jump was obtained at the molecular ratio of PbO: V_2O_5 as 1 : 1 confirming the formation of lead meta-vanadate ($PbO \cdot V_2O_5$). These observations are clearly borne out by the shape of pH-titration curves. The probable mechanism of the reaction can be stated as follows:

$$Pb(NO_3)_2 + 0.5(Na_2O \cdot V_2O_5) + H_2O \rightarrow Pb(VO_3)OH + HNO_3 + NaNO_3 \quad (1)$$

$$Pb(VO_3)OH + 0.5(Na_2O \cdot V_2O_5) \rightarrow Pb(VO_3)_2 + NaOH \quad (2)$$

The course of this reaction was also followed by means of conductometric titrations between the reactants at different concentrations. The end-points indicate the formation of lead meta-vanadate, $PbO \cdot V_2O_5$. The feeble breaks obtained in reverse titration curves as a consequence of appreciable increase in conductance values in initial stages of titration, indicates clearly the liberation of highly mobile H^+ ions and provide strong support to the observation noted in reverse pH titrations.

It was noticed that after each addition of the reagent, it takes a little time for the e.m.f., pH and conductance values to become steady. The presence of ethanol slightly improves the end-point as it decreases the dielectric constant of the medium and consequently the solubility of the precipitated compound. The accuracy and reproducibility of these electrometric titrations have been found to be excellent.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 380—384 (1968)

A Study on the Yield of (γ, p) Reactions with 20 MeV Bremsstrahlung

Yoshinaga OKA, Toyoaki KATO, Koichi NOMURA, Tatsuya SAITO and Hui-Tuh TSAI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received August 16, 1967)

The yields of the (γ, p) reactions on 13 elements up to an atomic number of 80, irradiated with 20 MeV bremsstrahlung, have been given through the γ-ray spectrometric measurements of the resultant activities. The yield values, as measured in absolute disintegration rates at the end of irradiation per mole per roentgen, have been plotted against atomic number of the target nuclides. The shape of the yield curve thus obtained is similar to that of the curve for the photoproton yield as a function of atomic number. The yield values are 10^5 order of magnitude in the lower-Z region, and drop rapidly with increasing atomic number up to a Z of 50. For barium and mercury targets, a yield value of 2.2×10^4 was obtained. Neutron excess nuclides were found to be restrictive to the (γ, p) processes. The present results permit a study of general behavior of the (γ, p) reaction yields as well as of the applicabilities of the resultant activities to photoactivation analyses for many elements distributed throughout the periodic table.

A general feature of the photon absorption cross section for a nucleus is characterized by a peak 5—6 MeV wide at an energy located between the photodisintegration threshold and about 30 MeV.[1] For most nuclei, an excitation energy of 20 MeV is sufficient to cause the emission of one neutron, or one proton, and occasionally two particles. When bremsstahlung, with a maximum energy of 20 MeV, is attenuated by various target elements, the resultant nuclides are mainly attributed to those arising from (γ, n), and (γ, p) reactions. In a previous paper,[2] the yields of radioactivities resulting from (γ, n) reactions on many elements from lithium up to bismuth have been determined by utilizing a 20 MeV linear electron accelerator and by applying the residual activity method based on the γ-ray spectrometry. The applicabilities of these photoactivation products to activation analyses have also been discussed from the data thus obtained.[3] Although the proton

3) Y. Oka, T. Kato, K. Nomura and T. Saito, *J. Nucl. Sci. Technol.*, **4**, 346 (1967).

yields from many elements irradiated with bremsstrahlung radiation of moderate energy have been determined by several workers through the direct detection of the emitted protons,[4-9] this only represents the sum of the yields of the (γ, p), (γ, pn), and other proton emitting reactions on the relevant element. These yield data will sometimes be ambiguous when applied to a more general consideration convering photoactivation analyses of many elements using particular residual nuclides generated from each of the (γ, p) reactions.

In the present work, consequently, a study has been carried out to obtain the yields of (γ, p) reactions of some 13 elements irradiated with 20 MeV bremsstrahlung γ-rays through γ-ray spectrometric measurements of the resultant activities. In addition, the yields of some (γ, pn) reactions which occurred in this energy region have been determined separately.

Experimental

Samples and Irradiation. Samples of the target materials with high chemical purity,[10] either in the form of the element or some simple compound, were irradiated for 1 hr with bremsstrahlung γ-rays of 20 MeV maximum energy produced by the linear electron accelerator of the Japan Atomic Energy Research Institute. Each sample had a weight of 100 mg and was contained in a small quartz tube having an internal diameter of 4 mm. It was located in a target holder immediately behind the converter platinum plate. To monitor the bremsstrahlung flux to which the sample was exposed, a gold foil[11] was wrapped around each sample tube, and after irradiation, the 6.18 d ^{196}Au activity produced by the ^{197}Au(γ, n) reaction was measured from its characteristic 0.354 MeV γ-ray photopeak. The dose rate of bremsstrahlung γ-rays to which the sample was exposed has been estimated to be 9.4×10^{6} R/min.

The above experimental method is essentially the same as that described in detail in previous papers.[2,3,12]

Chemical Separation. For many elements chosen for this experiment, non-destructive γ-ray spectrometric measurements could be performed after having been cooled for a time. It was possible to let the activities of the desired (γ, p) reaction products be much larger than those from the (γ, n) and other reaction products without any chemical separation. This is not the case, however, for zinc, germanium, strontium, and barium targets. After irradiation, chemical separation was performed for these targets by the following procedures.

Copper from Zinc. After the addition of copper carrier (25 mg), the zinc target was dissolved with 8 N hydrochloric acid, and then subjected to an anion exchange procedure.[13] Copper was eluted from a Dowex 1×8 column with 3.5 N hydrochloric acid, and precipitated from this eluate by the addition of aqueous sodium hydroxide solution at pH 7. After separation by centrifuge, the precipitate was ignited to obtain copper(II) oxide. The chemical yield was 67.3%. The final oxide was packed in a small glass tube having an internal diameter of 4 mm for γ-ray counting.

Gallium from Germanium. An irradiated germanium dioxide target was transferred to a 50 m*l* distilling flask, and was brought into solution by adding 7 N hydrochloric acid along with gallium (269 mg) and zinc carriers. Almost all germanium activities were removed by distillation. From the resultant solution, gallium was extracted with isopropyl ether. The organic layer was evaporated to dryness, and the residue was dissolved in dilute hydrochloric acid. Gallium hydroxide was separated from this solution by the addition of aqueous ammonia, and then ignited to obtain gallium(III) oxide. The chemical yield was 90.9%.

Rubidium from Strontium. A strontium carbonate target was dissolved in dilute hydrochloric acid with the addition of 40 mg of rubidium carrier, and evaporated to dryness. The residue was extracted with water. Sodium tetraphenyl borate was added to precipitate rubidium.

The precipitate was separated by centrifuge, washed with water containing a small amount of acetic acid, and dried at 110°C. The chemical yield was 72.1%.

Cesium from Barium. The chemical procedure for the isolation of cesium activity from a barium carbonate target was similar to that used for rubidium from strontium. Cesium tetraphenyl borate was used to determine the chemical yield, and γ-ray activity. The chemical yield was 91.6%.

Measurement of radioactivity was carried out with a 3″ dia. × 3″ NaI(Tl) detector coupled to a TMC 400-channel pulse-height analyzer.

Yield Determination. The yield value was obtained for each (γ, p) reaction through the absolute measurement of the resultant activity. To obtain the disintegration rate from the counting rate of the characteristic γ-ray photopeak, appropriate corrections were made for the variation of photopeak efficiency with γ-ray energy.[14] The decay schemes used were those listed in the Nuclear Data Sheets.[15] The tables of internal conversion coefficients were also used.[16] Decay curve analyses have been performed to separate the undesired activities. From the data thus obtained, the yield ($Y_{(E)}$) was calculated by the following equation.

$$Y_{(E)} = \frac{D_0}{IM(1-e^{-\lambda t})}$$

where D_0 is the disintegration rate at the end of irradiation; I is the radiation dose rate; M is the amount of target nucleus expressed in moles; λ is the decay constant.

Effect of Photoneutrons. During irradiation in this experiment, there was a considerable neutron flux at the site of the target sample which was due to photoneutrons ejected from the platinum converter. These photoneutrons induce extraneous neutron reactions such as (n, p), (n, α), and (n, 2n) reactions. For a number of elements the resultant nuclide formed by the (n, p) reaction is the same as that from the (γ, p) reaction on the corresponding element. In such cases, it was necessary to correct the observed activity for the contribution of the (n, p) reaction. To investigate such contributions, the neutron flux to which the sample was exposed has been determined. For this purpose, ^{27}Al(n, α)^{24}Na reaction was chosen as a monitor reaction.[17] The energy distribution curve of photoneutrons emitted from a bismuth target irradiated with 20 MeV bremsstrahlung which had been given by Mutsuro *et al.*[19] was also used.[20]

When a piece of aluminum metal of 4 mm×4 mm (126 mg) was irradiated for 1 hr with 20 MeV bremsstrahlung, as pecific activity of 3.2×10^{-3} μCi ^{24}Na/mg Al was found at the end of irradiation. By using this value, the intensity of the energy distribution curve was normalized to the neutron flux at the various neutron energies. The resultant curve is shown in Fig. 1-(1).[21]

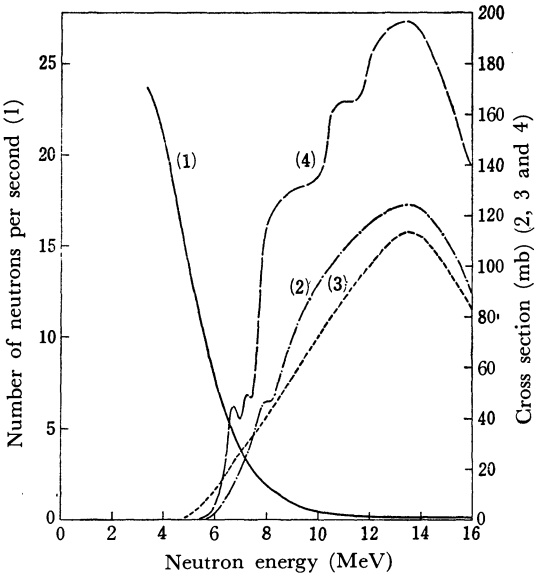

Fig. 1. Neutron flux at the target position as a function of neutron energy (1); The excitation curves for (2) the ^{27}Al(n, α)^{24}Na[18], (3) the ^{56}Fe(n, p)^{56}Mn[23] and (4) the ^{24}Mg(n, p)^{24}Na[18] reaction.

By using this curve and the excitation function for the particular (n, p) reaction, the reaction rate can be calculated in the form of $NS\int_{E_{th}}^{\infty}\sigma(E)\phi(E)dE$, where N is the number of target nuclides; S is the saturation factor; $\sigma(E)$ is the cross section at a neutron energy (E); $\phi(E)$ is the neutron flux at energy (E); and E_{th} is the threshold energy of the reaction.

In the irradiation of an iron target, ^{56}Mn activity is produced both by the ^{57}Fe(γ, p)^{56}Mn, and by the ^{56}Fe(n, p)^{56}Mn reactions. The production rate of the latter was estimated by the proposed method[22] to be 2.3×10^{-3} μCi ^{56}Mn/mg Fe. This corresponds to 2.8% of the total ^{56}Mn activity. Next, ^{24}Na activity from a magnesium target formed by the ^{24}Mg(n, p)^{24}Na reaction[24] was calculated to be 5% of the total ^{24}Na activity. Mostly, the excitation curve for the (n, p) reaction exhibits a threshold energy of 2—5 MeV, and is characterized by a maximum value of ~100 mb.[23] Because of this, it can be concluded that the (n, p) reactions contribute only a small fraction in the total resultant activity, which can thereby be attributed, in major part, to the decay of the (γ, p) reaction products.

Results and Discussion

The (γ, p) Reaction Yield. Table 1 lists the particulars and the data obtained on 16 γ-ray emitting products of the (γ, p) reactions from the elements studied. Column three in Table 1 gives the proton separation energy (S_p), the energy required to separate one proton from a parent nucleus, presented by Yamada and Matsumoto,[25] for most of the nuclei by the use of mass formulas and nuclear systematics. The last two columns show the experimental results. The yield value was expressed as the disintegration rate at the end of irradiation per mole of target nuclide per roentgen. This can be taken as the number of the (γ, p) processes which occurred during irradiation. The yield values were also plotted against atomic number of the parent nuclides in Fig. 2 in which the symbol noted near each plot indicates the parent nuclide. The shape of the yield curve is similar to that of the curve for the photoproton yield as a function of atomic number presented by Weinstock and Halpern.[9]

17) The cross section values for this reaction were taken from the data of Butler *et al.*,[18] which is shown in Fig. 1-(2).
18) J. P. Butler and D. C. Santry, *Can. J. Phys.*, **41**, 372 (1963).
19) N. Mutsuro *et al.*, To be published.
20) It can be said that this energy distribution curve is practically the same as that for photoneutrons from the converter platinum taking account of the characteristics of the photonuclear process.
21) From the result, the neutron flux necessary to produce the ^{24}Na activity was estimated to be 5.3×10^5 n/sec at the target position.
22) The excitation function for the ^{56}Fe(n, p)^{56}Mn reaction, shown in Fig. 1-(3), was taken from the data compiled by Hughes *et al.*[23]
23) D. N. Hughes and J. A. Harvey, "Neutron Cross Sections," BNL-325 (1955).
24) The excitation function presented by Butler *et al.*,[18] shown in Fig. 1-(4), was used.
25) M. Yamada and Z. Matsumoto, *J. Phys. Soc. Japan*, **16**, 1497 (1961).

a) The value corrected at the end of 1 hr irradiation (9.4×10^{6} R/min).

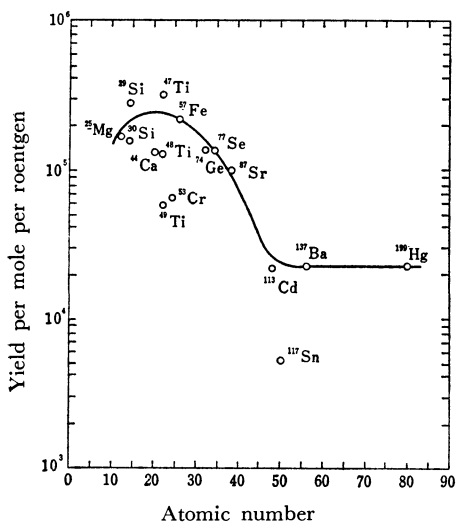

Fig. 2. The yield curve for the (γ, p) reaction with 20 MeV bremsstrahlung.

It has been pointed out that the photon absorption cross section for a nucleus is an increasing function of Z, and this fact has been well explained in a study on the relation between the (γ, n) reaction yield and the atomic number of the target nuclide.[1,2] The yield of radioactive nuclide increases regularly with atomic number from 10^3 to 10^7 orders of magnitude.[2] On the other hand, photoproton emission from a nucleus is a decreasing function of Z because of the restrictive effect of the Coulomb barrier. Accordingly, the yield curve for the photoproton emission will exhibit a peak.

According to the results of Weinstock and Halpern,[9] this peak occurs at nickel (Z=28). They have also shown that between a Z of 28 and 50 the experimental photoproton yields are in excellent agreement in absolute magnitude with those calculated from the evaporation model.

Although the initial rise of the yield curve, shown in Fig. 2, is not markedly observed in the lower-Z region, a typical decrease in the yield value with Z can be seen from iron (Z=26) up to tin (Z=50). On the barium and mercury targets, however, the yield values are much higher than those expected from a rapid drop until a Z of 50. These discrepancies can be attributed to the direct photoelectric emission mechanism. It has often been pointed out that the evaporation model as usually formulated is inadequate to explain the photoproton yields for elements of high atomic number.[9,26] In such cases, a considerable portion of the photoproton yield can be accounted for by the direct photoelectric emission of a proton without the formation of a compound nucleus.

As for titanium isotopes, including ^{47}Ti, ^{48}Ti, and ^{49}Ti, the yield values decrease in order. This fact shows that the cross section for photoproton emission from a neutron excess nuclide is expected to be small. Similarly, the yield for the ^{29}Si(γ, p)^{28}Al reaction is higher than that for the ^{30}Si(γ, p)^{29}Al reaction.

Of the target nuclides under study, ^{44}Ca (Z=20) and ^{117}Sn (Z=50) are proton magic. The yield values for these nuclides are fairly low as compared with those for the neighboring nuclides in the yield curve.

26) V. G. Shevchenko and B. A. Yuryev, *Nucl. Phys.*, **37**, 495 (1962).

In the comparison of the results in Table 1 with the yield values of the (γ, n) reactions, the (γ, p) reactions can be produced by same order of magnitude as the latter in elements with lower-Z. With higher-Z elements, however, they contribute only a small fraction to the observed activity. The yield values are less than 0.1% of those for the (γ, n) reaction in elements with Z greater than 50.

It would appear that the use of the resultant activities in Table 1 for photoactivation analysis of lighter elements should enhance the efficacy. Silicon, calcium, and titanium can be specifically detected by γ-ray counting. They are elements from which either very short-lived nuclides, or only low γ-activities, are produced by activation with thermal neutrons.

In conclusion, the authors believe that the present results permit a study of the general considerations covering photoactivation analyses of many elements utilizing (γ, p) reaction products.

The (γ, pn) Reaction. It is expected that the (γ, pn) reactions take place to an appreciable extent, apart from the (γ, n) and (γ, p) reactions, in various elements in the energy region covered in this experiments. The resultant activities from (γ, pn) reaction in iron, zinc,[27] and palladium targets could be measured. The yield values obtained are given in Table 2. This is a preliminary survey to indicate the yield values from the (γ, pn) reaction in various elements. It is obvious that more points at higher atomic number are required. It is planned to investigate these problems in the near future.

TABLE 2. THE YIELDS OF SOME (γ, pn) REACTIONS WITH 20 MeV BREMSSTRAHLUNG

Reaction	Half-life of product	Specific activity[a] (μCi/mg)	Yield ($mol^{-1} \cdot R^{-1}$)
$^{56}Fe(\gamma, pn)^{54}Mn$	314 d	2.5×10^{-6}	3.6×10^{2}
$^{66}Zn(\gamma, pn)^{64}Cu$	13 hr	7.2×10^{-3}	7.5×10^{3}
$^{104}Pd(\gamma, pn)^{102}Rh$	210 d	1.1×10^{-6}	1.7×10^{3}

a) The value corrected at the end of 1 hr irradiation (9.4×10^{6} R/min).

27) Apart from ^{64}Cu, ^{67}Cu from ^{68}Zn by the (γ, p) process was measured by its characteristic 0.093, 0.184, 0.296, and 0.388 MeV γ-rays. The yield calculation for this reaction was excluded in this experiment since the decay scheme for ^{67}Cu has not been well-established.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 384—389 (1968)

Kinetics of Isotopic Exchange between Acetylacetone-^{14}C and Tris-acetylacetonatoaluminum in Tetrahydrofuran

Kazuo SAITO and Kazuyo MASUDA

Chemistry Department, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received September 11, 1967)

Tris-acetylacetonatoaluminum [Al(acac)$_3$] is precipitated crystalline from tetrahydrofuran (THF) solution containing an excess of acetylacetone (acacH) by adding chilled petroleum ether. This fact enables a kinetic study of isotopic exchange of acac$^-$ between [Al(acac)$_3$] and acacH with the aid of acetylacetone-^{14}C. The exchange rate is independent of the concentration of acacH and dependent on that of water. The rate formula at 25°C is as follows:

$$R = [\mathrm{Al(acac)_3}](6\times 10^{-5} + 2.0\times 10^{-2}[\mathrm{H_2O}])\ \mathrm{mol}\ l^{-1}\ \mathrm{min}^{-1}$$

This exchange reaction is catalysed by acids; the stronger the acid, the greater the catalytic effect. One of the acetylacetonate ligands would be present with one end free, and break of the remaining bond of unidentate acetylacetonate seems to be the rate determining step. Water can occupy the vacant coordination site of aluminum ion to retard recombination of the unidentate ligand. The donation of proton to the free end of acetylacetonate appears to impede the recombination, too, and facilitate the exchange. Hydronium ion seems to be the unique proton carrier.

Little information is available concerning the isotopic exchange of organic ligands of non-electrolytic complexes in organic solvents. Such kinetic studies with complexes of typical elements seem very interesting, because no influence is expected from charge, ligand field stabilization energy, hydrolytic decomposition, and ionic strength. One of the present authors measured the exchange rate of radioactive indium between its tris-acetylacetonato- and tris - 8 - quinolinolato (oxinato) complex in chloroform and found that it is measurable at room temperature (*e. g.* half period

11 min at 25°C).[1] He also found that the exchange between the corresponding zinc complexes is very fast.[2] These experiments exemplified that complexes of tervalent typical elements can undergo slow isotopic exchange under certain conditions, but failed to give further information concerning the mechanism.

The difficulties involved in carrying out such studies are to separate one of the participants in the exchange reaction free from the other, and to measure the specific activity (or specific counting rate) with reasonable accuracies. The present authors have examined the solubility of acetylacetone (acacH) and tris-acetylacetonatoaluminum [$Al(acac)_3$] in a variety of organic solvents, and found that the latter is precipitated crystalline free from the former in tetrahydrofuran solution (THF) on addition of petroleum ether at a low temperature. By use of acetylacetone labelled with ^{14}C, they have succeeded in studying the isotopic exchange kinetics at room temperature, and have posturated a reasonable reaction mechanism.

Experimental

Materials. Acetylacetone-^{14}C was synthesized by the method given in Ref. 3, slightly modified to suit for a small scale synthesis. Metallic sodium powder (4.6 g) was refluxed with ethanol (12 m*l*) for 7 hr in ethylether, the ether evaporated off, the product treated with ethylacetate (80 m*l*), acetone-1, 3-^{14}C (0.5 mCi, 0.11 mg) and acetone (15 m*l*) for 1 hr with reflux, and set aside for 20 hr at room temperature. The product was treated with water (170 m*l*), the ether layer discarded, and the aqueous solution made acid with dilute sulfuric acid. The liberated acetylacetone-1, 3, 5-^{14}C was extracted with ethylether, dried with anhydrous sodium sulfate for 24 hr, and distilled to collect a fraction boiling at 120 to 134°C. The distillate was further dried with potassium carbonate, diluted with inactive acetylacetone to adjust the specific activity to the order of 0.02 μCi/mg, and distilled (boiling point 134 to 136°C). The water content of the product was estimated to be 0.31 and 0.71 M (two batches) as mentioned below.

Tris-acetylacetonatoaluminum was synthesized by the ordinary method,[4] from commercial aluminum sulfate made free from iron and inactive acetylacetone, and sublimed at 5 mmHg at 165°C, to give colorless crystals. Water content of the sublimate was *ca.* 0.06 M. Commercial extra pure THF was refluxed with sodium for 1 hr, distilled and the distillate further dehydrated with lithium aluminum hydride, and distilled. The product contained less than 0.005 M water, and preserved in a desiccator as long as two weeks without being contaminated by atmospheric moisture. *m*-Toluic acid, trichloroacetic acid and phenol were sublimed at 5 mmHg at 105, 50 and 35°C respectively and dissolved in THF without being in contact with air. The concentration and the water content were determined by alkalimetric and Karl Fischer titration, respectively.

Commercial anisole was shaken with sodium hydroxide solution, dried with calcium chloride, refluxed with sodium and distilled. *p*-Terphenyl was recrystallized from xylene. *p*-Di-(5-phenyl-2-oxazolyl)-benzene (POPOP) was of scintillation grade and used without further purification. Other chemicals were of chemically pure grade.

Experimental Procedure. A given amount of tris-acetylacetonatoaluminum (0.2 to 0.7 g) was dissolved in anhydrous THF (10.0 m*l*) and the acetylacetone-^{14}C (0.02 to 0.2 g) was added, the amounts being known from the weight difference. Other reagents such as acids and water were added to the THF in advance, whenever necessary, and their amounts known from the weight difference. The water content thus determined coincided well with those measured by Karl Fischer titration within an erorr less than 0.003 M in the reaction mixture.

The reaction mixture was kept in a thermostat at 25 or 35°C, and an aliquot (*e. g.* 1 m*l*) was added to chilled petroleum ether (−20°C) at appropriate intervals. Crystalline [$Al(acac)_3$] separated out on standing at −20°C for 4 hr. The standing time did not affect the results, and there was no appreciable zero-time exchange. The supernatant was decanted, the precipitate washed with petroleum ether and dried at 80°C. Its weighed portion (4 to 15 mg) was dissolved in anisole (15.0 m*l*), mixed with POPOP (0.02%) and *p*-terphenyl (0.8%) in anisole (15.0 m*l*) and the counting rate measured by the scintillation technique. Five to six aliquots were taken during one kinetic run and about 70 runs were carrierd out under various conditions as mentioned below.

The absorption spectra of reaction mixtures coincide with the sum of those of tris-acetylacetonatoaluminum and acetylacetone. Hence the reaction mixture does not undergo any reaction other than isotopic exchange, regardless of the presence of other ingredients such as water and organic acid.

Since water accelerates the exchange and the reaction mixture absorbs water slightly, the water content was carefully determined during the course of exchange reaction, to find that the change in content of water is less than 0.1 mg per m*l*, *i. e.* less than 0.005 M. In extreme cases, the mean value before and after the exchange reaction was used for calculation.

Measurement of Radioactivity. A coincidence liquid scintillation counter, made by Institute for Nuclear Study, the University of Tokyo was used for the β-ray counting. The quenching effect was examined with standard ^{14}C-benzoic acid and inactive acetylacetone and tris-acetylacetonatoaluminum, to find that it is negligible in the presence of less than 20 mg per 30 m*l* anisole under the given conditions. The counting rate was proportional to the amount of carbon-14 in the range from 10^{-3} to 10^{-2} μCi of either acetylacetone or tris-acetylacetonatoaluminum. The counting rate at the end of exchange reaction (infinite time) was calculated from that of the acetylacetone-^{14}C and the used amounts of the respective compounds.

Other Measurements. The NMR spectra were recorded with Varian A 60 Spectrometer (60 mega

cycle) at room temperature. The absorption spectra in the visible and ultraviolet region were measured with Hitachi EPU-2A Spectrometer. Karl Fischer titration apparatus of Mitsubishi Kasei type with electric end-point indicator was used for the analysis of water; propyleneglycol containing 25% (v/v) pyridine was the useful titration medium.

Results

The experimental data were treated in accordance with McKay's formula,[5]

$$R = -2.303 \cdot \frac{3ab}{3a+b} \cdot \frac{\log(1-F)}{t} \qquad (1)$$

where a and b are the molar concentrations of tris-acetylacetonatoaluminum (containing three moles of exchangable acetylacetonate per mole) and acetylacetone, respectively, F is the fraction of reaction and t the lapse of time in minutes.

Influence of the Concentration of Complex, Free Ligand and Water. The influence of a upon R is illustrated in Fig. 1, which clearly shows that R is proportional to a in the given concentration range. More dilute solutions did not yield the precipitate on addition of chilled petroleum ether.

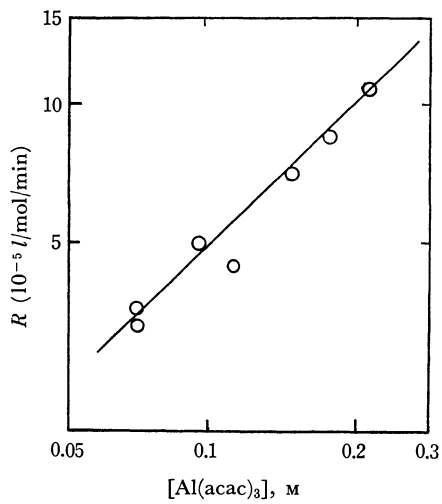

Fig. 1. Influence of the concentration of tris-acetylacetonatoaluminum on the exchange rate. [acacH], 0.070 M; [H_2O], 0.027 M; 25°C

Water in the reaction mixture accelerates the exchange reaction. So far as its concentration was kept constant, however, the rate was independent of b, as seen from Table 1. Hence R is expressed as

$$R = k_0 a \qquad (2)$$

Since the acetylacetone-^{14}C contained a small amount of water, which cannot be removed by accessible dehydrating agents, change in b also brought about change in concentration of water in the reaction mixture. However, such a contribution is negligible, when the amount of added water in THF is large. The difference in water content coming from varying amounts of the complex *etc.* is even smaller and can be ignored.

Table 1. Influence of concentration of acetylacetone-^{14}C on the exchange rate

[H_2O], M	[acacH], M	k_0, min^{-1}
0.0046	0.067	1.3×10^{-4}
0.0047	0.144	1.4×10^{-4}
0.045	0.031	1.1×10^{-3}
0.046	0.051	1.1×10^{-3}
0.046	0.066	1.1×10^{-3}
0.047	0.095	1.2×10^{-3}

[$Al(acac)_3$], 0.070 M; 25°C

When R was measured in THF solutions containing varying amounts of water at given a and b values, the R *vs.* [H_2O] diagram was almost a straight line on log-log scale (Fig. 2). On the other hand, when R was measured with varying b values in the absence of added water in THF containing a given amount of the complex, the diagram really indicates the influence of water concentration. Both the diagrams coincide with each other, to reconfirm that R is independent of b. By extrapolating the anti-logarithmic diagram corresponding to Fig. 2 to zero concentration, the k_0 value in the absence of water, k_1, is known. The accuracy of the concentration of water is low especially in less than 0.01 M solution, and only an approximate amount of k_1 is known by extrapolation, to be less than 6×10^{-5} min^{-1} or less. When this value is subtracted from the measured k_0 values and the difference plotted against [H_2O], a straight line of a gradient 45° is obtained on log-

Table 2. The influence of various acids on the exchange rate

No.	Acid (pK)	Concn. of acid (10^{-2} M)	Concn. of water (10^{-2} M)	k_0 10^{-4} min^{-1}	k_2'' l^2 mol^{-2} min^{-1}
1	Trichloroacetic (pK=0.635)	2.5	2.5	13.3	12
2		2.5	1.9	10.0	11
3		2.5	1.4	7.9	12
4	*m*-Toluic (pK=4.272)	1.5	3.0	12.3	1.3
5		1.5	1.6	9.0	2.1
6		1.5	1.0	6.8	2.8
7		0.27	1.6	5.8	2.2
8	Phenol (pK=9.998)	0.36	3.5	10.6	2.5
9		1.1	3.5	16.5	2.2
10		1.6	3.5	21.1	2.5
11		0.45	2.3	7.7	2.5
12		1.2	2.3	14.0	3.2

[Al(acac)$_3$], 0.070 M; [acacH], 0.070 M; 25°C

log scale, as seen in Fig. 2. Hence Eq. (2) is written as Eq. (3).

$$R = k_0 a = a(k_1 + k_2[H_2O]) \quad (3)$$

At 25° Eq. (3) is numerically expressed as Eq. (4).

$$R = [\text{complex}](6\times10^{-5} + 2.0\times10^{-2}[H_2O]) \quad (\text{mol } l^{-1} \text{ min}^{-1}) \quad (4)$$

Acid catalysis. The exchange is accelerated by acids, although the variety of useful acids is very much limited because of their solubility in THF. The influence of acid concentration in the presence of a given amount of water is shown in Fig. 3.*1 It is seen that the rate increases with increase in concentration of a particular acid. Figure 4 illustrates the influence of the concentration of water in the presence of a given amount of particular acids. Since water is contained more or less in the reagents and solvent, experiments in the absence of water could not be substantiated. However, when the diagrams are exptraporated to zero concentration, the intercept would indicate the rate in the absence of water.

The reaction kinetics is expressed by Eq. (5).

$$R = a\{k_1 + k_1'[\text{acid}] + [H_2O](k_2' + k_2''[\text{acid}])\} \quad (5)$$

The accuracy of the extrapolated values is low and

*1 The absolute water content is known only within an error *ca.* 0.003 M, but experience showed that the relative error for one sets of reaction mixtures simultaneously prepared was much less than that.

it remains uncertain whether the difference between the intercept of Fig. 4 (the second term of Eq. (5)) and k_1 in the absence of acid catalysis is really significant or not. Nevertheless it is quite clear that its contribution is of far less importance as compared with that of the last term of Eq. (5), when the mechanism of acid catalysis is discussed. The k_2'' values are listed in Table 2 together with the acid dissociation constants.

Temperature Dependence. The R values were measured at 0, 25 and 35°C to find the Arrhenius activation energy to be 22 kcal per mole in the presence of 0.020 M water. Since the contribution of k_1 is very small, this value is regarded as corresponding to that of water catalyzed exchange.

Discussion

Dissociation Mechanism. The experimental results indicate that the exchange mechanism is of dissociative nature and the rate determining step is the liberation of coordinated acetylacetonate from the complex. The second term of Eq. (3) corresponds to the catalytic action of water in THF. Since simultaneous break of two metal-oxygen bonds of one ligand is not probable, a possible reaction mechanism can be presented as shown in Fig. 5.

One of the three ligands can be present as unidentate and the break of its remaining bond will bring about the exchange of ligand. Thus the constant k_1 is expressed by $k_b^+ \cdot k_u^+ / k_b^-$, where k_b^+, k_u^+ and k_b^- are the rates of bond break of bidente and unidentate acetylacetonate and of bond formation to give bidentate acetylacetonate, respectively. The small value of k_1 reflects the ease with which the free end of unidentate ligand recombines with aluminum rather than the remaining bond is broken to result in isotopic exchange, in the absence of catalyst.

Function of Water. In the presence of water, it can occupy the vacant coordination site of aluminum formed by break of one of the Al-O bonds to retard the recombination and to facilitate the exchange (Fig. 5).

The k_1 is rather small as compared with $k_2[H_2O]$; especially when the water concentration is higher than 0.01 M as in most cases in experiments in atmosphere, the contribution of the former is negligible. In other words, the second term is really of great importance, unless the exchange reaction takes place under extraordinally dehydrated media. When tris-acetylacetonatoaluminum was to be precipitated on addition of petroleum ether to the THF solution containing a large amount of water (*e. g.* more than 0.1 M) gelatinous precipitate of aluminum was formed, which appeared to be hydrated aluminum oxide. This suggests that the water is present rather coordinated in the reaction intermediate. The same fact makes a kinetic run under such a condition impossible. Experiments with tris-acetylacetonatogallium and -indium under similar conditions could not be substanciated because gelatinous precipitate of the metal ions were formed. These findings could be also related with the ease with which water is substituted for acetylacetonate ligand even in such a medium as THF.

Acid Catalysis. As mentioned in "Results", the contribution of the second term of Eq. (5) would be very small, even if it were significant. The k_2'' values calculated by Eq. (5) without considering the contribution of the second term are practically constant for each of the three acids, (Table 2) to indicate that such a simplification is quite reasonable. The last term of Eq. (5) reflects the establishment of the following equilibrium,

$$HX + H_2O \rightleftarrows X^- + H_3O^+ \qquad (6)$$

where X^- stands for the acid anion. Rapid establishment of this equilibrium is also demonstrated by proton nuclear magnetic resonance (NMR) spectra of the acids in 1 M water solution in THF. They all give one sharp or broad band due to acid proton. The fact that the apparent k_2'' values calculated in No. 4—6 experiments in Table 2 decreases with increase in water concentration would indicate that an equilibrium as Eq. (6) should be attained for such a weak acid as *m*-toluic, when the concentrations of acid and water are comparable.

As illustrated in Fig. 5, hydronium ions give up proton to the free end of unidentate ligand to facili-

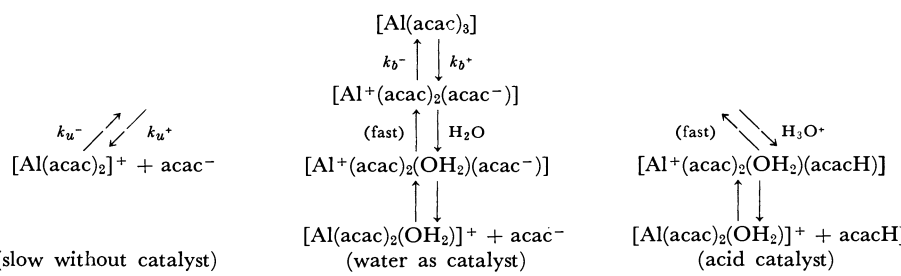

Fig. 5. A possible reaction mechanism of isotopic exchange reaction between tris-acetylacetonatoaluminum and acetylacetone-^{14}C in THF.

tate its liberation to a greater extent than water does. The difficulty of direct transfer of protons from the acid molecule, *i. e.*, the rather specific proton transportion by hydronium ions, could be understood by considering that the free end of unidentate acetylacetonate would remain in the neighborhood of the metal ion owing to electrostatic attraction, and that only a small particle like H_3O^+ can approach the end and hand over the proton to the negatively charged oxygen. Examination with molecular structure models discloses such a circumstance clearly.

Table 2 indicates that a strong acid accelerates the reaction more than a weak acid does. However, the Brønsted plot does not give a straight line. Some other factors, *e. g.* structural, could be operating. Further, free acetylacetone, being an acid with an acid dissociation constant 1.5×10^{-6}, could have acted as an acid catalyst. As carefully examined in Table 1 and Fig. 2, however, its concentration does not affect the rate of exchange at all, and this fact should be related to a structural factor, too.

Proton magnetic resonance spectrum of acetylacetone in THF has a sharp peak at 5.45 ppm and a very broad band at 14.5 ppm to indicate that this compound is present mainly in enol form and hydrogen bonded. The NMR spectrum of water has a sharp peak at 2.75 ppm to suggest a rapid exchange of protons with THF. An equimolar mixture of acetylacetone and water gives a broad band at 6.00 ppm and the peaks of water at 2.75 and of acetylacetone at 14.5 ppm disappear. The peak of vinyl proton remains at 5.35 ppm almost unchanged.

These spectra indicate that there could really be an interaction between acetylacetone and water in THF. However, the effective acid strength of acetylacetone in THF containing water to give H_3O^+ must be much weaker than that expected from its dissociation constant measured in water. Thus its failure to behave as an acid catalyst under the experimental condition would be ascribed to the difficulty with which proton is transferred from acetylacetone to water molecule. This "difficulty" certainly reasons rather thermodynamic sense than kinetic, because the proton exchange seems to occur at a rate of the order of 10^7 per sec as indicated by NMR studies at 60 Mc. The rather poor correlation between the acid dissociation constant and the k_2'' values is similarly accounted for by considering the different ease with which proton is transferred from the acid to water in THF. This ease is qualitatively parallel to the acid dissociation constant for the acids used, but would not be quantitatively.

An entirely different reaction mechanism could be encountered by considering direct attack by water, or proton transfer from hydronium ion upon the oxygen atom coordinated to aluminum ion. However, the fact that a spontaneous liberation of coordinated acetylacetonate is possible without catalytic action, although the rate is quite small, would be more reasonably understood by considering an intermediate, in which one of the ligands is unidentated. The catalytic actions are thus interpreted more consistently.

The authors wish to express their sincere thanks for financial support given by Nishina Memorial Foundation.

The Synthesis of Methacrylic Esters by the Carboxylation Reaction of Methylacetylene. II. Catalytic Synthesis of Methyl Methacrylate using Nickel Carbonyl as the Catalyst

Sango KUNICHIKA, Yasumasa SAKAKIBARA*1 and Tadao NAKAMURA*2

Institute for Chemical Research, Kyoto University, Daigaku-cho, Takatsuki, Osaka

(Received June 1, 1967)

The catalytic synthesis of methyl methacrylate by the carboxylation reaction of methylacetylene using nickel carbonyl as a catalyst was studied under various conditions. The experimental results concerning the effects of the reaction conditions on the reaction rate, the stability (regeneration) of nickel carbonyl, and the product yields suggested the most desirable conditions for the synthesis. It was ascertained that, in the catalytic process, the pressure of carbon monoxide played a very important roles; a high pressure gave a good regeneration of nickel carbonyl, *i. e.*, a high value of 95% in the so-called catalytic level, but the initial reaction rate decreased remarkably with an increase in the pressure, probably in reverse proportion to its second power, or more. A semicontinuous process was much better for the synthesis than a batch process. A good yield of 85% (based on the methylacetylene used) of the total of methyl methacrylate and methacrylic acid and a high catalytic level of 95% were obtained when the reaction was carried out semicontinuously in the presence of methacrylic acid and water at a total pressure of 13 atm (initial charge of carbon monoxide at room temp.: 4 atm) at 130°C. A mechanism for the catalytic reaction was proposed to account for the experimental results.

In a previous paper,[1] it has been reported that methylacetylene was more difficult to carboxylate than acetylene and that methyl methacrylate was obtained in unsatisfactory yields under the carboxylation conditions studied. It was also observed that, in the catalytic process using nickel carbonyl as a catalyst, the pressure of carbon monoxide appeared to play a very important role and that water acted as an accelerator of the reaction, as do mineral acids as well known.

The present paper will describe a further investigation of the catalytic synthesis of methyl methacrylate from methylacetylene and carbon monoxide, using nickel carbonyl as a catalyst. The effects of the reaction conditions on the reaction rate, the stability of nickel carbonyl, and the product yields will be examined in order to determine the most suitable conditions for this synthesis and in order to obtain useful information about the carboxylation reaction. Special attention will be paid to the stability (regeneration) of the nickel carbonyl catalyst. A mechanism for the carboxylation reaction will be proposed to account for the experimental results.

Experimental

Materials. Commercial methylacetylene was purified by fractional distillation through a Podbielniak-type low-temperature column (80 cm × 1.5 cm); bp −23—−22°C. The purity was higher than 98.5 mol% on gas chromatographic analysis. Commercial carbon monoxide (99.7 mol% pure) was used. Nickel carbonyl was prepared by the usual method[2]; bp 42—43°C (lit. 43°C).

Apparatus and Procedures. Two reaction processes were employed.

1) Batch Process. This process was favored over the semicontinuous process for collecting the kinetic data of the reaction. The general procedure was as follows. A 350 m*l* shaking-type stainless-steel autoclave (shaking speed: 240 times per min) was charged with methanol, additives such as water and/or acids, hydroquinone, and a catalytic amount of nickel carbonyl under nitrogen. The vessel was then cooled to about −50°C and evacuated, and the air was completely replaced by nitrogen. Carbon monoxide was introduced to give the specified pressures. Then the vessel was heated to the reaction temperature, at which temperature all the methylacetylene was injected at once through a pipe-line from an injection pump.*3 After the lapse of an introduction period, the absorption of carbon monoxide was observed; in most cases, the reaction was continued until the absorption had practically ceased. During the reaction period, the total reaction pressure was

kept constant by introducing carbon monoxide continuously from a 120 ml carbon monoxide-pressure storage tank. The amount of carbon monoxide introduced was calculated from the pressure drop in the pressure storage. After the reaction had been completed, the autoclave was cooled and the reaction mixture was analyzed.

2) Semicontinuous Process. A 200 ml rotational-stirring-type stainless-steel autoclave (used at about 900 rpm) was used as the reaction vessel. This process was the same as the above batch process except that methylacetylene was added continuously at the reaction temperature using the injection pump. The addition of methylacetylene was made by first introducing a small portion (0.5—0.8 g of it) quickly; after the reaction had started, the residual portion was added continuously at a moderate rate.

Analytical Procedures. The decomposed and, in several cases, undecomposed nickel carbonyl was analyzed to determine the catalytic level of nickel carbonyl; the catalytic level is expressed as the ratio of the product (ester, carbonic acid) carbonyl coming from gaseous carbon monoxide to the total available carbon monoxide, including that from the nickel carbonyl decomposed. The undecomposed nickel carbonyl was thoroughly removed from the reaction mixture after the gas remaining in the autoclave had been vented off, first by passing nitrogen through the vessel under a slight heating or under stirring, and then by bubbling nitrogen into the reaction mixture in a flask at about 50°C. All of these gases were passed through a mixture consisting of carbon tetrachloride, bromine, and water to decompose the nickel carbonyl, and the nickel was analyzed by the dimethylglyoxime method.[3] The decomposed nickel carbonyl was determined by analyzing the nickel in the aqueous layer coming from the extraction procedure described below.

The reaction products, esters and acetone, were determined by gas chromatography using a 2.5 m column of 25% polyethylene glycol 1000 and a 2.4 m column of 25% squalane at 70°C. Toluene was used as the internal standard substance. Carboxylic acids in the reaction mixture were titrated with a sodium hydroxide solution and were regarded as methacrylic acid because gas chromatographic analysis showed that the acids mainly consisted of methacrylic acid.[1] Furthermore, the yield of methacrylic acid given assumes that all the nickel resulting from the decomposed nickel carbonyl exists as nickel methacrylate. The remaining reaction mixture was poured into dilute sulfuric acid and extracted with methylene chloride. The aqueous layer was thus provided for the determination of the decomposed nickel carbonyl. The extract was condensed and flash-distilled under reduced pressure.

Results and Discussion

The experimental results for the batch and the semicontinuous process are shown in Tables 1 and 2.

The Effect of Reaction Conditions on the Reaction Rate. In order to examine the effect of reaction conditions on the reaction rate, the experiments were carried out by the batch process at a temperature regulated to about ±2°C (Table 1, Exps. 1—11). Concerning the reaction conditions, such conditions as that the catalytic level was over 90% were examined in order to obtain kinetic data about the catalytic reaction. Under the specified conditions, the reaction began after a short induction period and then proceeded smoothly and catalytically. In these cases, the resulting reaction mixture was a transparent yellow-green liquid without any precipitate. The absorption curves of carbon monoxide under various conditions, listed in Exps. 1—11 of Table 1, are shown in Figs. 1—5. In these figures, the absorption amount has been roughly corrected by taking into account the facts that the partial pressure of methylacetylene in the gas phase of the autoclave decreases with the progress of the reaction and that, as a result, carbon monoxide enters into the autoclave to compensate for the decrease. On the assumption that the partial pressure of methylacetylene is proportional to the total methylacetylene and that the partial pressure is zero at the 90% absorption of the theoretical amount of carbon monoxide, the following correction factor, f, was introduced:

The corrected absorption amount = The apparent absorption amount $\times f$

$$f = V_t \times 0.9/(V_t \times 0.9 + V_v \cdot P)$$

where V_t is the theoretical absorption amount of carbon monoxide; V_v, the volume of the vacant part of the autoclave; and P, the partial pressure of methylacetylene at the start of the reaction, being about 9 atm at 170°C and 10.5 atm at 180°C. The relative initial reaction rates were calculated roughly from the absorption curve of carbon monoxide.

The Effect of the Temperature. The reaction rate is quite sensitive to the temperature, as is shown in Fig. 1. Increasing the temperature from 170

to 180°C raised the initial rate by a factor of 3.0. With 160°C, a long induction period of about 1.5 hr was required for the reaction and the rate was very slow.

The Effect of the Pressure of Carbon Monoxide. Increasing the pressure reduces the reaction rate remarkably (Fig. 2). The relative initial rates at 10, 12, and 14 atm pressures (at room temperature) of carbon monoxide were 1.0, 0.6, and 0.3 respectively. From these values, it can roughly be estimated that the initial rate is reversely proportional to the second power of the pressure, or more.

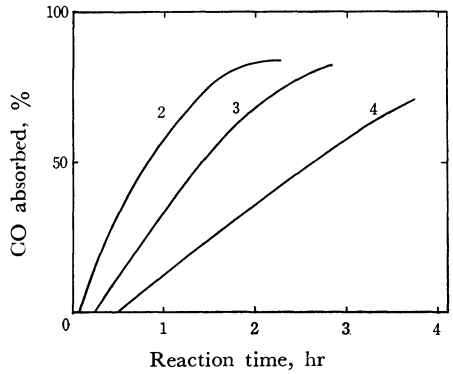

Fig. 2. CO absorption *vs.* time plots for the reaction—Effect of pressure of carbon monoxide.
Curve No.: Exp. No.
Curve 2: 10 atm, Curve 3: 12 atm, Curve 4: 14 atm

In addition, the induction period of the reaction was reduced with a decrease in the pressure, being about 5 min at the 10 atm pressure (Exp. 2).

The Effect of the Amounts of Nickel Carbonyl and Methylacetylene. A decrease in the amount of nickel carbonyl reduces the reaction rate (Fig. 3). The relative initial rates with 2.0, 1.3, and 1.0 g of nickel carbonyl were 1.0, 0.6, and 0.3 respectively.

* The percentage in parentheses is for Curve 7 in consideration of the absolute amount of carbon monoxide absorbed.

The results suggest that the initial rate might be first-order with respect to the concentration of nickel carbonyl.

Increasing the amount of methylacetylene raises the reaction rate (Fig. 4). The initial rate of Exp. 1, conducted with 8.1 g of methylacetylene, was just twice as fast as that of Exp. 7, with 4.0 g. These results suggest that the initial rate may be first-order also with respect to the concentration of methylacetylene, though the experimental data are yet incomplete.

The Effects of Additives. The reaction did not proceed easily without the addition of certain accelerators; substances with an active hydrogen as inorganic and organic acids and water are known to be effective. Figure 5 and Table 3 show the effects of additives on the reaction rate. Of water, methacrylic acid, isobutyric acid, and hydrogen chloride, hydrogen chloride is the most effective (Exp. 20 in Table 3); the decreasing order of the effect of these additives per mole is

11	10	1.0	(5.0)
	Water + Methacrylic acid		
19[b]	7.0	2.0	1.0[c]
	Water + Hydrogen chloride		
20[b]	7.0	0.9	(7)[c]

a) The Exp. No. corresponds with Exp. No. in Table 1 and Curve No. in Fig. 5.
b) Exps. 19 and 20 were made at 28 atm total pressure (initial charge of carbon monoxide at room temp.: 10 atm) at 130°C with 8.0 g C_3H_4, 50 m*l* CH_3OH, 2.0 g $Ni(CO)_4$, and 0.1 g hydroquinone using the rotational stirring-type autoclave descrived above.
c) These two values were expressed as Exp. 19=1.0.

as follows: hydrogen chloride > methacrylic acid ≒ isobutyric acid ≫ water. In the use of hydrogen chloride under the conditions studied, however, the reaction rate decreased quite rapidly, probably as a result of the loss of hydrogen chloride by the $CH_3OH + HCl \rightarrow CH_3Cl + H_2O$ reaction. In the case of both water and methacrylic acid, the reaction rate increased with an increase in their amounts. The initial rates were roughly twice as fast when their amounts were doubled (Exps. 1 and 8; Exps. 9 and 10).

A systematic examination of the effect of mixing was not made, though it appeared to be the most important physical variable. Recently,[4] in the catalytic reaction of acetylene under low pressure (total pressure 1.5 atm, usually under atmospheric pressure), it has been reported that the liquid diffusion of carbon monoxide is an important rate step and that it is necessary to keep the liquid diffusion of carbon monoxide rate-controlling in order to maintain the reaction. For obtaining most of the kinetic data, however, it is best to keep the chemical variables rate-controlling. Judging from the above results concerning the effects of certain variables on the reaction rate, the chemical reaction rate appeared to be rate-controlling under the conditions studied.

The Regeneration of Nickel Carbonyl (Catalytic Level). Concerning the catalytic level of nickel carbonyl in the catalytic carboxylation reaction, very little has been known except for the information on the low-pressure catalytic reaction of acetylene.[5] Recently, with acetylene, it has been reported by Ehrreich *et al.*[4] that a catalytic level of 85% at the maximum, and usually 70—80%, was obtained in the low-pressure process by controlling the material-feed rates accurately under certain conditions. Furthermore, they have pointed out that the maximum catalytic levels for the reaction of substituted acetylenes were much less than that for unsubstituted acetylene, though no details were given.

A high pressure of carbon monoxide was necessary for obtaining a high catalytic level, though the high pressure reduced the reaction rate: in practice, a pressure of about 10 atm (at room temperature) was used at 170°C and one of about 4 atm, at 130°C. Consequently, even in the batch method, catalytic levels higher than 90% were obtained easily (Table 1). In the semicontinuous method, the catalytic levels were all above 95% (Table 2). The carbon monoxide pressure in these experiments might be high enough to produce such catalytic levels, though the critical limits of carbon monoxide pressure have not been clarified. On the other hand, even if the apparent pressure of carbon monoxide was high, the catalytic levels were low in cases of either an insufficient mixing of the reactants or the occurrence of a temporary violent reaction. In the batch method especially it was necessary to choose the reaction conditions so that no violent reaction occurred in the early stage of the reaction.

By-products. Methyl crotonate, methyl isobutyrate, and acetone were found as the main by-products, besides the polymerization products of methylacetylene and/or methyl methacrylate formed.[1] Of these by-products, methyl crotonate was measured in largest quantities, especially at higher reaction temperatures. This amount

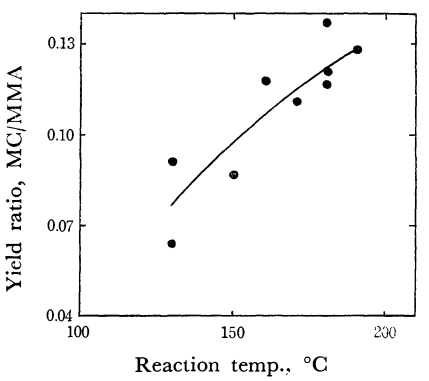

Fig. 6. Yield ratio of methyl crotonate to methyl methacrylate against reaction temp.

5) M. Salkind, E. H. Riddle and R. W. Keefer, *Ind. Eng. Chem.*, **51**, 1328 (1959); Numerous patents.

decreased, however, with a decrease in the reaction temperature and the yield ratio of methyl crotonate to methyl methacrylate dropped from about 0.13 at 190°C to about 0.08 at 130°C, as Fig. 6 shows. The amount of methyl isobutyrate was very small (below 0.2%), in most cases being only a trace, in the catalytic reactions conducted at high catalytic levels, as was to be expected from the very small decomposition of nickel carbonyl. Acetone also was found in only a trace under those conditions.

Although the loss of methylacetylene due to its polymerization appeared to be a main cause of the poor yield of the carboxylation products in the batch method, as has been described in the previous paper,[1] the polymerization was markedly decreased by adding methylacetylene continuously and by carrying out the reaction at a low temperature (Table 2).

Optimum Conditions for the Synthesis of Methyl Methacrylate. The above results concerning the reaction rate, the catalytic level, and the by-products in the catalytic reaction give some hints for a search after the optimum conditions for this synthesis, though their determination is difficult. As expected, it would be advantageous to carry out this reaction under the following conditions: at as low and constant a pressure as possible, in order to make the reaction rate fast, within the critical limits for maintaining high catalytic levels; at as low and constant a temperature as possible, to suppress the formation of methyl crotonate, taking account of the reaction rate; in the presence of such effective additives as acids and water; under a mixing sufficient to keep the liquid diffusion of carbon monoxide good; and by a continuous process, to suppress the polymerization of methylacetylene and methyl methacrylate and to avoid a temporary violent reaction.

Therefore, the synthesis was attempted semi-continuously using a laboratory apparatus by which at least methylacetylene and carbon monoxide were each introduced continuously, though it would be better to feed all the raw materials continuously under accurate control. Several results are shown in Table 2. Under the present conditions, the catalytic reaction began a short time after the addition of a small amount (0.5—0.8 g) of methylacetylene, and thence proceeded smoothly at a high catalytic level, over 95%. The total yield of methyl methacrylate and methacrylic acid was 82—85%. The best yield, 85%, was obtained when the reaction was carried out in the presence of methacrylic acid and a small amount of water at a total pressure of 13 atm (initial charge of carbon monoxide at room temperature: 4 atm), a reaction temperature of 130°C, and a feed rate of 4.8 g/hr (Exp. 16). The use of a lower carbon monoxide pressure is promising and would possibly be more advantageous. With a lower pressure, however, it was difficult to control and maintain the catalytic reaction using our apparatus, because the effect of the fluctuation of the carbon monoxide pressure on the reaction rate and the catalytic level becomes remarkably large with a decrease in the pressure. Recently, Happel *et al.*[6] have reported the synthesis of methyl methacrylate by a low pressure catalytic carbon monoxide-nickel carbonyl-methylacetylene process, as used with acetylene itself. The catalytic level, however, seems to be lower than 70%.

Reaction Mechanism. The mechanism of the catalytic carboxylation reaction has not yet been well clarified though it has been discussed by several workers.[7] On the basis of our experimental results, the following mechanism, similar to one of the possible mechanisms presented by Heck,[7a] may be proposed:

$$Ni(CO)_4 + HX \underset{k_2}{\overset{k_1}{\rightleftharpoons}} HNi(CO)_{4-n}X + nCO \quad (1)$$

$$CH{\equiv}CR + HNi(CO)_{4-n}X \xrightarrow{k_3} CH_2{=}\overset{R}{\overset{|}{C}}Ni(CO)_{4-n}X\ (+\ RCH{=}CHNi(CO)_{4-n}X) \quad (2)$$

$$CH_2{=}\overset{R}{\overset{|}{C}}Ni(CO)_{4-n}X + CO \xrightarrow{k_4} CH_2{=}\overset{R}{\overset{|}{C}}CONi(CO)_{4-n}X \quad (3)$$

$$CH_2{=}\overset{R}{\overset{|}{C}}CONi(CO)_{4-n}X + R'OH \xrightarrow{k_5} CH_2{=}\overset{R}{\overset{|}{C}}CO_2R' + HNi(CO)_{4-n}X \quad (4)$$

HX = water, organic or inorganic acids
R′ = H or alkyls

Assuming that reaction (1) is a rapid reversible reaction and that reaction (2) is the rate-determining step, which is followed by the two rapid reactions, (3) and (4), the initial rate of the overall reaction can be given by the following equation:

$$\text{Initial rate} = (k_1k_3/k_2)[Ni(CO)_4][HX][RC{\equiv}CH]/(P_{CO})^n$$

The experimental results concerning the initial reaction rate seem to confirm the above relation ship, though they are rough.

Reaction (1) forms a hydronickel carbonyl hydroxide ($HNi(CO)_{4-n}X$, X=OH), which is the true catalyst. This reaction (1) is supported by the experimental finding that the reaction rate was accelerated by the presence of such additives as water and acids, and markedly decreased with an increase in the carbon monoxide pressure.

6) J. Happel and C. J. Marsel, Belg. Pat. 639260 (1964) (*Chem. Abstr.*, **62**, 9019 (1965)).
7) a) R. F. Heck, *J. Am. Chem. Soc.*, **85**, 2013 (1963); b) C. W. Bird, *Chem. Revs.*, **62**, 283 (1962); c) P. L. Pauson, *Proc. Chem. Soc.*, **1960**, 297.

Furthermore, effective additives may be supposed to form a highly reactive $HNi(CO)_{4-n}X$. The n value in $HNi(CO)_{4-n}X$ would probably be 2 or higher, in view of the fact that the initial rate is reversely proportional to over the second power of the carbon monoxide pressure. The subsequent steps, reactions (2)—(4), are similar to those proposed to explain the hydroformylation reaction,[8] except for replacing hydrogen reduction with hydrolysis or alcoholysis. In addition, judging from the distribution of the reaction products, it may be concluded that, under the conditions studied, reaction (2) proceeds predominantly to give an addition product, alkenylnickel carbonyl hydroxide (X=OH), with a branched chain.

Dimerization of Acrylonitrile by Ruthenium Chloride

Akira MISONO, Yasuzo UCHIDA and Masanobu HIDAI

Department of Industrial Chemistry, The University of Tokyo, Hongo, Tokyo

and Hiroyuki SHINOHARA and Yoshihisa WATANABE

Mizonokuchi Research Laboratory, Mitsubishi Petrochemical Company Ltd., Kawasaki

(Received July 17, 1967)

The end-to-end dimerization of acrylonitrile was effected with a ruthenium trichloride trihydrate catalyst under a hydrogen atmosphere, thus obtaining a mixture of *cis*- and *trans*-1, 4-dicyano-1-butene as the main products. Under nitrogen, however, only very small amounts of these products were formed. The reaction occurred at temperatures of 120—200°C under moderate hydrogen pressures in alcoholic media such as ethanol. The effects of various salts or electron-donating compounds on the catalysis were examined.

Previously we reported[1] that acrylonitrile was, though not catalytically, converted at an elevated temperature to a mixture of propionitrile, 2-methylglutaronitrile, and adiponitrile with several systems involving hydride complexes of cobalt or iron. The end-to-end dimerization of methyl acrylate by a rhodium or ruthenium chloride catalyst has been found by Alderson *et al.*[2] However, acrylonitrile does not dimerize successfully in the same reaction. In this paper, we wish to report the successful catalytic dimerization of acrylonitrile, which primarily gives end-to-end coupling products. The reaction was effected with ruthenium trichloride trihydrate under a hydrogen atmosphere; it was not, however, catalytic under a nitrogen atmosphere. The variation in the reaction temperature and the hydrogen pressure was examined, and the effects of the addition of various salts or electron-donating compounds were also studied.

Results and Discussion

The reaction of acrylonitrile by the use of various second- and third-row transition metal compounds, especially chlorides, was investigated in order to obtain the dimers of acrylonitrile. A part of the results are shown in Table 1. The reaction of acrylonitrile by ruthenium chloride under a nitrogen atmosphere yielded only a small percentage of propionitrile and acrylonitrile dimers. The replacement of the nitrogen atmosphere with ethylene improved the yield of the dimers to 10%. When acrylonitrile was treated with an ethanol solution of ruthenium chloride under a hydrogen atmosphere, acrylonitrile was catalytically converted to a mixture of propionitrile and acrylonitrile dimers. Gas chromatographic analysis showed that the dimers were a mixture of three components. The three components were isolated by the fractional distillation of the mixture. The fraction with a bp of 107°C/2 mmHg was identified as adiponitrile by a comparison of the retention time and the infrared spectrum with those of an authentic sample. Both the fraction with a bp of 95°C/2 mmHg, A, and the fraction with a bp of 175—180°C/2 mmHg, B, were hydrogenated over palladium black at room temperature to

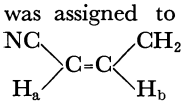
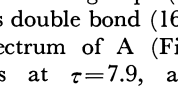
give adiponitrile. The amount of hydrogen gas absorbed indicated that both A and B were dimers of acrylonitrile carrying a double bond. The infrared spectrum of A (Fig. 1) showed the presence of two different nitrile groups (*ca.* 2230 and 2210 cm^{-1}) and a cis double bond (1630 and 750 cm^{-1}). The NMR spectrum of A (Fig. 2) showed the complex bands at $\tau=7.9$, a doublet at $\tau=4.9$, and the complex band at $\tau=4.1$ in an intensity ratio of 4 : 1 : 1. The bands at $\tau=7.9$ were assignable to the four methylene protons of $-CH_2CN$ and $-CH_2-CH=CH-$. The doublet at $\tau=4.9$ with a spin-spin coupling constant of 10 cps was assigned to the cis olefinic proton, H_a, in



, while the band at $\tau=4.1$ was assigned to the other olefinic proton, H_b. On the other hand, the infrared spectrum of B (Fig. 1) showed the presence of two different nitrile groups (*ca.* 2240 and 2220 cm^{-1}) and a trans double bond (1640 and 965 cm^{-1}). The NMR spectrum of B (Fig. 2) showed a doublet at $\tau=5.1$ with a large spin-spin coupling constant of 16 cps; it was assigned to the trans olefinic proton, H_a, in



. From these results, A and B were identified as *cis*- and *trans*-1,4-dicyano-1-butene respectively.

$$CH_2{=}CHCN \xrightarrow[\text{under } H_2]{RuCl_3 \cdot 3H_2O} \begin{cases} CH_3CH_2CN \\ NCCH{=}CHCH_2CH_2CN \text{ (cis and trans)} \\ NC(CH_2)_4CN \end{cases}$$

Other transition metal chlorides, such as rhodium, palladium, tungsten, molybdenum, or iridium chlorides, gave only propionitrile in reactions

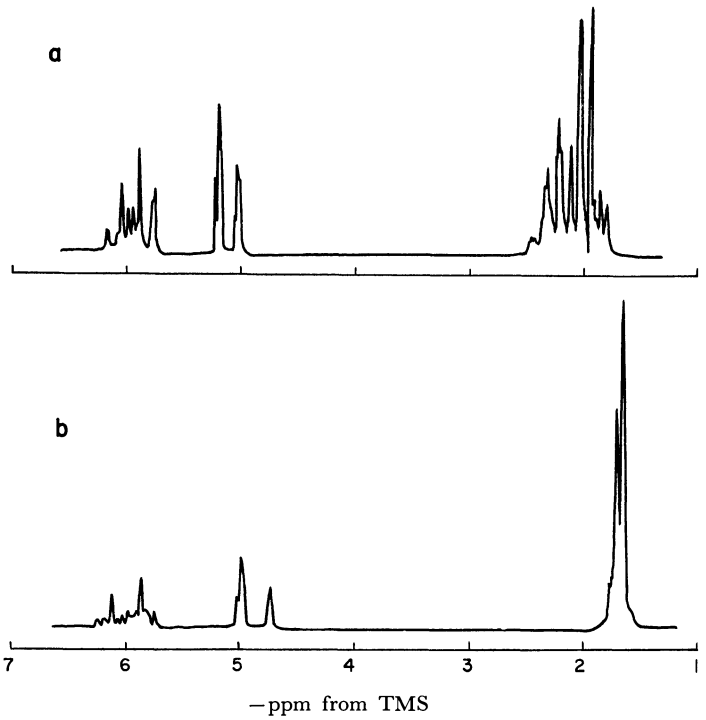


Fig. 2. NMR spectra of (a) *cis*-1,4-dicyano-1-butene and (b) *trans*-1,4-dicyano-1-butene in benzene.

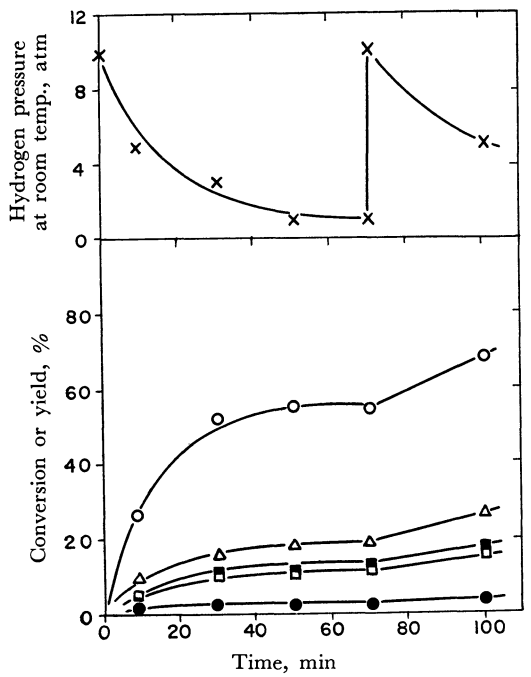

Fig. 3. Relationship between reaction time and hydrogen pressure or yields of products at 150°C: ○, conversion of acrylonitrile; △, yield of propionitrile; □, yield of *cis*-1,4-dicyano-1-butene; ●, yield of adiponitrile; ■, yield of *trans*-1,4-dicyano-1-butene.

under a hydrogen atmosphere.

In this catalytic conversion of acrylonitrile to a mixture of *cis*- and *trans*-1,4-dicyano-1-butene, adiponitrile, and propionitrile by the use of ruthenium chloride, hydrogen appears to play an important role in the reaction mechanism, as the reaction did not proceed catalytically in the absence of hydrogen. Figure 3 shows the relationship between the reaction time or the hydrogen pressure and the yields of the products. When 10 atm of hydrogen (the pressure at room temperature) was charged into the reaction vessel at 150°C, a rapid uptake of hydrogen occurred, and propionitrile and the dimers were formed. When the hydrogen pressure (converted to the value at room temperature) went below 1 or 2 atm after *ca.* 30 min, the reaction of acrylonitrile nearly stopped. However, when another 9 atm of hydrogen was charged into the reaction vessel after 70 min, the absorption of hydrogen again started, and propionitrile and the dimers were obtained. This would suggest that the reaction proceeds through a ruthenium hydride complex, which is regenerated by a large amount of hydrogen. We have already reported[3] that two yellow complexes, which catalyzed the dimerization of acrylonitrile, were obtained by the reaction of acrylonitrile and ruthenium trichloride under a nitrogen or hydrogen

3) A. Misono, Y. Uchida, M. Hidai and H. Kanai, *Chem. Commun.*, 357 (1967).

atmosphere. The first complex, $(CH_2=CHCN)_3RuCl_2$, was obtained by refluxing a solution of ruthenium trichloride in ethanol with a large excess of acrylonitrile under nitrogen. In the complex, acrylonitrile was bonded to the metal through the nitrogen lone pair. The other complex obtained by the reaction under hydrogen at 150°C had a cyanoethyl group attached to the metal. The following reaction mechanism may be assumed on the basis of these results. An intermediate complex may be formed in the reaction in which a hydride ion and at least two molecules of acrylonitrile are coordinated to ruthenium. When a cyanoethyl group formed by the insertion reaction of acrylonitrile into the ruthenium-hydride bond reacts with hydrogen, propionitrile will be formed, while a dicyanobutyl complex will be formed by the insertion of an acrylonitrile molecule into the ruthenium-cyanoethyl bond. This dicyanobutyl complex may decompose to give 1, 4-dicyano-1-butene or may react with hydrogen to yield adiponitrile.

Figure 4 shows the effect of the initial hydrogen pressure on the reaction. The yields of propionitrile and adiponitrile increased with an increase in the initial hydrogen pressure, while the yield of 1, 4-dicyano-1-butene decreased. This would imply that, under a high hydrogen pressure, a cyanoethyl complex and a dicyanobutyl complex easily react with hydrogen to give propionitrile and adiponitrile respectively.

The formation of the dimers and propionitrile is strongly dependent on the reaction temperature, as Fig. 5 shows. Below 120°C, the reaction was slow. The conversion of acrylonitrile varied with the reaction temperature, although the composition of the products was almost unchanged at temperatures of 140—180°C. Above *ca.* 180°C, the yield of propionitrile gradually decreased, while the yield of the dimers greatly decreased with an increase in the reaction temperature. These may be explained by the thermal instability of such reaction intermediates as a hydride complex and a cyanoethyl complex.

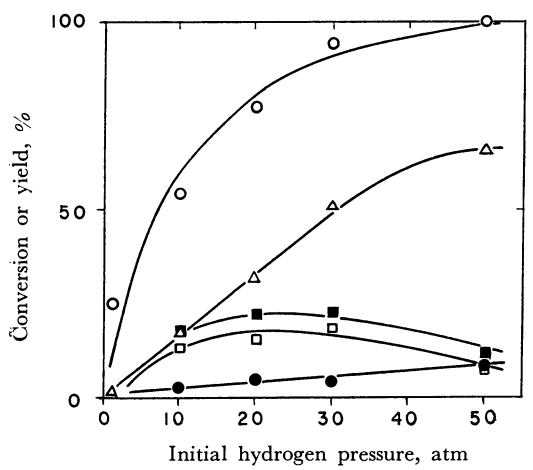

Fig. 4. The effect of initial hydrogen pressure on the formation of products: reaction temp., 150°C; about 0.5 hr was used for heating up, and the mixture was kept at 150°C for 0.5 hr; ○, conversion of acrylonitrile; △, yield of propionitrile; □, yield of *cis*-1, 4-dicyano-1-butene; ●, yield of adiponitrile; ■, yield of *trans*-1, 4-dicyano-1-butene.

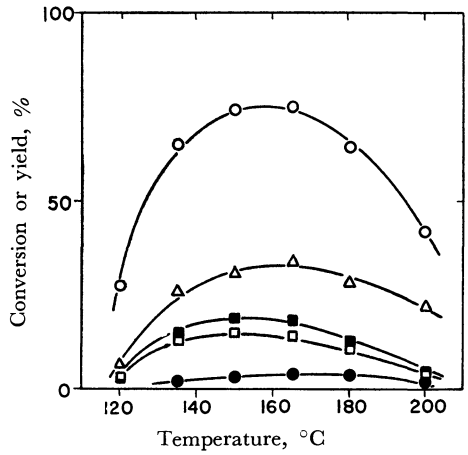

Fig. 5. The effect of reaction temperature on the formation of products: initial hydrogen pressure, 20 atm; reaction time, 40 min; ○, conversion of acrylonitrile; △, yield of propionitrile; □, yield of *cis*-1, 4-dicyano-1-butene; ●, yield of adiponitrile; ■, yield of *trans*-1, 4-dicyano-1-butene.

Various salts or electron-donating compounds were added to the reaction solution in order to change the valency state of ruthenium or to replace the ligands of ruthenium trichloride with other ligands. The results of the addition of those compounds are given in Table 2. Propionitrile was mainly formed when acrylonitrile was treated under a hydrogen atmosphere with a dark-blue ethanol solution of ruthenium(II) chloride prepared by the reduction of ruthenium trichloride with titanium trichloride. This ruthenium(II) chloride has been known to catalyze the homogeneous hydrogenation of olefinic bonds in compounds, such as maleic, fumaric, and acrylic acids, in which the double bond is activated by the presence of an adjacent carboxyl group.[4] Wilkinson has reported[5] that, on heating solutions of ruthenium trichloride trihydrate with tin dichloride in ethanol, dark-blue solutions which appear to contain ruthenium(II) are obtained. The addition of tin dichloride to the reaction solution also gave propionitrile as the main product.

a) Reaction conditions: 10m*l* of acrylonitrile; 20m*l* of ethanol; 0.200 g of $RuCl_3 \cdot 3H_2O$; 30 atm of initial hydrogen pressure. About 0.5 hr was used for heating up, and the mixture was kept at the designated temperature for 0.5 hr. b) Molar ratio of an additive to $RuCl_3 \cdot 3H_2O$. c) Abbreviations: PN, propionitrile; ADN, adiponitrile; cis, *cis*-1,4-dicyano-1-butene; trans, *trans*-1,4-dicyano-1-butene. d) Trace.

On the other hand, the reaction was hardly affected at all when potassium chloride, lithium chloride, lithium bromide, or sodium iodide was added to the reaction solution in order to vary the concentration of chloride ions or in order to replace the chloride ions of ruthenium trichloride with bromide or iodide ions.[6] The reaction was, however, strongly inhibited by the addition of two moles of pyridine per mole of ruthenium trichloride to the reaction solution. This may be explained by the coordination of pyridine to ruthenium, which prevents the coordination of the acrylonitrile molecules or the activation of the hydrogen molecule. The reaction was, however, hardly affected at all by the addition of large amounts of quinoline, which is a weaker coordinating agent than pyridine. In the dimerization of acrylonitrile, three coordination sites around the ruthenium atom may be required for a hydride ion and two molecules of acrylonitrile, as in the case of the dimerization of ethylene using a rhodium trichloride catalyst.[7] The reaction may be strongly affected when other ligands such as pyridine occupy those coordination sites.

Experimental

Reagents. Acrylonitrile was distilled under nitrogen, and 0.1% of hydroquinone was added to the acrylonitrile distilled. Methanol and ethanol were dried with Drierite and distilled under nitrogen. All transition-metal chlorides were commercially obtained.

The Reaction of Acrylonitrile by the Use of Ruthenium Trichloride Trihydrate. *A. The Reaction under a Nitrogen Atmosphere.* A 100-m*l* stainless-steel autoclave was charged with 20 m*l* of ethanol, 10 m*l* of acrylonitrile, and 0.200 g of ruthenium trichloride trihydrate under nitrogen. The mixture was then heated to 170°C and kept at that temperature for 4 hr. The reaction products, when quantitatively analyzed by means of gas chromatography, were found to be propionitrile (2% of the acrylonitrile originally fed in) and *cis*- and *trans*-1,4-dicyano-1-butene (5%).

B. The Reaction under a Hydrogen Atmosphere. A reaction solution was prepared as above. The atmosphere was replaced with 30 atm of hydrogen, and the mixture was heated to 150°C. About 0.5 hr was used for the heating-up, after which the mixture was kept at 150°C for 0.5 hr. Gas chromatographic analysis showed that the products were propionitrile (51%), adiponitrile (4%), *cis*-1,4-dicyano-1-butene (18%), and *trans*-1,4-dicyano-1-butene (22%). The conversion of acrylonitrile was 94%.

In order to examine the effects of the reaction temperature and the reaction time on the formation of the products, the reaction mixture prepared under a nitrogen atmosphere was heated up to a reaction temperature, and hydrogen gas of a definite pressure was charged into the reactor at that temperature. A rapid uptake of hydrogen occurred, and propionitrile, *cis*- and *trans*-1,4-dicyano-1-butene, and adiponitrile were formed.

C. Addition of Salts or Electron-donating Compounds. A reaction solution was prepared as above except that a calculated amount of an additive was added. The atmosphere was replaced with 30 atm of hydrogen, and then the mixture was heated to 150 or 170°C and kept at that temperature for 0.5 hr. The products were analyzed by gas chromatography.

The Reaction of Acrylonitrile by the Use of Other Transition-metal Chlorides. The reaction solution was prepared in a way similar to that used in the case of ruthenium chloride. The atmosphere was

7) R. Cramer, *J. Am. Chem. Soc.*, **87**, 4717 (1965).

replaced with 30 atm of hydrogen, and the mixture was heated to a reaction temperature. The products were analyzed by gas chromatography.

Isolation and Identification of the Products. The reaction products were isolated by the fractional distillation of the reaction solution. Propionitrile and adiponitrile were identified by a comparison of their retention times and infrared spectra with those of authentic samples. The *cis*- and *trans*-1, 4-dicyano-1-butene isolated by the fractional distillation were characterized by their infrared and NMR spectra. They were hydrogenated over palladium black at room temperature to give adiponitrile.

Gas Chromatographic Analysis of the Products. For the analysis of acrylonitrile and propionitrile, a 2.5-m tricresyl phosphate column was used. The conditions were: column temperature, 100°C; flash evaporator temperature, 150°C; helium gas speed, 40 m*l*/min. For the analysis of *cis*- and *trans*-1, 4-dicyano-1-butene and adiponitrile, a 2-m polyoxyethylene sorbitan monooleate column was used, and the conditions were: column temperature, 200°C; inlet temperature, 250°C; helium gas speed, 50 m*l*/min.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 401—407 (1968)

Studies on Separation of Amino Acids and Related Compounds. III. Separation of Diastereomers of Leucyl Dipeptides by Ion-Exchange Chromatography

Kosaku NODA, Hideo OKAI, Tetsuo KATO and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received July 21, 1967)

A series of experiments on a column chromatography of Dowex 50 with ammonium acetate solvent systems as eluent was carried out in order to find optimal conditions for the separation of the diastereomers of leucylalanine, leucylvaline, leucylleucine and leucyltyrosine. The effects of pH concentration of the salt and alcohols in the solvent systems for the separation of the diastereomers were studied. Among many conditions tested, the change of pH in the solvent system afforded most remarkable influence for the separation; the order of elution of the diastereomers of the dipeptide was found to be inverted at near pH 5.0. On a preparative scale L-leucyl-DL-valine was successfully separated into the two diastereomers by using a fairly large column. Attempt to separate benzyloxycarbonyl-L-leucyl-DL-valine benzyl ester with a column of Sephadex LH-20 was described, also.

Previous papers from this laboratory have dealt with the analytical and preparative separation of hydroxyproline diastereomers on columns of the ion-exchange resin.[1] In the present paper, we describe the manipulation of the variables in the ion-exchange technique and the preparative separation of leucyl dipeptide diastereomers.

Several investigators have reported the separation of the diastereomers of dipeptide on paper[2] and thin-layer chromatography.[3] On an ion-exchange column chromatography of Dowex 50, Blackburn and Tetley reported the separation of L-leucyl-L-tyrosine and L-leucyl-D-tyrosine with citrate buffer of pH 4.8,[4] and Neuhaus separated alanylalanine diastereomers.[5] Yanari *et al.* separated a mixture of leucyltyrosine diastereomers by the use of DEAE-cellulose column.[6] Although these investigators cited above carried out the chromatographies in analytical manner using several mg or less of dipeptide diastereomers, Wieland and Bende reported recently the separation of several dipeptide diastereomers on a preparative scale; for example, they separated 200 mg of DL-alanyl-L-tyrosine into each pure diastereomer with a Sephadex G-50 column (1.5 × 100 cm) using a solvent of aqueous pyridine.[3]

In this investigation, each diastereomer of leucylalanine, leucylvaline, leucylleucine and leucyltyrosine were prepared in the conventional manner as the first step of the experiment. For

example, L-leucyl-L-alanine was synthesized as follows:

$$\text{Z-Leu-OH} + \text{H-Ala-OBzl} \xrightarrow{\text{mixed anhydride method}}$$

$$\text{Z-Leu-Ala-OBzl} \xrightarrow{H_2/Pd} \text{H-Leu-Ala-OH}$$

(Z, benzyloxycarbonyl; OBzl, benzyl ester)

It was observed that a diastereomeric mixture of any peptide was separated appreciably enough by paper chromatography (Table 1).

As a preliminary experiment of a column chromatography, ion-exchange (strong acid type) paper chromatography was carried out with leucylleucine and leucyltyrosine in order to find the effect of pH and alcohols in an ammonium acetate solvent system (Tables 2 and 3). However, it was observed that anticipation to find the optimal condition for a separation of the diastereomers on a column through the study of ion-exchange paper chromatography appeared to be difficult. Then, the effects of variations of pH, alcohol, and concentration of ammonium acetate in the solvent system were studied by using a small column (0.9 $\times$ 50 cm) with Dowex 50X8.

In the course of the column chromatographic experiment, we observed the interesting phenomena; each L-L diastereomer of leucylalanine, leucylvaline or leucylleucine with a solvent of higher pH than 5.0 was eluted more rapidly than the corresponding L-D isomer, whereas each L-L isomer was eluted slower at pH 4.5 (Figs. 4—6). To elucidate these inversions, the titration experiments of the L-L and L-D isomer of each peptide were carried out by using a pH-stat, and it was found that the titration curves for the diastereomers of each peptide crossed each other around pH 5 (Figs. 10—12). Then, the inversion in the chromatographic pattern may be explained by the interpretation that the main interaction between the resin and the dipeptide is due to ionic forces and the ionic conditions of the diastereomers of the dipeptide are inverted each other at a definite pH near 5.

As an experiment on a preparative scale, a L-leucyl-DL-valine preparation was tried to separate with a large column (1.8 $\times$ 110 cm) of Dowex 50 under the good condition which was found previously by using smaller column. For the synthesis of L-leucyl-DL-valine, the mixed anhydride of benzyloxycar-L-leucinebonyl was coupled with DL-valine benzyl ester and the benzyloxycarbonyl-dipeptide ester obtained as syrup was hydrogenated to crude dipeptide, L-Leu-DL-Val, which was subjected to the separation experiment without further purification.[7] With the large column using 0.2 M ammonium acetate of pH 7.0, we could separate 1 g of the crude peptide into 0.40 g of pure L-leucyl-L-valine and 0.48 g of L-leucyl-D-valine.

Separation of the oily Z-L-Leu-DL-Val-OBzl preparation with a column (0.9 $\times$ 50 cm) of Sephadex LH-20 using dioxane or methanol as solvent was attempted; it was found that the separation was occurred partially (Fig. 13). Reviewing the literature on the separation of acyldipeptide ester, Weygand *et al.* reported the separation of the diastereomeric mixture of trifluoroacetyl-phenylalanylvalyl methyl ester by gas chromatographic technique.[8] As the studies using a Sephadex LH-20 or methylated Sephadex column, Waki and Izumiya applied it successfully for the separation of benzyloxycarbonyl-substituted gramicidin S and cyclosemigramicidin S,[9] and Mutt *et al.* reported the separation of Z-L-Leu-L-Leu-OMe and *p*-nitrophenol during a peptide synthesis by the active ester method.[10]

Experimental

The melting points were uncorrected. Optical rotations were determined with a Yanagimoto Photometric Polarimeter, OR-20 type.

D-Valine Benzyl Ester *p*-Toluenesulfonate (I). A mixture of D-valine, benzyl alcohol, *p*-toluenesulfonic acid monohydrate, and benzene was heated as has been described for the preparation of the corresponding L-isomer.[11] Yield, 78%; mp 157—158°C; $[\alpha]_D^{25}$ +4.8° (*c* 2, ethanol) (Found: C, 60.05; H, 6.74; N, 3.68%).

DL-Valine Benzyl Ester *p*-Toluenesulfonate (II). The crude crystals obtained by the usual way were recrystallized from ethanol-ether; yield, 94%, mp 138—140°C (Found: C, 59.88; H, 6.88; N, 3.75%).

D-Leucine Benzyl Ester *p*-Toluenesulfonate (III). This compound was obtained according to the procedure for the L-isomer.[11] Yield, 75%; mp 155—156°C; $[\alpha]_D^{25}$ −0.5° (*c* 2, ethanol) (Found: C, 60.96; H, 7.05; N, 3.67%).

Benzyloxycarbonyl-L-leucyl-L-alanine Benzyl Ester (IV)[12] To a chilled solution of benzyloxycarbonyl-L-leucine[13] (2.65 g) and triethylamine (1.4 ml) in tetrahydrofuran (20 ml), isobutyl chloroformate (1.32 ml) was added at −5°C. After 15 min, a mixture of L-alanine benzyl ester *p*-toluenesulfonate[11] (3.51 g) and triethylamine (1.4 ml) in chloroform (20 ml) was added. The mixture was left to stand overnight at room temperature, and then evaporated *in vacuo*. The residue was dissolved in ethyl acetate (30 ml), then the solution was successively washed with 4% sodium bicarbonate, 2% hydrochloric acid and water, and dried

7) It was found that the ratio of the L-L and L-D isomer in the crude dipeptide was 82 : 100 by an amino acid analyzer.

over sodium sulfate. The filtrate was evaporated *in vacuo*, and the oily residue was solidified by the addition of petroleum ether. The product was recrystallized from ethyl acetate - ether - petroleum ether; yield, 2.78 g (65%), mp 111°C; $[\alpha]_D^{25}$ −45.5° (*c* 2, ethanol).

Found: C, 67.55; H, 7.25; N, 6.69%. Calcd for $C_{24}H_{30}O_5N_2$: C, 67.58; H, 7.09; N, 6.57%.

Benzyloxycarbonyl-L-leucyl-D-alanine Benzyl Ester (V). The mixed anhydride of benzyloxycarbonyl-L-leucine was coupled with a mixture of D-alanine benzyl ester *p*-toluenesulfonate[14] and triethylamine in chloroform as described above; yield, 67%; mp 120—121°C; $[\alpha]_D^{25}$ +1.2 °(*c* 2, ethanol).

Found: C, 67.80; H, 7.14; N, 6.54%.

Benzyloxycarbonyl-L-leucyl-DL-valine Benzyl Ester (VI). Benzyloxycarbonyl-L-leucine (2.65 g, 10 mmol) was coupled with II (10 mmol) by the mixed anhydride, and the compound (VI) was obtained as syrup; yield, 4.01 g (88%).

Benzyloxycarbonyl-L-leucyl-D-leucine Benzyl Ester (VII). This compound was obtained from benzyloxycarbonyl-leucine and III; yield, 68%; mp 110—112°C; $[\alpha]_D^{25}$ +2.3° (*c* 2, ethanol).

Found: C, 68.96; H, 7.68; N, 5.99. Calcd for $C_{27}H_{36}O_5N_2$: C, 69.20; H, 7.74; N, 5.98%.

L-Leucyl-L-alanine. A solution of IV (2.13 g) in a mixture of acetic acid (30 m*l*), methanol (15 m*l*), and water (5 m*l*) was treated with hydrogen in the presence of palladium black. The filtrate from the catalyst was evaporated *in vacuo* to dryness. The residual crystals were recrystallized from methanol-acetone-ether; yield of L-Leu-L-Ala monohydrate, 0.96 g (87%); $[\alpha]_D^{25}$ +27.6° (*c* 1, H_2O), +21.8°C (*c* 1, methanol) (Found: C, 49.52; H, 9.15; N, 12.96%). Polglase and Smith reported the synthesis of L-Leu-L-Ala by the hydrogenolysis of Z-Leu-Ala-OH which was obtained by saponification of Z-Leu-Ala-OMe; $[\alpha]_D^{24}$ +22.9° (methanol).[15]

L-Leucyl-D-alanine. V (2.13 g) was hydrogenolyzed as described above; yield of L-Leu-D-Ala monohydrate, 0.93 g (85%); $[\alpha]_D^{25}$ +77.8° (*c* 1, H_2O) (Found: C, 45.67; H, 9.21; N, 12.02%). Reported value, $[\alpha]_D^{24}$ +76° (H_2O).[15]

L-Leucyl-L-valine. Benzyloxycarbonyl-leucine (1.32 g, 5 mmol) was coupled with L-valine benzyl ester as described for the preparation of IV. The oily Z-Leu-Val-OBzl thus obtained was hydrogenolyzed, and the residue was recrystallized from methanol-ether. Yield of L-Leu-L-Val monohydrate, 1.05 g (85%); $[\alpha]_D^{20}$ +18.0° (*c* 1, N HCl) (Found: C, 53.25; H, 9.46; N, 11.17%). Reported value, $[\alpha]_D^{23}$ +18.2° (N HCl).[16]

L-Leucyl-D-valine. Benzyloxycarbonyl-leucine (1.23 g) was coupled with I, and the oily Z-Leu-Val-OBzl obtained was hydrogenolyzed; yield of L-Leu-D-Val monohydrate, 90%; $[\alpha]_D^{20}$ +55.0° (*c* 1, H_2O) (Found: C, 53.41; H, 9.71; N, 11.32%). Reported value, $[\alpha]_D^{24}$ +55.3° (H_2O).[16]

L-Leucyl-DL-valine (VIII). The oily VII (2.27 g, 15 mmol) was hydrogenated in the usual manner, and the filtrate from the catalyst was evaporated to dryness; the yield of the residual powder was 1.18 g (95%, calcd as monohydrate). This powder was used for the experiment of separation without recrystallization. The weight ratio between the L-L and L-D diastereomer in the powder was determined as 82 : 100 by the use of an amino acid analyzer.

L-Leucyl-L-leucine. Benzyloxycarbonyl-leucine (1.32 g) was coupled with leucine benzyl ester, and the oily Z-Leu-Leu-OBzl obtained was hydrogenolyzed. Recrystallization from hot water yielded 0.79 g (63%) of L-Leu-L-Leu hemihydrate; $[\alpha]_D^{20}$ −13.4° (*c* 1, N NaOH) (Found: C, 56.67; H, 9.84; N, 10.89%). Reported value, $[\alpha]_D^{23}$ −13.4° (N NaOH).[16]

L-Leucyl-D-leucine. This compound was obtained from VII by the hydrogenolysis; yield of L-Leu-D-Leu dihydrate, 72%; $[\alpha]_D^{20}$ +68.0° (*c* 1, N HCl) (Found: C, 51.47; H, 9.63; N, 9.80). Reported value, $[\alpha]_D^{24}$ +68.5° (N HCl).[16]

L-Leucyl-L-tyrosine and L-Leucyl-D-tyrosine. These dipeptides were prepared as has been described in the literatures.[17]

Separation Studies on Paper Chromatographies. *a) Paper Chromatography.* A paper chromatography was carried out with ascending technique using Toyo Roshi No. 52 paper, and a peptide on the paper was revealed with ninhydrin. As shown in Table 1, it was observed that the diastereomers of each peptide were clearly separated on a chromatogram.

Table 1. R_f values of dipeptides on paper chromatography

Dipeptide	R_f	
	L-L	L-D
Leu-Ala[a]	0.73	0.52
Leu-Ala[b]	0.66	0.64
Leu-Val[b]	0.83	0.75
Leu-Leu[b]	0.90	0.81
Leu-Tyr[b]	0.78	0.66

a) Solvent system: pyridine-water (4 : 1, v/v)
b) Solvent system: *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2, v/v).

b) Ion-exchange Paper Chromatography. As the preliminary experiment for a column chromatography, a paper of Amberlite SA-II, NH_4^+ form, was applied for a dipeptide or a mixture of the two diastereomers using 0.2 M ammonium acetate solvent at a chosen pH. As shown in Tables 2 and 3, a mixture of the diastereomers was successfully separated at the different pH. Since a diastereomeric mixture of 4-hydroxyproline or 3-hydroxy-2-aminobutyric acid had been separated more effectively by the addition of alcohol such as methanol in the ammonium acetate solvent system,[1] the effect of alcohol to the solvent was studied; the addition of various alcohol afforded little effect on the separation pattern (Table 3).

Separation Studies on Column Chromatography. *a) Column and Solvent System.* A column (0.9×50 cm) was filled with Dowex 50WX8 (200—400 mesh), NH_4^+ form, and equilibrated by washing with an appropriate solvent system. A solvent of 0.2 M ammonium acetate, which was used in most cases, was prepared in the following manner. Ammonium acetate (15.4 g, 0.2 mol) was dissolved in water (500 m*l*), and acetic acid was added until the solution reached the desired pH. The solution was made up to 1 *l* with water, and adjusted again to the desired pH by the addition of acetic acid or ammonia.

b) Chromatography of Model Mixture. A mixture of each 0.05 mmol of a L-L form and L-D form of each dipeptide was dissolved in water (1 m*l*), and the solution was applied to the column and eluted with the appropriate solvent system at room temperature and a flow rate of about 10 m*l*/hr. Two-milliliter fractions were collected, and 0.01 m*l* of the eluate in each test tube was spotted on a strip of filter paper. The strip was dried up, immersed in a 0.2% ninhydrin-acetone solution, and heated at 100°C to find the presence of the peptide (Fig. 1A). Then, 0.01 m*l* of the eluate in the tubes which contain the peptide was applied on the paper chromatography (Fig. 1B). The amounts of color developed were determined by Atago AG-4 densitometer with slit 1×8 mm and 610 mμ (Fig. 1C) and

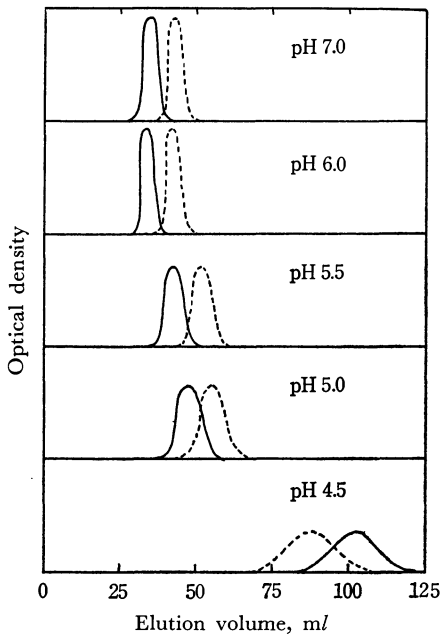

Fig. 4. Effect of pH in buffer system on separation of Leu-Ala.
Solid line, L-Leu-L-Ala; dotted line, L-Leu-D-Ala

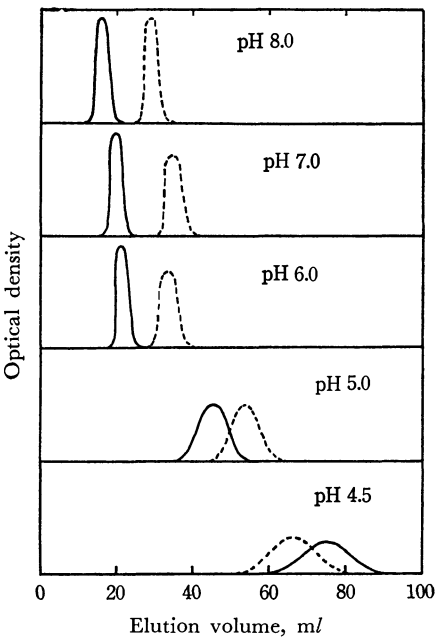

Fig. 5. Effect of pH in buffer system on separation of Leu-Val.
Solid line, L-Leu-L-Val; dotted line, L-Leu-D-Val

the integrated areas were plotted on a graph (Fig. 1D). It was observed that the color intensity of a L-D isomer was about 70% compared with that of the corresponding L-L isomer. In many figures (*e. g.*, Figs. 2—8) the area of the L-D isomer was corrected as of the value of the L-L isomer (Fig. 1E).

c) Effect of Concentration of Salt in Solvent System. Effect of variation in concentration (0.1—0.3 M) of ammonium acetate in a solvent was examined, and the patterns obtained were shown in Fig. 2 for Leu-Val and Fig. 3 for Leu-Leu. Since the 0.2 M ammonium acetate solvent gave best results for the separation, this solvent system was used in most cases in a series of experiments.

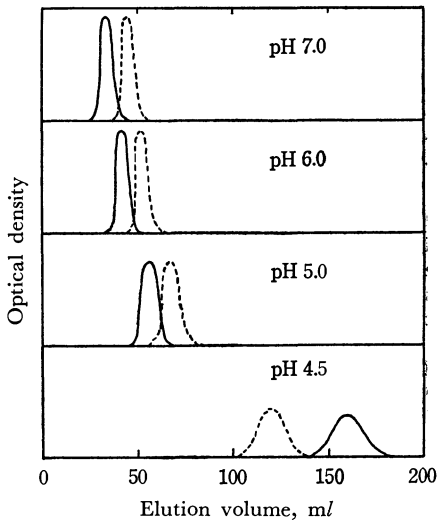

Fig. 6. Effect of pH in buffer system on separation of Leu-Leu.

In the case of pH 7.0 or 8.0 buffer, the curve by the L-L isomer coincided with that by the L-D isomer.

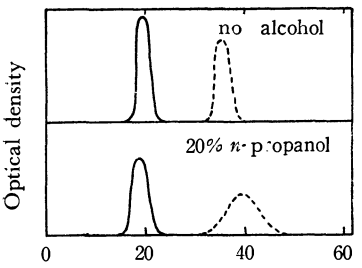

Fig. 8. Effect of alcohol in buffer system (pH 7.0) on separation of Leu-Val.
Solid line, L-Leu-L-Val; dotted line, L-Leu-D-Val

d) Effects of pH and Alcohol in Solvent System. Change of pH in the solvent was examined. As noted in Figs. 4—6, each L-L diastereomer of Leu-Ala, Leu-Val or Leu-Leu dipeptide with a solvent at higher pH than 5.0 was eluted more rapidly than the corresponding L-D isomer, on the contrary each L-L isomer was eluted slower at pH 4.5. In the case of Leu-Tyr, the observation of such an inversion of the order of elution was of difficult since the elution of this dipeptide was retarded and broadend remarkably at lower pH than 5. An optimum pH for best separation appeared to differ toward a diasteremeric mixture of each peptide; that pH are about 7.0 for Leu-Ala and Leu-Val, and 4.5 for Leu-Leu. Although it had been observed in the experiment with the ion-exchange paper that the addition of an alcohol in a solvent system hardly affected on separation, the effect of *n*-propanol in a column chromatography was examined (Fig. 8). The result showed again that the addition of the alcohol did not improve the separation.

e) Separation with Amino Acid Analyzer. A mixture of each 0.2 μmol of the L-L form and L-D form of Leu-Val was analyzed with Hitachi amino acid analyzer, model KLA-3, under these conditions: length of the column with spherical resin, 0.9×50 cm; solvent, citrate buffer at pH 4.25; flow rate, 60 ml/hr; jacket temperature, 55°C. The chromatogram obtained was shown in Fig. 9. The ratio of color intensities between L-Leu-L-Val and L-Leu-D-Val, which was calculated from the integrated areas on the chromatogram, was found to be 100 : 63.[18]

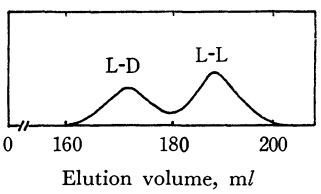

Fig. 9. Chromatogram of a diastereomeric mixture of Leu-Val by an amino acid analyzer.

18) In this connection, it would be noteworthy that the ratio of color intensities between L-Alloile-L-Tyr and D-Alloile-L-Tyr was 100 : 45; see, T. Yamashita, H. Uchio and N. Izumiya, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **80**, 767 (1959).

pH Titration Curve. Each diastereomer (0.05 mmol) of Leu-Ala, Leu-Val and Leu-Leu was dissolved in 1/30 N sodium hydroxide (3 ml), and automatic titration was carried out with 0.5 N hydrochloric acid with Radiometer pH-Stat, model TTT-1, at room temperature (Figs. 10—12). As noted from the figures, it was

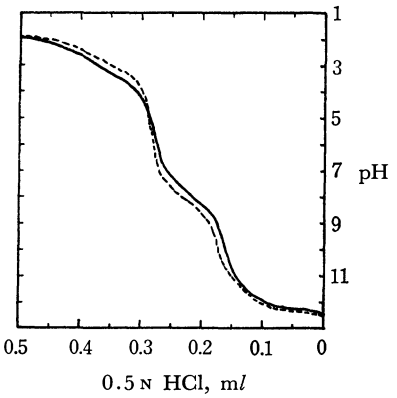

Fig. 10. pH titration curves of Leu-Ala.
Solid line, L-Leu-L-Ala; dotted line, L-Leu-D-Ala

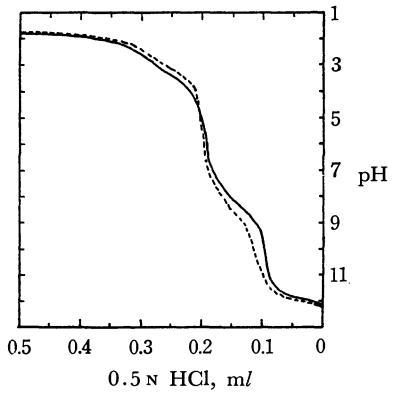

Fig. 11. pH titration curves of Leu-Val.
Solid line, L-Leu-L-Val; dotted line, L-Leu-D-Val

Solid line, L-Leu-L-Leu; dotted line, L-Leu-D-Leu

observed that the titration curves of the diastereomers crossed each other around pH 5 in which the inversions of the elution patterns of the diastereomers were observed as shown in Figs. 6—8.

Preparative Separation of L-Leu-DL-Val (VIII). A solution of VIII (1 g, 5 mmol) in a 0.2 M ammonium acetate solvent (40 m*l*) of pH 7.0 was put on a column (1.8×110 cm) of the Dowex 50, and eluted with the same solvent at a flow rate of 20 m*l*/hr. Each fraction (5 m*l*) was tested on a paper strip with ninhydrin, and the strip demonstrated that a mixture of the diastereomers was separated into two portions with the column. The faster eluting fractions from tube number 22 to 33 were evaporated *in vacuo* to dryness. Most of the ammonium acetate was removed by sublimation *in vacuo* for about 1 hr at 100°C. To remove completely the ammonium acetate still contaminated, a solution of the residue in water was put on a column of Dowex 50 (0.9×10 cm), H^+ form, and the column was eluted with 2 N ammonium hydroxide. The eluate was evaporated, and the residual crystals were recrystallized from methanol-ether; yield of L-Leu-L-Val monohydrate, 0.396 g (40%); $[\alpha]_D^{20}$ +17.5° (*c* 1, N HCl).

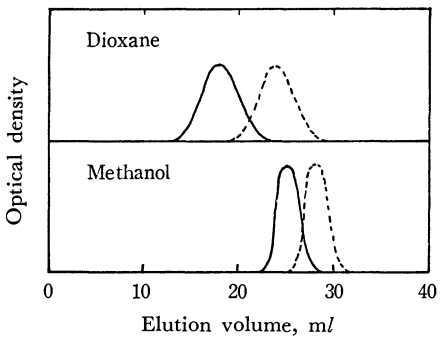

Fig. 13. Chromatogram of Z-L-Leu-DL-Val-OBzl on Sephadex LH-20 column.
Solid line, Z-L-Leu-L-Val-OBzl; dotted line, Z-L-Leu-D-Val-OBzl

Found: C, 53.13; H, 9.49; N, 11.15%. Calcd for $C_{11}H_{22}O_3N_2 \cdot H_2O$: C, 53.20; H, 9.74; N, 11.28%. The slower eluting fractions from tube number 34 to 47 were treated in the same manner as described above. Yield of L-Leu-D-Val monohydrate, 0.476 g (48%); $[\alpha]_D^{20}$ +55.0° (*c* 1, H_2O).

Found: C, 53.56; H, 9.53; N, 11.24%.

The weight ratio between the L-L and L-D isomer was calculated as 84 : 100 which agreed with the ratio of 82 : 100 observed for the crude L-Leu-DL-Val (VIII) by the amino acid analyzer.

Separation Studies of Z-L-Leu-DL-Val-OBzl (VII). Sample of the syrup (VII) (23 mg, 0.05 mmol) was applied to a column (0.9×50 cm) of Sephadex LH-20, and the column was eluted with dioxane or methanol at room temperature and a flow rate of about 5 m*l*/hr. One-m*l* fractions were collected, and small amount of each test tube was spotted on a thin-layer plate. The compound on the plate was detected by spraying 47% hydrobromic acid and then ninhydrin. Then, 0.05 m*l* of the elute in the test tubes which contain benzyloxycarbonyl-dipeptide ester was hydrogenated, and the filtrate from the catalyst was applied on paper chromatography, and Fig. 13 was prepared in the same manner as described for the preparation of Fig. 1B-1E.

Asymmetric Hydrogenating Activity of Modified Raney Nickel Catalyst

Susumu TATSUMI*1

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received July 22, 1967)

In the asymmetric hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate using Raney nickel catalysts modified with optically active hydroxy dicarboxylic acids and related compounds (for example, Y. Izumi, S. Tatsumi and M. Imaida, *Bull. Chem. Soc. Japan*, **39**, 2223 (1966)), the relationship between the asymmetric activities of the catalysts and the chemical or stereochemical structures of modifying reagents was discussed on the basis of data obtained previously. The effects of the conditions used for modification upon the asymmetric activity were also discussed inclusively. Moreover, the stability of asymmetric activity in the modified catalysts has been found to be very excellent.

Only a few attempts to obtain asymmetric hydrogenation using asymmetric catalysts have been recorded during the past ten years. In 1956, Akabori *et al.*[1-3] first reported on the asymmetric hydrogenation observed in experiments using silk-palladium catalysts. Subsequently, Isoda *et al.*[4] also reported the occurrence of asymmetric hydrogenation using an amino acid-palladium catalyst following a similar principle. The efficiencies of these catalysts, however, were rather low and the results were inconsistent because of the complexity of the conditions used.

Recently, Izumi and coworkers[5-6] obtained an excellent asymmetric hydrogenation catalyst. They reported that a Raney nickel catalyst treated with aqueous solutions of optically active amino acids has an asymmetric activity in the hydrogenation of carbonyl compounds to the corresponding alcohols. The author[7] also reported that in the hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate similar asymmetric activities are observed on the modifications*2 of a Raney nickel catalyst with optically active hydroxy acids, and that the hydroxy acids derived from the corresponding amino acids retaining their absolute configurations have reverse asymmetric effects in the direction of their optical rotation upon a Raney nickel catalyst to the parent amino acids. Subsequently, several reports on the asymmetric hydrogenation of methyl acetoacetate by catalysts modified with various optically active amino acids, hydroxy acids and their derivatives have appeared from our laboratory.[8-12]

$$CH_3COCH_2COOCH_3 \xrightarrow[\text{Modified Raney nickel catalyst}]{+2H} CH_3\underset{\displaystyle OH}{\underset{|}{C}}HCH_2COOCH_3$$

Thus, high asymmetric activities were obtained by modifications with optically active hydroxy dicarboxylic acids, such as D- or L-tartaric acid, L-malic acid and their *C*-alkyl or *C, C'*-dialkyl derivatives. An especially high asymmetric effect was observed on modification with optically active 2-methyltartaric acid,[10,13] the configuration of which has recently been assigned the threo form by the author.[14] However, there are no reports on the relationship between the chemical or stereochemical structures of modifying reagents and the

asymmetric activities of the catalysts. It is very important to find this relationship in order to obtain an effective asymmetric catalyst and elucidate the mechanism of this asymmetric hydrogenation.

In this paper, the relationship between the asymmetric activities of the catalysts in the hydrogenation of methyl acetoacetate to optically active methyl 3-hydroxybutyrate and the chemical or stereochemical structures of modifying reagents, such as optically active hydroxy dicarboxylic acids and related compounds, is discussed on the basis of the data obtained previously. The relation between the asymmetric activities and the conditions used for the modification of Raney nickel catalyst is also discussed. Moreover, the stability of asymmetric activity in the catalyst is studied.

The Occurrence of Asymmetric Activity*3

When a Raney nickel catalyst was modified with aqueous solutions of D- or L-tartaric acid[12] adjusted to pH 3—11, it had a high asymmetric hydrogenating activity, as shown in Fig. 1. On the contrary, under the same conditions the catalyst modified with optically inactive meso or racemic tartaric acid[12] did not.

Similar differences were observed on modifications with DL- and L-malic acid[12] and with DL- and L-citramalic acid (α-*C*-methylmalic acid),[12] as shown in Fig. 2.

These results clearly show that the presence or absence of asymmetric activity in the modified catalyst depends on the optical purity of the reagent used for the modification. Moreover, on modification with a reagent of the L-configuration, the catalyst produces the L-hydrogenation product, methyl L-3-hydroxybutyrate; while with a reagent of the D-configuration, the D-hydrogenation product is formed. The asymmetric activities of the catalysts in both cases were the same except for their direction of optical rotation. From these results, it is clear that on modification with a racemic form, two kinds of catalyst are produced in

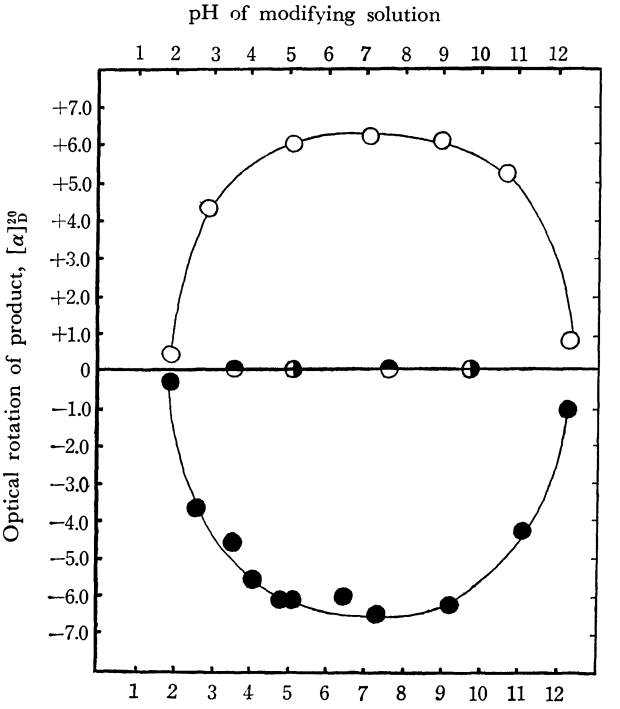

Fig. 1. Modifications with optically active and inactive tartaric acids. (Modified at 0°C)
● D-Tartaric acid ◑ DL-Tartaric acid
○ L-Tartaric acid ◓ *meso* Tartaric acid

*3 The asymmetric activity is provided by the observed specific rotation value of the hydrogenation product, methyl 3-hydroxybutyrate. According to Levene and Haller (Ref. 15), optically pure methyl 3-hydroxybutyrate has the value, $[\alpha]_D^{20}$ ±20.9° (without a solvent) and the levorotatory and dextrorotatory compounds correspond to the D- and L-series, respectively, in absolute configuration. The symbols, D and L, for the configurations used in this paper are based on the D_S- and L_S-series.

15) P. A. Levene and H. L. Haller, *J. Biol. Chem.*, **65**, 49 (1925).

◑ DL-Malic acid

the same ratio; one has the asymmetric activity to hydrogenate the substrate predominantly to the L-product and the other has the opposite asymmetric activity. As a result of the two activities the product is thus optically inactive and no asymmetric effect of the catalyst on the hydrogenation is observed.

On the other hand, when the modifying reagents loose their ability to be adsorbed on Raney nickel due to acylation of their hydroxyl groups and esterification of their carboxyl groups, the resulting catalysts have only very low asymmetric activities. In spite of the high asymmetric effect with D-tartaric acid, diethyl D-tartrate and *O*, *O'*-diacetyl D-tartaric acid had only very low or no asymmetric effects upon a Raney nickel catalyst.[6-7] These results show that the free hydroxyl and carboxyl groups of the modifying reagent play important roles in the asymmetric modification.

A similar result was observed on modification with an optically active dicarboxylic acid which has no hydroxyl groups in the molecule, such as L-methylsuccinic acid.[12] Although, like L-malic acid, L-methylsuccinic acid has one asymmetric center on the α-carbon atom, it has little or no asymmetric effect upon a Raney nickel catalyst. This is in marked contrast to the high asymmetric effect obtained on modification with L-malic acid, as shown in Fig. 2.

The difference in the asymmetric effects of these two optically active acids is clearly due to the fact that L-methylsuccinic acid does not contain a hydroxyl group which can be adsorbed or chelated to the nickel metal.

Thus it is concluded that to obtain an effective asymmetric catalyst the modifying reagent must possess at least two functional groups such as a hydroxyl group and a carboxyl group, and the reagent must have a strong ability to be adsorbed or chelated to a Raney nickel catalyst.

The Direction of Optical Rotation of the Asymmetric Activity

Catalysts modified with D-tartaric acid gave methyl D-3-hydroxybutyrate as a hydrogenation product, while those modified with L-tartaric acid gave methyl L-3-hydroxybutyrate, as shown in Fig. 1. Moreover, on modifications with compounds of the D-configuration, such as monomethyl D-tartrate,[12] *O*-monobenzoyl D-tartaric acid,[7] and D-*threo*-2, 3-dihydroxybutyric acid,[12] D-hydrogenation products were obtained. On the contrary, with compounds of the L-configuration, such as L-malic acid,[12] and several L-hydroxy monocarboxylic acids,[7,12] L-products were obtained. The same tendency was also observed on modification with an optically active α-*C*-alkyl-substituted hydroxy carboxylic acid such as L-citramalic acid.[12]

This relationship between the direction of optical rotation of asymmetric activity of the catalyst and the absolute configuration of the modifying reagent was also clearly recognized on modifications with solutions containing various proportions of D- and L-tartaric acid. As shown in Fig. 3, there was a linear relationship between the optical activity of the hydrogenation product and the ratio of modifying reagents in the mixture. An optically inactive product was obtained by catalyst modified with a solution containing equal proportions of D-tartaric acid and L-tartaric acid. These results offer additional evidence in support of the consideration on the occurrence of asymmetric activity mentioned in the preceding chapter.

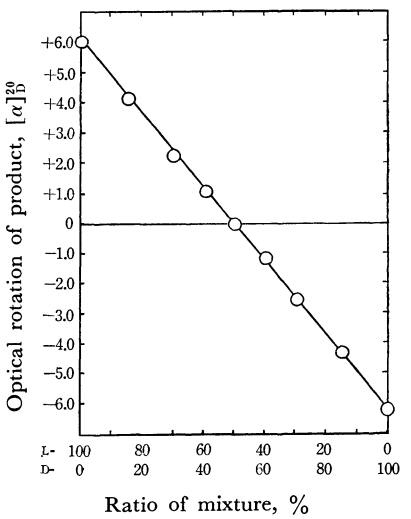

Fig. 3. Effect of ratio of mixture of D- and L-tartaric acid.
(Modified at 0°C and at pH 5.0)

Thus, on modifications with hydroxy carboxylic acids containing one asymmetric center or containing two asymmetric centers of identical absolute

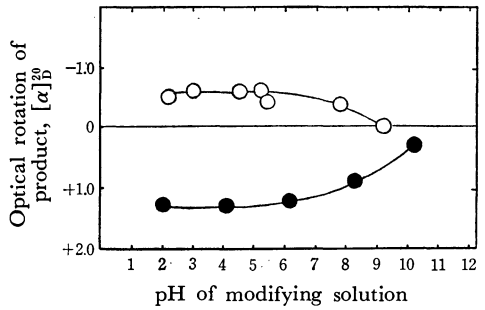

Fig. 4. Modifications with L-*erythro*- and D-*threo*-2, 3-dihydroxybutyric acid.
(Modified at 0°C)
○ D-*threo*-2, 3-Dihydroxybutyric acid
● L-*erythro*-2, 3-Dihydroxybutyric acid

configuration, it is concluded that catalysts modified with D-hydroxy carboxylic acids produce methyl D-3-hydroxybutyrate in the hydrogenation of methyl acetoacetate, while those modified with L-hydroxy carboxylic acids give methyl L-3-hydroxybutyrate.

Modifications with L-*erythro*- and D-*threo*-2, 3-dihydroxybutyric acid were also studied.[12] Since both the α- and β-asymmetric centers of L-*erythro*-2, 3-dihydroxybutyric acid are assigned the L-configuration,[16] the catalyst modified with this compound evidently gave the product of the L-configuration, as shown in Fig. 4.

With D-*threo*-2, 3-dihydroxybutyric acid, however, although the α- and β-asymmetric centers are opposite in configuration and belong to the D- and L-series respectively,[16] the product was predominantly of the D-configuration. This shows that, when a hydroxy monocarboxylic acid used for modification has two asymmetric centers of opposite configuration in its α- and β-carbon atoms, the direction of optical rotation of the asymmetric activity of the catalyst is decided by the configuration of the α-asymmetric center carrying the functional groups which have the highest affinity for the Raney nickel catalyst.

This conclusion will hold good for catalysts modified with optically active polyhydroxy monocarboxylic acids which have asymmetric centers of different configuration.

The Effect of the Modifying Conditions on the Asymmetric Activity

The Effect of the pH of the Modifying Solution. The asymmetric activities of catalysts modified with hydroxy dicarboxylic acids were influenced more by the pH of the modifying solution than those of catalysts obtained on modifications with hydroxy monocarboxylic acids.[7,10-12] Maximal asymmetric activities were observed at pH 5—9 on modifications with hydroxy dicarboxylic acids and there was considerable diminution in activity at both higher and lower pH values, as shown in Figs. 1 and 2. This optimum pH range approximately corresponded to the pH-jumping region of the neutralization curves of these acids.[10] However on modifications with hydroxy monocarboxylic acids,[7] a similar decrease in activity was observed only when the pH value was increased, as shown in Fig. 5.

Izumi *et al.*[5] reported that optically active α-amino acids have very small asymmetric effects on a Raney nickel catalyst under alkaline conditions. These workers determined the amount of amino acid adsorbed on the catalyst and concluded that the weak asymmetric effects of amino acids under alkaline conditions are caused by desorption of amino acids from the catalyst. On the other hand, it was reported from the Accumulatoren-Fabrik[17] that a Raney nickel catalyst maintains its original properties for a long time under strongly alkaline conditions, even if it is treated with solutions containing substances with which it can form complexes, such as tartaric acid and amino aliphatic compounds. This indicates that under strongly alkaline conditions a Raney nickel catalyst can hardly be affected by these substances.

In connection with these observations, the amount of hydroxy carboxylic acid adsorbed on the catalyst in the asymmetric modification was determined. The results[18-19] obtained with D-tartaric acid are

shown in Fig. 6.

The amount of D-tartaric acid adsorbed on the catalyst was much influenced by the pH of the modifying solution and decreased considerably with increase in the pH value. Under strongly alkaline conditions the reagent is adsorbed very little onto the catalyst. The acid must loose its ability to be adsorbed onto the nickel metal under these conditions because of the conversion to its alkali salt, and so it is desorbed. The weak asymmetric activity observed at high pH values, thus, is evidently caused by desorption of the reagent from the catalyst.

On the other hand, under acidic conditions there is a characteristic difference between the asymmetric activities of catalysts modified with hydroxy dicarboxylic acids and those of catalysts modified with hydroxy monocarboxylic acids. As pointed out at the beginning of this section, on modifications with hydroxy dicarboxylic acids the asymmetric activities decreased remarkably with increase of acidity, while with hydroxy monocarboxylic acids there was no similar decrease. However, as can be seen in Fig. 6, the amount of the hydroxy dicarboxylic acid adsorbed on the nickel metal does not decrease with increase of acidity, but in fact it increases considerably. The above difference in activity, therefore, cannot be explained by the amount of the reagent adsorbed on the catalyst. It is probably related to the presence or absence of the β-carboxyl group in the modifying reagent.[20]

The Effect of the Temperature of the Modifying Solution. On modifications with hydroxy dicarboxylic acids,[10-12] the asymmetric activities of catalysts increased with elevation of the modifying temperature except in the case of (−)-*erythro*-2-methyltartaric acid,[10] as shown in Fig. 7. A similar tendency was observed with several hydroxy monocarboxylic acids.[7]

As reported in a previous paper,[7] however, in contrast to the asymmetric activities of the modified catalysts their catalytic hydrogenation activities decreased considerably with elevation of the modifying temperature. It is likely that when a Raney nickel catalyst is modified at a certain pH value, the interaction between the modifying reagent and the nickel metal is intensified by elevation of the temperature, and the reagent spreads itself over the surface of the metal. Consequently a catalyst with many compactly adsorbed asymmetric centers is produced, which thus has a high asymmetric activity in spite of its decreased catalytic hydrogenation activity.

The Effect of the Time of Immersion. To study the effect of the time of immersion of a Raney nickel catalyst upon the asymmetric activity, modifications with a 2% aqueous solution of D-tartaric acid adjusted to pH 5.0 were carried out at 0°C.[18] The asymmetric activities of the resulting catalysts were compared and the results are shown in Fig. 8.

Maximal asymmetric activity was attained when a Raney nickel catalyst was immersed in the solution for 10 min. Immersion for more than 10 min resulted in no further increase in asymmetric activity. It is likely that the adsorption of the modifying reagent on the nickel metal reaches an equilibrium within 10 min at 0°C.

20) The role of the β-carboxyl group will be discussed in the subsequent chapter.

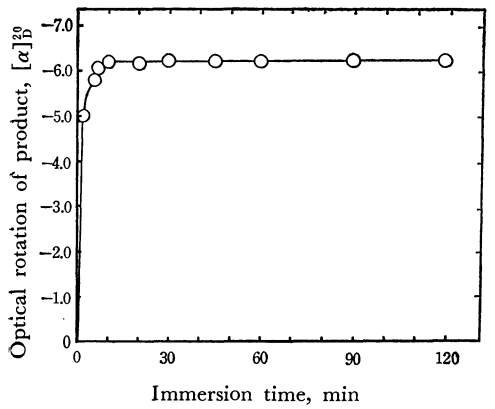

Fig. 8. Effect of time of immersion on modification with D-tartaric acid.
(Modified at pH 5.0 and at 0°C)

Even immersion for 2 or 5 min, however, gives a rather high asymmetric activity to a Raney nickel catalyst. It seems that as soon as Raney nickel is added to the modifying solution, it is strongly adsorbed by the reagent, and the adsorption quickly reaches almost the state of equilibrium.

The Effect of the Concentration of the Modifying Reagent. The effect of the amount of modifying reagent upon the asymmetric activity of the catalyst was studied using aqueous solutions of D-tartaric acid.[18] The results are shown in Fig. 9.

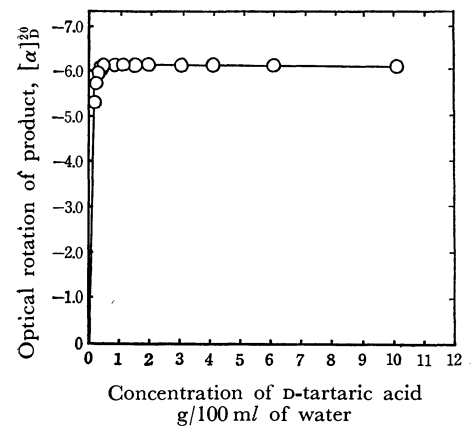

Fig. 9. Effect of concentration of modifying reagent.
(Modified at pH 5.0 and at 0°C)

The asymmetric activity of the catalyst was independent of the concentration of D-tartaric acid in the range of 0.4 to 10%.

Izumi *et al.*[5] observed a similar tendency on modification of a Raney nickel catalyst with an aqueous solution of L-glutamic acid. They reported that the asymmetric activity was not affected by the concentration of the acid in a range of 0.0625 to 6%.

These results clearly show that the adsorption of modifying reagent on Raney nickel readily reaches saturation at a lower concentration.

The Stability of the Asymmetric Activity

To study the stability of the asymmetric activity, a Raney nickel catalyst modified at 0°C with a 2% aqueous solution of D-tartaric acid adjusted to pH 5.0[18] was employed repeatedly in the hydrogenation reaction at 60°C.[21] The results of the stability test are shown in Table 1.

Table 1. Stability test of asymmetric activity

Catalyst sample	Optical rotation of product, $[\alpha]_D^{20}$
Original modified catalyst	−6.22°
After 1st recovery	−6.30°
After 2nd recovery	−6.09°
After 3rd recovery	−6.01°
After 4th recovery	−6.25°
After 5th recovery	−6.19°

As can be seen in Table 1, the asymmetric activity in the catalyst was very stable. The original asymmetric activity persisted to at least the sixth run. This shows that the modifying reagent is firmly adsorbed on the catalyst and hence the asymmetric centers formed on the surface of the metal are not destroyed during recovery or under the conditions used in the hydrogenation reaction.

The Effect of the Structure of the Modifying Reagent on the Asymmetric Activity

The Effect of the *α*-*C*-Substituted Alkyl Group of the Modifying Reagent. The asymmetric activity of catalyst modified with L-citramalic acid (L-*α*-*C*-methylmalic acid) was lower than that of catalyst modified with L-malic acid, as shown in Fig. 2. This difference is obviously caused by the methyl group on the asymmetric *α*-carbon atom of L-citramalic acid. Similar differences were observed between modifications with glutamic acid and those with *α*-*C*-substituted glutamic acids, such as (+)-2-*C*-methylglutamic acid and (+)-2-*C*-benzylglutamic acid.[9]

These results clearly show that the *α*-*C*-substituted groups play important roles in the formation of an asymmetrically active site of the catalyst, and that to obtain an effective asymmetric catalyst the asymmetric *α*-carbon atom of the modifying reagent should not possess a bulky substituted group in addition to the hydroxyl group, carboxyl

21) The hydrogenation reaction and the measurement of the asymmetric activity of the catalyst were performed as described in a previous paper.[7]

group and β-carbon chain. A small group, such as the hydrogen atom in L-malic acid or in L-glutamic acid, seems to be effective for the α-*C*-substituted group. Probably, four groups on the asymmetric α-carbon atom which are rather unbalanced in bulk favor asymmetric hydrogenation.

The Role of the β-Substituted Group of the Modifying Reagent and the Effect of Its Configuration. D-Tartaric acid was more effective for asymmetric activity of a Raney nickel catalyst than L-malic acid, as shown in Figs. 1 and 2. This clearly shows that the β (or α')-hydroxyl group of tartaric acid and its configuration have a great influence on the formation of an asymmetric catalyst. On the other hand, on modifications with isomeric optically active 3-methylmalic acids, both the (−)-*threo*- and (+)-*erythro*-compounds[12,22] were less effective for asymmetric activity than D-tartaric acid. However, the former was more effective than L-malic acid, while the latter was less effective.[12] The difference in the asymmetric effects of (−)-*threo*-3-methylmalic acid and D-tartaric acid is due entirely to their β-substituted groups, that is, the methyl group of (−)-*threo*-3-methylmalic acid and the hydroxyl group of D-tartaric acid, because *threo*-3-methylmalic acid has the same structure as tartaric acid except that one hydroxyl group is replaced by a methyl group. Moreover, the difference in the asymmetric effects of (+)-*erythro*- and (−)-*threo*-3-methylmalic acid and L-malic acid is also caused by the methyl group attached to the β-carbon atom of malic acid and by its configuration. Thus, like the β-hydroxyl group, the β-methyl group has a great influence on the formation of an asymmetric catalyst though less than the β-hydroxyl group.

▲ (−)-*threo*-3-Methylmalic acid
△ (+)-*erythro*-3-Methylmalic acid
The left scale represents (+)-*threo*- and (−)-*erythro*-2-methyltartaric acid, and the right scale represents (−)-*threo*- and (+)-*erythro*-3-methylmalic acid.

To study the effect of the erythro-threo configuration of a modifying reagent on the asymmetric activity, comparisons were made of the asymmetric activities of catalysts modified with optically active α, β-diasymmetric hydroxy dicarboxylic acids, such as (−)-*threo*- and (+)-*erythro*-3-methylmalic acid[12,22] and (+)-*threo*- and (−)-*erythro*-2-methyltartaric acid.[10,13] The results are shown in Fig. 10.

As can be seen in Fig. 10, optically active *threo*-3-methylmalic acid and *threo*-2-methyltartaric acid were more effective for asymmetric activity than the corresponding optically active erythro forms. These results clearly show that the asymmetric activities of catalysts are much influenced by the erythro-threo configuration of the modifying reagents.

The same absolute configuration is assigned to the α- and β-asymmetric centers of optically active *threo*-3-methylmalic acid,[23] and the β-methyl group is situated in the same position relative to the α-hydroxyl group as one hydroxyl group of optically active tartaric acid is to the other. However, the β-methyl group of optically active *erythro*-3-methylmalic acid is situated in the same position relative to the α-hydroxyl group as the one hydroxyl group of meso tartaric acid is to the other, since the α- and β-asymmetric centers of this compound have the opposite absolute configuration to each other.[23]

Moreover, in these two acids the functional groups to be adsorbed predominantly upon the nickel metal are similar; these are the α-hydroxyl group and the α-carboxyl group which have higher affinities for the metal than the other groups. Therefore, it is clearly conceivable that the difference in the asymmetric activities of catalysts modified with these two acids is caused by this difference in configuration of the asymmetric centers.

A similar difference can be seen between modifications with (−)-*erythro*-2-methyltartaric acid and

22) S. Tatsumi, M. Imaida and Y. Izumi, This Bulletin, **39**, 1818 (1966).

23) The threo isomer of 3-methylmalic acid was identified by deamination of *threo*-3-methylaspartic acid with nitrous acid. Since this deamination of an α-amino acid does not affect the configuration, the resulting α-hydroxy acid is identical in configuration with the parent amino acid. On the other hand, from the investigation of Baker *et al.* (H. A. Baker, R. D. Smyth, E. J. Wawszkiewicz, M. N. Lee and R. M. Wilson, *Arch. Biochem. Biophys.*, **78**, 468 (1958).) the α- and β-asymmetric centers of optically active *threo*-3-methylaspartic acid are assigned the same absolute configuration, while those of optically active *erythro*-3-methylaspartic acid are opposite in absolute configuration to each other. Therefore the configurations of *erythro*- and *threo*-3-methylmalic acid can easily be correlated.

(+)-*threo*-2-methyltartaric acid. The catalyst modified with the erythro form has only a very low asymmetric activity, while that modified with the threo form has a very high one. This difference in asymmetric activity can best be explained in a similar way to the difference between modifications with the optically active 3-methylmalic acids described above. As previously reported by the author,[14] the two hydroxyl groups of *threo*-2-methyltartaric acid are situated in the same position relative to each other as those of tartaric acid; while in *erythro*-2-methyltartaric acid the situation of the two hydroxyl groups corresponds to that of the two hydroxyl groups of meso tartaric acid. It thus appears that the α- and β-asymmetric centers of the threo form have the same absolute configuration and those of the erythro form have the opposite configuration to each other.

However, the difference between the asymmetric effects of these two reagents was greater than that between the effects of isomeric 3-methylmalic acids. This result is probably related to the fact that each of the two asymmetric carbon atoms of 2-methyltartaric acid, unlike those of 3-methylmalic acid, has a hydroxyl group. As has been pointed out above, the asymmetric activity of the catalyst is much influenced by a hydroxyl group located on an asymmetric carbon atom, this influence being greater than that of the corresponding methyl group, and also two hydroxyl groups which are identical in configuration cause an increase in the asymmetric activity, while two with the opposite configuration to each other decrease the activity. Therefore, the low asymmetric effect of (−)-*erythro*-2-methyltartaric acid and the high effect of (+)-*threo*-2-methyltartaric acid must be related to the roles of their hydroxyl groups and to their configurations.[24]

The Effect of the *C*, *C'*-Dialkyl Groups of Tartaric Acids. To study the effects of two alkyl groups attached to the asymmetric carbon atoms of tartaric acid upon the asymmetric activity, measurements were made of the asymmetric activities of catalysts modified with (+)-2, 3-dimethyltartaric acid[10,13] and (+)-1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acid.[11,25] The results are shown in Fig. 11.

On modification with (+)-2, 3-dimethyltartaric acid the asymmetric activity shows a tendency similar to that obtained on modification with D-tartaric acid, except for the direction of optical rotation.

(+)-2, 3-Dimethyltartaric acid has the same chemical or stereochemical structure as optically active tartaric acid except that both hydrogens on the asymmetric carbon atoms are replaced by

methyl groups. The two methyl groups, therefore, are situated in the same threo position relative to each other as the two hydroxyl groups.[14] The two asymmetric centers of this compound are assigned the same absolute configuration and contribute equally to the optical direction of the asymmetric activity of the catalyst. The resemblance in the asymmetric effects of (+)-2, 3-dimethyltartaric acid and D-tartaric acid is due entirely to the above similarity in configuration. In this respect, these reagents are quite different from (−)-*erythro*-2-methyltartaric acid and (+)-*erythro*-3-methylmalic acid.

On the other hand, it seems probable that, like meso tartaric acid, 2, 3-dimethyltartaric acid which is assigned the meso form, has no asymmetric effect upon a Raney nickel catalyst.

As shown in Fig. 7, (+)-2, 3-dimethyltartaric acid is less effective for asymmetric activity, particularly at high modifying temperatures, than (+)-*threo*-2-methyltartaric acid. This difference is considered to be due to the presence or absence of an α-*C*-methyl group in the modifying reagents. As can be seen from the difference in the asymmetric effects of L-malic acid and L-citramalic acid, the α-*C*-methyl group is unfavorable for asymmetric activity. In (+)-2, 3-dimethyltartaric acid the group is present, while in (+)-*threo*-2-methyltartaric acid it is not because this compound is preferentially adsorbed with its 3-hydroxyl group and 3-carboxyl group (C_4-carboxyl group) upon the nickel metal[26] and hence its C_2-asymmetric carbon atom, on which the methyl group is located, acts as a

24) Further discussion of this will be given in the subsequent section.

26) The form of adsorption of this compound on the nickel metal will be discussed in the next section.

β-carbon atom in the asymmetric modification. However, (+)-2, 3-dimethyltartaric acid is more effective for asymmetric activity than (−)-*erythro*-2-methyltartaric acid. This indicates that the asymmetric activities of catalysts are influenced far more by the configuration of the modifying reagents and orientation of methyl groups and hydroxyl groups in space, than by the hindrance due to the α-*C*-methyl group.

Thus, the asymmetric effects of tartaric acid and its *C*-methyl and *C*, *C'*-dimethyl derivatives assigned the threo form are greater than those of malic acid and its *C*-methyl derivatives. To obtain an especially high asymmetric activity, two hydroxyl groups situated in the threo position relative to each other are indispensable for a modifying reagent.

When a Raney nickel catalyst was modified with (+)-1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acid, its asymmetric activity was greatly influenced by the pH of the modifying solution, as shown in Fig. 11, the influence being quite different from those of catalysts obtained on modifications with optically active tartaric acid, malic acid and their *C*-methyl and *C*, *C'*-dimethyl derivatives. Maximal asymmetric activities were observed at pH 5—7; this pH range approximately corresponds to the pH-jumping region of the neutralization curve of this acid.[11] However there was a very great diminution in activity at pH values below pH 5. Under acidic conditions both carboxyl groups of the acid are adsorbed upon the nickel metal and hence the alicyclic ring forms a bulky steric hindrance over the surface of the metal. Therefore it seems that the hydrogenation substrate can hardly be affected by the stereoselectivity of asymmetric centers of the acid.

The Role of the β-Carboxyl Group and the Form of the Modifying Reagent Adsorbed on the Catalyst. To study the role of the β (or α')-carboxyl group of the modifying reagent, the asymmetric activities of catalysts modified with D-tartaric acid, monomethyl D-tartrate and D-*threo*-2, 3-dihydroxybutyric acid were compared.[12]

Monomethyl D-tartrate and D-*threo*-2, 3-dihydroxybutyric acid are characterized by the lack of an acidic property of one of the two carboxyl groups of D-tartaric acid. In the former compound it is lost by esterification and in the latter the carboxyl group is replaced by a methyl group.

As shown in Fig. 12, on modifications with these two reagents, a maximal asymmetric activity is observed under acidic conditions and there is a decrease in activity under alkaline conditions. These curves of asymmetric activity are quite different in character from that obtained on modification with D-tartaric acid but similar to those obtained with several hydroxy monocarboxylic acids. These results evidently show that the considerable decrease of asymmetric activity observed

○ Monomethyl D-tartrate
△ D-*threo*-2, 3-Dihydroxybutyric acid

under acidic conditions on modifications with hydroxy dicarboxylic acids depends on the presence of a functional β (or α')-carboxyl group. It is likely that both carboxyl groups of hydroxy dicarboxylic acids are readily adsorbed on the surface of nickel metal in the absence of alkali. When the acidity of the modifying solution decreases, one carboxyl group is detached from the surface of the metal and the resulting group, carrying a high polarity, produces a massive hindrance, which effectively regulates the form of approach of the hydrogenation substrate to the catalyst and causes an increase in asymmetric activity.

On the contrary, since on modifications with monomethyl D-tartrate and D-*threo*-2, 3-dihydroxybutyric acid the ester and methyl groups are less affected by the modifying conditions,[27] the form in which they are adsorbed on the surface of the metal is similar under all acidic conditions. Consequently, under acidic conditions catalysts modified with these two reagents do not show such a great decrease in asymmetric activity as the catalyst modified with D-tartaric acid.

This also holds good for modifications with other hydroxy monocarboxylic acids.

In dihydroxy dicarboxylic acids such as optically active tartaric acid, 2, 3-dimethyltartaric acid and 1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acid, the two asymmetric centers are similar in configuration or in the orientation of their groups in space, and hence whether the reagent is adsorbed preferentially by its α-hydroxyl and α-carboxyl groups upon the nickel metal or by its β (or α')-hydroxyl and β (or α')-carboxyl groups, the asymmetric

27) According to Welch, ester and methyl groups are poorly adsorbed upon Raney nickel irrespective of the conditions of treatment. C. M. Welch, H. A. Smith and J. B. Cole, *J. Phys. Chem.*, **65**, 705 (1961).

activity of the resulting catalyst is the same in capacity and in direction of optical rotation.

On the other hand, since the two asymmetric centers of optically active 2-methyltartaric acid are dissimilar, whether the adsorption with the 2-hydroxyl group and the 1-carboxyl group predominates or that with the 3-hydroxyl group and the 4-carboxyl group does, has a great influence on the asymmetric activity of the catalyst.

As can be seen from Figs. 1 and 10, (+)-*threo*-2-methyltartaric acid is more effective for asymmetric activity than D-tartaric acid. This result seems to indicate that this compound is not preferentially adsorbed by its 2-hydroxyl group and 1-carboxyl group on the catalyst, but by its 3-hydroxyl group and 4-carboxyl group. If the adsorption by the 2-hydroxyl group and the 1-carboxyl group were predominant, the 2-methyl group would serve as the α-methyl group in the asymmetric modification and would cause a decrease in the asymmetric effect. Consequently, the asymmetric activity of catalyst modified with this compound would be smaller than that of catalyst modified with D-tartaric acid. However, no such difference in asymmetric activity is observed. Moreover, this compound is more effective for asymmetric activity than (+)-2, 3-dimethyltartaric acid, as shown in Figs. 10 and 11. The difference in the asymmetric effects of these reagents is obviously caused by the α-methyl group of (+)-2, 3-dimethyltartaric acid and then it is nearly equal to the difference in the asymmetric effects of L-malic acid and L-citramalic acid. These results evidently support the above conclusion.

Considering the great influences of hydroxyl groups and their configurations upon the asymmetric effect, it seems reasonable that (−)-*erythro*-2-methyltartaric acid has only a very weak asymmetric effect on a Raney nickel catalyst.

Conclusion

The presence or absence of asymmetric activity in the modified Raney nickel catalyst depends on the optical purity of the reagent used for the modification. A racemate and a meso compound have no asymmetric effects upon Raney nickel. Moreover, there is a linear relationship between the capacity of asymmetric activity of the catalyst and the optical purity of the modifying reagent. When a modifying reagent loses its ability to be adsorbed on Raney nickel, the resulting catalyst has little or no asymmetric activity. To obtain an asymmetric catalyst an α-carbon atom of the modifying reagent must have at least two kinds of functional groups such as a hydroxyl group and a carboxyl group which can be adsorbed strongly or chelated to Raney nickel.

On modification with a hydroxy carboxylic acid containing one asymmetric center or containing two asymmetric centers of identical absolute configuration, the catalyst modified with a D-hydroxy acid has an asymmetric activity to produce predominantly the hydrogenation product of the D-configuration; while that modified with an L-hydroxy acid gives a product of the L-configuration. When enantiomeric compounds are used as the modifying reagents, the asymmetric activities of the resulting catalysts are the same except for the direction of optical rotation. On modification with a racemic compound, therefore, two kinds of catalyst are produced in the same ratio; one has the asymmetric activity to hydrogenate the substrate predominantly to the product of the L-configuration and the other has the opposite asymmetric activity. On modification with a hydroxy monocarboxylic acid containing two asymmetric centers of opposite absolute configuration in its α- and β-carbon atoms, the rotatory direction of the asymmetric activity is decided by the configuration of the α-asymmetric center.

The asymmetric activity of catalyst is much influenced by the pH of the modifying solution. On modification with a hydroxy dicarboxylic acid, the maximal asymmetric activity is obtained at pH 5—9 and there is a considerable diminution in activity at both higher and lower pH values; while with a hydroxy monocarboxylic acid a similar decrease is obtained only under alkaline conditions. In both cases, the weak asymmetric activity observed at high pH values is caused by desorption of the reagent from the catalyst. On the other hand, the weak asymmetric effect of a hydroxy dicarboxylic acid observed at low pH values is not related to desorption of the reagent, but to the presence of the β-carboxyl group.

The asymmetric activity of catalyst, in general, increases with elevation of the temperature of the modifying solution.

A maximal asymmetric activity is attained in 10 min when a Raney nickel catalyst is immersed in a modifying solution at 0°C. Immersion for more than 10 min results in no further increase in the activity. It is likely that the adsorption of the reagent on the catalyst reaches an equilibrium within 10 min. Moreover, the asymmetric activity of catalyst is independent of the concentration of reagent in the range of 0.4—10%. It seems that the adsorption of a reagent on Raney nickel readily reaches saturation at a low concentration.

The asymmetric activity in the modified catalyst is very stable. The original activity persisted for at least six runs of the hydrogenation reaction.

An α-*C*-substituted alkyl group in the modifying reagent, such as the methyl group of citramalic acid, reduces the asymmetric activity of the catalyst.

To obtain an effective asymmetric catalyst, an asymmetric α-carbon atom of α-hydroxy carboxylic acid used for the modification should not possess a bulky substituted group in addition to the carboxyl

group, hydroxyl group and β-carbon chain.

On modifications with tartaric acid and its derivatives, like their α-hydroxyl groups, the β (or α')-hydroxyl groups play an important role in the formation of an asymmetric catalyst. The methyl group of 3-methylmalic acid also has a great influence on the asymmetric activity of the catalyst though less than the β (or α')-hydroxyl groups of tartaric acid and its derivatives. On modifications with 2-methyltartaric acid and 3-methylmalic acid, the asymmetric activities of the catalysts are greatly influenced by the configurations of the α- and β-asymmetric centers of the reagents. To obtain an effective asymmetric catalyst, the same configuration should be assigned to the α- and β- asymmetric centers. Moreover, the asymmetric activities of catalysts are far more influenced by the configurations of the modifying reagents than by hindrances due to the substituted groups themselves. 2,3-Dimethyltartaric acid has a high asymmetric effect upon the catalyst similar to that of tartaric acid. However, 1,2-dihydroxycyclohexane-1,2-dicarboxylic acid, which is a sort of 2,3-dialkyl tartaric acid, has a quite different asymmetric effect from tartaric acid, malic acid and their *C*-alkyl derivatives. This difference is due to the alicyclic ring of 1,2-dihydroxycyclohexane-1,2-dicarboxylic acid.

The asymmetric effects of tartaric acid and its *C*-methyl and *C*, *C'*-dimethyl derivatives assigned the threo form are greater than those of malic acid and its *C*-methyl derivatives. To obtain an especially high asymmetric activity, two hydroxyl groups situated in the threo position relative to each other are indispensable for a modifying reagent.

On modification with a hydroxy dicarboxylic acid, both the β (or α')-carboxyl group of the reagent and the α-carboxyl group play important roles in the formation of an asymmetric catalyst. It is likely that both carboxyl groups are readily adsorbed on the surface of the catalyst in the absence of alkali. When the acidity of the modifying solution decreases, the β (or α')-carboxyl group is detached from the catalyst and the resulting group, carrying a high polarity, effectively regulates the form of approach of the hydrogenation substrate to the catalyst. On the contrary, on modification with a hydroxy monocarboxylic acid the form of adsorption of the reagent on the surface of the catalyst is similar under all acidic conditions used.

On modification with 2-methyltartaric acid, the 2-methyl group and 1-carboxyl group of this compound serve as a β-methyl group and a β-carboxyl group, respectively, in the formation of an asymmetric catalyst. It is likely that adsorption with the 3-hydroxyl group and 4-carboxyl group is predominant in the asymmetric modification.

Studies of Organic Catalytic Reactions. VI.[1] The Function of Pyridine and Copper in the Rosenmund-von Braun Reaction

Takehiko Ito and Ken-ichi Watanabe

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received July 28, 1967)

The Rosenmund-von Braun reaction with aryl halide, with its Ar-X+CuCN-Base→Ar-CN+CuX-Base, has been studied in nitrobenzene in place of an organic base at 160—180°C. The free nitriles formed during the reaction were determined exactly by gas chromatography. In the use of bases with suitable coordination forces to CuCN, the reactivity of the base for the substitution was found to be in the order: prim.>sec.>tert. A steric hindrance of the base was observed, and the reactivity of the pyridine homologue followed the order: pyridine>quinoline >α-picoline>2, 6-lutidine. Ortho-substituted groups in the halobenzene seem to manifest no steric hindrance on the reaction. From the results of the kinetic study, it can be said that CuCN participates in the reaction essentially in the form of a Base(1 mol)-CuCN complex. The overall reaction is second-order, $dc/dt=k$[Complex][Ar-X]. The rate-determining step may be in the halogen exchange stage in the intervening complex, Base-CuCN-Ar-X, where the plane including CN-Cu-X and that of the benzene ring may be nearly perpendicular to each other. When an excess of CuCN over the base is used, the base is liberated from the Base-CuX complex, after the displacement, and then coordinates to the unreacted CuCN again.

It has previously been reported[2] that the Rosenmund-von Braun reaction in which nitriles are obtained from aryl bromides and cuprous cyanide is generally useful for the preparation of aromatic nitriles. In that study, the aryl halides were converted to the nitriles in a good yield by refluxing them in pyridine. The succeeding study with four sorts of halobenzene established that the ease of the displacement of halogen is in the order: I>Br>Cl≫F. Representative examples are shown in Table 1.

Improvements of this reaction have been reported by Newman and his co-workers,[3,4] who used *N*-methylpyridone or dimethylformamide as the solvent. Bacon and his co-workers[5] studied the reaction, Ar-hal+Cu-X→Ar-X+Cu-hal (X=Cl, Br, CN, SCN), in various polar solvents and explained that the reaction proceeds as a bimolecular type between Ar-hal and Cu-X. In the studies mentioned above, however, the reactions were carried out through the dissolution of the complex (solvent-CuCN) in the same solvent (organic base); therefore, the quantity of the base that participated in the reaction could not be elucidated. Further, in the experimental procedure, the separation of the nitrile from the reaction mixture was very troublesome because the reaction mixture containing the nitrile was obtained as a solid complex at room temperature; it then had to be decomposed with ammonia or concentrated hydrochloric acid to get the free nitrile.

This paper will deal with studies of the Rosenmund-von Braun reaction in a nitrobenzene solution attempting to overcome the disadvantages mentioned above. In this way, the ratio of the organic base to CuCN can be calculated, and the nitrile formed during the reaction is liberated as a free form in a nitrobenzene solution. Therefore, the behavior of the organic base, aryl halide, and cuprous cyanide can be examined, and the formation of the nitrile can be determined exactly. The mechanism of this reaction is presented here.

In this study, bromobenzene and pyridine were mainly used; they were heated with cuprous cyanide at 180°C in nitrobenzene. It did not matter whether the reaction was carried out in the air or in an oxygen-free nitrogen atmosphere. Cuprous cyanide and cuprous chloride were hardly ever soluble in nitrobenzene and did not react with bromobenzene without the addition of pyridine or other organic bases. When the organic base was added to the copper salt in nitrobenzene, both of them were dissolved by the mild heating forming the complex. As far as our tests were concerned, nitrobenzene was the best solvent for this reaction.

Table 1. Rosenmund-von Braun reaction in pyridine[1]

Exp. No.	Aryl halide	g	CuCN g	Pyridine g	Reaction temp. °C	Reaction time hr	Yield of nitrile %
1	Iodobenzene	20	10.8	15	170—190	6	80
2	Bromobenzene	20	12.0	15	140—155	9	85
3	*o*-Bromonitrobenzene	10	5.0	10	140—155	2	91
4	*p*-Bromonitrobenzene	20	9.9	20	140—155	9	80
5	Bromomesitylene	20	9.9	10	165—175	8	80
6	*o*-Bromoacetophenone	25	12.5	75	120	1.5	70
7	β-Bromonaphthalene	5	6	10[2]	260—280	3	78
8[3]	Chlorobenzene	22.6	20	15	140—150	14	trace
9	*o*-Chloronitrobenzene	10	12.5	15	160—180	3	80
10	Fluorobenzene	5.8	14.4	10	140—160	3	—

1) The reaction method by Newman was employed; M. S. Newman, "Organic Syntheses," Coll. Vol. III, p. 631 (1955).
2) Quinoline was used as solvent instead of pyridine.
3) By the reaction in an autocreave at 250°C for 9 hr, the yield of the nitrile was 34%.

Decalin, benzyl alcohol, or cyclohexanone was unfavorable, and the reaction proceeded under heterogeneous conditions.

After the reaction was started, the heterogeneous reaction mixture turned into a brownish homogeneous solution at *ca.* 120°C. When the reaction was completed, the reaction mixture was cooled to room temperature; a brownish mass was then obtained by filtration. When the mass was extracted enough with ether, very small quantities of nitrile and unreacted bromobenzene were obtained. Both the ether fraction and the nitrobenzene solution were analyzed by gas chromatography; the ratios of nitrile to bromobenzene were almost the same in both fractions. By the IR spectrum analysis of the crystals after the ether extraction, only the pyridine used for the reaction was detected. Thus, the tests revealed that the quantities of halide and nitrile can be determined by the gas chromatographic analysis of the reaction mixture in the course of the reaction*1 (Fig. 1).

Table 2.*3 The reaction of bromobenzene with cuprous cyanide in nitrobenzene

Bromobenzene 4 m*l*, CuCN 3 g, Nitrobenzene 20 m*l*, React. temp. 180°C

Exp. No.	Base	m*l*	Reaction time hr	Benzonitrile %
1	Pyridine	0.2	6	49
2	Pyridine	0.5	6	86
3	Pyridine	1.0	6	79
4	Pyridine	5.0	6	82
5	Pyridine[2]	1.0	3	73
6	γ-Picoline	1.0	3	83
7	Quinoline	1.0	3	59
8	α-Picoline	1.0	3	28
9	2,6-Lutidine	1.2	3	26
10	Aniline	4.0	5	68
11	Diethylamine	1.0	3	24
12	Dimethylaniline	1.0	3	—
13	Ethylenediamine	3.0	6	25[3]
14	Picolinic acid	1.0	3	22

1) The yield was calculated by gas chromatographic analysis based on the amount of bromobenzene.
2) The yield of the product rised to 78% when 0.5 g of hydroquinone was added.
3) Unknown 35%.

*1 In the results of the gas chromatographic analysis, no other product was detected.

When a complex of CuCN with pyridine was prepared*2 beforehand and was used for the reaction with bromobenzene, the reaction proceeded as well as in the case of the ordinary method. In order to examine whether the free nitrile formed would participate in the reaction or not, benzonitrile was used in place of pyridine, but no change in bromobenzene was observed.

The results of the reactions with various kinds of bases in nitrobenzene are shown in Table 2.*3 The reactions were carried out at 180°C; no reaction occurred below 130°C. The organic bases used in the reaction should coordinate moderately to the copper atom of the cuprous cyanide.*4 In the use of bases with suitable coordination forces, the reactivity of the substitution depended on their basicity: prim.>sec.>tert. No reaction occurred with dimethylaniline. The steric hindrance of the substituents of bases had an influence upon the reactivity of the complexes of the pyridine homologues; the reactivity was found to be in the order: pyridine > quinoline > α-picoline > 2, 6-lutidine. Bacon[5] pointed out this problem as a solvent effect. The methyl group of the γ-picoline seemed to enhance the coordination ability of the base by means of its 1-effect (Exp. 6, Table 2). It is assumed that the activity of the complex is dependent upon both the character and the molecular structure of the base.

In order to investigate the mechanism of this reaction, simple kinetic studies were done. Some were carried out in a bromobenzene solution, the mole ratio of Py/CuCN was set up as 1, 2, or 3.

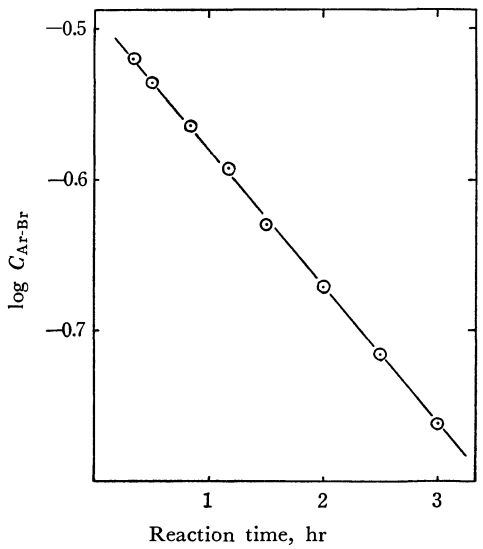

Fig. 3. The correlation of C_{Ar-Br} *vs.* reaction time.
Bromobenzene 1.0 m*l*, cuprous cyanide 4.0 g, pyridine 2.0 m*l*, nitrobenzene 30 m*l*, reaction temp. 159°C

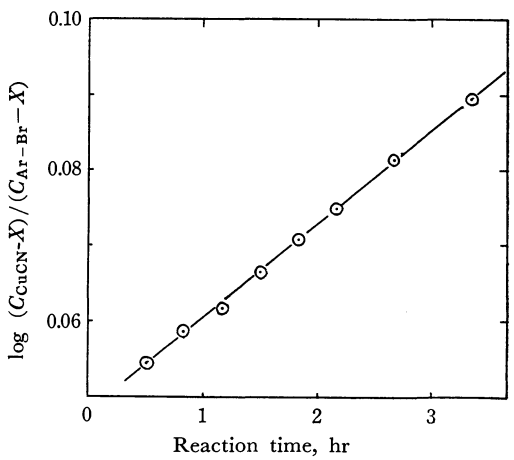

Fig. 4. Ar-Br (1.0 m*l*) + CuCN(1.0 g) + pyridine (1.0 m*l*) in nitrobenzene (20 m*l*) at 160°C.

*2 Pyridine and cuprous cyanide were heated at 120°C for about 30 min and then cooled. The yellow material thus obtained was used directly in the reaction.

*3 All the reactions except Exp. 4 proceeded heterogeneously, for the amount of the bases used was less than that of the cuprous cyanide, so a part of the cyanide remained insoluble in the solvent. On the other hand, the amount of the cyanide used was less than that of the bromobenzene; therefore, the conversion of the bromobenzene into benzonitrile could not reach 100% even if all of the cyanide did react with the bromobenzene.

*4 Ethylenediamine afforded a stable copper complex, the process being accompanied by a side reaction, and the yield of the nitrile was very low (Exp. 13, Table 2). No reaction occurred when dimethylglyoxime or acetyl acetone was used as the base. When 8-oxyquinoline or picolinic acid was used, the reaction proceeded extremely slowly.

Table 3.

A. Cyanization

Bromobenzene 1.0 m*l*, Nitrobenzene 20.0 m*l*, React. temp. 159±0.5°C

CuCl 1.0 g, Base/CuCl 1.8—2.2, Nitrobenzene 40 m*l* (solvent), React. temp. 181±0.5°C, in an atomosphere of oxygen-free nitrogen

Aryl halide (1.0 m*l*)	Base (2.0 m*l*)	Rate const. *l* mol⁻ min⁻¹	k_{ortho}/k_{para}
Bromobenzene	2,6-Lutidine	1.78×10^{-2}	
o-Bromotoluene	2,6-Lutidine	4.27×10^{-2}	2.07
p-Bromotoluene	2,6-Lutidine	2.05×10^{-2}	
o-Bromotoluene	Pyridine	3.82×10^{-1}	2.08
p-Bromotoluene	Pyridine	1.84×10^{-1}	
Bromobenzene	α-Picoline	3.29×10^{-2}	

Some representative results of the reactions are shown in Fig. 2, in which the reactions are first-order with regard to the CuCN. When an excess of CuCN over pyridine was used, the relation between the quantity of nitrile formed and the reaction time was linear. These facts indicate that the CuCN participates in the form of the CuCN-pyridine complex and that the concentration of the complex is approximately constant during the initial period of the reaction. On the other hand, other reactions were carried out in a nitrobenzene solution with an excess of CuCN over pyridine, these reactions were found to be first-order with regard to the bromobenzene (Fig. 3). As a result, the overall reaction is shown as a second-order reaction, $dc/dt=k$[Complex][Ar-Br], in Fig. 4.

To elucidate the correlation of the reaction rate with the number of base molecules coordinated to the copper atom, some kinetic studies were done in a nitrobenzene solution with bromobenzene. Pyridine, α-picoline, and 2, 6-lutidine were used as the bases, while CuCN and CuCl were used as the copper salt. The results of the experiments are shown in Table 3. The reaction rate was set at 1 when the mole ratio of the base to the Cu-salt was equal to 1 (Base/Cu-salt=1). When Base/Cu-salt>1, the ratio of the reaction rate was also equal to 1. On the other hand, when Base/Cu-salt<1, the ratio was equal to that of Base/Cu-salt. Accordingly, it could be inferred that the reaction may occur by the coordination of bromobenzene to the complex of one mole of the base with one mole of the Cu-salt. This is independent of the kinds of base and Cu-salt present. Even though more than one mole of the base coordinate to the copper, it still may not be capable of affecting the reaction essentially.

In order to study the steric hindrance of the halide coordinated to the copper salt, reactions

with bromobenzene, *o*-, and *p*-bromotoluene were examined. Pyridine, α-picoline, and 2, 6-lutidine were used as the bases, while nitrobenzene was used as the solvent. The rate constant is presented in Table 4. It is apparent that the methyl group in the ortho position of the halobenzene does not exert any steric hindrance on the reaction, but that, rather, the reaction is accelerated.*5 The ratio of the reaction rate of *o*- to *p*-bromotoluene is approximately equal to 2, independent of the kind of base. The promoting effect of the *o*-substituted group in the halobenzene might be explained by the effect of expelling the halogen from the ortho position (Table 4 and Table 1). On the other hand, the steric effect of the methyl group in the pyridine nucleus can be accurately observed (Table 4). It seems most reasonable to say that, in the coordination of base-CuCN-halide, the plane including CN-Cu-X and that of the benzene ring are nearly perpendicular to each other (Fig. 5).

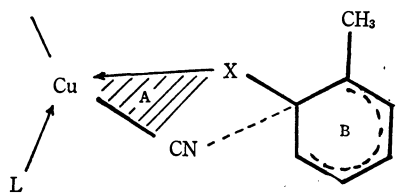

Fig. 5. The model of intervened complex Base-CuCN-Ar·X, L=Base, A⊥B.

From these discussions, it seems that the Rosenmund-von Braun reaction proceeds as follows:

$$\mathrm{CuCN} + \mathrm{L} \xrightarrow{\text{fast}} \underset{\mathrm{I}}{\mathrm{CN}\\ |\\ \mathrm{Cu\cdots L}} \quad (1)$$

$$\mathrm{Ar{-}X} + \mathrm{I} \rightleftarrows \underset{\mathrm{II}}{\mathrm{Ar\cdots CN}\\ |\quad |\\ \mathrm{X\cdots Cu\cdots L}} \quad (2)$$

$$\mathrm{II} \longrightarrow \mathrm{Ar{-}CN} + \underset{\mathrm{III}}{\mathrm{X{-}Cu\cdots L}} \quad (3)$$

$$\mathrm{III} \longrightarrow \mathrm{Cu{-}X} + \mathrm{L} \quad (4)$$

L: Ligand (Base) X: Halogen

When I which had been prepared beforehand was used in the reaction (2), no difference was observed in the kinetic study. Thus, it is conceivable that the rate-determining step is not in the reaction (1) but in the halogen-CN exchange stage in the intervening complex II, the reaction (3). The order of the reactivity, I>Br>Cl≫F, supports this assumption. When an excess of the CuCN over the base is used, a ligand is liberated from III (4); it coordinates to the unreacted CuCN to form I again (1).*6 That is, the base may act as a catalyst.

*5 No steric hindrance of the aryl halides in the reaction with CuCN is observed either as is roughly shown in Table 1.

Experimental

Materials. The cuprous chloride and cupric chloride, obtained from the Wako Pure Chemical Industry Co., Ltd., Tokyo, were used without further treatment. The cyanide was prepared from copper sulfate and sodium cyanide.[6] Commercial pyridine, picoline, 2, 6-lutidine, and nitrobenzene were diried and distilled under reduced pressure. All of the liquid reagents used in the studies was checked by gas chromatographic analysis.

Reaction Procedure in Table 2 (Exp. 4). In a 100-m*l*, three-necked, round flask fitted with a sealed stirrer, a thermometer, and a reflux condenser, were placed 4.0 m*l* of bromobenzene, 3.0 g of cuprous cyanide, 5.0 m*l* of pyridine (in the case of Exp. 4), and 20 m*l* of nitrobenzene. The contents were then heated to 180°C in 15 min while being stirred well; then the contents were maintained for 6 hr at 180°C. After the required time, the contents were cooled to room temperature, and a brownish complex of the CuBr-Base was precipitated from the solution. A part of the solution containing benzonitrile and bromobenzene was analyzed by gas chromatography; benzonitrile 82%; bromobenzene 18%. The other experiments in Table 2 were carried out using the same procedure.

Kinetic Measurements (Fig. 4). In a 100-m*l*, three-necked, round flask fitted with a sealed stirrer, a thermometer, and a reflux condenser, were placed 20.0 m*l* of nitrobenzene, 1.0 g of cuprous cyanide, and 1.0 m*l* of pyridine. The contents were then heated to 160°C on an oil bath. When the temperature became constant (160±0.5°C), 1.0 m*l* of bromobenzene was added to the mixture. A tiny quantity of the reaction mixture (nitrobenzene solution) was extracted every 20 min and analyzed by gas chromatography. From these measurements the reaction rate was calculated.

Gas Chromatography. Apparatus: Yanagimoto-GCG 220 Type. Yanagimoto Mfg. Co., Ltd., Kyoto, Japan. Column, 10% Cyanosilicone XF-1150 on Chromosorb 60—80 mesh; length, 2 m; temp., 160°C; flow rate, 35—40 m*l*/min; carrier gas, H_2. Relative retention time, ArBr : ArCN : $ArNO_2$=1 : 3 : 5.2. Column, 5% Carbowax 1500 on Chromosorb 60—80 mesh; length, 2 m; temp., 130°C; flow rate, 40 m*l*/min; carrier gas, H_2. Relative retention time, ArCl : ArBr : $ArNO_2$=1 : 1.4 : 5.7.

The authors wish to express their hearty thanks to Professor Kazuo Hata for his kind advice. Thanks are also due to Mr. Yoshiyuki Funakoshi and Miss Kimiko Horiuchi for their assistance in the first part of the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 424—429 (1968)

The Reaction of Tropolones with Phosphorus Oxychloride. The Rearrangement Reaction of 5-Arylazo-2-chlorotropones to 2-Aryl-4, 5-dichloroindazoles

Katsuo KIKUCHI, Masaki YAGI*1 and Kunio TAKADA*2

Department of Chemistry, Faculty of Liberal Arts and Science, Yamagata University, Koshirakawa-cho, Yamagata

(Received July 31, 1967)

The reaction of tropolone and phosphorus oxychloride gave 2-chlorotropone. Similarly, 5-cyano-, 5-nitro, and 5-chlorotropolones afforded the corresponding 2-chlorotropone derivatives in moderate yields. 3-Cyanotropolone gave 2-chloro-7-cyanotropone, while 3-phenyltropolone afforded only 2-chloro-3-phenylbenzaldehyde. When 3-bromotropolone and 5-bromotropolone were treated similarly, 2, 7-dichloro- and 2, 5-dichlorotropones were obtained respectively, with a facile halogen exchange. The further treatment of 2, 5-dichlorotropone with phosphorus oxychloride afforded 2, 5-dichloro- and 3, 4-dichlorobenzaldehydes. The reaction of 5-*p*-tolylazo-, 5-phenylazo-, and 5-*p*-nitrophenylazotropolones with phosphorus oxychloride gave the corresponding 5-arylazo-2-chlorotropones, which, on further treatment with an excess of the reagent, gave 2-aryl-4, 5-dichloroindazoles.

2-Chlorotropone derivatives, important intermediates for the preparation of many kinds of 2- (or 7-) substituted tropones, azulenes and seven-membered aromatic compounds fused with several kinds of heterocyclic rings, have generally been prepared (a) by the copper sulfate-catalyzed decomposition of 2-hydrazinotropones with concentrated hydrochloric acid,[1-3] and (b) by the reaction of thionyl chloride on appropriate tropolones.[2,4-6]

We have found that the reaction of tropolone derivatives with phosphorus oxychloride also gave 2-chlorotropones with moderate yields, and that the 5-arylazo-2-chlorotropones thus obtained were, by an excess of the reagent, rearranged to 2-aryl-4, 5-dichloroindazoles; these results will be described in this paper.

When tropolone in dimethylformamide was treated with phosphorus oxychloride at room temperature for about 4 hr, 2-chlorotropone (Ia) was obtained in about a 40% yield. When the reaction was carried out in benzene or chloroform under reflux, however, no detectable amount of Ia was isolated; only a colorless crystalline powder (II) was obtained. The compound (II), because of its sparing solubility in usual organic solvents, could not be purified. II was decomposed gradually with hot water to regenerate tropolone, and reacted with alcoholic methylamine to give 2-methylaminotropone and tropolone.

A similar reaction carried out with 5-cyanotropolone and 5-nitrotropolone gave 2-chloro-5-cyanotropone (Ib) in a 73% yield and 2-chloro-5-nitrotropone (Ic) in a 90% yield respectively. The reaction of 5-chlorotropolone with an equimolar amount of the reagent gave 2, 5-dichlorotropone (Id) in about a 50% yield. However, when an excess of the reagent was applied to 5-chlorotropolone or to Id, 2, 5-dichlorobenzaldehyde (III) and 3, 4-dichlorobenzaldehyde (IV) were isolated. Such a type of rearrangement had already been observed in the reaction of tropolone with thionyl chloride to give 2-chlorobenzaldehyde.[4] In the present reaction, these dichlorobenzaldehydes are thought to be formed through a tetrachloro compound. The attack of water on the intermediate, followed by rearrangement, will give the final products depicted below, though such an intermediate has not actually been isolated.

The reaction of 5-bromotropolone and phosphorus oxychloride also afforded Id, with a facile halogen exchange.

The reaction of 3-substituted tropolones with phosphorus oxychloride should give two isomeric products, *i. e.*, 2-chloro-3-substituted and 2-chloro-7-substituted tropones; actually, however, only one of the two was isolated. Thus, the reaction of 3-cyanotropolone and 3-bromotropolone with phosphorus oxychloride gave 2-chloro-7-cyanotropone (Ie)[3] in a 70% yield and 2, 7-dichlorotropone (If) in a 45% yield respectively. Contrary to the above two cases, the reaction of 3-phenyltropolone afforded colorless crystals (V), $C_{13}H_9OCl$, instead of the expected 2-chloro-phenyltropone, even when some of the reactant was recovered unchanged. The infrared spectrum of V exhibited an absorption band at 1683 cm^{-1}, and the oxidation of V with potassium permanganate afforded a monocarboxylic acid (VI), $C_{13}H_9O_2Cl$. The treatment of the acid with concentrated sulfuric acid did not afford a fluorenone derivative, suggesting that the carboxyl group is not adjacent to the phenyl group. V is thought to be 2-chloro-3-phenylbenzaldehyde formed in a manner similar to that in the formation of III from 5-chlorotropolone. In accordance with the postulated formula, the NMR spectrum[7] of V exhibited, besides the signals characteristic of an aldehyde proton (−0.40, singlet) and aromatic protons (2.35—2.8, multiplet, phenyl, C_4 and C_5 protons), an additional low-field quartet at 2.06 τ (J=6.7 and 2.8 cps, intensity one proton). The chemical shift and splitting indicate that this signal is generated by the C_6 proton coupled with the C_5 and C_4 protons. The ultraviolet spectrum of V in alcohol [λ_{max}, 241 and 307 mμ (log ε, 4.29 and 3.18)] is similar to that of 3-phenylbenzaldehyde,[8] and quite different from that of 4-phenylbenzaldehyde.[9]

We then turned our attention to the preparation of 5-arylazo-2-chlorotropones. When 5-*p*-tolylazotropolone in dimethylformamide was treated with an equimolar quantity of phosphorus oxychloride under ice-cooling, brownish-orange crystals (VIIa) and colorless crystals (VIIIa) were obtained in 78 and 6% yields respectively. VIIIa was also obtained in about a 50% yield when VIIa was treated with an excess of the reagent. The reaction of 5-*p*-tolylazotropolone with thionyl chloride in benzene also gave VIIa. The ultraviolet spectrum of VIIa exhibits absorption maxima at 300—315 and 385 mμ (log ε, 3.96 and 4.44), and the infrared spectrum shows a carbonyl band in the region below 1650 cm^{-1}, a spectral feature agreeing with that of troponoid compounds.[10] These data and the analytical values show that VIIa is 2-chloro-5-*p*-tolylazotropone.

The compound (VIIIa), $C_{14}H_{10}N_2Cl_2$, is stable toward dilute alkali and acids, and is not oxidized by potassium permanganate in acetone at room temperature. The ultraviolet spectrum of VIIIa is shown in Fig. 1. The NMR spectrum of VIIIa exhibits signals at 7.62 (3H, singlet), 2.15—2.85 (6H, multiplet) and 1.66 τ (1H, singlet), suggesting that VIIIa is an aromatic compound with a pyrazole or a similar heteroaromatic ring system.

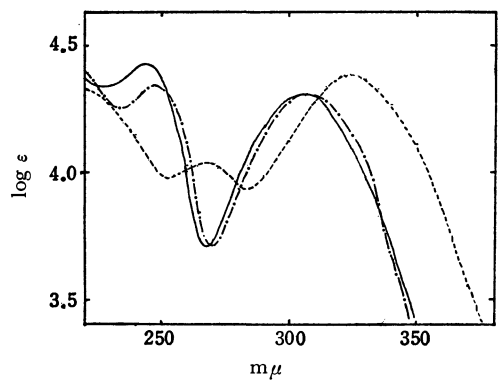

Fig. 1. Ultraviolet spectra of VIIIa (—·—·—) VIIIb (——) and VIIIc (----) in ethanol.

VIIIa was oxidized with chromic acid to give an acid (IX), $C_{14}H_{10}O_2N_2Cl_2$, and with nitric acid to give the same acid (IX), plus two mononitro compounds (XI and XII). The ultraviolet spectrum of the methyl ester (X) of IX exhibits maxima at 342 and 430—440 mμ, resembling those of azobenzene derivatives. The catalytic reduction of IX gave *p*-toluidine and 2-amino-5, 6-dichlorobenzoic acid (XIII), which decomposed above its melting point (175°C) to give 3, 4-dichloroaniline (XIV). The acid (IX) is, therefore, 3, 4-dichloro-4'-methylazobenzene-2-carboxylic acid. It is known that 2-phenylindazole, on oxidation with chromic acid, gives azobenzene-2-carboxylic acid;[11] the results obtained above can be explained on the assumption that VIIIa is 4, 5-dichloro-2-*p*-tolylindazole. This structure was confirmed by the following results. The catalytic reduction of VIIIa gave 2-*p*-tolyl-4, 5, 6, 7-tetrahydroindazole (XV). The NMR spectrum of XV exhibits signals at 8.25 (C_5- and C_6-methylene protons, multiplet), 7.68 (methyl protons, singlet), 7.40 (C_4- and C_7-methylene protons, multiplet) and 2.5-3.0 τ

7) The NMR spectra were measured in deuteriochloroform, using tetramethylsilane as an internal standard, on a Varian A-60 spectrometer.

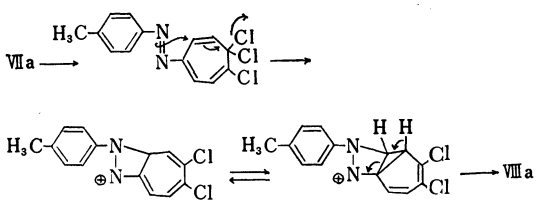
benzene-ring protons and C_3-proton, multiplet). The reduction of the ester (X) with lithium aluminum hydride gave a 2-hydroxymethylazobenzene derivative (XVI) and a 2-hydroxymethylhydrazobenzene derivative (XVII). The oxidation of XVII with bromine afforded XVI. The heating of XVI with 75% sulfuric acid afforded the original indazole (VIIIa), as expected.[11]

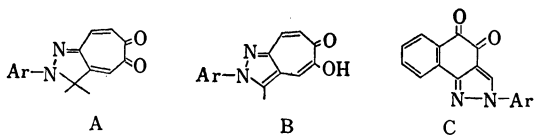
The bromination of VIIIa afforded 3-bromo-4, 5-dichloro-2-*p*-tolylindazole (XVIII); the position of the bromine atom was confirmed by the nitric acid oxidation aimed at giving IX. The position of the nitro group in XI and XII is not clear.

The reaction of 2-methoxy-5-*p*-tolylazotropone[12] and phosphorus oxychloride gave the same indazole (VIIIa) in about a 57% yield. The mechanism of the formation of VIIIa from VIIa is assumed to be as follows:



The reaction of 5-phenylazotropolone and phosphorus oxychloride gave 2-chloro-5-phenylazotropone (VIIb) and 4, 5-dichloro-2-phenylindazole (VIIIb). Similarly, 5-*p*-nitrophenylazotropolone afforded 2-chloro-5-*p*-nitrophenylazotropone (VIIc) and 4, 5-dichloro-2-*p*-nitrophenylindazole (VIIIc). The ultraviolet spectra of VIIIb and VIIIc are shown in Fig. 1.

It is known that 5-arylazotropolone with isopropyl, ethyl and acetamidoethyl groups on the 4-position undergo cyclization to give a cyclohepta[*c*]pyrazole-5, 6-dione derivative (A)[13] and a 5-hydroxycyclohepta[*c*]pyrazole-6-one derivative (B),[14,15] and that 7-bromo-3, 4-benzotropolone, upon an azo-coupling reaction, directly affords a benz[*g*]indazole-4, 5-dione derivative (C).[16] The formation of VIIIa-VIIIc is another interesting example of the rearrangement reaction of 5-arylazotropone derivatives.



Experimental

The Reaction of Tropolone and Phosphorus Oxychloride. a) To a solution of 2.0 g of tropolone in 8 m*l* of dimethylformamide, 3.0 g of phosphorus oxychloride was added; the mixture was then left to stand for about 4 hr. The mixture was diluted with water and extracted with chloroform. The chloroform solution was washed with water, and the solvent was evaporated under reduced pressure. The crystalline residue was recrystallized from cyclohexane to give 920 mg of colorless crystals, mp 59—62°C, not depressed on admixture with an authentic sample of 2-chlorotropone (Ia).

b) To a solution of 3.00 g of tropolone in 20 m*l* of dry benzene, 4.50 g of phosphorus oxychloride was added, after which the mixture was refluxed on a water bath for 5 hr. The crystalline solid that separated was filtered and washed successively with benzene and ether to give 4.57 g of white powder (II). It is insoluble in usual organic solvent, such as chloroform, benzene, acetonitrile, and dimethylformamide, and has no distinct melting point. The filtrate from II afforded 35 mg of a dark oil which could not be crystallized.

The Reaction of II and Methylamine. A 1.00-g sample of the II obtained above was suspended in 3.0 m*l* of ethanol, and then 2.0 m*l* of ethanol saturated with methylamine was added under ice cooling and stirring. After 30 min, the solvent was evaporated under reduced pressure. A dilute sodium carbonate solution was then added to the residue, and the mixture was extracted with chloroform. The chloroform solution was washed with water, and the solvent was evaporated to give reddish-orange crystals, mp 65—75°C. Chromatographic separation on an alumina column, followed by recrystallization from cyclohexane, afforded 310 mg of yellow crystals, mp 75—79°C, not depressed on admixture with an authentic sample of 2-methylaminotropone.[17] The alkaline solution was acidified with dilute hydrochloric acid and extracted with chloroform. The chloroform solution afforded 220 mg of tropolone, mp 46—50°C.

The Reaction of II and Water. A 1.00-g sample of II was suspended in 20 m*l* of water and then left at room temperature for about 5 hr, but no appreciable change was observed. When the mixture was heated at about 70°C, it gradually dissolved to give a pale brown solution. After it had stood overnight, the solution was extracted with chloroform to give 400 mg of tropolone.

2-Chloro-5-cyanotropone (Ib). To a solution of 100 mg of 5-cyanotropolone in 1.0 m*l* of dimethylformamide, 200 mg of phosphorus oxychloride was added under ice cooling. After it had stood for 1.5 hr, the mixture was poured into 10 m*l* of water. The crystals that separated were collected and washed with water to give 82 mg (73%) of pale brown crystals, mp 140—144°C, not depressed on admixture with an authentic sample of Ib.[18]

2-Chloro-5-nitrotropone (Ic). a) The similar treatment of a mixture of 200 mg of 5-nitrotropolone and 300 mg of phosphorus oxychloride in 1.0 m*l* of dimethylformamide gave 202 mg of Ic as pale yellow needles, mp 135—140°C. Recrystallization from a mixture of benzene and cyclohexane raised the melting point to 138—140°C. IR (KBr): 1632, 1602 cm^{-1} (C=C and C=O).

Found: C, 45.60; H, 2.28; N, 7.65%. Calcd for $C_7H_4O_3NCl$; C, 45.31; H, 2.17; N, 7.55%.

b) A mixture of 300 mg of 5-nitrotropolone and 900 mg of thionyl chloride in 10 m*l* of dry benzene was refluxed for 6 hr and then left to stand overnight. The evaporation of the solvent and an excess of thionyl chloride under reduced pressure afforded 330 mg of yellowish-orange crystals, mp 120—134°C. Recrystallization from benzene gave 245 mg of Ic, mp 133—138°C, not depressed on admixture with the sample obtained above.

2, 5-Dichlorotropone (Id) and Its Rearranged Products. *a) The Reaction of 5-Chlorotropolone and Phosphorus Oxychloride.* A mixture of 400 mg of 5-chlorotropolone and 400 mg of phosphorus oxychloride in 3.0 m*l* of dimethylformamide was left to stand at room temperature for 2.5 hr, and then diluted with 50 m*l* of water to give 246 mg of crystals, mp 90—98°C. Recrystallization from ethanol afforded 2, 5-dichlorotropone (Id), mg 95—97°C, not depressed on admixture with an authentic sample of Id.[2]

b) The Reaction of 5-Bromotropolone and Phosphorus Oxychloride. The similar treatment of 500 mg of 5-bromotropolone and 400 mg of phosphorus oxychloride in 4.0 m*l* of dimethylformamide gave 280 mg of crystals, mp 60—75°C. Recrystallization from ethanol afforded 143 mg of crystals, mp 91—95°C. Further recrystallization afforded Id as colorless crystals, mp 95—97°C, not depressed on admixture with the sample obtained above.

c) The Reaction of 5-Chlorotropolone with an Excess of Phosphorus Oxychloride. A solution of 400 mg of 5-chlorotropolone and 1.00 g of phosphorus oxychloride in 2.0 m*l* of dimethylformamide was left to stand overnight. The subsequent dilution of the mixture with water separated a viscous oil which gradually solidified. It was collected, washed with water, dissolved in cyclohexane, and passed through a silica gel column. The fraction eluted with cyclohexane afforded 158 mg (35%) of pale yellow crystals, mp 54—56°C. Recrystallization from aqueous ethanol afforded 2, 5-dichlorobenzaldehyde (III) as colorless needles, mp 55—56°C (Found: C, 47.59; H, 2.72%), which were identified by converting them to 2, 5-dichlorobenzoic acid; mp and mixed mp 152—154°C.

The fraction eluted with a mixture of benzene and cyclohexane (1 : 1) gave 58 mg of pale yellow crystals, mp 39—42°C. Recrystallization from aqueous ethanol afforded colorless crystals, mp 43—44°C, not depressed on admixture with an authentic sample of 3, 4-dichlorobenzaldehyde (IV).

d) The Reaction of 2, 5-Dichlorotropone and Phosphorus Oxychloride. The similar treatment of 350 mg of Id with 930 mg of phosphorus oxychloride gave 153 mg of III and 50 mg of IV.

2-Chloro-7-cyanotropone (Ie). The similar treatment of a mixture of 600 mg of 3-cyanotropolone and 960 mg of phosphorus oxychloride in 3.0 m*l* of dimethylformamide gave 532 mg of colorless crystals, mp 155—160°C. Recrystallization from benzene afforded Ie as colorless crystals, mp 159—161°C, not depressed on admixture with an authentic sample.[3]

2, 7-Dichlorotropone (If) from 3-Bromotropolone. The similar treatment of 3-bromotropolone with phosphorus oxychloride afforded If, mp 128—130°C, in about a 40% yield; no other pure substance was isolated.

The Reaction of 3-Phenyltropolone and Phosphorus Oxychloride. A solution of 600 mg of 3-phenyltropolone and 1.40 g of phosphorus oxychloride in 6 m*l* of dimethylformamide was left to stand for 6 hr and then diluted with water. The crystals, which separated at first as an oil, were collected, dissolved in benzene, and washed with dilute sodium hydroxide and water. The alkaline solution, on acidification with hydrochloric acid, gave 145 mg of 3-phenyltropolone. The benzene solution, after the evaporation of the solvent, left a crystalline residue which was dissolved in a mixture of benzene and petroleum ether (1 : 1) and passed through a silica gel column. The fraction eluted with the same solvent mixture gave 320 mg of 2-chloro-3-phenylbenzaldehyde (V) as colorless prisms, mp 104—106°C. Recrystallization from ethanol raised the melting point to 106—107°C.

Found: C, 72.24; H, 4.16%. Calcd for $C_{13}H_9OCl$: C, 72.40; H, 4.21%.

When an equimolar quantity of the reagent was used (6 hr, at room temperature), only 3-phenyltropolone was isolated unchanged.

The oxidation of V with potassium permanganate in acetone afforded 2-chloro-3-phenylbenzoic acid (VI) as colorless plates, mp 156—158°C (after recrystallization from ethanol).

Found: C, 67.13; H, 3.63%. Calcd for $C_{13}H_9O_2Cl$: C, 67.11; H, 3.90%.

2-Chloro-5-*p*-tolylazotropone (VIIa) and 4, 5-Dichloro-2-*p*-tolylindazole (VIIIa). a) To a suspension of 240 mg of 5-*p*-tolylazotropolone in 1.2 m*l* of dimethylformamide, 170 mg of phosphorus oxychloride was added under ice cooling. After the crystals were dissolved, 2-chloro-5-*p*-tolylazotropone (VIIa) gradually separated out. After the mixture had stood for 4.5 hr, these crystals were collected and washed with water. Recrystallization from benzene gave 155 mg of VIIa as brownish-orange plates, mp 161—163°C.

18) K. Kikuchi, This Bulletin, **40**, 355 (1967).

The filtrate was diluted with water, and the yellow crystals that separated out were collected and washed with water. These crystals, combined with the residue obtained by the evaporation of the mother liquor from the above recrystallization, were dissolved in a mixture of benzene and cyclohexane (1 : 1) and chromatographed on 1.5 g of silica gel. The fraction eluted with the same solvent mixture gave 16 mg of 4, 5-dichloro-2-*p*-tolylindazole (VIIIa), mp 130—134°C. The fraction eluted with benzene gave 48 mg of VIIa, mp 160—162°C.

An analytical sample of VIIa was recrystallized from ethanol to give brownish-orange plates, mp 162—163°C. IR (KBr): 1624, 1593 cm^{-1} (C=C and C=O).

Found: C, 65.15; H, 4.38; N, 10.56%. Calcd for $C_{14}H_{11}ON_2Cl$: C, 65.00; H, 4.25; N, 10.87%.

An analytical sample of VIIIa was recrystallized from ethanol to give colorless microcrystals, mp 136.5—137°C.

Found: C, 60.43; H, 3.55; N, 10.34%. Calcd for $C_{14}H_{10}N_2Cl_2$: C, 60.67; H, 3.64; N, 10.11%.

VIIIa was stable toward alkali and acids, and did not give a picrate.

b) To a solution of 240 mg of 5-*p*-tolylazotropolone in 2.5 m*l* of benzene, 130 mg of thionyl chloride was added; the solution was then refluxed for 2.5 hr. The evaporation of the solvent and an excess of the reagent left a dark brown crystalline residue, which was dissolved in benzene and passed through an alumina column. The fractions eluted with benzene and a mixture of benzene and chloroform (1 : 1) afforded 105 mg of VIIa, mp 157—159°C, undepressed on admixture with the sample obtained above.

The Reaction of 5-Phenylazotropolone (and 5-*p*-Nitrophenylazotropolone) with Phosphorus Oxychloride. a) A solution of 300 mg of 5-phenylazotropolone and 240 mg of phosphorus oxychloride in 1.2 m*l* of dimethylformamide was treated in the manner described above to give 200 mg of 2-chloro-5-phenylazotropone (VIIb), mp 127—129°C, and 32 mg of 4, 5-dichloro-2-phenylindazole (VIIIb), mp 90—92°C.

The recrystallization of VIIb from a mixture of benzene and cyclohexane gave reddish-orange plates, mp 128—129°C. IR (KBr): 1630, 1597 cm^{-1} (C=C and C=O).

Found: C, 64.69; H, 3.86; N, 11.11%. Calcd for $C_{13}H_9ON_2Cl$: C, 63.77; H, 3.70; N, 11.49%.

The recrystallization of VIIIb from methanol gave colorless needles, mp 93—94°C.

Found: C, 59.23; H, 3.18; N, 10.48%. Calcd for $C_{13}H_8N_2Cl_2$: C, 59.37; H, 3.06; N, 10.65%.

b) The similar treatment of 200 mg of 5-*p*-nitrophenylazotropolone and 120 mg of phosphorus oxychloride in 1.0 m*l* of dimethylformamide gave 118 mg of 2-chloro-5-*p*-nitrophenylazotropone (VIIc), mp 200—205°C (decomp.), and several milligrams of 4, 5-dichloro-2-*p*-nitrophenylindazole (VIIIc), mp 207—212°C.

The recrystallization of VIIc from dioxane afforded deep reddish-brown prisms, mp 205°C (decomp.). IR (KBr): 1630, 1598 cm^{-1} (C=C and C=O).

Found: C, 53.88; H, 2.87; N, 14.52%. Calcd for $C_{13}H_8O_3N_3Cl$: C, 53.90; H, 2.79; N, 14.51%.

The recrystallization of VIIIc from dioxane afforded yellow microcrystals, mp 212—213°C.

Found: C, 50.72; H, 2.91%. Calcd for $C_{13}H_7O_2N_3Cl_2$: C, 50.67; H, 2.29%.

The Formation of VIIIa from VIIa or 2-Methoxy-5-*p*-tolylazotropone. a) To a solution of 1.22 g of VIIa in 10 m*l* of dimethylformamide, 1.10 g of phosphorus oxychloride was added, after which the mixture was allowed to stand at room temperature overnight. The solution was then diluted with water, and the crystals were collected. The chromatographic separation of these crystals on an alumina column, followed by recrystallization from a mixture of benzene and cyclohexane, gave 615 mg of VIIIa, mp 135—137°C.

b) The addition of 300 mg of phosphorus oxychloride to a suspension of 200 mg of 2-methoxy-5-*p*-tolylazotropone in 3.0 m*l* of dimethylformamide gave a clear, deep red solution. After standing for 4 hr, the mixture was treated similarly to give 125 mg of VIIIa, mp 134—136°C.

The Formation of VIIIb (and VIIIc) from VIIb (and VIIc). a) The similar treatment of 1.00 g of VIIb gave pale brown crystals, mp 85—105°C. Distillation under reduced pressure (2 mmHg; bath temperature 100—125°C), followed by recrystallization from methanol, afforded 250 mg of VIIIb, mp 92—95°C.

b) The similar treatment of 200 mg of VIIc gave 90 mg of VIIIc as pale yellow crystals, mp 207—209°C.

Oxidation of 4, 5-Dichloro-2-*p*-tolylindazole (VIIIa). *a) Chromic Acid Oxidation.* To a solution of 133 mg of chromic anhydride in 0.2 m*l* of water and 2.0 m*l* of acetic acid, 140 mg of VIIIa was added; the mixture was then heated on a water bath for 4 hr. The mixture was diluted with water, and the crystals that separated out were collected and washed with water to give 110 mg of brownish-orange crystals, mp 210—225°C (decomp.). The separation of the acidic part with a dilute sodium hydroxide solution gave 44 mg of 3, 4-dichloro-4'-methylazobenzene-2-carboxylic acid (IX), mp 229—233°C (decomp.). An analytical sample was recrystallized from acetic acid to give reddish-orange prisms, mp 236—238°C (decomp.).

Found: C, 54.10; H, 3.03; N, 9.21%. Calcd for $C_{14}H_{10}O_2N_2Cl_2$: C, 54.39; H, 3.26; N, 9.06%.

Methyl Ester (X). Obtained by the addition of ethereal diazomethane to IX. Recrystallization from methanol gave X as orange plates, mp 95—96°C.

Found: C, 55.63; H, 3.80; N, 8.45%. Calcd for $C_{15}H_{12}O_2N_2Cl_2$: C, 55.74; H, 3.74; N, 8.67%.

b) Nitric Acid Oxidation. To a solution of 300 mg of VIIIa in a mixture of 3.0 m*l* of acetic acid and 0.3 m*l* of acetic anhydride, 300 mg of nitric acid (sp. gr., 1.50) was added; the mixture was then warmed at 85°C for 1 hr. The crystals that separated out were collected and washed with water to give 100 mg of IX, mp 228—235°C (decomp.). The filtrate was diluted with water, and extracted with chloroform, and the chloroform solution was treated with a dilute sodium hydroxide solution. The alkaline solution was acidified to give 60 mg of the second crop of IX, mp 232—236°C (decomp.).

The chloroform solution was washed with water, and dried, and the solvent was evaporated to give yellow crystals. These crystals were dissolved in a mixture of benzene and cyclohexane (1 : 1) and chromatographed on 1.5 g of silica gel. The first fraction, eluted with the same solvent mixture, gave 30 mg of 4, 5-dichloro-

x-nitro-2-*p*-tolylindazole (XI), mp 168—172°C. The third and fourth fractions, eluted with the same solvent mixture and with benzene, gave 27 mg of 4, 5-dichloro-*x'*-nitro-2-*p*-tolylindazole (XII), mp 189—192°C.

The recrystallization of XI from acetic acid gave fine yellow needles, mp 173—174°C.

Found: C, 52.36; H, 2.92; N, 12.72%. Calcd for $C_{14}H_9O_2N_3Cl_2$: C, 52.19; H, 2.82; N, 13.04%.

The recrystallization of XII from acetic acid gave yellow needles, mp 193—194°C.

Found: C, 52.19; H, 3.06; N, 12.31%. Calcd for $C_{14}H_9O_2N_3Cl_2$: C, 52.19; H, 2.82; N, 13.04%.

Catalytic Reduction of the Acid (IX). A 300 mg sample of IX in 60 m*l* of ethanol was catalytically hydrogenated in the presence of Adam's catalyst. The uptake of hydrogen was about 80 m*l* at an ordinary pressure and temperature. The removal of the solvent under reduced pressure afforded a brown oil. The benzene solution of this oil was shaken with a dilute sodium hydroxide solution, and the alkaline solution was acidified with acetic acid. The extraction of the solution with ether and the evaporation of the solvent gave 95 mg of colorless crystals, mp 160—168°C (decomp.). Several recrystallizations from aqueous ethanol afforded 2-amino-5, 6-dichlorobenzoic acid (XIII) as colorless needles, mp 173—175°C (decomp.) (Found: C, 41.08; H, 2.53; N, 6.75%).

The acid (XIII) was heated above its melting point for 5 min, and the product was recrystallized from cyclohexane to give colorless crystals, mp 69—71°C, not depressed on admixture with an authentic sample of 3, 4-dichloroaniline (XIV).

The benzene solution was washed with water, and the solvent was evaporated to give a dark red oil. Acetylation of this oil with acetic anhydride afforded 25 mg of acet-*p*-toluidide, mp 143—145°C.

Catalytic Reduction of 4, 5-Dichloro-2-*p*-tolylindazole (VIIIa). A solution of 400 mg of VIIIa and 250 mg of sodium acetate in 50 m*l* of ethanol was catalytically hydrogenated in the presence of 100 mg of Adam's catalyst. The removal of the catalyst and the evaporation of the solvent gave colorless crystals. Recrystallization from petroleum ether gave 125 mg of colorless crystals, mp 65—70°C. Purification through its picrate, followed by the recrystallization of the regenerated product from aqueous ethanol, gave 2-*p*-tolyl-4, 5, 6, 7-tetrahydroindazole (XV) as colorless prisms, mp 71—72.5°C.

Found: C, 79.64; H, 8.03; N, 13.00%. Calcd for $C_{14}H_{16}N_2$: C, 79.21; H, 7.60; N, 13.20%.

Reduction of the Ester (X) with Lithium Aluminum Hydride. To a solution of 380 mg of X in 5 m*l* of absolute ether, a solution of 45 mg of lithium aluminum hydride in 3 m*l* of absolute ether was added; the solution was then refluxed for 3.5 hr. The excess of the reagent was decomposed with water, the precipitate was filtered off, and the filtrate was washed with water. The solvent was removed, and the residue was dissolved in a mixture of benzene and cyclohexane (1 : 1) and passed through an alumina column (5 g). A fraction eluted with the same solvent mixture gave 130 mg of the unchanged ester (X), while a fraction eluted with a mixture of benzene and chloroform (1 : 1) gave 52 mg of reddish-orange crystals, mp 100—107°C. Recrystallization from ethanol afforded 3, 4-dichloro-2-hydroxymethyl-4'-methylazobenzene (XVI) as organge needles, mp 103—105°C (sintered at about 100°C).

Found: C, 56.94; H, 3.96; N, 9.24%. Calcd for $C_{14}H_{12}ON_2Cl_2$: C, 56.96; H, 4.10; N, 9.49%.

The fraction eluted with a mixture of chloroform and methanol gave 15 mg of pale brown crystals, mp 145—150°C. Recrystallization from benzene afforded 3, 4-dichloro-2-hydroxymethyl-4'-methylhydrazobenzene (XVII) as colorless crystals, mp 159—160°C.

Found: C, 56.78; H, 4.63; N, 9.12%. Calcd for $C_{14}H_{14}ON_2Cl_2$: C, 56.58; H, 4.75; N, 9.43%.

When about two molecular equivalents of lithium aluminum hydride were applied, XVII was isolated in about a 75% yield.

The Formation of XVI from XVII. To a solution of 240 mg of XVII in 6.0 m*l* of ethanol, a solution of 200 mg of bromine in 1.0 m*l* of ethanol was added. After the mixture had then stood for 30 min, the solvent was evaporated under reduced pressure and the residue was diluted with water. The crystals thereby obtained were dissolved in benzene and passed through an alumina column. The fraction eluted with a mixture of benzene and chloroform gave orange crystals, mp 92—105°C; yield, 130 mg. Recrystallization from ethanol gave XVI as orange needles, mp 95—105°C.

The Formation of VIIIa from XVI. A 30 mg sample of XVI in 0.4 m*l* of 75% sulfuric acid was heated at 90°C for 20 hr; the crystals thereby separated were then filtered and washed several times with water to give 15 mg of pale brown crystals, mp 134—136°C. These crystals showed no depression of the melting point on admixture with a sample of VIIIa, and the infrared spectrum was also identical with that of VIIIa.

Bromination of VIIIa. To a solution of 50 mg of VIIIa in 1.0 m*l* of acetic acid, 35 mg of bromine was added. After the mixture had been heated for about 15 min at 85°C, the crystals that separated out were filtered and washed with water to give 52 mg of crystals, mp 183—184.5°C. Recrystallization from acetic acid gave 3-bromo-4, 5-dichloro-2-*p*-tolylindazole (XVIII) as fine, colorless needles, mp 184.5—185.5°C.

Found: C, 47.06; H, 2.28; N, 7.61%. Calcd for $C_{14}H_9N_2BrCl_2$: C, 47.22; H, 2.55; N, 7.87%.

Oxidation of XVIII with Nitric Acid. A 80 mg sample of XVIII was treated with 100 mg of nitric acid (sp. gr., 1.50), as in the case of the oxidation of VIIIa, to give 9 mg of orange crystals, mp 236—238°C (decomp.). The infrared spectrum of these crystals was identical with that of IX.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 430—432 (1968)

The Cyclization of Malononitrile and Ketones by Ammonium Acetate

Akio SAKURAI and Hiroshi MIDORIKAWA

The Institute of Physical and Chemical Research, Komagome, Bunkyo-ku, Tokyo

(Received August 4, 1967)

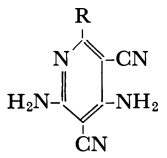
Hitherto various heterocyclic compounds have been synthesized by the reaction of ketones with ethyl cyanoacetate or ethyl acetoacetate in the presence of excessive ammonium acetate. On the basis of these facts, the reaction of malononitrile with ketones by ammonium acetate was carried out; aminopyridine derivatives, such as 2, 4-diamino-3, 5-dicyano-6-alkylpyridines (I) and 2-amino-3-cyano-4, 6-dialkylpyridines (II), were thus obtained.

Some active methylene compounds give heterocyclic compounds containing one nitrogen atom by condensation with ketones in the presence of ammonium acetate. Thus, ethyl cyanoacetate gives hydroxypyridines,[1] and ethyl acetoacetate gives hydroxyquinoline derivatives.[2]

The present paper will deal with the synthesis of aminopyridine derivatives by the condensation of malononitrile and various ketones (methyl ketones and α, β-unsaturated ketones) in the presence of ammonium acetate.

Condensations between aliphatic methyl ketones and malononitrile were carried out in a 1 : 2 molar ratio; 2, 4-diamino-3, 5-dicyano-6-alkylpyridines were thus obtained, with the elimination of one mole each of methane and water, as is indicated in the following scheme:

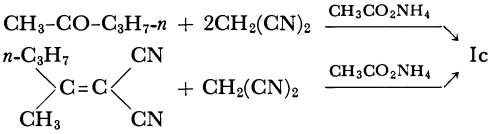
$$CH_3\text{-}CO\text{-}R + 2CH_2(CN)_2 \xrightarrow{CH_3CO_2NH_4}$$



I

a $R=CH_3$ b $R=C_2H_5$ c $R=n\text{-}C_3H_7$
d $R=n\text{-}C_5H_{11}$ e $R=n\text{-}C_6H_{13}$ f $R=n\text{-}C_9H_{19}$
g $R=i\text{-}C_4H_9$

The structure of I was proved from the infrared spectra and NMR spectra, as is shown in Tables 2 and 3. Furthermore, Ic was also obtained by the condensation of 1-methylbutylidenemalononitrile with malononitrile in the presence of ammonium acetate. The two products were established as identical by the results of elemental analyses, their infrared spectra, and by the fact these a mixed-melting-point determination showed no depression.



In the reaction with acetone, a compound (mp 340—342°C, $C_{14}H_{17}O_2N_5$) was obtained along with Ia. This compound was formed by the elimination of 1 mol each of methane, water, and hydrogen from 3 mol of acetone, 2 mol of malononitrile, and 1 mol of ammonia; it was also obtained by the use of mesityl oxide instead of acetone. Its structure could not be confirmed in this study.

α, β-Unsaturated ketones and malononitrile reacted in a 1 : 1 molar ratio to give 2-amino-3-cyano-4, 6-dialkylpyridines (II) through Michael reaction, with the elimination of 1 mol each of water and hydrogen.

$$R\text{-}CH{=}CH\text{-}CO\text{-}R' + CH_2(CN)_2 \xrightarrow{CH_3CO_2NH_4}$$

The hydrolysis of the cyano group of IId by heating with potassium hydroxide in alcohol gave an amide melting at 210—211°C; this amide was hydrolyzed to a carboxylic acid (III) by heating it with potassium hydroxide in glycerol. Compound III showed a mp of 233—234°C with decomposition. On the other hand, the reaction of ethyl cyanoacetate with benzalacetophenone in the presence of ammonium acetate[1] gave ethyl 2-amino-4, 6-diphenylnicotinate (IV). The carboxylic acid III was proved to be identical with the compound obtained by the hydrolysis of IV by the results of elemental analyses and by their infrared spectra.

The structure of II was supported by the infrared and NMR spectra, shown in Tables 2 and 3. The reaction with mesityl oxide did not give the expected product, but it was the same compound as that obtained by the reaction with acetone.

The reactions of malononitrile with acetophenone and cyclohexanone were abnormal, giving 3-cyano-5, 6-dihydro-4, 6-diphenyl-2-pyridone and 4-cyano-1, 5, 6, 7, 8, 8a-hexahydroisocarbostyryl-1-spiro-1'-cyclohexane respectively. The identities of these compounds with the substances obtained by the reactions of ethyl cyanoacetate with acetophenone and cyclohexanone respectively were supported by their melting points, and infrared spectra, and by the results of elemental analyses.

Experimental

All melting points are uncorrected.

The infrared spectra were determined by means of pressed potassium bromide disks.

The NMR spectra were determined in trifluoroacetic acid at a frequency of 60 Mc, using tetramethylsilane as an internal standard. The chemical shifts are given as ppm downfield from tetramethylsilane.

The Reaction of Malononitrile with Aliphatic Methyl Ketones. A mixture of malononitrile (0.1 mol), ketone (0.05 mol), and ammonium acetate (0.08 mol) was refluxed for 3—7 hr. From the solution a pale yellow, crystalline matter was then separated. The results are summarized in Table 1.

The Reaction of Malononitrile with 1-Methylbutylidenemalononitrile. A mixture of malononitrile (4.6 g, 0.07 mol), 1-methylbutylidenemalononitrile (9.4 g, 0.07 mol), and ammonium acetate (3.9 g, 0.05 mol) in 5 m*l* of alcohol was refluxed for 1.5 hr. After cooling, a crystalline matter separated; this was filtered and recrystallized from glacial acetic acid to give colorless crystals, mp 232—233°C. This compound was proved to be identical with Ic by a mixed-melting-point determination and by a study of its infrared spectrum.

Found: C, 59.42; H, 5.04; N, 35.00%. Calcd for $C_{10}H_{11}N_5$: C, 59.68; H, 5.51; N, 34.81%.

The Reaction with α, β-Unsaturated Ketones. A mixture of malononitrile (0.1 mol), ketones (0.1 mol), and ammonium acetate (0.8 mol) was refluxed in alcohol (15 m*l*) or without a solvent for 2—5 hr. After cooling, a crystalline matter precipitated; this was then worked up as usual. The results are summarized in Table 1.

Hydrolysis of 2-Amino-3-cyano-4, 6-diphenylpyridine (IId). Compound IId (2 g) was heated with 20% alcoholic potassium hydroxide (30 m*l*) for 5 hr. After the addition of water (20 m*l*) to the reaction mixture, it was left to stand overnight. The pale yellow crystals which precipitated were then recrystallized from alcohol to give 2-amino-3-carbamoyl-4, 6-diphenyl-pyridine, mp 210—211°C.

Found: C, 74.42; H, 5.00; N, 14.34%. Calcd for $C_{18}H_{15}ON_3$: C, 74.72; H, 5.23; N, 14.53%.

To a solution of potasium hydroxide (4 g) in glycerol (20 m*l*), 2-amino-3-carbamoyl-4, 6-diphenylpyridine (1 g) was added, and the mixture was boiled at 200°C for 5 hr. After cooling, the solution was neutralized with dilute hydrochloric acid; a crystalline solid separated, which was then recrystallized from methanol to afford 2-amino-3-carboxy-4, 6-diphenylpyridine, mp 232—234°C with decomposition. The results of elemental analyses and its infrared spectrum proved this substance to be identical with the compound obtained by the hydrolysis of ethyl 2-amino-4, 6-diphenylnicotinate.[1]

Found: C, 74.06; H, 4.55; N, 9.29%. Calcd for $C_{18}H_{14}O_2N_2$: C, 74.48; H, 4.83; N, 9.66%.

The Reaction with Acetophenone. A mixture of malononitrile (3.3 g, 0.05 mol), acetophenone (6 g, 0.05 mol), and ammonium acetate (3.85 g, 0.05 mol) was heated for 7 hr. After standing overnight, the crystalline matter which was precipitated was recrystallized from alcohol to give 3-cyano-5, 6-dihydro-4, 6-diphenyl-6-methyl-2-pyridone, mp 213—214°C (lit.[3] mp 213—214°C). This compound was identified with the compound obtained by the condensation of ethyl cyanoacetate and acetophenone by ammonium acetate.[1]

Found: C, 79.11; H, 5.33; N, 9.85%. Calcd for $C_{19}H_{16}ON_2$: C, 79.14; H, 5.59; N, 9.72%.

The Reaction with Cyclohexanone. A mixture of malononitrile (4.6 g, 0.07 mol), cyclohexanone (6.9 g, 0.07 mol), and ammonium acetate (5.4 g, 0.07 mol) was heated for 7 hr. After cooling, a crystalline matter separated; this was recrystallized from glacial acetic acid to afford 4-cyano-1, 5, 6, 7, 8, 8a-hexahydroisocarbostyryl-1-spiro-1'-cyclohexane, mp 244—246°C. By ts infrared spectrum and the results of elemental analyses, this compound was identified with the substance obtained by the reaction of ethyl cyanoacetate with cyclohexanone.[1]

Found: C, 73.69; H, 8.05; N, 11.38%. Calcd for $C_{15}H_{20}ON_2$: C, 73.77; H, 8.20; N, 11.47%.

The authors wish to express their grateful thanks to Dr. Taro Hayashi and Dr. Tatsuo Takeshima for their kind advice. Thanks are also due to Dr. Haruo Homma and his staff for their microanalyses, to Mr. Jun Uzawa for his measurements of the NMR spectra, and to Mr. Teruo Kurihara for his measurements of the IR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 433—437 (1968)

Synthesis of Natural Human Angiotensin I[1)]

Haruhiko AOYAGI,* Kikuo ARAKAWA** and Nobuo IZUMIYA*

* *Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka*

** *Research Institute of Angiocardiology, Faculty of Medicine, Kyushu University, Katakasu, Fukuoka*

(Received August 14, 1967)

The synthesis of a decapeptide, H-L-Asp-L-Arg-L-Val-L-Tyr-L-Ile-L-His-L-Pro-L-Phe-L-His-L-Leu-OH, which has an amino acid sequence assumed by Arakawa *et al.* for natural human angiotensin I, has been performed. The chemical and biological properties of the synthetic product have shown to be in agreement with those of the natural material, thus the structure of human angiotensin I has been confirmed by the present synthesis.

Angiotensin was found in 1939 during experiment with animals as a causal substance responsible for the experimental renal hypertension in animals.[2)] Angiotensin I, decapeptides, have been isolated from horse[3)] and bovine[4)] materials; these peptides have been liberated from precursor molecule angiotensinogen contained in plasma protein by the proteolytic action of renin which derived from kidney. The decapeptides are then converted to angiotensin II, octapeptides, by the removal of a dipeptide, H-His-Leu-OH, from its carboxy terminal by the action of a specific enzyme, called converting enzyme,[5)] which exists abundantly in plasma. The resulting angiotensin II are the most potent pressor substances ever known. The species difference resides in the fifth position which is occupied by isoleucine in horse[6)] and valine in bovine.[7)]

The menchanism of liberation of angiotensin, thus clarified only in animals except human, has been a working hypothesis in the pathogenesis of human hypertension. The fact that it had never been isolated nor elucidated in chemical terms in human has been the weekest point of the hypothesis in understanding the pathogenetic role of angiotensin in human hypertension. However, Arakawa *et al.* recently isolated pure human angiotensin from an incubation mixture of human serum protein and renin.[8)] They reported that amino acid analysis of the natural peptide from human revealed the same composition as that known for horse angiotensin in which the structure has been established to be [Ile^5]-angiotensin I, *i. e.*, H-L-Asp-L-Arg-L-Val-L-Tyr-L-Ile-L-His-L-Pro-L-Phe-L-His-L-Leu-OH.[9)]

Therefore, the amino acid sequence of human angiotensin has been plausibly anticipated to be same as that for [Ile^5]-angiotensin I. Since [Ile^5]-angiotensin I decapeptide had never been synthesized before, the present authors attempted to prepare the decapeptide (XVIII) mentioned above and to compare the identity of XVIII with the human angiotensin.

The sequence of reactions employed for the synthesis of the decapeptide (XVIII) is shown in Fig. 1. To obtain the final protected decapeptide *p*-nitrobenzyl ester (XVII), we selected a route involving the coupling of a mixed anhydride derived from benzyloxycarbonyl-β-benzylaspartic acid with the nonapeptide ester (XVI) which was derived from the benzyloxycarbonyl-nonapeptide ester (XV) by the action of hydrogen bromide in acetic acid. Similarly, the protected nonapeptide ester (XV) was prepared by coupling a mixed anhydride of benzyloxycarbonyl-nitroarginine with the octapeptide ester (XIV) which was obtained from the benzyloxycarbonyl-octapeptide ester (XIII). The acyl-octapeptide ester (XIII) was prepared by coupling the benzyloxycarbonyl-tripeptide azide derived from the hydrazide (XII) with the pentapeptide ester (VIII) which had been prepared from the benzyloxycarbonyl-pentapeptide ester (VII). Similarly, the acylpentapeptide ester (VII) was obtained by coupling the acyl-tripeptide azide from the corresponding hydrazide (VI)

with the dipeptide ester (III). The derivative (II, V or XI) of either the dipeptide or tripeptide was built up by stepwise elongation of the peptide chain from the carboxyl toward the amino end. Coupling of a benzyloxycarbonyl-amino acid with an amino component was mainly accomplished by carboxy activation through use of dicyclohexylcarbodiimide[10] or method of the mixed anhydride.[11]

The *p*-nitrobenzyl group was used for the protection of the carboxylic acid function of the *C*-terminal amino acid residue, and the benzyl group for the imidazoyl function of the histidine residue. It has been recognized that the action of hydrogen bromide in acetic acid removes the benzyloxycarbonyl group[12] without cleavage of the *p*-nitrobenzyl ester bond,[13] the imidazoyl-benzyl[14] or the nitro group;[13] many intermediate peptide ester hydrobromides (*e.g.*, XVI) were obtained in this manner.

The protected decapeptide *p*-nitrobenzyl ester (XVII) was hydrogenated with palladium black in a solvent of methanol - acetic acid - water at room temperature. The proceeding of the hydrogenolysis was followed at various times with the assay of paper chromatographic technique and with the bioassay of the pressor activity, and the highest activity was observed after some 48 hr though small part of the imidazoyl-benzyl groups was still remained untouched. The crude material after the hydrogenation was purified by a set of the column chromatographies which have proved to be very effective in isolating natural human

angiotensin.[8,9] The active fractions from the column were finally lyophilized leaving a white powder (acetate of XVIII, presumably); the homogeneity and stereospecific purity of the powder were ascertained by many chromatographic assays, the amino acid analysis and the digestion with the proteolytic enzymes.

The synthetic decapeptide obtained as the powder was then compared with natural human angiotensin I. In addition to having the same R_f values in paper and thin-layer chromatographies and affording a single peak in cochromatography of Bio-Gel column with the natural preparation, the synthetic and natural preparations were indicated to have the same specific activity on the bioassay of the rat pressor activity test. These results show that the synthetic product is identical to natural product, and the structure of human angiotensin I anticipated by Arakawa *et al.*[9] has been decided by the present synthesis.

Experimental

All the melting points are uncorrected. The optical rotations were measured on a Yanagimoto Photometric Polarimeter, OR-20 type.

L-Leucine *p*-Nitrobenzyl Ester *p*-Toluenesulfonate (I·TsOH). A solution of L-leucine (5.24 g, 40 mmol), *p*-nitrobenzyl alcohol (7.36 g, 48 mmol) and toluenesulfonic acid monohydrate (8.36 g, 44 mmol) in benzene (500 m*l*) was stirred under heating, and the water liberated was removed as an azeotropic mixture. The reaction mixture was concentrated *in vacuo*, and the residual oil was solidified by adding ether. The product was recrystallized from 80% methanol. Yield, 11.65 g (67%); mp 202°C; $[\alpha]_D^{22}$ +10.2° (*c* 1, ethanol); R_f 0.78.[15]

Found: C, 54.42; H, 5.98; N, 6.41%. Calcd for $C_{20}H_{26}O_7N_2S$: C, 54.78; H, 5.98; N, 6.39%.

Z-His(*im*-Bzl)-Leu-ONb (II). Into a solution of benzyloxycarbonyl-(*im*)benzyl-L-histidine[16] (3.80 g, 10 mmol) and I (4.36 g, 10 mmol) in dimethylformamide (30 m*l*) there were added triethylamine (1.40 m*l*) and dicyclohexylcarbodiimide[10] (2.08 g) at 0°C. After it had been stirred overnight at room temperature, the mixture was evaporated *in vacuo* and the residue was diluted with ethyl acetate; then the dicyclohexylurea thus precipitated was filtered off. The filtrate was washed successively with 3% hydrochloric acid, 4% sodium bicarbonate and water, and dried over sodium sulfate. The filtered solution was evaporated *in vacuo*. The product was obtained as an oil. Yield, 5.56 g (89%); R_f 0.76.[15]

H-His(*im*-Bzl)-Leu-ONb Dihydrobromide (III·2HBr). To a solution of II (5.00 g, 8 mmol) in acetic acid (8 m*l*), 3 N dry hydrogen bromide - acetic acid (16 m*l*) was added. After it had been stood for one hour, the solution was evaporated to dryness *in vacuo*. The residue was triturated with ether and washed repeatedly with ether by decantation. The product was collected by filtration with the aid of ether. Yield, 4.97 g (95%); mp 122—124°C; $[\alpha]_D^{22}$ +13.2° (*c* 1, ethanol); R_f 0.76.[15]

Found: C, 45.97; H, 5.23; N, 10.43%. Calcd for $C_{26}H_{35}O_5N_5Br_2 \cdot H_2O$: C, 46.37; H, 5.24; N, 10.40%.

Z-Pro-Phe-OEt (IV). *a) DCC Method.* Into a solution of benzyloxycarbonyl-L-proline (2.49 g, 10 mmol) and L-phenylalanine ethyl ester hydrochloride (1.93 g, 10 mmol) in chloroform (30 m*l*) there were added triethylamine (1.40 m*l*) and dicyclohexylcarbodiimide (2.06 g) at 0°C. After it had been stood overnight at 0°C, the desired product was obtained by the procedure described in the case of II. The residue obtained was solidified by adding ether and petroleum ether. The product was recrystallized from ethyl acetate - ether - petroleum ether. Yield, 3.30 g (78%); mp 65—68°C; $[\alpha]_D^{22}$ −33.8° (*c* 1, ethanol); R_f 0.87.[15] This compound was obtained previously as an oily product.[17]

Found: C, 67.72; H, 6.64; N, 6.61%. Calcd for $C_{24}H_{28}O_5N_2$: C, 67.90; H, 6.65; N, 6.60%.

b) MA Method. To a mixed anhydride prepared at −5°C from benzyloxycarbonyl-L-proline (2.4 g), isobutyl chloroformate (1.31 m*l*) and triethylamine (1.40 m*l*) in tetrahydrofuran (20 m*l*), a chilled solution of L-phenylalanine ethyl ester hydrochloride (1.93 g) dissolved in a mixture of triethylamine (1.40 m*l*) and chloroform (20 m*l*) was added. The reaction mixture was then allowed to stand overnight and then evaporated *in vacuo*. The oily residue was treated as described in the case of II. Yield, 3.00 g (71%); mp 65—68°C; R_f 0.87.[15]

Z-His(*im*-Bzl)-Pro-Phe-OEt (V). This compound was prepared by the same procedure as has been described for the preparation of II. One and ninety hundredths grams (5 mmol) of benzyloxycarbonyl(*im*)-benzyl-L-histidine and H-Pro-Phe-OEt·HCl[17] (1.64 g, 5 mmol), which was prepared from IV, gave 2.44 g (75%) of V as an oily product; R_f 0.73.[15]

Z-His(*im*-Bzl)-Pro-Phe-NHNH$_2$ (VI). A solution of V (3.00 g, 4.6 mmol) and hydrazine hydrate (4.6 m*l*, 92 mmol) in methanol (10 m*l*) was allowed to stand at room temperature for 2 days. The solution was then evaporated *in vacuo*. The oily residue was dissolved in ethyl acetate, washed with water and the organic layer was dried over sodium sulfate and then evaporated *in vacuo*. The semi-solid residue weighed 2.50 g (85%); R_f 0.77.[15]

Z - His(*im* - Bzl) - Pro - Phe - His(*im* -Bzl)-Leu-ONb (VII). To a solution of VI (2.16 g, 3.4 mmol) dissolved in dimethylformamide (10 m*l*) cooled at 0°C, 3.8 N hydrogen chloride (1.80 m*l*, 6.8 mmol) in dioxane was added, followed by isoamyl nitrite (0.46 m*l*, 3.4 mmol).[18] After it had been allowed to stand for 6 min with occasional stirring, triethylamine (0.95 m*l*, 6.8 mmol) was added to the solution. To this, a chilled solution of III·2HBr (2.28 g, 3.4 mmol) dissolved in

15) The R_f value refers to the thin-layer chromatography with Merck silica gel G and to the *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2, v/v) system. Compounds possessing a free amino group were detected by spraying them with ninhydrin, and those with a blocked amino group, by spraying them with 47% hydrobromic acid, and then with nihnhydrin.

a mixture of triethylamine (1.14 ml, 8.2 mmol) and dimethylformamide (7 ml) was added. The solution was stirred for 2 days at 0°C and then evaporated *in vacuo*. The oily residue was dissolved in ethyl acetate, and the solution was washed successively with 3% hydrochloric acid, 4% sodium bicarbonate and water, dried over sodium sulfate, and then evaporated *in vacuo*. The residual oil weighed 1.72 g (46%); R_f 0.84.[15] All attempts to crystallize this oil failed.

H-His(*im*-Bzl)-Pro-Phe-His(*im*-Bzl)-Leu-ONb Trihydrobromide (VIII·3HBr). To a solution of VII (3.85 g, 3.5 mmol) in acetic acid (10 ml), 3 N hydrogen bromide-acetic acid (20 ml) was added. After it has been allowed to stand for 1 hr, the solution was evaporated to dryness *in vacuo*. The oily residue was then treated as has been described in connection with the preparation of III. Yield, 4.02 g (95%); R_f 0.76.[15]

Z-Tyr(*O*-Bzl)-Ile-OEt (IX). Nine and ten hundredths grams (20 mmol) of benzyloxycarbonyl-*O*-benzyl-L-tyrosine[19] was coupled with L-isoleucine ethyl ester *p*-toluenesulfonate[20] (6.62 g, 20 mmol) by the mixed anhydride method, following the procedure described for the preparation of IV. Recrystallization from ethyl acetate-petroleum ether gave 8.58 g (82%); mp 128°C; $[\alpha]_D^{25}$ +10.7° (*c* 1, acetic acid); R_f 0.97.[15]

Found: C, 70.43; H, 7.03; N, 5.18%. Calcd for $C_{32}H_{38}O_6N_2$: C, 70.31; H, 7.01; N, 5.13%.

H-Tyr-Ile-OEt Hydrochloride (X·HCl). Three and forty hundredths grams (6.5 mmol) of IX dissolved in 0.5 N methanolic hydrogen chloride (14.3 ml) was hydrogenated in the presence of palladium black. The filtrate from the catalyst was evaporated to dryness *in vacuo*. Yield of an oily product, 2.40 g (94%); R_f 0.77.[15]

Z-Val-Tyr-Ile-OEt (XI). This compound was prepared by the mixed anhydride method as has been described for the preparation of IV. Two and fifty-one hundredths grams (9 mmol) of benzyloxycarbonyl-L-valine and X·HCl (3.53 g, 9 mmol) gave 4.40 g of the crude product. It was recrystallized from methanol-ether. Yield, 4.00 g (80%); mp 191°C; $[\alpha]_D^{22}$ −20.2° (*c* 1, acetic acid); R_f 0.97.[15]

Found: C, 64.68; H, 7.30; N, 7.75%. Cacld for $C_{30}H_{41}O_7N_3$: C, 64.84; H, 7.44; N, 7.56%.

Z-Val-Tyr-Ile-NHNH$_2$ (XII). To a solution of XI (5.56 g, 10 mmol) in dimethylformamide (30 ml), hydrazine hydrate (10 ml) was added; the solution was allowed to stand for 2 days at 30°C. The reaction mixture was evaporated *in vacuo*. The hydrazide which precipitated upon the addition of water was filtered, washed with water and dried. The product was recrystallized from dimethylformamide-ethyl acetate. Yield, 5.35 g (97%); mp 279—280°C.

Found: C, 60.98; H, 7.26; N, 12.59%. Calcd for $C_{28}H_{39}O_6N_5\cdot\frac{1}{2}H_2O$: C, 61.07; H, 7.32; N, 12.71%.

Z-Val-Tyr-Ile-His(*im*-Bzl)-Pro-Phe-His(*im*-Bzl)-Leu-ONb (XIII). To a solution of XII (0.54 g, 1 mmol) dissolved in a mixture of acetic acid (160 ml) and water (10 ml), N hydrochloric acid (3 ml) was added, followed by N sodium nitrite (1.1 ml). After it had stood for 5 min at 0°C, the solution was diluted with cold water (200 ml). The azide which precipitated was collected by filtration, washed with 4% sodium bicarbonate and water, and then dried in a desiccator *in vacuo* at 0°C. The dried azide was added to a chilled solution of VIII·3HBr (1.176 g, 1 mmol) dissolved in a mixture of triethylamine (0.50 ml, 3.6 mmol) and dimethylformamide (12 ml); the solution was stirred for 3 days at 0°C, and then evaporated *in vacuo*, The residual oil was dissolved in ethyl acetate, and the solution was washed successively with 3% hydrochloric acid, 4% sodium bicarbonate and water. Oily residue was solidified by adding ether and pertroleum ether. The product was recrystallized from ethanol-ether-petroleum ether. Yield, 0.506 g (34%); mp 125—134°C; $[\alpha]_D^{18}$ −41.0° (*c* 0.38, acetic acid); R_f 0.78.[15]

Found: C, 65.06; H, 7.15; N, 12.05%. Calcd for $C_{81}H_{95}O_{14}N_{13}\cdot H_2O$: C, 65.17; H, 6.55; N, 12.20%.

H-Val-Tyr-Ile-His(*im*-Bzl)-Pro-Phe-His(*im*-Bzl)-Leu-ONb Trihydrobromide (XIV·3HBr). XIII (472 mg, 0.3 mmol) was treated with 3 N hydrogen bromide-acetic acid (3 ml) as has been described in connection with the preparation of III. Yield of an oily product, 494 mg (97%); R_f 0.60.[15]

Z-Arg(NO$_2$)-Val-Try-Ile-His(*im*-Bzl)-Pro-Phe-His(*im*-Bzl)-Leu-ONb (XV). To a mixed anhydride prepared from of benzyloxycarbonyl-nitro-L-arginine[21] (170 mg, 0.48 mmol), isobutyl chloroformate (0.062 ml, 0.48 mmol) and triethylamine (0.068 ml, 0.48 mmol) in tetrahydrofuran (2 ml), a chilled solution of XIV·3HBr (508 mg, 0.32 mmol) dissolved in a mixture of triethylamine (0.162 ml, 1.15 mmol) and dimethylformamide (2 ml) was added. The reaction mixture was then allowed to stand overnight. The precipitate which formed upon the addition of 3% hydrochloric acid to the solution was collected, washed with 3% hydrochloric acid, 4% sodium bicarbonate and water, and dried. It was recrystallized from ethanol-ether. Yield, 448 mg (78%); mp 135—142°C; $[\alpha]_D^{18}$ −32.5° (*c* 0.4, acetic acid); R_f 0.75.[15]

Found: C, 58.19; H, 6.57; N, 14.54%. Calcd for $C_{87}H_{106}O_{17}N_{18}\cdot 6H_2O$: C, 58.57; H, 6.67; 14.13%.

H-Arg(NO$_2$)-Val-Tyr-Ile-His(*im*-Bzl)-Pro-Phe-His(*im*-Bzl)-Leu-ONb Trihydrobromide (XVI·3HBr). XV (428 mg, 0.24 mmol) in 3 N hydrogen bromide-acetic acid (3 ml) was treated as has been described in connection with the preparation of III. Yield of a hygroscopic powder, 412 mg (96%); R_f 0.68.[15]

Z-Asp(OBzl)-Arg(NO$_2$)-Val-Tyr-Ile-His(*im*-Bzl)-Pro-Phe-His(*im*-Bzl)-Leu-ONb (XVII). This compound was prepared by the mixed anhydride method as has been described for the preparation of XV. One hundred and twenty two milligrams (0.35 mmol) of benzyloxycarbonyl-β-benzyl-L-aspartic acid[22] and XVI·3HBr (410 mg, 0.23 mmol) gave 362 mg (79%) of XVII; mp 138—144°C; $[\alpha]_D^{18}$ −30.0° (*c* 0.3, acetic acid); R_f 0.90.[15]

Found: C, 58.82; H, 6.34; N, 13.38%. Calcd for $C_{93}H_{117}O_{20}N_{19}\cdot 6H_2O$: C, 59.17; H, 6.54; N, 13.39%.

H-Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His-Leu-OH (XVIII). Two hundred milligrams (0.1 mmol) of

XVII dissolved in a mixture (30 ml) of methanol : acetic acid : water (60 : 20 : 15, v/v) was subjected to hydrogenolysis in the presence of palladium black with vigorous stirring for 48 hr.[23] After removal of the catalyst by filtration the solvent was removed *in vacuo*. Evaporation was repeated with the addition of dioxane. The crude residue, 130 mg, was collected with the aid of a mixture of dioxane and ether. The paper chromatography of the residue indicated the presence of a major spot, R_f 0.53,[24] positive with ninhydrin, Sakaguchi and Pauly reaction, besides several weak spots positive with ninhydrin. A material in the major spot revealed strong pressor activity when it was extracted with dilute acetic acid. The crude residue (120 mg) was divided to six portions, and each portion was purified by subsequent column chromatography using carboxymethyl cellulose (2.5×50 cm; solvent, ammonium acetate with a gradient from 0.05 to 0.4 M), DEAE-Sephadex A-25 (1.5×50 cm; solvent, pyridine-collidine-acetate buffer with a gradient from pH 8.1 to 7.0), and Bio-Gel P-2 (0.8×100 cm; solvent, 0.1 N acetic acid) which have proved to be most effective in isolating natural human angiotensin I.[8,9] The six active fractions from the Bio-Gel column were pooled and lyophilized, leaving a white powder (acetate of XVIII, presumably), 8.6 mg; $[\alpha]_D^{26}$ $-63\pm3°$ (*c* 0.08, 0.05 N acetic acid;[25] amino acid ratios in acid hydrolysate, aspartic acid 0.98, arginine 1.03, valine 1.12, tyrosine 0.88, isoleucine 0.92, histidine 1.98, proline 1.10, phenylalanine 1.03, leucine 1.06. The homogeneity of the powder was ascertained by paper, thin-layer and column chromatography as described later. Furthermore, the stereospecific purity of each amino acid residue of the powder was confirmed by the enzymic method; with leucine aminopeptidase[7] the sample was degraded completely to nine amino acid residues leaving no decapeptide, while incubation of the sample with carboxypeptid ase A[26] caused the liberation of leucine, histidine and phenylalanine leaving H-Asp-Arg-Val-Try-Ile-His-Pro-OH as an unhydrolyzable core.

Comparison of Synthetic XVIII and Natural Human Angiotensin I. The powder (acetate of XVIII) obtained above was chromatographed on Toyo Roshi No. 51 paper affording R_f 0.53[24] and 0.51,[27] and on Serva TLC thin-layer affording R_f 0.71;[28] these values were exactly identical with those of natural human angiotensin I. The chemical identy was confirmed further by the cochromatography of a mixture of the preparations from the synthesis and the human origin with the Bio-Gel column (0.8×100 cm; solvent, 0.1 N acetic acid). Bioassay with the rat pressor activity was performed as has been described in the paper;[9] the specific pressor activity of the synthetic decapeptide was identical with that of the natural material within the limit of the experimental error. Oxytocic activity of the synthetic material was nil, also as has been observed in natural material.[9]

We wish to thank Mr. Kosaku Noda for amino acid analysis and Miss Junko Yamada for skillful technical assistance.

23) The reaction was followed at various times with a paper chromatography, and the bioassay of the pressor activity; the highest activity observed after the hydrogenation of some 48 hr. However, the chromatography indicated that a small part of the imidazoyl-benzyl groups was remained untouched; this fact might be one of the reasons that the yield (8.6 mg) of pure product was poor. Treatment of the hydrogenated material of XVII with sodium-liquid ammonia did not give a product bearing stronger pressor activity.

24) The R_f value refers to the paper chromatography with the solvent system of *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2 v/v).

25) We could not determine the specific rotation of natural human angiotensin I because of the scantity of material. Neither Skeggs *et al.* nor Peart *et al.*, also, did not determine the specific rotation of natural horse and bovine angiotensin I.[3,4] It would be of noteworthy that the specific rotations of synthetic [Val^5]-angiotensin I are reported as value of close resemblance with that of the powder (acetate of XVIII); $[\alpha]_D$ $-67.5\pm2°$ (*c* 1.69, H_2O) (R. Schwyzer *et al.*, *Helv. Chim. Acta*, **41**, 1273 (1958)) and $[\alpha]_D^{22}$ $-74\pm3°$ (*c* 1.6, 0.05 N acetic acid) (St. Guttmann, *ibid.*, **44**, 721 (1961)) for the synthetic [Val^5]-angiotensin I as an acetate salt.

26) F. Sanger and E. O. P. Thompson, *Biochem. J.*, **53**, 366 (1953).

27) Solvent, *n*-butanol - acetic acid - water (7 : 1 : 2, v/v).

28) Solvent, *s*-butanol - 3% ammonium hydroxide (100 : 44; v/v).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 438—441 (1968)

Use of Anhydrous Hydrogen Fluoride in Peptide Synthesis. II. Procedures for the Syntheses of Simple Peptides

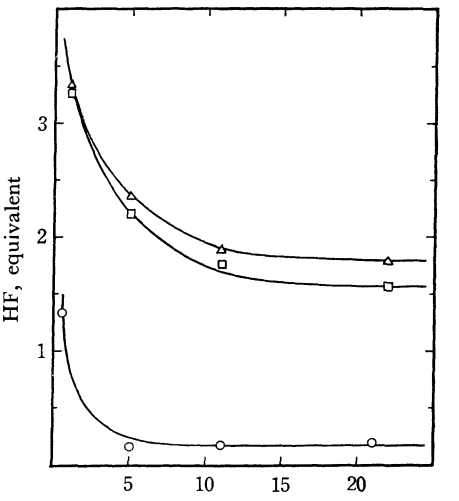
Shumpei SAKAKIBARA, Yasuo KISHIDA, Rinzo NISHIZAWA*1 and Yasutsugu SHIMONISHI

Peptide Center, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received August 10, 1967)

Detailed conditions for handling simple peptide-derivatives with anhydrous hydrogen fluoride (HF) were presented. Since HF has a strong affinity for peptides, the removal of excess HF from the reaction products is rather difficult, but is essential to obtain the product as good crystals. Syntheses of the following peptides were carried out successfully as examples of the HF procedure: tosyl-L-phenylalanyl-L-phenylalanine, L-leucylglycine, L-arginylglycine, carbobenzoxy-L-prolyl-L-leucylglycine ethyl ester, L-aspartyl-L-phenylalanine amide, and BOC-β-alanyl-L-tryptophyl-L-methionyl-L-aspartyl-L-phenylalanine amide.

The possibility of removing the S-benzyl group by acidolysis was the first indication of the usefulness of anhydrous hydrogen fluoride (HF) for peptide synthesis;[1] this was confirmed by the formation of oxytocin from the fully-protected nonapeptide. The general properties of HF as a reagent for the removal of various protective groups have been discussed in our preceding papers.[2,3] In this study, detailed conditions for the synthesis of simple peptides were investigated to demonstrate how the HF-procedure can be applied in general peptide synthesis. The HF reaction was carried out in the apparatuses described in the preceding papers.[2,3] Although completely dry HF is desirable for accelerating the cleaving reaction, a further drying procedure was unnecessary for the synthesis of simple peptides when HF of more than 99% purity was used under mild conditions. Generally, the HF molecule has a strong affinity for peptides through the hydrogen bonds, and it takes a very long time to remove the excess HF from peptides, even *in vacuo*. The results shown in Fig. 1 demonstrate that 0.19, 1.57, and 1.81 equivalents of HF were still attached to acetyl-L-leucine, L-leucylglycine and L-leucylglycylglycine respectively, even when their HF-solution had been kept under a vacuum (2—3 mmHg) for 20 hr at room temperature. These results indicate that about 1.4 equivalents of HF are bound to an amino group and that about 0.2 equivalent of HF is attached to one peptide-bond under these conditions. Therefore, the difficulty in removing HF from peptides increases with the number of the peptide-bonds. Nevertheless, the complete removal of the bound HF in some way is essential if we are to obtain the product as good crystals.



Evacuation time at 2—3 mmHg, hr

Fig. 1. Amount of absorbed HF in acetyl-amino acid or free peptides. Each material (0.1 g) was dissolved in HF (1 m*l*), and excess HF was removed using a plastic water pump (20—30 mmHg) for 30 min. Then, the residue was kept *in vacuo* (2—3 mmHg) at room temperature. Remaining HF was determined by titration with 0.1 N sodium hydroxide.
○ Acetyl-L-leucine
□ L-Leucylglycine
△ L-Leucylglycylglycine

First, we attempted to remove the isopropyl ester group from the tosyl-L-phenylalanyl-L-phenylalanine isopropyl ester. The reaction was carried out at 20°C for one hour in the presence of an equimolar amount of anisole. The excess HF was then removed by distillation *in vacuo*. In this case, the product is water-insoluble, and there is no free amino group in the molecule. Therefore,

the small amount of HF remaining was easily removed by washing the product with water. When carbobenzoxy-L-leucylglycine was treated with HF, the product was absorbed once on a Dowex-50 column (H^+ form), and the excess HF was washed out thoroughly with water. Then the desired free peptide was recovered quantitatively by elution with ammonia. In another example, the bound HF was removed by passing the aqueous solution through a column of IR-45 (acetate form); the product, free L-leucylglycine, was thus obtained in about a 70% yield. This lower yield may be attributed to the partial absorption of the small peptide on the resin.

N^{α}-Carbobenzoxy-N^{G}-nitro-L-arginylglycine was treated with HF at 0°C for 30 min in the presence of two equivalents of anisole. Since the product is strongly basic, it was treated with IRA-400 (OH^- form) and then crystallized as acetate in a satisfactory yield. This procedure should be useful for the general synthesis of arginine-peptides.

In the case of the carbobenzoxypeptide ethyl ester, only the carbobenzoxy group is susceptible to HF; the ethyl ester group should stay intact during the reaction.[2,3] Thus, the carbobenzoxy-L-leucylglycine ethyl ester was treated with HF, and the product was directly combined with the carbobenzoxy-L-proline *p*-nitrophenyl ester to transform the product into a crystallizable compound. The excess HF was neutralized with triethylamine for the coupling reaction; carbobenzoxy-L-prolyl-L-leucylglycine ethyl ester was thus obtained in more than a 90% yield.

Next, carbobenzoxy-β-isopropyl-L-aspartyl-L-phenylalanine amide was treated with HF in the presence of three equivalents of anisole, after which the product was treated with IR-45 (acetate form) to eliminate the remaining HF. During the treatment, this material was also found to be absorbed onto the resin; the yield of L-aspartyl-L-phenylalanine amide was 67%. Paper electrophoresis of the reaction mixture showed no evidence of the formation of β-aspartyl peptide during the treatment, and the analytical data on the final product were identical with those reported by Davey *et al.*[4] Generally, aspartyl peptides are sensitive to acid; Dowex-50 treatment to remove the HF, followed by elution with ammonia, resulted in the partial decomposition of the product.

Finally, *t*-amyloxycarbonyl-L-tryptophyl-L-methionyl-L-aspartyl-L-phenylalanine amide was treated with HF. The product was then coupled with the *t*-butoxycarbonyl-β-alanine *p*-nitrophenyl ester to convert the product into *t*-butoxycarbonyl-β-alanyl-L-tryptophyl-L-methionyl-L-aspartyl-L-phenylalanine amide, which has been reported to be a biologically-active and crystallizable compound.[4] The yield and purity of the reaction product were satisfactory, as will be shown in the Experimental section; these results also indicate that aromatic amino acid and methionine residues suffered no serious side-reactions with HF during the procedure.

The application of the HF procedure to more complicated peptide derivatives is now in progress in our laboratory.

Experimental

HF-Reactions. Anhydrous hydrogen fluoride with a purity of 99.5% was obtained from the Matheson Chemical Co., U. S. A. It was used for the reactions without further drying. The HF reactions were carried out in the apparatus shown in Figs. 1 and 2 of the preceding paper,[3] and the reported procedure[3] was generally followed in handling HF. Although the minimum amount of HF which is required for completion of the reaction has not yet been determined, 5 to 10 m*l* of HF were sufficient for one gram of peptide. When a protective group which is slow to be removed is applied to the HF reaction, the use of more HF is recommended. After each reaction, the excess HF was removed using a plastic water-pump at 0°C and then the residue was kept under a vacuum (2—3 mmHg) for more than 5 hr, as has been described before.[3] Stirring was continued as long as possible during the evacuation procedure. Then, the residue was extracted with water, and some water-insoluble material was removed by extraction with chloroform or by passing the mixture through Hyflo Super-cel before the succeeding treatment. Used reaction cylinders were washed successively with water, methanol, and acetone, and then further cleaned with a mixture of conc. hydrochloric acid and conc. nitric acid (3 : 1 v/v). The outer diameters of the reaction vessels, which are made of Daiflon, gradually increase during repeated dryings at temperatures above 50°C. Therefore, they should be dried in a desiccator at room temperature after washing.

***p*-Toluenesulfonyl-L-phenylalanyl-L-phenylalanine Isopropyl Ester.** A solution of tosyl-L-phenylalanyl chloride[5] (4.63 g, 0.0137 mol) in tetrahydrofuran (30 m*l*) was slowly added to a suspension of L-phenylalanine isopropyl ester tosylate[3] (5.20 g, 0.0137 mol) and triethylamine (2 m*l*, 0.0143 mol) in tetrahydrofuran (40 m*l*) at −10°C. One more equivalent of triethylamine was then slowly stirred into the reaction mixture at the same temperature. After 2 hrs' stirring, the precipitate which had formed was filtered off, and then the filtrate was concentrated to a syrup, which was dissolved in ethyl acetate. The solution was washed with N hydrochloric acid, 5% sodium bicarbonate, and water, and dried over magnesium sulfate. The concentration of the dried solution gave crystals which were recrystallized from ethyl acetate and petroleum ether; yield, 5.20 g (75%); mp 125.5—126.5°C; $[\alpha]_D^{23}$ +15.7° (*c* 2, dimethylformamide). Found: C, 65.81; H, 6.25; N, 5.41%. Calcd for $C_{28}H_{32}O_5N_2S$: C, 66.13; H, 6.34; N, 5.51%.

***p*-Toluenesulfonyl-L-phenylalanyl-L-phenylalanine.** The tosyl-L-phenylalanyl-L-phenylalanine isopropyl ester (1.13 g, 2.2 mmol) and anisole (0.24 g, 2.2 mmol) were placed in a reaction cylinder together

4) J. M. Davey, A. H. Laird and J. S. Morley, *J. Chem. Soc.* (C), **1966**, 555.

5) E. A. Popenoe and V. du Vigneand, *J. Am. Chem. Soc.*, **76**, 6202 (1954).

with a Teflon-coated stirring bar. HF (10 ml) was added to it by distillation, and then the mixture was allowed to react at 20°C for one hr while being stirred. The excess HF was removed by distillation with a plastic water pump, and then the residue was kept under a vacuum for about 5 hr at room temperature. The residue was dissolved in ethyl acetate, and the desired product was extracted with a 5% sodium bicarbonate aqueous solution. The bicarbonate solution was acidified to pH 2 with 6 N hydrochloric acid, and the oily material which appeared was taken up in ethyl acetate. The ethyl acetate extract was dried over sodium sulfate, and then concentrated to a syrup which was crystallized by adding petroleum ether; yield, 0.88 g (85%); mp 197°C; $[\alpha]_D^{21}$ +22.8° (*c* 2, dimethylformamide). Found: C, 64.57; H, 5.84; N, 5.84%. Calcd for $C_{25}H_{26}O_5N_2S$: C, 64.37; H, 5.62; N, 6.01%.

L-Leucylglycine. Carbobenzoxy-L-leucylglycine[6] (1.0 g, 3.1 mmol) and anisole (0.33 ml, 3.1 mmol) were placed in a reaction cylinder[3] together with a Teflon-coated stirring bar. HF (about 10 ml) was added, and the mixture was stirred for 30 min at 0°C. The excess HF was removed under reduced pressure, and the residue was dried thoroughly for 10 hr *in vacuo* (3 mmHg), as has been described before. The dried residue was then dissolved in water, some insoluble material was removed with Hyflo Super-cel, and the solution was passed through a column of IR-45 (acetate form; about 7 ml of the resin were required). After washing the column with 5% acetic acid, the combined effluent was concentrated under reduced pressure, and the residue was dissolved in a minimum amount of water and crystallized by adding ethanol and ether. The crystals were dried *in vacuo* at 80°C for 24 hr; yield, 0.42 g (72%); $[\alpha]_D^{29}$ +85.0° (*c* 2, water). Value reported in the literature[6]: $[\alpha]_D$ +85.8° (*c* 2, water).

The dried reaction product of another run on the same scale was dissolved in water, and the solution was passed through a column of Dowex 50, X-8 (100—200 mesh; H^+ form; about 4 ml of the resin were used). The column was washed thoroughly with water until the washings became neutral, and then the product was eluted with 6 N ammonia. The concentration of the eluate under reduced pressure gave crystals which were recrystallized as has been described before. Yield of the dried crystals, 0.53 g (91%); $[\alpha]_D^{27}$ +85.6° (*c* 2, water).

L-Arginylglycine Acetate, Acetic Acid Solvate. N^{α}-Carbobenzoxy-N^{G}-nitro-L-arginylglycine[7] (1.5 g, 3.7 mmol) and anisole (0.8 ml, 7.4 mmol) were placed in an HF-reaction cylinder,[3] together with a Teflon-coated stirring bar, and HF (10 ml) was added to the mixture. The HF reaction was carried out at 0°C for 30 min with stirring, and then the excess HF was removed by distillation. The residue was dissolved in water, an insoluble material was extracted with chloroform, and the water solution was passed through a column of IRA-400 (OH^- form; 15 ml of resin were used). After adding 0.5 ml of acetic acid, the effluent was concentrated to a residue which was crystallized from glacial acetic acid and ethyl acetate. The crystals (mono-acetate, acetic acid solvate) were dried over phosphrous pentoxide at 80°C for 20 hr; yield, 1.14 g (89%); mp 167—170°C; $[\alpha]_D^{28}$ +38.3° (*c* 1, water). Value reported in the literature: mp 167—169°C;[7] $[\alpha]_D^{28}$ +38.9° (*c* 5.75, water);[7] $[\alpha]_D^{24-25}$ +37.6° (*c* 1, water).[8]

Found: C, 41.01; H, 7.28; N, 19.69%. Calcd for $C_{12}H_{15}O_7N_5$: C, 41.01; H, 7.19; N, 19.93%.

Carbobenzoxy-L-prolyl-L-leucylglycine Ethyl Ester. The carbobenzoxy-L-leucylglycine ethyl ester[6] (1.75 g, 5.0 mmol) and anisole (0.5 ml) were treated with HF (10 ml) as has been described previously. The excess HF was removed by distillation *in vacuo*. The dried product was dissolved in chloroform (30 ml), and the carbobenzoxy-L-proline *p*-nitrophenyl ester (1.85 g, 5.0 mmol) was added to the solution. The mixture was then neutralized with triethylamine (1 ml, 7 mmol) and with the *N*, *N*-diethylglycine ethyl ester[9] (2 ml), and allowed to react for 2 days at room temperature. The solution was then washed with N ammonia to remove the *p*-nitrophenol, and dried over magnesium sulfate. The concentration of the dried solution left crystals which were recrystallized from ethanol-water; yield, 2.1 g (94%); mp 150—151.5°C; $[\alpha]_D^{26.5}$ −80° (*c* 2.5, ethanol). Ressler and du Vigneaud reported a mp of 148—149°C and $[\alpha]_D$ −79.8° (*c* 2, ethanol).[10]

Bis-(Carbobenzoxy-L-aspartic Acid β-Isopropyl Ester) Piperazine Salt. β-Isopropyl-L-aspartate (29 g, 0.165 mol)[3] was treated with carbobenzoxy chloride (30 g, 0.17 mol) at room temperature by the Schotten-Baumann reaction using sodium bicarbonate (34 g, 0.4 mol). The reaction mixture was washed 3 times with ether, and then acidified to pH 2 with 6 N hydrochloric acid. The oil which separated was extracted with ether, and the ether extract was dried over sodium sulfate. Then the dried solution was concentrated to a syrup under reduced pressure. The residue was dissolved in methanol, and piperazine hexahydrate (16.1 g, 0.083 mol) was added to the solution. The mixture was concentrated to a residue under reduced pressure; this residue was flushed twice with toluene, and then recrystallized from 300 ml of methanol; yield 41.2 g (71%); mp 149—151°C: $[\alpha]_D^{26}$ −3.6° (*c* 2, dimethylformamide).

Found: C, 57.93; H, 6.89; N, 7.92%. Calcd for $C_{34}H_{48}O_{12}N_4$: C, 57.94; H, 6.86; N, 7.95%.

Carbobenzoxy-β-isopropyl-L-aspartyl-L-phenylalanine Amide. The carbobenzoxy-L-aspartic acid β-isopropyl ester (0.05 mol), which had been prepared from the piperazine salt (17.6 g) by shaking it with excess 2 N hydrochloric acid, and L-phenylalanine amide hydrochloride (10.0 g, 0.05 mol) were dissolved in dimethylformamide (50 ml), after which triethylamine (7 ml, 0.05 mol) was added to the mixture. Dicyclohexylcarbodiimide (10.3 g, 0.05 mol) was then stirred into the mixture at −10°C. These reagents were allowed to react for 30 min at the same temperature, and then for an additional 5 hr at room temperature. The urea formed was filtered off, and water (250 ml) was added to the filtrate to precipitate the product as crystals, which were collected by filtration and then recrystallized from hot ethanol (300 ml) and water

(200 ml); yield, 17 g (74.6%); mp 171—174°C; $[\alpha]_D^{26}$ −27.5° (*c* 2.9, dimethylformamide).

Found: C, 63.11; H, 6.42; N, 9.22%. Calcd for $C_{24}H_{29}O_6N_3$: C, 63.28; H, 6.42; N, 9.23%.

L-Aspartyl-L-phenylalanine Amide. Carbobenzoxy-β-isopropyl-L-aspartyl-L-phenylalanine amide (1 g, 2.2 mmol) and anisole (0.71 ml, 6.6 mmol) were treated with HF (20 ml) at 0°C for 100 min. The excess HF was removed under reduced pressure, and the residue was dried thoroughly under a vacuum for more than 5 hr. The dried product was dissolved in water, and the solution was passed through a column of IR-45 (acetate form). The effluent was lyophilized, and the residue was crystallized from acetone and water and then dried over phosphorus pentoxide at room temperature; yield, 430 mg (66.6%); mp 189—190°C (decomp.); $[\alpha]_D^{23}$ +20.5° (*c* 1, dimethylformamide containing 1 eq. of N HCl).*2 Davey *et al.* reported mp 188—189°C (decomp.) and $[\alpha]_D$ +20.6° (*c* 1, dimethylformamide containing 1 eq. of N HCl).[4]

Found: C, 52.06; H, 6.62; N, 13.81%. Calcd for $C_{13}H_{17}O_4N_3 \cdot H_2O$: C, 52.51; H, 6.44; N, 14.13%.

***t*-Amyloxycarbonyl-L-tryptophyl-L-methionine Hydrazide.** Dicyclohexylcarbodiimide (2.1 g, 0.01 mol) was added to a solution of *t*-amyloxycarbonyl-L-tryptophan[11] (3.18 g, 0.01 mol) in tetrahydrofuran (60 ml) at −10°C. After about 10 min, a solution of L-methionine methyl ester hydrochloride (2.2 g, 0.011 mol) and triethylamine (1.54 ml, 0.011 mol) in chloroform (30 ml) was added to the reaction mixture. The whole mixture was kept 1 hr at 0°C, and then overnight at room temperature. The solvent was removed under reduced pressure, and the residue was dissolved in ethyl acetate (100 ml). Some insoluble materials were filtered off, and the filtrate was washed with 0.5 N hydrochloric acid, 5% sodium bicarbonate, and water, and dried over anhydrous sodium sulfate. The dried solution was concentrated to a syrup, which was then dissolved in ethanol (50 ml), and 90% hydrazine hydrate (5.56 g, 0.1 mol) was added to the solution. After 2 days at room temperature, the mixture was concentrated to a residue; this residue was flushed 3 times with toluene and then crystallized from ethanol by the addition of water. Yield of crude material, 3.50 g. This material was recrystallized from ethanol-water, and dried over phosphorus pentoxide *in vacuo* at 80°C for 10 hr; yield, 2.92 g (63.1%); mp 158—163°C; $[\alpha]_D^{24}$ −22.4° (*c* 1.08, dimethylformamide).

Found: C, 56.68; H, 7.30; N, 14.94%. Calcd for $C_{22}H_{33}O_4N_5S$: C, 57.00; H, 7.18; N, 15.11%.

***t*-Amyloxycarbonyl-L-tryptophyl-L-methionyl-L-aspartyl-L-phenylalanine Amide.** To a solution of *t*-amyloxycarbonyl-L-tryptophyl-L-methionine hydrazide (13.9 g, 0.03 mol) in dimethylformamide (30 ml), a 2.0 N hydrogen chloride-dioxane solution (30 ml, 0.06 mol) was added at −10°C, and then isoamyl nitrite (3.68 g, 0.0315 mol) was added slowly to the mixture at −20°C. After 30 min, a cold mixture of L-aspartyl-L-phenylalanine amide monohydrate (9.80 g, 0.033 mol) and triethylamine (15.6 ml, 0.11 mol) in dimethylformamide (75 ml) was added to the previous mixture, and the mixture was stirred at 0—3°C for 3 days. Then, cold water (300 ml) was added, and the pH of the mixture was adjusted to 2—3 with N hydrochlorci acid in order to precipitate the product. The precipitate was collected by filtration, and was washed with water and then ether. The crude product (19.4 g) obtained was recrystallized from ethanol; yield, 16.2 g (76.0%); mp 229—230°C (decomp.); $[\alpha]_D^{14}$ −31.3° (*c* 1, dimethylformamide).

Found: C, 59.04; H, 6.53; N, 11.67%. Calcd for $C_{35}H_{46}O_8N_6S$: C, 59.14; H, 6.52; N, 11.82%.

***t*-Butoxycarbonyl-β-alanine *p*-Nitrophenyl Ester.** Dicyclohexylcarbodiimide (2.50 g, 0.012 mol) was added to a solution of *t*-butoxycarbonyl-β-alanine (1.89 g, 0.01 mol)[12] and *p*-nitrophenol (1.67 g, 0.012 mol) in ethyl acetate (16 ml) at 0°C. The mixture was stirred for 1 hr at the same temperature, and then for an additional 24 hr at room temperature. The urea formed was removed by filtration, and the filtrate was concentrated to a residue under reduced pressure and crystallized by tritration with petroleum ether. The crude crystals were recrystallized from ethyl acetate-petroleum ether; yield, 1.53 g (49.3%); mp 59—61°C.

Found: C, 53.91; H, 5.82; N, 9.08%. Calcd for $C_{14}H_{18}O_6N_2$: C, 54.19; H, 5.85; N, 9.03%. The yield of the second crop of crystals was 0.36 g (11.6%).

***t*-Butoxycarbonyl-β-alanyl-L-tryptophyl-L-methionyl-L-aspartyl-L-phenylalanine Amide.** *t*-Amyloxycarbonyl-L-tryptophyl-L-methionyl-L-aspartyl-L-phenylalanine amide (294 mg, 0.41 mmol) and anisole (0.46 ml) were placed in a HF reaction cylinder, and then HF (about 5 ml) was distilled into the cylinder under a vacuum using a dry ice-methanol bath. The mixture was stirred for 30 min at 0°C, and then the excess HF was removed by distillation. After drying *in vacuo* for more than 10 hr at room temperature, the residue was extracted with water and some water-insoluble materials were removed with the aid of Hyflo Super-cel. The filtrate was lyophilized, the residue was suspended in dimethyl formamide (8 ml), and the *t*-butoxycarbonyl-β-alanine *p*-nitrophenyl ester (155 mg, 0.5 mmol) was added to the suspension together with triethylamine (0.2 ml, 1.50 mmol). The mixture was stirred at room temperature for 2 days, by which time the presence of free amino groups could no longer be recognized by thin-layer chromatography. Then, water was added to the mixture, and the pH was adjusted to 2 with 0.5 N hydrochloric acid. The mixture was kept for a while in a refrigerator, and then the crystalline product was collected by filtration. The crystals were washed with cold water and ether, and dried over phosphorus pentoxide *in vacuo*. The dried material was recrystallized from dimethylformamide-water, collected by filtration, washed with 50% aqueous dimethylformamide, water, and ether, and dried. After successive recrystallizations, the product was obtained as fine colorless crystals which were dried over phosphorus pentoxide *in vacuo* at room temperature for 24 hr; yield, 0.21 g (67%); mp 227—228°C (decomp.); $[\alpha]_D^{20}$ −28.8° (*c* 1, dimethylformamide). Values reported in the literature: mp 229—230°C (decomp.) and $[\alpha]_D^{20}$ −28.8° (*c* 1, dimethylformamide).[4]

Found: C, 57.80; H, 6.56; N, 12.51%. Calcd for $C_{37}H_{49}O_9N_7S$: C, 57.87; H, 6.43; N, 12.76%.

*2 This value was calculated from the dry weight.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 442—444 (1968)

Synthesis of Trimethylhydroquinone from *p*-Xylene*[1]

Kikumasa SATO, Yoshito FUJIMA and Arihiro YAMADA

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama

(Received August 31, 1967)

The synthesis of trimethylhydroquinone from *p*-xylene was carried out *via* two routes; one includes the formylation of *p*-xylene, followed by nitration, and the other, the chloromethylation of nitro-*p*-xylene. The oxidation of the trimethylanilines, VI and IX, prepared from 2, 5-dimethyl-6-nitrobenzaldehyde and 2, 5-dimethyl-3-chloromethylnitrobenzene and their subsequent reduction gave trimethylhydroquinone (TMH) in appreciable yields.

α-Tocopherol (vitamin E) may be obtained by the condensation of TMH with phytol[1] or its derivatives.[2] Earlier papers in this series have described how TMH has been synthesized from 2-methylhydroquinone, 3, 5-dimethylhydroquinone,[3] and pseudocumene.[4]

In this study the synthesis of TMH was carried out from *p*-xylene. No report could be found concerning such a synthesis of TMH from *p*-xylene. *p*-Xylene is now obtained readily through the petroleum chemical industry, so the synthesis of TMH from *p*-xylene may well prove of great interest. Two routes of synthesis are shown below.

The reaction of aromatic hydrocarbons with dichloromethyl methyl ether in the presence of a Lewis acid has been reported to give aromatic aldehydes.[5] The treatment of *p*-xylene with dichloromethyl methyl ether gave 2, 5-dimethylbenzaldehyde (II) in a 63% yield. The catalytic reduction of the 2, 5-dimethyl-6-nitrobenzaldehyde (III) prepared by the nitration[6] of II gave the methylolaniline IV, which was not reduced further even at a higher temperature. The attempted Clemmensen reduction of III or IV was also unsuccessful. The fact that the catalytic reduction of III can not provide VI is probably attributable

to the poisonous effect of the resulting amino-group on the catalyst.[7] The methylolaniline IV was converted into the hydrochloride V. The catalytic reduction of V gave 2, 3, 6-trimethylaniline (VI) in a 33% yield. TMH was obtained in a 67% yield by the oxidation of VI, followed by reduction. Each step in Route (1) gives a comparatively good yield except the reduction. If the method for the conversion of III to VI can be improved, therefore, Route (1) may be useful for the synthesis of TMH. The reduction of aldehyde involving the nitro-group was hard in Route (1), so chloromethylation was carried out *via* Route (2).

The chloromethylation of nitrotoluenes with bis-(chloromethyl) ether in chlorosulfonic acid has been reported by Berezovskii[8] and other workers.[9,10] The chloromethylation of VII with bis(chloromethyl) ether afforded 2, 5-dimethyl-3-chloromethylnitrobenzene (VIII) in a 67% yield, along with a considerable amount of a by-product. As Table 1 shows, when the reaction temperature was 5—10°C and the reaction time was 64 hr, the chloromethyl compound, VIII, was obtained in a maximum yield. The material VII was recovered at a lower temperature in spite of the long reaction time. The chloromethylation of VII at a higher temperature yielded more of the by-product.

Table 1. The chloromethylation of nitro-*p*-xylene with bis(chloromethyl) ether in various conditions

No.	Reaction		Yield of product, %	
	Temp. °C	Time hr	A[1]	B[1]
1	0— 5	36	32.4[2]	—[3]
2	0— 5	72	50.0[2]	—[3]
3	5—10	64	67.0	—[3]
4	7—10	12	21.6[2]	—[3]
5	10—15	24	44.5	12
6	10—15	64	25.2	32
7	15—20	24	41.6	15
8	20—25	16	27.6	24

1) A=2,5-dimethyl-3-chloromethylnitrobenzene (VIII); B=2,5-bis(chloromethyl)-3,6-dimethylnitrobenzene.
2) The material VII was recovered.
3) The yield was not measured.

The structure of VIII was identified on the basis of the infrared spectrum and confirmed by the retention time[11] of trimethylaniline, IX, in gas chromatography. The by-product was regarded as 2, 5-di(chloromethyl)-3, 6-dimethylnitrobenzene on the basis of the results of the elementary analysis and infrared spectroscopy, and by the fact that 2, 3, 5, 6-tetramethylaniline was obtained by the catalytic reduction.

The catalytic reduction of VIII gave 2, 3, 5-trimethylaniline (IX), which was then converted into TMH in a 44% yield.

Route (2) does not have the same difficulty in reduction as Route (1), as has fewer steps as well. TMH is obtained in a better yield from VI than from IX. Route (2), however, gives higher yields than Route (1) on the whole.

Experimental[12]

Materials. Dichloromethyl methyl ether was prepared from methyl formate by the procedure of Rieche.[5] The preparation of 2, 5-dimethyl-6-nitrobenzaldehyde-(III) followed the method of Gattermann.[6] Nitro-*p*-xylene was obtained by the nitration of *p*-xylene with mixed acid.[13] Bis(chloromethyl) ether was prepared by the procedure of Berezovskii.[8]

2, 5-Dimethylbenzaldehyde (II). Into a cold mixture of 106 g of *p*-xylene and 190 g of titanium tetrachloride, 57.5 g of dichloromethyl methyl ether was added, drop by drop, at 5—10°C, then the mixture was stirred for about 1 hr, poured into ice water, and extracted with benzene. After drying, the benzene was removed and the residue was distilled under reduced pressure. II was obtained in a yield of 42.2 g (63%), bp 99—100°C/16 mmHg; ν_{max}^{film} 1680 cm^{-1} (CHO). Its semicarbazone showed a melting point of 215°C.

Found: C, 62.80; H, 6.85%. Calcd for $C_{10}H_{13}N_3O_3$ of the semicarbazone: C, 62.81; 6.72%.

2, 3, 6-Trimethylaniline (VI). In the presence of 5%-palladium-carbon, 10 g of III in methanol was reduced under a pressure of about 100 atm of hydrogen at room temperature in an autoclave. After opening the bomb, the catalyst was removed by filtration and the solvent distilled off. Recrystallization from benzene gave 7.3 g (98%) of IV, mp 106°C. IV in methanol was converted into its hydrochloride V, mp 251°C (dec.), by dry hydrogen chloride. The methanol was then removed, and the V was dried over sodium hydroxide. The hydrochloride, V, in methanol was reduced in the presence of 5%-palladium-carbon under a pressure of about 110 atm of hydrogen in an autoclave at 60°C. After opening the bomb, the catalyst was removed and the solvent distilled off. The residue was

treated with a 30% aqueous solution of potassium hydroxide, and extracted with ether. After drying, the ether was removed, distillation under a reduced pressure then gave 2.8 g (33%) of VI, bp 98—99°C/8 mmHg. The melting point of its acetyl derivative was 188—189°C (Lit.[14] mp 186°C).

Trimethylhydroquinone from VI. A solution of 36 g of sulfuric acid in 160 g of water was cooled to 5°C, and then 2 g of VI was added. The subsequent addition of 1.8 g of potassium bichromate to the solution took about 1 hr, after which the solution was stirred for 11 hr at 3—5°C. To the solution, 2.6 g of potassium bichromate was added again over a 1-hr period. After stirring for thirty minutes, the solution was extracted with ether and treated with a saturated solution of sodium hydrosulfite in water. After drying, the ether was removed. Recrystallization from water gave 1.5 g (67%) of TMH, mp 168—169°C.

2, 5-Dimethyl-3-chloromethylnitrobenzene (VIII). Into a mixture of 20 g of VII and 16 g of bis-(chloromethyl) ether, 24 g of chlorosulfonic acid were added, drop by drop, the temperature being 5—10°C. After having been stirred for 64 hr, the mixture was poured into ice water and extracted with ether, and the ethereal extract was dried over sodium sulfate. The ether was removed, and the distillation of the residue under reduced pressure gave 16.7 g (67%) of VIII, bp 112—113°C/2 mmHg, ν_{max}^{film} 1525, 1370 (NO_2), 840 (C–H) and 720 cm^{-1} (C–Cl).

Found: C, 54.40; H, 4.98%. Calcd for $C_9H_{10}ClNO_2$: C, 54.15; H, 5.05%.

2, 3, 5-Trimethylaniline (X). In the presence of 4 g of 5%-palladium-carbon and 25 g of triethylamine, VIII (39.2 g) in ethanol was reduced under a pressure of about 80 atm of hydrogen at room temperature. After opening the bomb, the catalyst was removed by filtration and the ethanol was distilled off. The residue was dissolved into water and extracted with ether. After drying with potassium hydroxide, the ether was removed. The distillation of the residue under a reduced pressure gave 21.4 g (84%) of IX, bp 110°C/9 mmHg, mp 35—37°C (Lit.[15] mp 36°C).

Trimethylhydroquinone from IX. The trimethylaniline, IX (2 g), was added into a mixture of concentrated sulfuric acid (16 g) and water (60 ml). The mixture was then cooled to 10—15°C, and potassium bichromate (2 g) was added to the mixture over a 1-hr period. After the mixture had been stirred for about 10 hr, potassium bichromate (3.3 g) was further added. Then the mixture was extracted with ether, and the extract was treated with a saturated solution of sodium hydrosulfite in water. After drying, the ether was removed. Recrystallization from water gave 1 g (44%) of TMH, mp 168—170°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 444—450 (1968)

Correlation between the Chemical Reactivity and the Unpaired Electron Distribution of Anion Radicals

Kazuhiro MARUYAMA and Tetsuo OTSUKI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received September 5, 1967)

Anion radicals of mono-, di-nitrobenzophenones, dinitrobenzil, and nitrophenanthraquinone generated by reduction with alkali metal were studied by means of electron-spin resonance. The hyperfine coupling constant and the effect of the metal species on it were investigated. The correlation between the localization of the unpaired electron and the chemically reducible position was also discussed.

A large number of studies of anion radicals generated by the reduction of aromatic carbonyl compounds and aromatic nitro compounds, as made by means of ESR, have been reported.[1] The facility with which those compounds accept an electron and the rather great stability of the resultant anion radicals have attracted the attention of many investigators. Anion radicals can be generated by electrolytic reduction,[2] by reduction with alkali metal in a suitable solvent,[1,3] or by reduction with alkaline sodium dithionite in an aqueous solution.[4]

The investigation of anion radicals resulting from the compounds with both nitro and carbonyl groups in a molecule is of much interest from the viewpoint of their free-spin localization and their chemical reactivity. In this study, all the anion radicals were generated by reduction with alkali metal in order to get information about the ion-pair between the anion radical and the metal cation.

Experimental

All the compounds used were synthesized in our laboratory. Their physical constants and the methods of synthesis are shown in Table 1. For the ESR measurement, the compound to be reduced was dissolved in *ca.* 10 m*l* of dry dimethoxyethane to give about a 10^{-3} M solution *in vacuo*, and then the anion radical was generated by bringing the solution in contact with the fresh surface of an alkali metal. A 3BX-type ESR spectrometer with a 100 kc modulation manufactured by the Japan Electron Optics Lab. was used in these measurements. The spectra obtained were calibrated by reference to the hyperfine coupling constant of peroxylamine disulfonate.

Results and Discussion

Unpaired Electron Delocalization of Anion Radicals. Mono- and Di-nitrobenzophenone Anion Radicals. The results shown in Table 2 indicate that the unpaired electron of anion radicals generated from nitrobenzophenones is localized only on a nitro-substituted phenyl group, although the compounds have two reducible functional groups.[5] This was definitely confirmed by the observation of the ESR spectrum of the anion radical of d_5-phenyl *p*-nitrophenyl ketone. The spectrum observed was just the same as that of the anion radical generated from *p*-nitrobenzophenone. This conclusion can also be substantiated by other observations. The anion radicals generated from 4-methyl-4'-nitrobenzophenone and from 4-methoxy-4'-nitrobenzophenone showed spectra similar to that of the *p*-nitrobenzophenone anion radical. Furthermore, each of the observed hyperfine structures of nitrobenzophenone anion radicals was very similar to each of those of the corresponding monohalogeno nitrobenzene anion radicals.[6,7] The anion radicals of nitrobenzophenones, therefore, can be considered to be anion radicals of benzoyl-substituted nitrobenzenes.

There have been a large number of experiments and calculations on the free-spin delocalization of the substituted nitrobenzene anion radicals.[2-7] For example, Geske and his co-workers[8] investigated the substituted nitrobenzene anion radicals by ESR. Their calculation on the nitrobenzene anion radical consisting with their experimental

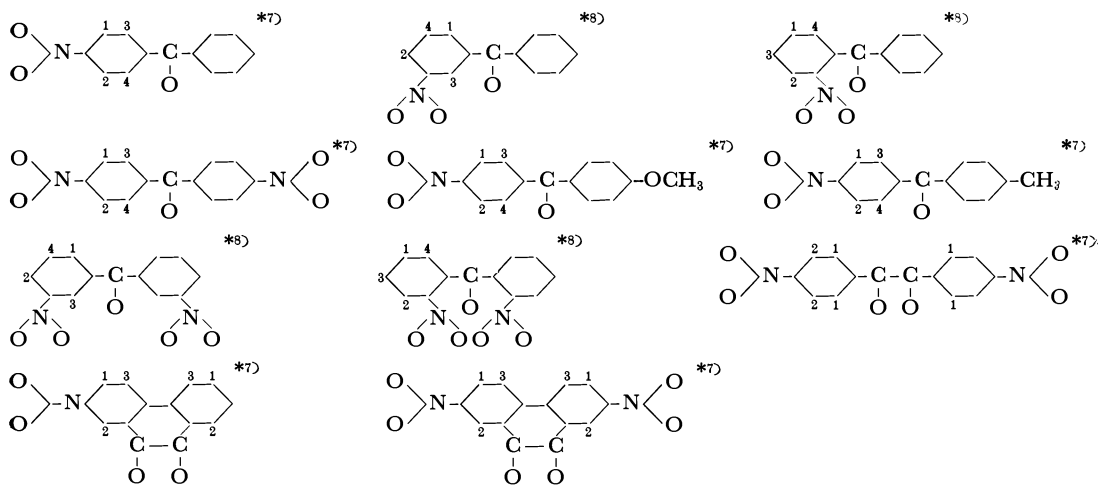
*5 Positions of protons are listed below.
*6 Coupling constant due to alkali metal.



*7) Assignment of splittings to positions was done on the basis of the experiments.
*8) Assignment of splittings to positions was done tentatively from a comparison with a result of SHMO calculation.

result showed that ~65% of the free spin was localized on the nitro group. Since such a substituent as a halogen atom or a carbonyl group can not induce an drastic change in the free-spin delocalization—— as can be deduced from a comparison with the coupling constant due to the nitrogen atom of the nitro group, the position of the highest free-spin density is on the nitro group.

Anion radicals of dinitrobenzophenone generated from 2, 2'-, 3, 3'- and 4, 4'-dinitrobenzophenone showed spectra indicating that the unpaired electron was delocalized only on one phenyl group; their ESR spectra quite resemble that of the anion radical generated from the corresponding mononitrobenzophenone.[5] Therefore, the position of the highest free-spin density is on one of two nitro groups for the same reason as has been given above.

Another outstanding phenomenon of these mono- and dinitrobenzophenone anion radicals was that the hyperfine coupling constant due to the nitrogen atom varied systematically with the species of alkali metal. This may be unambigously attributable to the ion-pair formation between the anion radical and the cation. It was found that the ^{13}C hyperfine coupling constant of benzophenone carbonyl carbon also varied with the species of alkali metal[9]; it was ascribed to the existence of the ion-pair.

Dinitrobenzil Anion Radicals. The anion radicals of dinitrobenzil obtained by reduction with alkali metals showed some unusual phenomena. Typical observed ESR spectra are shown in Fig. 1. By the usual procedure an unsymmetrical spectrum with a larger overall splitting was observed, regardless of the species of alkali metals. However, a symmetrical spectrum with a smaller overall splitting could be observed if it was very much diluted. This change from the unsymmetrical to the symmetrical was dependent on the temperature and on the ionic size of the cation with which anion radical was forming the ion-pair. In general, we could observe the unsymmetrical spectrum at lower temperatures, even if it was diluted. Moreover, if metallic lithium was used for the reduction, only the unsymmetrical spectrum could be observed, while if metallic rubidium was used, then the symmetrical spectrum with the smaller overall splitting was easily observed. From the results described above, it may

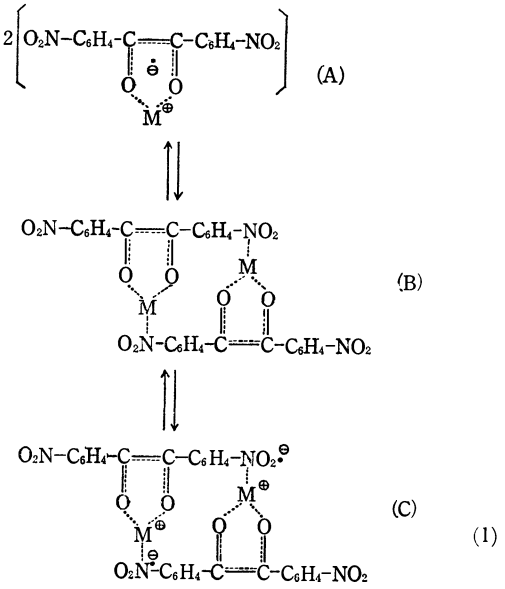
9) N. Hirota, *ibid.*, **89**, 32 (1967).

be concluded that there is an equilibrium between the ion-pair monomer, which shows a symmetrical spectrum, and the ion-pair dimer, which shows a spectrum with a larger overall splitting. Therefore, the spectrum actually observed in usual concentrations is a superposition of the two.



M⊕: metal cation
M: atomic metal

There must be a rapid equilibrium among the ion-pair monomer (A) and ion-pair dimers (B and C), for the observed spectrum is unusually broad. The symmetrical five line spectrum (intensity ratio; 1 : 4 : 6 : 4 : 1) with the smaller overall splitting (4.1 gauss) will correspond to the A structure, while the spectrum with the larger overall splitting (19.9 gauss) will correspond to the C structure. The B structure seems to be a transient stage for the electron-transfer reaction. This may be explained by the fact that the overall splitting of the spectrum of α-diketone ketyls is, in general, about 5 gauss, while that of anion radicals of nitro compounds is larger than 10 gauss, consisting of three equivalent lines due to the nitrogen atom accompanying with the other hyperfine structure.[1-8,10] For example, the overall splitting of potassium benzil ketyl is 4.5 gauss and the hyperfine coupling constant due to the four hydrogen atoms occupying the position α to α-dicarbonyl group is 0.96 gauss. Estimating from the hyperfine coupling constant (0.85 gauss), $\sim$75% of the free-spin is localized on the α-dicarbonyl group in A.

Mono- and Di-nitrophenanthraquinone. The anion radicals of 2-nitro- and 2, 7-dinitrophenanthraquinone, both generated by reduction with alkali metal, showed quite similar symmetrical ESR spectra, with an overall splitting of about 7 gauss. The solution of anion radicals was pink, but it turned into a green diamagnetic solution if it was present in a high concentration. Analogous phenomena have been found in the case of phenanthraquinone ketyls.[11] The hyperfine structure of 2, 7-dinitrophenanthraquinone can be analysed as a spectrum consisting of three sets of two equivalent hydrogen atoms (the coupling constants are 1.94 gauss, 0.97 gauss, and 0.44 gauss respectively). Estimating from the coupling constants obtained, more than 70% of the free spin is localized on the α-dicarbonyl group in the anion radical of 2-nitro- or 2, 7-dinitrophenanthraquinone. Thus, the unpaired electron delocalizes only on the aromatic ring, is highly concentrated on the α-dicarbonyl group, and does not delocalize on the nitro group.

The hyperfine coupling constants obtained are summarized in Table 2.

Correlation between Chemical Reactivity and Unpaired-electron Distribution. In the compounds which have two or three functional groups in a molecule, the problem of which group is the most reactive for a reagent is of great interest to the organic chemist. Nitrobenzophenones, nitrobenzil, and nitrophenanthraquinone have two or three functional groups for the reduction. From the results of the ESR study we can determine the position which has the highest free-spin density in a molecule. The positions to be reduced and the positions of the highest free-spin density in the compounds which have two or more functional groups are tabulated in Table 3. As can be seen in Table 3, there is a definite correlation between the most reactive position of a compound for the chemical reduction and the highest free-spin density of the anion radical generated from the corresponding compound. In nitrobenzophenone anion radicals, the position of the highest free-spin density is on the nitro group, and nitrobenzophenone can be reduced at the nitro group to the corresponding reduced compound, regardless of the species of the reducing reagent.

By the reduction of dinitrobenzil, both α-dicarbonyl and nitro groups can be reduced at the same time; the results obtained by ESR study show the existence of an equilibrium between the anion radical monomer and the anion radical dimer in the system because the concentration of the substrate is high enough to form the dimer. As has been described above, the unpaired electron delocalizes mainly on the α-dicarbonyl group in the monomer anion radical, whereas the unpaired electron delocalizes mainly on the nitro group in the anion radical dimer. The experimental results, therefore, completely support the idea that

the more reactive position is the position of the highest free-spin density. Thus, if the chemical reduction is performed under extremely diluted conditions, it can be supposed that dinitrobenzoin will be the reduction product.

Much as in the case of dinitrobenzil, the reduction products of mono- and dinitrophenanthraquinone are mono- and dinitro-9, 10-dihydrophenanthrene if reduction is performed under mild conditions using such reducing reagents as hydrogen disulfide and phenylhydrazine.[12] However, both nitro and α-dicarbonyl group can be reduced if one uses such a strong reducing reagent as tin and hydrochloric acid. The free-spin density of nitrobenzaldehyde anion radicals has been investigated by Rieger and Fraenkel[13]; the position of the highest free-spin density is on the nitro groups for all isomers. By the chemical reduction they are all reduced at the nitro group to give amino- or azobenzaldehydes according to the species of reducing reagent. Such a general rule can be applied even to the aromatic hydrocarbon. For example, the position of the highest free-spin density is the α-position in the naphthalene anion radical, and 1, 4-dihydro- or 1, 4, 5, 8-tetrahydronaphthalene is the first reduction product of naphthalene with metallic sodium and ethanol. Although it is generally accepted that the first stage of the reduction is the formation of the anion radical, the successive steps remain ambiguous. From the above discussion, however, it seems plausible that the successive reduction step is the formation of the dinegative ion which is in a state of contact ion-pair with the counter cation. The counter cation might be a cation from heavy metal, a cation from alkali metal, an ammonium cation, and or even a proton. In support of this discussion, it is instructive to consider the reduction of *m*-dinitrobenzene. The anion radical of the compound has been studied in detail by several investigators. If one reduces *m*-dinitrobenzene with alkali metal,[1b,3]: one of the two nitro groups has a higher free-spin density as a result of ion-pair formation, whereas if one reduces it electrolytically,[14] then the two nitro groups have an equivalent free-spin density. By the chemical reduction of *m*-dinitrobenzene with the usual mild reducing reagents, one of the two nitro groups can be reduced to amino, hydroxyamino, or azo groups, *etc.*[15] Even if the compound is reduced electrolytically, one of the two nitro groups can be reduced predominantly.[16] These experimental results suggest that there is a contribution of the ion-pair even in the course of the electrolytic reduction. Although the stable anion radical of *m*-dinitrobenzene has two equivalent nitro groups in such a aprotic solvent as acetonitrile, a proton might be a counter cation of the ion-pair in an electrolysis conducted in a protic solvent which is a usual solvent in electrolytic reduction, and the accession of a proton to the anion radical may cause the localization of an electron on one of the two nitro groups. Thus, for example, the reduction of nitro group may proceed as in Eq. (2);

$$\mathrm{R\text{-}NO_2} \xrightarrow{e} \mathrm{R\text{-}\dot{N}O_2^{\ominus}M^{\oplus}} \xrightarrow{e} \mathrm{R\text{-}\ddot{N}O_2^{\ominus\ominus}2M^{\oplus\oplus}}$$

$$\xrightarrow{H^{\oplus}} \mathrm{R\text{-}N(O)(OH)} \xrightarrow{H^{\oplus}} \mathrm{R\text{-}NO + H_2O}$$

$$\xrightarrow{2e,\ 2H^{\oplus}} \mathrm{R\text{-}NHOH} \xrightarrow{H^{\oplus}} \mathrm{R\text{-}NH^{\oplus}} \xrightarrow{2e} \mathrm{R\text{-}NH_2}$$

$M^{\oplus}$: metal cation (2)

Therefore, it may be concluded that the chemical reduction proceeds with an ion-pair formation in every case.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 451—454 (1968)

Coumarins. IV. The Acid-catalyzed Reaction of Phenols with Allyl Cyanide[1]

Takeshi AMAKASU[2]

Chemical Laboratory, Seimi Chemical Co., Ltd., Chigasaki, Chigasaki-shi, Kanagawa

(Received September 11, 1967)

A new route to the syntheses of 4-methyldihydrocoumarins has been developed by means of the aluminum chloride-catalyzed reaction of phenols with allyl cyanide. The reaction of excess phenol with allyl cyanide in the presence of 2 equivalents of anhydrous aluminum chloride and an excess of hydrogen chloride yielded β-(*p*-hydroxyphenyl)-butyronitrile in a 16% yield. In contrast, the corresponding 4-methyldihydrocoumarins were obtained, together with β-arylbutyronitriles, from *o*- and *m*-cresols. *p*-Cresol gave rise to 4, 6-dimethyldihydrocoumarin as the sole product in a 8% yield. In diisopropyl ether, resorcinol underwent a similar reaction with allyl cyanide and afforded 4-methyldihydroumbelliferone in a 50% yield.

In the first paper of this series[3] dealing with the direct synthesis of dihydrocoumarins, it was established that anhydrous aluminum chloride, accompanied by dry hydrogen chloride, was an effective catalyst for the reaction of phenols with α, β-unsaturated nitriles. These studies have now been extended to 3-butenenitrile, *i. e.*, allyl cyanide. Although the aluminum chloride-catalyzed addition reaction of benzene to allyl cyanide has previously been shown[4] to give an excellent yield of β-phenylbutyronitrile, the present author could find no report concerning the acid-catalyzed reaction of phenols with allyl cyanide.

In the present study the author has examined the acid-catalyzed reaction of phenols with allyl cyanide, using anhydrous aluminum chloride and dry hydrogen chloride (Scheme 1).

d, R=7-OH

Scheme 1

When 5 equivalents of *m*-cresol were treated with allyl cyanide in the presence of 2 equivalents of anhydrous aluminum chloride and an excess of hydrogen chloride, the corresponding dihydrocoumarin, Ib, and white crystals (mp 100—100.5°C) were obtained in 13 and 14% yields respectively. The structure of the former follows from the infrared spectrum (Table 2), which clearly shows a lactone C=O band at 1770 cm^{-1}. The analytical data of the latter agreed with the formula $C_{11}H_{13}NO$, which is in accord with the structures of the addition products, IIb, III, and IV. The infrared spectrum exhibited hydroxyl and cyano absorptions respectively at 3370 and 2230 cm^{-1}, in addition to an out-of-plane deformation of aromatic C–H at 810 cm^{-1}. This eliminates the possibility of such a structure as carbon-oxygen addition products, but not such as III and IV.

Finally, a NMR spectrum was obtained which was in complete accord with the β-aryl-butyronitrile structure. The characteristic doublets at 8.62 (J= 7 cps) and 7.51 (J=7 cps) τ were assigned to the terminal methyl and the methylene protons, while the two singlets at 7.73 and 5.25 τ were due to ortho-methyl and hydroxyl protons respectively. The aromatic multiplet appeared between 2.77—3.82 τ, along with that of the methine proton at

1) This investigation was presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967; and was supported mainly by Asahi Glass Co., for which the author is grateful. Part III of this series: T. Amakasu and K. Sato, This Bulletin, **40**, 1428 (1967).

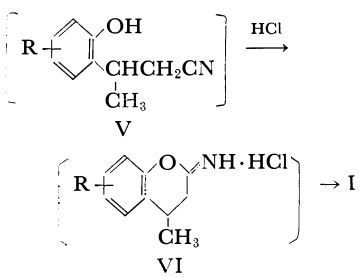
6.68 τ. Thus, it may be concluded that the β-substituted butyronitrile structure, II, must be assigned to the latter product from *m*-cresol.

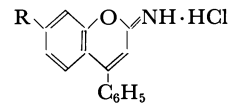
o-Cresol behaved analogously when treated with allyl cyanide, giving the corresponding dihydrocoumarin, IC, as well as the butyronitrile, IIc. In contrast, only 4, 6-dimethyldihydrocoumarin (Ia) was obtained from *p*-cresol, while phenol, upon similar treatment with allyl cyanide, underwent nuclear-addition reaction leading to β-(*p*-hydroxyphenyl)butyronitrile (IIa). The results, summarized in Table 1, indicate that phenols predominantly undergo the nuclear addition reaction to allyl cyanide, while the resulting *o*-addition



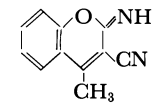
Scheme 2

intermediates V, β-(*o*-hydroxyphenyl)butyronitriles, afford the corresponding dihydrocoumarins, I, through subsequent intramolecular cyclization, followed by acid hydrolysis (see Scheme 2).

Neither V nor VI could be isolated in any case, whereas the acid-catalyzed reaction of phenols with benzoylacetonitrile has been demonstrated[5] to furnsih 4-phenyl-2-iminocoumarins, VII, corresponding to VI, and 3-cyano-4-methyliminocoumarin (VIII) may be obtained by the base-catalyzed condensation of 2-hydroxyacetophenone with malononitrile.[6] This is presumably due to the difference in resonance stability between the intermediates VI and either VII or VIII.



VII



VIII

R=OH, OCH_3, CH_3

On the other hand, 4-methyldihydroumbelliferone (Id) was obtained, in a 50% yield, on a similar treatment of resorcinol with allyl cyanide in a diisopropyl ether solution at 50—55°C for 4 hr. Under the same conditions, however, no reaction occurred between the less reactive phenols, such as crescls, and allyl cyanide. Moreover, the use of such other inert solvents as tetrachloroethane for the reaction of the monohydride phenols resulted in the recovery of the starting phenols.

Tables 2 and 3 summarize the analytical characteristics of compounds I and II respectively. The most significant feature in Table 3 is the definite difference between the physical properties of IIb and those of either IIa or IIc. This might be related, to a certain degree, to the steric strain and the conformational rigidity involved only in IIb.

It is interesting to note whether the Friedel-Crafts reaction of phenols, particularly *o*- and *m*-cresols,

takes place at the position ortho or para to the hydroxyl group. The results presented in Table 1 appear to contrast with those of a number of previous studies on the acid-catalyzed C-alkylation of them, indicating that attacks by electrophiles, in general, occur at both positions,[7] ortho and para to the hydroxyl group, except in some cases which lead to the predominant formation of an *o*-[8] or *p*-substituted product.[9] In addition, it is noteworthy that 4-methyldihydrocoumarin (I, R=H) can not be obtained from the reaction of phenol with allyl cyanide, while the reaction with crotononitrile may favor its formation.[3]

Experimental[10]

Materials. The allyl cyanide was prepared from allyl chloride and cuprous cyanide.[11] The other materials were obtained from commercial sources.

The Acid-catalyzed Reaction of Phenols with Allyl Cyanide. *General Procedure A.* Finely-powdered anhydrous aluminum chloride (0.4 mol) was added slowly to a mixture of allyl cyanide (0.2 mol) and the phenol (1 mol), after which stirring was vigorously continued at 30—40°C. Dry hydrogen chloride was passed into a viscous slurry; then the mixture, into which dry gas had been continuously passed, was gradually heated in an oil bath and kept under the conditions shown in Table 1. Thereafter the resulting mixture was chilled and poured over water containing crushed ice and concentrated hydrochloric acid. The organic layer was separated from the aqueous layer, which was then shaken with ether. The extract was combined with the separated organic material, and then washed with water. After the extract had been dried over anhydrous magnesium sulfate and the solvent had been removed, the residue was distilled under reduced pressure to give the crude products, I and/or II (containing phenol and unidentified by-products as contaminants). The analytical sample was prepared by vapor-phase chromatographic fractionation. The results with individual compounds are shown in Table 1. The infrared spectrum of 4, 6-dimethyldihydrocoumarin (Ia) was identical with that reported previously.[3] The analytical data for Compounds I and II are presented in Tables 2 and 3 respectively.

4-Methyldihydroumbelliferone (Id). *Procedure B.* To a stirred solution of resorcinol (22 g, 0.2 mol) and

10) All melting points and boiling points are uncorrected. Infrared spectra were recorded on a Hitachi Model EPI-S2, and gas chromatographic analyses were carried out on a Shimadzu Model GC-1b chromatograph. NMR spectra were taken in D-chloroform on a JEOL Model INM 4H-100 instrument with tetramethylsilane as an internal standard.

11) E. Rietz, "Organic Syntheses," Coll. Vol. III, p. 852 (1955).

allyl cyanide (13.4 g, 0.2 mol) in 200 m*l* of a solvent such as diisopropyl ether, anhydrous aluminum chloride (53.4 g, 0.4 mol) was added, portion by portion. The mixture, into which dry hydrogen chloride had been passed, was heated on a steam bath and kept for 4 hr at 50—55°C. The subsequent procedure followed Procedure A, already described. After the removal of the solvents, the residual oil was fractionated to give 17.6 g (50%) of a viscous oil: bp 164—169°C/1 mmHg (Lit.[12] bp 190—193°C/7 mmHg): ν_{max}^{film} 3280 (O-H), 1740 (lactone C=O), and 850, 810 cm^{-1} (aromatic C-H). It solidified after standing for a long time and melted at 108—110°C.

The recrystallization from benzene afforded Id; mp 110—110.5°C (lit.[12] mp 109—110°C). Compound Id showed a positive ferric chloride test.

On the other hand, the alternative procedure of adding a solution of resorcinol and allyl cyanide in ether to a stirred suspension of aluminum chloride in ether provided the same results as have been presented above.

The author wishes to thank Professor Kikumasa Sato of Yokohama National University for his valuable advice, and Mr. Katsuhiko Takeda for his great help in carrying out the study described in this report. The author is also indebted to the Central Research Laboratories of the Meiji Seika Kaisha, Ltd., for the determination of the NMR spectra reported in this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 454—460 (1968)

The Dimerization of Butadiene by Palladium Complex Catalysts

Shigetoshi TAKAHASHI, Toshiki SHIBANO and Nobue HAGIHARA

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received September 16, 1967)

It has been found that palladium-phosphine complexes coordinated by dienophile and tetrakis-(triphenylphosphine)palladium catalyzed the linear dimerization of butadiene. The dimerization of butadiene with bis(triphenylphosphine)(maleic anhydride)palladium in aprotic solvents, such as benzene, tetrahydrofuran, and acetone, gave octatriene-1,3,7 selectively in good yields. In such alcohols as methanol, ethanol, and isopropanol, butadiene was converted to 1-alkoxyocta-diene-2, 7 and/or octatriene-1, 3, 7, depending on the nature of the alcohols employed. The dimerization in secondary amines, such as morpholine, piperidine, and diisopropylamine, gave butadiene dimer-amine adducts of the $R_2N(C_8H_{13})$ type, while that in primary amines, such as aniline and *n*-butylamine, gave a mixture of $RNH(C_8H_{13})$ and $RN(C_8H_{13})_2$. Phenoxy- and acetoxyoctadiene were also obtained from the reactions in phenol and acetic acid respectively.

It is well-known that butadiene is converted selectively to cyclic oligomers with various catalysts, for example, Ziegler-type catalysts.[1] Recently, it has been reported that linear dimerizations of butadiene can be carried out with cobalt[2]-, iron[3]- or rhodium[4]-containing catalysts to form methyl-heptatriene and/or *n*-octatriene. The dimerization with a nickel catalyst usually gives cyclic dimers; however, there is a linear dimerization in alcoholic media with low-valent nickel complexes.[5] A large number of reports on the oligomerization of butadiene with nickel catalysts have been presented, but there have been only a few reports[6] on the catalytic behavior of the palladium complex in response to butadiene.

In the course of an examination of the reactions

of dienophile-coordinated palladium-phosphine complexes[7] with butadiene, we have found that bis(triphenylphosphine) (maleic anhydride) palladium catalyzed a dimerization of butadiene, thus forming a linear butadiene dimer in a good yield. The preliminary results have been described in previous papers.[8,9] We have also studied the dimerization of butadiene by palladium complexes in alcohols or amines in considerable detail and have found that the dimerization in these solvents gave butadiene dimer-alcohol or -amine adducts in good yields.

Results and Discussion

The Dimerization Reaction in an Aprotic Solvent. When butadiene was heated at 100—120°C in benzene in the presence of bis(triphenylphosphine) (maleic anhydride) palladium,[7] Pd-$(Ph_3P)_2(C_4H_2O_3)$, it was converted to octatriene-1, 3, 7; there were no other butadiene dimers except a small amount of a thermal reaction product, 4-vinylcyclohexene-1.[8]

$$2\ H_2C{=}CH{-}CH{=}CH_2 \rightarrow H_2C{=}CH{-}CH{=}CH{-}CH_2{-}CH_2{-}CH{=}CH_2 \quad (1)$$

The dependence of the yield on the reaction temperature was investigated between 80—120°C; the results obtained are summarized in Table 1.

Although the yield of octatriene was good at an elevated temperature, the reaction at 120°C caused the decomposition of the catalyst and the products contained butadiene trimer (ca. 5%) and vinylcyclohexene as by-products. For the preparation of octatriene-1, 3, 7 in benzene, therefore, the reaction might better be carried out at a temperature between 110—115°C.

The reactions in tetrahydrofuran and acetone also gave octatriene-1, 3, 7; the experimental results are shown in Table 1.

Table 1. The dimerization in aprotic solvents

Solvent	Reaction temp., °C	Reaction time, hr	Yield[a] of octatriene-1, 3, 7, %
Benzene	80	7	trace
Benzene	100	7	23
Benzene	110	7	46
Benzene	120	7	64
T.H.F.	115	7	82
Acetone	115	7	86

a) Gas chromatographic analysis.
Catalyst $Pd(Ph_3P)_2(C_4H_2O_3)$ 219 mg (0.3 mmol); Solvent 20 ml; Butadiene 13 g.

The Dimerization Reaction in Alcohol. The dimerization of butadiene was also carried out in alcohols. In contrast to the reactions in such aprotic solvents as benzene or acetone, the dimerization in alcohols proceeded smoothly even at lower temperatures (40—100°C) to give 1-alkoxyoctadiene-2, 7 and/or octatriene-1, 3, 7, depending on the nature of the alcohols employed. There have been a few reports on the oligomerization of butadiene, which affords a butadiene dimer-alcohol adduct.[5a,6b,10]

In methanol butadiene easily dimerized, at a low temperature and a short reaction time, with the bis(triphenylphosphine)(maleic anhydride)-palladium catalyst to give 1-methoxyoctadiene-2, 7 and its isomer, 3-methoxyoctadiene-1, 7, along with a small amount of octatriene-1, 3, 7 (Eq. (2), $R=CH_3$).

$$2\ H_2C{=}CH{-}CH{=}CH_2 + ROH \rightarrow R{-}O{-}CH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH_2{-}CH{=}CH_2 + H_2C{=}CH{-}CH(OR){-}CH_2{-}CH_2{-}CH_2{-}CH{=}CH_2 \quad (2)$$

It is obvious that methoxyoctadiene is not derived from the reaction of octatriene with methanol, for octatriene was found not to react with alcohol under the same reaction conditions as these employed in the dimerization reaction of butadiene. The trans-configuration of 1-methoxyoctadiene-2, 7 obtained from the above reactions was suggested by the fact that its infrared spectrum showed a strong band at 970 cm^{-1} which is attributable to the CH out-of-plane deformation of trans -CH=CH-.

Bis (triphenylphosphine) (dimethylfumarate) palladium, bis(triphenylphosphine)(*p*-benzoquinone)-palladium, tetrakis(triphenylphosphine)palladium, and -platinum could also be employed as catalysts, although these complexes were found to be almost ineffective in aprotic solvents. The dependence of the distribution of the products on the catalyst and reaction conditions is shown in Table 2.

The platinum complex was less effective than palladium complexes.

In abs. ethanol the dimerization of butadiene with the bis(triphenylphosphine)(maleic anhydride)-palladium catalyst gave octatriene-1, 3, 7 and 1-ethoxyoctadiene-2, 7, plus a small amount of an isomer of ethoxyoctadiene, whereas in isopropanol octatriene-1, 3, 7 was obtained as the main product. The ratio of ethoxyoctadiene to octatriene was independent of the reaction time, and the use of a large amount of ethanol as the solvent resulted in a higher ratio, as Table 3 shows.

Although bis(triphenylphosphine)(*p*-benzoquinone)palladium was found to exhibit similar catalytic behavior, tetrakis(triphenylphosphine)palla-

d) A small amount of a butadiene dimer-isopropanol adduct was detected by gas chromatography.

dium was less effective in ethanol and was almost entirely inactive in isopropanol. The dependence of the reaction products on the nature of the alcohols employed is of considerable interest in respect to the mechanism of the catalysis.

The Dimerization Reaction in Phenol or Acetic Acid. The dimerization of butadiene in more acidic solvents, such as phenol or acetic acid, was attempted; it was found to give a butadiene dimer-phenol or -acetic acid adduct. The reaction of butadiene and phenol in a benzene solution at 80°C with the $Pd(Ph_3P)_2(C_4H_2O_3)$ catalyst proceeded smoothly, giving the phenol adduct in a 57% yield and lower-boiling butadiene dimers

which were not completely characterized.

The gas chromatograph and the NMR spectrum indicated that the phenol adduct consisted of 78% 1-phenoxyoctadiene-2, 7 and 22% of its isomer, probably 3-phenoxyoctadiene-1, 7 (Eq. (2), R=C_6H_5), which could not been separated by fractional distillation. Recently, it has been reported[6b] that the reaction between butadiene and phenol with palladium chloride gives 1-phenoxyoctadiene-2, 7.

The dimerization of butadiene in acetic acid with $Pd(Ph_3P)_2(C_4H_2O_3)$ or $Pd(Ph_3P)_4$ at 120°C gave a low conversion to a mixture (*ca.* 30% yield) of esters, containing 1-acetoxyoctadiene-2, 7 and its isomer, probably 3-acetoxyoctadiene-1, 7 (Eq. (2), R=CH_3COO), and lower-boiling butadiene dimers.

The reaction at a higher temperature gave a somewhat higher conversion, but the yield of acetic acid adduct was almost unchanged.

The Dimerization Reaction in Amine. Attempts to synthesize butadiene dimer-amine adducts were also carried out. The reactions of butadiene with secondary amines, such as morpholine, piperidine and diisopropylamine, in the presence or absence of the solvent afforded butadiene dimer-amine adducts of the $R_2N(C_8H_{13})$ type, while reactions with primary amines, such as aniline and *n*-butylamine, afforded a mixture of $RNH(C_8H_{13})$ and $RN(C_8H_{13})_2$, as shown in Eqs. (3) and (4). The experimental results are summarized in Table 4.

$$2\ H_2C{=}CH{-}CH{=}CH_2 + R_2NH \rightarrow R_2N{-}CH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH_2{-}CH{=}CH_2$$
$$2\ H_2C{=}CH{-}CH{=}CH_2 + RNH_2 \rightarrow RNH{-}CH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH_2{-}CH{=}CH_2 \quad (3)$$
$$+$$
$$CH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH_2{-}CH{=}CH_2$$

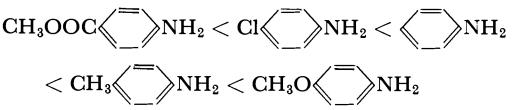
11) "Constants of Organic Compounds", in Series of Comprehensive Organic Chemistry, ed. by M. Kotake, Asakura, Tokyo (1963), p. 652.

The amine adducts produced from the above reactions were easily isolated by fractional distillation and were found to be somewhat unstable in air. Trans-configurations of octa-2, 7-dienylamine and diocta-2, 7-dienylamine derivatives were suggested by their infrared spectra, which showed a strong band near 970 cm^{-1}, as did 1-alkoxyoctadiene-2, 7. Although the products were thought to include a small amount of an isomer of the amine adduct as well as alcohol adducts, they could not be separated by fractional distillation.

The use of amines, such as morpholine and aniline, gave high conversions to amine adducts under mild reaction conditions, whereas a weak base such as carbazole gave a low rate of conversion to an amine adduct even under more vigorous conditions. When such amines as 2-pyrrolidone and acetoamide were employed, no amine derivatives were formed and octatriene-1, 3, 7 was obtained. The reactivities of aniline derivatives in terms of the dimerization rate of butadiene were investigated (Table 5) and found to increase in the order:



These facts suggest that there is a relationship between the reactivity and the basicity of amine in the dimerization reaction of butadiene.

The tetrakis(triphenylphosphine)palladium catalyst was less effective than the bis(triphenylphosphine)(maleic anhydride)palladium catalyst in amines. Under more vigorous conditions, the reaction in aniline with $Pd(Ph_3P)_4$ gave aniline adducts, as Table 4 shows.

Investigations of the mechanism of catalysis will be reported in a forthcoming publication.

Experimental

Reagents. Butadiene was dried over a molecular sieve. Tetrakis(triphenylphosphine)palladium, $Pd(Ph_3P)_4$, and -platinum, $Pt(Ph_3P)_4$, were prepared by a modification[12] of the method of Malatesta.[13,14] Bis(triphenylphosphine)(maleic anhydride)palladium and other dienophile-coordinated palladium complexes were prepared by the reaction of $Pd(Ph_3P)_4$ and dienophile by a method described in an earlier report.[7]

Analysis. The infrared spectra of the products were taken with a Jasco Model DS-402G grating spectrometer, while the ultraviolet spectra were taken with a Beckman DK-2 spectrophotometer. The NMR spectra were recorded on a Varian Model A-60 instrument, using tetramethylsilane as an internal standard in carbon tetrachloride. The molecular weights were measured in a benzene solution using a Knauer Vapor-pressure Osmometer.

Gas Chromatography. Octatriene-1, 3, 7 and alkoxyoctadiene were analyzed, using a 3 m silicon-grease 550 column, with a Shimadzu Gas Chromatograph, Model GC-2B. The conditions were as follows: octatriene-1, 3, 7: column temperature, 120°C; carrier gas (nitrogen) speed, 38 m*l*/min; internal standard, benzene; methoxyoctadiene: column temperature, 170°C; carrier gas (nitrogen) speed, 28 m*l*/min; internal standard, acetophenone; ethoxyoctadiene: column temperature, 175°C; carrier gas (nitrogen) speed, 27 m*l*/min; internal standard, nitrobenzene.

The Dimerization Reactions of Butadiene. The boiling points and refractive indices of the products obtained in this work are listed in Tables 6 and 7. The results of the elemental analysis and molecular-weight measurement of the compounds are summarized in Table 8. Typical procedures of the dimerization reactions of butadiene are as follows:

A) In an Aprotic Solvent. A 100 m*l*, stainless-steel autoclave was charged with 30 m*l* of acetone and 219 mg (0.3 mmol) of bis(triphenylphosphine)(maleic anhydride)palladium. Butadiene (20 g) was then condensed into the autoclave. The reaction mixture was heated to 115°C and held there for 8 hr while being stirred. In order to separate the reaction product from the catalyst, the yellow reaction mixture was distilled into a cold trap at ~60°C under reduced pressure. The distillate gave 14 g (70 % yield) of octatriene-1, 3, 7 (bp 124—125°C) by fractional distillation under a nitrogen atmosphere. It also contained a small amount of 4-vinylcyclohexene-1 (*ca.* 5%). The octatriene-1, 3, 7 was characterized[8] by its infrared, ultraviolet, and NMR spectra, and by hydrogenation to *n*-octane. The ultraviolet spectrum (C_2H_5OH solution) showed a band at 225 mμ (ε_{max} 22000). The infrared spectrum showed bands at 1638 (C=C), 1600

(conjugated C=C) and 1002, 912, and 898 cm^{-1} (-CH=CH_2). The NMR spectrum showed complex bands at 3.5—4.8 (=CH-), 4.8—5.4 (=CH_2) and centered at 8.0 τ (-CH_2-).

Other experiments on the dimerization of butadiene in aprotic solvents are summarized in Table 1.

B) In Methanol. The autoclave described above was charged with 30 m*l* of methanol, 73 mg (0.1 mmol) of bis(triphenylphosphine)(maleic anhydride)palladium, and 20 g of butadiene. The reaction mixture was heated to 70°C and held there for 2 hr while being stirred. The yellow reaction mixture was distilled into a cold trap at ~70°C under reduced pressure. The distillate gave 20 g (77% yield) of 1-methoxyoctadiene-2, 7 (bp 103—105°C/83 mmHg) by fractional distillation, which contains a small amount (*ca.* 3%) of 3-methoxyoctadiene-1, 7 (bp 145—146°C). The methoxyoctadiene was characterized[8,9] by its infrared and NMR spectra. The infrared spectrum of 1-methoxyoctadiene-2,7 showed bands at 1670 (internal C=C), 1638 (terminal C=C), 1115 (CH_3-O-), 970 (trans -CH=CH-) and 991, and 910 cm^{-1} (-CH=CH_2). Its NMR spectrum showed bands at 4.0—4.7 (multiplet, =CH-), 4.7—5.2 (multiplet, =CH_2), 6.22 (doublet, J=4 cps, O-CH_2-C=), 6.78 (singlet, O-CH_3), 7.7—8.2 (multiplet, =C-CH_2-C-CH_2-C=), and 8.2—8.7 τ (multiplet, -C-CH_2-C-).

Gas chromatography was employed to isolate 3-methoxyoctadiene-1, 7. Its infrared spectrum showed bands at 1643 (C-C), 1101 (CH_3-O-) and 994, 923, and 910 cm^{-1} (-CH=CH_2). The NMR spectrum showed bands at 3.9—4.7 (multiplet, =CH-), 4.7—5.3 (multiplet, =CH_2), 6.3—6.8 (multiplet, -C-CH-C), 6.88 (singlet, O-CH_3), 7.7—8.3 (multiplet, =C-CH_2-C-CH_2-C=), and 8.3—8.8 τ (multiplet, -C-CH_2-C-).

1-Methoxyoctadiene-2, 7 was hydrogenated over a platinum catalyst in n-hexane to give 1-methoxyoctane (bp 161—162°C, n_D^{20} 1.4137), and with a $Ru(Ph_3P)_3Cl_2$ catalyst[15] in ethanol-benzene to give 1-methoxyoctene-2[9] (bp 82—83°C/33 mHg, n_D^{20} 1.4307).

The results of other experiments on dimerization in methanol and other alcohols are summarized in Tables 2 and 3.

C) In Aniline. The autoclave described above was charged with 20 m*l* of acetone, 15 g (160 mmol) of

* Cryoscopic method in benzene.

aniline, 146 mg (0.2 mmol) of bis(triphenylphosphine)-(maleic anhydride)palladium, and 13 g (240 mmol) of butadiene. The reaction mixture was then heated to 100°C and held there for 0.5 hr while being stirred. The yellow reaction mixture was distilled to give 14.4 g (60% yield) of phenylocta-2, 7-dienylamine (bp 184—186°C/25 mmHg) and 4.8 g (25% yield) of phenyldiocta-2, 7-dienylamine (bp 209—210°C/5 mmHg).

The infrared spectrum of Phenylocta-2,7-dienylamine showed bands at 3420 (N-H), 1640 (C=C), 1605 (conjugated C=C), 971 (trans -CH=CH-), 993, 913 (-CH=CH_2) and 750, and 695 cm^{-1} (-C_6H_5). The NMR spectrum showed bands at 2.6—3.7 (multiplet, C_6H_5-), 4.2—4.7 (multiplet, =CH-), 4.7—5.3 (multiplet, CH_2), 6.36 (doublet, J=4 cps, N-CH_2-C=), 6.54 (singlet, N-H), 7.7—8.2 (multiplet, =C-CH_2-C-CH_2-C) and 8.2—8.8τ (multiplet, -C-CH_2-C-).

The infrared spectrum of phenyldiocta-2, 7-dienylamine showed bands at 1642 (C=C), 1602 (conjugated C=C), 971 (trans -CH=CH-), 993, 913 (-CH=CH_2) and 750, and 695 cm^{-1} (-C_6H_5). The NMR spectrum showed bands at 2.6—3.7 (multiplet, C_6H_5-), 4.0—4.7 (multiplet, =CH-), 4.7—5.4 (multiplet, =CH_2), 6.20 doublet, J=4 cps, N-CH_2-C=), 7.5—8.2 (multiplet, =C-CH_2-C-CH_2-C=), and 8.2—8.9 τ (multiplet, -C-CH_2-C-). Other experiments on dimerization in amines are summarized in Tables 4 and 5.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 461—464 (1968)

Oxidation of Phosphites by Means of *p*-Quinones and Benzyl Alcohol

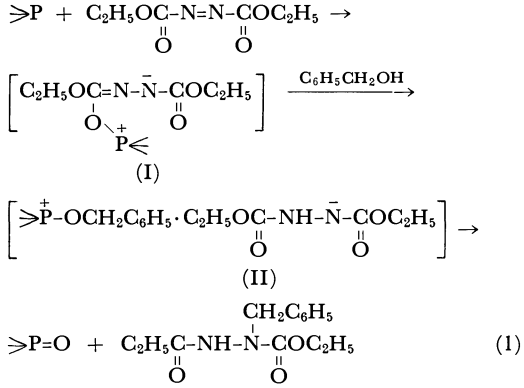
Oyo MITSUNOBU*1, Kyoko KODERA and Teruaki MUKAIYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 19, 1967)

Triethyl phosphite and tri-*n*-butyl phosphite were oxidized to the corresponding trialkyl phosphates by means of *p*-quinones and benzyl alcohol. On the other hand, when diethyl (*N*-diethyl)phosphoroamidite was treated with *p*-benzoquinone and benzyl alcohol, 4-ethoxyphenyl ethyl (*N*-diethyl)phosphoroamidate was obtained in a 69% yield and no diethyl (*N*-diethyl)-phosphoroamidate was isolated. The reaction of 2, 3, 5, 6-tetrachloroquinone with diethyl benzyl phosphite in the presence of ethanol resulted in the formation of triethyl phosphate and 4-benzyloxy-2, 3, 5, 6-tetrachlorophenyl diethyl phosphate in 16% and 68% yields respectively.

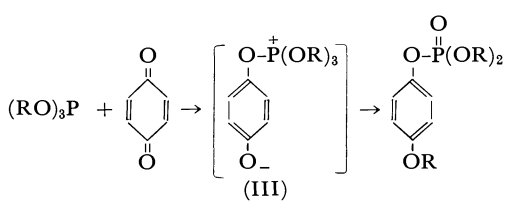
Preceding paper[1] describes the oxidation of phosphites or phosphines to the corresponding phosphates or phosphine oxides by means of diethyl azodicarboxylate and benzyl alcohol. The reaction proceeds through the proposed intermediates of an imidoyl phosphonium salt (I) and benzyloxy phosphonium salt (II) from which the corresponding pentavalent phosphorus compound and diethyl *N*-benzylhydrazodicarboxylate were formed (Eq. (1)).



(1)

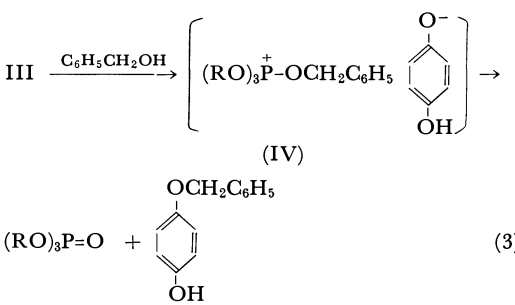
In the course of work aimed at the synthesis o esters of phosphoric acid, first objective of the present study was the oxidation of phosphites by the use of *p*-quinones and benzyl alcohol.

The reactions of quinones with trivalent phosphorus compounds have been investigated in considerable detail.[2] For example, Ramirez[3] demonstrated that the reaction of *p*-quinones with trialkyl phosphites resulted in the formation of the corresponding dialkyl 4-alkoxyaryl phosphates *via* quaternary phosphonium salt (III) (Eq. (2)).



(2)

Since the intermediate (III) is analogous in structure to I, III may be expected to react with benzyl alcohol to give benzyloxy phosphonium salt (IV). On the basis of the results reported earlier,[1,4] the phosphonium salt (IV) would decompose with the formation of trialkyl phosphate and 4-benzyloxyphenol (Eq. (3)).



(3)

When triethyl phosphite was treated with equimolar amounts of *p*-benzoquinone and benzyl alcohol in benzene at room temperature, triethyl phosphate, hydroquinone and hydroquinone dibenzyl ether were obtained in 80%, 71% and 44%

TABLE 1. THE OXIDATION OF TRIALKYL PHOSPHITES BY THE USE OF *p*-QUINONES AND BENZYL ALCOHOL

 X	Y	$(RO)_3P$	Product: $(RO)_3P=O$	Product: 	Product: 		R	Yield, %	Yield, %	Yield, %
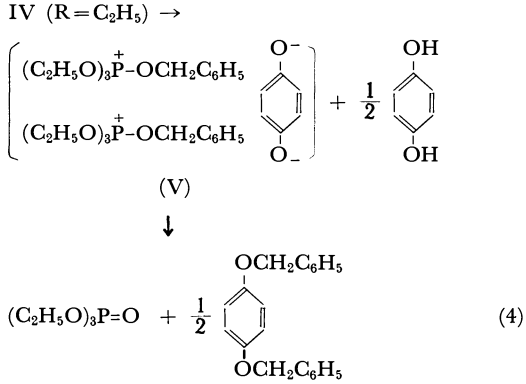
H	H	C_2H_5	80	71	44
H	H	*n*-C_4H_9	88		46
CH_3	H	C_2H_5	66	55	26
CH_3	H	*n*-C_4H_9	53		
Cl	Cl	C_2H_5	72	50	44
Cl	Cl	*n*-C_4H_9	47	53	54

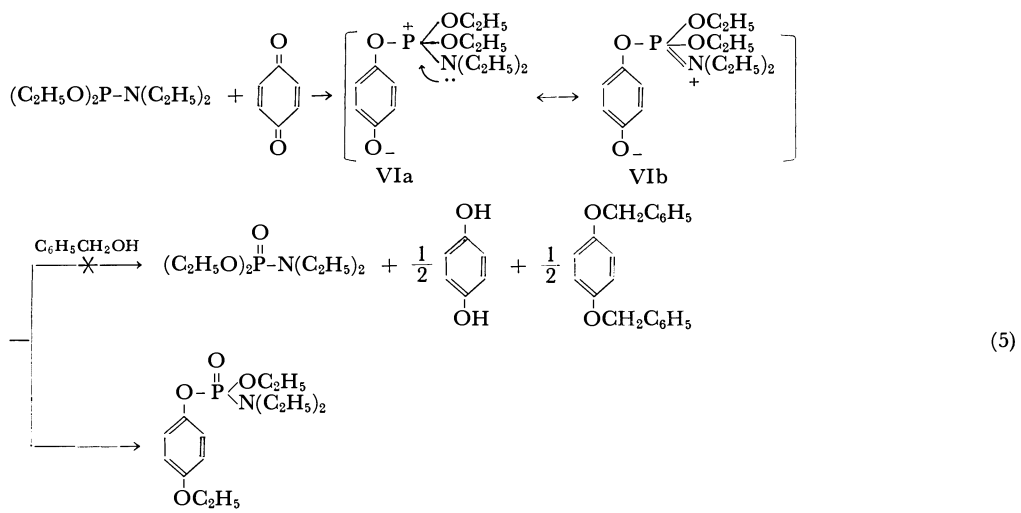
yields, respectively. No benzyloxyphenol, an expected product, could be isolated. The result suggests that an initially formed intermediate of benzyloxy phosphonium salt (IV) converts into a second quaternary phosphonium salt (V) and hydroquinone. The quaternary phosphonium salt (V) then in turn decomposes into the phosphate and the hydroquinone dibenzyl ether (Eq. (4)).



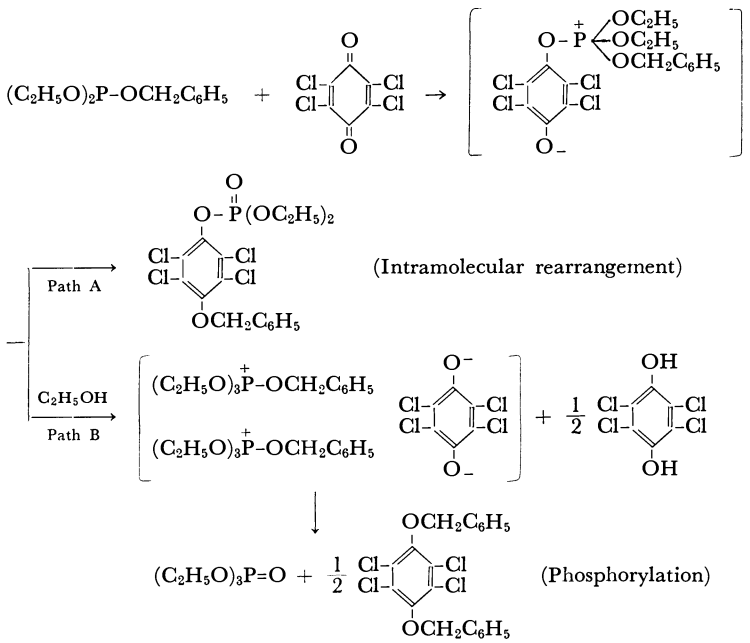
(4)

Similarly, triethyl phosphite and tri-*n*-butyl phosphite were oxidized to triethyl phosphate and tri-*n*-butyl phosphate by means of either 2, 3, 5, 6-tetrachloroquinone or 2, 5-dimethylquinone in the presence of benzyl alcohol. The results are summarized in Table 1.

Contrary to the successful oxidation of trialkyl phosphites by the use of *p*-quinones and benzyl alcohol, diethyl (*N*-diethyl)phosphoroamidate could not be obtained by the oxidation of diethyl (*N*-diethyl)phosphoroamidite by the present method. When diethyl (*N*-diethyl)phosphoroamidite was treated with equimilar amounts of *p*-benzoquinone and benzyl alcohol in refluxed benzene, 4-ethoxyphenyl ethyl (*N*-diethyl)phosphoroamidate was obtained in a 69% yield and benzyl alcohol(89%) was recovered. This result may be explained as follows. The positive charge of the initially formed phosphonium salt (VI) is not located on the phosphorus atom, but also resides partially on the nitrogen atom (VIa, b). Consequently, nucleophilic attack of the benzyl alcohol on the phosphorus atom becomes slower than the rearrangement of ethyl group and 4-ethoxyphenyl (*N*-diethyl)phosphoroamidate was predominantly formed (Eq. (5)).



(5)



(6)

As shown above, the reactions of *p*-quinones with trivalent phosphorus compounds in the presence of benzyl alcohol show close resemblance to those of diethyl azodicarboxylate and either benzyl or allyl alcohol.[1] Thus, the reaction of diethyl benzyl phosphite with 2, 3, 5, 6-tetrachloroquinone and ethyl alcohol was attempted with the assumption that the ethyl alcohol may be phosphorylated to give triethyl phosphate[1] (Eq. (6), Path B). However, contrary to our expectation, the main product of the reaction was 4-benzyloxy-2, 3, 5, 6-tetrachlorophenyl diethyl phosphate (68%) and triethyl phosphate was obtained only in 16% yield. This observation shows that the intramolecular rearrangement of the benzyl group of an intermediate (Eq. (6), Path A) take place more easily than the displacement of the aryloxy anion by the ethoxy anion (Eq. (6), Path B).

Experimental

Triethyl phosphite, tri-*n*-butyl phosphite and *p*-quinones were obtained from commercial sources. The solvents and alcohols were purified and dried by ordinary procedures. Diethyl benzyl phosphite was prepared by the procedure given in literature.[5]

Oxidation of Triethyl Phosphite by Means of *p*-Benzoquinone and Benzyl Alcohol. A solution of triethyl phosphite (8.30 g, 0.05 mol) in 10 m*l* of benzene was added drop by drop to a stirring solution of *p*-benzoquinone (5.40 g, 0.05 mol) and benzyl alcohol (5.40 g, 0.05 mol) in 100 m*l* of benzene at room temperature under nitrogen. Immediately, quinhydrone began to precipitate. After the reaction mixture was kept standing for 6 days at room temperature, quinhydrone was removed by filtration (0.32 g, 5.8%, mp 166—167°C, a mixture melting point with an authentic material was not depressed). The solvent was evaporated from the filtrate and hydroquinone dibenzyl ether thus formed was removed by filtration (3.17 g, 44%, an analytical sample was obtained by recrystallization from alcohol, mp 126—127°C. Found: C, 82.68; H, 6.39%). The filtrate was fractionated to give triethyl phosphate (7.30 g, 80%, bp 51—83°C/2 mmHg, redistillation nallowed the boiling point to 62—64°C/3 mmHg). The triethyl phosphate was shown to be identical with the authentic sample by comparison of infrared spectra. The residue of the fractionation was solidified on standing and washed with 10 m*l* of benzene-petroleum (1 : 1) to give hydroquinone (1.95 g, 71%).

Similarly, tributyl phosphate was obtained by the reaction of tri-*n*-butyl phosphite with *p*-quinone and benzyl alcohol.

Oxidation of Triethyl Phosphite by Means of 2, 3, 5, 6-Tetrachloroquinone and Benzyl Alcohol. A solution of triethyl phosphite (1.66 g, 0.01 mol) in 10 m*l* of benzene was added drop by drop to a stirring mixture of 2, 3, 5, 6-tetrachloroquinone (2.46 g, 0.01 mol) and benzyl alcohol (1.08 g, 0.01 mol) in 30 m*l* of benzene at room temperature. A red color appeared instantaneously together with dissolution of the quinone and faded after *ca.* 15 min. The mixture was refluxed for 100 min. After removal of the solvent, 2, 3, 5, 6-tetrachlorohydroquinone dibenzyl ether was obtained by filtration (0.95 g, 44%). An analytical sample was obtained by recrystallization from benzene, mp 174°C (Found: C, 55.37; H, 3.50%). Triethyl phosphate was obtained by fractionation of the filtrate (1.30 g, 72%). The residual oil which solidified on standing was taken up in benzene-ether (1 : 1). The solution was extracted with 5% aqueous sodium hydroxide. The aqueous solution was acidified to give 2, 3, 5, 6-tetrachlorohydroquinone (0.62 g, 50%, mp 234°C, undepressed by the admixture with an authentic sample).

5) F. W. Hofmann and R. J. Ess, *J. Am. Chem. Soc.*, **78**, 5817 (1956).

Reaction of Diethyl (*N*-Diethyl)phosphoroamidite with *p*-Benzoquinone and Benzyl Alcohol. A solution of diethyl (*N*-diethyl)phosphoroamidite (1.93 g, 0.01 mol) in 10 m*l* of benzene was added to a solution of *p*-benzoquinone (1.08 g, 0.01 mol) and benzyl alcohol (1.08 g, 0.01 mol) in 20 m*l* of benzene. Immediately, the orange color of the solusolution changed to a deep red. The solution was refluxed for 2 hr. After the solvent was removed, the residue was fractionated to give recovered benzyl alcohol (0.96 g, 89%, bp 100—104°C/14 mmHg, redistillation gave bp 100—101°C/8 mmHg) and ethyl 4-ethoxyphenyl (*N*-diethyl)phosphoroamidate (2.08 g, 69.0%, bp 120—130°C/0.03 mmHg. An analytical sample was obtained by redistillation, bp 115—120°C/0.05 mmHg).

Found: N, 4.42%. Calcd for $C_{14}H_{24}NO_4P$: N, 4.65%.

Reaction of Diethyl Benzyl Phosphite with 2, 3, 5, 6-Tetrachloroquinone and Ethyl Alcohol. A solution of diethyl benzyl phosphite (2.28 g, 0.01 mol) in 10 m*l* of benzene was added to the mixture of 2, 3, 5, 6-tetrachloroquinone (2.46 g, 0.01 mol) and ethyl alcohol (2 m*l*) in 40 m*l* of benzene. The solution was allowed to stand for 24 hr at room temperature. After the removal of the solvent, the residue was fractionated to give triethyl phosphate (0.29 g, 16%, bp 69—74°C/2 mmHg) and 2, 3, 5, 6-tetrachlorohydroquinone (0.11 g, 8.9%) deposited on the inner wall of condenser. The remaining oil crystallized on standing (3.20 g, 67.6%, mp 68—86°C, an analytical sample was obtained by recrystallization from ether, mp 95—96°C). The crystalline compound was shown to be 4-benzyloxy-2, 3, 5, 6-tetrachlorophenyl diethyl phosphate on the bases of elemental analysis and its conversion into 2, 3, 5, 6-tetrachlorohydroquinone monobenzyl ether as outlined below.

Found: C, 42.84; H, 3.87%. Calcd for $C_{17}H_{17}Cl_4O_5P$: C, 43.07; H, 3.59%.

Reaction of 4-Benzyloxy-2, 3, 5, 6-tetrachlorophenyl Diethyl Phosphate with Sodium Ethoxide. The white crystalline compound obtained in the above experiment was added to a solution of sodium ethoxide (0.12 g of sodium was dissolved in 5 m*l* of ethyl alcohol) and was refluxed for 1 hr. After removal of the solvent from the red colored solution, the residue was dissolved in water and acidified with hydrochloric acid. The mixture was filtered to give 2, 3, 5, 6-tetrachlorohydroquinone monobenzyl ether (mp 130—136°C). Recrystallization from benzene - petroleum ether gave an analytical sample, mp 136—138°C.

Found: C, 46.15; H, 3.10%. Calcd for $C_{13}H_8Cl_4O_2$: C, 46.16; H, 2.37%.

The authers wish to express their hearty thanks to members of Analytical Room, this Laboratory, for microanalyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 464—468 (1968)

Studies of Aminosugars. XVIII. Syntheses of Amino Derivatives of Schardinger α-Dextrin and Raffinose[1]

Sumio UMEZAWA and Kuniaki TATSUTA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received September 25, 1967)

In continuing our study of the relationship between structural and biochemical characteristics of aminoglycosides, amino-deoxy derivatives of polysaccharides have been synthesized. The six primary hydroxyl groups of Schardinger α-dextrin and the three primary hydroxyl groups of raffinose have successfully been replaced by amino groups respectively, to give hexa-(6-amino-6-deoxy)-cyclohexaglucan (α-1, 4) (IV) and 1'', 6, 6''-triamino-1'', 6, 6''-trideoxyraffinose (X). Their structures were confirmed by their NMR and IR spectra and by the studies of their chemical reactions. It has been found that hexa-(6-amino-6-deoxy)-cyclohexaglucan (α-1, 4) showed significant antitumor activity.

In a previous paper[2] the syntheses of several amino derivatives of disaccharides were reported.

The present paper is concerned with an extension of our study on aminosaccharides and reports the syntheses of amino-deoxy derivatives from the natural polysaccharides with α-anomeric configuration, *i. e.*, Schardinger α-dextrin and raffinose.

Schardinger α-dextrin[3] (I) is a kind of cyclic dextrins and contains eighteen hydroxyl groups, six out of which are primary and the others are secondary. On preferential tosylation of I with *p*-toluenesulfonyl chloride, followed by purification

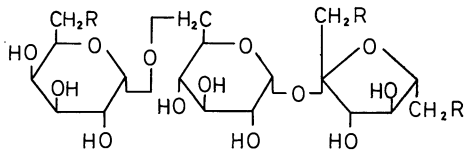
I : R = OH (Schardinger α-dextrin)

II : R = OTs

III : R = N_3

IV : R = NH_2

V : R = NHAc

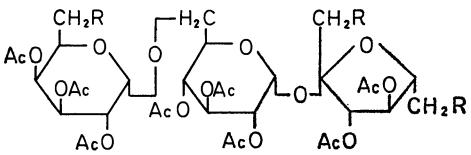


VI : R = OH (Raffinose)

IX : R = N_3

X : R = NH_2

XI : R = NHAc



VII : R = OTs

VIII : R = N_3

by column chromatography, hexa-(6-*O*-tosyl)-cyclohexaglucan (α-1, 4) (II) was obtained in a 12.2% yield. Though the preparation of II was previously reported by W. Lautsch, *et al.*,[4] the product has not been purified by chromatography and seemed to be the mixture of partially tosylated products. In the next step, the replacement of the tosyloxy groups of II with azido groups was carried out by heating II in dimethylformamide with sodium azide, thus affording hexa-(6-azido-6-deoxy)-cyclohexaglucan (α-1, 4) (III) in a 52% yield. The azide compound (III) was finally converted to hexa-(6-amino-6-deoxy)-cyclohexaglucan (α-1, 4) (IV) by catalytic hydrogenation with platinum oxide in aqueous methanol in a yield of 60%. The structure of IV was confirmed by the fact that the hydrolysis of IV with hydrochloric acid gave only 6-amino-6-deoxy-D-glucose on paper chromatogram, and furthermore by the nuclear magnetic resonance spectrum of the hexa-*N*-acetylated derivative (V) of IV. The signal at τ 8.07 (singlet) with a relative intensity of 3 may be ascribed to eighteen *N*-acetyl protons, and the doublet at τ 4.99 with a relative intensity of 1 may be assigned to six anomeric protons.

Raffinose (VI) was preferentially tosylated and acetylated to give 2, 2', 3, 3', 3'', 4, 4', 4''-octa-*O*-acetyl-1'', 6, 6''-tri-*O*-tosylraffinose (VII) in a 40% yield. The three tosyloxy groups of VII were then replaced by azido groups similarly as has been described in the preparation of III to give 2, 2', 3, 3', 3'', 4, 4', 4''-octa-*O*-acetyl-1'', 6, 6''-triazido-1'', 6, 6''-trideoxyraffinose (VIII). Treatment of VIII with sodium methoxide in methanol gave the de-*O*-acetylated product (IX), which was finally hydrogenated with platinum oxide to give 1'', 6, 6''-triamino-1'', 6, 6''-trideoxyraffinose (X). Structural evidences for X were obtained by the determination of NMR spectrum of the tri-*N*-acetylated derivative (XI) of X, and by means of the periodate oxidation of XI, where five moles of periodate were consumed for one mole of XI.

Experimental

Thin-layer Chromatography, Silica-gel Column Chromatography, and Paper Chromatography. Thin-layer chromatography was conducted by the use of silica gel (Daiichi Pure Chemicals Co.); the prepared plate was activated at 110°C and then stored in a desiccator. The spray reagent used was concentrated sulfuric acid. Solvent systems used: benzene-ethanol (4 : 1) (Solvent A); benzene-ethanol (3 : 1) (Solvent B); methanol-chloroform (5 : 2) (Solvent C); benzene-ethyl acetate (8 : 5) (Solvent D), and chloroform-ethanol (1 : 1) (Solvent E). Silica-gel column chromatography was carried out by the use of silica gel (Kanto Chemical Co.) activated at 110°C before use. Paper chromatography was conducted by the descending technique on Toyo filter paper No. 50, and the substances were detected by the use of ninhydrin spray (0.25% in pyridine). Solvent system used: *n*-butanol - pyridine - water - acetic acid (6 : 4 : 3 : 1) (Solvent F).

General Procedure for Nuclear Magnetic Resonance Spectrometry. The NMR spectrum was determined at a frequency of 60 Mcps with a Japan

4) W. Lautsch, R. Wiechert and H. Lehmann, *Kolloid-Zeitschrift*, **135**, 134 (1954).

Electron Optics JNM-C-60 spectrometer in deuterium oxide. Sodium 2, 2-dimethyl-2-silapentane-5-sulfonate was used as an internal reference in the sample. Peak positions are given in τ-values.

Hexa-(6-*O*-tosyl)-cyclohexaglucan (α-1, 4) (II). To a suspension of Schardinger α-dextrin anhydride [cyclohexaglucan (α-1, 4), I, 2.43 g, 2.50 mmol] in dry pyridine (35 m*l*) cooled at $-15°C$, *p*-toluenesulfonyl chloride (4.40 g, 23.1 mmol) was added; the mixture was then stirred at $-15°C$ for 1 hr and allowed to stand overnight at 0°C, at 5°C for 5 hr and at room temperature for 3 days. After the addition of a small volume of water, the solution was left for 30 min. The resulting solution was poured into a large volume of ice and water. The precipitate was collected by a centrifuge and washed with water; yield 2.7 g (S, 10.12%). Thin-layer chromatography with Solvent A proved the product to be composed of six components, with R_f-values of 0.66, 0.53, 0.39, 0.23, 0.09 and 0.00. This product was dissolved in a solvent mixture of benzene-ethanol (4 : 1) and chromatographed on a silica-gel column (49×540 mm) with the same solvent. After about 600 m*l* of eluate, fractions (15 g each) were tested by thin-layer chromatography. Each substance having the corresponding R_f value was recrystallized from methanol, and their yields and S-contents (%) were summarized as follows:

R_f value	Fraction No.	Yield mg	S-content %
0.66	5—16	965	11.49
0.53	18—26	204	11.15
0.39	27—34	88	10.51
0.23	33—45	572	10.36
0.09	45—64	250	9.57

As the substance at the origin seemed to be less tosylated than the substance having an R_f 0.09, it was not further investigated. The substance having an R_f 0.23 had mp 184—188°C (decomp.), $[\alpha]_D^{17}$ +101° (*c* 0.72, chloroform) [lit.,[4] mp 174°C, $[\alpha]_D^{20}$ +95° (*c* 1, chloroform)]; IR spectrum (KBr disk): 3440 (νOH), 2930 (νCH), 1600 (phenyl), 1175 (sulfonate) cm^{-1}.

Found: C, 49.64; H, 5.49; S, 10.36%; mol wt (Vapor pressure osmometer), 1970. Calcd for $(C_{13}H_{16}O_7S)_6$: C, 49.36; H, 5.10; S, 10.14%; mol wt 1898.

On the basis of these data, it seemed reasonable to assume that the product (R_f 0.23) was regarded as II, which contained six tosyloxy groups; Yield 572 mg (12.2%).

Hexa-(6-azido-6-deoxy)-cyclohexaglucan (α-1, 4) (III). To a solution of II (1.14 g) in dry *N*, *N*-dimethylformamide (11 m*l*) sodium azide (1.6 g) was added; the suspension was then vigorously agitated at 135°C for 6.5 hr. The resulting dark solution was filtered, and the filtrate was evaporated and coevaporated with toluene to give the residue, which showed essentially a single spot (R_f 0.20) on thin-layer chromatography with Solvent B. The residue was dissolved in a solvent mixture of benzene-ethanol (3 : 1) and chromatographed on a silica-gel column (49×325 mm) with the same solvent. After about 400 m*l* of eluate, fractions (15 g each) were tested by thin-layer chromatography. The substance having an R_f 0.20 was eluted in the fractions of tube Nos. 4—18; these fractions were combined and evaporated to yield 350 mg (52%) of III as a slightly yellow solid, which was used for the next step without further purification; IR spectrum (KBr disk): 3400 (νOH), 2920 (νOH), 2105 (azide) cm^{-1}, no sulfonate band.

Hexa-(6-amino-6-deoxy)-cyclohexaglucan (α-1, 4) (IV). A sample (350 mg) of III was dissolved in 75% aqueous methanol (24 m*l*) and hydrogenated with platinum oxide (160 mg) under 3 atm of hydrogen-pressure at 30—40°C for 4 hr. After removal of the catalyst, the filtrate was treated with active charcoal and evaporated to give a base of IV (260 mg). The aqueous solution of the base was neutralized with hydrochloric acid to pH 2 and evaporated to dryness. Recrystallization of the residue from aqueous ethanol gave crystalline hexahydrochloride of IV; yield, 240 mg (60%); mp 214°C (decomp.), $[\alpha]_D^{17}$ +103° (*c* 0.67, water). On paper chromatography with Solvent F, hexahydrochloride of IV showed a single spot with an R_f 0.01. IR spectrum (KBr disk): 3400—3300 (νOH, NH), 2910 (νCH), 1600 (δ_{as} NH_3^+), 1500 (δ_s NH_3^+) cm^{-1}.

Found: C, 36.91; H, 6.48; N, 6.71%. Calcd for $(C_6H_{11}O_4N \cdot HCl)_6$: C, 36.47; H, 6.12; N, 7.09%.

A small quantity of IV was heated with 3 N hydrochloric acid for 3 hr in a boiling water bath, and the hydrolyzate was paper chromatographed with Solvent F. Detections by ninhydrin and ammoniacal silver nitrate colorations showed only a spot corresponding to 6-amino-6-deoxy-D-glucose*1 as monosaccharide, respectively.

Hexa-(6-acetamido-6-deoxy)-cyclohexaglucan (α-1, 4) (V). To a stirred suspension of IV base (80 mg) in dry methanol (2 m*l*) acetic anhydride (0.3 m*l*) was added; the mixture was stirred for 1 hr and allowed to stand overnight at room temperature. After evaporation, the aqueous solution of the residue was treated with active charcoal and evaporated to give a solid, which was recrystallized from water by adding ethanol; yield, 70 mg (69%); mp 135—137°C (decomp.), $[\alpha]_D^{19}$ +92° (*c* 0.79, water).

On thin-layer chromatography with Solvent C, the product V showed a single spot with an R_f value of 0.21. NMR spectrum data: τ 4.99 (doublet, J= 2.9 cps, 6 protons, anomeric hydrogen), 8.07 (singlet, 18 protons, *NAc*); IR spectrum (KBr disk): 3380—3300 (νOH, NH), 2920 (νCH), 1645 (amide I), 1550 (amide II) cm^{-1}.

Found: C, 46.97; H, 6.31; N, 6.52%. Calcd for $(C_8H_{13}O_5N)_6$: C, 47.29; H, 6.45; N, 6.89%.

2, 2′, 3, 3′, 3″, 4, 4′, 4″-Octa-*O*-acetyl-1″, 6, 6″-tri-*O*-tosylraffinose (VII). To a solution of raffinose anhydride (VI, 1.01 g, 2.00 mmol) in dry pyridine (30 m*l*), Drierite (anhydrous calcium sulfate, 1.2 g) was added; the mixture was then allowed to stand for 30 min. After the mixture had been cooled to $-15°C$, *p*-toluenesulfonyl chloride (1.34 g, 7.06 mmol) was added in one portion, and the mixture was kept at $-15°C$ for 1.5 hr, at 0°C for 1 day and then at 5°C for 2 days. Acetic anhydride (4.5 m*l*) was added to the resultant cold solution, and the solution was again

*1 The specimen of 6-amino-6-deoxy-D-glucose was obtained from the hydrolyzate of kanamycin.

set aside overnight at room temperature. After the addition of a small volume of water, the solution was left for 30 min. The reaction mixture was then poured into a large volume of ice and water. The precipitate which separated was collected by a centrifuge and washed with water, yielding 2.1 g of a crude product. Thin-layer chromatography with Solvent D proved the product to be composed of two components, with R_f values of 0.48 (main) and 0.36 (minor). This product was dissolved in a solvent mixture of benzene - ethyl acetate (8 : 5) and chromatographed on a silica-gel column (47×220 mm) with the same solvent. After about 110 m*l* of eluate, fractions (15 g each) were tested by thin-layer chromatography. The substance having an R_f 0.48 appeared in the fractions of tube Nos. 24—34; these fractions were combined and evaporated under reduced pressure, and the residue was recrystallized from ethanol affording VII; yield, 1.04 g (40%), mp 90—93°C, $[\alpha]_D^{17}$ +95° (*c* 0.70, chloroform); IR spectrum (KBr disk): 2950 (νCH), 1755 (ester), 1600 (phenyl), 1370 (OAc), 1175 (sulfonate) cm^{-1}.

Found: C, 51.05; H, 5.31; S, 7.20%. Calcd for $C_{55}H_{66}O_{30}S_3$: C, 50.69; H, 5.10; S, 7.38%.

2, 2′, 3, 3′, 3″, 4, 4′, 4″-Octa-*O*-acetyl-1″, 6, 6″-triazido-1″, 6, 6″-trideoxyraffinose (VIII). A suspension of sodium azide (4.0 g) in dry *N, N*-dimethylformamide (55 m*l*)was stirred with VII (5.5 g) at 130°C for 7 hr. The solvent was then removed from the dark solution by distillation and codistillation with toluene under reduced pressure. As a part of the acetyl groups of VII had been found to be removed by the above procedure, the dark residue obtained was acetylated with acetic anhydride (40 m*l*) and dry pyridine (110 m*l*) for 2 days. After filtration, the filtrate was evaporated to a syrup, which, on thin-layer chromatography with Solvent D, showed two spots with R_f values of 0.72 (main) and 0.60 (minor). The syrup was then dissolved in a solvent mixture of benzene - ethyl acetate (8 : 5) and chromatographed on a silica-gel column (54×630 mm) with the same solvent. After about 830 m*l* of eluate, fractions (15 g each) were tested by thin-layer chromatography. The substance having an R_f 0.72 was eluted in the fractions of tube Nos. 46—60; these fractions were combined and evaporated to give a solid, which was recrystallized from aqueous ethanol affording VIII; yield, 1.48 g (38%); mp 180—184°C (decomp.), $[\alpha]_D^{17}$ +131° (*c* 0.63, chloroform); IR spectrum (KBr disk): 2930 (νCH), 2105 (azide), 1755 (ester), 1375 (OAc) cm^{-1}.

Found: C, 44.98; H, 5.13; N, 13.32%. Calcd for $C_{34}H_{45}O_{21}N_9$: C, 44.59; H, 4.95; N, 13.77%.

1″, 6, 6″-Triazido-1″, 6, 6″-trideoxyraffinose (IX) A suspension of VIII (380 mg) in dry methanol (7.6 m*l*) was treated with 0.75 N methanolic sodium methoxide (0.6 m*l*) at room temperature for 5 days. After neutralization to pH 7 with Amberlite IRC 50 (H form) (previously washed with methanol), the solution was evaporated to give the residue, which showed two spots with R_f values of 0.71 (minor) and 0.61 (main) on thin-layer chromatography with Solvent E. The residue was then dissolved in the same solvent system and chromatographed on a silica-gel column (27× 230 mm) with the same solvent. After about 40 m*l* eluate, fractions (3 g each) were tested by thin-layer chromatography. The substance having an R_f 0.61 was eluted in the fractions of tube Nos. 29—54; these fractions were combined and evaporated to give a solid of IX; yield, 132 mg (55%); mp 80—83°C (decomp.), $[\alpha]_D^{17}$ +117° (*c* 0.71, water); IR spectrum (KBr disk): 3370 (νOH), 2930 (νCH), 2110 (azide) cm^{-1}.

Found: C, 37.20; H, 5.27%. Calcd for $C_{18}H_{29}O_{13}N_9$: C, 37.31; H, 5.04%.

1″, 6, 6″-Triamino-1″, 6, 6″-trideoxyraffinose (X). A solution of IX (107 mg) in 50% aqueous ethanol (10 m*l*) was hydrogenated with platinum oxide (40 mg) under 3 atm of hydrogen-pressure at 35—40°C for 4 hr. After removal of the catalyst, the filtrate was evaporated and the aqueous solution of the residue was passed through a column (6×110 mm) of Dowex 1X2 (OH form). The ninhydrin-positive eluate, which was evaporated to give a base of X, was neutralized with hydrochloric acid to pH 2 and evaporated to dryness. Recrystallization of the residue from water-acetone gave crystalline trihydrochloride of X; yield, 76.8 mg (68%); mp 139—141°C (decomp.), $[\alpha]_D^{17}$ +114° (*c* 0.68, water). On paper chromatography with Solvent F, trihydrochloride of X showed a single spot with an R_f 0.02. IR spectrum (KBr disk): 3370—3260 (νOH, NH), 2900 (νCH), 1610 (δ_{as} NH_3^+), 1505 ($\delta_s NH_3^+$) cm^{-1}.

Found: C, 35.55; H, 6.57; N, 6.89%. Calcd for $C_{18}H_{35}O_{13}N_3 \cdot 3HCl$: C, 35.39; H, 6.27; N, 6.88%.

1″, 6, 6″ - Triacetamido - 1″, 6, 6″ - trideoxyraffinose (XI). To a suspension of X base (82 mg) in dry methanol (0.85 m*l*) acetic anhydride (0.25 m*l*) was added; the mixture was treated as has been described in the synthesis of V. The product was recrystallized from water by adding acetone; yield, 66 mg (64%); mp 142—144°C (decomp.), $[\alpha]_D^{17}$ +123° (*c* 0.65, water). On thin-layer chromatography with Solvent C, the product XI showed a single spot with an R_f value of 0.44. NMR spectrum data: τ ~8.0 (three singlets, 9 protons, NAc-1″, 6, 6″), 4.57 (doublet, 1 proton, H-1′, J=3 cps), 5.07 (doublet, 1 proton, H-1, J=2.5 cps); IR spectrum (KBr disk): 3400—3300 (νOH, NH), 2930 (νCH,) 1650 (amide I), 1555 (amide II) cm^{-1}.

Found: C, 45.48; H, 6.86; N, 6.70%. Calcd for $C_{24}H_{41}O_{16}N_3$: C, 45.93; H, 6.58; N, 6.70%.

The Periodate Oxidation of XI. An accurately-weighed sample (32.5 mg) of XI was dissolved in a mixture of a 0.1 N sodium acetate buffer solution (pH 4.7, 10m*l*) and a 0.1 M sodium metaperiodate solution (5.26 m*l*); the oxidation was then carried out at 0°C in the dark. Iodometric titrations with sodium arsenite[5] showed that the periodate consumption in moles per mole of XI was (time in hr, moles of oxidant consumed per mole of XI): 0.5, 3.16; 3.0, 4.17; 6.0, 4.37; 24.0, 4.55; 48.0, 4.99; 96.0, 5.00.

Preliminary Bioassay. It is noteworthy that the daily intraperitoneal injection of 100 mg/kg of the amino-deoxy derivative (IV) of Schardinger α-dextrin inhibited the ascites increase and prolonged the survival period of mice bearing ascites-type of Ehrlich carcinoma by intraperitoneal route. The compound IV also inhibited the growth of *Bacillus subtilis* PCI 219 completely at a dilution of 1 : 500, but showed no inhibition against *M. pyogenes var. aureus* 209p, *E. coli* and *Mycobacterium tuberculosis* 607 in a dilution of 1 : 1000. Compound

Photolysis of Nitrite Esters bearing Nitrogen on the β-Carbon

Hiroshi SUGINOME, Masakazu MURAKAMI and Tadashi MASAMUNE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 2, 1967)

The results of photolysis of a number of nitrite esters derived from jervine, in which the respective β-carbon of nitrite group bears nitrogen, are described. It has been found that in these nitrites when a nitrogen on β-carbon was in the amide group, the irradiation caused the cleavage of α, β-single bond to the nitrite group. The reaction is exemplified by photolysis of 3*O*, *N*-diacetyl-22, 27-imino-11-oxojerva-5, 13(17)-diene-3β, 23β-diol 23-nitrite ester (Ic) to afford an aldehyde II. When a nitrogen on β-carbon of nitrite was tertiary (*e.g.*, XIb), however, no photoinduced fission of carbon-carbon bond in these nitrites was observed and the starting alcohol recovered unchanged. These results coupled with others, *e.g.*, the result of photolysis of 3*O*-acetyl-*N*-benzoyl-22, 27-imino-11-oxojerva-5, 12-diene-3β, 23β-diol 23-nitrite ester (IIIf) indicate the selective cleavage of acyl-nitrogen bond followed by acidic hydrolysis to an aldehyde during chromatography, as shown in the scheme V to VIII. It is noted that this reaction is contrasted with the reported results with regard to photolysis of nitrites bearing oxygen in place of nitrogen.

The study of the photolysis of organic nitrites has received considerable attention over the past 7 years largely because of its synthetic utility.[2] Alkoxy radicals generated from nitrites were found to react in a variety of ways, depending on detailed structures around the nitrite group.

Our interest in this photochemical transformation is primarily a synthetic one and in this communication we describe some observations on a new mode of transformation.

22,27-Imino-11-oxojerva-5, 13(17)-diene-3β,23β-diol (Ia)[3] which was prepared by Birch reduction of jervine[4] was partially acetylated to yield the corresponding 30, *N*-diacetyl derivative (Ib) in 48% yield. The evidence for the introduction of an acetyl group at 3β-hydroxyl of Ia was provided by steric considerations and the disappearance of a band at 1050 cm^{-1} in its infrared pectrum which is characteristic of a Δ^5-3β-hydroxyl group.[5] This was converted on treatment with nitrosyl chloride in pyridine[6] into the corresponding nitrite (Ic). This was unstable[7] and was readily hydrolyzed to regenerate the alcohol Ib. This nitrite in benzene was immediately photolysed (150 W high pressure mercury arc lamp) under the conditions commonly used for the Barton reaction.[8] After about one hour no nitrite remained unchanged as indicated by a specific color test.[9] The

examination of the product by TLC showed this to be rather a complex mixture, and this was then subjected to chromatographic separation on the column of silicic acid. The least polar fraction which was eluted with a mixed solvent of benzene and ether crystallized on evaporation of the solvent, and had mp 150—152°C, after purification. A structure II could be assigned to this substance on the following basis. Elemental analysis and mass spectrometry (M^+ 384) indicated a molecular formula $C_{24}H_{32}O_4$, corresponding to the loss of nitrogen moiety in Ib. In the NMR spectrum of the compound Ib, signals due to *N*-acetyl, *O*-acetyl, 18- and 19-methyl groups appeared as singlets at τ 8.00,*1 τ 8.03,*1 τ 8.15 and τ 9.03, respectively, and those due to 21- and 26-methyl groups as a coincident broad doublet centered at τ 8.83 (J=6.6). However, the NMR spectrum of II retained only three singlets at τ 7.99, τ 8.16 and τ 9.05, which are attributable to *O*-acetyl, 18- and 19-methyl groups, respectively. A doublet in II was exactly a half of that of the corresponding doublet of Ib, indicating that either the 21-methyl or the 26-methyl had been removed from the starting diacetyl derivative Ib. Moreover, the NMR spectrum of II showed the presence of an aldehydic proton as a doublet centered at τ 0.56 (J=4.2). The IR spectrum of the product also showed the presence of typical aldehyde bands[10] at 2697, 2799 and 1740 cm^{-1} (shoulder) and a notable feature of this IR spectrum was the absence of a band due to an *N*-acetyl group. Only the structure II reasonably accommodates all the spectral data and the molecular formula mentioned above.

In a similar manner, the isomeric 3*O*, *N*-diacetyl derivative IIIb was prepared by partial

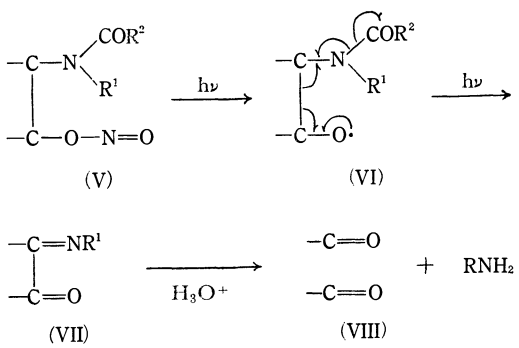
*1 These two signals are assigned to *N*- and *O*-acetyl groups but which is *O*-acetyl or *N*-acetyl was not determined.

10) S. Pinchas, *Anal. Chem.*, **27**, 2 (1955).

acetylation of *N*-acetyl-22, 27-imino-11-oxojerva-5, 12-diene-3β, 23β-diol[11] (IIIa) in good yield. The nitrite was again unstable and was immediately photolyzed in benzene. Examination of the product by thin layer chromatography showed that the composition of the product was noticeably simpler than that from the photolysis of Ic. Column chromatography with silicic acid enabled us to isolate a single compound IV as the least polar material in 13% yield.

The compound, which was analyzed for a formula $C_{24}H_{32}O_4$, melted at 192—194°C and had the bands at 1699 cm^{-1} (α, β-unsaturated C=O), 1727 cm^{-1} (*O*-acetyl), 1628 cm^{-1} (conjugated C=C) and 2700 and 1727 cm^{-1} (aldehyde) in its infrared spectrum. The NMR spectrum of this clearly indicated the compound to be an aldehyde. It showed signals corresponding to C-19 methyl at τ 8.93, C-21 methyl at τ 9.12 (doublet, J=6.6), *O*-acetyl at τ 7.97 and C-18 methyl at τ 7.85. A signal due to aldehydic proton appeared at τ 0.18 as doublet (J=1.4 cps). From these results it is clear that the compound is correctly formulated as IV.

The course of this reaction apparently involves the formation of imino-intermediates VII followed by acid hydrolysis during separation by chromatography on silicic acid. The following sequence V-VIII may be proposed for this photochemical fragmentation.



In the scheme shown the photochemical excitation of the system V generates an alkoxyl radical VI which collapses in a variety of ways to afford stable species, one being a process to lead to VII in which the acyl-nitrogen linkage would most probably be cleaved. In order to confirm this fission of acyl-nitrogen bond, we attempted to examine the photolysis of the nitrite Ig in which the nitrogen has a methyl group in place of an acetyl substituent. Although Birch reduction of *N*-methyl jervine[12] gave rise to a well-defined compound Ie having mp 185.5—189°C, the selective acetylation for the C-3 hydroxyl group to afford If proved to be difficult, owing to the facile migration of the 13(17) double bond to the α, β-position of 11-carbonyl, as shown by the appearance of the absorption at 1626 cm^{-1} in the crude product from acetylation, and subsequent interaction between the α, β-unsaturated double bond and the basic nitrogen to afford partly the cyclic product during acetylation procedure. Actually, the compound Ie was very easily convertible into a compound with base which is formulated as a zwitterion IX from its spectral and analytical data and by analogy of the reaction.[4,13] In the infrared spectrum the compound IX showed the bands at 1734 cm^{-1} and 3440 and 3630 cm^{-1} due to a five-membered ring ketone and a hydroxyl stretching vibration, respectively. Treatment of IX in acetic acid with aqueous potassium iodide afforded the highly crystalline hydriodide.

Furthermore, in the NMR spectrum of the starting compound Ie, three singlets due to *N*-methyl, C-19 methyl and C-18 methyl appeared at τ 7.76, τ 9.06 and τ 8.09. But all these peaks in the compound IX shifted to τ 7.84, τ 8.97 and τ 8.26, respectively.

The synthesis of the compound of type If was equally unsuccessful in isomeric 22, 27-imino-11-oxojerva-8, 13(17)-diene series in which a double bond is located at the 8-position instead of the 5-position in If and in this cyclopentenone system there seemed some possibility of affording the compound of type If. 5α, 6-Dihydroisojervine was oxidized selectively at 3-position to yield the corresponding 3-ketone X.[4] However, attempted *N*-methylation with methyl iodide and potassium hydroxide led exclusively to a weak tertiary base XIa as experienced in the analogous compounds.[4,13] The structure XIa was evident from its IR and the NMR spectra.

We then considered the use of nitrite of the hexacyclic base XIa or XIIa, in which the β-carbon of the nitrite group has a tertiary nitrogen, to obtain more insight into the process from V to VIII. As already cited, the formation of this type of compound was first observed by Wintersteiner and Moor.[13] Birch reduction product Ia of jervine was submitted to Oppenauer oxidation to yield the corresponding Δ^4, 3-ketone. Crude Δ^4, 3-ketone gave rise to a tertiary base XIIa which was treated with nitrosyl chloride in pyridine in the usual manner. After work-up as usual, an unstable nitrite, mp 143—146°C, XIIb was obtained in excellent yield. This was immediately photolyzed in dry benzene without further purification. The photolyzed product consisted solely of the starting alcohol XIIa and no other noticeable products were produced as revealed by thin-layer

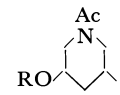
chromatography. The hexacyclic base XIa described above was also converted into the corresponding nitrite XIb and the nitrite was photolyzed. This likewise gave the original alcohol XIa exclusively.

These results demonstrate that in a photochemically excited system, ·O-C-C-N-alkyl, as that from XIb or XIIb, *N*-alkyl bonds are stable under the conditions of the Barton reaction and that acyl-nitrogen linkage is selectively cleaved in the scheme shown in V-VIII.

In order to probe further into the effect of *N*-substituents, *N*-benzoyl analogue of IIIc was newly synthesized. 22, 27-Imino-11-oxojerva-5, 13(17)-diene-3β, 23β-diol (Ia) was treated with benzoic anhydride to afford its crude tribenzoyl derivative Id. This was hydrolyzed to yield the corresponding *N*-benzoyl derivative IIId, mp 230.5—232.5°C. The *N*-benzoyl derivative IIId was submitted to partial acetylation to yield the corresponding 3*O*-acetate IIIe, mp 144.5—146°C. Conversion of this into the corresponding nitrite IIIf mp 206—208°C and the photolysis of the nitrite gave a mixture of the products. Column chromatography of the product afforded the aldehyde IV, which was identical with the specimen obtained from the photolysis of the nitrite IIIc, and also a small amount of benzoic acid. The nature of the reaction which leads to the formation of benzoic acid has not been fully understood. But this result supplements the evidence for the occurrence of acyl-nitrogen fission.

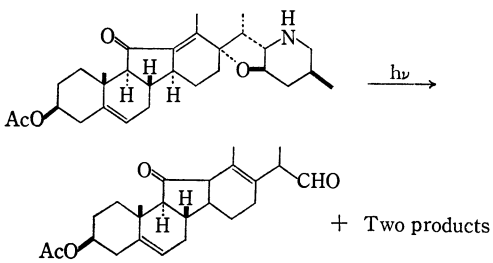
Moreover, we tried to confirm this acyl-nitrogen cleavage by studying some simpler system. *N*-Acetyl-3-hydroxy-5-methylpiperidine[14] XIIIa was converted into the corresponding unstable nitrite XIIIb. However, the photolysis of this nitrite gave rise to a complex mixture of amines which was characterized only by qualitative tests and we have not been successful in isolating any single amine.



XIIIa R=H
b R=NO

Although the cleavage reaction described here has obviously limited synthetic value, it may provide a useful synthetic route to certain aldehydes which are inaccessible by other procedures.[15]

It has been reported by Barton and coworkers[16] that in a number of nitrites vicinally substituted by an oxygen-bearing moiety, photolysis leads to an oxidative fission of carbon-carbon bond. In these cases the oxygen-bearing moieties could be carbonyl, hydroxyl-bearing tertiary carbon and ethyleneacetal groups. However, when the group was acetoxyl-bearing carbon, *i. e.*, the nitrite of 4-pregnene-3-one-17α, 20β-diol 20-acetate in which we have a system Ac-O-C-C-O-N=O, no carbon-carbon bond cleavage was observed and the starting alcohol was recovered unchanged. Moreover, several similar cases in the nitrite photolysis have been reported. For example, Kwok and Wolff[17] have reported that O-radical generated from the nitrite ester of 5α-androstane-2β, 3α, 17β-triol-3, 17-diacetate performed the normal Barton reaction. Moreover, Barton and his colleagues have reported[18] that the nitrite of 12α-hydroxy oleanolic acid acetate lactone was capable of achieving the normal Barton reaction. In these nitrites, ONO group is equally in the system



14) This compound was prepared by K. Orito in this laboratory through the catalytic hydrogenation of the corresponding aromatic amine, acetylation of the piperidine obtained and subsequent hydrolysis.

AcO–C–C–ONO and no products from carbon-carbon bond cleavage were obtained.[19]

The observed difference in the photolytic behavior between Ac–N–C–C–ONO system and Ac–O–C–C–ONO is of considerable interest. It may be noted that the difference in photolytic behavior between the two systems is parallel to the difference of the bond energy of O–C and N–C.

Nearly simultaneously with our preliminary publication[1] Jeger and his colleagues published[20] the results of the photolysis of *O*-acetyljervine which seem to be relevant to the problem discussed here. On irradiation with light of 253.7 mμ, *O*-acetyljervine gave a mixture of the products from which they isolated three compounds. One of these is an aldehyde which is, in all probability, identical with the aldehyde IV obtained by us during the photolysis of the nitrite IIIc.

It is to be noted that they have found *N, O*-diacetyljervine to be photochemically inert, since they postulated[21] a similar process to ours for the formation of this aldehyde. As in the photolysis of *O*-acetyljervine different energy source and solvent (20 W, low pressure mercury arc lamp, 16 hr, dioxane) were employed, it would be difficult to assess this difference in the results.

Experimental

All melting points were determined on a Yanagimoto-type hot-stage and uncorrected. Unless stated otherwise, infrared spectra were determined in Nujol using an Nihonbunko DS-402G type spectrophotometer. NMR spectra were determined on a Japan electron optics 3H 60 high resolution NMR spectrometer in deuteriochloroform solution using tetramethylsilane as an internal reference. The course of reactions and the progress in column chromatography were followed by thin layer chromatography on Merck silica gel G.

3*O*, *N*-Diacetyl-22, 27-imino-11-oxojerva-5, 13(17)-diene-3β, 23β-diol (Ib). 22, 27-Imino - 11 - oxojerva-5, 13(17)-diene-3β, 23β-diol[4] (Ia) (4.038 g) and freshly distilled acetic anhydride (2.003 g) in dry pyridine (7.14 g) were set aside at room temperature. After 24 hr, a further amount of acetic anhydride (0.201 g) was added and the mixture was set aside for an additional 24 hr and heated for 10 min on a water bath. Benzene was added to the cooled solution and the solvents were evaporated by a rotatory evaporator. To the residue, there was added 10% aqueous sodium carbonate solution (20 ml) and the mixture was extracted with chloroform (60 ml, 40 ml, 40 ml, successively). The chloroform solution was washed with water (50 ml,) dried with sodium sulfate and evaporated. The residue was chromatographed on silicic acid (80 g, Mallinckrodt, 100 mesh) eluting with benzene-ether mixtures with increasing amounts of ether to give, successively, 3*O*, 23*O*, *N*-triacetyl derivative (295 mg), a mixture of tri- and diacetyl derivatives (331 mg), 3*O*, *N*-diacetyl derivative (2.3 g). The latter was recrystallized from ethyl acetate and *n*-hexane to yield Ib (2.07 g), mp 112—134°C. This was again purified from ether. mp 159—161°C. $[\alpha]_D^{18}$ +41.4° (*c* 2.4, methanol). IR: ν_{max} 1733 cm^{-1} (O-Ac and 11-C=O), 3400 cm^{-1} (broad, C23-OH), 1625 cm^{-1} (N-Ac), NMR: τ 9.03 (C-19 methyl), τ 8.15 (C-18 methyl), τ 8.03 and τ 8.00 (O- and N-Ac). Found: C, 72.51; H, 8.87; N, 2.48%. Calcd for $C_{31}H_{45}O_5N$: C, 72.76; H, 8.86; N, 2.74%.

3*O*, *N*-Diacetyl-22, 27-imino-11-oxojerva-5, 13(17)-diene-3β, 23β-diol 23-Nitrite (Ic). To 3*O*, *N*-diacetyl 22, 27 - imino -11- oxojerva-5, 13(17)-diene-3β, 23β-diol (Ib) (202 mg) in dry pyridine (0.95 g) there was added a mixture of nitrosyl chloride and pyridine at −30—−35°C until the solution persisted orange color. The solution was allowed to stand for 20 min at −17—−40°C and the reaction was then quenched with ice water. The resultant precipitates of the nitrite were filtered, washed with water and dried at room temperature under vacuum to afford 212 mg of crude nitrite Ic, mp 87—90°C (decomp.). This nitrite was unstable and was positive in the color reaction with diphenylamine-sulfuric acid.[9] Owing to the presence of *N*-acetyl absorption, a double band due to N=O stretching frequency in the infrared spectrum was not clear. However, two bands (768 and 795 cm^{-1}), which are most probably due to N–O stretching,[22] were descernible.

After a few hours a thin layer chromatogram of this nitrite showed the appearance of a spot of significant amount of the starting material. Therefore, this nitrite was immediately used in the next step without further purification.

Photolysis of the Nitrite Ester (Ic). The nitrite ester Ic (212 mg) in dry benzene (10 ml) at 15°C and under an atmosphere of dry nitrogen was irradiated with a 150-W high pressure mercury arc lamp for 67 min. After removal of a small amount of precipitation, the dark brown solution was concentrated to dryness and the residue was chromatographed on silicic acid (6 g) with benzene containing an increasing amount of ether. The least polar product (50 mg), eluted with benzene and ether, crystallized on evaporation of the solvent. This was washed with *n*-hexane and recrystallized from aqueous ethanol to yield aldehyde II (22 mg) mp 149.5—152°C. IR: ν_{max} 1731 cm^{-1} (O-Ac and 11-C=O) 2697 cm^{-1}, 2799 cm^{-1} and 1740 cm^{-1} (shoulder) (aldehyde) NMR: τ 9.05 (C-19 methyl) τ 8.16 (C-18 methyl) τ 8.83 (doublet, J=6.6) (C-21 methyl), τ 7.99 (O-acetate) and τ 0.56 (doublet, J=4.2) (aldehyde). Found: C, 75.47; H, 8.62%. Calcd for $C_{24}H_{32}O_4$: C, 74.97; H, 8.39%.

3*O*, *N*-Diacetyl-22, 27-imino - 11 - oxojerva - 5, 12-diene-3β, 23β-diol (IIIb). *N*-Acetyl-22, 27-imino-11-oxojerva-5, 12-diene-3β, 23β-diol (2.477 g) and acetic anhydride (0.576 g) in dry pyridine (2.19 g) were set aside for 22 hr at room temperature and then heated for 10 min on the water bath. To this solution there was added acetic anhydride (200 mg) and the solution was

19) As Kwok and Wolff have quoted, there is naturally a possibility that both hydrogen abstraction and oxidative fission occurred competitively in their case and only the product of abstraction was isolated.

again heated for 30 min. After addition of benzene, the solvent was removed and to the residue were added water (30 m*l*) and 10% aqueous sodium carbonate (20 m*l*) and this was extracted with chloroform (50 m*l*, 40 m*l* and 40 m*l*, successively). The chloroform layer was washed with water (70 m*l*) and dried over magnesium sulfate. After evaporation of the solvent, the residue (3.03 g) was chromatographed on silicic acid (49 g). Elution with a mixture of benzene-ether with an increasing amount of ether afforded 3*O*, 23*O*, *N*-triacetyl-22, 27-imino-11-oxojerva-5, 12-diene-3β-, 23β-diol (0.227 g), a mixture of di- and triacetyl derivatives (38 mg) 3*O*, *N*-diacetyl-22, 27-imino-11-oxojerva-5, 12-diene-3β, 23β-diol (IIIb) (1.31 g) and a mixture of di- and monoacetyl derivatives (0.805 g) successively. The diacetyl derivative was recrystallized from aqueous ethanol to yield pure IIIb (0.741 g) mp 217.5—220°C. IR: ν_{max} 1645 cm^{-1} (N-Ac), 1697 cm^{-1}(11-C=O), 1733 cm^{-1} (O-Ac) 3505 cm^{-1} (OH) NMR: τ 9.25 (J=6.0) (C-26 methyl) τ 8.95 (C-19 methyl), τ 8.73 (J=6.0) (C-21 methyl), τ 7.92 (C-18 methyl), τ 8.00 and τ 7.83 (N-Ac and O-Ac). Found: C, 72.95; H. 8.94; N, 2.84%. Calcd for $C_{31}H_{45}O_5N$: C, 72.76; H, 8.86; N, 2.74%.

3*O*, *N*-Diacetyl-22, 27-imino-11-oxojerva-5, 12-diene-3β, 23β-diol Nitrite (IIIc). Compound IIIb (201 mg) was dissolved in dry pyridine and treated with nitrosyl chloride-pyridine mixture at −30°C until the solution persisted greenish yellow color. This was set aside for 7 min and poured into ice water. The resultant precipitates were collected by filtration to yield nitrite IIIc, 261 mg, mp 212—214°C (decomp.). This was unstable, and, dried for 4 hr under vacuum, was used immediately for the next photolysis.

Photolysis of Nitrite Ester (IIIc). The nitrite ester IIIc (261 mg) in dry benzene (12 m*l*) at 14°C and under an atmosphere of dry nitrogen was irradiated with a 150-W high pressure mercury arc lamp (Daikakogyo HLVA type, Japan) for 2 hr and 10 min. The residue was chromatographed on silicic acid (7 g). The least polar product (23 mg), eluted with benzene, crystallized on evaporation of the solvent. This was recrystallized from aqueous ethanol (17 mg) mp 192—194°C.[23] IR: ν_{max} 1699 cm^{-1} (α, β-unsaturated C=O), 1727 cm^{-1} (O-Ac and aldehyde) 1628 cm^{-1} (C=C) 2700 cm^{-1} (aldehyde). NMR: τ 8.97 (C-19 methyl) τ 9.12 (C-21 methyl) (J=6.6) τ 7.97 (O-Ac) τ 7.85 (C-18 methyl), τ 0.18 (J=1.4 cps) (aldehyde). Found: C, 75.03; H, 8.31%. Calcd for $C_{24}H_{32}O_4$: C, 74.97; H, 8.39%.

The Preparation of XIa. 5α, 6-Dihydroisojervone[4] (X) (200 mg), potassium hydroxide (63 mg) and methyliodide (82 mg) in ethanol (8 m*l*) were heated at 72°C for 95 min in a sealed tube. After the removal of ethanol, the residue was extracted with chloroform (20 m*l*) and water (10 m*l*). The organic layer was washed and dried. After the removal of the chloroform, the residue was recrystallized from acetone to yield 42 mg of XIa, mp 235—236°C (decomp.). The residue gave a further 84 mg of XIa by the preparative T.L.C. NMR: C-19 and C-18 methyls, τ 8.71 and τ 8.76. IR: 1703 cm^{-1} (six membered ketone), 1685 and 1635 cm^{-1} (CO-C=C), 3470 cm^{-1} (OH) Found: C, 75.93; H, 9.10; N, 3.54%. Calcd for $C_{27}H_{39}O_3N$: C, 76.19; H, 9.24; N, 3.29%.

The Preparation and Photolysis of Nitrite (XIb). The alcohol XIa (84 mg) in pyridine (1 m*l*) was treated with nitrosyl chloride in pyridine at −25°C in the usual manner. The nitrite obtained softened at 90°C and melted at 160°C with decomposition (63 mg). IR: 1713 cm^{-1} (six membered ketone), 1695 and 1640 cm^{-1} (CO-C=C). The nitrite (63 mg) in benzene (13 m*l*) was photolyzed in the usual manner for 90 min. After the removal of the solvent, T. L. C. revealed that the product was solely the starting alcohol XIa.

The Preparation of XIIa. (Experiments by N. Sato). 22, 27-Imino-11-oxojerva-5, 12-diene-3β, 23β-diol (Ia) (3.7 g) was dissolved in 500 m*l* of dry toluene and 150 m*l* of the solvent was removed by distillation. To this solution, there was added 40 m*l* of cyclohexanone and then 60 m*l* of the solvent was distilled to remove a trace of water. A solution of 3.7 g of aluminum isopropoxide in 19 m*l* of dry toluene was added. The reaction mixture was refluxed for 6.5 hr. On cooling, 10 m*l* of water was added to the solution and the precipitate was removed by filtration. To the filtrate there was added 2 N aqueous hydrochloric acid (50 m*l*) and the salt (3.0 g) formed was collected by filtration. The salt was dissolved in water (2.5 *l*) and the aqueous solution was extracted with ether. The aqueous solution was made up to pH 8.0 with 2 N aqueous ammonia, extracted with chloroform (total volume, 700 m*l*), washed with water and dried over sodium sulfate. After evaporation, 3.4 g of crude Δ^4, 3-ketone was obtained. This was purified by making the complex (2.0 g) with chloroform. The complex (1.0 g) was immediately submitted to cyclization with base to yield XIIa. The chloroform complex in 5% methanolic potassium hydroxide was refluxed for 1 hr. The resultant compound was extracted with ether. The ethereal solution was washed with water and dried over sodium sulfate. After evaporation of the solvent, the residue was recrystallized from ethanol to yield XIIa mp 222—224°C. IR: 1728 cm^{-1} (five membered ring ketone), 1655 and 1616 cm^{-1} (α, β-unsaturated ketone). UV λ_{max} 232 mμ (ε; 9800) (ethanol) NMR τ 8.81 and τ 8.70 (C-19 and C-18 methyls). Found: C, 76.31; H, 9.22; N, 3.41%. Calcd for $C_{29}H_{39}O_3$: C, 76.19; H, 9.24; N, 3.29%.

The Nitrite XIIb. Compound XIIa (200 mg) in pyridine (1 m*l*) was treated with nitrosyl chloride in pyridine at −30°C until dark green color persisted. The reaction mixture was poured into ice water. The resultant precipitate was collected by filtration and dried under vacuum. Mp 143—146°C (204 mg). T.L.C. gave only one spot. IR: 1730 cm^{-1} (five membered ketone), 1671 and 1638 cm^{-1} (α, β-unsaturated ketone) 1618 cm^{-1} (weak) 1660 cm^{-1} (shoulder), 795 and 802 cm^{-1} (doublet) and 675 cm^{-1} (-O-NO).

Photolysis of the Nitrite (XIIb). The nitrite (204 mg) in dry benzene (15 m*l*) was irradiated under an atmosphere of dry nitrogen at 14—16°C. After 68 min. no nitrite remained unchanged. The residue (233 mg) gave only one spot on T.L.C. This was dissolved in methanol. To the solution there was added ether and *n*-hexane to yield the crude alcohol XIIa. This was again recrystallized from acetone, mp 222—224°C.

23) In our preliminary communication,[1] the melting point of this was described as mp 167—171°C.

N-Benzoyl-22, 27-imino-11-oxojerva-5, 12-diene-3β, 23β-diol (IIId). 22, 27-Imino-11-oxojerva-5, 13-(17)diene-3β, 23β-diol (2.38 g) and benzoic anhydride (4.65 g) in dry pyridine (20 ml) were set aside overnight at room temperature. Then, the reaction mixture was further heated for 1 hr on a water bath. After the removal of pyridine under reduced pressure, there was added aqueous 5% sodium carbonate (80 ml). This was extracted with chloroform (100 ml, 50 ml, and 50 ml, successively).

The combined organic layer was washed with water (100 ml, twice) and dried over sodium sulfate. The residue (7.7 g) in 6% methanolic potassium hydroxide (50 ml) was refluxed for 1.5 hr under nitrogen atmosphere. After 30 min, solid appeared in the solution and methanol (20 ml) was added. The solution was further refluxed for 1 hr and cooled. The crystals that appeared were collected by filtration. A total amount of 2.32 g of crude benzoyl derivative IIIc was obtained. After purification from methanol, it melted at 230.5—232.5°C. $[\alpha]_D^{18}$ −8.2 (*c* 2.0, pyridine) IR: 1623 cm^{-1} (*N*-benzoyl), 1703 cm^{-1} (C=O). NMR: MeOH τ 6.49 C-18 methyl, τ 7.79 C-19 methyl, τ 8.93, phenyl proton, τ 2.62. Found: C, 75.74; H, 8.64; N, 2.29%. Calcd for $C_{33}H_{45}O_6N\frac{1}{2}MeOH$: C, 75.65; H, 8.65; H, 2.58%.

3O-Acetyl-N-benzoyl-22, 27-imino-11-oxojerva-5, 12-diene-3β, 23β-diol (IIIe). To *N*-benzoyl-22, 27-imino-11-oxojerva-5, 12-diene-3β, 23β-diol (1.01 g) in pyridine (20 ml) there was added acetic anhydride (2 ml) at −10°C. The reaction mixture was set aside for four days at −5°C. To the reaction mixture, methanol was added and the mixture was heated for 2 hr on a water bath. The solvent was removed and to the residue water was added and this was extracted with chloroform (50 ml, 50 ml and 30 ml).

The chloroform solution was washed and dried. After the removal of the solvent the residue was chromatographed on alumina (Merck, standard, 25 g). Elution with benzene containing an increasing amount of ether gave diacyl derivative (231 mg), the mixture of di- and mono-acetyl derivatives (110 mg) and desired 3*O*-acetyl derivative IIIe (680 mg, 62%). The mono-acetyl derivative was recrystallized from aqueous ethanol (644 mg) mp 144.5—146°C. $[\alpha]_D^{18}$ −67.7° (*c* 2.1, methanol). IR: 1629 cm^{-1} (Ph–C=O), 1705 cm^{-1} (C=C–C=O) and 1735 cm^{-1} (–O–$COCH_3$) 3400 cm^{-1} (broad, OH). Found: C, 72.89; H, 8.51; N, 2.28%. Calcd for $C_{36}H_{47}O_5N\cdot H_2O$: C, 73.06; H, 8.35; N, 2.37%. After purification from aqueous ethanol, diacetate had mp 233—235°C. IR: 1633 cm^{-1} (benzoyl), 1702 cm^{-1} (C=C–C=O) and 1739 cm^{-1} (–$OCOCH_3$). Found: C, 73.66; H, 8.06; N, 2.76%. Calcd for $C_{38}H_{49}O_6N$: C, 74.11; H, 8.02; N, 2.27%.

The Nitrite (IIIf). 3*O*-Acetyl-*N*-benzoyl-22, 27-imino-11-oxojerva-5, 12-diene-3β, 23β-diol (336 mg) in dry pyridine (4 ml) was treated with nitrosyl chloride-pyridine mixture at −40°C until the solution persisted blue color. This was set aside for 22 min and poured into ice water (500 ml). The resultant precipitates of the nitrite were collected by filtration, washed with water and dried at room temperature under vacuum (344 mg), mp 206—208°C (decomp.). This nitrite was positive for the nitrite color reaction with diphenylamine-sulfuric acid and was unstable.

Photolysis of the Nitrite Ester. The nitrite ester (334 mg) above in dry benzene (18 ml) at room temperature and under an atmosphere of dry nitrogen was irradiated with a 150 W high pressure mercury arc lamp for 85 min. After this period the color reaction disclosed complete disappearance of the nitrite. After removal of the solvent under reduced pressure, the oily residue was chromatographed on silicic acid (10 g). Elution with benzene and then benzene containing ether (0.5 vol%) gave 38 mg of the least polar fraction (A). Then, the column was eluted with ethyl acetate-methanol mixture. Eluate (B) (287 mg) was obtained. Tritulation of (A) above with ether gave 42 mg of the residue. This was dissolved in ether (20 ml) and extracted with 5% aqueous sodium hydrogen carbonate (1.5 ml) and water (3 ml). Ethereal layer was washed with water and dried over sodium sulfate. Removal of ether yielded 17 mg of the residue (C). Aqueous layer was acidified to pH 1 with 1 N hydrochloric acid and extracted with ether. From this ethereal solution, benzoic acid (2 mg) was obtained. Preparative thin layer chromatography of the eluate (B) afforded 39 mg of aldehyde as the least polar fraction. Recrystallization of this from aqueous ethanol afforded the aldehyde IV, 15 mg, mp 189—192°C. IR and NMR spectra of this aldehyde were completely superimposable with that obtained from IIIc.

N-Methyl-22, 27-imino-11-oxojerva-5, 13(17)-diene-3β, 23β-diol (Ie). To a solution of liquid ammonia (300 ml) containing lithium (474 mg) there was added *N*-methyljervine[12] (3.92 g) in tetrahydrofuran (70 ml). A further amount of tetrahydrofuran (30 ml) was added while stirring. The mixture was stirred for 35 min and the blue color of the reaction mixture disappeared after this period. A further amount of lithium (30 mg) was added. Ammonium chloride (5 g) was added and the resulting colorless solution was kept at room temperature to remove ammonia and then tetrahydrofuran was removed under reduced pressure. To the residue there was added water (100 ml) and this was extracted with chloroform (four times, the total volume 450 ml). The chloroform layer was washed with water (150 ml), dried and evaporated. The residue was recrystallized from methanol. Crude Ie (2.59 g) was obtained in three crops. This was further recrystallized from methanol. Mp 185.5—189°C $[\alpha]_D^{18}$ +30.8° (*c* 2.5, pyridine). IR: 3400 cm^{-1}(OH), 1731 cm^{-1} (five membered C=O). NMR: τ 7.76 (N–Me), τ 8.09 (C-18 methyl) τ 9.06 (C-19 methyl). Found: C, 76.07; H, 9.87; N, 3.13%. Calcd for $C_{28}H_{43}NO_3$: C, 76.15; H, 9.81; N, 3.17%.

The Preparation of the Compound (IX). The compound Ie (292 mg) in methanol (10 ml) and 5% methanolic potassium hydroxide (2 ml) was refluxed for 2 hr under an atmosphere of dry nitrogen. To the reaction mixture methanol (10 ml) and 5% methanolic potassium hydroxide (2 ml) were again added and this was refluxed for 1 hr. After the removal of methanol, the residue was washed with water (30 ml) and dried (237 mg). This was recrystallized from methanol (156 mg). Mp 275—302°C (decomp.). IR: 3400 cm^{-1} (OH), 1731 cm^{-1} (five membered ketone). NMR: τ 7.84 (N–Me) τ 8.26 (C-18 methyl) τ 8.95 (C-19 methyl). Found: C, 75.95; H, 9.92; N, 3.01%. Calcd for $C_{28}H_{43}O_3N$: C, 76.15; H, 9.81; N, 3.17%.

The hydriodide was obtained as follows: the zwitterion IX (126 mg) in acetic acid (0.3 ml) was admixed with

aqueous potassium iodide (20%, 0.4 m*l*). The highly crystalline hydriodide deposited immediately. This was collected by filtration and recrystallized from ethanol to yield colorless needles, (73 mg) mp 300°C. Found: C, 59.19; H, 7.89; N, 2.43%. Calcd for $C_{28}H_{44}O_3NI$: C, 59.04; H, 7.79; N, 2.46%.

The authors are grateful to Mr. S. Shimokawa for the measurements of NMR spectra and to the staff of the laboratory for microanalyses, the Faculty of Pharmaceutical Science of Hokkaido University, for the elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 475—478 (1968)

Analyses of Organic Soils Extracted from Naturally-soiled Cloths

Teruo TSUNODA

Central Research Laboratory, Hitachi, Ltd., Kokubunji, Tokyo

(Received April 22, 1967)

The analyses of organic soils extracted from naturally-soiled chloths were carried out by IR spectroscopy, gas chromatography, thin-layer chromatography (TLC), and gel filtration. The fatty-acid constituents involved in organic soil were determined by gas chromatography. The presence of triglycerides, cholesterol and its ester, and such hydrocarbons as paraffin and squalene in organic soil was also found by means of TLC. In gel filtration, two peaks were found in elution diagrams of the detergent solution after washing naturally-soiled cloths. The ultraviolet spectra, which were measured for the effluent corresponding to each peak, indicated that the nitrogen compound involved in each effluent is probably a protein-lipid complex such as lipoprotein. The nitrogen content in each effluent was also determined by the micro-Kjeldahl method. A smaller nitrogen content was given for the effluent corresponding to the first peak than for that of the second peak. The nitrogen compound involved in the effluent for the first peak was harder to remove from cloths than that for the second peak.

Knowledge concerning natural soils adhering on cloths is necessary in order to investigate the detergency mechanism. The natural soils may be divided into two main groups; one is an inorganic soil for which dirt floated in an atmosphere is considered to be the main constituent, while the other is an organic soil consisting of skin fats.

A study has been made by Brown[1] of the amount and composition of the organic soil adhering to domestically-soiled fabrics. However, the constituents have not been shown in detail for each component involved in the organic soils. Bey[2] has reported the results of his analysis of skin-surface lipids which were transferred on to textiles or underwear during wearing. Oldenroth *et al.*[3] have also reported similar analytical results for organic soils extracted from underwear. The composition of human foream sebum and of adult human-hair fat have been determined by Wheatly[4] and Nicolaides *et al.*[5] respectively. Further, the compositions of human surface lipids have been reported in detail by Nicolaides *et al.*[6]

With the recent advance in the separation techniques of lipid mixture, such as gas and thin-layer chromatography, it has become possible to determine the constituents of natural lipids in detail. The purpose of this work is to determine the composition of organic soils extracted from naturally-soiled collars with such techniques as infrared spectroscopy, gas and thin-layer chromatography (TLC), and gel filtration.

Experimental

Two kinds of organic soils were prepared for analysis. Sample 1 and Sample 2 were prepared by extraction with methylene chloride for the soiled cloths supplied by the Lion Fat and Oil Co. and with petroleum ether for the soiled cloths prepared in our laboratory in a manner similar to that described by Tomiyama *et al.*[7] The two samples were essentially similar.

The composition of free fatty acid involved in the organic soil was determined by a Hitachi F6-D gas

chromatograph (with a flame-ionization-type detector) using a Golay column B. D. S. 45 m in length. The methylation[8] was performed by refluxing Sample 2 with a 5% HCl - methanol solution at 100°C for several hours.

The lipid components were detected by the TLC method. Silica gel (Wako gel B-O, Wako Pure Chemical Ind., Ltd.) was used as the adsorbent. The commercial solvents and reagents were used without purification. The adsorbent layer was produced on a 20×20 cm clean glass plate with a thickness of about 250 μ and equipped with an applicator (Yamato TL-1, Yamato Sci. Co., Ltd.), and then activated by heating in an oven at 110—120°C for 1—2 hr. After 10 m*l* of a dilute methylene chloride solution of each sample had been applied to the adsorbent layer with a microsyringe, the chromatoplate was dipped up to the depth of 1 cm into some developing solvent in a covered-glass vessel. The identification was carried out by heating the plate at 120—180°C in an oven after spraying it with concentrated H_2SO_4.

The Sephadex gel filtration technique was also attempted in order to find the nitrogen compounds involved in natural soils. Completely-swollen Sephadex G-100 gel after been in a 1% NaCl aqueous solution for 2 days was packed in the column 2.5 cm in diameter and 45 cm in height. After 10 m*l* of the sample solution had been added to the column, 0.1% NaCl aqueous solution was poured in from the top of the column. Nitrogen compounds in the effluents were detected by measuring the absorbance at 280 mμ with a Hitachi Perkin-Elmer spectrophotometer, 139.

Results and Discussion

Infrared Spectrum. The infrared spectrum of Sample 2 in a carbon tetrachloride solution is shown in Fig. 1. (A similar spectrum was obtained for Sample 1.) The IR spectrum exhibited characteristic peaks at 1740 cm^{-1} and 1710 cm^{-1} and a broad peak in the 1300—1100 cm^{-1} region which can not seen in the spectrum of the solvent. The peaks at 1740 cm^{-1} and 1300—1100 cm^{-1} were identical with those of the triolein, but that at 1710 cm^{-1} could not be observed in the triolein spectrum. The peaks at 1740 and 1710 cm^{-1} may be identified as, respectively, the stretching vibration in carbonyl groups in glyceride molecules such as triolein and that in free fatty acid molecules. Since the infrared spectrum shown in Fig. 1 was essentially identical with that of triolein except for the peak at 1710 cm^{-1}, it can be estimated that such triglycerides as triolein are present in naturally-soiled cloths. On the other hand, the existence of the peak at 1710 cm^{-1} indicates that free fatty acids are also present in the samples.

Gas Chromatography. A gas chromatogram of the fatty acid in Sample 2 is shown in Fig. 2. The results show that most of the fatty acids involved in this organic soil have carbon numbers from 14 to 18 in their molecules. For the C_{14} fatty acids, the peak height of saturated acid was greater than that of unsaturated fatty acids. In the C_{16} fatty acids, both are of equal height. On the contrary,

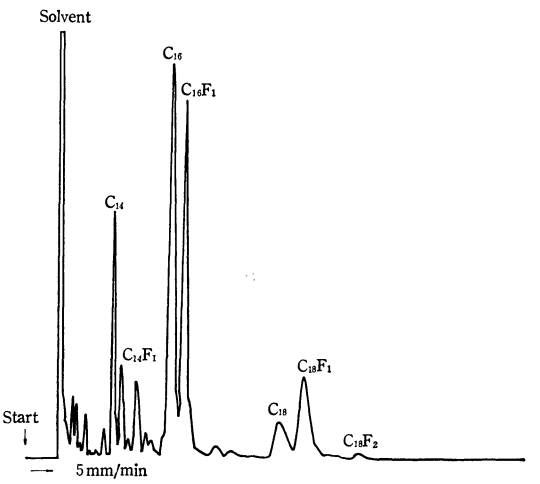

Fig. 2. Gas chromatographic analysis of fatty acids involved in a organic soil extracted from naturally soiled cloths.
Sample 2. 4 μ*l*, column: Golay B. D. S. 45 m, Oven temp.: 170°C, Injection block: 300°C, Carrier gas: N_2, Flow rate: 0.7 kg/cm², Attenuation: 10×4, Chart speed: 5 mm/min, Instrument: No. F6-D.

8) H. Schlenk and J. L. Gellerman, *Anal. Chem.*, **32**, 1412 (1960).

the order of peak height mentioned above was reversed in the case of C_{18} fatty acids. A similar result has been reported by Bey.[2] It is interesting that the ratio of the amount of unsaturated fatty acids to that of saturated acids increases with the increase in carbon number.

Thin-layer Chromatograph (TLC). By preliminary experiments it was found that the cyclohexane and a solution consisting of 1-nitropropane and *n*-hexane can be successfully used as solvents for the detection of nonpolar lipids, such as squalene and paraffin, and polar lipids, such as glycerides, cholesterol, and its stearate. It may be seen in Figs. 3 (solvent: cyclohexane) and 4 (solvent: solution consisting of 1-nitropropane and *n*-hexane) that paraffin, squalene, triglycerides, cholesterol, and its esters are involved in natural organic soils.

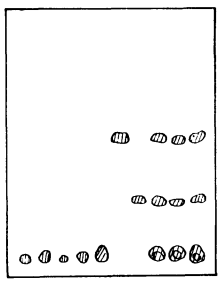

Fig. 3. Thin layer adsorption chromatographic separation of hydrocarbon involved in organic soils.
Solvent is cyclohexane.
a: Stearic acid b: Glycerin monostearate
c: Tristearin d: Cholesterol
e: Cholesterol stearate
f: Paraffin g: Squalene
h: Mixture of a—g lipids

h: Mixture of a—g lipids
i: Sample 1 j: Sample 2

Gel Filtration. Figure 5 shows the elution curves obtained for: (a) the distilled water, (b) the sodium dodecylbenzene sulfonate (NaBS) aqueous solution after washing the naturally-soiled cloths, and (c) a 0.1 wt% egg albumin aqueous solution containing 0.05 wt% NaBS.

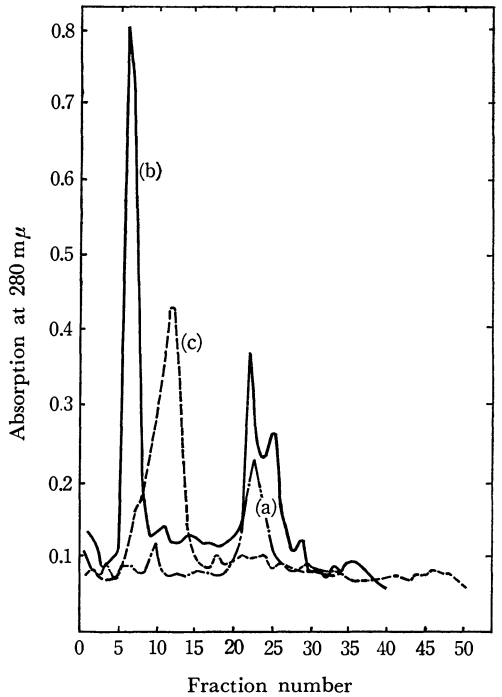

Fig. 5. The elution curve obtained for the distilled water (a), the NaBS aqueous solution after washing the naturally soiled cloths (b) and 0.1% NaBS (c).

A single peak appeared in fraction number 23 in the elution curve (a). On the other hand, two peaks were found in fractions number 6—8 and 22—26 in the elution curve (b). The heights of these peaks increase with the increase in the concentration of NaBS.

From a comparison of (b) with (c) in Fig. 5, we may find that the substance corresponding to the first peak in the curve (b) has a larger molecular size, while the substance corresponding to the second peak has a smaller molecular size, than the egg albumin molecule.

The nitrogen compound involved in the effluents of fractions number 6—8 could be removed from cloths only when a detergent solution was used for washing. Such interactions between proteins and detergents have been reported by Aoki *et al.*[9]

9) K. Aoki, *J. Am. Chem. Soc.*, **80**, 4904 (1958); K. Aoki and J. Hori, *ibid.*, **81**, 1885 (1959); K. Aoki, *Yushi*, **16**, [11] 21 (1963); **17**, [2] 26 (1964); **17**, [3] 12 (1964); **17**, [4] 20 (1964).

and by others.[10]

The Ultraviolet Spectra. Figure 6 shows the ultraviolet spectrum for each effluent corresponding to the first and second peaks in the elution curve (b) in Fig. 5, along with those of egg albumin and β-lipoprotein. The spectrum of egg albumin showed the characteristic absorption due to the polypeptide bond at 280 mμ, but a smaller plateau was found at 270 mμ in that of β-lipoprotein. In the spectrum of each effluent, the characteristic absorption found in egg albumin was not observed, but the inflection point near 270 mμ and the plateau in the region from 240 to 270 mμ were found for each effluent corresponding to the first and second peaks in Fig. 5, curve (b). The nitrogen compound involved in each effluent is not considered to be pure protein, but a protein-lipid complex such as lipoprotein.

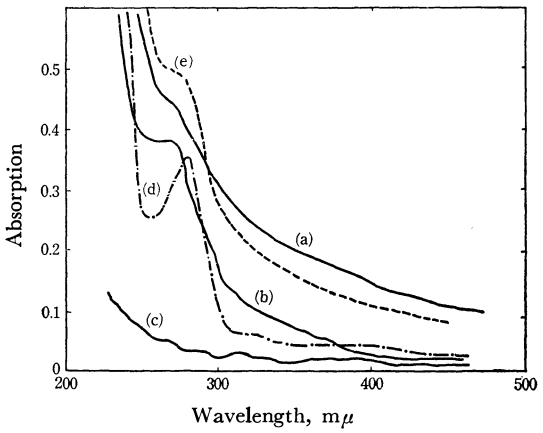

Fig. 6. Ultraviolet spectra.
- a : Effluent corresponding to first peak in curve (b) in Fig. 5.
- b : Effluent corresponding to second peak in curve (b) in Fig. 5.
- c : Effluent corresponding to fraction number 45 in Fig. 5.
- d : 1% egg albumin.
- e : β-Lipoprotein.

The nitrogen contents involved in the two effluents corresponding to the first and second peaks and egg albumin, as determined by the micro-Kjelder method, were 5.40, 13.50, and 65.60 γN/ml respectively.

The author wishes to express his hearty thanks to Professor I. Hara of Tokyo Medical and Dental University for his valuable discussions and for supplying the β-lipoprotein. He is also grateful to Mr. K. Komeji of Tokyo Metropolitan University and Mr. I. Kashiwa of Lion Fat and Oil Co. for supplying the cholesterol stearate and naturally-soiled cloth respectively. Grateful acknowledgment is also made to Mr. N. Ichiki for his gas chromatographic analysis of fatty acids and to Miss M. Imagawa for her assistance in the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 479—485 (1968)

The Zinc Oxide-Copper Catalyst for Carbon Monoxide-Shift Conversion. II. The Catalytic Activity and the Catalyst Structures

Hiroshi UCHIDA,*1 Masaaki OBA, Norio ISOGAI*2 and Toji HASEGAWA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received August 28, 1967)

Structures of the zinc oxide-copper catalysts, whose catalytic activity in carbon monoxide-shift conversion had been determined, were investigated by X-ray diffraction technique, mercury- and helium-volume measurement, and electron microscopy. The electron microscopic observations were conducted in two ways; one on a catalyst sample after the activity test and the other on a raw sample while undergoing specified treatments in a reaction chamber attached to the electron microscope. On the basis of models of particle geometry obtained from the electron microscopic images, the results on pore volume, average diameters of pores and particles, all dependent on the method of preparation and the chemical composition, are explained. The models and the observed dependency of the specific activity of copper surface on the copper content indicate that the finer copper particles, whether patch-like or massive, show the higher specific activity. The fine copper particle is apt to be oxidized more readily than the well-grown particle.

The preceding paper[1] described how the preparation method and the chemical composition of zinc oxide-copper catalysts are related to their catalytic activity in carbon monoxide-shift conversion. The catalysts studied were a series of catalysts of varying copper contents prepared by kneading zinc oxide powder with copper hydroxide cake (the kneaded series) and a couple of catalysts of an approximate copper content prepared by the impregnation and the coprecipitation method. Practicable catalysts could be produced only by the kneading process provided they contained appropriate amounts of copper. As regards the kneaded series, a model of particle geometry that copper forms its own particles among the original zinc oxide powders was tentatively proposed and successful in an attempt of explaining the observed dependency of catalytic activity on the chemical composition, but exact knowledge on structures of the catalysts is still lacking. In the present study, the catalyst structures will be investigated, the results of which may be used for an understanding of the catalytic activity from the structural viewpoint of the catalysts.

Experimental

Table 1 presents the method of preparation and the chemical composition of catalysts repeatedly. Experimental methods used for investigating catalyst structures include X-ray diffraction technique, mercury- and helium-displacement method, and electron microscopy.

The X-ray diffraction diagram for a powdered sample of the catalyst was obtained with an X-ray diffractometer of the Geigerflex D-3F type. The nickel filtered Cu$K\alpha$ radiation from a sealed-off tube with berylium windows was used. The tube was operated at 40 kV and 18 mA. The volumes by the mercury- and helium-displacement method were determined on catalyst grains after they had been used in the activity test for carbon monoxide-shift conversion.

TABLE 1. METHOD OF PREPARATION AND CHEMICAL COMPOSITION OF CATALYSTS

Catalyst No.	Method of preparation	Cu/Zn atomic ratio
1	Kneading[a)]	ZnO
2	Kneading[a)]	0.09
3	Kneading[a)]	0.25
4	Kneading[a)]	0.45
5	Kneading[a)]	0.68

1) H. Uchida, N. Isogai, M. Oba and T. Hasegawa, This Bulletin, **40**, 1981 (1967).

The size and shape of particles of a catalyst sample after the activity test were examined under an electron microscope of the JEM-6A type. Moreover, changes in shape of particles were pursued under the electron microscope on a dried paste (the sample after drying at 150°C a pasty mixture of oxide or hydroxide of zinc and copper hydroxide) while the paste was undergoing such treatments as heating in the air and subsequent reduction in hydrogen. In particular cases, the paste was oxidized finally in the air. These treatments were conducted in a reaction chamber attached to the electron microscope.

The reaction chamber is schematically drawn in Figs. 1A and 1B. The chamber is a stainless steel cylinder (C) (110 mm diameter by 100 mm long) and attached to the electron microscope by way of an air-lock (L). It is equipped with two valves, one (V) for introduction of a reactant gas (hydrogen or air) at a constant feed rate (10 *l*/hr) at atmospheric pressure and another (V') either for withdrawal of the gas at atmospheric pressure or for evacuation. A holding device (A, for details see Fig. 1B showing another side of 1A) of a sample is centrally held in the chamber by means of a perforated stainless steel rod (R) inserted from top of the chamber. Through the perforation pass an insulated Pt-Pt·Rh thermocouple and two insulated nichrome wires leading to a nichrome wire heater (I). A stainless steel sample holder (H), which is similar in dimension to the one as conventional in the electron microscopic observation and which has small ceramic protruding parts around its supporting drim, is mounted vertically in a notched steatite cylinder having a steatite drim (J). The nichrome wire heater (I) is wound along the notch. The steatite drim is fixed to the rod (R) one over another together with a stainless steel plate (K), into which a stainless steel tube for protection of the heater is screwed. A horizontally movable rod (M) with a fork at the end carries the sample holder, while the holder being hung by the ceramic protruding parts, into and out of the electron microscope through the air-lock open.*3

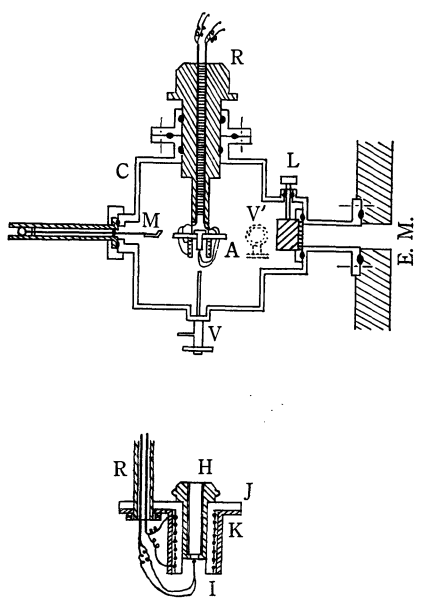

Fig. 1. Schematic diagram of reaction chamber.
Above: Fig. 1A, below: Fig. 1B

The sample was ground in a mortar to powder. The powder was sprinkled by means of an adsorbent cotton over an evaporated silica film supported on a stainless steel mesh, which was then placed at bottom in the sample holder. The temperature at which the sample was undergoing progressive reduction processes in hydrogen or oxidation in the air was measured with the Pt-Pt·Rh thermocouple just below the mesh. The electron microscopic observations were conducted at time intervals after the successive treatments of a short period.

Results

The X-Ray Diffraction Diagram. The raw copper hydroxide cake gave a complicated diffraction diagram, indicating the presence of basic copper hydroxide, $Cu_2(OH)_3(NO_3)$, in addition to that of copper hydroxide. However, no more sign other than oxides of copper and zinc appeared in the diagram of the finished sample.*4 This reveals rapid decomposition of both the basic hydroxide and the hydroxide into the oxide by a simple heat-treatment in the air at 250°C. After having been used in the activity test, all the samples including catalysts 21 (the impregnated catalyst) and 22 (the coprecipitated catalyst) gave sharp diffraction lines due to zinc oxide and copper in addition to very weak and diffused lines due to copper oxide (*e. g.* Ref. Fig. 2 for catalyst 4). Lattice constants of the zinc oxide were found to be $a=3.255$—3.285 Å and $c=1.60$ Å, while the constant of copper $a=3.618$—3.628 Å, the values being identical with the literature values.

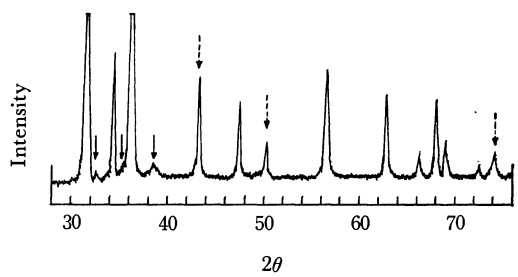

Fig. 2. X-Ray diffraction diagram of catalyst 4 after use in activity test.
The arrows indicate the lines due to copper oxide.

The Total Pore Volume and the Porosity. The mercury-volume and the helium-volume (hereafter denoted by V_{Hg} and V_{He} respectively) of catalyst grains are presented in Fig. 3 as a function of the catalyst chemical composition expressed

*3 Details of procedures for the observation will be described elsewhere.

*4 Refer to the foot note of Table 1.

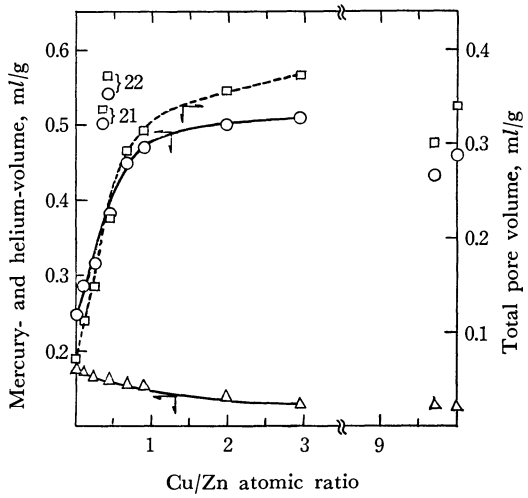

Fig. 3. Mercury- and helium-volume and total pore volume as function of Cu/Zn atomic ratio.
○: V_{Hg}, △: V_{He}, □: V_{po}

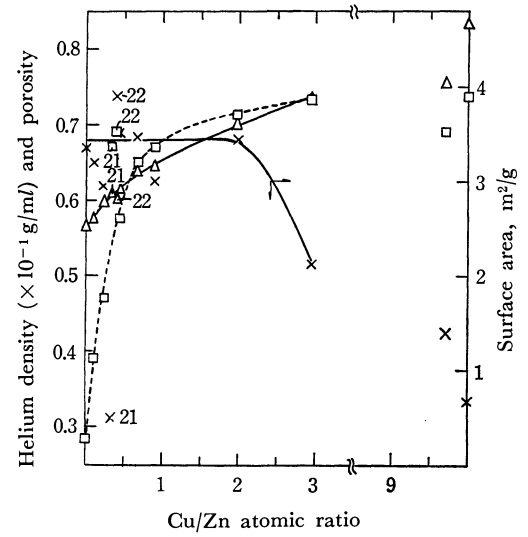

Fig. 4. Helium-density, porosity, and specific surface area plotted against Cu/Zn atomic ratio.
□: porosity, △: ρ_t, ×: S

by the Cu/Zn atomic ratio. The total pore volume (V_{po}) was then obtained as the difference between V_{Hg} and V_{He}, while the porosity (θ) as the ratio of V_{po} to V_{Hg}. The V_{po} and the θ are plotted in Figs. 3 and 4 against the Cu/Zn atomic ratio respectively. These two plots similarly rise rapidly with the ratio in the initial range below 1, less steeply in the intermediate range. In the final range of high ratios (probably >5), the V_{po} turns to fall, whereas the θ remains almost constant. The V_{po} values of catalysts 21 and 22 are much larger than those of catalyst 4, the corresponding catalyst (the catalyst approximate in copper content) of the kneaded series.

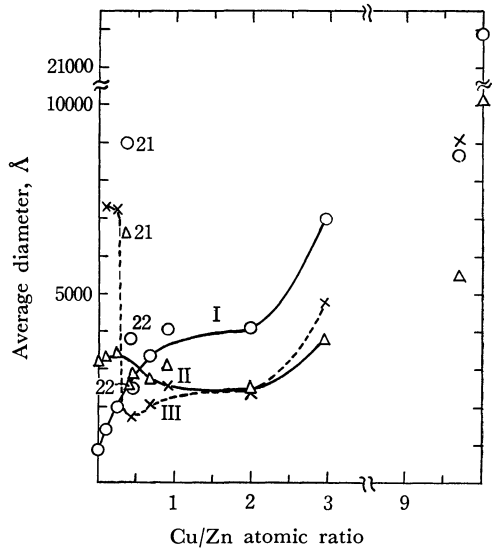

Fig. 5. Average diameters of pores and particles as function of Cu/Zn atomic ratio.
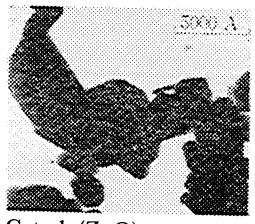
○ (I): $\bar{d}_{po}$, △ (II): $\bar{d}_{pa}$, × (IIII): $\bar{d}_{paCu}$ calculated on the basis of model II in the preceding paper.

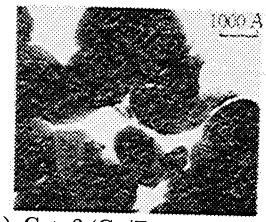
The Average Diameter of Pores and Particles. On the assumption of cylindrical pores the average pore diameter ($\bar{d}_{po}$) was claculated by the equation of $\bar{d}_{po}=4V_{po}/S$, where S was the specific surface area of catalyst, on the assumption of spherical or cubic particles the average particle diameter ($\bar{d}_{po}$) was calculated by the equation of $\bar{d}_{pa}=6/\rho_t S$, where ρ_t was the true density or $1/V_{He}$ (Ref. the plot in Fig. 4). Plots of the $\bar{d}_{po}$ and the $\bar{d}_{pa}$ against the Cu/Zn atomic ratio are shown in Fig. 5 (the plots I and II respectively). As the copper content increases, an initial rapid rise in the plot of $\bar{d}_{po}$ is followed with a slower rise. In contrast, the plot of $\bar{d}_{pa}$ first rises very slowly, turns to fall at a ratio of *ca.* 0.3, and finally rises again after passing through a minimum at a ratio of 2.0. For both of these plots, the rises in the range of very high ratios seem not so rapid.

The $\bar{d}_{po}$ and $\bar{d}_{pa}$ values of catalysts 21 and 22 do not fit the respective plots of the kneaded series; as compared with catalyst 4, these two catalysts show the $\bar{d}_{po}$ values somewhat large, but the $\bar{d}_{pa}$ value is slightly small for catalyst 22 and considerably large for catalyst 21.

The Electron Microscopic Image. Figure 6-(a) presents an electron micrograph of powders of the raw zinc oxide, while electron micrographs of catalysts 2, 4, and 8 after the activity test are shown in (b), (c), and (d), of the same figure respectively. On these latter micrographs, it is difficult to immediately distinguish between zinc oxide

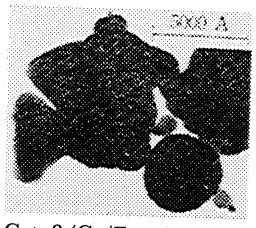


(a) Cat. 1 (ZnO)

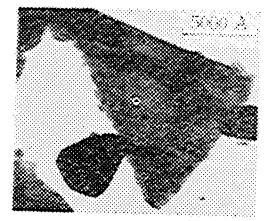


(b) Cat. 2 (Cu/Zn=0.09) after use in activity test

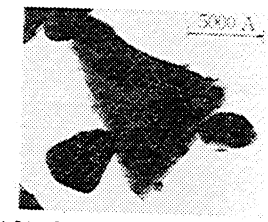
(c) Cat. 4 (Cu/Zn=0.45) after use in activity test



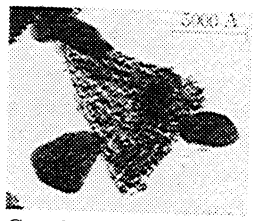
(d) Cat. 8 (Cu/Zu=2.95) after use in activity test



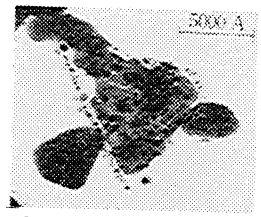
(e) Cat. 8 (Cu/Zn=2.95), dried paste



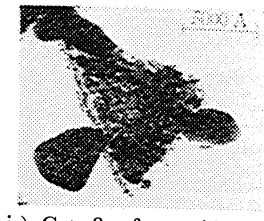
(f) Cat. 8, after heating of sample of (e) in air at 250°C for 5 min



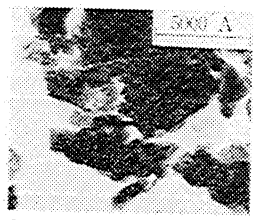
(g) Cat. 8, after reduction of sample (f) in H_2 at 180°C for 5 min



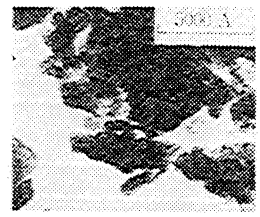
(h) Cat. 8, after further reduction of sample of (g) in H_2 at 350°C for 5 min



(i) Cat. 8, after oxidation of sample of (h) in air at 200°C for 2 min

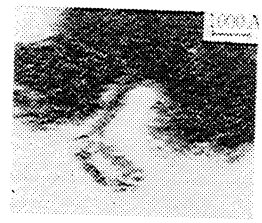


(j) Cat 21 (impregnated cat., Cu/Zn=0.34), after heating dried sample in air at 250°C for 5 min



(k) Cat. 21 after reduction of sample of (j) in H_2 at 250°C for 5 min and at 400°C for 5 min

(l) Cat. 22 (coprecipitated cat., Cu/Zn=0.40), after heating dried sample in air at 250°C for 5 min



(m) Cat. 22 after reduction of sample of (l) in H_2 at 250°C for 5 min at 400°C for 5 min

Fig. 6. Electron micrographs [(a)—(m)].

and copper, but further insight into this can be obtained by refering to a series of micrographs (e)-(h), which illustrate changes in size and shape of both a copper hydroxide particle and a zinc oxide powder of a dried paste (the paste for preparation of catalyst 8) while the paste is under going the specific treatments in the reaction chamber.

In contrast to the pracitcally non-porous zinc oxide powder of distinct contour, the copper hydroxide particle in the dried paste is characterized by its thin plate-like structure of a comparatively large dimension [Ref. (e)]; a part of this plate seems to have been torn into pieces, which lie on the surface of the zinc oxide powder. On heating at 250°C, the plate-like particle shrinks a little with simultaneous production of a large number of extremely fine copper oxide particles within [Ref. (f)]. When reduced with hydrogen at 180°C for a short period, these fine particles exhibit considerable mobility and grow to irregularly shaped particles of several hunderd Å in width [Ref. (g), conveniently designated as the primary particles hereafter]. On futher reduction at a higher temperature of 350°C, large majority of these primary particles stick together to form a plate-like aggregate (the secondary particle) of copper occupying a slightly smaller area than before, while a part of them is left behind along periphery of the previous plate-like particle [Ref. (h)]. This aggregate is rather inhomogeneous in structure. Meanwhile, the pieces of copper oxide having lied on the surface of a zinc oxide powder are reduced *in situ* to form patches of copper. It should be emphasized that the primary particles of copper do not tend to stick to the zinc oxide powder. The zinc oxide powder preserves its size and shape throughout these treatments, and this is also true even for the catalyst smaple after the activity test [Ref. (b) and (c)].

On the basis of information available on a series of micrographs (e)-(h), it is possible to state that the particle image with an obscure contour in the series (b)-(d) represents a copper particle. It has appeared, accordingly, that copper in the sample after the activity test often forms, in addition to its massive particles, its thin, small flakes lying flat on the surface of zinc oxide powder. This is particularly the case with catalysts containing relatively small amounts of copper [Ref. (b) and (c)]; as the copper content is increased progressively, the massive particles increase in number at the expense of the thin flakes, insofar as the copper content remains within a certain limit [compare (b) with (c)]. However, matters are different for catalyst 8 of a high copper content [Ref. (d)]; the zinc oxide powder in the sample after the activity test is seemingly covered, at least partially, with layers of copper and frequently a few of these powders collect together to form an irregularly shaped, much larger aggregate [Ref. (d)].

The electron micrographs of catalysts 21 and 22 after the activity test appear quite different from that of catalyst 4; the particle is as large as that of catalyst 4, but shows too homogeneous a structure to permit a distinction to be made between zinc oxide and copper.*5 Although the original zinc oxide powder is not at all disintegrated by having been kneaded with a copper hydroxide cake, the powder is disintegrated at some depth from periphery by impregnation with a copper nitrate solution [Ref. (j)], and copper produced by reduction in this region is disperesed homogeneously in zinc oxide [Ref. (k)]. With catalyst 22, mutual dispersion between the two components is finer in degree than with catalyst 21, before as well as after reduction [Ref. (l) and (m), and also compare (m) with (k)]. The pronounced particle growth taking place with these two catalysts during the activity test may perhaps be due to a some less stable structure of the particles, but nothing more decisive can be said.

Upon oxidation with air at 200°C for a short period, the copper aggreagte (the secondary particle) in (h) for catalyst 8 is readily back in size and shape to the previous aggregate in (g). No trasformation of this kind, however, was observed for such a well grown copper particle with a smoothed, sharply outlined contour of the same catalyst as shown in (d), even though the particle had been oxidized at a higher temperature of 300°C.*5 These findings reveal that the secondary particle which is an aggregate of the small primary particles with uneven surfaces is oxidized more easily than the massive, large particle with a smoothed surface.

Discussion

The Total Pore Volume and the Average Pore Diameter. In the light of the results of the electron microscopic observations, an attempt will be here made to explain the trends in the changes of V_{po} and $\bar{d}_{po}$ with the copper content for the catalysts of the kneaded series (Ref. Fig. 3 and the plot I in Fig. 5 respectively). If the catalyst contains not so large a amount of copper, the greater part of copper exists, immediately after reduction, as the plate-like aggregates among the zinc oxide powders, and each of these aggreagates transforms *in situ,* with shrinking, to a massive particle after the catalysts have been used in the activity test, whereas each of the original zinc oxide powders remains unaltered in size and shape. Accordingly, the larger the copper content is the larger is the V_{po}, which has been produced within original matrix of zinc oxide powders by the shrinking of aggreagates. Since the $\bar{d}_{po}$ is related to the V_{po} through the equation of $\bar{d}_{po}=4V_{po}/S$,

*5 The electron micrograph is not presented here in order to reduce number of micrographs.

the $\bar{d}_{po}$ is to change in the same way as the V_{po} does if the S differes little with copper content. This is, in fact, the case with this series of catalysts (Ref. the plot I in Fig. 4). If the catalyst, however, contains a very large amount of copper, the zinc oxide powder becomes covered with layers of copper after the activity test and, as a consequence, more easily sinter with each other to grow to large aggregates. This results in the V_{po} decreasing with the copper content (Ref. Fig. 3). In spite of this decrease in the V_{po}, the $\bar{d}_{po}$ in this range still decreases, which fact may come from the S decreasing more rapidly with the copper content (Ref. the plot in Fig. 4) than the V_{po}.

The abnormally high V_{po} values of catalyst 21 and 22, as compared with that of catalyst 4, can not be explained on the basis of the results of electron microscopic observations alone. This may perhaps be ascribed to the difficulty in finishing the raw paste to pellets as dense as those of the kneaded series.

The Average Particle Diameter. The previous particle model (model II in the preceding paper[1]) by no means accounts for the initial slow rise in the plot of $\bar{d}_{pa}$ (Ref. the plot II in Fig. 5). The model was conveniently proposed in order to explain the change in the specific activity of copper surface with varying copper contents, and it was assumed that, for every catalyst studied, particles consisting of copper alone were distributed among the original zinc oxide powders. However, the previous model has proved to agree only incompletely with the models of particle geometry presented in this paper. Provided the catalysts contain not a very large amount of copper, portion of copper exists as patches on the surface of zinc oxide powder, while another portion as massive particles. According to this model, the copper added is to contribute for enlarging the $\bar{d}_{pa}$ rather than reducing it, which is justified with the initial rise in the plot. In the range of moderate copper contents, the previous model has proved to be almost true; the $\bar{d}_{pa}$ is then likely to decrease as the copper content is increased, because the copper particles, which are small in size as compared with the zinc oxide powders, increase in number. The previous model differs again in the range of sufficiently large copper contents; the original zinc oxide powder is covered with layers of copper. This may bring about easier particle growth by agglomeration, and hence a rise in the plot of $\bar{d}_{pa}$. Neither the previous model fails to explain this rise, but the present explanation, being based on a more concrete model, is preferable.

In the preceding paper,[1] the surface area of copper per 1 g of catalyst, S_{Cu}, was calculated on the basis of the previous model. However, this model has proved to agree with the electron microscopic images only for the catalysts of moderate copper contents, and the S_{Cu} values might, in general, have been subject to considerable error except for the above-stated catalysts. In fact, calculation of the average diameter, $\bar{d}_{paCu}$, of copper particles by $\bar{d}_{paCu}=6/S_{Cu}\rho_{Cu}$ (ρ_{Cu}, the copper density$=8.92$) using the previous S_{Cu} values results in unreasonably large values with the catalysts of a very small copper content (Ref. the plot **III** in Fig. 5). The previously calculated values of S_{Cu} must have been underestimated for any of the catalysts containing either a very small or a very large amount of copper, because the calculation of S_{Cu} for this was conducted without consideration of the copper surface area due to patches or layers of copper on a zinc oxide powder. Unfortunately, it is difficult, however, to evaluate accurate extents of adjustment from the data available.

The Structure of Copper Responsible for the High Specific Activity. In the preceding paper,[1] the specific activity of copper surface (the activity per unit of area of the copper surface) at a reaction temperature, *e. g.*, of 180°C, k'_{Cu180}, was obtained by the equation of $k'_{Cu180}=k_{180}/\rho_b S_{Cu}$, where k_{180} was the rate constant*6 at 180°C per unit of volume of the catalyst bed, and ρ_b is the catalyst bed density, on the reasonable assumption that only the copper surface is effective in the reaction. The k'_{Cu180} values obtained by the use of the previous S_{Cu} values were very high in the range of very small copper contents, fell rapidly and then gradually with the copper content.[1] In this connection, the k'_{Cu180} values in each of the two extreme ranges of either very small (the lower range) or very large copper contents (the upper range) should be more or less reduced from the previous values owing to the k'_{Cu} values having been underestimated, whereas the values in the range between these extremes (the intermediate range, 0.4—2.0 in the Cu/Zn atomic ratio) are to vary little from the previous values. Nevertheless, the decreasing trend of k'_{Cu180} with the copper content is likely to be retained, though only qualitatively, over the whole range studied; even though the k'_{Cu180} value in the two extreme ranges is reduced, the decreasing trend of the k'_{Cu180} with the copper content in the upper range is not affected substantially and at the same time any downward bend is scarcely suspected with the plot of the k'_{Cu180} rising with the decreasing copper content in the lower range, where the activation energy of reaction is lowering with the decreasing copper content.[1] This and the present models of particle geometry indicate that the finer copper particles, whether patch-like or massive, are responsible in structure for the higher specific activity.

*6 The k was calculated by the aid of the rate equation of Kul'kova-Temkin.[2]

Taking into account the finding that the finer copper particles are oxidized more easily, it may be concluded that the copper surface participates in the reaction to the extent that the surface is apt to be oxidized. This may lend another support, though not directly, to the view of Temkin *et al.*[2,3] on the reaction rate over an iron oxide, who proposed a mechanism according to which the gaseous components react with oxidized and reduced surface sites as expressed by the following scheme:

$$CO + (O) = CO_2 + (\ )$$

$$H_2O + (\ ) = H_2 + (O)$$

where ( ) and (O) designate reduced and oxidized site respectively.

The poor and unstable activity, in spite of the mutual dispersion between zinc oxide and copper, of catalysts 21 and 22 is explained only with difficulty. A probable explanation for this may be that too fine a dispersion, in turn, causes copper to be included into interior of the particle and a small extent of copper becomes available on the particle surface.

Effect of Pressure on Graphitization of Carbon. I. Heat Treatment of Soft Carbon under 1, 3 and 5 kbar

Tokiti NODA,*1 Kanichi KAMIYA and Michio INAGAKI

Faculty of Engineering, Nagoya Universisty, Nagoya

(Received October 4, 1967)

Polyvinylchloride coke was heat-treated under the quasi-hydrostatic pressure of 1, 3, and 5 kbar by using a simple piston cylinder type high pressure apparatus. The process of graphitization under pressure was studied kinetically by analyzing the profile of the (002) diffraction line. It was found that the accelerating effect of pressure on the graphitization of carbon became more pronounced at higher pressure. The process of graphitization under 3, and 5 kbar seemed to take place in at least two stages. In the first stage, the profile of the (002) line shifted simply from the position of the original line to 26.0° in 2θ, which corresponded to a c_0-spacing of 6.85 Å. In the next stage, a new component, having a c_0-spacing of about 6.72 Å, appeared in addition to the first component, having a c_0-spacing of 6.85 Å. Therefore, the profiles of the (002) line became composite. Under 1 kbar, however, no composite profiles were observed and the c_0-spacing decreased gradually with heat treatment. Approximate values for the activation energy and activation volume for graphitization under 3—5 kbar were estimated to be 80—120 kcal/mol, and −7——9 cc/mol, respectively.

It has been reported that the graphitizing cokes, such as petroleum coke and polyvinylchloride coke, graphitized very rapidly at around 1500°C under a pressure of 10 kbar.[1] Profiles of the (002) diffraction line of the cokes heat-treated at 1400—1500°C under 10 kbar were found to be composite, while no composite profiles were found with heat treatment of the same cokes under a reduced pressure of 10^{-2} Torr.[1] A kinetic study of the graphitization could not be carried out at a pressure as high as 10 kbar, because of the high rate of graphitization.

In the present work, the heat treatment of polyvinylchloride coke under pressures of 1, 3, and 5 kbar was carried out for various durations at various temperatures, in order to learn the effect of pressure on the graphitization of carbon, and also to obtain more precise information on the composite profile of (00*l*) diffraction.

Experimental

Sample and Apparatus. The sample used was a graphitizing coke PV-7, which was also used in previous work.[1] The coke was prepared by carbonizing polyvinylchloride at 680°C, and was examined spectroscopically and found to contain only negligible amounts of inorganic impurities. The coke had a paricle size in the range of 0.1 to 0.4 mm.

The high pressure apparatus used was of a simple piston-cylinder type. It was made of tool steel, having a hardness of R. C. 64, and a bore diameter of 24 mm.

Such a piston-cylinder type apparatus made of tool steel has been known to last up to 10 kbar at room temperature.[2] The whole apparatus was immersed in water for cooling during the experiment. The arrangement of the specimen cell is shown in Fig. 1. Boron nitride (h in the figure) was placed between a graphite heater and pyrophyllite in order to prevent chemical reaction between them. A glassy carbon tube (f in the figure) played the role of preventing contamination of the sample. A heating current was passed through the pistons into a graphite tube heater. The pistons were insulated from the cylinder by a composite sheet of asbestos and Myler film. The temperature of the central part of the sample was evaluated from the relation between heating input power and temperature, which had been determined beforehand up to about 1200°C using a chromel-alumel thermocouple. The relations between input power and temperature were determined at different pressures and are shown in Fig. 2. A thermocouple inserted in the specimen probably makes a heat sink which may cause a small decrease in the temperature of the specimen. In most of the actual runs, no thermocouple was inserted in the specimen, and therefore the heat treatment temperature of the specimen could be a little higher than the temperature estimated from the input power. However, the difference may be within the error of temperature measurement, because the input power for the melting of platinum under 5 kbar (1800°C[3]) with in same arrangement was exactly on the extrapolated straight line of the upper part of the curve for 5 kbar.

There was a very large temperature gradient in the specimen along the axial direction of the graphite heater, the temperature of the end part of the specimen being about 10% lower than that of the central part. The temperature of the specimen was controlled manually by regulating the input power. The error in

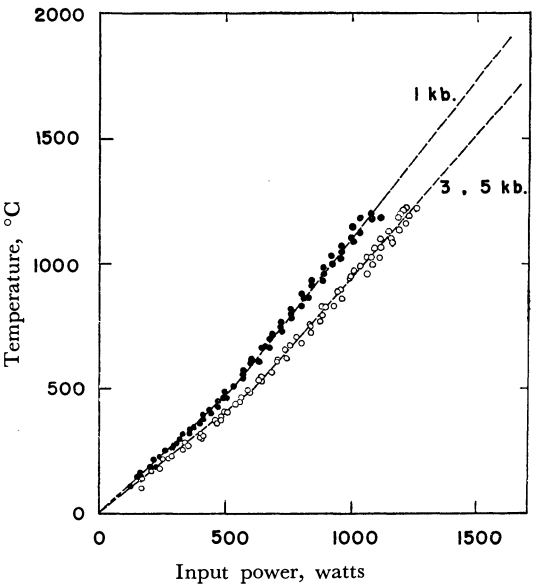

Fig. 2. Relations between input power and temperature under different pressures.

the determination of the heat treatment temperature was estimated to be ±50°C at 2000°C from the scattering of the points in the relation between input power and temperature, and from the variation of input power regulation. The heating rate was about 1000°C/min and the specimen was cooled down to room temperature within a few minutes by cutting off the power. The maximum temperature which was attainable depended strongly on the arrangement of the specimen cell. By using the arrangement shown in Fig. 1, a temperature up to 1800°C was attained under 1 kbar, and 2000°C under 5 kbar.

The pressure was transmitted through pyrophyllite, so that quasi-hydrostatic pressure was applied to the sample. The pressure was calibrated by use of the phase transition of neutral ammonium fluoride, which occurs at 3.7 kbar with a volume change of about 28%,[4] The error in the pressure measurement was estimated to be ±0.2 kbar from the scattering of four independently measured values of the phase transition.

The heat treatments of the sample were carried out at temperatures ranging from 1100°C to 1900°C for 3 to 90 min under 1, 3, and 5 kbar. The central part (about 1 mm thick) of the heat-treated specimen was used for the X-ray diffraction analysis, in order to avoid ambiguity caused by the temperature gradient along the specimen.

Analysis of X-Ray Diffraction Profiles. The profiles of the (002), and (004) diffraction lines for the heat-treated specimen were measured by using a recording X-ray diffractometer and Ni-filtered Cu$K\alpha$ radiation. Most of the profiles obtained were composite, as can be seen in Figs. 3b), and c). All the composite profiles appear to have two peaks at around 26.0° and 26.5° in 2θ. The occurrence of a composite profile indicates that there must be more than one independent range to produce coherent scattering of X-rays,

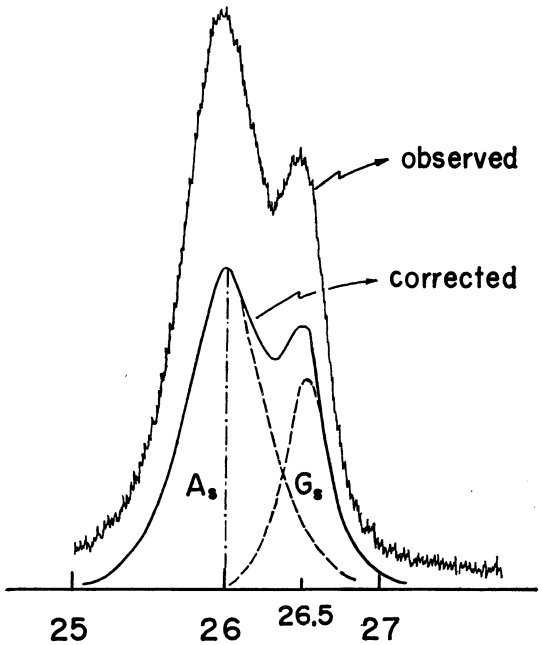

Fig. 4. Schema of separation of composite profile.

and therefore the composite profile can be separated into its component profiles.[5] The procedure for the separation of an observed composite profile into its component profiles is illustrated in Fig. 4. After correction for the Lorentz-polarization, atomic scattering and absorption factors by the conventional method,[6] the profile on the low angle side is folded at 26.0°, the reason for which will be described later. When the component profile at 26.0° is subtracted from the composite profile, the balance gives an almost symmetrical and sharp peak at around 26.5°. The components, correspond to the separated profiles at 26.0°, and at 26.5°, are designated as A_s, and G_s, respectively.*2 The areas under the separated component profiles were measured by using a planimeter, and the ratio of the area of the profile of the component G_s to the total area of the composite profile was calculated. This area ratio is sensitive to the preferred orientation of the crystallite in the specimen used for X-ray measurement. The correction of the area ratio for the preferred orientation was carried out by using the calibration curve, because the quantity of specimens for X-ray measurement was so small that direct measurement of the preferred orientation of crystallites in the specimen could not be carried out. The calibration curve was determined by using known mixtures of two kinds of petroleum cokes, one treated at 1600°C, and the other treated at 3200°C, which have the same diffraction angles as those of the component profiles, 26.0°, and 26.5°, respectively.

Results

Profiles of the (002) diffraction line for specimens heat-treated under 1 kbar are shown in Fig. 3 a). The diffraction angle of the line increased and its half-width decreased with increase in heat treatment temperature (HTT) and residence time, similar to the changes for heat treatments under room or reduced pressure. Changes of the (002) profile under 3 kbar are shown in Fig. 3 b). At low temperature and short residence time for heat treatment, the diffraction angle and half-width of the line changed the same as in the case of 1 kbar. When the diffraction angle of the line reached to

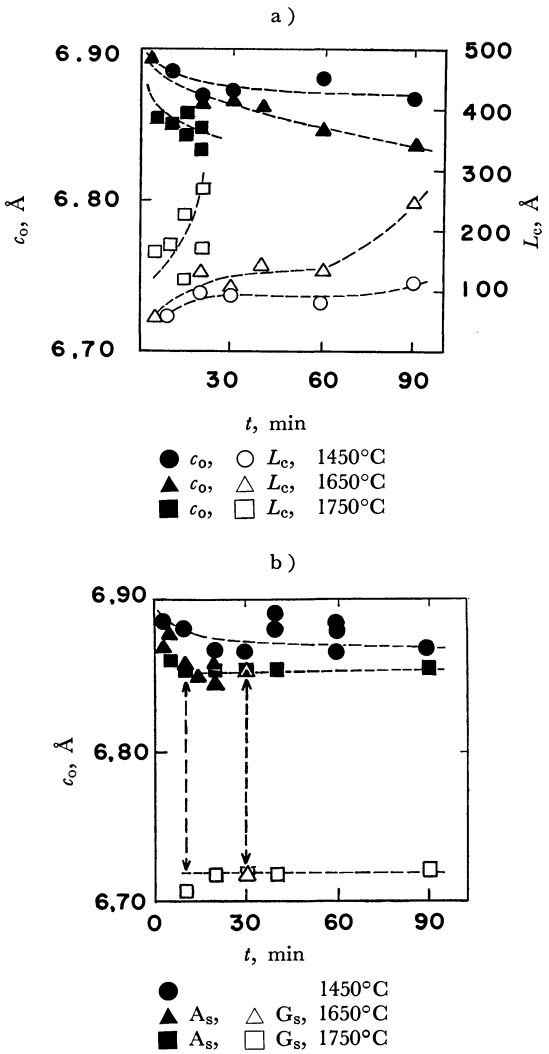

Fig. 5. Changes of c_o-spacing and crystallite size L_c with residence time.
a) under 1 kbar, b) under 3 kbar.

6) W. R. Ruston, *Fuel*, **32**, 53 (1953).
*2 For a hard carbon heat-treated under 5 kbar, the authors found a similar composite profile, which seemed to consist of two components. In the present work, the components of soft carbon were distinguished from those of hard carbon by using a suffix "s," because they might not have the same structures.

26.0°C, however, a new sharp peak for the component G_s appeared at 26.5°, overlapping the profile for the component A_s. With further heat treatment, this sharp profile for G_s developed without appreciable change in the diffraction angle. Almost the same changes in the profile of the (002) diffraction line were observed under 5 kbar (Fig. 3 c)), but the change occured at lower temperature, or in a shorter time than in the case of 3 kbar. In the heat treatments under 3, and 5 kbar, the diffraction angle of the profile for the component A_s stayed unchanged at 26.0° after the appearance of the profile for the component G_s. This is the reason why the position of the profile for A_s was fixed at 26.0° when the observed composite profile was separated into its component profiles, as illustrated above.

Changes in the c_0-spacing and crystallite size L_c of the specimens heat-treated under 1 kbar with residence time are shown in Fig. 5 a). Comparing these changes with those of the same coke under reduced pressure,[1] the accelerating effect of pressure on graphitization of carbon becomes very evident. In Fig. 5 b), the changes in the c_0-spacing of the specimens heat-treated under 3 kbar with residence time are shown. Under 3 kbar, the component G_s was observed to appear in 30 min at 1650°C, and in 10 min at 1750°C, while at 1450°C no indication of the component G_s was observed in 90 min. The crystallite size of the component A_s increased gradually from 100 to 200 Å, while that of the component G_s was about 300 Å. Change in the content of the component G_s with residence time is shown in Fig. 6. The content of G_s increased to about 50% in 90 min at 1750°C. Changes in the c_0-spacing of the components A_s and G_s of the specimens heat-

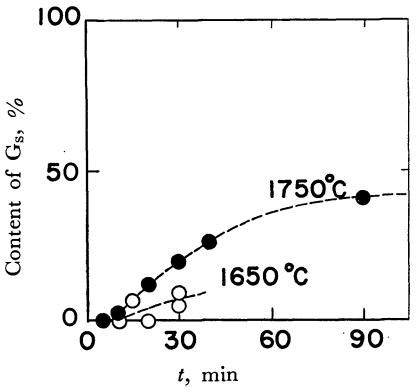

Fig. 6. Changes of content of the component G_s with residence time under 3 kbar.

treated under 5 kbar with HTT for various residence times are shown in Fig. 7 a). The c_0-spacing of the component A_s decreased to 6.85 Å around 1600°C in 3 min, around 1350°C in 20 min, and around 1300°C in 60 min. Changes in the content of the component G_s with HTT under 5 kbar are shown in Fig. 8 a) The intersection of these curves with the abscissa, or the temperature at which the component G_s begins to appear, should be about the same as those at which the c_0-spacing of the component A_s reaches 6.85 Å. The shape of the curves appears to be the same for different residence times, and they may be superimposed by translation along the abscissa. Such a superimposed curve for a residence time of 10 min is shown in Fig. 8 b). It is evident that the superimposition works quite well. Therefore, the curves for c_0-HTT and L_c-HTT were translated by the same amount. The superimposed curves make it easier

to view the general trends of the changes in c_0 and L_c with HTT (Fig. 7 b)).

From these figures, it can be seen that the graphitization of carbon under 3, and 5 kbar seems to proceed as follows. In the early stage of graphitization, there is one component A_s, of which the c_0-spacing decreases from the original value of 6.91 Å to 6.85 Å, and the crystallite size L_c increases to about 100 Å. In the next stage, the component G_s appears, and its content increases rapidly with increase in temperature and residence time for heat treatment. The c_0-spacing of the components A_s, and G_s remain unchanged at 6.85, and 6.72 Å, respectively. The crystallite sizes L_c of the

components A_s, and G_s are about 150—200 Å, and 300 Å, respectively.

Discussion

In a previous work,[1] composite profiles were also obtained in cases where a rapid change in the c_0-spacing was observed. It was suggested that there might be a possibility that each specimen used for X-ray study was a mixture of carbons heat-treated at different temperatures because of the steep temperature gradient in the specimen In the present work, pyrophyllite disks (e in Fig. 1) were inserted between the specimen chamber and the graphite terminal plates in order to minimize the temperature gradient in the specimen. Even in this modified arrangement a temperature difference was observed between the end and the central parts of the specimen, the temperature of the end part being about 10% lower than that of the central part, as mentioned previously. In addition to the temperature gradient, the pressure gradient along the specimen must be taken into account. The pressure at the end part of the specimen may be a little higher than that at the central part. The (002) profile of the end part of the specimen of which the central part had a composite profile was also composite, and its only difference from the central part was the degree of the developement of the component G_s, the content of G_s for the end part being smaller than that for the central part. This seems to show that temperature and pressure gradients along the specimen were not the cause of the occurence of a composite profile. The temperature difference itself affected the content of the component G_s. In other words, the structural change in the specimen under pressure was properly reflected in the diffraction profile.

In the graphitization process of PV-7 under a pressure of 3—5 kbar, there exist the components G_s and A_s side by side in the one specimen. In the early stage, there is only one component A_s, of which the mean c_0-spacing gradually decreases to 6.85 Å and the crystallite size L_c increases a little. In the next stage, in which the c_0-spacing of the component A_s has reached 6.85 Å, the component A_s begins to transform into the component G_s, and the main change at this stage is the increase in the content of the component G_s. The c_0-spacing of the component A_s stays unchanged at 6.85 Å, and its crystallite size L_c also remains unchanged at around 150—200 Å through this stage. The c_0-spacing of 6.85 Å is a little but evidently smaller than that of the so-called turbostratic structure, 6.88 Å. If the c_0-spacing of one component is assumed to be 6.88 Å, the balance of the profile becomes strongly un-symmetrical, and it is necessary to assume it consists of more than two components. The c_0-spacing of the component G_s is 6.72 Å and its crystallite size L_c is around 300 Å. The spacing of the component G_s measured from the (004) diffraction line is also 6.72 Å, and is clearly not 6.71 Å. Even though this spacing of 6.72 Å is a little larger than the spacing of natural graphite, 6.708 Å, specimens having a high content of the component G_s were found by X-ray diffraction to have a three dimensional structure, and by electron microscope and microdiffraction to contain flaky particles of which diffraction pattern was of the perfect six-fold symmetry of single crystal (Fig. 9a)). In the same specimen, however, some other particles showed continuous diffraction rings (Fig. 9b)). It is known that the c_0-spacing of the cokes graphitized as highly as possible can hardly be reduced to that of natural graphite.[7]

Phenomenally, the change in profile in the second stage of graphitization under a pressure of 3—5 kbar is similar to the so-called two-, or three-phase graphitization of non-graphitizing or hard carbons. The occurence of a composite profile,

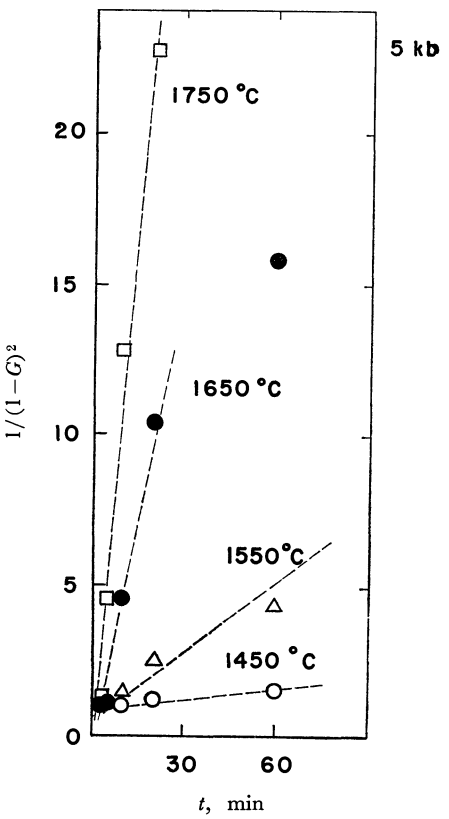

Fig. 10. Relations between content G of the component G_s and residence time t.

7) T. Noda and M. Inagaki, This Bulletin, **37**, 1709 (1964); T. Noda and H. Matsuoka, *Kogyo Kagaku Zasshi (J. Chem. Soc. Japan, Ind. Chem. Sect.)*, **63**, 465 (1960); P. L. Walker and G. Imperial, *Nature*, **180**, 1184 (1957).

which was composed of the components G_s and A_s, indicates that ranges having graphitic and non-graphitic structures have a sufficient extent to produce independent coherent scattering of X-ray in one specimen.

Under 1 kbar, no composite profile was observed and the c_0-spacing decreased continuously to 6.78 Å without the appearance of the second peak for the component G_s. This means that not a sufficient extent of lattice, having graphitic structure to produce coherent X-ray scattering, was formed in the specimen by the treatment, so that only a homogeneous decrease of the c_0-spacing was observed.

From these experimental results, it can be concluded that the accelerating effect of pressure on the graphitization of carbon increases with pressure. However, the graphitization process above 3 kbar seems to be different from that below 3 kbar. For experiments under 3, and 5 kbar, an approximate relation between the content, G, of the component G_s, and residence time t was investigated, although the accuracy of the measurements of temperature and pressure of heat treatment were not good enough, and also experimental data was not abundunt enough for a quantitative kinetic analysis of graphitization under pressure. A relatively good linearity between $1/(1-G)^2$ and t was obtained (Fig. 10). By using the experimental rate constant, the activation energy was calculated to be 80—120 kcal/mol, and the activation volume -7——9 cc/mol at temperature of 1650—1750°C.

The authors wish to thank Tokai Electrode Mfg. Co. for supplying the graphite materials used, and Professor K. Mihama, Department of Applied Physics, Faculty of Engineering, Nagoya University, for taking the electron micrographs.

NOTES

Thermal Decomposition of Ammonium Molybdoselenite and Its Iron Salt

the Late Sarju PRASAD and Virendra Nath GARG

Chemical Laboratories, Banaras Hindu University, Varanasi, India

(Received November 11, 1965)

The previous work[1] on the preparation of unsaturated heteropoly salts of selenium and molybdenum has now been extended to a study of the solid-state decomposition reactions of ammonium molybdoselenite and its iron salt at high temperatures. In the present communication thermogravimetric analysis (T. G. A.) and differential thermal analysis (D. T. A.) are used in conjunction with infrared spectroscopy to study the nature of the decomposition of the compounds by observing (a) the loss of water molecules, (b) the loss of volatile material, and (c) the breakdown by pyrolysis as the temperature is increased.

Experimental

The ammonium molybdoselenite and its iron salt of the composition: $3(NH_4)_2O \cdot 2SeO_2 \cdot 5MoO_3 \cdot 30H_2O$ and $Fe_2O_3 \cdot 2SeO_2 \cdot 5MoO_3 \cdot 24H_2O$ were prepared from seleneous acid and molybdic acid as has been described earlier.[1]

The T. G. A. studies were carried out by a Stanton Thermobalance (high-temperature model) with a 10-mg sensitivity. A heating rate of 3°C per min was employed, with a sample size ranging from 150—170 mesh. The loss in weight was within 2% of the theoretical values in all cases. The apparatus of differential thermal analysis employed in this work consists of an analytical furnace, a transformer, and recording equipment. The specimen holders, made of sintered alumina, have the dimensions $1'' \times 3/4'' \times 1/4''$. A heating rate[2] of 10°C per min was employed, with a sample size ranging from 100—120 mesh. For D. T. A. study the sample was well mixed with extra-pure alumina (E. Merck's) and tightly packed in one cell, whereas alumina alone as a reference material was placed in the other.

The infrared spectrum was recorded on a Perkin-Elmer Infracord apparatus in a potassium bromide medium by the disk method. The spectra are between 2—15 μ.

Results and Discussion

The T. G. A. curve of ammonium salt reveals that the compound loses 13 molecules of water at 120°C, and the rest in the temperature range from 230 to 320°C. The anhydrous ammonium salt thus obtained at 320°C is brown and gives the test for ammonia. It is insoluble in cold or strong acids and alkalies. Its insolubility shows that it is an interstitial solid solution in which selenium atoms are closely packed in the interstices of molybdenum atoms, this theory is supported by the D. T. A., in which an exothermic peak is obtained at 330°C which can be attributed to the lattice transition. The gradual cooling curve from high to low temperatures reveals no peak, thus indicating the irreversibility of the process.

After further heating the decomposition of the compound formed occurs mainly in the 330—420°C temperature range, with a loss of selenium dioxide and an oxidation of the ammonia released; this is confirmed by the strong exothermic peak at 390—420°C in the D. T. A. curve. The nitrogen atmosphere gives a normal endothermic peak, thereby showing that there is no oxidation of ammonia. It may be concluded that ammonia is either oxidized or decomposed at the surface of

molybdenum oxide through its catalytic action.[3]

In the case of iron molybdoselenite the T. G. A. curve shows a distinct region at 140°C where loss occurs due to 17 water molecules. Afterwards a flat plateau, corresponding to the iron salt with 7 water molecules, is obtained; these molecules are lost in the temperature range of 270—290°C. The two endothermic peaks, with maxima around 135°C and 280°C respectively, correspond to the dehydration of the compound. The exothermic peak at 310°C is interesting because no significant weight losses were noted in the T. G. A. curve in this temperature range; it can be attributed to the lattice transition, as in the ammonium salt. One endotherm, that at 360°C, may be due to the escape of selenium dioxide.

In the infrared spectra one peak is observed in the 3 μ region (3450—3400 cm^{-1}); this peak is due to the O–H stretching vibration of water. In the 6 μ region a weak absorption band appears at

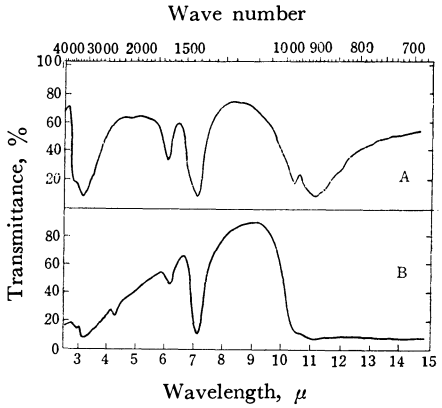

Fig. 3. Infrared spectra of ammonium molybdoselenite (A) and heated ammonium molybdoselenite (B).

1640—1620 cm^{-1} which corresponds to the bending mode of water. It has been found that on dehydration, these bands are fully or partially eliminated and that the overall spectrum is considerably altered. The introduction of water molecules into the lattice usually results in a rearrangement of the packing and in the adoption of a different crystalline form. The water molecules may form hydrogen bonding with some part of the anions and, consequently, their vibrational frequencies, may be affected. The regions of the absorption of Se–O and Mo–O[4] linkages are so close that, in the compounds, the absorption bands of the two overlap to a considerable extent to form a broad band about 900 cm^{-1}. In the case of ammonium salt, the absorbances at 3100 cm^{-1} and 1400 cm^{-1} are characteristic of the ammonium ion.

The authors are grateful to the authorities of the Banaras Hindu University for providing the necessary facilities and to the Director, C. B. R. I., Roorkee, for his kind permission to V. N. G. to work there. Our grateful thanks are also due to Dr. V. S. Ramachandran and Dr. N. G. Dave, C. B. R. I., Roorkee, for their helpful suggestions, and to Mr. K. P. Agarwal, C. D. R. I., Lucknow, for IR spectra. One of the authors (V. N. G.) wishes to thank the Council of Scientific and Industrial Research, New Delhi, for its financial assistance.

Aminobutadienes. IX.[1] The Synthesis of 2-Phthalimidomethyl-1, 3-butadiene

Kenichi MURATA and Akira TERADA*[1]

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka

(Received March 30, 1967)

In previous papers of this series, we reported that 1-phthalimido-,[2] 1-succinimido-,[2] and 1-(2-oxopyrrolidino)-1, 3-butadienes[1] were synthesized from 1, 3-butadiene, and that 2-phthalimido- and 2-succinimido-1, 3-butadienes[3] were derived either from ethyl α-oxyiminoacetoacetate or D-threonine. Among these monomers, 1-phthalimido- and 1-succinimido-1, 3-butadienes are easily polymerized in the presence of either radical[4] or cationic initiators,[5] while 2-phthalimido-1, 3-butadiene is very easily polymerized by radical initiators,[6] but not cationic ones.[6] The monomer reactivity ratios and Alfrey-Price *Q-e* values were determined by copolymerizations with styrene.[6,7]

In this paper, we wish to report on the synthesis of 2-phthalimidomethyl-1, 3-butadiene (VII) from isoprene.

The addition reaction of hypochlorous acid to isoprene was carried out by passing carbon dioxide gas into a liquid of isoprene and bleaching powder dispersed in a large amount of water. The main product was a fraction with a boiling point of 52—54°C/27 mmHg. The elemental analysis and infrared spectrum showed that this product was 1-chloro-2-methyl-3-buten-2-ol (I), and not either the 1, 4-, 3, 4-, or 1, 2, 3, 4-addition product. From the remaining part, white crystals melting at 81.5—83°C were separated. These crystals were found by elemental analysis to be isoprene dichlorohydrine. The infrared spectrum of this dichlorohydrine reveals the bands of primary and tertiary alcohols. On the other hand, this dichlorohydrine does not have the α, β-glycol unit in its structure, because it is negative on periodic acid oxidation, and its melting point does not agree with that of 1, 4-dichloro-2-methyl-2, 3-butandiol (mp 106.5°C).[8] Therefore, this dichlorohydrine

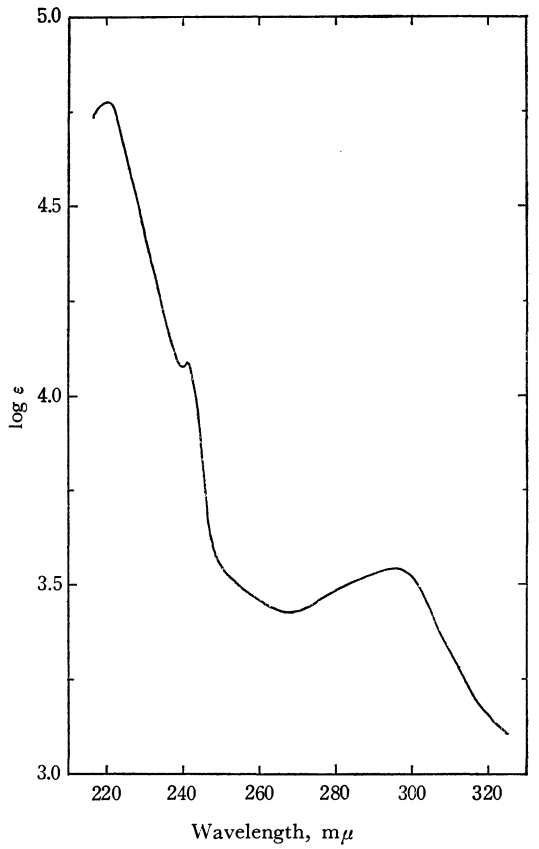

Fig. 1. Ultraviolet absorption spectrum of 2-phthalimidomethyl-1, 3-butadiene (VII) in ethanol. λ_{max} 219.5 mμ (ε 6.23×10^4); 240.5 mμ (1.28×10^4); 294 mμ (3.56×10^3).

was confirmed to be 1, 3-dichloro-2-methyl-2, 4-butandiol (II).

The dehydrochlorination of I by using alkali was easily carried out to give 1, 2-epoxy-2-methyl-3-butene (III), bp 80—82°C. III can also be obtained by the reaction of isoprene with perbenzoic acid.[9]

1-Amino-2-methyl-3-buten-2-ol (IV) was then prepared by the ammonolysis of III, according to the method of Ettlinger.[10]

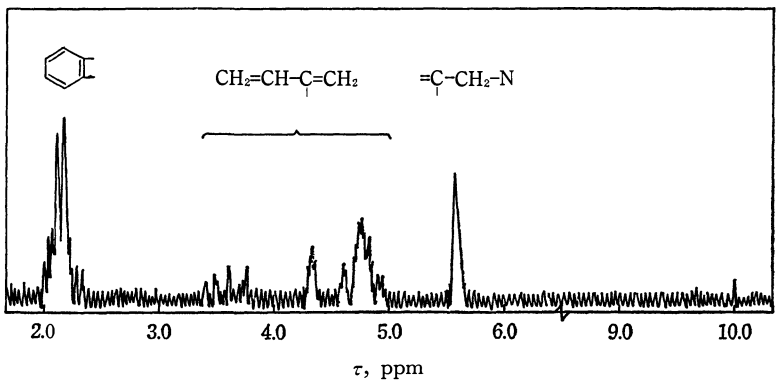

Fig. 3. NMR spectrum of 2-phthalimidomethyl-1, 3-butadiene (VII) in carbon tetrachloride at 60 Mc.

2-Methyl-1-phthalimido-3-buten-2-ol (V), mp 102—103°C, was obtained in a theoretical yield by the condensation reaction of IV with phthalic anhydride at 200°C. Although this intermediate, V, could also be prepared by the direct addition of phthalimide to III at 150°C using an alkali catalyst, the yield was very poor due to the difficult solubility of phthalimide in III.

The acetylation of V was carried out according to the ordinary method to give 2-acetoxy-2-methyl-1-phthalimido-3-butene (VI), mp 71—72°C.

The pyrolysis of VI at 550°C gave colorless crystals with a melting point of 114.5—116°C. The ultraviolet absorption spectrum is shown in Fig. 1, in which a strong absorption maximum appears at 219.5 mμ, almost the same position as those of isoprene (220 mμ),[11] 2-phthalimido-1, 3-butadiene (219 mμ),[3] and 2-succinimido-1, 3-butadiene (219.5 mμ),[3] all of which have been characterized as 2-substituted-1, 3-butadienes. On the other hand, 1-substituted-1, 3-butadienes, such as 1-phthalimido-1, 3-butadiene, 1-succinimido-1, 3-butadiene, and 1-(2-oxopyrrolidino)-1, 3-butadiene, show different absorption maxima, at 278.5,[2] 248,[2] and 268.5 mμ[1] respectively. The infrared absorption spectrum reveals a conjugated diene band at 1600 cm^{-1}, shown in Fig. 2, and the NMR spectrum in Fig. 3 shows methylene protons at 5.57 ppm, but no methyl protons.

The crystalline product prepared by the deacetylation of VI should be either 2-phthalimidomethyl-1, 3-butadiene (VII) or 2-methyl-1-phthalimido-1, 3-butadiene (VIII); from the results of the ultraviolet and NMR spectra, it is concluded that the product is VII.

Finally, a Diels-Alder reaction of VII with maleic anhydride gave 4-phthalimidomethyl-1, 2, 3, 6-tetrahydrophthalic anhydride.

Experimental

The infrared spectra were measured with a Perkin-Elmer spectrophotometer, model 221, and a Hitachi infrared spectrophotometer, model EPI-S. The NMR and ultraviolet spectra were recorded with a Varian NMR spectrometer, model A-60, and a Hitachi recording spectrophotometer, model EPS-2, respectively.

The Addition of Isoprene with Hypochlorous Acid. Into a dispersed solution of 50 g of isoprene, 100 g of bleaching powder (available chlorine 60%) and 1.0 g of Nonion N-1000 (Nissan Oils and Fats Co., Ltd.) in 1.2 *l* of water, 40 *l* of carbon dioxide gas was passed under stirring for 2 hr at 0—5°C. The reaction mixture was filtered to remove calcium carbonate, and then saturated with sodium chloride and extracted four times with ether. The combined ether extract was dried over calcium chloride. Then, after the ether had been removed, the residue was distilled through a Widmer column (length 200 mm) under a vacuum; 33.3 g (37.6%) of 1-chloro-2-methyl-3-buten-2-ol (I) was thus obtained as a colorless liquid with a boiling point of 52—54°C/27 mmHg.

Found: C, 49.66; H, 7.69%. Calcd for C_5H_9OCl (I): C, 49.81; H, 7.52%.

IR: 3470 (OH); 1175 (tertiary alcohol); 1870, 1410, 1290, 990, 927 (vinyl); 752 cm^{-1} (C-Cl).

After the I had been distilled out, the liquid residue was allowed to stand for a long time at room temperature; then a small amount of crystals was separated. When those crude crystals were recrystallized from benzene, isoprene dichlorohydrine was obtained as white crystals with a melting point of 81.5—83°C. This dichlorohydrine did not react with periodic acid.[12]

Found: C, 34.55, 34.80; H, 5.90, 6.02%. Calcd for $C_5H_{10}O_2Cl_2$ (II): C, 34.70; H, 5.78%.

IR: 3330 (OH); 1175 (tertiary alcohol); 1280, 1075 (primary alcohol); 724 cm^{-1} (C-Cl).

The Dehydrochlorination of I. To 200 g of 50% aqueous sodium hydroxide, 85.0 g of I was added, drop by drop, with a thorough agitation at about 130°C over a 3.0 hr period. In the course of this reaction, the reaction product was distilled with water; the distillate was separated into two phases, in both of which sodium chloride was then saturated. The upper organic layer was separated, dried over calcium chloride,

12) R. L. Shriner, R. C. Fuson and D. Y. Curtin, "The Systematic Identification of Organic Compounds," John Wiley and Sons, New York, N. Y. (1956), p. 129.

and distilled to yield 43.0 g (72.4%) of 1,2-epoxy-2-methyl-3-butene (III), bp 80—82°C. Lit., bp 81°C/735 mmHg.[9]

IR: 1860, 1425, 1300, 988, 915 (vinyl); 1233, 883 cm^{-1} (epoxide.)

The Ammonolysis of III. Into 500 g of ammonia water (concentration 28%), 36.3 g of III was added, drop by drop, under stirring at 5—10°C. After the addition had been finished, the mixture was stirred for 48 hr at room temperature. The excess ammonia water was removed through a Widmer column under a vacuum, and finally 20.6 g (47.1%) of 1-amino-2-methyl-3-buten-2-ol (IV) was distilled out at 50—54°C/4.5—6 mmHg.

IR: 3500 (OH); 3420—3300, 1618 (primary amine); 1170 (tertiary alcohol); 1870, 1655, 1427, 1305, 1000, 925 cm^{-1} (vinyl).

The Condensation of IV with Phthalic Anhydride. A mixture of 6.0 g of IV and 8.8 g of phthalic anhydride was slowly heated to 200°C, and then kept for half an hour at this temperature in order to remove 1.0 m*l* of water. The crude product (14.0 g) crystallized when it came to room temperature. Recrystallization from water gave 2-methyl-1-phthalimido-3-buten-2-ol (V) as colorless needles with a melting point of 102—103°C.

Found: C, 67.50, 67.67; H, 5.80, 5.83; N, 6.05%. Calcd for $C_{13}H_{13}O_3N$ (V): C, 67.52,; H, 5.67; N, 6.06%.

IR: 3520 (OH): 1770, 1705 (C=O, phthalimido); 1610 (phenyl); 1180 (tertiary alcohol); 1867, 1655, 1411, 1300, 998, 928 (vinyl); 725, 712 cm^{-1} (*o*-disubstituted benzene).

The Addition of Phthalimide to III. A mixture of 8.4 g of III and 14.7 g of phthalimide, plus 5 drops of 30% aqueous potassium hydroxide as a catalyst, was heated in a sealed tube for 24 hr at 150°C. After standing for one day, the reaction product was extracted with benzene; a solid residue (8.7 g) remained. The recrystallization of this residue from water gave colorless needles with a melting point of 230—233°C. These crystals were confirmed to be phthalimide by a mixed-melting-point test with an authentic sample.

After the benzene had been removed from the extract, the oily residue was subjected to distillation under a vacuum; it thus gave a fraction with a boiling point of 163—165°C/3 mmHg, 6.3 g (27%). This fraction slowly crystallized on standing. Recrystallization from water gave colorless needles, mp 102—105°C. These crystals were confirmed to be V by a mixed-melting-point test.

The Acetylation of V. To 4.0 g of V, 25 m*l* of acetic anhydride and 0.5 g of anhydrous sodium acetate as a catalyst were added; the mixture was then refluxed for 10 hr. After the excess acetic anhydride had been removed under a vacuum, the oily residue was poured into a large amount of cold water and neutralized with sodium bicarbonate. Then crude crystals appeared; they were dried after washing with water. Recrystallization from benzene - petroleum benzine gave 2-acetoxy-2-methyl-1-phthalimido-3-butene (VI) as colorless crystals, mp 71—72°C.

Found: C, 65.92, 66.01; H, 5.65, 5.71; N, 5.10%. Calcd for $C_{15}H_{15}O_4N$ (VI): C, 65.92; H, 5.53; N, 5.13%.

IR: 1770, 1725 (C=O, phthalimido); 1750 (C=O, ester); 1235 (acetate); 1610 (phenyl); 1650, 1395, 1300, 980, 940 (vinyl); 725, 710 cm^{-1} (*o*-disubstituted benzene).

The Pyrolysis of VI. A solution of 20.0 g of VI in 60 m*l* of acetone was pyrolyzed under a nitrogen atmosphere by being dropped into a reaction tube of porcelain (ϕ 20 mm, length 500 mm) kept at 550°C[13] in an electric furnace (ϕ 30 mm, length 230 mm). The dropping time needed was 2.3 hr. The pyrolyzate was then poured into cold water, neutralized with sodium bicarbonate, and extracted with benzene. The extract was dried over anhydrous sodium sulfate. After the benzene had been removed under a vacuum, the remaining part crystallized. By extraction with hot petroleum benzine and letting the mixture stand in a refrigerator, crude crystals (4.5 g) of mp 92—109°C were obtained; they were then recrystallized from petroelum benzine to give 2-phthalimidomethyl-1, 3-butadiene (VII) as colorless crystals, mp 114.5—116°C. The ultraviolet and NMR spectra are shown in Figs. 1 and 3 respectively.

Found: C, 73.23; H, 5.25; N, 6.44%. Calcd for $C_{13}H_{11}O_2N$ (VII): C, 73.22; H, 5.20; N, 6.57%.

IR (Fig. 2): 1770, 1700 (C=O, phthalimido); 1870, 1400, 1305, 958, 912 (vinyl); 1615 (phenyl); 1600 (conjugated diene); 725, 710 cm^{-1} (*o*-disubstituted benzene).

The Diels-Alder Reaction of VII with Maleic Anhydride. A solution of 0.27 g of VII and 0.14 g of maleic anhydride in 10 m*l* of benzene was refluxed on a water bath for 2 hr. After the benzene had been removed, the residue was crystallized by letting it stand overnight. Recrystallization from benzene-petroleum benzine gave 4-phthalimidomethyl-1, 2, 3, 6-tetrahydrophthalic anhydride as white crystals, mp 146—147.5°C.

Found: C, 65.73, 65.78; H, 4.25, 4.45; N, 4.36, 4.33%. Calcd for $C_{17}H_{13}O_5N$: C, 65.59; H, 4.21; N, 4.50%.

IR: 1850 (C=O, five-membered cyclic anhydride); 1770, 1720 (C=O, phthalimido); 1610 (phenyl); 721, 710 cm^{-1} (*o*-disubstituted benzene).

The authors are indebted to Professor Shizunobu Hashimoto of Doshisha University and Dr. Isao Shiihara of this Institute for their helpful suggestions, and to Noboru Kito, M. Sc. of the University of Colorado for his NMR spectrum measurements.

13) This temperature was measured in the central part of the tube by a thermo-couple.

The Alkaline Sulfide Reduction of Aromatic Nitro Compounds. XIII. The Processes in the Alkaline Sulfide Reduction of Aromatic Nitro Compounds*[1]

Shizunobu HASHIMOTO and Junzo SUNAMOTO*[2]

Department of Applied Chemistry, Doshisha University, Karasuma-imadegawa, Kamikyo-ku, Kyoto

(Received April 26, 1967)

Goldschmidt and Larsen have presented evidence[1] that the reduction of sodium *m*-nitrobenzenesulfonate by an aqueous hydro sulfide saturated with hydrogen sulfide gives the corresponding nitroso, *N*-phenylhydroxylamino, and an anilino compound, but the anilino compound was not produced *via* the *N*-phenylhydroxylamino compound. Recently, Cope and Brown have suggested the formation of *N*-phenylhydroxylamine by gas chromatography in the reduction of nitrobenzene with an aqueous monosulfide containing ammonium chloride (pH=10.5).[2] On the other hand, in an earlier paper dealing with the kinetics of the aqueous monosulfide and with hydrosulfide reductions of sodium *m*-nitrobenzenesulfonate, we have suggested[3] that the monosulfide and hydrosulfide must be essentially identical in their reactions, a fact related to the hydrolytic equilibrium of the monosulfide.

The present investigation was undertaken to determine the alkaline sulfide reduction process of aromatic nitro compounds.

Table 1 shows the reduction products of nitro, nitroso, *N*-phenylhydroxylamino, azoxy, and azo compounds with the aqueous monosulfide or disulfide. The nitro compound gave only the corresponding amine, VI, with both sulfides. The nitroso compound gave VI together with VII, the product ratio of VI to VII being approximately unity in the monosulfide reduction. In the disulfide reduction, however, the yield of VII became much higher than that of VI. The monosulfide reduction of the *N*-phenylhydroxylamino compound was very slow under the conditions shown in Table 1; traces of VI and of VIII, the acidic rearrangement product of III, were detected on the paper chromatogram. On the other hand, in the disulfide reduction of III, the formation of VI and VII were observed, and the reduction rate of III became rather higher. Anlike the nitroso and *N*-phenylhydroxylamino compounds, the azoxy and azo compounds were reduced to give only the corresponding VII, derived from hydrazo compound. A small amount of VI given by the disproportionation of the hydrazo compound[4] was also detected.

The reduction of the nitro and nitroso compounds with the aqueous monosulfide and disulfide are shown in Fig. 1, while those of azoxy and azo compounds are shown in Fig. 2. The reduction rate of the nitro compound with an aqueous disulfide was very different from that with an aqueous

monosulfide.[3,5] Anlike the monosulfide reduction of the nitro compound, that of the nitroso compound had no induction period and its reduction rate was much slower throughout the reaction. On the other hand, the disulfide reduction of the nitroso compound proceeded at approximately the same rate as that of the nitro compound. The monosulfide reduction rate of the *N*-phenylhydroxylamino compound was much lower than that of the nitroso compound, but the disulfide reduction rate was the same as those of the nitro and nitroso compounds. Our findings concerning the reduction rates listed above are consistent with the results obtained by Cope and Brown,[2] although our point of view was somewhat different from theirs. In the reduction of the azoxy and azo compounds, no comparable differences in the reduction rates were observed between the monosulfide and the disulfide reduction. In these cases, the initial reduction rates were rather high, and the reactions reached an apparent equilibrium rather early.

On the basis of the data thus obtained, it seems most reasonable to conclude that, in the alkaline sulfide reductions of sodium *m*-nitrobenzenesulfonate, but not the hydrogen sulfide reduction, methanilic acid will be directly produced from the nitro compound upon the attack of the disulfide on the positively-charged nitrogen of the nitro group[6] and upon the subsequent rapid interchange between hydrogen and oxygen, as is shown in Eq. (1):

$$\mathrm{Ar\text{-}\overset{+\delta}{N}{=}O} \xleftarrow{(S\text{-}S)^{2-}} \mathrm{Ar\text{-}N(O)\text{-}N\text{-}Ar} \quad \mathrm{Ar\text{-}\underset{\downarrow}{\overset{}{N}}{=}\underset{\downarrow}{O}} \quad \mathrm{Ar\text{-}\underset{-\delta}{O}} \quad + \quad \mathrm{H_2O} \rightarrow \mathrm{Ar\text{-}NH_2} + S_2O_3^{2-} \qquad (1)$$

No nitroso, *N*-phenylhydroxylamino, azoxy, or azo compounds is intermediately produced during the course of the reduction of the nitro compound. In the monosulfide or the hydrosulfide reduction, the disulfide is produced by the radical oxidation

of the monosulfide or the hydrosulfide with light, oxygen, and so forth.[5,7,8]

Experimental

Materials. The sodium monosulfide (M) and disulfide (D), sodium *m*-nitrobenzenesulfonate (I), sodium *m*-nitrosobenzenesulfonate (II), disodium *m,m'*-azoxybenzenedisulfonate (IV), and disodium *m,m'*-azobenzenedisulfonate (V) were the same as those used in previous papers.[3,5] The sodium *m*-(*N*-phenylhydroxylamino)benzenesulfonate (III) was prepared by the zinc reduction of the corresponding nitro compound, I; the sulfonate thus obtained, when recrystallized from aqueous methanol, was found to be chromatographically pure. Their purities were exactly determined before use by the usual reduction-diazometry.

Rate Measurement. The procedure for the rate measurements and analyses were the same as in the method described earler.[3,5]

When a nitroso, azoxy, or azo compound was reduced by aqueous alkaline sulfide, the corresponding hydrazo compound was obtained. After the benzidine rearrangement of the hydrazo compound with hydrochloric acid, the amine produced was determined by diazometry. When *m*-(*N*-phenylhydroxylamino)benzenesulfonate was reduced by aqueous monosulfide under the same conditions as those used in the reduction of the nitro or nitroso compound, the reduction rate of the former was much slower and most of the reactant was recovered.

The reaction was also followed by paper chromatography. The chromatograms were developed with *n*-butanol containing concentrated hydrochloric acid (4 : 1 by vol.). The R_f values and the detections were as follows: *m*-aminobenzenesulfonate (VI), $R_f=0.30$, reddish orange upon diazotization and coupling with α-naphthol-4-sulfonate (method A) or orange, with *p*-dimethylaminobenzaldehyde (method B); *m,m'*-benzidinedisulfonate (VII), $R_f=0.05$, red, with A or orange, with B; III, $R_f=0.22$, yellow, with B; and 2-hydroxy-5-aminobenzenesulfonate (VIII), $R_f=0.13$, dull red, with A or yellow, with B. No other materials were observed.

A New Method for the Quantitative Verification of the Butadiene-Styrene Copolymer

Koichi IRAKO, Shiro ANZAI and Akira ONISHI

Central Research Laboratory, Bridgestone Tire Company, Kodaira, Tokyo

(Received May 19, 1967)

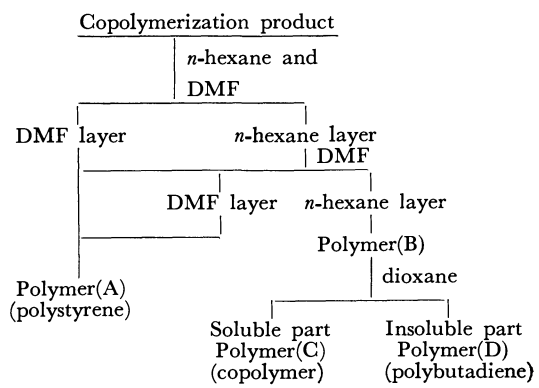
A new method to separate the homopolymer from butadiene-styrene copolymerization product, a "two-layer extraction method," has been developed.

Many new catalyst systems and copolymerization techniques (random, block or graft *etc.*) have previously been employed in the preparation of the butadiene-styrene copolymer.

It is important to characterize these products and identify the copolymer in the light of the evaluation of catalyst systems, copolymerization methods, and the physical properties of the products. Several solvent-extraction methods and fractional extraction methods have been employed in order to verify the existence of the copolymer and to separate a homopolymer from the copolymerization product. By these methods, however, a quantitative treatment was difficult. Moreover, the selection of a solvent and a nonsolvent was troublesome.

We have now succeeded in making a quantitative separation of the homopolymer from copolymerization products by a "two-layer extraction method," using *n*-hexane and *N*, *N*-dimethylformamide (DMF); the separation is accompanied by a dioxane extraction.

The butadiene-styrene copolymerization product (1.0 g) was dissolved or suspended in *n*-hexane (200 m*l*) under stirring for *ca.* 50 hr; then the solution or the suspension was placed in a 500 m*l* separating funnel and 100 m*l* of DMF was added. The funnel was shaken for *ca.* 15 min and then left standing for 1 hr, after which two layers, (the *n*-hexane layer(upper) and the DMF layer (lower)), were separated. The polymer (A) dissolved in the DMF layer and the polymer (B) dissolved or suspended in the *n*-hexane layer were isolated and dried under a vacuum. The polymer (B) was then further extracted with dioxane to



separate a dioxane-insoluble part (C) from a dioxane-soluble part (D).

The separation of homopolystyrene from the copolymerization product can be effectively carried out by the "two-layer extraction method" using *n*-hexane and DMF. Table 1 shows the results obtained by applying this method to a mixture of polystyrene and polybutadiene, or to each homopolymer. It is evident from the table that the homopolymers were separately extracted by the respective solvents, *i. e.*, polybutadiene by the *n*-hexane and polystyrene by the DMF.

Next, this method was applied to butadiene-styrene copolymerization product, and the copolymerization efficiency was determined by the following equation:

TABLE 1. EXTRACTION RESULTS OF HOMOPOLYMERS AND POLYBUTADIENE-POLYSTYRENE MIXTURES BY THE TWO LAYERS METHOD

TABLE 3. EXTRACTION RESULTS OF POLYBUTADIENE-BUTADIENE-STYRENE COPOLYMER MIXTURE BY THE DIOXANE METHOD

No.	Polymer	Styrene content %	Polymer C Dioxane soluble part		Polymer D Dioxane insoluble part	
			wt %	St %	wt %	St %
3-1	SBR 1502 (JSR)	24.5	100	24.5	—	—
-2	Polybutadiene-copolymer*1 mixture (5 : 5)	8.7	51.0	11.7	49.0	1.8
-3	Copolymer*1	14.4	100	14.4	—	—

Extraction condition

Polymer: 1.0 g; Solvent: dioxane 30 m*l*; Extraction time: 50 hr at 25°C.

*1 Copolymer obtained by $Ni(acac)_2$-BF_3Et_2O-$AlEt_3$ catalyst system (Japanese Pat. 42-7795) was used after two layers extraction method.

Copolymerization efficiency(%) =

$$\frac{S_T - S_H}{S_T} \times 100 = \frac{S_C}{S_T} \times 100$$

S_T: total styrene content (%)
S_H: homopolystyrene content (%)
S_C: copolymerized styrene content (%)

The results obtained are shown in Table 2.

We also found that dioxane extraction after the removal of homopolystyrene could be used to separate polybutadiene from a copolymer-polybutadiene mixture. Some results of the dioxane extraction are shown in Table 3.

The "two-layer extraction method" is also effective for a liquid-liquid extraction. This method is especially recommended for the isolation of a graft copolymer from the reaction products. The method described above was also applied to an isoprene-styrene copolymerization product. Similar quantitative extraction results were obtained. This method may also be applied to other conjugated diolefin-vinyl compound copolymerization products, such as butadiene-acrylonitrile, butadiene-methylmethacrylate, and isoprene-methylmethacrylate.

Surface Activity and Some Optical Properties of Na-1-acylaminonaphthalene-5-sulfonates in Solutions

Yoshinori MUSHA, Akio OKAGAWA and Tamotsu KONDO

Faculty of Phamaceutical Sciences, Science University of Tokyo, Funakawara-machi, Shinjuku, Tokyo

and Masuzo NAGAYAMA

Research Laboratory, Lion Fat & Oil Co., Ltd., Hirai, Edogawa-ku, Tokyo

(Received May 19, 1967)

Previous papers[1,2] have reported on the syntheses, properties, and possible applications in basic research and industry of new surface-active agents, which are fluorescent as well as surface-active in aqueous solutions.

There are two ways, in principle, of synthesizing a compound of this kind. First, a strong surface activity can be given to certain fluorescent dyes or intermediates by introducing one or more long-chain alkyl radicals into the dye or intermediate molecules. Secondly, some surface-active agents can be chemically modified to exhibit fluorescence by reaction with appropriate fluorescent reagents.

From the physicochemical point of view, however, the compounds obtained so far are not necessarily suitable for basic research in colloid and interface science, for some of them are subject to light-catalyzed cis-trans isomerization,[1] while others are hardly soluble in water at pH values around 7 or at room temperatures.[2]

In the present study, therefore, an attempt has been made to prepare the compounds by the first method without the shortcomings mentioned above. Thus, a homologous series of Na-1-acylaminonaphthalene-5-sulfonates has been synthesized from 1-naphthylamino-5-sulfonic acid (Laurent's acid) and acyl chlorides. Some properties of these compounds have also been studied.

1) T. Kondo, A. Okagawa and M. Nagayama, *Kogyo Kagaku Zasshi (J. Chem. Soc. Japan, Ind. Chem. Sec.)*, **68**, 2125 (1965).
2) S. Muto, T. Kondo and M. Nagayama, *Yukagaku (J. Japan Oil Chemists' Soc.)*, **15**, 26 (1966).

Experimental

Materials. Acyl chlorides were prepared from thionyl chloride and *n*-fatty acids by the usual method. The purity of all the *n*-fatty acids used was estimated to be more than 99.5% by gas chromatography. Laurent's acid was purchased from K & K Laboratories, Inc., Plainview, N.Y., U.S.A. This material was said to have a purity of about 95%.

Preparation and Purification. The reaction of acyl chloride with Laurent's acid easily gave the desired compound. As an example, the reaction of decanoyl chloride with Laurent's acid will be described below.

9.6 g (0.04 M) of Laurent's acid were dissolved in 150 m*l* of water, with the addition of sodium carbonate to make the resultant solution slightly alkaline. The reaction was initiated by simultaneously dropping 9.5 g (0.05 M) of decanoyl chloride dissolved in 20 m*l* of acetone and of an aqueous 5% sodium carbonate solution into the solution of the sodium salt of Laurent's acid obtained above. An hour was sufficient for the reaction to be completed at room temperature.

The product was purified by dry-column-chromatography[3] as follows. A column made of silica gel (Wako 100—200 mesh) was used. The column was filled with dry packing by slowly pouring in the absorbent while tapping the column. Appropriate quantities of silica gel and a methanolic solution of the product were mixed, and the solvent was evaporated to dryness, thus leaving the silica gel covered with the product. Then the column was loaded by pouring the silica gel on top of the packed column and covering it with a filter paper. The development was done by allowing a chloroform-methanol mixture (2 : 1, v/v) to move down the column. When the solvent reached the bottom of the column, the chromatogram was stopped at this point and the content of the column was extruded. The part exhibiting a violet fluorescence was cut off and treated with the same solvent as had been used in the development. The extracted product was precipitated out of the solution by evaporating the solvent under atmospheric pressure. The precipitate was collected and recrystallized at least two times from methanol, and once from water. The final product was obtained as a white powder; the yield was slightly less than 10%.

The high purity of the compounds thus obtained was checked by thin-layer-chromatography, which gave only one spot on the chromatogram.

In Table 1 are listed the results of the elemental analyses of the homologous compounds. Octanoyl, decanoyl, and dodecanoyl compounds are abbreviated as C_8, C_{10} and C_{12} compounds respectively.

Table 1. Elemental analyses

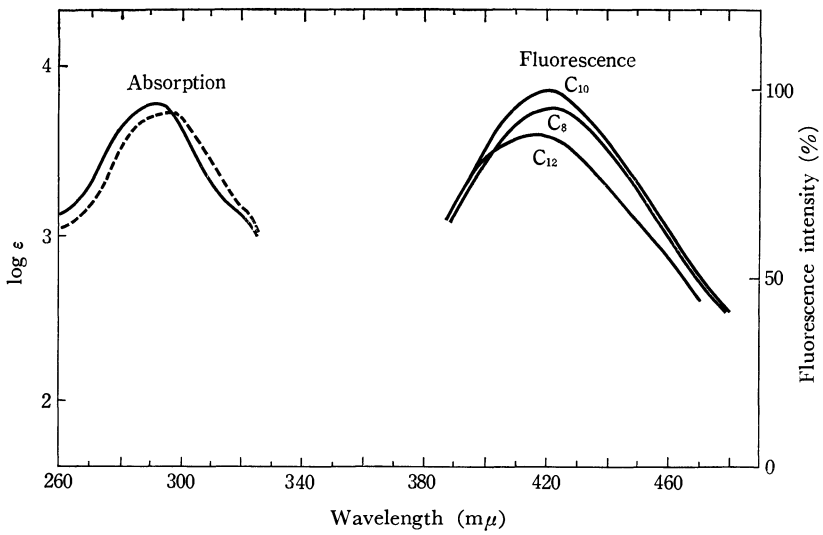

Fig. 2. Ultraviolet absorption and fluorescence spectra of the homologous compounds in water (——) and in methanol (- - -).

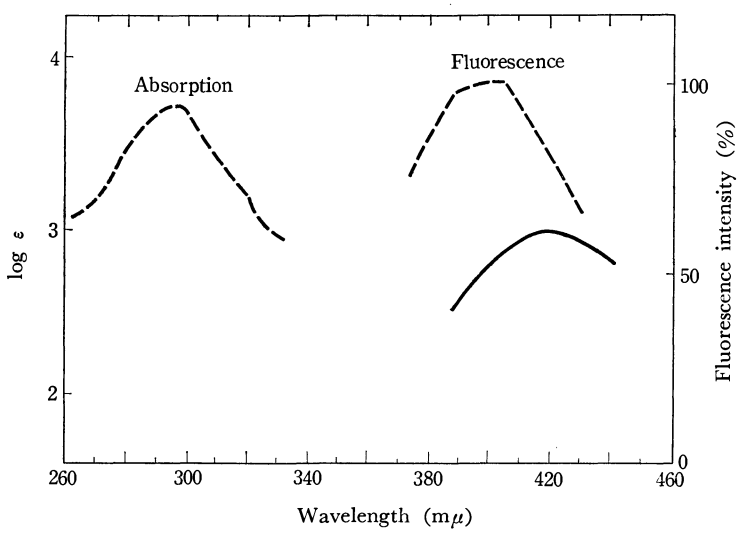

Fig. 3. Ultraviolet absorption and fluorescence spectra of C_{10} compound in methanol (——) and water (- - -)

The fluorescence spectra were obtained with a Hitachi Model ESP-2 spectrophotometer, with attachements for fluorescence measurements. The concentration of all the aqueous and methanolic solutions of the compounds used for the measurements was 5×10^{-5} M.

Surface-tension Measurements. The surface tensions of aqueous solutions of these compounds were measured by the drop-weight method, using a micrometer syringe at 50°C. Necessary precautions were taken to give the equilibrium values in these measurements.

Results and Discussion

Figure 1 gives the sulface tension *vs.* concentration curve for aqueous solutions of the homologous compounds. The concentration at the inflection point on each curve was taken as the CMC. The CMC values for the C_8, C_{10}, and C_{12} compounds were estimated from this figure to be 2.7×10^{-1}, 6.6×10^{-3}, and 1.5×10^{-4} M respectively.

The relation between the CMC and the hydrophobic chain length of the compounds is expressed by the equation: $\log \mathrm{CMC}=5.87-0.80N$, where N is the carbon atom number in a long hydrophobic chain. This means that the CMC of our compounds varies with the hydrophobic chain length in the manner of geometric progression, as does that of many common surface-active agents.

The UV absorption and fluorescence spectra are shown in Figs. 2 and 3. With the exception

of fluorescence spectra in water, only one curve is presented in these figures, since the remaining spectra were independent of the chain length. The reason why the fluorescence spectra in water vary with the carbon atom number in an alkyl chain has not been yet established. In the UV absorption spectra, the primary band appeared at about 225 mμ, and for ordinary naphthalene derivatives. The secondary band occured at 290 mμ in water and at 300 mμ in methanol. The peak of the fluorescence spectra was at 420 mμ in water, while it was located at 400 mμ in methanol.

From the experimental results presented above, the homologous compounds may be designated as fluorescent surface-active agents.

Some applications of these compounds in colloid and interface science are now being studied.

The Reduction of Schiff Bases with Aluminum Amalgam

Tatsuo TAKESHIMA, Motomu MURAOKA, Hiroe ASABA and Masataka YOKOYAMA

(Received June 7, 1967)

There are several common methods for the reduction of Schiff bases. Among them, the catalytic hydrogenation seems, in general, to be the most preferred, in part because of its neutral nature.

In the present experiment, aluminum amalgam, which almost fits the neutral conditions, was found to be an effective agent for this reduction. The aluminum amalgam was easily made in the usual way. The reduction was carried out under an atmospheric pressure and at room temperature. In addition, the treatment of the reaction product involved no troublesome manipulation.

The Schiff bases used were conveniently prepared by refluxing ketone with primary amine in the presence of potassium fluoride. Few new secondary amines were obtained besides the known ones.

All of the hydrochlorides of amines obtained showed several typical infrared absorption of NH_2^+ in the region of 2800—2000 cm^{-1} (stretching) and at ~1587 (deformation).[1]

Of the amines prepared, the known ones were identified as hydrochlorides (for melting point,[2] see Table 2). The assignment of the structure of the new amines was based on the results of the elemental analysis and the infrared spectra of the hydrochloride, and on the course of the synthesis. The structures of the Schiff bases prepared were deduced from the course of the synthesis and from the fact that the amines were reduced to the corresponding secondary amines.

The reduction of the Schiff bases was also carried out by means of lithium aluminum hydride. However, this method was not favorable from the standpoint of either the manipulation or the yield.

Experimental

Procedure. The Schiff bases were prepared by refluxing a mixture of the reactants in a ketone: amine ratio of 1 (mol): 1 (mol) in the presence of excess anhydrous potassium fluoride. The secondary amines were obtained by reducing the Schiff bases with an aluminum amalgam in the usual way. The amalgam was prepared by immersing aluminum foil, cut into pieces, in a dilute solution of mercuric chloride (less

min, the initial evolution of heat subsided. Then water (*ca.* 12 ml) was added, portion by portion, over a period of *ca.* 10 hr with shaking at room temperature. When the reaction was complete, an aqueous solution of sodium hydroxide (100 g of a 25% soln.) was added to dissolve the aluminum hydroxide produced. The whole was then filtered, sodium chloride was added, and the mixture was extracted with ether. The extract was concentrated, dried over potassium hydroxide, and distilled. A fraction which distilled at 57—59°C/12 mmHg was collected; colorless liquid, yield 5.4 g (*ca.* 54%).

The hydrochloride of the amine was prepared by passing dry hydrogen chloride into a solution of the amine in ether. The precipitates produced were recrystallized from hot dioxane to give long, colorless plates, mp 147—148°C.

The authors are grateful to Dr. Hiroshi Midorikawa for affording facilities for the present work.

Preparation of 1 : 1- and 2 : 1-Telomers of Allyl Acetate Using the Azeotropic Mixture with Carbon Tetrachloride[1)]

Masao Ōkubo

Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya

(Received June 15, 1967)

Recently, several relations were observed between the structure and the reactivity of carboxylic acid esters of allylic alcohols in their γ-ray induced telomerization with carbon tetrachloride.[2-4)]

In this paper, the results will be reported on an investigation to confirm the effect of temperature, the elevation of which caused an increase in the yield of 1 : 1-telomer as had been observed in the preliminary experiment.[2)] In consequence, an apparatus was devised to increase the yields of 1 : 1- and 2 : 1-telomers and to decrease simultaneously the yield of the 3 : 1-telomer of allyl acetate.

Experimental

Irradiation at an Elevated Temperature. By modifying the Soxhlet's extractor, an apparatus was constructed as shown in Fig. 1. A solvent of a suitable boiling point in the Flask 2 was heated to boiling by the Heating Mantle 1, and the temperature inside the Glass Mantle 4 could be maintained to be constant. A sample solution was introduced into the Ampoule 5, on the top of which is connected the U-Tube 6 containing a suitable amount of carbon tetrachloride to prevent the sample solvent from its escaping and, at the same time, to avoid the danger of an unexpected violent reaction. This apparatus was placed at a given distance from the γ-ray source 8. Methanol, bp 65°C, was used as the heating solvent, and the Flask is protected from γ-ray by the Pb-Block 9.

By this device, the strength of γ-ray falls only slightly, and the Ampoule can be placed, if necessary, at the least distance from the γ-ray source.

Irradiation of Circulated Sample. Again by modifying the Soxhlet's extractor, the other apparatus was constructed as shown in Fig. 2. A mixture of allyl acetate and carbon tetrachloride in the Flask 2 is heated to boiling by the Heating Mantle 1. The vapor of the azeotropic mixture goes through the Side

7 Condenser	8 γ-Ray source
9 Pb-block	

Tube 3 and the Glass Mantle 4, and then to the Condenser 7. The liquefied azeotrope comes down through the Long Funnel 6 and fills up the Reaction Tube 5 and is irradiated. The produced telomers and the unreacted materials run over the top of 5, passing through 3, and comes back to 2. The telomers are stored in 2, and protected from γ-ray by the Pb-Block 9. The unreacted azeotrope is brought to 5 and is irradiated again. So, this method is named the circulation technique in this paper.

The concentration of allyl acetate in the Reaction Tube 5 changes gradually, and it was determined by the titration with a KBr-$KBrO_3$ aqueous solution before and after the irradiation. Then, the remaining solution in 5 was put back into 2, and the resulting total solution was titrated to determine the overall consumption of ally acetate.

Results and Discussion

Effect of Temperature. Using the apparatus of Fig. 1, a solution of the molar ratio of 1/5 (allyl acetate, 0.0667 mol, and CCl_4, 0.333 mol) was irradiated at the dose rate of 5.5×10^4 R/hr, at 65°C. Table 1 lists this result together with the results of the preceding experiments at 25°C.[1] From these data, it can be seen that the elevation of the temperature makes the reaction faster, and the lowering of the initial concentration of the allyl ester causes an increase in % consumption of C=C bond. Furthermore, both of these changes of the reaction condition favor the yields of 1 : 1- and 2 : 1-telomers. Since these changes of the reaction condition may accelerate the chain transfer of the propagating radical to CCl_4, the above result is ascribed to the acceleration of the step (1) and, at the same time, to the relative retardation of the step (2).

$$\begin{aligned} &Cl_3C\text{-}CH_2\text{-}\dot{C}H \\ &\qquad\quad | \\ &\qquad CH_2O\text{-}OCOCH_3 \end{aligned} + CCl_4 \longrightarrow \begin{aligned} &Cl_3C\text{-}CH_2\text{-}CHCl \\ &\qquad\quad | \\ &\qquad CH_2O\text{-}OCOCH_3 \end{aligned} + \cdot CCl_3 \qquad (1)$$

$$\begin{aligned} &Cl_3C\text{-}CH_2\text{-}CH\text{-}CH_2\text{-}\dot{C}H \\ &\qquad\quad |\qquad\quad | \\ &\qquad CH_2\quad CH_2 \\ &\qquad |\qquad\quad | \\ &\qquad OCOCH_3\ OCOCH_3 \end{aligned} + \begin{aligned} &CH_2\text{=}CH \\ &\qquad\quad | \\ &\qquad CH_2 \\ &\qquad\quad | \\ &\qquad OCOCH_3 \end{aligned} \longrightarrow \begin{aligned} &Cl_3C\text{-}(\text{-}CH_2\text{-}CH\text{-})_2\text{-}CH_2\text{-}\dot{C}H \\ &\qquad\qquad\quad |\qquad\quad | \\ &\qquad\qquad CH_2\quad CH_2 \\ &\qquad\qquad |\qquad\quad | \\ &\qquad\qquad OCOCH\ OCOCH_3 \end{aligned} \qquad (2)$$

From the above observation, the increase in the yields of 1 : 1- and 2 : 1-telomers is expected when the irradiation is carried out at higher temperatures and lower concentrations.*1 However, the apparatus of Fig. 1 does not seem to fit for this purpose, since, besides the necessity of an heating solvent, a voluminous reaction tube is required to contain the large volume of a diluted solution of CCl_4. To avoid these inconveniences, the circulation technique was adopted and the apparatus of Fig. 2 was devised.

Results of Circulation Technique. Allyl acetate, 80 g, and CCl_4, 246 g (molar ratio of 1/2), were introduced into the Flask 2 in Fig. 2. The voltage applied on the Heating Mantle was controlled so that the azeotropic mixture came down from the Condenser at a rate of *ca.* two drops per second. In this condition, the molar ratio of the solution inside the Reaction Tube was found to be 1/7.5. After irradiation for 170 hr, it came down to 1/19. The results are shown in Table 2.

The reaction temperature was nearly the boiling point of CCl_4, 76°C. The production ratios of 3 : 1-telomer in Table 2 resemble the ratio obtained in the experiment of 1/5 molar ratio at 65°C, but are slightly higher than that obtained in the experiment of 1/10 molar ratio at 25°C in Table 1. Therefore, the concentration lowering by half is considered to be more effective than the temperature elevation by 40 or 50 degrees for the increase in the

*1 Both of 1 : 1- and 2 : 1-telomers can be isolated easily by distillation under the reduced pressure, and the 2 : 1-telomers of allyl carboxylates have been shown to give a trichloroethyl derivative of tetrahydrofurfuryl alcohol in good yields.[3]
