yields of 1 : 1- and 2 : 1-telomers. But, it is remarkable that, notwithstanding the use of the mixture as high molar ratio as 1/2, the content of 1 : 1- and 2 : 1-telomers reached 80.3% by weight of the total products, and therefore, this technique was shown to be useful for preparing these telomers.

Table 2. Irradiation of the circulated mixture
allyl acetate, 80 g; CCl_4, 246 g

Irradn. hours hr	C=C consumption %	Telomer production ratios		
		1 : 1	2 : 1	3 : 1
120	40	1	3.3	1.3
170	82	1	3.9	1.3

The advantages of this method are: that the concentrated solutions can be used and, therefore, a large quantity of the allyl ester can be treated at once; and that, as mentioned already, the heating of the reacting sample can be performed automatically without the heating solvent.

A disadvantage, the slightly higher yield of the 3 : 1-telomer than that obtained in the case of the molar ratio of 1/5 at 65°C, may be partly due to the fact that the concentrated solution of the allyl ester in the Flask 2 is irradiated continuously during the experiment with scattered γ-rays and, moreover, with weak γ-rays which have passed through the Pb-Block.

One of the well-known undesirable features of the telomerization reaction in general is that the telomer of a particular molecular weight cannot be prepared exclusively when a concentrated solution of taxogen is used. The present method suggests one of the directions to overcome this difficulty.

The author is indebted to Mr. Keichi Nunome of the present institute for operating the γ-ray irradiator. He also offers his gratitude to Professor Ryozo Goto of Kyoto University for his encouragement throughout the work.

The Photochemical Cleavage of Friedelin

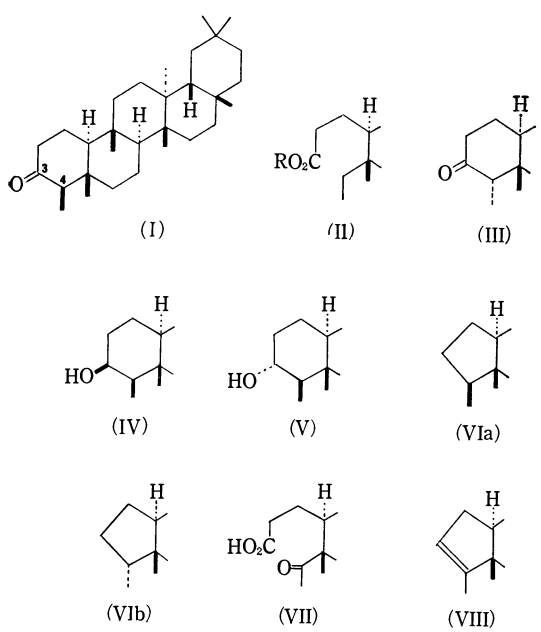
Takahiko TSUYUKI, Shûzô YAMADA and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 29, 1967)

We wish to report the formation of a series of compounds (II—VI) on the photolysis of friedelin.

A boiling solution of friedelin[1] (I; 1.00 g) in ethanol was irradiated with a high pressure mercury lamp under a nitrogen atmosphere for 9 hr. The reaction products were separated by preparative thin layer chromatography (TLC). The main product was 3, 4-seco-ester*1 (II, R=Et; 732 mg). The formation of 4-isofriedelin*1 (III; 49 mg), 3β-friedelanol[1] (IV; 11 mg), 3α-friedelanol[2] (V; 86 mg) and 3, 4-seco-acid*1 (II, R=H; 2 mg) was confirmed. A hydrocarbon (VI; 25 mg) was also isolated besides friedelin (I; 135 mg). The hydrocarbon (VI) showed two peaks on gas-liquid chromatography (GLC), though this compound gave only one spot on TLC (silica gel-silver nitrate). One of the peaks was shown to be due to 3-norfriedelane*1 (VIa) and the other would be due to 3-nor-4-isofriedelane (VIb) (*Cf.* Experimental). However, no isolation of VIb has yet been furnished. The structure III was confirmed by alkaline isomerization to I.



Friedelin (I; 1.00 g) in acetic acid-water (9 : 1) was heated under reflux and was photolyzed under the same condition as above for 27 hr. The product was mainly the acid (II, R=H; 883 mg) accompanied with the hydrocarbon mixture (VIa and VIb: 20 mg) and friedelin (I; 28 mg).

In ethanol solution, the formation of II (R=Et and H) and of hydrocarbons (VIa and VIb) could be interpreted by the known photochemical reaction processes.[3] The formation of III would be explained by recombination of a diradical formed by α-cleavage (between positions 3 and 4) of I. A part of recovered friedelin (I) should be resulted from diradical recombination of alternative fashion. Furthermore, the photoreduction was concomitant to form a pair of friedelanols (IV and V).[4] In the aqueous acetic acid solution, the formation of II (R=H) was predominant.

Experimental

Photochemical Cleavage of Friedelin in Ethanol. The suspension of friedelin (1.00 g) in ethanol (600 m*l*) was heated under reflux with bubbling of nitrogen for 30 min. The solution was then irradiated with a high pressure mercury lamp (100 W) under a nitrogen atmosphere for 9 hr. Repeated separation of the products by preparative TLC (SiO_2 and SiO_2-$AgNO_3$) afforded the compounds (I)—(VI).

3, 4-Seco-ester (II, R=Et). 3, 4-Seco-ester was recrystallized from ethanol and then from acetone, mp 116.0—116.7°C.

Found: C, 81.40; H, 11.85%. Calcd for $C_{32}H_{56}O_2$: C, 81.29; H, 11.94%. This material was identical with the authentic sample in mp, TLC and IR spectrum. The authentic sample was obtained from friedonic acid (VII).[2b,5] Huang-Minlon reduction of VII yielded 3, 4-seco-acid (II, R=H), mp 211°C.

Found: C, 80.77; H, 11.78%. Calcd for $C_{30}H_{52}O_2$: C, 81.02; H, 11.79%.

Esterification (EtOH-H_2SO_4) and recrystallization from ethanol and then from acetone gave the ester (II, R=Et), mp 116.3°C.

4-Isofriedelin (III). 4-Isofriedelin was recrystallized from petroleum ether, mp 257.5°C, $\nu_{C=O}$ 1706 cm^{-1}. The solution of III in dioxane was heated under reflux with sodium methoxide in methanol under a nitrogen atmosphere for 6 hr. GLC examination (Diasolid

H-523, 240°C) revealed that the most of III (t_R=36.6 min) isomerized to I (t_R=41.1 min). The isomerized product was purified by preparative TLC and recrystallization from petroleum ether. The IR spectrum, mp, mixed mp and R_f value on TLC were identical with those of friedelin (I).

3-Norfriedelane (VIa) and 3-Nor-4-isofriedelane (VIb). The hydrocarbon fraction was recrystallized from chloroform-methanol, mp ~210°C.

Found: C, 87.11; H, 12.49%. Calcd for $C_{29}H_{50}$: C, 87.36; H, 12.64%. The IR spectrum and R_f value on TLC (SiO_2-$AgNO_3$) were identical with those of the authentic 3-norfriedelane. However, two peaks appeared at t_R=12.5 and 13.4 min on GLC (Diasolid H-523, 240°C). The authentic 3-norfriedelane (VIa) was prepared as follows: Hydrogenation (5% Pd-C/AcOEt) of 3-norfriedelene[2b] (VIII) proceeded mainly from α-side to afford the sole product, 3-norfriedelane*[1] (VIa), mp 224°C (Found: C, 87.15; H, 12.41%. Calcd for $C_{29}H_{50}$: C, 87.36; H, 12.64%), which gave a single peak at t_R=13.4 min on GLC under the same condition, described above.

Photochemical Cleavage of Friedelin in Aqueous Acetic Acid. Friedelin (1.00 g) in acetic acid-water (9 : 1) (600 m*l*) was irradiated at reflux temperature under nitrogen with a high pressure mercury lamp (100 W) for 27 hr. Working up as before and 883 mg of the 3, 4-seco-acid (II, R=H), mp 214.5—215.0°C, 20 mg of the hydrocarbon mixture (VIa and VIb), mp ~212°C, (Found: C, 87.40; H, 12.77%. Calcd for $C_{29}H_{50}$: C, 87.36; H, 12.64%) and 28 mg of friedelin (I) were obtained.

Polymerization of Alkoxyacetylenes

Sun'ichi NOZAKURA,* Manabu TAGAYA*[1],* Heimei YUKI** and Shunsuke MURAHASHI**

* *Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka*

** *Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka*

(Received August 3, 1967)

Acetylene and its derivatives are known to undergo polymerization to linear polymers or cyclic oligomers depending on the polymerization conditions.[1] Alkoxyacetylene gives an interesting linear polymer which is susceptible to chemical transformations because of its unsaturated ether structure. There have been, however, only a few reports on its polymerization. Phenoxyacetylene has been polymerized thermally to a cross-linked polymer.[2] Ethoxyacetylene has been reported to give a cyclic trimer in the presence of $Ni(CO)_2(PPh_3)_3$.[3]

Since alkoxyacetylene was expected to polymerize cationically by analogy with vinyl ether, the polymerization of methoxy- and isobutoxyacetylene were attempted in the presence of Friedel-Crafts catalysts and soluble Ziegler catalysts, which were known to be effective for acetylene.

Monomers were prepared according to a known procedure.[4] Methoxyacetylene, bp 23.5°C; isobutoxyacetylene, bp 46.0—47.0°C/135 mmHg, n_D^{20} 1.4022.

The cationic polymerization was carried out in either *n*-hexane or methylene chloride (20 m*l*) at −78°C for 3 hr, using 2 m*l* of isobutoxyacetylene and a 0.1 mol equivalent of a catalyst. The polymerization was then quenched by the addition of methanol, followed by evaporation; this gave a 39% yield with $TiCl_4$ in methylene chloride, a 55% yield with BF_3 (saturated), and a 18% yield with $AlBr_3$. Catalysts such as $BF_3 \cdot Et_2O$, $SnCl_4$ and VCl_3 gave yields of only a few percentage points. The polymerizations in *n*-hexane resulted in lower yields than those in methylene chloride.

Soluble complex catalysts composed of transition-metal acetylacetonate and triisobutylaluminum (1 : 1) were found to be very effective. Polymerizations were carried out in benzene (20 m*l*) at 30°C for 3 hr, using 2 m*l* of isobutoxyacetylene and a 0.1 mole quivalent of the complex catalysts. These polymerizations were stopped by the addition of methanol, and the whole contents were evaporated. The yields were calculated using the correction of the catalyst residue, the following yields being found for the given acetylacetonate: Fe^{3+} 92, Cr^{3+} 91, Co^{3+} 89, VO^{2+} 81, Ni^{2+} 59, Co^{2+} 46, Cu^{2+} 42, V^{3+} 25, TiO^{2+} 16, Zr^{4+} 0, Mn^{3+} 0, Zn^{2+} 0%. It is interesting to note that Cr^{3+}, Fe^{3+} and Cu^{2+} had scarcely been at all effective in the polymerization of acetylene.[5]

The cationic polymers were viscous or tacky semisolids, in color ranging from a light brown to a reddish brown, and in molecular weight ranging around 500—600. The absence of IR absorption bands of trisubstituted benzene and NMR resonance due to aromatic hydrogen suggests a negligible formation of cyclic trimers, if any.*2

The polymers which were obtained with the Ziegler catalysts were partly soluble in methanol. The soluble part was a reddish-brown, tacky solid and resembled the cationic polymer. The insoluble part was a brown-to-black powder. Both the parts contained an inorganic ingredient originating from the catalyst, and purification was found to be difficult. For example, when a 0.1 mol equivalent of $Fe(acac)_3$-$Al(i\text{-}Bu)_3$ (1 : 1) to the monomer was used, the soluble part of the poly(isobutoxyacetylene) was found to contain 8.6% ash, and the insoluble part, 10.6%. The Al/Fe atomic ratio in the latter was found to be 0.31. Upon treatment with aqueous 2 N HCl, the polymer was almost free from ash, which amounted to only 0.28% in the soluble part and 0.51% in the insoluble part. Unfortunately, however, the treatment was accompanied by a chemical modification of the polymer, as will be mentioned below.

A crude poly(methoxyacetylene) showed in its infrared apectrum a broad band of a polyconjugated double bond around 1560 cm^{-1} (s), an ether linkage at around 1080(s), and an olefinic C-H bond at 820 cm^{-1}(m). On treatment with 2 N HCl, all these bands diminished in intensity, and new bands appeared around 1715(s), 1660(s) and 1600(s) cm^{-1}; these bands are considered to be due to various kinds of carbonyls. Poly(isobutoxyacetylene) showed essentially the same spectral change and weight loss of 20% upon treatment with 2 N HCl, followed by heat-treatment at 90°C. As a volatile product of the treamtent, isobutanol was identified by gas chromatography. Hence, the spectral change may be interpreted by the following reaction scheme:

$$-\underset{\underset{OR}{|}}{CH}=\underset{\underset{OR}{|}}{C}-\underset{\underset{OR}{|}}{CH}=\underset{\underset{OR}{|}}{C}- \rightarrow -CH_2-\overset{\overset{O}{\|}}{C}-\underset{\underset{OR}{|}}{CH}=\underset{\underset{OR}{|}}{C}- \rightarrow$$

$$-CH_2-\overset{\overset{O}{\|}}{C}-CH_2-\overset{\overset{O}{\|}}{C}-$$

In fact, the methanol-insoluble part of poly(methoxyacetylene) after the treatment with 2 N HCl showed the following analytical data, which correspond to those where 3/5 of the enol-ether structure was converted into ketone.

Found: C, 60.61; H, 5.40%. Calcd for $[(C_3H_4O)_2(C_2H_2O)_3]_n$: C, 60.50; H, 5.88%.

The halogenation of the polymers was attempted in chloroform at room temperature, 75—93% of the theoretical value of chlorine and 56—68% of that of bromine were introduced, a process accompanied by a slight evolution of hydrogen halide. The halogenated polymers were soluble in acetone and benzene. The molecular weight of the chlorinated poly(methoxyacetylene) were found by vapor-pressure osmometry to be 560 and 800 for the soluble and insoluble parts respectively, and the chlorine contents, 41.74 and 49.79% respectively.

The hydrogenation of the crude poly(isobutoxyacetylene) was attempted using Pd or Pt on carbon as a catalyst or with tri-*n*-butylboron,[6] but no hydrogenation was observed. Diels-Alder reactions with maleic anhydride or maleimide in refluxing toluene gave negative results.

*2 When ethoxyacetylene was treated with $TiCl_4$ in benzene at 40°C for 3 hr, there was obtained a polymer in a 51% yield; from this a cyclic trimer (13%, mp 35—36°C) was isolated by alumina-column chromatography.

The Infrared Spectra of *p*-Substituted Benzenediazonium Cations

Katsumi TABEI and Chihiro ITO

Tokyo College of Pharmacy, Kashiwagi, Shinjiku-ku, Tokyo

(Received August 8, 1967)

The infrared spectra of some aromatic diazonium cations have already been measured by several authors and the change of the diazonium group stretching frequency by the introduction of a substituent into the aromatic nucleus was discussed with reference to the change of N-N bond order.[1,2] However, any other vibration than the diazonium stretching one has never been studied.

In the present report, the infrared spectra of twenty kinds of *p*-substituted benzenediazonium cation were measured in the form of solid chloromercurate to study the aryl carbon - nitrogen bond (Ar-N) stretching vibration in relation to the electronic effect of a *p*-substituent.

In an aromatic diazonium cation, the aryl carbon-nitrogen bond stretching vibration appeared in the frequency region 1300—1400 cm^{-1}, and the above assignment was made with reference to that of nitrobenzenes[3] and phenyl isocyanides[4].

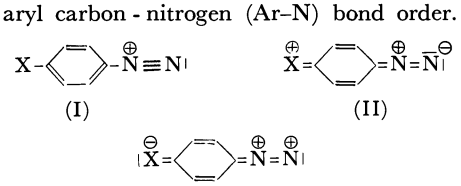
The wave numbers of the characteristic absorption band of diazonium cation, $\nu_{N\equiv N}$ and ν_{Ar-N} were listed in Table 1.

From the data of Table 1, it was shown that an electron-donating *p*-substituent increases the wave number of ν_{Ar-N} and decreases that of $\nu_{N\equiv N}$.

An electron-attracting *p*-substituent, on the other hand, seems to be rather less effective upon the above two absorption bands.

By plotting the wave numbers of ν_{Ar-N} and $\nu_{N\equiv N}$ against Hammett's σ_p value for the substituent in Figs. 1 and 2, it can be clarified that there is almost a linear correlation between them, and that the straight line was distorted as represented by the dotted line above the region of plus σ_p value.

The high frequency shift of the aryl carbon-nitrogen bond stretching vibration by the substitution of an electron-donating group can be explained in the same way as described in the case of the diazonium group stretching band,[5,6] that is, the substitution of an electron-donating group at the para position of the benzene ring increases the contribution of the polarized structure (II) to the ground state (I), namely it decreases the N≡N bond order and at the same time increases the aryl carbon - nitrogen (Ar-N) bond order.



(I) (II)

(III)

The break in the linear correlation by the substitution of a strong electron-attracting group, on the other hand, may be partly interpreted by taking the polarized structure (III) into consideration.

Since an increase in the contribution of the structure (III) to the ground state (I) increases the aryl carbon - nitrogen (Ar-N) bond order and

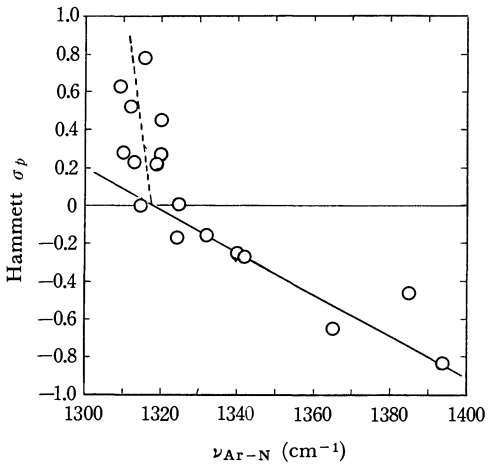

Fig. 1. Plot of aryl carbon-nitrogen bond stretching frequency *vs.* Hammett's σ_p constant for the corresponding *p*-substituent.

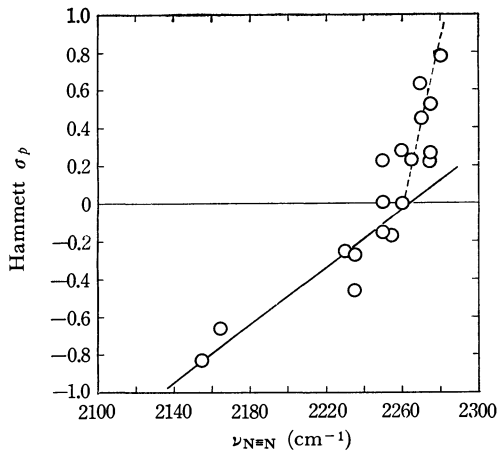

Fig. 2. Plot of diazonium group stretching frequency *vs.* Hammett's σ_p constant for the corresponding *p*-substituent.

at the same time, decreases the N≡N bond order, the substitution of a strong electron-attracting group shifts the aryl carbon - nitrogen (Ar-N) stretching vibration to the higher frequency side and at the same time, shifts that of the diazonium group to the lower frequency side. However, the above contribution of the structure (III) by the substitution of a strong electron-attracting group is less important than that of structure (II), because there is an unstable, doubly positive charged N=N bonding in the former structure.

The net effect of a strong electron-attracting group upon the characteristic infrared absorption bands of diazonium cation seems to be small and then the absorption band of ν_{Ar-N} and $\nu_{N\equiv N}$ of the diazonium salts having a strong electron-attracting group at para position of benzene nucleus appears in the narrow frequency regions 1310—1320 cm^{-1}, and 2260—2280 cm^{-1}, respectively.

Experimental

Preparation of Diazonium Double Salts. The preparation of the mercuric chloride double salt of *p*-substituted benzenediazonium chlorides was carried out following the method of Nesmejanow[7]; The diazotization of an arylamine was done by a usual method with the corresponding amount of moles of sodium nitrite in 20% hydrochloric acid solution at 0—5°C.

The diazotized solution was filtered and then poured into a solution of one and a half times as much as the corresponding amount of moles of mercuric chloride in 20—30 m*l* of cooled concentrated hydrochloric acid. The mixture was stirred at 0—5°C for ten minutes or so.

After precipitation of the double salt, the crystal was collected on a glass-filter, washed with cooled water, ethanol and ether, in that order, and dried in a vacuum desiccator. The yield of dried double salt was 10—60%.

Infrared Spectra of Diazonium Double Salts. The infrared spectra of the double salts were measured by using a JASCO DS-301 infrared spectrophotometer in a KBr disk. The wave numbers of $\nu_{N\equiv N}$ and ν_{Ar-N} are listed in Table 1.

The authors wish to express their deep gratitude to Miss Michiko Hayama of Tokyo College of Pharmacy for her infrared measurement.

π-Allylic Palladium Complexes from Methyl Sorbate

Akira KASAHARA and Taeko IZUMI

Department of Chemistry, Faculty of Liberal Arts and Science, Yamagata University, Yamagata

(Received August 15, 1967)

The reaction of sodium chloropalladite with conjugated diolefin in alcohols has been shown to result in the formation of alkoxy-π-allylic palladium complexes.[1,2] Thus, butadiene in methanol gaves the chloro-bridged 4-methoxy-π-butenyl complex, $[Pd_2Cl_2(C_4H_6OCH_3)_2]$,[1] while the reaction of cycloocta-1, 3-diene with sodium chloropalladite in methanol gives rise to di-μ-chlorodi-(4-methoxy-cyclooct-2-enyl)-dipalladium. When this is heated, *in situ*, the methanol is eliminated and an unsaturated complex, di-μ-chlorodi-(cycloocta-2, 4-dienyl)-dipalladium, is formed.[2]

This paper will describe the application of this reaction to methyl 2, 4-hexadienoate (methyl sorbate).

Results and Discussion

The treatment of methyl sorbate with sodium chloropalladite in methanol at room temperature for 20 hr gave two products, $[C_{16}H_{26}O_6Cl_2Pd_2]$ (mp 122—125°C) as the major product and $[C_{14}H_{18}O_4Cl_2Pd_2]$ (mp 116—119°C); the I and IIA structures respectively were assigned to these productes on the basis of their infrared and NMR spectra. The dimeric nature of these compounds was supported by the molecular-weight determinations, and by their reacting with pyridine to give readily-soluble monomeric derivatives (*cf.* Fig. 1).

The infrared spectrum of the major product (I) showed the presence of methoxy group at 2820 and 1097 cm^{-1} and an uncoordinated ester carbonyl group at 1728 cm^{-1}. The allylic structure of this complex was also supported by an examination of its NMR spectrum, which showed a doublet at 8.63 τ (3H, J=6 cps) for methyl protons on C_5, a singlet at 6.63 τ (3 H) for methoxy protons on C_4, a multiplet at 6.57 τ (1 H) for the proton on C_4, a doublet at 6.47 τ (1 H, $J_{1,2}$=10 cps) for the allylic proton on C_1, a singlet at 6.31 τ (3 H) for methyl protons of the ester group, a double doublet at 6.00 τ (1 H, $J_{2,3}$=10 cps and $J_{3,4}$=2 cps) for the allylic proton on C_3, and a triplet at 3.90 τ (1 H, J=10 cps) for the allylic proton on C_2. These spectral data suggest that

2) a) S. D. Robinson and B. L. Shaw, *ibid.*, **1964**, 5002. b) M. R. Churchill, *Chem. Commun.*, **1965**, 625; *Inorg. Chem.*, **5**, 1608 (1966).

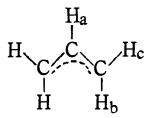

Fig. 2

the major product (I) is di-μ-chlorodi-[1-carbomethoxy-3-(1'-methoxyethyl) -π-allyl]-dipalladium. In addition, the proton on the center carbon atom (C_2) of the π-allyl system couples with the two trans protons on C_1 and C_3; their coupling constants were found to be both 10 cps. In the simple π-allyl complex (*cf.* Fig. 2), the trans coupling constant ($J_{a,b}$) between the proton on the center carbon and the proton on the terminal carbon is 11 cps and the cis coupling constant ($J_{a,c}$) is 7 cps.[3] Thus, it may be concluded that the orientation of the methoxyethyl and carbomethoxy groups in I is "*syn.*"

On the other hand, the minor product, [$C_{14}H_{18}O_4Cl_2Pd_2$], was less stable than the major product (I); it gradually decomposed in a solution to give a palladium mirror. In the infrared spectrum of this complex, there were no bands in the regions between 2810—2840 and 1080—1110 cm^{-1}, suggesting the absence of a methoxy group.[2a] Furthermore, the spectrum did not show the characteristic absorption bands due to a vinyl group. The ultraviolet absorption spectrum in ethanol did, however, show a strong absorption band at 211 mμ, suggesting the presence of a double bond conjugated with the ester group. These spectral data favor the conjugated structure (IIA) rather than the vinylic structure (IIB), formed simply by the loss of methanol from the structure (I). This structure was also supported by an examination of its NMR spectrum, which showed a doublet at 6.98 τ (1 H, $J_{1,2}=1.05$ cps) for the allylic terminal "*anti*" proton on C_1, a double doublet at 6.47 τ (1 H, $J_{3,4}=13$ cps and $J_{2,3}=10$ cps) for the allylic proton on C_3, a singlet at 6.33 τ (3 H) for methyl protons of the ester group, a doublet at 5.83 τ (1 H, $J_{1,2}=6.5$ cps) for the allylic "*syn*" proton on C_1, a multiplet at 4.04 τ (1 H) for the allylic center proton on C_2, a doublet at 3.74 τ (1 H $J_{4,5}=18$ cps) for the olefinic proton on C_5, and a double doublet at 2.60 τ (1 H, $J_{4,5}=18$ cps and $J_{3,4}=13$ cps) for the olefinic proton on C_4. The complex (IIA) seems to be derived from methyl sorbate by the activation of allylic hydrogen at the terminal methyl group, followed by eliminating hydrogen chloride,[4] rather than from the complex (I) by the loss of methanol, followed by a 1, 3 shift of the palladium atom.

Experimental

All the melting points are uncorrected. The infrared spectra were measured in KBr disks with a Hitachi EPI-S infrared spectrometer, while the ultraviolet absorption spectra were measured with a Hitachi recording spectrophotometer, model EPS-3T. The NMR spectra were recorded by a Varian Model A-60 instrument in deuterochloroform, using tetramethylsilane as an internal standard.

Reaction of Methyl Sorbate with Sodium Chloropalladite. Methyl sorbate (2.52 g) was added to a suspension of sodium chloropalladite trihydrate (7.0 g) in methanol (50 m*l*). After 20 hr, the metallic palladium thus deposited was removed by filtration, and then the brown filtrate was evaporated to dryness under reduced pressure. Chromatography in chloroform on an alumina column gave two complexes. The first complex eluted was di-μ-chlorodi-[1-carbomethoxy-3-(1'-methoxyethyl)-π-allyl]-dipalladium (1.10 g, 16.5 %). Recrystallization from cyclohexane gave yellow needles, mp 122—125°C (decomp.). λ_{max}^{EtOH}: 213 mμ (log ε 2.66). IR spectrum (KBr): 2820 (OCH_3), 1728 (ester), and 1098 cm^{-1} (OCH_3).

Found: C, 32.14; H, 4.77%; mol wt, 595 (in benzene). Calcd for $C_{16}H_{26}O_6Pd_2Cl_2$: C, 32.08; H, 4.67%; mol wt, 598.

The second complex eluted was di-μ-chlorodi-[1-(2'-carbomethoxy-ethenyl)-π-allyl]-dipalladium (0.09 g, 1.7%), yellow needles. Mp 116—119°C (decomp.). λ_{max}^{EtOH} 211 mμ (log ε 4.47). IR spectrum: 1720 cm^{-1} (ester).

Found: C, 31.22; H, 3.41%; mol wt, 529 (in benzene). Calcd for $C_{14}H_{18}O_4Pd_2Cl_2$: C, 31.43; H, 3.36%; mol wt, 534.

The Preparation of Chloro-(π-allyl)-pyridine-palladium Complexes. A solution of the chloro-bridged palladium complex (0.05 g) in dichloromethane (5 m*l*) was treated with a solution of pyridine (5% excess) in ether. After 10 min, the solvent was removed under reduced pressure, after which chromatography on alumina using chloroform afforded the expected product. The complexes below were prepared in this manner.

Chloro-[1-carbomethoxy-3-(1'-methoxyethyl)-π-allyl]-pyridine-palladium. Yellow crystal. Mp 128—132°C (decomp.).

Found: C, 41.47; H, 4.68; N, 3.81%. Calcd for $C_{13}H_{18}O_3NPdCl$: C, 41.25; H, 4.75; N, 3.70%.

Chloro-[1-(2'-carbomethoxy-ethenyl)-π-allyl]-pyridine-palladium. Yellow crystal. Decomp. p. 78—84°C (without melting).

Found: C, 41.85; H, 4.22; N, 4.18%. Calcd for $C_{12}H_{14}O_2NPdCl$: C, 41.59; H, 4.07; N, 4.04%.

A Study of the Charge-Transfer Complexes. VI. A Question on the Concept of the Weak Charge-Transfer Complexes*1

Taku MATSUO and Osamu HIGUCHI*2

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received August 18, 1967)

In the recent years, several criticisms have been made on the reliability of the equilibrium constant (K) and the extinction coefficient (ε) for weak charge-transfer (CT) complex as estimated by the Benesi-Hildebrand (B-H) equation or the modified ones.[1-4] The disbelief in the B-H equation has mainly come from the three facts: (1) the dependence of the K-value on the ratio between the concentrations of donor and acceptor molecules,[1] (2) the variation of the K-value with the wavelength of the absorption band which the B-H equation is applied to,[2,3] and (3) the inconsistent relationship between the K- and ε-values.[1,4] All of these criticisms may be summarized to indicate that the basic assumptions inherent to the B-H equation do not hold in the actual cases of weak CT complexes. In other words, the fundamental concept of weak CT complexes might have been in error. Dewar and Thompson, in this connection, have lately emphasized that the appearance of CT absorption band does not necessarily mean that the CT interaction is the main driving force in the formation of molecular complexes.[5] The present authors have reached similar conclusions as described below.

The CT absorption bands of tetracyanoethylene (TCNE) complexes with *p*-methylanisole (I) and *t*-butyl *p*-tolyl ether (II) have been measured in carbon tetrachloride. The ordinary B-H equation has been used to obtain the K- and $K\varepsilon$-values for the complexes as summarized in Figs. 1 and 2. If the K-values at the absorption maxima are compared, as usual, the TCNE complex with II is more stable than that with I. As to the CT bands themselves, on the other hand, the absorption maximum for the complex II is at considerably larger wave numbers than that for the complex I. This is a very peculiar situation. On the basis of the ordinary concept of CT complexes, it is expected that the more stable the complex becomes, the smaller the wave numbers at the absorption maximum are. The apparent contradiction to the expectation, as observed here, may be easily understood however if the associations are essentially due to the van der Waals forces as suggested by Dewar and Thompson.[5] If this assumption is correct, the CT absorption is expected to occur simply because the pair of donor- acceptor molecules are held at close distance where CT forces contribute additional stabilizing effects on the association. In the present case, the relative importance of CT interaction in the association may be considerably different between the two complexes.

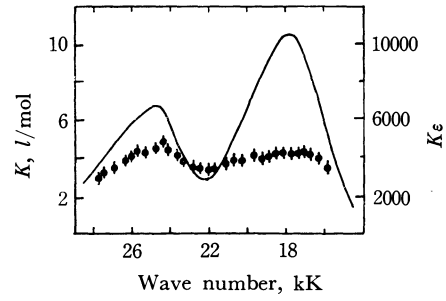

Fig. 1. The K- and $K\varepsilon$-values for TCNE complex of *p*-methylanisole. ●, K; —, $K\varepsilon$. The short, vertical line across the dot represents the standard deviation for the K.

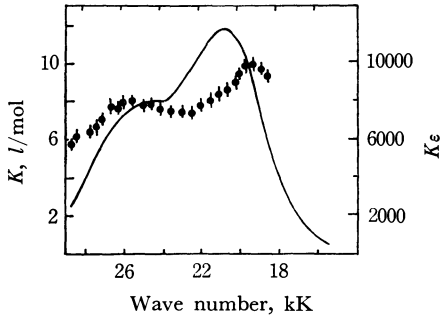

Fig. 2. The K- and $K\varepsilon$-values for TCNE complex of *t*-butyl *p*-tolyl ether. ●, K; —, $K\varepsilon$.

One of the present authors has found, in his study of the NMR solvent effects also, that the CT forces are merely complementary ones in the interaction between solvent benzene and polar solute such as maleic anhydride or *p*-benzoquinone.[6,7] It should be recalled further that the heats of formation for the weak CT complexes are of the order of a few kcal/mol, in general. Therefore, one can hardly distinguishes the energy of weak CT interaction from that of van der Waals interaction.

On the basis of the above discussion, the present authors propose a revised model for weak CT complexes as follows. The donor and acceptor molecules at close distance may be held each other mainly by the van der Waals-type forces. Then, the configurations (or mutual orientations) of the pair will follow a statistical distribution. The most stable configuration in the distribution is not necessarily the most favored one from the view points of CT interactions. The apparent CT bands in solution are considered to be originated from such assembly of the associated species. In short, the spectra may not be taken to represent a simple, rigid complex. The three problems about the B-H equation, as described in the beginning, have appeared to be reasonably solved by Foster and his associates who have assumed that the absorption of CT complexes deviates*3 from Beer's law.[1,2] It is suggested here that the deviation occurs simply because the relative importances among the configurations of the associated species vary with the change in the environment.

Experimental

Chemicals. *p*-Methylanisole and *t*-butyl *p*-tolyl ether were prepared from *p*-cresol by the use of dimethyl sulfate and *t*-butyl alcohol (together with concentrated sulfuric acid), respectively. The products were repeatedly purified by fractional distillations, and were identified by the IR and NMR spectra. The purities were proven to be above 99% by the gas chromatography. TCNE were prepared from malononitrile by the method of Carboni (mp 199—200°C).[8] Carbon tetrachloride was purified by the standard procedure.

Measurements. The spectra were measured under the temperature regulation (25±0.5°C) with a Hitachi model EPS-2U recording spectrophotometer. The *K*- and K_ε-values were obtained by the least-square-mean method as applied to the B-H equation.

On the Hydrothermal Behavior of the Solutions of Some Metal Complexes Observed by Means of Visual Autoclaving

Tominosuke KATSURAI and Kôzô SONE

Pilot Laboratory, Hiratsuka-Kanagawa and Department of Chemistry, Faculty of Science, Shizuoka University, Shizuoka

(Received August 28, 1967)

Visual autoclaving, a method of direct observation of autoclaving process, was worked out for the purpose of following the hydrothermal changes which take place during the course of autoclaving. The method turned out to be very effective, and the principal achievements so far obtained are (1) discovery of new examples of thermochromism,[1-3] (2) establishment of optimum concentration effect in hydrothermal precipitation,[4] (3) synthesis of a new magnetic compound Fe_3S_4, identified with the new mineral *greigite*, thiospinel of iron.[5,6] Study by means of this method is in progress. Some recent results which do not seem to have been reported so far are given in the following.

1. Ethylenediaminetetracetate (EDTA) Complexes. In order to see the effect of EDTA, a representative chelate-forming agent, on the hydrothermal behavior of heavy ions, *ca.* 0.1 M solutions of the chelate complexes of EDTA with bivalent Mn, Co, Ni, Cu, Zn, Pb, Hg and tervalent Fe were subjected to autoclaving at 200°C for one

hour.*[1] No noticeable change was observed in the solutions except in that of Hg(II) complex. No thermochromism was observed in the solutions of the complexes of Co(II), Ni(II) and Cu(II). This behavior is different from that of the simple salts of these bivalent metals, indicating the higher hydrothermal stability of the complex compounds. The stabilization caused by EDTA is particularly notable in the case of the Fe(III) complex, if we recall the fact that the solutions of the simple salts as well as those of the cyano-complexes of Fe(II) and of Fe(III) undergo decomposition above 100°C.[7]

A peculiar decomposition takes place in the case of Hg(II) complex. The colorless and transparent 0.1 M solution changes into a white suspension at 130°C. Coagulation is accelerated with the rise of temperature, and the suspension separates finally into two phases, *viz.* the shining Hg drops at the bottom and the brown supernatant liquid. Contrary to this, the 0.1 M solution of $HgCl_2$ remains intact at 200°C. This suggests that chelate formation diminishes the hydrothermal stability of the solution. In connection with this, it should be mentioned that the formation of metallic gold takes place when a Au(III) salt reacts with EDTA at room temperature.[8]

II. Halogeno-complexes of Some Noble Metals. In order to study the hydrothermal stability of noble-metal complexes, the 0.01 M and 0.1 M solutions of the following compounds were autoclaved up to 200°C and the resulting change was observed: Hexachloroplatinic(IV) acid $H_2[PtCl_6]$, potassium hexachloroplatinate(IV) $K_2[PtCl_6]$, tetrachloroauric(III) acid $H[AuCl_4]$, potassium tetrachloroaurate(III) $K[AuCl_4]$. It was found that all the solutions are thermochromic. The yellow color of these solutions turns red above 140°C. The change is enhanced with the rise of temperature. On cooling the colorations return to the original state. The change is thus reversible with respect to temperature.

The cause of the thermochromism might be attributed to the partial reversible hydrolysis of these chloro-complexes. We realize the facts herewith that the color of the solution of platinum(IV) chloride $H_2[Pt(OH)_2Cl_4]$ changes from greenish yellow to orange red with the progress of hydrolysis and that the solution of gold(III) chloride $H[Au(OH)Cl_3]$ is reddish yellow.[9] We see thus that the thermochrmomism of these noble-metal complexes and that of the solutions of Co(II), Ni(II) and Cu(II) chlorides are caused by different mechanisms. In the latter case, the cause is attributed to the formation of chloro complexes at elevated temperatures.

It should be added that the solutions of potassium tetrachloroplatinate(II) $K_2[PtCl_4]$ and potassium tetrachloropalladate(II) $K_2[PdCl_4]$ are both unstable above 100°C, and dark brown precipitates are formed at *ca.* 150°C.

*[1] The general formulas of the reagents: $Na_2Me^{II}(EDTA)\cdot 3\text{-}4H_2O$, $NaFe^{III}(EDTA)\cdot 2\text{—}3H_2O$. "Dotite" products were used.

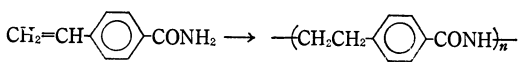
Base-Catalyzed Polymerization of *p*-Vinyl Benzamide

Hiroyuki NAKAYAMA, Tsutomu SOGO, Toshinobu HIGASHIMURA and Seizo OKAMURA

Department of Polymer Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received September 5, 1967)

Recently, it has been reported[1,2] that *p*-vinyl benzamide [I] was polymerized by a basic catalyst to give the proton transfer type polymer [II]. In these studies, alkali metals and their alkoxides were used as catalyst. The object of this paper is to elucidate the effect of catalyst and solvent on the polymerization of *p*-vinyl benzamide.



[I] [II]

p-Vinyl benzamide was synthesized from β-phenylethyl alcohol through *p*-carboxy-β-phenylethyl bromide[3] and *p*-vinyl benzoic acid[4]. The crude product was recrystallized from petroleum

ether/acetone mixture and benzene to give colorless powder, mp 171—172°C (Lit.[5] 168°C).

Catalyst was added to the test tube containing monomer, solvent and inhibitor for radical polymerization (*N*-phenyl-*β*-naphthylamine: 10 mg/10 m*l* solution) and then the test tube was sealed in a nitrogen atmosphere. After polymerization at constant temperature, the mixture was poured into a large amount of acetone. The polymer was removed by filtration, washed with acetone and dried at 40°C for 48 hr in vacuum.

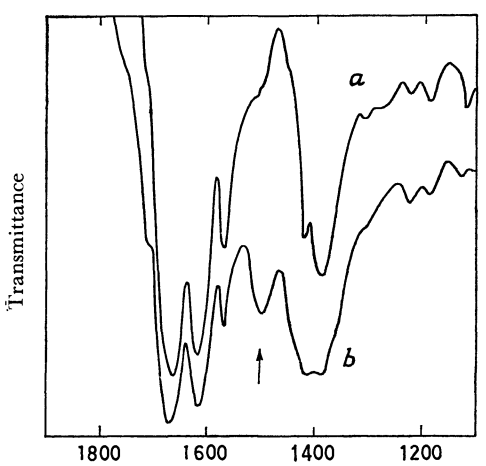

Fig. 1. IR spectra of poly(*p*-vinyl benzamide).
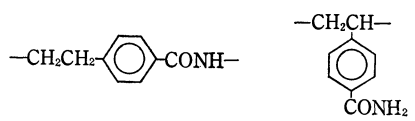
a: Polymer obtained by PhMgBr in toluene at 120°C. (D ratio=0)
b: Polymer obtained by BuLi in pyridine at 100°C. (D ratio=0.13)

5) D. Faulkner, C. E. Hollis and J. N. Mihe, Brit. Pat., 676376 (1952).

The results of polymerization catalyzed by *n*-butyllithium (*n*-BuLi) and phenylmagnesium bromide (PhMgBr) in toluene and pyridine are summarized in Table 1. It is estimated that the product is a polymer as the inherent viscosity of products was larger than 0.1. Moreover, the real values of inherent viscosity might be higher than the observed values since the polymer was to some extent decomposed in conc. H_2SO_4 at 100°C.

IR spectra of polymers obtained by two different polymerization conditions, that is, by *n*-BuLi in pyridine and by PhMgBr in toluene, are different in the absorption at about 1500 cm^{-1} as shown in Fig. 1. The absorption at 1500 cm^{-1} corresponds to secondary amide and the existence of this absorption shows that polymers contain the proton transfer unit [III]. On the other hand, the absence of the absorption at 1500 cm^{-1} indicates that the repeating unit of polymers may be the vinyl unit [IV].



[III] [IV]

In this paper, the fraction of the proton transfer unit [III] in polymer was not measured quantitatively, but could be compared qualitatively by *D*-ratio[6] which was defined as a ratio of optical densities at 1500 to 1660 cm^{-1}. Hence, *D*-ratio of the polymer which consists of only the vinyl unit [IV] is zero, and *D*-ratio is higher if the polymer contains larger amount of the proton transfer

6) H. Nakayama, T. Higashimura and S. Okamura, *Kobunshi Kagaku (Chem. High Polymers, Japan)*, **23**, 433 (1966).

unit [III]. In fact, *D*-ratio of vinyl polymer obtained by heat polymerization was zero. *D*-Ratio of the polymer[2] consisting of almost the proton transfer unit [III] was 0.7 according to our calculation.

The *D*-ratios of polymers shown in Table 1 suggest the following facts. In the use of PhMgBr as a catalyst, the polymer was obtained by vinyl polymerization in toluene, but proton transfer polymerization occured to some extent in pyridine. In the case of *n*-BuLi, the proton transfer unit was present in the resultant polymer, and the polymer obtained in pyridine seemed to contain larger amount of the proton transfer unit than that in toluene.

These results are summarized as follows. First, the fraction of the proton transfer unit was very much smaller in the case of *p*-vinyl benzamide than in the case of acrylamide or methacrylamide under the same polymerization condition. Second, in the base-catalyzed polymerization of *p*-vinyl benzamide, there were the polymerization conditions under which proton transfer polymerization did not proceed. These facts may be due to that intramolecular proton transfer might hardly occur in the polymerization of *p*-vinyl benzamide containing *p*-phenylene group between an ethylenic double bond and amide group.

Mass Spectrometric Studies of α, β-Epoxyketones

Shini-ichi SASAKI, Hidetsugu ABE and Koji NAKANISHI

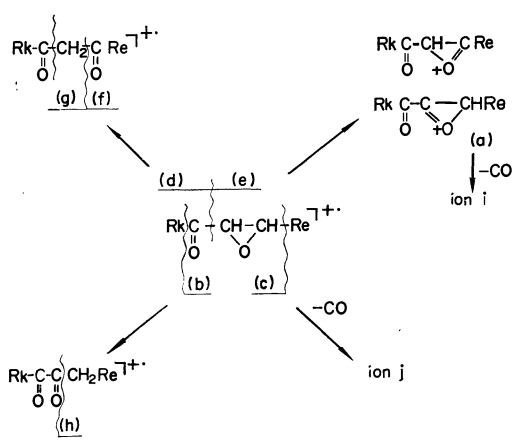
Department of Chemistry, Tohoku University, Katahira-cho, Sendai

and Yasuhiro ITAGAKI and Eiji WATANABE

Japan Electron Optics Laboratory Co., Ltd., Akishima, Tokyo

(Received September 7, 1967)

The mass spectra of epoxy compounds have already been published in some detail[1a-1d] and have proven to be of diagnostic use in the structure determination of natural compounds.[1a] We now extend our studies to several α, β-epoxyketones:



Scheme 1.

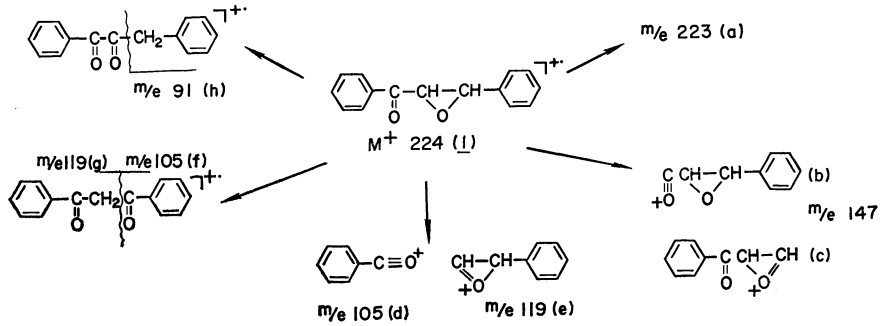
chalcone oxide (1), monodeuterated chalcone oxide (2), 2, 3-benzochalcone oxide (3), 4-methoxychalcone oxide (4), 1, 2-epoxy-1-phenyl-3-butanone (5), 2, 3-epoxy-1-phenyl-1-butanone (6) and *cis*- and *trans*-dypnone oxide (7 and 8).

The characteristic peaks observed in the spectra of these compounds are listed in Table 1 in which R_k and R_e represent the aromatic or aliphatic group adjacent to the carbonyl and epoxide group, respectively. The fragmentation of epoxy compounds are summarized in Scheme 1.

α, β-Epoxyketones (1—6), excepting the two dypnone oxides (7 and 8), lose one hydrogen radical to give ion (a), and groups R_k and or R_e to form ions (b) and (c), respectively. The CO-epoxide bond is also cleaved to afford cations (d) and (e). For instance, chalcone oxide (1) produces rather weak peaks at *m/e* 223 (M-1)(a), *m/e* 147 (M-C_6H_5)(b) and/or (c), *m/e* 119 (M-C_6H_5CO) (e) and a base peak at *m/e* 105 (C_6H_5CO) (d) as shown in Scheme 2, which is similar to that encountered in aromatic epoxides.[1b]

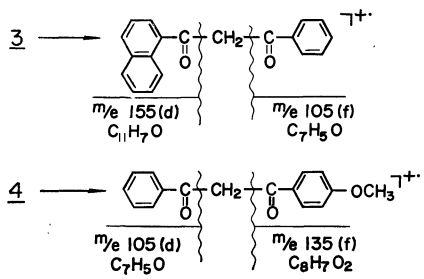
Ions (f) and (g) obviously arise from the β-diketone forms produced by rearrangement; similar ions (h) owe their geneses to the rearranged α-diketone form. It should be noted that the peaks (f) and (g) are not present in dypnone oxides, in which rearrangement to a β-diketone is not possible because of the extra methyl group. Furthermore, the spectrum of chalcone oxide (1) closely resembles

1) a) Y. Itagaki, T. Kurokawa, H. Moriyama, S. Sasaki and Y. Watanabe, *Chem. & Ind.*, **1965**, 1654; S. Sasaki, Y. Itagaki, H. Moriyama, K. Nakanishi, E. Watanabe and T. Aoyama, *Tetrahedron Letters*, **1966**, 623. b) E. H. Audier, J. F. Dupin, M. Fetizon and Y. Hoppilliard, *Tetrahedron Letters*, **1966**, 2077. c) N. S. Issacs, *Canad. J. Chem.*, **44**, 395 (1966). d) J. Baldas and Q. N. Porter, *Chem. Commn.*, **1966**, 571.



Scheme 2.

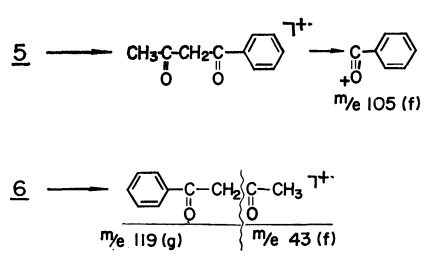
that of dibenzoylmethane[2] which corresponds to the rearranged β-diketone form. The formation of ions *m/e* 105 (f) and *m/e* 135 (f) in the mass spectra of (3) and (4), respectively, also support the occurence of the rearrangement mechanism. The composition of ions *m/e* 155 (d) and *m/e* 105 (f) of (3), and *m/e* 105 (d) and *m/e* 135 (f) of (4) was determined by high resolution mass spectrometry (Scheme 3).



Scheme 3.

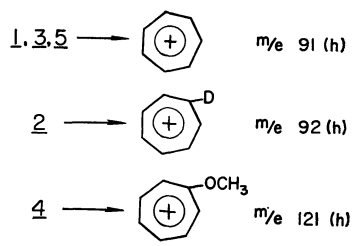
The ion *m/e* 105 decomposes further by successive elimination of carbon monoxide and acetylene to *m/e* 77 and *m/e* 51 as evidenced by appropriate metastable ions (*m/e* 56.5 and 33.8, respectively) in every case.

Compounds (5) and (6) carry alkyl groups, but their mass spectral fragmentations are almost identical with those of the chalcone oxides (1—4). The formation of ion *m/e* 105 (f) in (5), and ions *m/e* 43 (f) and 119 (g) in (6) are again due to hydrogen migration to form the corresponding β-diketones (Scheme 4).



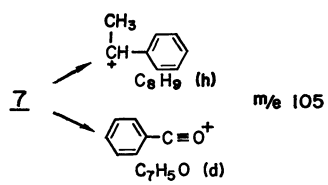
Scheme 4.

The conversion of epoxyketones to α-diketones is observed in the spectra of (1—5), in which tropylium ions are found at *m/e* 91, 92, 91, 121 and 91, respectively (Scheme 5).



Scheme 5.

Similarly the *cis* and *trans* dypnone oxide (7 and 8), which give identical spectra, also rearrange to the corresponding α-diketone to give the ion (h) at *m/e* 105. The fact that the base peak at *m/e* 105 also involves the benzoyl ion (d) as well indicated by measurements of high resolution mass spectrometry (Scheme 6).



Scheme 6.

Finally, the spectra of α, β-epoxyketones (1—5, 7 and 8) show ions corresponding to the loss of HCO and CO from the molecular ion. For instance, the ions *m/e* 195 (M-CHO) and *m/e* 196 (M-CO) appear in the spectrum of chalcone oxide (1). The geneses of these peaks are accounted for by the repulsion of carbon monoxide[3] from the M-1 ion and carbon monoxide from the molecular ion.

The ions marked with *1 and *1′ have the same mass units and are most probably originated from different parts of the molecular ion. Then the same mass and intensity are listed in this table. The pairs of ions marked with *2, *2′; *3, *3′; *4, *4′; *5, *5′ and *6, *6′ are listed in this manner.

Experimental

All the samples were synthesized according to known procedures. For instance, 4-methoxychalcone oxide (4) was prepared by the epoxidation of 4-methoxychalcone with alkaline hydrogen peroxide.[4] Monodeuterated chalcone oxide (2) was synthesized by the condensation of ω-d_3-acetophenone and benzaldehyde, following the epoxidation with hydrogen peroxide, mp 52—54°C.

Mass spectra were obtained with a Hitachi RMU-6D Mass Spectrometer, with an energy of 70 eV and an 80 μA ionizing current. The temperature of ion source was 250°C. High resolution mass spectra were dedetermined with a JMS-OIS Mass Spectrometer. The temperature of ion source 130—150°C, ionizing voltage 25—40 eV, ion accl. volt. 7.5 kV, and exposure 3×10^{-11} coulomb.

Composition of Fayalite and Its Standard Free Energy of Formation

Kenzo KITAYAMA and Takashi KATSURA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 19, 1967)

Data on fayalite (Fe_2SiO_4) stability have previously been studied by Schenck, Franz, and Laymann[1] at 900°C, and by Cirilli[2] at 900, 1000, and 1100°C, both controlled by the CO_2/CO equilibria in a gas phase co-existing with fayalite, silica, and metallic iron. These data have summarized by Richardson, Jeffes, and Withers,[3] and they proposed a linear free energy equation on the basis of the data obtained by Schenck *et al.* Pitzer and Brewer[4] also calculated the free energy function of fayalite based on H°_{298}. Recently Taylor and Schmalzried[5] determined the free energy of formation of fayalite by electromotive-force measurements between 900 and 1100°C, and they recalled a complication met with the formation of solid solutions at high temperatures.

Schwerdtfeger and Muan[6] determined the equilibrium ratio of CO/CO_2 of a gas phase co-existing with fayalite, silica and metallic iron, and calculated the standard free energy of formation of fayalite at temperatures of 1000, 1100, and 1150°C. Berliner and Shapovalova[7] determined the equation, $\Delta G^\circ = -135{,}320 + 33.20\,T$, for the reaction (3) which will be seen in later, on the basis of the reduction of fayalite by H_2 gas.

The present objectives are first to ascertain whether or not there exists an appreciable composition range in fayalite within the ternary system FeO-Fe_2O_3-SiO_2, and then to determine the standard free energy of formation of fayalite at temperatures slightly below the solidus after finding an equilibrium oxygen partial pressure obtained by a CO_2/H_2 gas mixture.

Experimental

Reagent grade chemicals are served as starting materials. Ferric oxide is heated at 900°C and silicic acid is heated at 1300°C for several hours in a global furnace. The desired amounts of the dry oxides are mixed and ground for several hours. Approximately a 20 g of each mixture is then heated in a platinum crucible in the globar furnace at 1300°C for 10—24 hr. The sintered mass is re-ground and re-heated at the same temperature for several hours. From the new sintered mass cut a disc weighing approximately 2 g and with a central bore for suspending the disc by

means of a thin platinum wire from one beam of an analytical balance.

Pellets consisting of fayalite-silica mixtures are kept at chosen constant temperature and chosen levels of oxygen partial pressure until equilibrium is attained.

Composition changes of the sample in response to changes in oxygen partial pressure are determined by both thermogravimetric and wet chemical analyses of quenched samples. Phases present are determined by microscopic and X-ray examination of quenched samples. The apparatus used in this study are the same as those used in a previous work.[8]

For determining the free energy of formation of fayalite, reagent grade chemicals are used without purification as starting materials. Ferric oxide is reduced to ferrous at 1200°C in an atmosphere consisting of CO_2/H_2 mixed gas ($CO_2/H_2=1$). The ferrous oxide is stoichiometrically mixed with silica to prepare fayalite. The mixtures are melted in the same atmosphere at 1300°C in a 80% platinum - 20% rhodium container which is previously saturated with iron. The melts are quenched and pulverized in an agate mortar. The powder (fayalite) is mixed with silica to avoid excess free iron oxide. The mixture is again melted, quenched and pulverized. The fayalite-silica powder is caked at 1154°C in the CO_2-H_2 atmosphere in the same container.

The standard quenching technique is adopted for the present study under controlled atmospheric conditions. The cakes are kept at chosen temperature and chosen levels of oxygen partial pressure. After 24 hr, these samples are quenched and metallic iron separated is ascertained by microscopic and dilute hydrochloric acid method. After repeating the procedure, a CO_2/H_2 ratio just appearing the metal iron is determined at four temperatures. The oxygen partial pressures corresponding to the CO_2/H_2 ratio are measured directly by a solid electrolyte. Details of the measurement have been reported by Katsura and Hasegawa.[9]

Results and Discussion

Composition of Fayalite. The FeO content of fayalite present in sample A through D after equilibration at various oxygen partial pressures at 1125, 1156, and 1170°C are listed in Table 1. Within the limit of experimental error (±0.4 mol%), the composition of fayalite is constant and corresponds to the formula $2FeO \cdot SiO_2$ around 1150°C

Free Energy of Formation of Fayalite. Phase equilibrium studies previously reported for the system Fe-Si-O (Bowen and Schairer[10]: Darken[11]: Muan[12]) are useful for defining the

—— from Schenck *et al.*, ····· from Darken and Gurry, ---- present study

upper temperature limit for the present investigation. An application of the phase rule to the various phase assemblages show that in composition area, where three crystalline phases coexist in equilibrium with, the oxygen pressure of the gas phase must be fixed. For instance, in the two areas where silica (tridymite) + fayalite + iron and fayalite + wüstite + iron coexist in equilibrium, different oxygen partial pressures, $P_{O_2}(1)$ and $P_{O_2}(2)$ respectively, prevail at equilibrium. The standard free energy changes, $\Delta G°(1)$ and $\Delta G°(2)$, are determined from the oxygen partial pressures in the isothermal invariant equilibrium as follow:

$$2Fe + SiO_2 + O_2 = Fe_2SiO_4 \quad (1)$$

$$K = a_{Fe_2SiO_4}/a^2_{Fe_2}\cdot a_{SiO_2}\cdot P_{O_2}(1)$$

$$\Delta G°(1) = 2.303\boldsymbol{R}T\log P_{O_2}(1)$$

and

$$1.90Fe + O_2 = 2Fe_{0.95}O \quad (2)$$

$$\Delta G°(2) = 2.303\boldsymbol{R}T\log P_{O_2}(2)$$

By substracting of Eq. (2) from Eq. (1) the standard free energy of formation of fayalite according to the equation

$$0.1Fe + 2Fe_{0.95}O + SiO_2 = Fe_2SiO_4 \quad (3)$$

is calculated as:

$$\Delta G°(3) = 2.303\boldsymbol{R}T\log P_{O_2}(1)/P_{O_2}(2)$$

The experimental results obtained are summarized in Table 2 together with Schenck's, Taylor's and Schwerdtfeger's data for comparison, while they are illustrated graphically in Fig. 1 with the width of experimental errors.

The standard free energy changes of reaction (1) are −86.0, −85.2, −84.4 and −84.6 kcal at temperatures 1129, 1144, 1160 and 1174°C, respectively. The values at each temperature in Table 2 and Fig. 1 are a mean for three experimental results except for the value at 1144°C, and we get an equation as a function of temperature:

$$\Delta G°(3) = -122{,}000+26.0\,T \text{ (cal)}$$

by means of the method of least squares.

The oxygen partial pressures for Eq. (2) obtained from Darken and Gurry's data[13] is shown in the second column of Table 3. Using these values for Eq. (2) and the present results for Eq. (1), $\Delta G°(3)$, that is the standard free energy of formation of fayalite relative to the oxide components SiO_2 and wüstite, is easily calculated. In the Table 3, $\Delta G°(3)$ is indicated at various temperatures together with other two experimental results. $\Delta G°(3)$ varies between -2.8 and -3.4 kcal in the present temperature range. Except for the value at 1160°C, the change in free energy of formation of fayalite relative to oxides is nearly constant (about -3.3 kcal) regardless of the temperature in this experiment. According to recent tabulations by Kelley,[14] $\Delta G°(3)$ varies approximately linearly between -2.3 and -1.7 kcal in the temperature range 1000 to 1150°C. His values are very larger than those in Table 3. The present value, -3.3 kcal, is in fairly good agreement with Taylor's.

SHORT COMMUNICATIONS

A New Monocyano Cobalt(III) Complex

Nobufumi MAKI, Takahiro ITOH and Shukichi SAKURABA

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received December 4, 1967)

Previously, dicyano-cobalt(III) complex, K-$[Co(CN)_2dg_2]\cdot 3/2H_2O$, was reported to have been prepared and reduced to a cobalt(I) complex polarographically.[1,2]

In the present communication, the preparation of the monocyanobis(dimethylglyoximato)ammine-cobalt(III) complex, $[Co(CN)dg_2(NH_3)]\cdot 1/2H_2O$ (trans-form), is described and was found to undergo stepwise reduction to a cobalt(0) complex at the dropping mercury electrode (DME).

The complex was prepared by the following method: To 15.0 g of $[Co(CN)(OH_2)(NH_3)_4]Cl_2$[3] in 150 m*l* of water was added 14.4 g dimethylglyoxime. The mixture was heated on a water bath (85°C) for three hours. The reaction proceeds, evolving ammonia, according to the following:

$$[Co(CN)(OH_2)(NH_3)_4]^{2+} + 2dgH \rightarrow [Co(CN)dg_2(NH_3)] + 3NH_3.$$

Every half hour during the reaction, 5—7 g of ammonium acetate was added to the solution. In total, 20 g of ammonium acetate was used. Lustrous orange-yellow needle-shaped crystals (17.2 g) separated from solution when it was allowed to stand. The product was filtered and washed with 80% ethanol to eliminate traces of unreacted dimethylglyoxime. The yield was above 82%. The complex was recrystallized from hot water (85°C) containing acetic acid.

Found: Co, 17.41; C, 32.08; N, 24.83; H, 5.43%. Calcd for $[Co(CN)dg_2(NH_3)]\cdot 1/2H_2O$: Co, 17.37; C, 31.83; N, 24.77; H, 5.64%.

The complex gave rise to the well-defined waves of three steps in 0.5 M sodium sulfate supporting electrolyte containing 0.007% Triton X100 at the DME (Fig. 1). For each, the limiting current was diffusion-controlled. The diffusion current and the concentration of the complex was linearly related in the concentration range between $5\cdot10^{-4}$ and 10^{-3} M. The first, second and third waves, each corresponding to an acceptance of one electron, represents the reduction of Co(III)→Co(II), Co(II)→Co(I) and of Co(I)→Co(0), respectively.

Table 1 shows the half-wave potentials of the

waves for the cobalt(III) complexes of the monocyano-series in 0.5 M sodium sulfate solution. The oscillopolarogram obtained with a Polaroscope P 576 indicates three cuts on both the cathodic and anodic branches. Namely, the process of oxidation occurs in three steps, almost the same as in reduction. This implies that the cobalt(0) complex exists in solution.

The net processes of the electrode reaction in the following are considered to be most plausible:

$$\begin{array}{ccc} [Co^{III}(CN)dg_2(NH_3)] & & \\ \downarrow & & \\ [Co^{II}(CN)dg_2(NH_3)]^- & \rightarrow & [Co^{I}(CN)dg_2(NH_3)]^{2-} \\ \downarrow & & \downarrow \\ [Co^{II}(CN)dg_2(OH_2)]^- & \rightarrow & [Co^{0}dg_2]^{2-} \\ & & \downarrow \\ & & Co \end{array}$$

The Absolute Configuration of the Tris(trimethylenediamine)cobalt(III) Ion, $(-)_D$-[Co tn_3]$^{3+}$

Yoshihiko SAITO, Teruo NOMURA and Fumiyuki MARUMO

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received December 4, 1967)

In a series of our investigation on the absolute configurations of tris(bidentate)cobalt(III) complex ions,[1-3] the absolute configuration of tris(trimethylenediamine)*1cobalt(III) ion, [Co tn_3]$^{3+}$, has been determined. The crystal structure of $(-)_D$-tris(trimethylenediamine)cobalt(III) bromide monohydrate, $(-)_D$-[Co tn_3]$Br_3 \cdot H_2O$, has been determined by three-dimensional Fourier methods.[4] The final R-value is 0.113 for 1890 observed reflections. The crystals were kindly supplied by Dr. Woldbye of the Technical University of Denmark. They are monoclinic with the space group $P2_1$: $a=16.274\pm0.009$ Å, $b=7.863\pm0.015$ Å, $c=9.489\pm0.005$ Å and $\beta=126.42°\pm0.06°$ (Cu$K\alpha$=1.5418 Å). A perspective drawing of the complex ion is presented in Fig. 1. The complex ion has

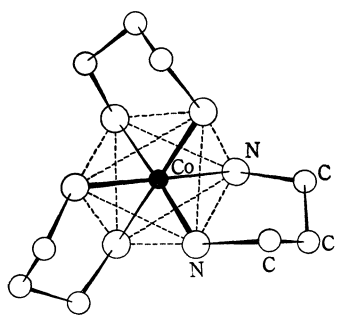

Fig. 1. A perspective drawing of the complex ion, $(-)_D$-[Co tn_3]$^{3+}$.

approximately a three-fold axis of rotation through the central cobalt atom. The three six membered Co-tn rings are nearly identical and take chair form. The chelate ring is rather flattened out, clearly owing to the strong H-H repulsion. Bond angles ∠CoNC are much larger than the normal tetrahedral angle, the average value being 117.4°. But the average value of ∠NCC and ∠CCC is 112.8°. The avarage ∠NCoN is 94.5°. The bond distances within the chelate ring are quite normal.

The absolute configuration of the complex ion was determined by using absorption edge technique.[5]

Some of the calculated intensities and observed relations between $I(hkl)$ and $I(\bar{h}\bar{k}l)$, the latter being equivalent to $I(\bar{h}\bar{k}\bar{l})$ because of the symmetry of the space group, are compared in Table 1.

TABLE 1. DETERMINATION OF THE ABSOLUTE CONFIGURATION

Indices $h\ k\ l$	$F_c^2(hkl)$	obs.	$F_c^2(\bar{h}\bar{k}l)$
1 1 $\bar{2}$	2284	>	2174
1 3 3	380	>	369
2 3 3	374	>	310
2 3 $\bar{3}$	394	>	319
5 2 $\bar{5}$	576	<	654
$\bar{3}$ 1 2	1287	<	1707
$\bar{4}$ 1 3	331	<	534
$\bar{5}$ 1 4	241	>	161

From these accordances in the table, it may be found that the complex ion, [Co tn_3]$^{3+}$, shown in Fig. 1 corresponds to the laevorotatory form with respect to the Na D lines. Thus the absolute configuration of $(-)_D$-[Co tn_3]$^{3+}$ can be represented by Δ according to the nomenclature proposed at the Meeting of the Commission on Inorganic Nomenclature of IUPAC, held at Beckenried, Switzerland in 1966. This configuration is enantiomeric to that assigned on the basis of the sign of the prominent Cotton effect.[6] The ORD and CD of [Co tn_3]$^{3+}$ have already been measured by Woldbye.[8] A simple empirical rule[8] relating the sign of the longer wavelength CD band and the absolute configuration of the chelate ring about the metal atom seems to hold in this case, too.

Vinyl Polymerization. 205.*[1] Polymerization of Methyl Methacrylate in the Presence of Cellulose Triacetate and Water

Minoru IMOTO, Kiichi TAKEMOTO and Tadashi TANIMOTO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 6, 1967)

In the series of our papers, we have shown that some sorts of macromolecule could initiate the polymerization of methyl methacrylate (hereafter abridged as MMA) by radical mechanism in the presence of water. It was concluded that the effective macromolecules contained -OH or -NHCO- groups.[1-7] In the present communication, the polymerization of MMA was carried out with the system of the partially or completely acetylated cellulose and water. The polymerization was found to be able to be initiated even with cellulose triacetate in which no -OH groups were contained.

Partially and completely acetylated cellulose fibers with different grade of acetylation were prepared by the reaction of commercial tissue paper (99.0% α-cellulose) in benzene with a mixture of acetic acid, acetic anhydride and sulfuric acid.

The reaction was carried out under stirring at 40°C in the range of 2—48 hr. Degree of acetylation was measured by alkaline hydrolysis.[8]

Polymerization was carried out in sealed tubes in dark, in the same manner as described earlier.[1] 0.2 g of acetylated cellulose, 10.0 m*l* of water and 4.68 g of MMA were charged in each tube, and the reaction was carried out for 5 hr at 85°C.

Figure 1 shows the results of the polymerization of MMA initiated with this system. It can be seen from the figure that the polymerization could proceed even in the case where cellulose triacetate having no hydroxy groups was chosen as a macromolecule, and that the total conversion resulted in almost the same amount as these by partially acetylated cellulose. These results differed from the case of polymerization initiated with water and partially hydrolyzed polyvinyl acetate system, where the completely acetylated polyvinyl acetate and completely hydrolyzed polyvinyl alcohol showed no initiating abilities.[9]

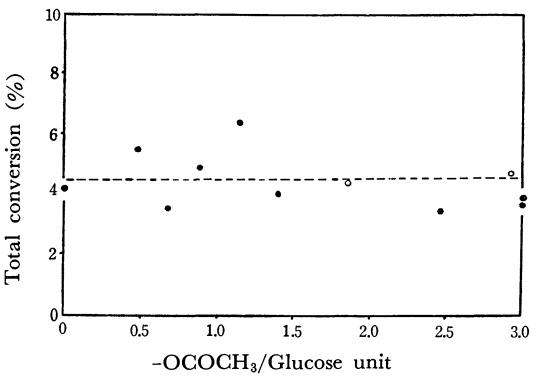

Fig. 1. Polymerization of MMA in the presence of acetylated cellulose fiber and water: Relationship between total conversion and the degree of acetylation of cellulose (85°C, 5 hr).
● Averaged value in two measurements,
○ Value in one measurement,
◐ Acetylation was repeated twice.

In 1961, Ceresa carried out a block copolymerization based on the vapor phase swelling of cellulose acetate (degree of acetylation 1.35 per glucose unit) with acrylonitrile.[10] Differed from his experiment, a large amount of water was present in our reaction system. Although the initiation mechanism by the system of cellulose or cellulose triacetate and water is not yet clear, it may be sure that the Ceresa's mechanism could not be applied to the present experiment from the formerly mentioned considerations[1-7] which include the homogeneous initiation of MMA in the presence of water and low molecular polyvinyl alcohol or soluble starch.

Insertion of Isonitrile into Alkyl-Nickel Bonds

Yasuhiro YAMAMOTO, Hiroshi YAMAZAKI and Nobue HAGIHARA

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received December 7, 1967)

There are many examples of the insertion reactions of carbon monoxide and olefins into transition metal-carbon σ-bonds. On the other hand, there has been no such example of isonitriles, although they are known as ligands similar to carbon monoxide.

In the course of our studies of the catalytic polymerization of isonitriles with transition metal complexes,[1] we found that cyclohexyl isocyanide could be inserted into nickel-carbon σ-bonds. Now we wish to report on the stable complexes derived from such reactions.

The treatment of triphenylphosphine-π-cyclopentadienyl methyl nickel[2] in benzene with cyclohexyl isocyanide at room temperature gave a red-brown solution. After the evaporation of the solvent, the residue was separated on an alumina column, using benzene-ether (2 : 1) as the eluant. The red-brown fraction was then concentrated, and the residue was crystallized from hexane to give red-brown crystals (I) (mp 72.5—73.5°C (decomp). Found: C, 67.08; H, 8.66; N, 7.70%. Calcd for $C_{20}H_{30}N_2Ni$: C, 67.24; H, 8.47; N, 7.84%.). The IR spectrum of I (KBr disk) showed the existence of a carbon-nitrogen triple bond (2140 cm^{-1}) and a double bond (1618 cm^{-1}). The NMR spectrum*1 indicated the existence of a cyclopentadienyl group (singlet at 4.72 τ, 5H), a methyl group (singlet at 7.73 τ, 3H), and a cyclohexyl group (broad bands at 6.36 τ, 2H and $\sim$8.5 τ, 20H). It was concluded from these results that I was π-cyclopentadienyl(cyclohexyl isocyanide)(methylcyclohexyliminomethyl)nickel, π-$C_5H_5Ni(C{\equiv}NC_6H_{11})(C(CH_3){=}NC_6H_{11})$. I is fairly stable to air in the solid state and is soluble in most organic solvents. The reaction of I with moist air gave *N*-cyclohexyl acetamide.

Similar red-brown compounds were also prepared by the reaction of cyclohexyl isocyanide and other triphenylphosphine-π-cyclopentadienylalkylnickel compounds.

π-$C_5H_5Ni(C{\equiv}NC_6H_{11})(C(C_6H_5){=}NC_6H_{11})$: Yield, 85%. Mp 113—114°C (decomp). IR: 2140 cm^{-1} (N≡C), 1589 cm^{-1} (C=N). Found: C, 71.46; H, 7.72; N, 6.70%. Calcd for $C_{25}H_{32}N_2Ni$: C, 71.62; H, 7.69; N, 6.68%.

π-$C_5H_5Ni(C{\equiv}NC_6H_{11})(C(p\text{-}CH_3C_6H_4){=}NC_6H_{11})$: Yield, 72%. Mp 99.0—101.5°C (decomp). IR: 2140 cm^{-1} (N≡C), 1589 cm^{-1} (C–N). Found: C, 71.92; H, 8.00; N, 6.19%. Calcd for $C_{26}H_{34}N_2Ni$: C, 72.07; H, 7.92; N, 6.19%.

π-$C_5H_5Ni(C{\equiv}NC_6H_{11})(C(p\text{-}ClC_6H_4){=}NC_6H_{11})$: Yield, 89%. Mp 126—128°C (decomp). IR: 2135 cm^{-1} (N≡C), 1587 cm^{-1} (C=N). Found: C, 66.19; H, 7.14; N, 6.39%. Calcd for $C_{25}H_{31}N_2ClNi$: C, 66.18; H, 6.89; N, 6.17%.

π-$C_5H_5Ni(C{\equiv}NC_6H_{11})(C(n\text{-}C_4H_9){=}NC_6H_{11})$: Yield, 68%. Mp 51—53°C (decomp). IR: 2140 cm^{-1} (N≡C), 1618 cm^{-1} (C=N). Found: C, 68.68; H, 9.14; N, 7.31%. Calcd for $C_{23}H_{36}N_2Ni$: C, 69.19; H, 9.09; N, 7.02%.

No reaction of cyclohexyl isocyanide with *o*-tolyl or mesityl nickel compounds was observed, suggesting steric hindrance by the ortho methyl group.

The reaction of *t*-butyl isocyanide with triphenylphosphine-π-cyclopentadienylphenylnickel proceeded to give tris(*t*-butyl isocyanide)triphenylphosphinenickel and biphenyl, without forming any complex of the I type. Detailed studies are now in progress.

The Total Synthesis of Kanamycin C

Sumio UMEZAWA, Shinkiti KOTŌ, Kuniaki TATSUTA and Takayuki TSUMURA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

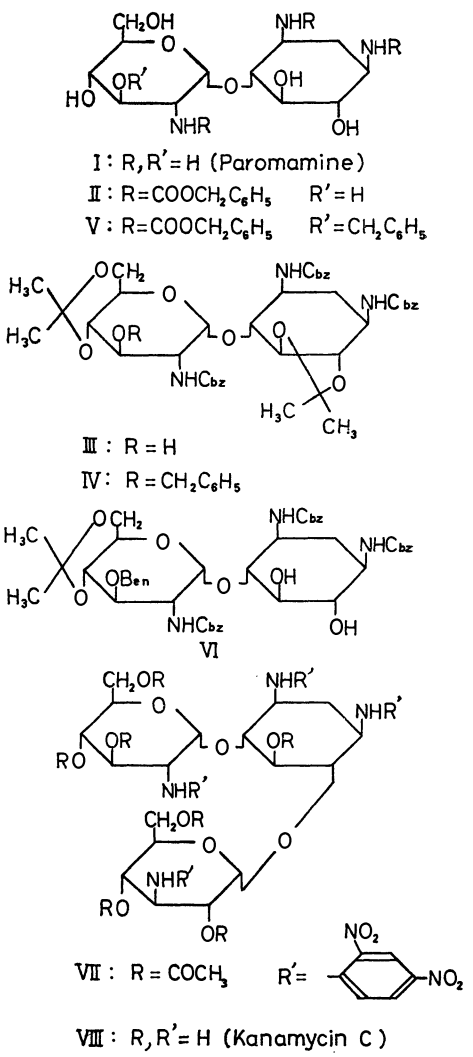
(Received December 14, 1967)

Kanamycin C[1] is a member of kanamycin congeners and composed of paromamine and 3-amino-3-deoxy-D-glucose. We wish to report a synthesis of this antibiotic. Since we have synthesized paromamine[2] (I), the combined achievements constitute the first total synthesis of kanamycin C (VIII).

Tri-*N*-carbobenzoxyparomamine (II), mp 258°C (decomp.), $[\alpha]_D^{18}$ +64.5° (*c* 0.67, DMF), was treated with 2, 2-dimethoxypropane and *p*-toluenesulfonic acid in *N*, *N*-dimethylformamide (DMF) to give the diisopropylidene derivative(III). Benzylation of III with benzyl bromide in the presence of barium oxide and barium hydroxide in DMF gave IV, which, by deacetonation, gave V. When partially acetonated, V gave monoisopropylidene-monobenzyl derivative (VI); mp 239—241°C, $[\alpha]_D^{18}$ +75° (*c* 0.63, DMF).

The condensation of VI with 3-acetamido-2, 4, 6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl chloride[3] [mp 143—144°C (decomp.), $[\alpha]_D^{23}$ +78° (*c* 1.0, $CHCl_3$)] in a mixture of benzene-dioxane in the presence of mercuric cyanide and Drierite gave the condensation product. After removal of the all protecting groups, the resulting free base was dinitrophenylated and *O*-acetylated. The product was chromatographed on a silica-gel column with a solvent system (A): toluene-MEK (2 : 1), to afford yellow crystals of VII; 15% over-all yield from VI; mp 208—211°C (decomp.), $[\alpha]_D^{18}$ +285° (*c* 0.75, acetone).

On the other hand, kanamycin C[1] was dinitrophenylated and acetylated to give hepta-*O*-acetyltetra-*N*-(2, 4-dinitrophenyl)-kanamycin C; mp 208—211°C (decomp.), $[\alpha]_D^{18}$ +299° (*c* 0.64, acetone). On TLC with a solvent system (A), the synthetic product VII and the above-mentioned derivative of natural kanamycin C showed identical mobilities andt heir IR spectra were superimposed. Hydrolysis of VII with methanolic ammonia followed by treatment with Dowex 1×2 (OH) gave a crude



free base, which was purified by column-chromatography to give VIII; $[\alpha]_D^{18}$ +139° (*c* 0.50, water). The natural kanamycin C showed $[\alpha]_D^{18}$ +145° (*c* 0.58, water) [lit.,[1] $[\alpha]_D^{20}$ +126° (water)]. Paper chromatography and IR spectra showed that VIII was identical with the natural kanamycin C. The antibiotic spectra and minimal inhibitory concentrations of the synthetic product VIII against test organisms were in agreement with those of the natural kanamycin C.

The Electron Spin Resonance of Mn^{2+} Ion in the Aqueous Solution of Surfactant

Masaji MIURA, Akinori HASEGAWA and Yasuyoshi MICHIHARA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received December 18, 1967)

Manganese ion is one of the typical paramagnetic ions and a number of ESR studies on this ion have been published. Most of them have dealt with it in solid; a minute amount of cation in solid is displaced with Mn^{2+} ion, and the magnitude of the crystal field and its symmetry are estimated through the ESR spectrum of Mn^{2+} ion. The method of spin label of cation with Mn^{2+} ion is expected to be applied not only to solid but to electrolytic solution.

It is well-known that cation plays an important role in the formation of surfactant micelle. So Mn^{2+} ion was added to the aqueous solution of surfactant and the effect of counterion in the solution was evaluated through the ESR spectrum of Mn^{2+} ion.

Theory of the ESR spectrum of Mn^{2+} ion in liquid solution has been recently presented by Garrett and Morgan in terms of solvent-fluctuation-induced relaxation.[1] They have shown that each of six hyperfine lines consists of five transitions of $\Delta m_S=1$, the line width of $m_I=-5/2$ is broadest and that of $m_I=1/2$ is narrowest, and that the latter is approximately proportional to the correlation time τ_C for solvent fluctuation.

Sodium dodecyl sulfate (SDS) and sodium decyl sulfate (NaDS) were employed as surfactant in this study. Each of them was added to the aqueous solution of 1×10^{-3} M $Mn(NO_3)_2$. The solution thus obtained was sealed in a capillary of glass and ESR measurements were carried out.

The ESR spectrum of Mn^{2+} ion in the aqueous solution is affected by the concentration of SDS. The variation in the line width accompanied with the concentration of SDS is shown in Fig. 1. When the concentration of SDS is below 3×10^{-3} or above 13×10^{-3} M, the line width is practically unaffected by the concentration. But line width increases with the concentration in the range from 3×10^{-3} to 13×10^{-3} M. As the line width of $m_I=1/2$ is proportional to the correlation time τ_C, τ_C increases up to 1.7 times in this region.

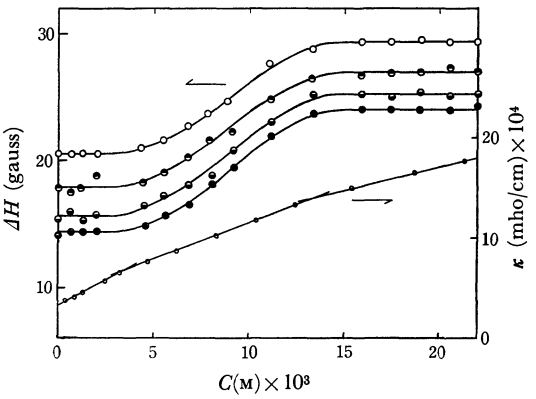

Fig. 1. The dependences of the line width (large circles) and the specific conductivity (smaller circle) on the concentration of SDS at 50°C.
○— $m_I=-5/2$, ◔— $m_I=-3/2$,
◒— $m_I=-1/2$, ●— $m_I=1/2$

Conductivity measurements were carried out in order to determine the CMC (critical micelle concentration). The specific conductivity-concentration curve broke at two points as is seen in Fig. 1. The concentrations corresponding to these two points are the first and second CMC_s from the side of the lower concentration of SDS, respectively, and agree well with the concentrations at which the line width of ESR of Mn^{2+} changes.

Similar experiments were also done on NaDS. Coincidence between CMC_s and the concentrations at which ESR line width changes was also found here. The correlation time increases in the range from the first CMC, 3×10^{-2} M, to the second CMC, 7×10^{-2} M, and that at the concentration above the second CMC is about 0.93 times of that in case of SDS.

The increase in the correlation time may be interpreted as that Mn^{2+} ion is bound to the surfactant micelle.

The details of this investigation will be published later.

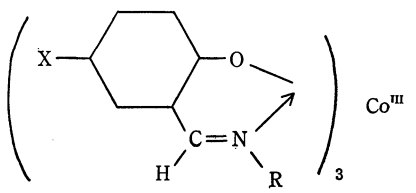
Synthesis of Tris(*N*-isopropyl-*C*-substituted salicylideneiminato)cobalt(III) Complexes

Shoichiro YAMADA, Emiko OHNO and Kuniko YAMANOUCHI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received December 22, 1967)

Numerous cobalt(III) complexes of the Co(X-sal.R)$_3$ type (Formula I)*1 have been reported, but Co(X-sal. *iso*-C_3H_7)$_3$ has never been synthesized up to the present.[1] Thus it has currently been believed that the steric condition arising from the isopropyl groups does not allow the formation of the complexes of this type.[2,3] This statement is no longer correct, as the present authors have succeeded in synthesizing the complexes of the Co(X-sal. *iso*-C_3H_7)$_3$ type, where X denotes 5-NO_2 and 5-Br.



Formula I

A typical method of preparation was as follows. To a solution of Co(X-sal. *iso*-C_3H_7)$_2$ (0.01 mol) and the ligand (0.01 mol) in ethanol (20 m*l*) was added with stirring a 30% solution of H_2O_2 (5 m*l*) drop by drop at about 60°C. The solution was kept at this temperature for about twenty minutes and then allowed to stand overnight at about 5°C. A crystalline precipitate which separated was filtered, and recrystallized from ethanol, chloroform or acetone. Dark-green crystals of Co(X-sal. *iso*-C_3H_7)$_3$ were obtained in good yield. The complexes of the Co(X-sal. *n*-C_3H_7)$_3$ were prepared as dark-green crystals by a method similar to that previously reported.[2]

Analytical data of these complexes, which are given in Table 1, agree with the above formulae. The fact that the complexes prepared are diamagnetic indicates that they are cobalt(III) complexes of a low-spin type. The complexes with R=*iso*-C_3H_7 show clear melting points which are different from those of the corresponding complexes with R=*n*-C_3H_7, as given in Table 1. The infrared spectra of the complexes with R=*iso*-C_3H_7 are different from the spectra of the complexes with R=*n*-C_3H_7, the latter showing bands due to C–C stretching vibrations of the *n*-propyl group at about 1000 to 1100 cm^{-1}, where no absorption band appears for the complexes with R=*iso*-C_3H_7.

Two configurations, a *mer*- and a *fac*-form, are possible for the complexes of the Co(X-sal. R)$_3$ type, but only the *mer*-form has been isolated for all the previously synthesized complexes.[4] It is, therefore, most likely that the complexes prepared in the present work are also of the *mer*-form. The maxima of d-d bands of Co(X-sal. *iso*-C_3H_7)$_3$ are nearly equal to the maxima of Co(X-sal. *n*-C_3H_7)$_3$, for which the *mer*-form is usually found.

It seems to be significant that the complexes which have been claimed to be incapable of existence are isolated as pure crystals. The result of the present work clearly demonstrates that the extent of the steric hindrance is not great enough to forbid the formation of the complexes of the Co(X-sal. *iso*-C_3H_7)$_3$ type, although it is true that there may be more or less remarkable steric hindrance.

TABLE 1. ANALYTICAL DATA OF Co(X-sal·R)$_3$

X	R	mp (°C)		C	H	N (%)
NO_2	*i*-C_3H_7	243.5—245	Found	52.40	4.90	12.22

Particle Size Dependence of the Magnetic Heat Capacity of $Ni(OH)_2$ Crystal at Low Temperatures

Michio SORAI, Akio KOSAKI, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received December 26, 1967)

The heat capacities of $Ni(OH)_2$ crystals with three kinds of particle sizes [*i. e.* (1) (~20 Å)×(~130 Å), (2) (30—1000 Å)×(200—10000 Å), and (3) (0.2—0.5 μ)×(1—3 μ), where we designate their particle size as (average distance in <001> direction)×(distance in <100> direction)] have been measured in the temperature region form 1.5 to 300°K. Each of these crystals showed a heat capacity anomaly associated with the spin ordering of the metal ions at 23.0±0.1°K, 24.25±0.05°K, and 24.80±0.05°K for the $Ni(OH)_2$-(1), -(2), and -(3), respectively.

The magnetic heat capacities of these substances were separated from the total heat capacities by a rather reasonable method. The reduced plots of the magnetic heat capacities thus obtained are shown in Fig. 1. The magnetic entropies of the Ni-salts associated with the spin ordering effect agreed well with the value of 9.134 J/°K·mol from $R\cdot\ln(2S+1)$ where $S=1$ for the spin of the Ni^{2+} ion, and about 50% of this was acquired in the region above the Néel point, T_N, indicating the characteristic behaviours due to much stronger two-dimensional interactions predicted from their layer lattice structures (the CdI_2-type).

The variation of the transition temperatures form sample to sample observed in the Ni-salts may be the largest effect ever known[1] and clearly regarded as the particle size effects on the magnetic heat capacity. Additional effect of the particle size could be observed in the rounding of the heat capacity maxima with decreasing size of the crystal particles (see Fig. 1). This particle size effect has long been one of the unsolved problems which could help to fulfill the gaps between theory and experiment.

The particle size effect was also reflected in the surface heat capacities. The excess heat capacity was estimated to be about 1.2 J/°K·mol at 100°K for $Ni(OH)_2$ with the surface area of 314 m^2/g. This magnitude of excess heat capacity is the largest effect ever known and is compared with the data for NaCl, MgO, and BeO crystals[2] in Fig. 2.

The detailed results and discussions will be published in due course.

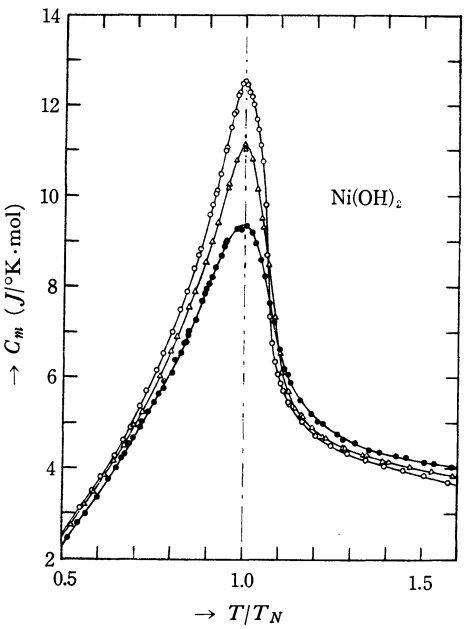

Fig. 1. The magnetic heat capacity C_m *versus* reduced temperature curves for $Ni(OH)_2$ with different crystal sizes. ●, the $Ni(OH)_2$-(1); △, the $Ni(OH)_2$-(2); ○, the $Ni(OH)_2$-(3)

Resolution of Optically Active Tris(1, 10-phenanthroline)vanadium(II) Complex

Ichiro FUJITA, Masayuki SHIMIZU, Youkoh KAIZU, Yasuo TORII and Hiroshi KOBAYASHI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 10, 1968)

Resolution of the optically active complexes with easily oxidized metal ions such as vanadium-(II) has never been reported. However inert gas atmosphere makes it possible to prepare and resolve them. Recently we succeeded in preparation and resolution of tris(1, 10-phenanthroline)vanadium(II) diperchlorate under the complete inert gas atmosphere.

This complex was obtained by the following procedure.[1] 0.001 mol vanadous solution prepared by electrolytic reduction of $VOSO_4$ was mixed with 0.003 mol 1, 10-phenanthroline (phen) and the mixed solution was stirred until it turned dark blue showing the formation of $[V(phen)_3]^{2+}$ ion. Then this solution was added the saturated solution of 1 g potassium antimonyl-*d*-tartrate as resolving agent. After the less soluble diastereomer was precipitated, the $(-)_{589}[V(phen)_3]^{2+}$ ion was precipitated as the perchlorate salt by the addition of ammonium perchlorate solution. The whole procedure was carried out in nitrogen gas. Solvent water was freed from oxygen by nitrogen bubbling. For the measurements of UV and visible absorption spectrum and circular dichroism (CD),*1 vacuum distilled methanol was used.

The absorption spectrum and also the CD curve resemble to those of $[Fe(phen)_3](ClO_4)_2$.[2] The observed spectra are shown in Fig. 1. The observed absorption intensity in UV region of vanadium complex is almost the same magnitude as those of the corresponding iron and nickel complexes. The observed CD intensity in the same region of vanadium complex is rather lower than those of the iron complex and nickel one,

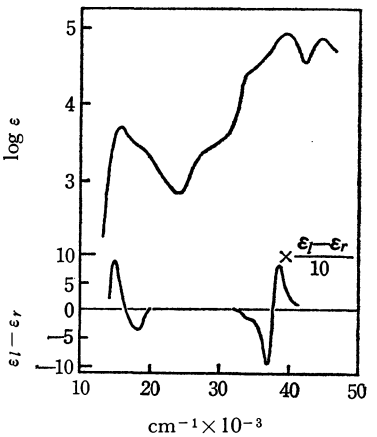

Fig. 1. Electronic absorption spectrum and CD curve of $(-)_{589}$-$[V(phen)_3](ClO_4)_2$.

while the CD intensity of the iron complex is comparable with that of the nickel one. The lower intensity of the vanadium complex might be interpreted as partial resolution. Any trial of the resolution of the vanadium complex could not get the corresponding values of the iron and nickel complexes, as far as potassium antimonyl-*d*-tartrate is used as resolving agent. Resolution using other resolving agents is being carried out. The CD curve of the less soluble diastereomer has not been obtained because of its insolubility.

The half-life of racemization assuming the first-order reaction is about 63 min in methanol at a room temperature. This value is as twice as that the iron complex and much less than that of the nickel complex.[3] When this complex was partially oxidized, the racemization became too fast to be measured.

Whole details will be published elsewhere.

The Excluded Volume Effect of Very-long-chain Molecules

Keizo SUZUKI

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received December 26, 1967)

The problem of the excluded volume effect upon the shape of the chain molecule was set twenty years ago[1] and has not been completely solved yet.[2] The approach by Monte Carlo simulation using an electronic computer has led to rather meagre results because of the extraordinarily poor yield of the overlapless form of the long chain; reliable results have been obtained only on chains with a few hundred bonds.[3]

The present author has found a new program to make the overlapless forms in a good yield, producing 8192-bond chains on a diamond lattice. Some results are shown in Table 1, where N is the number of the bonds, r is the radius of the gyration of the chain, a is the bond longth, and α is the exponent in the formula:

$$\langle r^2 \rangle = KN^{\alpha},$$

and is calculated by the equation:

$$\alpha = (\log \langle r^2{}_{2N} \rangle - \log \langle r^2{}_{N} \rangle)/\log 2.$$

Table 1

N	$\langle r^2 \rangle / a^2$	α	Yield (%)
1	0.2500	1.052	100
2	0.5185	1.092	100
4	1.105	1.145	94
8	2.444	1.19±0.01	87
16	5.560	1.20±0.01	78
32	12.78	1.20±0.01	71
64	29.31	1.20±0.01	62
128	67.37	1.19±0.01	56
256	153.4	1.19±0.02	50
512	350.3	1.17±0.04	46
1024	787.0	1.15±0.05	40
2048	1740	1.11±0.10	36
4096	3747	1.08±0.13	27
8192	7943		

With the increase in N, α increases at first but gradually decreases after passing a maximum value, 1.20. The previous studies did not find the decrease because they did not reach this region. Theoretically the exponent, α, can not go under 1; it probably approaches 1 very slowly, as previously expected by the present author.[4]

The scheme of the program to make overlapless chains with equal probability is as follows:

1 MAKE AN M-BOND CHAIN AT RANDOM. ($M=64$, for example)
2 IF THERE IS AN OVERLAP, GO TO 1.
3 $N=M$.
4 IF ANOTHER N-BOND CHAIN IS NOT STORED, STORE THE NEW CHAIN AND GO TO 1.
5 CONNECT THE STORED CHAIN TO THE NEW CHAIN AND MAKE A $2N$-BOND CHAIN.
6 IF THERE IS AN OVERLAP, OUTPUT AND CLEAR BOTH THE N-BOND CHAINS, AND GO TO 1.
7 $N=2N$, AND GO TO 4.

Full programs will appear elsewhere. The last column of Table 1 shows the average yield in getting an overlapless $2N$-bond chain by connecting two N-bond chains. The yield decreases with the increase in N, but it must converge to a finite value of not less than 1/9.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 539—542 (1968)

Studies of the ζ-Potential of Natural and Synthetic Fibers in Dye Solutions. XVIII. ζ-Potential and Surface Dyeability of Heat-Set Nylon 6 Fiber in an Acid Dye Solution

Toshiro SUZAWA and Tomoyuki SAITO

Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received June 12, 1967)

In order to ascertain the relation between the change in the fibrous fine structure and the dyeability of nylon 6 fiber caused by its heat-setting, the ζ-potential, the surface dye adsorption, and the total dye adsorption of the heat-set nylon 6 fiber in an acidic solution (pH 3.0) of acid dye—Orange II were determined. The crystallinity and the birefringence of the fiber increase in the order of the untreated, the wet-heat-treated, and the dry-heat-treated fiber. The isoelectric points of the untreated, the wet-heat-treated, and the dry-heat-treated fiber are pH 5.4, pH 4.6, and pH 2.8 respectively. With the increase in the dye concentration, the sign of the ζ-potential of the untreated and the wet-heat-treated fiber in a dye solution change from positive to negative because of the electrostatic bonds between the NH_3^+ of the fiber and the dye anion, RSO_3^-, while the ζ-potential of the dry-heat-treated fiber increases its negative value because of the van der Waals' forces between the fiber and the dye. The surface dye adsorption, as calculated from the difference between the surface charge density, $\Delta\sigma$, of the system with dye and that without dye, increases in any case as the dye concentration increases. The total dye adsorption increases as the dye concentration increases and attained the plateau regions at higher dye concentrations. The surface dye adsorptions become smaller in the order of the untreated, the dry-heat-treated, and the wet-heat-treated fiber. The total dye adsorptions become smaller in the order of the wet-heat-treated, the untreated, and the dry-heat-treated fiber. The differences in behavior among the fibers may be attributed to the adsorption of the dye to the loosely-packed portions in the amorphous region of the wet-heat-treated fiber, in addition to the differences in crystallinity and birefringence among the fibers. Moreover, the surface areas covered by adsorbed dye molecules, which were calculated from the reciprocal of the slope of the surface dye adsorption *vs.* the total dye adsorption curve of each fiber, were 1.8, 4.0, and 0.6×10^6 cm²/g fiber in the order of the untreated, the wet-heat-treated, and the dry-heat-treated fiber.

In manufacturing synthetic fibers such as polyamide nylon fibers, heat-setting is the usual processing practice. It is known that this treatment causes changes in the fibrous fine structure.

Hitherto, several articles on the relation between the changes in the fibrous fine structure and the dyeability of nylon 6 fiber caused by the heat-setting treatment have been published,[1] but few reports on the relation between the changes in the fine structure and the dyeability of the surface of the nylon 6 fiber caused by the heat-setting treatment are to be found. In this report the dyeability of the heat-treated nylon 6 fiber surface in an acid dye solution will be studied in relation to the ζ-potential, the surface dye adsorption, and the total dye adsorption in order to ascertain the influence of the changes in the fine structure upon the dyeability of the fiber surface.

Experimental

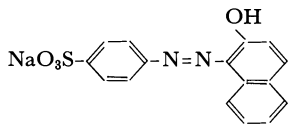
Fiber. Nylon 6 filaments (manufactured by the Toyo Rayon Co., Ltd.) were extracted with ethanol for about 24 hr at room temperature, and then dried in air. Three kinds of fiber were used. Some of the filaments were heat-treated as follows, while the rest were untreated specimens.

TABLE 1. NYLON 6 FIBERS USED

Fiber	Method of heat-treatment
Untreated fiber	(Draw ratio 4, 200 denier)
Wet-heat-treated fiber	Untreated fiber was treated 30 min in hot water (100°C) without tension
Dry-heat-treated fiber	Untreated fiber was treated 30 min in air at 170°C without tension

(All specimens were composed of 30 filaments)

Dye. The acid dye Orange II (I), which had been purified by recrystallization from an aqueous solution, was used.



(I)

ζ-Potential. The ζ-potential was measured by the method of the streaming potential, described in previous papers.[2] The dye solution was kept at pH 3.0 at 25°C with hydrochloric acid. Sodium chloride was added to the solution in order to prevent any influence of the ionic strength on the ζ-potential; its concentration was 10^{-4} mol/*l*.

Surface Charge Density and Surface Dye Adsorption. The surface charge density, σ, and the surface dye adsorption were calculated by method described in previous papers.[3]

Total Dye Adsorption, Crystallinity, Birefringence, Intrinsic Viscosity and End Groups. These values were measured and determined by the methods described in a previous paper.[3b]

Results and Discussion

End Groups, Crystallinity, Birefringence, and Intrinsic Viscosity of Nylon 6 Fiber. The values determined are shown in Table 2.

The end amino group decreased and the end carboxylic group increased in the order of the untreated, the wet-heat-treated, and the dry-heat-treated fiber. The intrinsic viscosity of the untreated fiber and that of the wet-heat-treated fiber were almost the same. However, the intrinsic viscosity of the dry-heat-treated fiber was about half of that of two former fibers; this result suggests that the decrease in the degree of polymerization is caused by the dry-heat-treatment. The crystallinity and the birefringence increase in the order of the untreated, the wet-heat-treated, and the dry-heat-treated fiber. These results suggest some change in the fine structure of these fibers, especially an increase in the crystalline region and in the degree of orientation.

The Isoelectric Point of Fiber. The ζ-potential of the fiber in solutions of hydrochloric acid or sodium hydroxide of various concentrations was measured in order to ascertain the influence of the pH on ζ. The results are shown in Fig. 1.

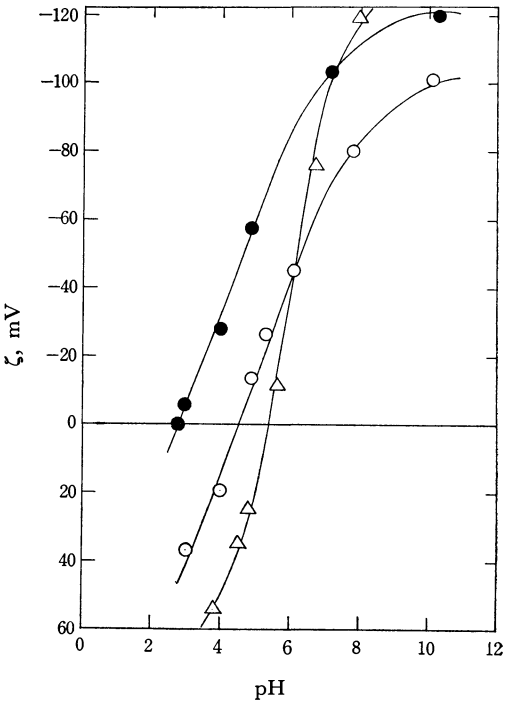


Fig. 1. Influence of pH on ζ-potential of heat-set nylon 6 fibers.
△: Untreated fiber
○: Wet-heat-treated fiber
●: Dry-heat-treated fiber

The ζ-potential of any fiber is positive in an acidic solution and negative in an alkaline one. From these results, it was found that the isoelectric points of the untreated, the wet-heat-treated, and the dry-heat-treated fiber are pH 5.4, pH 4.6, and pH 2.8 respectively. These differences in the isoelectric point among the fibers correspond to the differences in the end amino group and the end carboxylic group with the fibers, differences which are caused by the heat-treatment.

ζ-Potential with Dye Concentrations. The ζ-potential of the fiber *vs.* dye concentration curves

TABLE 2. END GROUPS, CRYSTALLINITY, BIREFRINGENCE AND INTRINSIC VISCOSITY OF THE NYLON 6 FIBERS USED

Fiber	End amino group (mol/g fiber) $\times 10^5$	End carboxylic group (mol/g fiber) $\times 10^5$	Crystallinity %	Birefringence $\times 10^3$	$[\eta]$
Untreated fiber	5.02	6.65	39.5	51.4	1.12
Wet-heat-treated fiber	4.28	7.92	42.5	53.2	1.10
Dry-heat-treated fiber	1.39	12.27	53.7	57.6	0.54

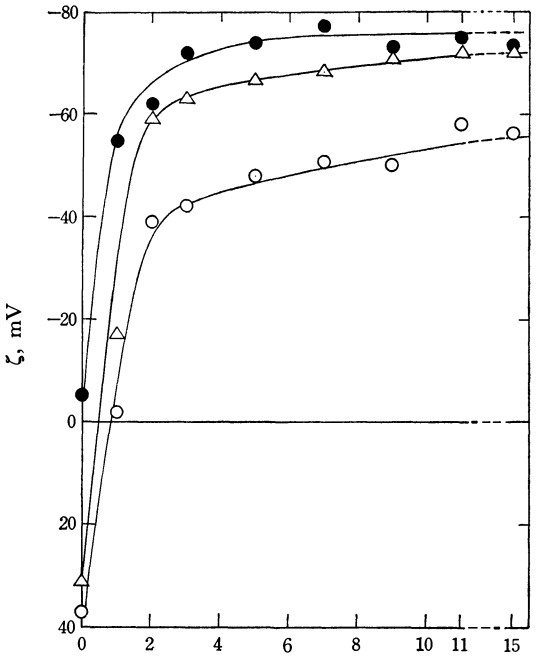

Fig. 2. ζ-Potential of the fibers with Orange II concentration.
△: Untreated fiber
○: Wet-heat-treated fiber
●: Dry-heat-treated fiber

are shown in Fig. 2. The ζ-potential was measured every hour on the hour; the values recorded in Fig. 2 are the equilibrium values, to which the potentials were approximated after four hours of immersion.

As the ζ *vs.* dye concentration curves in Fig. 2 show, the ζ-potentials of the untreated and the wet-heat-treated fiber are positive in a solution without dye, while the ζ-potential of the dry-heat-treated fiber is negative in the same solution. Such behavior may be expected from the dissociation of the NH_3^+ groups of the fiber in the former and that of the COO^- groups in the latter, because the pH of the solution used is smaller in the former, and larger in the latter, than the pH corresponding to the isoelectric point of the fiber.

Upon the addition of dye to this system, the ζ-potentials of the untreated and the wet-heat-treated fiber changed from positive to negative, while the ζ-potential of the dry-heat-treated fiber increased in its negative value. These facts may possibly be attributed to the formation of the electrostatic bond between the NH_3^+ of the fiber and the dye anion RSO_3^- in the former, and to the van der Waals' force between the fiber and the dye in the latter, because the pH of the dye solution used is smaller in the former, and larger in the latter, than the pH corresponding to the isoelectric point of the fiber. The ζ *vs.* dye concentration curves change rapidly in the range of concentrations smaller than 3×10^{-4} mol/*l*, and then the ζ-potentials (negative) approximate the saturated value.

Surface Dye Adsorption with Dye Concentration. The surface dye adsorptions increase with the dye concentration, as Fig. 3 shows.

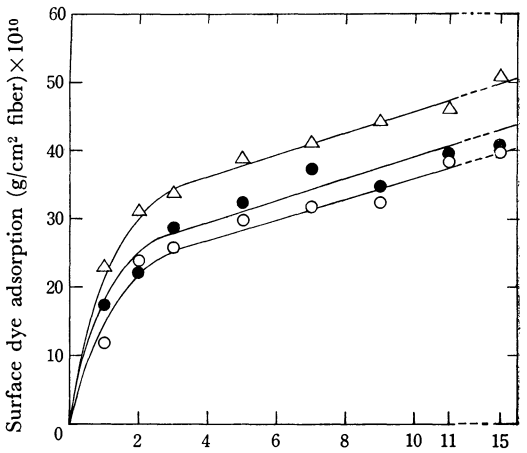

Fig. 3. Surface dye adsorption with Orange II concentration.
△: Untreated fiber
○: Wet-heat-treated fiber
●: Dry-heat-treated fiber

Throughout the range of dye concentrations, these values become smaller in the order of the untreated, the dry-heat-treated, and the wet-heat-treated fiber. This means that the surface of the untreated fiber, with a smaller crystallinity, a lower degree of orientation, and more end amino groups, adsorbs more dye than that of the dry-heat-treated fiber, with a larger crystallinity, a higher degree of orientation, and fewer end amino groups. Of course, this fact may also be related to the fact that the pH of the solution used is larger than the pH of the isoelectric point of the dry-heat-treated fiber.

In the case of the wet-heat-treatment, the intermolecular hydrogen bonds between the polymer-chain molecules of a fiber are broken by water molecules and the swollen, loosely-packed portions are formed in the amorphous region of the fiber.[1] The dyes adsorbed on these loosely-packed portions in the amorphous region cause the decrease in the dye concentration of the dye solution. This decrease in the dye concentration of the solution in the case of the wet-heat-treated fiber then gives rise to the decrease in the surface dye adsorption.

Therefore, it may be attributed to the adsorption of the dye to these loosely-packed portions in the amorphous region in the case of the wet-heat-treated fiber that the surface dye adsorption of the

wet-heat-treated fiber becomes smaller than that of the dry-heat-treated fiber, in spite of the smaller crystallinity and the lower degree of orientation of the former.

Total Dye Adsorption with Dye Concentration. The total dye adsorptions increase with the dye concentration, as Fig. 4 shows. Moreover, the plateau regions are attained at higher dye concentrations. The total dye adsorptions decrease in the order of the wet-heat-treated, the untreated, and the dry-heat-treated fiber. This means that the untreated fiber, with a smaller crystallinity, a lower degree of orientation, and more end amino groups, adsorbs more dye than does the dry-heat-treated fiber, with a larger crystallinity, a higher degree of orientation, and fewer end amino groups. Of course, this fact may also be related to the fact that the pH of the solution used is larger than the pH of the isoelectric point of the dry-heat-treated fiber. Moreover, the adsorption of the dye to the loosely-packed portions in the amorphous region of the wet-heat-treated fiber may be supposed to be the reason why the total dye adsorption of the wet-heat-treated fiber becomes larger than that of the untreated fiber, in spite of the larger crystallinity and the higher degree of orientation of the former.

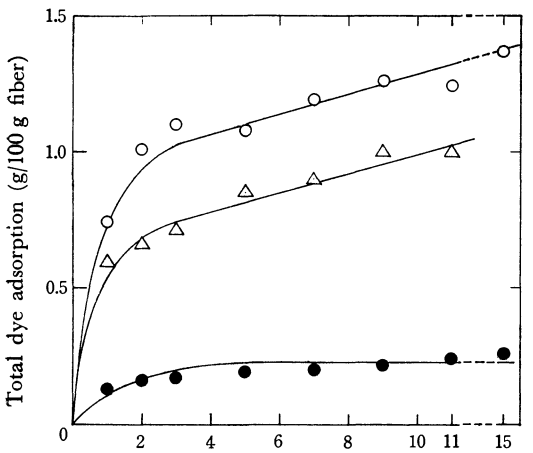

Fig. 4. Total dye adsorption with Orange II concentration.
△: Untreated fiber
○: Wet-heat-treated fiber
●: Dry-heat-treated fiber

Surface Area Covered by Adsorbed Dye Molecules on Fiber. The surface dye adsorption *vs.* the total dye adsorption curves were found to be linear, as Fig. 5 shows. These slopes are considered to be reciprocals of the surface area covered by adsorbed dye molecules on the fiber. These surface areas, as calculated from Fig. 5, are shown in Table 3.

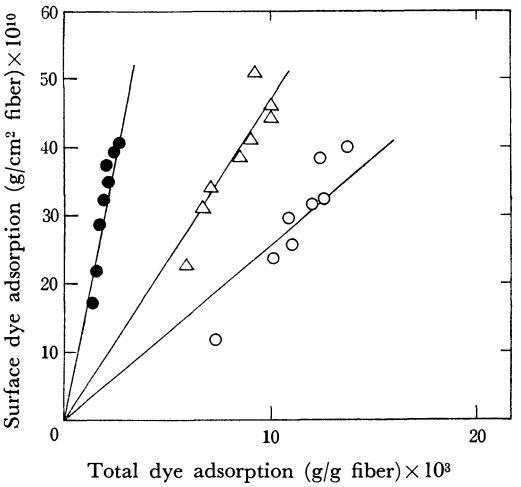

Fig. 5. Relation between surface dye adsorption and total dye adsorption.
△: Untreated fiber
○: Wet-heat-treated fiber
●: Dry-heat-treated fiber

TABLE 3. SURFACE AREA COVERED BY DYE MOLECULES ON FIBER

Fiber	Surface area (cm^2/g fiber)
Untreated fiber	1.8×10^6
Wet-heat-treated fiber	4.0×10^6
Dry-heat-treated fiber	0.6×10^6

The surface area of the wet-heat-treated fiber is twice of that of the untreated fiber, while that of the dry-heat-treated fiber is 1/3 that of the untreated fiber. The large surface area of the wet-heat-treated fiber is supposed to be caused by the loosely-packed portions in its amorphous region. Moreover, the small surface area of the dry-heat-treated fiber may possibly be attributed to its larger crystallinity and higher degree of orientation, and also to be related to the fact that the pH of the solution used is larger than the pH of its isoelectric point.

The authors wish to thank the Toyo Rayon Co., Ltd., for providing the fiber and for the measurement of its birefringence.

High Pressure Copolymerization of Styrene and Vinyl Acetate with Vinyl Chloride

Tatsuya IMOTO and Yoshiaki OGO

Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

and Hideo NAKAMOTO

Mitsubishi Rayon Co., Ltd., Misono-cho, Otake-shi, Hiroshima

(Received July 3, 1967)

The radical copolymerization of vinyl chloride and styrene, and that of vinyl chloride and vinyl acetate, were investigated in an acetone solution at 50°C under high pressures of up to 3000 kg/cm^2. The monomer reactivity ratios of these copolymers were not affected by the pressure, while their molecular weights and overall rates of copolymerization increased with the pressure. The increments of the four rate constants of the growing chain of copolymerization (k_{11}, k_{12}, k_{21}, and k_{22}) with the pressure are all of the same order. In such a case, ΔV^*_{11} is ΔV^*_{12}, and ΔV^*_{22} is ΔV^*_{21} (ΔV^*_{ij} is the activation volume in which the i radical reacted with the j monomer). The conclusion drawn from our previous works, that the monomer reactivity ratios of the copolymerization between nonconjugated monomers are independent of the pressure was supported by the experimental results of this report.

Radical copolymerization under high pressures has been studied by several groups of workers in recent years, but the great majority of works on high-pressure copolymerization have dealt with the effect of the pressure on the monomer reactivity ratio in the copolymerization system.

In the copolymerization processes, there are four possible ways in which a monomer can add:

$$M_1\cdot + M_1 \xrightarrow{k_{11}} M_1\cdot$$

$$M_1\cdot + M_2 \xrightarrow{k_{12}} M_2\cdot$$

$$M_2\cdot + M_1 \xrightarrow{k_{21}} M_1\cdot$$

$$M_2\cdot + M_2 \xrightarrow{k_{22}} M_2\cdot$$

where $M_1\cdot$ and $M_2\cdot$ represent chains ending in the M_1 and M_2 monomer units respectively, and where the parameters, $r_1=k_{11}/k_{12}$ and $r_2=k_{22}/k_{21}$, are defined as monomer reactivity ratios.

Zutty and Burkhart[1] investigated the copolymerizations of styrene and acrylonitrile, and of methyl methacrylate and acrylonitrile, under high pressures of up to 1000 kg/cm^2; they reported that their individual monomer reactivity ratios increase with the pressure.

On the other hand, the monomer reactivity ratios in the styrene - vinyl acetate and styrene - *n*-butyl vinylether systems were found in our previous experiment[2] not to change with the pressure.

Many investigations of high-pressure radical copolymerization have been undertaken in order to explain these disagreements. We investigated a series of copolymerizations under high pressure[3-8]; the most reasonable conclusion to be drawn from the available results was that the reactivity ratios of the copolymerization of the nonconjugated vinyl monomer with styrene did not vary with the pressure.

However, the vinyl acetate and *n*-butyl vinylether used in our previous work are monomers with the lowest reactivity of all the vinyl compounds. Therefore, the constancy of the reactivity ratios in copolymerizations under high pressure may be attributed to their original reactivities. The present investigation was undertaken to determine their effect by means of the copolymerization of vinyl chloride (VC) with a considerable reactivity among various conjugated monomers and styrene (St) or vinyl acetate (VAc).

Experimental

Styrene and vinyl acetate were distilled under a vacuum just before use. Benzoylperoxide (BPO), used as initiator, was purified by precipitating it from a chloroform solution into methanol, dried *in vacuo* at

room temperature, and stored in the dark. Vinyl chloride was purified with sodium hydroxide and dried with calcium chloride.

The acetone used as a solvent, the BPO, and the distilled vinyl monomer were placed in a polyethyrene tube with a capacity of 15 m*l*, and the tube was immersed in dry ice - methanol bath at −40°C. Purified gaseous vinyl chloride was introduced and liquified in the tube. Then the tube was immediately immersed in a high-pressure autoclave at 50°C.

The copolymer mixture thus obtained was precipitated into a large amount of methanol as a precipitant, dried completely *in vacuo* at room temperature, and its polymerization yield determined.

The compositions of the copolymers were calculated from the chloride contents as measured by Schöniger's flask-combustion method; then the reactivity ratios were evaluated by the Fineman-Ross method,[9] in which the $F=[M_1]/[M_2]$ and $f=d[M_1]/d[M_2]$ terms are connected by the following equation:

$$\frac{F}{f}(f-1)=r_1\frac{F^2}{f}-r_2 \qquad (1)$$

where $[M_1]$ and $[M_2]$ are the respective concentrations of the two monomers. Plotting the values of $F/f(f-1)$ *versus* F^2/f, r_1 and r_2 can be evaluated from, respectively, the slope and intercept of the straight line expressed by Eq. (1).

The pressure of the reaction system was measured by pressure guages (Bourdon tube and/or strain guage) directly connected to autoclaves.

Results and Discussion

Pressure Dependence of Monomer Reactivity Ratios. The experimental data for the St-VC and VC-VA systems are summarized in Tables 1 and 2. The monomer-polymer composition curves obtained at a 5% total conversion,

regardless of the reaction period under each pressure for the two systems, are shown in Figs. 1 and 2. In addition, the plots obtained by the Fineman-Ross method are illustrated in Figs. 3 and 4.

As Figs. 1 and 2 show, the copolymer compositions under high pressures form the same line as that of the atmosphere, within the limits of experimental error. The fact suggests that the copolymer compositions are quite independent of the pressure for the St-VC and VC-VA systems; that is the monomer reactivity ratios are not affected by the pressure.

The values of r_1 and r_2 evaluated from the slope and the intercept in Figs. 3 and 4 are summarized in Table 3. The values agree with those obtained by other workers[10,11] and show that the styrene monomer has a much greater tendency than does

vinyl chloride to add either to a styrene-free radical or to a vinyl chloride-free radical.

The results of the studies of the high-pressure copolymerization of the St-VC system lend some support to our previous conclusion about the pressure effect on copolymerization. Moreover, the conclusion may be extended as follows by considering the above findings regarding the VC-VA system: "The reactivity ratios of the copolymerization between nonconjugated monomers are also independent of the pressure. Therefore, the pressure affects only the copolymerization of a pair of conjugated monomer."

The effect of the pressure on the rate of chemical reactions can be related to the volume change from reactants to the transition state with Van't Hoff's expression:

$$\left(\frac{\mathrm{d}\ln k}{\mathrm{d}P}\right)_T = -\frac{\Delta V^*}{RT} \qquad (2)$$

where ΔV^* is an activation volume.

Assuming that ΔV^* does not vary with the pressure, Eq. (2) leads to:

$$\ln\frac{(k)_p}{(k)_1} = -\frac{\Delta V^*}{RT}(P-1) \fallingdotseq -\frac{\Delta V^*}{RT}P \qquad (3)$$

where $(k)_p$ and $(k)_1$ are the rate constants at P kg/cm^2 and atmosphere respectively.

By substituting r_1 and r_2 into Eq. (3), the following equations are obtained:

$$\ln\frac{(r_1)_p}{(r_1)_1} = \frac{\Delta V^*_{11} - \Delta V^*_{12}}{RT}P \qquad (4)$$

$$\ln\frac{(r_2)_p}{(r_1)_1} = \frac{\Delta V^*_{22} - \Delta V^*_{21}}{RT}P \qquad (5)$$

where $(r)_p$ and $(r)_1$ are the reactivity ratios at P kg/cm^2 and atmosphere respectively. ΔV^*_{ij} is the activation volume for the addition of the j monomer to a chain ending in the i radical.

The constancy of the reactivity ratios with the pressure leads to $\Delta V^*_{11}=\Delta V^*_{12}$ and $\Delta V^*_{22}=\Delta V^*_{21}$. This fact indicates that the two rate constants, k_{11} and k_{12}, similarly increase with the pressure.

In the case of styrene, since ΔV^*_{11} has been known to be -11.5 cc/mol from the data of Nicholson and Norrish,[12] the activation volume of the propagation reaction between the styryl radical and the vinyl chloride molecule, ΔV^*_{12}, may be -11 cc/mol.

Effect of Pressure on the Overall Copolymerization Rates in the St-VC System. The overall copolymerization rates in each pressure are shown in Fig. 5. St and VC are not easy to copolymerize and require a long time to produce VC-rich compositions (see Table 1).

The overall copolymerization rates are markedly accelerated by the pressure and become larger with an increase in the initial styrene mole fraction. This behavior is related to the activation volumes of styrene and vinyl chloride in homopolymerizations. The overall copolymerization rates at each pressure with 50 mol percent of styrene are illustrated in Table 4.

According to the transition-state theory, the following relation is given;

$$k_{11} = kT/h \exp(\Delta S^*_{11}/R)\exp(-\Delta H^*_{11}/RT) \qquad (6)$$

where k is Boltzman's constant, h is Planck's

12) A. E. Nicholson and R. G. W. Norrish, *Discussions Faraday Soc.*, **22**, 97, 104 (1956).

constant, ΔS^* is the activation entropy, and ΔH^* is the activation enthalpy. By substituting $r_1=k_{11}/k_{12}$ for Eq. (6), we have:

$$r_1 = \exp[(\Delta S_{11}^* - \Delta S_{12}^*)/\boldsymbol{R}] \times \exp[-(\Delta H_{11}^* - \Delta H_{12}^*)/\boldsymbol{RT}] \quad (7)$$

Since the activation enthalpies, ΔH^*, are almost invariable with the pressure,[13] the pressure dependence of the reactivity ratios may be attributed to the increment of the relative activation entropies $(\Delta S^*_{11}-\Delta S^*_{12})$.

Therefore, the relative activation entropies at high pressures, $(\Delta S^*_{11}-\Delta S^*_{12})_p$, would be equal to that of the atmosphere, $(\Delta S^*_{11}-\Delta S^*_{12})_1$, in the copolymerization of the nonconjugated monomer and styrene.

Effect of Pressure on the Molecular Weight of the Copolymer. The molecular weights of the copolymer in the St-VC system were not measured directly, but the intrinsic viscosity $[\eta]$ was determined as a approximate indication, whose relation to the copolymer composition is shown in Fig. 6.

Although the reason why these curves rise abruptly at higher styrene contents cannot be explained briefly, the increase in $[\eta]$ with the pressure can be recognized in the figure. This behavior must be due to the acceleration of the chain growth by the pressure.

Studies of Poly-2-vinylpyridine. V. Temperature Dependence of the Intrinsic Viscosity and Osmotic Pressure of an Ethanol Solution

Shizuo ARICHI

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received July 17, 1967)

The viscosity of a series of 10 fractions of poly-2-vinylpyridine and the osmotic pressure of a fraction of the same polymer in ethanol were measured at several temperature. The temperature coefficients of the intrinsic viscosities of all the fractions measured were found to be completely negative. The Mark-Houwink equations for molecular-weight-homogeneous samples were obtained in ethanol at 10, 25, 40, and 65°C. The Flory constant, $K=[\eta]_\theta/M^{1/2}$, obtained by the method of Fixman was found to be 13.0×10^{-4} at 25°C; this value is considerably larger than those estimated from the intrinsic viscosity data of this polymer in non-acidic solvents. The K value lowered to an ordinary level when it contained 2.7 N of dry ammonia in ethanol at 25°C. The values of the thermodynamic interaction parameters for dilution, ψ_1 and θ, were obtained from the viscosity data; the former was negative, but nearly zero (−0.02), while the latter was unusually large (397°C). The excess molar entropy of dilution obtained from the measurements of the temperature dependence of the osmotic pressure was found to be negative, but almost zero, which was in accordance with the value of ψ_1 described above; the excess molar heat of dilution obtained in the same way was found to be completely negative. Thus, the exhothermic interaction and negative excess entropy for dilution in this system were studied somewhat quantitatively.

In preceding papers[1-4] some results of the investigation of the solution properties of poly-2-vinylpyridine have been reported as a part of a series of studies of this polymer. Recently, several other papers concerning the solution properties of this polymer[5] and of a related polymer, poly-2-methyl-5-vinylpyridine[6,7] have also been reported. These papers have indicated that the Flory constants, $K=[\eta]_\theta/M^{1/2}$, of polyvinylpyridine homologues are exceptionally larger in alcohols or chloroform than those in the other solvents.[3,4,6,7] It has been also suggested that the thermodynamic interactions of polyvinylpyridine homologues with alcohols are peculiar; for example, in the cases of poly-4-vinylpyridine and poly-2-vinylpyridine, it has been suggested qualitatively that the contributions of enthalpy and entropy to the relative polymer-solvent interaction in alcohols are negative.[2,8]

The present investigation was intended to clarify more completely the solvent effects on the unperturbed dimension, and the thermodynamic interactions between poly-2-vinylpyridine and ethanol, by measuring the temperature dependence of the intrinsic viscosity of a series of fractions in ethanol, and also by measuring the temperature dependence of the osmotic pressure of a fraction in the same solvent.

Experimental

Materials. The poly-2-vinylpyridine fractions used in the viscosity and osmotic pressure measurements were all the same to those used in a previous study.[3] The ethanol was refluxed with freshly-burned calcium oxide and was then carefully distilled with the apparatus described in a previous paper.[1] Ethanol and methanol containing dry ammonia were prepared by introducing ammonia gas into these solvents. The ammonia gas was generated by slightly warming 32% ammonia water and was dried with soda lime, potassium hydroxide, and phosphorus pentoxide successively. The concentration of ammonia was determined by titration with hydrochloric acid.

Viscosity and Osmotic Pressure. The viscosity measurements were carried out with Ubbelohde-type capillary viscometers. The flowing volume was about 2 ml, and the flow time of ethanol for one of viscometers at 10, 25, 40, and 65°C were 187.5, 141.8, 109.5 and 74.3 sec, respectively. Nearly the same flow time was required for the other three viscometers. All the solutions were filtered through a glass filter immediately

before measurement. The initial concentrations of the solution ranged from 0.5 to 2.5 g/d*l* according to the molecular weight of the fractions measured; they were determined by the weight method at 25°C and were corrected for thermal expansion or contraction. The kinetic-energy correction was neglected.

The measurements of osmotic pressure were carried out with an apparatus of the type proposed by Sands and Johnson.[9] The detailed procedure and the complete construction of the equipment were described in their paper. Almost the same equipment was constructed; fifteen measurements could be carried out at the same time in the same water bath using a turntable. The membranes used were gel cellophane, # 300, kindly supplied by the Tokyo Cellophane Co., Ltd. At least 10 hr were required to attain equilibrium, regardless of the concentration of the solution, at 15°C. The lowering of height difference, $h-h_0$, between the head in the measuring capillary, h, and that in the reference capillary, h_0, after the equilibrium had been attained were not observed during the 15 days the solution was kept at 15°C. With an increase in the temperature, the linear line in $h-h_0$ *versus* the time plots inclined slightly, but when measurements were continued for at least 10 days, a sufficiently accurate extraporation to zero time could be made.

Results and Discussion

The Mark-Houwink Equation. The results of viscosity measurements for a series of fractions at 10, 25, 40, and 65°C in absolute ethanol are summarized in Table 1, while plots of the intrinsic viscosity number, $[\eta]$, *versus* the temperature are shown in Fig. 1. The fraction numbers in Table 1 and Fig. 1 correspond to those described in a previous paper,[3] where the measurement of the weight-average and the number-average molecular weight, M_w and M_n, for each fraction are described. The slopes of the line in Fig. 1, namely, the temperature coefficients of the intrinsic viscosity, are all negative, in contrast to the case in ordinary polymer-solvent systems.

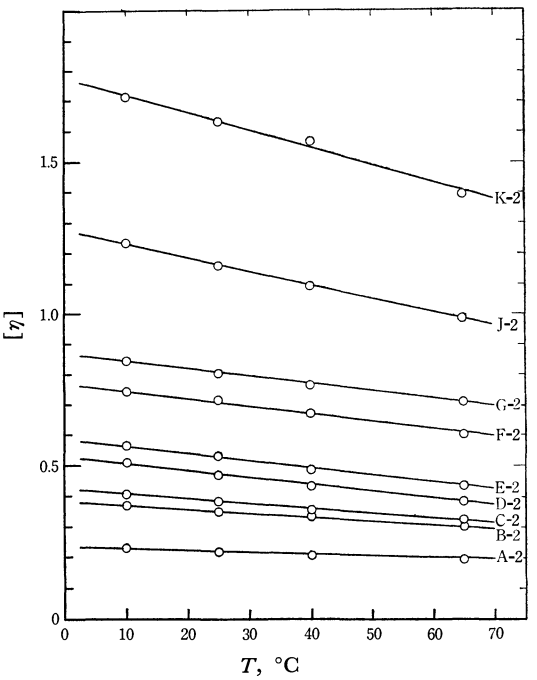

Fig. 1. Plots of intrinsic viscosity of poly-2-vinyl-pyridine fractions in ethanol *vs.* temperature.

Figure 2 shows plots of $[\eta]$ at four temperatures against M_w in double logarithmic scales. The Mark-Houwink equation at each temperature was obtained by the method of least squares as follows:

$$[\eta] = 1.03\times10^{-4} M_w^{0.746} \quad \text{at } 10°C$$
$$[\eta] = 1.09\times10^{-4} M_w^{0.729} \quad \text{at } 25°C$$
$$[\eta] = 0.99\times10^{-4} M_w^{0.733} \quad \text{at } 40°C$$
$$[\eta] = 1.06\times10^{-4} M_w^{0.718} \quad \text{at } 65°C$$

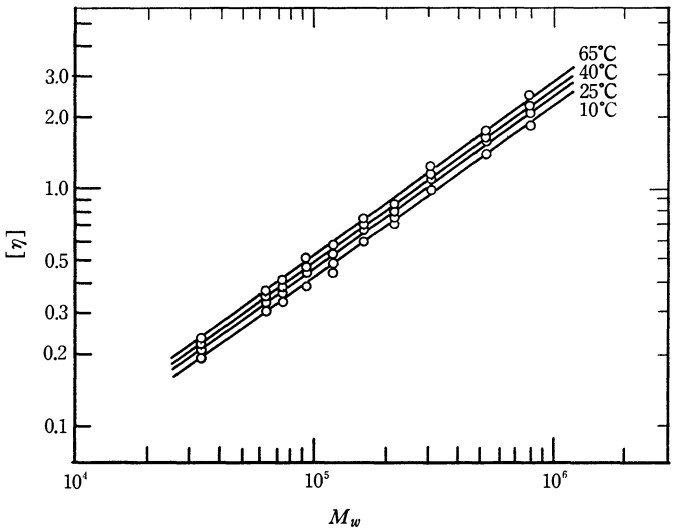

Fig. 2. Log-log plots of intrinsic viscosity of poly-2-vinylpyridine fractions in ethanol *vs.* weigt average molecular weight at 10, 25, 40 and 65°C.

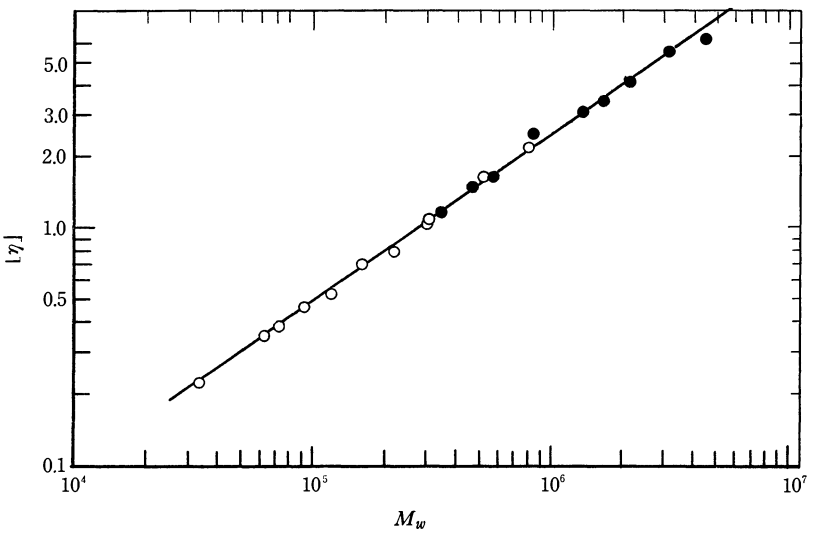

Fig. 3. Log-log plots of intrinsic viscosity of poly-2-vinylpyridine fractions in ethanol *vs.* weight average molecular weight at 25°C; (●): data obtained by Hyde and Taylor,[5] (○): data obtained in this study.

The Mark-Houwink equation for poly-2-vinylpyridine in absolute ethanol has already been reported by Hyde and Taylor[5] as follows:

$$[\eta] = 2.8\times 10^{-4} M_w^{0.66} \qquad \text{at } 25°C$$

The values of the two constants in this equation seem to be considerably different from those in our equation at the same temperature described above. However, if all the data for $[\eta]$ and M_w obtained by Hyde and Tailor and those obtained in this study are plotted together, the relation between $\log [\eta]$ and $\log M_w$ are sufficiently represented by a linear line for a very wide range of molecular weight, as is shown in Fig. 3. The line is consistent with the following equation, obtained by the method of least squares:

$$[\eta] = 1.50\times 10^{-4} M_w^{0.703} \qquad \text{at } 25°C$$

with the point of the lowest-molecular-weight sample, $M_w=8.6\times 10^4$, in the data of Hyde and Taylor being excepted.

The Mark-Houwink equations for the molecular-weight-homogeneous samples were obtained in the

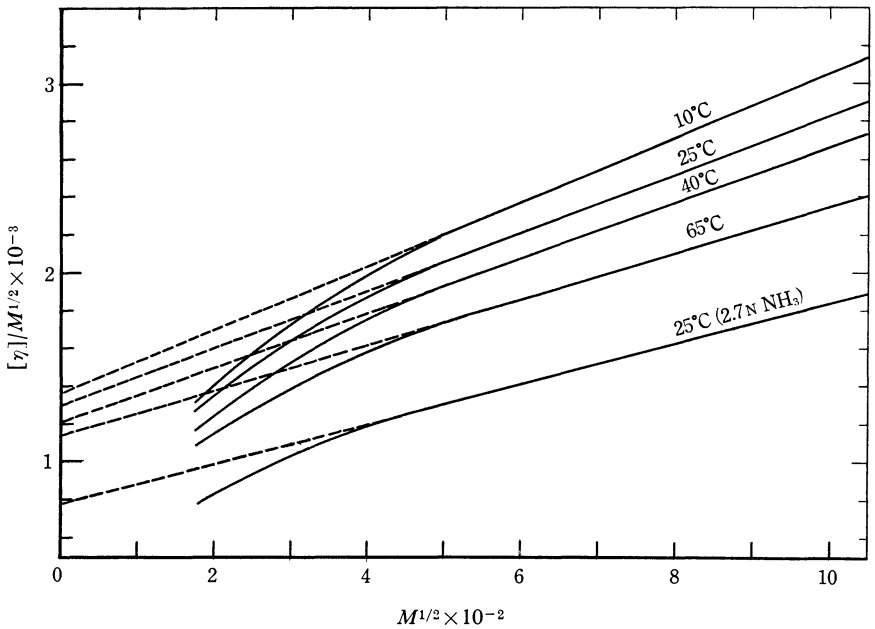

Fig. 4. Plots of $[\eta]/M^{1/2}$ *vs.* $M^{1/2}$ for poly-2-vinylpyridine in ethanol at 10, 25, 40 and 65°C and of those in ethanol contained ammonia (2.7 N) at 25°C.

same manner as before,[3] assuming that the molecular-weight distribution of each fraction is represented by the logarithmic normal-type molecular-weight-distribution function[10]:

$$w(M) = MA \exp\{-p^2(\ln M/M_0)^2\}$$

where the parameters are the same as in a previous paper.[3] The results are as follows:

$$[\eta] = 1.10\times10^{-4} M^{0.740} \quad \text{at } 10°C$$
$$[\eta] = 1.18\times10^{-4} M^{0.729} \quad \text{at } 25°C$$
$$[\eta] = 1.06\times10^{-4} M^{0.733} \quad \text{at } 40°C$$
$$[\eta] = 1.15\times10^{-4} M^{0.718} \quad \text{at } 65°C$$

These equations were used for the following evaluations of the Flory constants and of the thermodynamic interaction parameters.

The Flory Constant. The Flory constant, K, is defined by the following equations:

$$[\eta]_\theta = KM^{1/2} \tag{1}$$
$$K = \Phi_0(\langle L^2\rangle_0/M)^{3/2} \tag{2}$$

where $[\eta]_\theta$ and $\langle L^2\rangle_0$ are the intrinsic viscosity and the mean square of the end-to-end distance of a polymer molecule in the θ-solvent respectively; M, the molecular weight, and Φ_0, the universal constant (2.87×10^{21} for the molecular-weight-homogeneous polymer). The values of K were estimated according to the equation of Stockmayer and Fixman:[11]

$$[\eta]/M^{1/2} = K + 0.51\Phi_0 BM^{1/2} \tag{3}$$

where B is the long-range-interaction parameter. In spite of recent attempts to improve the graphical method for obtaining the unperturbed dimension, the Stockmayer and Fixman relation is still recommended as the most versatile form.[12]

Plots of the left-hand side of Eq. (3) against $M^{1/2}$ are drawn in Fig. 4. The calculations were carried out for a number of pairs of ideal values of M and $[\eta]$ obtained from the Mark-Houwink equation for molecular-weight-homogeneous poly-2-vinylpyridine in ethanol at each temperature described previously. The full lines show the range of molecular weight over which the original Mark-Houwink equations can be applied. Although the samples used in this study have quite a large inhomogeneity of molecular-weight distribution about their average values,[3] the corrected values of K may be obtained by the way of plotting shown in Fig. 4. A similar plotting method has been used by Gechel and others[7] in obtaining the value of K.

Because the lines in Fig. 4 show an appreciable downward curvature in the low-molecular-weight region, where, unfortunately, it is most important to extrapolate the lines to zero molecular weight, the values of K at each temperature were estimated by the extrapolation of the linear part of the lines in the relatively higher molecular-weight region.

10) R. Koningsveld and C. A. F. Tuijinman, *J. Polymer Sci.*, **39**, 445 (1959).

11) W. H. Stockmayer and M. Fixman, *ibid.*, *C*-**1**, 137 (1963).

Recently, the deviation from linearity in the Fixman plots has been discussed by several authors.[12,13] Berry[14] has proposed a new approximate expression instead of Eq. (3). However, most of these discussions have been based on the data of considerably higher-molecular-weight samples in good solvents. In this study, the molecular weights of the samples are not so large (less than 10^6), and the expansion coefficients, α_η, were mostly less than 1.4. Consequently, no correction has been applied further.

The values of K estimated from Fig. 4 are shown in Table 2; they are extraordinary large when compared with those estimated from the data in non-alcoholic solvents.[4] Gechel and others[6,7] reported just the same situation as to the trend of downward curvature shown in Fig. 4, and as to the estimation of the large value of K from the intrinsic viscosity data of poly-2-methyl-5-vinylpyridine in methanol and chloroform. They attributed these results to the association of solution components due to the polarity of the solvents.

TABLE 2. THE FLORY CONSTANT, K, OBTAINED FROM Fig. 4 FOR POLY-2-VINYLPYRIDINE AT VARIOUS TEMPERATURE

Temp. (°C)	Solvent	$K\times10^4$
10	Ethanol	13.7
25	Ethanol	13.0
40	Ethanol	12.2
65	Ethanol	11.5
25	Ethanol - 2.7 N NH_3	7.9

Attempts were made to clarify the effect of the acidity of methanol and ethanol on the values of the intrinsic viscosity of poly-2-vinylpyridine fractions in these solvents. Figure 5 shows the plots of the intrinsic viscosity of poly-2-vinylpyridine fractions in methanol and ethanol containing varying amounts of ammonia *versus* the concentration of ammonia in these solvents.

The sensitive lowering of the intrinsic viscosity with the increase in the concentration of ammonia, namely, with the decrease in the acidity of the solvent, is shown in Fig. 5. The plots of the intrinsic viscosity of the fractions in ethanol contained 2.7 N of dry ammonia *versus* M_w at 25°C; for purposes of comparison, those in absolute ethanol at 25°C *versus* M_w are shown in Fig. 6. The Mark-Houwink equation for the fractions of molecular-weight-homogeneous poly-2-vinylpyridine in ethanol containing 2.7 N dry ammonia were obtained in the same way as before to be as follows:

$$[\eta] = 0.64\times10^{-4} M^{0.74} \quad (4)$$

The lowest line in Fig. 4 resulted from the combination of Eq. (3) and Eq. (4); the value of K was estimated to be 7.9×10^{-4}, which is very close to the values obtained from the data of the intrinsic viscosity in non-acidic solvents.

The results obtained above are considered to be sufficient to show that the unperturbed dimension of poly-2-vinylpyridine in alcohols is influenced by the acidity of solvents.

Parameters for Thermodynamic Interaction. The thermodynamic interaction parameters for dilution, ψ_1 and θ, were obtained using

of the polymer; V_1, the molar volume of the solvent, and N, the Avogadro number.

With the aid of the Mark-Houwink equations for the molecular-weight-homogeneous samples at each temperature, we calculated the values of $[\eta]$ and $[\eta]_\theta$ and, consequently, the α_η value for an ideal polymer fraction whose molecular weight $M=10^6$; the values of the left-hand side of Eq. (5) and Eq. (6) are plotted against $1/T$ in Fig. 7. Apparently the slopes of the lines are the reverse of those for ordinary polymer-solvent systems. The values of ψ_1 and θ obtained by the method of least squares are summarized in Table 3.

TABLE 3. THE THERMODYNAMIC INTERACTION PARAMETERS FOR DILUTION OF POLY-2-VINYLPYRIDINE IN ETHANOL

Method	ψ_1	θ (°C)
Flory and Fox, Eq. (5)	−0.02	287
Kurata and Stockmayer, Eq. (6)	−0.02	397

The values of the entropy parameter obtained by the two equations are both very small, but negative, while the theta temperatures thus evaluated are unusually high. Such an anomaly as the occurrance of precipitation upon the heating of the solution can be predicted when the solution process is characterized by a negative excess entropy.[17]

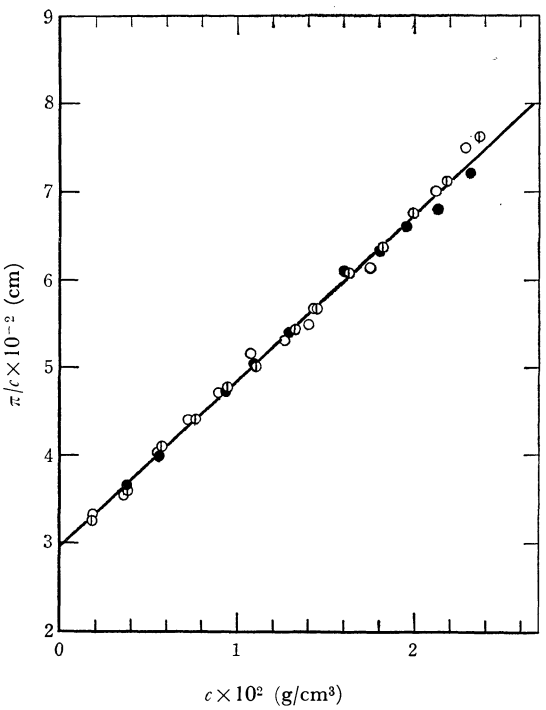

Fig. 8. Plots of reduced osmotic pressure *vs.* concentration of poly-2-vinylpyridine fraction, E-2, in ethanol at 15°C (ⓘ), 30°C (●), and 45°C (○).

The extraordinariness of the thermodynamic interaction between polyvinylpyridine and ethanol was further studied by investigating the temperature dependence of the second and the third virial coefficient, A_2 and A_3, of this polymer-solvent system.[18]

Figure 8 shows plots of the reduced osmotic pressure, π/c, *versus* the concentration, c. In spite of the measurements of the osmotic pressure over the range of very wide concentration, the temperature dependence of π/c is very small, as may be seen in Fig. 8; however, the data were treated with the method of Flory and Krigbaum,[19] assuming that the following equation is valid for this polymer-solvent system:

$$(\pi/c)^{1/2} = (\pi/c)_0^{1/2}[(1+\Gamma_2/2)c] \qquad (7)$$

The values of A_2 and A_3 were calculated from the values of $(\pi/c)_0$ and Γ_2 as evaluated by the method of least squares; they are plotted against the temperature in Fig. 9.

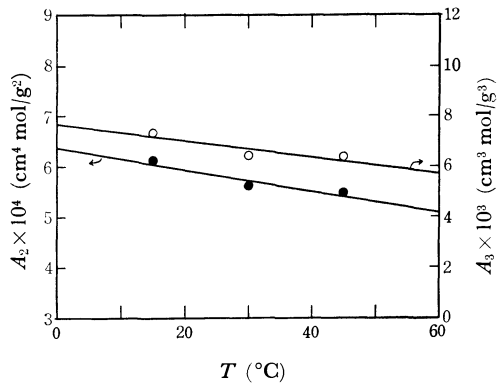

Fig. 9. Plots of osmotic the second, (●), and the third virial coefficient, (○), *vs.* temperature for poly-2-vinylpyridine fraction, E-2, in ethanol.

The excess thermodynamic functions of dilution for this system at 25°C were calculated by the following equations:

$$\Delta\mu_1^E/c^2V_1 = -RT(A_2 + A_3c)$$
$$\Delta h_1^E/c^2V_1 = RT^2\{(\partial A_2/\partial T) + (\partial A_3/\partial T)c\}$$
$$T\Delta s_1^E/c^2V_1 = RT\{A_2 + T(\partial A_2/\partial T) + A_3c + T(\partial A_3/\partial T)c\}$$

where $\Delta\mu_1^E$ represents the excess free energy of dilution; Δh_1^E, the excess molar heat of dilution, and Δs_1^E, the excess molar entropy of dilution. The results are summarized in Table 4.

Here again, it was confirmed that the contributions of both enthalpy and entropy to the relative polymer-solvent interaction in this system are

TABLE 4. THE EXCESS THERMODYNAMIC FUTNCTIONS OF DILUTION FOR POLY-2-VINYLPYRIDINE IN ETHANOL AT 25°C (cal cm³/g²)

$c \times 10^2$ g/100 cm³	$\Delta\mu_1^E/c^2V_1$	$\Delta h_1^E/c^2V_1$	$T\Delta s_1^E/c^2V_1$
0	−0.346	−0.376	−0.030
1	−0.387	−0.433	−0.046
2	−0.428	−0.489	−0.061

negative, indicating a very strong specific interaction between polymer and solvent upon their being mixed, and also, a very high degree of order in the packing of ethanol molecules and of the polymer segments (this is probably due to the hydrogen bond formation).[17]

The existence of some exhothermic interaction between poly-2-vinylpyridine and aliphatic alcohols or chloroform, and the resulting possibility of hydrogen-bond formation between the polymer and solvent, has been already suggested by investigations of the data of the intrinsic viscosity in many solvents at a constant temperature, 25°C, and those of the precipitation measurements of this polymer in mixed solvents consisting of alcohol and hexane, and of chloroform and hexane.[2] However, the parameters and the functions for the relative thermodynamic interactions between poly-2-vinylpyridine and absolute ethanol obtained by the data of the temperature dependence of intrinsic viscosity and osmotic pressure in this study confirm more directly and quantitatively the suggestions described above.

The author wishes to express his thanks to Professor Daisei Yamamoto of this University for his continued advice and encouragement in this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 555—563 (1968)

Effect of the Ionic Strength on the Behavior of Sodium Chondroitin Sulfate C in Aqueous Solutions*1

Masayuki NAKAGAKI and Kiyoshi IKEDA*2

Faculty of Pharmaceutical Science, Kyoto University, Sakyo-ku, Kyoto

(Received July 26, 1967)

Viscosity and light-scattering investigations were carried out in aqueous sodium chloride solutions at 25°C on a sample of sodium chondroitin sulfate C from shark cartilage. The weight-average molecular weight of 74000 was obtained. The molecular dimensions, obtained from the viscosity-partial specific volume, from the light scattering-partial specific volume, and from the light scattering-viscosity, were found to fit well for a long-rod model with a length of about 800 Å and a diameter of about 10 Å at the infinite ionic strength.

Sodium chondroitin sulfate is known to be an unbranched linear anionic polyelectrolyte. It has been considered that the molecule is fully stretched at a very low ionic strength by intramolecular electrostatic repulsion, but that it begins contracting with the increase in ionic strength because of the suppression of the repulsive force by ion-pair formation or by the electrostatic screening effect of the ion atmosphere, until at last it becomes randomly coiled.[1]

Chondroitin sulfate has three isomers, as is schematically illustrated in Fig. 1.[2] The B type of chondroitin sulfate has an axial carboxyl and sulfonic group, the A type, an equatorial carboxyl and an axial sulfonic group, and the C type, an equatorial carboxyl and sulfonic group. These differences in primary structure are considered to influence the behavior of the molecules in aqueous solutions. It has been known, actually, that the solubility in aqueous ethanol[3] is greater for the A and C types than for the B type; the value of pK_a on the potentiometric titration curve[3] is larger for the B type than for the A type, and the affinity of Ca^{2+} and Mg^{2+} under physiological conditions is greater for the B type than for the A type.[4] Furthermore, the affinity of a trivalent cation,

(a) A type; (b) B type; (c) C type

$Co(NH_3)_6^{3+}$, is greater for the B type than for the A type at a fixed ionic strength.[5] At a very low pH, where the ionization of carboxyl groups is mostly suppressed, there is not so large a difference in the affinity for $Co(NH_3)_6^{3+}$ among the three types of chondroitin sulfates at a low ionic strength; with an increase in the ionic strength, the affinity increases in the order of B>A>C types.[2] Further, only the B type of chondroitin sulfate is resistant to testicular hyaluronidase and possesses anticoagulant properties.[6]

It may be supposed from these facts that the C-type chondroitin sulfate has the least flexible structure of the three isomers, while the B type is the most flexible molecule. Recent studies of optical rotatory dispersion[7] have shown that a Cotton effect exists on the ultraviolet ORD curve with the C-type chondroitin sulfate, and an induced Cotton effect in the visible region is observed for the complex of this polymer with acridine orange. Comparing this phenomenon with other, similar phenomena shown by the helical polyglutamic acid,[8] tobacco mosaic virus,[9] and DNA,[10] chondroitin sulfate C may be supposed to have a helical structure at a suitable ionic strength.

In this paper, the effects of the ionic strength on the behavior of sodium chondroitin sulfate C prepared from shark cartilage is discussed quantitatively on the basis of viscosity measurements and light-scattering (Zimm-plot method) experiments.

Experimental

Materials and Solvent. The sodium chondroitin sulfate of the C type was kindly furnished by the Seikagaku-Kogyo Co., Ltd.,[11,12] the preparation being extracted from shark cartilage, fractionated, and carefully purified to remove any electrolyte except sodium chloride. The molecular weight of this preparation was 50000, as determined by the results of the terminal analysis, using D-galactosamine hydrochloride as a standard. The water content was 5.46%, and the specific viscosity of a one percent solution of this preparation was 2.03 at 30°C in a physiological solution of sodium chloride. Table 1 shows this preparation contained scarcely any diffusible ion species other than sodium ions.

For the purpose of serial experiments, a 1% stock solution was prepared by the dry-weight method and kept in a refrigerator. Water was distilled and refined by the ion-exchange method for the viscosity measurements. For light scattering, this water was distilled again with an all-glass unit.

Viscosity Measurements. The viscosity was measured at 25°C with a dilution viscometer of the Ubbelohde type. The filtering of the solution was omitted, because the solution was filtered automatically in the course of the experiment by the glass filter attached to the viscometer. The ionic strength and pH were adjusted with sodium chloride, sodium hydroxide, and hydrochloric acid.

Refractive Increment, dn/dc. The refractive increment, dn/dc, was measured with a Shimadzu electrophotometric differential refractometer at 25°C; the calibration was done by referring to a potassium chloride solution.[13] So as to remove errors due to the difference between the temperature of the solution and that of the solvent, and also because of the existence of bubbles, reading was carried out an hour after setting.

Light-scattering Measurements. A Shimadzu electrophotometric light-scattering photometer was employed. All the measurements were done with an unpolarized light of the 436 mμ wavelength, *in vacuo* and at the constant temperature of 25°C, controlled with circulated water. The apparatus was calibrated with the reduced scattering intensity at a 90° angle of benzene,[14] $R_{90}=48.5\times10^{-6}$. For this purpose, a reagent-grade commercial product of benzene was distilled twice with sodium metal, and filtered directly into the cell through a Cella Filter (Mittel) under pressing. A cylindrical glass was used as a solution cell, and its illuminated volume was corrected with a fluorescein solution. The solution and the solvent

Table 1. Analysis of sodium chondroitin sulfate C (N104)
(by Mr. T. Furuhashi,[11] Seikagaku Co., Ltd.)

		Method
pH	6.0	1% in distilled water
Uronic acid (as a glucronic acid)	38.46%	Dische's treatment using carbazole
Hexosamine (as a galactosamine)	33.88%	Modified Elson-Mogan procedure (Boas procedure)
Ester sulfate (SO_4)	20.94%	Chelate method
Total nitrogen	2.78%	Micro Kjeldahl method
Sodium ion	9.28%	Chelate titration
Potassium ion	negative	Ammonium oxalate method
Free sulfuric ion	negative	Nephelometry using barium sulfate
Chloric ion	negative	Direct titration using mercurous nitrate
Peptide or protein	negative	Biuret reaction
$[\alpha]_D^{28}$ (1% in water)	−13.4	Hitachi model POB polarimeter
Paper electrophoresis	one spot	0.1 M acetate buffer (pH 6), 12 v/cm, 90 min dying with toluidine blue

were optically clarified with Membrane Filter No. 15 under pressure. The pressure was given by the air, which was washed by passing a dilute alkaline solution and distilled water through it. The solution was prepared at each concentration by direct dilution in the cell, and the decrease in the concentration was determined by weighing the whole cell. The density decrease of the solution with dilution was neglected in this case. By measuring the refractive index of the solution before and after the filtration, it was confirmed that there is no appreciable decrease in the polymer concentration in the course of the filtration. The ionic strength and the pH were adjusted by the same method as has been described for the viscosity measurements. The scattering intensity was read about an hour later after setting.

Results

The relation between the reduced viscosity and the polymer concentration are shown in Fig. 2 at various ionic strengths. As the ionic strength was decreased, an unusual phenomenon characteristic of polyelectrolytes was observed at low concentrations. Nevertheless, extrapolation to zero concentration was possible except in the case of an extremely low ionic strength. The value of $[\eta]$ thus obtained decreased with an increase in the ionic strength. At a fixed ionic strength, the value of $[\eta]$ was largest in a neutral solution, middle in an alkaline solution, and the smallest in an acidic solution.

The results of light scattering are shown in Figs. 3, 4, 5, and 6. The experimental data were analyzed according to the equation for a two-component system:[15]

$$\frac{Kc}{R_\theta} = \frac{1}{M_w}\left(1+\frac{16\pi^2}{3\lambda^2}\langle\bar{S}^2\rangle \sin^2(\theta/2)\right) + 2A_2c \qquad (1)$$

and

$$K = 2\pi^2 n_0^2 (dn/dc)^2/(\lambda_0^4 N) \qquad (2)$$

R_θ is the reduced scattering intensity of the solution at a scattering angle of θ, from which the term of the solvent is subtracted. c is the polymer concentration, M_w is the weight-average molecular weight of the molecule, dn/dc is the refractive index of the medium, and λ_0 is the wavelength *in*

vacuo (4360 Å was used in this experiment). The wavelength, λ, in the medium is related to λ_0 as follows:

$$\lambda = \lambda_0/n_0 \tag{3}$$

$\langle\bar{S}^2\rangle$ is called the mean-square radius of gyration, which is the mean-square distance between the center of gravity and the respective mass element in the molecule; from it the molecular dimensions can be estimated. The following relation exists in the case of a long, rigid rod:[16]

$$\langle\bar{S}^2\rangle = L^2/12 \tag{4}$$

where L is the length of the rod. In the case of a randomly coiled molecule:

$$\langle\bar{S}^2\rangle = R^2/6 \tag{5}$$

where R is the root mean-square end-to-end distance of the flexible molecule.

In the Zimm plots of Figs. 3—6, the Kc/R_θ is

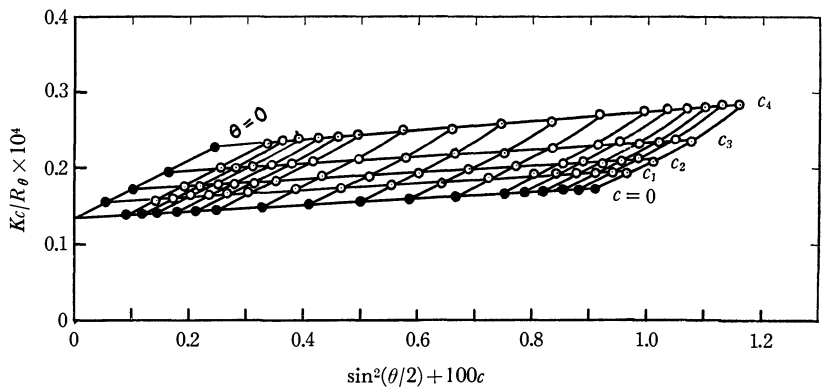

Fig. 6. Zimm plot for sodium chondroitin sulfate C in 0.2 M NaCl at 25°C. c_1, 0.05507%; c_2, 0.1028%; c_3, 0.1653%; c_4, 0.2464%

plotted as a function of $\sin^2(\theta/2)+100\,c$, where the value of 100 is an arbitrarily-selected constant. In Fig. 3, the open circles and squares are referred to independent experiments in order to show the reproducibility of the data. The refractive increment, dn/dc, was constant in every case within the limits of experimental error; its averaged value, 0.155, was used throughout.

On the basis of Eq. (1), the molecular weight was calculated from the intercept of the $c=0$ and $\theta=0$ lines on the ordinate; the mean-square radius of gyration, $\langle S^2 \rangle$ from the ratio of the initial slope of the $c=0$ line to the intercept on the ordinate, and the second virial coefficient, from the initial slope of the $\theta=0$ line. The results are collected in Table 2.

A constant molecular weight of 74000 was obtained in every case, and both the mean-square radius of gyration and the second virial coefficient decreased with an increase in the ionic strength or with a decrease in the pH of the solution at a fixed ionic strength. On the other hand, the molecular weight, estimated from the viscosity data according to this equation:[17]

$$[\eta] = 3.1\times10^{-4}\overline{M}_w{}^{0.74} \qquad (6)$$

was 80000 in a 0.15 M phosphate buffer (pH 7.0) containing 0.2 M NaCl at 25°C. The relation in Eq. (6) has been obtained for the A-type chondroitin sulfate; the molecular weight obtained from Eq. (6) is known to accord fairly well with that obtained from the results of terminal analysis for A-type molecule. However, the former is two or three times larger than the latter for the C type. In our case, the molecular weight determined by the

$dn/dc = 0.155$, $\bar{M}_w = 74000$

* $\langle\bar{S}^2\rangle$ and $[\eta]$ at $J=0.01$ (pH 3.5 or 2.7) is in the same order as that at $J=0.2$ as seen from Figs. 13 and 2, respectively. A_2 at $J=0.01$ (pH 3.5) is 8.00×10^{-3}.

results of terminal analysis is 50000, while that obtained from the viscosity is 80000, according to Eq. (6). The value of 80000 is about 1.6 times as large as the value of 50000. The molecular weight, 74000, obtained by light scattering is rather closer to the value, 50000, by the results of terminal analysis.

Discussion

Treatment as a Flexible Coil. The intrinsic viscosity tabulated in Table 2 is plotted as a function of the reciprocal root of the ionic strength, $1/\sqrt{J}$, in Fig. 7; then the intrinsic viscosity, $[\eta]_\infty$, at the infinite ionic strength was estimated. In the same manner, the mean square of the radius of gyration, $\langle\bar{S}^2\rangle$, from light scattering is plotted as a function of $1/\sqrt{J}$ in Fig. 8, and $\langle\bar{S}^2\rangle_\infty$ was estimated at the infinite ionic strength.

On the other hand, the second virial coefficient, A_2, in Table 2 is plotted against the reciprocal ionic strength, $1/J$, and the reciprocal root of the ionic strength, $1/\sqrt{J}$, in Figs. 9 and 10 respectively. As the A_2 value is small at the infinite ionic strength, it can be considered that the medium is practically

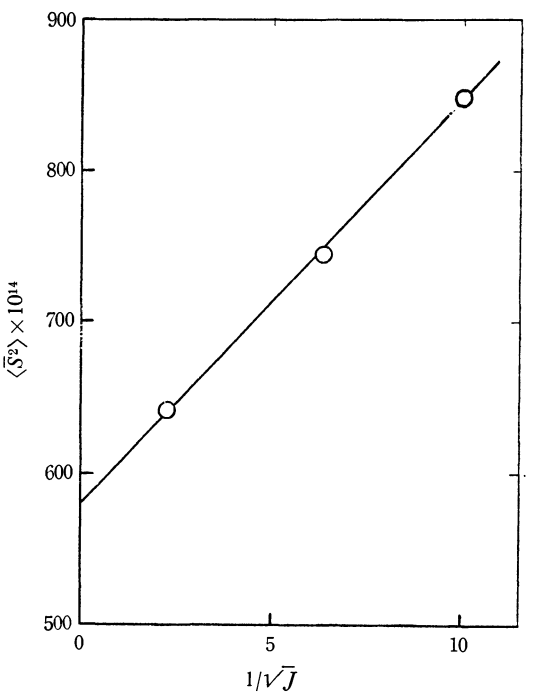

Fig. 8. Mean square radius of gyration $\langle\bar{S}^2\rangle$ plotted against reciprocal root of ionic strength $1/\sqrt{J}$.

a θ solvent at the ionic strength, and $[\eta]_\infty$ and $\langle\bar{S}^2\rangle_\infty$ may be regarded as $[\eta]_\theta$ and $\langle\bar{S}^2\rangle_\theta$ respectively.

The expansion factor of the macromolecule, α, is defined as the ratio of the radius of gyration to that in the θ solvent:

$$\alpha = \langle\bar{S}^2\rangle^{1/2}/\langle\bar{S}^2\rangle_\theta^{1/2} \quad (7)$$

Flory[18] has defined it as:

$$\alpha = [\eta]^{1/3}/[\eta]_\theta^{1/3} \quad (8)$$

Therefore, α^2 corresponds to $[\eta]^{2/3}/[\eta]_\infty^{2/3}$ or

18) P. J. Flory, "The Principles of Polymer Chemistry," Cornell Univ. Press (1953); P. J. Flory and T. G. Fox, *J. Am. Chem. Soc.*, **73**, 1904 (1951).

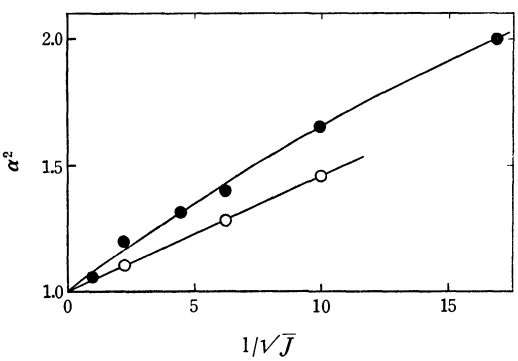

Fig. 11. Expansion factor α^2 obtained from viscosity (●) and light scattering (○), plotted against $1/\sqrt{J}$.

$\langle\bar{S}^2\rangle/\langle\bar{S}^2\rangle_\infty$. These quantities are plotted as a function of $1/\sqrt{J}$ in Fig. 11. With the decrease in ionic strength, the α^2 value obtained from the intrinsic viscosity increases more steeply than that obtained from light scattering. The discrepancy between the two curves can easily be expected to be even more severe when α is estimated from another relation obtained recently[19]:

$$\alpha \doteqdot [\eta]^{1/2.43}/[\eta]_\theta^{1/2.43} \tag{9}$$

The second virial coefficient calculated theoretically on the basis of the light-scattering data ($\langle\bar{S}^2\rangle$, $\bar{M}_w$, and α) and the following Flory relation,[19] is plotted as a function of $1/J$ and $1/\sqrt{J}$, together with the experimental second virial coefficient, in Figs. 9 and 10 respectively.

$$A_2 = (16\pi N/3^{3/2})[\langle\bar{S}^2\rangle^{3/2}/\bar{M}_w{}^2]\ln[1+(\pi^{1/2}/2)(\alpha^2-1)] \tag{10}$$

There is a large difference between the theoretical and experimental results here. It may, however, be meaningless to discuss the virial coefficient further, since no clear explanations have been obtained for many polyelectrolytes, such as sodium carboxymethyl cellulose,[20] sodium polyphosphate,[21,22] and potassium polyvinyl sulfonate.[22,23]

Considering a flexibly-coiled molecule as a sphere, the intrinsic viscosity (ml/g) of the spherical molecule can generally be expressed as follows:

$$[\eta] = 2.5\cdot\frac{4}{5}\cdot R_e\cdot\frac{N}{M} \tag{11}$$

where R_e is the effective radius of the sphere. By Kirkwood and Riseman's treatment,[24] the radius, R_e, is related to the radius of the gyration of the flexible coil of an adequately large degree of polymerization as follows:

$$R_e = 0.875\langle\bar{S}^2\rangle^{1/2} \tag{12}$$

Accordingly, the root mean-square radius of gyration $\langle\bar{S}^2\rangle^{1/2}$ is obtained through Eqs. (11) and (12) as 130 Å at the infinite ionic strength by consulting the value given in Table 2, $[\eta]=125$. On the other hand, the value of 241 Å was obtained as the value of $\langle\bar{S}^2\rangle^{1/2}$ from light scattering. In view of these facts, this molecule can not be considered as a flexible coil of a spherical shape.

Treatment as an Ellipsoid or a Rigid Rod. The intrinsic viscosity, $[\eta]$ (ml/g), is related to the hydrodynamic volume, V_h, molecular weight, M, and Avogadro's number, N, by:

	f(L.S.)	293	268	245	222

$$[\eta] = \nu\frac{N}{M}V_h \tag{13}$$

Moreover, V_h is connected with the partial specific volume, $\bar{v}_2$, of the solute by:

$$V_h = \frac{M}{N}(\bar{v}_2 + \delta_1 v_1^\circ) \tag{14}$$

where v_1° is the specific volume of the pure solvent and δ_1 is the adsorption coefficient of the solvent to the solute. The ν in Eq. (13) is expressed by Simha[25] for prolate ellipsoids with the axial ratio, f, as follows:

$$\nu = \frac{f^2}{15(\ln 2f - 3/2)} + \frac{f^2}{5(\ln 2f - 1/2)} + \frac{14}{15} \tag{15}$$

The values of ν have been computed and tabulated by Scheraga[26] for various f values. According to Eqs. (13), (14) and (15), the hydrodynamic volume and the axial ratio can be estimated from the experimental values of $[\eta]$, M, and $\bar{v}_2$, supposing $\delta_1 = 0$. If the molecules are thus assumed to be prolate ellipsoids, the two semi-axes, a and b, of the ellipsoid can be obtained from the values of the hydrodynamic volume and the axial ratio according to these equations:

$$V_h = \frac{4}{3}\pi ab^2 \tag{16}$$

$$f = a/b \tag{17}$$

If the molecules are, on the other hand, assumed to be rigid rods with the same volume and length as the ellipsoid, then the length, L, and the diameter, D, of the rod will be:

$$L = 2a \tag{18}$$

$$D = (2/3)^{1/2}2b \tag{19}$$

and the radius of gyration will be:

$$\langle\bar{S}^2\rangle^{1/2} = L/12 \tag{20}$$

The results obtained in this manner are shown in Table 3 on the lines designated as (vis.) and in Fig. 12 for various ionic strengths, J.

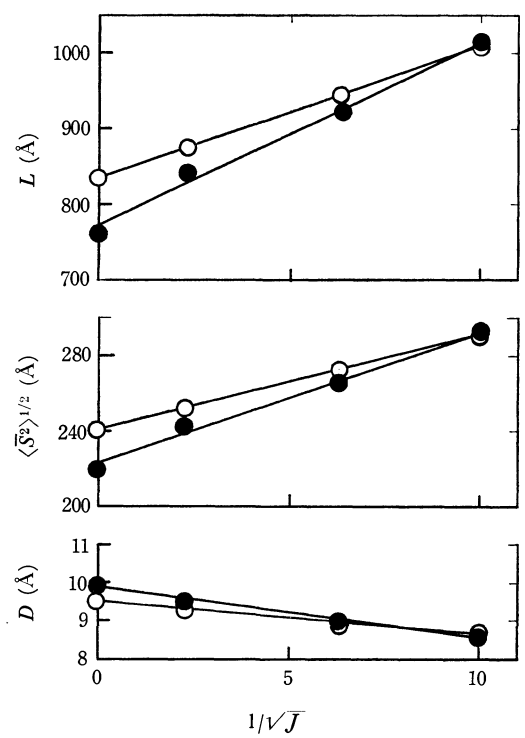

Fig. 12. Molecular dimensions of chondroitin sulfate C obtained, assuming a rigid rod.
○, light scattering-partial specific volume
●, intrinsic viscosity-partial specific volume

25) R. Simha, *J. Phys. Chem.*, **44**, 25 (1940); J. W. Mehl, J. L. Oncley, and R. Simha, *Science*, **92**, 132 (1940).
26) H. A. Scheraga, *J. Chem. Phys.*, **23**, 1526 (1955).

On the other hand, the length, L, and the diameter, D, of the rod can also be calculated from the radius of gyration by light-scattering experiments and from the molecular volume obtained from the specific volume, according to Eq. (20) and this equation:

$$V_h = \pi(D/2)^2 L \qquad (21)$$

These results, too, are shown in Table 3, on the lines designated as (L. S.) and in Fig. 12 for various values of the ionic strength, J.

As for the radius of gyration, it has been shown that the $\langle \bar{S}^2 \rangle^{1/2}/([\eta]M)^{1/3}$ quantity can be expressed as a function of the axial ratio, f, only.[27] Therefore, the value of $\langle \bar{S}^2 \rangle^{1/2}$ can be calculated by using the values of the axial ratio, f(vis.) or f(L. S.), together with the $[\eta]$ values and with $M=74000$. These results, shown in Table 3, show a fairly good agreement with each other.

As Fig. 12 shows, the results from the viscosity-partial specific volume and from the light scattering-partial specific volume show a certain disagreement with each other when the ionic strength is large. Even at the infinite ionic strength, however, the radius of gyration, 241 Å, obtained from light scattering, is much closer to the value as a rigid rod (219 Å) than to the value as a flexible coil (130 Å).

When we assume that the length of a repeating disuccharide unit is of the order of 10 Å, the residue weight, 490, and the molecular weight, 74000, will give a rough estimate of 1500 Å for the length of the polymer chain. Accordingly, the rod length of 843 Å obtained from light scattering or that of 760 Å obtained from the intrinsic viscosity must mean that the molecule is two-fold, if the polymer chain is assumed to be extended in full. If the polymer is, however, assumed to have a helical structure, as has been emphasized in an optical rotatory dispersion experiment,[7] sodium chondroitin sulfate C can probably be considered to be a helical rod with 5.0—5.6 Å of pitch per repeating disuccharide unit.

Consideration at Finite Polymer Concentrations. The slopes on the plot of Kc/R_θ against $\sin^2(\theta/2)$ at various concentrations:

$$g = \mathrm{d}(Kc/R_\theta)/\mathrm{d}\sin^2(\theta/2) \qquad (22)$$

are considered to be related to the dimentions of the solute.

They are plotted against the polymer concentration in Fig. 13. It is apparent that the magnitude

of the slope is unchanged up to a certain critical polymer concentration, and then steeply increases. It reaches a limiting value, when the ionic strength is low. This phenomenon can probably be considered to be related to its unusual viscosity behavior at low polymer concentrations, and also to the metachromatic color change,[28,29] observed at higher polymer concentrations. Furthermore, the chondroitin sulfate C is known to develop a non-Newtonian viscosity. It is, however, not sure at present that this behavior of chondroitin sulfate C is due to its rod shape, to the association of the molecules, or to the orientation of the highly-charged, rod-like macromolecules.

The authors wish to express their thanks to the Seikagaku Kogyo Co., Ltd., for furnishing the material and to Mr. Tamotsu Furuhashi for his analysis of the preparation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 564—569 (1968)

The Solution Properties of Nonionic Oligosoaps Derived from Nonylphenol Formaldehyde Resin

Yutaka ISHIGAMI and Hideo NARASAKI

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received July 28, 1967)

Nonionic oligosoaps (mol wt 6200 and 9700), consisting of a short polymer chain with chemically-attached soap-like groups, have been prepared from nonylphenol formaldehyde resin (mol wt 2000) by condensing 11 and 20 mol of ethylene oxide per nonylphenol ring making up the resin. Light-scattering, surface-tension, and vapor-pressure-depression measurements have been carried out. These oligosoaps formed agregates in water; the micellar weights were 81000 (11 mol condensate) and 70700 (20 mol), respectively, much as with the cationic oligosoap derived from polyallyl chloride reported elsewhere. The aggregation number, the dependence of the micellar weight on the sodium chloride concentration, the small surface area per molecule, in water, and the nonaggregation in nonaqueous solutions are discussed. It is noteworthy that these oligosoaps behave like monosoaps in various ways.

In a preceding paper,[1] we reported that a cationic polysoap (quaternization product (formura weight, 2770) of *N*-dodecyl-piperidine with polyallyl chloride (mol wt, 650)), consisting of a short polymer chain with chemically-attached soap-like groups (designated as "*oligosoap*" below) formed a micelle in water. It seems that such an oligosoap generally forms a micelle in aqueous media. The occurence of this phenomenon in a nonionic oligosoap was ascertained in the present investigation.

Regarding an aqueous solution of ethylene-oxide condensates of alkylphenol formaldehyde resin, Yamashita[2] mentioned that the critical micelle concentration (CMC) of a dimeric resin derivatives was lower than that of the corresponding alkylphenol derivative (monosoap). Hayano *et al.*[3] reported that even those surfactants equal to the dimer did not show the CMC when treated by the method of determining the CMC for nonionic surfactants developed by Ross *et al.*

The present situation of the problem of the aggregation of these nonionic oligosoaps is similar to the early studies of the micelle formation of polyoxyethylated nonionic monosoaps. Namely, the physicochemical properties of the nonionic surfactant solutions changed gradually over a relatively wide surfactant concentration range depending upon the presence of a wide range of molecular sizes and impurities. Therefore, the CMC's of these surfactants were not definite and, further, differed from method to method among the CMC determination methods. On the other hand, numerous papers on the physicochemical properties of Pluronic polyol homologues in aqueous and nonaqueous media have appeared.[4,5] The present authors are especially interested in whether these polyols form a micelle or not.

Experimental

Determination of Molecular Weight Using a Vapor-pressure Osmometer (VPO). Determinations were carried out with a Mechrolab vapor-pressure osmometer, Model 302, at 37°C. The instrument was calibrated with solutions of benzil and methyl linolate over a concentration range of 0.004—0.05 mol solute/kg solvent. Steady readings of the resistance in ohms (ΔR) of these solutions were attained for more than 5 min in benzene and 15 min in *n*-butanol. The ΔR of the unknowns (oligosoaps) were divided by the weight concentration (C), and these quotients were plotted against C. The molecular weights were obtained by dividing the cali- bration constant by $(\Delta R/C)_{c\to 0}$.

Light Scattering (LS). Light-scattering measurements were carried out at a room temperature of about 21°C with a wavelength of 436 mμ, using a Shimadzu photoelectric light-scattering photometer. Scattered light was observed at 90°, 45°, and 135° relative to the incident beam. The optical clarification of the solution to be examined was made by centrifuge at 21000 g and filtration with an ultrafine sintered glass filter. Aqueous solutions were prepared by diluting an original solution volumetrically. After these solutions had been

allowed to stand overnight, they were filtered by the filter directly into a light-scattering cell and measured. *n*-Butanol solutions were measured by successive dilutions of an original solution by filtering the solvent directly into the cell. The details have been given elsewhere.[1]

As a check on the entire calibration, the weight-average molecular weight ($\overline{M}_w$) of a standard polystyrene, Styron 683-7, supplied by the Asahi-Dow Co., was estimated by Hamashima and Hattori[6] by means of this instrument to be 234000; this value is in good agreement with the $\overline{M}_w$ values of 227000 for a column-fractionation method and 256000 for an ultracentrifuge.

Surface Tension. The surface-tension measurements were carried out by the drop-weight method in a thermostat maintained at 30.0±0.2°C, using the correction of Harkins and Brown.[7] More than two minutes were allowed for the formation of each drop of the solution in a saturated atmosphere (*cf.* Fig. 4).

Reagents. Nonylphenol was supplied by the Sanyo Yushi Kogyo Co.; the *p*- and *o*-nonylphenol contents were approximately 75% and 25%, respectively.[8] The benzene was dehydrated with sodium, and the *n*-butanol was dehydrated with calcium oxide. Methyl linolate supplied by Tanabe and Hashimoto,[9] was prepared from safflower oil; its minimum purity was found to be 98% (contained less than 2% methyl oleate) by gas chromatographic analysis. The other materials were reagent-grade materials.

Preparation of Oligosoaps. A mixture of 165 g (0.75 mol) of nonylphenol, 22.5 g (0.75 mol) of paraformaldehyde, and 225 m*l* of toluene were introduced, with 1.5 g of *p*-toluene sulfonic acid, into a two-necked 500 m*l*-flask, to which there were a reflux condenser and a thermometer. The reaction mixture was heated under reflux on an oil bath for 2.5 hr, and the resulting water was removed. The nonylphenol formaldehyde resin was then isolated by running the solution into stirred 90% methanol. The resin was purified by dissolving it in toluene and by adding this solution to 90% methanol; then it was dried at 60°C for 50 hr in a vacuum. The yield of the resin obtained was 44.5 g; its molecular weight was found to be $2.0\times10^3\pm100$ by means of VPO (the degree of number-average addition-condensation was 8.6).

Nonionic oligosoaps were prepared as follows, 15 g of the nonylphenol formaldehyde resin and 0.15 g of metallic sodium were dissolved in 45 g of xylene, after which ethylene oxide (EO) gas which had been dried through the layer of pellet pottasium hydroxide was bubbled into the solution at 120°C. The resulting products were poured into a 1 : 2 ether- *n*-hexane mixture. The precipitates were redissolved in methanol, and the solution was then treated with a great deal of *n*-hexane. An additional dissolution and precipitation were carried out. The oligosoaps were dried at 60°C for 50 hr in a vacuum. The EO contents of the compounds were determined by the weight increase in the EO condensation reaction. The oligosoap had the average EO chain lengths of 10.8 and 19.8 respectively per nonylphenol ring making up the nonylphenol formaldehyde resin molecule. These are abbreviated as NF-11 and NF-20 below. The corresponding molecular weights of these oligosoaps were $6.2\times$ and 9.7×10^3, respectively. A monosoap, NP-18, was similarly prepared from nonylphenol; it had an average EO chain length of 18.4 per mol.

Results and Discussion

Light Scattering of Aqueous Solutions. The reduced-intensity *vs.* oligosoap-concentration curves are shown in Fig. 1. The CMC's of the aqueous oligosoap solutions (NF-11: $6\times$; NF-20: 5×10^{-6} mol/*l*) corresponding to the sharp breaks on these curves are in good agreement with the inflection points (CMC: both, 2×10^{-6} mol/*l*) observed in the surface-tension *vs.* log-concentration curves, as is shown in Fig. 3. These CMC values (the order of 10^{-6} mol/*l*) of the oligosoaps are much smaller than that found for the monosoap (the order of 10^{-4} mol/*l*). The Debye plots of the oligosoaps in aqueous solutions are illustrated in Fig. 2. These CMC's and the micellar weights of these oligosoaps are given in Table 1. The micellar weights and the aggreagation numbers in water were 81000 and 13.0 in NF-11, and 70700 and 7.3 in NF-20.

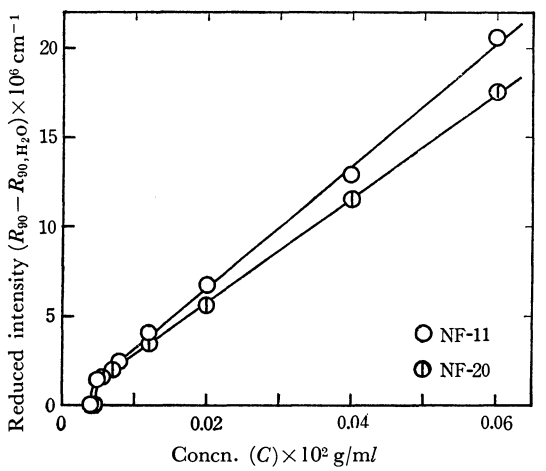

Fig. 1. Reduced intensity *vs.* concentration curves in water. (Wavelength 436 mμ, 21°C)

It was found that these nonionic oligosoaps formed aggregates in aqueous solution, much like the cationic oligosoap derived from polyallyl chloride already reported.[1] The micellar weights and the aggregation numbers of the cationic oligosoap were 18800 and 7.0 in water, 32300 and 11.8 in a 0.3 M aqueous sodium chloride solution. Taking account of the contribution of the presence of the

molecular-weight distribution for $\overline{M}_w$, or account of the possibility of the presence of a small number of very large particles to be mentioned below, the aggregation numbers of these oligosoaps may be smaller than the results shown in Table 1. In this manner, we concluded that these oligosoaps formed aggregates even in quite lower oligosoap concentration ranges, and that the aggregation numbers of these oligosoaps were relatively small.

The Effect of Added Sodium Chloride on Light-scattering Results. The effect of added sodium chloride on the CMC's and the micellar weights of the oligosoaps are included in Fig. 2. and Table 1. The micellar weight of NF-11 increased with an increase in the salt concentration except for the case of the 0.1 M salt concentration; namely, the aggregate grew from 81000 in water to 177900 (dissymmetry 1.04) in 2 M salt concentration. At the same time, the second virial coefficient (A_2) decreased gradually with an increase in the salt concentration.

This behavior was reversed for NF-20. A decrease in the micellar weight was observed with an increase in the salt concentration. The A_2 was little affected by the salt.

On the other hand, the CMC's of both NF-11 and NF-20 declined upon the addition of salt, although the CMC values are too low to estimate accurately. Such a behavior of NF-20 was different from the well-known fact that the addition of salt causes a decrease in the CMC and an increase in the micellar weight in ordinary ionic monosoaps.

Related results have been reported for polyoxyethylene alkyl ether by Becher,[10] and Schick *et al.*[11] Becher theorized that the added salts had no appreciable shielding effect on the micellar charge of higher EO condensates, whereas a

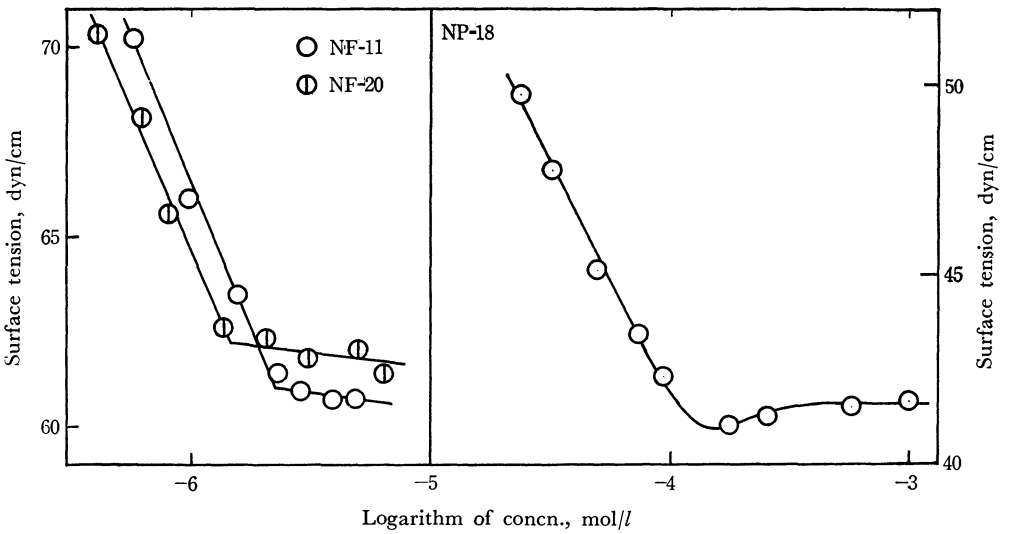

Fig. 3. Surface tension *vs.* logarithm of concentration curves at 30°C by the drop-weight method.

significantly larger charge on a single molecule (produced by the formation of hydronium ion) was smeared out into the interior of a micelle if the extension of the EO chains was at all great. Consequently, the effect of the added salt would be to lower the double-layer potential of the individual monomer molecules and render their incorporation into the micelle easier. In another way, this would seem to indicate that the dehydration effect of the added salt was minor for the higher EO condensates. For the lower EO condensates, he considered the result to be incipient coacervation rather than the formation of large micelles upon the addition of salt. Thus, he explained why the micellar weight of higher EO condensates remained unchanged upon the addition of salt in his cases. However, he did not explain why it decreased in other cases.

Schick *et al.* postualted that the increased length and lower solubility of EO chain enhanced the absorption of Na^+ to such an extent that it increased the overall solubility of the nonionic surfactant. In this case, they did not take the decrease in the CMC value into consideration.

Further, Becher pointed out that the EO contents in each EO condensate homologue in which the apparent size of the micelle did not increase upon the addition of salt, were about 70—75% of the EO by weight per molecule. The EO contents of NF-11 and NF-20 were 68 and 79% respectively. Therefore, the solution behavior of the oligosoaps under consideration here was consistent with Becher's results. It is noteworthy that these phenomena can be seen in the oligosoaps as well as in monosoaps.

From the viewpoint of the steric configuration of the oligosoaps, adjacent *p*-nonylphenol rings connected with a methylene group can not exist on the same plane because of the steric hindrance between the O atom of the 1-position and the *m*-H, or between the *m*-H of the nonylphenol ring themselves. This is true in the case of *o*-nonylphenol. Therefore, the aggregates of these oligosoaps perhaps form a crowded and interpenetrated structure in aqueous solutions. Namely, the aggregates may easily form intramolecular and intermolecular interpenetrated structures between the lyophilic and the EO groups making up these oligosoaps. Therefore, Becher's smearing-out effect of the charges into the aqueous portion of the micelle can take place, in NF-11 as well as in NF-20, because such interpenetrated structures can form in both NF-11 and NF-20 independent of the EO chain lengths of these oligosoaps. However, the results observed did not support this. Presumably we can interpret this phenomenon by the possibilities that there are two patterns in the hydration of the EO chain, for lower and higher EO condensates, or that the effect of the added salt concentration on the micellar weight of any EO condensate homologues can be divided into two regions which are combined at such a minimum micellar weight as for 0.1 M salt in the case of NF-11. The A_2 of NF-11 became negative and that of NF-20 remained positive upon the addition of salt, as is tabulated in Table 1. This appears to support this assumption that the hydrations of these micellar surface layers are different from one another.

Moreover, it would seem to be possible for us to consider separately the effect of added salt on a single molecule and on a micelle in explaining this phenomenon.

Surface-tension Results. The relations of the surface tension (γ) *vs.* the logarithm of concentration (C) are given in Fig. 3. The apparent

surface tension *vs.* the time required for each drop formation curves as determined by the drop-weight method are shown in Fig. 4. There are evident inflection points at about 2×10^{-6} mol/*l*, corresponding probably to the CMC and then a gentle descent of the γ follows.

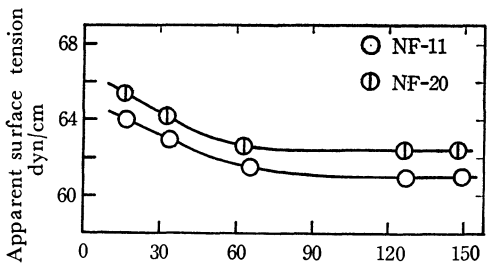

Fig. 4. Apparent surface tension *vs.* the time required for each drop formation curves at 30°C by the drop-weight method NF-11 : 2.90×10^{-6} mol/*l*; NF-20: 2.06×10^{-6} mol/*l*.

In view of the presence of the molecular-weight distribution in the oligosoaps under consideration here, the selected adsorption of smaller members of the molecules at the air-solution interface is, of course, to be expected. However, these oligosoaps show evident inflection points in the γ-log *C* plots and make straight lines below the concentration of the inflection points in the aqueous solutions. Therefore, in order to compare them approximately with monosoaps, we estimated the surface excess (Γ) and the corresponding surface area per molecule (A) of the oligosoaps at the air-solution interface from the slopes below the concentration of the inflection points by applying Gibbs adsorption isotherm, $\Gamma=-d\gamma/(\boldsymbol{R}T\,d\ln C)$, and $A=10^{16}/\boldsymbol{N}\Gamma$, where $\boldsymbol{R}$ is the gas constant; T is the absolute temperature; and $\boldsymbol{N}$ is the Avogadro number. The results obtained are listed in Table 2; they are of the same order of magnitude as that of monosoap, which is consistent with the findings concerning the cationic oligosoap reported on previously.[1] Moreover, the A values of NF-11 and NF-20 are almost the same. The small A values can be explained if the smaller molecules included in the oligosoaps are selectedly adsorbed at the air-solution interface at higher densities as a result of the Van der Waals attractive force.

Table 2. Surface tension results in water

	CMC mol/*l* $\times10^6$	Γ[a] mol/cm^2 $\times10^{10}$	A[b] Å^2/mol

NP-18	150	2.21	75

a) Surface excess calculated from the slopes of γ-log *C* plots below the CMC.
b) Corresponding surface area per molecule.

The Properties of Nonaqueous Solutions. The molecular weights of the nonionic oligosoaps under consideration here were determined in benzene and *n*-butanol by means of vapor-pressure depression (VPO) and light-scattering (LS) measurements. The results obtained are summarized in Table 3. The number-average molecular weight

Table 3. The molecular weights in nonaqueous solutions as determined by vapor pressure depression and light scattering

	$M(w, inc)$[a] $\times10^{-3}$	VPO $\bar{M}_n\times10^{-3}$		LS[c] $\bar{M}_w\times10^{-3}$
		benzene	*n*-butanol	*n*-butanol[d]
NF-11	6.2_1	7.0±0.5	5.4±0.5	18.6
NF-20	9.7_2	9.5±0.7	—[b]	25.9

a) Molecular weight determined by the weight increase in the ethylene oxide condensation reaction.
b) Turbid in the concentration range capable of determination.
c) Light scattering measurements in benzene were not made because dn/dc values were small and scattered.
d) NF-11: $A_2=1.6\times10^{-4}$, $dn/dc=0.106$
NF-20: $A_2=1.6\times10^{-4}$, $dn/dc=0.096$

($\bar{M}_n$) of NF-11 was 7000 (9500 in NF-20) in benzene and 5400 in *n*-butanol, as determined by means of VPO. These values were in tolerable agreement with the molecular weights ($M(w, inc)$) of 6200 in NF-11 and 9700 in NF-20 as determined from the weight increase in the EO condensation reaction. Therefore, it can be said that these oligosoaps did not form an aggregate in these solvents. The weight-average molecular weights ($\bar{M}_w$) of NF-11 and NF-20 were 18600 and 25900 in *n*-butanol, respectively, as determined by means of LS. Although the light-scattering results in *n*-butanol would suggest the formation of an aggregate, it would be possible to suppose that the oligosoaps did not aggregate; this seems possible because of approximate agreement with $\bar{M}_n$ and $M(w, inc)$, and because of the presence of molecular-weight distribution. It may be suggested that the difference between $\bar{M}_n$ and $\bar{M}_w$ is partly caused by a polydispersity in the micellar weight. Some reports have appeared to support this assumption.

Corkill, Goodman, and Walker[12] have shown that the $\bar{M}_w$ of Aerosol OT by LS diminishes in toluene with the time of aging after the preparation of the solution, at last reaching the same level as the $\bar{M}_n$ obtained by VPO, which remained constant independent of the solution's age. This phenomenon was attributed to a very small number

12) J. M. Corkill, J. F. Goodman and T. Walker, *Trans. Faraday Soc.*, **61**, 589 (1965).

of very large aggreagtes, which were formed by small quantities of water (or impurities) in the fresh solutions.

Cowie and Sirianni[5] showed that the $\overline{M}_w$'s of Pluronic polyol homologues were larger for the values determined from LS than for those determined from ultracentrifuge in water, butyl chloride, and dioxane. They explained this phenomenon by postulating the presence of a small number of large clusters which could be observed by LS but which were disrupted under the influence of the strong force field experienced in the ultracentrifuge, or by postulating the presence of a very broad spectrum of molecular sizes in the system. Therefore, nonaggregation of these oligosoaps is conceivable.

As has been mentioned above, it is noteworthy that such an oligosoap behaves like a monosoap in various ways. This indicates that such an oligosoap molecule is not as immobile as might be expected from its crowded and interpenetrated molecular structure.

The authors wish to express their hearty thanks to Dr. Toshio Kamata of our Institute for his valuable advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 569—572 (1968)

Determination of the Self-diffusion Coefficient of Nickel Atoms in Nickel Sulfide

Kazuo FUEKI, Yasuo OGURI and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received August 24, 1967)

The self-diffusion coefficient of ions or atoms in such crystals as halides, oxides and sulfides can be determined from the rate of the diffusion-controlled solid-state reaction as well as by the tracer method. In the present study, the self-diffusion coefficient of nickel atoms in nickel sulfide was determined from the rates of the sulfidation and desulfidation of nickel sulfide in H_2S-H_2 gas mixtures. The results agreed well with the data obtained by the previous investigators employing the tracer technique.

Although the self-diffusion coefficients of atoms in halides, oxides, sulfides and other crystals have been measured by tracer methods, it is also possible to determine them from the kinetic data of diffusion-controlled solid-state reactions, such as the parabolic oxidation of metals and sintering reactions. This paper will deal with the determination of the self-diffusion coefficient of nickel atoms in nickel sulfide from the kinetic data of the sulfidation and desulfidation of nickel sulfide.

The Ni-S binary system has several phases: Ni_3S_2, $Ni_3S_{2+\delta}$, Ni_6S_5, $Ni_{1-\delta}S$, NiS_2 and so on. The stability region for these sulfides has been established by Rosenquvist,[1] Leine and Laffitte,[2] and by other investigators. According to the result of the previous investigators, nickel monosulfide is a metal-deficient compound and is expressed by the formula $Ni_{1-\delta}S$, where δ is the metal deficit, varying from 0 to 0.05. In the present study, the sulfidation and desulfidation of this sulfide in H_2S-H_2 mixtures were followed by the gravimetric method, and the self-diffusion coefficient of nickel atoms was determined.

In order to confirm the predominant migrating species in nickel sulfide, a marker study was also carried out. Nickel atoms were found to be the predominant migrating species.

Experimental

Marker Study. A high-purity nickel specimen, $10\times30\times0.1$ mm, on both surfaces of which a slurry of fine Cr_2O_3 particles had been placed, was dried and then sulfidized in H_2S at 550°C until the nickel had been completely converted to nickel sulfide. The nickel is electrolytic Ni, 99.98% pure (impurities: 0.013% Co, 0.001% Cu, 0.002% C, 0.0003% S). After the sulfidation, the specimen was mounted in resin and sectioned in order to observe the location of Cr_2O_3

2) G. Leine and M. Laffitte, *Compt. Rend.*, **256**, 3306 (1963); M. Laffitte, *Bull. Soc. Chim. France*, **1959**, 1223.

markers. The positions of the markers were determined by means of a metallographic microscope and X-ray microanalyzer.

Kinetic Study of the Sulfidation and Desulfidation of Nickel Sulfide. Purification of Gases. Hydrogen sulfide gas, 99.9% pure, was supplied by the Suzuki Shokan Co. The gas was passed through a $Mg(ClO_4)_2$ column, and then a tube filled with porcelain pieces was heated at 500°C to convert the oxygen impurity into water vapor by the following reaction:

$$2H_2S + O_2 \longrightarrow 2H_2O + S_2$$

The gas was then dried again by passing it through a $Mg(ClO_4)_2$ column and stored in a bulb.

Hydrogen was passed through a $Mg(ClO_4)_2$ column on a Pd-asbestos catalyst in order to remove oxygen in the form of water vapor. The gas was then stored.

Apparatus. The apparatus used for the rate measurement of the sulfidation and desulfidation is shown in Fig. 1. A is a magnetic device used to raise and lower the specimen, suspended with the quartz fiber, and also to transfer them to and from the beam of the Gulbransen microbalance, C. H is the circulation pump for the gas, and G is a mercury manometer.

Specimens. The nickel sulfide specimens employed for the measurements of the sulfidation and desulfidation rates and for the determination of the metal deficit were prepared in the following manner. Nickel coupons, $10\times30\times0.1$ mm, were taken from a rolled sheet of highly-pure nickel, polished chemically with a mixture of nitric acid and sulfuric acid, and annealed in hydrogen (10 mmHg) for 4 hr at 550°C. A finished and weighed nickel specimen was then hung from a quartz spring balance and sulfidized in hydrogen sulfide (400 mmHg) for about 5 hr at 550°C. When the weight indicated the complete sulfidation of the nickel into nickel sulfide, the sulfidized specimen was quenched, annealed for a sufficient length of time in a H_2S-H_2 gas mixture of a desired composition in order to obtain a specific metal deficit of nickel sulfide, and weighed.

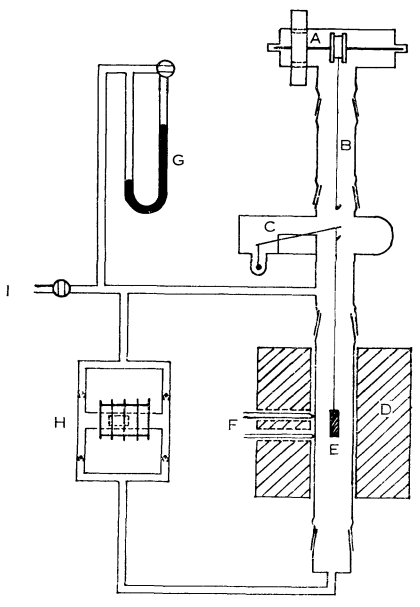

Fig. 1. Schematic diagram of apparatus.

From the weights before and after the sulfidation, the metal deficit of the nickel sulfide specimen was calculated. The thickness of the specimen was determined by means of a micrometer.

Experimental Procedure. A nickel sulfide specimen of a known composition was suspended from a chain by means of a fine quartz fiber, and the entire system was evacuated. Then a H_2S-H_2 gas mixture of a desired composition was introduced into the system and circulated by a circulation pump in order to keep its composition uniform. After the temperature of the furnace had attained the reaction temperature, the specimen was lowered to the heated zone, transferred, together with the quartz fiber, to the beam of the balance, and the weight change was followed by observing a marked point on the beam by means of a cathetometer. During the run the gas mixture was circulated except for those intervals when cathetometer readings were made. After the weight had reached the equilibrium value, the specimen and the quartz fiber were transferred to the chain and raised to the initial position, and the weight of the specimen was determined.

Results and Discussion

Marker Study. A section of a specimen completely converted to nickel sulfide is shown in Fig. 2. The markers are located at the center of the compact sulfide layer. It may be concluded from these results that the formation of nickel sulfide proceeded by means of the outward migration of nickel atoms. Since nickel sulfide is a metal-deficient compound, it is considered that nickel atoms migrate *via* nickel vacancies.

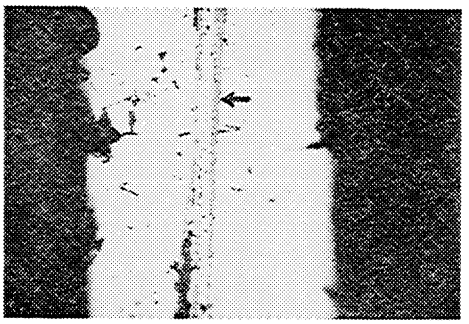

Fig. 2. Section of NiS. ← shows the Marker

Kinetic Study. Figure 3 shows some typcial weight change - time curves of sulfidation. In the figure, M_t is the weight change at the time t and M_∞ is the weight change after sufficient time has lapsed. When the total pressure of the gas mixture was changed while the other conditions, such as the thickness and the metal deficit of sulfide and the pressure ratio of H_2S to H_2, were kept constnat, the values of M_t/M_∞ obtained at a certain temperature lie on the same curve, which is only dependent on the temperature. This means that the reaction is controlled by the diffusion, because

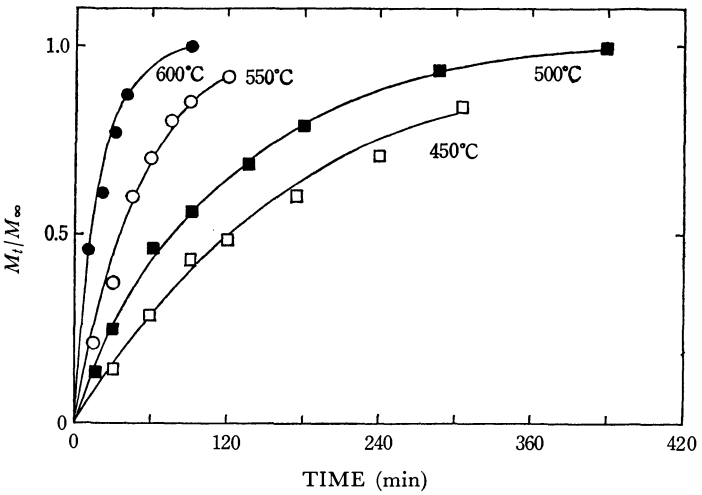

Fig. 3. Typical weight change time curves.
600°C=0.007 → 0.013 500°C=0.008 → 0.018

the rate of the diffusion-controlled reaction depends not on the total pressure but on the pressure ratio.

If a nickel sulfide slab is exposed to a H_2S-H_2 gas mixture which has sulfur with a higher activity than the sulfide, the specimen is sulfidized and the weight is increased. In this case sulfide atoms and nickel vacancies are introduced into sulfide at the gas-sulfide interface. Since nickel atoms migrate in nickel sulfide predominantly *via* nickel vacancies, as has been found in the marker experiment, nickel vacancies introduced at the gas-sulfide interface diffuse inwards. The rate equation for this process is:

$$\frac{\partial C_\square}{\partial t} = D_\square \frac{\partial^2 C_\square}{\partial x^2} \tag{1}$$

where $C_\square$ and $D_\square$ are the concentration and the self-diffusion coefficient of nickel vacancies respectively.

Solving the equation under the boundary conditions:

$$\left.\begin{aligned} C_\square &= C_\square^\circ \text{ for } -l < x < l \text{ and } t = 0 \\ C_\square &= C'_\square \text{ for } x = \pm l \text{ and } t > 0 \end{aligned}\right\} \tag{2}$$

one can obtain this equation:

$$\frac{C_\square - C_\square^\circ}{C'_\square - C_\square^\circ} = 1 - \frac{4}{\pi}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)} \times \exp\left\{\frac{-D_\square(2n+1)^2\pi^2 t}{4l^2}\right\} \times \cos\frac{(2n+1)\pi x}{2l} \tag{3}$$

where $C_\square^\circ$ is the vacancy concentration before the reaction, $C'_\square$ is the vacancy concentration at the gas-sulfide interface during the reaction, and $2l$ is the thickness of the sulfide slab. The replacement of the concentrations by M_t and M_∞ and integration with regard to x yields:

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=0}^{\infty}\frac{8}{(2n+1)^2\pi^2} \times \exp\left\{\frac{-D_\square(2n+1)^2\pi^2 t}{4l^2}\right\} \tag{4}$$

Omitting the higher terms of the series, one obtains:

$$-\ln\left(1 - \frac{M_t}{M_\infty}\right) = \frac{\pi D_\square t}{4l^2} \tag{5}$$

Figure 4 shows the plot of $-\log(1-M_t/M_\infty)$

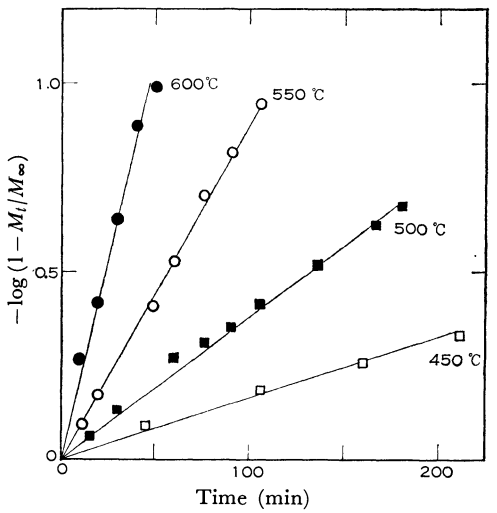

Fig. 4. Plot of $-\log\left(1-\frac{M_t}{M_\infty}\right)$ *vs.* time.
600°C=0.007 → 0.013
550°C=0.007 → 0.018
500°C=0.008 → 0.018
450°C=0.009 → 0.016

vs. t. A linear relationship is obvious. From the slope of the plot, $D_{\square}$, the self-diffusion coefficient of nickel vacancies is determined. When nickel atoms diffuse by the vacancy mechanism, the following relationship exists:

$$D_{\square}C_{\square} = DC \qquad (6)$$

where D and C are the self-diffusion coefficient and the concentration of nickel atoms respectively, accordingly, D can be determined from $C_{\square}/C$ and $D_{\square}$.

Since $C_{\square}$ and C are related to the metal deficit, δ, by the following equation:

$$\delta = \frac{C_{\square}}{C_{\square}+C}$$

and since $C_{\square}$ is small enough to be neglected, we obtain:

$$\delta \fallingdotseq \frac{C_{\square}}{C}$$

The metal deficit determined gravimetrically is given in Fig. 5 as a plot of δ *vs.* $\log(P_{H_2S}/P_{H_2})$.

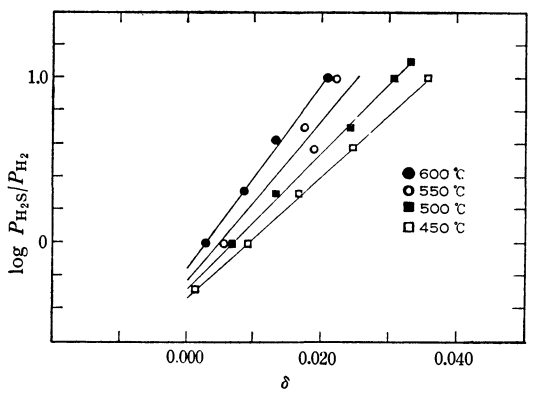

Fig. 5. Metal deficit of nickel sulfide as a function of temperature and P_{H_2S}/P_{2H}.

This result agrees well with the equilibrium data of Rosenquvist.[1] It can easily be seen that $C_{\square}/C$ ranges from 0 to 0.05. Assuming that $C_{\square}/C$ is the avarage of the initial and final values, we can obtain the D values by Eq. (6). These values are summarized in Table 1. Figure 6 shows the

Table 1

Temp °C	Change in δ	$C_{\square}/C$	$D_{\square}\times 10^7$ (cm²/sec)	$D\times 10^9$ (cm²/sec)

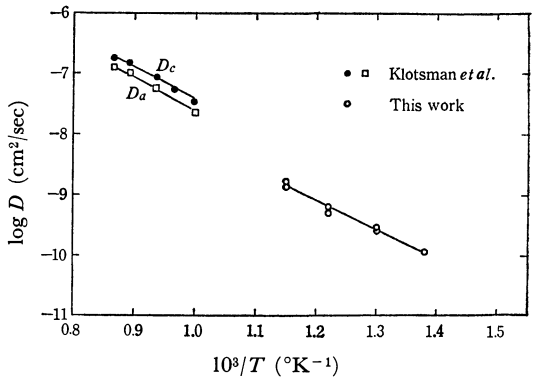

Fig. 6. Arrhenius plot of diffusion coefficient.

Arrhenius plot for the self-diffusion coefficient of nickel in nickel sulfide. The open circles indicate the data of this work. The present data are expressed by the equation:

$$D = 3.2\times 10^{-4} \exp\left(\frac{-21300}{RT}\right) \text{cm}^2/\text{sec} \qquad (7)$$

For comparison, the data obtained by Klotsman and his collaborators,[3] who employed the tracer method, are indicated by closed circles and squares in the same figure. The diffusion coefficients obtained by Klotsman and his collaborators are about three times higher than those extrapolated from the present data. They used nickel sulfide with a metal deficit of 0.03, while in the present work a deficit of 0.010—0.013 was employed. Since the diffusion coefficient is proportional to the vacancy concentration, the difference in diffusion data must be due to the difference in vacancy concentration of the sulfide employed in the experiments.

Summary

(1) The diffusivity of nickel was found, by means of a marker experiment on the sulfidation of nickel, to be much higher than that of sulfur.

(2) The rates of the sulfidation and desulfidation of nickel sulfide in H_2S-H_2 atmospheres were determined gravimetrically, and the diffusion coefficients of nickel vacancies were calculated.

(3) The metal deficit of nickel sulfide was determined as a function of the partial pressure ratio of H_2S to H_2 and of the temperature.

(4) From the concentrations and diffusion coefficients of nickel vacancies, the self-diffusion coefficients of nickel atoms were obtained.

The values agreed well with those determined by previous investigations employing the tracer technique.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 573—576 (1968)

Adsorption Behavior of Hydrogen and Carbon Monoxide over Zinc Oxide in the Mixed Gas Adsorption and during the Methanol Decomposition Reaction*1

Susumu TSUCHIYA and Tadao SHIBA

Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 4, 1967)

Adsorption of hydrogen and carbon monoxide at the different situations has been investigated with zinc oxide which is the principal component of ordinary methanol synthesis catalysts. In the simultaneous adsorption of hydrogen and carbon monoxide the mutual interaction was also observed. The results were explained as the displacement effect as well as the enhancement took place in a certain region of the partial pressures. Adsorption measurements during the decomposition reaction suggest that in initial state the adsorbed species are mostly the adsorbed methanol and that the step of the decomposition of it is the rate-determining step of the overall reaction. The mechanism of methanol synthesis over zinc oxide is suggested to proceed in the similar way as on the three component catalyst previously used.

In the previous papers,[1-4] adsorption behaviors of hydrogen and carbon monoxide in the mixed gas adsorption and during the methanol synthesis and decomposition reaction over three component methanol synthesis catalyst have been investigated in the relation to the mechanism of the methanol synthesis. The rate-determining step of the synthesis of methanol was suggested to be the process of the Eley-Rideal type hydrogenation of the surface complex. The mutual influence of the chemisorption of hydrogen and carbon monoxide has been observed, and the facts suggest that the adsorption behavior both in the mixed gas adsorption and that during the reaction can not be estimated from the single gas adsorption.

In this work, the similar investigations as previously[1-4] reported, have been carried out with zinc oxide in order to obtain further informations on the mechanism of the methanol synthesis and decomposition, because zinc oxide is the principal component of the three component methanol synthesis catalyst previously[1-4] used.

Experimental

The apparatus employed and method were the same as was previously reported.[1-4] Known amounts of the reactants were introduced into the system, the extent of the reaction was followed by pressure measurement. The amount of gas adsorbed on the catalyst surface was estimated by material balance of reactants introduced and the partial pressure and composition of the circulating gas. The composition of the circulating mixture was determined by gas chromatography. Due allowance was made for the analytical samples removed from the apparatus. The amount of gas adsorbed on the catalyst, including the surface complex, was obtained in terms of either the adsorbed hydrogen or the carbon monoxide.

The zinc oxide catalyst (13.7 g) employed was obtained by calcining zinc hydroxide at 300°C, which was precipitated from zinc nitrate solution by ammonium hydroxide. Before each run, the catalyst was evacuated for 10 hr at 400°C. The experimental results were satisfactorily reproducible.

Results and Discussion

Simultaneous Adsorption. Typical results of simultaneous chemisorption of hydrogen and carbon monoxide on the zinc oxide catalyst are shown in Figs. 1 and 2. Pure hydrogen was first introduced into the reaction system. A marked acceleration of hydrogen chemisorption at the addition of carbon monoxide was thus observed, as shown in Fig. 1. An enhanced adsorption of carbon monoxide by the presence of hydrogen was also observed when hydrogen was added to carbon monoxide as shown in Fig. 2, where pure carbon monoxide was first introduced and then hydrogen was admitted. In both cases of hydrogen and carbon monoxide, the enhanced adsorption of the pre-admitted gas by the addition of the other gas were also observed over zinc oxide, as well as over the three component methanol synthesis catalyst.[2] The mutual enhancement of the

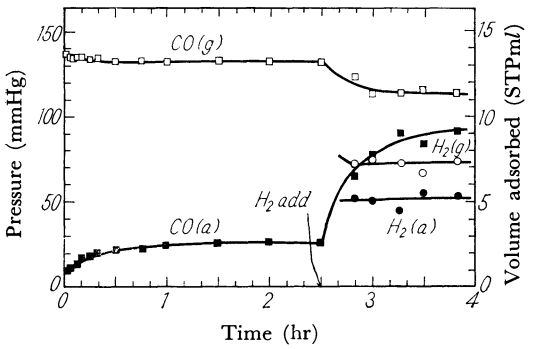

Fig. 2. Effect of hydrogen addition on the adsorption of carbon monoxide at 250°C.

adsorption was complicatedly varied by the added gas and the ratio of hydrogen to carbon monoxide.

The mutual interaction of the adsorption of hydrogen and carbon monoxide is shown more quantitatively in Fig. 3. The amounts of adsorption of hydrogen pre-admitted increased by the addition of the carbon monoxide, but the amounts of the increments rather decreased, when the pressure of carbon monoxide added increased. These results suggest that a part of the hydrogen adsorbed was displaced by carbon monoxide added. The similar results were observed when the same was done replacing carbon monoxide with hydrogen. It is consequently suggested that the mutual enhancement as well as displacement of the chemisorption of hydrogen and carbon monoxide take place on zinc oxide. The mutual enhancement effect might be due to the creation of additional sites as was suggested by Nagarjunan, Sastri and Kuriacose[5] and the displacement would

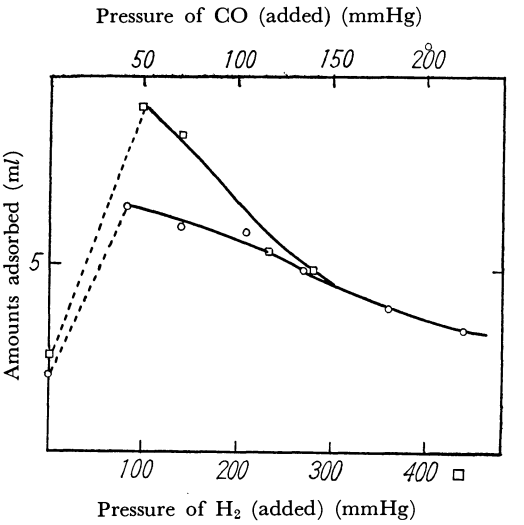

Fig. 3. Mutual interaction in the adsorption of hydrogen and carbon monoxide.

occur when the amounts of gas were in excess of the total sites.

The adsorption isotherms of hydrogen and carbon monoxide, are shown in Figs. 4 and 5, respectively. The mixed adsorption isotherms were obtained by introducing the mixtures of the $2H_2$: 1CO gases. The adsorption was more enhanced at 250°C than at 300°C.

Using the BET method for nitrogen adsorption at −190°C, the surface area and volume of gas which gives a complete monolayer v_m of the catalyst were estimated to be 6.7×10^5 cm^2 and 15 m*l*, respectively. As Figs. 4 and 5 show, in some

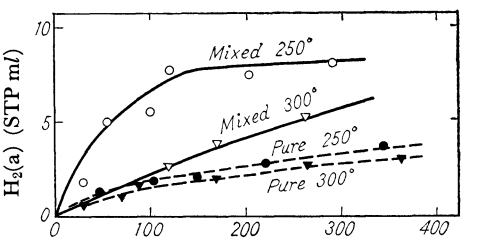

Fig. 4. Adsorption isotherms of hydrogen.

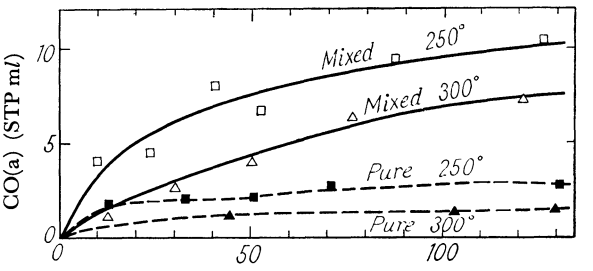

Fig. 5. Adsorption isotherms of carbon monoxide.

cases the sum of the amounts of hydrogen and carbon monoxide adsorbed exceeded v_m to some extent, which suggests the formation of surface complex from hydrogen and carbon monoxide, coupling with the fact that zinc oxide has the catalytic activity for methanol synthesis from hydrogen and carbon monoxide.

Decomposition Reaction. Typical result of the decomposition of methanol is shown in Fig. 6. As the decomposition proceeded, the partial pressure of methanol decreased with time, and those of hydrogen and carbon monoxide increased, while the ratio of adsorption of hydrogen to carbon monoxide changed.

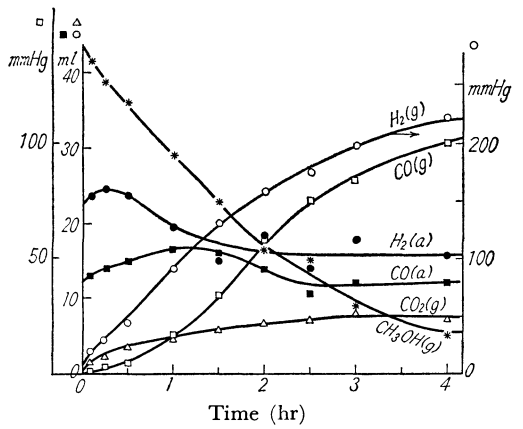

Fig. 6. Adsorption measurements during the methanol decomposition at 250°C.

At the initial stage, the ratio of the sum of the amounts of hydrogen adsorbed to that of carbon monoxide adsorbed, which include those in the surface complex formed from them, was nearly two. The adsorbed species on the zinc oxide is probably suggested to be CH_3OH at the initial stage of the reaction as was previously[3] concluded over the three component methanol synthesis catalyst. The results that the change of the ratio of hydrogen to carbon monoxide adsorbed during the course of the methanol decomposition, is explained in terms of the existence of "free hydrogen" and "free carbon monoxide" which was suggested previously,[4] as well as the surface complex.

If the decomposition of methanol over a zinc oxide and over a three component methanol synthesis catalyst proceeds in the same way as proposed previously,[3] the mechanism of the reaction would be as given by Scheme A.

The authors previously[3,4] expressed hydrogen adsorbed as $H_2(a)$, which include both atomic and molecular ones.

However, the hydrogen adsorbed might be atomic becaurse the hydrogen and deuterium equilibration reaction took place over a zinc oxide.[6]

The amounts of adsorption during the decomposition of methanol were always greater than those in the adsorption from the mixture $2H_2 : 1CO$; the amounts of the adsorption both of hydrogen and of carbon monoxide from the mixture were less than 10 m*l* even at 200 mmHg pressure. The results suggest that not all of the species adsorbed on the catalyst—hydrogen, carbon monoxide, and any intermediate complex formed from hydrogen and carbon monoxide—were in equilibrium with hydrogen and carbon monoxide in the gas phase, and that the process of the adsorption of methanol (process 1) can not be the rate-determining step of the reaction.

As shown in Fig. 7, the ambient pressure of hydrogen did not decrease when methanol was abruptly removed from the system during the reaction, and the amount of methanol in the trap stayed constant during the trapping. The facts suggest that the major part of the adsorbed species, hydrogen, carbon monoxide, and the complex formed from them, on the catalyst is not in equilibrium with the methanol in the gas phase; otherwise,

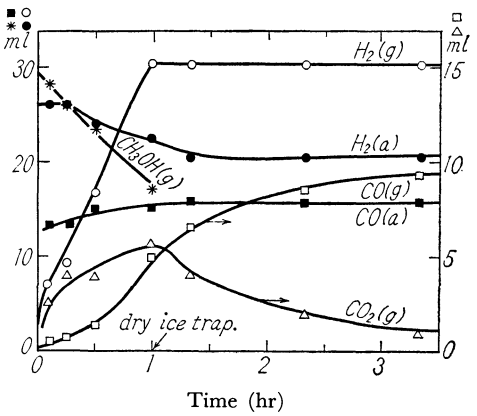

Fig. 7. The effect of methanol elimination during the decomposition reaction.

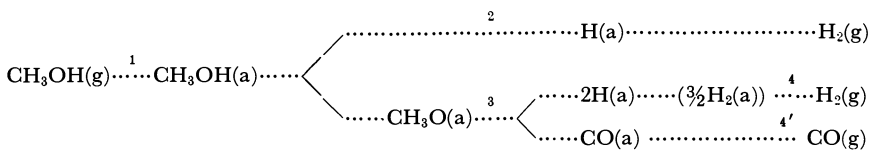

Scheme A.

6) E. Molinari and G. Parravano, *J. Am. Chem. Soc.*, **75**, 5233 (1953).

the major part of them would rapidly be desorbed to be caught by the trap. Neither of the processes of the desorption of hydrogen nor carbon monoxide (processes 3, 4, and 4') are accordingly suggested to be the rate-determining step of the reaction. Consequently, the rate-determining step is suggested to be the process of the dissociation of adsorbed complex (process 2). The suggestion conforms to the conclusion previously[1-4] reported in the case of the reaction over the three component methanol synthesis catalyst.

The results for decomposition of various amounts of methanol are shown in Fig. 8, where the pressure of methanol is plotted against time. The pressures at time zero were, however, estimated from the amounts of methanol introduced and the volume of the reaction system. The initial decreases in the methanol pressure represented by the upper dotted lines were followed by the linear part of the decreases in the pressure, represented by solid lines. The initial rate of the pressure decrease in the solid line range was almost independent of the methanol pressure; deviation from linearity, however, occured at later time.

The initial rapid decrease in the methanol pressure represented with the upper dotted lines can be considered to be due to the adsorption of methanol as menthioned above. Hence the order of methanol decomposition reaction is approximately zero and the rate of the reaction would be roughly expressed by Eq. (1), since the solid lines would show the methanol decomposition reaction.

$$r \doteqdot k \qquad (1)$$

The results agreed with those observed previously.[3] The apparent activation energy of the decomposition reaction was estimated to be 27.8 kcal/mol from the Arrhenius plots of k.

A curve considered to be an adsorption isotherm of methanol was obtained as shown with a solid line for 250°C in Fig. 9. The ambient pressure of methanol was obtained by extraporating the pressure-time curve in Fig. 8 to time zero (lower dotted lines), and the adsorbed amount was estimated from the mass balance between the amount of the methanol introduced and that in the gas phase at that time, because the methanol only adsorbed on the surface. It is thus shown in Figs. 8 and 9 that the nearer the amounts of methanol initially adsorbed approach v_m in BET equation (see Fig. 9), the nearer the reaction order comes to zero (see Fig. 8). At 150°C the decomposition of methanol was not observed, so the curve

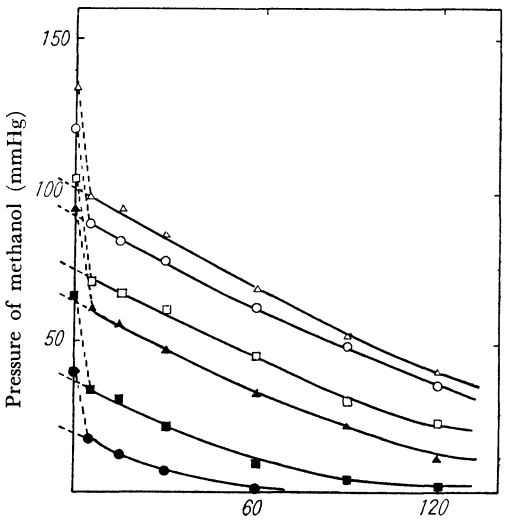

Fig. 8. The methanol decomposition at various initial pressure at 250°C.

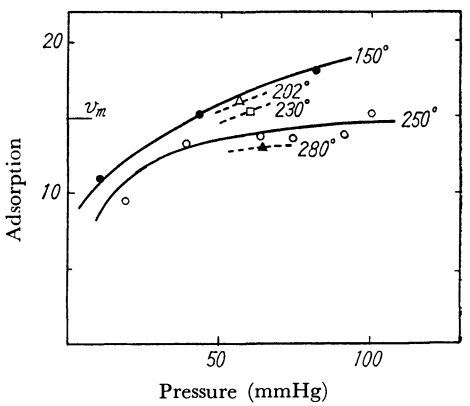

Fig. 9. Relation between adsorbed and gaseous methanol.

was obtained by means of the usual manner for the adsorption measurement.

As for the mechanism and kinetics of the methanol decomposition, it is consequently concluded that the process of the dissociation of the adsorbed methanol into the adsorbed intermediate complex and hydrogen is the rate-determining step of the overall reaction as on the three component catalyst. The mechanism of methanol synthesis on zinc oxide is thus suggested to proceed in the similar way as on the three component catalyst.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 577—582 (1968)

Faradaic Impedance of Fast Electrode Processes as Measured by an Impedance Bridge Using an Inductor

Takuma TANAKA and Hideo IMAI

Department of Chemistry, Faculty of General Education, Hiroshima University

(Received September 12, 1967)

An impedance bridge using an inductor in parallel with the cell is proposed for accurate measurement of kinetic parameters of fast electrode processes. The theory and method of analysis are given in detail. Its applicability was proved up to at least 50 kc, and possibly at higher frequencies. The kinetic parameters obtained by this method for the electrode reaction $Cd^{2+}+2e=Cd(Hg)$ in M Na_2SO_4 at the D. M. E. were $\alpha=0.17$, and $k^\circ=0.064$ cm/sec (25°C).

A conventional impedance bridge[1] for measurement of faradaic impedance is composed of resistors and capacitors, and the faradaic impedance is replaced by a series or parallel R-C network. This type of a.c. bridge has shown its usefulness in evaluating kinetic parameters of electrode processes, although it can not be applied to measurement at frequencies higher than several ten thousands cps due to its low response. The reason can easily be understood from the fact that the faradaic impedance is in parallel with the differential capacity, and that the impedance of the latter is very small at higher frequencies.

However, high frequency is necessary in order to evaluate the kinetic parameters of fast electrode processes.*1

For capacity measurement, Melik-Gaikazyan[2] recommended the use of a very small inductance in series with the cell, and Lorenz suggested the use of a T-bridge.[3] In this paper it is tentatively proposed to use an inductor*2 in parallel with the cell in an a.c. bridge in order to improve its applicability at higher frequencies. The inductor used was in parallel with the cell so as to be in resonance with the capacitive component of the electrode-solution double layer so that the impedance of the imaginary component will be infinite. (The series resonant circuit was also investigated, with the details omitted here because of its complexity for practical use.) It was found that this improved a.c. bridge can be used up to at least 50 kc. The method of analysis is described in detail with an application to the fast electrode process, $Cd^{2+}+2e=Cd(Hg)$, at the dropping mercury electrode.

Experimental

Reagents and Solution. All the reagents were of analytical grade. The solution contained 0.5 mM Cd^{2+} (weighed as $CdSO_4 \cdot H_2O$) in M Na_2SO_4 as the supporting electrolyte. Purified nitrogen was used for deaeration, and measurement was carried out in a nitrogen atmosphere. Temperature was kept constant at 25±0.1°C.

Electrode and Cell. The working electrode was a dropping mercury electrode (DME), and it was made of capillary tubing used in a usual Hg-thermometer. In the top of the capillary (17 cm in length) a Pt wire (0.012 cmϕ, 5 cm in length) was inserted, and the upper part of the capillary was constricted in order to give an appropriate flow rate of mercury. The lifetime of the D. M. E. was about 6 sec in the open circuit. A hammer was used to give drops at 4.0 sec intervals. The resistance of the DME was as small as 4.5 Ω. The auxiliary electrode was a smooth Pt cylinder, and a saturated-Hg_2SO_4 electrode (SSE) was used as the reference.

Generation of Reductant *in situ*. A potentiometer circuit (P in Fig. 1A) was used to give an optional

*1 When diffusion is the sole mode of mass transfer, the average flux of the reducing species diffusing toward a plane electrode is given by $2C^*(D/\pi t)^{1/2}$, where C^* is the bulk concentration of the reducing species, D the diffusion coefficient, and t the time elapsed since the beginning of the electrolysis. In a process with mixed control by both mass- and charge-transfer, this conclusion is qualitatively valid, and diffusion is no longer rate-determining for a measurement with very short electrolysis time, or at a sufficiently high frequency, the concentration gradient in the diffusion layer being steep enough. Thus the evaluation of kinetic parameters of fast charge transfer processes inherently necessitates measurement in a very short time interval, or the application of high frequency.

A B

Fig. 1. A: Bridge circuit for the faradaic impedance measurements. OSC, audio-generator; P, potentiometer; AMP, selective amplifier.
B: Bridge circuit for the measurement of the real (r_{Ls}) and imaginary (L_{Ls}) components of the inductor L in resonance with the cell.

electrode potential. Thus the reductant was generated *in situ*, and the concentrations of the oxidant (C_O) and reductant (C_R) at the pre-electrode layer can be calculated from polarographic theory, *i. e.*,

$$C_O = C_O^*\left(1-\frac{i}{i_d}\right) \quad (1)$$

$$C_R = C_O^*\left(\frac{D_O}{D_R}\right)^{1/2}\cdot\frac{i}{i_d} \quad (2)$$

where C_O^* is the bulk concentration of the reducing species, i the current flowing at a given potential, i_d the diffusion-controlled current, and the D's are the diffusion coefficients. The current was recorded by a Shimadzu Model RP-3 polarograph.

A. C. Bridge. The a. c. voltage applied to the cell was about 5 mV peak to peak and was supplied from an audio-generator, Trio Model AG-10 (OSC in Fig. 1A). The frequency was calibrated by a crystal oscillator (15 kc). The out-put of the bridge was fed to a selective amplifier (AMP in Fig. 1A), Yokogawa-Hewlett-Packard, Model AL-11, and was detected by a synchro-oscilloscope, Iwasaki Model SS-5302 with a plug-in amplifier, Model SP-30H-A.

The bridge circuit is shown in Fig. 1, where a variable inductor (L in Fig. 1, 400 μH—1 mH) was connected in parallel with the cell. A large capacitor (56 μF) was used in series with the cell in order to shut off the potentiometer circuit. The two resistors in the two arms of the bridge were 20.0 Ω and inductanceless. A variable resistor ($r°$ in Fig. 1) used for balancing the bridge was composed of a decade box (0.1 Ω—1.1 kΩ in 4 stages) and a manganin wire (0.01 Ω—0.1 Ω) with a sliding contact.

The bridge balance was detected at the maximum size of the mercury drop. The surface area of the DME was calculated by means of the following equation:

$$S(\mathrm{cm}^2,\ 25°\mathrm{C}) = 0.00852\ (mt)^{2/3}, \quad (3)$$

where m is the rate of flow of mercury in mg/sec, and t the life-time of the DME (=4.0 sec using the hammer).

Theoretical

Equivalent Circuit of the Cell. The equivalent circuit of the cell components is illustrated in Fig. 2A, where r_{cap} is the capillary resistance, r_e the solution resistance, r_s, and C_s the series resistive, and capacitive components of the faradaic impedance, respectively, and C_l the differential capacity of the double layer. The total impedance

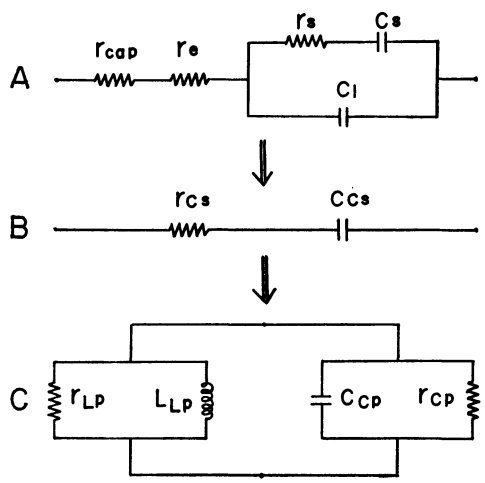

Fig. 2. Conversion scheme of the equivalent circuit of the cell.
A: Equivalent circuit of the overall cell circuit: r_{cap}, capillary resistance; r_e, solution resistance; r_s and C_s; series resistive and capacitive components of the faradaic impedance, respectively; C_l, differential capacity of the double layer.
B: Equivalent simple series circuit.
C: Equivalent simple parallel circuit of the cell and inductor in a resonant condition: The suffix, C or L represents the cell or inductor, respectively.

(Z) of this cell circuit is represented by:

$$Z = Z_{\text{real}} + \frac{1}{j} Z_{\text{Imaginary}} \tag{4}$$

with

$$Z_{\text{real}} = r_{\text{cap}} + r_e + \left(\frac{1}{\omega C_l}\right)^2 \frac{r_s}{r_s^2 + \left(\frac{1}{\omega C_s} + \frac{1}{\omega C_l}\right)^2} \tag{5}$$

and

$$Z_{\text{imaginary}} = \frac{1}{\omega C_l} - \left(\frac{1}{\omega C_l}\right)^2 \frac{\frac{1}{\omega C_s} + \frac{1}{\omega C_l}}{r_s^2 + \left(\frac{1}{\omega C_s} + \frac{1}{\omega C_l}\right)^2} \tag{6}$$

In Eqs. (5) and (6), r_{cap} and r_e can be determined separately, and C_l at a given potential can also be determined by using the base line shown in the plot of C_{Cs} *versus* E (Fig. 5).

Conversion to an Equivalent Simple Series Circuit of the Cell. In order to evaluate r_s and C_s in Eqs. (5) and (6), a conversion of the equivalent circuit in Fig. 2A to an equivalent simple series circuit as shown in Fig. 2B was made. Then the total impedance (Z) in Eq. (4) becomes:

$$Z = r_{\text{Cs}} + \frac{1}{j\omega C_{\text{Cs}}} \tag{7}$$

with $$Z_{\text{real}} = r_{\text{Cs}} \tag{8}$$

and $$Z_{\text{imaginary}} = \frac{1}{\omega C_{\text{Cs}}} \tag{9}$$

Equations (5), (6), (8) and (9) lead to the following expressions for r_s and $1/\omega C_s$;

$$r_s = \left(\frac{1}{\omega C_l}\right)^2 \frac{r_{\text{Cs}} - r_{\text{cap}} - r_e}{(r_{\text{Cs}} - r_{\text{cap}} - r_e)^2 + \left(\frac{1}{\omega C_l} - \frac{1}{\omega C_{\text{Cs}}}\right)^2} \tag{10}$$

$$\frac{1}{\omega C_s} = \left(\frac{1}{\omega C_l}\right)^2 \frac{\frac{1}{\omega C_l} - \frac{1}{\omega C_{\text{Cs}}}}{(r_{\text{Cs}} - r_{\text{cap}} - r_e)^2 + \left(\frac{1}{\omega C_l} - \frac{1}{\omega C_{\text{Cs}}}\right)^2} - \frac{1}{\omega C_l} \tag{11}$$

Inductor in Resonance with Cell. In the circuit shown in Fig. 1A the inductor is in parallel with the cell, and at the null point of the bridge the cell and inductor are in a resonant condition. The condition is taken into account by the conversion of the equivalent circuit given in Fig. 2B into the equivalent parallel circuit given in Fig. 2C. In Fig. 2C the inductor is also represented by an equivalent parallel circuit.

The resonant condition, in general, is given by

$$\omega L = \frac{1}{\omega C} \tag{12}$$

Accordingly, one is lead to the following relationship,

$$\omega L_{\text{Lp}} = \frac{1}{\omega C_{\text{Cp}}} \tag{13}$$

and

$$\frac{1}{r^\circ} = \frac{1}{r_{\text{Lp}}} + \frac{1}{r_{\text{Cp}}} \tag{14}$$

These parallel components are equivalent to the series components given in Fig. 2B, so that

$$r_{\text{Cs}} = \frac{\frac{1}{r_{\text{Cp}}}}{\left(\frac{1}{r_{\text{Cp}}}\right)^2 + (\omega C_{\text{Cp}})^2} \tag{15}$$

$$\frac{1}{\omega C_{\text{Cs}}} = \frac{\omega C_{\text{Cp}}}{\left(\frac{1}{r_{\text{Cp}}}\right)^2 + (\omega C_{\text{Cp}})^2} \tag{16}$$

Evaluation of Inductive and Resistive Components of the Inductor in Resonance with the Cell. The series inductive (L_{Ls}) and resistive (r_{Ls}) components of the inductor in resonance with the cell were measured by the impedance bridge shown in Fig. 1B. Under a series resonant condition, that is, at bridge balance, the following equation holds,

$$\omega L_{\text{Ls}} = \frac{1}{\omega C_{\text{Ls}}} \tag{17}$$

Conversion of Eq. (17) into a parallel equivalent circuit leads to the following expression;

$$\frac{1}{r_{\text{Lp}}} = \frac{r_{\text{Ls}}}{r_{\text{Ls}}^2 + \left(\frac{1}{\omega C_{\text{Ls}}}\right)^2} \tag{18}$$

Combining Eqs. (14), and (18), one obtains

$$\frac{1}{r_{\text{Cp}}} = \frac{1}{r^\circ} - \frac{1}{r_{\text{Lp}}} \tag{19}$$

and $$\omega C_{\text{Cp}} = \frac{\frac{1}{\omega C_{\text{Ls}}}}{r_{\text{Ls}}^2 + \left(\frac{1}{\omega C_{\text{Ls}}}\right)^2} \tag{20}$$

Method of Analysis of Experimental Data. The values of r°, r_{Ls}, and C_{Ls} can be directly determined by experiment. By using these data, C_{Cp} is calculated by Eq. (20), and $1/r_{\text{Cp}}$ is calculated by Eqs. (18) and (19). Then r_{Cs} and $1/\omega C_{\text{Cs}}$ are evaluated from Eqs. (15) and (16). Finally, r_s and $1/\omega C_s$ can be evaluated from Eqs. (10) and (11), using the values for r_{cap}, r_e, and C_l.

Results and Discussion

Variation of Bridge Component Values with Frequency. The bridge was composed of inductanceless resistors, and moreover, precaution was paid to the arrangement of the circuit in order to avoid any possible stray capacity. But the rather high resistance of the inductor may introduce bad effect. Figure 3 shows the direct reading of a standard resistor (20.0 Ω), and a capacitor (1.0000 μF) network which replaces the cell circuit in Fig. 1A. The variation in component values with frequency was fairly large. The ratio of the direct reading to the standard value at each frequency was used for calibration.

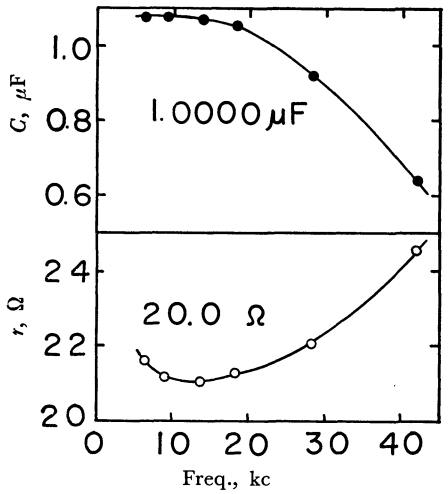

Fig. 3. Frequency dependence of direct reading values of the series $R(20.0\,\Omega)-C(1.0000\,\mu F)$ network.

Application to the Electrode Process $Cd^{2+}+2e=Cd(Hg)$ at the DME. The ability of this improved impedance bridge was tested by a fairly rapid electrode process, $Cd^{2+}+2e=Cd(Hg)$ in M Na_2SO_4 at the DME. The electrode process was assumed to involve no kinetic complication. Cd(II) ions (5×10^{-7} mol/cm^3) developed a well-defined polarographic wave in M Na_2SO_4. The half-wave potential was -1.020_5 V *vs.* SSE. The reductant (Cd(Hg)) was generated *in situ* by the application of a d.c. potential to the working electrode. The concentrations of the oxidant and reductant at the pre-electrode layer were calculated by Eqs. (1) and (2), using the polarographic data. The values, $D_O=0.72\times10^{-5}$ cm^2/sec and

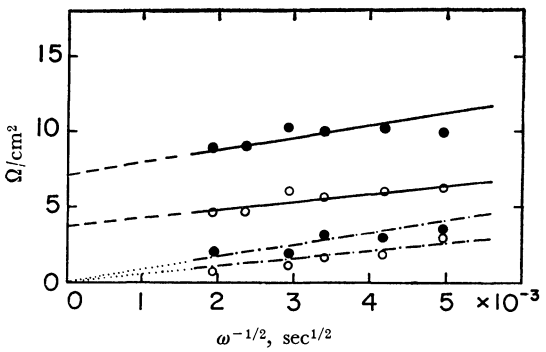

Fig. 6. Plot of the series components, r_s and $1/\omega C_s$, of the faradaic impedance *versus* $\omega^{-1/2}$ for the electrode reaction, $Cd^{2+}+2e=Cd(Hg)$ in M Na_2SO_4 at 25°C: —●— r_s at $E_{3/4}$, -·●·- $1/\omega C_s$ at $E_{3/4}$, —○— r_s at $E_{1/4}$, -·○·- $1/\omega C_s$ at $E_{1/4}$.

$D_R=1.63\times10^{-5}$ cm²/sec[5] were used for calculation.

Figures 4 and 5 show the variation of r_{Cs} and C_{Cs}, evaluated at frequencies of 6.42, 9.12, 13.92, 18.45, 28.25 and 41.99 kc with potential. Irregularities in the base line of the curves in Figs. 4 and 5 are attributed to the variation in the surface area of the DME in each measurement.

The values obtained for the series components, r_s and $1/\omega C_s$, of the faradaic impedance were plotted against $\omega^{-1/2}$ in Fig. 6.

According to theory on faradaic impedance[6]

$$r_s = \frac{RT}{nF}\left\{\frac{1}{I^\circ}+\frac{1}{2^{1/2}nF\omega^{1/2}}\left(\frac{1}{C_O D_O^{1/2}}+\frac{1}{C_R D_R^{1/2}}\right)\right\} \quad (21)$$

$$\frac{1}{\omega C_s} = \frac{RT}{nF}\left\{\frac{1}{2^{1/2}nF\omega^{1/2}}\left(\frac{1}{C_O D_O^{1/2}}+\frac{1}{C_R D_R^{1/2}}\right)\right\}, \quad (22)$$

where I° is the exchange current density, and ω the radial frequency. In accordance with this theory, the plots of r_s and $1/\omega C_s$ *versus* $\omega^{-1/2}$ gave straight lines as shown in Fig. 6. The value of I° was obtained from the intercept of the plot as:

$$I^\circ = \frac{RT}{nF}\frac{1}{(r_s)_{\omega^{-1/2}\to 0}} \quad (23)$$

and the numerical values of r_s extrapolated to infinite frequency were 3.5, 4.8 and 7.5 Ω at $E_{1/4}$, $E_{1/2}$ and $E_{3/4}$ respectively.

The transfer coefficient (α) was evaluated through use of the equation of Laitinen, Tischer, and Roe,[7] *i. e.*,

$$\frac{\partial \ln\left(\frac{I^\circ}{C_O}\right)}{\partial \ln\left(\frac{C_R}{C_O}\right)} = \alpha \quad (24)$$

Figure 7 shows the plot of $\log(I^\circ/C_O)$ *versus* $\log(C_R/C_O)$. From the slope of the plot the value of α was found to be as great as 0.17.

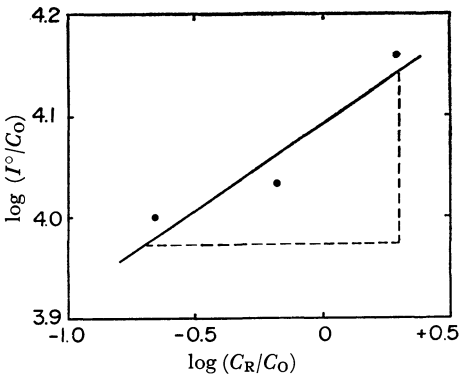

Fig. 7. Plot of $\log(I^\circ/C_O)$ *versus* $\log(C_R/C_O)$. The inclination $=\alpha=0.17$

The heterogeneous rate constant (k°) of the electrode reaction was computed by the following equation,

$$I^\circ = nFk^\circ C_O^{1-\alpha} C_R^{\alpha} \quad (25)$$

The kinetic parameters evaluated by this method are illustrated in Table 1, and related values previously reported are given in Table 2.

Table 1. Kinetic parameters of the electrode reaction, $Cd^{2+}+2e=Cd(Hg)$, in M Na_2SO_4 at the D.M.E. (25°C)

Electrode potential, V *vs.* SSE	$(r_s)_{\omega^{-1/2}\to 0}$ Ω/cm²	I° A/cm²	α	k° cm/sec
$E_{1/4}=-1.001_5$	3.5	0.0037		0.066
$E_{1/2}=-1.020_5$	4.8	0.0027	0.17	0.060
$E_{3/4}=-1.040_5$	7.0	0.0018		0.066
mean				0.064

In Table 2 the values of k° are comparatively low in most cases of the hanging mercury drop electrode. Moreover, the values show a trend to decrease with the lapse of time after the electrode is put into the solution. The authors ascribed this trend to the contamination of the electrode surface by the adsorption of surface active materials.

In the case of the DME, the electrode surface

* Calculated from data of frequencies up to 1 kc. ** An incorrect equation was used for the calculation, which was later admitted to be incorrect by Breyer and Bauer.[15]

is renewed every 2 or 3 sec, so that the contamination is much smaller than in the case of the hanging mercury drop. Thus, the values of k° obtained by the DME were much higher, as shown in Tables 1 and 2. Some data obtained by the faradaic impedance method with the DME, in Table 2, however, were computed from measurements at frequencies up to 1 kc, and the authors pointed out the discrepancy between the experimental data and the theory at frequencies higher than 1 kc.[11,16] This discrepancy seems to be attributed to the lack of correction for the bridge components in the high frequency range (*cf.* Fig. 3).

When diffusion is the sole mode of mass-transfer, the average flux of the reducing species toward a plane electrode is given by $2C_O^*(D/\pi t)^{-1/2}$, t being the electrolysis time. In a process with mixed control by both mass- and charge-transfer, this conclusion is qualitatively valid, and diffusion is no longer rate-determining for measurements in sufficiently short time intervals or at a sufficiently high frequency of electrolysis. Accordingly, the reason is well understood why our datum ($k^\circ=0.064$ cm/sec) shows fairly good agreement with Barker's datum[12] ($k^\circ=\simeq 0.08$ cm/sec), which has been obtained by the faradaic rectification method at very high frequencies (500 kc). It is worth consideration that in the faradaic rectification method the accuracy of determining the kinetic parameters is low due to the uncertainty in evaluating the radio-frequency voltage applied to the electrode-solution interface,[17] while the faradaic impedance method is sufficiently accurate so as to give at least three significant figures in the measurement of the bridge components. Our datum also shows good agreement with some data obtained by Christie *et al.*,[14] who used a modified potential-step method. In view of this agreement, the general feature of our method appears well substantiated.

The authors wish to express their hearty gratitude to Professor Herbert A. Laitinen for his interest and reading of the manuscript. Support by the Scientific Research Fund of the Ministry of Education is gladly acknowledged.

Thermodynamic Properties and Phase Transitions of Sodium Cyanide Crystal*[1]

Takasuke MATSUO, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received October 6, 1967)

The heat capacities of the sodium cyanide crystal were measured from 14 to 310°K by an adiabatic calorimeter. The two anomalous regions reported by Ziegler *et al.* are confirmed. The entropy changes associated with these anomalies is explained by proposing structural changes at the transition points. Analysis of the lattice heat capacity gives the average librational frequency of the cyanide ion at the lowest temperatures as 210 cm^{-1} in the Einstein approximation. For the higher temperature range, the cyanide ions may be described as undergoing a hindered rotation, with a barrier height of approximately 2 kcal/mol. The upper-phase transition is discussed in terms of a model based on the coexistence of the two crystalline phases. The lower transition and the analogous one reported previously for potassium cyanide are interpreted together as order-disorder phenomena with respect to the behavior of the cyanide ions. The thermodynamic functions of the crystal are also calculated by the graphical integration of the heat capacity data.

In a previous paper we reported the results of a thermal study of the potassium cyanide crystal.[1] Investigations of the sodium cyanide crystal along the same line of study will be presented in this paper. The present crystal has the same rod-like shaped anion as potassium cyanide as its constituent, so that in order to simulate the rock-salt structure observed at room temperature, the cyanide ion must be either rotating or randomly-orientated along one of the eight body-diagonal directions of the rock-salt-type lattice. Verweel and Bijvoet[2] investigated the structure by the X-ray diffraction method and interpreted their results in terms of the spherical rotation model of the cyanide ion. By the use of the same technique, Siegel[3] attempted to settle whether the dynamical or the statical model was more realistic. He could not, however, arrive at any definite conclusion, although he succeeded in detecting the presence of a new crystal phase of sodium cyanide. Verweel and Bijvoet found that, on cooling, the crystal is transformed into an orthorhombic modification at about 290°K. Messer and Ziegler[4] measured the heat capacity of the salt from 100°K to 350°K and observed an anomalous heat capacity at the corresponding temperature, 287°K, associated with an entropy change of approximately $R\ln 4$. They also concluded, by estimating the oscillation-rotation heat capacity of the cyanide ions, that their motion is rather restricted in the cubic phase and highly hindered in the orthorhombic phase.

For the potassium salt, Elliot and Hastings[5] suggested a free rotation model on the basis of their neutron diffraction data. More recently, after the completion of our study, Sequeira[6] published a short note in which he showed that even with the neutron diffraction, the dynamical and the statical states are indistinguishable as long as one employs a powdered sample. NMR[7] and infrared[8] studies have also been reported on these problems.

A theoretical treatment of the phase changes of these salts was carried out by Matsubara and Nagamiya[9]; they found that the potential barrier hindering the rotation of the cyanide ion is about 1.2 kcal/mol in the cubic phase and 6 kcal/mol in the orthorhombic phase for the sodium salt.

Besides the phase transition mentioned above, Messer and Ziegler observed another anomalous region in the heat capacity with its maximum value

at 172°K. The estimated entropy change is approximately $R\ln 2$, so they inferred that this anomaly is associated with a kind of ordering process with respect to the end-for-end rearrangement of the cyanide ions.

The present investigation aims at: (1) the extension of the temperature region of the heat capacity measurement down to the temperature of liquid hydrogen, (2) the analysis of the thermal motion of the cyanide ion using the low temperature heat capacity data and (3) the interpretation of the heat capacity anomalies in comparison with the analogous phenomena in the potassium cyanide crystal reported on previously.

Experimental

The sample employed was purified by the recrystallization of commercial sodium cyanide (Kantoh Kagaku, an extra pure reagent) twice from an absolute methyl alcohol, following the method by Thompson.[10] The dominant impurity detected by infrared absorption was found to be carbonate ions, which amounted to 0.3 percent. The weight of the specimen used for the measurement was 19.375 g, or 0.4027 mol, taking NaCN=49.008 g/mol. The buoyancy correction was not made. The apparatus and the procedure used for the measurement were the same as have been reported previously.[1,11]

Experimental Results

The observed heat capacity values are listed in Table 1 in chronological order; they are illustrated in Fig. 1. They are expressed in terms of the thermochemical calorie, equal to 4.1840 absolute joules. The ice point is taken as 273.15°K. The heat capacity values listed in the table are the ratios of the increase in enthalpy, ΔH, to the rise in temperature ΔT. The temperature given for each point is the arithmetic mean of the initial and the final temperatures.

As is shown in the figure, the lower anomaly was found to start at 70°K. The transition temperatures given by Messer and Ziegler[4] coincide very well with the present data. Their heat capacity values above 100°K are, however, lower by about 1 percent.

In Table 2 the heat capacity, the entropy, the enthalpy, and the Gibbs energy functions are given for the rounded temperatures. They were obtained by fitting a smooth curve on the observed values of the heat capacity, extrapolating it to 0°K, and integrating it graphically. The contribution from the extrapolated region below 15°K to the entropy amounts to 0.050 cal/mol degK. Around the upper phase transition, a direct summation of the input energy was carried out. The estimated error in

the C_v is about 1 percent at the temperature of liquid hydrogen and 0.4 percent at room temperature.

Discussion

Thermal Motion of the Cyanide Ion. The method of analyzing the heat capacity data is essentially the same as that used for the potassium cyanide crystal in the previous paper.[1] The observed heat capacity was transformed into the apparent Debye temperature, as shown in Fig. 2. We can see here that the presence of the transitions is more conspicuous than in the C_P-T curve itself. By a rather arbitrary interpolation of the normal Debye temperature below and above the transition regions, the anomalous heat capacities were estimated. This procedure is a convenient means of minimizing the ambiguity in separating the effect of the transition from the total heat capacity. In the present case of sodium cyanide, however, the anomalous effect due to the phase transitions contributes to the total heat capacities over considerably wide ranges of temperature, so we assumed three reasonable kinds of normal Debye temperature, as shown in Fig. 2 by A, B, and C. From these normal Debye temperatures, the normal heat capacity was calculated. This procedure may be convenient but not rigorous, since we are assuming a continuous temperature dependence of the normal heat capacity, even at the upper transition, where the crystalline field symmetry surrounding the cyanide ion changes abruptly from orthorhombic to octahedral. At the present stage of our knowledge, however, we have to content ourselves with the approximate procedure adopted here.

The normal heat capacity thus obtained comes from 6 N translational degrees of freedom of both the kinds of ions, and from 2N torsional degrees of freedom and N internal degrees of freedom of the cyanide ions (N, Avogadro constant).

In order to get more detailed knowledge about the motion of the ion, we first tried to estimated the torsional frequency of the cyanide ion. For this purpose, we adopted the following procedure. First, we subtracted the contribution of the internal vibration of the cyanide ion from the total heat capacity by using the Einstein function of the wave number, 2085 cm^{-1}.[12] Then, by taking a rather arbitrary value of the parameter, the C_P values were transformed to C_V by applying the approximate relation, $C_P-C_V=1.1\times10^{-5}C_P^2T$.[4] These C_V values yielded the Debye temperature, which is plotted in Fig. 3 (curve a), where only 6 N degrees of freedom are taken into account. The decline

of the curve above 40°K comes from the neglect of the $2N$ degrees of torsional freedom. Therefore, if we assume further that the temperature dependence of the translational Debye temperature is similar to that of the sodium chloride crystal,[13] we can estimate the torsional frequency by a trial-and-error calculation. With one and the same wave number of 210 cm^{1-} for the two degrees of freedom of the torsional motion, we obtained the most reasonable variation of the translational Debye temperature, as is shown in Fig. 3, curve b. This wave number may be looked upon as a kind of average value of two frequencies of an anisotropic, two-dimensional oscillator. Although the angular dependence of the potential energy of the cyanide ion in the crystal may be very complicated, for simplicity, we assume it to be $V=(1/2)V_0(1-\cos 2\theta)$, where θ is the polar angle from the equilibrium direction of the cyanide ion. Then V_0, which yields the torsional frequency of 210 cm^{-1} in the harmonic approximation, is calculated to be 13 kcal /mol. Extending the Debye temperature of the translational modes to higher temperatures, meanwhile keepting it parallel with that of NaCl, we can estimate the torsional heat capacity for all the temperature range (see Fig. 3) The results are plotted in Fig. 4. Above 70°K, no combination of two harmonic oscillators can produce the torsional heat capacity. This implies that the harmonic approximation fails around that temperature. Pitzer and Gwinn's treatment extend to two-dimensional motion by Stepakoff and Coulter[14] shows that the heat capacity of a hindered rotator can be larger than R per degree of freedom. Following this method, we can evaluated the V_0 from the experimental torsional heat capacity. The values of V_0 thus obtained are plotted in Fig. 5, in which the curves A, B and C correspond, respectively, to the three variations of the normal Debye temperature assumed in Fig. 2. The estimated V_0 value changes from 13 kcal/mol at the lowest temperatures to 2—3 kcal/mol at the higher temperatures. This is remarkable in view of the fact that there occurs no significant change in the crystal structure at the lower transition; it deserves further investigations, both theroetical and experimental. The high-temperature value may be compared with that of 1.8 kcal/mol derived by Sato[8] with combination of infrared data and Coogan and Gutowsky's result obtained by NMR.[7] (In passing, it might also be mentioned that the theoretical values of the barrier height given by Matsubara and Nagamiya are 6 kcal/mol in the orthorhombic and 1.2 kcal/mol in the cubic phases. These values represent the difference between the maximum and the minimum values of the hindering potentials, whose functional forms are different from those adopted here.)

Mechanism of the Phase Transitions. The temperatures, enthalpies, and entropy changes of the transitions are summarized in Table 3. Here, a "case B" estimation of the normal heat capacity was made. The entropy change of the upper transition amounts to approximately $R\ln 4$.

Table 3. Temperatures, enthalpies and entropies of transitions in NaCN crystal

	T °K	ΔH (cal/mol)	ΔS (cal/mol degK)
Lower transition	171.9±0.2	177.2±3.0	1.21±0.02
Upper transition	287.7±0.1	783.7±8.0	2.80±0.02

This implies that a kind of randomization in the alignment of the cyanide ions takes place at this transition point. Matsubara and Nagamiya treated this transition as a first order one. This treatment might be supported by the hysteresis phenomenon in the heat-capacity measurement found by Messer and Ziegler, and by the results of differential thermal analysis made in this laboratory. The heat-capacity peak is so sharp that 80 percent of the whole enthalpy change occurs in rather narrow range of 5°C for both the Na- and K-salts, although no latent heat effects were detected experimentally.

In principle, a first-order phase transition takes place at a definite temperature which is determined by the equality of the free energies of the two phases involved. Consequently, the heat capacity would behave normally at all but one temperature, where it would go on to infiinity. Experimentally, however, a number of phase transitions are known to occur over a finite temperature range. In some cases, *e. g.*, where the Ising model is an adequate picture, the phase transition is intrinsically diffused. In others, structurally different crystalline phases have to be in equilibrium with each other at the transition point, as is the present case; this gives rise to interfacial and strain energies in the crystal. As a result, the two phases can coexist over a finite range of temperature, since these variables provide extra degrees of freedom in the sense of the Phase Rule.[15] These ideas were used in quantitative calculations by Tobolsky, Kozak, and Canter.[16]

As has been mentioned above, the heat-capacity anomaly at the upper transition is over a temperature range of about 5°C for NaCN. For KCN also, the anomaly around 168°K takes place with a comparable diffuseness, as has been reported previously.[1] Seeking an explanation of this behavior,

we tried to apply the Tobolsky model of diffuse phase transitions to the present cases. The relevant parameters involved in the theory were determined with the experimental values of the transition temperature, the entropy of transition, and the maximum value of the heat capacity at the transition temperature. The last quantity was quite difficult to evaluate precisely, since at the critical temperature the thermal equilibrium in the calorimeter was achieved very slowly. To minimize the uncertainty due to the sluggishness of the transition in the experimental heat capacity, an extrapolation method was applied to the temperature change of the calorimeter after heating it, assuming an exponential decrease in the temperature.

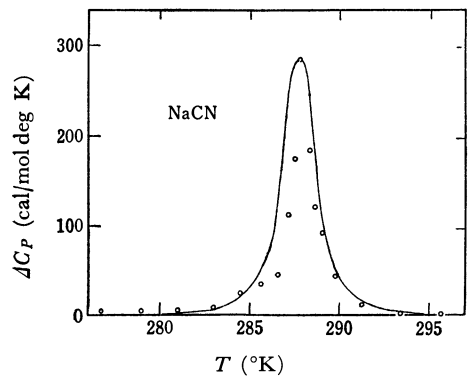

Fig. 6. Anomalous heat capacity at the upper transition of NaCN crystal.

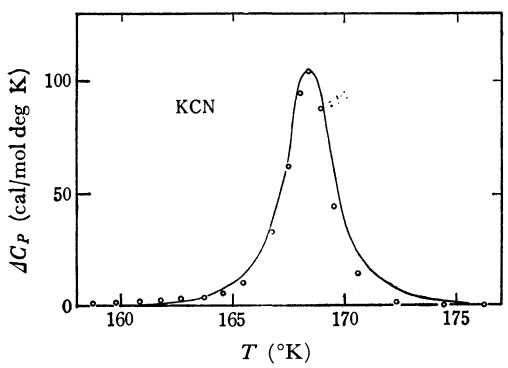

Fig. 7. Anomalous heat capacity at the upper transition of KCN crystal.
○: observed, —: theoretical

In Figs. 6 and 7, the calculated heat capacity is shown for NaCN and for KCN respectively, together with the experimental points. As may be seen in the figures, the heat-capacity anomalies are reproduced with reasonable success. The interfacial energy parameters are $\Delta G_K = 6.33$ kcal/mol and 3.07 kcal/mol for NaCN and KCN respectively. Here, ΔG_K indicates the molar Gibbs energy difference of the domain boundary from that of the bulk crystal in the orthorhombic modification.

One important point to be added is that the two crystalline phases co-exist in both these salts over the corresponding temperature ranges. Cimino, Parry, and Ubbelohde[17] showed by the X-ray Laue photographic method that orthorhombic and cubic phases can coexist in KCN at around 168°K. The symmetry relation of the coexisting domains was later discussed in detail by Cimino and Parry.[18] For NaCN, the coexistence of the two phases was observed at around 285°K by Nitta and Oda[19] by the use of the X-ray powder method. In concluding the discussion of the upper phase transition of the two salts, it might be said that if one disregards the difficulty arising from the hysteresis phenomenon, the coexistence model provides a reasonably satisfactory picture of the upper phase transition of NaCN and KCN crystals. For the hysteresis phenomena, however, one would have to take into account nucleation and other aspects of the transition. This is a problem still to be investigated.

Let us now proceed to the discussion of the lower phase transition. Figure 8 shows the anomalous part of the heat capacity at the lower transition as a function of T/T_c (T_c: temperature corresponding to the heat capacity maximum), together with that of KCN. A theoretical curve is also plotted; it will be explained later.

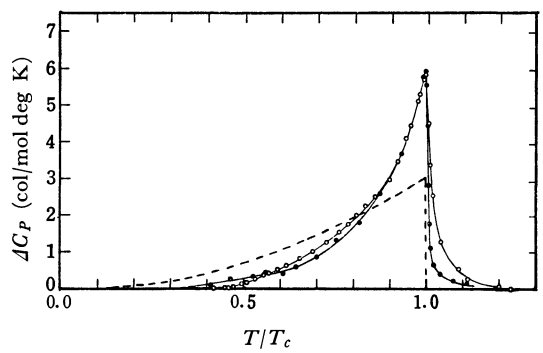

Fig. 8. Anomalous heat capacity at the lower transition of NaCN and KCN crystals.
-●-: NaCN, -○-: KCN, - - -: theoretical

Now we should like to treat these lower transitions of both the salts from the same point of view. Nagamiya presented a molecular field theory of order-disorder transition which includes Pauling's, Frenkel's and Weiss' treatments as extreme cases. In this theory the potential curve described in

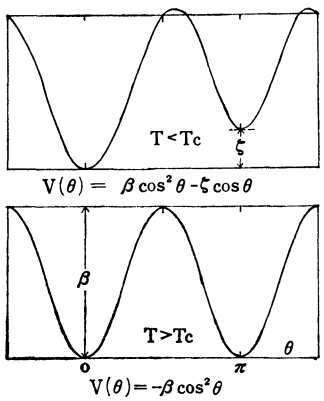

Fig. 9. Hindering potential in Nagamiya's theory of phase transition.

Fig. 9 is assumed for the molecular field, where β is a parameter related to the potential barrier height, and where ζ is an order paramater proportional to the population difference between the two potential minima. Equating β to the V_0 determined by the heat capacity analysis, ζ_0(=ζ at 0°K) can be evaluated by using the observed transition temperature. This treatment gives ζ_0=400 cal/mol for NaCN and 180 cal/mol for KCN. Thus, in either crystal β/ζ_0=30; this essentially corresponds to the Weiss case. Hereafter, therefore, we will adopt the Weiss model throughout. Another reason for using the Weiss model, which is less realistic than Nagamiya's, is that the latter gives 2 cal/mol degK per degree of freedom for the heat capacity, even at the temperature of absolute zero, since the treatment is classical. The Weiss model is originally a static one, but actually the ions oscillate even at the lowest temperature. This difference can be shown to be negligible for the present cases, because of the strong force constant and the large moment of inertia of the oscillator. The enthalpy, the entropy, and the heat capacity jump based on the Weiss model are listed in Table 4. The theoretical curve in Fig. 8 is also calculated by the Weiss approximation. If we keep in mind the fact that the observed value is C_P while the theoretical one is C_V, the agreement seems to be rather satisfactory, since the volume effect usually sharpens transitions.

Finally, we should like to proceed to a discussion of the ionic interaction in relation to the crystal structure at the lowest temperature. According to Verweel and Bijvoet,[2] no significant change in structure occurs at the lower transition for NaCN, even though they observed an unusual contraction of the b-axis around 170°K without being aware of any transition effect. This effect was later shown by Messer and Ziegler[4] to correspond to the lower phase transition. In KCN also, as has been described in a previous paper, no change was detected by the powder X-ray photographs. In view of these results and the small difference in the atomic-scattering factors of carbon and nitrogen atoms, it may be that the transition is of a order-disorder type with respect to the sense of the cyanide ions. If we assume some specific interactions between the ions as the origin of the energy difference between the two orientations of the anions at 0°K, we may obtain the lowest energy configuration as the plausible structure in the lowest temperature phase. The possible types of interaction may be dipolar interaction and steric effect. Considering the fairly spheroidal shape of the cyanide ion and its short range nature, we can neglect the steric effect and retain only the dipolar term as we consider the mechanism of the phase transition.

The energy difference between the two orientations of the cyanide ion at 0°K, 2ζ, arises, then, from the interaction of the electric dipole of the ion with the local electric field, E, produced at the position of the ion by the array of all other dipoles in the crystal. The local field in a dipole array may be written as:

$$E = \sum_i \frac{3(\vec{\mu}_i \cdot \vec{r}_i)\vec{r}_i - r_i^2 \vec{\mu}_i}{r_i^5},$$

where r_i and μ_i are the position vector and the moment of the ith dipole respectively. The summation can be extended over all the dipoles present. For the explicit calculation, let us resort to the approximate method of Lorentz.

Let E be written as:

$$E = E_1 + E_2 + E_3$$

Here, E_1 is the electric field due to the dipoles within a certain spherical region in the crystal; E_2,

TABLE 5. LOCAL ELECTRIC FIELD IN NaCN AND KCN CRYSTALS*

* In units of the dipole moment in cgs esu.

** The antipolar configurations (A) and (B) are the typical ones for the body centered orthorhombic cell as shown in Fig. 10. For detailed discussion of dipolar lattice, see Luttinger and Tisza, *Phys. Rev.*, **70**, 954 (1947); **72**, 257 (1947).

the cavity field produced by the charges which appear on the inside surface of the cavity left by the sphere, and E_3, the contribution from the charge on the outer surface of the crystal. If the crystal has not net polarization as a whole, then $E_2=E_3=0$ and only the contribution from the dipoles within the sphere is operative. On the other hand, if it has a net polarization, P, E_2 is equal to $(4/3)\pi P$ for a cubic crystal and E_3 is $-(4/3)\pi P$ for a spherical specimen and zero for a long, cylindrical specimen. E_1 was calculated by summing up the contribution from about 50 dipoles within a sphere. For three representative configurations, the results of calculation are summarized in Table 5. In the table E' represents the local field at the center of a long specimen ($12\times15\times250$ Å^3) polarized along the longest axis, calculated for the sake of comparison. If, as is usually assumed, there were some mechanisms supplying charges to the outer surface of the specimen, then $E_3=0$ for any shape of the crystal and the polar configuration would have the lowest energy. Or, following the discussion by Kittel,[20] the polar structure would be the most stable by forming long domains.

If we assume that this polar configuration is realized in the lowest temperature, we can estimate the dipole moment of the cyanide ion in the crystal as follows. By equating the interaction energy to kT_c, we get $\mu=0.55$D for NaCN and 0.42D for KCN. Although, at present, we unfortunately have no experimental data to compare with these values, their order of magnitude seems quite reasonable. We may mention here a recent calculation of the electronic structure of some cyanide compounds by Yonezawa, Kato and Konishi,[21] who used a semiempirical self-consistent field method. Their result was 0.49D for the dipole moment of the cyanide ion, a value which compares favorably with our experimental values, although their calculation refers to the free ion.

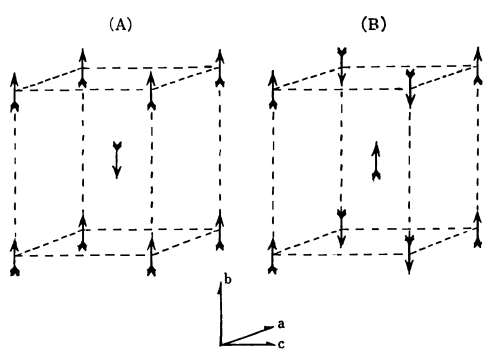

Fig. 10. Typical antipolar configurations of the CN^- dipoles in the lowest temperature phase of NaCN and KCN crystals.

The difference between the two values derived from Na- and K-salt, however, seems to point to the approximate nautre of our treatment; we can not expect the electronic structure in the two salts to be really different. We observed little difference in the infrared fundamental bands of the cyanide ion in the Na- and K-salts, while for thallium cyanide,[22] which is believed to be in electronically-different state, the C-N stretching band is greatly shifted. Accordingly, the difference between the two values may be accounted for more reasonably as a consequence of neglecting the steric, induced polarization and other effects. As may be seen in Table 5, the antipolar configuration, B, must be taken into consideration if the above-mentioned condition favoring the polar structure is in competition with other factors. Therefore, our results are not conclusive. In order to determine the structure of the lowest-temperature phase of the two salts, further experiments, such as neutron diffraction, far-infrared absorption, or dielectric measurements using single crystals, together with a more precise theoretical treatment of molecular interactions in crystals, are much desired.

Summary

The heat capacity of the NaCN crystal was measured from 14 to 310°K by using an adiabatic calorimeter. Two anomalous regions were confirmed, at 171.9±0.2°K and 287.7±0.1°K. The estimated entropy changes of these anomalies were approximately equal to $R\ln 2$ and $R\ln 4$, respectively. These values may be interpreted in terms of a step-by-step randomization process of the orientation of the cyanide ions.

By analyzing the observed heat capacities, the contribution from the torsional motion of the cyanide ion was derived on several assumptions. It was shown that, below 70°K, the separated torsional heat capacity can be reproduced by a two-dimensional harmonic oscillator with the average wave number of 210 cm^{-1}, a value which corresponds to a barrier height of 13 kcal/mol. At higher temperatures it may be compared to those of a hindered rotator with a barrier height of 2—3 kcal/mol. This behavior is quite similar to that of KCN.

By integrating the heat capacity data, $S°$, $(H°-H°_0)/T$, and $-(G°-H°_0)/T$ were calculated.

The upper phase transitions of NaCN and KCN conform rather well to the coexistence model of diffuse phase transition proposed by Tobolsky and others.

As to the relative orientation of the cyanide ions in the lowest-temperature phase, the lattice energy was evaluated for both NaCN and KCN, and the most stable configuration was inferred to be polar. These considerations, coupled with the observed transition temperatures, yield estimates of the magnitude of the dipole moment of the anion in the crystal, 0.55D for NaCN and 0.42D for KCN.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 593—600 (1968)

On the Glass Transition Phenomenon of Isopentane*[1]

Masayasu SUGISAKI, Keiichiro ADACHI, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received October 14, 1967)

Heat capacity measurement of isopentane was carried out for crystalline, liquid, glassy, and supercooled liquid states in the temperature region between 13 and 300°K. The glass transition phenomenon of isopentane was found around 65°K with drastic heat capacity change of 68.20 J/mol degK. This glass transition phenomenon is tentatively interpreted in terms of the Adam and Gibbs theory. The value of T_g/T_2, the ratio of glass transition temperature T_g, and the temperature of disappearance of the configurational entropy of the supercooled liquid T_2, for isopentane was found to be 1.30 which is concordant with the value cited by Adam and Gibbs. The residual entropy at absolute zero of the glassy isopentane was shown to be 14.06 J/mol degK. In addition the irreversible production of entropy during the glass transition intervals was found to be 0.08 J/mol degK. It is concluded that the neglect of the irreversible production of entropy leads no significant error in determing the residual entropy.

Recently, Turnbull and Cohen[1] have empirically found that the substance which satisfy the condition that the ratio T_b/T_m, of their normal boiling to their normal melting temperature is equal to or larger than 1.8 are easily supercooled. On the basis of this empirical rule they suggest that the substances which fulfill this condition may have much glass-forming tendency, if the liquid is cooled rapidly far below their melting point with no occurrence of crystallization.

There have been known many kinds of pure substances showing glass transition phenomenon. They may be classified into, (1) network glasses such as SiO_2 and other nonmetallic oxides, (2) inorganic and organic polymers, (3) hydrogen bonded substances, (4) low molecular weight materials, *etc.*[2] In order to study the essential feature of the glassy state from theoretical as well as experimental points of view, it seems much desirable to investigate the simple low molecular weight substances. For such purpose we have undertaken to study the glassy state in relation to

*1 This paper was read before the 19th Annual Meeting of the Chemical Society of Japan, Yokohama, March, 1966.

its crystalline phase by use of the method of heat capacity measurement, and really found a characteristic heat capacity jump associated with the occurrence of the glass transition phenomenon.

Experimental

Apparatus. The adiabatic Nernst-type calorimeter[3] used in our laboratory was partly modified, so that rapid cooling may be easily carried out. For this purpose, liquid nitrogen or liquid hydrogen is able to be charged directly into the space between the outer and inner adiabatic shields as is shown in Fig. 1. Measurements of temperature were made with platinum resistance thermometer calibrated in terms of International Temperature Scale between 90 and 500°K and the provisional scale of the National Bureau of Standards between 11 and 90°K.[3]

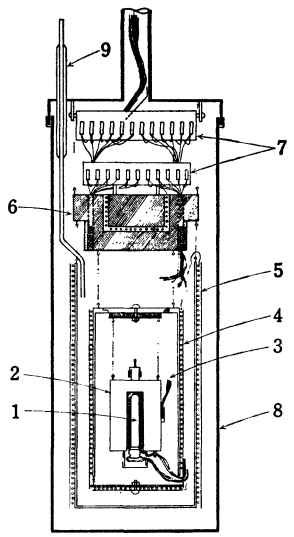

Fig. 1. Description of adiabatic calorimeter.
1) platinum resistance thermometer, 2) sample container, 3) thermo-couple, 4) inner shield, 5) outer shield, 6) copper block, 7) lead connector, 8) vacuum jacket, 9) transfer tube.

Sample. The commercial extra pure isopentane (Nakarai Chemicals, Ltd.) was purified by fractional distillation, and then distilled twice under high vacuum (10^{-6} mmHg). Impurities contained in each fraction were detected by gas chromatography technique and the purest fraction was employed for the heat capacity measurements. The amount of the impurities present in the sample was determined to be 0.014 mol percent by making use of thermo-analytical method as is described later.

Heat Capacity Measurements. Measurements of the heat capacities were made on a sample with single loading (0.2433 mol) which was sealed in a gold calorimeter cell, for the crystalline, liquid, glassy, and supercooled liquid states in the temperature region from 13 to 300°K. The reported values are based on a molecular weight 72.152 g and ice point is taken to be 273.15°K.

Our preliminary observation by differential thermal analysis clarified that cooling rate of 10°C/min was sufficient to supercool the liquid isopentane far below its melting point without any occurrence of crystallization. Consequently, liquid hydrogen was directly transferred into the space between outer and inner shields (see Fig. 1), in order to satisfy this cooling condition. From the results of the heat capacity measurements, it was found that the whole amount of the sample was completely superocooled down to 20°K without any occurrence of crystallization.

Furthermore, in order to determine the purity of the sample, detailed measurements of melting point and enthalpy analysis of melting, were also performed.

Experimental Results

Heat Capacity of Crystalline and Liquid States. The results of heat capacity measurements are listed in Table 1A for crystalline and liquid states, and are shown by hollow circles in Fig. 2. These values agree with those reported by Guthrie and Huffman[4] in 1943. They reported the nonexistence of the appearance of anomalous heat capacity of liquid state in the temperature region between 170—250°K which was first reported by Schumann and Aston (1942).[5] This fact coincides with our results.

The data of melting point in relation to mole fraction of the melt, and the heat of fusion, obtained from the results of heat capacity measurements, are shown in Table 2, and the relationship between melting point and inverse molten fraction is given in Fig. 3. The value obtained for the melting point of 100% pure isopentane is found to be 113.36±0.05°K.

From the melting curve, the amount of impurities in the sample was found to be 0.014 mol percent.

Heat Capacities of Glass and Supercooled Liquid. The results of the heat capacity measurements in the glassy and the supercooled liquid states of isopentane are shown in Table 1B, and shown by filled circles in Fig. 2. There appears a sharp rise of heat capacity at about 65°K which is characteristic to glass transition phenomenon of supercooled liquid. These results indicate that isopentane can be supercooled far below its melting point and can be transformed into a glassy state. It may be noted that the differences of the heat capacities between the crystalline and glassy states are smaller near 30°K in each side, similar to that of glycerol.[6]

The amount of heat capacity of the supercooled

liquid just above the glass transition point is nearly equal to the twice of that for the crystalline state. This fact is rather common feature at glass transition of almost all supercooled liquids.[7] When the supercooled liquid which had experienced glass transition, was heated up to above the glass transition temperature, the crystallization takes place at about 75°K. This crystallization phenomenon was observed experimentally with the start of gradual heat evolution effect. The heat capacity measurements, a little below the melting point were made with the supercooled liquid obtained by means of careful slow cooling. It was possible

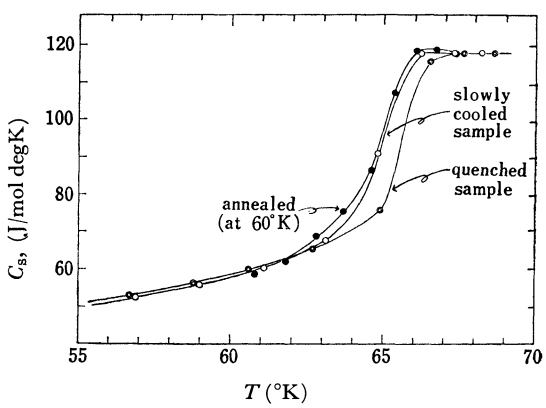

Fig. 4. Heat capacity of isopentane during the glass transition intervals.

7) R. O. Davies and G. O. Jones, *Proc. Roy. Soc.*, **A217**, 26 (1953).

for about 10°C below the melting point, and the temperature region where the heat capacity measurements were impossible is shown by dotted line in Fig. 2. Detailed measurements were also made in the glass transition intervals for various samples which had experienced the different thermal treatments. The results are shown in Fig. 4 and double circles represent the data for the quenched sample which was quenched to 25°K from room temperature during six minutes. The series of measurements for this quenched sample were made from 13°K to 68°K. After this series of measurements have finished at 68°K, the sample was slowly cooled down to 43°K during 4 hr.

The results with this slowly cooled sample are depicted by a series of circle in the Fig. 4.

Finally, this sample was again cooled down to 60°K from 68°K during 25 min and annealed for about 20 hr at this temperature. The filled circles are for this sample.

This series of measurements was continued to the temperature region above the glass transition

temperature, until the heat evolution due to the crystallization was observed.

While the crystallization proceeds, the adiabatic condition of the calorimeter was watched to be satisfied. When the heat evolution effect has ceased at 106.2°K, the temperature of the crystalline phase was determined accurately. This procedure was necessary in order to determine the enthalpy of the glassy state on the basis of the enthalpy of the crystalline states as will be given in the next section.

Enthalpy Curves of the Glass and the Supercooled Liquid. The enthalpy curves of the glass and the supercooled liquid, calculated with the results of the heat capacity data are shown in Fig. 5.

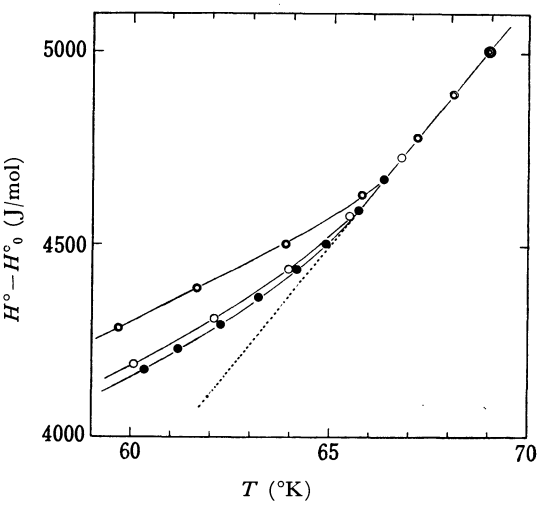

Fig. 5. Enthalpy curve of isopentane near the glass transition point.
●: annealed sample at 60°K, ○: slowly cooled sample, ◎: quenched sample

Each curve represents the various samples which had experienced different thermal treatments.

In the case of quenched sample, the enthalpy value of the supercooled liquid deviates from the equilibrium curve at about 66.5°K, and transforms into the glassy state. For slowly cooled sample, the curve deviates from the equilibrium value at the temperature 1°C lower than that for the quenched sample. The effect of annealing is really found in the enthalpy curve in such a way that the enthalpy curve of glass comes below the slowly cooled one. The triple circle near 69°K which is taken as the reference point for evaluation of absolute enthalpy of the glass was determined as the intersection of the curve for supercooled liquid and the isenthalpy straight line at 106.2°K of the enthalpy curve for crystalline state. The enthalpy curve of the crystalline state is easily

obtained by graphical integration of their heat capacity data.

Thermodynamic Properties of Isopentane. The values of heat capacity, entropy, and also the enthalpy and Gibbs energy functions of isopentane at selected temperature were listed for the liquid crystalline, glassy, and supercooled liquid states in Table 3.

Discussion

The heat capacities of isopentane have been measured by three investigators,[4,5,8] nevertheless, the occurrence of the glassy state of this compound

8) G. S. Parks, H. M. Huffman and S. B. Thomas, *J. Am. Chem. Soc.*, **52**, 1032 (1930).

had not been known by any authors. As is described already, we have succeeded in obtaining the glassy state of the present material. The relation of the normal boiling to its normal melting points of isopentane is equal to 2.70. This fact is concordant with the Turnbull-Cohen empirical rule[1] for obtaining glassy state by supercooling method; *i. e.*, the ratio should be equal to or larger than 1.8. The ratio $T_b/T_m=2.15$ for *n*-pentane suggests that this liquid might have also the tendency to be supercooled, whereas the crystallization has always occurred as far as our observation is concerned.

Now, in liquid isopentane two kinds of origin associated with the relaxation phenomenon may be considered, one is due to the degree of freedom of the internal rotation with respect to intramolecular C-C bond, and the other is due to the change of intermolecular configuration which is related to the shear and/or volume viscosity of liquid isopentane. Concerning the liquid state of isopentane, there is investigation with ultrasonic absorption technique by Young and Petrauskas.[9] Their results suggest that around 150°K the relaxation time with respect to the degree of freedom of internal rotation is longer than that for intermolecular configurational change. It is not clear, however, how is the relation between these two types of relaxation times for supercooled liquid near 65°K. We may safely conclude, anyhow, that ΔC_P, the increment of heat capacity at the glass transition point, is mainly associated with intermolecular configurational change, since the difference between the contributions due to the intramolecular rotation in the supercooled liquid and in the glass, may be too small to explain this ΔC_P.

Turning to the phenomenological interpretation of the glass transition phenomenon of supercooled liquid, there exist two kinds of opposite opinions. One is such that the glass transition occurs at temperature where a certain kind of thermodynamical quantity takes critical value; *i. e.*, the glass transition is like a second order phase transition.[10,11] The other is such that the glass transition may be interpreted as the relaxation phenomenon due to the degree of freedom of molecular motions.[12]

According to Adam and Gibbs, the relaxation time of a system can be uniquely related to the configurational entropy of the system. This idea is based on the resolution of the well-known Kauzmann's paradox.[13] This theory shows explicitly the existence of temperature at which the configurational entropy of the system has critical value and it is called T_2, a glass transition temperature in the sense of thermodynamical equilibrium. According to their theory, the actual glass transition temperature T_g can be related to T_2 in the following equation;

$$S_{\text{config}}(T_g) = \int_{T_2}^{T_g} \Delta C_P/T \, dT, \text{ and}$$

$$S_{\text{config}}(T_g) \equiv \Delta S_0 = (S_{\text{glass}} - S_{\text{cryst}})_{T=0}$$

From our results of the heat capacity measurements, ΔS_0 and ΔC_P are known, so the ratio T_g/T_2 can be calculated.

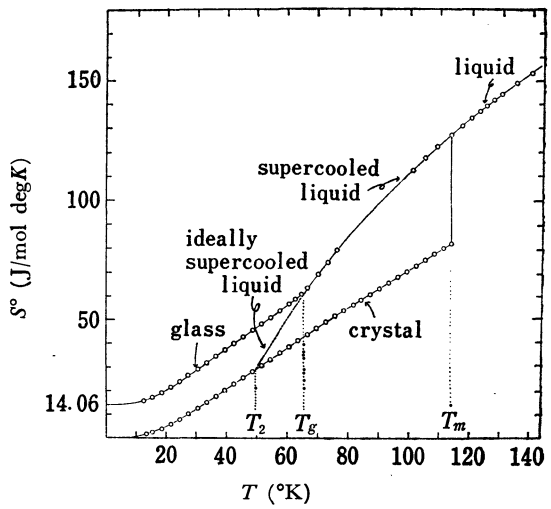

Fig. 6. Entropy diagram of isopentane.

Figure 6 shows the entropy diagram of isopentane calculated from the data of the heat capacity measurements. From this entropy diagram, it is clear that T_2 (the temperature at which the configurational entropy disappears) situates at about 50°K. Consequently, the following relations are obtained,

$$T_g/T_2=65/50=1.30$$

and $$T_g-T_2=65-50=15 \ (°K)$$

The relation, $T_g/T_2=1.30$, is corresponding to the average value of many substances cited by Bestul and Chang[14] and Adam and Gibbs.[11]

The consistency of the present results with Adam and Gibbs' theory seems to suggest that a certain kind of thermodynamical relation takes part in the glass transition phenomenon of the supercooled liquid.

Finally a few comments will be given concerning the irreversible phenomenon taking part in a glassy state.[7,15]

9) J. M. Young and A. A. Petrauskas, *J. Chem. Phys.*, **25**, 943 (1956).
10) M. Goldstein, *ibid.*, **39**, 3369 (1963).

15) A. B. Bestul and S. S. Chang, *ibid.*, **43**, 4532 (1965).

Near below the glass transition temperature, we can observe usually an exothermic effect due to the stabilization phenomenon of the glassy state into a supercooled liquid.

This stabilization gives rise to an irreversible entropy production within the system. It is well known that a residual entropy of the glassy state generally involves the excess entropy due to these irreversible phenomenon. Davies and Jones[7] suggested the possibility that this entropy production can be estimated by considering the heat conduction between a system of configurational part and a system of lattice, each of which is in different temperatures. Consequently, the irreversible production of entropy can be expressed very simply by the following expression,

$$\Delta S_{\mathrm{Irr.}} = \Delta C_P (1/\bar{T} - 1/T)\Delta T$$

where ΔC_P is the heat capacity of configurational part, T the temperature of a lattice, and $\bar{T}$ fictive temperature of a configurational system.

In order to estimate this quantity, the drift of temperature of the sample in the calorimeter was measured for long time during the glass transition intervals. This drift corresponds to the time derivative of T, or $\bar{T}$. Analysing the results of drift curve for quenched sample, $\Delta\bar{T}$ was found to be -0.0892°C with the assumption that configurational heat capacity is equal to that of the lattice. Taking the following data $\bar{T}=65$°K, $T=60$°K, $\Delta C_P=16.3$ cal/mol degK, we get $\Delta S_{irr}=.0.019$ cal/mol degK which is very small compared with the residual entropy at absolute zero, $\Delta S_0=3.36$ cal/mol degK.

We can safely conclude that the neglect of the irreversible production of entropy leads to no significant error on determing the residual entropy.

Summary

1) The results of the heat capacity measurements of isopentane were given for crystalline, liquid, glassy and supercooled liquid states in the temperature region between 13 and 300°K.

2) The glass transition phenomenon of isopentane was found near 65°K with the drastic change of heat capacity of 16.3 cal/mol degK.

3) The residual entropy of the glassy isopentane at absolute zero was found to be 3.36 cal/mol·degK.

4) The irreversible production of entropy during the glass transition intervals was estimated to be 0.019 cal/mol degK.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 600—603 (1968)

Extraction-Photometric Determination of Osmium with Thenoyltrifluoroacetone

Asha V. RANGNEKAR and S. M. KHOPKAR

Department of Chemistry, Indian Institute of Technology, Bombay-76, India

(Received June 21, 1967)

The study of the liquid-liquid extraction of some platinum group elements (A. V. Rangnekar and S. M. Khopkar, *Bull. Chem. Soc. Japan*, **38**, 1696 (1965); **39**, 2169 (1966)), with fluorinated β-diketones showed that, osmium reduced to trivalent state with hydroxylamine hydrochloride forms a red chelate with 2-thenoyltrifluoroacetone, TTA. The chelate is readily extracted in benzene giving strong absorbance at around 440 mμ.

The thiocarbonilide[1] complex of osmium is extracted with ether, where as complex with ephedrine hydrochloride[2] was extracted in carbon tetrachloride. Thiourea[3,4] was used for extraction and colorimetric determination of osmium. Such complex was extracted in chloroform and measured at 480 mμ. The osmium was found to be in the trivalent state with composition of the extractable[5] species as $[Os(NH_2\text{–}CS\text{–}NH_2)_6]^{3+}$. The other extracting agents include; thiosemicarbazide,[6] 1-naphthylamine -3, 5, 7-trisulphonic acid,[7] mercaptobenzimidazole[8] and *o*-(β-benzoylthiourido)benzoic acid.[9] Unfortunately these methods

are not rapid. An attempt is made in this paper to present a rapid method for the extraction-photometric determination of osmium at micro-levels with TTA.

Experimental

Apparatus and Reagents. A type SP-4 quartz spectrophotometer, Cambridge pH meter, wrist action flask shaker. TTA (E. Merck and Co.) 0.015 M solution in benzene. A stock solution of osmium was prepared from osmic acid as by Ayres' method.[4] On standardisation[3,10] it was found to contain 58.8 μg of osmium per m*l*. Hydroxylamine hydrochloride (B. D. H) 5% aqueous solution.

General Procedure. An aliquot of the solution (294 μg of osmium) was taken, 10 m*l* of 5% hydroxylamine hydrochloride was added to reduce osmium to trivalent state, the pH of the solution was then adjusted to pH 4.5 with 0.01 N sodium hydroxide, and 0.01 N sulphuric acid. The final volume of the solution was made upto 20 m*l* and the solution was then transferred to separatory funnel. Ten millilitres of 0.015 M TTA-benzene was added and it was shaken for about 10 min. After allowing the solution to settle and separate, organic phase was stripped into 10 m*l* volumetric flask. The absorbance of the colored complex was measured at 440 mμ. The amount of osmium was computed from the calibration curve.

Results and Discussion

Absorption Spectrum. The absorption spectrum of Os(III)-TTA complex (Os = 1.545×10^{-4} M) shows strong absorbance at 430 mμ (Fig. 1). Although the reagent blank shows significant absorbance at 420 mμ, it is negligible at 430 mμ. All absorbance measurements were therefore made at 440 mμ. The molar absorptivity is 1.42×10^2 at 440 mμ on the basis of osmium contents.

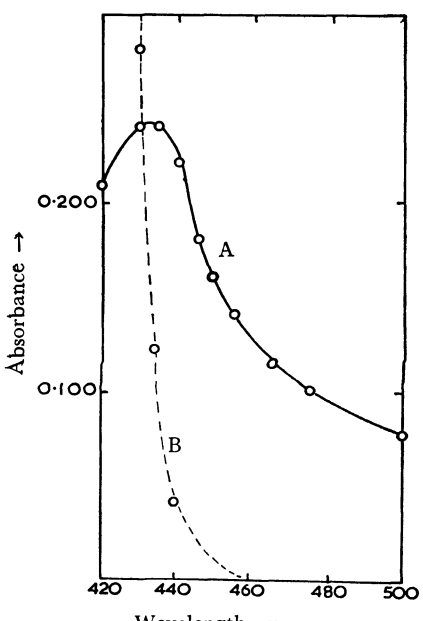

Fig. 1. Absorption spectra of osmium-TTA complex.

B Reagent blank *vs.* benzene at pH 4.5 TTA = 1.5×10^{-3} M

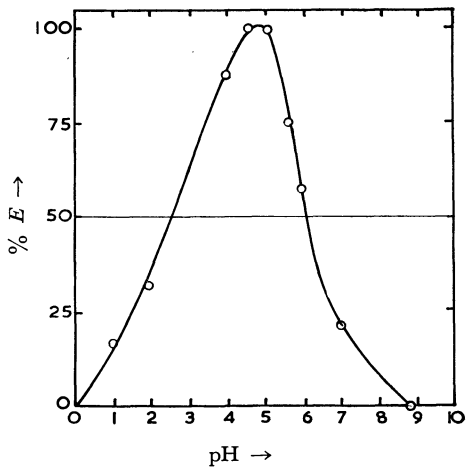

Fig. 2. Percentage extraction of osmium as the function of pH.

The Effect of pH Value. The extraction of osmium was carried out from pH 1.0—10.0 with TTA. (Fig. 2). The distribution ratio (*D*) was calculated as before[11,12] (Table 1). Between pH region of 3.5 to 5.5, more than 80% osmium is

176.4	0.140	0.140	0.135
235.2	0.190	0.180	0.175
294.0	0.230	0.230	0.220
352.8	0.270	0.270	0.265
441.0	0.300	0.300	0.320

Table 3. Effect of reagent concentration
Os=294 μg pH=4.5

Concentration M	Volume of reagent ml	Absorbance at 440 mμ
0.0015	10.0	0.000
0.0075	10.0	0.010
0.0150	5.0	0.100
0.0150	7.5	0.220
0.0150	10.0	0.220
0.0250	10.0	0.230
0.0500	10.0	0.240

extracted, but at pH 4.5 the extraction is quantitative. The $pH_{1/2}$ is 2.6 and 6.0.

Beer's Law Curve. The different amounts of osmium were extracted pH 4.5 (Table 2) and measured at 430, 435 and 440 mμ. The system conforms to Beer's law over the concentration range of 2.9 to 22 μg of osmium per ml at 440 mμ.

The Effect of Reagent Concentration. The osmium (294 μg) was extracted at pH 4.5 with varying concentration of the reagent (Table 3). The results indicate that 10 ml of 0.015 M TTA is quite adequate for quantitative extraction.

Stability of the Color. The absorbance of the colored complex was measured at lapsed interval of 30 min. Probably the complex decomposes after 6 hr. Therefore it is recommended to measure the absorbance within first 4 hr of complex formation.

Period of Shaking. The variation in period of shaking from 30 sec to 30 min revealed that the complex is quantitatively extracted within 10 min of shaking.

The Effect of Salting-out Agents. The sulphates of alkali and alkaline earth metals were used as the salting-out agents (Table 4). The results showed none of them have any pronounced effect upon the process of extraction.

The Effect of Diverse Ions. The effect of the presence of several ions on the extraction behaviour was studied (Table 5). About 5 mg of cadmium, tin(II), platinum(IV), palladium, rhodium, iridium, gold, manganese, cobalt(II),

a) Interference eliminated by masking with EDTA at pH 2.0.
b) Interference eliminated by forming anionic complex with citrate at pH=6.0.

arsenite, tartrate, citrate, and EDTA do not interfere. Similarly about 1 mg of antimony, zinc, lithium, tellurite, formate can be tolerated. The ions showing interference are thorium, bismuth, zirconium, cerium, uranium and iron; but their

interference can be easily eliminated by complexation with suitable masking agents.

From twenty determinations, it was observed that the absorbance of the solution ranged from 0.210 to 0.230. The standard deviation is $\pm 1.1\%$. As little as 1.33 μg of osmium per m*l* can be detected.

Summary

2-Thenoyltrifluoroacetone forms orange red chelate with trivalent osmium, the chelate which shows strong absorbance at 440 mμ. Beer's law is obeyed over the concentration range of 2.9 to 22 μg of osmium per m*l*. The color of the complex is stable. Large number of cations as well as anions are tolerated.

We are thankful to Council of Scientific and Industrial Research (India) for sponsering this project and awarding Senior Research Fellowship to one of us (A. V. R.).

(Received September 1, 1967)

A very rare yttrium mineral, yttrofluorite, from granite pegmatite found at Suishoyama, Fukushima Prefecture, was studied. Chemical analysis: Ca 35.50%, $\sum$ Rare earths 18.84%, Mg 0.42%, Fe 0.34%, Al 0.15%, Mn 0.08%, F (remainder) 44.67%. Cell constant calculated from the X-ray powder data: $a_0=5.500$ Å. Specific gravity: 3.51 (measured), 3.62 (calculated). Refractive index: $n=1.454$. The distribution pattern of lanthanide elements studied by the X-ray fluorescent method disclosed that the mineral is poor in cerium group lanthanide, rich in yttrium group with maxima at dysprosium and erbium. The mineral occurs as aggregates of small crystals in spessartine garnet embeded in large crystals of feldspars.

In spite of the many detailed chemical studies of pegmatite minerals from Japan, yttrofluorite was hitherto not reported, except for one[1] from Yamaguchi-mura, Nagano Prefecture, which was assumed because of the high refractive index (although the sample was too small to be analyzed).

Suishoyama pegmatite, Kawamata-machi, Fukushima Prefecture, is found in a Mesozoic biotite granite body, has a zonal arrangement of felsic minerals, and has been worked for quartz and feldspar for many years. The pegmatite is also well-known for the production of many rare element minerals, such as abukumalite (type locality), yttrialite, fergusonite, tengerite, thorogummite, allanite, uraninite, zircon, gadolinite, keilhauite, thalenite,[2] and some secondary uranium minerals such as autunite, torbernite, zeunerite, and a mineral[3] very close to uranophane, but which has higher refractive indices and larger d values obtained from X-ray powder diffraction.

The mineral herein described was collected from a waste outside the quarry, so the mode of occurrence or the paragenesis of minerals is not certain. The mineral usually occurs as irregularly shaped, fine grained agglomerate in spessartine garnet of a dark red brown color, and contains a small amount of yttrium group rare earths. The largest aggregate reaches 3 cm in size, but individual grains are too small to see with the naked eye.

The spessartine garnet is usually embeded in potash feldspars. This occurrence of yttrofluorite is very similar to that of tengerite[4] in Suishoyama pegmatite suggesting a close relationship between these two minerals.

2) K. Nagashima and A. Kato, This Bulletin, **39**, 925 (1966). Literatures describing these minerals from Suishoyama are cited in this paper.
3) K. Nagashima, A. Kato and M. Chiba, *Chigaku-kenkyu*, **17**, Nos. 10, 11, 12, p. 95 (1966). (in Japanese)
4) T. Iimori, *Sci. Pap. Inst. Phys. Chem. Research*, **34**, 832 (1938).

The mineral yttrofluorite is also important as an example of a complete assemblage of rare earth elements in which the yttrium earths are of the same abundance as the cerium earths. This kind of complete assamblage is known as "yttrofluorite type" (Goldschmidt and Thomassen[5]). However, as shown by Semenov,[6] the distribution of rare earth elements in fluorite is quite variable. In Dana's "System of Mineralogy,"[7] both yttrofluorites rich in yttrium group rare earths, $\sum Y_2O_3$ 17.35%, $\sum Ce_2O_3$ 1.68%, and those rich in cerium group rare earths, $\sum Y_2O_3$ 8.10%, $\sum Ce_2O_3$ 16.45% are described.

Optical and X-Ray Powder Studies

As the grains composing the aggregates are so small, clevages characteristic of fluorite is hardly observable with the naked eye. The color of the aggregates, and that of the powder is gray. The refractive index is 1.454. The value is much higher than that of the usual fluorite, and agrees with values, 1.4572, 1.4425, or 1.4483 for yttrofluorites of other localities.[7]

X-Ray powder diffraction measurements were made on a Norelco X-ray Diffractometer. The diffraction data are compared with those of pure artificial calcium fluoride in Table 1. D values and intensities of the present mineral are very close to those of calcium fluoride, but the d values of the mineral are definitely a little larger than those of artificial fluorite suggesting substitution of calcium by larger rare earth elements. From the d values, a_0 was calculated to be 5.500 Å.

Chemical Composition

Chemical analyses were carried out on the hand-picked material. Fluoride was not analyzed directly, but determined by subtracting analyzed

---- Yttrofluorite type (by V. M. Goldschmidt and Thomassen)

cations from 100%. The average atomic weight of the rare earth elements was determined by titrating the weighed mixed oxides with an EDTA standard solution after dissolving them in hydrochloric acid.

The results of the analyses are given in Table 2, together with the molecular ratios of the components. The experimental formula of the yttrofluorite from Suishoyama calculated on the bases of $\sum$ cation=1.00 is $(Ca_{0.8107}, \sum R.E._{0.1613}, Mg_{0.0158}, Fe, Al, Mn)_{1.00}F_{2.1524}$. The content of rare earth elements as fluoride is 28%, and the atomic ratio of rare earth elements to calcium reaches 1 : 5.04. This ratio is almost the same as that for the yttrofluorite from Hundholmen, Norway, in which (Y, Ce) : Ca is 1 : 6.0, and the yttrofluorite (more correctly cerium fluorite) from Fahlum, Sweden, in which the ratio is 1 : 5.2.

The Distribution Pattern of Rare Earth Elements

The distribution of lanthanum series elements was determined by the X-ray fluorescent technique. Cerium, neodymium, samarium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, and ytterbium (with the maxima at dysprosium and erbium) were found. Lutetium may be present, but could not be confirmed due to the overlapping diffractions of other spectra. A quantitative estimation, with the relative error of less than 10%, is given in Fig. 1, in which the atomic % of the elements is plotted. In the figure, the yttrofluorite type distribution pattern of rare earth elements by Goldschmidt and Thomassen[5] is also shown. As seen in the figure, the present mineral is richer in yttrium group rare earths than the so called yttrofluorite type. The higher concentration of the yttrium group in the mineral might be a reflection of the high concentration of yttrium group rare earths in the original solution of the Suishoyama pegmatite.

Specific Gravity

When divalent calcium ions in fluorite are substituted by trivalent rare earth ions, excessive fluoride ions are thought to enter the interstitial sites in the fluorite structure. This type of structural model is called the interstitial model. There could be another model —a vacant cation model— in which 1/3 of the lattice points of substituted calcium are left vacant. The phase relationship of the YF_3-CaF_2 system was studied by Short and Roy.[8] They also compared the measured specific gravity of a CaF_2-YF_3 solid solution with theoretical values calculated on the basis of the interstitial fluoride model, and the vacant cation model, and showed a beautiful agreement between the measured, and interstitial model values.

The specific gravity of the present yttrofluorite measured by the pycnometric technique is 3.51. The calculated value, adopting the interstitial model, and the concentration, and mean atomic weight of rare earth elements is 3.62. The difference may be explained by the fine, powdery nature of the specimen.

The authors wish to express their thanks to Dr. Kinichi Sakurai and Mr. Otokichi Nagashima for their interest in this work, and their help in collecting the mineral.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 606—609 (1968)

Conductance Behavior of Some Hexa-amminecobalt(III) Complexes and Their Ion Association in Aqueous Solutions

Shunzo KATAYAMA and Reita TAMAMUSHI

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received September 7, 1967)

The conductance behavior of some hexa-amminecobalt(III) complexes in dilute aqueous solutions at 25°C was studied in association with the ion-pair formation of hexa-amminecobalt(III) ions. The equivalent conductivities were analyzed according to the Onsager theory, and the thermodynamic formation constants, K, of the ion-pairs, $[Co(NH_3)_6]^{3+}\cdot A^{z}{}_{A}{}^{-}$, were determined. The log K values obtained are 1.4_0 (perchlorate), 1.6_3 (nitrate), 1.6_5 (bromide), 1.3_8 (iodide), and 3.2_5 (oxalate). These values were compared with the formation constants calculated from the spectroscopic data, and discussed in terms of Bjerrum's theory on ion association.

The measurement of electric conductivity of dilute solutions provides a valuable method of studying the outer-sphere ion association of inert complexes. The conductance behavior and the ion association of hexa-amminecobalt(III) chloride,[1,2] sulfate,[2] trimetaphosphate,[3] and tetrametaphosphate[3] in aqueous solutions were studied by Hartley and Donaldson and by Jenkins and Monk. In our previous papers,[4,5] the equivalent conductivities of nitroamminecobalt(III) complexes in dilute aqueous solutions were discussed in terms of the Onsager theory, and the ion-pair formation constants of $[Co(NH_3)_6]^{3+}\cdot Cl^-$ and $[Co(NO_2)(NH_3)_5]^{2+}\cdot Cl^-$ were determined. The present study deals with the conductance behavior and the ion-pair formation of hexa-amminecobalt(III) perchlorate, nitrate, bromide, iodide, and oxalate in dilute aqueous solutions at 25°C.

Experimental

The samples of hexa-amminecobalt(III) chloride, bromide, and iodide were prepared according to the procedure described in the literature.[6] Hexa-amminecobalt(III) perchlorate, nitrate, and oxalate were obtained by adding perchloric acid, nitric acid, and ammonium oxalate, respectively, to the aqueous solutions of hexa-amminecobalt(III) chloride. These samples were carefully purified by three recrystallizations from their aqueous solutions containing a few drops of acetic acid. The purity of the samples was examined by the conventional chemical analysis of the components; the results were in very good agreement with the theoretical values.

The solutions of different concentrations were carefully prepared by using the conductivity water of low specific conductance ($<2\times10^{-7}\Omega^{-1}\,cm^{-1}$) in an atmosphere of purified nitrogen gas. The electric conductivities were measured by the same apparatus as described in the previous papers.[4,5] The resistance readings of the conductivity cell were calibrated by the substitution method using a precision decade resistance box (Dekastat RS-624, Electro Scientific Industries; accuracy, ±0.005%), and their reproducibility was better than 0.1%. All measurements were carried out in a water-thermostat of 25.000±0.005°C.

Results

The hexa-amminecobalt(III) complexes are subjected to the slow decomposition in aqueous solutions; therefore, the conductivities were measured at different times after the preparation of the solution, and the equivalent conductivities at time zero, which were determined by the extrapolation of the measured conductivities against time, were used in the following discussion.[4,5]

The limiting equivalent conductivities, Λ°, of the complexes were determined by Onsager's method of extrapolation[7]: the Λ° of each complex gave consistent values of the limiting ionic equivalent conductivity, λ°, of hexa-amminecobalt(III) ion. The results are summarized in Table 1.

The relation between the equivalent conductivity, Λ, and the concentration, c (equiv./l) was analysed according to the limiting equation of Onsager,[7]

$$\Lambda = \Lambda^\circ - bc^{1/2} \qquad (1)$$

where b is a theoretical constant. Figures 1 and 2 show the plot of Λ against $c^{1/2}$; the broken lines

represent the theoretical Onsager lines calculated by Eq. (1). The equivalent conductivity of hexa-amminecobalt(III) oxalate gave a large deviation from the theoretical Onsager value even at very low concentrations. A small but significant deviation was also observed with the complexes of $[Co(NH_3)_6]A_3$ type.

Discussion

The deviation of the Λ *vs.* $c^{1/2}$ plot from the theoretical Onsager line in dilute solutions is considered to be due to the outer-sphere association of the complex cation, $[Co(NH_3)_6]^{3+}$, with the anion represented by A^{z_A-},

$$[Co(NH_3)_6]^{3+} + A^{z_A-} \rightleftarrows [Co(NH_3)_6]^{3+}\cdot A^{z_A-} \quad (2)$$

The degree of dissociation of the possible ion-pairs was determined from the conductivity data according to the successive approximation method of Jenkins and Monk,[2] and the concentration formation constants, K_c, of the ion-pairs were calculated at each concentration. In the present calculation, the λ° values of the ion-pairs were estimated from $\lambda^\circ([Co(NH_3)_6]^{3+})$ according to the following equation,

$$\frac{\lambda^\circ(\text{ion-pair})}{\lambda^\circ([Co(NH_3)_6]^{3+})} = \frac{|z|}{3} \quad (3)$$

where z is a net charge of the ion-pair; the equation is obtained from the Stokes' law by neglecting the ion-size effect on the mobility. This estimation of λ°(ion-pair) is rather arbitrary, but it is shown by calculation that a considerable change in λ°(ion-pair) does not affect the derived value of K_c appreciably.[8]

By using the modified Debye-Hückel equation suggested by Guggenheim[9] for the activity coefficient of an ion, the relation between the thermodynamic and the concentration formation constants, K and K_c, is given by the relation,[10]

$$\log K_c + A'\frac{I^{1/2}}{1+I^{1/2}} = \log K + CI \quad (4)$$

where I is the ionic strength, A', a coefficient obtained theoretically from the Debye-Hückel constant and the ionic charges of the ions involved in the ion-pair formation, and C, an arbitrary parameter. The thermodynamic formation constant of each ion-pair was determined by extrapolating the plot of $[\log K_c + A'I^{1/2}/(1 + I^{1/2})]$ against I to infinite dilution (Fig. 3). In Table 2 the present results are compared with the $\log K$ values obtained by Tanaka and his coworkers from the spectroscopic data.[11]

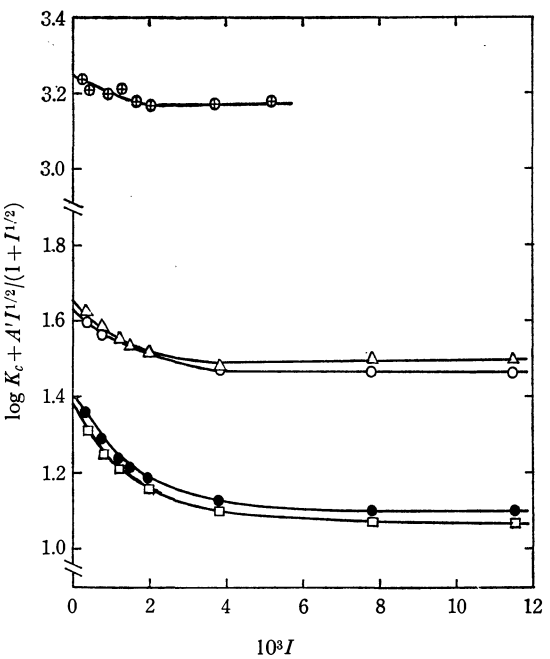

Fig. 3. The determination of thermodynamic formation constants of hexa-amminecobalt(III) perchlorate (-●-), nitrate (-○-), bromide (-△-), iodide (-□-), and oxalate (-⊕-).

If the distance of closest approach of the two ions of an ion-pair is assumed to be equal to the sum of their Stokes radii, the association constant of the ion-pair can be estimated by Bjerrum's theory.[12] The last column of Table 2 presents the log K values calculated theoretically.

In the present analysis of the conductivity data, the deviation of the measured equivalent conductivities from the theoretical Onsager values was entirely attributed to the ion-pair formation of one complex cation with an anion in the solution. Accordingly, the formation constants thus determined may be considered to involve the possible but small contribution from the ion-pairs containing more than one anions. The method of analysis is based upon the assumption that the free ions quantitatively obey the limiting equation of Onsager[7] in dilute solutions, the assumption which, unfortunately, has not been fully examined with higher charge-type electrolytes. Because of this uncertainty involved in the present treatment when applied to the determination of association constants of higher charge-type ions, the results obtained should be subjected to a critical discussion. However, a relatively good agreement of the log K values obtained by the conductivity method with those estimated from Bjerrum's theory (Table 2) suggests that the conductivity method gives reliable information on the ion-pair formation of hexa-amminecobalt(III) ions due to the electrostatic interaction.

A significant difference in the log K values

12) See for example: Ref. 8, pp. 272—275.

determined by the conductivity and spectroscopic methods (Table 2) is supposed to be due to the following reason. The conductometric determination of formation constants is based upon the change in the transport properties of ionic species under electric fields, the properties are not very specific to a particular type of ion interaction. On the other hand, the spectroscopic determination is based upon the change in the charge-transfer spectra; the spectroscopic properties are more specific to the short-range interaction than the transport properties. According to Tanaka and his coworkers, the spectroscopic behavior in the ultraviolet region is expected to give the information on the ion association due to the short-range interactions, and the formation constants determined by this method may be smaller than those obtained from the conductivity data.[11]

The perchlorate ion is usually assumed not to form appreciable ion-pairs with most cations in aqueous solutions. In the present study, however, the ion-pair formation of a perchlorate ion with a hexa-amminecobalt(III) ion was observed, the formation constant of which is of the same order of magnitude as that of iodide ion. This effect of the perchlorate ion must be remembered in the study of ion association in solutions containing relatively large amounts of perchlorate ions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 609—613 (1968)

The Coprecipitation and Spectrophotometric Determination of Iron as 8-Hydroxyquinolinate

Tsunenobu SHIGEMATSU, Masakazu MATSUI, Megumu MUNAKATA and Takayuki SUMIDA

Institute for Chemical Research, Kyoto University, Sakyo-ku, Kyoto

(Received September 16, 1967)

The coprecipitation and spectrophotometric method, which is likened to the solvent extraction and spectrophotometric method, was applied to the following system for the first time; ferric ion was coprecipitated as 8-hydroxyquinolinate with an organic coprecipitant, and was determined spectrophotometrically after the precipitate was dissolved with an organic solvent. The effect of the ligand concentration on the pH *vs.* absorbance curve in the present method was apparently similar to that for solvent extraction. A nearly constant absorbance was obtained above pH 4 at a ligand concentration of 4×10^{-3} M. Over 100 mg of *o*-phenylphenol, an almost quantitative coprceipitation was obtained, though the absorbance decreased gradually as the coprecipitant was increased. The effect of diverse ions was also examined. Titanium(IV), vanadium(V) and molybdenum(VI) interfered considerably, while others have little effect on the absorbance. The method was applied to the determination of trace amounts of iron in natural waters and reagent grade sodium chloride.

The coprecipitation method for trace metal ions with organic coprecipitants has been developed for the chemical separation of radioisotopes, and the chemical enrichment of trace elements in natural water and biological materials.[1-3] Compared with inorganic coprecipitants, such as ferric hydroxide, organic coprecipitants have several advantages such as they are easily eliminated from the precipitate by ashing. This fact is of use especially in the treatment of radioactive solutions, and they are very selective, free from trace elements, and easy to filter.

Kuznetsov[2] has studied several types of organic coprecipitation processes for over 35 elements, and compared them to extraction by solid extractants. Tappmeyer and Pickett[4] have investigated the coprecipitation mechanism of metal 8-hydroxyquinolinates with organic coprecipitants and indicated that the factors influencing the

coprecipitation of these metal chelates with organic coprecipitants like β-naphthol and phenolphthalein were the same as those that influenced solvent extraction. They also noted a similarity between the plots calculated by employing the equilibrium considerations of solvent extraction, and the plots experimentally determined showed good agreement. In our previous paper,[5] the influence of organic coprecipitants on the coprecipitation efficiency of six metals was examined, and it was found that organic coprecipitants with hydroxyl groups such as *o*-phenylphenol or α-naphthol were excellent for coprecipitation. Also it was suggested that a metal ion could be determined spectrophotometrically if the precipitate containing the coprecipitated metal chelate was filtered and dissolved in a suitable organic solvent. This new method is likened to the "solvent extraction and spectrophotometric method." It is expected that the method has the advantages of easiness in chemical treatment, and of good selectivity on chemical separation, which are observed in the extraction method, and a high concentrating efficiency, which is observed in the coprecipitation method.

In the present work, the main object is to examine whether ferric ion is coprecipitated as 8-hydroxyquinolinate with such an organic coprecipitant as *o*-phenylphenol, and is determined spectrophotometrically after the precipitate is dissolved with a suitable organic solvent.

Experimental

Reagents. A standard stock solution of iron was prepared by dissolving the pure metal in 6 N perchloric acid, by adding a few drops of 30% hydrogen peroxide solution, by fuming with concentrated perchloric acid repeatedly and by diluting with deionized water. Reagent grade *o*-phenyplhenol was purified by reduced pressure distillation. 8-Hydroxyquinoline was dissolved in dilute hydrochloric acid.

The other chemicals were chemically pure or reagent grade materials.

Apparatus. A SV 50 Shimadzu automatic recording spectrophotometer was used for the measurement of absorption spectra. For quantitative measurement, a Model 139, Hitachi manual spectrometer was used with absorption cells having a path length of 1.00 cm. pH measurements were performed with a Hitachi-Horiba Model M-3 pH meter.

Procedure. An aliquot of a ferric perchlorate solution containing 11.2 μg of iron per m*l* was taken. Then 2 m*l* of 0.1 M 8-hydroxyquinoline and 5 m*l* of buffered solution (1.0 M NaAc-HAc) were added to the solution. The pH of the solution was then adjusted to the desired pH by the addition of 1 M hydrochloric acid, or 1 M sodium hydroxide. The aqueous phase was finally diluted to 50 m*l* with water. The solution after the pH adjustment was transferred to a 100 m*l* Erlenmeyer flask. Then 0.25 g of *o*-phenylphenol which was ground with the same quantity of sodium chloride in an agate mortar was added to it. After the flask was properly stoppered, it was shaken for 30 min and the solution allowed to settle. The solid phase was carefully filtered with a glass filter and dissolved with a suitable organic solvent, followed by dilution to 10 m*l*. After the solution was filtered through filter paper, the absorbance was measured against a blank solution.

Results and Discussion

Choice of Organic Coprecipitant and Organic Solvent. *o*-Phenylphenol was selected as an organic coprecipitant because it is more stable toward color change over long periods and in alkaline solution than α-naphthol; that is, color change hinders the measurement of absorbance. There are a few methods of treatment for *o*-phenylphenol to increase its efficiency of coprecipitation. The first is the method of crushing the coprecipitant in an agate mortar. The second is that of crushing it together with the same quantity of sodium chloride in the mortar. The third is that of dissolving it in an alkaline solution, followed by fine recrystallization in an acidic solution. In this study, the second method was chosen because of high efficiency, good reproducibility, and an easy method of coprecipitation.

Several kinds of organic solvents were tested in order to examine the easiness of dissolving the precipitate into them, and the final absorbance. The absorbance was measured at 0.620, 0.612, 0.597, 0.510 and 0.470 for benzene, methylisobutylketone, cyclohexane, amylalcohol and benzylalcohol, respectively. Benzene and methylisobutylketone are better than the others in both absorbance and solubility. Methylisobutylketone was used for the present purpose as it is more nonvolatile than benzene. As the chelate reagent does not coprecipitate in the present system, methylisobutylketone containing 2×10^{-3} M of 8-hydroxyquinoline was used to make the 8-hydroxyquinolinate stable.

Absorption Spectra. The absorption spectra for the methylisobutylketone solutions of ferric 8-hydroxyquinolinate containing 0.2, and 5 g of *o*-phenylphenol are compared in Fig. 1. The spectra have their maximum absorptions at 465, and 580 mμ, and as described later, they are slightly affected by the amount of coprecipitant. As the reagent and coprecipitant blank at 465 mμ shows scarcely any absorbance, the absorbance was measured throughout the experiment at that wavelength.

The Effect of pH and the Concentration of Reagent. To establish the optimum pH value of the aqueous phase for the coprecipitation of iron, the dependence of the absorbance of the organic phase on the pH values was studied. In Fig. 2, the absorbance of the organic phase measured at

5) M. Matsui, M. Munakata and T. Shigematsu, *Bull. Inst. Chem. Res., Kyoto Univ.*, **45**, 273 (1967).

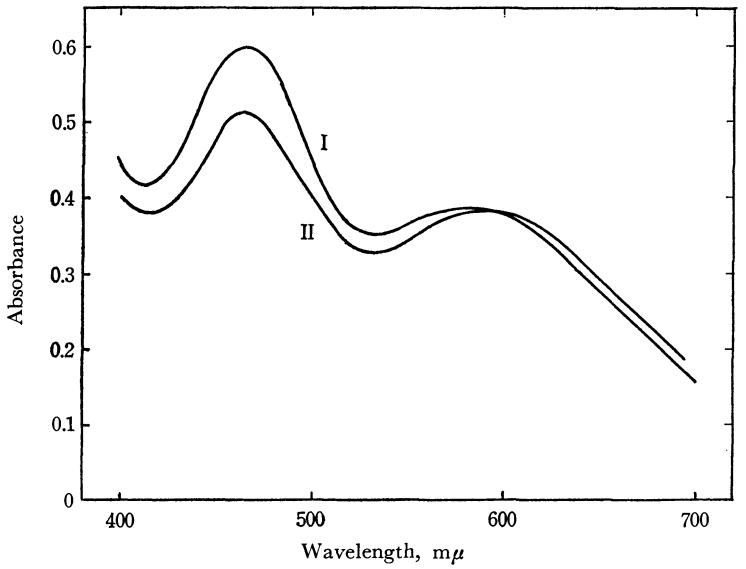

Fig. 1. Absorption spectra of ferric oxinate in methylisobutylketone. *o*-Phenylphenol: I 250 mg, II 5 g, 8-Hydroxyquinoline: 4×10^{-3} M Fe(III): 2×10^{-5} M in aqueous phase, Volume: aqueous phase 50 m*l*, organic phase 10 m*l*, pH: 4.50.

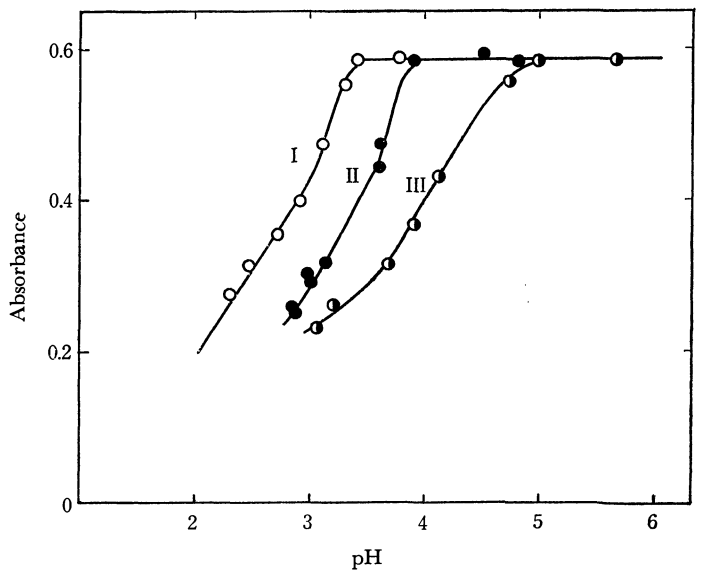

Fig. 2. Effect of pH and reagnet concentration. 8-Hydroxyquinoline: I 1×10^{-2} M, II 4×10^{-3} M, III 4×10^{-4} M. Others are same to in Fig. 1.

465 mμ was plotted against pH. The effect of the concentration of 8-hydroxyquinoline on the pH *vs.* the absorbance curve in the coprecipitation was similar to that in solvent extraction. That is, the chelate coprecipitated in the more acidic range of the solution as the concentration of the reagent became high. However, the shapes of the pH *vs.* absorbance curves of the present work were not so ideal as those of the solvent extraction. This fact shows that in the present system it is difficult to reach a state of true thermodynamic equilibrium. A nearly constant absorbance was obtained above pH 4 when the concentration of the reagent was 4×10^{-3} M. The pH value and reagent concentration were kept at 4.50, and 4×10^{-3} M, respectively, throughout the experiments.

The Effect of the Amount of Coprecipitant. The effect of the amount of *o*-phenylphenol on the

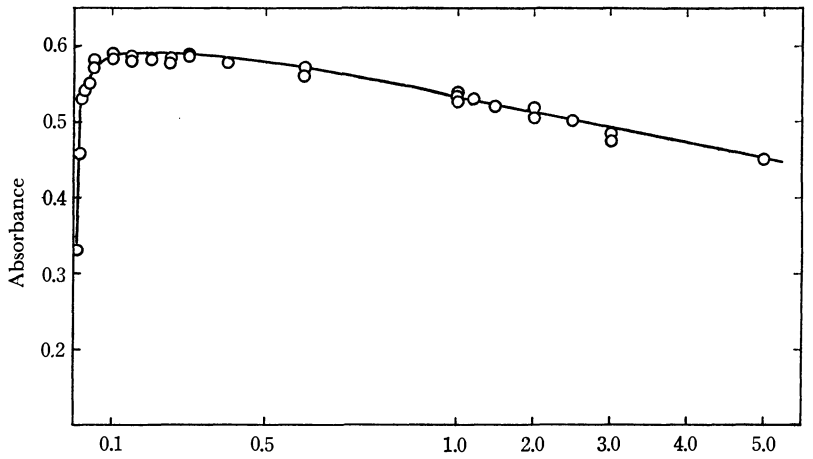

Fig. 3. Effect of *o*-phenylphenol.

absorbance of the organic phase was studied. As shown in Fig. 3, the absorbance of the organic phase increased rapidly until 100 mg of coprecipitant, had a nearly constant value from 100 to 400 mg, and decreased gradually as more coprecipitant was added. The gradual decrease in the absorbance does not mean the lowering of coprecipitation efficiency, but rather the fall in the absorption coefficient of the chelate probably is due to the solvation effect of the polar coprecipitant. This may be seen from the following: The absorbances in the coprecipitation method were identical for any certain of coprecipitant above 250 mg with those in the extraction method (where the same quantity of coprecipitant was added into the methylisobutylketone phase), by which iron was extracted quantitatively. This showed the quantitative coprecipitation of any amount of coprecipitant. Also, the solvation effect was suggested from the absorption spectra in Fig. 1, where there was almost no change in absorption intensity but some change in energy at the longer wavelength, though the absorbance at 465 mμ decreased as precipitant increased. Thus, 250 mg of *o*-phenylphenol was used throughout the experiments.

The Effect of Standing and Shaking Time. The absorbance of the methylisobutylketone solution of ferric 8-hydroxyquinolinate was measured at 465 mμ at appropriate intervals of time to examine the effect of the standing and shaking time. As shown in Fig. 4, little influence of the standing time was observed upon the absorvance of the organic phase. Similarly, the absorbance was almost constant for 5 min and over of shaking time.

Coprecipitation of the Chelate Reagent. To examine the coprecipitation of the reagent with coprecipitant, the following procedure was adopted. Two milliliters of 0.1 M 8-hydroxyquinoline and 1 m*l* of buffer solution was taken in an Erlenmeyer flask. The solution was then adjusted to pH 4.50 and diluted to 50 m*l* with water. The absorbance of the solution was measured at 410 mμ. After the solution was treated according to the process used in this study, the absorbance of the filtrate was measured at the same wavelength, and the procedure was repeated. The corresponding absorbances were 0.591, 0.602 and 0.597. This result indicates that the reagent was scarcely coprecipitated with the coprecipitant.

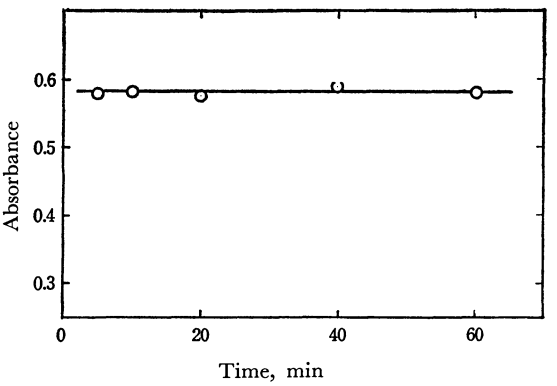

Fig. 4. Effect of shaking time.
pH: 4.5 Wavelength: 465 mμ

Calibration Curves. A calibration curve was made by coprecipitating different amounts of iron with 0.25 g of *o*-phenylphenol as a 8-hydroxyquinoline chelate. The absorbance of the solution at 465 mμ was measured against a blank. A good linear relationship was obtained by plotting the absorbance of the solution against the concentration of iron added in the aqueous solution, as shown in Fig. 5. The other curve in Fig. 5

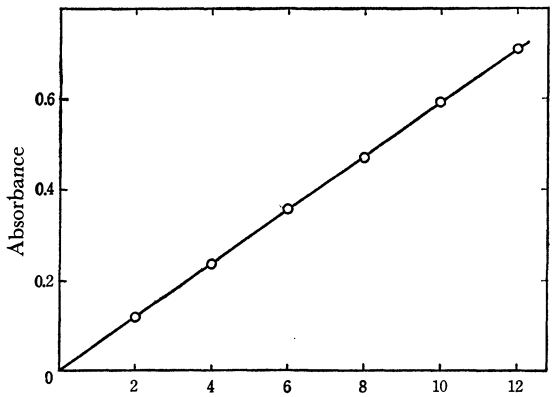

Fig. 5. Calibration curve of ferric oxinate.
pH: 4.5 Wavelength: 465 mμ

was made by extracting iron with 8-hydroxyquinoline into a 10 m*l* portion of methylisobutylketone with 0.25 g of the coprecipitant from 50 m*l* portions of the aqueous solution. As these calibration curves are in good agreement, it is considered that the coprecipitation of iron is almost quantitative.

Table 1. Effect of diverse ions

Zn(II)	0.5	49

* 50 μg of ferric ion was taken.

The Effect of Diverse Ions. The effect of diverse ions was examined with a solution containing 50 μg of iron and diverse ions. The pH value of the solution was adjusted to 4.50. Of the 21 cations tested, titanium(IV), vanadium(V) and molybdenum(VI) gave a positive error, while common di- and tervalent cations had little effect on absorbance, as shown in Table 1.

Applications. The effect of the volume of the solution, and the amount of coprecipitant on the absorbance of the organic phase was examined in order to determine iron in natural water, and in reagent grade sodium chloride. As shown in Table 2, a nearly quantitative recovery was obtained when the coprecipitant increased as the volume of the sample solution increased.

Table 2. The effect of the volume of the solution and the amount of coprecipitant

Volume m*l*	Carrying reagent g	Percent copptn.
100	0.25	99
200	1.0	101
500	1.5	100

Filtered sea and fresh water were acidified to pH 1 with concentrated hydrochloric acid (Sea water was collected in the open sea off Shirahama, Wakayama Pref., and fresh water from Lake Biwa.). Aliquots of these waters were put into Erlenmeyer flasks and 3 g of *o*-phenylphenol was added. These samples were treated according to the procedure used in this study. The results of the determination of iron in aliquots and commercial reagent sodium chloride (guaranteed reagent, and chemical pure grade) are shown in Table 3. These values were determined by the method of standard addition. The method provides several important advantages over the usual method of determination of trace elements in extremely dilute solutions described previously.

A New Anion Exchanger Containing Cobalticinium Cation

Takuji Ito* and Tadao Kenjo**

*Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
**Graduate School of Science and Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 27, 1967)

A New type of anion-exchanger, polymeric olygomethylene cobalticinium cation, was synthesized and its ion-exchange properties and stability toward heat and reagents were investigated in comparison with those of the ion-exchange resins. The preparative method of the exchanger was the same as that for polymeric olygomethylene ferrocene; hexamminecobalt(II) chloride was added to the product of α, ω-dicyclopentadienyl alkane with sodium. Although the pure products could not be obtained, the substance extracted with water showed several peaks common to a cobalticinium cation in IR spectra. The content of cobalt in tetraphenyl borate was 0.175 mmol/g, which corresponded to 91% trimethylene cobalticinium tetraphenyl borate. The saturated ion-exchange capacity of the eschanger was 1.75 meq/g, which was half the theoretical value. This discrepancy could be attributed to the shortage of cobalt according to the results of chemical analysis and magnetic susceptibility measurements. Although ion-exchange resins lose their exchange capacity by heating at 150°C in air, this exchanger was thermostable decreasing to only 70% in ion-exchange capacity. The ion-exchange capacity of the exchanger in hydrothermal water at 220°C decreased to 55—35%, while that of resins drops to as low as 20%. The selectivity coefficient for various anions became smaller in the order; $ClO_4^- > I^- > ClO_3^- > BrO_3^- > Br^- > Cl^- > IO_3^- > F^-$. This tendency was the same as that for ion-exchange resins.

The ion-exchange group as well as the structure of net-works influences the properties of ion-exchangers, such as stability toward high temperature and reagents, and selectivity for ions.

Quaternary ammonium salt type resin has been used most generally during the past decade. However, this type of resin is not stable at high temperature. This weak point can be attributed to the property of quaternary ammonium salt.

Inorganic ion-exchangers such as zirconium oxide, thorium oxide[1] and bismuth hydroxide were synthesized and their properties have been investigated from the point that these inorganic materials are stable at high temperature. In spite of many studies, some weak points, *e. g.*, lower ion-exchange capacity, lower exchange rate, lower reversibility of ion-exchange and higher solubility in acid or akaline solution, have not been improved.

Recently, dicyclopentadienyl metal compounds were found.[2,3] Some of them (compounds of Co(III), Rh(III) and Ir(III)) exist as stable cations in an alkaline medium as well as in water, and do not decompose at high temperature.[2,3] Accordingly, it is expected that a polymer containing these salts exhibits more thermostable properties than the quaternary ammonium type resin. Since the compound of Rh(III) and Ir(III) can not readily obtained, a polymer containing cobalticinium cation (π-dicyclopentadienyl cobalt-(III) cation) was synthesized. The synthesis of the polymer was made according to that of polymeric olygomethylene ferrocene.[4] The reaction steps and the probable structure of the product are as follows;

Experimental

Synthesis of Polymeric Olygomethylene Cobaltocene. Four kinds of α, ω-dibromoalkanes were used; 1, 3-dibromopropane, 1, 4-dibromobutane, 1, 5-dibromopentane and 1, 6-dibromohexane. After the reaction of α, ω-dicyclopentadienyl alkane with sodium metal was completed, the reaction mixture was cooled to 0°C and hexamminecobalt(II) chloride (75 g) added. The temperature was raised gradually in a water bath. Ammonia gas began to evolve at about 25°C. The temperature was maintained until the evolution ceased. Finally the reaction was completed by refluxing for 2 hr. Unreacted sodium and sodium compounds were decomposed with methanol. Solvent was removed by evaporation under reduced pressure after the mixture was centrifuged. The precipitates were extracted with 300 m*l* benzene, and the resulting solutions separated with a centrifuge. Benzene was removed by evaporation under reduced pressure.*1

An aqueous layer was separated and washed with benzene several times. Tetraphenyl borate solution was added to the aqueous solution. Resulting precipitates were dried at 110°C. The cobalt content was 0.175 mmol/g. The theoretical cobalt content calculated from the formula, $Co(C_5H_4)_2(CH_2)_3(C_6H_5)_4B$, is 0.192 mmol/g.

Samples for measurement of IR and UV spectra were prepared from the preceeding aqueous solution after converting to a triiodide, or hydroxide form.

The precipitate obtained from benzene solution was treated with 1 N hydrochloric acid, washed with water and dried at 60°C. Then it was ground and sieved to two kinds of mesh size; 50/100 mesh and 100/200 mesh. The exchangers were conditioned by alternate treatment with 2 N HCl and 2 N NaOH. After washing with distilled water, it was converted to the desired salt forms.

Preparation of Cobaltocene and Cobalticinium Salts. Cobaltocene was prepared in accordance with the method of Cordes,[5] from sodium cyclopentadienide and hexamminecobalt(II) chloride. Cobalticinium salts were obtained by treating cobaltocene with dilute hydrochloric acid and purified by recrystallization of the picrate. The desired salt forms were obtained by anion exchange resin columns.

Measurements of Ion-exchange Capacity, pH-titration Curves, Selectivity Coefficient and Ion-exchange Rate. Ion-exchange capacities at different pH, and pH-titration curves were measured in a 0.1 M (KCl+HCl) solution of constant ionic strength. The volume of the solution was 25 m*l*, and the amount of sample, 0.250 g. After equilibration, pH measurements were made with a pH-meter with a glass electrode. Adsorption capacities were measured from the decrease in the concentration of chloride ion, which was determined potentiometrically by titration with silver nitrate solution. pH-titration curves for cobalticinium hydroxide and polymeric tetramethylene cobalticinium hydroxide were measured by titrating 50 m*l* of 0.146 N solution of cobalticinium hydroxide, and 50 m*l* of 0.124 N solution of polymeric tetramethylene cobalticinium hydroxide with 0.1 N HCl, respectively.

Selectivity coefficients for ions of SCN^-, I^-, Br^- and Cl^- were measured on exchangers of the NO_3 form, and others on exchangers of the Cl form. Measurements were carried out at 25.00±0.01°C. Neutral salt solutions (0.1 M) were added to a certain amount of the exchangers. After 24 hr, halogenide ion, and thiocyanate ion concentrations were determined by the method previously mentioned. The selectivity coefficient (K_B^A) was computed according to the definition:

$$K_B^A = \left(\frac{m_B}{m_A}\right)_r \Big/ \left(\frac{m_A}{m_B}\right)_w ,$$

where m_B is meq. of B^- and m_A is that of A^-, the subscript r refers to the phase of the exchanger, and w the phase of the external solution. The amount of m_A and m_B in the exchanger can be obtained from the amount of ions adsorbed, and the saturated capacity.

The ion-exchange rate was measured at 25.00±0.01°C. After ion-exchangers of the OH form (100/200 mesh) were added to 100 m*l* of 0.1 N HCl with stirring, the decrease in concentration of Cl^- ion was determined by the method previously mentioned. The fractional attainment of equilibrium was computed as the fraction of ion adsorbed at a given time to the amount of ion adsorbed after equilibration.

Measurements of Stability toward Temperature and Reagents. Stability toward heat was measured by heating exchangers of the OH form in an oven, or in hydrothermal water in an autoclave. After treatment, the ion-exchange capacity was measured. Stability toward reagents was measured by treating exchangers of the OH form with hydrochloric, sulfuric and nitric acids of varying concentrations at room temperature for 24 hr. After the adsorbed ions were eluted with 5 N NaOH, the exchangers were washed with water, dried at 60°C, and the ion-exchange capacities measured.

Analysis of Cobalt and Measurement of IR and UV Spectra. Cobalt was determined by the gravimetric method as Co_3O_4, or by chelatometric titration with 0.01 N EDTA using XO as indicator, after cobaltocene was destroyed with fuming perchloric acid. UV spectra were recorded on an EPS-2 Hitachi recording spectrophotometer, and IR spectra on an EPI-S2 Hitachi spectrophotometer with a KBr disk.

The magnetic susceptibility of the pentamethylene cobalticinium compound was measured by the Guoy method using water ($\kappa = -0.72 \times 10^{-6}$ c.g.s. unit/g) as a standard.

Results and Discussion

The IR spectrum of polymeric tetramethylene cobalticinium triiodide exhibits 5 peaks common to those of cobalticinium triiodide, as shown in Fig. 1. The UV spectrum in Fig. 2 shows that the peaks of the polymer shift to longer wavelength relative to cobalticinium ion.

The ion-exchange of Cl^- ion from 0.1 N HCl on the exchanger of the OH form is rapidly attained, almost at the same rate as with the ion-exchange

*1 Ferrocene compounds were separated from organic impurities (hydrocarbons) by oxidation with $FeCl_3$ solution. The compounds of cobaltocene, however, were very difficult to separate in this manner owing to the formation of an emulsion of benzene and water.

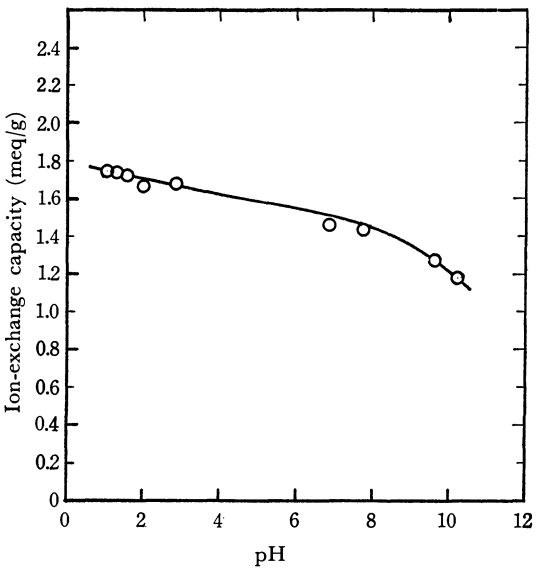

Fig. 4. pH dependence of the ion-exchange capacity of the polymeric pentamethylene cobalticinium (OH form).

hydrochloric acid and sodium hydroxide is shown in Table 1.

The magnetic susceptibility of the pentamethylene cobalticinium compound was 1.3×10^{-6} c.g.s.unit/g, whereas that of cobaltocene was 6.8×10^{-6} c.g.s. unit/g,[2] and cobalticinium ion was found to be diamagnetic.[2] Therefore, this weak paramagnetism of the compound suggests that the discrepancy between the saturated ion-exchange capacity and the cobalt content may be attributed to cobaltocene which is not oxydized to cobalticinium ion.

A discrepancy between the saturated ion-exchange capacity, and the value calculated from the formula weight indicates the presence of organic impurities. Although it is unknown what the impurities are, the main impurity could be supposed to be α,ω-dicyclopentadienyl alkane which did not react with sodium. Although these impurities decreased

the saturated ion-exchange capacity, they also decreased the solubility of the exchanger.

Ion-exchange capacity does not change greatly with pH, as may be seen in Fig. 4. This fact suggests that the exchanger is of a strong base type. Although cobalticinium hydroxide is a very strong base, it seems to become weaker with polymerization, as can be seen from the comparison of the pH-titration curve of cobalticinium hydroxide with that of polymeric tetramethylene hydroxide (Fig. 5).

Decreases in ion-exchange capacities with temperature in air are given in Fig. 6. Resins were decomposed completely at 150°C, while this exchanger decreased to 70% in ion-exchange capacity. Decreases in ion-exchange capacity in water are shown in Fig. 7. The exchanger did not decrease so greatly as ion-exchange resin in capacity. The resins were more stable toward heat in water than in air. This fact may be explained as being due to the sensitivity of the quaternary ammonium ion to air. From the fact that cobalt hydroxide was detected in water after heating in the autoclave, it is apparent that the cobalticinium ion decomposes to the hydroxide and hydrocarbons. As for the stability of other forms of exchangers to heat, salt forms were more stable than the OH form. After heating at 205°C for

6	1.029	1.209	1.272	0.909

0.764 meq/g, and 0.784 meq/g, respectively, under the same conditions.

The decrease in ion-exchange capacity with treatment by reagents is shown in Table 2. Hydrochloric, and sulfuric acids do not affect the exchangers as seriously as nitric acid. Possibly, nitric acid liberates cobalticinium cation from the polymer by destroying the olygomethylene links.

After a rather large decrease in the ion-exchange capacity due to the first treatment with acid, the anion-exchange capacity remained almost constant after several alternate treatments with acid and sodium hydroxide, as shown in Table 3. This means that almost all ions adsorbed were eluted with sodium hydroxide.

As for the influence of the number of carbon chains connecting cobalticinium cations, compounds with carbon chains of 4 or 5 are the most stable toward reagents (Table 2). As the number increases, however, grinding the sample becomes difficult owing to the increase of elasticity. From the point of practical application, compounds with carbon chains of 4 or 5 are the most suitable.

The selectivity coefficient of this exchanger is summarized in Table 4. The order of the coefficient is the same as that for resins. The properties of the cobalticinium salts are therefore nearly the same as those of the quaternary ammonium ion.

Solvent Extraction of Cadmium(II) from Aqueous Chloride and Bromide Solutions by Tri-*n*-octylamine

Hiroto WATANABE and Kunihiko AKATSUKA

Department of Industrial Chemistry, The Muroran Institute of Technology, Muroran

(Received October 11, 1967)

The distribution of cadmium(II) between dilute hydrochloric or hydrobromic acid solution and tri-*n*-octylamine dissolved in a number of diluents has been measured for several cadmium(II) loadings and amine concentrations. Diluents investigated are *n*-hexane, cyclohexane, benzene, xylene, toluene, carbon tetrachloride, chloroform, chlorobenzene and *o*-dichlorobenzene. The results show that all the species extracted into various diluents are present in the form of bis(tri-*n*-octylammonium)tetrahalocadmium(II). The specific ability of each diluent in extracting cadmium(II) from acidic halide solutions is approximately correlated with the dielectric constant of the pure diluent, suggesting that the dissociation of ion paired alkylammonium salt in the organic phase is responsible for the extraction.

It has been shown in our previous papers[1,2] that the formation of binegatively charged thiocyanate complexes is responsible for the extraction of iron(III) and cobalt(II) from acidic thiocyanate media with tri-*n*-octylamine in various organic diluents. The influence of diluents on the extraction of these metal ions was approximately correlated with the dielectric constant of the diluents. A similar study was carried out in the present investigation for the extraction of cadmium(II) from hydrochloric or hydrobromic acid solutions with tri-*n*-octylamine.

It is well known that cadmium(II) easily forms halo-complexes which are extractable into an organic phase with amines dissolved in various diluents,[3-6] and is generally accepted that the cadmium(II) species thus extracted is the tetrahalo-complexes of cadmium(II).[7,8] The present investigation was undertaken to obtain further information about the diluent influence on the extraction behavior of cadmium(II).

Experimentals

Apparatus. An Iwaki-V-S Shaking Unit was employed to carry out the equilibration. A Hitachi Model-139 Spectrophotometer was used to determine the concentration of cadmium(II) spectrophotometrically

Reagents. All reagents used were of analytical grade, and were further purified, if necessary. Tri-*n*-octylamine obtained from Kao Soap Co., Ltd. was converted to the chloride or bromide form by equilibrating the amine solution (0.1 N) in an appropriate dilutent twice with an equal volume of 0.5 N hydrochloric or hydrobromic acid. Then, the organic phase was separated and diluted to cover the concentration range studied. The concentration of the alkylammonium salt dissolved in various diluents was determined by potentiometric titration with a standard sodium hydroxide solution in ethanol medium.

The stock solution of cadmium(II) bromide was obtained by precipitation of the cadmium(II) hydroxide and subsequent dissolution in hydrobromic acid.

Diluents used and their dielectric constants in Debye Units were as follows[9]: *n*-hexane (1.9), cyclohexane (2.0), xylene, benzene (2.3), toluene (2.4), carbon tetrachloride (2.2), chloroform (5.0), chlorobenzene (5.8) and *o*-dichlorobenzene (9.9). The xylene used in this study was a mixture of three isomers and hence the dielectric constant was not given above.

Procedure. For all operations, 20 m*l* each of amine-halide solution and cadmium(II) halide solution were mixed together in a 100 m*l* glass separatory funnel and the mixture was equilibrated at room temperature. Fifteen minute shaking period at a rate of 120 strokes per minute was more than adequate. Then, the aqueous phase was filtered through paper to remove entrained organic phase. Aliquot portions were taken

and the cadmium(II) content in the aqueous phase was determined either spectrophotometrically with 4-(2-pyridylazo)resorcinol or complexometrically with Eriochrome Black T as an indicator. Spectrophotometric determination of cadmium(II) with 4-(2-pyridylazo)resorcinol has not yet been reported, but the following procedure used in our preliminary experiments is adequate both in the sensitivity and in the reproducibility for the purpose of the present investigation. One m*l* of aqueous 4-(2-pyridylazo)-resorcinol solution (2.5×10^{-3} M) is added to the aliquot of the aqueous phase. Adjusting the pH to 9.8 with a sodium hydroxide solution and a borate buffer solution prepared by the standard method, the orange color was developed and the solution was diluted to 25 m*l* with pure water. The absorbance was measured at 495 mμ in a 10 mm quartz cell using a reagent blank as a reference. Beer's law was followed up to 2 mg/*l* of cadmium(II) in the 20 m*l* of aqueous phase.

The amount of cadmium (II) in the organic phase was calculated by material balance.

Results

The effects of amine concetration on the distribution of cadmium(II) between both phases were examined at fixed concentrations of cadmium(II) and hydrochloric or hydrobromic acid. The distribution ratio, q, is defined as the total concentration of cadmium(II) in the organic phase divided by that in the aqueous phase,

$$q = \sum[\mathrm{Cd}]_o/\sum[\mathrm{Cd}]_w$$

where subscripts o, w stand for the organic and aqueous phase respectively. Figures 1 and 2 summarize the results on the various diluents. It is apparent that there is a close relationship between the extractability of the amine and the dielectric constant of the diluents. On the influence of diluents the order of increasing extractability agrees fairly well with those obtained by previous studies[1,2] for the extraction of iron(III) and cobalt(II) from acidic thiocyanate media.

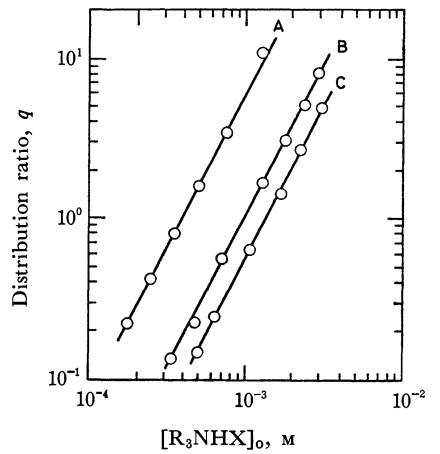

Fig. 2. Distribution of cadmium(II) as a function of amine concentrations from 0.10 N hydrobromic acid; 4.54×10^{-5} M total cadmium.
(A) benzene, (B) chlorobenzene, (C) *o*-dichlorobenzene

To determine the stoichiometry of the organic cadmium(II) species by measuring the maximum loading number which is the maximum equivalents of amine per mole of cadmium(II) in organic phase, loading curves were determined in a fixed concentration of amine (5×10^{-3} M) dissolved in cyclohexane and toluene. The results are shown in Figs. 3 and 4, which indicate a maximum $\sum[\mathrm{Cd}]_o/\sum[\mathrm{Amine}]_o$ for conditions of maximum loading being close to 0.5.

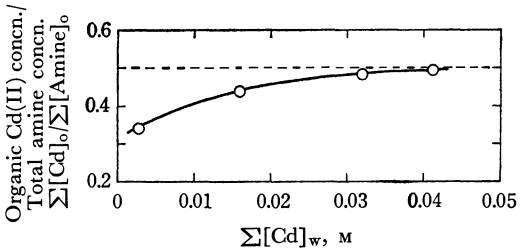

Fig. 4. Loading curve; 5.06×10^{-3} M tri-*n*-octylamine in toluene, 0.5 N hydrochloric acid in aqueous phase.

Discussions

In the present investigation, where the acids used are not over 0.5 N, the extraction of the excess acid by tri-*n*-octylamine can be assumed to be negligibly small.[10,11] Thus, the reaction between the amine in various diluents and hydrochloric or hydrobromic acids can be written as:

$$R_3N + H^+ + X^- \rightleftharpoons R_3NHX \qquad (1)^{12}$$

where R_3N refers to the tri-*n*-octylamine and R_3NHX indicates its ammonium salt form. As it has been indicated by several authors,[11,13] the equilibrium constant of reaction (1) is in the order of magnitude 10^6. Therefore, under the conditions of the present study, one equivalent of amine combines with one equivalent of hydrochloric or hydrobromic acid and the species, R_3NHX, is formed in the organic phase almost quantitatively.

The simplest generalized equation for the extraction of cadmium(II) can be written as follows:

$$mR_3NHX + CdX_2 \rightleftharpoons (R_3NH)_mCdCl_{2+m} \qquad (2)$$

Assuming that the amine salts exist as monomeric species and that the activity coefficients of each species in both phases are essentially unchanged throughout the experiments, the corresponding mass action law expression in terms of concentration is derived as

$$K_m = [(R_3NH)_mCdX_{2+m}]_o / [R_3NHX]_o^m[Cd^{2+}][X^-]^2\beta_2 \qquad (3)$$

where β_2 denotes the cumulative formation constant of the aqueous species, CdX_2. Then the distribution ratio, q, may be expressed in terms of K_m;

$$q = A\sum_{m=1}^{M} K_m[R_3NHX]_o^m \qquad (4)$$

where A denotes $\beta_2[X^-]^2/(1+\sum_{n=1}^{4}\beta_n[X^-]^n)$. If halide concentration $[X^-]$ in aqueous phase is kept constant, the product of $[R_3NHX]_o$ by the derivative of q with respect to $[R_3NHX]_o$ is given by;

$$dq[R_3NHX]_o/d[R_3NHX]_o = A\sum_{m=1}^{M} mK_m[R_3NHX]_o^m \qquad (5)$$

Using Eq. (3), we can now introduce the average number of amine molecules combined with cadmium(II) halo-complexes in the organic phase.

$$\bar{m} = \sum_{m=1}^{M} mK_m[R_3NHX]_o^m / \sum_{m=1}^{M} K_m[R_3NHX]_o^m \qquad (6)$$

From Eqs. (4) and (5), the average number of combined amines, $\bar{m}$, can be written as follows:

$$\bar{m} = d\log q / d\log [R_3NHX]_o \qquad (7)$$

Equation (7) shows that, if halide concentration $[X^-]$ is kept constant, the slope of the $\log q$ *vs.* $\log[R_3NHX]_o$ gives the average number of amine molecules combined with halide complex of cadmium(II) in the organic phase. As shown in Figs. 1 and 2, log-log plots of q *vs.* $[R_3NHX]_o$ for different diluents at a fixed concentration of the aqueous hydrochloric or hydrobromic acid yield straight lines of slope ~ 2 within the experimental error. This means that only a single species is extracted and the binegatively charged CdX_4^{2-} complexes are formed in the organic phase.

In Eqs. (4) and (7), $[X^-]$ and $[R_3NHX]_o$ denote the equilibrium concentrations. As the total concentration of cadmium(II) is in the order of magnitute of 10^{-5} M, the analytical concentrations of the amine ($>10^{-4}$ M) and the hydrohalic acids ($>10^{-1}$ M) are large enough and they can be assumed to be kept unchanged throughout the extraction.

The results in Figs. 1 and 2 are confirmed by the loading curves shown in Figs. 3 and 4. The maximum loading numbers indicate two equivalents of amine per mole of cadmium(II) in cyclohexane and toluene and presumably in other diluents. From these results it is concluded that the charge of the cadmium complex extracted is -2 and hence the species present is CdX_4^{2-}.

The influences of diluents on the extraction of cadmium(II) from the same aqueous phase by tri-*n*-octylamine are also shown in Figs. 1 and 2. These figures indicate that the extractability is correlated approximately with the dielectric constant of diluent; the smaller the value of dielectric constant, the larger the extractability. In the present results, the diluent effect is not so apparent compared with the previous ones on the extraction of iron(III) and cobalt(II) from acidic thiocyanate solutions, that is, in Fig. 1 benzene, toluene and xylene behave identically and carbon tetrachloride shows smaller extractability than that of aromatic diluents irrespective of the comparable magnitude of the dilelectric constant. However, in a series of the diluents of similar structures it can be said that the extractability is lowered with increasing dielectric constant except for nitrobenzene in the aromatic diluents which was examined in the previous study.[2] From the examination of the Eq. (1), Diamond *et al.*[13] reported that the alkylammonium salts dissociate in nitrobenzene. Assuming that the alkylammonium salt behaves as a Bjerrum type ion pair, the increase of the dissociation of $R_3NH^+X^-$ would occur with increasing the dielectric constant of the diluent. In other diluents the ion paired alkylammonium salt presumably dissociates to a smaller extent depending

on the dielectric constant of the diluent. From such considerations in the medium of smaller dielectric constants such as *n*-hexane or benzene, ion paired alkylammonium salts will not appreciably dissociate and hence the activity coefficient of amine salts should be unity under these experimental conditions. This may be an important factor illustrating the high extractability for these diluents. On the contrary, as a result of the dissociation of the ion pairs in the medium of the larger dielectric constant, the activity of amine salt is considered to be smaller than in the previous case, irrespective of the increased solvation by the dipole of the diluent molecules.

Such consideration may lead to the conclusion that the higher the dielectric constants is the lower is the extractability. However, as it has been shown in our previous paper,[2] nitrobenzene has the high extractability which is comparable to that of cyclohexane. In this case the interaction between the dipole of the dilutent molecules and the ion paired alkylammonium salt must be strong enough compared with other diluents used in the present study. Therefore, if strong dissociation may occur, the activity coefficient of amine salt would be approximately unity because of the strong affinity of nitrobenzene to the ion pairs. In a series of our researches the alkylammonium cation is tri-*n*-octylammonium ion, so the small difference in behavior between the thiocyanate, chloride and bromide systems must be due to the anion size. From such considerations it is evident that the dissociation of the ion paired alkylammonium salt and the solvating properties of the diluent molecules to the ion pairs are the important factors goverining the extraction of metal ions.

The authors wish to express their thanks to Professor Masayo Murozumi of The Muroran Institute of Technology for his encouragement and valuable discussions and to Professor Masaichi Nagayama, Dr. Katsumi Goto and Mr. Takao Yotsuyanagi of The Hokkaido University for their helpful discussions and for citicizing the manuscript. We are also indebted to Mr. Sakae Matsumura for assistance with part of the experimental work.

The Photochemical Reduction of Hydrazobenzene*1

Shizunobu HASHIMOTO, Junzo SUNAMOTO*2 and Syunpei NISHITANI

Department of Appied Chemistry, Doshisha University, Kamikyo-ku, Kyoto

(Received April 26, 1967)

Hydrazobenzene was irradiated with an ultraviolet light in *n*-hexane under a nitrogen atmosphere. The products were azobenzene, aniline, and a trace of semidines. The yield of azobenzene was usually larger than that calculated on the basis of the disproportionation of hydrazobenzene, while the yield of aniline was less. The reactions were followed by the determination of the disappearance of hydrazobenzene and that of the formation of azobenzene. On the basis of the available data, in the photochemical reaction of hydrazobenzene it was assumed that the formation of azobenzene was not due to the disproportionation, but to the oxidation of hydrazobenzene, and that no fission of the N–N bond of hydrazobenzene occurred to give azobenzene.

Hydrazobenzene and its derivatives partly disproportionate to give the aromatic amine and the aromatic azo compound in the acid-catalyzed benzidine rearrangement,[1] as in Eq. (1):

$$2\,\text{Ar-NHNH-Ar} \rightarrow \text{Ar-N=N-Ar} + 2\,\text{Ar-NH}_2 \quad (1)$$

The thermal reaction of hydrazobenzene has also been studied by Stiegliz and Crume,[2] who have presented evidence that the rate of this reaction was given by the first-order equation with respect to the concentration of hydrazobenzene and was according to the processes shown in Eqs. (2) and (3):

$$\text{Ar-NHNH-Ar} \rightarrow \text{Ar-N:} + \text{Ar-NH}_2 \quad (2)$$

*1 Presented at the 19th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1966.

*2 Present address; Department of Organic Synthesis, Fuculty of Engineering, Kyushu University, Hakozaki, Fukuoka.

$$Ar\text{-}N: \rightarrow Ar\text{-}N{=}N\text{-}Ar \quad (3)$$

On the other hand, Weiss has observed qualitatively the formation of azobenzene and aniline by irradiation with an ultraviolet light (2300—2700 Å) on a methanol solution of hydrazobenzene.[3]

The present investigation was undertaken in order to examine in detail the photochemical reaction of hydrazobenzene, which was irradiated with an ultraviolet light (2537 Å) in *n*-hexane.

Result and Discussion

Azobenzene Formation and Hydrazobenzene Disappearance. Hydrazobenzene was irradiated with an ultraviolet light in *n*-hexane at different temperatures. The results obtained are shown in Fig. 1. Clearly, the yield of azobenzene is dependent upon the reaction temperature and on

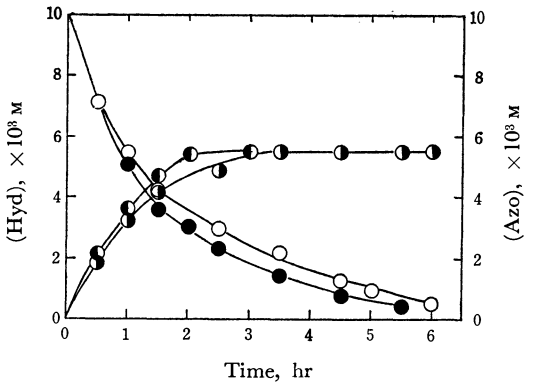

Fig. 1. The disappearance of hydrazobenzene at 35.0°C. (○) and at 45.5°C (●), and the formation of azobenzene at 35.0°C (◑) and at 45.5°C (◐) are indicated.

TABLE 1. THE PER CENT YIELDS OF AZOBENZENE IN THE PHOTOCHEMICAL REACTION OF HYDRAZOBENZENE

Temp. °C	Initial concn. of hydrazobenzene ×10³M				
	10	8	6	5	4
9.0±0.1	—	—	77	80	83
17.6±0.1	—	65	70	—	77
35.0±0.1	55	56	60	64	67

the initial concentration of hydrazobenzene, as Table 1 shows; as the reaction temperature becomes lower, the yield of azobenzene increases. In every run azobenzene was produced in an amount larger than that calculated on the basis of the disproportionation of hydrazobenzene. The aniline formation proceeded further after the azobenzene formation terminated. The formation of aniline was semiquantitatively identified by paper chromatography throughout the reaction. Therefore, it seems most reasonable to assume that there may be another process for the aniline formation, independent of the azobenzene formation. In addition, there seems certainly to be some kind of intermediate for the aniline formation. This intermediate may easily return to hydrazobenzene in the dark or during the determination of the hydrazobenzene. Unfortunately, we can not estimate the structure of this intermediate from the available experimental evidence.

The relation between the concentration of hydrazobenzene and the rates of the formation of azobenzene has been plotted, the rate of the formation of azobenzene was, thereby, given by this first-order equation (Eq. (4)):

$$\frac{d(Azo)}{dt} = k'_1(Hyd) \quad (4)$$

where (Azo) is a concentration of azobenzene, (Hyd) is that of hydrazobenzene, and k'_1 is an apparent rate constant. On the other hand, the rate of disappearance of hydrazobenzene is given by a second-order equation in the initial stage and by a first-order equation in the final stage, in which azobenzene is no longer produced, only aniline:
in the initial stage;

$$-\frac{d(Hyd)}{dt} = k'_2(Hyd)^2 \quad (5)$$

in the final stage;

$$-\frac{d(Hyd)}{dt} = k'_3(Hyd) \quad (6)$$

All the experimental data and the rate constants are given in Table 2.

N-N Fission of Hydrazobenzene. Holt and Hughes have reported[4] that no fission of the N-N bond of hydrazobenzene occurred in the pyrolysis of ^{15}N-labeled hydrazobenzene. In order to examine the N-N fission in the present reaction, *n*-hexane solutions of 4-chlorohydrazobenzene and of 4-methoxyhydrazobenzene were each irradiated under the same conditions as those used for hydrazobenzene above, and the products were identified by thin-layer chromatography (silica gel). No disubstituted or unsubstituted azobenzene was ever detected, only the corresponding monosubstituted azobenzene; that is, 4-chloroazobenzene and 4-methoxyazobenzene were obtained, respectively, together with a small amount of their cis isomers. Therefore, no N-N fission leading to the formation of an azo compound occurs in the present reaction.

Effects of Reaction Products. A definite amount of azobenzene or aniline was added from the beginning of the reaction. However, such

d) In the dark.

additions had no effects on the reaction (see Table 2). It is, therefore, clear that the azobenzene and aniline produced in the course of the reaction never reacted photochemically under our reaction conditions and had no inner-filter effect. Moreover, although hydrogen gas produced together with azobenzene in the present reaction, it was found that hydrazobenzene gas also had no effects on the reaction, and that no further reduction of azobenzene by hydrogen gas occured. In order to examine the possible formation of new products by radical-chain transfer to a solvent, the solvents used were examined by gas chromatography before and after the reaction (Shimadzu GC-50, DOP column 2.25 m long, H_2, 110 ml/min, at 51°C). However, no new products were observed on the gas chromatogram.

Assumption of Reaction Scheme. It is very difficult to estimate the reaction course on the basis of only the results obtained above. If the simplest case is assumed, however, without any deactivation processes of the photoexited molecules, the following processes are probable:

$$\text{Hyd} \xrightarrow{h\nu} \text{Hyd}^* \quad (7)$$

$$\text{Hyd}^* \longrightarrow \text{Ar-}\dot{\text{N}}\text{-NH-Ar} + \text{H}\cdot \quad (8)$$

$$\left.\begin{matrix}\text{Ar-}\dot{\text{N}}\text{-NH-Ar}\\ \text{Ar-NH-}\dot{\text{N}}\text{-Ar}\end{matrix}\right\} \rightarrow \left\{\begin{matrix}\text{Ar-N=N-Ar}\\ \text{Ar-NHNH-Ar}\end{matrix}\right. \quad (9)$$

$$2\text{H}\cdot \rightarrow \text{H}_2 \quad (10)$$

$$\text{Hyd} \underset{\text{in the dark, } -2\text{H}}{\overset{h\nu,\ +2\text{H}}{\rightleftarrows}} \text{(Intermediate)} \xrightarrow{h\nu} \text{Aniline} \quad (11)$$

First, hydrazobenzene absorbs the ultraviolet light and is excited. The monoradical (Ar-$\dot{\text{N}}$-NH-Ar)[5] may thereby be produced *via* the excited hydrazobenzene. Subsequently, azobenzene may be formed by the disproportionation of the monoradical. In the initial stage, the azobenzene formation may occur parallel to the aniline formation. When the hydrazobenzene has disappeared, however, the azobenzene formation may spontaneously terminate and only the aniline formation from the intermediate may proceed. The rate equations of the hydrazobenzene disappearance and the azobenzene formation, derived from the proposed reactions ((7)—(11)) on the basis of the stationary-state assumption for the concentrations of the

5) J. K. S. Wan, L. D. Hess and J. N. Pitts, Jr., *J. Am. Chem. Soc.*, **80**, 2069 (1964).

monoradical and the hydrogen radical, fit Eqs. (4), (5), and (6), obtained from the kinetic measurements.

Experimental

Materials. The hydrazobenzene was prepared from nitrobenzene by the usual method and used after careful purification (mp 126°C). *trans*-Azobenzene was prepared by the air oxidation of hydrazobenzene and was recrystallized from methanol (mp 67°C). The solvent used were obtained commercially and were purified by the usual method; *n*-hexane, bp 68.5°C, $n_D^{20}=1.3750$; *n*-heptane, bp 98.5°C, $n_D^{20}=1.3877$. They were completely deaerated and were replaced by nitrogen. The reagents of an analytical grade were obtained commercially and were used without any special pretreatment.

Identification of Products. The photochemical reaction of hydrazobenzene was carried out under the same conditions as those used in the kinetic experiments; after irradiation of a sufficient duration in *n*-hexane, the resulting solution was submitted to paper chromatography according to the method given in the literature.[6] After careful examination, the following products were identified: *p*-semidine (R_f 0.22, violet), aniline (R_f 0.43, red), *o*-semidine (R_f 0.80, reddish violet), and azobenzene (R_f 0.98, yellow). The yields of azobenzene, aniline, *o*-semidine, and *p*-semidine were 56 mol%, 40 mol%, 0.25 mol%, and 0.25 mol% respectively on the basis of the hydrazobenzene.

Procedures for Rate Measurement. About 100 m*l* of a *n*-hexane or *n*-heptane solution of hydrazobenzene was placed in a 200 m*l* four-necked flask equipped with a reflux condenser, an outlet tube, a nitrogen-inlet tube, and a low-pressure mercury vapor lamp (2537 Å, 15 W). The flask was immersed for five minutes at a given temperature in a thermostat regulated and flushed by nitrogen. The reaction begun by the irradiation. At appropriate time intervals, samples were pressed out by nitrogen and were submitted to iodometry and photometry as follows.

Analytical Procedures. The unchanged hydrazobenzene was determined by iodometry modified from the method of Stieglitz and Crume.[2] Although the effects of coexistent materials, such as azobenzene, aniline, or a small amount of semidines, were investigated in detail, there is no interference by them with the determination of hydrazobenzene in this procedure. The probable error in the determination of hydrazobenzene was ±0.02%.

The azobenzene produced was determined by the usual photometry on a Erma Type-5 photometer, since azobenzene has the characteristic absorption bands in the visible region. However, a calibration curve prepared with *trans*-azobenzene could not be used for the determination of the azobenzene produced in the course of the reaction, because *trans*-azobenzene isomerizes to give the *cis*-isomer upon irradiation.[7] Therefore, the calibration curve was corrected by the use of irradiated azobenzene in a state of cis-trans equilibrium. The calibration curves were in good accordance with Beer's law.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 626—628 (1968)

The Synthesis of Agarobiose*[1]

Susumu HIRASE, Choji ARAKI[2]* and Kiyoshi ARAI

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Kyoto

(Received May 13, 1967)

Agarobiose, 3, 6-anhydro-4-*O*-β-D-galactopyranosyl-L-galactose, was synthesized by a series of reactions involving the condensation of 1, 2-*O*-isopropylidene-3, 6-anhydro-L-galactopyranose with tetra-*O*-acetyl-α-D-galactosyl bromide, deacetylation with sodium methoxide, and the hydrolytic removal of the *O*-isopropylidene group. The resulting disaccharide, and its osazone and dimethyl acetal were identical with the corresponding authentic samples obtained naturally.

Agarobiose is a disaccharide which has been obtained from agar by a partial acid hydrolysis.[1] The structure has been dientified as 3, 6-anhydro-4-*O*-β-D-galactopyranosyl-L-galactose (I) on the basis of chemical evidence.[2,3] The idsaccharide was later isolated in the forms of diethyl thioacetal

*1 This paper was reported in outline by one of the authors (C. A.) at the 5th International Seaweed Symposium, Halifax, Canada, August, 1965.

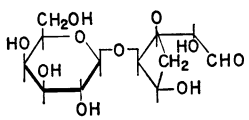
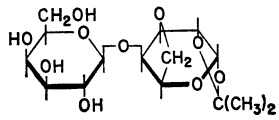
and dimethyl acetal from agar[3,4] and the polysaccharide of the red seaweed *Gloiopeltis furcata*.[5] The present paper will deal with the synthesis of the disaccharide.



(I)



(IV)

The starting compound, 1, 2-*O*-isopropylidene-3, 6-anhydro-L-galactopyranose (II), prepared by the condensation of 3, 6-anhydro-L-galactose (III) with acetone in a manner previously reported,[6] was allowed to condense with tetra-*O*-acetyl-*α*-D-galactopyranosyl bromide in chloroform in the presence of silver oxide and anhydrous calcium sulfate. The deacetylation of the product with sodium methoxide and subsequent purification on a cellulose-powder column gave crystalline 1, 2-*O*-isopropylidene-3, 6-anhydro-4-*O*-*β*-D-galactopyranosyl-L-galactose (IV). The removal of the *O*-isopropylidene group with dilute sulfuric acid yielded 3, 6-anhydro-4-*O*-*β*-D-galactopyranosyl-L-galactose (I) in an amorphous form. This disaccharide was then converted to the crystalline phenylosazone. Furthermore, IV was treated with dilute methanolic hydrogen chloride to give the dimethyl acetal of I. These derivatives were identical with those prepared from natural agarobiose.

Experimental

General Procedure. Solutions were evaporated under reduced pressure at about 40°C. Paper chromatography was performed on Toyo Filter Paper No. 51 using a 1-butanol - acetic acid - water (4 : 1 : 2 v/v) mixture. The chromatographic spray reagent used was *o*-aminophenol in ethanol acidified with phosphoric acid.[7]

1, 2-*O*-Isopropylidene-3, 6-anhydro-L-galactopyranose (II). III (4.5 g), obtained by the hydrolysis of the dimethyl acetal,[8] was shaken in a mixture of acetone (300 m*l*) and concentrated sulfuric acid (3 m*l*) with anhydrous cupric sulfate (30 g) at room temperature for 5 hr. The mixture was then filtered, neutralized with sodium carbonate, and re-filtered. The filtrate was evaporated to a syrup, which was then dissolved in water (30 m*l*). An insoluble oil was removed by filtration with charcoal, and the filtrate was repeatedly extracted with chloroform. The evaporation of the extracts gave a mobile syrup (3.0 g) which crystallized on standing. The product was recrystallized twice from ether-hexane (1 : 1 v/v); yield 1.2 g; mp 91—92°C, $[\alpha]_D^{20}$ −26.8° (*c* 1.17, water). The values reported for the enantiomorph are mp 92°C and $[\alpha]_D^{14}$ +26.94° (water).[6]

Found: C, 53.28; H, 6.89%. Calcd for $C_9H_{14}O_5$: C, 53.46; H, 6.98%.

1, 2-*O*-Isopropylidene-3, 6-anhydro-4-*O*-*β*-D-galactopyranosyl-L-galactopyranose (IV). A mixture of II (3.0 g), silver oxide (7.5 g), Drierite[9] (15 g), and some pieces of glass beads was shaken in chloroform (60 m*l*) for 1 hr. Tetra-*O*-acetyl-*α*-D-galactopyranosyl bromide[10] (6.2 g) was then added, and the resulting mixture was shaken at room temperature for 24 hr. The mixture was filtered, and the filtrate was evaporated to dryness. The residue (7 g) was dissolved in a mixture of absolute methanol (50 m*l*) and a 0.1 N sodium methoxide solution (5 m*l*), and left at room temperature for 3 hr. The neutralization of the solution with carbon dioxide and subsequent evaporation afforded a syrup, which was then taken up in water (20 m*l*) and washed with chloroform (recovery of II: 1.2 g). The aqueous layer of the extraction was evaporated to a syrup (4.9 g), which was then repeatedly extracted with boiling acetone. The syrup (3.0 g) obtained on the evaporation of the extract showed several spots on a paper chromatogram. This syrup was chromatographed on a cellulose-powder column (4×35 cm) using a 1-butanol - water (6 : 1 v/v) mixture. Fractions of 14 m*l* were collected and monitored by paper chromatography. A compound with R_f 0.49 was obtained as a syrup (1.8 g). Crystallization was effected by dissolving it in acetone (5 m*l*), and by adding ethyl acetate (5 m*l*) and then ether (5 m*l*); yield 1.3 g, mp 173—175°C. Two recrystallizations from an acetone - ethyl acetate (1 : 2 v/v) mixture gave IV in prisms; mp 175—177°C, $[\alpha]_D^{16}$ −24.8° (*c* 1.29, water), $[\alpha]_D^{16}$ −35.0° (*c* 1.03, methanol).

Found: C, 49.62; H, 6.52%. Calcd for $C_{15}H_{24}O_{10}$: C, 49.45; H, 6.64%.

Agarobiose (I). The compound IV (0.20 g) was heated with 0.02 N sulfuric acid (10 m*l*) at 100°C. The optical rotation of the solution changed from $[\alpha]_D$ −25.5° to a constant value of $[\alpha]_D$ −18.0° within 45 min. The solution was then neutralized with barium carbonate and filtered, and the filtrate was evaporated to dryness. The residue was dissolved in methanol, filtered, and then evaporated to give a colorless, amorphous solid (I) (0.15 g), $[\alpha]_D^{15}$ −15.9° (*c* 0.82, water). It reduced a Fehling solution at room temperature and restored the color to a Schiff reagent.

Phenylosazone: mp 220—221°C, $[\alpha]_D^{16}$ −136.2° (5 min)→−109.2° (44 hr, *c* 0.42, pyridine-methanol (2 : 3 v/v)). (For the reported physical constants, see Refs. 3 and 4.) The melting point was not depressed on admixture with an authentic sample of natural origin.

Found: C, 57.88; H, 5.74; N, 11.11%. Calcd for $C_{24}H_{30}O_8N_4$: C, 57.36; H, 6.02; N, 11.15%.

Agarobiose Dimethyl Acetal. The compound IV (0.30 g) was refluxed with 0.5% methanolic hydrogen

Synthesis of Pyridoxine. II. The Preparation of Pyrrole Derivatives

Masuo MURAKAMI, Kozo TAKAHASHI, Jun MATSUMOTO, Kazuharu TAMAZAWA, Kiyoshi MURASE, Hidenori IWAMOTO and Masaru IWANAMI

Central Research Laboratory, Yamanouchi Pharmaceutical Co., Ltd., Azusawa-cho, Itabashi-ku, Tokyo

(Received June 16, 1967)

A new method for the synthesis of 2-acetyl-3, 4-diethoxycarbonylpyrrole and its derivatives by the Diels-Alder reaction is described, and the reaction mechanism of their formation is discussed.

In the previous paper,[1] we reported that 5-ethoxycarbonyloxy-4-methyloxazole (I) reacted with diethyl fumarate (II) to give 4, 5-diethoxycarbonyl-3-hydroxy-2-methylpyridine (III). Investigating this reaction furthermore, we found an isomer of III was produced as by product. The isomer III was also obtained by treatment of the intermediate (V), shown in Scheme 1, in the aftermentioned reaction, with ethanolic hydrochloric acid only in 10—20% yield, but the yield of IV was increased to 50—60%, when the ethanolic hydrochloric acid was replaced by aqueous hydrochloric acid as shown in Table 1.

In this paper, we will confirm the structure of IV as 2-acetyl-3, 4-diethoxycarbonylpyrrole and discuss the reaction mechanism. Although the synthesis of pyridine derivatives by the Diels-Alder reaction has been reported by a number of workers,[2] the formation of pyrrole derivatives as described here has never been noticed.

The compound IV is a weakly acidic substance and insoluble in both diluted hydrochloric acid and sodium bicarbonate solution. An ultraviolet (UV) spectrum of IV had absorption maxima at 281 mμ (log $\varepsilon = 4.712$) in ethanol. The nuclear magnetic resonance (NMR) spectrum of IV had two triplets at δ 1.31 and 1.40 (6H), a singlet at 2.41 (3H), two quartets at 4.26 and 4.42 (4H), a doublet at 7.53 (H) and a broad peak at about 10.50 (H) (ppm, $CDCl_3$). On treatment with D_2O, the doublet at δ 7.53 due to an aromatic proton collapsed to a singlet, which indicated

that the aromatic proton was adjacent to =NH or –OH group. The infrared (IR) spectrum of IV had the absorption bands at 3260 (=NH), 1700, 1280 (–CO–) and 1670, 1360 (C=O) (cm^{-1}, KBr). The presence of an acetyl moiety was ascertained both by the formation of 2, 4-dinitrophenylhydrazone (VI) and a positive iodoform test. Chlorination of IV with phosphorus pentachloride gave the trichloro compound (VII). The NMR spectrum of VII showed no signal at δ 2.41, indicating the CH_3CO– group of IV had been chlorinated to CCl_3CO–. The reaction of IV with diazomethane gave colorless crystals (VIII). The IR spectrum of VIII showed no absorption band at 3260 cm^{-1}, suggesting the absence of =NH group. The presence of =NH group in IV was ascertained also by the formation of its *p*-acetoaminobenzenesulfonamide derivative (IX). Alkaline hydrolysis of IV gave the corresponding dicarboxylic acid (X), proving that IV is an ester. Refluxing of X in acetic anhydride yielded 2-acetyl-3, 4-dicarboxylpyrrole anhydride (XI), the structure of which was confirmed by the characteristic absorption bands of anhydride at 1850 and 1790 cm^{-1} in the IR spectrum. This fact indicated that two –COOH groups in X were situated vicinal to each other. Decarboxylation of the calcium salt of X gave 2-acetylpyrrole (XII). Reduction of IV with sodium borohydride gave a

* as hydrochloride

secondary alcohol XIII, which in turn was transformed into 3, 4-diethoxycarbonyl-2-ethylpyrrole (XIV) by hydrogenation over palladium-charcoal in methanol under acidic condition. This compound XIV was identified with the authentic sample which was prepared from diethyl propionyl succinate (XV) by the method of Kornfeld.[3] (Scheme 2)

Next we examined the NMR spectrum of the reaction mixture of the Diels-Alder reaction and noticed that there was no signal of ring proton as I, III and IV. On the basis of this result, it was presumed that V is considerably stable in the course of the Diels-Alder reaction and is decomposed only by the addition of acid to give pyridine and pyrrole derivatives. As shown in Scheme 3, V would be decomposed by two different pathes (A) and (B). When ethanolic hydrochloric acid was added to V, the oxygen bridge of V would be cleaved to III according to the process A. When aqueous hydrochloric acid was added to V, the hydrolysis of -CH=N- bond of V would predominantly occur to give IV *via* B. The reaction of 5-ethoxy-4-methyloxazole (XVIII) or 2, 4-dimethyl-5-ethoxyoxazole (XIX) with diethyl fumarate (II), or XVIII with diethyl maleate also gave the corresponding pyrrole derivatives as shown in Table 2.

Experimental

The Diels-Alder Reaction (Pyrrole Derivatives): The Reaction of 5-Ethoxycarbonyloxy-4-methyloxazole (I) with Diethyl Fumarate (III). *A) Decomposition of the Reaction Mixture, Adduct (V), with Ethanolic Hydrochloric Acid. A-1)* A mixture of I (8.6 g) and II (34.5 g, 4 equiv.) was heated at 100°C for 2 hr. After cooling, 8 N ethanolic hydrochloric acid (50 m*l*) was added and the mixture was allowed to stand for 30 min at room temperature, then the ethanol was

3) E. C. Kornfeld and R. G. Jones, *J. Org. Chem.*, **19**, 1671 (1954).

removed *in vacuo*. When ether (100 m*l*) was added to the resulting residue, 4, 5-diethoxycarbonyl-3-hydroxy-2-methylpyridine (III) was precipitated as hydrochloride, which was collected by filtration, 7.0 g (48.6%), mp 147—148°C (decomp.).

Found: C, 49.70; H, 5.58; N, 5.07%. Calcd for $C_{12}H_{15}O_5N \cdot HCl$: C, 49.74; H, 5.57; N, 4.84%.

The mother liquor was washed with water, 5% aqueous sodium bicarbonate and water successively, and dried over anhydrous magnesium sulfate. The solvent, ether and excess II, was removed by evaporation to afford pale yellow oily residue. The residue was dissolved in a small volume of benzene and by addition of petroleum ether, 2-acetyl-3, 4-diethoxycarbonylpyrrole (IV) was precipitated. The product was recrystallized from benzene - petroleum ether to give the pale yellow crystals, mp 101—102°C (2.6 g, 12.6%).

Found: C, 57.21; H, 5.92; N, 5.48%. Calcd for $C_{12}H_{15}O_5N$: C, 56.91; H, 5.97; N, 5.53%.

A-2) A mixture of I (2.0 g) and II (4.0 g, 2 equiv.) was heated at 90°C for 6 hr and the reaction mixture was treated as above. The yield of the hydrochloride of III was 1.65 g (48.8%) and the yield of IV was 0.6 g (19.5%).

B) Decomposition of the Adduct (V) with Aqueous Hydrochloric Acid. B-1) A mixture of I (17.0 g) and II (69.0 g, 4 equiv.) was heated at 100°C for 2 hr. After cooling, 10% aqueous hydrochloric acid (50 m*l*) was added to the reaction mixture and it was allowed to stand for 30 min at room temperature. The resulting solution was extracted with ether and the ether layer was washed with 5% aqueous hydrochloric acid, water, 5% aqueous sodium bicarbonate and water succesively, and dried over anhydrous magnesium sulfate. The solvent, ether and excess II, was removed by evaporation to afford pale yellow oily residue. The residue was treated as described in A-1) to give IV, yield 12.5 g (50%). The aqueous layer was neutralized with sodium bicarbonate, and was extracted with ether. After the ether solution was washed with water and dried over anhydrous magnesium sulfate, gaseous dry hydrogen chloride was bubbled into the ethereal solution. The compound III was deposited as hydrochloride, yield 5 g (17.4%).

B-2) A mixture of I (1.6 g) and II (3.2 g, 2 equiv.) was heated at 90°C for 6 hr and the reaction mixture was treated as described in B-1). The compound IV was yielded 1.27 g (54%) and III was also obtained as hydrochloride, yield 0.3 g (11.1%).

The Reaction of 5-Ethoxy-4-methyloxazole (XVIII) with Diethyl Fumarate (II). A mixture of XVIII (2.0 g) and II (5.0 g) was heated at 90°C for 1.5 hr and the reaction mixture was decomposed with 10% aqueous hydrochloric acid (5 m*l*). Treatment of the solution obtained according to the same method as in B-1) yielded IV, 1.8 g (45%) and III, 1.4 g (30%) as hydrochloride. When the reaction mixture was decomposed with 8 N ethanolic hydrochloric acid and the resulting solution was treated by the same method as in A-1), III was obtained as hydrochloride in the yield of 80% and IV in a trace amount.

Instead of II, when the diethyl maleate as dienophile was reacted with XVIII, the results were similar to those mentioned before.

The Reaction of 2, 4-Dimethyl-5-ethoxyoxazole (XIX) with Diethyl Fumarate (II). A mixture of XIX (1.0 g) and II (1.35 g) was heated at 80°C for 1 hr. After removing the excess II *in vacuo*, aqueous hydrochloric acid (20 m*l*) was added to the resulting mixture. After stirring for 20 min, ethanol (10 m*l*) was added to the solution, and homogeneous solution thus obtained was stirred for further 10 min. The solution was evaporated *in vacuo* until ethanol was largely removed and the remaining aqueous phase was extracted twice with chloroform (50 m*l*). The chloroform layer was washed with 5% aqueous sodium bicarbonate and water, and dried over anhydrous magnesium sulfate. The solvent was removed by evaporation to yield an oily residue. On addition of 8 N ethanolic hydrochlorio acid, the pyridine derivative, 3, 4-diethoxycarbonyl-2, 6-dimethyl-5-hydroxypyridine (XX), was precipitated as hydrochloride. After collecting the product by filtration, *n*-hexane was added to the mother liquor, 2-acetyl-3, 4-diethoxycarbonyl-5-methylpyrrole (XXI) was precipitated, which was recrystallized from benzene - *n*-hexane to afford colorless needles, mp 103—104°C. Yield 200 mg.

Found: C, 58.64; H, 6.21; N, 5.69%. Calcd for $C_{13}H_{17}O_5N$: C, 58.42; H, 6.41; N, 5.24%. IR (KBr-Wafer): 3300 (=NH); 1652 cm^{-1} (C=O)

The aqueous layer, after being extracted with chloroform, was neutralized with 5% aqueous sodium bicarbonate and extracted with ether. The extract was washed with water and dried over anhydrous magnesium sulfate. Gaseous hydrogen chloride was passed into this ethereal solution to give XX as hydrochloride, mp 150°C (decomp.). The total yield of XX as hydrochloride was 1.8 g (80%).

Found: C, 51.69; H, 6.00; N, 4.85%. Calcd for $C_{13}H_{17}O_5N \cdot HCl$: C, 51.40; H, 5.97; N, 4.61%.

The Reaction of the Isomer (IV). 2, 4-Dinitrophenylhydrazone of IV (VI). To a solution of IV (0.5 g) in 95% ethanol, 2, 4-dinitrophenylhydrazine sulfuric acid solution was added. After heating at 50°C for several min, the reaction mixture was allowed to stand overnight at room temperature. The precipitated crystals were collected and recrystallized five times from 95% ethanol. The compound VI was obtained as monohydrate of orange needles, yield 0.7 g. After drying over phosphorus pentoxide at 100°C for 6 hr *in vacuo*, VI changed into anhydrous red crystals, mp 195°C (decomp.).

Found: C, 49.84; H, 4.55; N, 16.29%. Calcd for $C_{18}H_{19}O_8N_5$: C, 49.88; H, 4.42; N, 16.16%.

3, 4-Diethoxycarbonyl-2-trichloroacetylpyrrole (VII). A mixture of IV (0.4 g), phosphorus oxychloride (5 m*l*) and phosphorus pentachloride (1.5 g) was heated at 120°C for 4 hr. After phosphorus oxychloride was removed, water was added to the oily residue and the mixture was extracted with ether. The ethereal extract was dried over anhydrous magnesium sulfate and evaporated *in vacuo* to give white crystals. Recrystallization of the product from benzene afforded VII (0.2 g), needles, mp 195°C (decomp.). Found: Cl, 30.38%. Calcd for $C_{12}H_{12}O_5NCl_3$: Cl, 29.83%.

2-Acetyl-3, 4-diethoxycarbonyl-1-methylpyrrole (VIII). Into an ethereal solution of diazomethane which was prepared from *N*-nitrosomethyl urea (4 g), 2.0 g of IV was dissolved and the mixture was allowed to stand overnight at room temperature. VIII was deposited

from the solution as white needles, mp 117—118°C. Yield 1.4 g.

Found: C, 58.54; H, 6.35; N, 5.43%. Calcd for $C_{13}H_{17}O_5N$: C, 58.42; H, 6.41; N, 5.24%. IR (KBr-Wafer): 1660 cm^{-1} (C=O). NMR ($CDCl_3$): singlet (3H) at δ 3.90 ($N-CH_3$).

1-(*p*-Acetoaminobenzenesulfonyl)-2-acetyl-3,4-diethoxycarbonylpyrrole (IX). To a suspension of the sodium salt of IV (1.53 g) in anhydrous pyridine (10 m*l*), *p*-acetoaminobenzenesulfonyl chloride (1.8 g) was added at room temperature. After stirring for 2 hr, the reaction mixture was poured into water and extracted with chloroform. The extract was washed with 5% aqueous hydrochloric acid, water, 5% aqueous sodium bicarbonate and water successively, and dried over anhydrous magnesium sulfate. Evaporation of the solvent left a crude product of IX, which was recrystallized from chloroform-ether to give 1.6 g of IX mp 179—180°C. Found: C, 53.28; H, 4.82; N, 6.23%. Calcd for $C_{20}H_{22}O_8N_2S$: C, 53.33; H, 4.92; N, 26.2%.

2-Acetyl-3,4-dicarboxylpyrrole (X). The compound IV (3.0 g) was dissolved in 20% aqueous sodium hydroxide (20 m*l*) and the solution was refluxed for 1.5 hr. The reaction mixture was cooled with ice-water and then strongly acidified with conc. hydrochloric acid. The precipitated product was collected and recrystallized from water. After drying over phosphorus pentoxide at 100°C for 6 hr, 2.0 g of X was obtained as yellow platelets, mp 210°C (decomp.).

Found: C, 48.72; H, 3.66; N, 7.42%. Calcd for $C_8H_7O_5N$: C, 48.74; H, 3.58; N, 7.11%.

2-Acetyl-3,4-dicarboxylpyrrole Anhydride (XI). A mixture of X (500 mg), acetic anhydride (6 m*l*) and glacial acetic acid (2 m*l*) was heated at 140°C for 4 hr. After cooling, the solvent was removed *in vacuo*. The residue was dissolved in ether and an insoluble product was removed. The ethereal solution was evaporated to give the crude product of XI, which was recrystallized from ethyl acetate to afford pale yellow needles, mp 196—197°C (decomp.). Yield 360 mg.

Found: C, 53.62; H, 2.82; N, 8.10%, Cacld for $C_8H_5O_4N$: C, 53.64; H, 2.81; N, 7.82%. IR (KBr-Wafer): 1850, 1790 cm^{-1} (-CO-O-CO-)

2-Acetylpyrrole (XII). To an aqueous solution of X (1.0 g), calcium carbonate (0.5 g) was added and heated at 110°C. The slurry was dried up to give the calcium salt of X, which was heated over an alcohol lamp under reduced pressure (15—20 mmHg) to give dark yellow oily product. This material was fractionally distilled under the same pressure to afford pale yellow oily product, which was crystallized to give white needles of XII, mp 90—91°C. Yield 50 mg.

Found: N, 12.62%. Calcd for C_6H_7ON: N, 12.84%. IR (KBr-Wafer): 3240 (=NH), 1640 cm^{-1} (C=O).

3,4-Diethoxycarbonyl-2-(α-hydroxyethyl)pyrrole (XIII). To a methanolic solution of IV (5.0 g), sodium borohydride (2.0 g) was added in portionwise at 5—10°C for 20 min. The reaction mixture was neutralized to pH 7 with 10% aqueous hydrochloric acid and methanol was largely removed, and the remaining aqueous phase was extracted with ether. After the ethereal solution was dried over anhydrous magnesium sulfate, the solvent was distilled off and the residue was recrystallized from benzene to afford white crystal of XIII, mp 109—110°C. Yield 4.5 g.

Found: C, 56.45; H, 6.65; N, 5.68%. Calcd for $C_{12}H_{17}O_5N$: C, 56.46; H, 6.71; N, 5.49%.

3,4-Diethoxycarbonyl-2-ethylpyrrole (XIV). To a methanolic solution of XIII (500 mg), conc. hydrochloric acid (0.1 m*l*) and 5% palladium charcoal (1.2 g) were added and hydrogenation was carried out at room temperature. After the reaction was over, the catalyst was filtered off and the filtrate was evaporated *in vacuo* at or below 40°C. The oily residue was extracted with ether, washed with water, 5% aqueous sodium bicarbonate and water successively, and dried over anhydrous magnesium sulfate. After removing the solvent, colorless oily residue was dissolved in a small amount of benzene, and *n*-hexane was added until the solution became turbid. The resulting mixture was allowed to stand several days in a freezer. The product XIV was crystallized as white prisms, which was recrystallized from benzene-*n*-hexane, mp 106—107°C. Yield 90 mg.

Found: C, 60.15; H, 7.10; N, 6.16%. Calcd for $C_{12}H_{17}O_4N$: C, 60.24; H, 7.16; N, 5.86%.

The structure of XIV was identified with an authentic sample prepared from diethylpropionyl succinate (XV).

3,4-Diethoxycarbonyl-2-ethylpyrrole (XIV) from Diethylpropionyl Succinate (XV). Diethyl-1-(α-ethylenedioxy)propyl Succinate (XVI). A mixture of diethylpropionyl succinate (XV) (10 g), ethylene glycol (10 m*l*), *p*-toluenesulfonic acid (0.7 g) and benzene (350 m*l*) was refluxed for 25 hr. The benzene solution was washed with 5% aqueous sodium bicarbonate, dried over anhydrous magnesium sulfate and fractionally distilled under reduced pressure to give XVI, bp 115—120°C/0.3 mmHg. Yield 4 g.

Diethyl-1-(α-ethylenedioxy)propyl-2-formyl Succinate (XVII). Finely divided sodium (0.35 g) was suspended in 10 m*l* of absolute ether, and absolute ethanol (0.1 m*l*) was added with stirring. A mixture of XVI (3.5 g) and ethyl formate (1.45 g) was added dropwise to the ethereal solution during 1 hr and the reaction mixture was allowed to stand overnight. Ice and water were added to the solution, the aqueous layer was separated and acidified with 10% aqueous sulfuric acid at or below 0°C. The aqueous layer was extracted twice with ether (20 m*l*) and the extract was dried over anhydrous magnesium sulfate. After removing the solvent, the oily residue was distilled under reduced pressure at 120°C to afford XVII 0.9 g. The crude product was sufficiently pure for cyclization.

3,4-Diethoxycarbonyl-2-elthylpyrrole (XIV). A solution of crude XVII (0.75 g) in 5 m*l* of absolute ether was mixed with ammoniac ethanol (0.6 m*l*). The mixture was stirred for 10 min and evaporated under reduced pressure to remove ether and ethanol. The residual oily product was mixed with 2 m*l* of concentrated sulfuric acid keeping the temperature below 55°C. After 5 min, the sulfuric acid solution was poured onto 10 g of ice with stirring. The mixture was extracted twice with 10 m*l* of ethyl acetate and the extract was washed with 5% aqueous sodium bicarbonate, dried over anhydrous magnesium sulfate and the solvent was evaporated. The residual product was extracted with boiling water. After cooling the extract, the deposited white crystalline product was collected and dried over phosphorus pentoxide *in vacuo*.

Recrystallization from benzene-*n*-hexane afforded XIV as white needles, mp 106—107°C. Yield 120 mg.

Found: C, 60.41; H, 7.27; N, 5.78%. Calcd for $C_{12}H_{17}O_4N$: C, 60.24; H, 7.16; N, 5.86%.

The authors wish to express their gratitude to the staffs of the analysis labolatory of this faculty for elemental analyses, infrared and nuclear magnetic resonance spectra measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 633—635 (1968)

Chemical Synthesis of *O*-Ethyl-L-homoserine, a New Amino Acid Produced by *Corynebacterium Ethanolaminophilum*

Yoshikatsu MUROOKA, Tokuya HARADA and Yoshiharu IZUMI*1

Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received June 22, 1967)

The synthesis of *O*-ethyl-DL-homoserine (V) was achieved by the condensation of β-ethoxyethylbromide (II) with diethyl acetoaminomalonate (III) and by the successive hydrolysis of diethyl ethoxyethylacetoaminomalonate (IV) with hydrochloric acid. The optical resolution of *O*-ethylhomoserine was performed enzymatically using papain. The *O*-ethyl-L-homoserine (VIII) obtained by the resolution was shown to be identical with the amino acid formed ethanol by *Corynebacterium ethanolaminophilum*, sp.nov.

In a previous paper,[1] *Corynebacterium ethanolaminophilum*, strain E17, was reported to form new amino acids when grown in a well-aerated medium containing ethanol, *n*-propanol, or *n*-butanol. The chemical properties and structures of these compounds were investigated by Murooka and Harada; the amino acids formed from ethanol, *n*-propanol, and *n*-butanol were assumed to be, respectively, *O*-ethylhomoserine (Compound E), *O*-propylhomoserine and *O*-butylhomoserine on the basis of a study of the infrared spectrum and the nuclear magnetic resonance spectrum and on the basis of an elemental analysis.

In the present paper, in an attempt to identify the structures of these compounds, the DL- and L-forms of *O*-ethylhomoserine were prepared by the process described in the following scheme (a preliminary account of part of this work has already appeared):[2]

$$\underset{\text{I}}{CH_3\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}OH} \xrightarrow{PBr_3}$$

$$\underset{\text{II}}{CH_3\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2Br} \xrightarrow[NaOC_2H_5]{HC(COOC_2H_5)_2NHCOCH_3} \underset{\text{III}}{}$$

$$\underset{\text{IV}}{CH_3\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}C(COOC_2H_5)_2\text{-}NHCOCH_3} \xrightarrow{HCl}$$

$$\text{DL-}CH_3\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}CHNH_2\text{-}COOH \quad \underset{\text{V}}{}$$

$$\downarrow C_6H_5CH_2OCOCl$$

$$\underset{\text{IV}}{\text{DL-}CH_3\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}CH(NH\text{-}CO\text{-}O\text{-}CH_2\text{-}C_6H_5)\text{-}COOH}$$

$$\downarrow \text{papain},\ C_6H_5NH_2$$

$$\text{L-}CH_3\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}CH(NH\text{-}CO\text{-}O\text{-}CH_2\text{-}C_6H_5)\text{-}CONHC_6H_5$$

$$\downarrow HCl$$

$$\text{L-}CH_3\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}CHNH_2\text{-}COOH$$

The optical rotatory value of the L-compound (VIII) obtained was $[\alpha]_D^{30}$ −14° (*c* 2.5, water); this value was accordant with that[1] of the compound formed from ethanol by the bacterium. The infrared spectrum of the *O*-ethyl-L-homoserine (VIII) obtained by the optical resolution was identical with that of the bacterial product, while that of the racemate was rather different from that of the L-compound (Fig. 1). Thus, it was confirmed that Compound E was *O*-ethyl-L-homoserine. The syntheses of *O*-propylhomoserine and *O*-butylhomoserine are in progress.

Experimental

β-Ethoxyethylbromide (II). β-Ethoxyethanol (I) was brominated with phosphorus tribromide by the

procedure of Harrison and Diehl.[3]

***O*-Ethyl-DL-homoserine (V).** To 700 m*l* of an ethanolic solution of sodium ethylate (prepared from 30 g of sodium), 217 g of III and 1 g of potassium iodide were added. To the reaction mixture, 212 g of II were then added with heating over a 4-hr period, after which the reaction mixture was heated for a further 3 hr. The reaction mixture was removed from the sodium bromide by filtration, and the filtrate was evaporated to dryness. The residue was hydrolyzed with 1.5 *l* of 10% hydrochloric acid for 7 hr. The hydrolysate was evaporated to dryness *in vacuo* to remove the hydrochloric acid. The residue was dissolved in 300 m*l* of water and adjusted to pH 6.0 with sodium hydroxide. This solution was evaporated to dryness *in vacuo*, and the residue was extracted with 500 m*l* of 80% methanol. The solution was concentrated *in vacuo*, and the residue was dissolved with 50 m*l* of hot water. This solution was stored in a cold room, and then the crude material was collected and washed with aqueous acetone. The concentration of acetone was increased from 40% to 80%. The crystals which formed were dissolved in 100 m*l* of water, and a pure crystalline material was precipitated by the addition of 200 m*l* of acetone; yield, 95 g; mp 262°C.

Found: C, 49.25; H, 8.85; N, 9.58%. Calcd for $C_6H_{13}NO_3$: C, 48.96; H, 8.90; N, 9.52%.

Carbobenzoxy-*O*-ethyl-DL-homoserine (VI). Sodium hydroxide (50 g) in 100 m*l* of water and 63 g of carbobenzoxy chloride in 50 m*l* of dioxane were simultaneously added to a 400 m*l* aqueous solution of 50 g of V and 13 g of sodium hydroxide at 5°C over a period of about 3 hr. Stirring was then continued for another hour at the same temperature. The reaction mixture was washed twice with 150 m*l* of ether, and the aqueous layer was acidified to pH 3 with 5 N hydrochloric acid. The resulting oily precipitate was extracted with 300 m*l* of ethyl acetate. The ethyl acetate layer was extracted with 400 m*l* of 3.4% sodium bicarbonate solution.

The aqueous layer was acidified again and reextracted with 300 m*l* of ethyl acetate. The organic layer was washed twice with 30 m*l* of water to remove hydrochloric acid and dried over anhydrous sodium sulfate. The solution was then concentrated *in vacuo*. After the solution had been cooled in an ice bath, crystalline carbobenzoxy-*O*-ethyl-DL-homoserine appeared. The crystalline material was dissolved into 50 m*l* of benzene, after which 10 m*l* of petroleum ether were added to the solution. White, crystalline carbobenzoxy-*O*-ethylhomoserine was collected and dried in air; yield, 82 g; mp 65—66°C.

Found: C, 59.86; H, 6.77; N, 4.99%. Calcd for $C_{14}H_{19}NO_5$: C, 59.77; H, 6.81; N, 4.98%.

Carbobenzoxy-*O*-ethyl-L-homoserine Anilide (VII). The procedure was a modification of the method of Bergmann and Fraenkel-Conrat.[4]

An enzyme solution was prepared from 20 g of papaya latex by extraction with a mixture of 40 m*l* of a 0.5 M citrate buffer (pH 5.5) and 60 m*l* of water, and the suspension was filtered after incubation for one hour. Then 80 g of VI, 28 g of aniline, and 1 g of potassium cyanide were dissolved in 500 m*l* of water at 40°C. The solution was mixed with a papain-buffer solution at pH 7.0, and then the pH was adjusted to 5.5 with citric acid. After about ten minutes incubation at 38°C, synthetic anilide separated out as an oily material. It was dissolved by adding water to the incubated mixture, and the pH was readjusted to 5.5 with citric acid. After two days storage, 28 g of crude anilide separated out as crystals. These were filtered and washed with water and methanol. The crude material was recrystallized from 70 m*l* of aqueous ethanol (60%) (as white crystals); yield, 25 g; mp 105°C.

Found: C, 67.38; H, 6.83; N, 7.93%. Calcd for $C_{20}H_{24}N_2O_4$: C, 67.39; H, 6.79; N, 7.86%.

***O*-Ethyl-L-homoserine (VIII).** Twenty-five grams of VII were hydrolyzed with 10% hydrochloric acid for 7 hr. The lower layer of benzyl chloride separated off and was discarded. The upper layer was washed with ether and evaporated to dryness. The residue was dissolved in water and passed through Dowex

Episulfones. III. Reductive Cleavage of Episulfones by Complex Metal Hydrides

Shoichi MATSUMURA, Toshikazu NAGAI and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Higashinoda, Osaka

(Received July 15, 1967)

The reduction of *cis*-stilbene episulfone (I) by such a complex metal hydride as lithium borohydride, sodium borohydride, or lithium aluminum hydride gave dibenzylsulfone (V) selectively as a result of the unusual cleavage of the carbon-carbon single bond. Comparing the difference between lithium aluminum hydride and lithium borohydride or sodium borohydride in various solvent systems, we suggest that particular solvent effects are operating in the present reaction. The reduction of I with lithium aluminum hydride resulted in a low yield (0—10%) of V, while the reduction with lithium borohydride afforded V in a 45% yield. The reduction of styrene episulfone (II) gave no carbon-carbon cleavage product, but it did give a carbon-sulfur fission product, yielding sulfinic acid salt (VIII). The formation of VIII is interesting compared with the reduction of styrene oxide by lithium aluminum hydride. Tetraphenylethylene episulfone (III) produced a carbon-carbon cleavage product, 1, 1, 3, 3-tetraphenyl dimethyl sulfone (XI), in a 68% yield. A reaction mechanism for the reductive cleavage reaction has been proposed on the basis of the above-mentioned results. In addition, we observed that diborane was evolved by the reaction of sulfur dioxide with lithium- or sodium borohydrides.

Much work has been done on the reactivity of heteroatom-containing three-membered ring compounds, for example, epoxides, episulfides, and aziridines. However, the reactions of three-membered rings containing a sulfone group (episulfones) have not yet been studied, except for base-catalyzed reactions.[1,2]

It is very interesting to investigate the physical and chemical behavior of episulfones.

In previous papers[3,4] the present authors have reported the alkaline cleavage of *cis*-stilbene episulfone (I) and the reduction of I by complex metal hydrides. In this paper, we wish to report on the reduction of such episulfones as *cis*-stilbene episulfone (I), styrene episulfone (II), and tetraphenylethylene episulfone (III) by complex metal hydrides. (The episulfones isolated before have been few[1-3,5] because it is difficult to synthesize them because of their unstability.)

Selective Reduction by Complex Metal Hydrides. Reduction of I with complex metal hydrides were carried out under various conditions; the results are summarized in Table 1. The yields of dibenzylsulfone (V) and *cis*-stilbene (VI) obtained totalled almost 100%. No sulfinic acid salt was detected. Therefore, it can be said that the carbon-carbon bond cleavage occurs selectively, without any carbon-sulfur bond fission[6] (Eq. (1)).

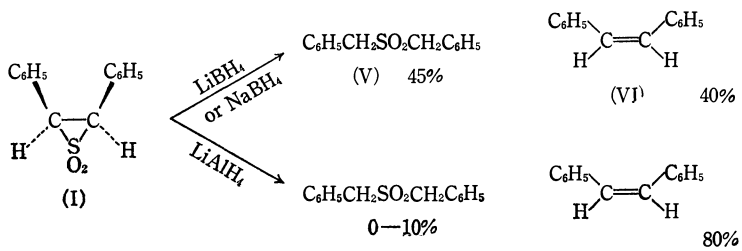
6) The stereospecific formation of *cis*-stilbene from I was the result of thermal decomposition.[3] Though I is stable below its dec. pt. (87—88°C) in a pure state without a solvent, it has been found that I decomposes to give *cis*-stilbene in some yield, even at room temperature, if it is dissolved in such solvents as are listed in Table 1. The yield of the olefin from this decomposition in a solvent seems to depend on the solvent used and on the coexistence of a metal cation, though its quantitative relationship is not clear.

TABLE 1. REDUCTION OF *cis*-STILBENE EPISULFONE (I) BY COMPLEX METAL HYDRIDES

Entry	Reducing agent[a)]	Solvent	Temp. °C	Products (mol%)	
				Dibenzyl-sulfone (V)	*cis*-Stilbene (VI)
1	$LiAlH_4$	Tetrahydrofuran	15	0	89
2	$LiAlH_4$	Diethyl ether	15	10	65
3	$LiAlH_4$	Diglyme[b)]	15	12	77
4	$LiAlH_4$	Tetrahydrofuran	70	4	77
5	$LiBH_4$	Tetrahydrofuran	15	47	40
6	$LiBH_4$	Diethyl ether	15	43	58
7	$LiBH_4$	Diglyme	15	48	28
8	$LiBH_4$	Tetrahydrofuran triethylamine	15	29	65
9	$NaBH_4$	Tetrahydrofuran[c)]	15	33	66
10	$NaBH_4$	Diglyme	15	49	50
11	$NaBH_4$	Dimethyl sulfoxide	20	44	61
12	$NaBH_4$	Methanol	15	0	85
13	BH_3[d)]	Tetrahydrofuran	15	0	60[f)]
14	AlH_3[e)]	Tetrahydrofuran	15	0	83
15	H_2AlCl[e)] $HAlCl_2$[e)]	Tetrahydrofuran	15	0	100
16	LiH	Tetrahydrofuran	15	0	100
17	NaH	Tetrahydrofuran	15	0	100

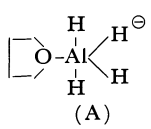
a) A molar ratio of I to the reducing agents of 1 : 2 was used.
b) Diethylene glycol dimethyl ether.
c) Suspension of sodium borohydride in tetrahydrofuran was used.
d) Diborane was generated externally in the reaction flask by adding diglyme saturated with sodium borohydride to boron fluoride etherate. (H. C. Brown and B. C. Subba Rao, *J. Am. Chem. Soc.*, **81**, 6428 (1959).) Excess diborane was used in this reaction.
e) AlH_3, H_2AlCl and $HAlCl_2$ were prepared by the method of Ashby. (E. C. Ashby and J. Prather, *J. Am. Chem. Soc.*, **88**, 749 (1966).) In these reactions, we directly used them prepared from lithium hydride and aluminum chloride in ether.
f) Yield was based on 1,2-diphenyl ethanol obtained.



(1)

Remarkable solvent effects on the reductive cleavage were observed (Table 1). Thus, no dibenzylsulfone (V) was produced when I was treated with lithium aluminum hydride in tetrahydrofuran at room temperature. When diethyl ether or diglyme was used as the solvent, however, V was formed under the same conditions.

This reason might be that tetrahydrofuran forms a complex[7,8)] with lithium aluminum hydride (Fig. (A)), thus prohibiting the reactions more or less due to steric reasons. In ether and diglyme, which are weaker bases than tetrahydrofuran, such complexes are dissociated at room temperature, so the yields of V are more in these solvent than in tetrahydrofuran.



(A)

When tetrahydrofuran,[9)] diethyl ether, diglyme, and dimethyl sulfoxide (Entries 5-11) were treated

8) D. Nafstein and C. Vogel, *J. Am. Chem. Soc.*, **88**, 1576 (1966).
9) The decrease in the yield of V in tetrahydrofuran may be ascribed to the low solubility of sodium borohydride.

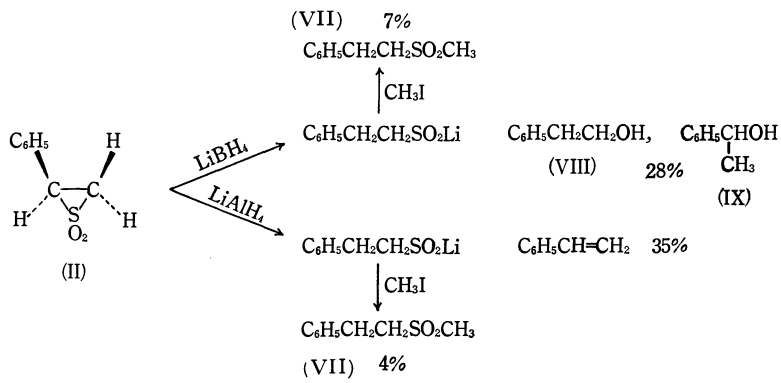
with lithium borohydride or with sodium borohydride, V was produced in very similar yields. Thus, the suggestion has been made that the interactions of lithium borohydride or sodium borohydride with these solvents are diminished.[10] In methyl alcohol, on the contrary, sodium borohydride reacts with the solvent to give[11] sodium tetramethoxyboron, $NaB(OCH_3)_4$ before reduction; thus V is not produced (Entry 12). In the reduction of I in the presence of triethylamine, no marked decrease in the yield of V was observed.

This remarkable difference in reactivity between the aluminum- and boro-hydrides can be explained by the fact that aluminum can expand its octet to form A, while boron cannot.[8]

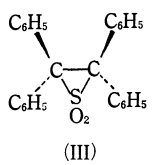
Recently, many workers have discussed the solvent effects on reductions by complex metal hydrides. Eliel *et al.*[12] concluded that sodium borohydride in inert solvents brings about the same steric results as does lithium aluminum hydride in ether, and Dauben[13] postulated that the borohydride species has a greater effective size than the aluminum hydride anion. Wheeler and Huffman[14] claimed that neither borohydride ion nor aluminum hydride ion is solvated.

Contrary to the above suggestions, we have concluded that the marked solvent effect on reduction by alkaline aluminum hydride is due to a complex formation such as A.

The present authors investigated the reductions of styrene episulfone (II) and tetraphenylethylene episulfone (III), formulated below;



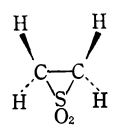
(2)



(III)

$\xrightarrow[\text{or } NaBH_4]{LiAlH_4}$ $(C_6H_5)_2CHSO_2CH(C_6H_5)_2$ (3)

(XI) 68%



(IV)

$\xrightarrow{LiAlH_4}$ $(C_2H_4S)_n$ (4)

To clarify the driving force of the carbon-carbon bond cleavage of I, we reduced styrene episulfone (II) by lithium aluminum hydride and lithium borohydride in diethyl ether at 0°C, but the carbon-carbon bond cleavage product was not detected, even after careful alumina-column chromatography. Instead, β-phenylethyl sulfinic acid salt, which was identified as β-phenylethyl methyl sulfone (VII) by the reaction with methyl iodide, was formed, indicating a carbon-sulfur bond cleavage.

It is interesting to note that the normal cleavage product, α-phenylethyl methyl sulfone, was not detected in the reaction mixtures. In the reduction of styrene oxide by lithium aluminum hydride or lithium borohydride, it has been observed[15] that the former gives only α-phenylethyl alcohol, while the latter, on the other hand, gives α- and β-phenylethyl alcohols in a ratio of 74 : 26.[15] This difference may arize from the greater size of the aluminum hydride anion species. In the case of styrene episulfone (II), however, both reducing agents gave abnormal products. The explanation for this unusual reaction is that the carbon-carbon bond length of the episulfone is longer than that of epoxides, thus relaxing the steric prohibition.[16]

During the reaction using lithium borohydride

10) Lithium borohydride forms a 1 : 1 complex with diethyl ether, but this complex dissociates at the reaction stage. (E. Wiberg, H. Hoth and R. Uson, *Z. Naturforsch.*, **11b**, 490 (1956).

11) R. E. Davis and J. A. Gottbrath, *J. Am. Chem. Soc.*, **84**, 895 (1962).

12) H. Haubenstock and E. L. Eliel, *ibid.*, **84**, 2368 (1962).

13) W. G. Dauben, G. J. Forken and D. S. Noyce, *ibid.*, **78**, 2579 (1956).

14) D. M. S. Wheeler and J. W. Huffman, *Experientia*, **16**, 516 (1960).

16) We are now studying the physical properties of the episulfone by means of the NMR and UV spectra.

as a reducing agent, we observed that the hydroboration of styrene occurred: α-(IX) and β-phenylethyl alcohol (VIII) were produced in a ratio of about 20 : 80; this ratio was the same as that obtained by the usual hydroboration of styrene.[17a,b]

Such an evolution of diborane is interesting, we first assumed as follows: the produced sulfinic acid salt can not form a complex with diborane, which is different from the behavior of carbanion or oxoanion. Accordingly, the diborane could react with styrene in the case of the present reduction (Eq. (5)):

$$\left.\begin{aligned} &R^{\ominus}M^{\oplus} + BH_3 \rightarrow R\text{-}\overset{\ominus}{B}H_3\ M^{\oplus} \\ &RO^{\ominus}M^{\oplus} + BH_3 \rightarrow R\text{-}O\text{-}\overset{\ominus}{B}H_3\ M^{\oplus} \\ &RSO_2^{\ominus}M^{\oplus} + BH_3 \not\rightarrow R\text{-}SO_2\text{-}\overset{\ominus}{B}H_3\ M^{\oplus} \end{aligned}\right\} \quad (5)$$

However, as will be described below, we discovered a new route to the formation of diborane by the reaction of lithium borohydride or sodium borohydride with sulfur dioxide. Therefore, this hydroboration must mainly come from the diborane[18] formed by the reaction of the borohydride with sulfur dioxide, which is obtainable from the episulfone. (In the case of lithium aluminum hydride, allane (AlH_3) might be formed, but in our study this reaction did not occur.)

The reduction of tetraphenylethylene episulfone (III) by lithium aluminum hydride or sodium borohydride gave 1, 1, 3, 3-tetraphenyl dimethyl sulfone (XI) in good yields. The formation of XI showed the occurrence of carbon-carbon bond fission, though it was sterically much hindered.

Previously, Hesse *et al.*[2] found that ethylene episulfone (IV) was reduced to give polyethylene sulfide (XII) by lithium aluminum hydride, indicating that no carbon-carbon cleavage of the compound occurred.

To summarize the above results, both *cis*-stilbene episulfone (I) and tetraphenylethylene episulfone (III) gave products formed by selective carbon-carbon-bond fission by complex metal hydrides. On the other hand, neither styrene episulfone (II) nor ethylene episulfone (IV) have the carbon-carbon bonds cleavage products; only the carbon-sulfur bond was cleaved.

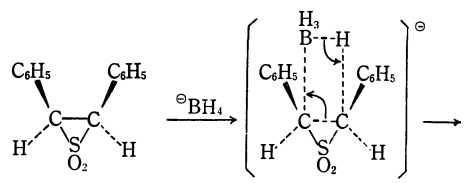
From these results, it seems that at least two phenyl groups are required for the carbon-carbon bond fission.[19] An inductive effect of phenyl groups weakens the carbon-carbon bonds, and a resonance effect of the groups may act to stabilized the resonance forms (B and C) mentioned below. Also, the steric effect by the phenyl groups would make the carbon-carbon bond longer; as a result, the carbon-carbon bond is more vulnerable to attack by nucleophiles.

The driving force for these reactions cannot be the carbanion stabilization of an intermediate or transition state.[20] If this were the case, the carbon-carbon bond of styrene episulfone would be cleaved, giving a carbanion almost identical (formation of benzyl carbanion formed by attack at the α-carbon) to the case of *cis*-stilbene episulfone (I).

The driving force for the reductive cleavage of the carbon-carbon bond should include a relief of the strain.

Thermally, carbon-carbon bond would be stronger than carbon-sulfur bonds, for sulfur dioxide is evolved by the thermal decomposition of episulfones, affording olefins.[6] However, the carbon-carbon bonds have a π-character; in other words, they have a double-bond character according to the Walsh model.[21] Therefore, if carbon-carbon bonds were weakened by such electron-withdrawing substituents as sulfone and phenyl groups in this case, the carbon-carbon bonds would be attacked by nucleophiles.

Let us now discuss the mechanism of these reactions in the case of I. We proposed, in a previous report,[4] a four-centered reaction mechanism for the reduction by lithium borohydride, sodium borohydride, and lithium aluminum hydride (Eq. (6));



(I)

$$C_6H_5CH(\overset{\ominus}{B}H_3)SO_2CH_2C_6H_5 \xrightarrow{H_2O} C_6H_5CH_2SO_2CH_2C_6H_5 \quad (6)$$

(V)

The following mechanism would also be attractive:

17) a) H. C. Brown and G. Zweifel, *J. Am. Chem. Soc.*, **82**, 4708 (1960). Review: G. Zweifel and H. C. Brown, "Org. Reactions," Vol. 13, John Wiley and Sons, New York (1963), p. 1. b) In the case of the *cis*-stilbene episulfone (I) reduction, 1, 2-diphenylethanol was not formed because of the short reaction time.

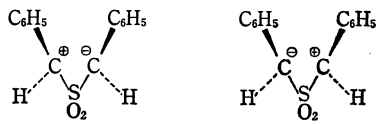
18) We will report on the reaction in the near future.

19) G. W. Griffin *et al.* recently reported the photocleavage of phenyl-substituted cyclopropane in ionic fashion to give substituted propanes. This reaction proceeded by a photochemical process, not by heating. On the other hand, in our study, episulfones gave carbon-carbon bond cleavage products more easily, even at room temperature. This difference may be ascribed to the higher energy of the ground state of episulfones. (G. S. Irving, R. C. Petterson, I. Sarkar, H. Kristinsson, C. S. Aaron, G. W. Griffin and G. J. Boudreaux, *J. Am. Chem. Soc.*, **88**, 5675 (1966)).

20) B. Franzus and E. I. Snyder, *ibid.*, **87**, 3423 (1965).

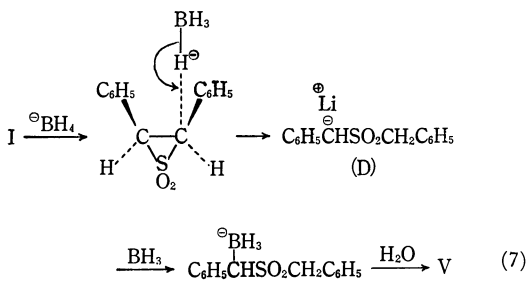
21) M. Pomerantz *et al.* have reported on the electronic structure and reactivity of bicyclobutanes, showing a π-character in the peripheral and bridgehead bonds (M. Pomerantz and W. Abrahamson, *J. Am. Chem. Soc.*, **88**, 3970 (1966)).

Three-membered rings involving the electron-withdrawing groups, such as tetracyanoethylene oxide,[22] 1, 2-diphenylaziridine,[23] and cyclopropanones,[24] react with olefins, acetylenes, and dienes by 1, 3-dipolar or 1, 3-diradical concerted mechanisms, resulting in carbon-carbon bonds fission. Similarly, the present reaction might occur by a promotion of the episulfone to activated species B and C, which then react with complex metal hydrides by a 1, 3-dipolar-type reaction.



(B) (C)

There also is another mechanistic route to give V, *i. e.*, the S_N2 type, as shown by epoxide reduction[25] (Eq. (7)):



(7)

There is no clear reason to exclude these mechanisms, since stereochemical and kinetical data are lacking.[26,27] Solvent effects also give no suggestion about the problem. Since the carbanion leading to the formation of V could not be trapped, the fast attack on the carbanion by the liberating hydrogen, as shown in Eq. (8), could not be omitted. The backside-attack mechanism of the reagent due to its complex formation with sulfone group may, however, be ruled out, for borane (BH_3) did not give V at all, though borane would more easily attack the oxygen atom of the sulfone group.

There remains a question of the fate of the liberated sulfur dioxide (liberated by thermal decomposition).

It is noteworthy that sulfur dioxide reacts selectively with lithium borohydride or sodium borohydride to give diborane, without reacting with alkyl lithium (D). To investigate the reductive-cleavage mechanism, the authors added triethylamine to the reaction mixture. The products were V, VI, and, interestingly, triethylamine borane (XIII). If sulfur dioxide did not react with lithium borohydride or sodium borohydride, triethylamine borane would not be formed, since the carbanion (D) would be stronger base than triethylamine, giving no XIII.[28] In addition, the reaction of sulfur dioxide with complex borohydride to give borane was verified (Eq. (8)):

$$4LiBH_4 + SO_2 \xrightarrow{THF} 2BH_3 + Li_2S + 2LiOBH_3 + 2H_2 \quad (8)$$

The formation of diborane by this method was confirmed by the hydroboration of styrene, and the lithium sulfide liberated was ascertained by a reaction with Pb $(OAc)_2$ to form PbS.[29]

The results of the new route to borane formation and the subsequent use of diborane in sulfur dioxide will be reported elsewhere in detail.

Experimental[30]

Materials. The solvents were purified as follows. Tetrahydrofuran, diethyl ether, dimethyl sulfoxide and triethylamine were obtained from Wako Pure Chemicals. The tetrahydrofuran was purified by refluxing it with sodium for two days. It was then treated with lithium aluminum hydride, and distilled. The diethyl ether was dried over sodium and distilled over lithium aluminum hydride. The dimethyl sulfoxide was refluxed for 10 hr over calcium hydride and distilled at reduced pressure. The triethylamine was distilled over potassium hydroxide pellets. The diglyme (diethylene glycol dimethyl ether) (Aldrich Chemical Co., Inc.) was first distilled over calcium hydride, and then over lithium aluminum hydride.

Lithium borohydride (98%), lithium aluminum hydride, sodium borohydride, lithium hydride, sodium

22) W. J. Linn, *J. Am. Chem. Soc.*, **87**, 3665 (1965).
23) a) A. Padwa and L. Hamilton, *Tetrahedron Letters*, **1965**, 4363; b) A. E. Pohland, R. C. Badger and N. H. Cromwell, *ibid.*, **1965**, 4369; c) R. Huisgen, W. Scheer, G. Szeimies and H. Huber, *ibid.*, **1966**, 397, 405.

Turro, P. A. Leermaker, H. R. Wilson, D. C. Neckers, G. W. Byers and G. F. Vesley, *ibid.*, **87**, 2613 (1965).
25) The borohydride ion, which is more ionic in character than the aluminum hydride ion, yields more V. This suggests that a transition state, such as B or C, may be favored by a more ionic reagent.
26) R. E. Parker and N. S. Lsaacs, *Chem. Revs.*, 737 (1959).
27) A few examples of supposed four-centered transition states by sodium borohydride have appeared. CF. F. G. Bordwell and M. L. Douglass, *J. Am. Chem. Soc.*, **88**, 993 (1966); R. E. Dessay and E. Grannen, Jr., *ibid.*, **83**, 3953 (1961).
28) The carbanion (D) is a stronger base, since α-chlorobenzyl benzyl sulfone treated with triethylamine did not give stilbene.[3]
29) The reaction of diborane with KOH has recently been reported by Jolly and Schmitt (W. J. Jolly and T. Schmitt, *J. Am. Chem. Soc.*, **88**, 4282 (1966)).
30) All melting points and boiling points are uncorrected. The infrared absorption spectra were determined on a Hitachi infrared spectrophotometer. The nuclear magnetic resonance spectra were run on a Nihondensi spectrometer at 60 Mc. Tetramethylsilane was used as an internal standard, and chloroform-d was used as the solvent (Chiba Ltd.). V. p. c. analysis was carried out on a Yanagimoto, Model GCS-100, instrument.

hydride, and aluminum chloride were obtained commercially. All these compounds were used without further purification.

Liquid sulfur dioxide was donated by Seitetsu Kagaku and was used after having been dried over phosphorus pentoxide for at least one day.

cis-Stilbene episulfone (I) was synthesized as has been described in a previous report;[3] a phenyldiazomethane solution[31] (about 0.05 mol in 300 m*l* ether) in a 1-*l* Erlenmeyer flask had a sulfurous acid solution added (6%) over a five-minute period. The solid obtained on cooling was filtered and recrystallized from ether-benzene at about 50°C. Mp 87—88°C (dec.).

Styrene episulfone (II) was obtained by the method of Opitz;[5c] in a three-necked, 500 m*l*, round-bottomed flask, equipped with a reflux condenser, a stirrer, and a dropping funnel, there were placed about 0.05 mol of diazomethane and 7.0 g of triethylamine in 100 m*l* of ether. In a dropping funnel there were placed about 11.0 g benzylsulfonyl chloride in 300 m*l* of ether. The solution was then added slowly, over a period of 30 min, to diazomethane triethylamine solution, with the temperature maintained at −30°C (dry ice - triclene bath). After the addition, the solid (triethylammonium chloride) was filtered off and the mother liquor was concentrated by distillation under reduced pressure as fast as possible. The resulting solid (6.5 g (0.039 mol)) was filtered off, washed once with cold ether, and used without further purification; mp 40°C (dec.) (yield 70%). Styrene episulfone was too unstable to be stored it at noom temperature and dried it in a round-bottom flask kept at 0°C (ice bath) by pumping.

Tetraphenylethylene episulfone (III) was synthesized by the method of Staudinger *et al.*[5a] Because of its poor stability, III was used as soon as it had been dried for 30 min in a desiccator.

Reduction of *cis*-Stilbene Episulfone (I) by $LiAlH_4$, $LiBH_4$ and $NaBH_4$ (General Procedure). In a three-necked, 200 m*l*, round-bottomed flask, equipped with a reflux condenser and a stirrer, there were placed 0.04 mol of complex metal hydride and 100 m*l* of a solvent. To a well-stirred suspension, there were then added 0.02 mol of *cis*-stilbene episulfone (I) under nitrogen. After 4 hr at room temperature (15° C), the reaction mixture was added to 100 m*l* of ice-water and extracted twice with 150 m*l* of ether. After the combined ether layer had been dried over anhydrous sodium sulfate, the ether was removed under reduced pressure. The white precipitate was washed with ether to give dibenzylsulfone (V).[32] V was identified by comparison with an authentic specimen; mp 148—149°C. IR ν_{max}^{KBr} 1302, 1286, 1125, 1113 cm^{-1} (SO_2-stretching). NMR $\tau=5.9$ ppm (methine). The residue (liquid) was *cis*-stilbene, identified as before.[3] No product was obtained from the water layer.

Reduction of Styrene Episulfone (II) by $LiBH_4$. In a three-necked flask there was placed 0.764 g (0.035 mol) of lithium borohydride in 150 m*l* of anhydrous ether. To this solution there were then added 2.894 g (0.0172 mol) of styrene episulfone (II). The mixture was stirred at 0°C for 3 hr, and then poured over ice water. It was extracted with ether and dried over Na_2SO_4, after which the ether was evaporated under reduced pressure.

Remaining was a liquid (1.96 g). G. l. c. analysis at 170°C on a PEG 6000 column showed the formation of α- and β-phenylethyl alcohol in the ratio of 20 : 80.[33]

The water extract was refluxed with methyl iodide (10 g) for two days, and was then extracted with ether. The evaporation of the solvent gave 0.210 g (0.00114 mol) of white crystals (VII) (mp 87—88°C). β-Phenylethyl methyl sulfone (VII) was identified by comparison with an authentic sample.[33]

Reduction of Styrene Episulfone (II) by $LiAlH_4$. Using the technique described above, 0.954 g (0.0261 mol) of lithium aluminum hydride in a 150 m*l* ether solution was added to 3.177 g (0.0189 mol) of styrene episulfone, and the reaction mixture was stirred at 0°C for 3 hr. After having been treated as above, a liquid (0.832 g) remained; it was identified as styrene by g. l. c. analysis (PEG 6000 at 70°C). The water extract was refluxed with methyl iodide (10 g) for two days; it was then extracted with ether to give α-phenylethyl methyl sulfone (0.135 g (0.0011 mol)), which was identical with an authentic sapecimen.

Reduction of Tetraphenylethylene Episulfone (III) by $NaBH_4$ or $LiAlH_4$. To 150 m*l* of a tetrahydrofuran solution containing 0.280 g (0.0074 mol) of sodium borohydride, there was added tetraphenylethylene episulfone (III) (1.127 g (0.00285 mol)) at room temperature (15°C).

The reaction mixture was stirred for 6 hr and then poured into water. The ether extract, after drying, gave 0.59 g of white crystals, which were recrystallized from benzene petroleum ether (30—60°C) to give 1, 1, 3, 3-tetraphenyl dimethyl sulfone (XI) (mp 185—186°C (dec.)).

Found: C, 78.40; H, 5.42%. Calcd for $C_{26}H_{22}O_2S$: C, 78.37; H, 5.57%.

NMR $\tau=2.5$ ppm (phenyl), 4.78 ppm (methine: singlet).

IR ν_{max}^{KBr} 1312, 1130 cm^{-1} (SO_2-stretching).

When treated with lithium aluminum hydride, (III) give a 28% yield of (XI). The residual, tar-like substance was not identified.

Reduction of (I) by $LiBH_4$ or $NaBH_4$ in the Presence of Triethylamine. To a stirred solution of 0.463 g (0.0212 mol) of lithium borohydride and 1.40 g (0.0139 mol) of triethylamine in 100 m*l* of tetrahydrofuran, 2.287 g (0.00937 mol) of *cis*-stilbene episulfone (I) were added, after which the reaction mixture was stirred for 4 hr at room temperature and then decomposed by water. After the residue had been treated as in the above procedure, dibenzylsulfone (V) (0.601 g (0.00244 mol)) and triethylamine-borane (0.580 g (0.00504 mol)) were produced; they were identified by comparison with authentic specimens.[34]

IR ν_{B-H} 2300 cm^{-1}, bp 76°C/4 mmHg.

The residual *cis*-stilbene was identified by the coincidence of the IR spectra.

The Autoxidation of Toluene Catalyzed with Cobalt Monobromide in Acetic Acid

Koichiro SAKOTA, Yoshio KAMIYA and Nobuto OHTA

Department of Fuel Technology, The University of Tokyo, Hongo, Tokyo

(Received August 17, 1967)

The kinetics of cobalt-catalyzed autoxidation of toluene have been studied in acetic acid in the presence of sodium bromide. The reaction is found to proceed of apparent zero-order in the concentration of toluene for a long duration and of first-order in its initial concentration and of second-order in cobalt ion concentration. In case of ethylbenzene or cumene the rate of oxidation is of first-order in its concentration. This zero-order dependence is explained as a result of the co-oxidation of toluene and its intermediate reaction product, benzaldehyde. A reaction scheme is proposed, which has been shown to be consistent with experimental data by solving out the rate equations simultaneously with a computer, co-oxidation of toluene and benzaldehyde being taken into consideration.

The profound accelerating effect of the bromide on the rate of the autoxidation of aromatic hydrocarbons catalyzed by cobalt salt in organic acid media has been recognized and commercially in practice. Several papers have been published on this reaction mechanism after Revens' paper in 1959. Recently Hay and Blanchard[1] made some experimentals to examine the elementary reactions. We also have made kinetical experimentals treating with tetralin and ethylbenzene to obtain the detail of the reaction mechanism and extended our study to the oxidation of *p*-xylene under its low conversions. The characteristics of the cobalt-catalyzed autoxidation of methylbenzenes in the presence of bromide were as follows.

The rate of oxidation of methylbenzenes keeps constant for a long duration in spite of the decrease of their concentrations, even though the rates are of first-order dependence with respect to their initial concentrations. There are many complexities in the oxidation of methylbenzenes, since the aromatic aldehydes produced as intermediate products of reaction are easily oxidized and the reaction turns into co-oxidation of toluene and benzaldehyde. In this paper we studied the oxidation of toluene kinetically in detail in stead of *p*-xylene to avoid the difficulties caused by the number of the intermediate products which prevent us from satisfactory kinetical analysis when high conversions are attained. The co-oxidation reaction of toluene and benzaldehyde was taken into consideration.

Results and Discussion

The Effects of Hydrocarbons. The oxygen uptake took place after a few minutes of induction period, when toluene was oxidized with oxygen in acetic acid solution with cobalt acetate and sodium bromide as catalysts. It was observed that the rate of oxidation was increased by a factor of about 300 in the presence of bromide. As is observed in Fig. 1, there is a long duration where the rates of the consumption of toluene and of the accumulation of benzaldehyde kept constant. We regard these phenomena characteristic in the oxidation of methylbenzenes in a cobalt bromide - acetic acid-system. Kinetical experiments were made to obtain the accounts. The fact that so much of benzaldehyde was accumulated may be partly attributed to the low temperatures of reaction but

strongly suggests that the reaction of the hydrogen abstraction from toluene is more profoundly accelerated than that from benzaldehyde by the catalysis of bromide. It was observed in this case that the stronger the C-H bond, the more profoundly catalyzed the hydrogen abstraction reaction from the hydrocarbons, say, in the case of ethylbenzene (*ca.* 30 fold) and of tetralin (*ca.* 4 fold). This may be explained from the difference of the degree of the C-H bond rupture in the transition state of the hydrogen abstraction stage by peroxy radicals and by cobalt-bromide complexes. The profound effect of bromide implies that cobalt-bromide complex is more active than peroxy radicals. So the stretching of C-H bond in transition state is thought to be larger for peroxyradicals than for cobalt-bromide complex. The larger the stretching of a C-H bond, the more the contribution of the C-H bond energy to the activation energy of the process. And the order of acceleration by bromide was observed as *p*-toluic acid > toluene > ethylbenzene > tetralin. The bond formation between peroxyradical and toluene, ROO···H-CH_2-ϕ, may be less favoured than between bromide and toluene, Co-Br···H-CH_2-ϕ, because bromine atom is more capable of covalent bond formation and less oriented to form a bond due to the presence of d-orbitals and its larger size than oxygen. These properties may explain that the activation energy of the reaction catalyzed by bromine is less affected by the bond energy of the C-H bond to be broken. Benzaldehyde is oxidized into perbenzoic acid *via* benzoyl radical. Perbenzoic acid suffers homolytic decomposition by cobalt salt to give radicals. These radicals can abstract the hydrogen atom from toluene or increase the concentration of the active cobalt complex, which can also abstract hydrogen atom from toluene. In other words, benzaldehyde can accelerate the consumption of toluene—co-oxidation of toluene and benzaldehyde—. The behaviors of benzaldehyde explain qualitatively the apparent zero-order dependence of the rate of toluene consumption on the concentration of toluene. It was observed also in case of *p*-xylene and *p*-toluic acid that the profile of the reaction was the same as in case of toluene. To determine the effect of the concentration of the hydrocarbon, the initial concentration of toluene was varied. As presented in Fig. 2, the variation of the initial concentration of toluene with constant concentrations of cobalt acetate and sodium bromide showed first-order dependence of the rate of toluene consumption and of accumulation of benzaldehyde. It follows from this fact the hydrogen abstraction stage is the rate-determining step. Benzaldehyde and benzoic acid were produced mainly, with a little amount of benzyl alcohol. The concentration of peroxidic compounds was less than 10^{-3} mol/*l*. Ethlbenzene and cumene were oxidized to give acetophenone mainly. In either case, the rates of oxygen uptake and of consumption of hydrocarbon were proportional to the concentration of their own during the oxidation, namely the rate of oxidation is of first-order with respect to the concentration of hydrocarbon in contrast to the case of toluene (Fig. 3).

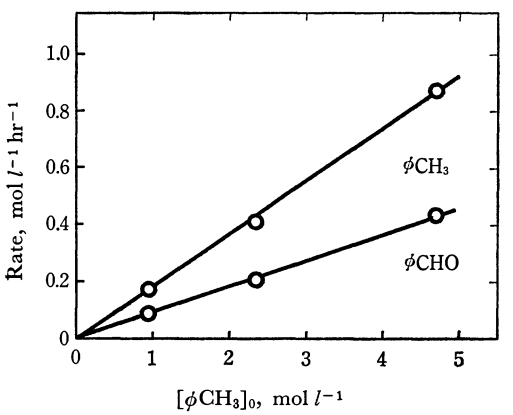

Fig. 2. The rates of toluene consumption and of accumulation of benzaldehyde at 80°C with 2×10^{-2} mol/*l* cobalt, 4×10^{-2} mol/*l* sodium bromide.

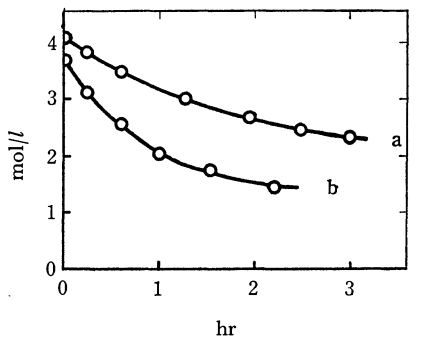

Fig. 3. Oxidation of ethylbenzene and cumene at 80°C with 2×10^{-2} mol/*l* cobalt and 4×10^{-2} mol/*l* sodium bromide.
a, ethylbenzene; b, cumene

This difference of the reaction profile is ascribed to the difference between the stability of benzaldehyde and acetophenone against oxidation. The facts above make it necessary that the oxidation of toluene is treated kinetically as co-oxidation when high conversions of toluene are reached. In general, it might be said in the oxidation of aromatic hydrocarbons in cobalt bromide - acetic acid-system that: (1) the oxidation of the hydrocarbons with only primary hydrogens in the side chains, proceeds of apparent zero-order dependence on the concentration during the oxidation and shows first-order dependence on the initial concentration of the hydrocarbons to be oxidized, (2) the oxidation of hydrocarbons with secondary and/or

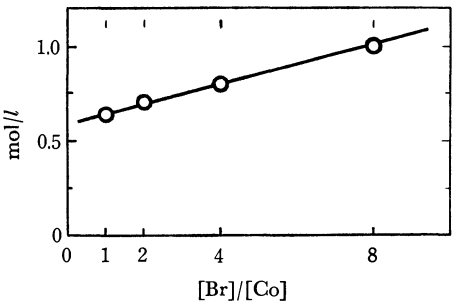

Fig. 4. The maximum amount of benzaldehyde accumulated *vs.* ratio of sodium bromide to cobalt.

tertiary hydrogens in the side chains, is of first-order dependence on the concentration and gives corresponding ketones as oxidation products.

The Effect of The Concentration of Sodium Bromide. As mentioned above the bromide seems to catalyze the process where toluene is oxidized into benzaldehyde, and the amount of bromide added has a profound effect on the oxidation rate (Figs. 1 and 4). The rate of toluene consumption increased continuously as the concentration of bromide increased until the ratio of [bromide]/[cobalt acetate] attained near two and kept constant when the ratio became higher than two. We conclude from the facts mentioned above and other papers[2,3] that the catalytic species is cobalt monobromide. It seems, however, that our proposed reaction mechanism may be insufficient to explain the length of the duration where the rate of toluene consumption kept constant and the maximum amount of accumulated benzaldehyde became larger according to the increase of the amount of the added bromide. But these behaviors can be fully understood from the data in Fig. 5. The line (a) stands for the change of the concentration of the bromide anion and has good correspondence to the toluene consumption curve. It implies that bromine atoms were consumed proportionally to the extent of the reaction. When bromide was analyzed quantitatively after the reaction solution was diluted with alkaline solution and refluxed sufficiently, the values obtained were equal to the initial concentration of bromide (the line (b)). Bromine atom seems to be consumed as benzyl bromide. The number of toluene molecule oxidized per one bromine atom was about 25. This number is temperature dependent and becomes larger at higher temperatures because organic bromides may be decomposed to regenerate bromine atoms. The electronic spectra of the reaction solution are shown in Fig. 6. Optical density readings were taken at the reaction temperature. Oxygen feed and time count were started when the temperature of the solution reached the designated value. The decrease in the optical densities at 14.5 kK corresponded satisfactorily to the change of the concentration of the bromide anion shown in Fig. 5. The increases in optical densities in the ultraviolet region are due to the increase in the concentration of benzaldehyde formed. The shape of the electronic spectra changed and had a stronger resemblance to that of cobaltous acetate after the consumption of bromine atom. The reaction rate also began to tail off according to the decrease of the concentration of the bromide. Now it was understood easily that the more the added amount of bromide, the longer the length of the duration where the sufficient amount of bromide anion is present to maintain the catalytic activities of the cobalt-bromide complex.

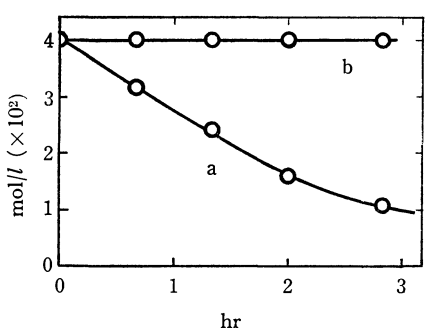

Fig. 5. Concentration of bromide anidn *vs.* reaction time at 80°C with 2×10^{-2} mol/*l* cobalt.

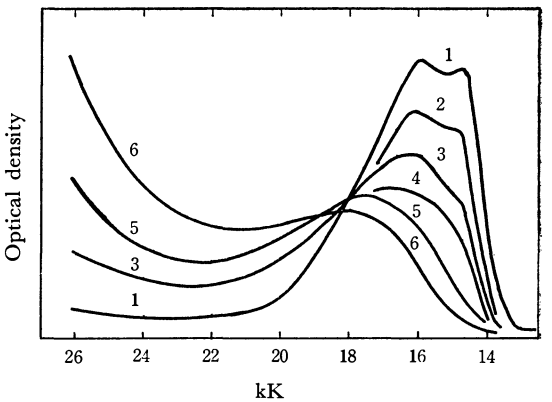

Fig. 6. Electronic spectra of reaction solution at 80°C with 5×10^{-3} mol/*l* cobalt and 1×10^{-2} mol/*l* sodium bromide.

The Effect of Cobalt Concentration. The dependence of the rate of oxygen uptake was shown in Fig. 7. At the concentrations from 5×10^{-3} to 4×10^{-2} mol/*l* of cobalt acetate, the rate of oxygen uptake was of second-order with respect to the

2) Y. Kamiya, *Kogyo Kagaku Zasshi (J. Chem. Soc. Japan, Ind. Chem. Sect.)*, **69**, 897 (1966); Y. Kamiya, *Tetrahedron*, **22**, 2029 (1966).
3) Y. Kamiya, J. Nakajima and K. Sakoda, This Bulletin, **39**, 2211 (1966).

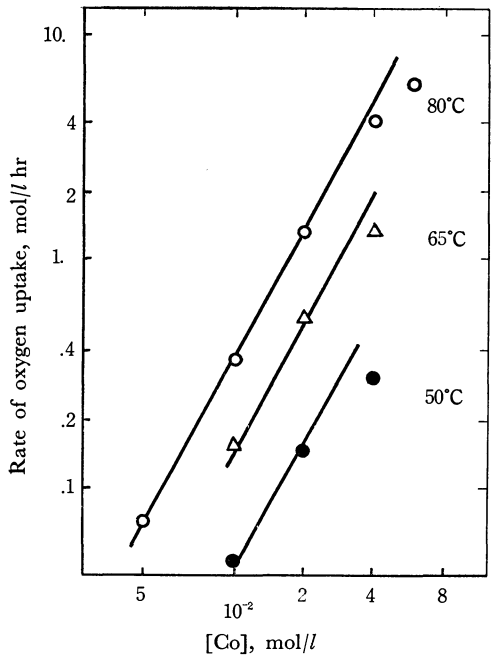

Fig. 7. The rates of oxygen uptake *vs.* concentration of cobalt acetate at $[NaBr]/[Co(OcA)_2 \cdot 4H_2O]=2$.

concentration of cobalt salt, showing some departure from linearity at high concentrations of cobalt salt. This may be partly due to the limitation of solubility of sodium bromide to maintain the ratio of [bromide]/[cobalt acetate] higher than about two, which assures the maximum concentration of cobalt monobromide. If the cobalt ion only affects the catalysis of decomposing hydroperoxides, the rate of toluene consumption will be of less first-order to the concentration of cobalt acetate assuming a bi-molecular termination process. Since the decomposition of hydroperoxide by cobalt ions in glacial acetic acid (referred to as (Co)) is expressed as follows[4] under the conditions employed here.

$$\text{hpo} + 2(\text{Co}) \longrightarrow \text{radicals}$$

The second-order dependence to cobalt ion implies the following reactions with participation of cobalt ion into propagation steps.

$$\phi CH_3 + \text{Co(III)Br}^- \longrightarrow \phi CH_2\cdot + \text{Co(II)BrH} \quad (1)$$

$$\phi CH_2\cdot + O_2 \longrightarrow \phi CH_2OO\cdot \quad (2)$$

$$\phi CH_2OO\cdot + \text{Co(II)BrH} \longrightarrow \phi CHO + \text{Co(III)Br} + H_2O \quad (3)$$

Benzaldehyde can behave like initiator. So the concentration of active species which are capable to abstract hydrogen atom from methyl groups may increase, as the concentration of benzaldehyde increases. It seems inadequate to apply stationary state treatment in this system when the amount of benzaldehyde accumulated is considerable. Co-existence of active species, such as $\phi CH_2OO\cdot$, $\phi COOO\cdot$ and Co(III)Br^-, and the occurrance of cross-termination prevent from solving out equations directly to show the second-order dependence on cobalt concentration, the apparent zero-order dependence on toluene concentration, *etc.*

The Cobalt-Bromide Complexes. It has been reported that $Co(H_2O)_6^{2+}$, $Co(H_2O)_4Cl_2$ are octahedral and $CoBr_4^{2-}$ is tetrahedral. Cobalt acetate will be changed into $CoBr^+$(Oh), $CoBr_2$(Oh),$\cdots CoBr_4^{2-}$(Td) step by step according to the addition of bromide. The absorption band at 14.5 kK in Fig. 8 is considered to be caused by the transition $^4T_1 \leftarrow {}^4A_2$ of $CoBr_4^{2-}$, because it has the strongest intensity and is located at the longest wavelength and the intensity at 14.5 kK decreased continuously according to the extent of the reaction (Fig. 6). The bands around 16 kK may be the bands splitted and shifted of that of cobalt acetate at 18.7 kK by the lowering of the symmetry caused by the coordination of bromide anion to cobalt ion. The Co–Br bond is expected to be more covalent than the Co–OAc bond from the values of nephelauxetic ratios and nuclear quadrupole resonance data and so on. This covalency will make the electron transfer easier from bromide anion to cobaltic cation which is formed *via* oxidation of Co(II) by hydroperoxides or peroxyradicals. This tranfer will stabilize the Co(III) state and as a result, give the radical character to the bromine ligated to the Co(III). And the bromine may gain the ability of hydrogen abstraction. Because of the presence of *d*-orbitals and its larger size, bromine is less oriented and easier for hydrogen to form a bond with than oxygen in acetate or cobalt ion is. This favours the bond formation with hydrogen atom of alkyl groups.

The Reaction Mechanism. The detailed mechanism of initiation steps is not still fully explained but we gave some discussions in other papers.[2,3] When the reaction proceeds to some extent and the concentration of benzaldehyde becomes considerable, the initiation reaction (12) is predominant over other initiation processes. When benzylhydroperoxide is decomposed catalytically by cobalt ion, benzyloxy and benzylperoxy radicals are formed in equal amount. Benzyloxy radical abstracts hydrogen and become benzylalcohol. If benzylperoxy radical became benzylhydroperoxide, benzylalcohol would be accumulated to considerable amount. Because benzylalcohol was rather stable and oxidized at the rate of 5% of that of toluene. But little amount of benzylalcohol was detected in experiments. This suggests thatthe contribution of the reaction (4) is small. An alternative mechanism below, where benzaldehyde is formed from benzylhydroperoxide without formation of benzylalcohol,

$$\phi CH_2OOH + Co(II) \rightarrow [\phi CH_2O\cdots Co(III)] + OH^- \rightarrow \phi CHO + Co(II) + H^+ + OH^-$$

$$\phi CH_2OOH + Co(III) \rightarrow [\phi CH_2OO\cdots Co(II)] + H^+ \rightarrow \phi CHO + Co(III) + OH^- + H^+$$

may not be operative. Because it may be unreasonable that above reactions proceed without migration of radicals formed from hydroperoxide out of the solvent cage around the cobalt ion. The reaction (3) is probable. The following elementary reactions will explain the experimental observations after the initial stage of the reaction.

$$\phi CH_3 + Co(III)Br \xrightarrow{k_1} \phi CH_2\cdot + Co(II)BrH \quad (1)$$

$$\phi CH_2\cdot + O_2 \xrightarrow{k_2} \phi CH_2OO\cdot \quad (2)$$

$$\phi CH_2OO\cdot + Co(II)BrH \xrightarrow{k_3} \phi CHO + Co(III)Br + H_2O \quad (3)$$

$$\phi CH_2OO\cdot + \phi CH_3 \xrightarrow{k_4} \phi CH_2OOH + \phi CH_2\cdot \quad (4)$$

$$\phi CH_2OO\cdot + \phi CHO \xrightarrow{k_5} \phi CH_2OOH + \phi CO\cdot \quad (5)$$

$$\phi CHO + Co(III)Br \xrightarrow{k_6} \phi CO\cdot + Co(II)BrH \quad (6)$$

$$\phi CO\cdot + O_2 \xrightarrow{k_7} \phi COOO\cdot \quad (7)$$

$$\phi COOO\cdot + Co(II)BrH \xrightarrow{k_8} \phi COOOH + Co(III)Br \quad (8)$$

$$\phi COOO\cdot + \phi CH_3 \xrightarrow{k_9} \phi COOOH + \phi CH_2\cdot \quad (9)$$

$$\phi COOO\cdot + \phi CHO \xrightarrow{k_{10}} \phi COOOH + \phi CO\cdot \quad (10)$$

$$\phi CH_2OOH + Co_2 \xrightarrow{k_{11}} \text{radical} \rightarrow 2Co(III)Br \quad (11)$$

$$\phi COOOH + Co_2 \xrightarrow{k_{12}} \text{radical} \rightarrow 2Co(III)Br \quad (12)$$

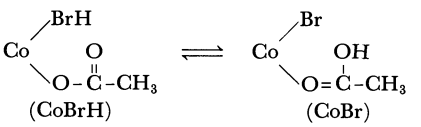
$$\phi COOOH + \phi CHO \xrightarrow{k_{13}} 2\phi COOH \quad (13)$$

$$2\phi CH_2OO\cdot \xrightarrow{k_{14}} \phi CHO + \phi CH_2OH \quad (14)$$

$$2\phi COOO\cdot \xrightarrow{k_{15}} (\phi COO)_2 + O_2 \quad (15)$$

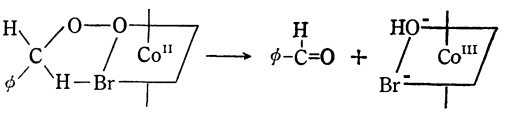
$$\phi CH_2OO\cdot + \phi COOO\cdot \xrightarrow{k_{16}} \phi CHO + \phi COOH + O_2 \quad (16)$$

The equilibrium below exists and reactions (3) and (1) are expressed as follows.

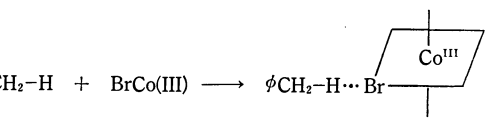


reaction (3):

$$\phi CH_2OO\cdot + Co(II)BrH \longrightarrow$$



reaction (1):



Benzoyloxy radical has not hydrogen atom and cannot proceed *via* reaction (3), so might be converted to perbenzoic acid.

$$\phi COOO\cdot + HBrCo(II) \rightarrow \phi COOOH + BrCo(III)$$

The reactions (2) and (7) are very fast, therefore can be simplified as follows.

$$\phi CH_3 + Co(III)Br \xrightarrow{k_1'} \phi CH_2OO\cdot + Co(II)BrH$$

$$\phi CHO + Co(III)Br \xrightarrow{k_6'} \phi COOO\cdot + Co(II)BrH$$

Above reactions are rewritten as ordinary differential equations.

$$-d[\phi CH_3]/dt = k_1'[\phi CH_3][Co(III)Br] + k_4[\phi CH_3][\phi CH_2OO\cdot] + k_9[\phi CH_3][\phi COOO\cdot]$$

$$d[\phi CH_2OO\cdot]/dt = k_1'[\phi CH_3][Co(III)Br] - k_3[\phi CH_2OO\cdot][Co(II)BrH] - k_5[\phi CHO][\phi CH_2OO\cdot] + k_9[\phi CH_3][\phi COOO\cdot] - 2k_{14}[\phi CH_2OO\cdot]^2 - k_{16}[\phi CH_2OO\cdot][\phi COOO\cdot]$$

$$d[\phi CHO]/dt = k_3[\phi CH_2OO\cdot][Co(II)BrH] - k_5[\phi CHO][\phi CH_2OO\cdot] - k_6'[\phi CHO][Co(III)Br] - k_{10}[\phi CHO][\phi COOO\cdot] - k_{13}[\phi CHO][\phi COOOH] + k_{14}[\phi CH_2OO\cdot]^2 + k_{16}[\phi CH_2OO\cdot][\phi COOO\cdot]$$

$$d[\phi COOO\cdot]/dt = k_5[\phi CHO][\phi CH_2OO\cdot] + k_6'[\phi CHO][Co(III)Br] - k_8[\phi COOO\cdot][Co(II)BrH] - k_9[\phi CH_3][\phi COOO\cdot] - 2k_{15}[\phi COOO\cdot]^2 - k_{16}[\phi CH_2OO\cdot][\phi COOO\cdot]$$

$$d[\phi COOOH]/dt = k_8[\phi COOO\cdot][Co(II)BrH] + k_9[\phi CH_3][\phi COOO\cdot] + k_{10}[\phi CHO][\phi COOO\cdot] - k_{12}[\phi COOOH][Co(II) + Co(III)]^2$$

$$d[Co(III)Br]/dt = -k_1'[\phi CH_3][Co(III)Br] + k_3[\phi CH_2OO\cdot][Co(II)BrH] - k_6'[\phi CHO][Co(III)Br] + k_8[\phi COOO\cdot][Co(II)BrH] + 2k_{12}[\phi COOOH][Co(II) + Co(III)]^2$$

As the concentration of benzaldehyde become higher according to the consumption of toluene, the concentration of perbenzoic acid may increase. Perbenzoic acid is decomposed to give radicals. This increase may raise the rate of initiation step and compensate the decrease of toluene concentration to keep the rate of toluene consumption constant for a long time. But this explanation is only qualitative. Above simultaneous six first-order ordinary differential equations have been solved after Runge-Kutta Gill's method with a OKITAC 5090 electronic computer to see the dependence on the initial concentration of the toluene and cobalt salt. The meaningful results may be obtained in spite of some arbitraliness of the values of rate constants used.

The values of rate constants were changed little by little in order that the curves of the concentrations of toluene and benzaldehyde against reaction time have stronger resemblance to those obtained in experiments. One set of the rate constants which gave satisfiable calculation results are as follows.

k_1': 1×10^{-2}, k_3: 1, k_4: 1×10^{-5}, k_5: 5×10^{-5}, k_6': 1.5×10^{-2}, k_8: 2, k_9: 1×10^{-4}, k_{10}: 2×10^{-4}, k_{12}: 2×10^{1}, k_{13}: 5×10^{-3}, k_{14}: 3×10^{-1}, k_{15}: 3×10^{-1}, k_{16}: 3×10^{-1}, $mol^{-1}\,l^{-1}\,sec^{-1}$ except k_{12} ($mol^{-2}\,l^{2}\,sec^{-1}$)

According to the assumed predominance of the reaction (12) in initiation steps mentioned above, the initial conditions for intermediates, $\phi CH_2OO\cdot$, ϕCHO, $\phi COOO\cdot$, $\phi COOOH$, Co(III)Br, were given as 5×10^{-3}, 5×10^{-2}, 2×10^{-4}, 2×10^{-3}; $1—4\times10^{-3}$, mol l^{-1}, respectively.

The calculation results suggest that above elementary reactions are consistent with the observations: the apparent zero-order dependence of the rate of toluene consumption on the concentration of toluene in the solution, and the constancy of the ratio of $d[\phi CH_3]/d[\phi CHO]$ in the earlier stage of the reaction and the first-order dependence on the initial concentration of toluene and the second-order with respect to the concentration of cobalt acetate. The ratio of k_1' to k_6' suggests that the oxidation of toluene was more efficiently catalyzed than that of benzaldehyde.

Experimental

Reagents. Hydrocarbons such as toluene, were washed with sulfuric acid till the solutions were not colored and with alkaline solution, then distilled as usually. Acetic acid, cobalt acetate and sodium bromide of guaranteed grade were used without further purification.

Reaction Vessels. All runs were carried out in a 50 m*l* glass flask connected to the oxygen reservoir and the pressure was kept constant automatically in a thermostatted water bath. All measurements of absorption spectra were made by means of a Hitachi EPS-2 spectrophotometer, using 10 mm quartz cell mounted in a thermostated cell holder under temperature controll to ±0.5°C. The cells are equipped with a condenser, a oxygen inlet tube and a glass thermister to controll the reaction temperature automatically. The solution was stirred by oxygen gas.

Analysis. Quantitative analysis was made by gas chromatography and polarography, under the conditions—polyethylene glycol 6000, 20 wt%, on Flusin-T; and 50% alcoholic McIlvaine buffer solution, respectively. The concentration of bromide was determined by potentiometric titration with a siver electrode coated with argentous bromide by a standard argentous nitrate solution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 647—652 (1968)

Macro Rings. I. Syntheses of a Novel Class of Compounds with a Chain of Alternating Benzene Rings and Methylene Groups[1]

Takahiko INAZU and Tamotsu YOSHINO

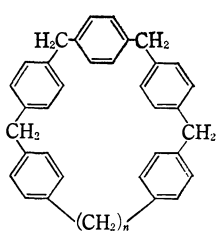
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received August 22, 1967)

As starting materials for the synthesis of a macrocyclic compound, I, bridged diphenylmethane derivatives of the general formula p-$XC_6H_4CH_2(C_6H_4CH_2)_mC_6H_4X$-$p$ were synthesized; X is hydrogen or $(CH_2)_nCOOR$ (n=0—3), m=2 or 3, and R=hydrogen or alkyl.

Because of the possibility of forming clathrate compounds and other charge-transfer complex, a macrocyclic compound constructed of four or five benzene rings and intervening methylene bridges attached to their para positions is of particular interest.

In the hope of synthesizing a paracyclophane such as I carrying four or five benzene rings, the cyclization of a chain compound with the same number of benzene rings in its molecule has been attempted several times,[2,3] all these attempts have been unsuccessful. As a result of a preliminary experiment, it seemed necessary for a compound to be cyclized to have both an appreciable solubility in an inert solvent suitable for ring closure and some crystallizability in order to avoid difficulty of isolation. For the purpose of finding an accessible and suitable material for the synthesis, bridged diphenylmethane derivatives of the general formula p-$XC_6H_4CH_2(C_6H_4CH_2)_mC_6H_4X$-$p$ were synthesized; X stands for hydrogen or $(CH_2)_n$·COOR (n=0—3), m means 2 or 3, and R represents hydrogen or alkyl.



I

Fig. 1

Esters of dicarboxylic acids derived from p-bis(p-benzylbenzyl)benzene, Vb—f, were synthesized as shown in Fig. 2 by the Friedel-Crafts acylation of 4-substituted diphenylmethanes, II, with terephthaloyl chloride to terephthalophenone derivatives, III, and either by the Wolff-Kishner reduction of III and subsequent esterification or by the formation of thioketals, IV, and subsequent desulfurization with Raney nickel. Their characteristic infrared absorption bands over the 2000—1660 cm^{-1} range obviously showed that the Friedel-Crafts acylation products, III, and the reduction products, V and VI were para-substituted compounds.

Although the Friedel-Crafts acylation of p-dibenzylbenzene VIII with p-ethoxycarbonylbenzoyl chloride yielded, as is shown in Fig. 3, p-bis[p-(p-ethoxycarbonylbenzoyl)benzyl]benzene, IX, which might be reducible to Vb, this route seemed to be less general than that illustrated in Fig. 2.

The p-dibenzylbenzene, VIII, has been obtained by the Friedel-Crafts reaction of benzyl chloride and benzene, but it has also been reported that the product was accompanied by other isomers and that the separation was fairly difficult because of the similarity of boiling point, melting point and other characteristics between these isomers.[4] The p-dibenzylbenzene, VIII, was prepared in a pure state either by the Friedel-Crafts alkylation of benzene with p-xylylene chloride, using sulfuric acid as a catalyst, or by the Grignard-coupling reaction of phenylmagnesium bromide with p-xylylene chloride.

Dimethyl bis(p-benzylphenyl)methanedipropionate, XII, was synthesized as shown in Fig. 4. The condensation of p-substituted diphenylmethane, IId, with chloral gave a DDT-type compound, X. The hydrolysis and decarboxylation of X according to the method of Bergmann[5] led to XI, which was then esterified to XII.

Of all the reactions leading to cyclic compounds, the acyloin condensation of diester is one of the

most popular methods, especially when a satisfactory yield is needed. However, acyloin condensation is usually inapplicable to a compound with a carboxylate group or an acetate group attached to a benzene ring. The Blomquist cyclization method,[6] utilizing the intramolecular condensation of a bifunctional ketene derived from a dicarboxylic acid chloride, is also unsuitable for a compound with an chloroformyl group substituted in

6) A. T. Blomquist and R. D. Spencer, *J. Am. Chem. Soc.*, **70**, 30 (1948).

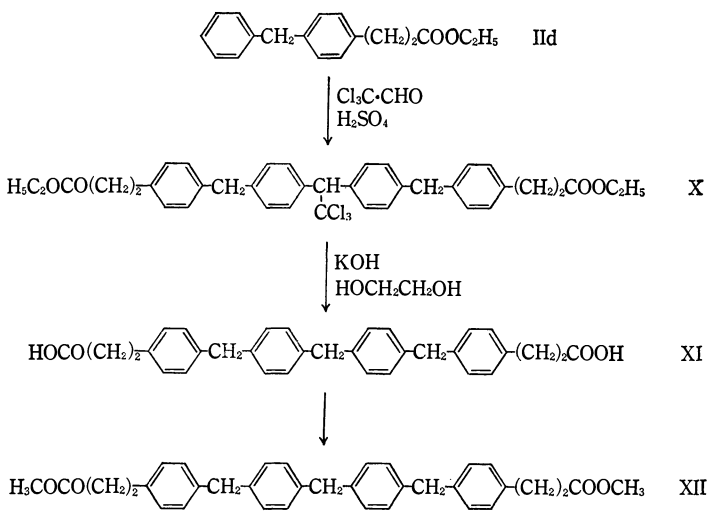

Fig. 4

a benzene ring. For the purpose of obtaining a compound adaptable to cyclization by acyloin or a like reaction, the synthesis of the diphenylmethane derivative, XX, carrying three benzene rings and two cyclohexane rings was carried out as shown in Fig. 5 in a way analogous to that outlined in Fig. 2.

4-Benzylcyclohexanecarboxylic acid, XV, obtained by the reduction of diphenylmethane-4-carboxylic acid, XIV, with sodium and isoamyl alcohol, was confirmed to be identical with the *trans*-4-benzylcyclohexanecarboxylic acid derived from *trans*-hexahydroterephthalic acid, by a comparison of the melting points, infrared spectra, and thin-layer chromatograms of the two anilides.[7]

As a result of the present work, some synthetic procedures for obtaining a compound to be cyclized have been found to be disadvantageous because of either a poor over-all yield or a tedious separation of an intermediate difficult to crystallize or of an end product.

Experimental

All melting points are uncorrected. The physical properties and analytical data of the products are summarized in Table 1.

4-Substituted Diphenylmethanes (IIb—f). *The Ester IIb.* A haloform-reaction product of 4-acetyldiphenylmethane was esterified with ethanol and sulfuric acid.

The Ester IIc was prepared by the hydrolysis[8] and esterification of the 4-cyanomethyldiphenylmethane derived from 4-chloromethyl diphenylmethane.

The Ester IId was prepared by the hydrolysis, decarboxylation, and esterification of the condensation product of 4-chloromethyldiphenylmethane and diethyl sodiomalonate.[8,9] The ester IId was also obtained by the hydrolysis and esterification of a thiomorphoride which had been derived, by a modified Willgerodt reaction, from 4-propionyldiphenylmethane.[10]

The Ester IIe was prepared by the Friedel-Crafts acylation of diphenylmethane with β-methoxycarbonylpropionyl chloride.[11]

The Ester IIf was prepared by the reesterification of the Wolff-Kishner reduction product of IIe.

Terephthalophenone Derivatives (IIIb). To a stirred mixture of 9.2 g of terephthaloyl chloride[3] and 27.5 g of anhydrous aluminum chloride in 100 m*l* of carbon disulfide, there was added slowly, at room temperature, 21.0 g of ethyl 4-diphenylmethanecarboxylate. After the addition, the mixture was stirred for 5 hr at room temperature, left to stand overnight, and refluxed with stirring for 5 hr. After the distillation of the carbon disulfide, the residue was poured onto crushed ice and water. The white solid which deposited was collected by filtration and washed with water, dilute hydrochloric acid, and again with water. Recrystallization from ethanol gave 23.2 g of colorless crystals, mp 162—164°C. An analytical sample was recrystallized from a benzene-ethanol mixture to give colorless needles.

The Thioketal (IVAb). To a mixture of 10.0 g of the keto ester, IIIb, and 4 m*l* of ethanedithiol in 150 m*l* of benzene, 4 m*l* of boron trifluoride etherate were added, after which the mixture was refluxed for 2 hr. After it had then stood for 3 hr at room temperature, 50 m*l* of methanol were added. The removal of the solvent gave 12.0 g of a pale yellow, crystalline powder, which was then washed with acetone and ethanol. An analytical sample was recrystallized from benzene-ethanol mixture.

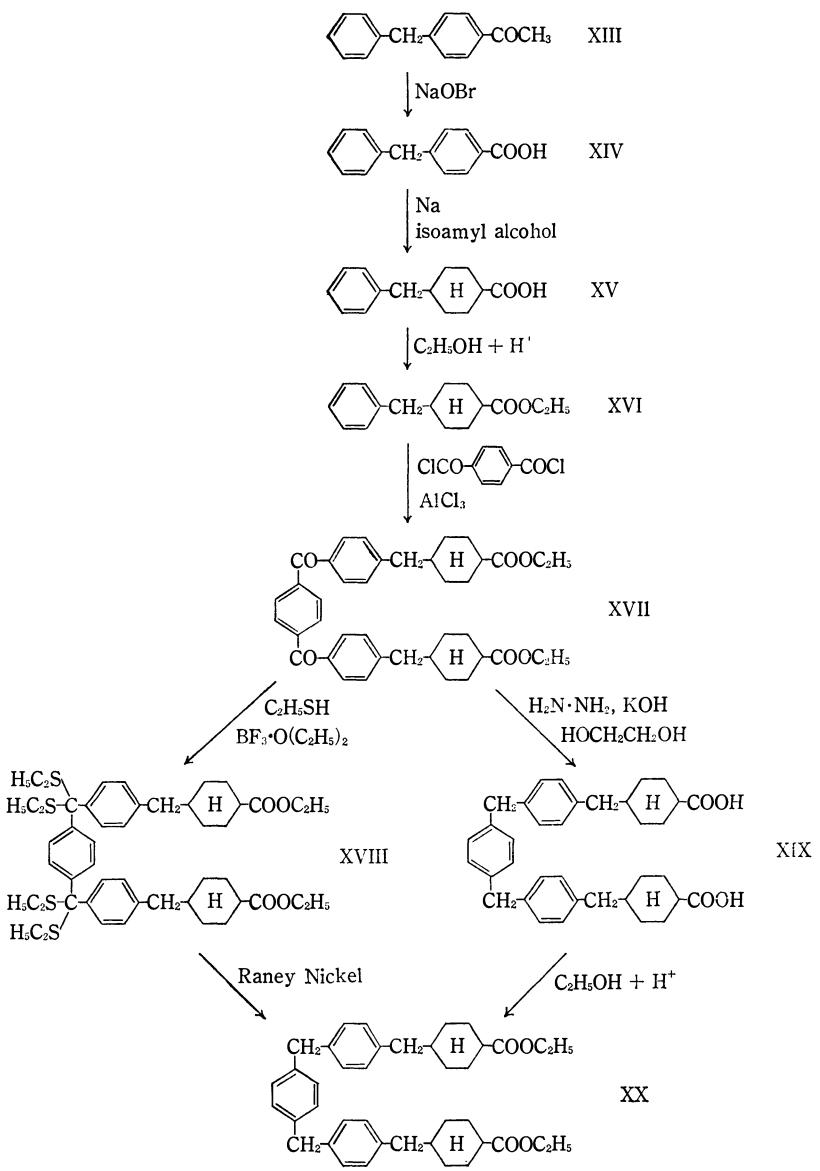

Fig. 5

The Ester (Vb). The thioketal, IVBb, obtained from 1.0 g of the keto ester, IIIb, was refluxed for 16 hr with an excess of Raney nickel in a benzene-ethanol mixture, after which the catalyst was filtered off. The concentration of the filtrate gave 500 mg of colorless crystals, which were recrystallized from a benzene-ethanol mixture, mp 140—141°C.

Carboxylic Acid (VIj). A mixture of 40 m*l* of 90% hydrazine hydrate, 40 g of potassium hydroxide, 250 m*l* of ethylene glycol, and 10 g of keto acid, IIIi, was refluxed for 12.5 hr. After cooling, the deposit, consisting of 5 g of the potassium salt of VIj, was recrystallized from acetic acid to give needles of free acid, mp 225—229.5°C. The potassium salt was converted to free acid during the recrystallization.

The Ester (Vf). Carboxylic acid, VIj (14.5 g, dissolved in benzene), was esterified with methanol and sulfuric acid, and then recrystallized from a benzene-ethanol mixture to give 13.7 g of colorless crystals, mp 133.5—135°C.

***p*-Dibenzylbenzene (VIII).** *Method A*: A mixture of 10 g of *p*-xylylene chloride,[12] 5 m*l* of sulfuric acid, and 100 g of benzene was refluxed for a few days. After the removal of the acid, the mixture was distilled to remove the benzene, and then fractionated under diminished pressure. The first fraction removed, boiling at 125°C/5 mmHg, was an unchanged chloride amounting to 2.5 g; the successive fraction, boiling at 185°C/5 mmHg, was collected to give 3.4 g of colorless crystals, which were recrystallized from ethanol to give VIII, mp 85—86.5°C (reported mp 86°C).[4]

p) as a hydrate with a half molecule of water. q) as a hydrate with one fourth molecule of water.
Ac=acetone, AcOH=acetic acid, B=benzene, c=crystals, E=ethanol, liq=liquid, M=methanol, n=needles, PB=petroleum benzin, p=powder, pr=prisms, py=pale yellow, w=white, W=water.

Method B: A solution of 10 g of *p*-xylylene chloride in 80 m*l* of benzene was added to a solution of phenylmagnesium bromide in 60 m*l* of ether. The mixture was refluxed and then distilled to remove the ether. After the solution had been left standing overnight, crushed ice and dilute hydrochloric acid were added. An oily substance which separated from the organic layer was distilled at 140—185°C/4 mmHg to give 7.6 g of colorless crystals, which were recrystallized to give colorless plates, mp 85.5—87°C.
No melting-point depression was observed when this substance was admixed with a sample prepared by the method A.

Keto Ester (IX). To a stirred mixture of 25.5 g of powdered anhydrous aluminum chloride and 15 g of *p*-ethoxycarbonylbenzoyl chloride[13] in 50 m*l* of carbon disulfide, there was added a solution of 10 g of *p*-dibenzylbenzene VIII in 80 m*l* of carbon disulfide. After additional stirring for 2 hr at room temperature, the mixture was refluxed for 21 hr, and decomposed with dilute hydrochloric acid and crushed ice after the removal of the carbon disulfide by distillation. The deposit was extracted with benzene to yield 5.6 g of colorless crystals. An analytical sample was recrystallized from ethanol to give colorless crystals, mp 121—126.5°C.

Carboxylic Acid (XI). To a stirred mixture of 2.75 g of freshly-prepared anhydrous chloral and 10.0 g of the ester IId, 25 m*l* of concentrated sulfuric acid were added, drop by drop, under cooling. After additional stirring for 3.5 hr, the mixture was poured onto crushed ice. The pale pink, gummy deposit was refluxed with a solution of potassium hydroxide in 100 m*l* of ethylene glycol for 14 hr, and then poured onto crushed ice and acidified with dilute hydrochloric acid. The deposit afforded XI as a pale brown powder (600 mg); this powder was crystallized from ethanol to give a crystalline powder with a mp 212—213°C.

***trans*-4-Benzylcyclohexanecarboxylic Acid (XV).** Into a solution of 60 g of 4-benzylbenzoic acid, XIV, obtained from 4-acetyldiphenylmethane, XIII, by haloform reaction and dissolved in 1250 m*l* of isoamyl alcohol, there were stirred, portion by portion, 148.9 g of sliced sodium. The mixture was refluxed with stirring for 3 hr, and then cooling water was added. After the removal of the isoamyl alcohol by steam distillation, the solution was neutralized and extracted with ether. The usual treatment gave 42 g of colorless needles, mp 79—80°C. An analytical sample was recrystallized from a methanol-water mixture.

Macro Rings. II.[1] Synthesis of [2.1.1.1.1]Paracyclophane

Takahiko INAZU and Tamotsu YOSHINO

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received August 22, 1967)

A macrocyclic compound which incorporates five benzene rings and intervening methylene bridges as parts of a large ring structure, [2.1.1.1.1]paracyclophane I ($n=2$), was synthesized and then compared with a corresponding open-chain analog, X.

Because of its ability to form clathrates or charge-transfer complexes, a macrocyclic compound, I, furnished with an empty space of an appropriate size at the center of its molecule is of particular interest.

Although several attempts have been made to synthesize paracyclophane with four or five benzene rings by an intramolecular cyclization reaction, these attempts have all resulted in failure.[2,3]

As an initial step of the present investigation, [2.1.1.1.1]paracyclophane I ($n=2$) was synthesized. This may be the first example of a paracyclophane constructed with five benzene rings and intervening methylene bridges. As the result of several preliminary experiments, the Wurtz reaction was adopted for the synthesis of the paracyclophane.

The yield of a macrocyclic compound by the usual Wurtz reaction is generally poor, but the modified Wurtz reaction using sodium adduct of tetraphenylethylene has been proved to be useful for improving the yield of cyclization. It has also been verified that the improved, intramolecular Wurtz-type reaction is appreciable to a large ring formation from a compound with two distant halogen atoms in a chain molecule.

Although a chain compound of the benzyl-bromide type, IX, seemed to be a reactive material, an attempt to cyclize the compound IX was thwarted because of the compound's insufficient solubility in tetrahydrofuran at room temperature. This difficulty was surmounted by using the corresponding compound of the benzyl-chloride type, VIII, in place of the bromide, IX.

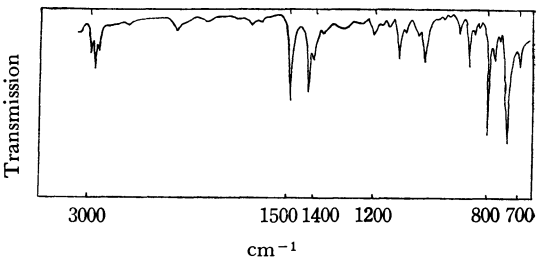

Fig. 4. Infrared spectrum of the open chain analog X in KBr disk.

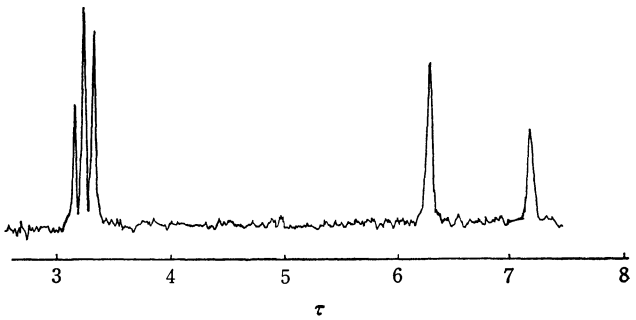

Fig. 5. The NMR spectrum of [2.1.1.1.1]paracyclophane I.

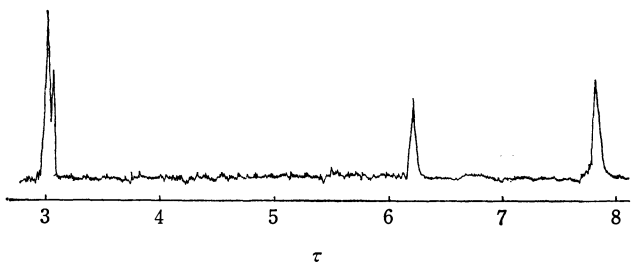

Fig. 6. The NMR spectrum of the open chain analog X.

The synthetic route is outlined in Fig. 1. A keto ester, II,[1] was converted to another ester, VI, either by the desulfurization of a thioketal, V, with Raney nickel, or by the Wolff-Kishner reduction to an acid, III, followed by esterification *via* acid chloride, IV. The ester VI was reduced with lithium aluminum hydride, and the resulting carbinol, VII, was treated with phosphorus tribromide or phosphorus pentachloride to give, respectively, a bromide, IX, or a chloride, VIII. This bromide and this chloride were each then reduced with lithium aluminum hydride to a compound, X. This compound was synthesized as a reference compound which served as a chain analog of the cyclophane, I, for a comparison of their spectra.

With the aid of a modified high-dilution technique, [2.1.1.1.1]paracyclophane, I, was obtained as colorless crystals by the intramolecular condensation of the chloride VIII with the sodium adduct of tetraphenylethylene in tetrahydrofuran at room temperature under a nitrogen atmosphere; this was done according to the method of Müller and Röscheisen.[4]

The close resemblance of the ultraviolet spectrum of the compound I to that of a corresponding chain compound, X, reveals that benzene rings of the compound I are probably planar, unlike the distorted non-planar rings in [2.2]paracyclophane.[5] This fact was anticipated from our having been able to assemble a molecular model of the macrocyclic compound, I, without any strain.

The NMR spectrum of the compound I was in accord with that assumed tentatively for the cyclic structure: $\tau=7.13$ singlet (ethylene protons), $\tau=6.26$ singlet (methylene protons), and three singlets (benzene ring protons) at $\tau=3.13$, 3.20, and 3.29. Each of the peaks for protons of the benzene ring and methylene and ethylene groups was a singlet; this suggests that the conformation of the cyclic compound, I, may be flexible, without any rigid fixation, in a solution at room temperature. In the NMR spectra, the peak for methylene protons in the cyclic compound, I, was found to shift upfield by 0.14 ppm from that for the methylene protons of diphenylmethane. Peaks for benzene the rings A, B, and C in the cyclic compound, I, were also found to shift upfield by 0.17, 0.24, and 0.33 ppm respectively from those for benzene protons in diphenylmethane. These upfield shift is attributable to the fact that protons of the cyclophane I may be a little more shielded by transannularly-situated benzene rings than are protons of diphenylmethane.

Although no marked difference was observed between the IR spectra of the cyclic compound, I, and that of the chain analog, X, the results of the molecular-weight determination excluded the possibility of the compound I being a polymer. The cyclic structure of the compound I being different from that of the chain compound, X; this

4) E. Müller and Röscheisen, *Chem. Ber.*, **90**, 543 (1957).
5) D. J. Cram and H. Steinberg, *J. Am. Chem. Soc.*, **73**, 5691 (1951).

fact was confirmed by the NMR spectrum, as has been described above.

Experimental

All melting points are uncorrected. The ultraviolet spectra were measured on a Hitachi EPS-3T spectrophotometer. The infrared spectra were measured on a Hitachi EPI-S2 spectrophotometer. The NMR spectra were recorded on a Varian Associates A-60 model, using tetramethyl silane as the internal standard and carbon tetrachloride as the solvent.

***p*-Bis[*p*-(*p*-carboxybenzyl)benzyl]benzene (III).** A mixture of 20 g of a keto ester, II, 80 m*l* of 80% hydrazine hydrate, 60 g of potassium hydroxide, and 240 m*l* of ethylene glycol was refluxed for 17.5 hr. After cooling, the mixture was neutralized with concentrated hydrochloric acid to give 17.2 g (almost a theoretical yield) of a white powder, mp above 290°C. Found: C, 81.51; H, 5.82%. Calcd for $C_{36}H_{34}O_4 \cdot \frac{1}{4}H_2O$: C, 81.41; H, 5.80%.

***p*-Bis[*p*-(*p*-chloroformylbenzyl)benzyl]benzene (IV).** A mixture of 24.5 g of the acid, III, and 70 g of phosphorus pentachloride in 200 m*l* of chloroform was refluxed for 3 hr; after the solvent and phosphoryl chloride had been removed by distillation under reduced pressure, pale pink crystals were obtained in an almost theoretical yield.

***p*-Bis[*p*-(*p*-ethoxycarbonylbenzyl)benzyl]benzene (VI).** To a solution prepared by dissolving the acid chloride, IV, derived from 24.5 g of the acid, III, in 100 m*l* of chloroform, 100 m*l* of ethanol was added, little by little under cooling, and the mixture was refluxed for 30 min. The removal of the chloroform by distillation gave 20.3 g (74.5%) of colorless crystals, which were confirmed to be identical with a smaple prepared from the compound II *via* a thioketal, V, by a comparison of their infrared spectra and melting points.

***p*-Bis[*p*-(*p*-hydroxymethylbenzyl)benzyl]benzene (VII).** A solution of 7.8 g of the ester VI in 200 m*l* of tetrahydrofuran was added, at room temperature, to a mixture of 1.9 g of lithium aluminum hydride in 100 m*l* of tetrahydrofuran placed in a flask fitted with a reflux condenser, after which the mixture was refluxed for 1¾ hr with stirring. After being cooled and treated with hydrochloric acid, the mixture was distilled under diminished pressure to remove the solvent. The residue gave 6.4 g (96% yield) of a white powder, which was recrystallized from tetrahydrofuran to give a white crystalline powder, mp 203—205°C. Found: C, 86.53; H, 7.04%. Calcd for $C_{36}H_{34}O_2$: C, 86.71; H, 6.87%.

***p*-Bis[*p*-(*p*-chloromethylbenzyl)benzyl]benzene (VIII).** A mixture of 6.4 g of the diol, VII, 25 g of phosphorus pentachloride, and 150 m*l* of chloroform was refluxed for 3 hr, and then distilled under diminished pressure to remove the chloroform and phosphoryl chloride. The residue gave a white crystalline mass, which was recrystallized from tetrahydrofuran to give 5.05 g (73.5% yield) of colorless crystals, mp 182.5—183°C. Found: C, 80.47; H, 6.02%. Calcd for $C_{36}H_{32}Cl_2$: C, 80.74; H, 6.02%.

***p*-Bis[*p*-(*p*-bromomethylbenzyl)benzyl]benzene (IX).** A mixture of 1.0 g of the diol VII and 12 m*l* of phosphorus tribromide was refluxed for 3.5 hr and then, after the addition of 50 m*l* of chloroform, refluxed for an additional 5 hr. After cooling, the whole was poured onto crushed ice. The evaporation of the chloroform gave 1.3 g (almost a theoretical yield) of a white crystalline powder, mp 191°C (dec.). Found: C, 69.38; H, 5.36%. Calcd for $C_{36}H_{32}Br_2$: C, 69.24; H, 5.17%.

***p*-Bis[*p*-(*p*-methylbenzyl)benzyl]benzene (X).** A suspension of 500 mg of the bromide, IX, in 100 m*l* of tetrahydrofuran was stirred, drop by drop, into a mixture of lithium aluminum hydride in 40 m*l* of tetrahydrofuran at room temperature; after stirring for an additional 1.5 hr, the mixture was refluxed for 2 hr. After cooling, the mixture was treated with water and then with dilute hydrochloric acid. The removal of the tetrahydrofuran under reduced pressure gave a pale yellow powder, which was recrystallized from an ethanol-benzene mixture to give 240 mg (65% yield) of a white crystalline powder, mp 153°C. Found: C, 91.86; H, 7.41%. Calcd for $C_{36}H_{34}$: C, 92.66; H, 7.34%.

[2.1.1.1.1]Paracyclophane (I). Into a dark-violet solution of an adduct of sodium and 1.8 g of tetraphenylethylene in 100 m*l* of tetrahydrofuran, there was stirred a solution of 2.0 g of the chloride, VIII, in 400 m*l* of tetrahydrofuran; the addition was made *via* a modified Hershberg dropping funnel[6] at room temperature, under a nitrogen atmosphere, and over a period of 14.5 hr. After being left standing for several hours, the mixture was distilled to remove the tetrahydrofuran; then water and ethanol were added to give 3.5 g of a pale yellow powder, which was collected by filtration and then subjected to fractional crystallization from a benzene-ethanol mixture to give 87 mg of colorless crystals, mp 257°C. Found: C, 92.73; H, 6.96%; mol wt, 495 (Rast). Calcd for $C_{36}H_{32}$: C, 93.06; H, 6.94%; mol wt, 464.62.

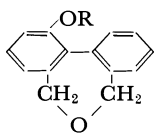
The rates of inversion of 1-hydroxy-5, 7-dihydrodibenz[*c*, *e*]oxepin (I) and its methyl ether (II) have been measured by NMR line-shape method in several solvents. The activation parameters for inversion of II are insensitive to the change in solvents, while the activation energy of I in strongly proton-accepting DMSO is clearly smaller by one kcal/mole than that of I in $CDCl_3$ and those of II. The solvent effect may be due partly to the enhanced mesomerism of the biphenyl system as the result of hydrogen bonding and partly to the inhibition of the intramolecular O–H$\cdots\pi$ interaction which will otherwise stabilize the non-planar ground state in the inert solvents.

NMR spectroscopy has lately been applied to the study of rates of the restricted rotation of biphenyls with the rate constants of 1 to 10^3 sec^{-1} by observing the temperature-dependent signal shape of the dissymmetrically disposed methylene protons which are originally diastereomeric but tend to be equalized by mutual exchange of their magnetic environments through rotation around the pivot bond of the biphenyl skeleton.[1-5] Before the advent of this NMR technique of kinetics, rates of the restricted rotation and inversion of biphenyl derivatives had solely been measured by following rates of racemization of the optically active biphenyls through polarimetry.[6,7] Although some criticisms have been thrown on both theoretical and practical conformities of the kinetic parameters obtained by the two independent methods,[8,9] the equivalence between them has been demonstrated experimentally by comparing directly the kinetic results derived from the two methods with the same rate process.[5,10] It has also been demonstrated that the solvent effect on the rates of biphenyl inversion is rather small as far as there is no special solute-solvent interaction.[4,5,11] In the present paper the NMR method is developed to explore the effect of solvents on the rates of inversion of 1-hydroxy-5, 7-dihydrodibenz[*c*, *e*]oxepin (I) and its methyl ether (II), where strong solute-solvent interaction may be expected to take place in the former through hydrogen bonding when a suitable solvent is used.



I (R=H)

II (R=CH_3)

Experimental

Materials and Solvents. *1-Hydroxy-5, 7-dihydrodibenz[c, e]oxepin (I).* Preparation of this compound was described elswhere.[12]

1-Methoxy-5, 7-dihydrodibenz[c, e]oxepin (II). I was methylated with dimethyl sulfate as usual to give an oil, bp 153°C/2 mmHg. Found: C, 79.44; H, 6.33%. Calcd for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24%.

All the solvents were of spectro-grade containing enough TMS to make the reference signals of comparable intensity to those of CH_2 resonances investigated. To dimethyl-d_6 sulfoxide was added 5% w/w acetone-d_6 in order to lower the freezing point.

Spectral Measurements. The NMR spectra were obtained on a Varian A-60 spectrometer operating at 60 Mc/sec and equipped with a variable temperature accessory. TMS was used as the internal reference,

and the calibration of the spectrometer checked by the usual side-band technique. Temperature reading was calibrated by examining the CH_3 and OH signal separation of a methanol sample as prescribed in the instruction manuals, and the reading is accurate to ± 2.0°C.

Within the measurement of a given sample, the strength of the radiofrequency was held sufficiently small and the spectra were assured of being far below saturation by observing no lowering in the peak intensity on a slight raising of the r.f. field. Since the apparent amplitude of the normal signals decreases as the temperature is raised mainly because of the thermal expansion of the solvent and the consequent apparent dilution, the recorder gain was adjusted to attain the desired amplitude of the signals. Each resonance was swept three times in turn without altering the controls. The usual sweep rate was 1 cps/sec.

The exchange broadening of the two interacting nuclear spin resonance signals has been written down by Alexander.[13] Under slow-exchange limit at lower temperature, the observed change in the line-width w is correlated to the life-time τ by Eq. (1);

$$\tau = \frac{1 \pm J_{AB}/\sqrt{\delta_{AB}^2 + J_{AB}^2}}{\pi(w - w_0)} \qquad (1)^{5}$$

At the very point of the coalescence of the AB-quartet signal, τ_c is given by Eq. (2) when natural line-width in the absence of exchange, w_0, is negligible.

$$\tau_c = \frac{\sqrt{2}}{\pi\sqrt{\delta_{AB}^2 + 6J_{AB}^2}} \qquad (2)^{2,3}$$

Above the coalescence temperature, the width of the coalesced singlet relative to that at $\tau=0$ can again be used to calculate τ from Eq. (3);

$$\tau = \frac{2(w - w_0)}{\pi\delta_{AB}^2} \qquad (3)^{4,5}$$

Equations (1) to (3) were employed to calculate the exchange life-time from the observed change in the line shapes. The line-width in the absence of the exchange, w_0, was read directly from the CH_2 signals at enough low (−20°C) and/or high (150°C) temperature where $\tau=\infty$ and $\tau=0$ hold approximately.

Results and Discussion

In every solvent examined, both I and II at the lower temperature show double AB-quartet signals due to the presence of two pairs of the methylene groups. In Tables 1 and 2 are shown the spectral parameters. The quartet at the higher applied magnetic field can be assigned to the methylene protons attached to the benzene ring carrying the hydroxyl group and the methoxyl group in I and II, respectively. The assignment bases upon the fact that the aromatic methyl signal of *m*-methylanisole resonates at τ 7.77 which is located at the higher field than that of toluene, τ 7.66,[14] but the reverse assignment does not affect the following discussion. From the fact that the chemical shifts of the four protons on a pair of methylene groups can be differentiated, it

Table 1. The methylene proton spectra of I at the lower temperatures

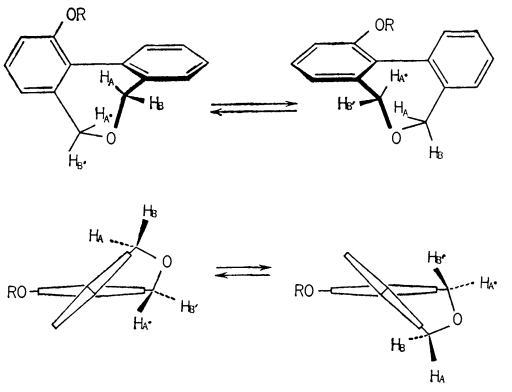
is concluded that at these temperatures specified in Tables 1 and 2 the two benzene rings in I and II are fixed as non-planar in the sense of NMR and that the rate of restricted rotation around the pivot bond (Eq. (4)) should be less than a few times in a second.

At enough elevated temperatures, the methylene groups show two singlet signals at the center of the original pair of AB-quartets. In these circumstances, the thermal motion is active enough to bring the rates of inversion (Eq. (4)) faster than 10^3 sec^{-1}, and thus the two methylene protons on the same carbon atom cannot be distinguished.



(4)

In the intermediate temperature, as the temperatures is raised, the line-width of the quartet broadens at first with the two outer lines broadening more rapidly than the two inner lines. The broadened signals coalesce gradually to a singlet, and then the peak intensity of the singlet increases at the expense of the line-width. Some typical

experimental curves are shown in Fig. 1. Two pairs of AB-quartet overlap rather heavily on a 60 Mc/sec NMR chart, and therefore the estimated error of the coalescence temperature (T_c) is ±5°C. In Table 3 are shown the approximate T_c's of the spectra. It is to be emphasized that, in a given sample, an AB-quartet of a smaller δ_{AB} has the lower T_c. I in DMSO is unique in that it has rather low T_c's with respect to the greater δ_{AB}. The data are indicative of the lower activation energy for inversion than those in the other systems.

Table 3. The coalescence temperature (T_c) of the AB-quartets and the life-time (τ_c) at the temperature

	Solvent	δ_{AB} cps	T_c °C	τ_c 10^{-3} sec
I	$CDCl_3$	27.4	48	11.6
		19.1	40	13.6

TABLE 6. ACTIVATION PARAMETERS FOR THE INVERSION OF I AND II IN SEVERAL SOLVENTS

	Solvent	E_a kcal/mol	log A
I	$CDCl_3$	16.9±1.0	13.6±0.8
	DMSO	15.6±1.2	13.6±0.9
II	C_2Cl_4	17.0±1.0	13.5±0.8
	$CDCl_3$	16.9±1.0	13.5±0.8
	DMSO	17.2±1.4	13.7±1.0

determined by the method of least squares.[16] The results are summarized in Table 6. Although the number of solvents examined is quite limited, they cover wide varieties of the solvent properties; dielectric constant, polarity, basicity, viscosity,[17] *etc.* From the data obtained for II in Table 6, it follows again that the kinetic parameters for inversion are, within the experimental error, almost independent of the solvents.[18] Because the energy of activation for inversion of biphenyls such as II may be regarded to be governed by the non-bonded repulsion and the ring-strain in the activated state for the process, and because they are rather insensitive to the intermolecular interaction, the indifference to the change in solvent is not unreasonable.

To the contary, the activation parameters for the inversion of I in $CDCl_3$ and DMSO are decidedly different. Since DMSO is famous for its strong proton-accepting ability for phenols,[19] the hydrogen bonding must be playing some role. Two mechanisms may then be considered to be operative. Firstly, the strong hydrogen bonding between the hydroxyl group of I and DMSO will

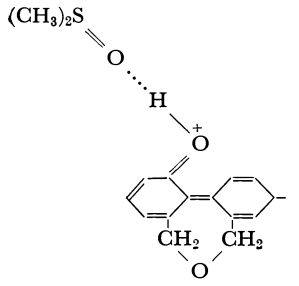
16) The probable errors in the values of E_a and log A thus determined are ±0.3 kcal/mol and ±0.2, respectively. For a more realistic estimate of the uncertainty in these kinetic paramaters, each point was marked as a rectangle corresponding to the uncertainty of the point; two straight lines with maximum and minimum slopes were drawn in such a manner as to pass through each rectangle. The probable errors thus obtained are listed in Table 6.

17) A change in viscosity of the medium will contribute to the width of the NMR lines investigated and may affect the activation parameters, but the contribution of this relaxation width is discarded from the constancy of the width of other lines in the same molecule, *e. g.*, that of CH_3O signal.

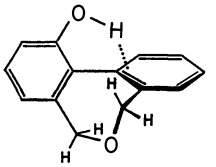
18) Graybill and Leffler[11] examined the rates of racemization of dimethyl *o, o'*-dimethoxydiphenate in 23 solvents. The rates vary by about a factor of two and the activation energy has a range of 2.1 kcal/mol. There is a general tendency for the ester to racemize more rapidly in polar solvents and the alcoholic proton donor solvents ratard the racemization, although the latter solvents have not been tested for the present examples.

19) A. Wagner, H. J. Becjer and K.-G. Kottenhahn, *Chem. Ber.*, **89**, 1708 (1956); S. Ghersetti and A. Lusa, *Spectrochim. Acta*, **21**, 1067 (1965).

reduce the electronegativity of the hydroxyl oxygen and the consequent conjugation between the two benzene rings. This contribution III stabilizes the planar conformation corresponding to the activated state for inversion more than the non-planar ground state. In effect E_a will be reduced relative to that of non-hydrogen bonded cases.



III



IV

Secondly, it has been shown by the infrared spectroscopy of the ν_{O-H} region that there is an intramolecular interaction between the hydroxyl group and the π-electrons on the benzene ring (IV) in the ground state of I in non-associative solvents, while no such intramolecular O–H$\cdots\pi$ interaction takes place in the planar 2-hydroxybiphenyl derivatives which may represent a model for the activated state for inversion.[12] The ground state of I in $CDCl_3$ is, therefore, stabilized with respect to the activated state by the energy of that interaction which is expected to be of the order of 1.5 kcal/mol.[20] Since DMSO is a powerful proton acceptor[19] and the hydroxyl group in I is essentially deprived of the intramolecular O–H$\cdots\pi$ interaction in this solvent, the ground state of I is not stabilized relative to the excited state. Accordingly E_a for inversion should be smaller in DMSO than in $CDCl_3$ by the amount of the energy of that O–H$\cdots\pi$ interaction (IV). The observed value is compatible with that obtained by the IR measurements.[12,20]

The experiments are now in progress to separate the contribution of the two factors.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 660—664 (1968)

Kinetic Studies of the Oxidation of Benzils with Peroxyacetic Acid in Acetic Acid

Yoshiaki FURUYA and Iwao URASAKI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto

(Received September 4, 1967)

The oxidation of benzils with peroxyacetic acid in the presence of sulfuric acid in acetic acid has been studied kinetically. The rate of the consumption of peroxyacetic acid has been found to be the sum of the four terms shown in the following equation:

$$-\mathrm{d}[AcO_2H]/dt = \{k_d + k_t[H_2SO_4]\}[AcO_2H] + \{k_2 + k_2'[H_2SO_4]\}[Bz_2][AcO_2H]$$

It is considered that the first and second terms correspond to the decomposition of peroxyacetic acid itself and to the acid-catalyzed reversible transformation of peroxyacetic acid to acetyl peroxide, while the third and fourth terms represent, respectively, the non- and the acid-catalyzed oxidations of benzils with peroxyacetic acid. In both non- and acid-catalyzed oxidations, a probable mechanism passing through benzoic anhydride is postulated.

When the α-diketones are treated with oxidizing agents, such as hydrogen peroxide,[1] potassium periodate[2] and peroxyacetic acid,[3] the corresponding carboxylic acids are obtained. One mechanism of the reaction has already been discussed[1] briefly on the basis of the synthetic results. The present authors have now followed the reaction of benzils with peroxyacetic acid by iodometry and will here discuss a probable mechanism.

Experimental

Materials. Peroxyacetic acid was prepared by the reaction of acetic anhydride with hydrogen peroxide in the presence of sulfuric acid.[4] The benzils were prepared by means of the benzoins[5] obtained from the

1) J. E. Leffler, *J. Org. Chem.*, **16**, 1785 (1951).
2) V. J. Shiner and C. R. Wasmuth, *J. Am. Chem. Soc.*, **81**, 37 (1959).
3) J. Böeseken and G. Slooff, *Rec. trav. chim.*, **49**, 91 (1930).

corresponding aldehydes, and were then recrystallized from methanol; benzil,[6] mp 95.5—96°C (lit., 94—95°C); *p*-tolil,[7] mp 103—104°C (lit., 104—105°C); *p*-anisil,[8] mp 133.5—134°C (lit., 133°C). Benzoic anhydride was recrystallized from a mixture of benzene and petroleum ether; mp 43—43.5°C. Benzoic acid was recrystallized from water; mp 122.5—123°C.

Reaction Products Criterion. A mixture (20 m*l*) of benzil (0.1 M), peroxyacetic acid (0.5 M), and sulfuric acid (0.2 N) in acetic acid was heated at 70°C for 10 hr, and then allowed to stand 2 days at room temperature. The reaction mixture was poured into water (100 m*l*). The product extracted with chloroform (30 m*l*) was identified as benzoic acid by the mixed-melting-point method; yield 90%, mp and mmp 122—122.5°C. The evolution of oxygen gas during the reaction was found by means of gas chromatography employing a Hitachi gas chromatograph, model KGL-2A, operated with a 3-m column packed with molecular sieve 13X and using helium with a flow rate of 25 m*l*/min at 38°C. The retention time was 2.5 min for oxygen and 3.2 min for nitrogen. The formation of acetyl peroxide was observed by paper chromatography under the same conditions as have been previously reported.[9]

Typical Run for the Rate Measurements. A solution of 1 m*l* of *ca.* 1 M peroxyacetic acid in acetic acid was poured into a solution of 9 m*l* of 0.11 M benzil in acetic acid to start the reaction after the two solutions had attained a temperature equilibrium at 70°C. Aliquots (each 1 m*l*) were taken out at appropriate time intervals and introduced to 100 m*l* of an ice-cooled aqueous solution of *ca.* 0.06% potassium iodide. The iodine liberated by peroxyacetic acid was quickly titrated with 0.01 N sodium thiosulfate in order to estimate the concentration of the remaining peroxyacetic acid.

Results and Discussion

The initial rate of the reaction satisfied the first-order equation in the concentration of the remaining peroxyacetic acid, as is illustrated in Table 1.

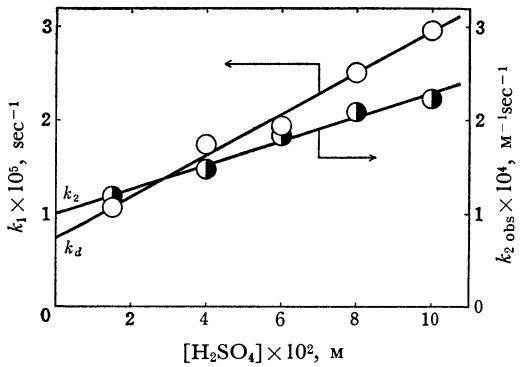

Fig. 3. Effect of the acidity of medium on the rate constants at 70°C.
Initial concn. of CH_3CO_3H: 0.1 M

Fig. 2, however, the plots of $k_{1\,obs}$ *vs.* the initial concentration of benzil gave a straight line, which satisfied the following equation:

$$k_{1\,obs} = k_1 + k_{2\,obs}[Bz_2]$$

The plots of k_1 and $k_{2\,obs}$ *vs.* the concentration of sulfuric acid gave straight lines, as Table 2 and Fig. 3 show; these lines followed the accompanying equations, respectively:

$$k_1 = k_d + k_t[H_2SO_4]$$

and $$k_{2\,obs} = k_2 + k_2'[H_2SO_4]$$

The plots of $\log(k_1 - k_d)$ and $\log(k_{2\,obs} - k_2)$ *vs.* H_0[10] gave straight lines with slopes of -0.94 and -0.95 respectively (Fig. 4). From these results,

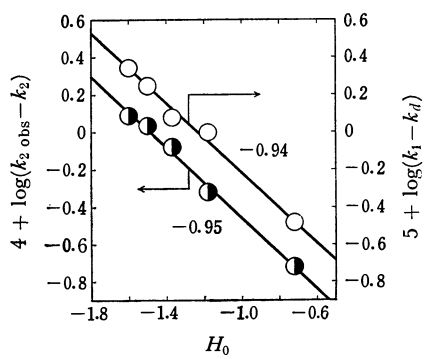

Fig. 4. Plots of $\log(k_1 - k_d)$ and/or $\log(k_{2\,obs} - k_2)$ *vs.* H_0 in acetic acid at 70°C.

it may be considered that the proton participates once before the rate-determining step in both the acid-catalyzed first-order and second-order reactions.

Finally, the rate equation is expressed as:

$$-d[AcO_2H]/dt = \{k_d + k_t[H_2SO_4]\}[AcO_2H] + \{k_2 + k_2'[H_2SO_4]\}[Bz_2][AcO_2H]$$

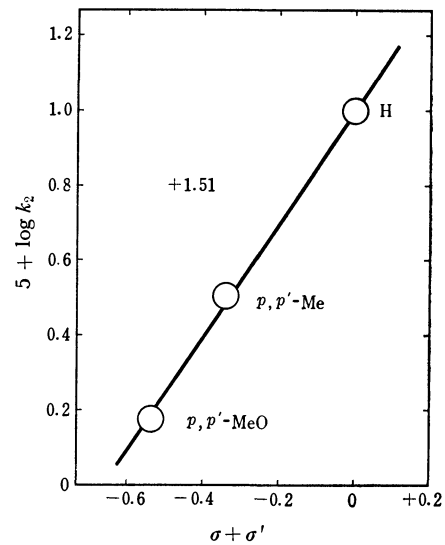

Fig. 5. Hammett plots for the non-catalyzed oxidation of substituted benzil to the corresponding benzoic acid in acetic acid at 70°C.

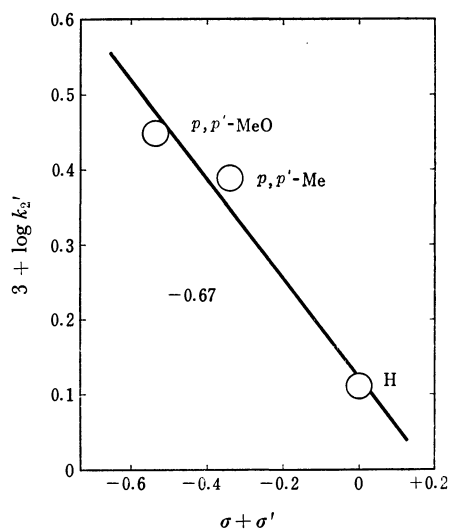

Fig. 6. Hammett plots for the acid-catalyzed oxidation of substituted benzil in acetic acid at 70°C.

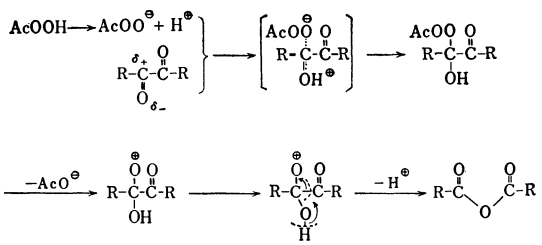
It may be considered from the reaction products that the first, second, third, and fourth terms represent the decomposition of peroxyacetic acid itself,[11] the acid-catalyzed reversible transformation of peroxyacetic acid to acetyl peroxide,[9] and the non-catalyzed and the acid-catalyzed oxidation of benzils with peroxyacetic acid respectively. In this paper, only the third and fourth terms have been dealt with.

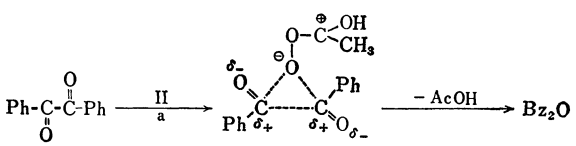
The introduction of an electron-releasing group into the benzil retarded the non-catalyzed oxidation of benzil and accelerated the acid-catalyzed oxidation (Table 3), and Hammett's plot gave positive and negative ρ-values of $+1.51$ and -0.67 respectively, as shown in Fig. 5 and/or 6.

On the oxidation of benzil with hydrogen peroxide in benzene, Leffler obtained an oily matter which gave benzoic acid by hydrolysis.[1] Thus, a reaction mechanism passing through acid anhydride has been suggested. The reaction scheme in Leffler's fashion is described as:



The mechanism consists of three steps, such as the addition of peroxyacetic acid to the carbonyl group of benzil, the elimination of the acetoxy anion from the adduct, and the deprotonation. Neither the step 1 nor 2 is the rate-determining step in this reaction, since the step 1 is the protonation and the step 2 should have a $-\rho$ value. Only the deprotonation could satisfy the experimental results shown in Fig. 5. It has not been confirmed by Leffler that the deprotonation is the rate-determining step. For these reasons, Leffler's scheme is unbelievable. A more probable mechanism is considered to be as follows:

(I) (II)

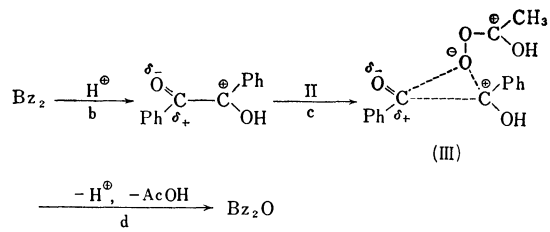


From the results such as the second-order in the concentrations of benzil and peroxyacetic acid and/or the positive ρ-value in the Hammett plots of $\log k_2$ *vs.* $\sigma+\sigma'$, the step a is probably the rate-determining step in the non-catalyzed oxidation of benzil with peroxyacetic acid, and the non-catalyzed oxidation is probably a nucleophilic attack by negative oxygen of peroxyacetic acid, II. If the reaction is an electrophilic attack of peroxyacetic acid, I, the value of ρ must be negative.

On the other hand, it is presumed that protonation to a substrate occurs once before the rate-determining step in the acid-catalyzed oxidation, as has been described above. In fact, the absorption maximum of benzil in acetic acid at 260 mμ decreases with an increase in the acidity. This phenomenon is probably due to the protonation to the carbonyl group of benzil.

Also, the acid-catalyzed reaction is probably a nucleophilic attack of peroxyacetic acid, II, because the k_2'/k_2 ratio is nearly 10. As the positivity on the carbonyl carbon in protonated benzil is much larger than that in free benzil induced by only the polarity of the C–O bond of the carbonyl group, the rate of the acid-catalyzed reaction will be ten times larger than the non-catalyzed one. A nucleophilic attack on the positive carbonyl carbon atom of free or protonated benzil by positive oxygen of peroxyacetic acid can not be considered. The existence of protonated benzil was observed by the ultraviolet spectrophotometry described above.

These results suggest this probable mechanism in the acid-catalyzed oxidation of benzil:



(III)

If the deprotonation determines the reaction, Hammett's plot of $\log k_2'$ *vs.* $\sigma+\sigma'$ is expected to give a positive ρ-value. It cannot be supposed that the elimination of acetic acid from the transition state, III, is influenced by a substituted group on the benzene ring. The step c probably determines the reaction rate.

The negativity of a carbonyl oxygen atom in benzil is increased by an electron-releasing group. Thus, the concentration of protonated benzil is enlarged with an increase in the electron-releasing degree. In other words, the equilibrium constant, K, for the protonation to benzil is enlarged with an increase in the electron-releasing force.

$$Bz_2 + H^{\oplus} \overset{K}{\rightleftharpoons} Bz_2H^{\oplus}$$

11) T. Suzuki, I. Iwamoto and S. Suzuki, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **83**, 1212 (1962).

$$Bz_2H^{\oplus} + AcO_2H \xrightarrow{k}$$

$$[Bz_2H^{\oplus}] = K[H^{\oplus}][Bz_2]$$

$$v_{(acid\ cat)} = k[Bz_2H^{\oplus}][AcO_2H]$$
$$= kK[H^{\oplus}][Bz_2][AcO_2H]$$

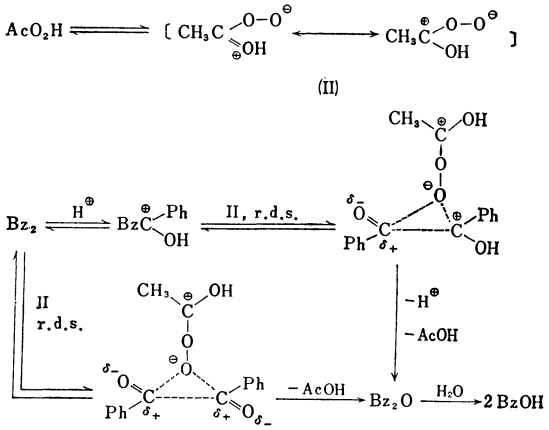
$$\therefore\ k_2' = kK$$

On the other hand, the rate constant, k, for the reaction of protonated benzil with peroxyacetic acid may decrease with an increase in the electron-releasing degree, since the positivity of a carbonyl carbon atom in protonated benzil will be decreased by an electron-releasing group. However, the proportion of the diminution in the positivity of carbonyl carbon in protonated benzil caused by an electron-releasing group is not so great as to have a considerable influence upon the reaction rate. Thus, the influence of a substituent on the equilibrium constant, K, may be much larger than that on the k rate constant. Consequently, the acid-catalyzed rate constant, k_2', which is equal to the product of k by K, will be increased by an electron-releasing group with a Hammett ρ-value of -0.67. By means of these hypotheses, the kinetic findings can be explained without difficulty.

The value of 3×10^{-3} sec^{-1} was obtained as the rate constant for the hydrolysis of benzoic anhydride in the presence of 0.027 N sulfuric acid at 70°C. The value divided by the calculated concentration of water in the reaction solvent is about two hundred times larger than the value of $k_{2\ obs}$ obtained under the same reaction conditions. Hence, the step of the hydrolysis of benzoic anhydride is undoubtedly not the rate-determining step.

The oxidation is a sort of Baeyer-Villiger reaction.

The non- and acid-catalyzed oxidations may be summarized as follows:



BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 664—668 (1968)

Thermal Transformation of Alkali Salts of Aromatic Carboxylic Acids. V.[1] Reaction of Potassium and Sodium Salts of Naphthoic Acids

Yasuhiko DOZEN

Government Industrial Research Institute, Osaka, Ikeda-shi, Osaka

(Received September 6, 1967)

The cadmium fluoride-catalyzed thermal transformation of potassium and sodium salts of naphtoic acids has been investigated. At the initial reaction stage both potassium and sodium α-naphthoate gave naphthalene and naphthalene-1, 2- and 1, 3-dicarboxylates, which were converted to naphthalene-2, 3- and 2, 6-dicarboxylates. The products composition, however, differed between potassium and sodium salts. Potassium β-naphthoate gave naphthalene and naphthalene-1,2- and 2,3-dicarboxylates, which were then further converted to naphthalene-2, 6-dicarboxylate. On the other hand, sodium β-naphthoate gave naphthalene and naphthalene-1, 2- and 2, 3-dicarboxylates. In the presence of potassium cyanate, potassium α- and β-naphthoates gave a high yield of naphthalene-2, 6-dicarboxylate. The mechanism of the reaction was discussed.

Raecke[2,3] found that potassium α- and β-naphthoates gave naphthalene-2, 6-dicarboxylate in the presence of a catalyst under carbon dioxide pressure and under heating at a high temperature. The reaction conditions have been studied by Yamashita, Enomoto, Ebisawa, and Kato,[4] **and**

d) Zink chloride instead of cadmium fluoride was added.

an improvement of the reaction apparatus has been reported by Dorschner, Markworth, and Plenz.[5]

In the previous paper,[1] it has been reported that potassium methylbenzoates gave *o*-, *m*-, and *p*-directed disproportionation products, while sodium methylbenzoates gave an *o*-directed one. It was also observed in 1965 that sodium β-naphthoate gave naphthalene-2, 3-dicarboxylate. At that time, similar results were reported by McNelis,[6] and Patton and Son.[7] This paper will report the results of more detailed studies of the difference in orientation between potassium and sodium salts of naphthoic acids in the disproportionation.

5) O. Dorschner, H. Markworth and J. Plenz (to Metallgeselschaft A.-G.), German Pat. 1155770 (1963).

6) E. McNelis, *J. Org. Chem.*, **30**, 1209 (1965).
7) J. W. Patton and M. O. Son, *ibid.*, **30**, 2869 (1965).

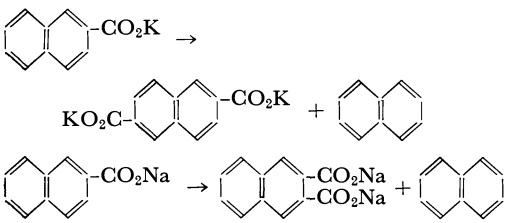

Table 1 shows the reaction products from potassium and sodium salts of α-naphthoic acid. Both salts, in each case, gave naphthalene and naphthalene-1, 2- and 1, 3-dicarboxylates as the primary product at a low temperature. With a rise in the temperature, however α-naphthoate disappeared, and β-naphthoate, naphthalene-2, 3-, 2, 6-, and 2, 7-dicarboxylates were produced. The potassium salt gave the 2, 6-isomer predominantly, while the sodium salt gave the 2, 3-isomer as the main product.

In the presence of potassium cyanate and potassium carbonate, potassium α-naphthoate gave a higher yield of naphthalene-2, 6-dicarboxylate than in the absence of potassium cyanate. This may be explained in terms of direct carboxylation with potassium carbonate, as has been reported in the reactions of potassium benzoate, potassium carbonate, and potassium cyanate.[8]

Table 2 shows the reaction products from potassium and sodium salts of β-naphthoic acid. Potassium β-naphthoate gave naphthalene-2, 3-dicarboxylate at low temperatures and 2, 6-isomer at high temperatures. In the presence of potassium cyanate, the yield of 2, 6-isomer was increased. On the other hand, sodium β-naphthoate gave naphthalene-2, 3-dicarboxylate selectively.

These results indicate that α-naphthoate is disproportionated to naphthalene-1, 2- and 1, 3-dicarboxylates in the initial stage of the reaction, and then a thermally-unstable α-carboxyl group of these acids is decarboxylated or cross-disproportionated to β-naphthoate. Thermally-stable naphthalene-2, 3- and 2, 6-dicarboxylates may be produced by the disproportionation of β-naphthoate or by the cross-disproportionation of β-naphthoate and another carboxylate, as shown in Chart 1. The facts that potassium β-naphthoate gave naphthalene-2, 3- and 2, 6-dicarboxylates, and that sodium β-naphthoate was converted to naphthalene-2, 3-dicarboxylate, may be explained in terms of the difference in thermal stability between the potassium and sodium salts of naphthalene-2, 3-dicarboxylate.

McNelis[6] reported the decarboxylation-recarboxylation mechanism for the reaction of potassium β-naphthoate to naphthalene-2, 6-dicarboxylate. In the reaction of potassium benzoate, a similar mechanism has been discussed by Furuyama[9] using deuterated or radioactive benzoate. In the reaction of potassium phthalates and benzoate under an atmosphere of radioactive carbon dioxide, it has been reported by Riedel and Kienitz[10] that the quantity of $^{14}CO_2$ incorporated into the molecules of benzene carboxylates was lower than the calculated value. This reaction was further investigated by Ratusky and Sorm[11] in a thin-layer state of carboxylates with perfect mixing; there results suggest the decarboxylation-recarboxylation mechanism.

When the decarboxylation - recarboxylation mechanism is involved in the reaction, the α-hydrogen of the naphthalene ring, which is more reactive than the β-hydrogen, will be abstracted by the carbanion which is produced by the decarboxylation of β-naphthoate, and α-naphthoate

will be obtained as the reaction product. α-Naphthoate, however, could not be detected in the reaction product of the β-naphthoate (see Table 2). This fact may be explained by the intermolecular disproportionation mechanism.

Experimental[12]

Materials. α-Naphthoic acid was prepared by the Grignard reaction of α-bromonaphthalene[13]; mp 161—162°C (benzene). β-Naphthoic acid was synthesized by the hypobromite oxidation of β-acetylnaphthalene,[14] which had been prepared by the Friedel-Crafts reaction of naphthalene and acetyl chloride[15]; mp 183—184°C (EtOH).

General Method. A naphthoic acid was neutralized with aqueous potassium (or sodium) hydroxide to pH 7.0—7.5. The solution was then evaporated to dryness and further dried under a vacuum (*ca.* 5 mmHg) at 150—180°C. The alkali salt of naphthoic acid (15.0 g) was mixed with cadmium fluoride (1.0 g) and potassium (or sodium) carbonate (5.0 g). The mixture was dried under a vacuum (*ca.* 5 mmHg) at 150—180°C, charged in a rotary autoclave (160 m*l*, 60 rpm), and allowed to react under the pressure of carbon dioxide (initial pressure of 40 kg/cm² gauge). The warm-up period was *ca.* 1 hr. After cooling, the reaction product was extracted with ether (Soxhlet) to remove the naphthalene, which was identified by means of its melting point. The ether-insoluble substance was dissolved in hot water (500 m*l*). The solution was neutralized with hydrochloric acid to pH 6—7, treated with active carbon, and further acidified to pH 1. The precipitate was filtered while hot and dried (Acid I). The aqueous solution was evaporated to dryness, and the residue was extracted with ethanol to give an acidic substance (Acid II).[16]

Analysis. Each fraction of Acid I and II (1—2 g) was converted to silver salt, and the salt was esterified with methyl iodide in benzene. After the evaporation of the solvent, the residue was dissolved in chloroform and analyzed by vapor-phase chromatography. α- and β-Naphthoates were analyzed with 25% Silicone DC 550 on Shimalite (30—60 mesh; 4 mmφ × 1.5 m; column temperature, 190°C; flow rate of He, 50 m*l*/min), and naphthalene dicarboxylates were determined with 15% Silicone DCHV Grease on Celite 545 (Nishio Kogyo Co., Ltd.) (40—60 mesh; 4 mmφ × 1.5 m; column temperature, 220°C; flow rate of He, 50 m*l*/min). The retention times of the authentic samples are shown in Fig. 1. The analytical data of the esters derived from an authentic mixture of α-naphthoic (24.8 wt%), β-naphthoic (26.7%), naphthalene-2, 3-dicarboxylic (23.5%), and 2, 6-dicarboxylic (25.0%) acids gave 21.8, 29.5, 23.4 and 25.4 wt% respectively.

Identification of the Reaction Products. *Naphthalene-2, 6-dicarboxylic Acid.* The dimethyl ester obtained from the reaction product of potassium β-naphthoate (430°C for 1.5 hr) or α-naphthoate (Table 1, run 5) was recrystallized from ethyl acetate or benzene to give dimethyl naphthalene-2, 6-dicarboxylate; mp 189.0—189.5°C (lit., mp 187—188°C[17]).

Naphthalene-2, 3-dicarboxylic Acid. The reaction products of sodium β-naphthoate (445°C for 1.5 hr) were extracted with ether (Soxhlet, 8 hr); the insoluble substance (1.5 g) was then treated with acetic anhydride to give 0.9 g of naphthalene-2, 3-dicarboxylic anhydride; mp 245—246°C (lit., mp 246°C[18]).

Found: C, 72.59; H, 2.74%. Calcd for $C_{12}H_6O_3$: C, 72.72; H, 3.05%.

The infrared spectrum had acid anhydride bands at 1841 and 1764 cm^{-1}.

Naphthalene-1, 2-dicarboxylic Acid. The ester of the Acid II fraction obtained by the reaction of potassium α-naphthoate (Table 1, run 7) was recrystallized from methanol to give dimethyl naphthalene-1, 2-dicarboxylate (mp 78—82°C), which was identified by a mixed-melting-point determination and by a comparison of the infrared spectra with those of an authentic sample (see the next paragraph).

Naphthalene-1, 3-dicarboxylic Acid. The ester obtained from the reaction product of potassium α-naphthoate Table 1, run 2) was distilled to remove the methyl naphthoates. The residue had all the peaks of the infrared spectrum appearing in dimethyl naphthalene-1, 3-dicarboxylate, but all attempts to isolate it failed.

12) All melting points are corrected. Vapor-phase chromatography, infrared spectroscopy, and micro analysis were performed using a Shimadzu G. C-1B, a Hitachi Infrared Spectrophotometer EPI-SII (in Nujol), and a Yanagimoto C. H. N. Corder MT-1 apparatus respectively.

Synthesis of Dimethyl Naphthalene Dicarboxylates as the Standard Sample of the Vapor-phase Chromatography.[19] *1, 2-Isomer.* 1, 2-Dicyanonaphthalene (mp 190.5—191.5°C; lit., mp 190°C[20]) was synthesized by the method of Brandbrook and Linstead[20] from 2-aminonaphthalene-1-sulfonic acid (Tobias Acid), and the nitrile was hydrolyzed to naphthalene-1, 2-dicarboxylic acid. The dimethyl ester had a melting point of 84—85°C (MeOH) (lit., mp 85°C[20]).

1, 3-Isomer. Brandbrook and Linstead[20] have reported that they prepared naphthalene-1, 3-dicarboxylic acid (mp 267—268°C) by the hydrolysis of 1, 3-dicyanonaphthalene (mp 179°C), which had been synthesized by the reaction of sodium 3-cyanonaphthalene-1-sulfonate and potassium ferrocyanide. The physical constants of these substances as prepared by the following route, however, differ from those reported by Brandbrook and Linstead.

A) 2, 4-Dibromo-1-naphthylamine (mp 115—117°C (EtOH); lit., mp 116—118°C[21]), which had been prepared by the method of Consden and Kenyon,[21] was converted to 1, 3-dibromonaphthalene (mp 61—62°C (EtOH); lit., mp 64°C[22]) by the method of Meldra.[22] The dibromonaphthalene (6.1 g, 0.021 mol), cuprous cyanide (5.0 g, 0.056 mol), and dimethyl formamide (30 ml) were heated at 180—185°C for 4 hr by a method similar to that of Friedman and Shechter[23] to give 1, 3-dicyanonaphthalene (0.8 g); mp 226.5—227.5°C (EtOH).

Found: C, 81.11; H, 3.48; N, 15.44%. Calcd for $C_{12}H_6N_2$: C, 80.87; H, 3.39; N, 15.72%.

The dinitrile was hydrolyzed with aqueous sulfuric acid to give naphthalene-1, 3-dicarboxylic acid (0.7 g); mp>300°C. The methyl ester has a melting point of 105—106°C (EtOH).

Found: C, 69.12; H, 4.73%. Calcd for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95%.

B) 1, 3-Dimethylnaphthalene (bp 100°C/4 mmHg; lit., bp 129°C/9 mmHg[24]) was prepared by the method of Balaban and Barabas[24] from acetyl acetone and benzyl magnesiumchloride. A mixture of dimethylnaphthalene (7.2 g), sodium bichromate (22 g), and water (40 ml) was heated at 250—260°C for 22 hr in an autoclave by a method similar to that of Friedman, Fishel, and Shechter[25] to give naphthalene-1, 3-dicarboxylic acid. The dimethyl ester had a melting point of 104.5—105.5°C. It was identified by a mixed-melting-point determination and by a comparison of the infrared spectrum with that of the sample obtained in A).

1, 4-Isomer. Naphthalene-1, 4-dicarboxylic acid was prepared from 1, 4-dicyanonaphthalene (mp 207.5—208.5°C (EtOH); lit., mp 208°C[20]), which had been prepared by the method of Brandbrook and Linstead[20] from 1-aminonaphthalene-4-sulfonic acid (Naphthionic Acid). The dimethyl ester had a melting point of 65—66°C (dil. AcOH) (lit., mp 67°C[20]).

1, 5-Isomer. 1, 5-Dicyanonaphthalene was synthesized from disodium naphthalene-1, 5-disulfonate and potassium ferrocyanide by a method similar to that of Brandbrook and Linstead[20]; mp 263—264°C (EtOH) (lit., mp 263°C[20]). The dinitrile was converted to the corresponding acid, which gave dimethyl naphthalene-1, 5-dicarboxylate (mp 116—117°C (EtOH); lit., mp 119°C[20]).

1, 6-Isomer. 1, 6-Dicyanonaphthalene was prepared by the method of Brandbrook and Linstead[20] from 1-aminonaphthalene-6-sulfonic acid (1, 6-Cleve's Acid); mp 210—211°C (EtOH) (lit., mp 211°C[20]). The nitrile was hydrolyzed to acid. The dimethyl ester had a melting point of 97—98°C (aq. MeOH) (lit., mp 98°C[20]).

1, 7-Isomer. 1, 7-Dicyanonaphthalene was prepared from 1-aminonaphthalene-7-sulfonic acid (1, 7-Cleve's Acid); mp 166—167°C (EtOH) (lit., mp 167°C[20]). The nitrile was hydrolyzed to acid, which gave dimethyl naphthalene-1, 7-dicarboxylate (mp 89—90°C (aq. EtOH); lit., mp 90°C[20]).

1, 8-Isomer. Dimethyl naphthalene-1, 8-dicarboxylate was prepared from naphthalic acid; mp 102—103°C (MeOH) (lit., mp 104°C[20]).

2, 3-Isomer. Naphthalene-2, 3-dicarboxylic anhydride, which had been obtained by the reaction of sodium β-naphthoate, was converted to dimethyl naphthalene-2, 3-dicarboxylate; bp 191—192°C/6 mmHg, mp 48—50°C (lit., mp 47°C,[20] 50—51°C[26]).

2, 6-Isomer. Dimethyl naphthalene-2, 6-dicarboxylate was prepared from the corresponding dicarboxylic acid, which had been obtained by the reaction of potassium β-naphthoate; mp 189.0—189.5°C.

2, 7-Isomer. 2, 7-Dicyanonaphthalene was obtained by the reaction of disodium naphthalene-2, 7-disulfonate and potassium ferrocyanide by a method similar to that of Brandbrook and Linstead[20]; mp 264°C (AcOH) (lit., mp 267°C[20]). The nitrile was hydrolyzed to an acid, which gave dimethyl naphthalene-2, 7-dicarboxylate (mp 135—136°C (EtOH); lit., mp 135°C[20]).

The author is indebted to Professor Haruo Shingu, Kyoto University, for his help and encouragement, and to (Mrs.) Shizu Fujishima of our laboratory for her assistance in the microanalysis.

19) The ester of the carboxylic acid was synthesized by the reaction of the silver salt of the carboxylic acid and methyl iodide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 669—672 (1968)

Ribonuclease T_1 Peptides. II. Synthesis of a Protected Pentapeptide Corresponding to Sequence 12—16

Michinori WAKI, Nobuo Mitsuyasu, Tetsuo KATO, Satoru MAKISUMI and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received September 16, 1967)

A protected pentapeptide corresponding to sequence 12—16 of ribonuclease T_1, namely benzyloxycarbonyl-L-seryl-L-seryl-L-seryl-β-*t*-butyl-L-aspartyl-L-valine ethyl ester (XI), was synthesized by coupling of benzyloxycarbonyl-seryl-serine azide with a tripeptide ester, seryl-β-*t*-butyl-aspartyl-valine ethyl ester, which is derived from benzyloxycarbonyl-seryl-β-*t*-butyl-aspartyl-valine ethyl ester by the hydrogenolysis. The hydrogenolysis and the subsequent treatment with trifluoroacetic acid of the protected pentapeptide ester (XI) yielded a neutral pentapeptide ester, seryl-seryl-seryl-aspartyl-valine ethyl ester, as a crystalline product.

The synthesis of the protected *N*-terminal undecapeptide (1—11) of ribonuclease T_1 containing asparagine residue in the 3rd position was previously reported.[1] In the present paper, we will describe the synthesis of the protected pentapeptide corresponding to sequence 12—16, that is benzyloxycarbonyl-L-seryl-L-seryl-L-seryl-β-*t*-butyl-L-aspartyl-L-valine ethyl ester (XI).

This pentapeptide sequence possesses several functional groups, three hydroxyl ones of serine and an acidic one of aspartic acid, in a rather short peptide, so the preparation of this peptide derivatives seemed to be interesting as an object of organic synthesis.

In the synthesis of the protected pentapeptide (XI), we first selected a route involving the coupling of benzyloxycarbonyl-seryl-seryl-serine azide derived from the corresponding hydrazide (VI) with β-*t*-butyl-aspartyl-valine ethyl ester (VIII). However, the coupling reaction did not afford the desired product (XI); it was found that the product isolated was benzyloxycarbonyl-seryl-seryl-serine amide. In this connection, it would be noteworthy that several workers have reported the formation of acylamino acid or peptide amide from the corresponding azide during the peptide synthesis.[2]

The successful synthesis of the desired product (XI) was performed through the sequence of reactions as shown in Fig. 1. Benzyloxycarbonyl-seryl-serine ethyl ester (II) was prepared by coupling benzyloxycarbonyl-serine azide obtained from the corresponding hydrazide[3] using isoamyl nitrite[4] with serine ethyl ester (I). The dipeptide ester (II) obtained was converted to the hydrazide (III) by the treatment with hydrazine. Benzyloxycarbonyl-β-*t*-butyl-aspartyl-valine ethyl ester (VII) was prepared by coupling benzyloxycarbonyl-β-*t*-butyl-aspartic acid[5] with valine ethyl ester[6] using dicyclohexylcarbodiimide[7] as a coupling reagent or by the mixed anhydride method.[8] The oily product (VII) was hydrogenated to yield the dipeptide ester hydrochloride (VIII·HCl), which was then coupled with benzyloxycarbonyl-serine azide derived from the corresponding hydrazide[3] to give the protected tripeptide ester (IX). This protected peptide ester (IX) was subjected to hydrogenolysis to yield the tripeptide ester (X), which was coupled with benzyloxycarbonyl-seryl-serine azide derived from III as the same manner used for the preparation of II. This coupling gave the desired protected pentapeptide ester (XI) as a crystalline product.

Thus we could prepare the protected pentapeptide ester (XI) by coupling of benzyloxycarbonyl-dipeptide azide derived from III with the tripeptide ester (X). In this connection, it should

be pointed out that Hofmann *et al.*[9] reported the successful synthesis of the protected hexapeptide *t*-butyl ester (sequence 15—20 of ribonuclease A) by coupling of benzyloxycarbonyl-seryl-serine azide with threonyl-seryl-alanyl-alanine *t*-butyl ester and Scoffone *et al.*[10] similarly prepared the protected pentapeptide ester (sequence 16—20 of ribonuclease A) from benzyloxycarbonyl-seryl-threonine azide and seryl-alanyl-alanine *t*-butyl ester.

The protected pentapeptide ester (XI) was hydrogenated in a solvent of acetic acid to remove the benzyloxycarbonyl group, and the pentapeptide ester acetate (XII·AcOH) obtained was then treated with trifluoroacetic acid to remove the β-*t*-butyl group. The resulting pentapeptide ethyl ester (XIII) was obtained as a crystalline product. The homogeneity of the peptide (XIII) was ascertained by paper and thin-layer chromatography and the expected molar ratio of the constituent amino acids was observed in the acid hydrolysate of XIII by the amino acid analysis. Furthermore, the stereospecific purity of the peptide (XIII) was ascertained by the digestion with leucine aminopeptidase.

Experimental

All the melting points are uncorrected. The paper and thin-layer chromatographies were carried out on Toyo Roshi No. 52 paper and on Merck silica gel G, respectively. Spots of materials possessing a free amino group on a thin-layer plate were detected by spraying ninhydrin, and those of the amino group-blocked materials, by spraying 47% hydrobromic acid and then ninhydrin.

L-Serine Ethyl Ester *p*-Toluenesulfonate (I·TsOH). This compound was prepared according to the general procedure of Kato *et al.*[6] A suspension of L-serine (10.51 g) and *p*-toluenesulfonic acid monohydrate (19.02 g) in a mixture of ethanol (60 m*l*) and carbon tetrachloride (300 m*l*) was refluxed for 48 hr, and the water liberated was removed as an azeotropic mixture. The reaction mixture was then evaporated to dryness *in vacuo* to give an oily product; yield, 30.66 g (100%); R_f 0.67.[11]

Benzyloxycarbonyl-L-seryl-L-serine Ethyl Ester (II). To a chilled (−5°C) solution of benzyloxycarbonyl-serine hydrazide[3] (5.06 g, 20 mmol) in dimethylformamide (60 m*l*) containing 12.12 m*l* of 3.3 N hydrogen chloride in ethyl acetate, there were stirred isoamyl nitrite[4] (2.34 g, 20 mmol). After 10 min, triethylamine (5.6 m*l*, 40 mmol) was added. To the solution was added a mixture of I·TsOH (6.11 g, 20 mmol) and

11) The R_f value of the thin-layer chromatography with Merck silica gel refers to a solvent system of *n*-butanol-acetic acid-pyridine-water (4 : 1 : 1 : 2, v/v).

triethylamine (2.8 ml, 20 mmol) in dimethylformamide (40 ml). The reaction mixture was then stirred for 2 days at 0°C and evaporated *in vacuo*. The residue was dissolved in ethyl acetate (120 ml), and the solution was washed successively with a 4% sodium bicarbonate solution, 3% hydrochloric acid and water, dried over sodium sulfate, and then evaporated *in vacuo*. The crystalline residue was collected with the aid of ether-petroleum ether. It was recrystallized from ethyl acetate-petroleum ether; yield, 5.0 g (71%); mp 127—129°C; $[\alpha]_D^{22}$ −8.3° (*c* 1, methanol); R_f 0.82.[11]

Found: C, 54.10; H, 6.26; N, 7.95%. Calcd for $C_{16}H_{22}O_7N_2$: C, 54.23; H, 6.26; N, 7.91%.

Benzyloxycarbonyl-L-seryl-L-serine Hydrazide (III). A solution of II (3.18 g, 9 mmol) and hydrazine hydrate (1.09 ml, 22.5 mmol) in ethanol (20 ml) was allowed to stand overnight at room temperature. The excess hydrazine was evaporated *in vacuo*, and the resulting crystals were collected by filtration with the aid of cold ethanol. It was recrystallized from hot water; yield, 1.96 g (64%); mp 221—222°C (decomp.); $[\alpha]_D^{25}$ −30.0° (*c* 1, N hydrochloric acid); R_f 0.75.[11] Hofmann *et al.* had prepared this compound (III) previously from benzyloxycarbonyl-seryl-serine methyl ester with hydrazine; mp 221—222°C (decomp.); $[\alpha]_D^{20}$ −30.5° (*c* 1, N hydrochloric acid).[9]

Benzyloxycarbonyl-L-seryl-L-seryl-L-serine Ethyl Ester (IV). III (1.26 g, 3.7 mmol) in dimethylformamide (8 ml) containing 2.24 ml of 3.3 N hydrogen chloride in ethyl acetate was treated with isoamyl nitrite (432 mg, 3.7 mmol) for 10 min, and then triethylamine (1.03 ml, 7.4 mmol) as described above. To this solution was added a mixture of I·TsOH (1.13 g, 3.7 mmol) and triethylamine (0.51 ml, 3.7 mmol) in dimethylformamide (20 ml). The mixture was stirred for 3 days at 0°C and then evaporated *in vacuo* to a small volume. The precipitate which formed upon the addition of water was collected (the mother liquor was set aside for further isolation of IV), washed with a small amount of 4% sodium bicarbonate solution, 3% hydrochloric acid and water, and dried; yield, 0.43 g.

The mother liquor was extracted with chloroform, and the extract was washed with water, and dried. The filtrate was evaporated, and the residual syrup was solidified by the addition of ether and petroleum ether; yield, 0.56 g. The combined product (0.99 g) was recrystallized from methanol - ether - petroleum ether; yield, 0.90 g (56%); mp 184—185°C; R_f 0.77.[11]

Found: C, 50.95; H, 6.24; N, 9.30%. Calcd for $C_{19}H_{27}O_9N_3 \cdot \frac{1}{2}H_2O$: C, 50.66; H, 6.27; N, 9.33%.

Benzyloxycarbonyl-L-seryl-L-seryl-L-serine Methyl Ester (V). To a chilled solution of III (0.96 g, 2.8 mmol) in a mixture of glacial acetic acid (10 ml) and water (15 ml), there were stirred 6 N hydrochloric acid (1.13 ml) and a 0.4 M sodium nitrite solution (7.05 ml). After 5 min, the azide was extracted with ethyl acetate (100ml), and the organic layer was washed with a 4% sodium bicarbonate solution and water, and dried. The filtrate was added to a mixture of serine methyl ester hydrochloride[12] (0.44 g, 2.8 mmol) and triethylamine (0.4 ml) in dimethylformamide (20 ml). The mixture was stirred for 2 days at 0°C and evaporated *in vacuo*. The precipitate which formed upon the addition of 2% hydrochloric acid was collected, and washed with water and dried; yield, 0.37 g (30%); mp 195—196°C; R_f 0.73.[11]

Found: C, 50.76; H, 6.06; N, 9.79%. Calcd for $C_{18}H_{25}O_9N_3$: C, 50.58; H, 5.90; N, 9.83%.

Benzyloxycarbonyl-L-seryl-L-seryl-L-serine Hydrazide (VI). To a solution of IV (358 mg, 0.81 mmol) in methanol (6 ml), hydrazine hydrate (0.16 ml, 3.24 mmol) was added and the solution was allowed to stand for 2 days at 30°C. The reaction mixture was then evaporated *in vacuo*. The resulting crystals were collected with the aid of cold ethanol; yield, 327 mg (92%); mp 232—234°C (decomp.); R_f 0.68.[11]

Found: C, 47.48; H, 5.99; N, 16.06%. Calcd for $C_{17}H_{25}O_8N_5$: C, 47.77; H, 5.90; N, 16.39%.

VI was also prepared from V (261 mg, 0.61 mmol) and hydrazine hydrate (0.59 ml) by the same procedure as described above; yield, 157 mg (60%); mp 233—234°C (decomp.); R_f 0.68.[11]

Benzyloxycarbonyl-β-*t*-butyl-L-aspartyl-L-valine Ethyl Ester (VII). *a) Mixed Anhydride Method.* To a chilled solution of benzyloxycarbonyl-aspartic acid β-*t*-butyl ester[5] (404 mg, 1.25 mmol) and triethylamine (0.175 ml) in tetrahydrofuran (6 ml), isobutylchloroformate (0.164 ml, 1.25 mmol) was added. After 15 min, a mixture of valine ethyl ester *p*-toluenesulfonate[6] (397 mg, 1.25 mmol), triethylamine (0.175 ml) and chloroform (3 ml) was added to the solution. The reaction mixture was allowed to stand overnight and then evaporated to dryness *in vacuo*. The residual oil was dissolved in ethyl acetate (15 ml), and the solution was washed successively with 0.5 M citric acid, a 4% sodium bicarbonate solution and water, dried over sodium sulfate, and then evaporated to dryness *in vacuo*. The product was obtained as an oil; yield, 483 mg (86%); R_f 0.94.[11]

b) Dicyclohexylcarbodiimide Method. To a solution of the dicyclohexylammonium salt of benzyloxycarbonyl-aspartic acid β-*t*-butyl ester[5] (4.04 g, 8 mmol), valine ethyl ester *p*-toluenesulfonate[6] (2.54 g, 8 mmol) in chloroform (80 ml) was added dicyclohexylcarbodiimide[7] (1.65 g, 8 mmol) at 0°C. The reaction mixture was stirred for 1 hr at 0°C and then kept overnight in a refrigerator. The mixture was evaporated *in vacuo*, and ethyl acetate (100 ml) was added to the residue. After the insoluble dicyclohexylurea was filtered off, the filtrate was treated following the same procedure as described above; yield of the oily VII, 3.17 g (88%); R_f 0.94.[11]

β-*t*-Butyl-L-aspartyl-L-valine Ethyl Ester Hydrochloride (VIII·HCl). A solution of VII (3.38 g, 7.5 mmol) in methanol (20 ml) was hydrogenated in the presence of palladium black at 0°C. After 5 min, 0.408 N methanolic hydrogen chloride (18.38 ml) was added and hydrogenolysis was continued for 2 hr at 0°C. The filtrate from the catalyst was evaporated to dryness *in vacuo* at room temperature, and the yield of the oily product was 2.44 g (92 %). The oily product was crystallized upon the standing in a refrigerator for several days. A portion (352 mg) of this crystal was recrystallized from methanol-ether; yield, 226 mg; mp 147—148°C; R_f 0.77.[11] This sample was dried over phosphorus pentoxide for 2 hr at 45°C and 2 mmHg for the analysis.

Found: C, 50 40; H, 8 24; N, 7.95%. Calcd for

12) S. Guttmann and R. A. Boissonnas, *Helv. Chim. Acta*, **41**, 1867 (1958).

$C_{15}H_{28}O_5N_2 \cdot HCl \cdot \frac{1}{4}H_2O$: C, 50.41; H, 8.04; N, 7.83%.

Benzyloxycarbonyl-L-seryl-β-*t*-butyl-L-aspartyl-L-valine Ethyl Ester (IX). This compound was obtained by the same procedure as described for the preparation of II. Benzyloxycarbonyl-serine hydrazide (1.77 g, 7 mmol) and VIII·HCl (2.47 g, 7 mmol) afforded 2.28 g of the crude product. It was recrystallized from methanol-ether-petroleum ether; yield, 2.07 g (55%); mp 134—137°C; $[\alpha]_D^{25}$ −29.0° (*c* 1, methanol); R_f 0.96.[11]

Found: C, 57.96; H, 7.37; N, 8.01%. Calcd for $C_{26}H_{39}O_9N_3$: C, 58.08; H, 7.31; N, 7.82%.

L-Seryl-β-*t*-butyl-L-aspartyl-L-valine Ethyl Ester Hydrochloride (X·HCl). IX (1.85 g, 3.4 mmol) was subjected to hydrogenolysis in the presence of palladium black using 0.408 N methanolic hydrogen chloride (8.48 m*l*) as has been described in the case of VIII·HCl. The product was obtained as an oil; yield, 1.41 g (94%); R_f 0.76,[11] 0.94.[13]

Benzyloxycarbonyl-L-seryl-L-seryl-L-seryl-β-*t*-butyl-L-aspartyl-L-valine Ethyl Ester (XI). This compound was prepared by the same procedure as described for the preparation of II. III (1.17 g, 3.4 mmol) and X·HCl (1.50 g, 3.4 mmol) gave 2.14 g of the crystalline product. It was recrystallized from methanol-ether; yield, 1.62 g (67%); mp 174—175°C; $[\alpha]_D^{25}$ −26.4° (*c* 0.3, methanol); R_f 0.91.[11]

Found: C, 52.74; H, 6.96; N, 9.63%. Calcd for $C_{32}H_{49}O_{13}N_5 \cdot H_2O$: C, 52.66; H, 7.04; N, 9.60%.

L-Seryl-L-seryl-L-seryl-β-*t*-butyl-L-aspartyl-L-valine Ethyl Ester Acetate (XII·AcOH). XI (107 mg, 0.15 mmol) in acetic acid (5 m*l*) was subjected to hydrogenolysis in the presence of palladium black at 0°C. The filtrate from the catalyst was evaporated to dryness *in vacuo* at room temperature and the oily residue was triturated with ether. The hygroscopic powder was collected by filtration; yield, 91 mg (95%). The homogeneity was ascertained by the chromatographies; R_f 0.74,[11] 0.83,[13] 0.24.[14]

L-Seryl-L-seryl-L-seryl-L-aspartyl-L-valine Ethyl Ester (XIII). XII·AcOH (73 mg) was dissolved in trifluoroacetic acid (2.5 m*l*) and the solution was left to stand for 30 min at room temperature. The solution was evaporated to dryness *in vacuo* to yield a hygroscopic solid. The residue was dissolved in water and the solution was neutralized with the addition of triethylamine (*ca.* 0.025 m*l*). Then, the solution was evaporated to dryness and the remaining crystals were collected by filtration with the aid of ethanol; yield, 40 mg (67%); mp 182—183°C; $[\alpha]_D^{25}$ −22.7° (*c* 0.15, acetic acid); R_f 0.51,[13] 0.02;[14] amino acid ratios in acid hydrolysate, $Ser_{2.9}Asp_{1.0}Val_{1.1}$.[15]

Found: C, 44.57; H, 6.80; N, 12.90%. Calcd for $C_{20}H_{35}O_{11}N_5 \cdot H_2O$: C, 44.52; H, 6.91; N, 12.98%.

The digestion of XIII by leucine aminopeptidase was carried out by the procedure of Hofmann and Yajima.[16] The paper chromatography[13] of the digest revealed the presence of only three ninhydrine-positive components with R_f values identical with those of authentic samples of aspartic acid (R_f 0.20), serine (0.28) and valine (0.58).

13) The R_f value of the paper chromatography refers to the same solvent system described.[11]

14) The R_f value of the thin-layer chromatography with Merck silica gel refers to a solvent system of chloroform-methanol (5 : 1, v/v).

15) The authors are indebted to Mr. Kosaku Noda for the amino acid analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 673—676 (1968)

S-Alkylthioamidium Salt. II.[1] The Reactions of S-Alkylthioamidium Iodides with Mercuric Compounds

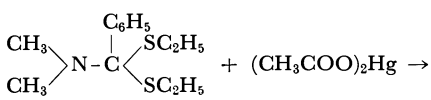
Tatsuaki YAMAGUCHI, Katsuhiko INOMATA and Teruaki MUKAIYAMA

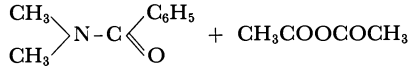
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 18, 1967)

The reactions of S-alkylthioamidium iodides with some mercuric compounds have been studied. Mercuric carboxylates were found to react with S-alkylthioamidium iodides giving the corresponding acid anhydrides and amides in good yields along with alkylmercaptomercuric iodide. In addition, it was established that the reaction of mercuric cyanide with the iodides afforded α-dimethylaminomalononitriles by the elimination of alkylmercapto mercuric iodide. Further, α-morpholino-β-phenylacrylonitrile was obtained in 87% yield by treating S-ethylthiophenylacetomorpholidium iodide with silver cyanide.

In the previous paper, the reaction of *N, N*-dimethylbenzamide diethylmercaptole with mercuric acetate has been reported to yield *N, N*-dimethylbenzamide, acetic anhydride and mercury ethylmercaptide.[2]





+ $(C_2H_5S)_2Hg$

In connection with this reaction, S-ethylthioamidium iodide (I) and its analogs (II and III) were tried to react with mercuric carboxylates in order to find a more convenient method for the preparation of acid anhydride.

III

When mercuric carboxylate was added to a solution of *N, N*-dimethyl-S-ethylthiobenzamidium iodide (Ia) in acetonitrile at room temperature, a yellowish or colorless clear solution was obtained at first with a slight heat evolution, and in a few minutes a white precipitate of ethylmercaptomercuric iodide was separated from the solution. Since the ethylmercapto mercuric iodide (C_2H_5SHgI), which is 1 : 1 adduct[3] of mercury ethylmercaptide and mercuric iodide, is quite insoluble in almost all solvents, it can be easily separated by filtration. From the filtrate, corresponding acid anhydrides and *N, N*-dimethylbenzamide were obtained in good yields. Mercuric salts of aromatic carboxylic acids were less reactive toward Ia than aliphatic one, and a higher temperature was necessary to obtain the anhydrides in better yields. Lower yield of benzoic anhydride against that of the amide will be due to the hydrolysis of the reactive intermediate by the water of crystallization of mercuric benzoate; indeed, free benzoic acid was also isolated in 19% yield. The results of the reaction of S-alkylthioamidium iodides with some mercuric carboxylates are summarized in Table 1.

The reaction may be considered to proceed as follows. A nucleophilic attack of carboxylate anion upon the central carbon atom of S-alkylthioamidium ion might be assisted by ^+HgOCOR, which readily abstracts the ethylthio group attached to the same carbon atom;[2] for, by the separate experiment, it was established that sodium carboxylate did not react with S-alkylthioamidium iodide at all under the similar condition. Subsequently, acyloxyimmonium type intermediate would be resulted. The intermediate, in turn,

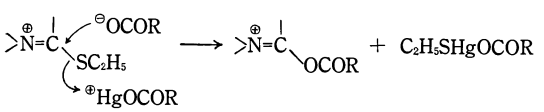
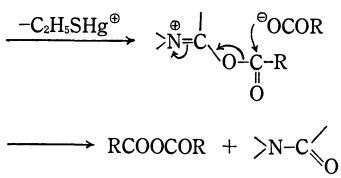
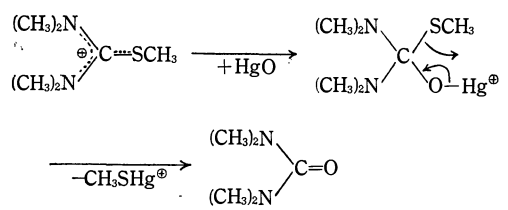
would act as a strong acylating agent[4] toward another carboxylate anion to form acid anhydride and amide.





Next, the reactions of I, II or III with mercuric oxide were studied. When a suspension of mercuric oxide in acetonitrile was treated with I, II or III, the corresponding *N, N*-disubstituted amides, *N, N*-dimethyl-*S*-methylthiolcarbamate and *N, N, N', N'*-tetramethylurea, respectively, were obtained in good yields along with alkylmercaptomercuric iodide (Table 2). It is noted that Id is the most reactive toward mercuric oxide and III is less reactive than I and II. The poor reactivity of III may be due to its high resonance-stabilization of the structure, which retards the nucleophilic attack of mercuric oxide on the central carbon atom.



In addition, it was found that α-dimethylamino-malononitriles (IVa, b, c) were afforded in good yields by treating Ia, Ib or Ic with equimolar

4) H. K. Hall, *J. Am. Chem. Soc.*, **78**, 2717 (1956).

amount of mercuric cyanide in acetonitrile at room temperature. Similarly, II reacted with mercuric cyanide giving α-dimethylamino-α-methylthiomalononitrile (V) in 60% yield. They were identified by elemental analyses and infrared spectra. The results are listed in Table 3.

$$\text{I or II} + Hg(CN)_2 \xrightarrow[-R''SHgI]{} (CH_3)_2N-C(R)(CN)_2$$

IVa R=C_6H_5
IVb R=CH_3
IVc R=H
V R=SCH_3

Further, Ia was found to react with silver cyanide in acetonitrile at room temperature giving 61% yield of α-dimethylamino-α-ethylthiophenylacetonitrile (VI) along with silver iodide. On the other hand, when Ie was treated with silver cyanide under the same condition, the evolution of ethyl mercaptan was observed and α-morpholino-β-phenylacrylonitrile (VII) was obtained in 87% yield. The elimination of ethyl mercaptan may be explained by considering the similar pathway, shown in the reaction of Ib with sodium ethylmercaptide giving ketene *N, S*-acetal.[5]

7) This compound has been reported to melt at 95—96°C by K. Hartke, E. Schmidt, M. Castillo and J. Bartulin, *Chem. Ber.*, **99**, 3268 (1966).
8) J. Braun and K. Weissback, *Ber.*, **63**, 2846 (1930).

allowed to stand at room temperature for a day long; mp 77—78°C (decomp.).

Found: C, 21.52; H, 4.49; N, 4.83%. Calcd for $C_5H_{12}INS_2$: C, 21.66; H, 4.33; N, 5.05%.

N, N, N', N'-Tetramethyl-*S*-methylthiuronium iodide (III) was synthesized by the reaction of the corresponding thiourea, prepared by the thermal decomposition[8] of *N, N, N', N'*-tetramethylthiuram disulfide, and methyl iodide in refluxing acetone; mp 172—173°C.

Found: C, 26.59; H, 5.81; N, 10.10%. Calcd for $C_6N_{15}IN_2S$: C, 26.28; H, 5.48; N, 10.21%.

Mercuric salts of isobutyric, *n*-butyric, benzoic and phthalic acid were prepared by the method described in the literature.[9] Mercuric acetate, mercuric cyanide, mercuric oxide and silver cyanide were obtained from commercial sources.

Reaction of Ia with Mercuric Isobutyrate. To a solution of Ia (6.42 g, 0.02 mol) in acetonitrile (40 m*l*) was added 7.50 g (0.02 mol) of mercuric isobutyrate in portions. Immediately, a clear solution was obtained with a slight heat evolution, and in a few minutes a white precipitate began to separated from the solution. The reaction mixture was then stirred at room temperature for 4 hr. The precipitate of ethylmercaptomercuric iodide (mp 180°C decomp.) was filtered and washed with acetonitrile. It weighed 7.30 g (94%). After the solvent had been evaporated from the filtrate, the residue was distilled under reduced pressure giving 2.56 g (81%) of isobutyric anhydride and 2.39 g (80%) of *N, N*-dimethylbenzamide.

By a similar procedure, the other mercuric carboxylates were converted to the corresponding acid anhydrides by Ia or II. The reaction conditions and results are summarized in Table 1.

Reaction of Id with Mercuric Oxide. Into a stirred suspension of mercuric oxide (2.17 g, 0.01 mol) in 40 m*l* of acetonitrile was added 3.49 g (0.01 mol) of Id in portions. The yellow color of mercuric oxide disappeared gradually. After the stirring had been continued for 5 hr at room temperature, the resulting white precipitate of methylmercaptomercuric iodide (mp 186.5°C decomp.) was filtered and washed with acetonitrile. It weighed 3.51 g (94%). The filtrate was concentrated and distilled under reduced pressure to give 1.75 g (92%) of benzomorpholide; bp 140—141°C/1.5 mmHg, mp 74—75°C (lit.[10] 74°C).

Similarly, *N, N*-dimethyl-*S*-methylthiolcarbamate and *N, N, N', N'*-tetramethylurea were obtained by the reaction of II or III with mercuric oxide (Table 2).

Reaction of Ia with Mercuric Cyanide. To a solution of Ia (16.05 g, 0.05 mol) in acetonitrile (100 m*l*) was added 12.63 g (0.05 mol) of mercuric cyanide. The mixture was stirred at room temperature for 2 hr and the resulting white precipitate of ethylmercaptomercuric iodide was filtered off (18.56 g, 96%). After the acetonitrile had been evaporated from the filtrate, distillation of the residual liquid gave 8.47 g (92%) of α-dimethylaminophenylmalononitrile (IVa); bp 98.5—99.5°C/4 mmHg. The elemental analysis (Table 3) and infrared spectrum of the product were found to be consistent with the structure assigned.

Reaction of Ia with Silver Cyanide. A suspension of Ia (16.05 g, 0.05 mol) and silver cyanide (6.70 g, 0.05 mol) in acetonitrile (100 m*l*) was stirred at room temperature for 2 hr. After the resulting pale yellow precipitate of silver iodide had been filtered off, the filtrate was concentrated and distilled to yield 6.76 g (61%) of α-dimethylamino-β-ethylthiophenylacetonitrile (VI); bp 113°C/1.5 mmHg, n_D^{23} 1.5366. This compound was identified by comparing the infrared spectrum with the authentic sample.[2]

Reaction of Ie with Silver Cyanide. When a suspension of Ie (3.62 g, 0.01 mol) and silver cyanide (1.29 g, 0.01 mol) in acetonitrile (50 m*l*) was stirred at room temperature, the evolution of ethyl mercaptan was observed and a pale yellow precipitate of silver iodide was separated. After the stirring had been continued for 4 hr, the precipitate was filtered off and the filtrate was concentrated to give a solid, which was then recrystallized from ethanol as colorless needles, mp 100—100.5°C, yield 87%. This compound had the correct analysis for α-morpholino-β-phenylacrylonitrile (VII) and the infrared absorption at 2220 cm^{-1}, assigned for C≡N bond.

Found: C, 72.67; H, 6.28; N, 12.78%. Calcd for $C_{13}H_{14}N_2O$: C, 72.87; H, 6.59; N, 13.08%.

NMR $\delta_{TMS}^{CDCl_3}$: 2.85 (triplet, 4H, $-N(CH_2-)_2$), 3.65 (triplet, 4H, $O(CH_2-)_2$), 5.92 (singlet, 1H, $-CH=$), 7.15—7.34 (multiplet, 5H, phenyl).

Reaction of Allylbenzene with *n*-Butyllithium in Tetrahydrofuran

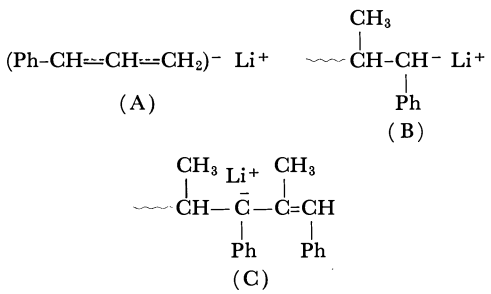
Yoshio OKAMOTO and Heimei YUKI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received September 22, 1967)

The reaction products between allylbenzene and *n*-butyllithium in tetrahydrofuran at 60°C were fractionated and investigated by elementary analysis, a molecular-weight determination, and a study of the IR, UV, and NMR spectra. The products were hydrocarbons and alcohols, the latter of which were formed by the reaction of the carbanions with tetrahydrofuran. The main products were 3-phenylheptene-2, 5-methyl-6-phenyldecane, 5-phenyl-5-heptene-1-ol, 5-phenyl-5-vinylnonane-1-ol, and 5-phenyl-5-vinylnonane-1, 9-diol. 3-Phenylheptene-1 was not obtained. In the resonance structures of allyl anions, a and b, $Ph\text{-}\bar{C}R\text{-}CH{=}CH_2$ (a) ↔ $Ph\text{-}CR{=}CH\text{-}CH_2^-$ (b), the reaction with tetrahydrofuran took place only in the form a. The observed results are correlated with those of the anionic polymerization of *trans*-β-methylstyrene reported previously.

Recently, the present authors have examined the anionic polymerization of *trans*-β-methylstyrene.[1] In the polymerization of this monomer with *n*-butyllithium in tetrahydrofuran at room temperature, a benzyl-type living anion (B) was easily converted into an allyl-type anion (A) by a chain-transfer reaction to the monomer. At a high temperature such as 60°C, the anions A and B further changed to inactive anions which possessed no reactivity to the monomer; this resulted in the cessation of the polymerization reaction. The anions A and B had absorption maxima at 340 and 398 mμ respectively, while the inactive anions had theirs at 510 and 570 mμ. The species having a λ_{max} at 510 mμ was supposed to be an anion C, but the species showing a λ_{max} at 570 mμ (anion D) was not confirmed.



On the other hand, only the anion D was formed in the reaction of allylbenzene with *n*-butyllithium at 60°C in tetrahydrofuran.[1]

This paper will be concerned with investigations of the reaction of allylbenzene with *n*-butyllithium carried out in order to determine the structure of the anion D.

Experimental and Results

Materials. *Allylbenzene.* This was prepared from phenylmagnesium bromide and allyl chloride,[2] and was purified by fractional distillation. Bp 72—73°C/39 mmHg. The purity was checked by gas chromatography.

Tetrahydrofuran (THF). Tetrahydrofuran was refluxed first over sodium and then over lithium aluminum hydride. The solvent was distilled onto sodium-potassium alloy and benzophenone, from where it was transferred into a reaction vessel on a vacuum line.

n-Butyllithium (n-BuLi). According to the method of Gilman,[3] *n*-BuLi was prepared in THF. The concentration was determined by double titration.[4] The presence of the unchanged *n*-butyl chloride, which was used for the preparation of *n*-BuLi, was not detected by gas chromatography, while the formation of *n*-octane was observed.

Reaction. The reaction was carried out under dry nitrogen in a glass vessel equipped with a three-way stopcock. To a solution of allylbenzene (13 g, 0.11 mol) in THF (200 ml), *n*-BuLi (0.11 mol) was added with a syringe over a ten minute period at room temperature. As soon as the *n*-BuLi was added, the solution turned red and generated gas and white precipitates. The reaction mixture was then allowed to stand at 60°C for 48 hr. During this time, the solution turned gradually red-purple. The reaction was terminated by adding methanol after the white precipitates

2) E. B. Hershberg, *Helv. Chim. Acta*, **17**, 351 (1934).
3) H. Gilman and B. J. Gaj, *J. Org. Chem.*, **22**, 1165 (1957).

had been isolated under dry nitrogen. The white precipitates must have been lithium hydride because they showed flame-test results characteristic of lithium and reacted with methanol violently. The THF was then removed from the reaction mixture. The residue was dissolved in diethyl ether and washed with water. The ethereal layer was dried over magnesium sulfate, and then the ether was removed to give 16 g of an oily product.

Fractionation of Reaction Mixture. The above product was first separated into fractions by distillation under nitrogen, and subsequently the fractions were treated by column chromatography with activated alumina, using *n*-hexane, benzene, and methanol as eluents. The results are summarized in Table 1. The fractions eluted with *n*-hexane were hydrocarbons, while those eluted with benzene and methanol were alcohols.

Table 1. Fractionation of reaction product

Fraction	Distillation Bp /1.5 mmHg °C	Yield g	Yield %	Column chromatography Eluent	Recovery %
F1H	48— 52	0.3	2	Hexane	90
F2H				Hexane	63
F2B	77—104	1.6	10	Benzene	2
F2M				Methanol	33
F3H				Hexane	35
F3B	104—114	1.4	9	Benzene	46
F3M				Methanol	19

F4B	114—154	2.9	18	Benzene	1
F4M				Methanol	43
F5H	154—160	2.0	13	Hexane	54
F5M				Methanol	46
F6	Residue	7.8	49	—	—

Measurement. *Molecular Weight and Elementary Analysis.* The molecular weight was measured on a Mechrolab Vapor Pressure Osmometer, Model 301 A, using a benzene solution for the hydrocarbon and an ethanol solution for the alcohol. The elementary analyses and the molecular weights of the fractions are listed in Tables 2 and 3.

Infrared Spectrum. The spectrum was obtained with a Nihon Bunko Model IR-S Spectrometer in a liquid state. The hydrocarbons showed the absorption bands at 1945, 1860, and 1800 cm^{-1} due to a mono-substituted benzene, at 2960 and 1380 cm^{-1} due to a methyl group, and at 2925 cm^{-1} due to a methylene group. The alcohols showed the absorptions due to a hydroxy group at 3300 and 1050 cm^{-1}, besides the absorption bands due to a mono-substituted benzene and a methylene group.

Table 2. Elementary analyses and molecular weights of hydrocarbons

Fraction number	Elementary analysis C%	H%	Molecular weight	Molecular formula
F1H	89.00	11.24	185	$C_{13}H_{19.1}$

Table 3. Elementary analyses and molecular weights of alcohols

Fraction number	Elementary analysis C%	H%	Molecular weight in EtOH	Molecular formula
F2M	81.43	9.57	192	$C_{13}H_{18.3}O_{1.09}$
F3B	81.91	10.68	244	$C_{17}H_{26.4}O_{1.15}$
F4M	79.01	10.27	248	$C_{17}H_{26.0}O_{1.73}$
F5M	77.56	9.90	259	$C_{17}H_{25.9}O_{2.06}$

Electronic Spectrum. The measurements were made with a Hitachi EPS-2 Spectrophotometer using cyclohexane solutions for the hydrocarbons and ethanol solutions for the alcohols. The respective characteristics of the IR and UV spectra are summarized in Tables 4 and 5. In these tables, the molar extinction coefficient, ε_{max} is based on the observed molecular weight of each fraction.

NMR Spectrum. The NMR spectrum was taken in a carbon tetrachloride solution with a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.) at 100 Mc/sec, using tetramethylsilane as an internal standard. The spectra of the fractions F1H, F2H, F2M, and F3B are shown in Figs. 1, 2, 3, and 4 respectively.

a) The ratio of the numbers of aliphatic protons to aromatic protons.

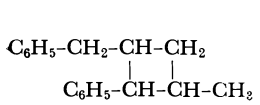
Probable Products of the Reaction. Tables 6 and 7 list some compounds which seem to be produced in this reaction. The alcohols listed in Table 7 were considered to be produced by the reactions of carbanions with THF. Their molecular formulae, structural formulae, elementary analyses, and molecular weights, and the ratios of the numbers of aliphatic protons to aromatic protons (H_{al}/H_{ar}) in them are also shown in the tables. From these characteristic features the structure of the compound contained in each fraction was estimated to be one of those included in Tables 6 and 7.

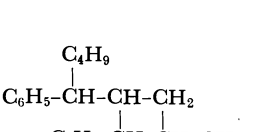
Determination of the Structure. *Fraction F1H.* The elementary analysis and the molecular weight of the fraction F1H were most similar to those of 3-phenylheptene-1 (Ia in Table 6) or 3-phenylheptene-2 (Ib). The IR spectrum showed a strong absorption due to a three-substituted olefin, $>C=CH-$, at 835 cm^{-1}; the NMR spectrum also indicated the existence of a $>C=CH-CH_3$ structure by the peaks at 8.2 and 4.3 ppm (Fig. 1). In the UV spectrum a strong absorption due to the conjugation between a benzene ring and a C=C double bond was observed at the same wavelength as that of the absorption of 3-phenylhexene-2 (λ_{max} 242 mμ, ε_{max} 4700 in cyclohexane).[5] These results showed that this fraction consisted mostly of Ib. However, the absorptions at 8.7 and 9.1 ppm in the NMR spectrum, attributed to the methylene and methyl groups respectively, are too strong if 3-phenylheptene-2 is the only component of the fraction. It seems that the fraction may also contain an other compound, probably 5-methyl-6-phenyldecane (II in Table 6); if so, the elementary analysis, the molecular weight, and the H_{al}/H_{ar} ratio show that the ratio of Ib to II will be about 2. The clear separation into these two components could not be attained by further fractionations, however.

Fraction F2H. The molecular formula of the fraction F2H was consistent with that of 5-methyl-6-phenyldecane. The IR spectrum showed the absence of an olefinic double bond, and the chemical shift and the relative area of each peak (Ph : $>CH-$: $-CH_2-$: CH_3-=5.0 : 2.2 : 11.3 : 8.8) in the NMR spectrum also supported the above consistence.

Fractions F3H and F4H. Both the fractions showed the absence of a C=C double bond in their IR and NMR spectra. Judging from the molecular weight and H_{al}/H_{ar}', III and IV might be suggested as the components of both the fractions, whose difference may be that of the relative amounts of these compounds.



III



IV

Fractions F5H and F6. These fractions were composed of higher-molecular-weight products, the structures of which were not determined in this study.

Fraction F2M. The elementary analysis and the molecular weight of this fraction were similar to those of 5-phenyl-6-heptene-1-ol (Va in Table 7), 5-phenyl-5-heptene-1-ol (Vb), or 7-phenyl-6-heptene-1-ol (Vc). The NMR spectrum showed the respective absorptions at around 4.3 and 8.2 ppm for an olefinic proton and methyl protons in a $CH_3-CH=C$ unit and no absorption due to a *n*-butyl group, suggesting that this fraction consisted of Vb. The relative intensities of the peaks (Ph: C=CH– : $-CH_2OH$: $-CH_2-C=C$: CH_3- : $-CH_2-$= 5.0 : 1.0 : 3.0 : 2.0: 2.7 : 4.4) in the NMR spectrum were consistent with the above estimation. The IR and UV spectra also gave the same conclusion.

Fractions F2B and F3B. The molecular formula of the fraction F3B was most in accord with 5-phenyl-5-vinylnonane-1-ol (VIa in Table 7) or 7-phenyl-6-undecene-1-ol (VIb). Both IR and NMR spectra strongly suggested the existence of a vinyl group. The similarity of the UV spectrum with that of allylbenzene indicated that this fraction was VIa. The structure of VIa was also confirmed by the chemical shift and the relative intensities of the peaks (Ph : $CH_2=CH-$: $-CH_2O-$: $-OH$: $-CH_2-$: CH_3-=5.0 : 2.9 : 2.0 : 1.0 : 12 : 3.2) in the NMR spectrum. The IR spectrum of the fraction F2B was very similar to that of the fraction F3B.

Fractions F3M and F5M. The structure of 5-phenyl-5-vinylnonane-1, 9-diol (VIIa in Table 7) and that of 5-phenyl-5-undecene-1, 11-diol (VIIb) might be assigned to the fraction F5M on the basis of the elementary analysis and the molecular weight. The NMR and IR spectra indicated that this fraction was compound VIIa, for it contained a C=C double bond, but only a vinyl group. The IR spectrum of the fraction F3M was similar to that of the fraction F5M.

Fraction F4M. The data suggest that this fraction consists of almost equal amounts of VIa and VIIa present in the fractions F2B and F5M respectively.

Discussion

The compounds identified as the main products in the reaction between allylbenzene and *n*-BuLi were found to be Ib, II, Vb, VIa, and VIIa, listed in Tables 6 and 7. The following reactions may be suggested as the processes by which these compounds are formed.

(II)

$$\mathrm{Ph\text{-}\overset{-}{C}H\text{-}CH{=}CH_2} \xrightarrow{\diagup\!\!\!

Although it has been known that organolithium compounds more or less easily decompose in ether solvents at room temperature,[3] the processes have not been studied in detail. Recently several groups have found that alkyllithium compounds react with THF to give alcohols. Rembaum *et al.*[9] reported the following reaction:

$$C_2H_5^- Li^+ + \boxed{\quad O \quad} \rightarrow C_2H_5\text{-}(CH_2)_4\text{-}O^- Li^+$$

Fetters *et al.*[10] investigated the reaction of polystyryl anion with THF and found it to be as follows:

$$\sim\sim CH_2\text{-}\underset{\underset{Ph}{|}}{CH}^- Li^+ + \boxed{\quad O \quad} \rightarrow$$

$$\sim\sim CH_2\text{-}\underset{\underset{Ph}{|}}{CH}\text{-}(CH_2)_4\text{-}O^- Li^+$$

In the reaction of allylbenzene with *n*-BuLi, an anion, a_1, formed by the process (1) reacts with THF to give an alcoholate, as is shown in the process (6). The alcoholate Va thus produced may isomerize to Vb through the processes (7) and (8) just the same as is isomerized Ia to Ib. On the other hand, the alcohol derived from the anion b_1 in the process (1) was not detected at all. The anions a_3 and a_7 in the processes (3) and (7) also react with THF to give alcoholates, VIa and VIIa, through the processes (9) and (10) respectively. In these cases the isomerizations of VIa and VIIa do not proceed because of the lack of a hydrogen atom at the 3-position in each compound. Moreover, the corresponding alcohols can not be derived from the anions b_3 and b_7 in the processes (3) and (7).

The above results show that, in the resonance structures of the allyl anions, a and b;

$$\underset{(a)}{Ph\text{-}\bar{C}R\text{-}CH{=}CH_2} \leftrightarrow \underset{(b)}{Ph\text{-}CR{=}CH\text{-}CH_2^-}$$

the form b is more stable than a; in other words, the form a is more reactive with THF to give an alcohol.

The allyl anions formed here reacted with THF to give alcohols in good yields, while a lot of allyllithium compounds abstract a proton from THF to yield alkanes.[11] This may be caused by the difference in the reactivity between these organolithium compounds.

At the present time, from the results of this study alone it seems to be difficult to determine the structure of the above-mentioned anion, D, having a λ_{max} at 570 mμ. However, it has been found that many of the anions derived from allylbenzene were converted into the alcoholate anions by the reaction with THF. In the anionic polymerization of *trans*-β-methylstyrene, the allyl anion, A, is formed by the chain transfer to the monomer. Therefore, the same reaction of the anion A with THF should also occur to produce alcoholate anions in this anionic polymerization at high temperatures, this reaction being one of the main causes why the polymerization ceases.

The poly-β-methylstyrene obtained by the anionic polymerization has no C=C double bond in the chain, and the structure of cyclic butane was proposed as that of the terminal unit.[1] The existence of compounds III and IV, the supposed components of the fractions F3H and F4H, may be connected with this saturated chain terminal, although the structures of III and IV have, so far, not been exactly determined.

Organic Catalysts. IV.[1] The Role of the Iron as an Oxidation Catalyst in Copper-Iron-Polyphthalocyanine

Hiroo INOUE, Yasuji KIDA and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, The University of Osaka Prefecture, Sakai, Osaka

(Received September 22, 1967)

The role of the iron in copper-iron-polyphthalocyanine in the catalytic action in the oxidation of acetaldehyde ethylene acetal and cyclohexene was investigated on the basis of the inhibition of the reaction by the treatment of copper-iron-polyphthalocyanine with iron-binding agents and oxidizing agents. The catalytic action of copper-iron-polyphthalocyanine decreased or disappeared upon the addition of 2-phenylimidazole and pyridine to the reaction system, and upon the treatment with bromine or concentrated hydrochloric acid in the presence of air. However, the reduction of the oxidized copper-iron-polyphthalocyanine with ascorbic acid or sodium thiosulfate recovered the catalytic activity. Furthermore, the catalytic activities of iron-metal-polyphthalocyanines (metal; V, Cr, Mn, Co, Ni, Cu and Zn) and copper-metal-polyphthalocyanines (metal; V, Cr, Co, Ni and Zn) in the oxidation of acetaldehyde ethylene acetal were investigated. The former groups showed the catalytic actions, but no catalytic actions were observed in the latter groups. The catalytic activities of iron-metal-polyphthalocyanines increased with a decrease in the activation energy of the electrical conductivity of the polymer. From these results, it was presumed that the Fe(II) ions located in the conjugated system act as active sites for the activation of oxygen and for the decomposition of peroxide.

Copper-iron-polyphthalocyanine, which has a unit structure similar to the structure of an iron or copper porphyrin in biological oxygenases, shows a remarkable acceleration in the oxidation of acetaldehyde ethylene acetal with oxygen.[1)]

The copper-iron-polyphthalocyanine has a sensitive catalytic activity related to its electronic and stereochemical structure. Furthermore, the action of the iron ion in the activation of oxygen and in the decomposition of peroxide may be interpreted in terms of the electronic character of the iron ion with the assistance of coordination chemistry.

In this paper, we will describe the role of the iron ion in polyphthalocyanine in the catalytic action. Our conclusions are based on the following results: 1) the inhibition of the reaction by iron-binding agents, such as pyridine and 2-phenylimidazole; 2) the disappearance of the catalytic activity upon treatment with an oxidizing agent, such as bromine or hydrochloric acid in the presence of oxygen; 3) the requirement of a reducing agent, such as ascorbic acid, for the catalytic activity, and 4) the effect on the catalytic activity of the coexistence of vanadium, chromium, manganese, cobalt and zinc instead of copper with the iron in the polyphthalocyanine structure.

Experimental

Preparation of Metal Polyphthalocyanine. *Iron- and Copper-Iron-Polyphthalocyanine (Fe-poly PC and Cu-Fe-poly PC).* Cu-Fe-poly PC was prepared according to the method described in a previous paper,[1)] except that the reaction temperature was 175°C instead of 190°C. Fe-poly PC was prepared under various conditions: at different temperatures, with different solvents, and with different amounts of anhydrous ferric chloride. The results are shown in Table 1. The results of the elementary analyses of the Fe-poly PC and Cu-Fe-poly PC obtained are shown in Table 2.

Iron- and Copper-Metal-Polyphthalocyanine (Fe-M-poly PC and Cu-M-poly PC). Fe-M- and Cu-M-poly PC were prepared according to a method, A, described in the previous paper.[1)] However, the reaction temperatures for the preparation of the metal polyphthalocyanines in this paper were changed according to the kinds of metal ions coexisting with the iron ion. The reaction mixture turned green. For all the experiments, the product, 1.2—1.4 g of an infusible bluish or greenish-black powder, was obtained from the starting materials of 4.26×10^{-4} mol of anhydrous ferric chloride, 4.22×10^{-4} mol of metal salt, and 4.21×10^{-3} mol of 1, 2, 4, 5-tetracyanobenzene.

The properties and the conditions for the preparation of all the polymers obtained here are summarized in Tables 5 and 6.

Treatment of Metal Polyphthalocyanines (Cu-Fe-Poly PC and Fe-Poly PC (No. 1)). *By Bromine.* Into a solution of 5 g of potassium bromide and 10 m*l* of bromine in 100 m*l* of distilled water, 0.5 g of metal polyphthalocyanine was added; the mixture was then stirred at room temperature for 9 hr. After filtering off, the precipitate was washed sequentially with distilled water, methanol, and ether, and was dried over calcium chloride under a reduced pressure of 10 mmHg,

TABLE 1. THE CONDITIONS OF THE PREPARATIONS OF Cu-, Fe- AND Cu-Fe-POLY PC

Polymer	Material, g			Solvent[a]	Reaction temperature, °C
	T. C. B.[b]	$CuCl_2$	$FeCl_3$		
Cu-Poly PC	1.5	0.67	0.00	E. G.	175
Cu-Fe-poly PC	1.5	0.11	0.14	E. G.	175
Fe-poly PC (No. 1)	1.5	0.00	0.67	E. G.	175
Fe-poly PC (No. 2)	1.5	0.00	0.67	E. G.	190
Fe-poly PC (No. 3)	1.5	0.00	0.48	E. G.	175
Fe-Poly PC (No. 4)	1.5	0.00	0.67	D. E. P.	190

a) The amount of the solvent is 16 g.
E. G. and D. E. P. mean ethylene glycol and diethyl phthalate, respectively.
b) T. C.B. means 1, 2, 4, 5-tetracyanobenzene.

TABLE 2. THE ELEMENTARY ANALYSES OF Cu-, Fe- AND Cu-Fe-POLY PC

Polymer	Elementary analysis, %				
	C	H	N	Cu	Fe
Cu-poly PC	50.7	2.13	18.3	11.6	0.0
Cu-Fe-poly PC	54.5	2.22	21.6	3.8	2.8
Fe-poly PC (No. 1)	46.7	2.76	14.2	0.0	12.6
Fe-poly PC (No. 2)	54.6	2.70	16.9	0.0	—
Fe-poly PC (No. 3)	50.8	2.80	18.0	0.0	—
Fe-poly PC (No. 4)	55.5	2.11	20.5	0.0	—

thus yielding 0.5 g of the powder.

By Ascorbic Acid. A solution of 2 g of ascorbic acid in 40 m*l* of distilled water was adjusted to pH 4 with sodium acetate; then into the solution there was added 0.5 g of the polymer treated by bromine, and the mixture was stirred under a nitrogen atmosphere for 2 hr at room temperature. After filtering off, the precipitate was washed and dried as has been described above.

By Sodium Thiosulfate. Into 100 m*l* of a 0.5 N sodium thiosulfate solution there was added 0.2 g of the polymer treated by bromine, and then the mixture was stirred at room temperature for one day. After filtering off, the precipitate (about 0.2 g) was washed and dried as has been described above.

By Concentrated Hydrochloric Acid. A solution of 0.4 g of the polymer in 300 m*l* of concentrated hydrochloric acid was heated while being stirred at 90°C for 1.5 hr according to Linstead's method, in which Fe(II) phthalocyanine is oxidized by air to Fe(III) phthalocyanine.[2] After the reaction, the precipitate was washed and dried by the method described above.

Oxidation of Acetaldehyde Ethylene Acetal and Cyclohexene with Oxygen. *Materials.* Acetaldehyde ethylene acetal and cyclohexene were prepared according to the methods described in the literature[3,4] and were purified before use by distilling them repeatedly through a Vigreux column over sodium under a nitrogen atmosphere. Acetaldehyde ethylene acetal; n_D^{25} 1.3960, bp 85°C, and cyclohexene; n_D^{25} 1.4465, bp 83°C. The absence of peroxide was confirmed by an iodine-starch test.

Apparatus and Procedure. The oxidation of acetaldehyde ethylene acetal or cyclohexene was carried out by stirring a suspension of 30 mg of the polymer in 5 m*l* of acetaldehyde ethylene acetal or cyclohexene at the atmospheric pressure of oxygen at 30°C using the same apparatus and procedure as have been described in a previous paper.[1]

Analyses of the Oxidation Products. The oxidation products, ethylene glycol monoacetate, 2-cyclohexenol, and 2-cyclohexenone, were analyzed with a gas chromatograph, Yanagimoto GCG-5DH, in which polyethylene glycol-6000 was used as an adsorbent and helium gas as a carrier gas. The results were similar to those described previously.[1]

The Measurement of the D. C. Resistivity. The d. c. resistivity of the polymer was measured in an applied electric field of 100—200 V/cm under a pressure of 1000 kg/cm² *in vacuo* according to a method described in a previous paper.[5] The electrical resistivity (ρ) at an ascending temperature (T) was identical with that at a descending temperature, and a linear relationship between log ρ and $1/T$ was observed. The resistivities of the polymers, as typical organic semiconductors, fit the following equation;

$$\rho = \rho_0 \exp(\Delta\varepsilon/2\boldsymbol{k}T)$$

where $\Delta\varepsilon$ is the energy gap and $\boldsymbol{k}$, the Boltzmann constant.

Results and Discussion

Properties of the Polymers. *Cu-, Fe-, and Cu-Fe-Poly PC.* Cu-, Fe-, and Cu-Fe-poly PC are insoluble in any organic solvents, but are soluble in concentrated sulfuric acid, giving a green color. The elementary analyses, the ratio of carbon to nitrogen (C/N ratio), the ratio of copper to iron (Cu/Fe ratio), and the electrical conductivities of Cu-, Fe- and Cu-Fe-poly PC are summerized in Tables 2 and 3. These results and, furthermore, the visible absorption spectra of the polymers are identical with those of the phthalocyanine polymer of Type A described previously.[1] The infrared absorption spectra of the polymers differed from those of the previously-prepared polymers[1] only in the absorption of the -CN group, 2200 cm^{-1}. Therefore, the structure of the polymers obtained here must be of a phthalocyanine type, with end groups of -CN and -CONHCO-. Furthermore, the degree of the polymerization of the phthalocyanine unit of Cu-Fe-poly PC is presumed to be larger than that of Cu- and Fe-poly PC on the basis of the C/N ratios and the electrical conductivities, which are shown in Table 3.

The electron spin resonance spectra of the polymers were measured in the air at room temperature. The results are shown in Fig. 1. The electron spin resonance spectra of Fe-poly PC (No. 1—4) have no absorption. These facts indicate that the central iron ion of Fe-poly PC has an oxidation state of +2 and a coordination number of 6.[6] On the other hand, the electron spin resonance spectra of Cu- and Cu-Fe-poly PC have absorptions at the g values of 2.072 and 2.055 respectively. Therefore, the central iron and copper ions of Cu- and Cu-Fe-poly PC must have oxidation states of +2 and coordination numbers of 6 and 4 respectively. Furthermore, in the case of Cu-Fe-poly PC only, one more absorption was observed, as shown in Fig. 1. This must be based on the free electron in the conjugated system of the polymer. This fact may mean that

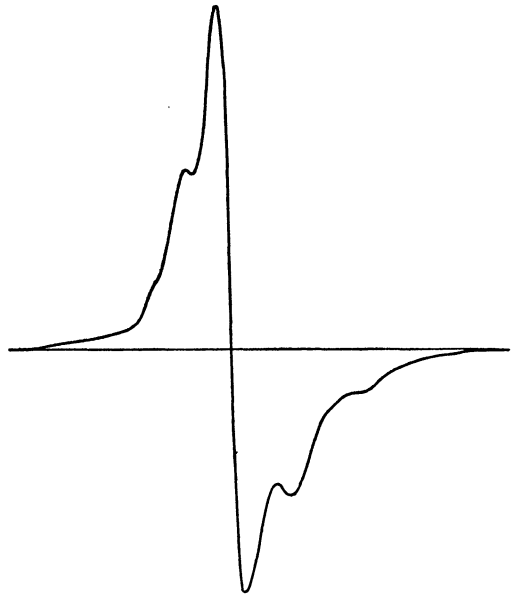

Fig. 1. ESR spectrum of Cu-Fe-poly PC (g: 2.055).

Cu-Fe-poly PC has a larger degree of polymerization of the phthalocyanine unit than that of Fe- or Cu-poly PC.

Fe- and Cu-Fe-Poly PC Treated with Bromine, Ascorbic Acid, and Sodium Thiosulfate. The treatment of Cu-Fe-poly PC and Fe-poly PC with bromine resulted in an increase in the halogen content from 0.85 to 4.07%; the halogen content was then recovered almost quantitatively to 0.78% by treatment with ascorbic acid or sodium thiosulfate, as shown in Table 4. By treatment with bromine and then with ascorbic acid, no significant differences in the C/N ratios, the infrared absorption spectra, the visible absorption spectra, and the electron spin resonance spectra of the polymers were observed from those of the untreated polymers, although some variations in the electrical conductivities were observed. This means that the phthalocyanine structure of the polymers, and

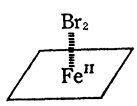
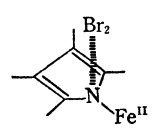
both the oxidation states and the coordination numbers of the central metal ions do not change with the treatment with bromine and ascorbic acid. Moreover, the bromine treatment may form a complex between bromine and the central iron ion (1), or between bromine and the nitrogen atom of the pyrrole of the phthalocyanine structure (2).



(1)



(2)

Fe- and Cu-Fe-Poly PC Treated by Air in Concentrated Hydrochloric Acid. The oxidation of the central iron ions of Fe- and Cu-Fe-poly PC by air was carried out in concentrated hydrochloric acid as has been described before. The polymer obtained from Fe-poly PC showed properties similar to those of the untreated Fe-poly PC in respect to the C/N ratios, the electrical conductivities, and the infrared absorption spectra (Table 4). However, the infrared absorption spectrum of the polymer obtained from Cu-Fe-poly PC showed an increase in the absorption of the –CONHCO– group with a decrease in that of the –CN group. This means that some of the –CN groups were changed to –CONHCO– groups in the process of the treatment with concentrated hydrochloric acid. In the case of both Fe- and Cu-Fe-poly PC, the electron spin resonance spectra showed absorption at the g value of 2.051 in the existence of the Fe(III) ion.

Fe-M- and Cu-M-Poly PC. The polyphthalocyanines containing various metals (M) with iron or copper (Fe-M- or Cu-M-poly PC) were bluish

or greenish-black powders; those powders were insoluble in any organic solvents, but were soluble in concentrated sulfuric acid. The results of the elementary analyses (Table 5), the C/N ratios (Table 6), and the infrared absorption spectra of Fe-M- and Cu-M-poly PC were similar to those of Cu-Fe-poly PC. On the other hand, the visible absorption spectra of Fe-M-poly PC, observed by the use of a KBr disk method, showed differences from those of Cu-M-poly PC, which have two absorption maxima, at about 720—740 mμ and 880—900 mμ. Most of the Fe-M-poly PC's showed an absorption maximum at 570—580 mμ besides those at 720—740 mμ and 880—900 mμ. Among the Fe-M-poly PC's, the absorption maxima of Fe-Zn-poly PC and Fe-Mn-poly PC at 750 mμ, and of Mn-poly PC at 770 mμ and 935 mμ, were shifted toward the longer wavelength side by 10—30, 50, and 55 mμ respectively as compared with those of the other Fe-M-poly PC's. The values of ρ_{20} and $\Delta\varepsilon$ of the electrical conductivity were in the range of 10^4—10^8 ohm-cm and 0.4—1.3 eV respectively (Table 6). The values of the electrical resistivities of Cu-M-poly PC and Mn-poly PC were lower than those of Fe-M-poly PC. Mn-poly PC showed the highest electrical conductivity, ρ_{20}-3.4×10^3 ohm-cm.

Table 6. The values of C/N ratio, $\Delta\varepsilon$ and ρ_{20} of Fe-M- and Cu-M-poly PC

Polymer	C/N ratio	Electrical properties	
		$\Delta\varepsilon$, eV	ρ_{20}, Ω-cm

Oxidations of Acetaldehyde Ethylene Acetal and Cyclohexene. *Catalytic Actions of Fe-Poly PC and Cu-Fe-Poly PC.* The oxidations of acetaldehyde ethylene acetal and cyclohexene by Fe-poly PC and Cu-Fe-poly PC with oxygenat 30°C were carried out as has been described previously.[1] The catalytic ability of Fe-poly PC depends on the synthetic conditions, that is, on the reaction temperature and on the ratio of anhydrous ferric chloride to 1, 2, 4, 5-tetracyanobenzene, as shown in Fig. 2. There were some difficulties in preparing the catalytically active Fe-poly PC as compared with the case of Cu-Fe-poly PC. Although the (No. 1 and 3) Fe-poly

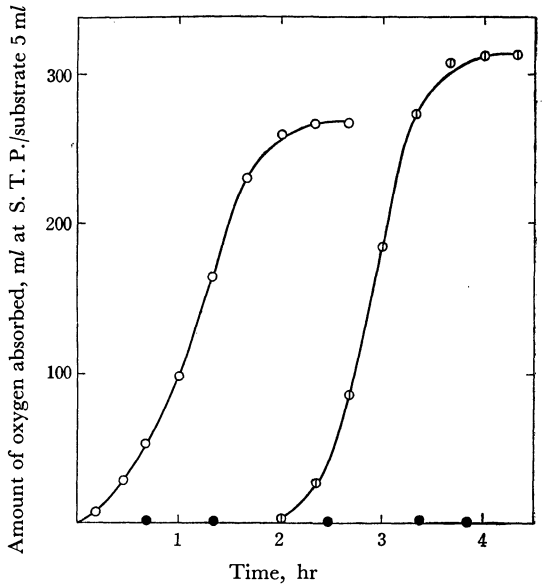

Fig. 2. The catalytic activity of Fe-poly PC prepared under the different conditions: Fe-poly PC; 30 mg.

◑ *t*-BuOOH alone (0.5 m*l*)

PC's showed catalytic activity in the oxidation of acetaldehyde ethylene acetal, the (No. 2 and 4) Fe-poly PC's did not show any activity. The (No. 3) Fe-poly PC showed a long induction period in the oxidation of acetaldehyde ethylene acetal, but the induction period disappeared upon the addition of *t*-butyl hydroperoxide to the reaction system (Fig. 3). Thus, the catalytic action of the (No. 3) Fe-poly PC is not effective in the activation of oxygen, but it is effective in the decomposition of the peroxide formed in the oxidation process. Remarkable differences in catalytic activity between Fe-poly PC and Cu-Fe-poly PC were observed in the case of the oxidation of cyclohexene. As shown in Fig. 4, even Fe-poly PC (No. 1), which showed a significant catalytic action in the oxidation of acetaldehyde ethylene acetal, showed a longer induction period for the oxygen absorption than that of Cu-Fe-poly PC. These facts must mean that the catalytic action of Cu-Fe-poly PC in the oxidation of acetaldehyde ethylene acetal and cyclohexene is more effective than that of Fe-poly PC.

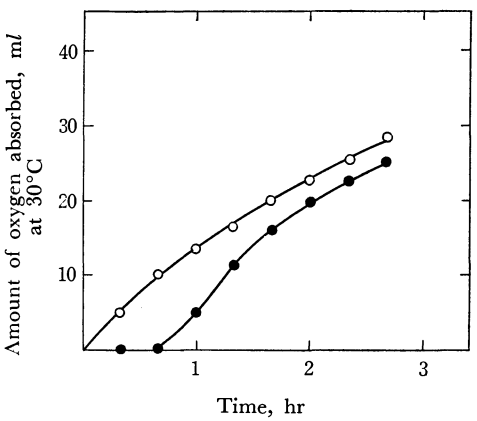

Fig. 4. The oxidation of cyclohexene in the presence of Fe- and Cu-Fe-poly PC: Catalyst; 30 mg.
○ Cu-Fe-poly PC ● Fe-poly PC (No. 1)

Effects of Various Treatments on the Catalytic Activities of Fe- and Cu-Fe-Poly PC. Cu-Fe-poly PC and Fe-poly PC treated with bromine showed no catalytic action in the oxidation of acetaldehyde ethylene acetal. However, the catalytic action was recovered to some extent by the reduction of bromine in Fe- and Cu-Fe-poly PC by ascorbic acid or sodium thiosulfate. The rate and the total amount of oxygen absorption into the system are shown in Fig. 5. Thus, bromine acts as an inhibitor of the catalytic action of Fe- and Cu-Fe-poly PC in the oxidation of acetaldehyde ethylene acetal. Probably this inhibition is caused by the formation of a complex between bromine and the polymer, as has been assumed previously.

by Fe- and Cu-Fe-poly PC treated with concentrated hydrochloric acid and air showed the induction period of the oxygen absorption of 4 or 5 hr, as shown in Fig. 6. This indicates that the change of the Fe(II) to the Fe(III) ion in Fe- or Cu-Fe-poly PC upon treatment of concentrated hydrochloric acid and air results in a lowering of the catalytic activity in the activation of oxygen in the oxidation process. That is, the Fe(II) ion should be involved in Fe- and Cu-Fe-poly PC in order to contribute effectively to the acceleration of the oxygen absorption in the oxidation of acetaldehyde ethylene acetal. Furthermore, the addition of 2-phenylimidazole or pyridine to the reaction system containing Fe- or Cu-Fe-poly PC resulted in an increase in the induction period for oxygen absorption or a decrease in the rate of oxygen absorption. The effect of the inhibition by 2-phenylimidazole was greater than that by pyridine (Figs. 7 and 8). This may be caused by the stronger ligand field of 2-phenylimidazole as compared with that of pyridine. In the case of Fe-poly PC, the induction period increased proportionally with an increase in the amount of 2-phenylimidazole added, as shown in Fig. 9. The

Fe-poly PC as a catalyst, that is, the difference in the electronic properties of the Fe(II) ions located in the conjugated system. Thus, the electronic property of the Fe(II) ion conjugated with the π electron of the ligand seems to be important in making it an active site for the

activation of oxygen.

Oxidation of Acetaldehyde Ethylene Acetal in the Presence of Fe-M-Poly PC or Cu-M-Poly PC. As shown in Fig. 10, Fe-M-poly PC (M; Cr, V, Co, Ni and Zn), Cu-Mn-poly PC, and Mn-poly PC all showed catalytic activity in the oxidation of acetaldehyde ethylene acetal with oxygen, while Cu-M-poly PC did not. Therefore, the iron and manganese ions contained in the polyphthalocyanine polymer must play important roles in the catalytic action, probably as active sites. Furthermore, in the case of Fe-M-poly PC (M; Cr, V, Mn, Co, Ni and Cu), there was a linear relationship between the catalytic activity (the rate of oxygen absorption) and the activation energy ($\Delta\varepsilon$) of the electrical conductivity of Fe-M-poly PC, as shown in Fig. 11. That is, the catalytic activity of Fe-M-poly PC increases with a decrease in the $\Delta\varepsilon$ value of Fe-M-poly PC, namely, with an increase in the conjugated system of the π electron. Thus, the electronic property of an iron or manganese ion, which is modified by the conjugation of the π electron of ligand and the electronic property of the other metal ion coexisting with the iron or manganese ion, seems to contribute effectively to the catalytic action of Fe-M-poly PC.

Organic Catalysts. V.[1] Specific Catalytic Properties of Copper-Iron-Polyphthalocyanine in the Oxidation of Aldehydes

Hiroo INOUE, Yasuji KIDA and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, The University of Osaka Prefecture, Sakai, Osaka

(Received September 22, 1967)

Copper-iron-polyphthalocyanine showed a specific catalysis for the oxidations of the substituted benzaldehydes and the saturated aldehydes with oxygen. The catalytic activity of copper-iron-polyphthalocyanine was solvent-dependent: tetrahydrofuran, ethanol, acetonitrile, ethyl acetate and anisole inhibited the oxidation of benzaldehyde by copper-iron-polyphthalocyanine and oxygen, while benzene and acetone resulted in catalytic oxidation. Benzaldehyde and the saturated aliphatic aldehydes in benzene were oxidized catalytically with copper-iron-polyphthalocyanine and oxygen to afford the corresponding peroxy acids and acids in quantitative yields. Furthermore, oxygen was absorbed with no induction period; the rate of oxygen absorption was in the range of 8—13 m*l*/min. On the other hand, the unsaturated aliphatic aldehydes, cinnamaldehyde and acrolein, were oxidized with a very slow rate of oxygen absorption in spite of the existence of copper-iron-polyphthalocyanine in the reaction system. *p*-Methylbenzaldehyde and *p*-chlorobenzaldehyde were oxidized by copper-iron-polyphthalocyanine and oxygen in induction periods of about 8 and 15 min respectively, thus affording the corresponding peroxy acids and acids. However, no oxidations of *p*-nitrobenzaldehyde, *p*-hydroxycarbonylbenzaldehyde, *p*- and *m*-hydroxybenzaldehyde, *p*- and *m*-methoxybenzaldehyde and *p*-dimethylaminobenzaldehyde with copper-iron-polyphthalocyanine and oxygen were observed.

The autoxidations of aldehydes to carboxylic acids have been shown by a large number of investigators to be catalyzed by metal ions and peroxy acids.[2] It is the purpose of this paper to describe the specific catalytic activities of copper-iron-polyphthalocyanine in the oxidations of a series of aliphatic and aromatic aldehydes. The series of aldehydes chosen for investigation includes benzaldehyde, monosubstituted benzaldehydes (*p*-substituents: $-NO_2$, $-Cl$, $-CH_3$, $-OH$, $-OCH_3$ and $-N(CH_3)_2$, and *m*-substituents: $-OH$ and $-OCH_3$), and saturated and unsaturated aliphatic aldehydes.

Experimental

Materials. All of the aldehydes used here were of a commercial grade and had been purified by recrystallization or by distillation before use. It was confirmed by gas chromatography that aldehydes contain no impurity after purification. The absence of peroxide was confirmed by an iodine-starch test. Copper-polyphthalocyanine (Cu-poly PC), iron-polyphthalocyanine (Fe-poly PC), and copper-iron-polyphthalocyanine (Cu-Fe-poly PC), which were used as the catalysts for the oxidations of aldehydes, were prepared by the method (A)[3] or by the method used to prepare Fe-poly PC (No. 1)[1] in previous papers.

Oxidation. In most of the experiments, the oxidations of aldehydes were carried out by the same apparatus and procedure as have been described in the previous paper.[3] For the measurement of the rate of oxygen absorption, 5 m*l* of a solution of aldehyde at 6×10^{-1} M in an organic solvent, such as benzene, was oxidized at the atmospheric pressure of oxygen at 30°C. The oxidation products were determined after the oxygen absorption had been completed. The time-course investigation of the amounts of the oxidation products was carried out by using 450 m*l* of a solution of benzaldehyde at 6×10^{-1} M in benzene. 5-m*l* portions of the reaction mixture were pipetted out at appropriate time intervals, and the oxidation products were determined.

Analyses. The peroxy acids and acids formed in the oxidation process were identified by means of the iodine-starch test, the infrared absorption spectrum, and gas chromatography. The peroxy acid was determined by iodometric titration, the unreacted aldehyde by 2, 4-dinitrophenylhydrazone method. The formed acid was calculated by subtracting the sum of the amounts of peroxy acid and the unreacted aldehyde from the initial amount of the aldehyde.

Results and Discussion

Oxidation of Benzaldehyde. *The Catalytic Properties of Cu-, Fe- and Cu-Fe-Poly PC.* Fe-, Cu- and Cu-Fe-poly PC showed catalytic activity in the oxidation of benzaldehyde with oxygen. As

3) H. Inoue, Y. Kida and E. Imoto, This Bulletin, **40**, 184 (1967).

Fig. 1 and Table 1 show, a remarkable difference in the catalytic activity for Fe-, Cu-, and Cu-Fe-poly PC was observed. The oxidation of benzaldehyde in the presence of Cu-poly PC as a catalyst proceeded very slowly, with a rate of oxygen absorption of 0.7 ml/min in the stationary state after an induction period of about 10 min; the oxidation percentage of benzaldehyde at the reaction time of 107 min was about 60%.

In the case of Fe-poly PC, the oxygen absorption was started after an induction period of about 2 min and reached to completion after a reaction time of 25—30 min, with a rate of oxygen absorption of 8.1 ml/min in the stationary state.

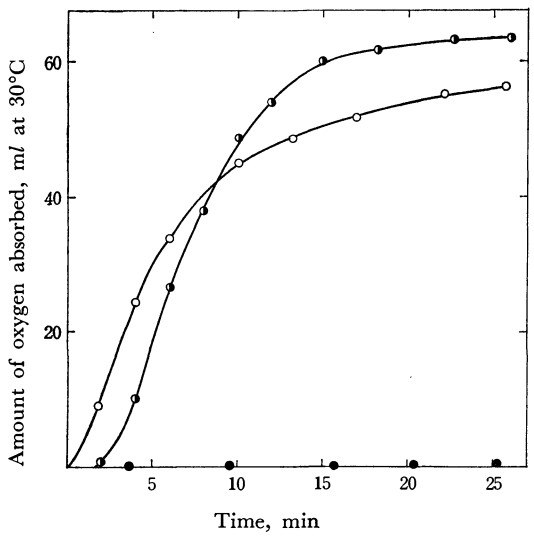

Fig. 1. The oxidation of benzaldehyde in the presence of Cu-, Fe- or Cu-Fe-poly PC : Catalyst ; 50 mg.
○ Cu-Fe-poly PC, ◑ Fe-poly PC,
● Cu-poly PC.

The catalytic action of Cu-Fe-poly PC differed from those of Cu- and Fe-poly PC in the initial state of the oxygen absorption. As shown in Fig. 1, the oxygen absorption started as soon as Cu-Fe-poly PC and benzaldehyde are mixed in benzene. There was, however, no significant difference in the rate of oxygen absorption in the stationary state between the cases of Fe- and Cu-Fe-poly PC. Thus, the action of Cu-Fe-poly PC seems to be characteristic of the activation of oxygen in the initial state of the oxidation process.

As shown in Table 1, peroxybenzoic acid and benzoic acid were obtained as the oxidation products. In all cases of Fe-, Cu-, and Cu-Fe-poly PC, the amount of the oxidized benzaldehyde was identical with the sum of the amounts of benzoic acid and peroxybenzoic acid produced. The catalytic efficiency (the reaction percentage of benzaldehyde per unit of weight of the catalyst until the oxygen absorption becomes constant) of each catalyst for the oxidation of benzaldehyde was higher than that of acetaldehyde ethylene acetal described previously.[1] No significant difference in the molar ratio of peroxybenzoic acid to benzoic acid, however, was observed in the cases of Cu-, Fe-, and Cu-Fe-poly PC.

Variations in the Amounts of Products in the Reaction Course. The amounts of the products, peroxybenzoic acid and benzoic acid, were determined by taking out portions of the reaction mixture at appropriate times during the oxidation of benzaldehyde. These results are shown in Fig. 2.

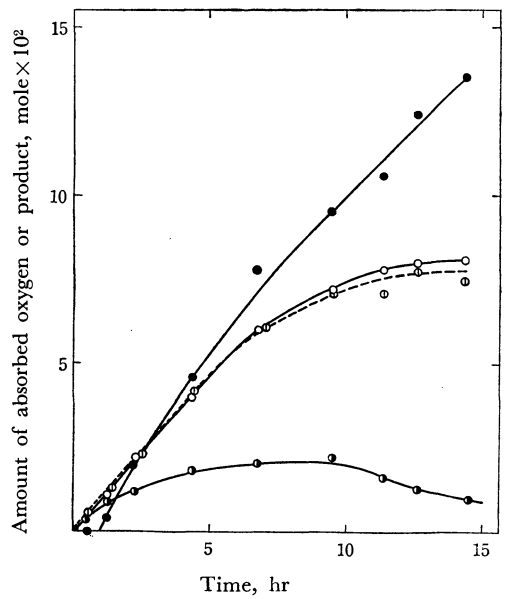

Fig. 2. The amounts of oxygen absorbed and the oxidation products in the oxidation course of benzaldehyde : Cu-Fe-Poly PC ; 0.3 g. Benzaldehyde solution ; 450 ml (6×10^{-1} M in benzene).
○ Absorbed oxygen, ◑ C_6H_5COOOH,
● C_6H_5COOH,
① $C_6H_5COOOH+\frac{1}{2}C_6H_5COOH$.

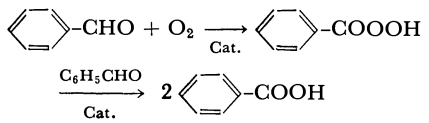
The absorption of oxygen was observed as soon as benzaldehyde and Cu-Fe-poly PC were mixed in benzene at an atmospheric pressure of oxygen at 30°C, and it increased linearly with the reaction time. After a reaction time of 7 hr, the rate of oxygen absorption decreased, however, until the absorption of oxygen stopped after a reaction time of about 15 hr.

The amount of peroxybenzoic acid produced increased with an increase in the amount of oxygen absorbed, and reached a constant after a reaction time of 3 hr. After staying almost constant for several hours, it started to decrease when the rate of oxygen absorption decreased.

On the other hand, another product, benzoic acid, was not produced even after a reaction time of 2 hr after the absorption of oxygen started.

After 2 hr, the amount of the benzoic acid started to increase with the reaction time. Even after the absorption of oxygen had become almost constant, the production of benzoic acid was observed. In the reaction mixture, no water or other compounds were produced. Furthermore, during the course of the oxidation, the amount of oxygen absorbed was identical with the sum of the amount of peroxybenzoic acid produced and half the amount of benzoic acid produced.

These facts show that the catalytic oxidation of benzaldehyde by Cu-Fe-poly PC with oxygen proceeds *via* the reaction steps represented by the following equation:



The catalyst contributes to the activation of oxygen, giving perbenzoic acid through the reaction of the activated oxygen and benzaldehyde, and to the decomposition of perbenzoic acid, thus giving benzoic acid quantitatively by the reaction of peroxybenzoic acid and benzaldehyde. Furthermore, the catalytic oxidation processes seem to indicate the character of Cu-Fe-poly PC as an oxidation catalyst.

The Effects of Solvents on the Oxidation of Benzaldehyde. The Fe(II) ion of Cu-Fe-poly PC acts as an active site for the activation of oxygen and for the decomposition of peroxide in the oxidation process. The catalytic activity of Cu-Fe-poly PC may be affected by the kind of solvent, since the Fe(II) ion may be solvated or coordinated by the solvent. The influence of solvents in the catalytic oxidation of benzaldehyde by Cu-Fe-poly PC with oxygen were investigated. As the solvents, benzene, acetone, ethyl acetate, tetrahydrofuran, acetonitrile, ethanol, and anisole were chosen. These results are shown in Fig. 3 and Table 1. Benzaldehyde in benzene or acetone containing Cu-Fe-poly PC was oxidized with oxygen to peroxybenzoic acid and benzoic acid, but no

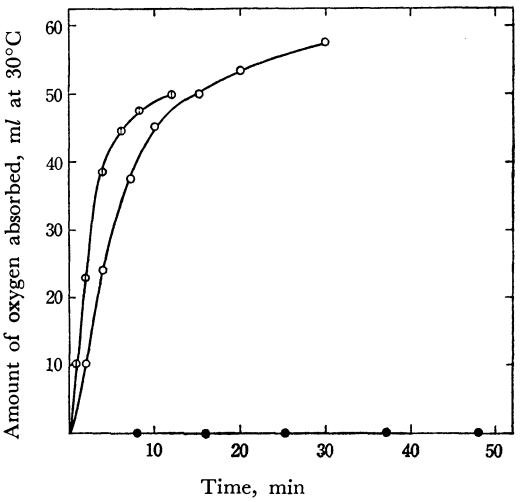


Fig. 3. Influence of solvent in the oxidation of benzaldehyde: Cu-Fe-Poly PC; 50mg,
① acetone, ○ benzene and ● tetrahydrofuran, acetonitrile, ethyl acetate, ethanol and anisole.

oxidation of benzaldehyde with oxygen was observed in tetrahydrofuran, ethanol, acetonitrile, ethyl acetate, or anisole, despite the presence of Cu-Fe-poly PC. The disappearance of the catalytic activity of Cu-Fe-poly PC when the latter solvents were used may be caused by the solvation or the coordination of the solvent to the Fe(II) ion as an active site, or by solvation to the Fe(II)$\cdots O_2$ intermediate. Furthermore, these phenomena must be related to the inhibition of pyridine and 2-phenylimidazole for the catalytic action of Cu-Fe-poly PC in the oxidation of acetaldehyde ethylene acetal, an inhibition described previously.[1]

The Oxidations of Monosubstituted Benzaldehydes. The oxidations of *p*-substituted benzaldehydes by peroxybenzoic acids are affected by the electron-donating or electron-withdrawing power of the substituent, although the rate of oxidation is independent of the Hammett substituent

TABLE 1. THE CATALYTIC ACTION OF Cu-, Fe- AND Cu-Fe-poly PC IN THE OXIDATION OF BENZALDEHYDE

c) The solvent: benzene.
d) The solvent: acetone.
e) The solvent: tetrahydrofuran, acetonitrile, ethanol and ethyl acetate, respectively.

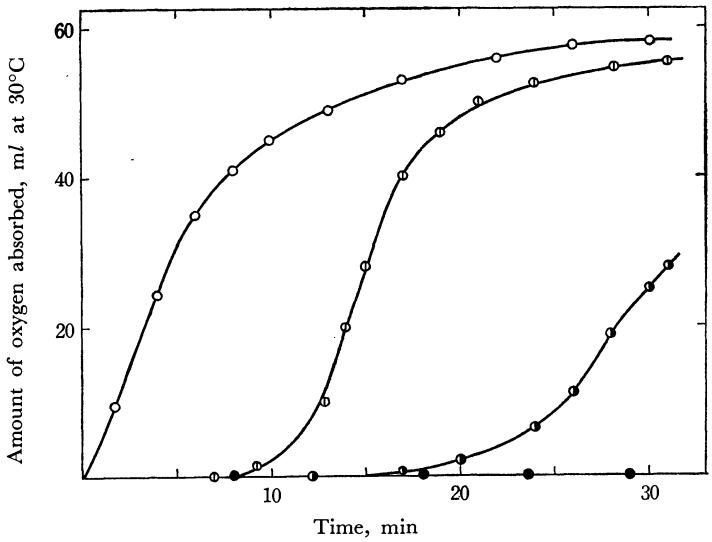

Fig. 4. The oxidation of monosubstituted benzaldehydes in the presence of Cu-Fe-poly PC : Cu-Fe-poly PC; 50mg.

○ Benzaldehyde, ⓘ *p*-CH_3–, ◑ *p*-Cl- (5×10^{-1} M, Cu-Fe-poly PC 20 mg), ● *p*-$(CH_3)_2N$–, *p*-HO–, *p*-CH_3O–, *p*-O_2N–, *p*-HOOC–, *m*-HO–, *m*-CH_3O– and *o*-HO-benzaldehyde.

constant.[4] The substituent effects on the catalytic oxidations of monosubstituted benzaldehydes by Cu-Fe-poly PC were also investigated. The oxidations of the monosubstituted benzaldehydes (*p*-substituents: $-NO_2$, –Cl, $-CH_3$, –OH, $-OCH_3$ and $-N(CH_3)_2$, and *m*-substituents: –OH and $-OCH_3$) with oxygen in the presence of Cu-Fe-poly PC were carried out under the same conditions as in the case of benzaldehyde. These results are shown in Fig. 4. *p*-Methylbenzaldehyde and *p*-chlorobenzaldehyde were oxidized catalytically by Cu-Fe-poly PC and oxygen to give the corresponding peroxy acids and acids, with induction periods of 8 min or 15 min respectively, while no oxidations of the other monosubstituted benzaldehydes were observed. That is, the catalytic effect of Cu-Fe-poly PC on the oxidation of monosubstituted benzaldehyde with oxygen was independent of the electron-donating or electron-withdrawing power of the substituent, and monosubstituted benzaldehydes, the substituents of which may coordinate to the Fe(II) ion, seem not to be oxidized by Cu-Fe-poly PC and oxygen. This is probably caused by the inhibition of the activation of oxygen in the oxidation processes; these facts seem to be related to the findings regarding the solvent effects on the catalytic action of Cu-Fe-poly PC.

The Oxidations of Aliphatic Aldehydes. Investigation was extended to the oxidations of aliphatic aldehydes, propionaldehyde, *n*-butyraldehyde, caprylaldehyde, 2-ethylcaproaldehyde, crotonaldehyde, cinnamaldehyde, and acrolein with Cu-Fe-poly PC and oxygen. The relation between the amount of oxygen absorbed and the

e) The reaction time ; 1 hr.

reaction time in the oxidation of each of the aliphatic aldehydes is shown in Fig. 5. Cu-Fe-poly PC showed a remarkable catalytic action in the oxidations of the saturated aliphatic aldehydes; the oxidations gave the corresponding peroxy acids and acids as the oxidation products in nearly quantitative yields (Table 2). On the other hand, the unsaturated aliphatic aldehydes, cinnamaldehyde and acrolein, were oxidized very slowly in spite of the presence of Cu-Fe-poly PC in the reaction system. Crotonaldehyde was oxidized, however, more easily than acrolein and cinnamaldehyde. These facts were similar to those of the case of metal-salt-catalyzed oxidation of unsaturated aldehydes in acetic acid.[5]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 696—701 (1968)

Concurrent Oxygen Exchange and Racemization Reactions of Diaryl Sulfoxides in Concentrated Sulfuric Acid[1)]

Shigeru OAE and Norio KUNIEDA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku Osaka

(Received September 25, 1967)

When diaryl sulfoxides are dissolved in concentrated sulfuric acid at 0°C, characteristic bluish colored solutions are obtained, from which the starting sulfoxides can be recovered quantitatively upon quenching with a large amount of water. When ^{18}O-labeled and optically active sulfoxides are used, one observes the concurrent oxygen exchange and racemization reactions of the sulfoxides. The kinetic behaviors of these reactions have been studied in detail using various substituted diaryl sulfoxides. The rate of the oxygen exchange was found to be identical to that of the racemization while the rates of the racemization were nicely correlated with the Hammett acidity functions (H_0) (Slope$=1.07$). Meanwhile the polar effect of subsituents on the rates of both oxygen exchange and racemization was found to be very small. From these results possible mechanisms for these reactions have been discussed.

The sulfur-oxygen linkage in sulfoxides is known to be considerably weaker than that of sulfones and there are number of reactions which involve the facile cleavage of the sulfur-oxygen bond of sulfoxides.[2)] In the meantime, sulfoxides, being of pyramidal structure, have been resolved to pairs of optical isomers when the two substituents on the sulfur atom are different. An interesting reaction,

1) Paper XX on Sulfoxides.

2) For details see Chapter 4 of "Sulfur Bonding," by C. C. Price and S. Oae, Ronald Press., N. Y. (1962).

in these connection, is the concurrent oxygen exchange and racemization reactions of sulfoxides, which have attracted considerable attentions at various laboratories in recent years.[3] Previously, we have reported that sulfoxides undergo an oxygen exchange reaction in concentrated sulfuric acid and the concurrent racemization also takes place when (+)-*p*-aminophenyl *p'*-tolyl sulfoxide is used.[4] Based on a few observations such as the complete lack of oxygen exchange in sulfones, aromatic *N*-oxides and phosphine oxide, rough kinetics and stereochemical data, *etc.*, the mechanism involving the nucleophilic attack of sulfoxide on sulfuric acid was tentatively suggested as a working hypothesis, however, more careful kinetic studied were critically needed in order to elucidate a plausible mechanism for the reaction.

We now have compiled substantial amounts of kinetic data on the concurrent oxygen exchange and recemization reactions of diaryl sulfoxides and hence would like to report our further observations and comments concerning the nature of the reactions.

Results and Discussion

Sulfoxides used for this kinetic study are ^{18}O-labeled diaryl sulfoxides and optically active aryl-*p*-tolyl sulfoxides, and all of the sulfoxides were nicely recovered almost quantitatively and in no case the formation of the respective sulfones or sulfides was noticed.

At first careful kinetic experiments were conducted on the rates of both oxygen exchange and racemization reactions using (+)-*p*-tolyl phenyl sulfoxide in 95.5% sulfuric acid. The results, shown in Table 1, clearly reveal that the rate of the oxygen exchange is identical to that of the racemization ($k_{ex}/k_{rac}=0.97$), suggesting that the reaction proceeds through a SN_1 like S–O bond cleavage at the rate-determining step.[5] The energy and entropy of activation of this reaction are found to be 27.4 kcal/mol and +21.5 e. u., respectively. The positive value of the entropy of activation also favors the rate determining SN_1 like cleavage of S–O bond of the sulfoxide. Since our preliminary investigation has shown that the reaction is very fast in sulfuric acid of a high concentration and almost nil in a sulfuric acid of less than 85% concentration at a low temperature,[6] the rates of racemization were carefully measured in sulfuric acids of various concentrations. The results are shown in Table 2 and Fig. 1.

7) M. A. Paul and F. A. Long, *Chem. Revs.*, **57**, 1 (1957).

As shown in Table 2 and Fig. 1, the rates are nicely correlated with the Hammett acidity functions (H_0) (Slope=1.07).[8] This means that the protonated species are involved in the transition state of the reaction, indicating that the reaction follows the A-I type mechanism of the Zucker-Hammett's hypothesis.[9] Meanwhile it have been shown by Gillespie and Passerini[10] and us[11] through the cryoscopic measurement and the ^{18}O-tracer experiment that sulfoxides ionize in concentrated sulfuric acid in the following manner (Eq. (1)).

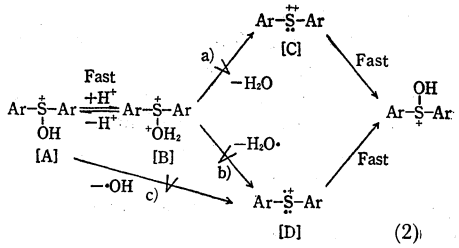
$$\underset{\underset{O}{\downarrow}}{R\text{-}S\text{-}R} + H_2SO_4 \rightleftharpoons \underset{\underset{OH}{|}}{R\text{-}\overset{+}{S}\text{-}R} + HSO_4^- \qquad (1)$$

[A]

(Cryoscopic i-facter=2)

Therefore, the hydroxysulfonium ion [A] formed by the protonation of the sulfoxides in sulfuric acid in the preequilibrated ground state will probably pick up another proton from sulfuric acid before reaching the transition state of the reaction where the partial cleavage of the S–O bond will take place, as in the reduction of dimethyl sulfoxide with hydroiodic acid.[12]

There are a few ways conceivable for the cleavage of the S–O bond that fit in these observations, as shown by Eq. (2).



(2)

Path a is the heterolysis of the S–O bond involving the rate-determining formation of the doubly positive charged "sulfidonium ion" [C] intermediate. By the ^{18}O-tracer experiment and the freezing-point measurement the formation of the diaryl sulfidonium ion was excluded, but this *path a* is still attractive if one assumes that the formation of the sulfidonium ion [C] is the slow rate-determining step and that the sulfidonium ion [C] hydrolyzes to give the protonated sulfoxide [A] or [B] in the subsequent fast step.

Path b and *c* is the homolysis to form the cation radical intermediate [D]. The several ESR studies of the sulfur-containing aromatic compounds have been done. Schmidt[13] has reported that the concentrated sulfuric acid solutions of some aryl sulfoxides are paramagnetic. Especially well-studied are the sulfuric acid solutions of thianthrene oxide and phenoxathin oxide, *etc.*[14] We could

detect no noticeable ESR signal from the solution of diphenyl sulfoxide in our previous work.[4] Recently, Shine and co-workers[15] have also reported that no noticeable ESR signal was found from the solution of diphenyl sulfoxide, but noticeable ESR signals were found from 96% sulfuric acid solutions of *p, p'*-substituted diphenyl sulfoxides when *p, p'*-substituents are good electron donating groups such as $-OCH_3$, $-CH_3$ and -OH, and ascribed it to the existence of the positive ion radicals.

We have also repeated the ESR measurements of *p*-tolyl phenyl, *p, p'*-ditolyl and *p, m'*-ditolyl sulfoxides in 96.3% sulfuric acid, and found that the same ESR signal with 15 major lines from the blue solution of *p, p'*-ditolyl sulfoxide as that of Shine. The 15 lines ESR spectra of the solution which are shown in Fig. 2 and Fig. 3 decay in a relatively short time, indicating the short life of this cation radical. The solutions of *p*-tolyl phenyl and *p, m'*-ditolyl sulfoxides gave very weak ESR signals which have no satisfactory hyperfine structure and *g* values of these were 2.0082 and 2.0080, respectively (Fig. 4 and Fig. 5). The one day old solution of *p*-tolyl phenyl sulfoxide gave a simple singlet ESR signal, but we do not know the origin of this signal. However, these ESR results suggest that the path involving the homolytic cleavage to form a incipient cation radical intermediate [D] is a likely possibility.

If the reaction follows the *path a*, the rate would

be markedly effected by polar substituents like the SN_1 type reactions of benzhydryl compounds,[16] on the other hand, the effect of polar substituents would be very small when the reaction proceeds through the path of homolytic cleavage. The rates of both oxygen exchange and racemization of several substituted diaryl sulfoxides were measured and the results are tabulated in Table 3.

TABLE 3. RATE CONSTANTS OF ^{18}O-EXCHANGE AND RACEMIZATION OF R_1-⟨⟩-SO-R_2

a) Sulfoxide=0.1 mol/*l*
Run No. 10—12; in 95.5% sulfuric acid at 5°C.
Run No. 13—18; in 96.7% sulfuric acid at 0°C.

Inspection of the kinetic data reveals clearly that the polar effect of substituents on the rates of both oxygen exchange and racemization is very small in comparison with that of the typical SN_1 type reactions. For example, the substitution of *p*-methyl group accelerates the rate of oxygen exchange by only less than two fold while the electron-withdrowing *p*-chloro group also gave a small acceleration. These tendencies are shown equally in the racemization reactions. These rather small polar effects seem to favor the homolytic cleavage for the reaction.

The rates of racemization of *p*-tolyl *o*-chlorophenyl sulfoxide and *p*-tolyl mesityl sulfoxide were found to be about ten fold slower than that of *p*-tolyl phenyl sulfoxide. The marked rate retardation by ortho substituents is perhaps due to the steric hindrance of protonation to form the corresponding diprotonated intermediates.

Reaction with Dilute Sulfuric Acid at Higher Temperature. Although our earlier paper reported that the oxygen exchange was almost nil in a sulfuric acid of less than 85% concentration at around 0°C, we have found that diaryl sulfoxides racemize readily in a sulfuric acid of less than 85% concentration when the reaction was carried out at a considerably higher temperature. For example, *p*-tolyl phenyl sulfoxide was found to be racemized in 82% sulfuric acid at 40—50°C. Both the energy (ΔE=21.6 kcal/mol) and entropy (ΔS=−7.5 eu) of activation of this reaction were quite different from those of the lower temperature reaction. Apparently, the mechanism of this reaction is different from that at the lower temperature and similar to those in polychloroacetic acid[17] and phosphoric acid[18] in which the reaction is presumed to depend on pK_a of the medium used and not on the Hammett acidity function. Detailed discussion on these reactions will be the subject in our forthcoming paper of this series.

Experimental

Materials. *^{18}O-Labeled Diaryl Sulfoxides* were prepared by the oxidation of the corresponding sulfides with bromine complex of pyridine and ^{18}O-enriched water (1.63 atom% ^{18}O) in acetic acid by the same procedure as described in our previous paper.[19] Diphenyl sulfoxide; mp 71°C, 0.85_2 atom%. Phenyl-*p*-tolyl sulfoxide; mp 71—71.2°C, 0.72_0 atom%. Phenyl *p*-Cl-phenyl sulfoxide; mp 45—46°C, 0.95_2 atom%.

Optically Active Aryl p-Tolyl Sulfoxides were prepared from (−)menthyl (−)-*p*-toluenesulfinate according to the method developed by Andersen.[20] *p*-CH_3-C_6H_4-SO-R; (R, mp, $[\alpha]_D$(c); *l*=1 in absolute ethanol). Phenyl, 91.5, +27.2°(3.65). *p*-Cl-phenyl, 80—80.5, +25.9°(2.85). *o*-Cl-phenyl, 89—89.5, −120.7°(1.43). *m*-Tolyl, 63.5—64, +25.1°(3.10). *p*-NH_2-phenyl, 150.5−151, +105.3°(2.21). Mesityl, 107—107.5, −265.0°(2.00).

Kinetic Procedure of the Oxygen Exchange and Racemization Reactions of Diaryl Sulfoxides. In order to compare the rate constants of all the sulfoxides, both oxygen exchange and reacemization reactions were carried out under identical conditions.

An ^{18}O-labeled or an optically active sulfoxide was dissolved in a sulfuric acid, in such a way as to maintain the concentration of the sulfoxide just about 0.1 mol/*l*, at a preset temperature (0±0.06, 5±0.08 or 10±0.08°C). An aliquot portion (5.0 m*l*) of the solution was taken up from time to time for 5—7 times and was quenched with ice water. The precipitate formed was extracted with carbon tetrachloride, and the carbon tetrachloride solution was washed with water, 10% aqueous solution of sodium carbonate and water, respectively, and dried over anhydrous sodium sulfate. Finally, carbon tetrachloride was distilled *in vacuo* and then the sulfoxide recovered was subjected to the ^{18}O-analysis or the optically active measurement. The mass-spectrometric analysis was carried out with the carbon dioxide gas and the atom% ^{18}O was calculated from the mass peak heights 44 and 46 according to the following equation.

$$\text{Atom\% } ^{18}O = \frac{\text{Peak 46/Peak 44}}{2 + \text{Peak 46/Peak 44}}$$

The rate constants of the oxygen exchange and racemization were calculated from the following equations. For oxygen exchange; $\log \alpha_0 - \alpha/\alpha_t - \alpha = kt/2.303$, where α_0 and α_t are the atom% ^{18}O at times 0 and t, respectively, and α is the atom% ^{18}O of natural CO_2, and for racemization; $\log \beta_0/\beta = kt/2.303$, where β_0 and β are the rotatory powers at times 0 and t, respectively.

(Received September 25, 1967)

2-Piperazinone oxime, 2-piperazinoneimine, and 2-piperazinethione were synthesized. The reaction mixture of ethylenediamine and glycolonitrile was treated with an excess amount of hydroxylamine in methanol to give 2-piperazinone oxime in a 53% yield. 2-Piperazinone oxime was easily reduced to 2-piperazinoneimine, which was then treated with hydrogen sulfide to yield 2-piperazinethione. Some reactions of these compounds are described.

Many methods of synthesizing 2-piperazinones have been developed since the derivatives were found to possess some pharmacological activities.[2] However, no variation in the exocyclic oxo-group has ever been reported.[3] It thus appeared of interest to obtain nitrogen- or sulfur-analogs of 2-piperazinone.

The present paper will describe the syntheses of 2-piperazinone oxime (VIIIa), 2-piperazinoneimine (IIIb), and 2-piperazinethione (XV), and their reactivities.

Strong *et al.* reported the synthesis of 2-piperazinone by the reaction of ethylenediamine (I) with formaldehyde and sodium cyanide in an aqueous solution.[2a] This reaction was postulated to involve, as an intermediate, *N*-(2-aminoethyl)glycinonitrile (IIIa) or cyclic amidine (IIIb), which would be hydrolyzed to afford 2-piperazinone. Thus, the isolation of the intermediate (III) might be possible, provided the reaction of I with glycolonitrile (II) was carried out in a non-aqueous medium. When I was treated with an equimolar amount of II in methanol at room temperature for 2 days, a yellow, oily material was obtained. The infrared absorption spectrum of the oil showed a medium absorption band at 1660 cm^{-1} characteristic of the carbon-nitrogen double bond, while a control measurement of infrared absorption spectrum showed that the initial mixture of I and II exhibited no band at 1660—1630 cm^{-1} in the region for the carbon-nitrogen double bond. The oil was treated with sulfuric acid in methanol to yield pale yellow crystals with a melting point of 205—208°C (decomp.). The elementary analysis of the product indicated the empirical formula, $C_4H_9N_3 \cdot H_2SO_4$, corresponding to the sulfate (IV) of III. A thin-layer chromatogram (TLC) of IV showed two spots. The R_f value (0.31) of one spot was found to be identical with that of an authentic 2-piperazinoneimine sulfate prepared by another route, described below. From these observations as well as the following reactivities, it seemed reasonable to assume that the above products (III) consisted of IIIb and another substance (IIIa).[4] When II was treated with an excess amount of I in methanol at 55—60°C, *N, N'*-bis-cyanomethylethylenediamine (V) was obtained as the sole isolated product. This was characterized by means of its infrared absorption spectrum and by conversion into a dibenzoyl derivative (VI) (Chart I).

In order to examine the reactivities of III, the reaction of III with hydroxylamine was attempted. When the reaction mixture of I and II (III) was treated with an excess amount of hydroxylamine in methanol, a slightly exothermic reaction occurred with an evolution of ammonia, and colorless crystals with a melting point of 171—173°C were obtained. The product gave an intense purple color with an aqueous solution of

3) Only one British Patent (Rohm & Hass Co.; 875135 (Aug. 16, 1961)) has referred to 4-substituted 2-piperazinethiones; unfortunately, neither the synthetic method nor their properties have been recorded.

4) The other substance, with a R_f value of 0.58, might be IIIa, but it was not further investigated.

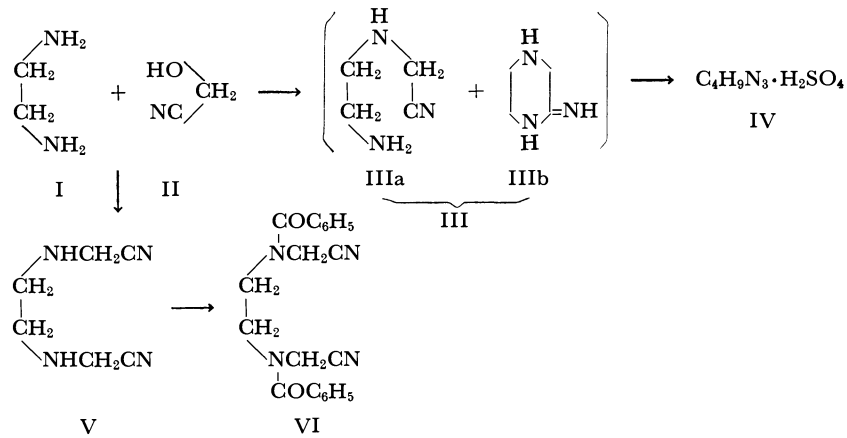

Chart I

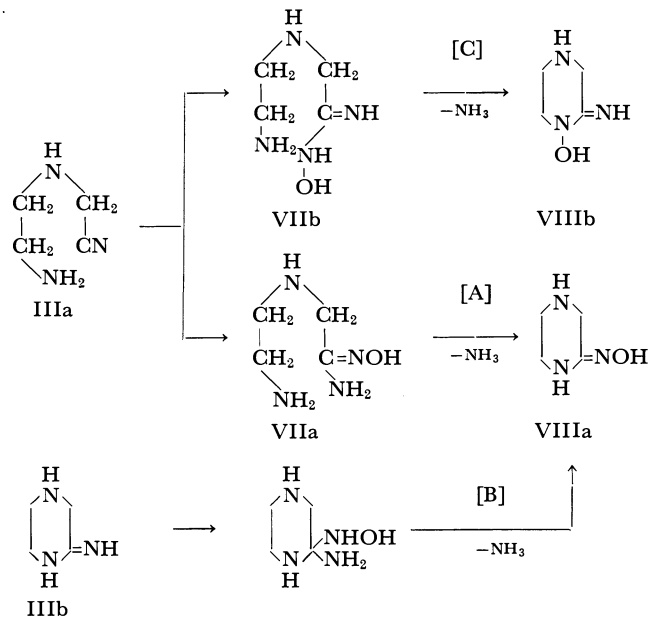

Chart II

ferric chloride and exhibited a strong infrared absorption band at 1660 cm^{-1}, which might be ascribed to the carbon–nitrogen double bond of amidoxime.[5] This observation and the elementary analysis indicate the structure of 2-piperazinone oxime (VIIIa) or 1-hydroxy-2-piperazinoneimine (VIIIb) for the product. Compound VIIIa would be formed from the reaction of either IIIa or IIIb with hydroxylamine (Course A or B), while VIIIb might be derived only from the reaction of IIIa and hydroxylamine (Course C) (Chart II).

However, only the structure VIIIa was supported by the following reactions. The product (VIIIa) was treated with 3N hydrochloric acid and methanol to afford methyl *N*-(2-aminoethyl)glycinate dihydrochloride (IX), which was isolated in a form combined with water. On the treatment of VIIIa with benzoyl chloride, a dibenzoyl derivative (X) was obtained, while treatment with tosyl chloride gave a tritosyl derivative (XI). The infrared absorption spectrum of the dibenzoyl derivative showed strong absorption bands in the ester region. The amidoximes have been known to react with nitrous acid or alkyl nitrite, yielding the corresponding amide.[6] The reaction of VIII with nitrous acid or amyl nitrite was next attempted, since it was expected to yield 4-nitroso-2-piperazinone (XII). All attempted reactions, however,

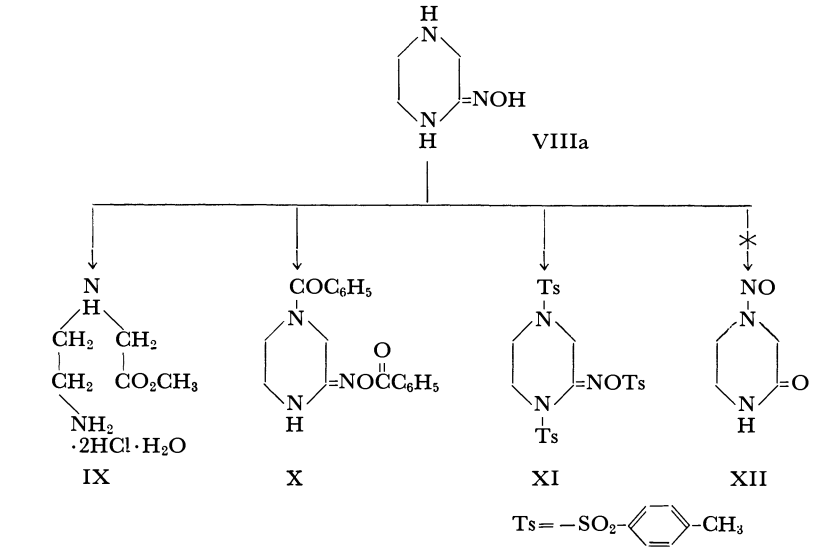

Chart III

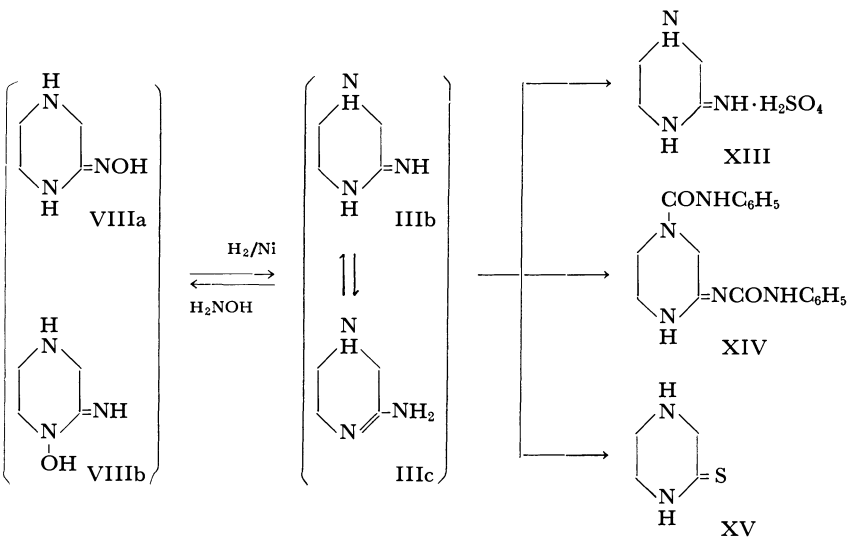

Chart IV

resulted only in the formation of a viscous oily substance, which gave a positive Lieberman test but which was unidentified, while the authentic XII was obtained in the form of crystals by the treatment of 2-piperazinone with amyl nitrite in *n*-butanol (Chart III).

Barber *et al.* have reported that the catalytic reduction of amidoxime gave the corresponding amidine.[7] The amidoxime (VIIIa) was hydrogenated at room temperature in the presence of Raney-nickel to give, as expected, 2-piperazinone-imine (IIIb) which was characterized by means of its infrared absorption spectrum and by conversion into the crystalline sulfate (XIII) or the crystalline phenylureido derivative (XIV). Compound XIII had a melting point of 212°C (decomp.) and gave a spot (R_f 0.31) on thin-layer chromatogram. When the reduction product was again treated with hydroxylamine in methanol at room temperature, ammonia was evolved and the amidoxime (VIII) was obtained in a 46% yield.[8] The amidoxime produced was identified by a comparison of its infrared absorption spectrum and by a mixed-melting-point determination with the original amidoxime (VIIIa). This fact excludes the alternative structure (VIIIb) for the amidoxime

7) H. J. Barber and A. D. H. Self (of May & Baker, Ltd.), U. S. Pat. 2375611 (May 8, 1945).

8) The yield was calculated from the first material (VIIIa) used for reduction.

(VIIIa), because an easy transformation between the amidoxime (VIIIb) and the amidine (IIIb) would be impracticable under the above mild conditions.

When the cyclic amidine (IIIb) was treated with hydrogen sulfide, 2-piperazinethione (XV) was obtained in a 20% yield. The structure of XV was confirmed by its infrared absorption spectrum and by elementary analysis. In an attempt to prepare XV by another route, 2-piperazinone was directly treated with phosphorus pentasulfide in benzene or toluene, but no definite product could be obtained (Chart IV).

In a further investigation of the reactivities of III, the methanolic solution of III was treated with *N*-phenylhydroxylamine at 60°C; a small quantity of yellow needles (XVI) was thus obtained. The reaction of IIIb, prepared by the reduction of VIIIa, with *N*-phenylhydroxylamine also gave XVI. The elementary analysis of the product (XVI) showed the empirical formula $C_{10}H_9N_3$, which may suggest that XVI is 2-anilinopyrazine. Thus, 2-anilinopyrazine was synthesized by the reaction of 2-chloropyrazine with an excess amount of aniline.

However, the chemical properties of XVI apparently differed from those of 2-anilinopyrazine and the structure of XVI remains unidentified.

Experimental[9]

Ethylenediamine (I). Commerical anhydrous ethylenediamine was dried over metallic sodium. The dried ethylenediamine was then filtered and distilled; bp 116—117°C.

Glycolonitrile (II) was prepared by the published procedure[10] and had a bp of 97—99°C/15 mmHg (lit.[10] bp 99—100°C/17 mmHg).

Reaction of I with II. a) A solution of II (2.0 g) in methanol (3 m*l*) was added, drop by drop, to a solution of I (2.1 g) in methanol (3 m*l*), and the mixture was allowed to stand at room temperature for 2 days. After the solvent and the starting materials had been removed under reduced pressure from the reaction mixture, an oily product (III) was obtained. Its infrared spectrum showed an absorption band at 1660 cm^{-1} (m). The oily product (III) was converted to a crystalline solid by adding a solution of sulfuric acid in methanol. The solid was collected to give 6.8 g (98.5% yield) of brown crystals, which, after recrystallization from aqueous methanol, afforded a mixture of 2-piperazinoneimine sulfate (IIIb) and an unidentified compound as pale yellow crystals, mp 205—208°C (decomp.). TLC[11] R_f=0.58 and 0.31.

Found: C, 24.03; H, 5.82; N, 22.12%.

b) A mixture of I (12.0 g) and II (5.7 g) in methanol (30 m*l*) was warmed, with stirring, at 55—60°C for 5 hr. The mixture was then concentrated under reduced pressure to give a syrup which was distilled under reduced pressure to yield *N, N'*-bis-cyanomethylethylenediamine (V) as a viscous liquid (2.73 g, 27.3%), bp 133—135°C/1 mmHg. IR (liquid): 3300 (–NH–) and 2200 cm^{-1} (–CN).

N, N'- Bis-benzoyl - *N, N'*- bis - cyanomethylethylenediamine (VI), mp 142—144°C (from ethanol), was also prepared.

IR (KBr disk): 2240 (–CN) and 1665 cm^{-1} (–CONH–).

Found: C, 68.93; H, 5.37; N, 15.96%. Calcd for $C_{20}H_{18}N_4O_2$: C, 69.35; H, 5.24; N, 16.18%.

2-Piperazinone Oxime (VIIIa). A solution of hydroxylamine [from the hydrochloride (10.4 g) and sodium (3.4 g) in methanol (160 m*l*)] was stirred into a solution of III (corresponding to 0.1 mol) in methanol (20 m*l*) at room temperature. The mixture was then kept at room temperature for 2 days, by which time the evolution of ammonia had ceased. The solution was concentrated under reduced pressure to yield a brown syrup. The syrup solidified spontaneously upon standing. The product was recrystallized from isopropyl alcohol to give 6.1 g (53%) of colorless plates, mp 171—173°C. The crystals are very soluble in water and give an intense purple color with an aqueous ferric chloride solution. IR (KBr disk): 3380 and 3320 (–NH–), 3180—2800 (broad band) and 1660 cm^{-1} (>C=N–).

The NMR spectrum exhibited a multiplet in the τ 6.7—7.1 region (4H) and a singlet at τ 6.6 (2H).[12]

Found: C, 41.97; H, 8.11; N, 36.74%. Calcd for $C_4H_9N_3O$: C, 41.72; H, 7.88; N, 36.50%.

Methyl *N*-(2-Aminoethyl)glycinate Dihydrochloride (IX). A solution of VIIIa (0.5 g) in 3 N hydrochloric acid (14.5 m*l*) was heated at 80°C for 3 hr, and the resultant solution was concentrated to dryness under reduced pressure. On adding methanol (4 m*l*) to the residue, 0.8 g (82.8%) of colorless needles was obtained. A portion of the product was recrystallized from methanol and analyzed; mp 188—190°C (decomp.).[13]

IR (KBr disk): 3480(OH), 3000—2500 (broad band) and 1720, 1250 cm^{-1} (–$COOCH_3$).

Found: C, 27.09; H, 7.37; N, 13.10%. Calcd for $C_5H_{12}N_2O_2 \cdot 2HCl \cdot H_2O$: C, 26.92; H, 7.23; N, 12.55%.

Dibenzoyl Derivative (X) of VIIIa. This derivative (mp 190—191.5°C (from ethanol)) was obtained as colorless needles.

Found: C, 66.86: H, 5.30; N, 13.00%. Calcd for $C_{18}H_{17}N_3O_3$: C, 67.17; H, 5.42; N, 13.16%.

IR (KBr disk): 3320(–NH–), 1725 and 1250 ($OCOC_6H_5$), 1660—1620 cm^{-1} (=NCO– and –CN).

1, 4-*O*-Tritosyl-2-piperazinone Oxime (XI). A solution of tosyl chloride (3.8 g) in dioxane (30 m*l*) and a solution of sodium hydroxide (0.8 g) in water

9) All the melting points are uncorrected. The infrared spectra of the samples were measured on a Hitachi spectrophotometer, Model EPI S II.

10) D. T. Mowry, *J. Am. Chem. Soc.*, **66**, 371 (1944).

11) TLC: Solvent system: *n*-Butanol(4) - Acetic acid(2) - Water (1). Adsorbent: Silica gel (Wakogel 10). Sample: 2.5—5 μg (0.01 m*l* applied to plates). Detection: A solution of 1 g of *p*-dimethylaminobenzaldehyde in 100 m*l* of a mixture of 35% hydrochloric acid (50 m*l*) and ethanol (50 m*l*).

12) The NMR spectrum was kindly determined by the Japan Electron Optics Lab. Co. on its Model G-60 at 60 Mc in a deuterium oxide solution, sodium dimethylsila pentasulfonate being used as the internal standard.

13) T. S. Moore, M. Boyle and V. M. Thorn, *J. Chem. Soc.*, **1929**, 51.

(10 ml) were alternatively stirred into a solution of VIIIa (1.2 g) in water (12 ml). The temperature of the mixture was then raised from 15°C to 30°C. After the addition had been completed, the mixture was stirred for several more hours, and then the pale yellow solution was allowed to stand overnight, thus yielding 0.7 g of XI as amorphous crystals, mp 206—209°C. The analytical sample was recrystallized from ethanol to give colorless plates, mp 210—211°C. The infrared absorption spectrum of XI showed no absorption band in the regions for both the amino group and the hydroxyl group.

Found: C, 51.74; H, 4.53; N, 6.90%. Calcd for $C_{25}H_{27}N_3O_7S_3$: C, 51.97; H, 4.71; N, 7.27%.

4-Nitroso-2-piperazinone (XII). A mixture of 2-piperazinone (3 g) and amyl nitrite (4 g) in *n*-butanol (30 ml) was heated on a water bath for 2 hr, and the resultant solution was allowed to stand overnight at room temperature. The precipitate (XII) was then collected and recrystallized from ethanol to give yellow plates, mp 124—125°C. The yield was 2.7 g (70%).

Found: N, 32.77%. Calcd for $C_4H_7N_3O_2$: N, 32.55%.

2-Piperazinoneimine Sulfate (XIII). A solution of VIIIa (1.5 g) in ethanol (70 ml) was shaken with Raney-nickel (1.0 g) at a pressure of 100 kg/cm² of hydrogen at room temperature for 1 hr. The catalyst was then removed by filtration, and sulfuric acid (1.0 g) in ethanol (20 ml) was added to the filtrate in order to precipitate a crystalline substance, which, after recrystallization from methanol-water, afforded the sulfate of IIIb as colorless needles, mp 212°C (decomp.). The yield was 1.9 g (76.0%).

IR (KBr disk): 3300—2500 (broad), 1660 (>C=N–) and 1120 cm^{-1} (sulfate).

Found: C, 24.08; H, 5.76; N, 21.00%. Calcd for $C_4H_9N_3 \cdot H_2SO_4$: C, 24.37; H, 5.63; N, 21.32%.

2-(*N*-Phenylcarbamoyl)imino-4-phenylcarbamoylpiperazine (XIV). The ethanolic solution obtained by the reduction of VIIIa (0.38 g) was evaporated to give IIIb (0.3 g) as an oil, which was used directly in the following reaction. The crude IIIb (0.3 g) and phenyl isocyanate (0.95 g) in chloroform (20 ml) were heated under refluxing for 4 hr. The resultant clear solution was passed through an activated alumina column. The column was then washed with ethanol (50 ml). The evaporation of the ethanolic eluate yielded a brown-yellow solid, which was recrystallized from *n*-butanol-ligroin to give 0.3 g (30%) of XIV as colorless needles, mp 172—173°C.

IR (KBr disk): 3370—3270 (–NH–, broad) and 1700, 1660—1640 cm^{-1} (–NHCO–).

Found: C, 64.18; H, 5.68; N, 21.23%. Calcd for $C_{18}H_{19}N_5O_2$: C, 64.08; H, 5.68; N, 20.76%.

Reaction of IIIb with Hydroxylamine. A solution of hydroxylamine [from the hydrochloride (0.42 g) and sodium (0.13 g) in methanol (8 ml)] was added to a solution of IIIb (0.4 g prepared from VIIIa) in ethanol (40 ml). The mixture was kept at 40°C for 5 hr, by which time the evolution of ammonia had ceased, and then warmed at 60°C for 1 hr. The solution was concentrated under reduced pressure to give a yellow solid. The product was recrystallized from isopropyl alcohol to yield 0.2 g of 2-piperazinone oxime (VIIIa) as colorless plates, mp 171—172°C, the melting point showed no depression in a mixing test with the VIIIa synthesized by the reaction of III (obtained by the reaction of I with II) with hydroxylamine.

2-Piperazinethione (XV). A solution of IIIb (1.95 g, prepared from VIIIa) in ethanol (125 ml) was saturated with hydrogen sulfide under cooling. The resultant yellow solution was allowed to stand at room temperature overnight, and then heated at 80°C for 4 hr. On cooling, the sulfur which separated from the solution was removed by filtration; the filtrate was concentrated under reduced pressure to give a viscous liquid. The oil solidified spontaneously upon standing. The product was recrystallized from isopropyl alcohol to give colorless prisms (0.45 g, 20%), mp 155—156°C (decomp.).

IR (KBr disk): 3200, 3150 and 3050(–NH) and 1585 cm^{-1} (–NHCS–).

Found: C, 41.64; H, 6.87; N, 24.32%. Calcd for $C_4H_8N_2S$: C, 41.37; H, 6.94; N, 24.13%.

Reaction of III (Obtained from I and II) with *N*-Phenylhydroxamine. A solution of *N*-phenylhydroxylamine[14] (1.8 g) in methanol (10 ml) was added, drop by drop, to a solution of III (corresponding to 0.0016 mol) in methanol (4 ml) at room temperature. When the mixture was warmed at 60°C with stirring, a yellow solid soon began to separate. After 5 hr, the mixture was concentrated under reduced pressure to yield an oily brown product. This oily product slowly solidified. The solid was collected, washed with isopropyl alcohol, and recrystallized from a small amount of benzene to yield yellow prisms (0.4 g; mp 265°C (decomp.)). The product (XVI) was soluble in dilute hydrochloric acid; it showed ultraviolet absorptions at $\lambda_{max}^{dioxane}$ 235 mμ (ε=13000) and 293 mμ (ε=10700).

IR (KBr disk): 3400, 1660, 1630, 1240 and 1250 cm^{-1}.

Found: C, 70.01; H, 5.24; N, 24.80%. Calcd for $C_{10}H_9N_3$: C, 70.15; H, 5.30; N, 24.55%.

Reaction of IIIb (Obtained from VIIIa) with *N*-Phenylhydroxylamine. A solution of *N*-phenylhydroxylamine (1.0 g) in ethanol (10 ml) was added to a solution of IIIb (0.92 g) in ethanol (60 ml), and the mixture was heated at 80°C for 5 hr, by which time the evolution of ammonia had ceased. Removal of the solvent yielded the product as a syrup, which was dissolved in hot isopropyl alcohol (4.5 ml); the solution was then filtered. The filtrate was allowed to stand in a refrigerator. After 2 days, the crystals were collected by filtration and washed with a small portion of benzene to give 0.62 g of XVI as yellow prisms, mp 265—266.5°C (unchanged by admixture with the XVI obtained by the reaction of III with *N*-phenylhydroxylamine).

2-Anilinopyrazine. A mixture of 2-chloropyrazine[15] (1.0 g) and aniline (4.0 g) was heated, with stirring, at 160°C for 7 hr. After the mixture had been kept overnight at room temperature, the aniline hydrochloride which had separated was filtrated off. Benzene (30 ml) was added to the filtrate. The benzene layer was washed twice with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure in order to recover the original aniline and benzene.

15) G. W. H. Cheeseman, *J. Chem. Soc.*, **1960**, 242.

When carbon tetrachloride was added to the residue small needles slowly crystallized out. The product was collected (0.5 g, 33.4%) and recrystallized from ethanol-isopropyl ether to give yellowish plates, mp 132—133°C; the crystal showed ultraviolet absorptions at λ_{max}^{EtOH} 275 mμ (ε=23000) and 345 mμ (ε=6000).

IR (KBr disk): 3270 and 3200 (-NH-), 1630 and 1520 cm^{-1}.

Found: C, 69.85; H, 5.09; N, 24.38%. Calcd for $C_{10}H_9N_3$: C, 70.15; H, 5.30; N, 24.55%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 707—712 (1968)

Synthesis and Reactions of Functional Polymers. XXXIV. Low Polymerization of Ethylene Oxide with Sodium *N*, *N*-Dimethyldithiocarbamate in Dipolar Aprotic Solvents*[1]

Takeshi NAKAI and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 9, 1967)

The low polymerization of ethylene oxide with sodium dimethyldithiocarbamate in a homogeneous system was studied. This reaction was verified as proceeding through a step-by-step addition mechanism, due to the enhanced nucleophilicity of the dithiocarbamate anion in dipolar aprotic solvents. The solvent effects and the catalyses of various dithiocarbamate salts were also examined. Epichlorohydrin was reacted with this salt in dimethylformamide to afford a polymer with a dithiocarbamate moiety through both ring-opening and substitution processes.

In previous papers[1] we have reported that polymers containing a dithiocarbamate moiety are effective as photosensitive resins. We prepared these polymers exclusively by polymer reactions since no monomer with a moiety has been readily available and since the radical polymerization of the monomers did not produce polymers of a high molecular weight. For example, *S*-vinyl-*N*, *N*-dialkyldithiocarbamates (I) were found to be polymerized with a radical initiator to give polymers of a low molecular weight, a low weight arising from the radical-stabilizing effect of the sulfur atom attached to the vinyl group (the *Q*-value for *N*, *N*-diethyl derivative is 0.45[2]). Thus, attempts have been made to prepare 1-*N*, *N*-dialkylthiocarbamylthio-2, 3-epoxy propane (II) by the reaction of epichlorohydrin (EPCl) with sodium dithiocarbamate and to produce a polymer by the ionic polymerization of the epoxide. As yet, however, we have not succeeded in the preparation of II.

During the course of our work on the reaction of EPCl with sodium dithiocarbamate in various solvents, it was found that epoxides were readily polymerized with sodium dithiocarbamate in dimethylformamide (DMF) at room temperature. This led us to our present study of the catalysis and of the solvent effect on the polymerization of ethylene oxide. It may be noted that this is in direct contrast to the observation that the transient dithiocarbamate anion (III) from triethylamine and carbon disulfide reacts with epoxides at 150°C under pressure, resulting in the formation of the corresponding ethylene trithiocarbonates *via* the episulfides, as is shown below,[3] just as in the well-known reactions of the alkylxanthate anion (⊖SCSOR) with epoxides at room temperature.[4]

On the other hand, although many earlier studies[5] of base catalyzed polymerization of epoxides have been carried out in heterogeneous systems, little information is available on the polymerization in a homogeneous system. Recently, however, Price and his co-workers[6] have reported the polymerization of epoxides with potassium *t*-buthoxide in dimethyl sulfoxide (DMSO).

This paper will describe how ethylene oxide can be polymerized with sodium dimethyldithiocarbamate in DMF at room temperature by means of a step-by-step addition mechanism.

Results and Discussion

Preliminary Experiments. Initially we attempted to react 2 mol of dithocarbamate salt with 1 mol of various epoxides in DMF, since we expected that the dithiocarbamate anion would react with epoxides in the same manner as the xanthate does.[4] Contrary to our expectations, however, many viscous materials were obtained, accompanied by a violent generation of heat, while the expected ethylene trithiocarbonates were not obtained at all. The presence of a non-volatile residue, after a portion of the liquid phase had been heated on a steam bath, was taken to be a positive criterion of polymerization. Thus, ethylene oxide (EO) and propylene oxide (PO) were reacted with about 5 mol% of sodium dimethyldithiocarbamate hydrate (MDTC) in DMF or in bulk at room temperature, resulting in the formation of viscous polymers of a low molecular weight, as is shown in Table 1. This led us to a detailed study of the polymerization of EO with MDTC.

Effect of MDTC Concentration on the Rate of Polymerization and on the Molecular Weight of the Resulting Polymer. In order to examine the mechanism for the initiation process of this polymerization, EO was polymerized in DMF at 30°C in the presence of various amounts of MDTC. As Fig. 1 shows the time-conversion curves were straight up to 80% of conversion.

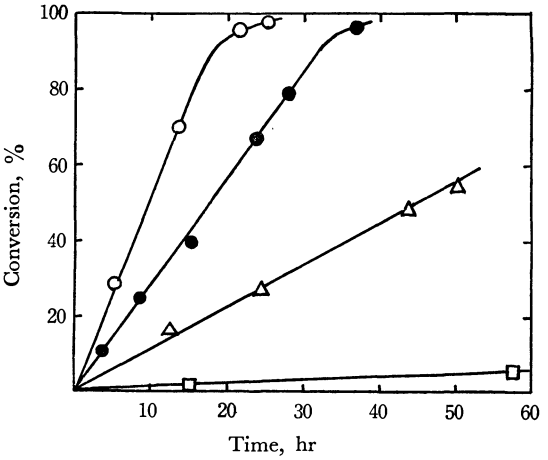

Fig. 1. Time-conversion curves.
EO 10.0 g; DMF 8.0 g; Temp. 30°C
MDTC=1.5 g (○), 0.8 g (●). 0.4 g (△) and 0.8 g (DMF none) (□)

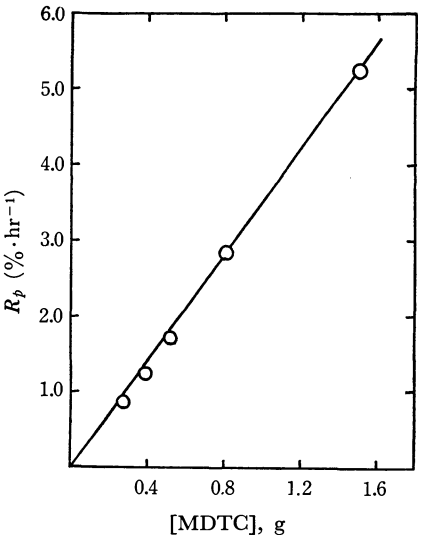

Fig. 2. Relationship between concentrations of MDTC and rates of polymerization.

The dependence of the rate of polymerization (R_p) on the concentration of MDTC is shown in Fig. 2. The relationship between the molecular weight of the resulting polymer and conversion is given in Fig. 3. These experimental results indicate the following facts; (i) the rate of polymerization is proportional to the concentration of MDTC; (ii) the molecular weight of the polymer increases gradually with conversion and (iii) the molecular weight of the polymer at the definite conversion increases with a decrease in the initial concentration of MDTC. These facts lead to the reasonable conclusion that this ring-opening polymerization proceeds through the anionic multistage polymerization mechanism, which is generally

Table 1. Polymerization of epoxides with MDTC*1

Epoxide, g		MDTC mol%	DMF ml	Product		
				Yield,*2 g	η_{rel} *3	Mol wt*4
EO	15.0	4.9	10	13.5	1.15	456
EO	14.3	3.2	0	4.3	1.11	374
PO	11.0	6.0	7	6.8	6.8	
PO	13.3	5.1	0	2.5		

*1 Temp.: room temperature Reaction time: 55 hr

*2 The product was isolated by the following procedure: the reaction mixture was poured into a large amount of ethyl acetate to form the precipitate, unreacted MDTC, which was then filtered off. The filtrate was distilled up to 80°C under 2 mmHg, giving a viscous residue in the flask, which was weighed.

*3 4% dioxane solution

*4 $[\eta]$ $(ml \cdot g^{-1}) = 0.083\, M^{0.59}$ (Ref. 5b; also see Experimental Section).

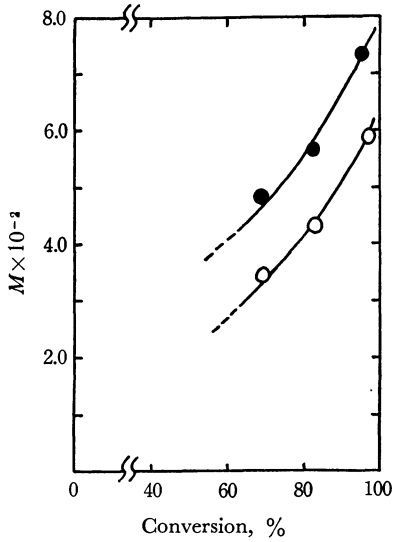

Fig. 3. Relationship between mol. wt. of polymers and conversions.
MDTC=0.8 g (●) and 1.5 g (○)

accepted for the ring-opening polymerization of epoxides with various anionic catalysts.[7] Consequently, the initiation and propagation reactions would be as follows:

$$Me_2NCSS^{\ominus}(Na^{\oplus}) + C_2H_4O \rightarrow$$

$$Me_2NCSSCH_2CH_2O^{\ominus}(Na^{\oplus})$$

$$Me_2NCSS(CH_2CH_2O)_{n-1}CH_2CH_2O^{\ominus}(Na^{\oplus}) \xrightarrow{C_2H_4O}$$

$$Me_2NCSS(CH_2CH_2O)_nCH_2CH_2O^{\ominus}(Na^{\oplus})$$

The IR spectrum (Fig. 4) of the resulting polymer shows absorptions of a double bond and of carbonyl groups, the formation of which might arise from the chain transfer or side reactions. The decolorization of bromine in carbon tetrachloride with the polymer also indicates the presence of the double bond. The treatment of the polymer with 2, 4-dinitrophenylhydrazine did not give the hydrazone, indicating that the polymer does not contain any ketone or aldehyde group. No further attempts were made to examine the chain-transfer reaction or to analyze the end groups.

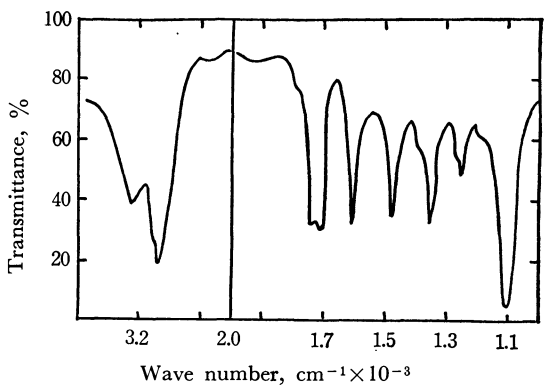

Fig. 4. IR spectrum of poly(EO) (liquid film).

According to Kagiya's equation[8] for successive high polymerizations, we tentatively calculated the catalytic activity coefficient (α), which denotes the number of active sites of MDTC:

$$\alpha = \frac{m \cdot M_p}{M \cdot C}$$

where m and M are molecular weights of the monomer and of the resulting polymer respectively, where M_p is the polymerized monomer (mol), and where C is the amount of MDTC (mol).

Table 2 indicates the α-values of MDTC thus obtained. It is surprising that the values ranged

TABLE 2. THE CATALYTIC ACTIVITY COEFFICIENT OF MDTC

C mol×10³	Time hr	M_p mol×10³	M	α
4.5	24	154	559	2.7
	28	179	568	3.0
	42	222	738	2.9
8.3	13	154	351	2.3
	17	181	450	2.2
	22	225	555	2.1

from 2 to 3; this variation cannot be reasonably explained at present. Alternatively, the application of the equation to low polymerizations remains in some doubt, since this equation has been originally devised for high-polymerization reactions.

Solvent Effect. It may be reasonably expected that the rate of polymerization is dependent on the nucleophilicity of the catalyst, varying with the nature of the solvent used. Thus, polymerizations were carried out in various aprotic solvents; the results are shown in Table 3.

TABLE 3. POLYMERIZATION IN VARIOUS SOLVENTS

Solvent	Dielectric constant	Polymerized monomer, g	Solubility of MDTC
DMF	37.6	8.4	soluble
DMSO	45.0	5.1	
CH_3CN	39.5	3.8	partially sol.
Acetone	21.2	0.5	insoluble
Dioxane	2.2	0.9	

EO 10.0 g; MDTC 0.5 g; Temp. 30°C; Time 65 hr; Solvent g

As expected, polymerization was accelerated in dipolar aprotic solvents in the following order: DMF>DMSO>CH_3CN, while the reaction was not accelerated in dioxane and acetone, in which MDTC is insoluble. This observation leads to the important conclusion that the major factor influencing the polymerization under homogeneous conditions is the enhanced nucleophilicity of the dithiocarbamate anion[9] in dipolar aprotic solvents; this is in agreement with many other observations[10] of nucleophilic substitutions and base-catalyzed reactions in these media. In the present case the catalysis of MDTC can be solely explained by the enhanced nucleophilicities of the thio anion in the initiation process and of the oxy anion in the propagation.

Catalysis of Various Dithiocarbamate Salts. Furthermore, we investigated the catalysis of various dithiocarbamate salts; the results are given in Table 4. It is not surprising that dithiocarbamate salts of bivalent metals, which are soluble in ordinary organic solvents, exhibit a small accelerating effect, or none at all, on this polymerization, since the metal-sulfur bonds in these dithiocarbamates are well-known to be chelate, not ionic bonds, and so the degree of the following dissociation is very small in solution.

$$M(SCSNR_2)_2 \rightleftarrows M^{2+} + 2R_2NCSS^-$$

It was also found that the ammonium salt of dithiocarbamate did not exhibit the catalysis on this polymerization; this implies a serious effect of the counter cation on the propagation process.

TABLE 4. CATALYSIS OF VARIOUS DITHIOCARBAMATE SALTS

Catalyst	polymerized monomer, g
$NaSCSNMe_2 \cdot 2H_2O$(MDTC)	6.6
$NaSCSNEt_2 \cdot 2H_2O$	7.7
$Nn(SCSNMe_2)_2$	2.7

$Ni(SCSNBu_2^n)_2$	2.0
$Et_2NHHSCSNEt_2$	0

EO 10.0 g; Catalyst 0.88 mol%; Temp. 30°C; Time 66 hr; DMF 8.0 g

Reaction of Epichlorohydrin with MDTC. Next, we attempted the reaction of epichlorohydrin (EPCl) with a small excess of MDTC in DMF. A DMF solution of MDTC was stirred into a DMF solution of EPCl to generate heat and to produce a precipitate (NaCl). After 20 hr, the mixture was poured into a large amount of water to give a white precipitate. The polymer obtained was soluble in DMF, DMSO, and acetonitrile, and was purified by reprecipitation (DMF-H_2O) to afford a white powder, which exhibited a negative Beilstein test. The reaction in DMSO gave a similar polymer. The experimental results are shown in Table 5.

Figure 5 indicates that the polymer exhibits characteristic bands of *S*-alkyl dithiocarbamate in the range from 1490 to 1375 cm^{-1} (–S–CS–N$\langle$), and ether linkage at 1140 cm^{-1} ($\rangle$C–O–C$\langle$). The IR spectrum of this polymer was essentially identical with that of the polymer obtained by the reaction of epichlorohydrin rubber (V) (prepared by the Nihon Zeon Co.) with MDTC in a mixture of DMF and toluene, except in the range from 1700 to 1650 cm^{-1}. These observations indicate that the reaction of EPCl with MDTC involves the following two processes in affording the polyether

9) Dithiocarbamate anions are ranked with the strongest nucleophiles in aqueous solutions: R. E. Davis, "Survey of Progress in Chemistry," Vol. 2, ed. by A. Scott, Academic Press Inc., New York, N. Y. (1964), p. 189; R. E. Davis, H. Nakshbendi and A. Ohno, *J. Org. Chem.*, **31**, 2702 (1966).

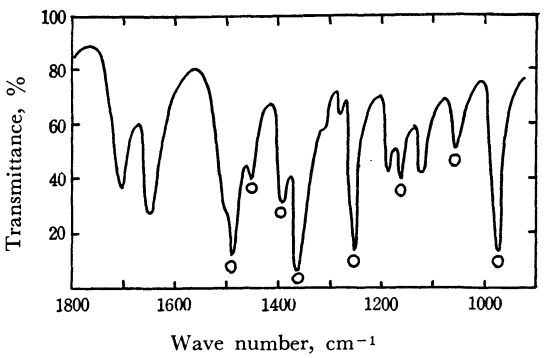

Fig. 5. IR spectrum of product from EPCl and MDTC (KBr disk). The sign ○ denotes the adsorption band observed CH_3-$SCSN(CH_3)_2$.

IV containing the dithiocarbamate moiety: the nucleophilic substitution (S_N) reaction on the chloromethyl carbon atom, and the ring-opening polymerization of the epoxy group. As is shown below, Chart, there are two possible mechanisms for the formation of the polymer IV. The first mechanism involves the initial polymerization of the EPCl catalyzed by MDTC, as has been verified above, followed by the S_N reaction (pathway a). The other consists of pathway b, which involves the initial formation of II, followed by the polymerization of II with MDTC. It seems reasonable to assume that pathway a is operative, since heat was usually evolved in the initial stage of the reaction and since EPCl reacted with less than 100 mol% of MDTC to give a viscous polymer, which exhibited a positive Beilstein test.

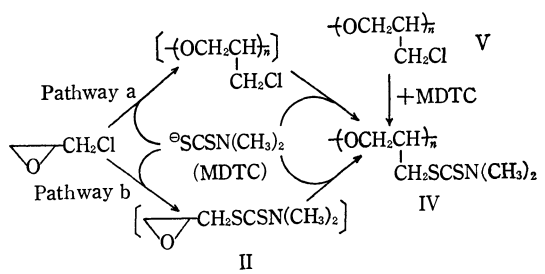

Figure 5 also indicates that the polymer IV exhibits two carbonyl bands, at 1700 and 1650 cm^{-1}. The former cannot be assigned, but the band was also observed for the polymer obtained by the polymerization of EO with MDTC (see Fig. 4). The latter band is assigned to the thiolcarbamate structure (-S-CO-N<) (1650 cm^{-1} for various *S*-alkyl *N, N*-dimethylthiolcarbamates); its formation can reasonably be explained by the following reaction sequence, involving the 1, 3-dithianylium ion (VI), through anchimerism by the dithiocarbamate function:[11]

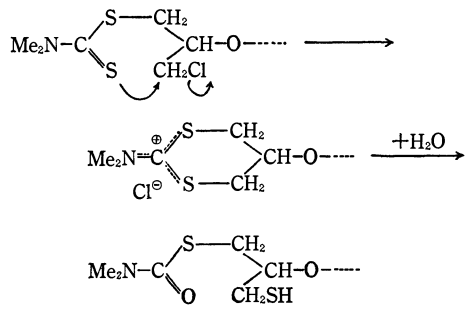

The formation of the thiolcarbamate structure also provides another evidence for the initial polymerization of EPCl with MDTC (pathway a). Further, the equimolar reaction of EPCl with sodium *N, N*-diethyldithiocarbamate in dioxane or benzene did not give any polymeric materials, but a distillable liquid, bp 118—120°C/0.15 mmHg; n_D^{30} 1.5420. (Found: S, 31.09%. Calcd for $C_8H_{15}NOS_2$: S, 31.22%). This unidentified compound also exhibits a same strong carbonyl band at 1650 cm^{-1}. This observation gives another support to anchimerism by the dithiocarbamate function.

Experimental

Materials. *Sodium N, N-Dimethyldithiocarbamate Hydrate (MDTC).* Commercial MDTC was washed several times with chloroform and then dried *in vacuo*.

11) T. Nakai, Y. Ueno and M. Okawara, *Tetrahedron Letters*, No. 39, 3831 (1967).

According to the reported method,[12] it was determined that this salt contained two molecules of coordinated water. The other dithiocarbamate salts used were available commercially and were employed without further purification.

Epoxides and Solvents. EO and PO were purified by distillation over solid potassium hydroxide. EPCl was purified by distillation. The solvents employed were purified by the usual methods.

Polymerization Procedure. A purified, anhydrous monomer and the solvent were added to a given amount of MDTC in a hard-glass tube at −78°C. The tube was then sealed and immersed in the stirring-thermostat adjusted at 30°C. After a given interval, the tube was removed from the thermostat and opened at −78°C. The unreacted monomer was readily removed on the steam-bath. From the decrease in the weight observed, the weight of the polymerized monomer was calculated.

Procedure of Isolating the Polymer. Anhydrous benzene (*ca* 80 m*l*) was added to the reaction mixture, and the precipitate formed was removed off using the centrifuge. The benzene and the solvent were removed by heating the clear solution to 80°C under reduced pressure (1 mmHg), thus producing a viscous residue. Viscosity measurements were made in dioxane solutions with an Ostwald viscometer at 30°C. The molecular weight of the polymer was calculated using Gee's equation,[5b] $[\eta]$ $(ml \cdot g^{-1}) = 0.083 M^{0.59}$. It has been verified that molecular weights ranging from 300 to 5100 can be determined by this equation, although no high precision is claimed.

Reaction of EPCl with MDTC. To a solution of 4.7 g (0.05 mol) of EPCl in 15 m*l* of DMF, 15 g (0.08 mol) of MDTC in 35 m*l* of DMF were added, little by little, at room temperature; the mixture was then stirred for 19 hr at room temperature. The white precipitate formed (NaCl) weighed 2.8 g (0.05 mol). The mixture was stirred into a large amount of water to give a white precipitate, which was collected by filtering and then dried *in vacuo* (yield 8.3 g). The product was purified by reprecipitation (DMF-H_2O). The reaction conditions and the results of individual experiments are shown in Table 5.

IR Spectra. The IR spectra were measured using a Hitachi Model EPI-2 Infrared Spectrometer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 712—716 (1968)

Azetidines. IV. The Reaction of 1-*t*-Butylazetidinyl-3 Tosylate with Amines and Mercaptans[1]

Teng-yueh CHEN,[2] Hiroshi KATO and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 21, 1967)

3-Amino and 3-mercapto-azetidine derivatives were prepared by the reaction of 1-*t*-butylazetidinyl-3 tosylate with ammonia, primary and secondary amines, and mercaptans. Ring cleavage was observed when the tosylate was reacted with compounds of higher acidity, such as thiobenzoic acid.

In a previous communication,[1] we reported that a nitrile group could be introduced onto the azetidine ring by the reaction of 1-*t*-butylazetidinyl-3 tosylate (I) and potassium cyanide; the nitrile was then hydrolyzed to 1-*t*-butylazetidine-3-carboxylic acid in fairly good yield.

This result suggests that tosylate I is a promising starting material for the preparation of a wide variety of azetidine derivatives. In this communication we report the preparation of amino and mercapto derivatives of azetidine by the reaction of I with amines and mercaptans.

When 1-*t*-butylazetidinyl-3 tosylate (I) was allowed to react with dimethylamine, 1-*t*-butyl-3-dimethylaminoazetidine (IIa) was obtained in 40% yield. The NMR spectrum of IIa (Fig. 1) exhibits two singlets at τ 9.01 (9H) and 7.90 (6H) and a complex multiplet between 6.5—7.3 (5H), corresponding to the *t*-butyl group, the dimethylamino group and the ring protons respectively. The treatment of I with piperidine and morpholine likewise afforded the corresponding amino derivatives, 1-*t*-butyl-3-(1-piperidino)-azetidine (IIb) and 1-*t*-butyl-3-(1-morpholino)-azetidine (IIc). The reaction of I with methanolic ammonia also gave the expected derivative, 1-*t*-butyl-3-aminoazetidine (IId), but in lower yield. The infrared spectrum of IId shows a characteristic bands of a primary amino group at 3360 and 3280 cm^{-1} and a NH bending band at 1610 cm^{-1}. The NMR spectrum of IId (Fig. 1) which consists of a nine-proton singlet at τ 9.05 for the *t*-butyl

1) Part III: T. Chen, T. Sanjiki, H. Kato and M. Ohta, This Bulletin, **40**, 2401 (1967).

2) On leave of absence from National Tsing Hua University, Taiwan, The Republic of China.

group, a two-proton broad singlet at 8.19 for the amino group and two complex multiplets at 7.05—7.35 (2H) and at 6.40—6.75 (3H) for the cis and trans protons of the methylene group plus the methine proton, agrees with the assigned structure (IId), if not prove it.

The reaction of I and cyclohexylamine, a primary amine, gave directly the disubstituted derivative, di-(1-*t*-butylazetidinyl-3)-cyclohexylamine (III) as an oil, which was purified by conversion to its trihydrochloride monohydrate. The hydrochloride shows bands of an OH and N^+H groupings at 3500—3280 and 2800—2400 cm^{-1}. When I was treated with a large excess of cyclohexylamine,

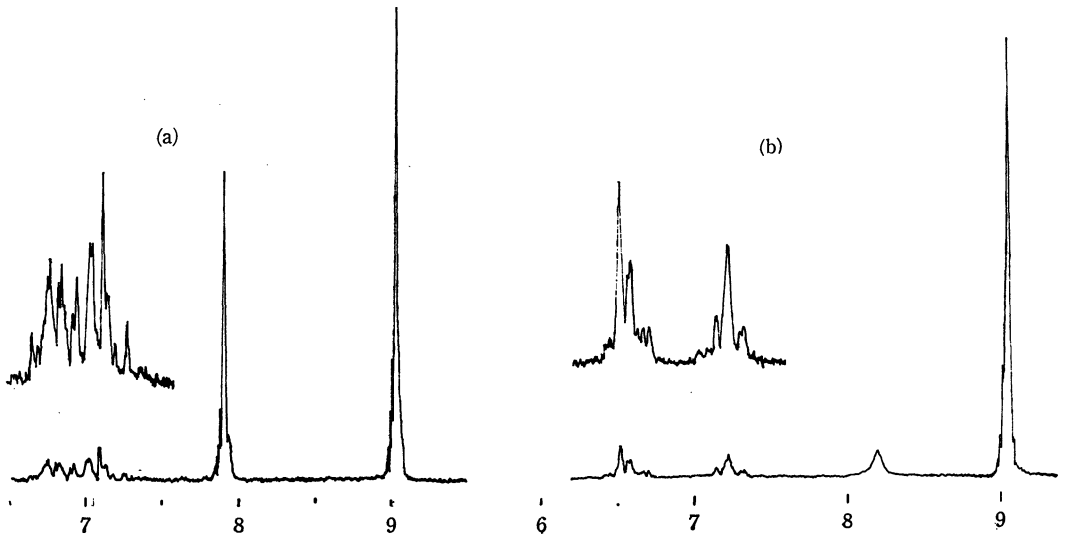

Fig. 1. The NMR spectrum of 1-*t*-butyl-3-dimethylaminoazetidine (a) and 1-*t*-butyl-3-amino-azetidine (b).

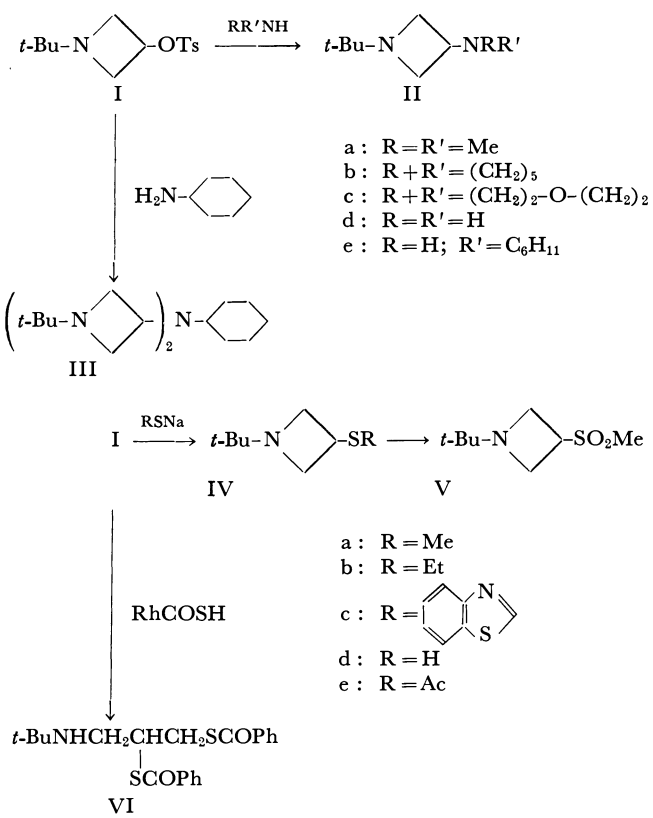
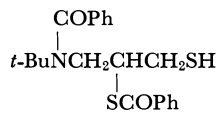


however, mono-substituted derivative IIe was obtained. Compound IIe was also a liquid but it could be crystallized in the form of its monohydrate. The infrared spectrum of IIe monohydrate shows a broad band of an OH group between 3500—3200 cm^{-1} and a band of an NH group at 3260 cm^{-1}.

The reaction of I with methyl mercaptan, ethyl mercaptan, and 2-mercaptobenzothiazole in ethanol in the presence of sodium ethoxide proceeded smoothly to give the corresponding sulfide, 1-*t*-butyl-3-methylthioazetidine (IVa), 1-*t*-butyl-3-ethylthioazetidine (IVb) and 1-*t*-butyl-3-(2-benzothiazolylthio)azetidine (IVc) respectively in good yields. Permanganate oxidation of IVa gave the corresponding sulfone V as a solid. The NMR spectrum of IVa consists of two sharp singlets at τ 9.12 (9H) corresponding to the *t*-butyl group and 8.00 (3H) corresponding to the methyl group, and a complex multiplet between 6.50 and 7.10 (5H) for the ring protons.

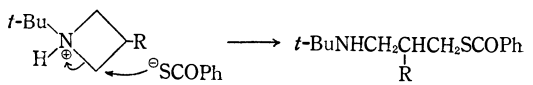
The reaction of I and potassium hydrogen sulfide in methanol was also tried with a hope of obtaining 1-*t*-butylazetidine-3-thiol (IVd). The crude reaction product was treated with acetic anhydride and distilled to give two components. The minor, lower boiling fraction shows a carbonyl absorption band at 1695 cm^{-1} and the elemental analysis was in agreement with the composition of 1-*t*-butyl-3-acetylthioazetidine (IVe). The major component, a highly viscous higher boiling liquid shows two carbonyl absorption bands at 1695 (acetylthio) and 1640 (amide) cm^{-1}, suggesting this component to be a ring cleavage product, but attempts of its purification failed. The ring cleavage reaction may have taken place at the stage of treatment with acetic anhydride rather than at the stage of treatment with potassium hydrogen sulfide.

The reaction of I with an excess of thiobenzoic acid in the presence of potassium carbonate also provided a ring cleavage product as a highly viscous oily substance which was purified by conversion to its hydrochloride. The infrared spectrum of the base shows a weak band at 3320 cm^{-1} (NH), a strong band of a carbonyl group at 1660 cm^{-1} and no absorption due to an SH group was found around 2600 cm^{-1}. The infrared spectrum of its hydrochloride shows a group of bands between 2800—2500 cm^{-1} besides the carbonyl band at 1660 cm^{-1}. These spectral data, as well as the results of elemental analyses suggest its structure to be VI rather than VII.



VII

This ring cleavage reaction may be considered to proceed through a protonated azetidinium salt (VIII; R=TsO or PhCOS) followed by an attack of an thiobenzoate anion to the ring, as is shown as follows:



VIII

There have been ample examples[3] of such a mode of ring cleavage of azetidine ring.

The reaction of I with thioacetic acid also gave a highly viscous intractable substance. The infrared absorption spectrum of this crude substance was almost identical with that of the high boiling product obtained by acetic anhydride treatment of the reaction product of I and potassium hydrogen sulfide, but trials of its purification failed.

From the results described above, it may be concluded that amino and mercapto groups can be introduced to the 3 position of azetidine ring by the reaction of an azetidinyl-3 tosylate with an appropriate amine or mercaptan, but the reaction of the tosylate with compounds of higher acidity such as thiobenzoic acid leads to ring cleavage product.

Experimental[4]

1-*t*-Butyl-3-dimethylaminoazetidine (IIa). To a solution of 6 m*l* (0.07 mol) of dimethylamine in 20 m*l* of methanol were added 5 g (0.017 mol) of I and 2.7 g (0.02 mol) of potassium carbonate successively with cooling and stirring. After stirring for five hours at room temperature, the mixture was allowed to stand overnight. After removal of the precipitate by filtration, the filtrate was concentrated under reduced pressure, and was diluted with 40 m*l* of water and filtered again to remove unchanged I. The filtrate, after being saturated with potassium carbonate, was extracted with ether, and the ether extract was dried over sodium sulfate. Distillation under reduced pressure afforded 1 g (40% yield) of colorless liquid boiling at 60—64.5°C/20 mmHg. n_D^{25} 1.4232, IR: 2960—2780, 1460, 1360 and 1240 cm^{-1}. The NMR spectrum is shown in Fig. 1 (a).

Found: C, 68.99; H, 12.69; N, 17.57%. Calcd for $C_9C_{20}N_2$: C, 69.17; H, 12.90; N, 17.93%.

Picrate of IIa melted once at 133—135°C, then solidified and melted again at 220—251°C with decomposition.

4) The general conditions for the measurements of physical constants and spectra were the same as described in Part I, T. Chen, H. Kato and M. Ohta, This Bulletin, **40**, 1964 (1967).

Found: C, 47.06; H, 6.20; N, 18.19%. Calcd for $C_{15}H_{23}N_5O_7$: C, 46.75; H, 6.02; N, 18.17%.

The following compounds were obtained by a similar method as described above.

1-*t*-Butyl-3-(1-piperidino)azetidine (IIb). (55% yield) Bp 64—67°C/1.5 mmHg, n_D^{25} 1.4678. IR: 2980—2660, 1460, 1360 and 1240 cm^{-1}.

Found: C, 73.27; H, 12.48; N, 14.38%. Calcd for $C_{12}H_{24}N_2$: C, 73.41; H, 12.32; N, 14.27%.

Picrate of IIb: partially melted at 150°C, then solidified and melted again at 202—225°C with decomposition.

Found: C, 50.55; H, 6.56; N, 15.96%. Calcd for $C_{18}H_{27}N_5O_7$: C, 50.81; H, 6.40; N, 16.46%.

1-*t*-Butyl-3-(1-morpholino)azetidine (IIc). (90% yield—crude). Very hygroscopic colorless prisms, mp 43—45°C (from petroleum ether). IR: 2980—2800, 1480, 1360, 1240 and 1120 cm^{-1}.

Found: C, 66.30; H, 11.20; N, 13.76%. Calcd for $C_{11}H_{22}N_2O$: C, 66.62; H, 11.18; N, 14.13%.

Dipicrate of IIc: mp 223—230°C (decomp.).

Found: C, 42.54; H, 4.30; N, 17.30%. Calcd for $C_{23}H_{28}O_{15}N_8$: C, 42.07; H, 4.29; N, 17.06%.

1-*t*-Butyl-3-aminoazetidine (IId). This was prepared in 35% yield by treatment of 10 g of I with 40 m*l* of saturated methanolic solution of ammonia for a week at room temperature. Colorless liquid, bp 55—61°C/13.5 mmHg, n_D^{25} 1.4545, IR: 3360, 2380, 1610, 1480, 1360 and 1240 cm^{-1}. The NMR spectrum is shown in Fig. 1 (b).

Found: C, 64.72; H, 12.65; N, 21.93%. Calcd for $C_7H_{16}N_2$: C, 65.57; H, 12.58; N, 21.85%.

p-Nitrobenzamide of IId: mp 163.5—165°C.

Found: C, 60.49; H, 6.58; N, 15.42%. Calcd for $C_{14}H_{19}O_3N_3$: C, 60.63; H, 6.91; N, 15.15%.

Monopicrate of IId: Mp 245—250°C (decomp.).

Found: C, 43.95; H, 5.50; N, 19.26%. Calcd for $C_{13}H_{19}N_5O_7$: C, 43.69; H, 5.36; N, 19.60%.

Dipicrate of IId: Mp 224—228°C (decomp.).

Found: C, 38.49; H, 3.80; N, 19.28%. Calcd for $C_{19}H_{22}N_8O_{14}$: C, 38.91; H, 3.78; N, 19.10%.

***N*, *N*-Di-(1-*t*-butylazetidinyl-3)cyclohexylamine (III).** This was obtained in *ca.* 60% yield by the reaction of 0.02 mol of I and 0.04 mol of cyclohexylamine.

Trihydrochloride monohydrate of III: Mp 194—196°C (white needles from ethanol). IR: 3480, 3440, 3300, a group of absorption between 2800—2400, 1470, 1430 and 1380 cm^{-1}.

Found: C, 53.02; H, 10.41; N, 9.53%. Calcd for $C_{20}H_{44}N_3OCl_3$: C, 53.50; H, 9.80; N, 9.36%.

1-*t*-Butyl-3-cyclohexylaminoazetidine (IIe). This was prepared in *ca.* 22% yield by the reaction of 5.8 g (0.02 mol) of I and 30 m*l* of cyclohexylamine.

Monohydrate of IIe: Colorless plates, mp 37—39°C (from hexane), IR: a broad peak between 3500—3200, 3260, 1448, 1360 and 1240 cm^{-1}. This substance melted to a liquid when kept in a desiccator, which resolidified to give the monohydrate when allowed to stand in the open air.

Found: C, 68.67; H, 12.16; N, 12.54%. Calcd for $C_{13}H_{28}N_2O$: C, 68.37; H, 12.36; N, 12.27%.

Dipicrate of IIe: mp 199.5—202°C (decomp.).

Found: C, 44.92; H, 4.98; N, 16.24%. Calcd for $C_{25}H_{32}N_8O_{14}$: C, 44.90; H, 4.82; N, 16.76%.

1-*t*-Butyl-3-methylthioazetidine (IVa). To a solution of *ca.* 0.1 mol of sodium methylmercaptide in 50 m*l* of ethanol was added 11.5 g (0.04 mol) of I and the mixture was stirred for a day at room temperature and was allowed to stand overnight. It was then treated in the same way as in the reaction of I and secondary amines. 4.7 g (74% yield) of colorless liquid was obtained. Bp 80—83°C/13 mmHg, n_D^{25} 1.4741. IR: 2980—2820, 1480, 1430, 1360, 1250 and 1080 cm^{-1}. NMR(τ): 9.12 (singlet, 9H); 8.00 (singlet, 3H); 6.50—7.10 (multiplet, 5H).

Found: C, 60.46; H, 11.00; N, 8.34%. Calcd for $C_8H_{17}NS$: C, 60.34; H, 10.76; N, 8.80%.

Picrate of IVa: Mp 165—167.5°C.

Found: C, 43.39; H, 5.12; N, 14.60%. Calcd for $C_{14}H_{20}N_4O_7S$: C, 43.30; H, 5.19; N, 14.43%.

The following sulfides were prepared by the same method as described above:

1-*t*-Butyl-3-ethylthioazetidine (IVb). (63% yield) Bp 95—102°C/22 mmHg, n_D^{25} 1.4705, IR: 3000—2820, 1480, 1450, 1360, 1250 and 1080 cm^{-1}.

Found: C, 61.91; H, 11.05; N, 8.00%. Calcd for $C_9H_{19}NS$: C, 62.39; H, 11.05; N, 8.09%.

Picrate of IVb: Mp 134—135°C.

Found: C, 44.60; H, 5.29; N, 14.14%. Calcd for $C_{15}H_{22}O_7N_4S$: C, 44.77; H, 5.51; N, 13.93%.

1-*t*-Butyl-3-(2-benzothiazolylthio)azetidine (IVc). (41% yield). White fine crystals (from petroleum ether), mp 48—49°C. IR: 3053, 2900, 2834, 1450, 1366, 1240 1000 and 765 cm^{-1}.

Found: C, 60.62; H, 6.66; N, 10.42%. Calcd for $C_{14}H_{18}N_2S_2$: C, 60.42; H, 6.52; N, 10.07%.

Picrate of IVc: Mp 144.5—145.5°C.

Found: C, 46.99; H, 4.27; N, 14.01%. Calcd for $C_{20}H_{21}N_5O_7S_2$: C, 47.33; H, 4.17; N, 13.80%.

Reaction of I and Potassium Hydrogen Sulfide. Hydrogen sulfide was saturated to a solution of 5 g of potassium hydroxide in 50 m*l* of methanol. To the above solution, 11.5 g (0.04 mol) of I was added and the mixture was processed according to the method described above. To the residue obtained by removal of the solvent was added with cooling 12 m*l* of acetic anhydride and the solution was warmed on a water bath for three hours. After setting aside at room temperature overnight, the reaction mixture was poured into water, made alkaline with potassium carbonate and was extracted with ether. The extract was concentrated and the residual oil was distilled to give 0.8 g of a colorless liquid, bp 44—56°C/1.5 mmHg, and 2 g of a light yellow viscous liquid, bp 142—152°C/1.5 mmHg.

Low boiling fraction: n_D^{25} 1.4805, IR: 3000—2820, 1695, 1480, 1360, 1240, 1120 cm^{-1}.

Found: C, 58.02; H, 9.65; N, 7.52%. Calcd for $C_9H_{17}NOS$: C, 57.73; H, 9.15; N, 7.48%.

Picrate of low boiling fraction: mp 168—170°C.

Found: C, 43.11; H, 4.78; N, 14.46%. Calcd for $C_{15}H_{20}N_4O_8S$: C, 43.27; H, 4.84; N, 13.46%.

High boiling fraction: n_D^{25} 1.4850, IR: 3000—2800, 1695, 1640, 1480, 1390, 1360, 1230 and 1130cm^{-1}.

Methyl 1-*t*-Butylazetidinyl-3 Sulfone (V). To a solution of 2 g (0.0125 mol) of IVa in 20 m*l* of glacial acetic acid was added dropwise with stirring a solution of 2.5 g (0.016 mol) of potassium permagnate in 25 m*l* of water. The mixture was stirred for half an hour at room temperature and then for another half an hour at 40—50°C. The precipitate was filtered off and the filtrate was treated with an aqueous sodium bisulfite.

Extraction with ether and removal of the solvent afforded 1.9 g of crude solid, which was recrystallized from ether to give 0.7 g (29% yield) of colorless plates, mp 46—48.5°C. IR: a group of absorption between 1330—1200 and 1140 cm^{-1}.

Found: C, 50.18; H, 9.15; N, 7.11%. Calcd for $C_8H_{17}NO_2S$: C, 50.25; H, 8.96; N, 7.33%.

Picrate of V: Mp 188—190.5°C.

Found: C, 40.27; H, 4.91; N, 13.31%. Calcd for $C_{14}H_{20}N_4O_9S$: C, 40.00; H, 4.79; N, 13.33%.

Reaction of I and Thiobenzoic Acid. To a solution of 10 g (0.07 mol) of thiobenzoic acid in 9 m*l* of dimethylformamide was added successively 1.6 g (0.01 mol) of potassium carbonate and 5.8 g (0.02 mol) of I and the mixture was stirred for six hours and was set aside overnight. The reaction mixture was then diluted with 30 m*l* of water, made strongly alkaline with potassium carbonate and was extracted with ether. A reddish brown viscous oil remained after removal of the solvent. The oil was dissolved again in ether and treated with dilute hydrochloric acid. A light colored precipitate (3.9 g) was obtained, which was recrystallized from ethanol-hexane to give white needles, mp 160—166°C. IR: 3060, 2800—2500, 2420, 1660 cm^{-1}.

Found: C, 59.45; H, 6.35; N, 3.22%. Calcd for $C_{21}H_{26}NO_2S_2Cl$: C, 59.50; H, 6.18; N, 3.30%.

A light-colored viscous oil was recovered by neutralization and extraction of the above hydrochloride. IR: 3320, 3060, 1660 cm^{-1}. (No absorption due to SH was observed.)

Found: C, 65.58; H, 6.63; N, 3.83%. Calcd for $C_{21}H_{25}NO_2S_2$ (VI): C, 65.10; H, 6.50; N, 3.83%.

We are indebted to Miss Mizuko Yoshida for the measurement of the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 716—721 (1968)

A Study on Mixed Vanadium Catalysts for the Ammoxidation of Xylene

Masatomo Ito, Hazime Tanaka and Akira Matsumoto

The Central Research Laboratory, Showa Denko K. K., Tamagawa, Ohta-ku, Tokyo

(Received September 23, 1967)

The phase composition and the physicochemical properties of an antimony-vanadium catalyst and a chromium-vanadium catalyst for the ammoxidation of xylene were studied by X-ray diffraction method, differential thermal analysis, infrared absorption analysis and ESR measurement. An antimony-vanadium catalyst consisted essentially of $SbVO_4$ which contained no double covalent bond V=O, while a chromium-vanadium catalyst consisted essentially of a chemical compound which was different from $CrVO_4$. $SbVO_4$ and $CrVO_4$ were hard to be reduced with ammonia at 400°C, while a chemical compound in the chromium-vanadium system was reducible. The activity and the selectivity of reaction were affected by the nature and the distribution of metal ions and oxygen ion on surface.

The kinetic study of the vapor-phase ammoxidation of xylene over a vanadium oxide catalyst and mixed vanadium catalysts, an antimony-vanadium catalyst and a chromium-vanadium catalyst, showed that the rate and the selectivity of the reaction were affected by the adsorbability and the reactivity of related reactants.[1] A basic study on mixed vanadium catalysts for the ammoxidation of xylene was, therefore, of interest in order to gain a better understanding of the reaction processes which take place on the catalyst surface.

The present study is an attempt to clarify the physicochemical properties of mixed vanadium catalysts for the ammoxidation of xylene.

Experimental

Sample Preparation. Catalyst samples, which were free of carrier, were prepared by mixing a solution of vanadyl oxalate with a solution of chromium oxalate or a solution of vanadyl tartarate with a solution of antimonyl tartarate in the desired proportions. After evaporating the mixture to dryness on a steam bath the sample was calcinated in air for periods up to 2 days.

Physical Measurement. The powder-type X-ray diffraction patterns of samples were recorded using a Rigaku Denki model D-2F Geigerflex with a copper target.

The infrared absorption spectra of samples were recorded using a JASCO model IR-S infrared spectrophotometer and preparing the samples in the form of KBr pressed discs (1 mg sample in 0.5 g KBr).

The differential thermal analysis curves for the samples were run in air heating at a rate of 10°C/min using a Shimadzu model DT-1A differential thermal analyzer.

The ESR absorption spectra of samples were measured at room temperature by using the same apparatus and procedure employed in a previous work.[2]

1) M. Ito and K. Sano, This Bulletin, **40**, 1321 (1967).

2) H. Tanaka and A. Matsumoto, *ibid.*, **39**, 876 (1966).

The oxygen loss during the reduction of samples with ammonia was determined at 400°C by using a Shimadzu thermal balance. Weighed powdered sample (0.3 g) was heated to 400°C in a nitrogen atmosphere and ammonia was then introduced at a rate of 200 cc/min.

Results

Antimony-Vanadium System. The differential thermal analysis curves of the mixtures of an antimonyl tartarate and a vanadyl tartarate are shown in Fig. 1. Taking account of the X-ray diffraction patterns (Fig. 2) of samples which were

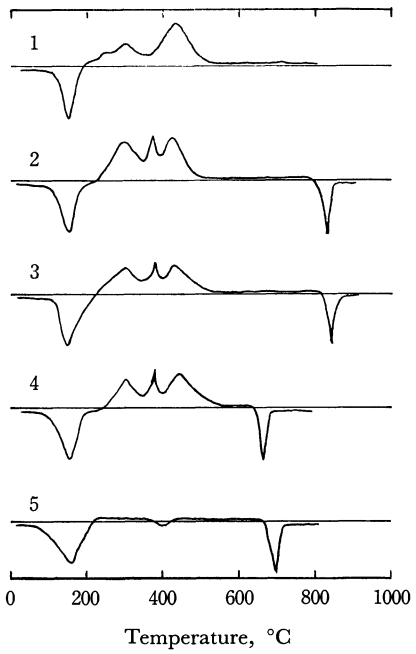

Fig. 1. Differential thermal analysis curve of the mixture of antimonyl tartarate and vanadyl tartarate.

treated in air at desired temperature for 4 hr, they were interpreted in the following way. The endothermic peak in the range from 100 to 200°C and the following exothermic peak in the range from 200 to 300°C were ascribed to the dehydration and the decomposition of tartarates respectively. Two exothermic peaks at 300 and 420°C in an antimonyl tartarate were seemed to indicate the formation of antimony trioxide(cubic type) and tetraoxide (orthorombic type) respectively. In mixed tartarate samples a new crystal phase was formed below 300°C. This new crystal phase was in good agreement with one which was prepared by treating the equimolar mixture of antimony trioxide and vanadium pentoxide in a sealed Pt tube at 700°C.[3]

3) R. S. Roth and J. L. Waring, *Am. Mineral.*, **48**, 1348 (1963).

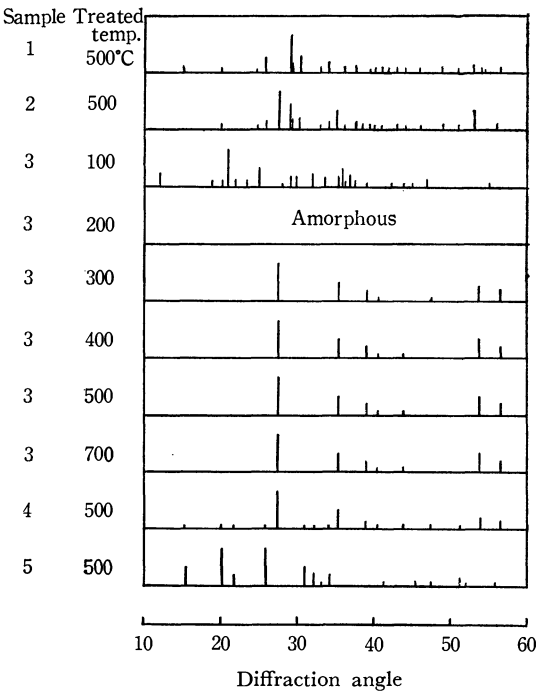

Fig. 2. X-Ray diffraction pattern of antimony-vanadium sample.

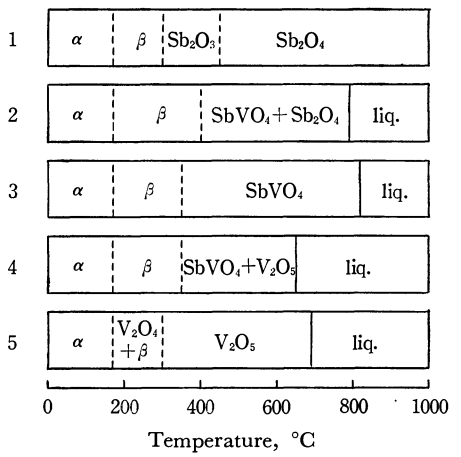

Fig. 3. Phase diagram in antimony-vanadium system.
Sb/V ratio: 1) 1/0, 2) 2/1, 3) 1/1, 4) 1/2, 5) 0/1

The exothermic peaks near 400°C were seemed to be ascribed to the crystallization of this chemical compound and the temperature at the last peak was regarded the melting point.

In view of above results, the phase diagram in this system is presented in Fig. 3. The α-phase was the crystalline of tartarates and the β-phase was the amorphous intermediate.

Infrared absorption spectra of the samples are shown in Fig. 4. The mixed sample in the atomic

ratio of 1 : 1 had only a very weak absorption near 1000 cm^{-1}. This indicates that $SbVO_4$ contains no double covalent bond V=O.

The heat-treated samples of this system except Sb_2O_4 gave a single broad ESR absorption spectrum. Figure 5 shows the variation of the ESR intensity of the sample in the atomic ratio of 1 : 1 with heat treatment. The intensity of ESR signal decreased with an increase in treated temperature, while the width increased. The *g*-value,

1/2	1.96	500	0.007
1/10	1.98	95	
0/1	1.98	85	0.0008

a : very broad signal
b : relative intensity to vanadyl tartarate

ΔHmsl and relative intensity of ESR signal of samples heat-treated at 480°C are listed in Table 1. The signal intensity passed through a maximum at the atomic ratio of 1 : 1. Further details on the ESR study in this system will be reported in a separate paper.

Chromium-Vanadium System. The differential thermal analysis curves of the mixtures of a chromium oxalate and a vanadium oxalate are shown in Fig. 6. The X-ray diffraction patterns of samples, which were treated in air at desired temperature for 4 hr, at shown in Fig. 7. The endothermic and the following exothermic peaks near 400°C were seemed to be the decomposition of oxalates. The exothermic peaks in the mixed oxalate sample in the range from 500 to

620°C were seemed to be ascribed to the formation of x-phase compound which was in good agreement with $CrVO_4$ described by Brandt.[4] The last endothermic peak was regarded the melting point.

The X-ray diffraction pattern also showed that there were two new phase present in mixed samples. When the atomic ratio of chromium to vanadium was near 1 : 3, the y-phase was present in the range from 400 to 600°C. This phase could be obtained by the heat-treatment of chromium metavanadate[5,6] at 500°C. When the atomic ratio was near 1 : 1, the z-phase was present and was stable up to a higher temperature at the atomic ratio of 1 : 1. In view of above observation and the result by Amiel and his co-workers,[7] the phase diagram in this system is presented in Fig. 8.

Infrared absorption spectra of the heat-treated samples are shown in Fig. 9. The spectra of mixed samples differed from that of V_2O_5 and Cr_2O_3. In the atomic ratio of 1 : 1 the spectra showed remarkable change by the temperature of heat treatment. The spectrum of a brownish black amorphous material obtained by the heat treatment at 400°C was similar to one of chromium orthovanadate obtained by precipitating chromic nitrate solution with sodium orthovanadate and

heating the precipitate at 400°C. In the spectrum of a grayish black crystal powder obtained by the heat treatment at 500°C three broad absorption bands were observed at 950, 870 and 740 cm^{-1}. The spectrum of a yellowish brown crystal powder obtained by the heat treatment at 800°C showed

7) J. Amiel, D. Colaitis and D. Olivier, *ibid.*, **263**, 224 (1966).

three very strong absorption bands at 970, 880 and 740 cm^{-1}. This observed change in the spectra is seemed to be ascribed to the formation of the chemical compounds, in good agreement with phase analysis described above.

The heat-treated samples in this system gave a single broad ESR absorption spectrum. Figure 10 shows the variation of the ESR intensity of the sample in the atomic ratio of 1 : 1 with heat treatment. The intensity of ESR signal passed through a minimum at the sample heat-treated at 500°C, while the sample heat-treated at 800°C gave a very intense signal with a *g*-value of 1.98 and a width of 90 gauss. The *g*-value, *ΔHmsl* and relative intensity of ESR signal of samples heat-treated at 500°C are listed in Table 2. The sample in the atomic ratio of 1 : 1 gave a broad signal with a weak intensity.

0/1	1.98	70	0.0008

a : relative intensity to vanadyl oxalate

Permanganate titration indicated also that the sample heat-treated in the range from 400 to 500°C presented no vanadium in the V^{4+} state.

Reduction of Sample with Ammonia. In Fig. 11 the thermogravimetric analysis curves treated with ammonia at 400°C are shown. Vanadium pentoxide was very reducible under the given condition, while mixed samples were hard to be reduced. However the z-phase in the chromium-vanadium system was reducible. The phase analysis by X-ray diffraction method and infrared absorption analysis showed that each mixed sample treated with ammonia retained the original composition. These results indicate that mixed samples have no covalent double bond V=O to be easily reducible.

1) V_2O_5
2) chromium-vanadium (1:1) treated at 500°C
3) antimony-vanadium (1:1) treated at 500°C
4) chromium-vanadium (1:1) treated at 800°C

Phase Composition of Used Catalysts. The fresh catalysts used for the ammoxidation of xylene[1] consisted essentially of V_2O_5, $SbVO_4$ and z-phase for a vanadium oxide catalyst, an antimony-vanadium catalyst and a chromium-vanadium catalyst respectively. X-Ray diffraction patterns for used catalysts showed that a vanadium oxide catalyst consisted essentially of V_2O_4, while mixed catalysts retained the original composition even after prolonged usage.

Discussion

Roth and Waring[3] and Brandt[8] have shown that $SbVO_4$ has the rutile structure with the metal ions randomly distributed. Taking account of the results for infrared absorption analysis, ESR measurement and reactivity with ammonia, it is suggested that the nature of vanadium ion in $SbVO_4$ is similar to one of V_2O_4.[9]

The chromium-vanadium system is more complicated. Brandt has shown that x-phase, that is $CrVO_4$, has a defect spinal structure having the vanadium atoms in tetrahedral coordination.[4]

8) K. Brandt, *Structure Reports*, **9**, 178 (1942—4).
9) K. Narita, *Nihon Butsuri Gakkaishi (J. Applied Phys. Japan)*, **20**, 748 (1965).

The very intense absorption bands of infrared spectrum and the intense signal of ESR indicate also that octahedral chromium ion and tetrahedral vanadium ion are regularly distributed. The metal ions in $CrVO_4$ are also not reduced under reaction conditions.

The infrared absorption spectrum of amorphous phase was similar to one of amorphous chromium metavanadate. The amorphous phase is, therefore, seemed to have the polyanion of VO_3^-.

On the other hand X-ray diffraction pattern indicates that the structure of z-phase is quite different from one of x-phase. Ioffe and his co-workers[10,11] have obtained the similar compound by heat-treating the mixture of vanadyl oxalate and chromic acid at 400°C, but X-ray diffraction pattern is not in agreement with one of the z-phase of this work. The infrared absorption spectrum of z-phase was similar to one of x-phase rather than one of amorphous phase, but each absorption band of its spectrum was broad and considerably weak. The absorption band near 1000 cm^{-1} also shifted to the longer wavelength than one of x-phase. The ESR absorption spectrum of 1 : 1 sample heat-treated in the range from 400 to 500°C was similar to one of Cr_2O_3 which had a single broad signal. Furthermore the z-phase was reducible with ammonia at 400°C differing from x-phase. The surface of the catalyst consisting of z-phase is seemed to become partially reduced under reaction condition. In view of above results, the z-phase is seemed to have the transitional structure with the elongated double convalent bond V=O.

A vanadium oxide catalyst, a chromium-vanadium catalyst and an antimony-vanadium catalyst had similar activity in the ammoxidation of xylene as described in the previous paper,[1] while a chromium-vanadium catalyst in which x-phase was one of major constituent of catalyst had a little catalytic activity in this reaction. These observations indicate that the nature and the distribution of metal ions and oxygen ion on catalyst surface affect the catalytic activity and the selectivity of reaction. It is difficult to expect the relationship between the adsorbability of reactant and the selectivity of reaction, but it may be assumed that the addition of more electronegative metal ions affects the electronic property of vanadium ion functioning as an adsorption center.[12,13]

Ioffe and his co-workers[10,11] showed that a chromium-vanadium catalyst in the atomic ratio of 1 : 1 had low activity and selectivity for the oxidation of benzene to maleic anhydride. An antimony-vanadium catalyst and a chromium-vanadium catalyst had an activity for the oxidation of *o*-xylene to phthalic anhydride, but the selectivity to phthalic anhydride showed less than 35%. Furthermore the relationship between the catalytic activity and the physical property of mixed catalysts for the ammoxidation of xylene are different from that for the oxidation of benzene.[11] These results suggest that the oxidative dehydrogenation is more significant than the formation of carboxylic acid for the mechanism of ammoxidation.[14]

The authers wish to thank Messrs. Hideo Ichinokawa, Tadashi Aoki, Nobuhisa Goto and Ken-ichi Sano for their valuable discussion.

NOTES

Polymerization of Styrene by Ceric *n*-Dodecylbenzene Sulfonate in the Presence of Alcohol or a Carbonyl Compound

Kyoji KAERIYAMA

The Textile Research Institute of Japanese Government, Sawatari, Kanagawa-ku, Yokohama

(Received June 10, 1967)

The present investigation was undertaken to seek for a better co-catalyst for the polymerization of styrene by organoceric compounds. As an organoceric compound ceric *n*-dodecylbenzene sulfonate[1] was used. From the results of the similar studies by Iwakura *et al.*[2] and Ogiwara *et al.*,[3] in the present paper alcohols and carbonyl compounds were selected as the co-catalysts.

To a solution of 22 g of ceric ammonium nitrate dissolved in 200 cc of 0.1 N aqueous nitric acid, a solution of 27.6 g of sodium *n*-dodecylbenzene sulfonate in 200 cc of water was added. The yellow precipitate was then separated by filtration and dried *in vacuo* at 40°C. This precipitate will hereafter be referred to as ceric *n*-dodecylbenzene sulfonate (CDBS) according to the reference.[1] The yield was 41.9 g. When CDBS was burned in a crucible, 21.14% of the CDBS (in weight) remained as an ash. This ash was presumed to be ceric dioxide. In addition to the bands observed in the IR spectra of sodium *n*-dodecylbenzene sulfonate, the IR spectra of CDBS contain a band at 1380 cm^{-1}, assignable to the nitric ion, and a shoulder at 3150 cm^{-1}, assignable to the ammonium ion. These data show that 1.03 of the nitric ions in the original ceric diammonium hexanitrate were replaced by *n*-dodecylbenzene sulfonic ions. CDBS is soluble in ethyl acetate, methyl ethyl ketone, benzene, styrene, and diethyl ether, while it is insoluble in methyl, ethyl, amyl, *n*-octyl alcohol, and in acetone.

Polymerization was carried out *in vacuo* at 60°C for 48 hr. The concentration of CDBS in the polymerization mixture were expressed by the concentration of ceric ions. The results are shown in Table 1. Judging from the low conversions for such a long polymerization time, it can be said that the catalytic activity is low. It was an unexpected feature that ketone and aldehyde were better co-catalysts than alcohol. When ketones are used, radicals may be formed by the elimination of α-hydrogen atoms, because benzophenone, which has no α-hydrogen atoms, shows no catalytic activity. As for aldehyde, radicals may be formed, at least partly, by the elimination of aldehyde-hydrogen atoms, because benzaldehyde does show catalytic activity.

Table 1. Polymerization in the presence of various co-catalysts

Co-catalyst	mol/*l*	Conversion %
Methyl alcohol	1.0	1.81
Ethyl alcohol	0.50	1.8
Ethyl alcohol	1.0	2.2
Ethyl alcohol	1.5	1.6
Cyclohexanone	0.50	8.4
Cyclohexanone	1.0	11.3
Cyclohexanone	1.5	13.4
Cyclohexanone	2.0	12.7
Diethyl ketone	1.0	10.2
Caproic aldehyde	0.50	8.35
Caproic aldehyde	1.0	9.14
Benzaldehyde	1.0	3.46
Acetophenone	1.0	12.3
Acetone	1.0	5.4
Methyl ethyl ketone	1.0	10.8
Benzophenone	0.50	0

Diethyl ether	1.0	0.33
—		0

CDBS: 4.43×10^{-3} mol/*l*
Styrene: 1.0 mol/*l*
Solvent: benzene

If the termination reaction is a combination of polymer radicals and if a steady state is assumed,

$$fk_i[Ce^{IV}\text{-complex}] - 2k_t[Mn\cdot]^2 = 0$$

the rate of polymerization can be expressed as follows:

1) S. Kaizerman, N. Plainfield and G. Mino, U. S. Pat. 2922801.
2) Y. Iwakura, T. Kurosaki and Y. Imai, *J. Polymer Sci.*, **A3**, 1185 (1965).
3) Y. Ogiwara, Y. Ogiwara and H. Kubota, Preprints for the 20th Annual Meeting of the Chemical Society of Japan (April, 1967), 4P213.

$$-d[M]/dt = k_p[Mn\cdot][M]$$
$$= k_p(fk_i/2k_t)^{1/2}[Ce^{IV}\text{-complex}]^{1/2}[M]$$

The rate of polymerization is proportional to the square root of the concentration of the Ce^{IV}-complex. If the termination reaction is the reaction of the polymer radical with the Ce^{IV}-complex and if a steady state is assumed,

$$fk_i[Ce^{IV}\text{-complex}] - k_t'[Mn\cdot][Ce^{IV}\text{-complex}] = 0$$

then

$$-d[M]/dt = fk_ik_p/k'_t[M]$$

Thus, the rate of polymerization is independent of the concentration of the Ce^{IV}-complex.

As shown in Fig. 1, when diethyl ketone or cyclohexanone was used, the rate of polymerization was proportional to the square root of the concentration of CDBS; therefore the termination reaction was a combination of polymer radicals: when ethyl alcohol was used, the rate of polymerization was independent of the concentration of CDBS; therefore, the termination reaction was a reaction of the polymer radical with CDBS.[2,4,5] When caproic aldehyde was used, the rate of polymerization increased with a decrease in the concentration of CDBS. This phenomenon may be interpreted in terms of the change in the dissociation constant of the complex of Ce^{IV} and aldehyde.

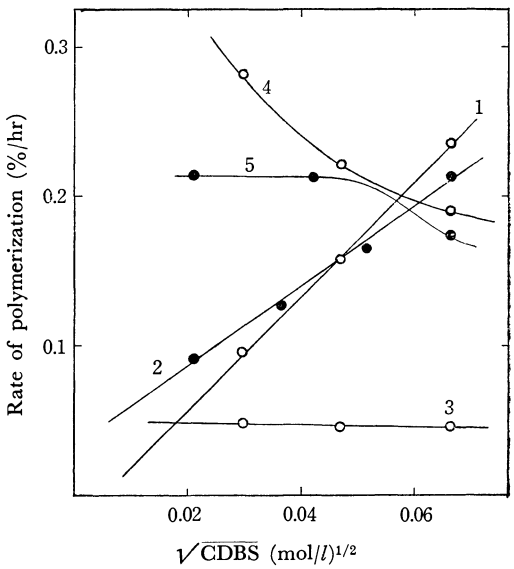

Fig. 1. Rate of polymerization *vs.* square root of the concentration of CDBS.
1 Cyclohexanone (1.0 mol/*l*)
2 Diethyl ketone (1.0 mol/*l*)
3 Ethyl alcohol (1.0 mol/*l*)
4 Caproic aldehyde (1.0 mol/*l*)
5 Caproic aldehyde (0.5 mol/*l*)

Further investigations are in progress on other organoceric compounds.

Self-heating of a Thermistor in Temperature Measurements

Satohiro TANAKA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received June 16, 1967)

The electrical resistances of a thermistor have found wide application as thermometric parameters. For this purpose, suitable resistance bridges are used to measure the resistance or unbalanced voltages of the bridges due to the variation in resistance accompanying a change in the ambient temperatures to be measured. Usually, the sensitivity of the bridge is improved as the bridge voltage is increased; however, this improvement encounters self-heating or rises in the temperature of the resistance thermometer element due to the dissipation of the electrical power produced in the element. At first, there is difference in temperatures between that of the thermometer element and the ambient medium. Secondly, a considerable deviation from the simple $\exp(b/T)$ law for thermistors is anticipated. For instance, Hutchinson and White[1] showed that, above a certain value of bridge voltage, unsatisfactory results were obtained in calorimetry. Therefore, it is necessary to clarify the effect before proceeding to precise measurements in thermometry.

If we assume a thermal equilibrium between the heat due to electrical power dissipation, W, produced in a thermistor element and the thermal leakage, which is proportional to the difference between the temperature, T, of the thermistor element and the ambient temperatures T_0 (Newton's law of cooling): then

1) W. P. Hutchinson and A. G. White, *J. Sci. Instrum.*, **32**, 309 (1955).

$$h(T - T_0) = W = V^2/R \quad (1)$$

where h is the heat transfer coefficient between the thermistor element and the ambient medium, R is the electrical resistance of the thermistor, and V is the voltage across the thermistor. Further, we assume a usual $\exp(b/T)$ temperature-variation law of the resistance:

$$R=A\exp(B/T), \quad (2)$$

where A and B are experimentally-determined constants. Then, from Eq. (1), the temperature, T, of the thermistor element is given by the equation:

$$T = T_0 + (V^2/hR), \quad (3)$$

and the temperature differences, ΔT, between the element and the ambient medium, by:

$$\Delta T = T - T_0 = V^2/hR. \quad (4)$$

By substituting the T from (3) into (2), one obtains:

$$R = A \exp\left\{B\Big/\left(T_0 + \frac{V^2}{hR}\right)\right\}. \quad (5)$$

If the temperature rise, ΔT, of the thermistor element due to electrical-heat dissipation is small compared to T_0 and T ($\Delta T \ll T_0$, T), Eq. (5) can be approximated as follows:

$$R = R_0 - \frac{BV^2}{hT_0^2}, \quad (6)$$

where R_0 is a extrapolated resistance value as $V\rightarrow 0$ on the straight portion of the plots in Fig. 1, an explanation of which will be given later.

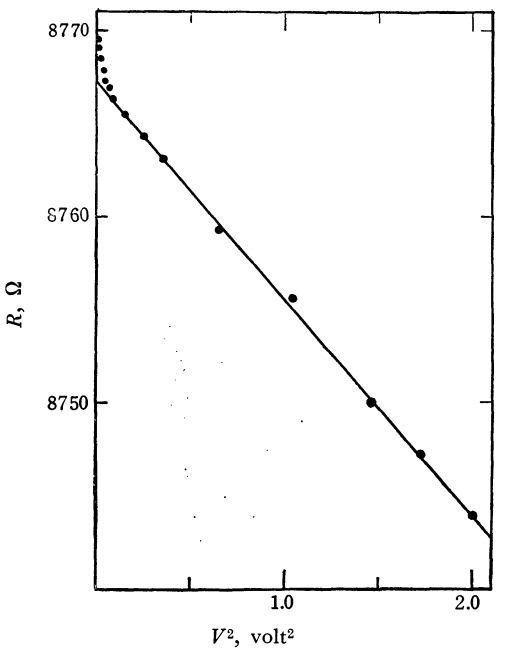

Fig. 1. Variation of electrical resistances with squares of voltage across thermistor at 25.00°C in water.

Experimental

Measurements were done on a bead-type OS41B-2 thermistor manufactured by Ōizumi Seisakusho, Ltd. The bead is coated with a skin film of glass to protect it. A d. c. Wheatstone bridge was used for the measurements of the resistance of the thermistor, and a National FM-5 primary cell was used for the power supply to the bridge. The thermistor was immersed in a thermostat held constant at ±0.002°C for extended periods of time. The signal from the bridge was amplified by a d. c. current amplifier (Ōkura AMl001B), the output of which was used to derive a recorder (Yokogawa LER-12). The bridge voltage was varied and measured by a conventional d. c. voltmeter. The measurements were carried out at 25, 35, 40, and 45°C.

Results and Discussion

The results of the measurements are shown in Fig. 1. This figure shows that Eq. (6) is valid except in low voltages across the thermistor. The slope of the plot in Fig. 1, together with the measurements of the variation in the resistance of the thermistor with the temperature, allows the constants A, B, and h to be approximately obtained; the values are:

$$A = 3.76\times 10^{-2}\ \Omega,$$
$$B = 3.69\times 10^{3}\text{°K} \quad (7)$$

and

$$h = 3.54\times 10^{-3}\ \text{W°K}^{-1},$$

where A and B are evaluated by assuming a simple relation, $R_0=A\exp(B/T)$, of the R values and h extrapolated from Eq. (6).

The effects of the variation in the voltage across the thermistor during temperature measurements are examined on this thermistor, the constants of which are given by (7) as follows:

1. The differences in temperature, ΔT, between that of the thermistor element and that of the ambient medium are evaluated from Eq. (4) as, for example, 7.05×10^{-3} ° (V=0.5 V) and 3.22×10^{-2} ° (V=1.0 V) on this thermistor.

2. The variation, ΔT, in the temperature of the thermistor due to the variation, ΔV, in voltage across the thermistor is given by:

$$\Delta T = (2V/hR)\Delta V \quad (8)$$

on the basis of Eq. (1). The variation in voltage must be maintained, if the variation in temperature should be kept less than ΔT, as follows:

$$(\Delta V/V)\times 100 < (hR/2V^2)\cdot\Delta T\times 100\%. \quad (9)$$

If the values of $\Delta T=10^{-5}$° and V=0.5 V are taken, Eq. (9) gives:

$$(\Delta V/V)\times 100 < 0.062\% \quad (10)$$

on the above-mentioned thermistor.

3. Let us now determine the errors in the temperature measurements caused by the self-heating of thermistor, if the simple $\exp(b/T)$ law of the thermistor is used. For this purpose, some numerical calculations were carried out on a model thermistor; in these calculations Eq. (5) was assumed to be valid, and the A, B and h constants were given by Eq. (7). Now let us see the temperature differences, δT, between the temperature, $T°$, obtained by using a simple $R=a\exp(b/T)$ law for this thermistor and that, T, given by Eqs. (5) and (7). The a and b constants can be determined by $R=a\exp(b/T)$ if the resistances are given as $R_1=10500\ \Omega$ and $R_2=7000\ \Omega$, and corresponding temperatures as T_1 and T_2 by Eq. (5), substituting the resistance values, R_1 and R_2. Then, using these values of a and b, the temperature, $T°$, is calculated for an arbitrary resistance, R, and for temperature differences, δT, between the $T°$ and T values given by Eqs. (5) and (7) for the same resistance, R. Figure 2 shows the temperature differences, $\delta T=T°-T$, thus calculated for various values of voltage, V, across the thermistor. Deviations from the true values of the temperature increase with the voltage across a thermistor, as shown in Fig. 2, if a thermistor whose calibration has been carried out at about 20 and 30°C using

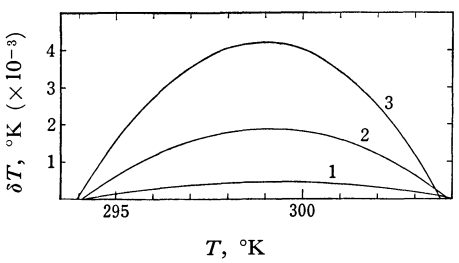

Fig. 2. Temperature differences $\delta T=T°-T$. T are given by Eqs. (5) and (7). $T°$ are calculated using relation $R=a\exp(b/T)$. Voltage V across the thermistor are $1V$ (1), $2V$ (2) and $3\,V$ (3).

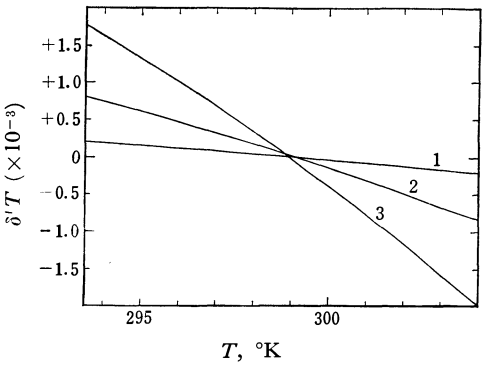

Fig. 3. First derivatives $\delta' T$ of δT with respect to T. $\delta' T$ are thought to be errors in measurements of temperature variations. Voltage V across the thermistor are $1V$ (1), $2V$ (2) and $3V$ (3).

$R=a\exp(b/T)$ is used to measure an absolute temperature between about 20 and 30°C.

A thermistor is generally used to measure temperature variations rather than absolute temperatures. Therefore, errors in the measurement of temperature variations should be examined. These errors may be defined as first derivatives, $\delta' T$, of δT with respect to T; they are shown in Fig. 3 for various voltages, V. Figures 2 and 3 also show an upper-limit value of voltage across the thermistor, a value which must not be exceeded for a desired degree of precision in the measurement of absolute temperatures and temperature variations when a simple $\exp(b/T)$ law is used.

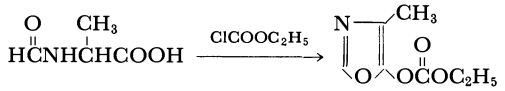
Synthesis of Pyridoxine. I. Synthesis of 4-Methyl-5-ethoxycarbonyloxyoxazole

Masuo MURAKAMI and Masaru IWANAMI

Central Research Laboratory, Yamanouchi Pharmaceutical Co., Ltd., Azusawa-cho, Itabashi-ku, Tokyo

(Receved June 16, 1967)

Recently, Firestone *et al.*[1] reported the synthesis of pyridoxine by the Diels-Alder reaction of 4-methyl-5-alkyoxyoxazole with various dienophiles followed by acid treatment and reduction. They prepared the oxazoles from alanine through three steps, but the yield of the last step was very low.[2] In the present paper, We describe an efficient synthetic method of 4-methyl-5-ethoxycarbonyl-oxyoxazole (I) as well as its Diels-Alder reaction.

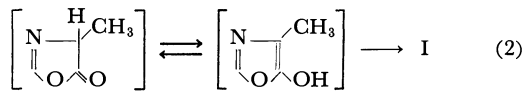


(I)

(1)

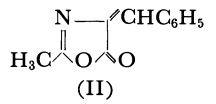
Compound I was obtained in 80% yield by treatment of *N*-formylalanine (1 mol) with ethyl chlorocarbonate (2 mol) in the presence of triethylamine at −10——20°C. The structure of I was confirmed by the elemental analysis and the spectral data.

A synthetic method of oxazole by the reaction of acylamino acid with ethyl chlorocarbonate has never been reported, except the report on the synthesis of 2-methyl-4-benzal-5-oxazolone (II) by the reaction of α-acetoaminocinnamic acid (III) with ethyl chlorocarbonate.[3] This result suggests that 4-methyl-5-oxazolone (IV) was intermediately formed and its enolized form, 4-methyl-5-hydroxyoxazole (V), further reacted with ethyl chlorocarbonate to form I.

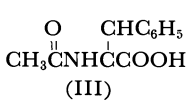


(IV) (V)

(2)

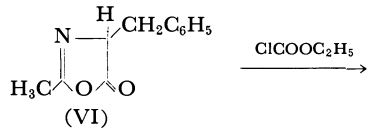


(II)

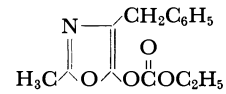


(III)

Although, IV could not be isolated, this mechanism may be supported by the following fact: 2-methyl-4-benzyl-5-oxazolone (VI)[4] was converted into 2-methyl-4-benzyl-5-ethoxycarbonyloxy-oxazole (VII) by treatment with ethyl chloro-carbonate under the same conditions.



(VI)



(VII)

(3)

As 4-methyl-5-alkoxyoxazole, I underwent the Diels-Alder reaction with various dienophiles. The resulting adducts were converted into pyridine derivatives on acid treatment: *e. g.*, by reaction with diethyl maleate, dimethyl thiofumarate or maleimide, I gave 2-methyl-3-hydroxy-4, 5-disubstituted pyridines. These pyridines were converted into pyridoxine by reduction. The reaction of I with maleic anhydride gave ethyl 2-methyl-3-hydroxypyridine-5-carboxylate accompanying with decarboxylation. But that of I with fumaronitrile in acetic acid produced 2-methyl-3-hydroxy-4, 5-dicyanopyridine, which was converted into pyridoxine by reduction.

Experimental

4-Methyl-5-ethoxycarbonyloxyoxazole (I). To a suspention of 10 g of formylalanine in 50 m*l* of chloroform, 18 g of triethylamine was added. The solution was cooled at −10——20°C. To the solution, 18.8 g of ethyl chlorocarbonate was added drop by drop at −10——20°C under stirring. After being kept for 2 hr at the same temperature, the reaction mixture was washed succesively with water, 1% hydrochloric acid and water, and dried over anhydrous magnesium sulfate. The solvent was removed from the reaction mixture to give an oily residue, which was distilled under reduced pressure to give 11.8 g of I, bp 80—82°C/5—6 mmHg, λ_{max} 1780 cm^{-1} (carbonic ester $\nu_{C=O}$), τ ($CDCl_3$): 8.60 (3H, triplet), 7.85 (3H, singlet), 5.70 (2H, quartet), and 2.39 (1H, singlet).

Found: C, 49.08; H, 5.47; N, 8.46%. Calcd for

$C_6H_9NO_4$: C, 49.12; H, 5.30; N, 8.18%.

Similarly, VII (170—171°C/7 mmHg, yield 6.2 g) was obtained from the reaction of VI[4] (6.1 g) with ethyl chlorocarbonate (3.1 g) in the presence of triethylamine (2.9 g).

Found: C, 64.44; H, 5.67; N, 5.31%. Calcd for $C_{13}H_{13}NO_4$: C, 64.36; H, 5.79; N, 5.36%.

The Reaction with Diethyl Maleate, Diethyl Fumalate or Dimethyl Thiofumarate. A mixture of 0.85 g of I and 1.7 g of diethyl maleate was heated at 120°C for 6 hr. After cooling, 20 m*l* of ethyl alcohol and 1 m*l* of 5 N ethanolic hydrochloric acid were added to the solution. The substance, which was obtained by evaporation of ethanol from the reaction mixture, was recrystallized from acetone to give 1.2 g of 2-methyl-3-hydroxy-4, 5-diethoxy carbonylpyridine, mp 149°C. It was identified with an authentic sample[5] by the mixed melting point.

Similarly, I reacted with diethyl fumarate to give 60% of 2-methyl-3-hydroxy-4, 5-diethoxycarbonylpyridine, and with dimethyl thiofumarate to give 1.2 g of 2-methyl-3-hydroxy-4, 5-dicarboxylic acid methyl thioester hydrochloride, mp 210—212°C.

Found: C, 40.53; H, 4.29; N, 4.79%. Calcd for $C_{10}H_{11}NO_3S_2$: C, 40.88; H, 4.12; N, 4.77%.

The Reaction with Maleic Anhydride. A solution of 1.7 g of I and 1.2 g of maleic anhydride in 20 m*l* of benzene was heated under refluxed for 30 min. After cooling, 2 m*l* of 5 N ethanolic hydrochloric acid was added to the solution. The solvent was evaporated at reduced pressure. The oily residue was dissolved in water and extracted with ether. After drying over anhydrous magnesium sulfate, the ether was removed. The residue was recrystallized from ethyl acetate to give 0.8 g of 2-methyl-3-hydroxy-5-ethoxycarbonylpyridine, mp 205—207°C.

Found: C, 59.65; H, 6.00; N, 7.25%. Calcd for $C_9H_{11}NO_3$: C, 59.70; H, 6.08; N, 7.44%.

5) E. E. Harris and R. A. Firestone, *J. Org. Chem.*, **27**, 2075 (1962).

The Reaction with Maleimide. A solution of 2.0 g of I and 1.0 g of maleimide in benzene was heated under reflux for 4 hr. The solvent was removed under reduced pressure. The residue was recrystallized from ethyl acetate to give 1.8 g of 2-methyl-3-hydroxypyridine-4, 5-dicarboximide, mp 250—252°C.

Found: C, 53.93; H, 3.49; N, 15.50%. Calcd for $C_8H_5NO_3$: C, 53.93; H, 3.40; N, 15.73%.

The Reaction with Fumaronitrile. A mixture of 1.0 g of I and 2.0 g of fumaronitrile was dissolved in 4 m*l* of acetic acid in a sealed tube. After heating at 140°C for 3 hr, the solvent was removed from the reaction mixture to give an oily residue, which was taken up in ether. The ethereal layer was dried over anhydrous magnesium sulfate and the ether was evaporated to give 0.6 g of 2-methyl-3-hydroxy-4, 5-dicyanopyridine, mp 189—191°C. It was identified with an authentic sample[5] by the IR spectra and the mixed melting point.

2-Methyl-3-hydroxy-4, 5-diaminomethylpyridine Trihydrochloride. A mixture of 1.3 g of 2-methyl-3-hydroxy-4, 5-dicyanopyridine and 1.0 g of palladium charchoal (1 : 10) was suspended in 100 m*l* of methanol. The reduction was carried out for 6 hr under hydrogen of the atomospheric pressure at room temperature. After absorption of 4 mol of H_2 was over, the catalyst was filtered off and 1 m*l* of 5 N methanolic hydrochloric acid was added to the filtrate. The solvent was removed from the reaction mixture to give 1.7 g of 2-methyl-3-hydroxy-4, 5-diaminomethylpyridine trihydrochloride, mp 296°C dec. (lit., 296°C dec.)[5] It was identified with an authentic sample by the IR spectra.

Pyridoxine Hydrochloride. To a solution of 4.9 g of 2-methyl-3-hydroxy-4, 5-diaminomethylpyridine trihydrochloride dissolved in 80 m*l* of 2 N hydrochloric acid, 1.7 g of sodium nitrite in 10 m*l* of water was added in small portions at room temperature. After stirring for 4 hr, the solvent was evaporated *in vacuo* below 40°C. Pyridoxine hydrochloride was obtained from the residue by recrystallization from dilute ethanol, mp 206—208°C. It was identified with an authentic sample by the mixed melting point and IR spectra.

Hydrogenation, Hydrogenolysis, or Isomerization of Dienes and Monoenes Catalyzed by the Nickel Cyanide Complex

Taiichi MIZUTA, Hiroshi SAMEJIMA and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Tokyo

(Received June 28, 1967)

The hydrogenation, hydrogenolysis, and isomerization of allene, butadiene, isoprene, butene, and some of their derivatives were studied in an aqueous solution containing the nickel cyanide complex and excess sodium borohydride. The catalytic behavior of the nickel cyanide complex appeared to be somewhat different from that of the cobalt cyanide complex reported on in previous works.[1-5]

The catalyst formation was as follows. A tetracyanonickelate(II) complex, $Ni(CN)_4^{2-}$, dissolved in an aqueous solution gave a homogeneous red solution, accompanied by the evolution of hydrogen

gas when excess sodium borohydride was added. The UV absorption peaks shifted from 268 and 285 mμ to 318 and 475 mμ. A red crystalline compound was isolated and subjected to the IR absorption measurement. The spectra appeared to agree entirely with that reported by El-Sayed and Sheline,[6] who studied the IR spectrum and the structure of the hexacyanodinickelate (I) complex, $K_4[Ni_2(CN)_6]$. The addition of allene, butadiene, or isoprene made the color of the solution change from red to yellow. The UV absorption measurements showed maxima at 303 mμ (allene), 315 mμ (butadiene), and 302 mμ (isoprene).

The apparatus and procedure for the measurement of the reaction were almost the same as those reported previously.[3,5] The reaction took place rapidly and was completed within ten to thirty minutes, depending on the kind of substrates at 0°C, when the amount of the substrate was not greater than that of the complex. The products were usually collected after thirty minutes' contact and were analyzed by gas chromatography. Their compositions are shown in Table 1, where the substrates investigated are listed in the first column.

As is shown in Table 1, isoprene gave three olefins, with no paraffin, just as in the case of the cobalt cyanide complex with a CN/Co molar ratio of less than five.[4] Butadiene and butenyl derivatives also gave rise to three olefin isomers. Table 1 shows also that the reductive elimination of a substituted group, such as halogen or hydroxyl, takes place. In this connection it is of interest to note that the distribution of the three isomers produced is sensitive to the kind and the position of the substituted group.

Allene and allyl derivatives gave both propane and propylene, proving that the nickel cyanide complex is active in both hydrogenation and hydrogenolysis. As has already been reported,[3] the cobalt cyanide complex yielded propylene exclusively from allyl halides. Again, the selective formation of propane and propylene appeared to depend on the kind of substituted group; that is, both allyl alcohol and allyl amine gave more propylene than allyl halides. It should be mentioned that the rate of the reaction is faster with allyl halides than with allyl alcohol or amine.

When 1-butene or *cis*-2-butene was introduced,

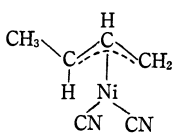
60	60	1	38	1
120	55	2	41	2
180	53	2	43	2

the isomerization of the butene took place, and a small amount of *n*-butane was formed. The results are shown in Tables 2 and 3. The isomerization of butenes was not detectable with the cobalt cyanide complex.[3] It can be seen from Tables 2 and 3 that *trans*-2-butene, thermodynamically most stable, surpasses the other isomer during the course of the reaction. The rate of the isomerization seems much slower than that of the hydrogenation of butadiene, but faster than the rate of formation of butane.

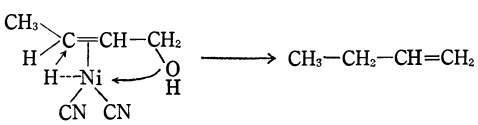
Let us now discuss some of the results. The hydrogenation of acetylene or butadiene in the presence of the nickel cyanide complex and sodium amalgam has been reported briefly.[7,8] Little is known, however, about the mechanism of the reaction. We have already shown[4] that isoprene is hydrogenated almost exclusively to 2-methyl-2-butene by the cobalt cyanide complex only when the CN/Co molar ratio is kept below five. In other words, two-site coordination[9] is necessary for isoprene to be hydrogenated to 2-methyl-2-butene.

The hydrogenation of isoprene and butadiene by sodium borohydride in the present case yielded 2-methyl-2-butene and *trans*-2-butene, respectively, as the major products. Therefore, it seems reasonable to assume that the same sort of interaction is operative between dienes and the nickel cyanide complex. Thus, it is tentatively suggested that the nickel cyanide complex forms a π-allyl type of intermediate, such as:



The addition of a hydrogen atom to the less hindered terminal methylene may produce *trans*-2-butene, although it is not certain whether the hydrogen atom comes directly from sodium borohydride or from nickel hydride.

It is of interest to note that butenyl chloride and butenyl alcohol react at different rates and give different distributions of the butene isomers produced. The difference can probably be explained as follows. Butenyl chloride loses its chlorine atom easily and gives a π-allyl type intermediate, for it gave almost the same distribution of the olefins formed as did butadiene. On the other hand, butenyl alcohol may form a π-type intermediate complex without losing its hydroxyl group.



If the hydrogen atom attacks the γ-carbon of the intermediate, followed by the elimination of the hydroxyl group, 1-butene may be expected to form mainly, as was the case. The dominant formation of *trans*-2-butene from CH_3-CH(OH)-CH=CH_2 can also be explained if a similar sort of mechanism is assumed.

Cyclizations of Acetylene Derivatives with Tri-β-styrylchromium*[1]

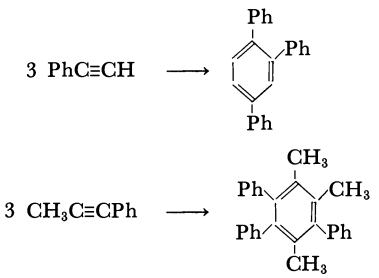
Masao SATO and Yasumasa ISHIDA

Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 13, 1967)

It is known that triorganochromium compounds are decomposed rapidly by either the acidic hydrogen of acetylene or monosubstituted acetylenes to give no cyclization product,[1] and that those materials cyclize disubstituted acetylenes to give two types of products,[1-3] hexasubstituted benzene derivatives and condensed products in which two molecules of the acetylene are combined with one of the groups attached to chromium by hydrogen abstraction. In these reactions, an unsym-disubstituted acetylene derivative has not been used as the acetylene derivative.

In cyclizations with tri-β-styrylchromium, 1, 2, 4-triphenylbenzene was obtained from phenylacetylene, *i. e.*, monosubstituted acetylene. Moreover, 1, 2, 4-trimethyl-3, 5, 6-triphenylbenzene was produced, with no 1, 3, 5-trimethyl-2, 4, 6-triphenylbenzene, from methylphenylacetylene, *i. e.*, unsym-disubstituted acetylene. In these reactions no condensed product was obtained.



It seems that the tri-β-styrylchromium compound is stabilized by a great conjugated system of the styryl group to be stabilized against the acidic hydrogen of phenylacetylene.

The reason why 1, 2, 4-triphenylbenzene is produced from phenylacetylene, while 1, 2, 4-trimethyl-3, 5, 6-triphenylbenzene is produced from methylphenylacetylene, is probably as follows: two molecules of the acetylene derivative approach a chromium compound along the direction of less resistance, forming a 1, 4-disubstituted cyclobutadiene complex or a 1, 4-disubstituted butadiene biradical, and then the third acetylene molecule reacts with the complex or the biradical formed above to produce a 1, 2, 4-trisubstituted benzene derivative.

Experimental

Cyclization of Phenylacetylene with Tri-β-styrylchromium. A tetrahydrofuran solution of β-styrylmagnesium bromide (63 m*l*, 40.4 mmol) was added, under nitrogen at −75°C, to 5.0 g (13.3 mmol) of chromium trichloride tristetrahydrofuranate[4] suspended in 200 m*l* of tetrahydrofuran. This solution changed rapidly from deep purple to brown. After the mixture had been stirred for 1 hr at −75°C, 4.4 m*l* (40.4 mmol) of phenylacetylene were added to the solution obtained above. The reaction mixture was allowed to warm to 20°C over a 2 hr period and then refluxed for 6 hr. After the solvent had been evaporated *in vacuo*, the residue was hydrolyzed with ice water and the organic products were extracted with benzene. The brownish residue obtained from the benzene solution was dissolved in a minimum amount of benzene and chromatographed on 80 g of activated alumina. Elution with 150 m*l* of *n*-hexane gave 2.6 g of a white crystalline material. The recrystallization of this material from *n*-hexane gave 1, 2, 4-triphenylbenzene melting at 120°C (lit.[5] mp 119—120°C). The present sample was identical in all respects with an authentic sample.

Found: C, 93.65; H, 6.32%. Calcd for $C_{24}H_{18}$: C, 94.12; H, 5.88%. Further elution with 150 m*l* of *n*-hexane gave 2.1 g of 1t, 4t-diphenylbutadiene-(1, 3) melting at 152.5°C (lit.[6] mp 152°C).

Found: C, 92.84; H, 7.12%. Calcd for $C_{16}H_{14}$: C, 93.15; H, 6.85%. Finally, elution with 300 m*l* of benzene gave intractable tars which were not investigated further.

Cyclization of Methylphenylacetylene with Tri-β-styrylchromium. A tetrahydrofuran solution of β-styrylmagnesium bromide (94 m*l*, 60.4 mmol) was added, under nitrogen at −75°C, to 7.5 g (20 mmol) of chromium trichloride tristetrahydrofuranate suspended in 250 m*l* of tetrahydrofuran. After the mixture had been stirred for 1 hr at −75°C, 22 m*l* (180 mmol) of methylphenylacetylene were added to the solution. This reaction mixture was allowed to warm to 20°C over a 2-hr period and then refluxed for 6 hr. Then, the tetrahydrofuran and the unreacted methylphenylacetylene were evaporated *in vacuo*. The residue was hydrolyzed with ice water, and the organic products

*1 The essence of this paper was presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.

were extracted with benzene. The brownish residue obtained from the benzene solution gave, by chromatography on activated alumina, 1.8 g of 1t, 4t-diphenylbutadiene-(1, 3) and 7.1 g of white crystalline of 1, 2, 4-trimethyl-3, 5, 6-triphenylbenzene melting at 224°C (lit.[7] mp 225—227°C).

Found: C, 93.10; H, 6.85%. Calcd for $C_{27}H_{24}$: C, 93.06; H, 6.94%. The remainder was intractable tars which were not investigated further.

Cyclization of Diphenylacetylene with Tri-β-styrylchromium. A tetrahydrofuran solution of β-styrylmagnesium bromide (118 m*l*, 60.7 mmol) was added to 7.5 g (20 mmol) of chromium trichloride tristetrahydrofuranate and 3.6 g (20 mmol) of diphenylacetylene in 250 m*l* of tetrahydrofuran under nitrogen at −75°C. After it had been stirred for 1 hr at −75°C, the reaction mixture was allowed to warm to 20°C over a 2 hr period and then refluxed for 15 hr. After the solvent had been evaporated *in vacuo*, the residue was hydrolyzed with ice water and the organic products were extracted with benzene. The brownish residue obtained from the benzene solution gave, by chromatography on activated alumina, 1.77 g of 1t, 4t-diphenylbutadiene-(1, 3) and 3.10 g of white crystalline of hexaphenylbenzene melting at 415°C (lit.[3] mp 408—415°C). The present sample was identical in all respects with an authentic sample.

Found: C, 93.94; H, 5.80%; mol wt, 520 (osmotic pressure in benzene). Calcd for $C_{42}H_{30}$: C, 94.38; H, 5.62%; mol wt, 534.

Raman Spectra of DNA in Aqueous Solution

Koichi HIRANO

Department of Natural Sciences, Faculty of Education, Tohoku University, Kawa-uchi, Sendai

(Received July 21, 1967)

The infrared absorption spectra of DNA and polynucleotide have been studied by several workers,[1-3] but little work has been reported on the Raman spectra of an aqueous solution of DNA. In this note the author will report on the Raman spectra of an aqueous solution of DNA.

The calf-thymus DNA was purchased from the Sigma Chemical Co. The concentrations used were *ca.* 2 mg/25 m*l* tris buffer solution at pH=7.4. In order to cancel out the background due to the solvent molecules, tris buffer solutions were used as the reference substances. Before measurement the solutions were centrifuged at 1×10^4 g for 60 min. All the measurements were made at room temperature. The excitation wavelengths were in the vicinity of 260 mμ and of 400 mμ. A slightly-modified Hitachi photoelectric spectrofluorometer was used for both the selection of the excitation ray and the analysis of the scattering spectrum. No fluorescence was observed in these measurements. To obtain the Raman spectra, the correction for Rayleigh scattering was made by the use of Eq. (1)[4,5]:

$$\left.\begin{aligned} &I_{\theta=(\pi/2)}(\lambda) = \\ &\left\{\frac{2\pi^2n_0^2}{Nr^2\lambda^4}\right\}\left(\frac{dn}{dc}\right)^2 CM^2 2/z^2\{z-1+e^{-z}\}I_0(\lambda) \\ &z = 2/3\left\{\frac{2\pi Rn_0}{\lambda}\right\}^2 \sin^2\left(\frac{\pi}{4}\right) \end{aligned}\right\} \quad (1)$$

where $I_{\theta=(\pi/2)}(\lambda)$ is the relative intensity of the Rayleigh scattering in the direction of $\theta=\pi/2$; $I_0(\lambda)$ the relative intensity of the incident ray; λ, the wavelength; r, the constant determined from the instrument; N, the Avogadro number; c, the concentration of the sample solution (g/m*l*); M, the molecular weight; R, the end-to-end distance of the random-coiling DNA,[6] and n_0 and n, the refractive indices of the solvent and of the solution, respectively.

The corrected scattering spectrum of DNA

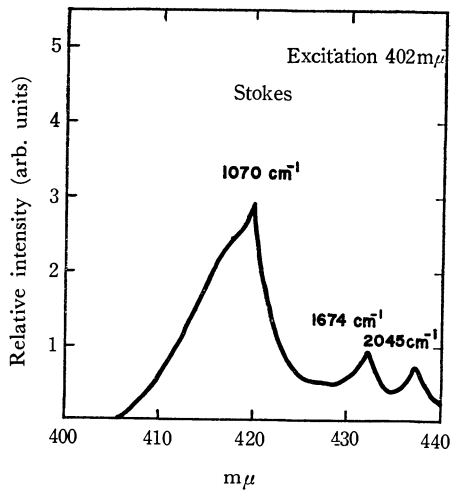

Fig. 2. Raman spectrum of DNA solution.

excited at 260 mμ is illustrated in Fig. 1, in which four frequencies, $\tilde{\nu}_1 \simeq 908\ cm^{-1}$, $\tilde{\nu}_2 \simeq 1079\ cm^{-1}$, $\tilde{\nu}_3 \simeq 1697\ cm^{-1}$ and $\tilde{\nu}_4 \simeq 2230\ cm^{-1}$, are characteristic. In Fig. 2 a similar spectrum excited at 402 mμ is displayed. From the figure it is obvious that three frequencies, $\tilde{\nu}_2 \simeq 1070\ cm^{-1}$, $\tilde{\nu}_3 \simeq 1674\ cm^{-1}$ and $\tilde{\nu}_4 \simeq 2045\ cm^{-1}$, are very similar to those of Fig. 1. These facts lead us to the conclusion that the corrected scattering spectra presented here are the Raman spectra of DNA in solution. That the anti-Stokes line, $\tilde{\nu}_1 \simeq 908\ cm^{-1}$, was not observed in the spectra may be attributed to the error arising from the correction of Rayleigh scattering, because the spectral intensity of the scattering ray deviates from the Gaussian distribution. On the basis of these results, the Raman frequencies of DNA in a tris buffer solution were estimated to be as shown in Table 1. The assignment of the frequencies listed in Table 1 based on the data of the infrared spectra of the purine base,[7] poly-A, DNA,[8,9] and on the Raman spectra of dimethyl phosphate anions.[10]

Table 1. Raman frequencies of DNA in an aqueous solution

	Frequency, cm^{-1}	Assignment
$\tilde{\nu}_1$	908	Sym. [OPO] stretching
$\tilde{\nu}_2$	1070—1079	Sym. $[PO_2]^{-1}$ stretching
$\tilde{\nu}_3$	1674—1697	C=C, C=N stretching in the purine ring
$\tilde{\nu}_4$	2045—2230	?

The Raman frequencies listed in Table 1 correspond well to the infrared absorption maxima of poly-A or DNA.[2] On the contrary, the chart produced by the commercial Raman spectrophotometer did not give any significant frequencies for these solutions. Therefore, the measurement of the Raman scattering described here would be a very useful tool for the study of macrobiomolecules in solution.

(Received August 8, 1967)

Following the work of Adam and Weissman[1] and Atherton and Weissman,[2] a number of ESR investigations of radical anion-alkali metal ion pairs have been reported. In the pioneering work of Atherton and Weissman, they suggested that in naphthalene-alkali metal ion pairs the equilibrium position of the alkali ion was situated above the nodal plane of the lowest antibonding molecular orbital of naphthalene, *i. e.*, above the 9—10 bond; they suggested this on the basis of an examination of the temperature dependence of the alkali metal hyperfine splittings. Although they found no variation in the proton-coupling constants on the formation of the ion pair, thereafter a few examples showing a variation in the proton coupling

TABLE 1. THE COUPLING CONSTANTS OF THE NAPHTHALENE RADICAL ANION*

Solvent	Cation	Proton coupling constant (in gauss)		Metal coupling constant (in gauss)
		a_α	a_β	a_M
Dioxane	Li	4.792	1.788	1.213
Dioxane	Na	4.871	1.857	1.295
Dioxane	K	4.861	1.837	—
DMF	Li, Na, K	4.906	1.812	—

* the values at 24°C.

TABLE 2. THE EFFECT OF CATIONS ON THE PROTON COUPLING CONSTANTS

	Observation (in gauss)*1			Calculation (in gauss)	
	$Naph^-$-Li^+	$Naph^-$-Na^+	$Naph^-$-K^+	Model A*2	Model B*3
a_α	−0.114	−0.035	−0.045	−0.176	−0.349
a_β	−0.024	+0.045	+0.025	+0.205	+0.003

*1 The values were obtained by taking the difference between the proton coupling constants observed in dioxane and in DMF; $a_{diox.}-a_{DMF}$.

*2 The cation was assumed to be above the center of the molecular plane of the radical anion and at a distance of 3.5 Å from it.

*3 The cation was assumed to be hopping rapidly from the position above the center of the one benzene ring to that of the other benzene ring. The distance between the two ions was taken to be 2.8 Å.

constants with alkali ions have been reported.[3] In this paper we wish to report the effect of the ion pair formation on the proton-coupling constants observed for the naphthalene-alkali ion system in dioxane. As is well known, dioxane is a good solvent for the formation of ion pairs; we could observe significant changes in the proton-coupling constants, changes attributable to the effect of the alkali ion in the solvent. Through an examination of these data in terms of the MO method, we will estimate the structure of the ion pairs.

Table 1 gives the observed proton-coupling constants of the naphthalene radical anion in dioxane, together with the data observed in dimethylformamide (DMF). As the table shows, in dioxane the proton-coupling constants varied significantly with the alkali ions, while no variation was observed in DMF. In DMF, the radical anions showed no alkali metal hyperfine splittings, either. The negligible cation effect on the proton-coupling constants and the lack of the alkali metal coupling constant suggest that the radical anion may exist as a "free" anion, or as "a weak ion pair" (a solvent-separated ion pair) in which the radical anion is scarcely perturbed at all by the cation. Hence, one may estimate the effect of the formation of the ion pair on the proton-coupling constants by taking the difference between the proton-coupling constants observed in dioxane and in DMF. Table 2 shows the difference between the coupling constants observed in these two solvents. It shows that the proton-coupling constant at the α position may decrease on the formation of the ion pair with a sodium or potassium ion, while that at the β position may increase. Interestingly, however, on the formation of the ion pair with a lithium ion, the proton-coupling constants at both the α and β positions decrease, the coupling constant at the α position more extensively than is the case for the ion pair with sodium or potassium ion, while that at the β position does so only slightly.

To account for these observations and to obtain information on the structure of the ion pairs, we examined the interaction between the two ions in terms of the MO method. The details of the method used for the calculations have been described in a previous paper.[3b] For the present paper the proton-coupling constants were calculated from the spin densities using Colpa and Bolton's relation.[4]

In the naphthalene-alkali metal ion pairs, the most plausible structure for the ion pairs may be that in which the equilibrium position of the alkali ion is just above the center of the molecular plane of the radical anion. As is shown in Fig. 1, the MO calculation admittedly suggests that such an ion-pair structure may be most likely when the distance between the two ions is larger than about 3.5 Å.

4) J. P. Colpa and J. R. Bolton, *Mol. Phys.*, **6**, 273 (1963).

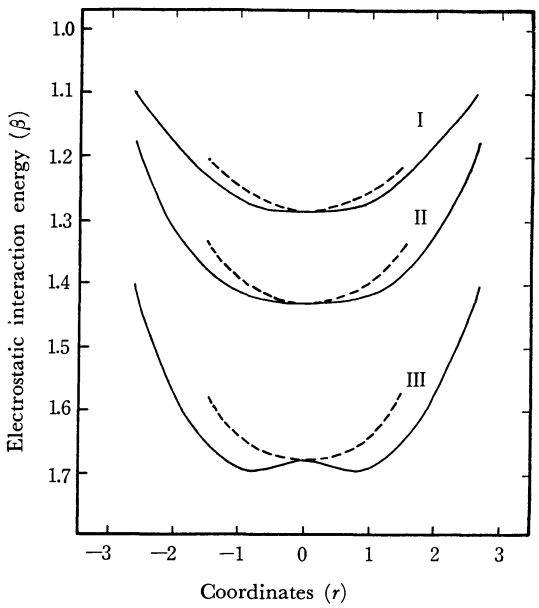

Fig. 1. Electrostatic interaction within Naphthalene-alkali metal ion-pair.
The origin of the coordinates is taken at the center of the anion molecule. Solid lines correspond to x coordinate (long axis) and dotted lines to y coordinate (short axis). The coordinates are in unit of r, a C–C bond length (1.39 Å). The distance between the two ions is taken as I: 4.0 Å, II: 3.5 Å and III: 2.8 Å, respectively.

Then, we attempted to calculate the proton-coupling constants in the presence of the cation, assuming that the alkali ion is placed just above the center of the molecular plane and at a distance of 3.5 Å from it. The results are shown in Table 2 (model A). As the table shows, the qualitative behavior of the calculations is in good agreement with the observation for the ion pairs with sodium and potassium ions rather than for the ion pair with a lithium ion; *i. e.*, the calculation predicts well the decrease in the α proton-coupling constant and the increase in the β proton-coupling constant.

As has been noticed above, the ion pair with a lithium ion shows a different behavior in the proton-coupling constants from in the cases of the ion pairs with sodium and potassium ions. This fact may imply that the structure of the ion pair is somewhat different from those of the ion pairs with a sodium or potassium ion. As it is, one may notice that in Fig. 1 the double minima occur well in the potential as the distance between the two ions becomes shorter. Since the lithium ion can approach the molecular plane more closely, it may be expected that with the lithium ion we can see a potential with double minima. Therefore, the calculation for the proton-coupling constant was attempted on the assumptions that the equilibrium position of the alkali ion is above the center of the benzene ring and that the alkali ion migrates rapidly back and forth between the two equilibrium positions above the anion molecule, so as to average the coupling constants of the protons at positions symmetrical to the short axis of the molecule. As Table 2 (model B) shows, the calculation predicts well the qualitative change in the effect of the cation upon going from the ion pair with a sodium or potassium ion to that with a lithium ion. Although the changes in the proton-coupling constants calculated are rather large compared to the observed ones, considering the nature of the calculation the results of the calculation are rather satisfactory. Therefore, one may conclude that the most likely structure of the naphthalene-sodium or -potassium ion pair in dioxane is that in which the equilibrium position of the alkali ion is situated above the center of the molecular plane of the naphthalene radical anion, while in the case of the ion pair with a lithium ion in dioxane the equilibrium position of the lithium ion may be rather above the benzene ring and the lithium ion may migrate between the two equilibrium positions.

In the case of the naphthalene-potassium system in dioxane, no potassium hyperfine splitting was observed. However, in view of the fact that the proton-coupling constants are affected by the potassium ion in a way similar to the case of the sodium ion, an ion pair must be formed. The lack of a splitting from the potassium ion is probably due to the small magnetogyric ratio of ^{39}K.

Recently, Smid *et al.*[5] reported that the naphthalene sodium metal ion pair in dioxane must be a contact ion pair. Our conclusion regarding the ion pair with a lithium ion may suggest that the naphthalene-lithium metal ion pair is also a contact ion pair in dioxane.

The numerical calculations were carried out on the NEAC 2230 at the Computer Center, Tohoku University.

The authors wish to express their appreciation to Miss Akie Sakai for her help throughout this work.

On the Formation of Benzonitrile from Benzaldehyde and Ammonia. III. A Role of the Existing Base[1,2]

Akira MISONO, Tetsuo OSA and Seiichiro KODA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received August 15, 1967)

In the preceding paper,[1] the authors reported on the mechanism of the oxidative formation of benzonitrile from benzaldehyde and ammonia in a methanol solution with oxygen catalyzed by some copper compounds. It was assumed that the aldehyde and ammonia reacted to produce benzilideneimine, from which was produced the corresponding nitrile oxidatively. Though it was observed that the basicity played an important role in the oxidation step, its exact role remained ambiguous to be made clear in this paper. The rates of the formation of benzonitrile against various concentrations of cupric chloride as a main catalyst with the concentration of sodium hydroxide being kept constant were observed and are shown in Fig. 1. The reaction rates were almost independent on the concentration of cupric chloride in the region where the concentration of cupric chloride was over a certain limit. From the consideration of this result and of the experimental results reported in the preceding paper,[1] such as

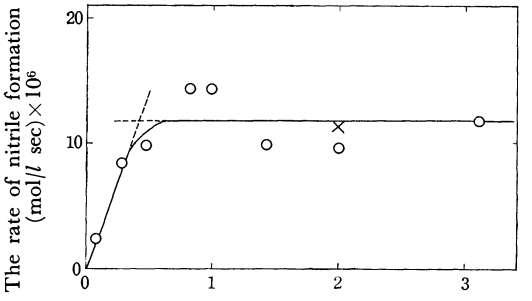

Fig. 1. The dependence of the reaction rate on the concentration of cupric chloride.
Initial conditions:

$CuCl_2$	0.095—3.11 mmol
NaOH	3.00 mmol
NH_3	103 mmol
Benzaldehyde	30 mmol
Solvent ($+NH_3$)	100 ml
Reaction temperature	29.5±0.2°C

×: the corrected value from the datum in the preceding paper[1] according to the equation;

$$\text{the rate} \propto \frac{[NH_3][\text{benzaldehyde}]}{([NH_3]+[\text{Benzaldehyde}])}$$

the first-order dependence of the reaction rate upon the concentration of cupric hydroxide as the catalyst (the basicity of the system may be proportional to the concentation of cupric hydroxide), the linear relation of the reaction rate to the concentration of sodium hydroxide and the relation between the basicity and the activity of catalysts, the rate-determining step of the formation of the nitrile would be the deprotonation of benzilideneimine and the oxidation reaction of the formed anion or the corresponding sodium salt would be sufficiently fast. Of course, in the case when the concentration of cupric ion is very small, the rate-determining step may be alternatively the oxidation step of the formed anion.

To investigate on this oxidation step further, the oxidation of the sodium derivative of benzophenoneimine was tried. This stable N-unsubstituted imine was selected in place of the unstable benzilideneimine. Though some difference may be between these two imines, the reaction may begin at the position of the imino-group (=N–H) in both of the imines. The sodium derivative of benzophenoneimine, which was prepared from benzophenoneimine and sodium amide in benzene (or tetrahydrofuran), was oxidized with suspended cupric chloride after the removal of unreacted sodium amide. The oxidation reaction seemed to proceed rapidly, judging from the observation that the characteristic deep red color of the sodium derivative disappeared immediately after the contact of the derivative with the oxidant. The corresponding oxidative dimerization product, benzophenone azine was obtained in an about 70% yield. The fact that a complex of benzophenoneimine with cuprous chloride, $CuCl\cdot Ph_2C{=}NH$, was detected as a by-product may mean that the oxidation step is an one-electron transfer reaction. Benzophenoneimine may be resulted from the hydrolysis of the sodium derivative, as a trace of water could exist in the oxidant or the solvent. The oxidation reaction of the sodium derivative may proceed much faster than the oxidation reaction of the parent imine by cupric chloride, judging from the fact that the complex of benzophenoneimine with cupric chloride, $CuCl_2\cdot 2Ph_2C{=}NH$, is observed to be stable at room temperature.[3] Potassium permanganate and manganese dioxide

1) Part I: A. Misono, T. Osa and S. Koda, This Bulletin, **40**, 912 (1967).

3) A. Misono, T. Osa and S. Koda, *ibid.*, **41**, 373 (1968).

also oxidized the sodium derivative to the ketazine in gross yields of 51% and 22%, respectively. Palladium chloride and silver nitrate also oxidized the sodium derivative to the ketazine, though not quantitatively observed. As for other oxidants, Morton[4] oxidized the sodium derivative to benzophenone oxime by air and to benzophenone azine by iodine in a yield of 17%. From the consideration of the above stated observations, the oxidation of the imines may plausibley proceed as follows.

$$PhCH{=}NH \xrightarrow{base} PhCH{=}N^- \xrightarrow{Cu^{II}} \text{(rate-determining)}$$

$$PhCH{=}N\cdot \xrightarrow{oxidation} PhCN$$

$$Ph_2C{=}NH \xrightarrow[NaNH_2]{} Ph_2C{=}N\cdot Na \xrightarrow[Oxidant]{} Ph_2C{=}N\cdot \rightarrow (Ph_2C{=}N)_2$$

Experimental

The Oxidation of Benzaldehyde and Ammonia with Oxygen Catalyzed by Cupric Chloride and Sodium Hydroxide. The materials and the reaction apparatus were all the same as in the preceding paper.[1] The procedure were also same except the following treatments before the start of the reaction; the methanol containing ammonia and sodium hydroxide was introduced in the flask and was stirred for 15 min. Then the introduction of oxygen gas was started. When 10 min passed after the beginning of the introduction of oxygen, the given amount of cupric chloride was added to at one time. When additional 5 min passed, benzaldehyde was introduced to start the reaction.

The Oxidation of the Sodium Derivative of Benzophenoneimine. All treatments were carried out at room temperature under dried nitrogen before the oxidation products were separated by filtration.

Oxidation by Cupric Chloride in Benzene. In 20 m*l* of benzene, 1 g (26 mmol) of sodium amide and 1.890 g (10.4 mmol) of benzophenoneimine (prepared from phenylmagnesium bromide and benzonitrile,[5] bp 146.5—148°C/7.5 mmHg) were agitated for 1 hr. Then, undissolved substances were separated and washed with 10 m*l* of benzene. The filtrate together with the washing was added to 2.708 g (20.1 mmol) of cupric chloride (prepared through dehydration by thionyl chloride from commercial cupric chloride dihydrate[6]) and the mixture was stirred for 3 hr. Then 20 m*l* of benzene was added to the mixture, and the resulted mixture was filtered. After stripping off benzene, 1.281 g (gross yield, 68%, mp 148—156°C) of yellow solid of benzophenone azine became available (recry. from ethanol. mp 164.5°C, lit.[7] 164°C. Its infrared spectrum agreed with that of an authentic sample.). In this process, small amount of $CuCl\cdot Ph_2C{=}NH$ was precipitated from benzene solution by adding *n*-hexane. Its infrared spectrum agreed with that of an authentic sample.[3] Found: C, 55.57; H, 3.87; N, 5.00%. Calcd for $CuCl\cdot C_{13}H_{11}N$: C, 55.71; H, 3.96; N, 5.00%.

In tetrahydrofuran as a solvent, benzophenone azine was obtained in a 72% yield after a similar treatment.

Oxidation by Potassium Permanganate. In 20 m*l* of benzene, 1 g of sodium amide and 1.905 g (10.5 mmol) of benzophenoneimine were agitated together for 1 hr, and treated similarly. The filtrate was added to 1.591 g (10.1 mmol) of potassium permanganate. The mixture was stirred for 2.5 hr and then kept for 40 hr at standing. The resulted mixture was treated similarly. Solids with little liquids remained after the removal of benzene. The mixture was again dissolved in 100 m*l* of ethanol with 10 m*l* of benzene. The solution was concentrated, then the resulting precipitate was separated at −30°C. The precipitate, 0.959 g (51%, mp 160.5—161.5°C) in weight, proved to be benzophenone azine (recry. from ethanol, 164.8°C). From the filtrate, 0.769 g (40%) of yellow liquid, which was mainly benzophenoneimine, contaminated with a little benzophenone, judging from its infrared spectrum, was obtained.

The oxidation by activated manganese dioxide (prepared from potassium permanganate[8]) of the sodium derivative of benzophenoneimine for 3 hr yielded benzophenone azine in a 22% gross yield after similar treatments.

Organotin Compounds of the $R_2SnO \cdot SnR'_2X_2$ and $H(R_2SnO)_3OH \cdot SnR'_2X_2$ Mixed Types

Taichi HARADA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received August 16, 1967)

The characteristic nature of R_3SnX, *i. e.*, its property of combining with one or two R_3SnOH and forming $R_3SnOH \cdot SnR_3X$ or $(R_3SnOH)_2 \cdot SnR_3X$,[1,2] was found first; for it 5 or 6 coordination bond linkings were first introduced to organotin chemistry by the present author.[3-6] Then this conception is extended to the formation of many complexes of the type $R_2SnO \cdot SnR_2X_2$*1 (I) and $H(R_2SnO)_3OH \cdot SnR_2X_2$ (II) types and, further, to the mixed-type compound:[7] $R_2SnO \cdot SnR'_2X_2$ (III) and $H(R_2SnO)_3OH \cdot SnR'_2X_2$ (IV), and also $(Me_2SnO)_2 \cdot SnMe_2Cl_2$ (V), in which the $(Sn-O)_2$ ring is present.[3,5] Recently, Rochow *et al.*[8] proposed a dimeric conception for I; then Okawara[9-11] proposed one for the compound of the I type where $X=OSiMe_3$ and the II type. The existence of III and IV, therefore, is very important in checking whether or not I, II, and V can be formulated by the dimeric hypothesis. The present investigation was carried out again with some new compounds of the R_2SnO and R'_2SnX_3 types, and of $3R_2SnO$ and R'_2SnX_2 compounds in the R°OH (R°=alkyl) solvent.

Experimental

Preparations. 1) n-$Pr_2SnO \cdot SnEt_2Br_2$[7] prepared by fusion. Both Et_2SnO and n-Pr_2SnBr_2, as well as n-Pr_2SnO and Et_2SnBr_2, in an exact mole ratio of 1 : 1, were fused at 110°C under exactly the same conditions; a melting point of 102—103°C was thus obtained for the former (A) and one of 104—105°C when crystallized from n-butyl alcohol, but the latter (B) gave a melting point of 83—84°C, which, upon its crystallization from the alcohol, was elevated to (87→93→97) 101°C. These two substances, A and B, are the same; *i. e.*, they gave the same amount of n-Pr_2Sn upon reduction with the Na-equivalent to Br_2 in liquid ammonia.[12] The process will be described later.

Other compounds of a similar type, 2) $Et_2SnO \cdot SnMe_2Cl_2$, 3) n-$Bu_2SnO \cdot Sn$$n$-$Pr_2Cl_2$, and 4) n-$Bu_2SnO \cdot SnMe_2Cl_2$, were also prepared.

The results of the analysis of the halogen contents, and the melting points or decomposition points are gives in Table 1. It is interesting to note here that n-$Bu_2SnO \cdot SnMe_2Cl_2$ (or this composition) could not be obtained by the action of n-Bu_2SnCl_2 on Me_2SnO as the case of n-Bu_2SnCl_2 on Et_2SnO.

Molecular Weight. The molecular weight of this mixed-type compound was not determined, but those of $Et_2SnO \cdot SnEt_2Br_2$ with higher concentrations in freezing benzene were obtained as 763, 900, and 947 at 5.000, 4.000, and 3.240 (by weight %) respectively. As has been shown above, the molecular weight decreases with the concentration or increases with the dilution (just as with n-$Bu_2SnO \cdot Sn$$n$-$Bu_2Br_2$,[13] Et_2SnI_2,[14] $SnCl_4$[14] and tetraalkyl ammonium halides[14]). Therefore, the compound may associate little or not at all at a point of saturation where a crystal sppears. On the other hand, $Me_2SnO \cdot SnMe_2(OAc)_2$[7] (which gives the 460 cm^{-1} band) indicates the reversing tendency (as do tetraalkyl ammonium nitrates[14]). Furthermore, the molecular weight of $H(Et_2SnO)_3OH \cdot SnEt_2(OAc)_2$[3] increases rapidly with the lapse of time, tripling in weight. Indeed, none of the halogen compounds in question except n-$Bu_2SnO \cdot Sn$$n$-$Pr_2Cl_2$ (Table 2) show the ring $(Sn-O)_n$ band[15] in the infrared spectrum. Therefore, there remains some uncertainty in determining whether they are in a monomer form or in a dimer on the base of these data only.*1

$(Me_2SnO)_2 \cdot SnMe_2Cl_2$. The electric conductivity of this compound, formed between $(Me_2SnO)_2$ and Me_2SnCl_2, was measured. From the results (Table 3), the compound may be considered to be $[(Me_2SnO)_2 \cdot SnMe_2]Cl_2$, since there are three ions and it gives an infrared 467 cm^{-1} ring band.[15] It is insoluble in organic solvent, Therefore, the molecular weight was not determined.

Reduction of $H(Et_2SnO)_3OH \cdot SnMe_2I_2$[6] in Liquid Ammonia. Compound (3.000 g) with the Na-equivalent to I_2 in liquid ammonia gave a 1/3 equivalent of (very roughly) Et_2Sn (0.35 g, free from the Me_2Sn group) upon being freed by 0.5 N HCl - aqueous alcohol (50/50 by volume). On the other hand, *n*-$Pr_2SnO \cdot SnEt_2Br_2$ (3.000 g) gave *n*-Pr_2Sn (1.0 g, free from the Et_2Sn group), but not $(Cl$*n*-$Pr_2Sn)_2$ nor $(ClEt_2Sn)_2$; $Et_2SnO \cdot SnEt_2Br_2$ (6.000 g) gave Et_2Sn (1.8 g) upon a similar treatment. This may be explained as follows:

$$n\text{-}Pr_2SnO \cdot SnEt_2Br_2 \xrightarrow{2Na} n\text{-}Pr_2SnO \cdot SnEt_2$$

$$\longrightarrow n\text{-}Pr_2Sn \cdot OSnEt_2$$

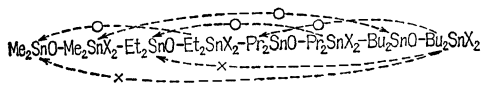
$$(\text{or} \longrightarrow n\text{-}Pr_2Sn + Et_2SnO)$$

$$\xrightarrow{2HCl} n\text{-}Pr_2Sn + Et_2SnCl_2.$$

For $H(Et_2SnO)_3OH \cdot SnMe_2I_2$, the same explanation can be given.

Discussion

On Formation and Stability. The linking of $R_2SnO{\cdot}SnR'_2X_2$ where R (*e. g.*, R=*n*-Bu) is larger than R' (*e. g.*, R'=Me) usually takes place along the model "streaming-down bridge" (*e. g.*, $Me_2SnO—Bu_2SnX_2$); it is somewhat difficult against the stream →, and it is impossible or very difficult to jump over one or more bridges to the left, as shown below with the arrow (←-⊗--):



where the arrow --⊖→ in dicates a possibility of linkings, of greater or lesser difficulty, whereas linking ←-⊗-- is impossible or very difficult. In comparison, R_2SnX_2 (R=*n*-Bu) is somewhat organic, whereas R'_2SnX_2 (R'=Me) is of an inorganic nature for solvents, causing the formation of disporportionate products when R_2SnX_2 is subjected to reaction on R'_2SnO. The *n*-$Bu_2SnO{\cdot}SnMe_2Cl_2$ compound clearly differes from the mixture of *n*-$Bu_2SnO{\cdot}Sn$*n*-Bu_2Cl_2 and $Me_2SnO{\cdot}SnMe_2Cl_2$ toward heat; it melts at 95—96°C (clearly or almost clearly) with a mild decomposition above the melting point; it gradually becomes very opaque, perhaps because of the formation of a mixture of the two chlorides, whereas the mixture (in an exact mole ratio of 1 : 1) melts partially at about 102°C, giving two layers (liquid of the former and solid of the latter), leaving the solid of the latter on the bottom of the capillary tube readily. A tendency more or less similar is seen in the case of $Et_2SnO{\cdot}Me_2Cl_2$. When the compound is heated at or near 140°C under a reduced pressure, it gives pure *n*-Bu_2SnCl_2 (as in the case of *n*-$Bu_2SnO{\cdot}Sn$*n*-Bu_2Cl_2). Therefore, the change may take as follows:

$$n\text{-}Bu_2SnO{\cdot}SnMe_2Cl_2 \xrightarrow[\text{heat}]{\text{Partially}} n\text{-}Bu_2SnCl_2 + OSnMe_2,$$

as in the case of the liquid ammonia method described above.

On the Migration of X_2. The oxide having the $R_2Sn\langle{}^{O}_{O}\rangle SnR_2$[15] skeleton is affected by two molecules of R'_2SnX_2, forming a new structural product, $R_2SnO{\cdot}SnR'_2X_2$ (which polymerizes[5] loosely in a solvent) at a moderate dilution. In the both X_2's are unstable and, hence, may migrate very mildly from the tin of the larger alkyltin to the tin of the smaller alkyltin; *e. g.*, $Me_2SnO{\cdot}SnEt_2Cl_2$, $Et_2SnO{\cdot}Sn$*n*-Pr_2Br_2, and *n*-$Pr_2SnO{\cdot}Sn$*n*-Bu_2Cl_2, as in the cases of the liquid ammonia treatments, give $Et_2SnO{\cdot}SnMe_2Cl_2$, *n*-$Pr_2SnO{\cdot}SnEt_2Br_2$, and *n*-$Bu_2SnO{\cdot}Sn$*n*-Pr_2Cl_2, respectively. Thus, the two reactions, that between R'_2SnO and R_2SnX_2 and that between R_2SnO and R'_2SnX_2, should give only one compound as the stable product. Therefore, the difference in the melting points of the two products (Table 1) prepared by the two different reactions is due to the degrees of purity. This is shown by X-ray diffraction patterns; *e. g.*, the product (mp 103°C) prepared by the action of *n*-Pr_2SnCl_2 on *n*-Bu_2SnO appeared to be pure, whereas the product (mp 102°C) prepared by the action of *n*-Bu_2SnCl_2 on *n*-Pr_2SnO appeared to be slightly impure. On the other hand, in the reaction between Me_2SnO and *n*-Bu_2SnCl_2 in a solvent, the *n*-Bu_2SnO formed in the migration of X_2 readily combines with the free *n*-Bu_2SnX_2 to form the most stable linking products (disproportionate products). The reaction between *n*-Bu_2SnO and Me_2SnX_2 proceeds fairly normalily, giving *n*-$Bu_2SnO{\cdot}SnMe_2X_2$. In a very dilute solution, this mixed-type compound, the oxide, and the halogens are freely move, giving a mixture of the most stable compounds. The stability in question, therefore, depends completely on the energy level between R'_2Sn– and –SnR_2 in the linkings.

Mode of Formation. For the formation mechanism of the compounds of the II type, Davies *et al.*[13] Proposed the following hydrolytic mechanism:

$$R_2SnX_2 \rightarrow R_2SnXOH \rightarrow$$
$$XR_2Sn\text{-}O\text{-}SnR_2X \rightarrow XR_2Sn\text{-}O\text{-}SnR_2OH$$

the latter two dimerise readily in non poler solvents. On the other hand, the present author[5,6] has proposed the following mechanism:

$$R_2SnO \xrightarrow[\substack{2R°OH\\(\text{alcohol})}]{2HX} R_2SnX_2 \xrightarrow{R_2SnO}$$
$$R_2SnO{\cdot}SnR_2X_2 \xrightarrow{2R_2SnO} R°(R_2SnO)_3OR°{\cdot}SnR_2X_2.$$

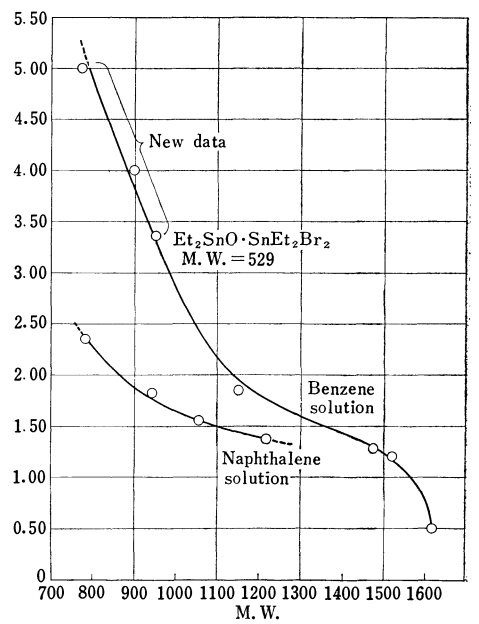


Fig. 1

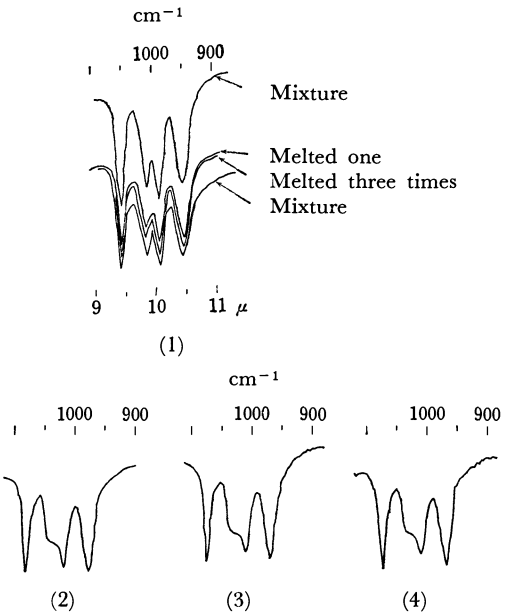

Fig. 2. Infrared spectral bands (Nujol).

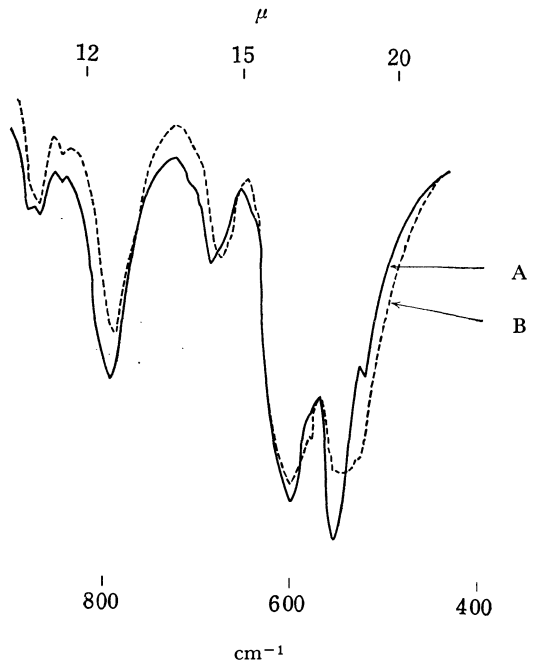

Fig. 3

A: n-$Bu_2SnO \cdot SnMe_2Cl_2$
B: Mixture of n-$Bu_2SnO \cdot Sn$$n$-$Bu_2Cl_2$ and $Me_2SnO \cdot SnMe_2Cl_2$ in exact mole ratio 1 : 1

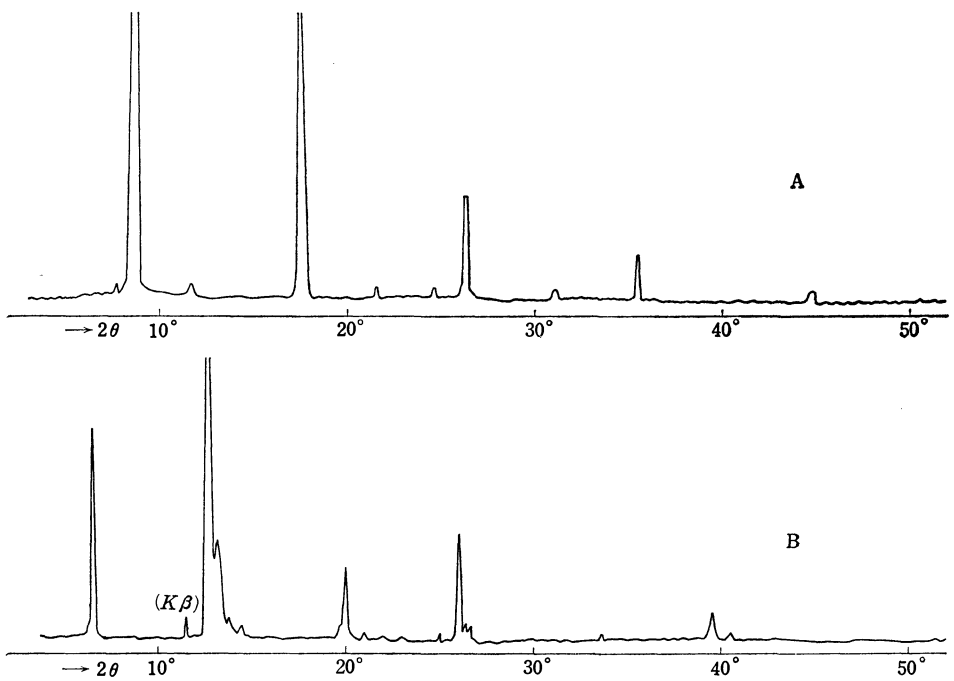

Fig. 4. X-Ray diffraction pattern.
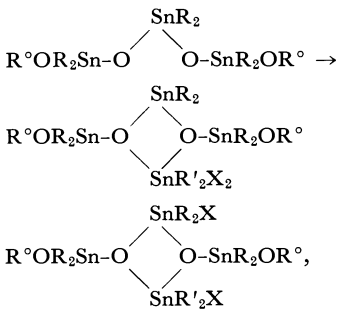
A: n-$Bu_2SnO \cdot MeSnCl_2$ B: $Me_2SnO \cdot Me_2SnCl_2$ - n-$Bu_2SnO \cdot n$-Bu_2SnCl_2 mixture

If we accepted the former mechanism and applied it to mixed type compounds, it should give (XR_2Sn-O-SnR'_2OH). In fact, however, no such compound was formed. However, the latter mechanism accounts for the formation of mixed-type compounds, which can be represented as follows:

$$3R_2SnO + R'_2SnX_2 + 2R°OH \rightarrow$$



$$\text{or}\quad R°OR_2Sn\text{-}O\quad O\text{-}SnR_2X\quad SnR'_2X,$$

which gives the free OH band[11] in the case of R°=H, R'=R.

This $>SnR_2X$ linking is possible, but improbable judging from the results of the Na-liquid ammonia treatment and from the formation of R_2SnS and SnR_2X_2 (but not XR_2Sn-S-SnR_2X) upon H_2S treatment; it may differ from the structure of $(Me_3SiOMe_2Sn)_2O$[16] pointed out by Poller *et al.*[17] Very recently Davies *et al.*[18] have prepared several mixed-type compounds, $R_2SnO{\cdot}SnR'_2Cl_2$, $R_2SnO{\cdot}SnR'_3Cl$, $R_2SnO{\cdot}SnCl_4$, *etc.* They reported that the degree of association of these compounds is slight.

On Infrared Spectral Bands. In the region of 800—4000 cm^{-1}, bands of *n*-$Bu_2SnO{\cdot}SnMe_2Cl_2$ and a mixture*2 (in an exact mole ratio of 1 : 1) of the two compounds *n*-$Bu_2SnO{\cdot}Sn$*n*-Bu_2Cl_2 and $Me_2SnO{\cdot}SnMe_2Cl_2$ are the same, but in the 400—800 cm^{-1} region the first compound gives bands at 530, 558, 608, 643, 698, and 780, while the mixture gives a broad band (530—570) and others at 607, 683 and 780. In the case of *n*-$Pr_2SnO{\cdot}SnEt_2Br_2$, shoulder bands (Nujol) appear at 995 and 1020, but in the case of a mixture (exact mole ratio of 1 : 1) of *n*-$Pr_2SnO{\cdot}Sn$*n*-Pr_2Br_2 and $Et_2SnO{\cdot}SnEt_2Br_2$, there are sharp individual bands at 995 and 1020 cm^{-1}. These are listed in Table 2 and illustrated in Fig. 2. For *n*-$Pr_2SnO{\cdot}SnEt_2Br_2$, see Fig. 3.

The author is grateful to Professor Saburo Nagakura of The University of Tokyo, and to Dr. Hiroshi Midorikawa and Dr. Tetsuzo Atoda, chief chemists of The Institute of Physical and Chemical Research, for their encouragement. He also greatly indebted to Dr. Isaburo Hori, Dr. Kiyoko Yamamoto, Mr. Iwami Higashi, and Mr. Shunzo Katayama of The Institute of Physical and Chemical Research, who partly helped him with this study. Finally, thanks are due to the Sankyo Organic Chemicals Co., Ltd., Kawasaki, for supplying some organotin materials for this work. This work was carried out partly at the laboratory of the Takaido Chemical Co., Ltd., Itabashi, Tokyo, and partly at The Institute of Physical and Chemical Research.

*2 X-Ray diffraction analysis shows these two substances to be quite different from each other. (Fig. 4A and B) The same is true in the case of *n*-$Bu_2SnO{\cdot}Sn$*n*-Pr_2Cl_2 (mp 103°C).

Delta- and Theta-Al_2O_3 under Hydrothermal Conditions

Goro YAMAGUCHI and Wen-Chau CHIU

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received August 18, 1967)

In a previous paper,[1] Yamaguchi *et al.* reported that under hydrothermal conditions, γ-Al_2O_3 obtained from the dehydration of boehmite was deformed further, more tetragonally, but not inverted into δ-Al_2O_3. In this experiment the authors treated η- and γ-Al_2O_3, with various origins, under hydrothermal conditions.

1) G. Yamaguchi and H. Yanagida, This Bulletin, **35**, 1896 (1962).

Preparation of Standard Samples

In order to compare and discriminate the polymorphs, standard samples were prepared.

Preparation and Identification of η-Al_2O_3. Commercial fine gibbsite was heated in vacuum at 900°C for 30 min. The X-ray diffraction pattern of this product is given in Fig. 1a showing the character of η-Al_2O_3.

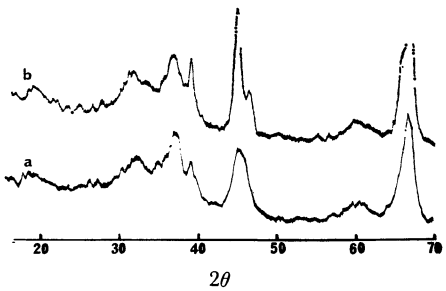

Fig. 1. X-ray diffraction patterns of η-Al_2O_3 (a) and γ-Al_2O_3 (b).

Preparation and Identification of γ-Al_2O_3. Well crystallized boehmite obtained hydrothermally from gibbsite was treated again under hydrothermal conditions (500°C, 50 atm) for 20 hr. The X-ray diffraction pattern of this product is given in Fig. 1b, showing the character of γ-Al_2O_3.

Preparation and Identification of δ-Al_2O_3. Well crystallized boehmite obtained hydrothermally from gibbsite was heated in air at a heating rate of 5°C/min, up to 1000°C, and kept there for 1 hr. The X-ray diffraction pattern of this product is given in Fig. 2a, showing the character of δ-Al_2O_3.

Preparation and Identification of θ-Al_2O_3. Bayerite, obtained by aging alumina gel[2] in conc. NH_3 aqueous solution, was heated in air at a heating rate 5°C/min, up to 1100°C, and kept there for 1 hr. The X-ray diffraction pattern of this product is given in Fig. 2b, showing the character of θ-Al_2O_3.

The characters of the X-ray diffraction pattern of these polymorphs are summarized in Table 1.

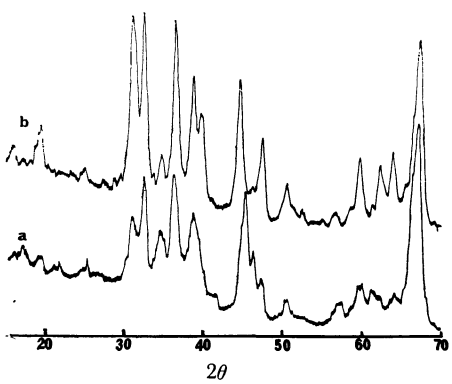

Fig. 2. X-ray diffraction patterns of δ-Al_2O_3 (a) and θ-Al_2O_3 (b).

Hydrothermal Treatment of η- and γ-Al_2O_3

Starting materials were as follows:

1. η-Al_2O_3 A. Bayerite, obtained by treating alumina gel with conc. NH_3 aqueous solution at room temperature for 3 days, was heated and dehydrated in air at 800°C for 1 hr.

2. η-Al_2O_3 B. Bayerite, obtained by hydrolyzing sodium aluminate aqueous solution (NaOH 3.5 mol/l, Na/Al=1.35) at 15°C for 3 days, was heated and dehydrated in air at 800°C for 1 hr.

3. η-Al_2O_3 C. Nordstrandite, obtained by treating alumina gel with a 5% ethylenediamine

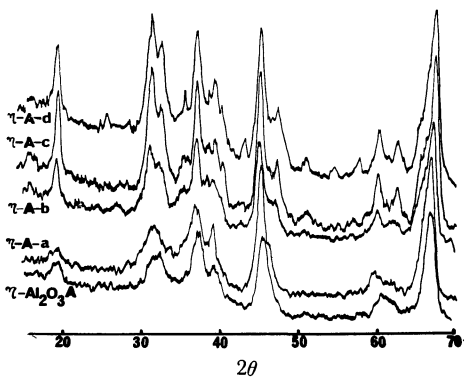

Fig. 3. X-ray diffraction patterns of products from η-Al_2O_3 A.

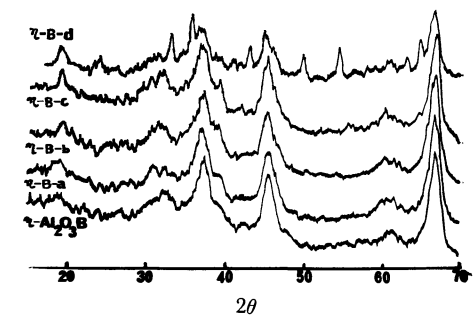

Fig. 4. X-ray diffraction patterns of products from η-Al_2O_3 B.

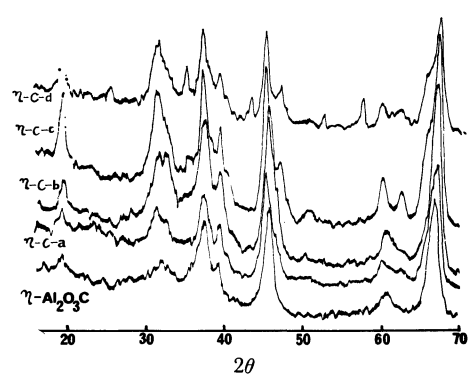

Fig. 5. X-ray diffraction patterns of products from η-Al_2O_3 C.

aqueous solution at 40°C for 2 days, was heated and dehydrated in air at 700°C for 1 hr.

4. η-Al_2O_3 D. Commercial gibbsite was heated and dehydrated in vacuum at 900°C for 0.5 hr.

5. η-Al_2O_3 E. Well crystallized boehmite was heated and dehydrated in vacuum at 900°C for 0.5 hr.

6. η-Al_2O_3 F. Bayerite, obtained by treating alumina gel with conc. NH_3 aqueous solution at room temperature for 3 days, was heated and dehydrated in vacuum at 800°C for 1 hr.

7. γ-Al_2O_3. Well crystallized boehmite was heated in air at 650°C for 0.5 hr.

These materials were treated under hydrothermal conditions and examined by an X-ray diffraction method. Results are given in Table 2, and Fig. 3 through Fig. 9.

Conclusion and Discussion

1. Similar to the previous paper, 1) γ-Al_2O_3, obtained from the dehydration of well crystallized boehmite was deformed further, more tetragonally, but not inverted into δ- or θ-Al_2O_3. As for η-

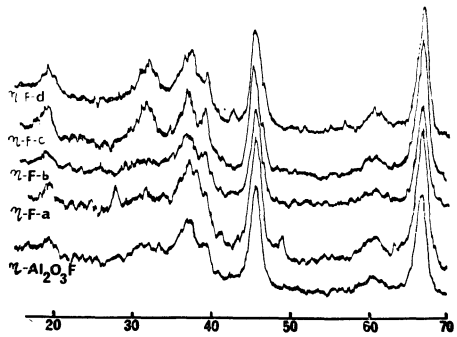

Fig. 8. X-ray diffraction patterns of products from η-Al_2O_3 F.

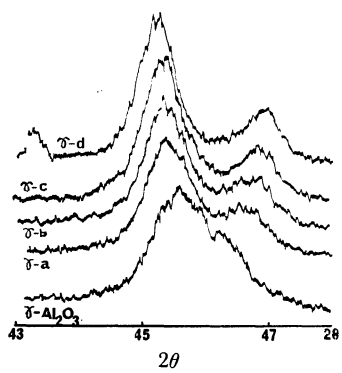

Fig. 9. X-ray diffraction peaks of (400) and (004) of γ-Al_2O_3 under hydrothermal condition.

Al_2O_3 however, some was only deformed into γ-Al_2O_3, while the rest was inverted into θ-Al_2O_3 before being finally inverted into α-Al_2O_3; η-Al_2O_3 A, and C belonged to the latter.

2. Before the formation of θ-Al_2O_3, η-Al_2O_3 A, and C seemed to pass through an intermediate phase like δ-Al_2O_3 but the X-ray diffraction pattern of this intermediate phase was not correctly coincident with that of standard δ-Al_2O_3 (Fig. 2a). Interpretation of this phenomenon can not be accomplished before the structural problem of δ-Al_2O_3 and θ-Al_2O_3 is clarified. Whether or not δ-Al_2O_3 and θ-Al_2O_3 are considered to be of different phases is a problem which is now being investigated by the present authors.

3. Among η-Al_2O_3 specimens obtained from different origins, there were two types. One was hardly inverted into θ-Al_2O_3, and the other was easily inverted under hydrothermal conditions. This difference seems to be due to a delicate structural difference, but the explanation is left as a future problem.

Photo-Claisen Rearrangement. The Photochemical Rearrangement of Allyl Phenyl Ethers*[1]

Gen KOGA and Noriko KIKUCHI*[2]

Department of Chemistry, Ibaraki University, Mito

and Nobuo KOGA

Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama

(Received August 18, 1967)

Two years ago, Woodward and Hoffmann presented an ingenious theory in an attempt to interpret the stereochemical cours of the so-called "electrocyclic" and "sigmatropic" transformations.[1] They suggested[1b] that the photo-Claisen rearrangement reported to give a para-rearrangement product[2] would serve as an example of the [3, 5] sigmatropic transformation. Another example of the photo-Claisen rearrangement had previously been reported to give only a para-rearrangement product.[3]

Although this interpretation of the photo-Claisen rearrangement was highly attractive, the following facts seemed to us conflicting enough to warrant a thorough reinvestigation of the photo-rearrangement of allyl phenyl ethers:

(1) An eight-membered cyclic transition state these systems seems sterically impossible.

(2) γ-^{14}C-Allyl 2, 6-dimethylphenyl ether has been shown to rearrange to 4-α- and 4-γ- ^{14}C-allyl-2, 6-dimethylphenols.[2]

$$(CH_3)_2C_6H_3\text{-}OCH_2CH\overset{*}{=}CH_2 \rightarrow \overset{*}{C}H_2\text{=}CH\overset{*}{C}H_2\text{-}C_6H_2(CH_3)_2OH$$

(3) Several related systems, phenyl esters,[4] acyl anilides,[5] phenoxyacetic acid,[6] and ethyl phenyl carbonate,[7] have been reported to rearrange photochemically to ortho- and para-rearrangement products.

The recent publication of a communication[8] dealing with an investigation closely related to ours prompts us to publish our own results.

Experimental

Materials. The allyl phenyl ethers for the photoreaction were purified by rectification until no appreciable impurity was observed by glc.

Reaction Procedure. A 5% solution of a sample in isopropyl alcohol was irradiated with an immersion-type 10W low-pressure mercury lamp (Ricoh Kagaku Sangyo Co., UVL300Q) under a nitrogen atmosphere. After irradiation, most of the solvent was removed under reduced pressure, and the residual mixture was analyzed by glc.

Identification of Products. *o*- and *p*-Allylphenols, 2-allyl-3, 5-dimethylphenol, *trans-o*- and *-p*-but-2-enylphenols, and *o*- and *p*-(1-methyl-prop-2-enyl)phenols were identified by a comparison of their retention times with those of authentic sample. 4-Allyl-3, 5-dimethylphenol was isolated from the reaction mixture by means of preparative glc and was identified spectrometrically. Two unknown peaks in the gas chromatogram of the reaction mixture from *trans*-but-2-enyl phenyl ether were tentatively assigned to *cis-o*- and *-p*-but-2-enylphenols on the basis of their having been formed by the irradiation of their trans-isomers.

Analyses. The samples were analyzed by the use of a Hitachi K-23 gas chromatograph. A 1-meter Celite-545 (60—80 mesh) column with 33% Silicon KF-54 was used. The results in the table are given as the percentage ratio of the peak area.

Results and Discussion

As shown in the table, all the compounds rearranged to give ortho- and para-rearrangement products in addition to the parent phenols of the starting ethers. Some unidentified products were also present. *trans*-But-2-enyl phenyl ether was shown to give *o*- and *p*-but-2-enyl and *o*- and *p*-(1-methylprop-2-enyl)phenols. The results are consistent with those of Schmid[2] and clearly indicate that the rearrangement does not proceed

Table 1. Analyses of products

(1) Allyl phenyl ether

Time of irradiation (hr)	Starting material			12	84.2%	2.3%	7.3%	6.3%
24	68.6	4.9	14.3	12.3
48	39.6	10.2	26.8	23.4

(2) Allyl 3,5-dimethylphenyl ether

Time of irradiation (hr)	Starting material			12	81.5%	3.9%	8.8%	5.8%
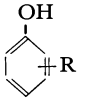
24	67.5	7.3	15.2	10.0
48	36.5	14.7	29.4	19.4

(3) *trans*-But-2-enyl phenyl ether

Time of irradiation (hr)	Starting material	Phenols (%)						
		I	*o*-II	*p*-II	*o*-III	*o*-IV	*p*-III	*p*-IV
24	77.3%	3.7	3.6	3.7	4.7	1.2	4.6	1.2
48	53.3%	8.6	6.6	6.9	9.1	3.4	8.3	3.8



(I) R = -H
(II) -CHCH=CH_2 (CH$_3$)
(III) -CH_2CH=CHCH$_2$ (*trans*)
(IV) -CH_2CH=CHCH$_2$ (*cis*)

via a cyclic process, but probably involves a radical or an ionic recombination of two fragments.

The products do not seem to undergo further rearrangement; in each case, the ortho/para ratio of the products*3 was unchanged during the irradiation. In fact, as has been reported by Kelly *et al.*,[8] these phenols are quite stable to any irradiation except for trans-cis isomerisation.

In the rearrangement of but-2-enyl phenyl ethers, the ratio of (1-methylprop-2-enyl)phenols to but-2-enylphenols was about 0.6. Although some steric factors may be responsible for the observed ratio, this value strongly suggests that the reaction mechanism is a radical process. If the reaction proceeded through an ionic path, the fragmentation would lead to a phenoxide anion and an allyl cation, and from the reported data of the SN1 reaction of crotyl and methylallyl substrates, the ratio would be expected to be about 0.1—0.2.[9]

The ortho/para ratio of the products is 1.1 for allyl phenyl ether, 1.5 for allyl 3, 5-dimethylphenyl ether, and 1.0 for but-2-enyl phenyl ether, showing in each case a slight preference for the attack on the para-position. Although somewhat different results have been previously reported,[8] the discrepancy may be ascribed to the differences in the experimental conditions. Steric factors seem to be operative in the rearrangement of allyl 3, 5-dimethylphenyl ether.

To ascertain whether the rearrangement is intra- or inter-molecular, a mixed solution of allyl 3, 5-dimethylphenyl ether and *trans*-but-2-enyl phenyl ether, each 5% in isopropyl alcohol, was irradiated. The products were analyzed both as free phenols and as their methyl ethers. Other than the rearrangement products expected for each component separately, no trace of crossed products could be detected, a clear indication of the intramolecular nature of the reaction. The mechanism of the photo-Fries rearrangement has been suggested[4a] to be a radical recombination within a solvent cage. Arenesulfonyl anilides have also been shown to rearrange photochemically *via* an intramolecular process.[10] Thus, as in the preceding cases, the photo-rearrangement of allyl phenyl ethers can most consistently be interpreted by a radical recombination mechanism within a solvent cage.

*3 Although the ratio of the peak area was used for the isomer ratio without calibration throughout the discussion, the error seems to be small, as was found to be the case with *o*- and *p*-allylphenols.

On the Estimation of Alloy Film Thickness by X-Ray Fluorescent Spectroscopy

Kichinosuke HIROKAWA and Hidehiro GOTÔ

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received August 23, 1967)

For the simultaneous determination of alloy film thickness and its composition, several methods in which experimental equations were employed have been proposed.[1-3] In the present report it shall be shown that thickness of a binary alloy film can be easily obtained with two experimental absorption parameters, when the composition of the film is known.

Usually the X-ray intensity from a film of thickness z is given by Eq. (1),

$$I_z = \int_{\lambda_{\min}}^{\lambda_{\text{edge}}} \int_0^z \frac{I_0(\lambda)\rho_j Q(\lambda)}{\sin\beta} \cdot \exp\left\{-\left(\frac{\sum \mu^j{}_{(\lambda)} W_j}{\sin\alpha} + \frac{\sum \mu^j{}_f W_j}{\sin\beta}\right)z\right\} \mathrm{d}z \cdot \mathrm{d}\lambda \quad (1)$$

where α is the incident angle of primary X-rays; β is the emergent angle of fluorescent X-rays; $Q(\lambda) = \mu_j/\rho_j W_j K_j w_j R_p{}^j$ (μ_j/ρ_j is the mass absorption coefficient of element j; W_j is the weight fraction of element j ; K_j is the term $(r_j-1)/r_j$ in which r_j is the ratio of absorption coefficient at the K discontinuity, *i. e.*, r_j is the K jump for j : w_j is the fluorescent yield of j; $R_p{}^j$ is the intensity ratio of the measured p line of element j, which belongs to the K series, to the total intensity of K lines, *i. e.*, the fraction of the measured p line in the characteristic X-ray series which the p line belongs to); $\mu^j{}_{(\lambda)}$ is the absorption coefficient of j for the incident ray of wavelength λ; $\mu_f{}^j$ is the absorption coefficient of j for the fluorescent beam; $I_0(\lambda)$ is the primary X-ray intensity; I_z is the X-ray intensity from a film of thickness z; ρ_j is the density of the element j.

To obtain an exact expression for fluorescent X-ray intensity, of course, Eq. (1) must be integrated with respect to the wavelength λ, together with respect to thickness z. However, if we assume that $I_0(\lambda)$ and $\mu_{(\lambda)}$ are constant at the definite experimental condition,[4] the approximate expression for the intensity ratio of X-rays from a film to that from the bulk sample with a constant composition A_j is given by Eq. (2):

$$-\ln\left(1 - \frac{I_z{}^{A_j}}{I_\infty{}^{A_j}}\right) = \left(\frac{\sum \mu_i{}^{A_j} W_{Aj}}{\sin\alpha} + \frac{\sum \mu_A{}^{A_j} W_{Aj}}{\sin\beta}\right)z \quad (2)$$

The approximate X-ray intensity ratio of an element A in an alloy film to the pure element A can be also obtained by Eq. (3),

$$-\ln\left(1 - \frac{\rho_{AA}}{\rho_{Aj}} \cdot \frac{1}{W_A} \cdot \frac{I_z{}^A}{I_\infty{}^A} \cdot \frac{\dfrac{\sum \mu_i{}^A W_A}{\sin\alpha} + \dfrac{\sum \mu_A{}^A W_A}{\sin\beta}}{\dfrac{\mu_i{}^A}{\sin\alpha} + \dfrac{\mu_A{}^A}{\sin\beta}}\right) = \left(\frac{\sum \mu_i{}^A W_A}{\sin\alpha} + \frac{\sum \mu_A{}^A W_A}{\sin\beta}\right)z \quad (3)$$

where ρ_{AA} is the density of pure element A, and ρ_{Aj} is the density of the alloy. When Eq. (3) is applied to an element A in a binary alloy AB, Eq. (4) can be derived:

$$-\ln\left\{1 - \frac{I_z{}^A}{I_\infty{}^A} \cdot \frac{\rho_{AA}}{\rho_{AB}}\left[1 - \frac{\left(\dfrac{\mu_i{}^B}{\sin\alpha} + \dfrac{\mu_A{}^B}{\sin\beta}\right)W_B}{\left(\dfrac{\mu_i{}^A}{\sin\alpha} + \dfrac{\mu_A{}^A}{\sin\beta}\right)W_A}\right]\right\} = \left\{\left(\frac{\mu_i{}^A}{\sin\alpha} + \frac{\mu_A{}^A}{\sin\beta}\right)W_A + \left(\frac{\mu_i{}^B}{\sin\alpha} + \frac{\mu_A{}^B}{\sin\beta}\right)W_B\right\}z \quad (4)$$

Equation (4) was applied to a nickel-iron alloy (81.5% Ni) film. The experimental conditions were the same as described in previous reports.[1,2] In this case it is necessary to get the $\mu_i{}^A$ and $\mu_i{}^B$ values. Fortunately, in this experiment the value of $\mu_i{}^{Ni}$ or $\mu_i{}^{Fe}$ could be obtained by the applica-

TABLE 1. EXPERIMENTAL AND CALCULATED VALUES OF X-RAY INTENSITY RATIO OF Ni AND Fe IN Ni-Fe ALLOY FILMS

4) a) H. T. Beattie and R. M. Brissey, *Anal. Chem.*, **26**, 980 (1954). b) J. Sherman, "Advances in X-Ray Analysis," Vol. 1, ed. by W. M. Mueller, Plenum Press, New York (1960), p. 244. c) K. Hirokawa and H. Goto, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **87**, 383 (1966).

tion of Eq. (2) to a nickel or iron film; the value of μ_i^{Ni} was 1750, and that of μ_i^{Fe}, 977. Using these values, the X-ray intensity ratios of nickel and iron were calculated with Eq. (4). These results were shown in Table 1 together with the experimental results. From this experiment it was recognized that the thickness of a binary alloy film could be easily obtained from the X-ray intensity ratio of an element in the film to that of the pure element.

However, for the element that receives inter-element effects from accompanying elements in the film, or from backing materials, of course, the correction for these effects must be considered, as for iron in the nickel-iron alloy film used in this experiment. For the normal case, the calculated results are in good agreement with experimental values, as nickel in this experiment.

The Preparation of Several Tetrakis(triorganosiloxymethyl)methanes

Toshio TAKIGUCHI, Minoru ABE and Yukio MORIMURA

Department of Synthetic Chemistry, Kiryu College of Technology, Gunma University, Tenjin-cho, Kiryu

(Received September 2, 1967)

As regards the organosilyl or silylene derivatives of pentaerythritol (hereinafter called PET), very little has been said in the literature.[1-3]

In our investigations involving the reactions of PET with triorganochlorosilanes, some tetrakis-triorganosilyl derivatives of PET with the formula of $(R_3SiOCH_2)_4C$(hereafter R_3PET) were isolated in a pure form. They are tetrakis(trimethylsiloxymethyl)methane (Me_3PET), terakis(dimethylbutylsiloxymethyl)methane (Me_2BuPET), tetrakis-(dimethylphenylsiloxymethyl)methane (Me_2Ph-PET), tetrakis(diphenylbutylsiloxymethyl)methane (Ph_2BuPET), and tetrakis(triphenylsiloxymethyl)-methane (Ph_3PET), the last four being new compounds.

They were obtained from the reaction of PET either with the corresponding triorganochlorosilanes or with aminosilanes according to the following schemes.

$$(HOCH_2)_4C + 4R_3SiCl \rightarrow (R_3SiOCH_2)_4C + 4HCl$$

or $$(HOCH_2)_4C + 4R_3SiNH_2 \rightarrow (R_3SiOCH_2)_4C + 4NH_3$$

The products were all soluble in toluene and dioxane, and were found to be quite stable towards hydrolysis in the absence of ionic catalysts.

Experimental

Triorganochlorosilanes. A pure sample of trimethylchlorosilane (bp 58°C) was obtained from the Shin-etsu Chemical Industrial Co. Dimethylbutylchlorosilane (bp 139—140°C), dimethylphenyl chlorosilane (bp 76—78°C/2 mmHg), and diphenylbutylchlorosilane (bp 129°C/1 mmHg) were prepared by the Grignard route.[4] Triphenylchlorosilane (mp 98—99°C) was isolated from a high-boiling residue[5] of the direct synthesis of phenylchlorosilanes. They were further purified by conventional methods immediately before use.

Triorganoaminosilanes. Hexamethyldisilazane (bp 121°C), dimethylbutylaminosilane (bp 128°C), dimethylphenylaminosilane (bp 142°C/3 mmHg), diphenylbutylaminosilane (bp 139°C/1.5 mmHg), and triphenylaminosilane (mp 60°C, bp 156°C/1.8 mmHg) were prepared from the reaction of dried gaseous ammonia with the corresponding chlorosilanes dissolved in ether; the yields were consistently 85—88%.

The Preparation of R_3PET. Typical procedures will be described in detail, using the preparations of Me_3PET and Ph_3PET as examples.

Me_3PET: When a mixture of trimethylchlorosilane (0.44 mol, 47.7 g) and PET (0.1 mol, 13.6 g) was gently refluxed, PET gradually dissolved with the evolution of hydrogen chloride, and the temperature rose to 120°C after 30 hr. The resultant substance was then fractionated and a fraction boiling at 105—115°C/1 mmHg was collected. The further purification of the product was effected by fractional vacuum distillation, giving pure Me_3PET, mp 27.5—28.5°C, bp 110°C/1 mmHg (lit.[2] bp 128—129°C/5 mmHg) in a yield of 77% (mean).

Found: Si, 26.4; C, 48.52; H, 10.54%; mol wt, 418 (determined cryoscopically in dioxane). Calcd for $C_{17}H_{44}O_4Si_4$: Si, 26.4; C, 48.06; H, 10.44%; mol wt, 425.

Several modifications of the above procedure, using some organic bases (aniline, *N*, *N*-dimethylaniline, pyridine, *etc.*) as a hydrogen-chloride acceptor and toluene as a reaction medium unfailingly gave identical products in similar yields.

1) L. W. Breed, W. J. Haggerty, Jr. and J. Harvey, *J. Org. Chem.*, **25**, 1804 (1960).
2) M. M. Sprung and L. S. Nelson, *ibid.*, **20**, 1750 (1955).
3) B. N. Dolgov, G. Vinter, V. A. Komarov, N. P. Kharitonov and Y. I. Khudobin, *Izvest. Akad. Nauk SSSR, Ser. Khim.*, **1963**, 2146; *Chem. Abstr.*, **60**, 9305c (1964).
4) T. Takiguchi and M. Abe, *Kogyo Kagaku Zasshi (J. Chem. Soc. Japan, Ind. Chem. Sect.)*, **66**, 625 (1963).
5) T. Takiguchi and M. Abe, *ibid.*, **68**, 679 (1965).

Another effective method of preparing the product was by the reaction of PET with hexamethyldisilazane; here, there was a consistent yield of 83—86%.

Ph_3PET: When a mixed sample of triphenylaminosilane (0.44 mol, 123.4 g) and PET (0.03 mol, 4.1 g) was gently heated, a reaction occured with the evolution of ammonia. After the addition of PET (0.07 mol, 9.5 g) to the mixture, portion by portion, over a 1-hr period, the whole was further maintained at 160—170°C for 6 hr. After the resultant substance had stood, there was obtained a transparent viscous liquid from which a white crystalline mass, melting at 255—267°C, was obtained by the extraction of impurities with hexane. The recrystallization of the crude product from hexane-dioxane (1 : 1) gave 82 g (70%) of pure Ph_3PET, mp 285°C, as fine cubic crystals.

Found: Si, 9.6; C, 77.73; H, 5.15%; mol wt, 1165. Calcd for $C_{77}H_{68}O_4Si_4$: Si, 9.6; C, 79.07; H, 5.86%; mol wt, 1170.

Ph_3PET was readily soluble in dioxane, soluble in hot toluene, soluble only with difficulty in boiling benzene, and insoluble in ether, hexane, and ethanol. This was also found highly resistant to hydrolysis and was recovered quite unchanged after prolonged boiling with water.

The preparation of this compound from a direct reaction between PET and triphenylchlorosilane was also attempted; however, this attempt failed because of the presumably lower reactivity of triphenylchlorosilane. The yield of the tetrakis-derivatives always remained below 20%, even when an organic base was used as a hydrogen-chloride acceptor, the majority of the by-product being partially triphenylsilyl-substituted PET with hydroxyl groups.

Other Tetrakis-derivatives. Me_2BuPET (bp 155°C/1 mmHg), Me_2PhPET (bp 224°C/0.1 mmHg), and Ph_2BuPET (mp 76°C, bp 332°C/0.1 mmHg) were prepared by procedures similar to those used for Me_3PET or Ph_3PET. Throughout all the preparations, reactions with aminosilanes proved to be more advantageous than those with chlorosilanes, both in the marked simplicity of the procedure and in the higher yield of tetrakisderivatives.

Me_2BuPET Found: Si, 18.5; C, 58.95; H, 12.61%; mol wt, 575. Calcd for $C_{29}H_{68}O_4Si_4$: Si, 18.9; C, 58.73; H, 11.56%; mol wt, 593.

Me_2PhPET Found: Si, 16.5; C, 65.89; H, 7.97%; mol wt, 665. Calcd for $C_{37}H_{52}O_4Si_4$: Si, 16.7; C, 66.02; H, 7.97%; mol wt, 673.

Ph_2BuPET Found: Si, 10.2; C, 75.78; H, 7.96%; mol wt, 1075. Calcd for $C_{69}H_{84}O_4Si_4$: Si, 10.3, C, 76.05; H, 7.77%; mol wt, 1090.

The products thus obtained were all readily soluble in dioxane and were soluble in acetone, toluene and boiling benzene. The compounds with methyl groups were soluble in hot hexane and ethanol. They were all fairly resistant to solvolysis in the absence of an ionic catalyst. However, the addition of a few drops of acid or alkali to the boiling ethanolic solution readily decomposed it to the original PET and the ocrresponding hexaorganodisiloxanes.

IR Absorption Spectra and X-Ray Powder Patterns. All the products were well defined and were characterized by their IR spectra. The X-ray powder diffraction data were also recorded for crystalline products by using Cu$K\alpha$ radiation filtered by Ni.

Some Reactions of Di-π-cyclopentadienyldiphenyltitanium

Haruo MASAI, Kenkichi SONOGASHIRA and Nobue HAGIHARA

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received September 7, 1967)

In the course of our study of the isomerization of olefin catalyzed by $(\pi\text{-}C_5H_5)_2Ti(C_6H_5)_2$ and related complexes,*1 it was found that the isomerization was inhibited by diphenylacetylene and carbon monoxide (CO). These phenomena were studied in some detail in relation to the investigation of the mechanism of the isomerization, and the following results were obtained.

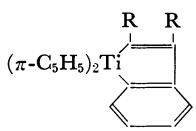
When $(\pi\text{-}C_5H_5)_2Ti(C_6H_5)_2$ was refluxed in benzene with diphenylacetylene under nitrogen, a new organotitanium complex (I) was obtained. The dark green crystals of the complex (I), having the empirical formula, $C_{30}H_{24}Ti$, are stable in air at room temperature. For the determination of the structure of this complex, the reactions described below have been investigated.

By the reaction of I with aq. HCl in $CHCl_3$, $(\pi\text{-}C_5H_5)_2TiCl_2$ and triphenylethylene were isolated in good yields. This result suggests the existence of a $(\pi\text{-}C_5H_5)_2Ti$ fragment in I.

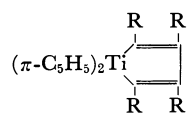
The complex (I) easily reacted with pressured CO at room temperature to afford 2, 3-diphenylindone in good yields. An attempt to isolate the organotitanium fragment was, in this case, unsuccessful.

The decomposition of the complex (I) by iodine in benzene gave *cis*-1-iodo-1, 2-diphenyl-2-(*o*-iodophenyl)-ethylene in good yields.

These facts lead us to the structure (A), namely, *Ti*-di-π-cyclopentadienyl-2, 3-diphenylbenztitanacyclopentadiene.



(A) (R=C_6H_5)



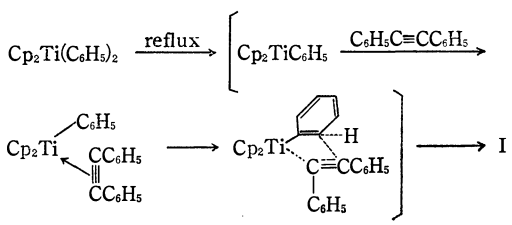
(B) (R=C_6H_5)

An analogous complex (B) has been prepared by us[1] and by Vol'pin *et al.*[2] independently. We obtained the complex (B) from the reaction of $(\pi\text{-}C_5H_5)_2Ti(CO)_2$ with diphenylacetylene.

The structure of the complex (I) is also supported by the NMR spectrum, which shows a sharp singlet at τ 3.9 and a multiplet centered at τ 3.4. The former is assignable to the cyclopentadienyl protons, and the later to the aromatic protons. The relative intensities observed are 10 and 13.5 (calcd for the structure (A): 10 and 14) respectively.

The infrared spectrum of I shows no bands due to Ti-H and coordinated C≡C stretching absorptions.

An attempt to prepare the analogous complex from the reaction of $(\pi\text{-}C_5H_5)_2Ti(CH_3)_2$ with diphenylacetylene by the similar procedure was unsuccessful.[3] Therefore, it is not likely that the complex (I) is formed through the insertion of acetylene in the Ti-alkyl bond. It seems more reasonable to describe the route of the formation of the complex (I) as follows:



(Cp = π-C_5H_5)

The complex (I) was not attacked by atmospheric hydrogen at the reflux temperature in benzene, while diphenyl and dimethyl derivatives easily reacted under the same conditions.[4] This might be due to the stability of the titanacyclopentadiene ring caused by the partial double-bond character of the Ti-C σ-bond.

When $(\pi\text{-}C_5H_5)_2Ti(C_6H_5)_2$ was reacted with pressured CO at room temperature, benzophenone was isolated in good yields. It is considered that CO should initially coordinate to the vacant orbital of Ti. The insertion of CO in the Ti-phenyl bond will occur in the next step, and finally another phenyl group will migrate to the acyl group, producing benzophenone.

Experimental

$(\pi\text{-}C_5H_5)_2Ti(C_6H_5)_2$ was prepared by the method reported by Summers *et al.*[5]

Synthesis of I. A solution of 0.5 g of $(\pi\text{-}C_5H_5)_2Ti(C_6H_5)_2$ and 0.28 g of diphenylacetylene in 10 ml

of benzene was refluxed under nitrogen for 1 hr. The orangecolored solution turned dark green. The solution was then purified by column chromatography, using alumina under nitrogen. A dark green band eluted by benzene was collected. After the removal of the benzene, 0.18 g of crude, dark green crystals were obtained (46%). An analytical sample was obtained by recrystallization from CH_2Cl_2 - petroleum ether, mp 227—228°C.

Found: C, 83.64; H, 5.58%; mol wt (cryoscopic method in benzene using a Dampfdruckosmometer des Dr-Ing Herbert Knauer), 435. Calcd for $C_{30}H_{24}Ti$: C, 83.33; H, 5.59%; mol wt, 432.

The NMR spectrum of I in CCl_4 was recorded by a Varian A-60 spectrometer, using TMS as the internal standard.

The infrared spectrum was taken with a KBr tablet.

This complex was hydrogenated in Hershberg's apparatus in benzene at a reflux temperature. No hydrogen was absorbed.

Reaction of I with Aq. HCl. To a solution of 0.4 g of I in 15 m*l* of $CHCl_3$, an excess of aq. HCl was added. The color of the $CHCl_3$ layer immediately changed to red. The organic layer was then separated, and the aqueous layer was extracted by $CHCl_3$. After the removal of the $CHCl_3$, the residual mass was extracted by petroleum ether. Fine red crystals remained in the flask. The infrared spectrum of these crystals, obtained by the KBr method, was thoroughly coincident with that of authentic $(\pi\text{-}C_5H_5)_2TiCl_2$[6] (0.199 g, 70%).

The extract was purified by chromatography over alumina. After the evaporation of the solvent, white crystals were obtained, and the crystals were recrystalized from petroleum ether. The melting point and the infrared absorption spectrum of these crystals were identical with those of authentic triphenylethylene[7] (0.166 g, 70%), mp 72.5—73.5°C. Found: C, 93.63; H, 6.51%; mol wt (by vapor pressure osmometer, Dampfdruckosmometer des Dr-Ing Herbert Knauer), 256.8. Calcd for $C_{20}H_{16}$: C, 93.61; H, 6.29%; mol wt, 256.3.

Carbonylation of I. A solution of 0.068 g of I in 10 m*l* of benzene was reacted with CO under 200 atm at room temperature for 7 hr. An orange-yellow solution containing a yellow precipitate was thus obtained. This reaction mixture was chromatographed over alumina and eluted with benzene. After the removal of the benzene, 0.03 g of ruby-red crystals was obtained and recrystallized from benzene-petroleum ether. The melting point and the infrared spectrum of these crystals were identical with those of authentic 2, 3-diphenylindone[8] (70%), mp 156.5—157.5°C.

Found: C, 89.28; H, 5.07%. Calcd for $C_{21}H_{14}O$: C, 89.33; 5.00%.

Decomposition of I by Iodine. To a solution of 0.2 g of I in 10 m*l* of benzene, an excess of an iodine solution in benzene was gradually added at room temperature. After the addition, the mixture was left for 1 hr. After the removal of the solvent, the residue was extracted by petroleum ether, and the extract was chromatographed. A slightly-colored solution eluted by petroleum ether was thus obtained. After the removal of the solvent, 0.15 g of yellowish crystals recrystalized from benzene-petroleum ether were obtained. The melting point of these crystals was identical with that of *cis*-1-iodo-1, 2-diphenyl-2-(*o*-iodophenyl)-ethylene found in the literature[9] (64%), mp 172—173°C. Found: C, 47.33; H, 2.70%. Calcd for $C_{20}H_{14}I_2$: C, 47.27; H, 2.78%.

Carbonylation of $(\pi\text{-}C_5H_5)_2Ti(C_6H_5)_2$. A solution of 3.2 g of this complex in 20 m*l* of benzene was reacted with CO by a procedure similar to that used in the case of I. After the removal of the solvent, the residue was extracted by petroleum ether. The extract was concentrated in a vacuum, and then the residual liquid was distilled. A colorless liquid of benzophenone was thus obtained (bp 118°C/3 mmHg). The infrared spectrum in CCl_4 was coincident with that of authentic benzophenone (1.5 g, 83%).

Found: C, 85.00; H, 5.64%. Calcd for $C_{13}H_{10}O$: C, 85.69; H, 5.53%.

2, 4-Dinitrophenylhydrazone of this sample showed the same melting point as that of authentic benzophenone 2, 4-dinitrophenylhydrazone, mp 247—248°C.

Found: C, 62.94; H, 3.66; N, 15.45%. Calcd for $C_{19}H_{14}N_4O_4$: C, 62.98; H, 3.39; N, 15.45%.

Radical Copolymerization of *m*-Bromostyrene with Liquid Sulfur Dioxide*[1]

Masashi IINO, Takeshi MASUDA and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Higashinoda, Miyakojima-ku, Osaka

(Received September 12, 1967)

The simple olefins, such as ethylene, propylene, and butenes, readily form alternating copolymers with sulfur dioxide from a wide range of feed compositions by means of a radical initiator.

Styrene also reacts with sulfur dioxide by means of a radical initiator and forms a 2 : 1 copolymer (molar ratio of styrene unit to sulfur dioxide unit) from a wide range of feed compositions above room temperature.[1,2] The fact that the resulting copolymers are not alternating but 2 : 1 copolymers suggests that the propagation reaction can not be elucidated by the ordinary mechanism of copolymerization.

Thus, Barb[1] has given an interpretation involving reversible propagation steps and the inclusion of sulfur dioxide in the copolymer only by the reaction of a growing chain with a 1 : 1 styrene-sulfur dioxide complex, which can be shown to be present spectroscopically.

However, as an entirely equivalent scheme can be derived without invoking any complex participation,[3] Barb's postulation appears to be uncertain.

Concerning this problem, we have investigated the copolymerization of various styrene derivatives with sulfur dioxide.[4] We have found that *p*-isopropylstyrene[4b] or *p*-methylstyrene,[4a] whose substituent is an electron-donating group, forms a 2 : 1 copolymer like that in the case of styrene, but *p*-nitrostyrene,[4c] with an electron-withdrawing group, does not form a 2 : 1 copolymer.

The results in the case of *p*-nitrostyrene are thus different from those in the case of styrene, but *p*-nitrostyrene reacts with sulfur dioxide heterogeneously, unlike as in the case of styrene; therefore, it is possible to consider that this abnormality in the *p*-nitrostyrene - sulfur dioxide system is due to its heterogeneity.

To elucidate this problem we have investigated the copolymerization of *m*-bromostyrene with sulfur dioxide, because *m*-bromostyrene, whose substituent, *m*-Br, was electron-withdrawing, as in the case of *p*-nitrostyrene, has reacted with sulfur dioxide homogeneously.

Experimental

Styrene, α, α'-azobisisobutyronitrile (AIBN), and liquid sulfur dioxide were purified by a method similar to that described in a previous paper.[4]

m-Bromostyrene was prepared from *m*-bromobenzaldehyde.[5] Elementary analysis: Found: C, 52.78; H, 4.11; Br, 43.36%. Calcd for C_8H_7Br: C, 52.48; H, 3.82; Br, 43.68%.

Bp 76.5—78.0°C/11 mmHg; n_D^{17}, 1.5882. The *m*-bromostyrene thus obtained was distilled twice in a nitrogen atmosphere at a reduced pressure.

The *n*-hexane used in the measurement of the ultraviolet spectra was purified in the usual way.

The method of the copolymerization was similar to that described in a previous paper.[2]

The compositions of the copolymers were determined from the results of elementary analyses of carbon. The ultraviolet spectra of a *m*-bromostyrene-liquid sulfur dioxide mixture were measured in *n*-hexane by using a pressure cell.

Results and Discussion

Copolymerization of *m*-Bromostyrene and Liquid Sulfur Dioxide. The radical copolymerization of *m*-bromostyrene with sulfur dioxide was carried out at 50°C, using AIBN as an initiator, and was stopped at a low conversion (below 7%).

As is shown in Fig. 1, the sulfur dioxide contents (mol%) in the resulting copolymers vary with the feed composition but are all below that (about 33 mol%) in the case of styrene.

The *e* value (*Q-e* scheme) of styrene, *m*-bromostyrene, and *p*-nitrostyrene are −0.8, −0.21, and 0.39 respectively.[6] The sulfur dioxide contents (mol%) of the copolymers obtained at 50°C from an equimolar feed composition in the case of styrene, *m*-bromostyrene, and *p*-nitrostyrene are 33, 24, and 8 respectively.

Therefore, it may be concluded that styrene derivatives, having an electron-withdrawing substituent and a larger *e* value than styrene, have no tendency toward constant copolymer compositions, and that the sulfur dioxide contents in the

copolymers are lower than that in the case of styrene.

Ultraviolet Spectra of the *m*-Bromostyrene-Liquid Sulfur Dioxide Mixture. It is well known that sulfur dioxide forms a charge-transfer complex with some olefins, in which complex sulfur dioxide acts as an electron acceptor and olefin, as an electron donor.[7] In Fig. 2 the ultraviolet spectra of *m*-bromostyrene, sulfur dioxide, and *m*-bromostyrene - sulfur dioxide mixture are shown. It may be seen in Fig. 2 that a complex is formed in the *m*-bromostyrene - sulfur dioxide mixture, because there is a large shift in the absorption of the mixture in comparison with that of *m*-bromostyrene or sulfur dioxide only in the same concentration as in the mixture.

From the above results, in the *m*-bromostyrene - sulfur dioxide system a charge-transfer complex is formed as in the case of styrene; however, the compositions of the copolymers vary with the feed compositions, unlike the case of styrene.

As has previously been described, in the case of the *p*-nitrostyrene - sulfur dioxide system, the compositions of the copolymers vary with the feed compositions; the results of the ultraviolet spectra of the *p*-nitrostyrene - sulfur dioxide mixture suggest that no charge-transfer complex is formed.[4c]

Therefore, it may be concluded that, in the radical copolymerization of sulfur dioxide with styrene or its derivative (and perhaps also in that of sulfur dioxide with another olefin), the formation of a charge-transfer complex is not related to the constancy of the compositions of the copolymers when the feed compositions are varied.

The authors wish to thank the Seitetsu Kagaku K. K. for its gift of liquid sulfur dioxide.

Oxidation of Graphite by Carbon Dioxide - Carbon Monoxide Gas Mixtures

Shigeru YAMAUCHI and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 14, 1967)

Graphite has been considered to be oxidized by carbon dioxide by the following mechanism[1];

$$C + CO_2 \underset{i_2}{\overset{i_1}{\rightleftarrows}} C(O) + CO \quad (1)$$

$$C(O) \xrightarrow[i_3]{} CO \quad (2)$$

where i_1, i_2, and i_3 are rate constants and C(O) is the surface oxide.

From Eqs. (1) and (2) the over-all oxidation rate is expressed as follows;

$$R = i_1 P_{CO_2}/(1 + (i_2/i_3)P_{CO} + (i_1/i_3)P_{CO_2}) \quad (3)$$

In this study the over-all oxidation rates were measured in the carbon dioxide - carbon monoxide gas mixtures and the values of rate constants, i_1, i_2 and i_3 for elementary reactions were determined at temperatures from 1100°C to 1175°C. Activation energies for elementary reactions were determined and discussed in connection with the surface oxide.

Experimental

Two types of high purity artificial graphite made from petroleum coke were used. In the course of preparation, graphites A and B were heat-treated at 2400°C and 3000°C, respectively. Both kinds of graphite did not contain any metallic impurities more than 1 ppm, as determined by the spectroscopic analysis.

Results and Discussion

Equation (3) is rewritten in the form;

$$1/R = (1/i_3) + (i_2/i_1 \cdot i_3)(P_{CO}/P_{CO_2}) + (1/i_1)(1/P_{CO_2}) \quad (4)$$

Equation (4) shows that: (1) If the rates are measured at various total pressures with a constant ratio of (P_{CO}/P_{CO_2}), the plot of $1/R$ *vs.* $1/P_{CO_2}$ gives the value of $1/i_1$. (2) The intercept on the axis of $1/R$ (of the above straight line) gives the value of $1/R^\circ = (1/i_3) + (i_2/i_1 \cdot i_3)(P_{CO}/P_{CO_2})$. Moreover, the plot of $1/R^\circ$ *vs.* P_{CO}/P_{CO_2} gives a straight line and the slope gives the value of $(i_2/i_1 \cdot i_3)$ and the intercept on the axis of $1/R^\circ$ gives the value of $1/i_3$. The value of the above slope should coincide with the value of a slope when $1/R$ is plotted against

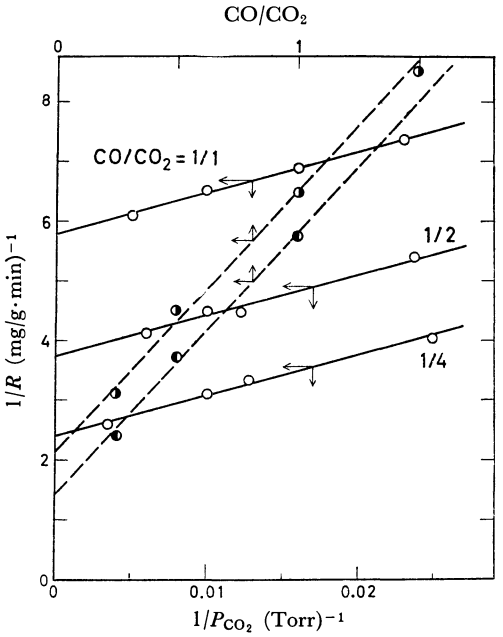

Fig. 1. Plot of $1/R$ *vs.* $1/P_{CO_2}$ and $1/R$ *vs.* P_{CO}/P_{CO_2} of graphite A at 1150°C.
-○-: plots of $1/R$ *vs.* $1/P_{CO_2}$ at constant ratios of P_{CO}/P_{CO_2}
-◑-: plot of $1/R^\circ$ *vs.* P_{CO}/P_{CO_2}
-◐-: plot of $1/R$ *vs.* P_{CO}/P_{CO_2} (P_{CO_2} = 100 Torr)

P_{CO}/P_{CO_2} at a constant partial pressure of carbon dioxide.

The plots of $1/R$ *vs.* $1/P_{CO_2}$ and $1/R$ *vs.* (P_{CO}/P_{CO_2}) are shown in Fig. 1. The values of i_1, i_2 and i_3 are calculated from the values of $1/i_1$, $1/i_3$ and $i_2/i_1 \cdot i_3$. They are shown in Figs. 2 and 3 as Arrhenius plots. The values of activation energies are also given in these figures.

The value of $\Delta H_1 = E_1 - E_2$ gives the enthalpy change of the reaction (1). The values of ΔH_1 obtained in this study are 24 kcal/mol and 20 kcal/mol for graphites A and B, respectively.

Assuming the value of ΔH_1 to be 25 kcal/mol, the enthalpy of formation of surface oxides is calculated as follows.

$$\Delta H^\circ_{f,C(O)} = \Delta H_1 - \Delta H^\circ_{f,CO} + \Delta H^\circ_{f,C} + \Delta H^\circ_{f,CO_2} = 42 \text{ kcal/mol}$$

Bull and co-workers[2] reported the value of the

1) P. L. Walker, Jr., F. Rusinko, Jr. and L. G. Austin, Advances in Catalysis, Vol. 11, Academic Press, New York (1959), p. 133.

2) H. I. Bull, M. H. Hall and W. E. Garner, *J. Chem. Soc.*, **19**, 837 (1931).

heat of adsorption of oxygen on the surface of carbons to be 100 kcal/mol. If the adsorption results in the formation of surface oxide, the heat of formation of this surface oxide is 50 kcal/mol. $\Delta H^\circ_{f,C(O)}$ determinedk inetically in this study seems to meet this value.

Effect of Chlorine on the Oxidation of Graphite by Carbon Dioxide

Shigeru YAMAUCHI, Takashi MUKAIBO and Tadao IKEDA

Department of Industrial Chemstry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 14, 1967)

In the previous papers[1-3] the effects of iodine and bromine on the oxidation of graphite were reported to be an accelerating one. This note reports the experimental results on the effect of chlorine on the oxidation of graphite by carbon dioxide.

Experimental

High purity artificial graphite made from petroleum coke and graphitized at 2400°C was used. The results of a spectroscopic analysis showed that this graphite contained only 0.05 ppm Mg and 0.5 ppm Si as impurities. Impurities other than Mg and Si were not found.

The chlorine gas was fed from a bomb at a constant flow rate and the partial pressure of chlorine was determined by the ratio of the flow rate of chlorine to that of carbon dioxide. The apparatus and the experimental procedures were the same as described in detail in a previous paper.[1]

Results

As shown in Fig. 1, the oxidation rate increased rapidly during an initial period following the supply of chlorine gas into the carbon dioxide gas stream and then gradually decreased to a steady value. This steady value was considered to be that of oxidation rate affected by the presence of

1) T. Mukaibo and S. Yamauchi, *Carbon*, **3**, 87 (1965).
2) S. Yamauchi and T. Mukaibo, *ibid.*, **4**, 455 (1966).
3) S. Yamauchi, T. Mukaibo and M. Hirano, *ibid.*, **5**, 243 (1967).

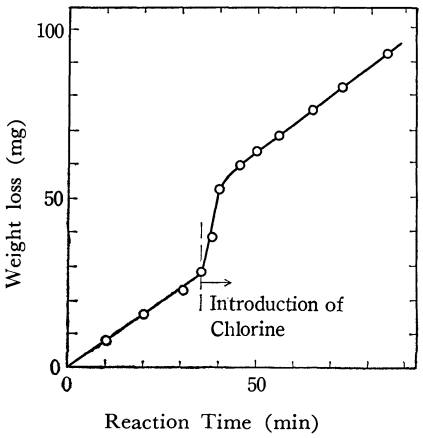

Fig. 1. Weight loss *vs.* time curve (1100°C).

chlorine gas.

The oxidation rate was markedly affected by the partial pressures of chlorine gas as shown in Fig. 2. Oxidation rates accelerated by iodine and bromine are also presented in Fig. 2 in order to compare the effect of halogenous gases. It is seen that the oxidation rate has a maximum point at 0.9 Torr in the case of bromine and 0.1 Torr in the case of chlorine, respectively. Any maximum point was not observed in the case of iodine at the partial pressure of 0.3 to 10 Torr.

The most remarkable observation in Fig. 2 is that the effect of chlorine at the partial pressures above 3.5 Torr is an inhibiting one, although an accelerating effect was observed on the effect of iodine and bromine.

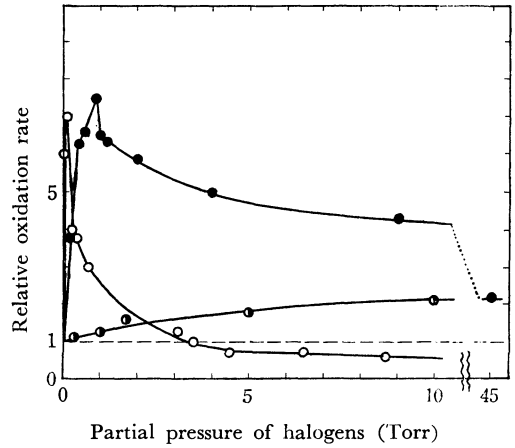

Fig. 2. The dependence of oxidation rates on the partial pressure of halogens.

The relative oxidation rate is defined as a ratio of oxidation rate affected by halogens to that in pure carbon dioxide. If the value of the relative oxidation rate is larger than unity, the effect of halogens is accelerating and if the value is smaller than unity, the effect is inhibiting.

Preparation of 1-Choro-1-fluoroethylenes *via* Chlorofluorocarbene

Hiroki YAMANAKA, Teiichi ANDO and Wataru FUNASAKA

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 11, 1967)

It has already been reported that chlorofluorocarbene reacts with triphenylphosphine to yield chlorofluoromethylenetriphenylphosphorane, and that the ylid reacts with benzophenone to give 1-chloro-1-fluoro - 2, 2 - diphenylethylene.[1] This paper will deal with the synthesis of some other 1-chloro-1-fluoroethylenes by a modification of this method.

Chlorofluorocarbene was generated by the addition of methanol to a mixture of sodium hydride and methyl dichlorofluoroacetate.[2] After it had been allowed to react with triphenylphosphine, the reaction mixture was treated, without the isolation of the ylid, with a carbonyl compound. The reaction scheme is shown below, and the results are summarized in Table 1.

$$CFCl_2COOCH_3 + CH_3OH/NaH \rightarrow :CFCl$$

$$:CFCl + Ph_3P \rightarrow Ph_3P{=}CFCl$$

$$Ph_3P{=}CFCl + RCOR' \rightarrow RR'C{=}CFCl + Ph_3PO$$

The main product obtained from an aldehyde or an unsymmetrical ketone gave a gas chromatogram composed of two peaks, indicating the formation of two geometrical isomers. Unfortunately, however, the retention times of the isomers under the conditions employed were too close to each other to make the gas chromatographic separation of the

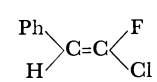
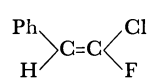
isomers feasible,[3] except in the following two cases.

The product obtained from benzaldehyde (β-chloro-β-fluorostyrene) was successfully separated, by preparative gas chromatography (TCP 10%, 80°C, He 30 ml/min) into two isomers, the *anti*- (Ia) and the *syn*-form (Ib). The structures of the isomers were determined by their proton NMR spectra,[4] and the ratio of Ia to Ib (57 : 43) was determined by gas chromatography before distillation. The *anti*-isomer had a longer retention time than the *syn*-isomer.

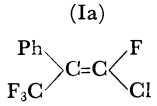
Similarly, the product from α, α, α-trifluoroacetophenone (1 - chloro - 1, 3, 3, 3 - tetrafluoro-2-phenylpropene) could also be separated into *anti*-(IIa) and *syn*- (IIb) isomers (PEG 6000 10%, 120°C, He 30 ml/min). The ratio of IIa to IIb was 52 : 48, the *anti*-isomer again possessing a longer retention time.



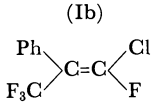
(Ia)



(Ib)



(IIa)



(IIb)

The structural assignments of the ethylenes derived from aryl trifluoromethyl ketones, including IIa and IIb, were made by means of their fluorine NMR spectra, based on the fact that the coupling constant between $-CF_3$ and =CF in the $-C(CF_3)$=CF– system is larger when they are cis to each other than when they are trans.[5] The NMR data are shown in Table 2.

Table 3 shows the results of the competition reactions which were carried out in order to examine the relative reactivities of carbonyl compounds toward chlorofluoromethylenetriphenylphosphorane. As is evident from the table, the ylid reacts with aldehydes or with ketones having electron-withdrawing groups more rapidly than with ketones having electron-releasing groups. Analogous results have been obtained with dichloromethylenetriphenylphosphorane.[1]

3) As judged from the areas of the NMR signals and/or the half-height widths of the gas chromatographic peaks, the ratio of the isomers formed was estimated to be approximately 50 : 50 in all of these cases.

5) J. W. Emsley, J. Feeney and L. H. Sutcliffe, "High Resolution NMR Spectroscopy," Vol. 2, Pergamon Press, London (1966), p. 909.

As compared with the other methods for preparing 1-chloro-1-fluoroethylenes,[6] the method described in this paper seems to have the advantages of being simpler and of wider applicability, although the yields are not always satisfactory.

Experimental

General Procedure for Preparing 1-Chloro-1-fluoroethylenes. A mixture of 0.2 mol of triphenylphosphine, 0.25 mol of sodium hydride, 0.25 mol of methyl dichlorofluoroacetate,[4] and 100 m*l* of dry petroleum ether (bp 60—70°C) was placed in a 200-m*l*, four-necked flask equipped with a stirrer, a thermometer, a gas inlet tube for introducing nitrogen, and a reflux condenser. To the mixture was added, under an atmosphere of nitrogen, 0.25 mol of methanol at 25—30°C (3—5 hr), and then 0.25 mol of a carbonyl compound at the same temperature (0.5 hr). After the reaction mixture had been allowed to stand at 60—80°C for 10 hr, it was cooled to room temperature and poured into 100 m*l* of water. The organic layer was separated from the aqueous layer, the aqueous layer was extracted twice with 50 m*l* portions of ether, and the combined organic layer was dried over anhydrous sodium sulfate. The distillation of the organic layer gave the desived ethylene (8—63%), the unchanged carbonyl compound (10—25%), and an unidentified product whose bp was a little higher than that of the ethylene. The ethylenes were identified by elemental analysis as well as by IR and /or NMR spectroscopy.

Competition Reaction. A mixture of two different carbonyl compounds (each 0.017 mol) was gradually added, at 25°C (0.5 hr), to a reaction mixture containing chlorofluoromethylenetriphenylphosphorane, which had been obtained, in the way described above, from 0.017 mol of triphenylphosphine, 0.02 mol of sodium hydride, 0.02 mol of methyl dichlorofluoroacetate, 0.02 mol of methanol, and 20 m*l* of benzene. The reaction mixture was kept at 60—80°C for 10 hr, and then cooled to room temperature. The ratio of the olefinic products was determined, without distillation, by gas chromatography with TCP, Apiezon Grease L, PEG 4000, or Silicone Grease as the liquid phase. All the olefins were assumed to have the same molar response under the conditions employed.

The authors wish to express their gratitude to Dr. Hiroshige Muramatsu of the Government Industrial Research Institute, Nagoya, for his measurements of the fluorine NMR spectra.

Stabilities of Rare Earth Chelates of 5-Sulphosalicylic Acid

C. R. KANEKAR

Tata Institute of Fundamental Research, Colaba, Bombay 5, India

and N. V. THAKUR and S. M. JOGDEO

Bhabha Atomic Research Centre, Trombay, Bombay 74, India

(Received September 16, 1967)

The spectrophotometric and potentiometric study of complex formation between gadolinium ions and 5-sulphosalicylic acid (SSA) has been reported in an earlier paper.[1] It was observed that at pH lower than 7, the reaction between the metal ion and the ligand results in the formation of a protonated complex of the type MHL in equilibrium with the usual ML complex; between pH 7 and 9, however, ML_2 species are predominantly present in solution. We have now studied the reaction of SSA with other rare earths. The data of stability constants obtained will be discussed in this paper in terms of the bonding in these complexes.

Experimental

The stability constants were determined at 20°C and at constant ionic strength of 0.1 M. The technique used for the potentiometric and the spectrophotometric measurements was similar to that described earlier.[1] The spectrophotometric measurements were made at pH 6.0 which was much below the pH of hydrolysis in each case. The spectra of all the rare earth complexes with this ligand were similar; two maxima were observed. The wavelengths corresponding to them are given in Table 1. At the wavelength of 340 mμ and the concentration chosen, the metal perchlorate had negligible absorption. The ligand, however, had finite absorption and during the evaluation of the stability constants the values of the optical density were corrected for this absorption by Beer's law.

The results obtained for all the rare earth complexes were remarkably similar. In the range of pH investigated (5 to 10), both 1 : 1 and 1 : 2 complexes are formed with this ligand. Below pH 7, the reaction is of the type

$$M+HL \overset{k}{\rightleftharpoons} MHL \overset{k'}{\rightleftharpoons} ML+H$$

The equilibrium constants k and k' have been evaluated in each case by exactly the same manner as described

in the previous paper[1] using both potentiometric and spectrophotometric data. The values of k were also calculated independently from the potentiometric data alone assuming the equilibrium of MHL and ML and this served as a further check on the reliability of the previous calculations.

The values of the stability constant (K_1) for the reaction $M+L \rightleftharpoons ML$ have been calculated using the relation

$$K_1 = k \cdot k' \cdot K_1^H$$

where K_1^H is the first proton ligand stability constant ($10^{11.72}$), involving the phenolic group. The values of K_2 for the reaction $ML+L \rightleftharpoons ML_2$ have been also calculated. The data of k, k', K_1, K_2 and $(K_1 \cdot K_2)$ are given in log units in Table 2.

Discussion

There is considerable evidence that rare earths form compounds involving ionic bonds and that the "f" orbitals are not generally involved in bond formation as they are considerably shielded from the influence of the ligand orbitals. If bonds are ionic, one expects Born's energy relationship to be valid and that, for the complexes of various rare earths, the values of stability constants should increase linearly with e^2/r where r is the radius of the rare earth ion. Such a relationship has been tested for a number of rare earth complexes.[2-5] Moeller *et al.*[6] have reviewed the present state of our knowledge on this subject.

Briefly, the work so far reported indicates that, although the bonding may be predominantly ionic in all the rare earth complexes and the electrostatic description may be fairly adequate for the complexes of the cerium earths, other factors such as steric effect, crystal field stabilisation, the coordination of water molecules in addition to that of the ligand around the rare earth ion and the possibility of $f\pi$-$p\pi$ bonding may be important in the formation of complexes of heavier rare earths. In the light of the previous work the data of the stability constants for SSA complexes can now be examined. The data obtained in this work for k, K_1 and K_2 for various rare earth sulphosalicylates have been plotted in Fig. 1 against e^2/r. For this purpose the values of crystal radii given by

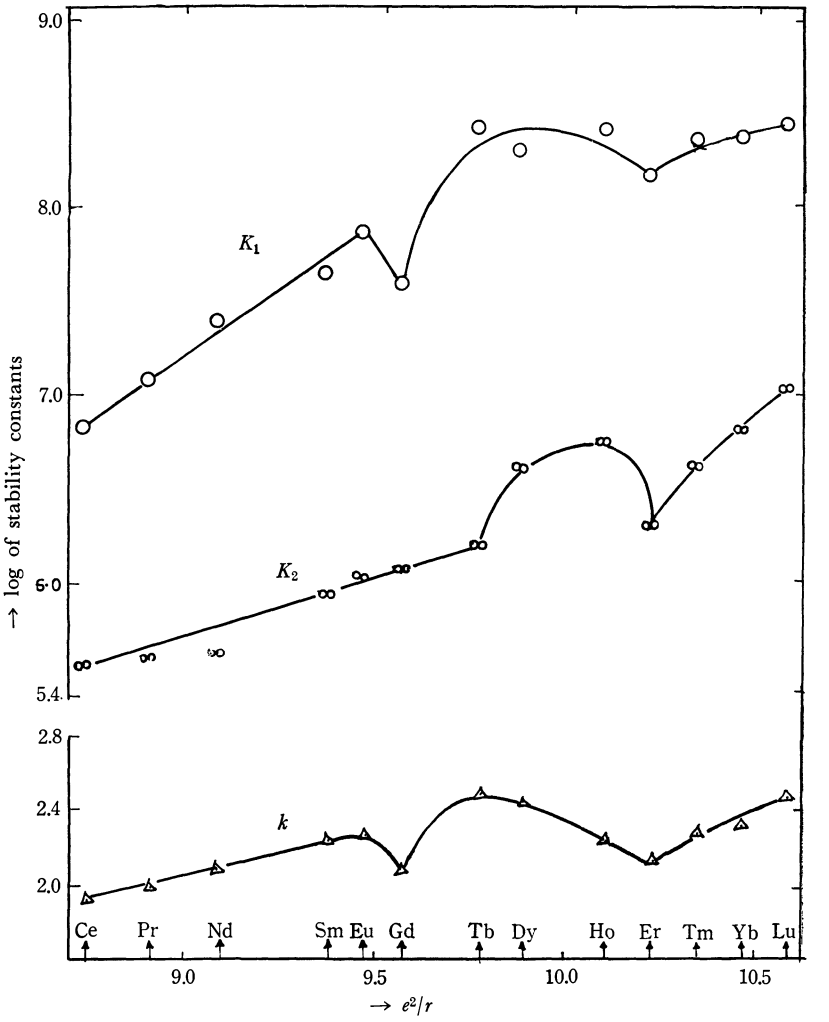

Fig. 1. Graph of stability constants (log units) for rare earth-SSA complexes as a function of ionic potential e^2/r.

Zachariasen[7] have been used. It is seen that the stability constants show in general a monotonic increase with decreasing ionic radius and the increase is approximately linear for the cerium earths (Ce^{3+} to Eu^{3+}). For complexes of rare earths heavier than gadolinium, however, the relationship between log of the stability constant and e^2/r is definitely non-linear. The observed stability constants for the rare earths heavier than gadolinium are in general less than expected from the extrapolation of the straight line observed for the complexes of the lighter rare earths. The progressively smaller radii of these rare earths may impose an increasing steric hindrance to the ligands and thus effect may partly account for the decrease. In the SSA complexes there are only two possible bonding sites and the chelate ring would utilise both these points. If the steric effect is to be operative there should be a change in the number of coordinated atoms. One is, therefore, led to speculate that the number of water molecules coordinated to the rare earths heavier than gadolinium in SSA complexes may be different from the number attached in complexes of the lighter rare earths. This speculation cannot be tested as the data for $\Delta H°$ and $\Delta S°$ for the formation of these complexes is not available. It is reasonable to expect that the steric effect, if present, should be pronounced for the formation of 1 : 2 complex because two chelate rings have to be formed. However, the ratios of K_1/K_2 for the heavier rare earth complexes are not appreciably different from the corresponding ratios for the complexes of the lighter rare earths. It appears, therefore, that the steric effect alone cannot account for the observed departure from the Born relationship and

7) W. H. Zachariasen in G. T. Seaborg and J. J. Katz, eds., "The Actinide Elements," McGraw Hill Book Co., New York (1954), Chap. 18

other factors must be considered. One of them appears to be the interaction of the 4-f orbitals with the ligand orbitals. This may produce different degrees of stabilisation for the various rare earth complexes. To test whether such interactions are significant in rare earth complexes of SSA, it is necessary to study the magnetic susceptibilities of these complexes in the solid state. Such work is in progress.

The values of log k for the SSA complexes are comparatively lower than Fleischer's data[5] for ethylglycolates (EG), ethylmethylglycolates (EMG) and diethylglycolates (EEG) (Ce^{3+} to Lu^{3+} log k (EG) 2.45—3.14; (EMG) 2.47—3.45; (EEG) 2.05—3.25; (SSA) 1.93—2.47). This is probably because SSA complex involves a six membered ring while glycolates form five membered rings.

Our thanks are due to Shri S. Fareeduddin, Head, Chemical Engineering Division, Bhabha Atomic Research Centre, Trombay for his keen interest and encouragement.

SHORT COMMUNICATIONS

Gas Chromatography of Rare Earth Chelates of Pivaloyltrifluoroacetone

Tsunenobu SHIGEMATSU, Masakazu MATSUI and Kei UTSUNOMIYA

Institute for Chemical Research, Kyoto University, Sakyo-ku, Kyoto

(Received January 24, 1968)

The gas chromatography of rare earth chelates of a new β-diketone, pivaloyltrifluoroacetone (PTA) was investigated. The trifluoromethyl group enhances the volatility of these chelates and the *t*-butyl one shows the shielding effect to weaken the intermolecular bonding. By these effects, rare earth PTA chelates were eluted in the gas phase as well as dipivaloylmethane[1] and 1,1,1,2,2,3,3-heptafluoro-7, 7-dimethyl-4, 6-octanedione (fod)-chelates.[2]

PTA was synthesized by condensation of ethyl trifluoroacetate with pinacolin with sodium methoxide. The crude product was purified by converting it into the copper chelate, which was dissolved in ether, decomposed in 10% sulfuric acid, and distilled (bp 39—41°C/17 mmHg). Tris PTA chelates of the following rare earth elements were prepared; Sc, Y, Lu, Yb, Er, Dy, Tb, Gd, Eu, Sm and Nd. The column (75 cm × 3 mm i. d. stainless steel) was packed with 5% (W/W) silicone grease on 60—80 mesh Chromosorb W. The chromatograms of these metal chelates were obtained, of which a typical example was shown in Fig. 1. The order of elution is the same with that of increasing ionic radius of the central metal. The thermogravimetric curves are shown in Fig. 2. They approach 100% weight loss of the chelates, except the case of $Nd(PTA)_3$. Figure 2 indicates that the volatility of the chelate increases with decrease in the ionic radius of rare earth metal ion.

The Temperature Dependence of Absorption Spectra of Cation Radicals of Benzidine and *N, N, N,' N'*-Tetramethyl-benzidine and Their Dimerization in Solution

Katsuo TAKEMOTO, Hiroshi MATSUSAKA, Shigeki NAKAYAMA, Keisuke SUZUKI and Yuzuru OOSHIKA

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received December 20, 1967)

Detailed spectroscopic studies of cation radicals of *p*-phenylenediamine and its methyl derivatives have already been reported,[1-4] but those of benzidines have not yet been obtained. In the present letter, the absorption spectra of the cation radicals of benzidine (I) and *N, N, N', N'*-tetramethyl-benzidine (II) are reported.

Bromides of radicals, which were obtained by oxidation of their parent bases by bromine, were used for this study. Alcoholic solutions of the two radicals were stable enough to obtain quantitative spectrophotometric data below 0°C, although they gradually decomposed at room temperature.

Spectra of the alcoholic solution of II are shown in Fig. 1. Spectra of the solution of I (not shown here) are very similar to those of II except that the A band of II is shifted towards longer wavelengths compared with the corresponding band of I. This red shift of II is perhaps due to the hyperconjugation effect of the methyl groups. Therefore, we suppose that the A band has a transition moment oriented towards the longer molecular axis.

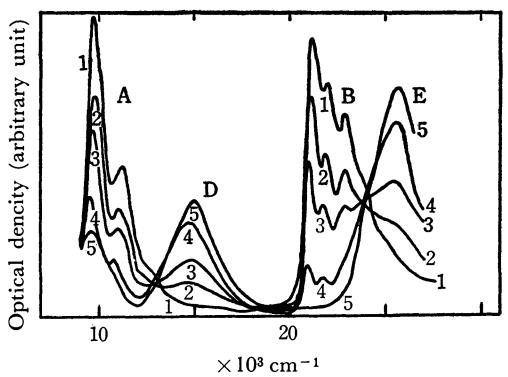

Fig. 1. Spectra of *N, N, N', N'*-tetramethyl-benzidine radical in ethanol.
Curve 1: 25°C, 2: −47°C, 3: −56°C, 4: −77°C, 5: −117°C

The temperature dependent spectra of II were analyzed by assuming an equilibrium $nR^+ \rightleftarrows R_n^{n+}$. Intensity data at each temperature are best fitted by assuming n values between 2.0 and 2.3. Therefore, it is concluded that the radicals form dimers as in the case of phenylenediamines at low temperature. The heat of dimerization of II is estimated to be 13 kcal/mol from the above analysis.

A similar analysis of I leads to the same conclusion, but the data contain greater experimental error. The heat of dimerization of I agreed with that of II within the error (±1 kcal/mol).

It is interesting to add that the heat of dimerization of tetramethyl-*p*-phenylenediamine radical (5 kcal/mol) is smaller than that of *p*-phenylenediamine (8 kcal/mol).

The spectra of solids of I and II are compared with those of their solutions at low temperature in Fig. 2. The solid spectra are very different from those of the solutions at room temperature (the monomer spectra), and have some resemblance to those at low temperature (the dimer spectra). The bands of the solids are, however, shifted towards the red. These suggest that the radicals in the solids interact strongly with each other and exist as dimers of some kind.

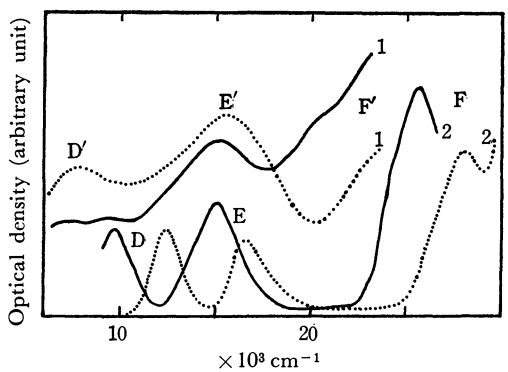

Fig. 2. Spectra of solids and low temperature solutions of benzidine cation radical (·····) and *N, N, N', N'*-tetramethyl-benzidine cation radical (——).
Curve 1: solids (25°C), 2: solutions (about −117°C)

More detailed experimental and theoretical research is now in progress in this laboratory.

Copper(II) Catalyzed Oxidation of Molybdenum(V) in Aqueous Solutions*1

Yukichi YOSHINO, Toshio TAKEUCHI, Hisashi KINOSHITA and Shin UCHIDA

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received December 27, 1967)

Molybdenum(V) with the $4d^1$ electronic structure has been the subject of a number of recent studies from the viewpoints of magnetic susceptibility,[1] ESR,[2] electronic spectra[3] and redox enzyme activity.[4] In connection with these studies, it has been generally believed that molybdenum(V) in aqueous solutions is easily oxidized to molybdenum(VI) by atmospheric oxygen.[5] During the course of investigating stabilization of molybdenum(V) by complex formation, we have found that the oxidation of molybdenum(V) is strongly catalyzed by the presence of metal cations, such as copper(II) and iron(III).

In order to clarify the nature of this reaction, kinetic measurements were carried out as follows. Standard molybdenum(V) solutions prepared by reduction of sodium molybdate(VI) solutions with mercury[6] were used in the preliminary experiments. In the later runs, solid complex, $(NH_4)_2MoOCl_5$, prepared after Klason's method[7] was conveniently employed. Copper(II) and iron(III) solutions were prepared from JIS*2 special grade copper(II) sulfate pentahydrate and iron(III) alum, respectively. Other chemicals were all of JIS special grade and used after purifying by recrystallization or distillation. Thrice-distilled water was used for all experiments. Just before each run, a certain amount of $(NH_4)_2MoOCl_5$ was weighed out and dissolved in the acetate buffer solutions of appropriate pH and temperature. All experiments were conducted with dissolved molybdenum(V) concentration of about 2×10^{-4} M. The oxidation reaction was followed spectrophotometrically by measuring extinction at 320 mμ which is at the maximum of the absorption spectrum of molybdenum(V) species.

After a number of preliminary runs, it was found that, under the conditions given above, the rate of catalytic oxidation of molybdenum(V) was independent of the kind of standard molybdenum(V) species employed, and small amounts of anions, such as acetate, chloride, perchlorate, sulfate and nitrate, had no effect on the oxidation rate.

The results of systematic experiments showed that the rate of oxidation of molybdenum(V) was first order with respect to the concentration of molybdenum(V), when other conditions were kept the same. In the range of pH 2.4—5.2, the rate was inversely proportional to the square of hydrogen ion concentration.

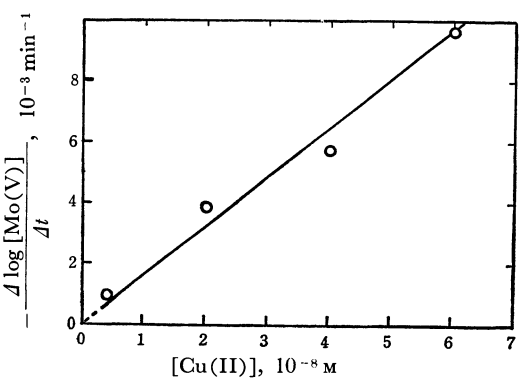

Fig. 1. A plot of the rate of oxidation of molybdenum(V) *vs.* concentration of copper(II).
0.01M acetate buffer, pH: 5.1, 25°C. Initial concentration of molybdenum(V): 2×10^{-4}M

As is seen from Fig. 1, it was also confirmed that under a definite condition the rate is proportional to the concentration of copper(II). In an extreme case where the concentration of copper(II) is less than 10^{-9} M, almost no oxidation of molybdenum(V) was seen to take place. It appeared that the rate is independent of the partial pressure of oxygen.

From the above-mentioned results, the experimental rate law may be expressed as follows:

$$-d[Mo(V)]/dt = k[Mo(V)][Cu(II)]/[H^+]^2.$$

The value of the apparent rate constant k was estimated as *ca.* 2×10^{-4} M min^{-1} at 25°C.

Electron Spin Resonance Study of Carbamoyl Radical*[1]

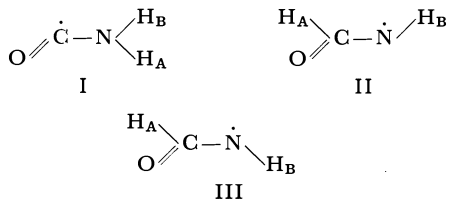
Teijiro YONEZAWA, Isao NODA and Takashi KAWAMURA

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received January 24, 1968)

An ESR study is made of intermediate radicals in the oxidation of amides with hydroxyl radical in aqueous solution by using rapid flow technique with hydrogen peroxide and titanous chloride redox system. The ESR spectrum attributed to acyl type radical is observed. The ESR parameters of the radical from formamide are $g=2.00167$, $a_N=21.8$ gauss (one nitrogen nucleus), $a_H=30.8$ gauss (one proton), and $a_H=1.3$ gauss (one proton). Smith and Wood[1] observed the same spectrum and assigned the radical to HCONH (π electron radical). But we identify it as NH_2CO (carbamoyl σ electron radical) according to the following consideration.

One of characteristics of the spectrum is that the g value is smaller than that of free spin (2.00232). Unusually small g values are observed for some σ electron radicals such as vinyl (2.00220)[2a] and formyl (2.0009)[2b] radicals, on the other hand g value of the π electron radical is generally larger than 2.00232.[3] So the radical from formamide is considered to be a σ electron radical with a configuration I, II, or III.



I II III

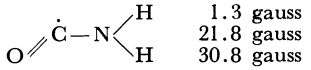
Isotropic hyperfine coupling (hfc) constants and g values of the radicals with structures I, II, and III are calculated with the extended Hückel method.[4,5] The calculated g value[3] for I is 2.00131, for II 2.00427, and for III 2.00984. In Table 1 the calculated hfc constants[4b] are compared with the observed ones.

TABLE 1. CALCULATED hfc CONSTANTS

	a(N)	a(H_A)	a(H_B)
(I)	8.0	31.3	3.1
(II)	1.9	115.9	4.3
(III)	30.2	92.0	33.5
Observed	21.8	30.8	1.3

Only the calculated g value for I is smaller than the g value of free spin (2.00232), and shows a good agreement with the observed value. The calculated hfc constants for I also agree with the observed ones. In view of the above bases it can be concluded that the observed radical is carbamoyl σ electron radical.

These calculated results suggest that in the carbamoyl radical the larger one of the hfc constants of the two protons is due to the *trans* proton to the odd electron orbital and the smaller one to the *cis* proton.



This assignment is consistent with those of vinyl[2a] and iminoxy[6] radicals.

N-Alkyl substituted carbamoyl radicals as well as other π electron radicals formed in the oxidation of amides will be reported in near future.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 767—773 (1968)

A Measure of the Electron-donating Power and Electron-accepting Power of Liquid Organic Compounds

Tsutomu KAGIYA, Yūzō SUMIDA and Tokuji INOUE

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received July 20, 1967)

A quantitative study has been made of the measurement of the electron-donating nature and the electron-accepting nature of various liquid organic compounds. The position of the O–D or C=O absorption band of a liquid compound which contained a small quantity of methanol-d or of acetophenone was measured by means of an infrared spectrophotometer. The relative magnitude of the electron-donating nature or of the electron-accepting nature of the compound was compared by a measurement of the perturbation which it produced on the O–D vibrational band of methanol-d or on the C=O vibrational band of acetophenone. The electron-donating power or the electron-accepting power of a compound is defined as the relative difference (counted as wave numbers) of the O–D or the C=O absorption band observed in the compound from that in benzene. From the results, it was found that, in a homologous series, the electron-donating power decreased with an increase in the ionization potential in the gaseous phase, or with an increase in the pK_b value in the liquid phase, and that it increased linearly with the co-ordination power to diethyl zinc. It was also found that the electron-accepting power increased with an increase in the electron affinity in the gaseous phase and decreased with an increase in the pK_a value in the liquid phase. Moreover, the various liquid organic compounds, classified into four typical groups, were considered on the basis of their electron-donating and electron-accepting power.

It has previously been reported[1,2] that the solvent effect in ionic polymerization was dependent on the relative magnitude of the electron-donating power or on that of the electron-accepting power of the monomer and solvent used.

On the other hand, Gordy *et al.* have made a study of the proton-attracting properties of various liquid compounds,[3] while the relative acceptor strengths of some inorganic halides have been reported on by Lappert *et al.*[4]

The purpose of this report was to evaluate the relative magnitude of the electron-donating nature or the electron-accepting nature of various liquid organic compounds on the basis of the infrared spectral data. The O–D or the C=O vibrational band of the compounds containing a small amount of methanol-d or acetophenone were measured by means of an infrared spectrophotometer. On the basis of these data, a measure of the electron-donating power and of the electron-accepting power of liquid organic compounds was proposed.

Experimental

Materials. The aromatic and aliphatic hydrocarbons, esters, ethers, nitriles, amines, ketones, aldehydes, amides, imines, lactones, sulfoxides, nitro compounds, and inorganic halides were all obtained commercially and were purified by the usual method. Methanol-d, bp 64.5—65.0°C; acetophenone, bp 202°C/750 mmHg.

Apparatus and Method. The infrared spectra of the O–D band of methanol-d or of the C=O band of acetophenone in the mixture were determined with a Hitachi EPI-2 infrared spectrophotometer (resolving power: 3 cm^{-1} at 10 μ; slit width: 0.03 mm at 10 μ), equipped with a sodium chloride prism; the cell used was 0.010 cm, thick. A small quantity of methanol-d or acetophenone was added to a solution of 1.0 m*l* of the liquid organic compound in a 2.0 m*l* weighing bottle. The concentration of acetophenone was 0.1 mol/*l* while that of methanol-d was 0.4 mol/*l*, because the position of the O–D vibrational band was not clear when the concentration of methanol-d was lower than 0.4 mol/*l*. After having been shaken for 10 min at room temperature (18 ± 3°C), the mixture was used for the measurement of the infrared spectrum. The error in the measured shifts of the O–D band is not more than ±1 cm^{-1}, whereas that of the C=O band is ±0.3 cm^{-1} (with the scale up). The electronic properties of various liquid organic compounds were then compared by a measurement of the different perturbations which they caused in the O–D vibrational band of methanol-d or in the C=O vibrational band of acetophenone in the mixture.

Results and Discussion

The positions of the monomeric O–D and C=O vibrational bands of various liquid organic compounds are listed in Table 1, together with the

chemical structures of the compounds. The positions of the O–D vibrational band vary from about 2400 to 2700 cm^{-1} with the kind of compound, and the Lewis bases, such as the ethers and amines, shift to lower frequencies because of the formation of hydrogen bonds. In the C=O band, on the other hand, the Lewis acids which form the coordination bonds with another atom having an electron-pair cause a greater shift to a lower frequency.

Electron-donating Power and Electron-accepting Power. It is considered that the electron-donating nature of liquid compounds corresponds to the proton-attracting force and that the electron-accepting nature is the electron-pair-attracting force. On the basis of the considerations described above, we propose that the electron-donating power or the electron-accepting power of a liquid organic compound is to be defined as the relative difference (counted as wave numbers) of the O–D or the C=O absorption band observed in the compound from that in benzene, chosen as a reference compound.

Electron-donating Power:

$$\Delta\nu_D = \nu_D(\text{benzene}) - \nu_D(\text{compound})$$

Electron-accepting Power:

$$\Delta\nu_A = \nu_A(\text{benzene}) - \nu_A(\text{compound})$$

From the above definition, it can be said that the greater the $\Delta\nu_D$ or the $\Delta\nu_A$ value, the stronger is the proton-attracting force or the electron-pair-attracting force.

Examination of $\Delta\nu_D$ Values. The $\Delta\nu_D$ as defined above expresses the electron-donating power in the state of aggregation. On the other hand, since the ionization potential is the smallest energy which is necessary for taking a valence electron from a gaseous atom or molecule, it is reasonable to consider that the ionization potential is related to the electron-donating power. The relation between the $\Delta\nu_D$ values of several typical liquids and the ionization potentials[5,6] in the gaseous phase is shown in Fig. 1. That the $\Delta\nu_D$ values decreased with an increase in the ionization potentials was observed in any homologous series of aliphatic and aromatic hydrocarbons, ethers, esters, or ketones.

A regular relationship was also observed between the $\Delta\nu_D$ and pK_b values[7] of various aliphatic

and aromatic amines. Figure 2 shows that the larger the $\Delta\nu_D$ value is, the smaller is the pK_b value of the liquid organic compound.

On the other hand, Ishimori and Tsuruta have spectrally investigated the co-ordination power of cyclic ethers to diethyl zinc, which is regarded as an electrophilic compound.[8] It may be inferred that the ether having the stronger co-ordination

7 Triethylamine

power to diethyl zinc has the larger electron-donating power. Figure 3 shows that the co-ordination power to diethyl zinc increases linearly with the $\Delta\nu_D$ value.

Moreover, since it is considered that the hydrogen bond formed between the methanol-d molecule and the solvent molecule is due to the charge transfer, the $\Delta\nu_D$ value may be expected to be related to the bond dissociation energy of the charge-transfer complex[9] formed between the iode molecule and the electron-donor molecule. In order to discuss this relation, we tried to plot the $\Delta\nu_D$ values of the electron donors against the bond dissociation energies of the charge-transfer complexes. As Fig. 4 shows, the energies of the bond dissociation of the charge-transfer complexes are in better correlation with the $\Delta\nu_D$ values than with the ionization potentials.

From these results, it may be concluded that the $\Delta\nu_D$ value expresses quantitatively the electron-donating power in both the gaseous and liquid phases.

Examination of $\Delta\nu_A$ Values. The $\Delta\nu_A$ value of liquid compound is defined above as the electron-accepting power in the state of aggregation. On the other hand, the electron affinity of a compound is defined as the energy generated when its molecule absorbs an electron; this has been regarded as a measure of the electron-accepting power in the gaseous phase. Scarcely no experimental values of the electron affinities have, however, been reported. In order to evaluate the electron affinity, the energy ($\varepsilon_{lv}=\alpha-\eta_{lv}\beta$, α, $\beta<0$) of the lowest unoccupied σ level was used, since it is reasonable to consider that the smaller the coefficient (η_{lv}) of β in the energy of the lowest unoccupied level, the greater is the electron affinity, *i.e.*, the electron-accepting power of the compound in the gaseous phase. Figure 5 shows that the $\Delta\nu_A$ values decrease with an increase in the η_{lv} values.[10]

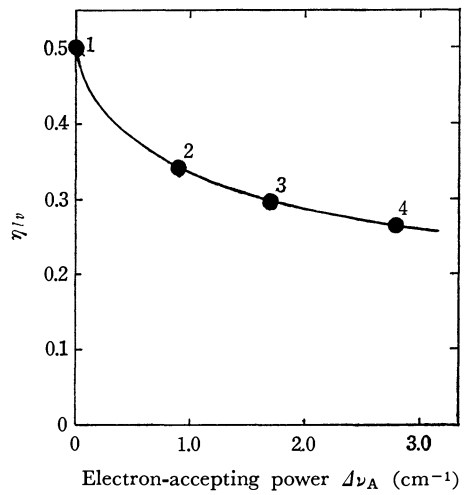

Fig. 5. Relation between the energies of the lowest unoccupied σ level and the electron-accepting powers ($\Delta\nu_A$) of aromatic halides.

1 Tetrahydropyran, 2 Diisopropyl ether, 3 *n*-Butyl ethyl ether, 4 Di-*n*-butyl ether, 5 Anisole, 6 Nitrobenzene

On the other hand, a linear relation was found to exist between the $\Delta\nu_A$ values and the pK_a values[11] of various ethers and aromatic compounds, as is shown in Fig. 6. The $\Delta\nu_A$ values of liquid compounds decrease with an increase in the pK_a values.

From these results, it may be concluded that the $\Delta\nu_A$ values express quantitatively the electron-accepting power in both the gaseous and liquid phases.

A Consideration of Liquid Organic Compounds on the Basis of the Electron-donating Power and the Electron-accepting Power. It is well known that Lewis bases like the ethers employed in the Grignard reaction and in the S_N2 reaction are the nucleophilic solvents, that the nitro compounds employed in the Friedel-Crafts reaction and Lewis acids are electrophilic solvents, and that the hydrocarbons have scarcely no ionization power. From these facts, the liquid organic compounds have been classified qualitatively into the following four groups: (1) amphoteric liquids,

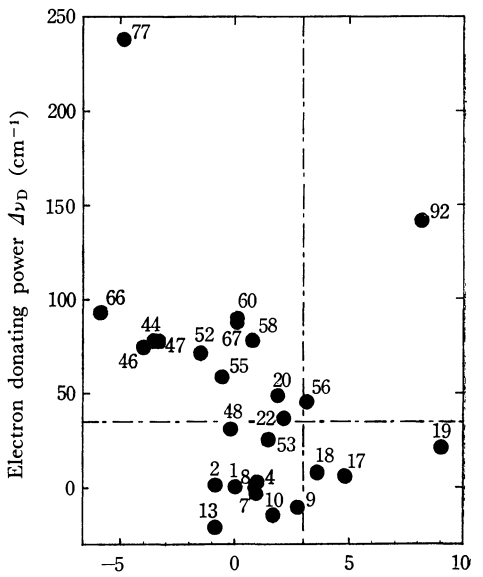

Fig. 7. Relation between the electoron-donating power ($\Delta\nu_D$) and the electron-accepting power ($\Delta\nu_A$) of various liquid organic compounds. The number of a point represents the number in Table 1.

11) E. M. Arnett and C. Y. Wu, *J. Am. Chem. Soc.*, **84**, 1684 (1962).

(2) nucleophilic liquids, (3) electrophilic liquids and (4) non-philic liquids.

Little attention has, however, been paid to the quantitative consideration of the liquid compounds on the basis of the electronic features, in spite of the importance of this approach. In Fig. 7 we have plotted the relation between the $\Delta\nu_D$ values and the $\Delta\nu_A$ values of various liquid organic compounds. As Fig. 7 shows, the electron-donating power is more dominant than the electron-accepting power in most liquid organic compounds. In view of the classification on the basis of the results shown in Fig. 7, it is reasonable to take a point, with a $\Delta\nu_D$ value of 35 cm^{-1} and a $\Delta\nu_A$ value of 3 cm^{-1} as the standard point. In the amphoteric liquids the $\Delta\nu_D$ and $\Delta\nu_A$ values are both larger than the standard point, while, in the non-philic liquids both are smaller. The nucleophilic liquids have larger $\Delta\nu_D$ values and smaller $\Delta\nu_A$ values, while the electrophilic liquids have smaller $\Delta\nu_D$ values and larger $\Delta\nu_A$ values than the standard point. This quantitative classification, based on the electronic features of liquid organic compounds, seems useful as an unifying interpretation for many kinds of experimental results.

The authors are grateful to Professor Kenichi Fukui for his valuable suggestions while carrying out this study and to Mr. S. Nakao and Mr. K. Ueda for their technical assistance. They also wish to thank Sumitomo Atomic Energy Industries, Ltd., for supplying the materials and equipment used in this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 773—778 (1968)

A Study of the Nucleophilic Solvation Based on the Theory of Chemical Equilibrium

Tsutomu KAGIYA, Yūzō SUMIDA and Tokuji INOUE

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received July 20, 1967)

The nucleophilic solvation to a deuterium atom in a methanol-d molecule has been quantitatively studied by using the infrared spectroscopic data of the O–D vibrational band. The position of the O–D band did not change in spite of the variation in the methanol-d concentration in solutions of a single solvent, whereas the area of the O–D peak changed in proportion to the first-order of the methanol-d concentration. From these results, it has been concluded that the area of the O–D band corresponds to the concentration of the methanol-d solvated. In a binary solvent system, which consisted of components with substantial differences in the electron-donating power, two positions of the O–D peak were observed at positions identical to those in the component examined in a single solvent system, and the area of each O–D peak changed with the composition of the system. These results led to the conclusion that the nucleophilic solvation of each component in the binary system took place competitively and individually. From the quantitative treatment of the results on the basis of the theory of chemical equilibrium, the equilibrium constant of the nucleophilic solvation of a solvent to methanol-d was calculated. The following empirical formula was obtained between the electron-donating powers and the nucleophilic equilibrium constants of various solvents:

$$\log K_{\mathrm{D}} = -\frac{3.67}{1 + 8.14 \times 10^{-3} \Delta\nu_{\mathrm{D}}} + 2.16.$$

It is well known, regarding an ionic reaction in solution, that the reaction rate is markedly affected by the kind of solvent, and by the characteristic features of the solvation. Scarcely no quantitative studies of solvation have, however, been reported.

On the other hand, Gordy *et al.* have made a study of the proton-attracting properties of various liquid compounds, using methanol-d as an indicator.[1] In a previous paper[2] the electron-donating power ($\Delta\nu_{\mathrm{D}}$) and the electron-accepting power ($\Delta\nu_{\mathrm{A}}$) of liquid compounds have been measured, and it has been found that the electron donating power of a liquid organic compound is more dominant than the electron-accepting power.

2) T. Kagiya, Y. Sumida and T. Inoue, This Bulletin, **41**, 767 (1968).

The purpose of the present investigation is to study quantitatively the nucleophilic solvation, also making a theoretical treatment of the data on the position and the area of the O–D band of methanol-d in solution.

Experimental

Materials. Tetrahydrofuran, benzene, nitroethane, ethyl propionate, phenetole, triethylamine, pyridine, and methanol-d were obtained commercially. All but methanol-d were purified by the usual methods.

Apparatus and Method. A typical infrared spectroscopic experiment was carried out as follows. A small quantity (0.4 mol/*l*) of methanol-d was added to 1.0 m*l* of the solvent, which consisted of one or two components, in a weighing bottle (2.0 m*l*). After the bottle had then been shaken for 10 min at room temperature (18±3°C), the infrared spectra of the O–D absorption band of methanol-d in the mixture were determined with a Hitachi EPI-2 infrared spectrophotometer (resolving power: 3 cm^{-1} at 10 μ, slit width: 0.03 mm at 10μ) equipped with a sodium chloride prism. The thickness of the cell used in this experiment was 0.010 cm.

Evaluation of the Integrated Intensity of the O-D Absorption Band. The O–D vibrational curve ought theoretically to be symmetrical. In most of the compounds in which the O–D vibrational band shifted to a lower frequency, symmetrical absorption bands were observed (Fig. 1(a)). On the other hand, asymmetrical O–D absorption bands were observed in some compounds which had small shifts (Fig. 1(b)). It may be considered that the phenomenon is caused by the overlapping of the unassociated and associated bands (2400—2500 cm^{-1}). Similarly, two O–D absorption bands in the binary solvent system were observed as asymmetrical bands by the overlapping of two unassociated absorption bands due to each solvent (Fig. 1(c)). Therefore, we estimated the integrated intensity of the unassociated O–D absorption band using the method of the half-value-width. For example, the integrated intensity of a symmetrical band (a) was evaluated as a triangular area (△ABC). In an asymmetrical band (b) or (c), each integrated intensity was separately determined, using each shoulder without an overlapping (*i.e.*, 2△DEF, 2△GIK and 2△HJL). We then took the average values of several measurements (maximum experimental errors: ±1.5%).

(b) Single-solvent system; an asymmetrical band
(c) Binary-solvent system

Results and Discussion

In a Single-solvent System. Since it was observed that the solvent which shifted the O–D band to a lower frequency had the stronger integrated intensity (area) of the O–D band, the

⊗ Triethylamine

positions of the O–D band in various solvents were plotted against the total area (*cf.* Fig. 2). A linear relation was found to exist between the position and the area of the O–D band at the same concentration (0.40 mol/*l*) of methanol-d; that is, the electron-donating power ($\Delta\nu_D$) proposed by us[2] increased as the area (A) increased.

The influence of the methanol-d concentration on the position and the area of O–D peak was also studied. The infrared spectra of tetrahydrofuran systems with various concentrations of methanol-d are shown in Fig. 3. It is evident that the position of the O–D absorption band does not change, regardless of the variation in its concentration, whereas its area increases with the concentration of methanol-d. Such features were also observed in other solvent systems. As shown in Fig. 4, this linear relation between the area of the O–D band and the methanol-d concentration was found to exist in various solvents. Therefore, the following equation was obtained:

$$A = \alpha(CH_3OD)_0 \qquad (1)$$

where $(CH_3OD)_0$ is the concentration of methanol-d in a pure solvent, and α is a constant, its exact nature depending on the kind of solvent. The area of the band depending only on the kind of solvent increases with the concentration of methanol-d. This fact suggests that the area of the O–D band corresponds to the concentration of the methanol-d solvated. This led to the following relation:

$$A = \frac{1}{\beta}(CH_3O\text{–}D\cdots nS) \qquad (2)$$

where $(CH_3O\text{–}D\cdots nS)$ is the concentration of methanol-d solvated by n molecules of the solvent, and β is a proportional constant.

On the basis of the above considerations, the nucleophilic solvation of a solvent to methanol-d may be quantitatively studied on the basis of the theory of chemical equilibrium; that is, the solvent, methanol-d, and solvated methanol-d are considered to be in equilibrium:

$$CH_3OD + nS \overset{K_D}{\rightleftharpoons} CH_3O\text{–}D\cdots nS \qquad (3)$$

K_D is the equilibrium constant. The concentration of methanol-d solvated in the equilibrium state is expressed by Eq. (4):

$$(CH_3O\text{–}D\cdots nS) = \frac{K_D(S)^n(CH_3OD)_0}{1 + K_D(S)^n} \qquad (4)$$

The parentheses indicate the concentration of each component in equilibrium. Using Eqs. (2) and (4), Eq. (5) is given as follows:

$$A = \frac{K_D(S)^n(CH_3OD)_0}{\beta(1 + K_D(S)^n)} \qquad (5)$$

Consequently, it is found that the constant (α) in Eq. (1) corresponds to $K_D(S)^n/\beta(1+K_D(S)^n)$ in Eq. (5).

In a Binary-solvent System. As a sample of a binary solvent system consisting of components with large differences in the electron-donating power, the infrared spectra in the tetrahydrofuran-nitroethane system are shown in Fig. 5. It is evident from Fig. 5 that the positions of the two O–D bands do not change in spite of the variation in the composition of the system, while the areas of the two bands do markedly vary with the composition. Moreover, the position of each

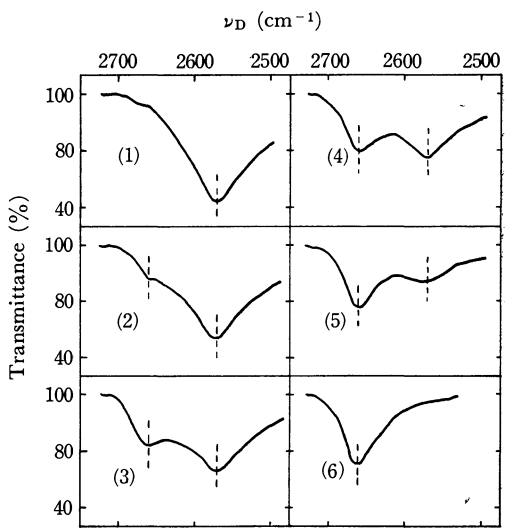

Fig. 5. Infrared spectra of the O–D absorption bands in tetrahydrofuran-nitroethane systems.
Tetrahydrofuran : Nitroethane (volume ratio)
(1) 1 : 0, (2) 3 : 1, (3) 1 : 1, (4) 1 : 3,
(5) 1 : 19, (6) 0 : 1

of the two peaks is identical with that due to tetrahydrofuran or nitroethane in a single-solvent system. Similar features were observed in other binary systems. If both components, S_1 and S_2, simultaneously solvate to one molecule of methanol-d, the position of the O-D band might be different from the position of each O-D peak appearing in the single solvent (S_1 or S_2) and might be observed between them. The experimental results, however, did not agree with this prediction. This fact leads to the conclusion that each component in a binary-solvent system solvates to each molecule of methanol-d individually and competitively.

On the basis of these findings, the solvation may be considered to consist of the following equilibrium reactions:

$$CH_3OD + nS_1 \overset{K_{D1}}{\rightleftharpoons} CH_3O\text{-}D\cdots nS_1 \qquad (6)$$

$$CH_3OD + mS_2 \overset{K_{D2}}{\rightleftharpoons} CH_3O\text{-}D\cdots mS_2 \qquad (7)$$

where n or m is the number of solvent molecules coordinating to a deuterium atom of methanol-d, and K_{D1} or K_{D2} is the equilibrium constant of each reaction. $CH_3O\text{-}D\cdots nS_1$ and $CH_3O\text{-}D\cdots mS_2$ indicate the state of methanol-d solvated by n molecules of the component S_1 and by m molecules of the component S_2 respectively. From the reactions (6) and (7), Eqs. (8) and (9) are obtained as follows:

$$(CH_3O\text{-}D\cdots nS_1) = \frac{K_{D1}(S_1)^n(CH_3OD)_0}{1 + K_{D1}(S_1)^n + K_{D2}(S_2)^m} \qquad (8)$$

$$(CH_3O\text{-}D\cdots mS_2) = \frac{K_{D2}(S_2)^m(CH_3OD)_0}{1 + K_{D1}(S_1)^n + K_{D2}(S_2)^m} \qquad (9)$$

As has been described previously, the concentration of the solvated methanol-d can be evaluated as the area of the O-D absorption band; that is $(CH_3O\text{-}D\cdots nS_1)$ may be expressed by $\beta_1 A_1$. A_1 is the area due to the component S_1. By substituting the relation described above into Eqs. (8) and (9), and by taking the ratio of Eq. (8) to Eq. (9), Eq. (10) is given:

$$\frac{(CH_3O\text{-}D\cdots nS_1)}{(CH_3O\text{-}D\cdots mS_2)} = \frac{\beta_1 A_1}{\beta_2 A_2} = \frac{K_{D1}(S_1)^n}{K_{D2}(S_2)^m} \qquad (10)$$

Equation (10) shows that a straight line exists between $\beta_1 A_1/\beta_2 A_2$ and $(S_1)^n/(S_2)^m$.

Since the interaction force that we are considering is a kind of hydrogen bonding, it seems reasonable to consider that the solvation number of methanol-d is unity in all systems, *i. e.*, that $n=m=1$. Moreover, in order to simplify Eq. (10), it is assumed that β is a constant independent of the kind of solvent. Using the above considerations, Eq. (10) is expressed as Eq. (11):

$$\frac{A_1}{A_2} = \frac{K_{D1}(S_1)}{K_{D2}(S_2)} \qquad (11)$$

As shown in Fig. 6, we tried to plot A_1/A_2 against $(S_1)/(S_2)$ in all binary systems. In view of this fact, it may be concluded that the solvation number is unity and that β is a constant which is independent of the kind of solvent used. A straight-line slope indicates the relative ratio of the equilibrium constant of the solvent for a standard solvent. The ratios of the equilibrium constants of various solvents against tetrahydrofuran as a standard solvent are listed in Table 1.

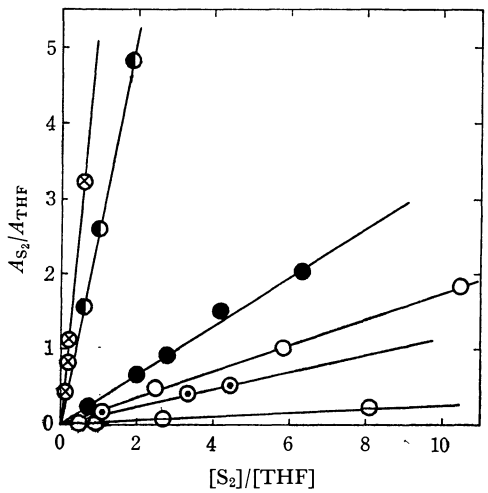

Fig. 6. Relation between the area ratios of O-D bands and the mol ratios of solvents S_2 in tetrahydrofuran-solvent S_2 systems.
Solvent S_2: ⊖ Benzene, ⊙ Nitroethane, ○ Phenetole, ● Ethyl propionate, ◐ Pyridine, ⊗ Triethylamine

Using Eqs. (8) and (11), we can obtain an equation by which the equilibrium constant can be calculated. When we substitute Eq. (11) into the reciprocal of Eq. (8), Eq. (12) is given as:

$$(S_1)\left(1 + \frac{A_2}{A_1}\right) = \frac{(CH_3OD)_0}{\beta}\frac{(S_1)}{A_1} - \frac{1}{K_{D1}} \qquad (12)$$

From Eq. (12), it may be expected that there is a linear relation between $(S_1)(1+A_2/A_1)$ and $(S_1)/A_1$, that its slope is constant in any kind of solvent at the same concentration of methanol-d, and that the value of the armature gives the reciprocal of the equilibrium constant. In Figs. 7 and 8, the propriety of Eq. (12) is confirmed in two cases, a tetrahydrofuran-solvent S_2 system and an ethyl propionate-solvent S_2 system. It may be seen in the two figures that a linear relationship exists between $(S_1)(1+A_2/A_1)$ and $(S_1)/A_1$. The values of the equilibrium constants of typical compounds are listed in Tables 1 and 2. The results in Table 1 show that the values $(K_{D2}/K_{D,THF})_{Fig.}$ obtained from the slope of the line in Fig. 6 agree well with

the values $(K_{D2}/K_{D,THF})_{Calc.}$ calculated by means of the K_D values, so we can approximately estimate the unknown K_D value by measuring the $K_{D2}/K_{D,THF}$ value.

It may also be seen in Table 2 that the equilibrium constant increases with the electron-donating power of the solvent. With the purpose of considering this relation, we plotted the equilibrium constants against the electron-donating powers; we thus obtained the following empirical formula:

$$\log K_D = -\frac{3.67}{1 + 8.14 \times 10^{-3} \Delta\nu_D} + 2.16 \quad (13)$$

This empirical formula shows that the equilibrium constant of nucleophilic solvation to methanol-d can be quantitatively estimated by measuring the shift of the O–D vibrational band of methanol-d.

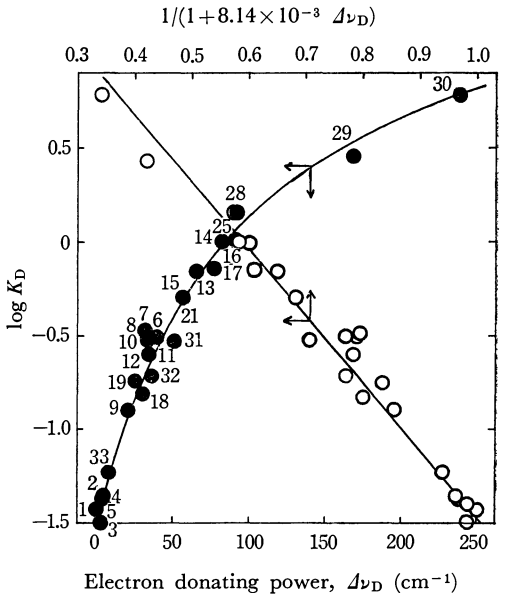

Fig. 9. Relation between the nucleophilic equilibrium constants of solvents and the electron-donating powers.
The number of a point represents the number in Table 2.

On the other hand, as has been reported previously, the shift of the O–D band is linearly related to the co-ordination power to diethyl zinc as an electrophilic compound. On the basis of these facts, it may be concluded that the equilibrium constant of the solvation to methanol-d can be used as a measure of the force of the general nucleophilic co-ordination to electrophilic compounds.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 779—782 (1968)

A Definition of Selectivity of Nucleophilic Solvation in a Binary Solution

Tsutomu KAGIYA, Yūzō SUMIDA and Tokuji INOUE

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received July 26, 1967)

This is the third paper of a series in which the behavior of nucleophilic solvation is investigated by a measurement of the position and the area of the O-D vibrational band of methanol-d. In a binary solution which consisted of two components remarkably different in electron-donating power, the relation between the mol fraction (n_1) of the S_1 component and the area fraction (N_1) of S_1 was not a straight line, but a concave or convex curve. This fact suggests that a component co-ordinates selectively to a deuterium atom in a methanol-d molecule. The following definition of the selectivity of nucleophilic solvation to methanol-d as a cation model of the S_2 component to the S_1 component is proposed:

$$(S^{S_2}_{S_1})_D = \sqrt{\left(\frac{dN_2}{dn_2}\right)_{n_2=0} \Big/ \left(\frac{dN_1}{dn_1}\right)_{n_1=0}}$$

The selectivity of the S_2 solvent to the S_1 solvent was considered in detail in connection with the equilibrium constant of the nucleophilic solvation to methanol-d of the solvent; the selectivity was also found to be defined as the ratio of the equilibrium constants of the solvents used. Since there was a correlation between the equilibrium constants and the electron-donating powers, it was concluded that the selectivity of an S_2 solvent to a standard solvent, S_1, could be quantitatively estimated by measuring only the position of the O-D vibrational band of methanol-d in each solvent.

It has previously been reported in connection with ionic copolymerization that the monomer reactivity ratios are significantly affected by the kind of solvent and catalyst used;[1,2] the systematic interpretation is difficult even in the simplest cases.[3] Recently, Overberger and Kamath have tried to explain this phenomenon on the basis of the preferential solvation of the growing ion pair by the more polar monomer in nonpolar solvents.[4] This concept of the preferential solvation makes it possible to explain qualitatively many experimental results.[5,6] There have been, however, few quantitative investigations of the preferential solvation.

In the first paper of this series,[7] the electron-donating power ($\Delta\nu_D$) and the electron-accepting power ($\Delta\nu_A$) of liquid organic compounds have been defined by using methanol-d and acetophenone as indicators. The second paper[8] was undertaken to make clear the characteristic behavior of the nucleophilic solvation in single or binary systems on the basis of the theory of chemical equilibrium.

The main purpose of the present work is to define the selectivity of nucleophilic solvation to the methanol-d of the solvent in a binary solution and to consider it in connection with the equilibrium constant of the nucleophilic solvation to the methanol-d of the solvent. It has been found that the selectivity defined is equal to the ratio of the equilibrium constants of the two components in a binary solution.

Experimental

The experimental technique is the same as that used before[8] and so will not be described here.

Results and Discussion

As has been described previously,[8] in a binary solvent system consisting of two components remarkably different in electron-donating power, it was observed that the position of neither O-D absorption bands changed in spite of the variation in the composition of the system, while the area

of each band changed remarkably with the composition. It was therefore concluded that the nucleophilic solvation to methanol-d of each component in a binary system took place competitively and individually.

On the other hand, with such a system, it may also be that a component with a strong electron-donating power preferentially solvates to a deuterium atom in a methanol-d molecule. With the purpose of considering this phenomenon, the area of each O-D band due to one of the two components was measured in tetrahydrofuran (THF=S_1, $\Delta\nu_D=90$) - solvents (S_2) systems by the half-value-width method.[8] Benzene ($\Delta\nu_D=0$), nitroethane (8), phenetole (25), ethyl propionate (32), pyridine (168), and triethylamine (238) were employed as the S_2 solvents. From the experimental results obtained, the relation between the mol fractions (n_{THF}) of THF and the area fractions (N_{THF}) of THF was plotted in Fig. 1. The

$$n_{THF} = \frac{(THF)}{(THF) + (S_2)} \quad (1)$$

$$N_{THF} = \frac{A_{THF}}{A_{THF} + A_2} \quad (2)$$

parentheses indicate the concentration of the component, and A is the area of an O-D absorption band due to the component.

It is apparent from Fig. 1 that N_{THF} increases with an increase in n_{THF}. The n_{THF}-N_{THF} curves do not give straight lines, but vary convexly or concavely, depending on the kind of S_2 solvent; that is, N_{THF} values in the same mol fraction of THF are remarkably dependent on the electron-donating powers of S_2. In the case of using an S_2 whose electron-donating power is weaker than that of THF, for example, in the tetrahydrofuran-benzene and tetrahydrofuran-nitroethane systems, the N_{THF} value increases precipitously upon the addition of a small amount of tetrahydrofuran to a single S_2 solvent. In the contrary case, N_{THF} increases slowly. Similar features were also observed in ethyl propionate-S_2 solvents systems (Fig. 2). These facts indicate that one component with a strong electron-donating power solvates to methanol-d selectively.

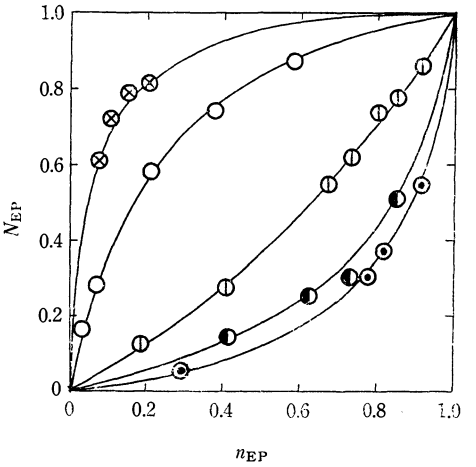

Fig. 2 Relation between the area fractions of O-D bands and the mol fractions of solvents in binary solvent systems containing 0.40 mol/l methanol-d.
Standard solvent: Ethyl propionate
Solvent S_2: ⊗ Benzene, ○ Nitroethane, ① Tetrahydrofuran, ◐ Pyridine, ⊙ Triethylamine

In order to investigate quantitatively the behavior of selective solvation, the selectivity $(S_{S_1}^{S_2})_D$ of nucleophilic solvation to methanol-d of an S_2 solvent to an S_1 solvent is defined as follows:

$$(S_{S_1}^{S_2})_D = \sqrt{\left(\frac{dN_2}{dn_2}\right)_{n_2=0} \Big/ \left(\frac{dN_1}{dn_1}\right)_{n_1=0}} \quad (3)$$

This definition is given graphically in Fig. 3, where the slope of the tangent line at the origin (0, 0) or the spot (1, 1) on the n_1-N_1 co-ordinates corresponds to the square of the denominator or the numerator in Eq. 3.

With the use of tetrahydrofuran or ethyl propionate as a standard solvent S_1, the selectivities of various solvents to the standard solvent were calculated by Eq. (3); they are listed in Table 1. It is obvious that the selectivity of benzene or of nitroethane to tetrahydrofuran is about 1/30 or 1/20, whereas that of triethylamine to tetrahydrofuran is about 6.

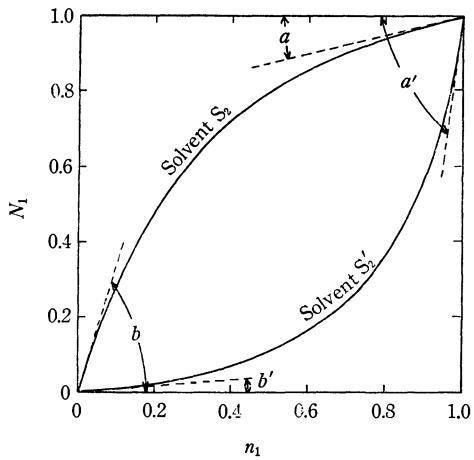

Fig. 3. Graphical evaluation of the selectivity of nucleophilic solvation of solvent S_2 to solvent S_1.

$$(S^{S_2}_{S_1})_D = \sqrt{\left(\frac{dN_2}{dn_2}\right)_{n_2=0} \Big/ \left(\frac{dN_1}{dn_1}\right)_{n_1=0}} = \sqrt{\frac{a}{b}}\ ,\quad \sqrt{\frac{a'}{b'}}$$

It may be also considered from Table 1 that the selectivity is closely correlated to the electron-donating power. On the other hand, it has previously been reported that the electron-donating power ($\Delta\nu_D$) is good relation with the equilibrium constants of solvents.[8] Consequently, a correlation also seems to exist between the selectivities and the equilibrium constants of solvents. Therefore, the selectivity of solvents was considered in detail in connection with the equilibrium constant. The square of the numerator $(dN_2/dn_2)_{n_2=0}$ in Eq. (3) is expressed as the following formula:

$$\left(\frac{dN_2}{dn_2}\right)_{n_2=0} = \lim_{n_2\to 0}\frac{N_2}{n_2} = \lim_{(S_2)\to 0}\frac{1+(S_1)/(S_2)}{1+A_1/A_2} \qquad (4)$$

In the second paper,[8] a linear relationship through the point of origin was observed to exist between the area ratio and the concentration ratio of two components, and it was found that the slope corresponded to the ratio of the equilibrium constants of the two solvents:

$$\frac{A_1}{A_2} = \frac{K_{D1}(S_1)}{K_{D2}(S_2)} \qquad (5)$$

When we place the relationship of Eq. (5) into Eq. (4), Eq. (4) is simplified as follows:

$$\lim_{(S_2)\to 0}\frac{1+(S_1)/(S_2)}{1+A_1/A_2} = \lim_{(S_2)\to 0}\frac{1+(S_1)/(S_2)}{1+K_{D1}(S_1)/K_{D2}(S_2)} = \frac{K_{D2}}{K_{D1}} \qquad (6)$$

By the same method, the square of the denominator $(dN_1/dn_1)_{n_1=0}$ is given by Eq. (7):

$$\left(\frac{dN_1}{dn_1}\right)_{n_1=0} = \frac{K_{D1}}{K_{D2}} \tag{7}$$

Consequently, the selectivity of an S_2 solvent to an S_1 solvent is defined as the following equation by using Eqs. (3), (6) and (7):

$$(S^{S_2}_{S_1})_D = \frac{K_{D2}}{K_{D1}} \tag{8}$$

Equation (8) shows that the selectivity so defined can be calculated by using the ratio of the equilibrium constants. In order to confirm the propriety of Eq. (8), the selectivities of the S_2 solvents to tetrahydrofuran calculated by the various methods are listed in Table 2. Column 3 shows the value obtained by Eq. (3), column 4 the ratio of the equilibrium constants of the two solvents, and column 5 the value calculated by the following equation:

$$\text{column } 5 = (S^{S_2}_{EP})_D \times (S^{EP}_{THF})_D = 0.320(S^{S_2}_{EP})_D \tag{9}$$

It is evident from the results shown in Table 2 that the observed values of selectivity are in good accordance with the calculated values.

Similarly, the selectivities of S_2 solvents to ethyl propionate are listed in Table 3. The observed values accord well with the calculated values. This fact indicates that the relationship of multiplication or division plays a part in the selectivity.

On the other hand, it has previously been concluded that the equilibrium constant of the nucleophilic solvation to methanol-d can be used as a measure of the force of the general nucleophilic co-ordination to the electrophilic compounds.[8] It has now also been found that the equilibrium constants are related to the electron-donating powers as follows:

$$\log K_D = -\frac{3.67}{1+8.14\times 10^{-3}\,\Delta\nu_D} + 2.16 \tag{10}$$

These facts make reasonable the conclusion that the selectivity of the co-ordination of an S_2 solvent to a standard solvent, S_1, can be estimated by using Formula (10) and Eq. (8).

The authors are grateful to Professor Kenichi Fukui for his valuable suggestions while carrying out this study.

The Structure-Stability Relationship of the Metal Ion Complexes of Unsaturated Compounds. III.[1] The Effects of Polar Substituents on the Silver Ion - Olefin Complexation

Takayuki FUENO,*[1] Okitsugu KAJIMOTO*[1] and Junji FURUKAWA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received September 9, 1967)

The equilibrium constants for the formation of silver ion complexes of various vinyl compounds in water were determined at 25°C by the distribution method. It has been found that the equilibrium constants obtained are closely related to the Hammett sigma meta values of the relevant substituents, the reaction constant being $\rho = -5.07$ with the correlation coefficient $r = 0.974$. The results have been interpreted in terms of the inductive effect of the substituents as the most dominant contribution to the stabilities of these complexes.

The polar effect of substituents in the argentation (silver ion complexation) equilibria of unsaturated compounds was first discussed by Andrews ant Keefer[2] for benzene derivatives in terms of the Hammett ρ-σ relation. We also reported the results of similar studies for the case of ring-substituted styrenes,[3] and presented a theoretical interpretation of the observed substituent effects.[1] For olefinic compounds, however, available experimental data, though may be numerous, only indicate the importance of inductive, steric and structural strain effects of alkyl

groups on the relative stabilities of the complexes.[4-9] No work has ever been reported as to the role of polar substituents in the Ag^+-olefin complex stabilities.

In the present work we have measured argentation equilibrium constants of several "polar" vinyl compounds in water at 25°C, in order to compare the electronic contributions of various substituents to the stabilities of the ethylene complexes. It has been found that the equilibrium obeys the Hammett relation, provided the sigma meta values are used for the polar groups. Thus, the ease of complexation of an ethylenic bond appears to be governed primarily by the inductive effect of its neighboring groups.

Experimental

Materials. Silver nitrate and potassium nitrate were of the best grade commercially available. Carbon tetrachloride was washed successively with aqueous sodium hydroxide and water, dried over potassium carbonate and fractionally distilled. Most of the vinyl compounds studied were commercially obtained and purified by standard procedures. Phenyl vinyl ether was prepared by the methods of McElvain and Fajardo-Pinzón.[10] All these substrate compounds were checked for purity by gas chromatography before use.

Equilibrium Measurements. Equilibrium constants, K_1 and K_2, for the formation of the silver ion complexes in the aqueous phase

$$Ag^+ + M = AgM^+,$$

$$K_1 = [AgM^+]/[Ag^+][M] \quad (1)$$

$$Ag^+ + AgM^+ = Ag_2M^{2+}$$

$$K_2 = [Ag_2M^{2+}]/[Ag^+][AgM^+] \quad (2)$$

were measured at 25°C by the distribution method.[4] The polar olefins, M, were allowed to distribute between water and carbon tetrachloride by vigorously stirring the mixtures for 20 hr. The aqueous layer contained silver nitrate, whose concentration was in the range 0.1 to 0.6 M. The ionic strength of the layer was fixed at unity by the addition of a required amount of potassium nitrate. The initial concentration of the olefins dissolved in the organic layer was 1.0 M.

The constants, K_1 and K_2, may be related to an apparent equilibrium constant K in the following manner:

$$K = (k - k_0)/k_0[Ag^+] = K_1 + K_1K_2[Ag^+] \quad (3)$$

Here, k_0 is the distribution coefficient of an olefin between the aqueous and organic layers measured in the absence of the Ag^+ ions, while k is a similar coefficient measured in the presence of the ions. Measurements of the values of K for varying silver-ion concentrations, $[Ag^+]$, permit the evaluation of both K_1 and K_2 for each olefin.

The magnitudes of k as well as k_0 were obtained from the initial concentration of olefin in the organic layer and its concentration in either organic or aqueous layer after distribution. In the case of unsaturated hydrocarbons, the total concentrations of these compounds, both free and complexed, in the aqueous phase were determined by the spectrophotometric method. The procedure adopted was the same as had been described previously.[3] In the case of polar olefins, on the other hand, the decreases in their concentrations in the organic layer were measured by gas chromatography. The conventional half-height width method was found to suffice for this purpose, insofar as the volume ratio between the organic and aqueous layers was so adjusted as to suit such measurements.

Results

The values of K were measured for various vinyl compounds at varying silver ion concentrations. In evaluating the K-values, the concentration, of the silver ion $[Ag^+]$, which remained intact in the aqueous phase was assumed to be equal to its initial concentration. In other words, the variations in the concentration of free silver ions, which were caused by the formation of the complexes, were assumed to be negligibly small compared with the initial concentration. It was ascertained that this approximation introduced practically no error into the values of K.

If the presumptions underlying Eq. (3) are basically correct, then, for a given substrate, plots of K against $[Ag^+]$ should give a straight line with the intercept K_1 and the slope K_1K_2. Such linear

relations were substantiated with sufficient precision with all the compounds studied here. Typical examples of such linearities are shown in Fig. 1.

The values of K_1 and K_2 obtained for the various vinyl compounds at 25°C are given in Table 1. Also listed in Table 1 are the distribution constant, k_0, of each compound between 1 N aqueous potassium nitrate solution and carbon tetrachloride and the volume ratio, r, between the aqueous and organic layers adopted for the distribution experiments of each compound.

Discussion

A number of workers[1-9] have already noted that the argentation equilibria of unsaturated compounds are sensibly influenced by the electronic, steric and strain factors of substituents. Among others, Muhs and Weiss[8] studied a large number of olefins by the gas chromatographic technique and extended detailed discussion of the steric and strain effects involved. As for the electronic contribution of substituents, the demonstrations that the relative stabilities of the silver ion complexes formed from substituted benzenes[2] and styrenes[3] obey the Hammett relation are noteworthy. In general cases, these factors join together in a complicated manner, and it is often extremely difficult to assess their relative importances in a simple yet general manner. All that has been possible to do is to isolate one major contributing factor or two, which may be different depending on the type of the substrate structures.

In an effort to disentangle the effects of polar substituents on the stabilities of the olefin complexes under study, we have plotted in Fig. 2 the values of log K_1 against the Hammett σ_m values of the substituents. The result was that the log K_1 was linearly related to the σ_m, though only roughly. The slope of the linear correlation was $\rho=-5.07$, and the correlation coefficient was $r=0.974$. As for the varia tions of the K_2 values with substituents, on the other hand, no simple generalization was possible to make.

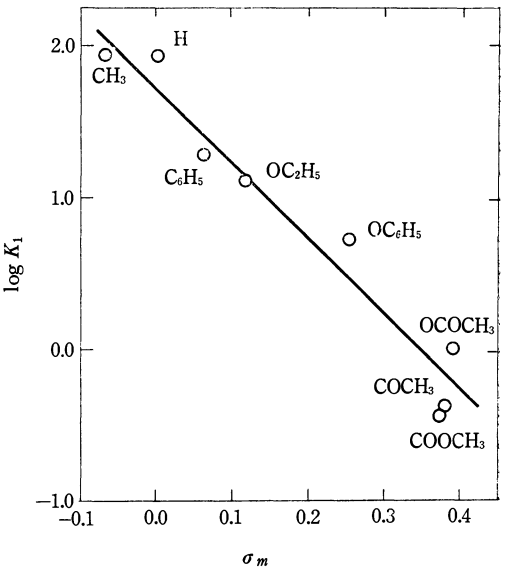

Fig. 2. Plots of log K_1 *vs.* σ_m for the silver ion complexation equilibria of some vinyl compounds in water at 25°C.

The finding that a linear relation holds between log K_1 and σ_m is not grossly fortuitous. The linearity may be rationalized as follows:

First of all, if the electronic effect of substituents is the most predominant contribution to the relative stabilities of polar olefin complexes, it will be nothing odd to expect that the values of log K_1 will be correlated, to a first approximation, with the Hammett sigma values of the substituents. One may inquire at the second step why then the stabilities should be functions of the sigma meta rather than sigma para values. Perhaps, the most plausible answer to this question may be given in terms of the inductive effect of the polar substituents. The view that the σ_m values of polar groups are associated primarily with their inductive effects is of wide acceptance, even though the way how the

effect would come into play and the extent to which it might contribute to the σ_m relative to the resonance contribution are still debatable.[11-14] No doubt, the argentation of vinyl compounds involves the interactions of the silver ion with the α-carbon just as well as the β-carbon of the vinyl linkage. Thus it is very likely that, in the case of vinyl compounds, the availability of the α-β bond for the complexation is greatly influenced by the inductive effect of its neighboring polar groups, and hence is correlated with their σ_m value.

The reaction constant, -5.07, obtained for a series of vinyl compounds as above is considerably larger in magnitude than the values of -1.6[2] and -0.766[3] which have previously been reported for ring-substituted benzenes and styrenes, respectively.[15] It may be said that the sensitivity of substrates toward the variation of substituents decreases in the order: ethylene > benzene > styrene. This order of sensitivity is readily understandable qualitatively in view that the polar effect of substituents should diminish with the increase in the distance between the substituents and the reaction center.

The above arguments, however, do not necessarily imply that the steric effect of substituents is wholly unimportant. For instance, one may clearly notice the importance of such an effect when he compares the K_1-values of heavily substituted ethylenes with those of the monosubstituted.[4,8,9] In the series of polar vinyl compounds studied here, possible steric effects of the various polar groups are apparently overshadowed by the more dominant contributions of their inductive effects. Hence, the steric effect is more conspicuous between ethylene derivatives of different degrees of substitution than between those that belong to the identical type of substitution but carry different substituent groups. Thus, it may be concluded that, so far as the silver ion complexation of vinyl compounds is concerned, the relative stabilities of the complexes formed is controlled most influentially by the inductive effect of the polar groups.

The Structure-Stability Relationship of the Metal Ion Complexes of Unsaturated Compounds. IV.[1,2] Argentation Equilibria of Alkenyl Alkyl Ethers

Takayuki FUENO,*1 Okitsugu KAJIMOTO,*1 Tadashi OKUYAMA and Junji FURUKAWA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received September 9, 1967)

The equilibrium constants, K, for the formation of 1 : 1 Ag^+ - alkenyl alkyl ether complexes were measured in the temperature range 10 to 30°C by the gas chromatographic method. It has been found (1) that *cis* isomers have the values of K several times greater than those of the corresponding *trans* isomers, (2) that the K-value tends to diminish with the increasing degree of β-substitutions, (3) that, in a series of *cis* ethers, K increases as the β-alkyl substituent becomes bulkier, and (4) that the variation of the alkoxy groups causes little change in the K-value. The difference in the K-values between the *cis* and *trans* complexes is found to be ascribable mainly to their difference in the enthalpy changes, ΔH, accompanying the complexation. These trends have been discussed on a thermodynamic ground in comparison with those already noted for olefins.

The relations between the stability of the Ag^+-olefin complexes and the structure of the olefins have already been investigated and discussed to a considerable extent by several groups of workers.[3]

*1 Present address: Faculty of Engineering Science, Osaka University, Toyonaka, Osaka.

1) Part III: The preceding article.

2) Presented in part at the IUPAC International Symposium on Macromolecular Chemistry, Tokyo—Kyoto, September, 1966.

3) See, for example, Refs. 4, 5 and 6 and the papers cited therein.

Until recently, however, such investigations have never been extended to include "polar" olefins, *i. e.*, those olefinic compounds bearing polar groups. In the preceding paper of this series,[1] we have dealt with some vinyl compounds and reached the conclusion that the inductive effect of the substituents is of primarily importance to the relative stabilities of the complexes.

In the present communication, we treat the silver ion complexation equilibria of various alkenyl alkyl ethers, $R_1R_2C{=}CR_3(OR_4)$, with particular attention to the effect of the geometrical structures on the stabilities of the complexes formed. In measuring the equilibrium constants, we have utilized the gas chromatographic technique which has recently been developed by Muhs and Weiss.[4] This technique has greatly facilitated the comparison of the complexation abilities of *cis* and *trans* ethers as well as the examination of the temperature dependences of the equilibrium constants. Despite a possible influence of a large polarization of the carbon-carbon double bond in unsaturated ethers, the equilibrium data obtained for these compounds have manifested general features similar to those already recognized for olefins.[4-6] Apparently, the difference in the mesomeric effects of various alkoxy groups on the complexation is overshadowed by the difference in other contributions such as the inductive and steric effects of various alkyl groups present as well as the effect of the substrate structure.

Experimental

Materials. Silver nitrate, acetone and hexene-1 were of the best grade commercially available and were used without further purification. Ethylene glycol was obtained commercially and fractionally distilled immediately before use. Alkyl ethers were prepared by the methods described elsewhere[7] and were checked for purity by gas chromatography. Geometrical isomers of the ethers, when these occurred, were not separated. In all cases, the ethers were rich in *cis* isomer.

Equilibrium Measurements. The equilibrium constants for the Ag^+-olefin complex formation in ethylene glycol were measured by the gas chromatographic method developed by Muhs and Weiss.[4] It will be advantageous to briefly duplicate the principle here.

The distribution coefficient of the sample between liquid and vapor phases can be expressed as[4]

$$H = \frac{3}{2} \cdot \frac{(P_i/P_o)^2-1}{(P_i/P_o)^3-1} \cdot \frac{Ft_r}{V_L} \quad (1)$$

where P_i and P_o are the inlet and outlet pressures, respectively; F is the carrier gas flow rate; V_L is the volume occupied by liquid phase at the column temperature; and t_r is the retention time. The distribution coefficient varies with the Ag^+ concentration in the liquid phase as a result of complex formation. Thus, from the distribution coefficient, H_0, measured for a column without the Ag^+ ions and a similar coefficient, H, observed for an Ag^+-containing column, the equilibrium constant, K, for the complexation can readily be evaluated:[5]

$$K = [\text{Ether-Ag}^+]/[\text{Ether}][\text{Ag}^+] = (H-H_0)/H_0[\text{Ag}^+] \quad (2)$$

A Yanagimoto gas chromatograph model 3DH was operated at the column temperatures 10, 20 and 30°C with the hydrogen flow of 80 ml/min. A thermal conductivity detector and a soap bubble flowmeter were used. Special cautions were taken to minimize the scatters in the observed retention times which arose when the sample sizes were not strictly constant. The sample size finally adopted was 0.4 μl. The values of K obtained as above were fairly well reproducible, irrespective of the Ag^+ concentration not greater than 1.0 M. Mixtures of a given pair of geometrical isomers were subjected to the equilibrium measurements as such, but their retention times recorded separately. This expedience proved to introduce no error into the final results.

Preparation of Columns. Yanagimoto Celite 545 (80—100 mesh) was immersed in a silver nitrate solution in ethylene glycol diluted with acetone. The mixture was stirred until it attained homogeneity. Acetone was then evaporated off at room temperature. The ratio of the liquid phase to the support was 3 : 10 by weight. A weighed amount of packing was placed in a 1-m stainless steel column of 5 mm in diameter. Columns required *ca.* 9 g of packing. Three columns with 0, 0.5 and 1.0 M silver nitrate were prepared.

Results

Operating Conditions. Preliminary measurements of the equilibrium constants, K, indicated that the measured K-values were markedly dependent upon both the flow rate and the sample size adopted. Therefore, the effects of these factors had to be examined quantitatively in order to establish a routine operating condition.

For hexene-1, which showed relatively large variation in K with operating conditions, the following trends were observed:

The value of K tended to decrease considerably with the increasing sample size, whereas it slightly increased as the flow rate became greater. In magnitude, the effect of the sample size was the more appreciable, as may be seen in Fig. 1.

In such situations, it would be the most reasonable procedure in principle to extrapolate the K-values to both the zero flow rate and the zero sample size. Practically, however, a number of runs would then necessarily have to be performed for

c) Accurate only to within ±0.6 e. u.

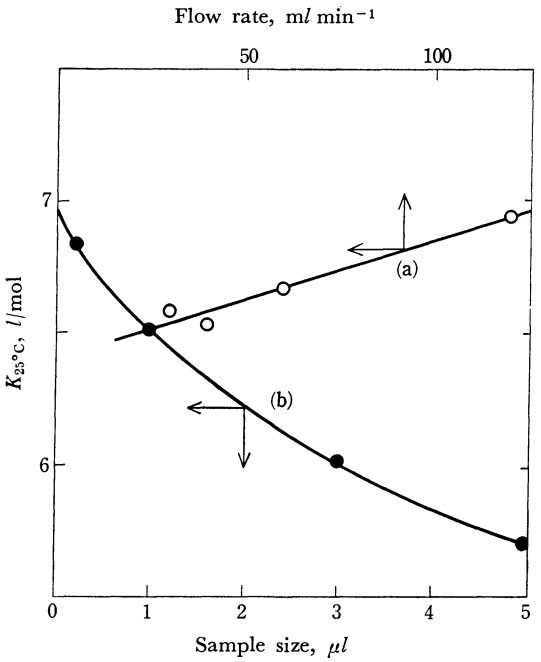

Fig. 1. Variations of K for hexene-1 (a) with the flow rate at constant sample size 1.0 μl and (b) with the sample size at constant flow rate 40 ml min^{-1}.

each compound under study, which might lead to undesirable deterioration of the column packings, introducing even more crucial experimental errors into the final results. Furthermore, experiments with too slow a flow rate coupled with a small sample size would make it extremely difficult to get precise retention times because of the large broadening as well as the small height of the sample peaks.

Under these circumstances, we have decided to compromise the cumbers by adopting such operating conditions that the relative magnitudes of the equilibrium constants for the various compounds to be examined were not seriously affected. The choices of the flow rate ranging from 40 to 80 ml/min and the sample size in the range 0.4 to 1.0 μl met this requirement. The flow rate and the sample size finally adopted as the routine conditions were 80 ml/min, and 0.4 μl, respectively, as has been specified in the experimental section.

Equilibrium Constants. The equilibrium constants were calculated from Eqs. (1) and (2). In obtaining the distribution constant, H, at a given Ag^+ concentration at a given temperature, three independent measurements were performed for each compound. The reproducibility of the equilibrium constants, K, was satisfactory. The values of K listed in Table 1 are the averages of the three independent measurements at each of the temperatures 10, 20 and 30°C. It was observed that at both 20 and 30°C alkenyl alkyl ethers were liable to suffer solvolysis during the distribution measurements in the column containing silver nitrate. Yet, the peaks of the reactant ethers and the products were separated sufficiently far to enable the recordings of the retention times of the ethers with fair accuracy. Above 40°C, however, the alkenyl alkyl ethers were consumed to a considerable extent so that the measurements of H were hardly feasible.

The changes of enthalpy, ΔH, and entropy, ΔS, in complexation were evaluated from the K-values given in Table 1. Plots of the logarithms

of K against the reciprocal of temperature were satisfactorily linear for all the unsaturated ethers investigated. An example of such plots is shown in Fig. 2. The values of ΔH and ΔS obtained in the temperature range 10 to 30°C are given in the final two columns of Table 1.

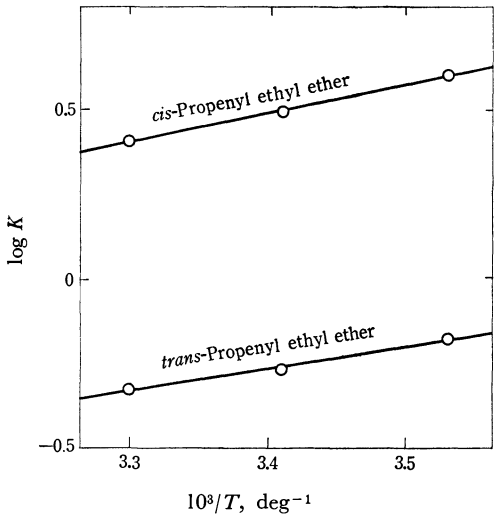

Fig. 2. Temperature dependence of log K for the silver ion complexation of *cis*- and *trans*-propenyl ethyl ethers (4c and 4t).

Discussion

Effects of Alkyl Substitutions. From the equilibrium constants listed in Table 1, the following generalizations can be made for the silver ion complexation of alkenyl alkyl ethers:

(1) The *cis* isomers have K values several times greater than those of the corresponding *trans* isomers.

(2) The K values largely decrease with the increasing degree of β-substitutions.

(3) As the substitutent on the β-position varies in the order CH_3, C_2H_5 and i-C_3H_7, the value of K of *cis* ethers increases asymptotically in this order.

(4) The K-value varies little when the ethoxy group is replaced by the isobutoxy or n-butoxy group.

The features (1) and (2) are in agreement with those already noted in the olefin complexation and may most simply be interpreted in terms of the adverse steric effect of the alkyl substituents.[4,5,8] However, the effect appears, in some cases, to be coupled with the favorable inductive effect of the alkyl groups. Perhaps, the order of the effects of β-alkyl groups $CH_3 < C_2H_5 < i$-C_3H_7 mentioned in the item (3) is a result that the latter contribution outweighs the former. It is noteworthy in this connection that the K-values of the olefin homologs have been reported to *decrease* in this same order in one case[4] while they show a maximum in another,[5] as in the case of our *trans* ethers, depending on the environments where the measurements of K have been made. This coupling of the two opposing contributions may also be a factor underlying the item (4).*2

In order to gain further insights into the nature of the complexation, it will no doubt be more advantageous to discuss the structure-stability relation in terms of the thermodynamic quantities, ΔH and ΔS. Thus, in Fig. 3, the values of ΔH for the various alkenyl alkyl ethers were plotted against the ΔS-values. It may be seen in Fig. 3 that the plotted points fall on a group of parallel straight lines which were drawn according to the types of β-substitution. We have found a similar relationship to hold (Fig. 4) between the ΔH and ΔS values for olefins which have recently been reported by Cvetanović *et al.*[5],*3 The slopes of these straight lines (*i. e.*, the isokinetic temperatures) corresponded to 310 and 350°K for the ethers and the alkenes, respectively.

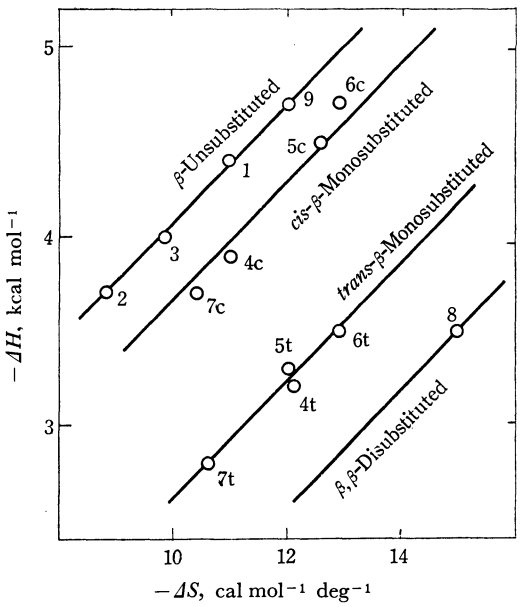

Fig. 3. Plots of ΔH *vs.* ΔS for the silver ion complexation equilibria of α, β-unsaturated ethers in ethylene glycol.
The numbers 1—9 refer to the unsaturated ethers listed in Table 1.

The families of linear ΔH-ΔS relationships in Figs. 3 and 4 may permit the following considerations:

First, since the isokinetic temperatures are only slightly above the temperatures at which the

*2 The finding that an α-methyl group produces no appreciable influence on the K-value (No. 9) may also have some bearing on this coupling effect.

*3 The essential feature is discernible, even though the number of the experimental points is limited.

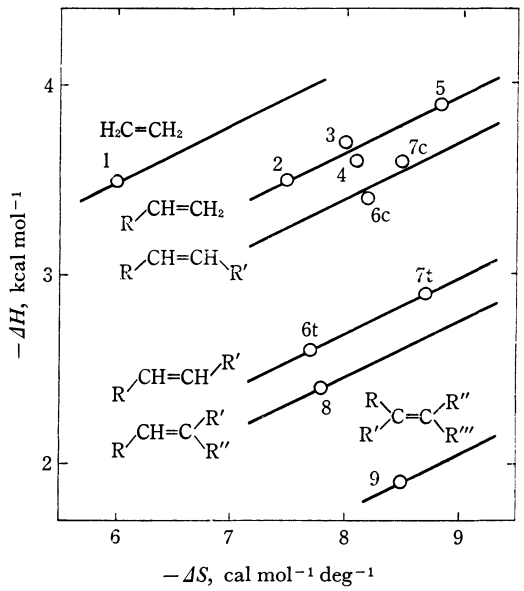

Fig. 4. Plots of ΔH *vs.* ΔS for the silver ion complexation equilibria of olefins in ethylene glycol. Data were taken from Ref. 5. The numbers 1—9 refer to the following olefins: 1, $CH_2=CH_2$; 2, $CH_3CH=CH_2$; 3, $C_2H_5CH=CH_2$; 4, *n*-$C_3H_7CH=CH_2$; 5, *i*-$C_3H_7CH=CH_2$; 6, $CH_3CH=CHCH_3$; 7, $C_2H_5CH=CHCH_3$; 8, $(CH_3)_2C=CHCH_3$; 9, $(CH_3)_2C=C(CH_3)_2$.

complexation studies have been carried out, it may not be quite proper to decide which of the two effects, enthalpy or entropy, is the more important factor to control the different complexation abilities of different alkenes or ethers of a given type of β-substitution. In fact, a closer examination of the thermodynamic data shows that the differentials in ΔH and $-T\Delta S$ between given pairs of substrate compounds are subject to complete cancellation between each other within the limit of experimental errors. As a consequence, no generalizations can possibly be made as to the relative importance of the two contributions in the temperature range studied.

Second, for compounds which belong to different classes of β-substitution, the relative importance of the enthalpy and entropy terms can be asscssed more easily. In particular, the greater stabilities of the complexes formed from *cis* ethers as compared with those from the corresponding *trans* isomers are evidently due to the greater enthalpy loss (*i. e.*, the greater heat evolution) of the former upon complexation.

Third and finally, one should be cautioned against a risk of ascribing different complexation abilities of arbitrarily selected two alkenes or ethers to a difference in either enthalpy or entropy effect in a simple and general manner. By the same token, it should be realized that the complex stability is by no means directly associated with the strength of the complexation bonds. This phase of the problem has previously been emphasized by us[9,10] in regard to the substituent effects in the silver ion complexation of aromatic hydrocarbons.

In the coordination of the silver ions with the double bond of olefins, there seems to be a favorable space (line, surface or volume) around the double bond for the ions to be located. As this space gets narrowed by the increasing substitution of alkyl groups, the degree of freedom of the coordinated silver ions would decrease correspondingly and, as a consequence, the loss of entropy would become larger to that extent. In the case of the tri- and tetra-substitutions, the silver ion may rather experience hindrance against approaching the most favorable space, so that the complexation bond would become the weaker.

Effects of the Geometrical Structure. As has already been mentioned, the difference in stability between the complexes of *cis* and *trans* ethers may most simply be interpreted in terms of the difference in adverse steric effect of substituents. The steric hindrance to complex formation by the two bulky groups, one being a β-alkyl group and the other an alkoxy group, may be greater when they are *trans* to each other.[8] Thus, *cis* isomers may tend to give more stable complexes. Incidentally, this interpretation implicitly assumes that the difference in the free energies of geometrical isomers is a less important factor than that of the resulting complexes.

Alternatively, it may also be conceivable that the energy difference between the Ag^+-complexes of the geometrically isomeric substrates is small as compared to the difference in total energy between the substrate molecules themselves. If this is true, the isomers which are less stable in total energy will experience larger enthalpy loss upon complexation, thus forming more stable complexes. The greater heat of complexation of *cis* ethers may thus be ascribable, for instance, to the relief of strain[4,10] of the two bulky groups *cis* to each other, when the complex is formed.

It is not quite an easy task to decide which of the above two interpretations is more plausible. However, it may be pointed out with some emphasis that the latter view receives support from the results of independent studies of the relative stabilities of the geometrical isomers of olefins as well as alkenyl ethers. Specifically, studies of the geometrical isomerization equilibria of both olefins[12]

and alkenyl alkyl ethers[13] have shown that the *cis* isomers are less stable than the corresponding *trans* isomers by approximately 1 kcal mol^{-1}. The energy difference roughly checks with the difference in the heats of complexation observed.

Thus, so far as the relative stabilities of the silver ion complexes of the *cis* and *trans* isomers of olefins or ethers are concerned, the concept of steric hindrance of bulky groups affecting the ΔH to different extents appears to be improbable. We feel that it is rather through the ΔS term that the steric effect of bulky groups influences the complexation to different extents depending on their placements, *cis* and *trans*. That is, the spatial limitation imposed on the location of the silver ion in the complexes of *trans* isomers perhaps has reflected in larger losses of entropy than would be expected if no such limitation existed. Thus, the entropy losses of *trans* isomers may well become comparable in magnitude with those of *cis* isomers, despite the smaller enthalpy losses of the former. This violation of the compensation rule between ΔH and ΔS must be an origin of such a separation of the ΔH-ΔS linear relationships for the two isomers as has been shown in Figs. 3 and 4.

Solvent Effects on the Proton Magnetic Resonance Spectra of 2,3-Dichlorobutane and the Problem of Rotational Isomers

Shoichi KONDO,*1 Eijiro TAGAMI,*2 Kazuyoshi IIMURA and Masatami TAKEDA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Shinjuku-ku, Tokyo

(Received September 28, 1967)

Effect of solvent on the coupling and magnetic shielding constants of *meso* and *racemic* 2,3-dichlorobutanes has been examined using proton magnetic resonance (PMR). The iterative method of spectrum analysis is applied to the simple sub-state in order to improve the computation speed and the computer capacity. The variations in the coupling constants for the *meso* configuration are to some extent correlated with the population as a function of dielectric constant ε of solvent using an Onsager model. The coupling constants of the *racemic* configuration were almost independent of the solvent dielectric constant. The estimated chemical shift dependence on ε of the reaction field does not adequately describe the experimental data.

The PMR spectra of 2,3-dichlorobutane have been studied by Bothner-By *et al.*,[1] but further investigation seems worthwhile concerning the change in spectra with solvent polarity. A molecule having rotational isomers is known to have various populations in solution, since the relative energies of these isomers are considerably affected by the medium. This is due to the fact that the polar isomer, which corresponds to a higher energy in the gaseous state than the nonpolar isomer, is stabilized in solution by the action of a reaction field induced by the surrounding polar medium. In this paper, the effect of solvent on the population, obtained from the vicinal coupling constant, and on the chemical shift will be discussed in terms of reaction field theory.

Experimental

The preparation and characterization of the *meso* and *racemic* 2,3-dichlorobutanes will be described elsewhere. PMR spectra were taken on a Varian A-60 as 5 and 10% wt/vol solutions in solvents with different dielectric constants and recorded over a temperature range of −60 to 40°C.

The spectrum was calculated as a $X_3AA'X_3'$ system. The Hamiltonian matrix is factorized to reduce it to minimal dimensions by taking advantage of magnetic equivalence.[2] The spectrum of a $X_3AA'X_3'$ system is made up of a superposition of four sub-spectra $Q_XD_AD_{A'}Q_{X'}$, $Q_XD_AD_{A'}D_{X'}$, $D_XD_AD_{A'}Q_{X'}$ and $D_XD_AD_{A'}D_{X'}$. A nomenclature has been developed for the sub-states corresponding to the possible values

$D_XD_AD_A'D_X'$ system only to obtain improvements in computation speed, computer program capacity and convenience of use. Calculations of PMR spectra were carried out on an IBM 1620 computer using Fortran II_D.

The final calculated spectra obtained by this method agreed very closely with the observed spectra. As an example of the fit achieved, a methine proton spectrum of *racemic* 2,3-dichlorobutane in carbon tetrachloride is compared with the calculated spectra in Fig. 2.

Results and Discussion

Estimation of Population of Rotational Isomers from the Vicinal Coupling Constants. The values of chemical shifts and coupling constants $J_{AA'}$ for various solvents are shown in Table 1. Three different rotational isomers are possible for both *meso* and *racemic* 2,3-dichlorobutane as shown in Fig. 3.

1) Experimental Results of meso 2,3-Dichlorobutane. The *meso* configuration has two effective conformations, the trans (M_T) and gauche (M_G), ($M_{G'}$) existing in two mirror-image forms. First, we shall attempt to obtain some information concerning the molecular conformation of the isomers in solution from the values of the vicinal coupling constants, $J_{AA'}$, of *meso*-DCB which is solvent dependent. $J_{AA'}$ may be regarded as an average value, given by

$$J_{AA'} = P_T J_T + P_G J_G, \qquad P_T + P_G = 1 \qquad (1)$$

where P_T and P_G are the populations of M_T and ($M_G + M_{G'}$), respectively, and J_T and J_G are the coupling constants for 60° and 180° dihedral angles between the methine protons. In Table 1 the populations obtained at 29°C, are summarized, assuming $J_T = 11$ c/s and $J_G = 2$ c/s.*3 As can be seen in Fig. 4, there is a fair correlation between the population and the dielectric constant of the solvent, except for benzene solution. Thus, the populations are shown to be given by the following experimental equation, as shown in Fig. 4.

$$\log (P_G/P_T) = -0.66 + 2.0(\varepsilon - 1)/(2\varepsilon + 1)$$

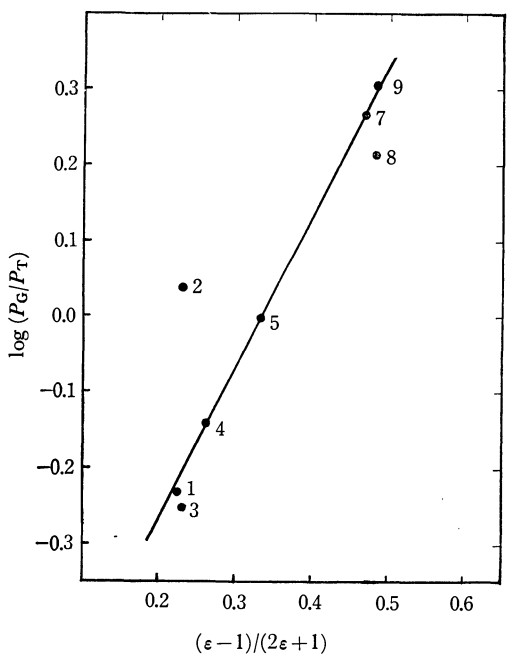

Fig. 4. The possible conformations for *meso* and *racemic* 2,3-dichlorobutanes.

*3 We have adopted these values instead of $J_T = 11$c/s and $J_G = 1$c/s, which are used by Bothner-By *et al.*,[1b] taking account of the theoretically calculated values of $J_T = 9.2$c/s and $J_G = 1.7$c/s for substituted ethanes (see M. Karplus, *J. Chem. Phys.*, **30**, 6 (1958)), and the recent experimental values of $J_T = 13.6$ c/s and $J_G = 2.6$ c/s used for the conformational analysis of amino acid (see H. Ogata, Y. Arata and S. Fujiwara, *J. Mol. Spectroscopy*, **23**, 76 (1967)), and of $J_T = 10$ c/s and $J_G = 2$ c/s used for studying the PMR spectra of 2, 4-dichloropentane (see T. Shimanouchi, M. Tasumi and Y. Abe, *Makromol. Chem.*, **86**, 43 (1965)).

TABLE 2. CONFORMATIONAL ENERGIES (in kcal/mol)

	M_T	M_G	$M_{G'}$	R_T	R_G	$R_{G'}$
Steric interaction (ΔE_1)	1.67	1.96	1.96	1.69	2.10	1.79
Dipole interaction (ΔE_2)	1.56	2.72	2.72	2.72	1.56	2.72
Total energy	3.23	4.68	4.68	4.41	3.66	4.51

$\Delta E(M_G - M_T) = 1.45$ $\Delta E(R_{G'} - R_T) = 0.10$
$\Delta E(R_T - R_G) = 0.75$

2) Estimation of Influence of Solvent upon Population of Rotational Isomers.[3,4] If M_T and M_G are considered to be in simple equilibrium, their relative proportions should be in accordance with the expression

$$P_G/P_T = 2(Z_G/Z_T)\exp(-\Delta E/\boldsymbol{R}T) \quad (2)$$

in which Z_T and Z_G are the partition functions of the two isomers, and the factor 2 is introduced to account for the mirror-image isomerism of the gauche form. It is a well known fact that the energy difference between rotational isomers ΔE changes considerably in the transition from gas to liquid, and is dependent on solvent. The energy of this change, ΔE_{reac}, was calculated by taking Onsager's field[5] as the reaction field,

$$\Delta E_{reac} = \Delta E_{gas} - \Delta E_{solu} = (\varepsilon-1)\mu^2/(2\varepsilon+1)a^3$$
$$\Delta E_{solu} = \Delta E_{gas} - (\varepsilon-1)\mu^2/(2\varepsilon+1)a^3 \quad (3)$$

where ΔE_{gas} and ΔE_{solu} are the energy differences between the gauche and trans forms referred to the gaseous state and to the solution, respectively; μ is the dipole moment of the gauche form, and a the radius of the solute molecule. If the solute molecular radius is estimated from the density and molecular weight of the liquid solute, and by assuming a perfect packing of the spheres, ΔE will be approximately

$$\Delta E = \Delta E_{gas} - (4\pi \boldsymbol{N}d/3M)\mu^2[(\varepsilon-1)/(2\varepsilon+1)] \quad (4)$$

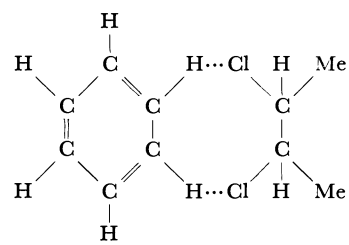
combining with Eq. (2) and substituting numerical values, we obtain at 30°C

$$\log(P_G/P_T) = \log 2(Z_G/Z_T) - (\Delta E_{gas}/2.303\boldsymbol{R}T) + 2.16[(\varepsilon-1)/(2\varepsilon+1)] \quad (5)$$

Here the dipole moment of conformation M_G is approximated by vector addition of bond moment taken from C-Cl (1.86 D). The resultant dipole moment for M_G is 3.08 D.[6]

Furthermore, ΔE_{gas} can be calculated considering two factors; ΔE_1, which results from interactions between non-bonded atoms and groups, and ΔE_2, from the interaction of neighboring dipoles. ΔE_1 has been calculated assuming interactions in accordance with Lennard-Jones type potentials, and ΔE_2 calculated using a point dipole approximation.[7] The calculated results are also given in Table 2.

3) Comparison with the Experimental Results. To compare this estimate with the experimental results, the energy difference between the two isomers is evaluated to be 1.4 kcal/mol with M_T being the more stable form by extrapolating the line in Fig. 4 to $\varepsilon=1$, and assuming equal partition functions for M_T and M_G in the liquid state. The agreement between the observed and calculated values of ΔE_{gas} is gratifying, considering the assumptions involved in the calculation of energy difference. The slope predicted by Eq. (5) agrees closely with the observed values, 2.0. An abnormal phenomenon in the benzene solution was observed, and this "benzene effect" is assumed to be due to the fact that the molecule associates with the solvent molecule by affinity between the hydrogen atoms of the benzene ring and halogen atoms in 2,3-dichlorobutane as follows[8]:



4) Interpretation of PMR Spectra of Racemic 2,3-Dichlorobutane. For *racemic* 2,3-dichlorobutane, the coupling constants $J_{AA'}$ are almost independent of the dielectric constant of the solvents within the limits of detection as can be seen in Table 1. This result is in direct contrast to that for the *meso*-2,3-dichlorobutane. The complexity introduced by consideration of three different isomers makes determination of the energy differences between isomers from $J_{AA'}$ of the spectra difficult. The situation is further complicated by the fact that the superposed peaks in the methyl spectrum render accurate measurements very difficult. As shown in Table 2, R_G is assumed to be the lowest in energy in the gaseous state. The energy difference between R_G and the two other conformers was con-

sidered to be about 0.8 kcal/mol. Since R_T and $R_{G'}$ are polar the energy in solution is stabilized by reaction fields. This energy of stabilization is calculated from Eq. (3) by use of the parameters $\mu=3.0$ D and $(\varepsilon-1)/(2\varepsilon+1)=0.25$ for nonpolar solvents. The value of 0.75 kcal/mol obtained indicates that the energy of each isomer seems to be comparable in nonpolar solvents. As the stabilized energy is 1.38 kcal/mol in acetonitrile which is the most polar solvent used, the energy difference between these and R_G becomes 0.6 kcal/mol which corresponds to a variation of 1 c/s in $J_{AA'}$. It seems to be detectable in the spectra. In contrast to PMR data, the populations of $R_{G'}$ in carbon disulfide and acetonitrile from infrared data are 24% and 43%, respectively.[6] A change of more than 1 c/s in $J_{AA'}$ is expected because of the difference of 20% in the population obtained from IR. Since accuracy is within ± 0.1 c/s, this is considerably different from the result shown in Table 1 that a slight change in $J_{AA'}$ was observed between polar and nonpolar solvents. We have at present no good explanation for this disagreement, but this problem should be worth further investigation.

Solvent Effects on Chemical Shift. The formation of an X-H bond causes an increase in the charge between the two nuclei, and an electric field E applied in the bond direction will draw this excess charge away from the hydrogen nucleus, thus decreasing its shielding coefficient. The magnitude of the decrease is given by the following equation[9]:

$$\sigma = -2\times 10^{-12}E\cos\theta - 10^{-18}E^2 \qquad (6)$$

where θ is the angle between the X-H axis and E.

This experiment was designed to test qualitatively the validity of Eq. (6) at different protons of *meso*-2,3-dichlorobutane. The chemical shifts of methyl and methine protons are plotted *versus* a function of ε at 29°C in Fig. 5.

If the reaction field is adequately given by Eq. (3) and the population is independent of the ε of the solvent, these curves would be straight lines with the slope for methyl and methine protons of gauche form -0.1 and -0.3 ppm, respectively. Instead of straight lines, however, smooth curves with an opposite slope are obtained. The curvature of the curve for the methine proton may be due to the fact that populations of the gauche form become larger as the ε of the solvent increases. The fact that the curve for σ_{CH_3} bends in the opposite direction indicates that the reaction field along the C-CH_3 bond must have a sign opposite to that along the C-H bond, which is not true considering the molecular structure of the gauche form. Even if the estimated reaction field changes in magnitude and direction at each methyl and methine proton, it does not adequately describe the experimental chemical shift dependence on ε.

Thus, long range shielding by carbon-carbon single bonds must be considered.[10] The two

forms of the molecule differ in that for M_T, the C-CH_3 bonds are gauche to the methine proton and for M_G, trans and gauche to the methine proton. The chemical shift difference is 0.11 ppm with the methine proton of the M_T to high field. Similarly, for the methyl group, the other C-CH_3 bond is trans to the methyl group in M_T, and gauche in M_G. The predicted shift is 0.15 ppm with the M_T to low field. This is also in fair agreement with the observed shifts for methyl and methine protons. The qualitative agreement is sufficient to support the assumption that the chemical shifts are primarily caused by the anisotropy of the C-C bond due to the difference in population of rotational isomers in each solution, rather than by the reaction field from the polar effect of the solvent. The contributions to the shielding of a nucleus from the two factors appear to be additive.

Temperature Dependence of Isomer Ratio. Figure 6 shows the populations of the trans and gauche forms in solvents as a function of temperature. It will at once be clear that the curves of populations in polar solvents is of opposite slope to that in nonpolar solvents. This result suggests that M_G is preferred in solvents of high dielectric constants. This is coincident with the tendency of solvent effects observed in the preceding section.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 795—799 (1968)

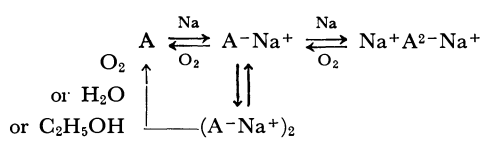
The Behavior of Radical Anion of Acridine as Revealed from ESR Studies

Shigeya NIIZUMA, Michio OKUDA and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received October 16, 1967)

Nature of acridine anions produced by the addition of alkali metals to the tetrahydrofuran solutions of acridine has been studied by means of ESR and VU spectra. In excess of acridine (A), a green species G is produced. This has been identified as A^-Na^+ (or A^-K^+ *etc.*). A^-Na^+ gives under suitable conditions, ESR spectra with hfs consisting more than fifty lines. This species reverts to acridine upon addition of a small quantity of water or ethanol. With the fall of temperature, the intensity of ESR spectra of G decreases remarkably and accompanied with it, UV spectra of G also decline with no change of the spectral shape. $\log I$ *vs.* $1/T$ plots where I is either the intensity of UV absorption or of the ESR signal are satisfactorily linear; this has been interpreted to be due to a large equilibrium constant of the process, $2A^-Na^+ \rightleftarrows (Na^+A^-)_2$ in which $(Na^+A^-)_2$ is a colorless diamagnetic substance. This interpretation has led to the value of enthalpy of dissociation of $(Na^+A^-)_2$ as *ca.* 14 kcal. When sodium is in excess, a diamagnetic violet species is produced. This has been assigned as $Na^+A^{2-}Na^+$. The chemical processes pertaining to A^-Na^+ and $Na^+A^{2-}Na^+$ can be summarized as follows:



In a series of papers on the photoreduction of acridine reported by one of the present authors (M. K.) and his collaborators, it was established that semiquinone or half-reduced radical of acridine is formed in the irradiated alcoholic solution.[1] In connection with these studies, it is interesting to study the chemical nature of the various forms of half-reduced acridine such as neutral radical and radical anion by means of an ESR technique in addition to UV measurement.

This paper reports the behavior of radical anion which is produced by treating acridine with alkali metals in tetrahydrofuran (THF). Hitherto, there seems to be no papers on the ESR spectra which were decisively attributed to acridine radical anion, although some reports were made on other *N*-heterocyclics.[2,3] Carrington[4] said, by the

analogy with pyridine which upon contact with sodium in DME (dimethoxyethane) or THF, yields dipyridyl anion, that acridine radical anion, being also unstable, might convert to a dimeric form. Kuwata *et al.*[5] found that acridine, upon contact with metallic sodium in THF, gives a diamagnetic substance red in color, and the solution, when heated, turns blue and gives broad ESR spectra consisting of a single line with $\Delta H_{msl}=$ 13G and $g=2.003$. They suggested that this is due to a radical anion of acridine. Russel *et al.*[6] reported in a paper dealing with some radical anions existing in a 1 : 1 solution of some unsaturated and its dihydro compounds in $(CH_3O)_2SO$ containing *t*-Bt-OK), that electron transfer occurs between acridine and acridan. No remark was made, however, on the ESR spectra.

In the present paper, we would like to report the following findings; 1) Radical anion of acridine, A^- gives under suitable conditions, ESR spectra with hfs consisting more than fifty lines. 2) A^- transforms to dianion A^{2-} when the quantity of sodium is in excess. 3) The intensity of ESR decreases remarkably at lower temperatures; this suggests the existence of a dimerization (or polymerization) equilibrium of the type $2A^-Na^+ \rightleftarrows (A^-Na^+)_2$.

Experimental

A Nippon-Denshi P-10 type ESR spectrometer was used; its characteristics are X-band, 100 kc field modulation and H_{011} mode of cavity. The constancy of temperature was maintained within $\pm 2°C$ by streaming through a cavity either nitrogen gas (from the liquid nitrogen) for low temperatures or hot air for high temperatures.

Materials. First grade tetrahydrofuran (THF) from Wakojunyaku was refluxed with sodium for several hours, distilled and then stored *in vacuo*. Na-K-alloy was added to the stock solvent to remove a trace of water. Sodium and potassium were made free from surface contamination by dropping fused metals down through a capillary *in vacuo*. Lithium was not specially purified. Acridine was purified by a usual method.

UV Spectra of the Solution in Contact with Alkali Metals. Several mg of acridine dissolved in 2 m*l* of degassed THF was brought into contact with *ca.* 0.2—0.4 g sodium through a breakable seal. The solution gradually turned green in several to ten and several minutes and finally became violet after a long time. The two species will be designated as G and V. Essentially similar results were obtained with both potassium and lithium. The absorption spectra are shown in Figs. 1 and 2. Table 1 gives the comparison of the

peak positions of G and V for the longest wavelength absorption in the case of sodium and potassium.

It was established that as long as unreacted acridine exists, only G is produced and that the production of V occurs as soon as acridine disappears.

Behavior of Green Species. Species G displays ESR spectra which are shown in Figs. 3—5. Upon addition of a very small quantity of water or ethanol, it transformed entirely to acridan; this was confirmed by UV spectra. G is photochemically stable; any slight change does not occur by 5890 Å illumination. The influence of temperature change on the intensity of ESR (produced by the addition of sodium) was investigated. It increases with the rise of temperature from −42 to ~77°C; at −63°C the signal was scarcely detected. Hfs in the ESR spectra at 77°C is essentially the same as the ones at ordinary temperatures except for fine details. This implies that one radical species is responsible to ESR spectra. At extremely low temperatures, the solution becomes colorless and is accompanied with the appearance of a white precipitate. This precipitate is redissolved by the introduction of air or by warming the solution. Figure 6 shows the temperature change of UV spectra.

As seen from the figure, the intensity at −47°C decreases nearly ten times as that at 20°C without any change in the spectral shape. Thus the intensity change in the absorption spectra runs parallel with that in the ESR signal. The determination of ε for G was performed by measuring the ESR signal and UV spectra at the same temperature and by using the radical concentration evaluated from the former. The value obtained is ε (at 620 mμ) $=6900\pm500$ M^{-1}cm^{-1}.

Behavior of Violet Species. The following observations were made on the samples treated with sodium. ESR signals decrease as G transforms to V and no signal is observed in the solution containing only species V. V is stable both thermally (from room temperature up to +70°C) and photochemically. The introduction of air causes the change V→ G→acridine to occur. From the change of UV spectra observed when the air is introduced to the solution containing only V species, it is concluded that V transforms to acridine at one to one ratio. This enables one to evaluate ε_{570} of V as 4600 ± 300 M^{-1}cm^{-1}. The temperature effect on the absorption spectra is shown in Fig. 7. For the sample treated with potassium, such temperature effect is given as the change with time, after the solution which had been kept in the dry ice bath was put out of the bath. The complicated change in both cases suggest that more than two species or two states may exist in thermal equilibrium. The present result is somewhat similar to the one reported by Smid[7] for fluorene radical anion.

Finally, it may be worthwhile to add that the temperature effect on the absorption spectra of the solution

containing both V and G, appears to be mere superposition of that on the solution containing only V or G alone.

Discussion

By the analogy with the general behavior of aromatic compounds in contact with alkali metals, there is scarcely any doubt that G species is a radical anion A^- (or A^-Na^+) produced by the electron transfer from alkali metals to acridine. The finding that the admittance of air transforms G into acridine is thought to negate the formation of diacridyl anion, which is expected to yield diacridan. It is most reasonable to identify V species as dianion A^{2-}, since V species is diamagnetic and is produced only in the existence of excess alkali metals. It is interesting to compare the above behavior with that of pyridine. According to Ward,[2] pyridine, when treated with alkali metals in DMF solutions, changes to a reddish violet substance in a short time but after a long time, becomes a yellow substance, the former being paramagnetic and the latter diamagnetic. In this case, however, the paramagnetic species was identified as dipyridyl anion on the basis of hfs of its ESR spectra. Thus one can say that acridine radical

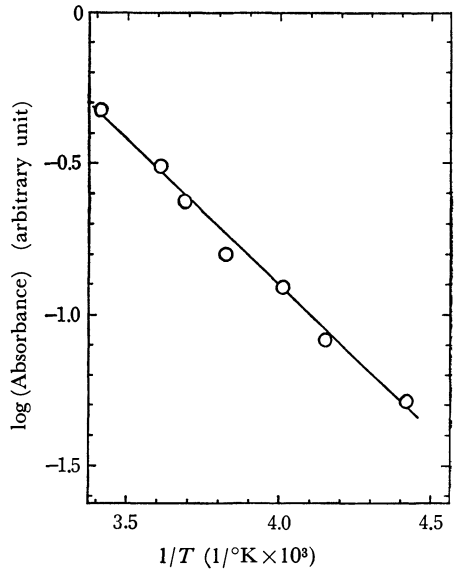

Fig. 8a. log (Absorbance) *vs.* $1/T$ plot of G species. Absorbance, at 619 mμ (ε_{max})

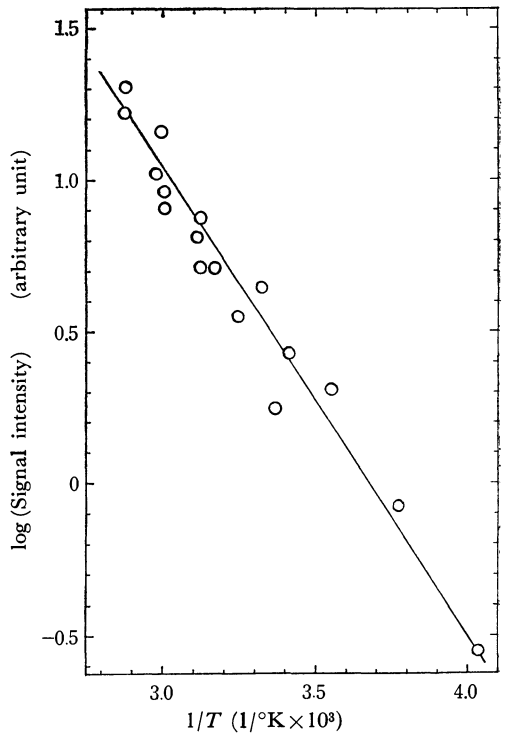

Fig. 8b. log (Signal intensity of ESR) *vs.* $1/T$ plot of G species.

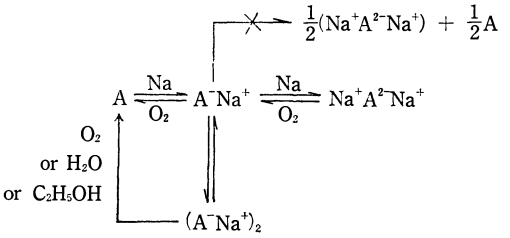
anion is more stable than pyridine radical anion.

The effect of temperature on the intensity of both ESR spectra and of the visible absorption spectra, clearly indicates that the paramagentic G species is in thermal equilibrium with another diamagnetic species (having no absorption spectra in the visible region), the formation of the former being favored by the rise of temperature. It is most plausible to attribute this equilibrium to the following process

$$2A^{-}Ma^{+} \rightleftarrows (A^{-}Na^{+})_2 \qquad (1)$$

or to an association of higher degree. A white precipitate obtained at lower temperatures may be $(A^{-}Na^{+})_2$ or the higher associate. This is consistent with the finding that it is redissolved upon the introduction of air. Figure 8 gives a logarithmic plot of the intensity in the absorption spectra and in the ESR signal (Curie law is taken into consideration) against the reciprocal temperature. The linear relationship holds for the both plots although the slopes are somewhat different. This suggests that the equilibrium constant of (1) is quite large; if this is assumed, the heat of dissociation for the (1) process is estimated to be $\sim$14 and $\sim$9 kcal respectively from ESR and UV data. Perhaps the former value is more reliable.

In conclusion, the chemical processes related with the acridine radical anion in the THF solution (containing sodium, for instance) may be summarized as follows:



A species represented as $(A^{-}Na^{+})_2$ may alternatively be a higher associate or a mixture of various associates.

Analysis of the HFS is not yet thoroughly successful. Judging from the entire width, the McConnell's Q-value seems to be much larger than 23 gauss. It appears that the unpaired spin densities evaluated on the basis of a simple LCAO method assuming $\alpha_N=\alpha_C+\chi\beta_{CC}$, $\beta_{CN}=\beta_{CC}$, $\chi=$ 0.8 or 0.6 or 0.4, cannot give a satisfactory interpretation. The exact analysis is now being attempted, which will be published in near future.

Initiation Step of Methane Pyrolysis*[1]

Takayuki YANO and Kenji KURATANI

Institute of Space and Aeronautical Science, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received October 16, 1967)

Equimolar mixtures of CH_4 and CD_4 were pyrolyzed at 1560°K by a reflected shock wave. From the isotope distribution of H_2, HD and D_2 which are components of the product in early stage, the initiation step of methane pyrolysis is concluded to be the splitting to a methyl radical and a hydrogen atom.

Recently, the vacuum ultraviolet photolysis[1] and the radiolysis[2] of methane were recognized to begin with the decomposition to a methylene radical and a hydrogen molecule. The reaction mechanism of the methane pyrolysis, especially the initiation step of this reaction, however, has not been settled yet and two hypotheses have been discussed during these thirty years. One of which[3] suggested the same mechanism as proposed in the case of the ultraviolet photolysis and the radiolysis, while the splitting to a methyl radical and a hydrogen atom was assumed by the others.[4]

It is the purpose of this paper to study the thermal

decomposition of the equimolar mixture of methane and tetradeuteromethane around 1560°K using a single pulse shock tube and to decide which of these two aforementioned hypotheses is correct.

Experimental

The shock tube used in this study is similar to a magic hole type developed at Cornell University[5] (the detail of this tube will be described in near future). Mixtures of 6% each of CH_4 and CD_4 in argon were heated by the reflected shock wave to 1560+30°K for dwell times of about 1 msec. The reaction mixture was withdrawn to an evacuated vessel and its composition was determined by the gas chromatographic analysis. Isotope mixtures of hydrogen molecules were separated using an alumina column coated with $MnCl_2$ of 5 m length at 77°K and detected by a cathalometer (He was used as carrier gas.) Hydrocarbons were separated by a 3 m activated charcoal column at 150°C and analyzed by a flame ionization detector. CH_4 and CD_4 were supplied by Takachiho Chemicals Co. and Merck respectively, and used without further purification.

Results and Discussion

It is well known that methane is converted into ethane in the early stage of the reaction and ethane formed is decomposed further into ethylene, acetylene, *etc.* in the later stage. The presence of one mole of ethane in products corresponds to the formation of one mole of hydrogen, and similarly the findings of one mole each of ethylene and acetylene are equivalent to the production of two and three moles of hydrogen respectively. Therefore, it is the proper requirement to suppress the occurence of the secondary reactions such as ethylene and acetylene formations in order to study the initiation step of methane pyrolysis in terms of the isotopic distribution of the produced hydrogens. The another restriction is concerned with the deviation from the ideal behavior of gases behind a reflected shock wave. The use of high dilution with argon is essential to avoid this difficulty, but the limitation by the sensitivity of our analytical apparatus should be also taken into account. From these reasons, the aforementioned experimental conditions about temperature range, dwell time and concentration of reactants were adopted.

In order to confirm the experimental accuracy, yields of reaction products of three experimental runs are compared and mass balances in regard to hydrogen are testified. In Table 1 $\sum H_2$ means sum of observed values of H_2, D_2 and HD, and $\sum(C_2H_6+2C_2H_4+3C_2H_2)$ corresponds also to the total yield of hydrogen expected from the formation of these hydrocarbons. The agreement between these two values is satisfactory and we believe that analytical accuracy of our experiment is sufficient, though the chromatographic separation of the small amount of H_2, HD, and D_2 is rather troublesome, since the tailing of an individual peak interferes the distinct separation between the adjacent peaks.

In Table 2, experimental results on additional runs as well as the above described runs are summarized. The relative yields of HD and D_2 to H_2 are shown in this table along with those of ethylene and acetylene to ethane. As shown in Table 2 there are considerable scatters of experimental values, but the average value of the relative yields of H_2 : HD : D_2 is estimated to be 1 : 1.7 : 0.6. As already pointed out, hydrogen molecules are produced not only by the primary process from methane to ethane but also by the secondary processes from ethane to ethylene and acetylene, and

5) J. E. Klepeis, Thesis, Graduate School of Aeronautical Eng., Cornell University (1961); A Lifshitz, S. H. Bauer and E. L. Resler, Jr., *J. Chem. Phys.*, **38**, 2056 (1963).

the contribution of the primary process relative to the overall reaction is represented by the ratio $(1-R)$, where

$$R = [(C_2H_4) + 2(C_2H_2)]/[(C_2H_6) + 2(C_2H_4) + 3(C_2H_2)]. \quad (1)$$

If we assume the elimination of molecular hydrogen in the initiation step, then the following reaction scheme corresponding to the primary process will be formulated,

$$CH_4 \rightarrow CH_2 + H_2$$
$$CH_2 + CH_4 \rightarrow CH_3 + CH_3$$
$$CH_3 + CH_3 \rightarrow C_2H_6$$

That is, from this scheme only H_2 and D_2 are produced. Then, even if we further assume the elimination of atomic hydrogen from any step among the processes from ethane to ethylene and acetylene, the observed high yield of HD cannot be explained, since the contribution of the primary process relative to the overall reaction is rather large and the values of $(1-R)$ exceed 0.6 in all experimental runs.

From this consideration, we conclude qualitatively that the initiation steps of methane pyrolysis are the elimination of atomic hydrogen,

$CH_4 \rightarrow CH_3 + H$ yields of H atom a mol

and

$CD_4 \rightarrow CD_3 + D$ yields of D atom b mol

To explain the observed values of $H_2 : HD : D_2$ semiquantitatively, it is necessary to take into account the isotope effect on the reaction rates. If we assume the relative rate of the first step is equal to $a : b$, the amounts of hydrogen molecules produced from the primary processes will be represented as follows,

$H + CH_4 \rightarrow H_2 + CH_3$ yield of H_2 $a/2$,
$H + CD_4 \rightarrow HD + CD_3$ yield of HD $a/2$,
$D + CH_4 \rightarrow HD + CH_3$ yield of HD $b/2$,
$D + CD_4 \rightarrow D_2 + CD_3$ yield of D_2 $b/2$.

That is, in the primary processes the relative yields of $H_2 : HD : D_2$ are given as

$$H_2 : HD : D_2 = a : a+b : b, \quad (2)$$

and the methyl radicals produced both in the initiation steps and the abstraction reactions will be combined together to form ethanes. The isotopic distributions of the latters are

$$C_2H_6 : CH_3CD_3 : C_2D_6 = (3a+b)^2 : 2(3a+b)(a+3b) : (a+3b)^2. \quad (3)$$

As it is well known,[6] on the way of the secondary processes from ethane to ethylene, a hydrogen atom is removed from the parent molecule by the following mechanism,

$$C_2H_6 \rightarrow CH_3 + CH_3 \quad (R1)$$
$$CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5 \quad (R2)$$
$$C_2H_5 \rightarrow C_2H_4 + H. \quad (R3)$$

Here we assume tentatively that these reaction steps are independent on the presence of a large amount of methane in order to simplify the algebraic treatment. Therefore, from an ethane molecule a hydrogen atom is removed and an ethylene molecule is produced. The hydrogen atom produced in the step (R3) reacts with a large excess of methane, and it is converted to the molecular hydrogen,

$$H(D) + CH_4(CD_4) \rightarrow (H_2, HD, D_2) + (CH_3, CD_3). \quad (R4)$$

In our experiment, not only ethylene but also acetylene are produced step by step,

$$C_2H_6 \rightarrow C_2H_4 \rightarrow C_2H_2. \quad (R5)$$

As acetylene is formed from ethylene, the quantity of ethylene, which is equivalent to the amount of the hydrogen atom formed in process (R3), must be the sum of the observed values of ethylene and acetylene. Of course, in a process $C_2H_4 \rightarrow C_2H_2$, atomic or molecular hydrogen may be produced. But in our experiment, the yield of acetylene is relatively small compared with those of ethane and ethylene, and the amount of hydrogen formed in the process from ethylene to acetylene is omitted from the following discussions.

If we assume that the isotope effect on the process (R3) is negligible, H and D atoms are formed in proportion to the hydrogen isotopic distribution in ethane molecules. Since the relative yields of the isomeric ethanes are represented by Eq. (3), the distribution of H and D atoms in ethanes is given by

$$H : D = (3a + b)(4a + 4b) : (a + 3b)(4a + 4b) = (3a + b) : (a + 3b). \quad (4)$$

Therefore, the isotopic distributions of the hydrogen molecules produced by the process (R4) will be represented as

$$H_2 : HD : D_2 = (3a+b) : (3a+b)+(a + 3b) : (a+3b) = (3a+b) : (4a+4b) : (a+3b). \quad (5)$$

On the other hand, if we assume the same isotope effect on the process (R3) as that on the splitting of methane to a methyl radical and a hydrogen atom, the amounts of the hydrogen atoms liberated in the process (R3) are given as

$$H : D = a(3a+b) : b(a+3b),$$

and the ratios of hydrogen molecules produced by

6) B. S. Benson, "The Foundations of Chemical Kinetics," McGraw-Hill Co., New York (1960), p. 349.

(R4) process are expressed as

$$H_2 : HD : D_2 = a(3a+b) : a(3a+b)+b(a+3b) : b(a+3b). \quad (6)$$

The observed isotopic distributions of hydrogen molecules should be expressed as the sum of the contributions of the primary and secondary processes. That is, in the former case, where the isotope effect in the secondary process is ignored, the relative yields of hydrogens are given by combining Eqs. (2) and (5),

$$\begin{aligned} H_2 : HD : D_2 &= (1-R)a/[2(a+b)] + R(3a+b)/[8(a+b)] : \\ &\quad (1-R)(a+b)/[2(a+b)] + R4(a+b)/ \\ &\quad [8(a+b)] : \\ &\quad (1-R)b/[2(a+b)] + R(a+3b)/[8(a+b)] \\ &= [4a-R(a-b)]/[8(a+b)] : 1/2 : \\ &\quad [4b-R(b-a)]/[8(a+b)] \end{aligned}$$

and in the latter case, where the same isotope effect in the secondary process as in the primary process is assumed, the ratios are expressed by combining Eqs. (2) and (6),

$$\begin{aligned} H_2 : HD : D_2 &= (1-R)a/[2(a+b)] + Ra(3a+b)/ \\ &\quad [2(3a^2+2ab+3b^2)] : \\ &\quad (1-R)(a+b)/[2(a+b)] + \\ &\quad R(3a^2+2ab+3b^2)/[2(3a^2+2ab+3b^2)] : \\ &\quad (1-R)b/[2(a+b)] + Rb(a+3b)/ \\ &\quad [2(3a^2+2ab+3b^2)] \\ &= (1-R)a/[2(a+b)] + Ra(3a+b)/ \\ &\quad [2(3a^2+2ab+3b^2)] : \\ &\quad 1/2 : \\ &\quad (1-R)b/[2(a+b)] + Rb(a+3b)/ \\ &\quad [2(3a^2+2ab+3b^2)]. \end{aligned}$$

The experimental results shown in Table 2 are interpreted by these equations and the values of $a : b$ are determined as nearly equal to 1 : 0.6—0.7 in both cases. If we assume that the ratio of the isotopic rate constants k_H/k_D of the initiation step is expressed by the zero-point energy difference of the reaction coordinates of this process,

$$a/b = k_H/k_D = \exp[-(h\nu_D - h\nu_H)/2\boldsymbol{k}T]$$

and take the values of $\nu_H = 3000\ cm^{-1}$, $\nu_D = 2200\ cm^{-1}$, the ratio of a/b at 1560°K is calculated as 1/0.69, and agrees with the observed values. However, this calculation is an approximate one, and we are planning to obtain the more accurate ratio taking into account the differences in partition functions. The result will be reported in near future.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 802—809 (1968)

Rectification Effects Using Polyelectrolyte Solutions

Kunitoshi SHIMIZU, Manabu SENŌ and Hiroshi NOZAKI

The Institute of Industrial Science, The University of Tokyo, Azabu Roppongi, Tokyo

(Received October 18, 1967)

The rectifying properties of liquid junctions of polyelectrolyte solutions are examined and discussed. In the case of liquid junctions between aqueous solutions of poly(styrene-sulfonic acid) and poly(2-vinyl-*N*-*n*-butylpyridinium hydroxide), the rectification effects greatly depend on the concentrations of the polyelectrolytes and on the frequencies of the voltages applied, that is, rectification effects can not be found when the concentrations of polyelectrolytes are lower than 0.68×10^{-3} equivalents per liter and when the frequencies of the alternating voltages are higher than 200 cps. The mechanism of rectification can be explained to some extent by a semiconductor analogy. In the case of liquid junctions between poly(styrene-sulfonic acid) and poly(2-vinyl-*N*-*n*-butylpyridinium bromide), the static current *versus* voltage curves have strong hysteresis loops. The rectification effects can be slightly observed when alternating voltages with frequencies lower than 100 cps are applied. In this case, however, the mechanism of rectification can not be explained by the semiconductor analogy.

Reiss[1] and Fuller[2] have pointed out that the electron excess and the electron defficiency in a semiconductor correspond to the proton excess and the proton defficiency in an aqueous solution

1) H. Reiss, *J. Chem. Phys.*, **21**, 1209 (1953).

2) C. S. Fuller, *Rec. Chem. Progr.*, **17**, 75 (1956).

respectively. An *n*-type semiconductor is strongly analogous to an alkaline solution, containing highly mobile hydroxide ions together with corresponding cations so large as to be entirely immobile, while a *p*-type semiconductor is analogous to an acid solution, containing highly mobile protons together with corresponding anions so large as to be entirely immobile.

In view of these analogies, we may make electrolytic junctions in polyelectrolyte solutions corresponding to *p-n* junctions in semiconductors.

As a matter of fact, Lovreček,[3] Läuger,[4] Senō[5] and others[6] found rectification effects using cation-exchange membranes and anion-exchange membranes. In linear polyelectrolyte systems, however, only Lovreček[3] has observed rectifying effects, and he has reported only very simple data.

In the present investigations, electrolytic liquid junctions separating the solutions of a polyacid and a polybase by a milipore filter (a cellulose-acetate membrane) were prepared and their rectifying properties were examined. Further, the rectifying properties of liquid junctions between the salt of a polybase and of a polyacid were examined.

Experimental

Materials. *Poly(styrene-sulfonic Acid) (PVSA).* This product was prepared by a method in the literature[7]; one molecule of this product (molecular weight: 100000) has 420 sulfonic groups.

Poly(2-vinyl-N-n-butylpyridinium Bromide) (NBPB). From 2-vinylpyridine, poly(2-vinyl pyridine) was obtained according to a procedure previously reported.[8] NBPB was synthesized from poly(2-vinyl pyridine) by a method in the literature.[9] The product was analyzed for Br titmetrically[10] and for N by the micro-Dumas method. Found: Br, 21.2%; N, 8.0%. One molecule of NBPB (molecular weight: 15000) has 44 bromide atoms. The conductance of aqueous solutions of this NBPB at 25°C is given in Table 1, where C is the equivalent of bromide per liter and L is the observed specific conductance. The figures in the fourth column would be the equivalent conductance if the effect of the acidity were corrected. The fifth column shows the equivalent conductance, in which the effect of acidity is corrected by R. M. Fuoss' method.[9]

Poly(2-vinyl-N-n-butylpyridinium Hydroxide) (NBOH). An aqueous solution of NBOH was prepared by treating an NBPB aqueous solution with an anion-exchange resin (OH-form).

Apparatus and Procedure for Measurement. Figure 1 shows a block diagram of the apparatus used for the measurement of the currents *versus* the applied voltages.

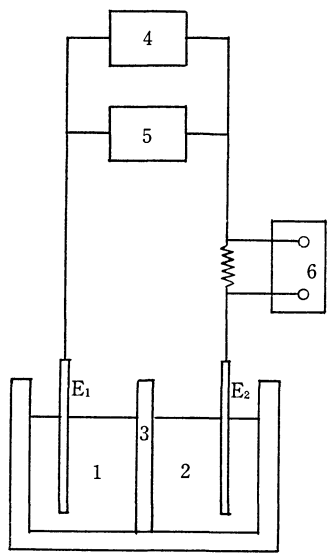

Fig. 1. Apparatus.

1. PVSA aqueous solution, the concentration of which is C_p.
2. NBOH (or NBPB) aqueous solution, the concentration of which is C_h (or C_{Br}).
3. Milipore filter (pore radius, 10 mμ).
4. Voltage source.
5. Voltmeter.
6. Osciloscope or X-Y recorder.

E_1 and E_2: Platinum electrodes.

The aqueous solutions of NBOH (or NBPB) and of PVSA were separated by a thin porous membrane (thickness: 0.1 mm, pore radius: 10 mμ), and a platinum electrode was immersed in each of the solutions. A constant voltage was supplied by a battery, and an alternating voltage was supplied by an ultra-low-frequency oscillator (10^{-3}—10^{3} cps), Toa-Dempa CR-IE, through a pair of electrodes, E_1 and E_2. The electric current was measured with an X-Y recorder or an osciloscope.

Results

NBOH-PVSA Systems. *Static Voltage-Current Characteristics.* The system in which E_2 is the positive electrode and E_1 is the negative electrode was much more resistant to the direct current than when voltages with the reverse polarity were applied. The curves of the currents *versus* the voltages are shown in Figs. 2 and 3.

The data given in Figs. 2 and 3 were read 30 sec after the voltage was applied. The curves in Fig. 2 were measured while the concentration of NBOH (C_h) was maintained at a constant value (1.36×10^{-2} equivalents per liter), while the concentrations of PVSA (C_p) were varied from 1.36×10^{-2} to 0.68×10^{-3} equivalents per liter. The curves in Fig. 3 were measured while C_p was maintained at a constant value (1.36×10^{-2} equivalents per liter) and the C_h values were varied from 1.36×10^{-2} to 0.68×10^{-3} equivalents per liter.

The curves in Figs. 2 and 3 are well reproduced by the following equation:

$$J = J_s(\exp(\alpha eV/kT) - 1) \qquad (1)$$

where J is the electric current, V is the applied voltage, k is the Boltzmann constant, e is the charge of the electron, α is a parameter that shows the effective portion of an applied voltage, and J_s is an experimental parameter. The experimental

parameters, J_s and α, can be directly decided from the curves in Figs. 2 and 3; they are shown in Table 2.

Alternating Voltage-Current Characteristics. The rectification phenomena are effective when alternating voltages of ultra low frequencies are applied to the systems. The rectification ratio becomes poorer with an increase in the frequency. An example is shown in Fig. 4. The dependency of the rectification ratio on frequencies is illustrated in Fig. 5.

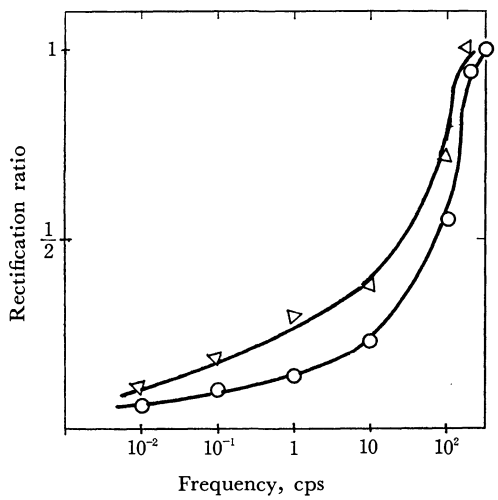

Fig. 5. Dependence of rectification ratio on frequencies in NBOH-PVSA systems. (Rectification ratio stands for the current ratio of the backword against the forward direction.)

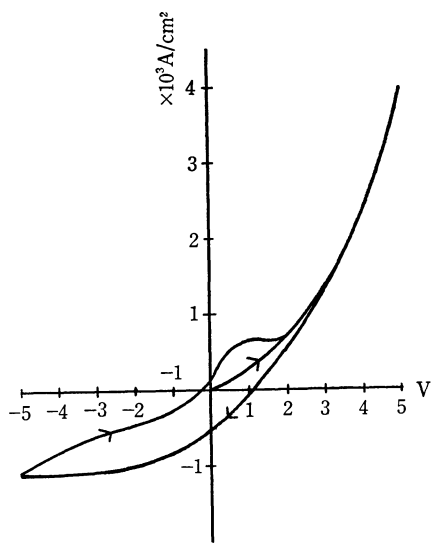

Fig. 6. Current plots *versus* constant voltages in NBPB-PVSA systems.
$C_{Br}=C_p=1.36\times10^{-2}$ equiv/l

From Fig. 4 we can see that the backward current is not very small. As is shown in Fig. 5, when frequencies are higher than 200 cps, the rectification ratio becomes unity, whatever concentrations of NBOH and PVSA are employed.

NBPB-PVSA Systems. *Static Voltage-Current Characteristics.* The static voltage-current characteristics of the NBPB-PVSA systems are similar to those of the NBOH-PVSA systems, but when the voltage was applied in an inverse direction, the voltage-current curve shows a remarkable hysteresis loops. A typical voltage-current curve is shown in Fig. 6.

The data given in Fig. 6 were read 30 sec after the voltages were applied. Figure 6 was obtained when we started from the application of a forward-bias voltage.

The areas of the loops decrease with a decrease in the concentrations of NBPB and PVSA. The dependency of the areas of loops on the concentrations of NBPB and PVSA is shown in Fig. 7.

The experimental values of J_s and α are shown in Table 3.

Alternating Voltage-Current Characteristics. Slight rectification effects were observed when frequencies lower than 100 cps were applied. An example is shown in Fig. 8. The rectification characteristics were not reproducible.

Theoretical

Theoretical considerations of the electrolytic rectification in double-membrane systems have been made by several authors. Katchalsky,[11] Ohki[12] and Läuger[4] developed the theory from the point of view of membrane phenomena. Senō[5] and Oshida[13] treated it as a semiconductor analogy. We also consider the electrolyte-membrane junction as a *p-n* junction in semiconductors.

NBOH-PVSA Systems. The potential profile of protons in the transient region is shown in Fig. 9.

The electrolytic current of the protons is given by the so-called Nernst-Planck equation:

$$J_p = e\mu_p C_p \mathrm{d}\varphi/\mathrm{d}x + eD_p \mathrm{d}C_p/\mathrm{d}x \qquad (2)$$

where μ_p: the mobility of the protons, C_p: the concentration of the protons, D_p: the diffusion coefficient of the protons, and φ: the electrical potential. In the absence of a bias voltage, the electric current equals zero. Then the solution of the above equation is as follows:

$$C_p(x) = C_{p,0}\,\mathrm{epx}(-e\varphi/kT) \qquad (3)$$

where $C_{p,0}$ is the concentration of the proton at $\varphi=0$.

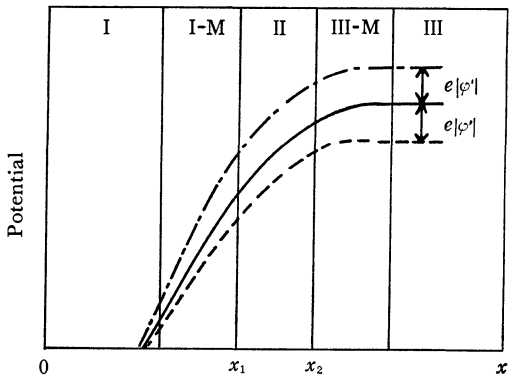

Fig. 9. Potential curve for protons.
I: PVSA aqueous solution. II: Membrane. III: NBOH aqueous solution. I-M, III-M: transition region. Steady line: no applied voltage. Dotted line: forward bias voltage. Chain line: inverse bias voltage.

When a forward voltage is applied, the potential barrier in the transient region becomes lower, as is shown by the dotted line in Fig. 9. As a result, the diffusional current (the second term of Eq. (2)) surpasses the driving current (the first term of Eq. (2)) and protons diffuse from the membrane region into the III-M region. Then the concentration of protons in the III-M region becomes:

$$C_p = C_{p,3} + \Delta C_p \qquad (4)$$

where the subscript 3 refers to the NBOH region.

As soon as the protons enter into the III-M region, the excess protons disappear as a result of the formation of water molecules with hydroxide ions.

The rate of this coupling reaction, R, is:

$$R(x) = \overleftarrow{r}C_pC_{h,3} = \overleftarrow{r}C_{p,3}C_{h,3} + \overleftarrow{r}C_{h,3}\Delta C_p(x)$$
$$= g + \overleftarrow{r}C_{h,3}\Delta C_p(x) \qquad (5)$$

where C_h is the concentration of hydroxide ions, $g=\overleftarrow{r}C_{p,3}C_{h,3}$ is the exchange velocity in the dissociation equilibrium of water, and $\overleftarrow{r}$ is the rate constant of the coupling reaction of protons and hydroxide ions. Under such circumstances, the diffusional flow of protons is expressed by Fick's second law:

$$\partial C_p/\partial t = D_p\partial^2 C_p/\partial x^2 \qquad (6)$$

The change of C_p in the III-M region is as follows:

$$\partial C_p/\partial t = R(x) - g \qquad (7)$$

Then, from Eq. (6) and Eq. (7), we get the following equation:

$$D_p\partial^2 C_p/\partial x^2 = R(x) - g \qquad (8)$$

If we accept $x=\infty$; $C_p=C_{p,3}$ as the boundary condition, then the solution of Eq. (8) becomes as follows:

11) A. Katchalsky and O. Kedem, *Biophys. J.*, **2**, 53 (1962).
12) S. Ohki, *J. Phys. Soc. Japan*, **20**, 1674 (1965).
13) I. Oshida, "Ekitai no Denki Bussei," Maki Shotten, Tokyo (1964), p. 317.

$$C_p(x) = C_{p,3} + C'\exp(-(x-x_2)/L_p) \quad (9)$$

where $L_p=\sqrt{D_p/\overleftarrow{r}C_{h,3}}$ is the mean distance which protons proceed in the III-M region untill their disappearance and where C' is the integral constant. Therefore, the current carried by the protons is given by:

$$J_p(x_2) = -eD_p(\mathrm{d}C_p/\mathrm{d}x)_{x_2} = eD_p(C_p(x_2)-C_{p,3}) \quad (10)$$

From Boltzmann's distribution law (we suppose that the concentration distribution of protons obeys Boltzmann's law just as in Eq. (3), even if the electric current is not equal to zero.*1), we get Eq. (11).

$$C_p(x_2) = C_{p,3}\exp(e\varphi'/kT) \quad (11)$$

These relations lead to the following expression:

$$J_p(x) = (eD_pC_{p,3}/L_p)\{\exp(e\varphi'/kT)-1\} = (eD_pC_{p,3}/L_p)\{\exp(\alpha eV/kT)-1\} \quad (12)$$

where α is a parameter which shows the effective portion of applied voltage,

$$\varphi' = \alpha V \quad (13)$$

Exactly the same procedure is used for hydroxide ions. Therefore, the total current is expressed by:

$$J = e(D_pC_{p,3}/L_p + D_hC_{h,1}/L_h)\{\exp(\alpha eV/kT)-1\} \quad (14)$$

where the subscript h refers to hydroxide ions, the subscript p refers to protons, and the subscript 1 refers to the PVSA region.

When a reverse bias voltage is applied, the density of protons at $x=x_2$ decreases by a ratio of $\exp(-e\alpha|V|/kT)$. As a result, protons diffuse out from the region III. However, this current is small and soon attains saturation because of the low density of protons in this region.

NBPB-PVSA Systems. Here also we adopt the above procedure, in which the role of hydroxide ions is to be displaced by bromide ions. Then the relation of the electric current *versus* the voltage is expressed by:

$$J = e(D_pC_{p,3}/L_p + D_{Br}C_{Br}/L_{Br})\{\exp(\alpha eV/kT)-1\} \quad (16)$$

where the subscript Br represents bromide ions.

Discussion

NBOH-PVSA Systems. Currents *versus* voltages curves are expressed by Eq. (14). Comparing Eq. (1) and Eq. (14), we get the following relation:

$$J_s = e(D_pC_{p,3}/L_p + D_hC_{h,1}/L_h) \quad (17)$$

Considering the dissociation equilibrium of water, we get the following equation:

$$C_{p,1}C_{h,1} = C_{p,3}C_{h,3} = K_w \quad (18)$$

where K_w is the ionic product of water.

Then Eq. (17) and Eq. (18) lead to:

$$J_s = eK_w\sqrt{\overleftarrow{r}}\ (\sqrt{D_h/C_{p,1}} + \sqrt{D_pC_{h,3}}) \quad (19)$$

From Eq. (19) we can calculate the values of J_s. Then the calculated values of $J_s/(J_s)_{1,1}$, where $(J_s)_{1,1}$ is the value of J_s at $C_{p,1}=C_{h,3}=1.36\times10^{-2}$ equivalents per liter, and the experimental values of $J_s/(J_s)_{1,1}$ are compared in Table 4.

Table 4. Comparison of $\{J_s/(J_s)_{1,1}\}_{calc}$ with $\{J_s/(J_s)_{1,1}\}_{exp}$ in NBOH-PVSA systems

$C_h\times10^2$	$C_p\times10^2$	$\{J_s/(J_s)_{1,1}\}_{calc}$	$\{J_s/(J_s)_{1,1}\}_{exp}$
1.36	1.36	1.00	1.00
1.36	1.02	1.07	1.35
1.36	0.68	1.18	1.85
1.02	1.36	1.09	1.42
0.68	1.36	1.23	1.54
0.272	1.36	1.68	3.26

We can see from Table 4 that the calculated values show characteristics similar to the experimental values, although no quantitative coincidence is found.

When a backward-bias voltage is applied, the electric current is independent of the concentrations of NBOH and PVSA (as is clear from Figs. 2 and 3). On the other hand, Eq. (14) shows that it must depend on the concentrations of NBOH and PVSA. Therefore, when a backward-bias voltage is applied, the diffusional mechanism can not be adopted as the conduction mechanism.

Therefore, it may be supposed that, while a backward-bias voltage is being applied, the electric currents are controlled not by the rate of diffusion, but by the rate of the dissociation of water in the transient region.

$$H_2O \underset{\overleftarrow{r}}{\overset{\overrightarrow{r}}{\rightleftharpoons}} H^+ + OH^-$$

*1 When the electric current is not equal to zero, we get the following solution from Eq. (2):

$$C_p(x) = \exp\left(-e\int_0^x \mathrm{d}\varphi\right)\left\{\int_0^x (-J/eD_p) \times \exp\left(e/kT\int_0^{x'}(\partial\varphi/\partial x'')\mathrm{d}x''\right)\mathrm{d}x' + C_{p,1}\right\} \quad (15)$$

Then we must use Eq. (15) as the concentration distribution function. However, when a bias voltage is not applied, the potential difference in the transient region, $\Delta\varphi=(kT/e)\times\ln(C_{p,1}/C_{p,3})$, is about 0.6 V at $C_{p,1}=C_{h,3}=1.36\times10^{-2}$ equivalents per liter, and when a bias voltage ($V\leq5$ V) is applied, the effective portion of the applied voltage in the transient region is found from Table 2 to be of the order of 10^{-2}. Then the potential difference does change not so much that we must not adopt Boltzmann's law instead of Eq. (15) as the concentration distribution function.

where $\vec{r}$ and $\overleftarrow{r}$ are the rate constants in each direction. In the absence of a bias voltage, the rate of dissociation equals that of the recombination reaction:

$$\vec{v} = \vec{r}_0[H_2O] = \overleftarrow{v} = \overleftarrow{r}_0[H^+][OH^-] = g \quad (20)$$

where g is the exchange velocity, and $\vec{r}_0$ and $\overleftarrow{r}_0$ are the rate constants in each direction in the absence of a bias voltage. In the presence of a bias voltage $(-V)$, the potential of the reactants (H_2O) increases by δG_1^*, and that of the products ($H^+ + OH^-$) decreases by δG_2^*, while the potential at the transition state remains constant (ΔG^*), then

$$\delta G_1^* + \delta G_2^* = \boldsymbol{N}e V \quad (21)$$

where $\boldsymbol{N}$ is the Avogadro number.

The rates of the reactions in the forward and backward directions becomes as follows:

$$\vec{v} = \vec{r}[H_2O] = \boldsymbol{kT}/\boldsymbol{h}\exp\{-(\Delta G^* - \delta G_1^*)/\boldsymbol{RT}\}[H_2O] = g\exp(\delta G_1^*/\boldsymbol{RT}) \quad (22)$$

$$\overleftarrow{v} = \overleftarrow{r}[H^+][OH^-] = \boldsymbol{kT}/\boldsymbol{h}\exp\{-(\Delta G^* + \delta G_2^*)/\boldsymbol{RT}\}[H^+][OH^-] = \overleftarrow{r}_0[H^+][OH^-]\exp(-\delta G_2^*/\boldsymbol{RT}) \quad (23)$$

The H^+ and OH^- produced by the electric field are quickly caused to migrate by the electric field. Therefore, the concentrations of H^+ and OH^- would not be influenced by the electric field.

Then the total rate of the reaction is:

$$v = \vec{v} - \overleftarrow{v} = g[\exp(\delta G_1^*/\boldsymbol{RT}) - \exp(-\delta G_2^*/\boldsymbol{RT})] = g[\exp(\beta e V/\boldsymbol{kT}) - \exp\{-(1-\beta)eV/\boldsymbol{kT}\}] \quad (24)$$

where β is the so-called transfer coefficient.

$$\delta G_1^* = \boldsymbol{N}\beta e V, \quad \delta G_2^* = \boldsymbol{N}(1-\beta)eV \quad (25)$$

Therefore, the electric current is as follows:

$$J = eg[\exp(\beta eV/\boldsymbol{kT}) - \exp\{-(1-\beta)eV/\boldsymbol{kT}\}] \quad (26)$$

The J derived from Eq. (26) does not depend on the concentrations of NBOH and PVSA.

Therefore, it can be considered that when a forward-bias voltage is applied, the current *versus* voltage curves are decided by Eq. (14), while when a backward-bias voltage is applied, the current *versus* voltage curves are decided by Eq. (26).

The dynamic characteristics are shown in Fig. 5. From Fig. 5 we can see that the rectification effect becomes poorer as the frequencies become higher. The primary cause is probably the contribution of the capacitance of the systems.[5] The contribution of the relaxation effect of the ionic atmosphere can be neglected, because the Wien effect and the Falkenhagen effect will appear at the frequencies higher than 10^7 cps.[14]

NBPB-PVSA Systems. Just as in the NBOH-PVSA systems we can get the following equation instead of Eq. (19):

$$J_s = eK\sqrt{r'}(\sqrt{D_{Br}/C_{p,1}} + \sqrt{D_p/C_{Br}}) \quad (27)$$

where $K = K_{HBr}[HBr]$, where K_{HBr} is the dissociation constant of HBr, and where r' is the rate constant of the dissociation equilibrium of HBr. In Table 5 the values of $J_s/(J_s)_{1,1}$ calculated using Eq. (27) are compared with the experimental values.

TABLE 5. COMPARISON OF $\{J_s/(J_s)_{1,1}\}_{calc}$ WITH $\{J_s/(J_s)_{1,1}\}_{exp}$ IN NBPB-PVSA SYSTEMS

$C_{Br}\times 10^2$	$C_p\times 10^2$	$\{J_s/(J_s)_{1,1}\}_{calc}$	$\{J_s/(J_s)_{1,1}\}_{exp}$
1.36	1.36	1.00	1.00
1.36	1.02	1.05	0.98
1.36	0.68	1.13	1.61
1.36	0.136	1.69	1.43
1.02	1.36	1.11	1.17
0.68	1.36	1.27	1.00
0.272	1.36	1.82	2.05
0.136	1.36	2.47	1.43
1.02	1.02	1.16	1.09
0.68	0.68	1.40	1.35
0.272	0.272	1.88	3.05

From Table 5 it is clear not only that the values of $[J_s/(J_s)_{1,1}]_{calc}$ do not agree quantitatively with those of $[J_s/(J_s)_{1,1}]_{exp}$, but also that the qualitative tendency of the calculated values does not agree with that of the experimental values.

This disagreement and the hysteresis of the current *versus* voltage curves (Fig. 6) may be caused by the high degrees of the dissociation of hydrogen bromide and by the acidity of NBPB.

Another experiment was then carried out. At first a backward-bias voltage $(-V)$ was applied for 60 sec (while a backward-bias voltage is being applied, only the dissociation reaction of water occurs in the membrane region); the current after 60 sec was denoted I_{60}. Then suddenly we applied the forward-bias voltage (V) for 30 sec, after which we again applied $-V$ until the current became equal to I_{60} (in the transient region, at first the HBr accumulated by the forward current would begin to flow out). We then again applied the forward-bias voltage (V) for 60 sec, followed by the backward-bias voltage until the current equaled to

14) H. S. Harned and B. B. Owen, "The Physical Chemistry of Electrolytic Solutions," Reinhold Pub. Corp., New York (1950), p. 211.

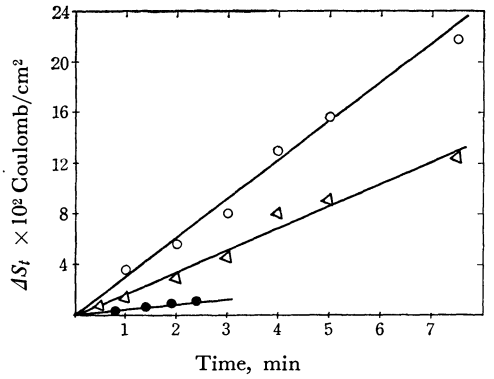

Fig. 10. The change of the backward electric quantities by the forward electric quantities. $C_{Br}=C_p=1.36\times10^{-2}$ equiv/l

I_{60}. Then we applied the forward-bias voltage for 120 sec, and so on.

In Fig. 10 the $\Delta S_t(=S_t-S_0)$-t curves are shown, where S_t are the electric quantities carried by the backward currents, which flowed after the forward-bias voltage was applied for t sec, until the currents became equal to I_{60}. S_0 is the electric quantities which flowed while we first applied the backward voltage. ΔS_t indicates the extra electric quantities caused by applying the forward voltage and corresponds to the quantities of HBr accumulated in the transient region.

Figure 10 shows that the relation between ΔS_t and t is linear. This means that hysteresis is caused by the HBr accumulated in the membrane region.

While a forward-bias voltage is applied, HBr is accumulated in the transient region. When a backward-bias voltage is applied thereafter, the electric current is at first carried by H^+ and Br^-, and then, when the accumulated HBr has disappeared, the H_2O may begin to dissociate into H^+ and OH^-. Thus, the greater the quantity of HBr in the transient region, the larger the areas of the hysteresis loops.

Low Frequency Bands and Barrier to Internal Rotation in Pentafluoroethane

Susumu KINUMAKI and Muneteru KOZUKA

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai

(Received October 18, 1967)

The infrared absorption spectra of gaseous and liquid CF_3CHF_2 were examined in the region from 500 to 60 cm^{-1}. The Raman spectrum of the liquid at room temperature was also photographed. In the gas-phase spectrum, bands were observed at 414, 363, 306, 246, 216 and 82 cm^{-1}. The contour of the medium-intensity band at 82 cm^{-1} was consistent with that to be expected for torsional oscillation. This frequency would correspond to a triple cosine barrier of 4.4 kcal/mol.

Although infrared and Raman spectra of CF_3CHF_2 have already been studied by Nielsen, Moran and Moran[1] in 1954, the detection and assignment of low frequency bands remain incomplete.

Of low frequency bands, the torsion band, which is expected to be observed as the lowest fundamental, is especially interesting in connection with the barrier height of the internal rotation of the molecule. Ward and Ward[2] have pointed out that the barrier height of CH_3CHF_2 was lower than either that of CH_3CH_2F or CH_3CF_3 by 0.2—0.3 kcal/mol, and suggested that, in general, an ethane-like molecule containing the CHX_2 (X: halogen) group might have an abnormally low barrier. Recently, Tipton, Britt and Boggs[3] measured the microwave spectrum of CF_3CHF_2, and calculated the torsional frequency 74 cm^{-1}, and the corresponding barrier height 3.51 kcal/mol, on the basis of the relative intensity method. The latter, which was considerably less than either 4.2 kcal/mol for CF_3CH_2F or 4.35 kcal/mol for CF_3CF_3, led us to favor the suggestion of Ward and Ward. Furthermore, Tipton *et al.* mentioned that their calculated torsional frequency 74 cm^{-1}, was in good agreement with the infrared frequency 73.3 cm^{-1},

3) A. B. Tipton, C. O. Britt and J. E. Boggs, *J. Chem. Phys.*, **46**, 1606 (1967).

observed by Clague and Danti.[4] However, in the present investigation it was found that the center of the torsion band was located at 82 cm^{-1}, which corresponds to a barrier height of 4.4 kcal/mol, while the absorption maximum of the lower wing was located at 74 cm^{-1} (see Fig. 2). Hence, we reinvestigated the barrier height of the molecule, referring to the theory of Scott and Scheraga[5] concerning the origin of the barrier, and the barrier heights of the chlorine-substituted ethanes reported by Allen, Brier and Lane[6] (see Table 3).

Experimental

The sample of pentafluoroethane, bp −48.5°C, was obtained through the courtesy of Dr. R. J. Plunkett, the E. I. du Pont de Nemours and Company. It was purified by vapor-phase chromatography and dried with phosphorus pentoxide.

The infrared absorption spectra of the gas and the liquid at room temperature were obtained in the region from 500 to 60 cm^{-1} with a Hitachi model FIS-I vacuum, grating, double-beam spectrometer. The gas was contained in a long-path cell built especially for this instrument; its path length was variable in increments of 1.2 m up to 6 m. For the liquid-state spectrum, a polyethylene liquid cell was used, whose effective path length was obscure because of infiltration of the sample into the polyethylene. A spectrum of the sample imprisoned in polyethylene was the same as that of the liquid in the frequency region higher than 200 cm^{-1}, at least, in which the KRS-5 cell could also be used. The Raman spectrum of the liquid at room temperature was photographed with a Yuki-Gosei model RL-II spectrograph of linear dispersion 19 Å/mm at 4358 Å.

All the absorption bands observed are summarized in Table 1. Infrared spectra are shown in Fig. 1.

In order to ascertain the purity of the sample and the correctness of the vibration analysis, an infrared spectrum of the gas between 4000 and 400 cm^{-1} was also obtained with a Perkin-Elmer model 125 grating, double-beam spectrometer.

Discussion

Bands in the Region from 500 to 100 cm^{-1}. The CF_3CHF_2 molecule may be assumed to have the symmetry C_s, and the 18 normal vibrations divide themselves into 11 of species a' and 7 of species a''. In the frequency region lower than 500 cm^{-1}, it is expected that there are two fundamentals for each of the species a' and a''. They are the CF_3 symmetric deformation mode, two CF_3 degenerate deformation modes, and the torsional mode.

The molecule is an asymmetric top. The principal moments of inertia, calculated from microwave data by Tipton *et al.*,[3] were 136.92, 208.86 and 251.93 amu.$Å^2$. The axis of the intermediate moment is perpendicular to the symmetry plane. From Badger and Zumwalt's curves,[7] it is found that the a'' fundamentals should have type B contours with a doublet separation of 4.6 cm^{-1}, whereas the a' fundamentals should have contours that are hybrids between type A and C.

In the infrared spectrum of the gas, the medium-intensity band at 414 cm^{-1} has a typical contour of type B and a weak and diffuse counterpart in the Raman spectrum. It is undoubtedly an a'' fundamental. The band at 363 cm^{-1} appears to have PQR structure, and the corresponding Raman band is sharp. It was therefore identified with an a' fundamental. The weak, diffuse and structureless bands at 306 and 216 cm^{-1} had no counterparts in the Raman spectrum. They could be interpreted as difference bands, that is, 829(a')−523(a')= 306 cm^{-1}(a') and 1359(a') − 1143(a'')=216 cm^{-1}(a''), respectively. These higher frequency bands were assigned in the present study independently of the previous work by Nielsen *et al.*,[1]

in which the 829 cm^{-1} band was not assigned to any fundamental. Also, Nielsen *et al.* observed a band at 270 cm^{-1}, and assigned it to an a'' fundamental. However, we could detect no absorption band around 270 cm^{-1} in both infrared and Raman spectra. It should be noted that they had no information concerning the purity of their sample.

The population factor for the excited levels of any low frequency fundamental, such as that at 246 cm^{-1}, will be rather large at room temperature. Indeed, the contour of this band has a slightly diffused structure. Its corresponding Raman band at 250 cm^{-1} was weak, but distinct. With somewhat less certainty, it was interpreted as an a' fundamental.

It is well known that in the frequency region higher than 250 cm^{-1}, liquid-phase data is shifted to the lower frequency side of the corresponding vapor-phase data, whereas in the frequency region lower than 250 cm^{-1}, the reverse is the case.[8] Our data also show this feature.

The 82 cm^{-1} Band. This medium-intensity band was only one band that could be detected in the gas-phase infrared spectrum between 120 and 60 cm^{-1}. In the liquid-state data, it was shifted toward a higher frequency of 90 cm^{-1}, and was a comparatively strong band having its Raman counterpart in a weak, diffuse line, at 92 cm^{-1}.

For reference, infrared torsional frequencies for related compounds are collected in Table 2.

The contour of the perpendicular-type torsional fundamental, calculated by the method of Badger and Zumwalt,[7] and shown in Fig. 2, also includes contributions from five "hot bands" which originate from excited vibrational states of the torsion (quantum numbers $v=1, 2, \cdots, 5$). These have a marked effect on the band contour of the torsional frequency, since the population factor $\exp(-h\nu/kT)$ for the excited torsional states is relatively large, and further, the anharmonicity of the cosine potential results in the centers of the hot bands somewhat displaced from that of the $v=0\rightarrow1$. Thus the $v=1\rightarrow2$ band falls 1.2 cm^{-1} below the $v=0\rightarrow1$ band. The rotational structure was expected to be beyond the limit of resolution of the instrument, and no evidence of such structure was found. The observed contour of the 82 cm^{-1} band is consistent with the interpretation of this as the torsional fundamental. Apparently, the absorption minimum of the calculated total band contour resulted in the same wave number as that of the $v=0\rightarrow1$ transition.

For a rough consideration of the intensity of the band, the harmonic oscillator approximation is satisfactory. The dipole moment of the molecule being 1.54 D,[9] it is conjectured that the torsional fundamental will be a band of medium-intensity, or a slightly weaker band than that of CF_3CH_2F (about 2.0 D).

Barrier. Using the method of solving the wave equation for internal rotation,[10,11] the observed torsional frequency 82 cm^{-1}, and the molecular parameters reported by Tipton *et al.*[3] gave a value of 4.4 kcal/mol as the barrier height of the molecule, in which the tables of Blanch and Rhodes[12] were used to obtain the reduced barrier from the difference in the Mathieu's eigenvalues.

The barrier heights for the molecules formed by the successive substitution of fluorine for hydrogen in

ethane are given in Table 2. In the third column of the table, theoretical values calculated by the method of Scott and Sheraga[5] are listed. In the fourth one, experimental values are collected, which were obtained by each experimental method written in the fifth column.

In the method of calculating the barrier from the infrared or Raman data, it is not taken into account that the infrared torsional frequency is shifted by coupling with other molecular vibrations. Hence, it was checked that, in CH_3CH_2F and CH_3CHF_2, the barrier heights calculated from infrared data were almost equal to those obtained from microwave data. In these molecules, it is supposed that the torsional vibration is quite pure, because the torsional vibrations in the trans configuration of 1,1-dichloro-[13,14] and 1,1-dibromoethane[15] have the potential energy distribution of 90 and 80%, respectively. Consequently, if it may be supposed that the degree of mixing of molecular vibrations is almost equal in CF_3CH_2F and CF_3CHF_2, the experimental barrier heights of these molecules would be as reliable, at least, as the relative values.

According to Scott and Scheraga,[7] the origin of the internal rotation barrier in ethane-like molecules is mainly attributed to two effects, exchange interactions of the electrons in bonds adjacent to the bond about which internal rotation occurs, and nonbonded or van der Waals interactions. They used a modified Buckingham or "6-exp" potential to calculate the nonbonded interaction, and developed a method for obtaining the constants in the 6-exp potential for any pair of atoms based on experimentally available parameters for inert gases. For the exchange interactions, the theory proposed by Pauling was

adopted,[16,17] who showed that, in a molecule of the type $(X_1\ X_2\ X_3)X_4\text{-}X_5(X_6\ X_7\ X_8)$, U_0, which would be the barrier height in the absence of nonbonded interaction, should be a constant for each class of molecules having the same atoms, X_4 and X_5, regardless of the substitutent atoms X_1, X_2, X_3, X_6, X_7 and X_8. For example, there would be a single U_0 for ethane and all the substituted ethanes, another U_0 for disilane and all its substituted derivatives and another U_0 for acetaldehyde and its halogen derivatives, *etc.* From the above theories, it follows that the difference in the barrier heights of the halogenoethane molecules considered in the present study should be due mainly to the difference in the effects of nonbonded interactions. Since the effect of the H···H nonbonded interaction is comparable to that of H···F and H···Cl in magnitude,[5] both the experimental and theoretical data in Tables 2 and 3 show that the barrier in each of CH_3CHF_2 and CH_3CHCl_2 is almost equal to, or, within the experimental error, slightly less than that of CH_3CH_2F and CH_3CH_2Cl. On the other hand, the X···X (X: F or Cl) nonbonded interaction has an effect so much larger than that of H···H, that either CF_3CHF_2 or CCl_3CHCl_2 has a higher barrier than CF_3CH_2F or CCl_3CH_2Cl. Consequently, we were led to the conclusion that the CHX_2 (X: halogen) group had no unique property; that is, the barrier height of an ethane-like molecule containing this group was not abnormally low, although it is inconsistent with the suggestion by Ward and Ward.[2]

The torsional frequency 74 cm^{-1}, calculated by Tipton *et al.*, and corresponding to a barrier of 3.51 kcal/mol, seems to us to be abnormally low. Here, it should be recalled that their values were calculated by a relative intensity method, which was based on the microwave spectrum of only one kind of isotopic species of the molecule, and frequently led to considerable errors.

The authors wish to express their indebtness to Dr. R. J. Plunkett of the E. I. du Pont de Nemours and Company for the gift of the sample. Thanks are also due to Dr. F. Watari of Tohoku University for the measurement of the Raman spectrum.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 813—817 (1968)

Thermal Decomposition of Hexamethylene Tetramine

Yoshitomo IWAKAMI and Masao TAKAZONO

Industrial Research Institute of Kanagawa Prefecture, Kanazawa-ku, Yokohama

and Toshikazu TSUCHIYA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received October 28, 1967)

In order to get information about the mechanism of the thermal decomposition of hexamethylene tetramine (hexa), hexa was decomposed thermally in a vacuum vessel, and the composition of the gas thus produced was determined with a mass spectrometer. The main products found were ammonia and a carbon-rich solid residue. The carbon in the carbon-rich residue seems to act as a catalyst for the decomposition.

In a thermal decomposition product of phenol resin, one of the present authors (T. T.) has found an appreciable amount of ammonium compounds.[1] The origin of the compounds was inferred to be the hexamethylene tetramine (hexa) which is added to resol or novolak, the precursory products of the resin, as a hardening reagent of the resin. The purpose of the present study is to confirm the origin of the ammonium compounds mentioned above and to clarify the thermal decomposition mechanism of hexa.

Stranski *et al.*[2] reported on the thermal decomposition of hexa. They investigated the total pressure of the decomposition gas produced in the presence (180—250°C) and in the absence (250—

500°C) of the solid phase, and found that in both systems the decomposition has similar characteristics and that the ratio of the final pressure to the initial pressure increases with the temperature. They did not study the compounds produced by the decomposition.

Experimental

The hexa was a G. R.-grade substance obtained from the Tokyo Kasei Kogyo Co., Ltd. The hexa was heated in a vacuum ampoule. Figure 1 shows the hard glass ampoule used for thermal decomposition. About 0.5 g of hexa was into the ampoule, A, through the side tube, B. After the ampoule had been evacuated for about an hour at room temperature with a diffusion pump, it was sealed off at C. The volume of the ampoule was about 13 m*l*. In each of the pyrolysis experiments, the furnace was first preheated to the required temperature. Then the ampoule containing the sample was placed in the furnace up to the dotted line, D (Fig. 1), for an hour. At the end of this period the furnace was quickly evacuated and cooled. After cooling, the ampoule was attached to a mass spectrometer through the common joint, E, for analysis. The experiments were carried out at temperatures of 200, 270, 300 and 400°C.

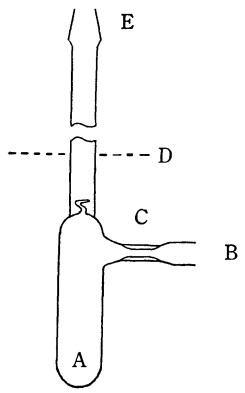

Fig. 1. Ampoule for thermal decomposition.

As the amount of ammonia, which is the main component of the products, as is shown in Table 1, reached a nearly constant value after about an hour of heating at 300°C, we fixed the heating time at one hour in the following experiments.

Besides the gaseous products, the samples treated at temperatures higher than 300°C gave a dark carbonaceous product. The gas products were analyzed with a CEC 21-103C mass spectrometer. The gaseous fraction was cooled in a liquid nitrogen trap. The gaseous and the trapped materials at a certain temperature were analyzed separately. The accuracy of analysis was better than ±5%. The total amount of gas produced was measured with a gas burette and a mercury manometer. The residue obtained in pyrolysis at temperatures higher than 270°C was out-gassed thoroughly, washed with water and alcohol, dried, and weighed. The treated residue was inferred, from its color and for a reason which shall be discussed later, to consist in the main of carbon and shall be referred to as "residual carbon."

Results and Discussion

Figure 2 shows the amount of residual carbon and total gas produced as functions of the decomposition temperature. The figure indicates that hexa begins to decompose at approximately 270°C. At 400°C, the weight percentages of the products are: residual carbon, 60%; gaseous compounds, 33%, and water- or alcohol-soluble material, 7%. Table 1 shows the amount of gaseous products formed per mole of hexa on thermal treatment. Because the *m/e* 28 peak was rather weak and because accurate analysis from *m/e* 14 and *m/e* 12 was impossible, we assumed that the peak is composed of CO^+ and of N_2^+ ions. Each of the gas products at various temperatures (P-T curve) is shown in Fig. 3.

From the data given in Table 1 and Fig. 2, the overall composition of the products at 400°C, other than the gaseous species shown in Table 1, is estimated to be $C_{5.9}H_{6.1}N_{2.1}$. About 12% of

the $C_{5.9}H_{6.1}N_{2.1}$ is soluble in water or in alcohol; the remaining 88% was inferred to be residual carbon. The hydrogen atom is considered to be present in the main in the soluble substances. The main component of the residual carbon is, therefore, the carbon atom, though it is shown from the material balance that at least 24% of the weight of the residual carbon is composed of hydrogen and nitrogen atoms. We assume that at least a part of the residual carbon is bulk carbon.

As is seen in Fig. 3, the P-T curves of various products may be divided into two types, *i. e.*, those which show a tendency toward saturation (Type 1; the curves for ammonia, methane and hydrogen), and those which have a maximum (Type 2, the curves for methylamines). We will ignore the behavior of carbon dioxide, because its amount is very small. The compounds of Type 1 are considered to be the final products of the decomposition because they show saturation and because they are stable, low-molecular-weight compounds. The compounds of Type 2 are inferred to be intermediate products which can decompose further when heated to higher temperatures.

As the decomposing temperature increases, the molecular weight of the gaseous products tends to drop (Table 1). This phenomenon suggests the possibility that the compounds produced will decompose further into compounds of lower molecular weights as the temperature rises. The shape of the P-T curves of Type 2 is compatible with this inference. In order to check it, each of the compounds of a higher molecular weight in Table 1, *i. e.*, trimethylamine, dimethylamine, methylamine, propionitrile, acetonitrile, and ethylene imine, was heated individually and the decomposition products were investigated. The three amines were obtained from the Tokyo Kasei Kogyo Co., Ltd., as a 40% aqueous solution, and were dried with caustic potash and distilled under reduced pressure. The two nitriles and the imine were guaranteed reagents obtained from the same company as the amines, and were used without further purification. About 0.1 m*l* of each of these reagents was directly distilled under reduced pressure into the glass ampoule shown in Fig. 1; the ampoule was then treated just as in the case of hexa, and each reagent was decomposed at 300°C for an hour. The compositions of the gaseous compounds produced are shown in Table 2. The 1st column in the table shows the samples treated, and the 1st row shows the decomposition products. Though trimethylamine and propionitrile were not decomposed, the other compounds were more or less decomposed into lighter compounds. The common products from all the reagents were ammonia and methane. Other than these products, acetonitrile and ethylene imine gave hydrogen and nitrogen. In addition to these products, ethylene imine gave hydrogen cyanide and an appreciable amount of methylamine.

From Table 2, it may be seen that some of the compounds, for instance, ethylene imine, produced from hexa under lower decomposition temperatures (Table 1) decompose further, when heated to higher temperatures, into compounds of a lower molecular weight. The behavior of ethylene imine, for instance, which was found at temperatures below 270°C but which could not be detected

at temperatures higher than 300°C, can be elucidated by the results given in Table 2.

On the other hand, trimethylamine, which tends to decrease from 300°C with an increase in the temperature (Table 1), does not decompose at 300°C (Table 2). However, as has been described, residual carbon was obtained when hexa was treated above 270°C. The primary products produced under a lower heating temperature may decompose further in the presence of residual carbon. In order to estimate the influence of the catalytic action of the residual carbon on the decomposition reaction, the following experiment was carried out.

Instead of residual carbon, a commercial active carbon was used. The active carbon powder obtained from Takeda Yakuhin Kogyo (pure grade "Shirasagi") was heated at 360°C for 2 hr in a vacuum obtained with a diffusion pump. The sample substance (0.05 m*l*) was distilled, under a reduced pressure, into an ampoule which contained 0.1 g of the treated carbon at room temperature; then the system was heated by just the same procedure as has been described before, and the gas produced was analyzed. The temperature of the furnace was 300°C. All of the sample materials studied were found to have been decomposed thermally into ammonia, methane, hydrogen, nitrogen, and ethane. The results are shown in Table 3. We can see that trimethylamine and propionitrile, which were not decomposed at 300°C without active carbon, decompose when treated with active carbon. Ethane and ethylene are detected in the decomposition products when samples are heated with active carbon (Table 3), while the two compounds were not found in the case of a reaction without active carbon (Table 2). We cannot decide from this experiment whether or not the decomposition mechanism differs essentially according as active carbon is present during the decomposition, because the production of ethane or ethylene can depend on the degree of decomposition. The actual experimental conditions of the thermal decomposition of hexa are considered to be intermediate between the two extreme conditions, under which the results of Table 2 and Table 3 have been obtained.

Figure 4 shows the potential pathways of the thermal decomposition of hexa deduced from Table 2 and Table 3. The actual pathways of

the production of lighter substances, such as nitrogen, methane, ammonia, and hydrogen, produced at higher temperatures may not necessarily follow the course suggested. They can be produced, for instance, directly from hexa. However, at least a part of these lighter compounds can legitimately be considered to be produced *via* intermediate products, such as trimethylamine and dimethylamine, because all these compounds, except for ethylene imine, are contained in the decomposition product of hexa at higher temperatures and can be shown to decompose into the lighter substances at these temperatures.

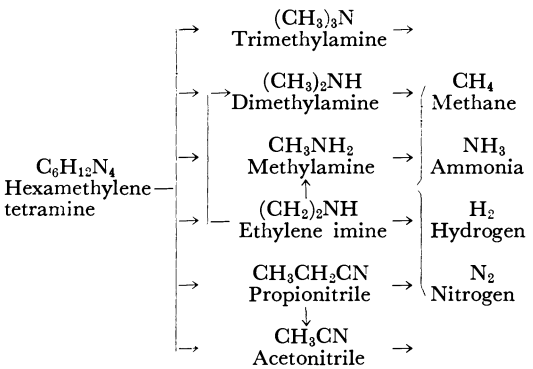

Fig. 4. Potential pathway of thermal decomposition of hexa.

We cannot expect to obtain direct information about the mechanism of the decomposition reaction of hexa itself from the results of the present experiment, because the primary thermal decomposition products of hexa react further with each other under the present experimental conditions and the information we get is the overall result of these primary and secondary reactions.

Based on these experimental results, however, the following possible profile of the reactions can be inferred. When heated to 200°C, a part of the hexa is decomposed and small amounts of ammonia, trimethylamine, acetonitrile, ethylene imine and methane are produced. The amounts of the last three substances are just the same. This suggests that their formations are closely related to each other. At 270°C, the amount of ammonia increases markedly, and hydrogen comes out for the first time. The carbon-rich solid phase is produced, it acts more or less as a catalyst for the following reactions, again promoting the production of the solid phase itself. At 300°C, the P-T curves for ammonia and methane are nearly saturated, monomethylamine and dimethylamine appear for the first time, ethylene imine disappears completely, and the trimethylamine curve reaches its maximum. The appearance of methylamine and dimethylamine and the disappearance of ethylene imine seem to have some interrelation. Ethylene imine gives methylamine, as is shown in Table 2, and the reaction of ethylene imine with hydrogen, which is detected at this temperature, as is shown in Fig. 3, would probably give dimethylamine at this stage of the reaction. Between 300 and 400°C, methylamine, dimethylamine and trimethylamine decrease, while ammonia and methane increase slightly. The increments of the latter compounds are approximately equal to the amounts of those substances expected, from Table 3, to be produced from the decrements of the former compounds.

The amount of water detected is about 0.1% of the weight of the charged hexa. Much should not be inferred from this result, because water molecule is known to be adsorbed on various parts of the gas-handling manifold and of the mass spectrometer. However, from the amount detected and its behavior, the water appears to originate mainly from that adsorbed on the hexa. The small *m/e* 28 peak is considered to be due mainly to nitrogen, as there is no source of carbon monoxide.

From the present results, the hexa, dipped in phenol resin, may be considered to be the origin of the ammonium compounds found in the thermal decomposition product of the resin.

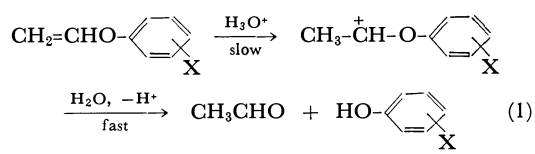
(Received October 30, 1967)

The rates of hydrolysis of various ring-substituted phenyl vinyl ethers, $CH_2=CHOC_6H_4X$, have been measured in 80 : 20 dioxane-water containing hydrochloric acid as catalyst. The ring substituents investigated include H, *p*-CH_3O, *m*-CH_3O, *p*-CH_3, *m*-CH_3, *p*-Cl and *m*-Cl. The reaction was first order with respect to both the acid and the ethers. It has been found that the effect of substituents on the hydrolysis rates obeys the Hammett $\rho\sigma$ relationship with the reaction constant $\rho = -2.21$ at 35°C. These results are compatible with the previous conclusion that the acid-catalyzed hydrolysis of alkenyl ethers involves the rate-determining protonation of the ethers at their β-carbon atom, to form intermediate oxycarbonium ions. It has been shown that the observed substituent effect can be rationalized from the π-electronic energy changes of the ethers on protonation, which have been calculated by an empirical molecular orbital method.

It is generally accepted that the acid-catalyzed hydrolysis of α, β-unsaturated ethers involves irreversible protonation of the β-carbon atom of the unsaturated bond.[2-6] In a previous paper (Part I) of this series,[7] we investigated the kinetic courses of hydrolysis of various alkenyl alkyl ethers, $R_1R_2C=CH(OR_3)$, and presented direct evidence that the protonation step is rate-determining. It was also shown that the relative reactivities of the various ethers may best be interpreted in terms of the conjugative stabilities of the intermediate carbonium ions that are formed on the transfer of a proton from a hydronium ion to the ethers.

In the present communication, we will report the rates of hydrolysis of several ring-substituted phenyl vinyl ethers in an acidic dioxane-water medium in the temperature range 25 to 45°C. From the outset, we may assume, in analogy to the hydrolysis mechanism of alkenyl alkyl ethers, that the reaction under question will proceed according to the scheme:



(1)

where the first protonation step is rate-determining. The rate data obtained have shown that the effects of substituents on the hydrolysis rates nicely fit the Hammett $\rho\sigma$ relationship with the reaction constant, ρ, ranging from -1.89 to -2.26, depending on the reaction temperature selected. That the observed substituent effects are compatible with the mechanism (1) appears to be justifiable from the linear correlation which has been found to hold between the Hammett σ constants and the β-carbon localization energies of the phenyl vinyl ether derivatives as calculated by an empirical molecular orbital method.

Experimental

Materials. Phenyl vinyl ether (PVE) and its *p*-CH_3O, *m*-CH_3O, *p*-CH_3, *m*-CH_3, *p*-Cl and *m*-Cl derivatives were prepared from ethylene dibromide and appropriate substituted phenols according to the method of McElvain and Fajardo-Pinzón.[8]

(2)

Syntheses of the intermediate β-bromophenetole derivatives were carried out by heating a mixture of ethylene dibromide, sodium hydroxide and phenols in boiling water for 10 hr. The phenetoles were separated from the aqueous layer and distilled. Their boiling points were as follows: H, 90—94°C/5.5 mmHg; *p*-CH_3O, 125.5°C/6 mmHg; *m*-CH_3O, 93°C/2.5 mmHg; *p*-CH_3, 87°C/3 mmHg; *m*-CH_3, 94—99°C/2.5 mmHg; *p*-Cl, 102—105°C/3 mmHg; *m*-Cl, 110.5—112.5°C/3 mmHg.

The phenetole derivatives were then subjected to dehydrobromination by heating in the presence of an equal amount (in weight) of powdered potassium hydroxide in a copper flask at *ca.* 200°C. The resulting PVE derivatives were collected in a glass flask, distilled over calcium hydride and stocked in the dark under a nitrogen atmosphere.

Gas chromatography of the ethers prepared as above indicated that they were over 99.5% pure. The ethers were also checked for isomeric purity by both infrared and NMR spectroscopies. Some physical constants of these ethers are summarized in Table 1, together with their elemental analysis data.

Tetralin, which was used as an internal standard for gas chromatography, was of the best grade commercially available. Dioxane of guaranteed grade was further purified by a conventional method.

Kinetic Measurements. Hydrolysis was carried out in 80% aqueous dioxane containing 0.2 N hydrochloric acid at 25, 35 and 45°C, thermostatically maintained.

The initial concentrations of the reactant ethers were typically *ca.* 1.5×10^{-2} M. The courses of the hydrolysis reactions were pursued by gas chromatographic determinations of the ethers remaining in the reaction mixtures. Details of the procedures for the rate measurements were the same as those described previously.[7]

Product Identifications. Phenyl vinyl ethers are expected to give acetaldehyde and the corresponding phenols on hydrolysis. For the case of the nonsubstituted PVE, the formations of these products were confirmed by gas chromatography; their retention times were in perfect agreement with those of the authentic samples. The products were also identified by the routine procedures of qualitative analysis. Tollens' reagent[9a] and an aqueous ferric chloride solution[9b] were used to identify acetaldehyde and phenol, respectively; both reagents gave positive results.

Experimental Results

Kinetic Data. The hydrolysis of phenyl vinyl ethers (PVE) was found to be first order with respect to both ether and acid. The first-order decay of the reactant ether, as is seen in Fig. 1, proved to hold uniformly down to over 80% conversions for all the PVE derivatives investigated.

The first-order rate constants, k_1, were exactly proportional to the concentration of hydrochloric acid, as may be seen in Fig. 2. These results preclude the possibility that the phenols which were produced on hydrolysis may partake in the kinetics to any appreciable extent as acid catalysts, whether as the Brönsted-type or as the general acid catalyst.

The second-order rate constants, defined as $k_2=k_1/[\mathrm{HCl}]$, were measured for the various PVE derivatives at varying temperatures. The results are given in Table 2, where it may be seen that electron-releasing substituents enhance the reactivity of PVE, while electron-attracting ones lower it.

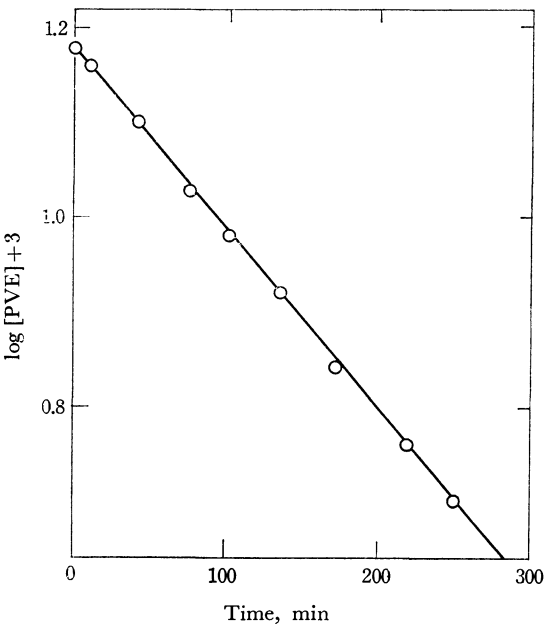

Fig. 1. First-order plots for the hydrolysis of phenyl vinyl ether.
The initial concentration, 1.53×10^{-2} M.
[HCl], 0.2 N. Temperature, 35°C.

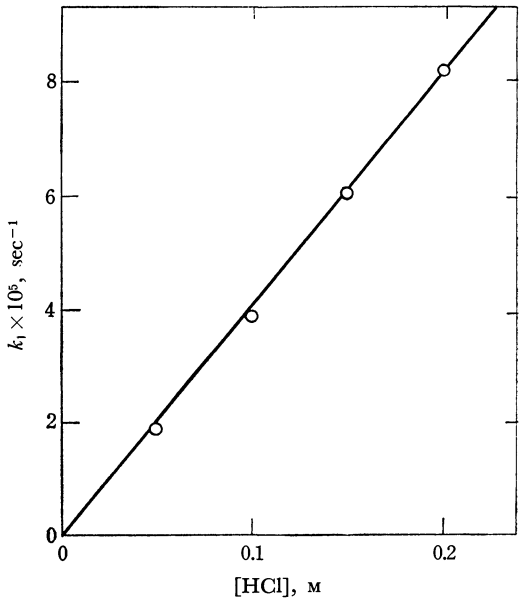

Fig. 2. Linear dependence of the first-order rate constant of the phenyl vinyl ether hydrolysis on the hydrochloric acid concentration.
Temperature, 35°C.

From the k_2 values listed in Table 2, the heats and entropies of activation, $\Delta H^{\neq}$ and $\Delta S^{\neq}$, at 35°C were evaluated in a usual manner. The linearities of the plots of $\log(k_2/T)$ *vs.* $1/T$ were satisfactorily good for all the PVE derivatives studied here. The activation parameters obtained are included in Table 2.

Free Energy Correlations. In Fig. 3 the logarithms of the rate constants, k_2, listed in Table 2 have been plotted against Hammett's σ values. The plots are satisfactorily linear at every temperature studied.

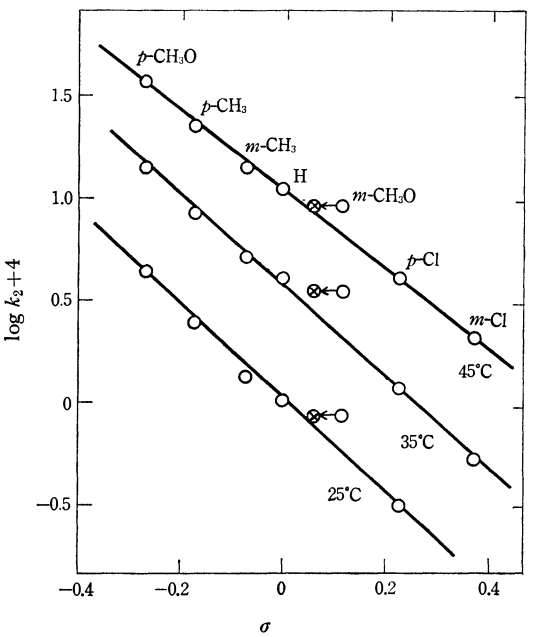

Fig. 3. The Hammett correlations of the acid-catalyzed hydrolysis rates of ring-substituted phenyl vinyl ethers.
The crossed circles are plots for the m-CH_3O group, for which a special value (0.060) has been adopted.

It is noticeable, however, that the m-CH_3O points uniformly deviate from linearity. Yet, these points become aligned with the others if we use the "special" σ value, 0.060, that Taft recommended for the m-CH_3O group in the free energy correlations of the reactions in nonaqueous and mixed solvents.[14] Such an improvement in the Hammett correlation by use of the value 0.060 for the m-CH_3O group has also been noted recently by Ceska and Grunwald for the ionization equilibria of anilines in acetic acid.[15]

The least squares treatments of the linearities of Fig. 3 have led to the reaction constants, ρ, which are given in Table 3. Also listed in Table 3 are the correlation coefficients, r, of the plots, and their standard deviations, s,[16] from the regression lines.

For the sake of comparison, the two σ values, 0.115 and 0.060, have been used for the m-CH_3O group. Although the number of points included in the correlations is only modest, the linearities may be regarded as sufficiently good, especially when the m-CH_3O group is allowed to have the value 0.060.

The Extrathermodynamic Relation. It is known that in a series of reactions a change of substituent tends to cause $\Delta H^{\neq}$ and $\Delta S^{\neq}$ to vary in the same direction. This extrathermodynamic relation[17] between $\Delta H^{\neq}$ and $\Delta S^{\neq}$ is often linear so as to permit the quantitative assessment of the relative importances of the two quantities governing the observed substituent effects.

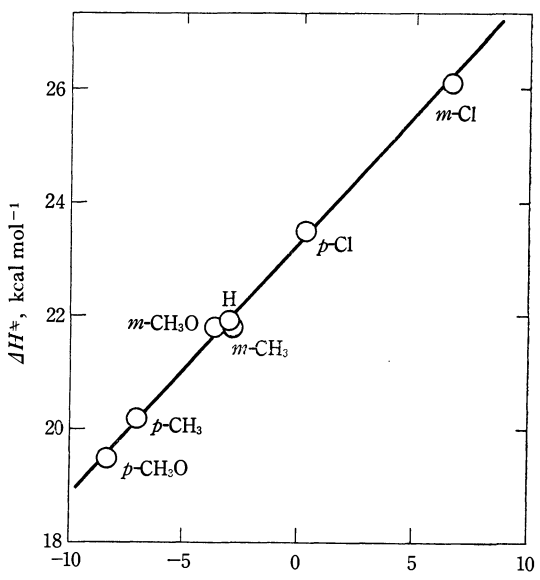

Fig. 4. Plots of $\Delta H^{\neq}$ *vs.* ΔS.

In our present series of reactions, such a linear, compensating relationship between $\Delta H^{\neq}$ and $\Delta S^{\neq}$ is indeed discernible with fair precision, as may be seen in Fig. 4. The isokinetic temperature, defined as the slope of the linearity, has been found to be 465°K. Thus we may draw the conclusion

that the observed substituent effects are primarily enthalpy-controlled.

Empirical Molecular Orbital Considerations

It is a widely accepted view that the sigma values of para substituents are more or less subject to a variation in magnitude, depending on the type of reaction being investigated. This nonlinearity of free energy correlations is believed to arise from the different extents of direct conjugation between substituents and reaction centers in the transition states of different reaction types.

We have previously reported that such a multiplicity of substituent constants, as represented by σ°, σ, σ^+ and σ^-, can be interpreted on a unified ground in terms of the π-electron energy changes as calculated by the empirical molecular orbital method for the activation processes of relevant side-chain reactions of benzene derivatives.[18] In the following, we will apply an analogous treatment to the hydrolyses of ring-substituted PVE's and examine whether or not the general trends of the observed substituent effects may be justifiable.

We will be primarily concerned with the difference in the total π-electronic energies between reactants, XC_6H_4Y, and intermediates, XC_6H_4Y'. Here, X is a substituent, and Y and Y' are the side-chain reaction centers in the initial and intermediate states, respectively, which are $-O-CH=CH_2$ and $-O-\overset{+}{C}H-CH_3$ in the present instance. In conformity with our previous treatments,[18] the energy difference under question may be expressed as

$$\begin{aligned} &E(XC_6H_4Y') - E(XC_6H_4Y) \\ &\quad = [E(XC_6H_5) + E(Y') - DE'] \\ &\qquad - [E(XC_6H_5) + E(Y) - DE] \\ &\quad = [E(Y') - E(Y)] - (DE' - DE) \end{aligned} \tag{3}$$

where E's are the π-electronic energies of the compounds or groups specified in the parentheses, and where DE and DE' are the delocalization energies of the two states due to the linkage of XC_6H_5 with Y and Y' to form XC_6H_4Y and XC_6H_4Y', respectively. The delocalization energies can be computed from the following familiar expression that Dewar[19] derived by a perturbation technique:

$$DE = 2\left\{\sum_i^{occ}\sum_j^{un} - \sum_i^{un}\sum_j^{occ}\right\} \frac{c_{ir}^2 c_{js}^2}{m_i - m_j}\left(-\frac{\gamma^2}{\beta}\right) \tag{4}$$

The notations involved in Eq. (4) are the same as have been described previously.[18]

Since, in Eq. (4), the difference between E (Y') and E (Y) is constant for a given reactive side chain, the difference between the delocalization energies, defined as

$$\Delta E = DE' - DE \tag{5}$$

should be a quantity which may be regarded as a measure of the effects of substituents on the stabilities of the intermediate carbonium ions. Thus, it is to be expected that the greater the ΔE, the more stable is a carbonium ion, $XC_6H_4O\overset{+}{C}HCH_3$, and hence the greater is the reactivity of its parent PVE derivative, $XC_6H_4OCH=CH_2$.

Perturbation calculations of ΔE have been carried out for the various phenyl vinyl ethers. The molecular orbital functions and energies of monosubstituted benzenes as unperturbed systems were the same as those used previously.[18] The integral parameters adopted for the composite groups Y and Y' were as follows:

For $-O-CH=CH_2$, the Coulomb integral parameters were $k_O=0.5$, $k_{C\alpha}=0.1$ and $k_{C\beta}=0$, and the resonance integral parameters were $h_{C-O}=0.5$ and $h_{C=C}=1$. For $-O-\overset{+}{C}HCH_3$, these parameters were $k_O=0.5$, $k_{C\alpha^+}=0.3$ and $h_{O-C}=0.5$. The value of $k_{C\alpha^+}=0.3$, which was most crucial to the calculated results, was simply a sum of $k_{C^+}=0.2$ that was adopted previously for a side chain $-\overset{+}{C}(CH_3)_2$ and $k_{C\alpha}=0.1$ that was assumed for the α-carbon of an ether in the initial state. Variations of the other parameters caused no material changes in the general trends of the calculated results.

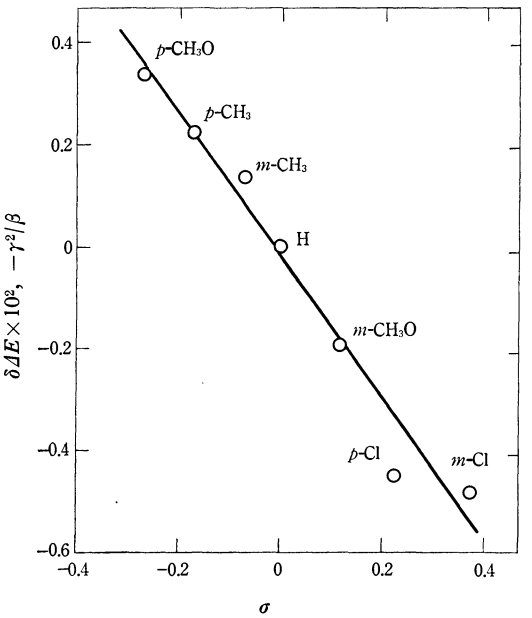

Fig. 5. Linear variation of the relative stabilities, $\delta\Delta E$, of the carbonium ions, $XC_6H_4O\overset{+}{C}HCH_3$, as calculated by the empirical molecular orbital theory, with the Hammett σ values of the substituents, X.

18) T. Fueno, T. Okuyama and J. Furukawa, This Bulletin, **39**, 569 (1966).
19) M. J. S. Dewar, *J. Am. Chem. Soc.*, **74**, 3341 (1952).

The delocalization energy differences, ΔE, obtained for the various PVE's were as follows: 0.0552 (p-CH_3O), 0.0443 (p-CH_3), 0.0353 (m-CH_3), 0.0218 (H), 0.0022 (m-CH_3O), -0.0232 (p-Cl) and -0.0265 (m-Cl) in units of $-\gamma^2/\beta$. Denote by $\delta\Delta E$ each value of ΔE relative to that (0.0218) obtained for the unsubstituted PVE. The $\delta\Delta E$ may then be regarded as a measure of the relative stabilities of the carbonium ions, $XC_6H_4O\overset{+}{C}HCH_3$, taking the unsubstituted ion as the standard. These values of $\delta\Delta E$ have been found to be proportional to the Hammett σ values of the substituents, as may be seen in Fig. 5. These results of calculation rationalize the observation that the effects of substituents on the rates of the acid-catalyzed hydrolysis of phenyl vinyl ethers obey the Hammett correlation, in which the original Hammett σ values have been used for substituents.

Discussion

The observed Hammett correlations, coupled with molecular orbital considerations, allow us to postulate that the Hammett σ value of the ring substituents is an adequate measure of the relative stabilities of the various intermediate carbonium ions, $XC_6H_4O\overset{+}{C}HCH_3$. The intervention of an oxygen atom between the benzene ring and the charged center suppresses direct conjugation between them, which otherwise would have permitted the correlation of $\log k_2$ with Brown's σ^+ values,[20] as in the case of the acid-catalyzed hydration of styrene derivatives.[21]

Perhaps the following are the best pictorial representations of the origin of the different effects of para $-R$ substituents on the stabilities of the carbonium ions formed from styrene and phenyl vinyl ether:

For ions formed from styrene derivatives,

For ions formed from phenyl vinyl ether derivatives,

In the latter ions, the strong electron demand of the electron-deficient carbon is saturated by the migration toward it of the lone pair electrons of the neighboring oxygen, leaving no valency available to permit direct conjugation between the substituent and the side chain group.

Nonetheless, the oxygen atom certainly transmits the mesomeric effect of substituents onto the reaction center, even though only slightly. Otherwise, $\log k_2$ would have been better correlated with Taft's normal substituent constants, σ°.[14] Conjugation between the ring and the extracyclic vinyl linkage through the oxygen atom in phenyl vinyl ethers is also evidenced by the observed effect of ring substituents on the NMR chemical shifts of the β-protons of the ethers.[22] In our specific series of reactions, then, the stabilizations of the initial states and the intermediate cations due to such conjugations must have been of proper amount to just cancel each other, leading, as a net result, to the substituent effects which have been observed to conform to the Hammett σ constants.

Effects of Heating Temperature and Irradiation on the Catalytic Activities of Active Carbons for Phosgene Synthesis

Shoichi SATO*1 and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received November 4, 1967)

The kinetic factors for phosgene synthesis over thermal and irradiated sucrose carbons were examined in particular regard to their dependences on the heating temperature and irradiation. Gamma-irradiation on carbons prepared at 900 or 1000°C produced new active sites with E_A of 11—12 kcal/mol. An explanation is suggested of the effects of heating temperature and irradiation on the catalysts; the catalytic activity is most reasonably related to the degree of growth of the network structure of carbons. In the case of carbons prepared by heating at 900 or 1000°C and having the structure grown to the largest extent, a high dose of gamma-rays presumedly destroys most efficiently the thermally generated active sites and forms sites with a high activation energy. Free radicals and peripheral atoms which also comprise characteristics of amorphous carbons seem to behave independently of catalytic activities and are supposed to have no direct relation to the activities.

The ionizing radiation has been known to affect the catalytic activity of metals, oxides and other salts.[1,2] None has been reported, however, about the irradiation effect on active carbon, which has a unique structural character among inorganic catalysts with its disorderly layered ring networks, peripheral atoms and free radicals. It is well known that carbons catalyze phosgene synthesis from carbon monoxide and chlorine as well as some other reactions.[3] No relation has yet been reported between the catalytic activity for this synthesis and other nautres of the catalysts.

We will report about catalytic activities of sucrose carbons prepared by evacuation within a range of temperatures, the effect of irradiation and some related behaviors of the carbons.

Experimental

Catalysts. Reagent grade sucrose was heated in air at around 350°C, crashed and heated twice, then ground to pass between 20 and 80 mesh (Primary Carbon, Pri. C.). Pri. C. was evacuated below 10^{-3} mmHg in a quartz tube for 20 hr at temperature (T) between 500 and 1000°C, at intervals of 100°C (C^T catalysts). Each C^T: catalyst was heated in an ampoule at 450°C for an hour in a helium stream and sealed while it was still hot. The ampoules were gamma-irradiated at room temperature with a ^{60}Co source at a dose rate of 1.0×10^6 R/hr to a total dose of 1.0×10^8 R (C^{T*} catalysts).

Catalytic Activity Measurements. The flows of tank chlorine (electrolytic) and of carbon monoxide (gas chromatographically pure) were mixed after being measured by flowmeters filled with concd. sulfuric acid and were introduced into a glass U-tube reactor of 6 mm I. D.; the tail gas was pulsed into a gas chromatographic system. A catalyst, 0.1—1 g, was placed on glass wool in the reactor, preheated to 450°C in the helium stream (about 20 ml/min) and kept for over an hour. Then the helium flow was stopped and chlorine flow (about 20 ml/min) was admitted for over 4 hr at the same temperature. The reactor was cooled to the reaction temperature (100—220°C) in the chlorine stream, then carbon monoxide was introduced in order to begin the reaction. The reaction products were analyzed over 100 min after the start of the reaction. The flow rates of both reactants were about 40 ml/min throughout the experiment. Such a pretreatment, without which no catalysis for the reaction was detectable, secured the constancy and reproducibility of the catalytic activity.

A fixed amount of the tail gas (2 ml), containing carbon monoxide, chlorine and the sole reaction product, phosgene, of less than 10% was analyzed by a gas chromatographic system after Runge[4] with a minor modification for convenience. The system was composed of a thermal conductivity cell with platinum filaments, a 4.5 m long glass tube analyzing column of 6 mm I. D. packed loosely with about 50 g of polytetrafluoroethylene powder*2 on which trichlorinated diphenyl*3 was carried in weight ratio of 1/20, and a

1 m long glass tube with Molecular Sieve 5A for desiccating helium carrier gas. All parts were connected with polyvinyl chloride tubes and set in a wooden case lined inside with aluminum plates. The analysis was done at a helium flow rate of 50 ml/min and a bridge current of 80 mA at room temperature. The retention times were 0, 2.0 and 6.6 min for carbon monoxide, chlorine and phosgene, respectively. The analytical accuracy and reproducibility were satisfactory. The system was operated without any trouble for one year.

B. E. T. Surface Areas. Specific surface areas of C^T catalysts were measured by the B. E. T. method with nitrogen.

Infrared Spectra of Catalysts. The infrared spectra of the carbon catalysts, ground into fine powder, were observed by the KBr pellet method in the wavelength range, 650—4000 cm^{-1}.

Results and Discussions

Surface Area. Specific surface areas of C^T catalysts are shown in Table 1. The data show a drastic change of the catalyst structures by heating.

Elementary Analysis. It was reasonably expected that the contact of the carbon with chlorine at 450°C and perhaps with phosgene up to 220°C may cause considerable change in its structure and elementary composition. Carbon blacks[5] were reported to react with chlorine with the maximum uptake at 400—500°C, nearly total content of hydrogen being substituted. However, our results of the elementary analysis of the carbons before and after use, does not exhibit any general relationship among components. Atomic ratios of the components, hydrogen, oxygen and chlorine (C=1.000) are shown in Table 1.

The increase of the specific surface area as the heating temperature of carbons was raised from 500 to 700°C corresponds to a loss of hydrogen and oxygen. The decrease of the surface area at higher heating temperature (800—1000°C) is accompanied with a loss of hydrogen but not with that of oxygen.

After use as the catalyst, the carbons were hydrogenated, deoxygenated and chlorinated. The dehyderogenation was severe for low temperature carbons. A remarkable deoxygenation was however, limited to occur to C^{500} alone, and beyond C^{600} the oxygen content with regard to carbon remains almost unchanged. The degree of chlorination is not associated with that of dehydrogenation, though the chlorine content is comparable to the hydrogen content before reaction for higher temperature carbons. Considering that conditions of the pretreatment and the reaction were common to all samples, the rather small divergence of the amount of the chlorine introduction into carbons, which is in remarkable contrast to a large change in the B. E. T. surface areas, suggests that chlorine does not necessarily combine with or substitute peripheral atoms but rather attacks peripheral and even inner carbon atoms with equal probability; one chlorine atom corresponds with 13—19 carbon atoms. That is, chlorine may react with carbon atoms to the same extent although they are present in a variety of imperfect polycondensed system.

Infrared Spectra. IR spectra of chars and coals have been observed and several assignments[6-8] have been made for characteristic absorption.

The spectra of some of our samples were examined in order to find any relation between the catalytic activities and the structures of the catalysts.

The low temperature carbon C^{500} did not show perceptible absorption before and after reaction in the wave number range 550—800 cm^{-1} ($\nu_{\phi-Cl}$= 702 cm^{-1}) or at around 950 and 1100 cm^{-1} (ν_{C-Cl} in RCOCl), in spite of the large uptake of chlorine by the catalyst. The appearance of the

absorption due to R-Cl group was neither observed for the high temperature carbon C^{1000} after its use as the catalyst.

The pile irradiation was reported to have an effect on the IR spectra of carbons simply to make them diffuse.[6] In our case, gamma-rays were likewise proved to have the similar effect on the spectrum of the carbon C^{1000}.

Dependences of Kinetic Constants on Heating Temperature and Irradiation. A rate equation was reported for phosgene synthesis over a commercial carbon catalyst by Potter and Barron.[9] Their results were found to obey either the mechanism of the surface reaction of molecular carbon monoxide with molecular chlorine or that with atomic chlorine, but they rejected the atomic chlorine mechanism because of the reaction temperature (31—99°C) and some other factors. However, a re-examination[10] of their data showed that rates could be expressed simply in the form;

$$\text{Rate} = k p_{CO} p_{Cl_2}^{1/2} \qquad (1)$$

where k is the rate constant per unit catalyst weight.

In our work, the almost constant partial pressures of the reactants made no significant difference in quality of the kinetic canstants whichever nearly linear[9] or square root[10] dependence of the rate on chlorine pressure might be adopted. Considering our higher reaction temperatures employed, we adopted the expression of reaction rate given in Eq. (1).

○ Unirradiated catalysts (C^T)
● Irradiated catalysts (C^{T*})

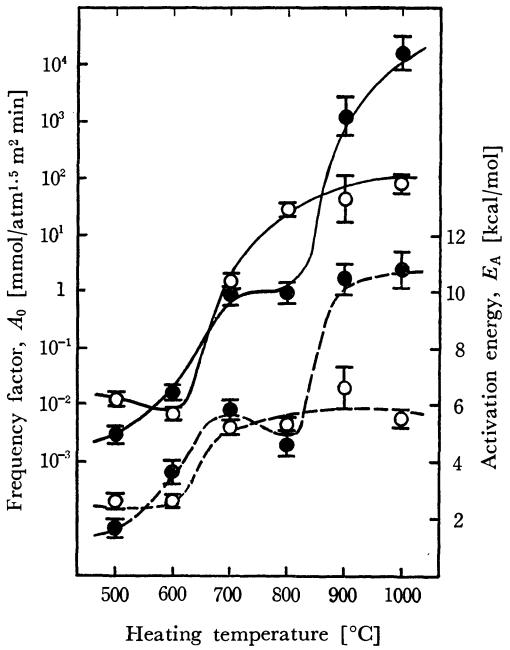

Fig. 2. Frequency factors and activation energies. ○ Unirradiated catalysts ● Irradiated catalysts
Full line Frequency factors
Broken line Activation energies

Rate constants per unit area, k_0, at 180°C are plotted against the heating temperature, T, in Fig. 1, where k_0 is k/S, and S is the specific area. The rate constant, k, at 180°C increases monotonously as the heating temperature is raised, while k_0 exhibits a slight decrease with T from 500°C to 600°C. Since C^{600} has the surface area three times as large as that of C^{500}, it is shown that the newly developed surface on C^{600} may have a smaller catalytic activity. With the heating temperature increased from 600°C to 700°C, both k and k_0 increase about tenfold, whereas the surface area is scarcely changed.

Gamma-irradiated carbons (C^{T*}) have always lower k and k_0 than the corresponding catalysts (C^T), as shown in Fig. 1. But an apparent parallelism of temperature dependences of the rate constants of the two catalyst groups may not have any significance. Analyses of k_0 values by separating them into frequency factors, A_0, and activation energies, E_A, reveal a definite dissimilarity between the two groups.

The A_0 values of C^T catalysts (Fig. 2) increase with the increasing heating temperature, but at higher heating temperatures they seem to be saturated. Those of C^{T*} catalysts do not show such a saturation, and A_0 of C^{1000*} exceeds that of C^{1000} by more than two orders of magnitude.

9) C. Potter and S. Barron, *Chem. Eng. Progr.*, **47**, 473 (1951).
10) S. Weller, *Am. Inst. Chem. Eng. J.*, **2**, 59 (1956).

The A_0 values of lower temperature carbons are less affected by irradiation.

The activation energies of C^T group can be classified into two groups. Both C^{500} and C^{600} have activation energies of about 2—3 kcal/mol and higher temperature catalysts about 5—6 kcal/mol. The general feature of C^{T*} carbons is similar to C^T ones for heating temperatures lower than 800°C, however C^{900*} and C^{1000*} have activation energies nearly doubled.

Changes in A_0 and E_A by the irradiation indicate that to lower (T=500 and 600°C) and middle (T=700 and 800°C) temperature carbons the gamma-dose of 1.0×10^8 R gives only a vague effect, the quality and the quantity of catalytic sites being not greatly affected.

The disappearance of the saturation of A_0 and the remarkable increase of E_A upon irradiation for higher heating temperature (900 and 1000°C) carbons will be associated with the destruction of some of the thermally generated sites and with the creation, by gamma-irradiation, of new sites of different nature which may not be produced by any thermal treatment of the carbons.

Conclusions

Characteristics of structure of amorphous carbons are peripheral atomic groups, free radicals and π-electron systems. Free radicals do not disappear but are indeed produced by pile-irradiation in 90% carbon coals which behave much alike the carbons from carbohydrates.[6] If the catalytic activity is to be related with free radicals, irradiation should enhance the activities of carbons. Moreover, succrose carbons have a maximum concentration of free spins when heated around 600°C,[11] although C^{600} is not active as shown in Fig. 1. It is clear from the results of elementary analyses that the increasing tendency of the catalytic activity with increasing heating temperature can not be related to the content of any component nor to the change in the content of C^T carbons. The measurement of the IR spectra could not point out any special bonding in carbons, which is positively responsible for the catalytic activity. The only remaining possible explanation for the effect of structure for the catalysis seems to be the correlation of the catalytic activity to the growth of the condensed ring system.

The radiation is able to destroy the π-electron system through bond ruptures, resulting certainly in an activity decrease. Atomic displacements of 0.35—0.7 per 10^4 atoms occurred in the graphite sample pile-irradiated to about 10^8 rad.[12] This leads to the radiation yield of the atomic displacement, G_d=0.03—0.05. For polystyrene, the most stable polymer to radiation, the G-value of C–C splitting by electron irradiation[13] could be estimated to about 0.04. Also C–H splitting yield in carbons could be assumed from some reported radiolytic yields; for n-hexane, $G(C_6H_{13})=5.5$,[14] for cyclohexane, $G(C_6H_{11})=7.2$,[15] and for benzene, twice of $G(H_2)$ is about 0.08.[16]

There would be a possibility to explain the radiation effect by correlating the varied activity directly with the radiation induced point defects. The broken bonds might be associated with the irradiation effect. But the radiolytic yield is too low. For carbon with a surface area of 100 m^2/g, about 8% of the total carbon atoms exist on the surface, if only the (001) planes were exposed on particles of graphite structure. If any speculative mechanism allowed radiation damage to occur preferentially on surface atoms, 1.6% of the surface atoms (0.13% of the total atoms) could be damaged by doses of 10^8 R through a process with G=1.

This value is not recognized as sufficient so long as the catalytic action of the carbons is related simply to atomic lattice points. However, when a considerably developed carbon network as a whole is thought effective for the catalysis, the damaged several tenths percents of the total carbon atoms may suffice the observed radiation effect on the reaction rate.

Study of Motion of D_2O in $Ba(ClO_3)_2D_2O$ by Transient NMR

Takehiko CHIBA*1 and Yoshinobu KAKIUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received November 6, 1967)

Deuteron spin lattice relaxation time T_1 and the reorientation rate of D_2O have been measured at various temperatures on a single crystal of $Ba(ClO_3)_2D_2O$ by transient nuclear magnetic resonance method. Temperature dependence of T_1 is similar to that of corresponding proton resonance but three to four orders of magnitude smaller than the latter. From the slope of log T_1 *vs.* $1/T$ curve, activation energy of reorientation of D_2O of 6.5—6.8 kcal/mol is obtained in agreement with that from line width transition. Theoretical values of T_1 minima were in good agreement with the observed. Direct measurement of reorientation rate is made by observing a signal recovery from saturation of one of the two deuteron sites of D_2O due to the exchange with unsaturated spins at the other site. The Arrhenius plot of the reorientation rate down to -170°C determined in this manner smoothly connects to that derived from the line width transition. A revision of the previous treatment of line width change is described and the reorientation rates of $Ba(ClO_3)_2D_2O$ are re-evaluated according to this method. A satisfactory agreement is found among the conclusions from the three different types of experiment, T_1, the line width transition and the directly measured reorientation rate. The motion is a random reorientation of D_2O with a rate governed by an activation process of 7 kcal/mol.

In a deuteron magnetic resonance the splitting due to a deuteron quadrupole coupling is usually of the order of 100 kc/sec. If a motion that interchanges two deuterons with different electric field gradient (EFG) components in the direction of H_0 is rapid enough, one gets a splitting corresponding to the averaged EFG of these two deuterons. Thus in hydrates a rapid reorientation of D_2O about its bisector causes the averaged spectra at high temperatures, while at low temperatures the spectra correspond to the stationary deuterons. From the line width change at both the slow and fast exchange limits, the reorientation rate of deuterons can be obtained employing the theory of motional narrowing process.[1] The method has an advantage over the usual line width transition due to dipole interactions in that the separation between the lines can be made as large as 200 kc/sec. However, because of insufficient signal-to-noise ratio usually encountered in deuteron resonances, observation of the broadening process is rather limited to a narrow range of temperatures and the presence of the dipole structure of the lines often imposes additional difficulty in extracting the rate of exchange. An activation energy of 6.5 kcal/mol for the reorientation in $Ba(ClO_3)_2D_2O$ determined in this way is somewhat larger than 5.0 kcal/mol for $Ba(ClO_3)_2H_2O$ determined from the temperature dependence of spin-lattice relaxation time, T_1, by Silvidi *et al.*[2]

It seems therefore worthwhile to study the motion by different method and compare the resulting value of reorientation rate with those obtained from the line width change for $Ba(ClO_3)_2 \cdot D_2O$ to examine whether the latter method gives the correct value. The present paper describes the measurements of T_1 and the reorientation rate in D_2O in this suitably simple system. The whole procedure of the present experiment and analysis are similar to the work of Schmidt and Uehling[3] of KD_2PO_4. A refined treatment of the line width transition for the derivation of exchange rate is also given.

Experimental

Single crystals of $Ba(ClO_3)_2D_2O$ are prepared as in the previous study.[1] All measurements were made using a pulse method. The pulse apparatus is of coherent type using Blume's gate circuit[4] operated at a frequency of crystal-controlled 10 Mc. Programmed pulses are furnished by the combination of Tektronix type 162, and 163 generators. The sample coil in a probe is incorporated in a single coil arrangement. Signal was detected by PA-620-L preamplifier and WA-600-D wideband amplifier of Arenberg Ultrasonic Laboratory Inc. Recovery time of the apparatus is about 15 μs. Rf field strength used was such that width of 90° pulse for D was about 15 μs.

Results and Discussion

Measurement of T_1. $Ba(ClO_3)_2D_2O$ crystal is monoclinic. Bisector of D_1OD_2 is a two-fold axis parallel to the crystallographic b axis.[5] D has nearly axially symmetric EFG about the D-O direction.[1]

For a deuteron nuclear spin $I=1$, therefore, an inclusion of a quadrupole interaction gives three unequally-spaced Zeemen levels. If only one of the two transitions (say, $m=1\rightarrow0$) is saturated, the recovery to the equilibrium cannot in general be represented by a single exponential function. If $P_1 \neq P_2$ as is generally the case, where P_1 is the thermal transition probability of $\Delta m=\pm1$ and P_2 is that of $\Delta m=\pm2$, unique T_1 can be defined only when three levels become equidistant as

$$1/T_1 = 2P_2 + P_1 \qquad (1)$$

Therefore, the measurement of T_1 is to be made for the crystal orientation where the quadrupole splitting is zero. Moreover, in the present case, because of the rapid exchange motion of D_1 and D_2 at high temperatures, in order to be able to observe T_1 for a wide temperature range the crystal orientation must be so chosen that the quadrupole splitting vanishes both for D_1 and D_2. There are two directions specified as direction I and II in Fig. 1 where this condition is met. The observed T_1 in these directions at various temperatures are

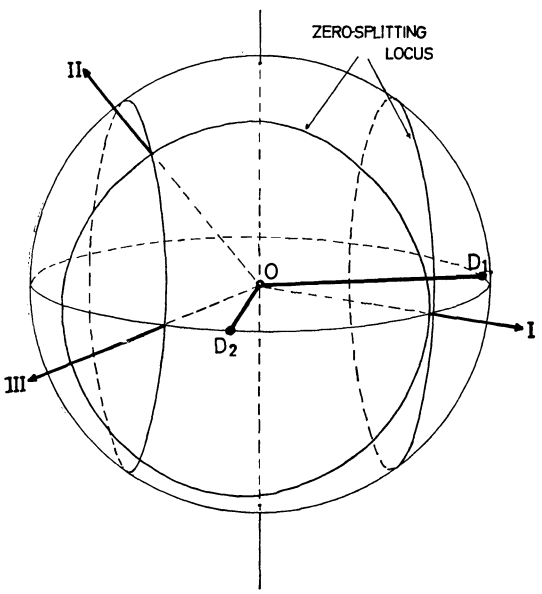

Fig. 1. Directions of magnetic field relative to the orientation of the D_2O molecule in the present study: Direction I and II for the measurement of T_1, Direction III for the direct measurement of jump rate.

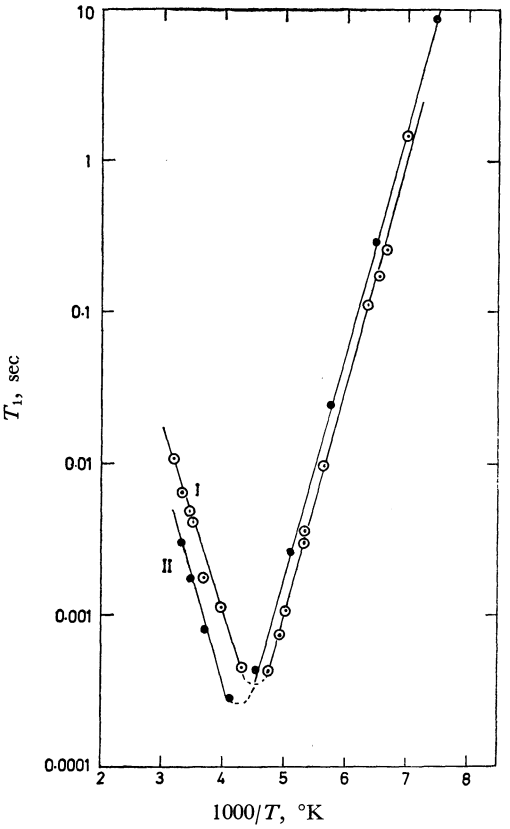

Fig. 2. Temperature dependence of T_1.
⊙ Measured in Direction I.
● Measured in Direction II.

plotted in Fig. 2. A typical V-shaped curve indicates that the reorientation with the jump rate ν_j governed by Arrhenius equation is a principal relaxation mechanism. The activation energy (in kcal/mol) is obtained from the slopes at the high and low temperature sides of the T_1 minimum as,

H_0 direction	High temp. side	Low temp. side	Averaged
I	6.1	6.9	6.5
II	6.85	6.8	6.8

These values are in good agreement with that of 7.0 kcal/mol from the line width transition.

The curve is similar to the one obtained from the proton resonance in $Ba(ClO_3)_2H_2O$ by Silvidi and McGrath,[2] but T_1 is 3 to 4 orders of magnitude smaller in the present case indicating predominant quadrupolar relaxation mechanism of deuteron. Theoretical values of T_1 minimum are calculated as follows.

The matrix elements of quadrupole interaction Hamiltonian are given as

$$(m\pm1\,|\,\mathscr{H}_Q\,|\,m) = \frac{eQ}{4I(2I-1)} \times (2m\pm1)[(I\pm m+1)(I\mp m)]^{1/2}(\varphi_{xz}\mp i\varphi_{yz}) \qquad (2)$$

5) G. Kartha, *Acta Cryst.*, **5**, 845 (1952).

$$(m\pm2|\mathscr{H}_Q|m) = \frac{eQ}{8I(2I-1)} \times [(I\pm m)(I\mp m-1)(I\pm m-1)(I\pm m+2)] \times (\varphi_{xx}-\varphi_{yy}\mp 2i\varphi_{xy}) \quad (3)$$

where φ's represent the matrix elements of EFG tensor. The z axis is taken along H_0. φ's which are different for the D_1 and D_2 of D_1OD_2, fluctuate with the random flip of D_2O, and cause relaxation among different m levels.

Denoting the mean lifetime of a deuteron in one of the site by τ, the autocorrelation function of the fluctuating φ can be written as

$$\langle\varphi(0)\varphi^*(t)\rangle = \varphi_\Delta^2 \exp(-2t/\tau), \quad (4)$$

where

$$\varphi_\Delta = [\varphi(D_1) - \varphi(D_2)]/2, \quad (5)$$

and $\varphi(D_1)$ and $\varphi(D_2)$ are φ at D_1 and D_2 respectively. Corresponding spectral density $J(\omega)$ is given by

$$J(\omega) = |\varphi_\Delta|^2 j(\omega), \quad (6)$$

$$j(\omega) = 4\tau/(1 + 4\omega^2\tau^2). \quad (7)$$

The transition probabilities of $1\rightarrow0$ and $1\rightarrow-1$ due to this motion are

$$P_1 = \hbar^2|A_1|^2 J(\omega), \quad (8)$$

$$P_2 = \hbar^2|A_2|^2 J(\omega), \quad (9)$$

where A_1 and A_2 represent spin parts of (2) and (3), respectively. T_1 is given by Eq. (1). To calculate T_1 in the direction I, the quadrupole coupling tensor $(eQ/h)q$ of D in the principal axis system as determined in Ref. 1 is transformed into the coordinate system where the z axis is along H_0 and the x axis perpendicular to the molecular plane. By the 180° flip motion the yz element changes as $\varphi_{yz}\rightarrow-\varphi_{yz}$. All the other elements are unchanged by the motion. $|(eQ/h)\varphi_{yz}| = 167$ kc/sec. Then from (1), (2), (6), and (8)

$$1/T_1 = (1/8\hbar^2)(167\times10^3h)^2 j(\omega). \quad (10)$$

Similarly in the direction II, when transformed into the coordinate system where z is along H_0 and x along bisector of D_2O, only the xy and xz elements of EFG tensor change by the flip motion, namely,

$$\varphi_{xy} \rightarrow -\varphi_{xy} \quad \text{and} \quad \varphi_{xz} \rightarrow -\varphi_{xz}.$$

$$|(eQ/h)\varphi_{xy}| = 117 \text{ kc/sec},$$

and $$|(eQ/h)\varphi_{xz}| = 119 \text{ kc/sec},$$

T_1 in this case will be,

$$1/T_1 = (1/8\hbar^2)(119\times10^3h)^2 j(\omega) + (1/4\hbar^2)(117\times10^3h)^2 j(2\omega). \quad (11)$$

The T_1 minimum and corresponding ν_j from (10) and (11) are 0.45 msec and 3.1×10^7 sec^{-1} for the direction I, and 0.24 msec and 4.5×10^7 sec^{-1} for the direction II respectively. Observed T_1 minimum values are about 0.4 msec and 0.3 msec

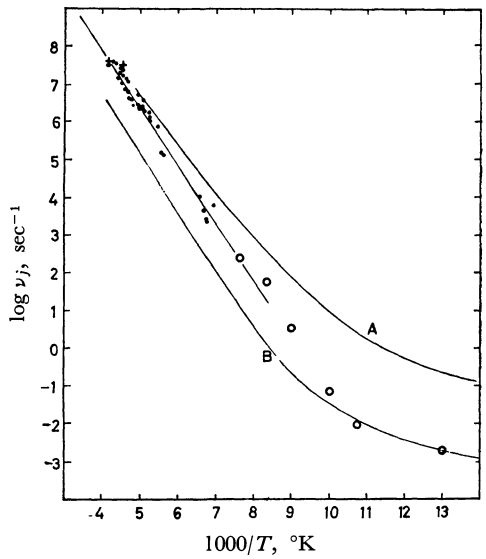

Fig. 3. Temperature dependence of jump rate ν_j determined from T_1 minimum, +, from direct measurement, ○, and from the line width change, ●. Curves A and B are theoretical ones from quantum mechanical tunneling process with potential barrier of 6.17 and 7.61 kcal/mol, respectively.

for the directions I and II, respectively. The agreement between the calculated and the observed is quite satisfactory. The parallel shift of the curve I from curve II of Fig. 2 is in the right direction, but a few times larger than that expected from the theory. ν_j at the T_1 minima are indicated in Fig. 3 of ν_j *versus* $1/T$ curve.

Direct Reorientation Rate Measurement. The rate of reorientation or the jump rate of a deuteron from the site 1 to site 2 can be directly measured in the following experiment, if one observes a recovery from saturation of a signal of site 1 by diffusion of site 2 spins, which has been kept in thermal equilibrium. Suppose the crystal is oriented in such a way that the signal of site 1 is unsplit, while that of site 2 has large splitting. We apply two 90° pulses in succession at the Larmor frequency. The first pulse saturates site 1 line. Then the magnitude of the Bloch decay signal after the second pulse shows a recovery due to the diffusion of unsaturated spins from the site 2 to site 1 by reorientation in addition to the recovery by spin-lattice relaxation. The method is applicable when T_2 is much shorter than this recovery time, that is, the two successive Bloch decay signals can be well separated. Also the rf pulse strength H_1 should be such that $\gamma H_1 \ll 2\pi\Delta\nu$, where $\Delta\nu$ is the frequency difference between the two sites, in order that the rf pulse has negligible effect on the site 2 nuclei. Direct measurement of τ, the lifetime in one of the sites, $(\tau = 1/\nu_j)$, is made when $\tau \ll T_1$ and $\tau \ll T_{12}$, the latter being the condition

that the cross-relaxation time T_{12} due to spin flip between the two sites should be negligible. This method has been applied to study the jump rate between bonds of deuterons in KD_2PO_4 by Schmidt and Uehling.[3] The relation of jump rate with recovery time constant given in Appendix I of their paper exactly applies to the present case, and the recovery time constant $=\tau/2=1/2\nu_j$. In order to avoid the error due to possible nonlinearity in the observed signal amplitude, they used the following method. Three 90° pulses are applied in succession, the time interval being t_1 between the first and second pulses, and t_2 between the first and third. t_1 is varied while t_2 is fixed at a value $t_2 \gg \tau$. t_1 is so adjusted that the Bloch decay signals after the second and the third pulses are made to have equal height. Then τ is given by $t_1=(\ln 3)\tau$. We used this method, and also two 90° pulse sequence, where the signal height following the second pulse is compared with the first one to observe the exponential growth. The measurement was done with H_0 in the direction III shown in Fig. 1, where site 1 line is at the Larmor frequency and $\Delta\nu$ is about 150 kc/sec. In $Ba(ClO_3)_2D_2O$, lines of stationary water molecule are observed below -120°C, and this is well below the temperature of the T_1 minimum. Since quadrupole relaxation due to reorientation is a principal relaxation mechanism, and the quadrupole interaction is only a small perturbation to the Zeeman energy, the inequality $T_1 \gg \tau$ holds. Therefore, the direct measurement of jump rate is applicable below -120°C. At very low temperatures, however, T_1 gets so large that it is necessary to irradiate the crystal with γ ray to bring T_1 to the workable range. Thus after this treatment, T_1 measured at direction I is about 90 sec at liquid nitrogen temperature, and stays nearly constant up to the temperature where relaxation due to the motion becomes appreciable (~ -140°C). The observed recovery is found to be much faster than 90 sec except at liquid nitrogen temperature where it becomes comparable to 90 sec. With this sample, we can conclude that the condition $\tau \ll T_1$, T_{12} is valid down to -170°C since T_{12} should be nearly constant, and T_1 due to paramagnetic centers is also rather insensitive to temperature variation, whereas the observed recovery gets much longer at the liquid nitrogen temperature. To estimate τ at the liquid nitrogen temperature, the observed recovery curve is compared with the calculated one with various τ values assuming $T_1=90$ sec, same as in direction I. If τ of 5 min at liquid nitrogen temperature thus obtained is correct, a bend in the plot of $\log \nu_j$ *vs.* $1/T$ would show a departure from the Arrhenius equation, and indicate quantum mechanical tunnel effect. ν_j calculated from the tunnelling process shown in the figure suggests that such a bend is quite probable.

Since the lines are narrow while $\Delta\nu$, the separation between the lines of D_1 and D_2, is large, the cross-relaxation between D_1 and D_2 is probably ineffective. It should be definitely ineffective from the formalism of Bloembergen *et al.*[6] However, to get an experimental justification for excluding cross-relaxation process at liquid nitrogen temperature, we measured the recovery at the crystal orientation where $\Delta\nu$ is about 80 kc/sec. Unless the recovery rate changes drastically, the cross-relaxation could be neglected.*2 In this case the recovery at liquid nitrogen temperature is found to be shorter by a factor of about 3 than the other case. However, that this is not due to the cross-relaxation is seen from the fact that the recovery toward a full intensity is observed instead of one half as expected from the cross-relaxation process. This shortening of recovery can be understood as the T_1 diminution due to cross-relaxation to the Ba nuclei which have short T_1 due to a quadrupole interaction. Using a quadrupole coupling tensor for ^{135}Ba and ^{137}Ba by Nakamura and Enokiya[7] the transition frequencies of Ba in the present experiment are calculated. The result turned out that one of the transitions falls in fact almost at 10 Mc. The whole task for such an experiment is rather involved. Moreover, transition frequencies of Ba resonances depend in a complex manner on crystal orientation, and the Ba quadrupole coupling and its temperature dependence have been determined only at higher temperatures, which situation makes the estimation of exact transition frequencies in the present experiment difficult. For this reason no further experiment on this line is made.

Values of ν_j determined in the present work are to be compared with those from the line width change. In the following a revision of the previous treatment[1] of line width transition will be described.

A random motion of atoms has an effect both on the quadrupole splitting and on dipole structure. It would be possible to derive a reorientation rate by comparing the observed broadened spectra with the numerically calculated one at each particular case taking into account the effect of motion on both quadrupole and dipole interaction in an exact fashion according to the theory of motional broadening.[8] However, poor quality of the observed line shape prevents the analysis of detailed line shape, and also the fact that the observations have to be made at various orientations of the crystal (that is, various values of quadrupole and dipole interactions) which requires much

*2 The authors are indebted to Professor C. P. Slichter for suggesting this measurement.

too laborious calculations, this exact method seems to be impractical.

Generally signal-to-noise ratio of the broadened spectra is such that, 1) spectra can only be observed at the fast and slow exchange limits of the quadrupole broadening, 2) the only quantity which can be measured with a reasonable accuracy is the signal amplitude of the derivative curve between the points of maximum and minimum slopes of the absorption line. This signal amplitude will be denoted by S.

Since in general practice, one measures the line broadening where the quadrupole interaction is much larger than the dipole interaction the effect of motion upon the dipole width is relatively small (particularly so in the 180° flip of a water molecule where the intramolecular dipole interaction is unaffected by the motion). The change in dipole line width should therefore take place at the temperature range different from those of quadrupole structure. It may then be permissible to assume that the dipole width is invariant under the present condition of observation.

To derive an exact effect on quadrupole broadening it is, however, necessary to separate this effect from the dipole structure. Since S depends on the line width strongly (as the inverse square of the width if the dipole width is absent*3) the following procedure will be used.

A width between the maximum slopes, $\Delta\nu_{ms0}$, and a signal intensity S_0 is defined at the point where the exchange motion is either sufficiently rapid or sufficiently slow so that practically no motional broadening is involved in the line shape.

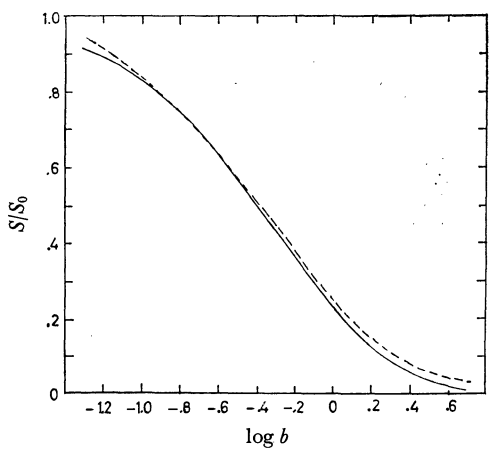

Fig. 4. Diminution of derivative signal intensity (S/S_0) due to broadening.
—— Gaussian line (half width $(\ln 2)^{1/2}$) broadened inhomogeneously by Lorentzian curve (half width b).
---- Lorentzian line (half width 1) broadened to half width $1+b$.

*3 Previous treatment (Ref. 1) is inadequate since $S/N \propto 1/\Delta\nu$ is assumed.

Numerical calculation of line shape is made, assuming a Gaussian dipole line shape (half maximum half width $(\ln 2)^{1/2}$) and each component of it is further broadened by a Lorentzian line shape of a given width (half maximum half width b). Then S/S_0 has a dependence on the line width parameter b as shown in Fig. 4. From the observed S/S_0, b is read off. $\Delta\nu_M$ $(=1/(2\pi T_2'))$, the half width due to motion) is obtained as,

$$\Delta\nu_M = \Delta\nu_{ms0} \times b/\sqrt{2},$$

a factor $1/\sqrt{2}$ coming from the normalization.

S and S_0 are obtained at different temperatures, and the signal height may therefore vary with temperature, according to various factors such as sensitivity of the instrument, the relaxation time, the Boltzmann factor, and the thermal noise, but difference between the temperatures of observation of S and S_0 is usually not so large to give serious effect.

If the original line is approximately Lorentzian with T_2 as in the case of certain paramagnetic substances, added breadth by motion can be separated by use of the similar curve also shown in Fig. 4, through the formula $\Delta\nu_M = \Delta\nu_{ms0} \times b \times 2\sqrt{3}$. $\Delta\nu_M$ is related to the jump rate in the case of 180° flip of a water molecule as $\Delta\nu_M = \nu_j/2\pi$ for the slow exchange limit, and $\Delta\nu_M = (\pi/4) \times (\Delta\nu^2/\nu_j)$ for the fast exchange limit.

The above procedure is applied to the case of $Ba(ClO_3)_2D_2O$. In Fig. 3 is shown the revised result including some added experimental points. The activation energy is 7.0 kcal slightly higher than the previous value, and the pre-exponential factor is 10^{14-15}.

As shown in Fig. 3, a satisfactory agreement is found among the experimental results of T_1, line width and jump rate, interpreted as due to random 180° flip of D_2O with a rate $\nu_j \propto \exp(-\Delta E/\boldsymbol{R}T)$, ΔE being 7 kcal/mol. Such a simple picture of the motion is probably true in case of this crystal. In this connection it is interesting to note that the good agreement of the frequency of twisting mode of D_2O derived from the recent neutron scattering experiment on this compound by Prask and Boutin[9] with those from ΔE with the assumption of cosine type potential.

Finally, it may safely be said that the present results give also a support to the reliability of deriving activation energy of the motion from the line width transition of quadrupole splitting by the procedure described above.

We are grateful to Assistant Professor Kiyoshi Kume of Tokyo Metropolitan University for many helpful comments for the construction of the pulse apparatus.

Electron Spin Resonance Study on Ultraviolet Light Irradiated Benzene Adsorbed on Silica Gel and Alumina

Tadayoshi TANEI*1

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received November 9, 1967)

Benzene adsorbed on silica gel was irradiated at 77°K with ultraviolet light. Three kinds of samples, with different degree of adsorption, were examined. ESR spectra were strongly dependent on the amount of benzene adsorbed and three different spectra were observed; (1) six-line spectrum with a splitting value of 6 gauss, assigned to phenyl radical, (2) seven-line spectrum with a splitting value of 4.5 gauss, assigned to benzene cation radical, and (3) apparent nine-line spectrum with 2.4 gauss splitting due to benzene dimer cation radical. Upon raising temperature, benzene cation radical was found to transform into benzene dimer cation radical. In UV-irradiated benzene-alumina system, cyclohexadienyl radicals were observed in addition to the ion radicals. It is suggested that the above reaction may be occurred by two photon absorption process involving the excitation of triplet benzene.

Photochemical studies on benzene have been carried out in various organic rigid glasses, mainly by optical spectroscopic methods. Gibson *et al.*[1] showed an evidence that benzene was photochemically decomposed in the rigid glasses of EPA and 3-methyl perfluoropentane to produce hexatriene-1,3,5 and diphenyl, respectively. Subsequently, Porter[2] and Leach *et al.*[3] independently investigated these reactions and led to a conclusion of the formation of substituted hexatriene. Migirdicyan[4] made an attempt to observe photochemical intermediates of benzene in organic rigid glasses by the method of electron spin resonance, but failed to observe any intermediate signal from benzene.

In the previous paper,[5] we reported that an ESR spectrum, consisting of six lines with the splitting value of 6 gauss, was observed from benzene irradiated with ultraviolet light from high-pressure mercury lamp at 77°K. In relation to this investigation, the present work was undertaken in order to obtain more insight in unstable photochemical intermediates from UV-irradiated benzene and to examine its reaction mechanism, using the method of ESR. We obtained an evidence that benzene adsorbed on silica gel can be photoionized by UV-irradiation at 77°K and that, when alumina is used as an adsorbent, hydrogen addition reaction to benzene ring can take place in addition to photo-ionization. A subsequent conversion reaction of benzene cation radical has also been investigated. On the basis of these experimental results, a photochemical reaction mechanism of benzene has been presented.

Experimental

Materials. Benzene was obtained from two commercial sources, Dotite spectrosol benzene manufactured by the Dojindo Research Laboratories Co., Ltd., and Merck's spectro-grade benzene. These samples were purified by recrystallization according to the method of Kanda *et al.*[6] In some experiments, benzene was purified in the presence of Na-K alloy through repeated freezing and thawing *in vacuo*. Hexadeuterobenzene of Merck (purity: 99%) was used without further refining. Silica gel from Mallinckrodt Chemical Works (100 mesh silica gel) was heated *in vacuo* for about 5 hr at 413 to 773°K. In some experiments, the silica gel was washed with special grade concentrated hydrochloric acid and distilled water, immediately before its use. Silica powder was obtained from ground quartz ampoules. Activated alumina for chromatographic adsorption from Nakarai Chemical Company Ltd. was used without further refining. It was heated *in vacuo* at 573°K for about 5 hr.

Adsorption Procedures. The adsorption apparatus was made modifying a vacuum transfer apparatus by Lewis *et al.*[7] and was connected to vacuum line. All samples were treated in the adsorption apparatus and subsequently the vapor was led to adsorbent in the ESR ampoule. The amount of adsorption of

benzene was not measured, but controlled by the following three procedures. 1) ESR quartz ampoule was cooled by liquid nitrogen for a moment (Sample-1). 2) Silica gel was exposed to benzene vapor for about 5 to 10 min at room temperature (Sample-2). 3) Sample-2 was pumped off at 323 to 333°K for about 2 to 3 hr (Sample-3).

Light Source and Irradiation. Either high-pressure mercury lamp (Toshiba 400W) or low pressure mercury lamp (Toshiba germicidal lamp) was used. As the filters were used Toshiba UV-25, UV-D25 and UV-29, respectively. γ-Irradiation was performed with Co-60 (700 Ci) at 77°K.

ESR Measurement. Spectra were recorded on a Varian V-4560 EPR spectrometer with 100kc modulation at 77°K and at higher temperatues up to about 173°K by using the Varian liquid nitrogen and variable temperature accessories.

Results

Benzene-Silica Gel Adsorption System. ESR spectra of UV-irradiated Sample-1, Sample-2 and Sample-3 are shown in Fig. 1. The effective wavelength to produce these spectra was found in the region from 2300 Å to 2600 Å by using filters. It is demonstrated that the spectra are strongly dependent on apparent amount of adsorption of benzene. UV-Irradiated hexadeuterobenzene, corresponding to Sample-2 and Sample-3,

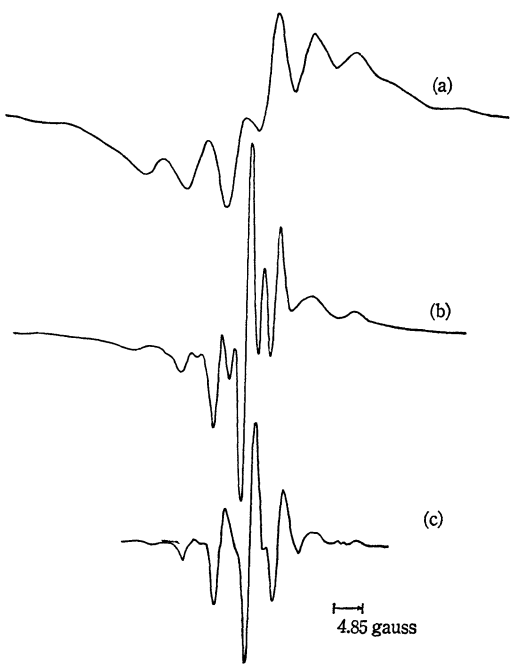

Fig. 1. ESR spectra of UV-irradiated benzene adsorbed on silica gel. The alphabetical marks in the figure, (a), (b) and (c), corresponds to Sample-1, Sample-2 and Sample-3 (see Experimental in this paper), respectively. UV-irradiation was performed for 100 min at 77°K.

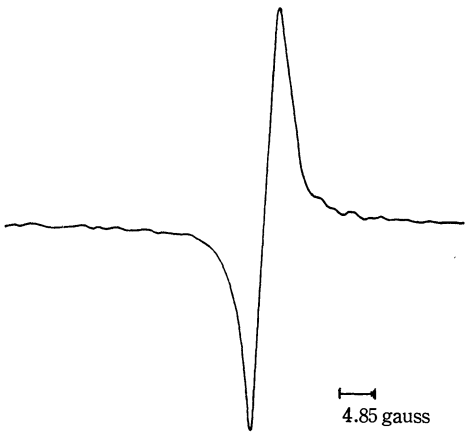

Fig. 2. ESR spectrum of UV-irradiated hexadeuterobenzene adsorbed on silica gel. UV-irradiation was performed for 100 min at 77°K.

gave only a singlet spectrum with ΔH_{msl} value of 3.4 gauss (see Fig. 2). Irradiated silica gel without adsorbed benzene gave no ESR signal, nor did adsorbed benzene without irradiation.

On raising temperature, these spectra change as shown in Figs. 3 to 5. In the spectrum of Sample-1 (see Fig. 3), a sharp component of the splitting 2.4 gauss appears in the central part. The seven-line spectrum of Sample-3 (see Fig. 5) gradually disappears and an apparent nine-line spectrum, with the intensity ratio of 1 : 2 : 5 : 8 : 14 : 8 : 5 : 2 : 1 and the splitting value of 2.4 gauss, appears, when the sample was kept at dry ice - methanol temperature. The behavior of Sample-2 (see Fig. 4) is also analogous to those of Sample-1 and Sample-3.

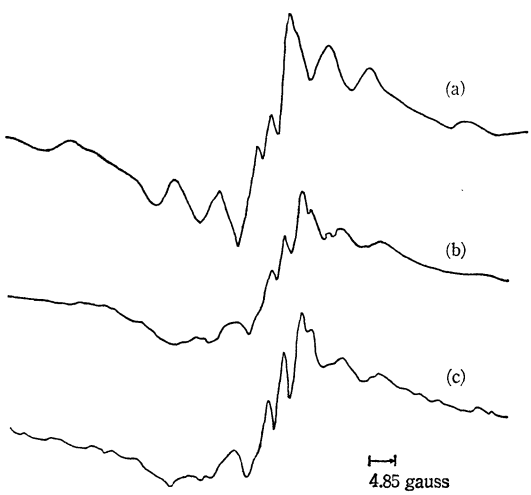

Fig. 3. Change with increasing temperature of ESR spectrum of Sample-1. Spectra were recorded at the temperatures of 77°K (a), 123°K (b) and 153°K (c).

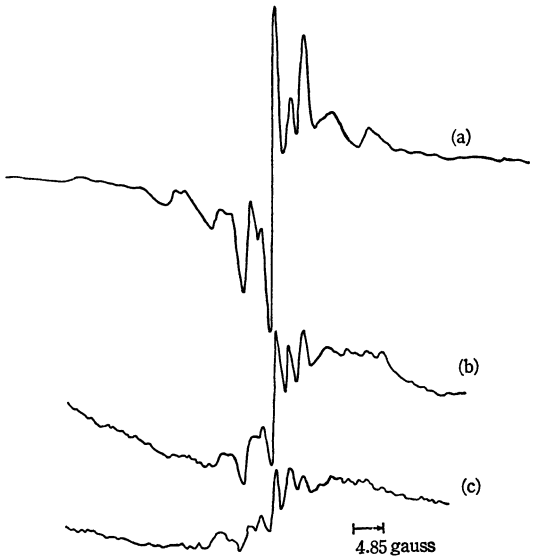

Fig. 4. Change with increasing temperature of ESR spectrum of Sample-2. Spectra were recorded at the temperatures of 77°K (a), 128°K (b) and 173°K (c).

The spectrum of Sample-1 mainly consists of six lines with the splitting value of 6 gauss (see Fig. (1 a)), which is essentially the same as the six-line spectrum[5] observed from UV-irradiated polycrystalline benzene at 77°K. The spectrum of Sample-2 is a superposition of the six-line spectrum and some sharp line spectrum in the central part, with the splitting value of 2.4 gauss (see Fig. 1(b)). The spectrum of Sample-3 is a sharp seven-line one, with the intensity ratio of 1 : 5 : 16 : 24 : 15 : 4.5 : 1, and its splitting value is approximately 4.5 gauss (see Fig. 1(c)).

From the UV-irradiated mixture of benzene with ground silica powder was observed a poorly resolved six-line spectrum, with the splitting value of 6 gauss, which is quite similar to the six-line spectrum of UV-irradiated polycrystalline benzene.

To summarize, we have observed three different spectra from UV-irradiated benzene adsorbed on silica gel. One is the six-line spectrum of 6 gauss separation (Fig. 1(a)). The second one is the seven-line spectrum of 4.5 gauss splitting (Fig. 1(c)) and the third one is the apparent nine-line spectrum of 2.4 gauss splitting (Fig. 5(c)).

Benzene-Alumina Adsorption System. The ESR spectrum of UV-irradiated benzene-alumina system (see Fig. 6) consists of a triplet of about 47 gauss splitting, each component with further quartet splitting of about 10.5 gauss, and in addition, it has a six-line component analogous to the benzene-silica gel system in the central part. The triplet spectrum of about 47 gauss splitting can be ascribed to the cyclohexadienyl radical.[8,9]

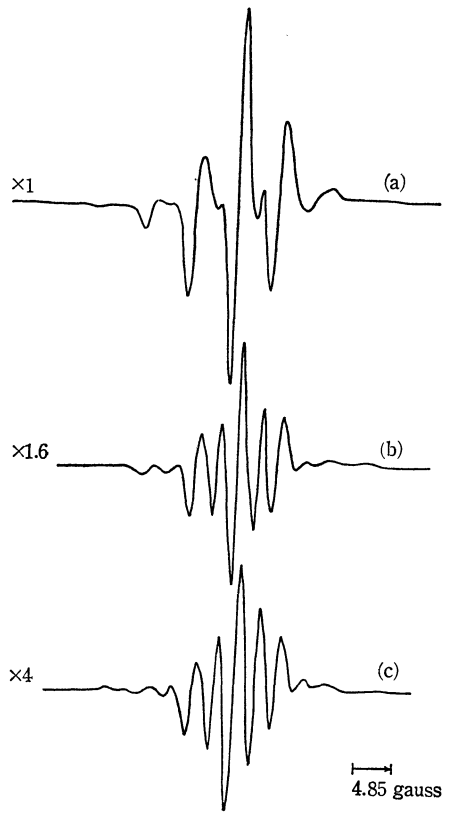

Fig. 5. Change with increasing time of ESR spectrum of Sample-3 kept at dry ice - methanol temperature.
(a) sample kept at 77°K. (b) sample kept at dry ice - methanol temperature for 57 min. (c) sample kept at dry ice - methanol temperature for 16 hr.
In this figure, numerical figures represent the relative sensitivity of spectrometer.

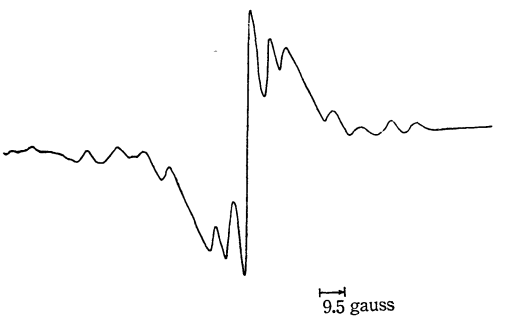

Fig. 6. ESR spectra of UV-irradiated benzene adsorbed on alumina. This sample corresponds to Sample-2. UV-irradiation was performed for 75 min at 77°K.

9) H. Fisher, *Kolloid Z.*, **180**, 64 (1962).

Appearance of this triplet component is in contrast with the benzene - silica gel system. Upon subsequent γ-irradiation at 77°K, increase in triplet component was observed.

Discussion

Interpretation of ESR Spectra. According to the presentation in the preceding paper,[5] the six-line spectrum of 6 gauss splitting in Fig. 1(a) can be interpreted as the phenyl radical. The seven-line spectrum of 4.5 gauss splitting (Fig. 1(c)) can be assigned to the benzene cation radical. The splitting value is found to be 25% larger than that of the benzene anion radical. The difference between negative and positive ion radicals of alternant aromatic hydrocarbons has been studied by many workers from experimental and theoretical points of view.[7,10-17] Bolton *et al.*[12] have predicted that proton hyperfine coupling constants of positive ions should be larger than those of corresponding negative ions as a result of difference in charge density and obtained the following equation.

$$a_H^{\pm} = (Q\rho \pm K\rho^2) \qquad (1)$$

a_H: the hyperfine coupling constant between electron and an aromatic proton
ρ: the spin density on the adjacent carbon atom
Q: a constant charateristic for an aromatic C–H bond
K: excess charge density

Lewis *et al.*[7] have measured the proton coupling constants of cation radicals of alternant aromatic hydrocarbons and concluded that hyperfine coupling constants of cation radicals are 25% larger than those of corresponding anion radicals. Their empirical values of Q and K in the Eq. (1) are 32.2 and 16, respectively.

The experimental result in the present work is found to agree quite well with the general tendency ascertained as for the difference between corresponding anions and cations. However, we have to use a different set of Q and K values. Namely, Q should be 25 and K be 15, in the Eq. (1). Most recently, in an independent work of the present study, Edlund *et al.*[18] have observed the ESR spectrum of the benzene cation radical from γ-irradiated benzene adsorbed on silica gel. Their splitting value is found to be in accord with the present value.

As shown in Fig. 5, benzene cation radical gradually decays and changes to show an apparent nine-line spectrum, on being preserved at dry ice-methanol temperature. The splitting value of nine-line spectrum corresponds to one half of that of benzene cation radical. On the basis of these data, it seems the most reasonable to assume that the apparent nine-line spectrum is responsible for the benzene dimer cation radical $(C_6H_6)_2^+$, in which the spin density on carbon atom should be 1/12 and its theoretical spectrum should consist of 13 lines with the intensity ratio of 1 : 12 : 66 : 220 : 495 : 792 : 924 : 792 : 495 : 220 : 66 : 12 : 1. The above ratio indicates that the intensities of outer peaks become almost negligible as compared with those of the central part. Therefore, its relation seems to be consistent with the experimental fact that only the nine lines, with the intensity ratio of 1 : 2 : 5.4 : 8.1 : 14 : 8.1 : 5.4 : 2 : 1, were observed from the benzene dimer cation radical. The central intensity ratio in the experimental nine-line spectrum, however, seems to be rather higher in comparison with the theoretical intensity ratio. Its difference is probably due to the overlapping of the initial seven-line spectrum still just remaining in the central part of the nine-line spectrum. Edlund *et al.*[18] have also observed this nine-line spectrum from γ-irradiated benzene adsorbed on silica gel.

The spectrum shown in Fig. 1(b) can be interpreted as an overlapping of six-line spectrum in Fig. 1(a), seven-line spectrum in Fig. 1(c) and nine-line spectrum in Fig. 5(c).

In benzene-alumina system (Fig. 6), one can interpret that cyclohexadienyl radicals are produced in addition to phenyl and benzene ion radicals.

Bubnov *et al.*[19] have observed ESR spectra from ultraviolet light irradiated "benzene-phosphoric acid matrix" (benzene concentration; 2×10^{-2} mol/l) at 77°K. And very recently, Carter *et al.*[20] have observed the seven-line and nine-line spectrum from UV-irradiated "benzene-sulfuric acid matrix" and the six-line spectrum from UV-irradiated polycrystalline benzene, while we are preparing the present manuscript.

Photochemical Reactions of Adsorbed Benzene. Photo-ionization of benzene derivatives has been observed in various media by many

workers[21-25] and its mechanism has been interpreted by two photon absorption process involving an excitation of triplet state. In the case of photo-ionization of adsorbed benzene, the absorption of one photon, with the energy of 4.75 to 5.37 eV, would be energetically insufficient to photoionize benzene, because the first ionization potential of benzene corresponds to 9.2 eV. In the radiolysis of hydrocarbons adsorbed on silica gel, an increase in G values has been confirmed.[26] Moreover, it has also been reported that some catalytic sites are generated in silica gel irradiated with ionizing radiation.[27] In the photolysis, however, such a phenomenon has never been reported. Accordingly, it seems reasonable to assume that silica gel, generally well known as a physical adsorbent, would only act as a trapping site for very unstable paramagnetic species. As a trapping site in silica gel, one can suppose OH group, by which π-type hydrogen bond can be formed between benzene and silica gel surface.[28,29] From such a point of view, the photochemical reactions in benzene - silica gel system could be interpreted in terms of the following processes involving an excitation of triplet state benzene.

$$C_6H_6(\text{ads}) \xrightarrow{2h\nu} C_6H_6^+ + e \qquad (2)$$

$$C_6H_6^+ + C_6H_6 \rightarrow \{C_6H_6 \cdots C_6H_6\}^+ \qquad (3)$$

In the process (2), photo-ionization is induced by two photon absorption to lead to the formation of benzene cation radical. Namely, two photon absorption mechanism in benzene could be attained through transitions between the following excited states.

$$^1A_{1g} \xrightarrow{h\nu} {}^1B_{2u}(4.84\,\text{eV}) \qquad {}^1B_{2u} \rightarrow {}^3B_{1u}(3.7\,\text{eV})$$

$$^3B_{1u} \xrightarrow{h\nu} {}^3E_{2g}(8.4\,\text{eV})$$

In fact, triplet-triplet absorption in benzene has been successfully observed in organic rigid glasses of isopentane and 3-methyl-pentane at 77°K by Godfrey *et al.*[30] in recent years. Furthermore, the experimental fact that UV-irradiation at dry ice-methanol temperature gave no paramagnetic species and the emittance of phosphorescence at 77°K seem to suggest that the photo-excitation of $^3B_{1u}$ state plays a very important role in photo-ionization of benzene. The energy of $^3E_{2g}$ state, theoretically calculated by Pariser,[31] is approximately comparable to the benzene ionization potential energy.

Benzene cation radical is known as very unstable paramagnetic species. In the process (3), benzene cation, weakly adsorbed in polylayer state, and with more mobility, is followed by dimerization with surrounding benzene molecules to produce benzene dimer cation.

The process of the phenyl radical formation can not be reasonably explained from the present experimental results, although Carrington *et al.*[32] have suggested a possibility of phenyl radical being produced from benzene cation by ring proton detachment. According to the prediction by Carrington *et al.*,[32] the six-line spectrum of Fig. 1(a) can be responsible for the phenyl radical, the unpaired electron being localized on the carbon σ orbital.

The observation of cyclohexadienyl radicals in benzene-alumina system is rather different from the result in benzene - silica gel system, where cyclohexadienyl radicals can hardly be observed. This phenomenon can be reasonably interpreted as being responsible for the catalytic activity of alumina for the hydrogenation.[33]

The author wishes to thank Professors Hiroyuki Hatano and Shunichi Ohnishi for their helpful discussions and encouragement during this work. Thanks are also due to Professor Isamu Nitta for his favor to provide Varian V-4560 EPR spectrometer and to Professor Keiji Kuwata for his interest.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 838—843 (1968)

Synthesis of Chelating Agents. V.*1 1,2,3-Triaminopropanehexaacetic Acid and Its Acid Dissociation Scheme*2

Mitsumasa MIYAZAKI,*3, *4 Yoshiki MORIGUCHI and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received October 30, 1967)

1,2,3-Triaminopropane-*N,N,N',N',N'',N''*-hexaacetic acid (TAPHA) was synthesized by the carboxymethylation of 1,2,3-triaminopropane. The acid dissociation scheme of the ligand was studied by means of potentiometric titration, infrared absorption spectroscopy and proton nuclear magnetic resonance spectroscopy. It is found that TAPHA exists as a zwitter ion in aqueous solution, in which protons attach to each nitrogen atom of 1- and 3-carbon, and that the dissociations of first four and the last two steps correspond to the dissociations of carboxylic protons and ammonium protons, respectively. The stepwise proton dissociation constants of the ligand is determined as $pK_1 \approx 2$, $pK_2 = 2.43$, $pK_3 = 3.52$, $pK_4 = 4.30$, $pK_5 = 8.26$ and $pK_6 = 9.88$ ($\mu = 0.1$, 25°C).

Many multidentate complexanes such as EDTA, DTPA (diethylenetriaminepentaacetic acid)[1] and TTHA (triethylenetetraminehexaacetic acid[2]) have been synthesized and the relationships between their structures and chelating behaviors have been discussed in various ways. In our laboratories, our efforts have been focused to the syntheses of multidentate complexanes with a hope of finding the ligands with high metal ion specificity, and some of the results have been published in the previous papers of this series.[3]

This paper is to report on the synthesis of the new ligand, 1,2,3-triaminopropane-*N,N,N',N',N'',N''*-hexaacetic acid (TAPHA), and on the acid dissociation scheme of this ligand. TAPHA has been synthesized in 84% yield from 1,2,3-triaminopropane by the alkaline condensation of three moles of bromoacetic acid per mole of triamine, followed by the repeated carboxymethylation with sodium cyanide and formaldehyde.

Before going into the investigation on the chelating behavior of the ligand, the acid dissociation scheme of TAPHA has been investigated by the conventional potentiometry, the infrared absorption spectroscopy and the proton nuclear magnetic resonance spectroscopy. A microscopic picture of the acid dissociation scheme of this nonadentate hexabasic acid has been establsihed from these results.

During the course of our investigation, a British Patent has been published on the synthesis of TAPHA just after we have succeeded in the synthesis, but no detailed procedure of the synthesis nor detailed chelating behavior of this ligand was available.[4]

Experimental

Synthesis of Ligand. 1,2,3-Triaminopropane-*N,N,N',N',N'',N''*-hexaacetic acid (TAPHA) was synthesized by the carboxymethylation of 1,2,3-triaminopropane.

1,2,3-Triaminopropane (IV).[5] The triamine was synthesized from allyl chloride (I) *via* allylamine (II)[6] and 1-amino-2,3-dibromopropane hydrobromide (III)[7] succesively. The crude triamine was purified by vacuum distillation, bp 89—90°C/15 mmHg. The triamine was identified by the melting point and elementary analysis of tribenzoyl derivative, and IR spectra of free amine. The purity of the triamine determined by the perchloric acid titration in acetic acid, was 97.4%.

TAPHA (VI). The alkaline condensations of chloroacetic acid or bromoacetic acid with triamine (IV) have been tried in various conditions. The reaction

with chloroacetic acid gave no desired product, but gave unidentified partially carboxylated products. The reactions with bromoacetic acid gave TAPHA in very low yield (less than 3.5%). The repeated carboxymethylation of triamine with sodium cyanide and formaldehyde[8] gave also TAPHA, but still in low yield (less than 6.1%). The best result was obtained by the alkaline condensation of three moles of bromoacetic acid with one mole of triamine, followed by the repeated carboxymethylation with sodium cyanide and formaldehyde. The condition of the typical run is as follows.

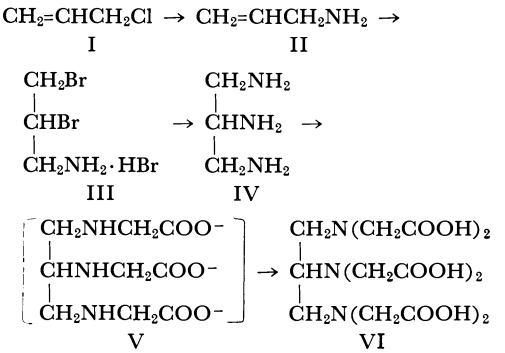

Plate 1

In a 300 m*l* reaction flask, a solution of 94.2 g (1.0 mol) of monochloroacetic acid in 70 m*l* water was neutrized to phenolphthalein with 10 N sodium hydroxide solution below 15°C. To this solution, 17.8 g (0.20 mol) of triamine (IV) was added with stirring, and the mixture was heated to 30—45°C. The pH of the mixture was maintained at 10—11 (red to phenolphthalein) by adding sodium hydroxide solution intermittently. It took 25—35 hr to consume theoretical amount of alkali. After then, another 5 m*l* of 10 N sodium hydroxide solution was added and the reaction mixture was heated at 45°C for an additional hour. In a 500 m*l* three-necked flask fitted with a stirrer, a dropping funnel and a distilling column, the above reaction mixture (V) was placed with 6.8 g of sodium hydroxide and 43.6 g (0.89 mol) of sodium cyanide. To this solution, 70 m*l* of aqueous solution containing 0.10 mol of formaldehyde was dropped continuously with stirring at 25°C for 5 hr. After the addition of formaldehyde, the reaction mixture was distilled at reduced presure below 60°C. After 70 m*l* of distillate was obtained, 100 m*l* of water was added to the residue and the distillation was continued under the same condition until 100 m*l* of water distilled. Then the reaction mixture was cooled to 25°C and another formaldehyde solution was dropped slowly into it. After addition of formaldehyde the distillation was repeated again. This process was repeated for eight times. The total amount of formaldehyde added was 0.80 mol. Finally, the pH of the reaction mixture was adjusted to about 1 with 6 N HCl. After keeping the solution in an refrigerator overnight, the white precipitate was separated by filtration, washed with water and was dried at reduced pressure overnight (55.7 g). An additional amount (20.6 g) of the product was obtained by concentrating the filtrate. Total yield 76.3 g (84% for triamine (IV)). The crude product was purified by repeated recrystallization from hot water. When it was dried in vacuum over phosphorus pentoxide or silica gel at 120°C overnight, monohydrate was obtained as white crystalline powder that was slightly soluble in cold water and decomposed at 233.5—230°C.

Found: C, 39.85; H, 5.51; N, 9.16%; mol wt, 458 (Neut. equiv.). Calcd for $C_{15}H_{25}O_{12}N_3 \cdot H_2O$: C, 39.56; H, 5.53; N, 9.23%; mol wt, 455.

Measurement of Infrared Absorption Spectra. The spectra were recorded with a Nippon Bunko Model DS 301 double-beam spectrophotometer equipped with sodium chloride optics. The spectra of free ligand as well as its sodium salts were studied in solid phase by Nujol mull method (Fig. 1). The spectra were also measured in a deuterium oxide solution as a function of pD using a cell with calcium fluoride windows. The p*d* of the solution was adjusted by adding sodium deuteroxide solution which was prepared by dissolving metallic sodium in deuterium oxide. Three characteristic absorption bands of 1720, 1625—1630, 1590 cm^{-1} were assigned to $=NCH_2COOH$, $=N^+HCH_2COO^-$, $=NCH_2COO^-$ respectively,[9] and their spectra at various pD values are reproduced in Fig. 2.

Measurements of Proton Nuclear Magnetic Resonance Spectra. The spectra were studied as a function of pH with a Varian A-60 high resolution spectrometer equipped with a 60 Mc oscillator. *t*-Butylalcohol was used as an internal reference (τ= 8.78 ppm). The pH of the aqueous solution was adjusted by the careful addition of 5 N nitric acid to 1 m*l* of 0.5 M TAPHA stock solution (pH≒12), which was prepared by dissolving free acid in aqueous potassium hydroxide solution. The pH of sample solutions was measured with a Hitachi-Horiba Model P pH meter equiped with a micro glass electrode.

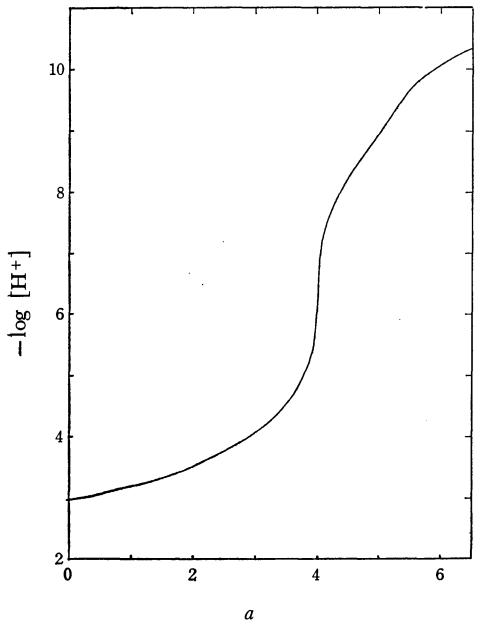

Fig. 3. pH titration curve of TAPHA (5×10^{-4} M) at 25°C in 0.1 M KNO_3.

Measurements of Acid Dissociation Constant. The same apparatus as described in our previous paper was employed.[3] The measurements were carried out at 25±0.1°C in aqueous solution of ionic strength μ=0.1 with KNO_3. For the determination of acid dissociation constant, a 200 m*l* of 5—6×10^{-4} M solution of the ligand was titrated with carbonate free 1×10^{-1} N potassium hydroxide solution. The pH meter was a Hitachi-Horiba Model P and was calibrated under a constant ionic stregnth (0.1) by refering to hydrogen ion concentration calculated from the acetic acid - potassium hydroxide system. A typical result of the titration is shown in Fig. 3.

Calculation of Acid Dissociation Constants

It is seen from Fig. 3 that the dissociations of first four steps are clearly separated from the last two steps. Thus, the calculation of dissociation constants of first four steps and last two steps can be conducted separately.

In general, when the successive acid dissociation constants of *m*-basic acid are defined by Eq. (1), these constants can be calculated from a set of *m* equations as expressed by Eq. (2) using *m* numbers of data of a pH titration curve.[10]

$$\left.\begin{aligned} K_1 &= [H][H_{m-1}L]/[H_mL] \\ K_2 &= [H][H_{m-2}L]/[H_{m-1}L] \\ &\vdots \\ K_m &= [H][L]/[HL] \end{aligned}\right\} \quad (1)$$

$$(1-n_i)[H]_i/K_m + (2-n_i)[H]_i^2/K_mK_{m-1} + \cdots + (m-n_i)[H]_i^m/K_mK_{m-1}\cdots K_1 - n_i = 0 \quad (2)$$

where

$$n_i = m - a_i + ([OH]_i - [H]_i)/L_t \quad (3)$$

and a_t and L_t represent the moles of alkali added per mole of ligand at *i*th datum in a pH titration curve and total concentration of ligand respectively. In this paper, the equation for solving Eq. (2) is expressed as the matrixes of Eqs. (4) and (5) and the calculation were carried out at the Computation Center of Kyushu University with a program of Gauss-Jorden method.

$$\begin{vmatrix} J_{11} & J_{12} & J_{13} & J_{14} & n_1 \\ J_{21} & J_{22} & J_{23} & J_{24} & n_2 \\ J_{31} & J_{32} & J_{33} & J_{34} & n_3 \\ J_{41} & J_{42} & J_{43} & J_{44} & n_4 \end{vmatrix} \qquad a_i \leqq 4 \quad (4)$$

$$\begin{vmatrix} J_{11} & J_{12} & n_1 \\ J_{21} & J_{22} & n_2 \end{vmatrix} \qquad 4 < a_i \leqq 6 \quad (5)$$

in which, elements of the matrixes are expressed by Eqs. (3) and (6).

TTHA	2.42	2.95	4.16	6.16	9.40	10.19	2b

TMDTA: Trimethylenediaminetetraacetic acid
DTPA: Diethylenetriaminepentaacetic acid
TTHA: Triethylenetetraaminehexaacetic acid

$$J_{ij} = (j-n_i)[H]^i \quad (6)$$

For Eq. (4), $m=4$; $i, j=1, 2, 3, 4$

For Eq. (5), $m=6$; $i, j=1, 2$

The results are shown in Table 1 along with those of other complexanes of related structure.

Results and Discussion

As shown in Fig. 3, there is a marked pH jump at $a=4$, so it is expected that the nature of the acid dissociation of the first four steps are quite different from those of the last two steps, and that TAPHA exists as zwitter ion in aqueous solution. If one compares the acid dissociation constants of TAPHA with those of the other complexanes (Table 1), it is clear that the first four and the last two steps correspond to the dissociations of the carboxylic protons and ammonium protons respectively.

This view is also confirmed from the pD dependence of infrared absorption spectra of TAPHA in deuterium oxide solution. The characteristic absorption bands of TAPHA in deuterium oxide solution over a range of 1800—1300 cm^{-1} are reproduced in Fig. 2. Three bands at 1720, 1630—1625 and 1590 cm^{-1} can reasonably be assigned to $\bar{\nu}_{C=O}$ of $=NCH_2COOH$, $=\overset{+}{N}HCH_2COO^-$ and $=NCH_2COO^-$ groups respectively.[9] In the pD region which corresponds to the pH region on the titration curve at $a>4$, a weak band at 1720 cm^{-1} disappeared completely, indicating the dissociation of carboxylic proton. It was also noticed that a strong band at 1630 cm^{-1} increased in its intensity with an increase of pD, indicating the deprotonation from ammonium nitrogens at higher pH region. Because of the poor solubility of TAPHA in water at low pH region, the dissociation in acidic solution could not be followed by the solution spectra. However, these results show that the acid dissociations of the first four steps correspond to those of carboxylic protons and the last two dissociation steps are related with the deprotonation from ammonium groups.

Thus, it may be concluded that, in aqueous solution, TAPHA takes a zwitter ion structure, in which only two of three basic nitrogens exist as protonated state. Then, we can write two possible structures for TAPHA, the one having two α-ammonium carboxylate groups at 1- and 2-positions (VIIb) and the other having two α-ammonium carboxylate groups at 1- and 3-positions (VIIa). These two structures resemble with EDTA and TMDTA (trimethylenediaminetetraacetic acid) respectively with regard to their relative positions of protonated nitrogen atom.

Now, it has been known that $\Delta pK_{4-3}(=pK_4-pK_3)$ of TMDTA (2.36)[11] is smaller than that of EDTA (4.07),[12] while the pK_4 values being about the same. This indicates that the dissociation of third step, which is a deprotonation from one of two protonated nitrogen atoms, occurs more easily in EDTA than in TMDTA. This effect can be explained by the electrostatic repulsion between protons on two positive nitrogens, which are closer in EDTA, receiving stronger repulsive force between them. The similar effect has been also observed for trimethylenediamine (1,3-diaminopropane) and 1, 2-diaminopropane. ΔpK_{2-1} for trimethylenediamine (1.76)[13] is smaller than that of 1,2-diaminopropane (2.87).[14] If one compares these values with ΔpK_{6-5} of TAPHA which corresponds to ΔpK_{4-3} of EDTA or TMDTA, and ΔpK_{2-1} of the diamines, the value for TAPHA (1.62) is rather closer to those of TMDTA and trimethylenediamine than those of EDTA and 1,2-diaminopropane. This result may suggest that TAPHA will take the structure VIIa rather than VIIb.

A more direct confirmation on the zwitter ion structure of TAPHA in aqueous solution was undertaken by the proton nuclear magnetic spectroscopy. The pH dependence of chemical shift

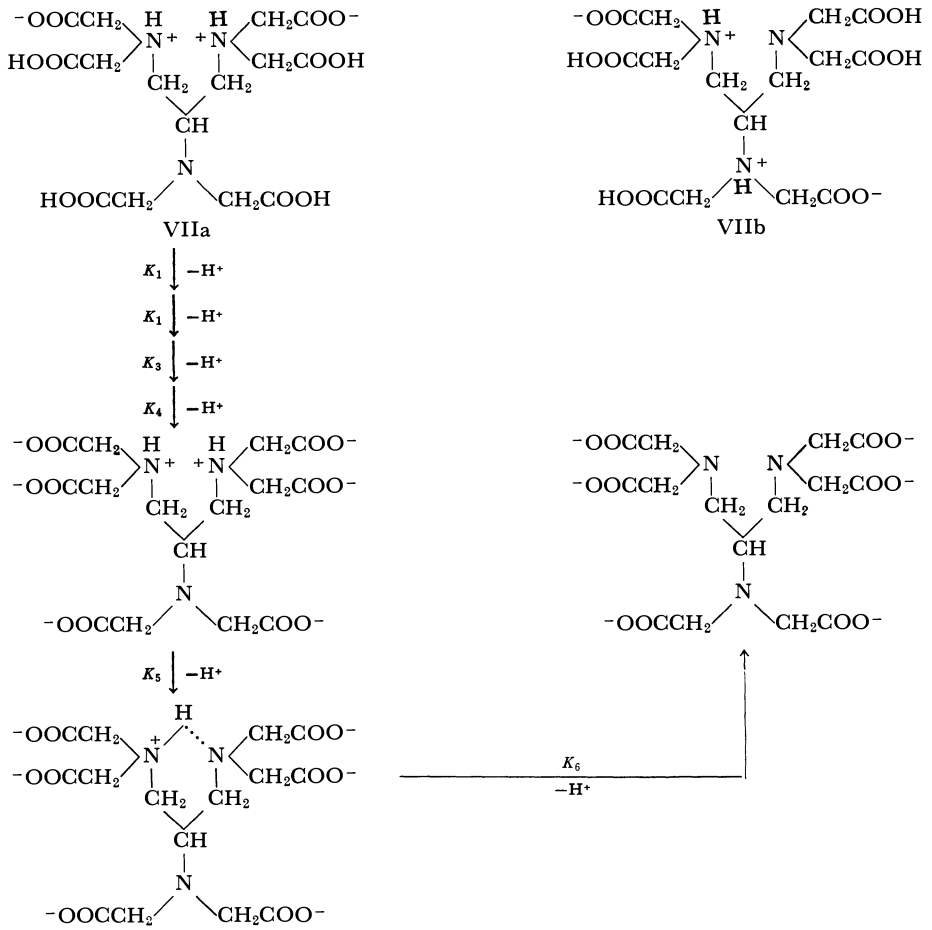

Plate 2

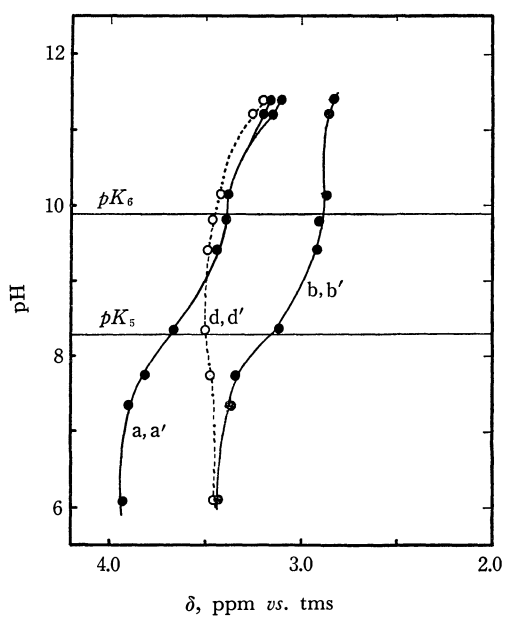

Fig. 4. Chemical shifts of TAPHA at various pH values.

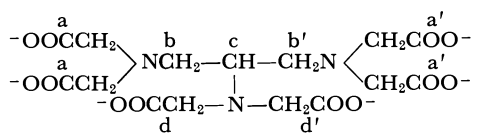
(δ) of TAPHA is shown in Fig. 4. The spectra were assigned by refering to the data of various complexanes which were reported by Reilley *et al.*[15]



As TAPHA is not soluble enough in water at pH lower than 6, the deprotonation process from carboxyl groups could not be followed. The assignment of methyne proton (–CH–) at c-position was also difficult because the corresponding peak was too weak to be distinguished from noise at the concentration level investigated.

As shown in Fig. 4, the peak of methylenic protons at a, a′ and b, b′ position shift markedly over the pH range of 8—10. On the other hand, a very slight shift was observed for the peak of d, d′ methylenic protons. As it is expected that the chemical shifts of a(a′), b(b′) and d(d′)

15) J. L. Sudmeier and C. N. Reilley, *Anal. Chem.*, **36**, 1698 (1964).

methylenic protons are mainly influenced by protonation to its neighboring basic nitrogen atom or carboxylate ion, a most reasonable conclusion is that, when the pH of solution increased from 8 to 10, the deprotonation occures on the nitrogen atoms attached to 1- and 3-carbons. It is also expected from the NMR spectra that TAPHA takes VIIa structure, since the peaks of a- and a'-protons could not be differentiated and no splitting was observed on this peak. If TAPHA would take VIIb structure, which is no longer symmetric with regard to 2-carbon, the peaks due to a, a' and d, d' protons probably split each other.

In view of above facts, the most reasonable scheme of the acid dissociation of TAPHA may be expressed as shown in Plate 2.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 843—849 (1968)

Copper Catalyzed Oxidation of As(III) by Peroxydisulphate

A. P. BHARGAVA and Y. K. GUPTA

Department of Chemistry, University of Rajasthan, Jaipur, India

(Received May 17, 1967)

A kinetic study of the oxidation of As(III) by peroxydisulphate catalyzed by Cu(II) has been made. The rate has been measured by estimating As(III) by the permanganate. The data follow the rate expression,

$$-\frac{d[As(III)]}{dt} = \frac{k'[Cu(II)]^{1/2}[S_2O_8^{2-}][As(III)]}{1 + K_2[As(III)]}$$

A chain mechanism has been suggested in which the decomposition of peroxydisulphate is the chain initiating step. Cu(II) and As(III) participate in the chain propagating steps. Allyl acetate and Mn(II) inhibit the reaction. The mechanism also involves a complex formation between Cu(I) and As(III) with an equilibrium constant, K_2, having a value of about 1475 M^{-1} at 35°C. Energy and entropy of activation have been found to be 24190 calories and +10.46 e. u. respectively.

Universality of Ag^+ as a catalyst in peroxydisulphate oxidations is very well known[1] and there is probably no species of lower oxidation state which the higher valent silver so formed can not oxidise. If there is no reducing substance, the medium itself, whether it is water, alcohol, dioxane or any other solvent, is oxidised.[2,3] The use of copper(II) as a catalyst, however, is limited to a particular type of reactions. The catalysed reactions reported so far are those of thiosulphate,[4-6] oxalate,[7,8] 2-propanol[9] and hydrogen peroxide.[10] Some catalytic activity of Cu(II) has also been found in the persulphate oxidations of phenylacetic and aliphatic acids.[11]

Gupta and Ghosh[12] found that Cu(II) catalyses the oxidation of As(III) by persulphate, and based on this catalytic activity, there appeared a paper[13] on the determination of As(III). Recently Woods and coworkers[14] have investigated the kinetics of this oxidation. This study is mainly based on the assumption of As(IV) as an intermediate and that Cu(II) is reduced to Cu(I) which is subsequently oxidised back to Cu(II) by peroxydisulphate. This mechanism is more or less similar to the one adopted by Morgan[5] in the oxidation of thiosulphate. Another mechanistic view involving the

transient formation of Cu(III) is held by Ben-Zvi and Allen[8] and Srivastava[7,10] in the oxidation of oxalate and hydrogen peroxide. Ball and coworkers[9] on the other hand assume the formation of both Cu(III) and Cu(I) to explain their results. In view of two differing views, though not opposed, it appeared to us that the problem is still worth investigation. Some work on As(III) in this laboratory was done three years back and it was therefore, thought worthwhile to begin an investigation with As(III). In fact the investigation has been extended to the oxidation of other related compounds also and the results will appear in subsequent papers.

Experimental

Potassium sulphate, copper sulphate, arsenious oxide and all other chemicals used were of B. D. H. Analar or E. Merck G. R. quality. Stock solutions of 0.1 M arsenious acid was prepared by dissolving the requisite amount of arsenious trioxide, sufficient to give a little more than 0.1 M acid, in boiling water. After cooling it was filtered and standardised against standard permanganate solution.[15] It was found and as reported[12,16] earlier that the results were reproducible within 5% only when the same stock solution of arsenious acid was used and that the rate constants changed within a factor of ten if different solutions of arsenious acid were used. Hence wherever the results have been compared the same stock solution has been used. No definite reason could be assigned for this behaviour but it appeared that some impurity to which the reaction is very much susceptible, enters into the solution of As(III) or the distilled water while it is being prepared and the amount of this impurity is always changing. However, this explanation has to be accepted with slight reservation because this type of behaviour in peroxydisulphate oxidations is reported only in a few cases *e. g.* oxalate,[17] thiosulphate[4] and arsenious acid.[12,16]

Apart from the impurities, peroxydisulphate oxidations are susceptible to a small extent to the nature of the glass vessel and hence all the vessels and apparatus used were of pyrex glass. The medium was redistilled water, the second distillation being done, in presence of permanganate. Peroxydisulphate solution was always freshly prepared and its concentration checked, by Eckardt's[18] or arsenite[19] method.

All the reactions have been carried out at 35°C unless otherwise mentioned, in a thermostat and peroxydisulphate was always added at the end. There was no reaction between copper sulphate and arsenious acid or precipitation in acid solutions of the concentration employed. Ten millilitres of the reaction mixture were pipetted out at suitable intervals of time, and the concentration of the unreacted arsenious acid was determined by titration against a standard permanganate solution. Peroxydisulphate or copper sulphate did not interfere with the titration. The reaction was completely checked by inhibiting chloride ions.[29] All solutions were prepared in freshly boiled and cooled double distilled water from day to day except that of As(III). The reaction rates are different in presence and absence of oxygen as reported by Woods and coworkers.[14] A few experiments were carried out in an atmosphere of nitrogen and the rate was found to be slightly faster than the situation when reactions are carried out in boiled and cooled distilled water as stated above, but the rates were quite different if the solutions are air or oxygen saturated. Bacon[11] has reported large induction periods in peroxydisulphate polymerisation reactions in oxygen saturated solutions. Inhibiting action of air is much less than that of oxygen. The importance of absence or presence of oxygen or air becomes much less in presence of a reducing substance. In no case we could observe an induction period even though the solutions were not completely free of air.

A literature survey reveals that air does not readily oxidise As(III) in acid solution[21] even in presence of Cu(I) or Cu(II) which have been regarded as catalysts.[22,23] These oxidations take place only in alkaline medium. In view of the fact that the nature of the reaction in ordinary solutions is not different than in nitrogen saturated systems, we thought it convenient to work in air atmosphere. Another reason which led us to do so was the fact that the results were less reproducible in case when nitrogen gas was flushed through the reaction mixture, probably because nitrogen gas itself brings some impurities with it.

Results and Discussion

The reaction is first order with respect to peroxydisulphate and some of these first order plots are

shown in Fig. 1. The order with respect to reducing substance, aresenite is not zero, as found in the other silver catalyzed oxidations *i.e.* of Mn(II),[24] hydrazine,[25] Ce(III),[26] Cr(III),[27] Tl(I),[2] *etc.* and for the concentrations employed in the investigation, is found to be 0.17 by van't Hoff's differential method. A plot of the reciprocal of the observed rate constant *vs.* reciprocal of the arsenite concentration gives a straight line not passing through the origin (Fig. 2). The rate has one half order dependence on the concentration of the catalyst, $CuSO_4$ (Fig. 3). The rate law, therefore, should be of the form,

$$-\frac{d[As(III)]}{dt}=\frac{[Cu^{2+}]^{1/2}[S_2O_8^{2-}][As(III)]}{1+K_2[As(III)]}$$

For the same concentration of Cu^{2+} and high As(III), the rate law assumes the form:

$$-\frac{d[As(III)]}{dt}=k'[S_2O_8^{2-}]$$

with k' as the observed first order rate constant. However, whether k' will have uniformly the same values or not would depend on the relative magnitudes of 1 and K_2[As(III)]. K_2 has a value of 1475 (as will be found later) and, therefore, for concentrations of As(III), 1×10^{-2} M and above, 1 may be neglected in comparison to the term K_2[As(III)] and for constant concentration of [Cu(II)], the rate will be first order with respect to $[S_2O_8^{2-}]$. For low concentrations of As(III) such as 1×10^{-4} M or less the second term of the denominator may be neglected and the order with respect to As(III) would be one. The combined total order for As(III) and $[S_2O_8^{2-}]$ would be two. If, however, $[S_2O_8^{2-}]$ is in excess over that of [As(III)], the reaction would be of pseudo first order. Such low concentrations of [As(III)] could not be employed because of the difficulty in its determination. However, for concentrations of 1×10^{-3} or 5×10^{-4} M of As(III), we do find this tendency to give pseudo first order straight lines with respect to As(III).

The first order plots with respect to peroxydisulphate for As(III) concentration 1×10^{-3} to 7.5×10^{-3} M deviate from the straight line relationship towards the end of the reaction, but the tendency becomes less and less as the concentration of As(III) is increased and we have good first order plots for 7.5×10^{-3} M concentration or above (Fig. 1). For concentrations, 2×10^{-3}, 3×10^{-3} and 5×10^{-3} M, *etc.* of As(III), good half order plots with respect to As(III) are also obtained, but for 1×10^{-3} or 5×10^{-4} M a tendency for first order reaction is indicated. These half order plots and the tendency of some of them indicating first order reaction are shown in Fig. 4. Woods and coworkers[14] have also reported the order of 1/2 for $1—2\times10^{-3}$ M As(III). They did not investigate a wider range of concentration and hence failed to notice the rate being a complex function of As(III) concentration.

Effect of Ionic Strength. The ionic strength was changed by varying the concentration of sodium perchlorate at constant $HClO_4$ concentration. A plot of log k' *vs.* $\sqrt{\mu}$ gives a straight line with a slope of -1.18. Although this would

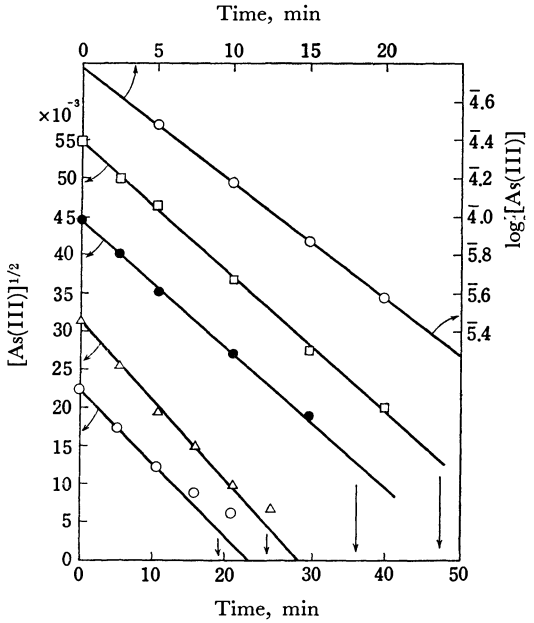

Fig. 4. $[S_2O_8^{2-}]=0.02$ N; $[NaClO_4]=0.2$ M; $[HClO_4]=0.2$ M; $[CuSO_4]=1\times10^{-4}$ M; half order plots ○, 5×10^{-4} N [As(III)]; △, 1×10^{-3} N [As(III)]; ●, 2×10^{-3} N [As(III)]; □, 3×10^{-3} N [As(III)]; first order plot ○, 5×10^{-4} N [As(III)].

indicate a slow reaction step involving ions of unit opposite charge,[28] the reaction is quite complicated (the rate determining step being preceded by a number of steps) to draw any such conclusion, particularly when the ionic strengths are not in the range in which Debye-Hückel theory is applicable.

Effect of Hydrogen Ions. The concentration of hydrogen ions was varied with the help of perchloric acid at almost constant ionic strength (0.2 M $NaClO_4$). The rate slightly decreases by increasing the concentration of perchloric acid as shown in Table 1.

TABLE 1

$[As(III)]=1\times10^{-2}$ M; $[S_2O_8^{2-}]=1\times10^{-2}$ M; $[CuSO_4]=1\times10^{-4}$ M; $[NaClO_4]=2\times10^{-1}$ M

$[HClO_4]$, M×10⁻²	0	0.5	1	2	4
$k'\times10^2$ min⁻¹	1.996	1.90	1.81	1.675	1.37

Increase in the concentration of perchloric acid involves a small increase in the ionic strength also but the change in the rate constant is not much. It, therefore, appears that the effect of hydrogen ion concentration reaches a limiting value. This would happen if arsenious acid which is almost unionised, is involved in an equilibrium like

$$H_3AsO_3 \rightleftarrows H_2AsO_3^- + H^+ .$$

28) A. A. Frost and R. G. Pearson, *Kinetics and Mechanism*, **1961**, 151.

All reactions were, therefore, studied in a high concentration *e. g.* 0.2 M $HClO_4$ where small changes in $[H^+]$ would be without any effect. Similarly ionic strength was kept constant by adding 0.2 M $NaClO_4$. Table 2 brings out the fact that the effect of perchloric acid in higher concentration range is equivalent to that of decrease in ionic strength. The concentrations of perchlorate and perchloric acid have been changed so that the ionic strength does not change. It was found that the rate constants also are reasonably constant.

TABLE 2

$[As(III)]=1\times10^{-2}$ M; $[S_2O_8^{2-}]=1\times10^{-2}$ M; $[CuSO_4]=1\times10^{-4}$ M

$[NaClO_4]$, M×10	1	1.5	2	2.5	3	3.5
$[HClO_4]$, M×10	3	2.5	2	1.5	1	0.5
$k'\times10^3$ min⁻¹	7.16	7.05	8.06	7.37	7.78	8.05

At low concentrations of perchloric acid the first order plots deviated a lot from the straight line towards the end of the reaction, but this tendency decreased as the concentration of perchloric acid was increased. No such tendency was noticed if the concentration of perchloric acid is 0.1 M and above. This behaviour is in some way connected with the different forms of As(III) in which it can exist in solution.

Effect of Reaction Products. Bisulphate and As(V) are the products of the reaction, but they do not seem to affect the rate (Table 3).

TABLE 3

$[As(III)]=1\times10^{-2}$ M; $[S_2O_8^{2-}]=1\times10^{-2}$ M; $[CuSO_4]=1\times10^{-4}$ M; $[HClO_4]=2\times10^{-1}$ M; $[NaClO_4]=2\times10^{-1}$ M

$NaHSO_4$, M×10²	0.5	1	2	5	10
$k'\times10^3$ min⁻¹	5.25	5.29	5.18	5.08	5.11

Similarly added disodium hydrogen arsenate (5×10^{-3}, 1×10^{-2} and 2×10^{-2} M) had absolutely no effect on the rate. The rate determining step is, therefore, not a mass law term.

Energy and Entropy of Activation. Table 4 gives the rate constants at different temperatures.

A plot of log k' *vs.* $1/T$ gives a straight line from the slope of which the energy of activation was calculated and found to be 24190 calories. The entropy of activation was found to be +10.46 e.u.

Effect of Manganous Ions. Mn(II) has been found to be an anticatalyst in the silver catalysed peroxydisulphate oxidations of oxalate,[29] formate,[30] As(III),[16] citrate,[31] tartrate,[31] malonate[31] and also in the uncatalysed oxidation of As(III).[20] This behaviour of Mn(II) is also found in the present reaction. Table 5 gives the rate constants for different concentrations of manganous sulphate.

It is observed that as the concentration of Mn(II) is increased, the rate constants appreciably decrease. For 100×10^{-3} M Mn(II), the rate constant has the value which is comparable to that of the rate constant for the decomposition of peroxydisulphate which at 35°C calculated from the data of Kolthoff and Miller,[32] is 5.49×10^{-5} min^{-1}. It is thus found that Mn(II) acts in such a way that it checks all the steps of the catalysed reaction and only thermal decomposition of peroxydisulphate can take place. Incidentally here we come across the main difference between the silver catalysed reactions[31] and this copper catalysed reaction. In the former case the rate approaches a limiting value (0.3—0.5 min^{-1}) as the concentration of Mn(II) is increased. This points to a two term rate law in case of Ag(I) catalysed reactions. One of them is a non-chain process and the other is a chain mechanism which is altogether stopped in presence of sufficient concentration of Mn(II). In case of copper(II) catalysed reaction which as we shall see, is a chain reaction, the catalytic activity of Cu(II) is completely masked by the presence of sufficient Mn(II).

Allyl Acetate Inhibition. A few reactions were studied in presence of allyl acetate to see whether the reaction is a chain process or not. As the permanganate reacts with allyl acetate, the reaction could not be followed by estimating the arsenite with permanganate. In all such experiments alcoholic iodine was used to estimate the arsenite iodometrically. Preliminary work in connection with such titrations, showed that peroxydisulphate and allyl acetate do not interfere. Following the kinetics in this way the rate constant was found to be 1.56×10^{-2} min^{-1} (with 0.2 M $NaClO_4$ and no $HClO_4$) which is reasonably of the same order of magnitude as the value (1.99×10^{-2} min^{-1}) obtained by the permangnate method under almost similar conditions.

Rate inhibition by allyl acetate is very well known.[8,33] It has been shown by Kolthoff and coworkers[34] that allyl acetate is a highly efficient captor of sulphate radicals. Since peroxydisulphate has been reported to initiate polymerisation of vinyl compounds[35,36] through the sulphate ion radical,[37] it seems reasonable that the allyl acetate reacts with sulphate ion radical and its presence is confirmed by the incorporation of ^{35}S from ^{35}S labelled peroxydisulphate into polymer chains. The very marked inhibition in the present investigation by allyl acetate is indicative of a chain reaction involving sulphate free radicals. In presence of 0.5 or 0.2 M allyl acetate, there is almost no change in the concentration of As(III) even after 150 min. The rate constant in presence of 0.1 M allyl acetate is 3.58×10^{-5} min^{-1}. This rate is even lower than the thermal decomposition[23] of $S_2O_8^{2-}$ according to the following reaction:

$$S_2O_8^{2-} \xrightarrow{k} 2SO_4^-$$
$$(k=5.49\times10^{-5}\ \text{min}^{-1}\ \text{at}\ 35°C)$$

because it is here $-d[As(III)]/dt$ which is being measured and so sulphate ion radicals will be captured by allyl acetate leaving none or few SO_4^- for the oxidation of As(III). If it were possible to estimate peroxydisulphate in such a case, $-d[S_2O_8^{2-}]/dt$ will have a value of 5.49×10^{-5} at 35°C. At higher concentrations of allyl acetate, As(III) is not at all oxidised, but $S_2O_8^{2-}$ will decompose with a rate constant of 5.49×10^{-5} min^{-1}.

It is, therefore, obvious that neither As(III) nor Cu(II) participates in the chain initiating reaction which is the homolytic cleavage of $S_2O_8^{2-}$, but they are definitely involved in chain propagating steps. Allyl acetate cuts off all these chains by taking away the sulphate free radical.

Comparison with Reported Results. The notable point of difference observed in the present investigation and between that in the work of

Woods and coworkers is that the rate is not independent of arsenite concentration at low Cu(II) concentration, although the effect is not much. A two hundred fold change in As(III) concentration (5×10^{-4}—1×10^{-2} M) increases the rate approximately only three times (1.94×10^{-3}—6.33×10^{-3}). The change in k' is so small that the earlier workers failed to notice this. Apart from this, the more important fact is the increase in the order of As(III) as its concentration is lowered in conformity with the linear relationship of Fig. 2. These workers also report a half order dependence on As(III) when the concentration of the latter is approximately 1×10^{-3} M. In spite of the conditions which were by no means identical, under which the two investigations have been made the values of the rate constant (2.25×10^{-3} min^{-1}) found by us compare remarkably well with that of Woods and coworkers[14] (2.7×10^{-3} min^{-1}) both at 25°C.

These workers further report that the rate constant tends to a limiting value at higher concentration of Cu(II) (1×10^{-3} M and more). In our case, though the rate constant at higher [Cu(II)] was less than that expected no limiting value was reached even for 5×10^{-3} M Cu(II). It appears that the reason for the limiting value is the formation of a turbidity of copper arsenite in absence of sufficient hydrogen ions. We did not notice any such limiting tendency because we used higher (0.2 M) concentration of perchloric acid.

Mechanism. Any proposed mechanism must incorporate (a) the first order character in respect of peroxydisulphate (b) half order dependence on Cu(II) concentration (c) variation of order from 0 to 1 with respect to As(III) (d) inhibition by Mn(II) and allyl acetate.

We postulate sulphate ion free radicals and As(IV) as intermediate as was done by Woods and coworkers.[14] Sulphate ion free radicals are now well known to be formed by the thermal and photochemical decomposition of peroxydisulphate.[32,35,38-40] Similarly the intermediate formation of As(IV) now seems to be well founded. Woods and coworkers[41,42] have found it in the induced oxidation of As(III) by $S_2O_8^{2-}$-Fe(II) and Fe(II)-H_2O_2 systems. Daniels and Weiss[43] proposed the production of As(IV) by the reaction of hydroxyl radical with As(III) to occur during the oxidation of arsenite by the action of X-rays. In the photochemically induced oxidation of As(III) also, Daniel[44] concluded the existence of As(IV). Csyani postulated its intermediate formation in the titration[45] of As(III) by $S_2O_8^{2-}$-H_2O_2 mixture and also in the induced induction[46] of chlorate by As(III).

We propose the following mechanism:

$$S_2O_8^{2-} \xrightarrow{k_1} 2SO_4^- \quad (1)$$

$$SO_4^- + \text{As(III)} \xrightarrow{k_2} SO_4^{2-} + \text{As(IV)} \quad (2)$$

$$\text{As(IV)} + \text{Cu(II)} \xrightarrow{k_3} \text{As(V)} + \text{Cu(I)} \quad (3)$$

$$2\text{Cu(I)} \overset{K_1}{\rightleftarrows} \text{Cu}^0 + \text{Cu(II)} \quad (4)$$

$$\text{Cu(I)} + \text{As(III)} \overset{K_2}{\rightleftarrows} [\text{Cu}^{\text{I}}\text{As}^{\text{III}}] \quad (5)$$

$$[\text{Cu}^{\text{I}}\text{As}^{\text{III}}] + S_2O_8^{2-} \xrightarrow{k_4} \text{Cu}^{3+} + \text{As(III)} + 2SO_4^{2-} \quad (6)$$

$$\text{Cu}^{3+} + \text{As(III)} \xrightarrow{k_5} \text{Cu}^+ + \text{As(V)} \quad (7)$$

$$\text{Cu}^0 + S_2O_8^{2-} \xrightarrow{k_6} 2SO_4^{2-} + \text{Cu(II)} \quad (8)$$

$$SO_4^- + \text{As(IV)} \xrightarrow{k_9} SO_4^{2-} + \text{As(V)} \quad (9)$$

If $k_3>k_2$, k_5 and $k_6>k_4$; $k_2[SO_4^-][\text{As(III)}]>k_9[SO_4^-][\text{As(IV)}]$ (because the steady state concentration of SO_4^- and As(IV) both will be small) and K_1 and K_2 are rapid equilibria, the rate of decrease of As(III) is given by the equations,

$$-\frac{d[\text{As(III)}]}{dt} = k_5[\text{As(III)}][\text{Cu}^{3+}] + k_2[SO_4^-][\text{As(III)}]$$

$$= \frac{K_2}{K_1^{1/2}} \frac{k_4[\text{Cu(II)}]^{1/2}[\text{As(III)}]}{1+K_2[\text{As(III)}]} + \frac{k_1}{2}[S_2O_8^{2-}]$$

k_1 is of the order[32] of 1×10^{-5}—10^{-6} min^{-1} and hence can be neglected in comparison to the first term:

$$-\frac{d[\text{As(III)}]}{dt} = \frac{K_2}{K_1^{1/2}} \frac{k_4[\text{Cu(II)}]^{1/2}[\text{As(III)}]}{1+K_2[\text{As(III)}]}[S_2O_8^{2-}]$$

The above expression has the same form as the experimental rate law provided the concentrations of Cu(I), Cu(II) and Cu^0 and also the complex of Cu(I) are very small and the only significant species of copper in solution is Cu(II). Cu(II) is not known to form any complex with arsenite and a spectrophotometric investigation in the range 600—750 mμ also indicated no complex formation. In the above mechanism a complex

formation between Cu(I) and As(III) has been postualted although there is no direct evidence for it. However substituted arsine complex of Cu(I) has been reported by Cass and coworkers.[47] Cu(I) complex of peroxydisulphate itself has been postulated by Chaltkyan and Beileryan[48] in the oxidation of Cu(I) by persulphate, and a complex of Cu(I) and thiosulphate by Morgan[5] in the oxidation of the latter by peroxydisulphate. The existence of tripositive copper is now beyond doubt, though the knowledge about it is limited. Sneed, Maynard and Brasted[49] report quite a few complex compounds of Cu(III) and Latimer[50] has given its approximate oxidation potential. Of particular mention in this study is the fact that a series of complex salts containing tripositive copper has been prepared by peroxydisulphate oxidation.[51] The disproportionation reaction of cuprous ion (step 4) postulated to explain half order dependence on Cu(II) is well known in aqueous solution.[52,53] The equilibrium constant for the reaction (4) is 1.2×10^6 and thus the concentration of Cu (I) or Cu(I) complex is very small. The oxidation of zerovalent copper to cupric ion (step 8) is also known.[54]

From the intercept (=205) and the slope (=0.139) of the straight line in Fig. 2, the value of K_2, the equilibrium constant for the complex formation (step 5) of the mechanism is found to be approximately 1475. With this value of K_2, it can now be easily understood that 1 can be neglected as compared to K_2[As(III)] in the denominator of the above rate expression. This would give a zero order dependence on As(III). For sufficiently low concentrations of As(III) (10^{-4} M or less), K_2[As(III)] can be neglected as compared to one, giving first order dependence on As(III). It has already been mentioned earlier about this tendency. From the interecept which is equal to $K_1^{1/2}/K_4$[Cu(II)]$^{1/2}$, the approximate value of k_4 can be calculated, provided we know K_1 at 35°C. Its value at 25°C (1.2×10^6) is known from the works of Fenwick[52] and Heinerith[53], but we have no straight line at 25°C corresponding to Fig. 2. However, the intercept for a corresponding straight line plot at 25°C would be within a factor of two or three and this would give a value of approximately 150 to 270 for k_4.

We have assumed the following chain terminating step in the mechanism.

$$SO_4^- + As(IV) \rightarrow SO_4^{2-} + As(V) \quad (9)$$

The other probable chain breaking steps,

$$Cu(I) + SO_4^- \rightarrow Cu(II) + SO_4^{2+} \quad (10)$$

$$Cu(I) + Cu(III) \rightarrow 2Cu(II) \quad (11)$$

have not been considered important because the increase in the concentration of Cu(II), produces an almost expected increase in the rate (Fig. 3), though at higher concentrations of Cu(II) than those employed, these chain breaking steps are likely to become important.

In presence of Mn(II), SO_4^- oxidises it to Mn(III) and the latter oxidises As(III) instantaneously. Thus no chains are initiated and the rate decreases considerably. Allyl acetate also takes away the sulphate ion radical but it does not oxidise As(III) at all and hence in presence of its sufficient concentration, no decrease in concentration of As(III) would be found. Peroxydisulphate, however, would decrease at the same rate as that of its thermal decomposition.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 850—854 (1968)

Distribution of Some Minor Elements in Sulfide Ores from the Hitachi Mine, Ibaraki Prefecture, Japan

Shuichi HAMADA, Ryuji SATO and Toshiaki SHIRAI

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received July 14, 1967)

The contents of some minor elements in copper-bearing ores from the Fujimi ore deposit No 5, the Hitachi mine, were determined. The selenium content in 46 samples was found to vary from 0.5 to 117 ppm. Though selenium seems to be concentrated in the ores rich in chalcopyrite, that is not always the case, as there are pyrite-rich ores with higher selenium contents than those rich in chalcopyrite. The average value of the atomic ratio of Se/S in the pyrite ores was calculated to be 3.48×10^{-5}; this value was larger than those found for the ores from the Minenosawa and the Chichibu mines, and about the same as those found for the ores from the Nakase, the Ashio, and the Hanaoka mines. The variations with depth in the atomic ratios of Se/S and Co/Ni are closely related to each other. The atomic ratio of Se/S increased with an increase in that of Co/Ni. It has been concluded that selenium is concentrated in the pyrite ores of the high-temperature-type rather than in those of the low-temperature-type. The mercury content was small in general, but a large content of mercury was observed at the depth where the values of the atomic ratios of Se/S and Co/Ni were at their maxima.

Several papers about the selenium content in sulfide ores have been published.[1-6] For example, Takimoto and Minato compared the selenium content in sulfide ores from several mines in Japan, and discussed the correlation between the selenium contents and the formation temperatures of the ores.

In the present paper, the distribution of such minor elements as selenium, nickel, cobalt, and mercury in the sulfide ores from the Hitachi mine will be reported.

Geology of the Hitachi Mine[7] and Sampling of Ores. Rocks of the paleozoic strata occupy the major part of this region, although igneous rocks lie in the northwestern part, as is shown in Fig. 1. The major part of the paleozoic strata consists of dynamo-metamorphosed greenschist and siliceous schist. Granodiorite intruded upon the paleozoic strata at the northwestern part of this region.

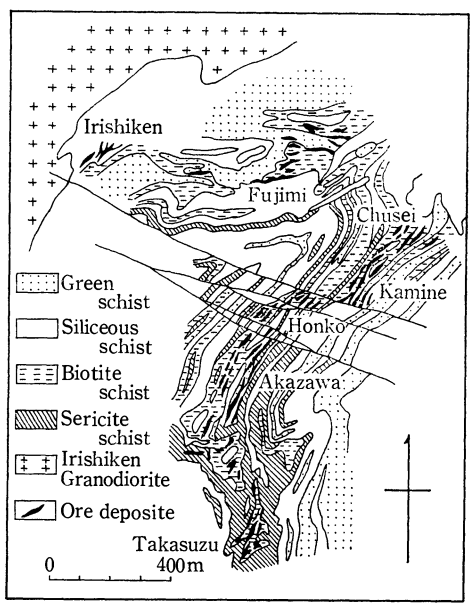

Fig. 1. Geology of Hitachi mine.

The vicinity in contact with this igneous rock suffered thermal metamorphism. The area of the ore deposits is the polymetamorphosed area which suffered both dynamic and thermal metamorphisms.

The ores were obtained from the Fujimi ore deposit No. 5, which suffered a strong thermal metamorphism by the northwestern granodiorite. The samples were obtained at vertical intervals of

fifty or twenty-five meters over the range from 300 ML to 650 ML.*1 The sampling points are shown in Fig. 2. The ores mainly consisted of intimate aggregates of fine crystals of pyrite. Some of these contained chalcopyrite, pyrrhotite, and other materials. The pyrite ore was separated visually from the crushed sample, and the chalcopyrite ore, from the chalcopyrite-rich sample.

Experimental

Determination of Selenium. The selenium content was estimated by the colorimetric method using 3,3'-diaminobenzidine, as has been described in a previous paper.[6]

Determination of Sulfur. The sulfur content was estimated by the combustion method of JIS K 1331.

Determination of Metals. The iron content was estimated as ferric oxide by the usual gravimetric method. The copper content was estimated as cuprous thiocyanate by the gravimetric method for the high-copper-content ore, and by the polarographic method for the low-copper-content ore. The nickel, cobalt, and mercury contents were estimated by the colorimetric method as nickel dimethylglyoximate,[8] as the cobalt complex of Nitroso R salt,[9] and as mercury dithizonate[10-12] respectively.

*1 The symbol "ML (meter level)" is the depth measured from the base level of the Hitachi mine, 350 m above sea level. The symbol "SL (sublevel)" is 25 m above each ML.

Results

The amounts and the atomic ratios of the several elements in the ores are listed in Table 1.

The selenium content in 46 samples was found to range from 0.5 to 117 ppm. The atomic ratio of Se/S in the chalcopyrite-rich ores was larger than that in the chalcopyrite-poor ores when the respective ores were separated from samples obtained at the same point. However, selenium can not be said to be always concentrated in the chalcopyrite-rich ores, because a higher content of selenium was observed in the pyrite-rich ores than in the chalcopyrite-rich ores.

The Contents of Nickel and Cobalt. The nickel content in the pyrite ores was usually about 10—50 ppm. The nickel content was lower than those in the pyrite ores from the Daikoku ore deposit, the Chichibu mine (20—110 ppm, 26 samples), and the Okutomi, the Taisho and the Himi ore deposits, the Tsushu mine (20—100 ppm, 7 samples), and was similar to that from the Kajika ore deposit, the Ashio mine (20—50 ppm, 6 samples).[13]

The cobalt content in the pyrite ores was estimated to range from 0.0 to 654 ppm. Unlike the nickel content in the ores, a wide fluctuation of the cobalt content was observed. The cobalt content in the pyrite ores was larger than in those from the Chichibu and the Tsushu mines (10—200 ppm and 20—150 ppm, respectively), and was quite large compared with that from the Ashio mine (10—30 ppm).

The Mercury Content. The mercury content in the ores was estimated to range from 0.0 to 176 ppm. No correlation could be found between the contents of copper and mercury.

The Relationship between the Depth and the Atomic Ratio of Se/S. The atomic ratio of Se/S in the pyrite ores changed within the range from 4×10^{-7} to 1.10×10^{-4}. The atomic ratio of Se/S in the pyrite ores was correlative with the depth within the range from 300 ML to 650 ML, as is shown in Fig. 3. The atomic ratios of Se/S at 300 ML were quite small, but the ratio increased with an increase in the depth, the maximum appearing at the depth of 450 ML—550 ML.

The Relationship between the Depth and the Atomic Ratio of Co/Ni. Figure 4 shows the relationship between the depth and the atomic ratio of Co/Ni. The values of the atomic ratio of Co/Ni were small at the upper part of the ore deposit, but they increased with an increase in the

depth. The maximum appeared at the depths from 450 ML to 550 ML, as with the atomic ratio of Se/S. Increases in the atomic ratio of Co/Ni with an increase in the depth were observed at the Chichibu mine (within the range of 120 m), the Tsushu mine (within the range of 150 m), and the Ashio mine (within the range of 100 m). The atomic ratio of Se/S in the pyrite ores increased with an increase in that of Co/Ni, as is shown in Fig. 5. The coefficient of the correlation of Fig. 5 is 0.70; therefore, the correlation is significant.

The Relationship between the Depth and the Mercury Content. The mercury content is generally very small, but quite a large content of mercury was observed at the depth of 450 ML—550 ML, in which range the maxima of the atomic ratios of Se/S and Co/Ni appeared, as is shown in Fig. 6.

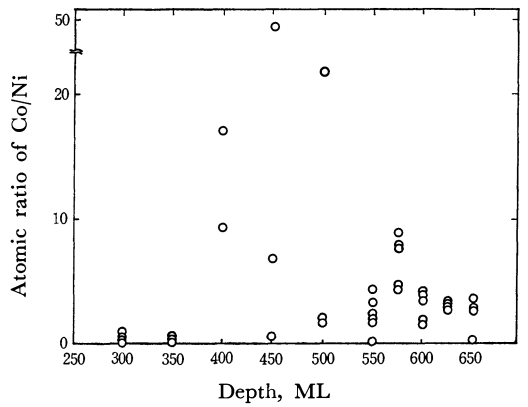

Fig. 4. Plot of atomic ratio of Co/Ni in pyrite ores against depth.

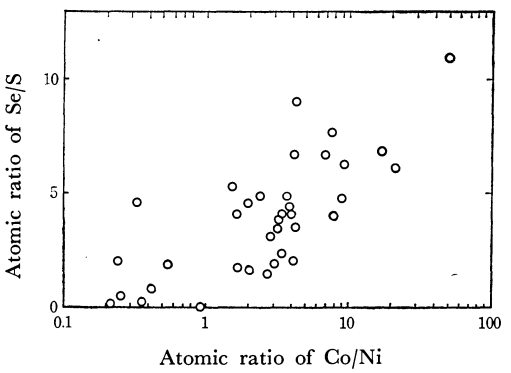

Fig. 5. Plot of atomic ratio of Se/S against atomic ratio of Co/Ni.

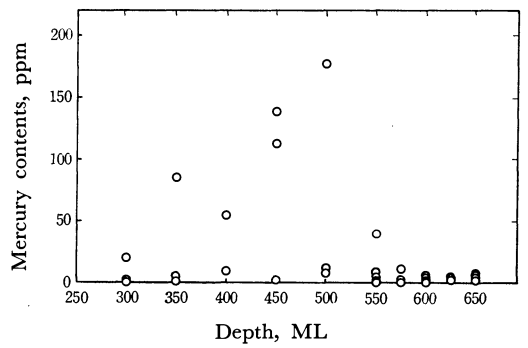

Fig. 6. Plot of mercury content in pyrite ores against depth.

Discussion

The atomic ratios of Se/S and Co/Ni are found to vary with the depth in the same manner at the Fujimi ore deposit No 5. This suggests that a certain correlation between the atomic ratios of Se/S and Co/Ni should exist. Carstens[14] reported that cobalt was concentrated in the pyrite ores of the high-temperature-type rather than in those of the low-temperature-type, and large values of the atomic ratio of Co/Ni were observed when the ore deposits were formed by the hydrothermal process. Hawley[15] described how large values of the atomic ratio of Co/Ni were observed in the pyrite ores of high formation temperatures when several pyrite ores of known formation temperatures were examined. Hegeman[16] stated that the values of the atomic ratio of Co/Ni became larger as the degree of metamorphism rises. The values of the atomic ratio of Co/Ni in the pyrite ores of the high-temperature-type from the lower part of the Daikoku ore deposit, the Chichibu mine, which is of contact-metasomatic origin (2.7—6.5), were larger than those of the low-temperature-type from the upper part of the ore deposit, which is of hydrothermal origin (0.2—1.6).[13] The formation or metamorphism temperatures of the lower part of the Fujimi ore deposit No. 5 were probably higher than those of the upper part, because the vertical distribution of the atomic ratio of Co/Ni showed a dependence on the depth. This is supported by the fact that sphalerite of the low-temperature-type exists in the upper part of the ore body and chalcopyrite of the high-temperature-type, in the lower part. Therefore, it may be considered that selenium is concentrated in the pyrite ores of the high-temperature-type rather than in those of the low-temperature-type; this conclusion agrees with Takimoto's results.[2,5]

Krauskopf[17] reported that mercury in vein fluid was transported as mercuric chloride or as free mercury and free sulfur in a high-temperature gas phase. In both case, merucry should be concentrated in the low-temperature-type ores. Therefore, the vertical distribution of mercury is

contradictory to that of the atomic ratios of Se/S and Co/Ni on the temperature-type of the ores. This discrepancy has not yet been solved, because it is not evident whether the present distributions of selenium, cobalt, and nickel in pyrite ores at the Fujimi ore deposit were formed at the same time with that of mercury or not.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 854—862 (1968)

Metal Complexes with Amino Acid Amides. I. Preparations and Electronic Spectra of the Nickel(II) and Palladium(II) Complexes

Takashi KOMORITA, Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 31, 1967)

Several planar bis(amino-acid-amidato) complexes of nickel(II) and palladium(II) have been newly synthesized and characterized mainly spectroscopically. The geometrical structures of these $[M(N)_4]$-type complexes have been determined: palladium(II) produced both cis and trans complexes with L-alanine- and L-leucine-amidate ligands, while nickel(II) did only trans forms with glycine-, L-alanine- and L-leucine-amidates. Nickel(II) also produced cationic complexes, Ni(L-alanine-amide)$_2SO_4$ and its glycine amide analogue. The circular dichroism spectra and rotatory dispersion of the complexes containing optically active amino acid amide have been measured and discussed as for the assignments of the ligand field absorption bands of the diamagnetic planar complexes. A good correspondence was observed between the circular dichroism spectra of the nickel(II) and the palladium(II) complexes.

A number of reports[1-3] have been presented for the electronic structures of the tetracoordinated planar complexes with d^8 electron configuration. It seems, however, that the attempts have been less successfully carried out, partly because of the rather simple feature of the ligand field bands of these complexes and partly because of the lack of favorable series of complexes suitable to systematic studies. In these circumstances, it is thought of as desirable to study the circular dichroism (CD) and the rotatory dispersion (RD) of the planar complexes containing optically active ligands.[4,5]

It is well known that the bidentate ligand with amide or amidino groups, such as biuret, biguanide, oxamide or dicyandiamidine, is coordinated planarly to copper(II) or nickel(II) through its two nitrogen atoms;[6,7] an authentic example is the bis(biuretato)-cuprate(II) ion whose structure has been established by X-ray analysis of its potassium salt tetrahydrate.[8] The α-amino acid amide, such as L-alanine amide *etc.*, belongs to the category of ligands above shown and furthermore has one asymmetric carbon atom in the structure. Therefore the complexes of optically active α-amino acid amides will be excellently suitable for CD or RD studies of the planar complexes. Such complexes have not been isolated heretofore, except for a few copper(II) complexes, which have been prepared by Rising and Yang,[9] and Rosenberg.[10]

In the present paper, the preparations of several nickel(II) and palladium(II) complexes with glycine amide, L-alanine amide and L-leucine

amide*[1] are reported, and the electronic absorption and CD spectra of these complexes are discussed in relation to their geometrical structures.

Experimental

Preparation. *1) Glycine Amide, L-Alanine Amide and L-Leucine Amide.* These were derived from the corresponding amino acids by the similar methods described in literature.[11]

2) trans-Bis(glycine-amidato)nickel(II) Monohydrate: trans-[Ni(glya)$_2$]·H$_2$O. To the suspension of 2.43 g of [Ni(NH$_3$)$_6$](ClO$_4$)$_2$ in 20 m*l* of water was added 1.00 g of glycine amide, and the suspension was mechanically stirred for a few minutes. When the solution containing 0.54 g of sodium hydroxide and 5 m*l* of water was dropped into the suspension with stirring, the color of the mixture changed from blue to orange brown. After the mixture was stirred for several minutes and the residue, [Ni(NH$_3$)$_6$](ClO$_4$)$_2$, filtered off, the filtrate was cooled in an ice bath until the desired complex began to crystallize out as orange needles. The crystals obtained were washed with water-methanol mixture (1 : 1) and with methanol and then dried in air.

Found: C, 21.89; H, 5.24; N, 25.21%. Calcd for C$_4$H$_{12}$N$_4$O$_3$Ni: C, 21.56; H, 5.43; N, 25.14%.

An additional crop of the complex was obtained by adding methanol to the mother liquor which was concentrated by evaporation below 35°C. Total yield, 0.7 g.

This complex is soluble in water, but the solution is not very stable. It is slightly soluble in methanol, and insoluble in ethanol, acetone, benzene and chloroform.

In the preparation above, it is also possible to use nickel(II) acetate tetrahydrate instead of [Ni(NH$_3$)$_6$](ClO$_4$)$_2$.

3) trans-Bis(L-alanine-amidato)nickel(II): trans-[Ni(L-alaa)$_2$]. A solution of 0.46 g of sodium hydroxide in 4 m*l* of water was gradually added to a solution containing 1.41 g of nickel(II) acetate tetrahydrate and 1.00 g of L-alanine amide in 7 m*l* of water. After about 60 m*l* of methanol was added to the mixture, the resultant orange solution was filtered. By adding 30 m*l* of methanol and about 300 m*l* of ether to the filtrate, the complex desired was crystallized out as glistening orange plates. The crystals were filtered and washed with methanol-ether mixture and then with ether and dried *in vacuo* over calcium chloride. The complex was recrystallized by adding ether to its methanolic solution. Yield, 0.9 g.

Found: C, 31.26; H, 6.11; N, 24.26%. Calcd for C$_6$H$_{14}$N$_4$O$_2$Ni: C, 30.90; H, 6.06; N, 24.05%.

This complex is soluble in water, but the solution is not very stable. It is soluble in methanol and ethanol, but insoluble in other organic solvents.

4) trans-Bis(L-leucine-amidato)nickel(II): trans-[Ni(L-leua)$_2$]. To a solution containing 0.93 g of purified nickel(II) sulfate heptahydrate in 30 m*l* of water was added a solution of 1.00 g of L-leucine amide in 10 m*l* of water and then the mixture was mechanically stirred. A small fraction of the desired complex already began to deposit in this step. A solution of 0.31 g of sodium hydroxide in 10 m*l* of water was added drop by drop to the mixture with stirring. The orange microplates deposited were filtered out and washed with water, methanol and ether, and then dried *in vacuo* over calcium chloride. The yield was nearly quantitative.

Found: C, 45.10; H, 8.14; N, 17.60%. Calcd for C$_{12}$H$_{26}$N$_4$O$_2$Ni: C, 45.46; H, 8.27; N, 17.67%.

This complex is soluble in methanol, and insoluble in water and ethanol.

5) Bis(glycine-amide)nickel(II) Sulfate Sesquihydrate: Ni(glyaH)$_2$SO$_4$·1.5H$_2$O and Bis(L-alanine-amide)nickel(II) Ni(L-alaaH)$_2$SO$_4$. These complexes were prepared by adding methanol to an aqueous solution of nickel(II) sulfate containing glycine amide or L-alanine amide. After the desired complex began to appear, the resultant mixture was stirred mechanically for a few hours. The blue crystals were soluble in water and insoluble in methanol and ethanol. The complex sulfate with L-alanine amide was very hygroscopic.

Found: C, 14.73, 14.69; H, 4.75, 4.55; N, 16.33, 16.41%. Calcd for Ni(glyaH)$_2$SO$_4$·1.5H$_2$O=C$_4$H$_{15}$N$_4$O$_{7.5}$SNi: C, 14.56; H, 4.58; N, 16.98%.

Found: C, 21.01; H, 4.99; N, 15.18%. Calcd for Ni(alaaH)$_2$SO$_4$=C$_6$H$_{16}$N$_4$O$_6$SNi: C, 21.77; H, 4.87; N, 16.93%.

The elemental analysis data fluctuated slightly, and this may be caused by a partial hydrolysis of the ligands.

An attempt to obtain the complex salt with L-leucine amide was unsuccessful because of the precipitation of insoluble [Ni(L-leua)$_2$].

6) trans-Bis(glycine-amidato)palladium(II): trans-[Pd(glya)$_2$]. Palladium(II) chloride (2.86 g) was dissolved in 130 m*l* of water with stirring and filtered once. By adding a solution of 3.00 g of glycine amide in 20 m*l* of water to the dark brown solution, a light brown precipitate appeared. When an aqueous solution of 1.30 g of sodium hydroxide was dropped into the mixture, the light brown precipitate disappeared. Within several minutes after the dissolution of the precipitate, pale yellow fine needles began to appear. The mixture was mechanically stirred until the crystals did not increase further (about 20 min). The crystals filtered off mainly consisted of the pale yellow needle crystals. The second and third crops of crystals were fractionally obtained from the mother liquor by concentrating it to 10—20 m*l* *in vacuo* at about 30°C. These second and third crops were contaminated by another kind of pale yellow crystals which were prismatic. However, the two kinds of crystals have not been separated as yet. Recrystallization was repeated until the pure *needles* were obtained, by dissolving the crude complex in water and by evaporating the solution *in vacuo* at about 30°C. The needle crystals obtained were washed with cold water and dried *in vacuo* over phosphorus pentoxide. The yield was 1.6 g in total.

Found: C, 19.08; H, 4.16; N, 21.94%. Calcd for C$_4$H$_{10}$N$_4$O$_2$Pd: C, 19.02; H, 3.99; N, 22.19%.

This complex is moderately soluble only in water.

7) trans-Bis(L-alanine-amidato)palladium(II): trans-[Pd(L-alaa)$_2$]. Two grams of palladium(II) chloride was suspended in a solution of 2.00 g of L-alanine amide in 20 m*l* of water, and to this suspension was added a

*1 The following abbreviations are used in this paper: glyaH=glycine amide, alaaH=alanine amide, and leuaH=leucine amide.

11) P. S. Yang and M. M. Rising, *J. Am. Chem. Soc.*, **53**, 3183 (1931); G. Hillmann, *Z. Naturforsch.*, **1**, 682 (1946).

solution containing 0.90 g of sodium hydroxide in 5 m*l* of water with stirring. After the continuous stirring for about 2 hr, the palladium(II) chloride dissolved gradually. The insoluble materials were filtered off and the pale yellow filtrate was concentrated at about 30°C. When a pale yellow microplates began to separate, the mixture was diluted by adding 30 m*l* of ethanol. The whole of them was concentrated to about 10 m*l* by evaporation at about 30°C. The crystals deposited were gathered by filtration and washed with a small amount of ethanol. The mother liquor and the washings were kept for obtaining the cis complex in 8). The crude complex was recrystallized by concentrating its aqueous solution at about 30°C and then by adding methanol and ether to it. Yield, 0.7 g.

Found: C, 26.08; H, 4.96; N, 19.62%. Calcd for $C_6H_{14}N_4O_2Pd$: C, 25.68; H, 5.03; N, 19.97%.

This complex is soluble in water, slightly soluble in methanol and insoluble in ethanol.

8) cis-Bis(L-alanine-amidato)palladium(II) Monohydrate: cis-[Pd(L-alaa)$_2$]·H_2O. The combined mother liquor and washings from 7) was filtered once more. The filtrate was concentrated to half of its original volume under a reduced pressure and a few milliliters of methanol was added to the yellow solution. At this stage, a small amount of *trans*-[Pd(L-alaa)$_2$] and sodium chloride has precipitated. After those were filtered off, the desired complex, which is pale yellow, was formed by adding a large amount of ether to the filtrate. The crude complex obtained was dissolved in a small amount of methanol, and the solution was filtered. An appropriate amount of ether was added to the filtrate, and the vessel was scratched with a glass rod if necessary to obtain crystals. This purification procedure was repeated until a uniform mixture of the pure prisms was obtained. The crystals were washed with ether and dried *in vacuo* over calcium chloride. Yield, 0.6 g.

Found: C, 24.15; H, 5.34; N, 18.73%. Calcd for $C_6H_{16}N_4O_3Pd$: C, 24.13; H, 5.40; N, 18.76%.

This complex is very soluble in water, methanol and slightly soluble in ethanol.

9) trans-Bis(L-leucine-amidato)palladium(II): trans-[Pd(L-leua)$_2$]. Thirty milliliters of aqueous solution containing 1.25 g of potassium tetrachloropalladate(II) was added little by little to the solution of 1.00 g of L-leucine amide in 30 m*l* of water with stirring. A solution of 0.5 g of potassium hydroxide in 10 m*l* of water was added to the solution. The desired complex, pale yellow precipitate, began to deposit soon after. After the mixture was stirred for about 2 hr, the precipitate was filtered off, washed with water three times, and with methanol, and then with ether. This was dried *in vacuo* over calcium chloride. Yield, 0.7 g.

Found: C, 39.55; H, 7.15; N, 15.39%. Calcd for $C_{12}H_{26}N_4O_2Pd$: C, 39.51; H, 7.18; N, 15.36%.

This complex is very sparingly soluble in water, methanol and ethanol.

10) cis-Bis(L-leucine-amidato)palladium(II) Hexahydrate: cis-[Pd(L-leua)$_2$]·$6H_2O$. A mixture of 1.40 g of L-leucine amide in 10 m*l* of water and 0.45 g of sodium hydroxide in 15 m*l* of water were added to the suspension of 1.00 g of palladium(II) chloride in 10 m*l* of water with stirring. Being stirred for about 30 min until it became very pasty, the mixture was diluted with 60 m*l* of water. After the continuous stirring for 1 hr further, a mixed precipitate of cis and trans forms appeared: then it was filtered out (ppt. 1). After the mother liquor was concentrated to about 1/5 volume by evaporation at about 30°C, the solution was kept in a refrigerator overnight. A large amount of pale yellow fine needles (desired cis complex) were separated by filtration (ppt. 2).

The ppt. 1 was suspended in an appropriate amount of ethanol: in this procedure only the cis form dissolved. This extraction was repeated several times. When the combined extracts was kept in a refrigerator overnight, a small amount of trans form was deposited, which was discarded by filtration. The pale yellow filtrate was concentrated under reduced pressure at about 30°C until it became yellow syrup. From this syrup crystallization was started by scratching the vessel with a glass rod. This crude cis complex and the ppt. 2 obtained above were dissolved in an appropriate amount of methanol-water mixture (10 : 1). By concentrating the solution to 15 m*l* at about 30°C, a very small amount of the trans complex was deposited and then filtered off. Pure crystals of cis complex were obtained by concentrating the yellow filtrate to about 5 m*l*. The crystals, elongated rectangular plates, were gathered and washed with a little of ice water three times and dried in a desiccator over calcium chloride.

Found: C, 29.82; H, 8.03; N, 11.85%. Calcd for $C_{12}H_{38}N_4O_8Pd$: C, 30.48; H, 8.10; N, 11.85%.

The crystal form of the final product was different from that of ppt. 2, but the infrared absorption (IR) spectra of these two kinds of crystals agreed well with each other (in NaCl region) except for the bands due to crystalline water.

This complex is soluble in water, methanol and ethanol. It was noted that the cis forms of [Pd(L-alaa)$_2$] and [Pd(L-leua)$_2$] are more soluble in water and in alcohols than the corresponding trans forms.

Measurements. The following instruments were employed for the measurements: for the visible and ultraviolet absorption spectra, a Beckman DU spectrophotometer; for the diffuse reflectance spectra, a Hitachi EPU-2A spectrophotometer (in visible region) and a Hitachi EPS-3T recording spectrophotometer (in ultraviolet region); for the CD spectra, a Roussel-Jouan dichrographe; for the RD curves, a Yanagimoto recording spectropolarimeter Model-185; for the IR absorption spectra, a Model DS-402G infrared spectrophotometer of Japan Spectroscopic Co. (700—4000 cm^{-1}) and a Hitachi EPI-2 spectrophotometer (1300—1500 cm^{-1}); and finally for the nuclear magnetic resonance (NMR) spectra, a Japan Electron Optics JNM 3H-60 spectrometer using tetramethylsilane as an internal reference. All the measurements were made at room temperature.

Results and Discussion

1) Palladium(II) Complexes. The five palladium complexes obtained are classified into two groups, (A) and (B), on the basis of their absorption and diffuse reflectance spectra; (A) group consists of [Pd(glya)$_2$], [Pd(L-alaa)$_2$] and [Pd(L-leua)$_2$], and (B) group [Pd(L-alaa)$_2$]·H_2O and [Pd(L-leua)$_2$]·$6H_2O$. The spectral behavior of the complexes is the same in each group, but is

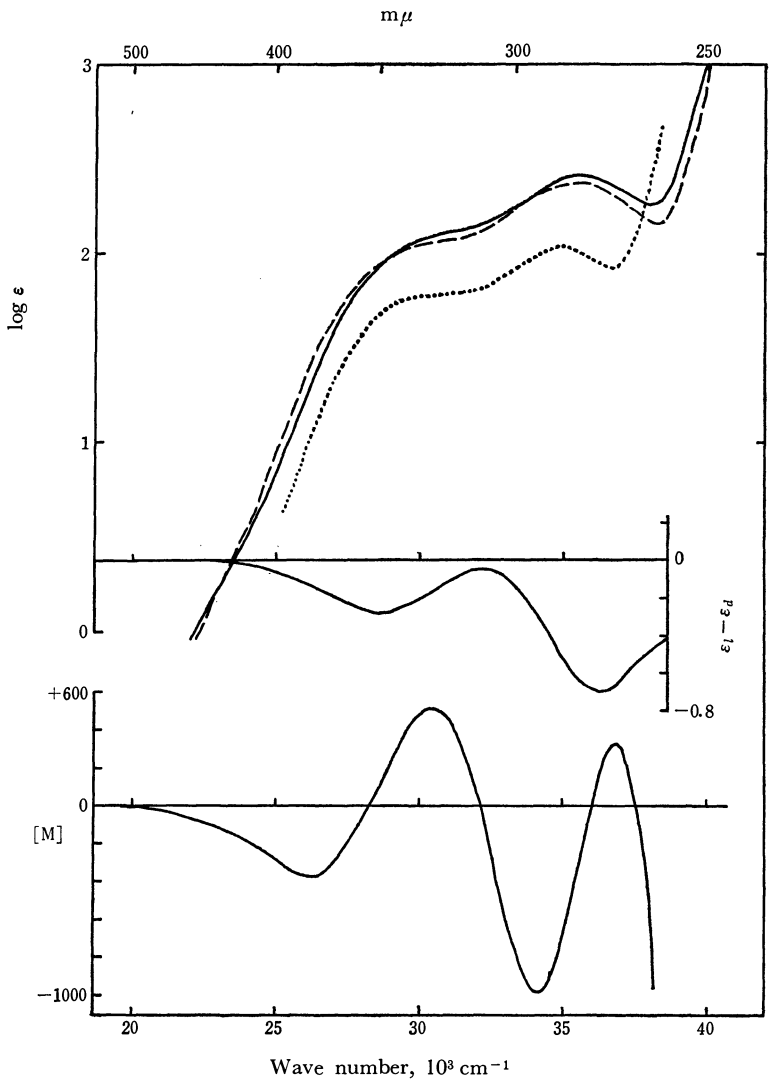

Fig. 1. Absorption and CD spectra, and RD of *trans*-[Pd(amino-acid-amidate)$_2$].
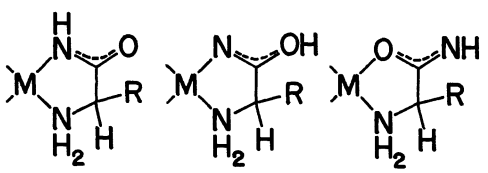
—— L-alaa complex in water; ---- glya complex in water; and ····· L-leua complex in the solid state.

remarkably different from that of the other group, as can be seen in Table 1 and Figs. 1—3.

The NMR spectra of (A) group's [Pd(L-alaa)$_2$] and of (B) group's [Pd(L-alaa)$_2$]·H_2O, in deuterium oxide, show only one kind of sharp doublet line due to the methyl protons of the ligands; τ-value of the former is 8.29 and that of the latter 8.16. This fact confirms, together with the results of the elemental analyses, that two coordinated alanine amidate ligands are not hydrolyzed. The IR spectra also support this conclusion (Table 2).

From these facts, it was concluded that the groups, (A) and (B), represent a couple of geometrical isomers, *i. e.*, cis and trans isomers concerning the two amino groups.

It may be expected that double bond character of the amidate's C–N bond is rich for the coordination type II or III in comparison with the type I.



I II III

In IR spectra of the complexes (Table 2), very intense C–O stretching bands are observed at about 1600 cm^{-1} for both groups of complexes, (A) and (B). This behavior did not contradict[7] the theory that these palladium(II) complexes have structure I. A similar behavior of the amidate's C=O

stretching bands has been reported in several current papers, for example, for bis(biuretato)-cuprate(II),[12] bis(oxamidato)-cuprate(II) and -nickelate(II) complexes,[7] and bis(glycine-amidato)- and bis(L-leucine-amidato)-copper(II) complexes.[10]

Now, considering the absorption spectra, we find those of (B) group's complexes are quite similar to that of tetramminepalladium(II) ion,[13] as shown in Figs. 2 and 3. From the point of view of ligand field theory, it may be concluded that the complexes belonging to (B) group are cis form of the structure I, since the effective field symmetry is approximately D_{4h} in these cis complexes even by considering a moderate π-interaction between the metal d-orbitals and the ligand π-orbitals.

Another support for the geometrical structures can be furnished by comparing their absorption spectra with those of the [Pd(Cl)$_2$(N)$_2$]-type complexes of known geometrical structures. A trans complex, [Pd(Cl)$_2$(1-phenylethylamine)$_2$], has been reported[4] to show two "spin-allowed" ligand field bands at about 25500 and 30000 cm^{-1}, while a cis(N)-type complex, [Pd(Cl)$_2$(1-pn)], shows[5] a broad band at 26200 cm^{-1} with a weak shoulder at the lower wave number side. The comparison of these data with the spectra in Figs. 1—3 clearly shows that (A) group is trans and (B) group cis.

The solution absorption spectra of *trans*-[Pd(glya)$_2$] and *trans*-[Pd(L-alaa)$_2$] are quite similar to those in their solid states (Table 1). It may be concluded that the structures of these complexes in solution and in solid state are not very different each other. This conclusion may also be supported by the two cis complexes, though their absorption spectra slightly depended upon the solvents used (Figs. 2 and 3).

It seems likely that the σ-lone pair electrons of an amidate nitrogen alone do not give effects to the electronic structure of the complex much different from those of an amino nitrogen. Consequently, to explain the significant difference between the absorption spectra of cis and trans forms, it is necessary to consider π-interactions between the palladium 4d- and the ligand π-orbitals through metal-amidate linkages. By an inspection of the orbital overlaps, it is expected that the most sensitive one to this kind of π-interaction is the d_{xz}- or d_{yz}-orbital. If the antibonding effects are predominant, only the d_{xz}-orbital will be strongly instabilized in trans form, while both the d_{xz} and d_{yz} will be moderately instabilized in cis form. The d_{yz}-orbital of the trans form will be nearly non-interacted. Accordingly, the energy order, $\nu_4 > \nu_3' \sim \nu_4' > \nu_3$, is expected.*2 Thus the band at about 30000 (CD, 28700) cm^{-1} in *trans*-[Pd(L-alaa)$_2$] may be assigned to ν_3 while the band at about 34500 (CD, 36000) cm^{-1} in the cis form and one at 35500 (CD, 36400) cm^{-1} in the trans form to (ν_3', ν_4') and ν_4' respectively (Figs. 1 and 2).

The *cis*-[Pd(L-leua)$_2$] has two CD components at about 31300 and 36000 cm^{-1} corresponding to one broad ordinary absorption band at 24800 cm^{-1}. The component at 36000 cm^{-1} is considered to be a combined peak of ν_3' and ν_4' corresponding to 36000 cm^{-1} band of *cis*-[Pd(L-alaa)$_2$]. Therefore the CD component at 31300 cm^{-1} should be another component, ν_1' or ν_2', whose absorption component is also included in the lower wave number side of the broad absorption band at 34800 cm^{-1}. In the CD spectra of *cis*- and *trans*-[Pd(L-alaa)$_2$], the band at about 31000 cm^{-1} did not appear clearly, but it seems likely that a positive CD band is canceled out almost completely by the strong negative CD bands. These bands at about 31000 cm^{-1} may be ν_1 and ν_1', or ν_2 and ν_2'. Theoretically,[1-3] it is expected that the order is $\nu_1 > \nu_2$, and $\nu_1' > \nu_2'$. But the absorption and CD bands at the region lower than 27000 cm^{-1} in the cis complexes and the CD tail in lower wave numbers of the trans complex may be assigned to "spin-forbidden" ligand field transitions, judging from their band intensities. Also a theoretical consideration expects that the Cotton effect in

*2 ν_1, ν_2, ν_3 and ν_4 mean transitions $(z^2)\rightarrow(x^2-y^2)$, $(xy)\rightarrow(x^2-y^2)$, $(xz)\rightarrow(x^2-y^2)$ and $(yz)\rightarrow(x^2-y^2)$ in trans form respectively, and ν_i' ($i=1-4$) means corresponding transition in cis form. Here, (k) means a molecular orbital composed mainly of d_k-orbital. Coordinate systems adopted for cis and trans forms are different, as in Ref. 1.

transitions ν_1 and ν_1' are forbidden under an appropriate approximation.*3 Therefore the present CD measurements suggest that the bands at about 31000 cm^{-1} are ν_2 and ν_2' and the transitions ν_1 and ν_1' are located in the region of higher wave numbers.

The ordering of d-levels assumed above (Table 3) agrees essentially with that proposed recently for tetrachloropalladate(II) ion.[3]

2) Bis(amino-acid-amidato)nickel(II) Complexes. The diffuse reflectance spectra of the three neutral nickel(II) complexes in their solid states are very similar to those of the diamagnetic planar [Ni(N)$_4$]-type complexes,[6,14] as may be seen in Fig. 4 and Table 1. Their IR spectra (Table 2 and Fig. 5) indicate that also the structure I is suitable to these complexes by the similar

*3 Pure d-orbitals can not produce magnetic moment for transitions ν_1 and ν_1' without configuration interaction.

reason for the palladium(II) complexes. Moreover, the IR spectra of the nickel(II) complexes show good correspondence to those of the trans palladium(II) complexes throughout NaCl region (700—4000 cm^{-1}). In Fig. 5 amidate's C–N stretching and C–H bending bands are shown; these kinds of bands have been believed to be less sensitive to the hydrogen bonding in crystal lattices. For instance, the spectra of [Ni(glya)$_2$]·H_2O and *trans*-[Pd(glya)$_2$] are very similar to each other in the region, 1300—1500 cm^{-1}. It may be concluded, therefore, that the remarkable difference between the IR spectra of the cis and the trans palladium(II) complexes in 1300—1500 cm^{-1} region should not be assigned to the difference due to the waters of hydration, but to the difference of geometrical configurations of the complexes. These observations strongly suggest that the three nickel(II) complexes concerned are the trans forms. It was confirmed, from the absorption data of Fig. 4 and in Table 1, that these trans structures were retained in their solutions also.

The band assignments of these nickel(II) complexes may be in parallel with those for the trans palladium(II) complexes. Thus the CD extrema of [Ni(L-alaa)$_2$], 18700, 20800 and 24100 cm^{-1},

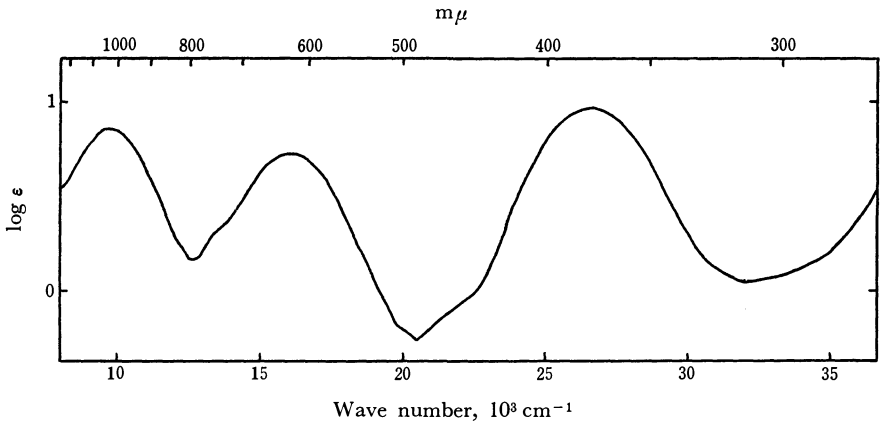

Fig. 6. Absorption spectrum of $Ni(glyaH)_2SO_4 \cdot 1.5H_2O$ in water.

are assigned to transitions ν_3, ν_2 and ν_4 respectively. It is most probable that the ν_2 band is hidden at about 21000 cm^{-1} in the CD spectrum of [Ni(L-leua)$_2$], since this complex should have an electronic structure which is not so different from that of [Ni(L-alaa)$_2$]. The rotatory strength of the band, which is assigned to ν_2 or ν_2', is strongly dependent upon the terminal alkyl groups of the ligands in both nickel(II) and palladium(II) complexes.

3) Bis(amino-acid-amide)nickel(II) Complexes. From the absorption spectra given in Table 1 and Fig. 6, it was inferred[15] that these two cationic complexes have approximately octahedral configurations, with spin triplet ground states, in the solutions and in the solid states. This hexacoordinated configuration will become possible by the coordination of sulfate ions or water molecules besides the amino acid amide ligands.

The structures of nickel(II) complexes with various amino acids[16,17] or with picoline amide,[18,19] which belong to $[Ni(N)_2(O)_4]$-type, have been studied previously, and it has been known that most of those complexes are of trans(N) structures. The absorption spectra of $Ni(glyaH)_2SO_4$ and $Ni(L\text{-}alaaH)_2SO_4$ in water (Table 1 and Fig. 6) are very similar to those of bis(glycinato)nickel(II) dihydrate[20] and of bis(picoline-amide)nickel(II) chloride dihydrate,[18] the structures of which have been determined by X-ray analyses.[16,19] In conclusion, it may be said that an oxygen of amide and an amino nitrogen are coordinated to nickel(II) in the blue complexes with glycine amide and with L-alanine amide.

It will be worthwhile to note that picoline amide, as amino acid amides, also produces a diamagnetic nickel(II) complex, bis(picoline-amidato)nickel(II) dihydrate,[18] the planar $[Ni(N)_4]$-structure of which has also been established by an X-ray analysis.[21]

The authors express their sincere thanks to Assistant Professor Tetsuo Shiba and Mr. Shuji Futakawa of Osaka University for their helpful suggestions about the preparations of amino acid amides. The authors wish to thank also Assistant Professor Fukiko Yamada of Kansai University for her measurements and discussion of the NMR spectra. Their thanks are also due to Dr. Seiko Komorita of Osaka University for her continuing interest.

Spectroscopic Studies of Mixed Amine Carbonyl Complexes of d^6 Structure. II. Solvent Effect on the Ultraviolet and Visible Absorption Spectra of Diamine-tetracarbonyl Complexes of Chromium(0), Molybdenum(0) and Tungsten(0)

Hide SAITO, Junnosuke FUJITA and Kazuo SAITO

Chemistry Department, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received August 11, 1967)

Absorption bands, especially metal to amine charge transfer bands of bipyridyl- and phenanthroline-tetracarbonyl chromium(0), molybdenum(0) and tungsten(0) are shifted in various solvents by less than 4500 cm^{-1}. The shift is discussed in accordance with McRae's equation, which was derived with the point-dipole approximation. The solvents can be classified into two groups, the alcohol and the ester group. When three constants corresponding to (1) the interaction between induced dipoles of the solute and of the solvent, (2) the interaction between permanent dipole of the solute and induced dipole of the solvent, and (3) the interaction between permanent dipoles of the solute and of the solvent, are duely chosen for the two groups of solvent individually, the experimental values are satisfactorily accounted for. Short range interactions, such as hydrogen bonding can be ignored.

Many studies have been made of the solvent effect (frequency shift) on visible and ultraviolet absorption spectra of π-conjugate organic compounds, and theoretical interpretation on the basis of simple electrostatic model, among them, seems quite successful.[1-5] On the other hand, little information is available concerning the solvent effect on absorption spectra of coordination compounds. Nakamoto *et al.* studied the absorption spectra of tervalent chromium and cobalt complexes in water, methanol and acetic acid.[6] The *d-d* transition bands exhibited red shift by less than 200 cm^{-1} and the extent increased in the order given. The intraligand transition bands, however, did not always give such a shift with a definite tendency. Alderdice[7] reported that the charge transfer band ($M\rightarrow\pi^*_{CO}$(1)C.T.)*1 of hexacarbonyltungsten(0) showed small blue shift in water and cyclohexane. Behrens and Harder[8] described that bisbipyridyl- and bisphenanthrolinedicarbonyl molybdenum(0) and tungsten(0) changed their colors according to the solvent and temperature.

We have found that several absorption bands of diamine-tetracarbonyl complexes of chromium(0), molybdenum(0) and tungsten(0) are shifted in various solvents. Especially the shift of the metal to diamine transition bands in the visible region is remarkable, *e.g.* shift by 3800 to 4500 cm^{-1} in acetonitrile and cyclohexane. In this paper the frequency shift of absorption bands of diamine-tetracarbonyl complexes of chromium(0), molybdenum(0) and tungsten(0) has been described and discussed on the basis of McRae's equation for solvent effect, which was derived with the point-dipole approximation.

Experimental

Preparation of the compounds was described elsewhere.[9] The solvents were carefully purified by the usual methods from commercial extra pure grade products. The absorption spectra were measured with Hitachi EPS-3 Automatic Recording Spectrophotometer at 20 to 25°C, with a slow scanning speed, (6 min 700—340 mμ, 360—210 mμ) and 1 cm quartz cells. Sparingly soluble compounds in *e.g.* cyclohexane, *n*-butyl ether and carbon tetrachloride were measured with 2, 5 or 10 cm quartz cells. The solution was filtered through a glass filter of G4 texture, whenever necessary.

Results

The absorption curves are shown in Figs. 1 to 5 and the numerical data for the bands showing distinct shifts are summarized in Tables 1 to 4. The constancy of integrated intensities and the small change in shapes of the absorption band indicate that no substantial change occurs in the complexes themselves. The tungsten(0) compound $[W(CO)_4en]^0$ decomposed rapidly and its spectrum was not measured.

The bands generally show blue shifts to various extents according to the dielectric constant of solvents, and it appears reasonable to classify the solvents into two groups, the alcohol (solvents Nos. 1 to 7 in Tables 1 to 4) and the ester group (Nos. 8 to 13), because the correlation seems better within one particular group.

Application of McRae's Equation I. McRae[2] gave a theoretical equation for solvent effects on absorption spectra. His theory is based on a simple electrostatic model in which the solvent-solute interaction is only long-range dipole interaction. (Onsager's approximation) The equation in a simplified form[4] is as follows:

$$\tilde{\nu} = \tilde{\nu}_{gas} + (A + B)\frac{n^2 - 1}{2n^2 + 1} + C\left(\frac{D - 1}{D + 2} - \frac{n^2 - 1}{n^2 + 2}\right) \quad (1)$$

where $\tilde{\nu}$ is the wave number of bands in a given solution, and D and n are static dielectric constant, and refractive index of the solvent, respectively.

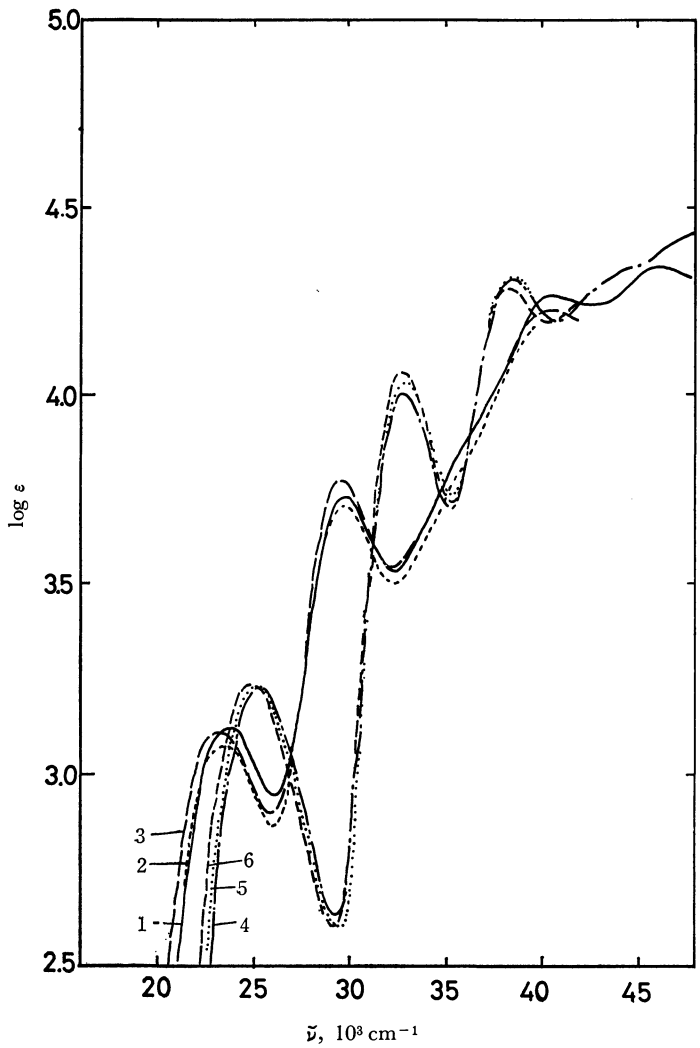

Fig. 1. Absorption spectra of ethylenediamine-tetracarbonyl chromium(0) and molybdenum(0) in some solvents:
$[Cr(CO)_4en]$ 1 —— in methanol, 2 ---- in methylacetate, 3 —— —— in *p*-dioxane;
$[Mo(CO)_4en]$ 4 — — — in methanol, 5 ····· in methylacetate, 6 — — in *p*-dioxane.

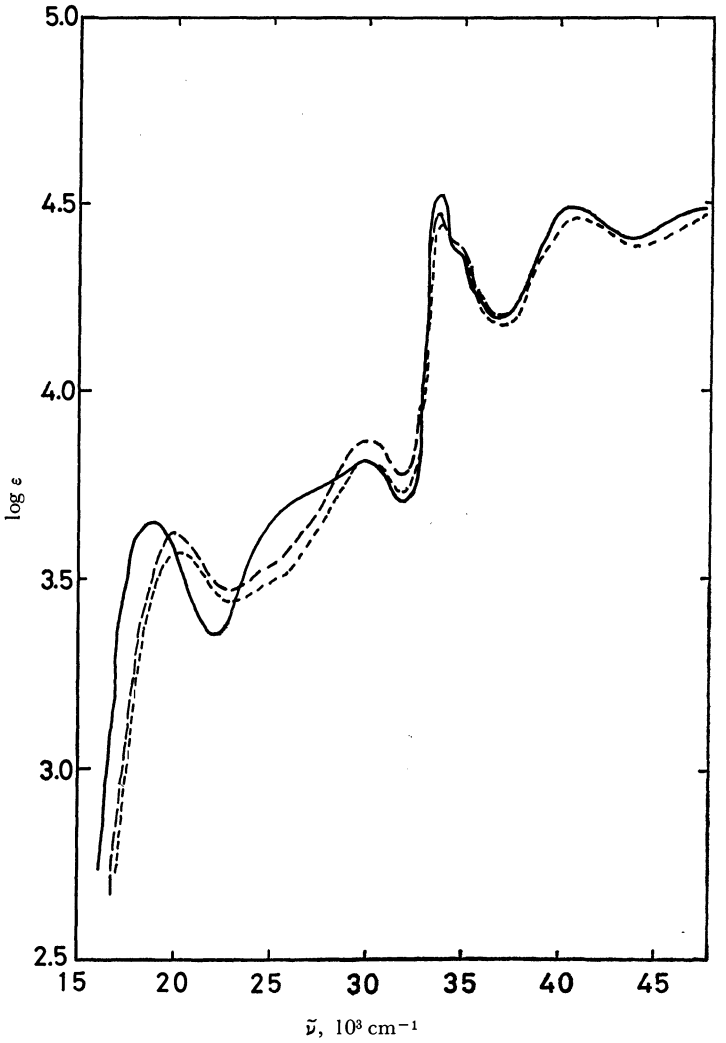

Fig. 2. Absorption spectra of bipyridyl-tetracarbonyl chromium(0) in some solvents: ---- in methanol, — — in methylacetate, —— in ethylether.

$\tilde{\nu}_{gas}$ denotes the wave number of bands of the compound in "vapor state," which is not subject to solvent effect. The term $A\cdot(n^2-1)/(2n^2+1)$ represents the induced dipole-induced dipole interaction (dispersion force). The term $B\cdot(n^2-1)/(2n^2+1)$ indicates the interaction between permanent dipole of the solute and induced dipole of the solvent (induced force). The last term shows interaction between permanent dipoles of the solute and the solvent (orientation force). Equation (1) ignores any short range interaction including hydrogen bonding, π-π interaction and short range dipole interaction, as if the cavity radius, a, of Onsager's approximation were equal in all solvents in an ideal case. The equation also excludes the interaction between permanent dipole of the solvent and induced dipole of the solute.

McRae gave different values to the "weighted mean wavelength" L_0, which is expressed by $A=-2.14\times10^{-14}\, fL_0/\tilde{\nu}a^3$ as the first approximation (f, integrated intensity, a, cavity radius) and involves the influence of all transitions of both solvent and solute. However, this value L_0 was assumed to be constant by several workers[3,4] and we have applied Eq. (1) to the M→π^*_{AA}C.T. bands of diamine-tetracarbonyl chromium(0) complexes, assuming that L_0 is constant for all solvents. The cavity radius, a, is also assumed to be constant. The constants n and D were taken from Landolt-Börnstein's tables. The values for n are those for Na-D line at 20°C and those of D at 20°C. The constants, $\tilde{\nu}_{gas}$, $(A+B)$ and C in Eq. (1) were determined by the least square method for the solvents Nos. 1 to 13 in Table 5. Then the expected wave number $\tilde{\nu}_{calcd}$ obtained from these values, should coincide with the observed value $\tilde{\nu}_{obs}$ if the shifts

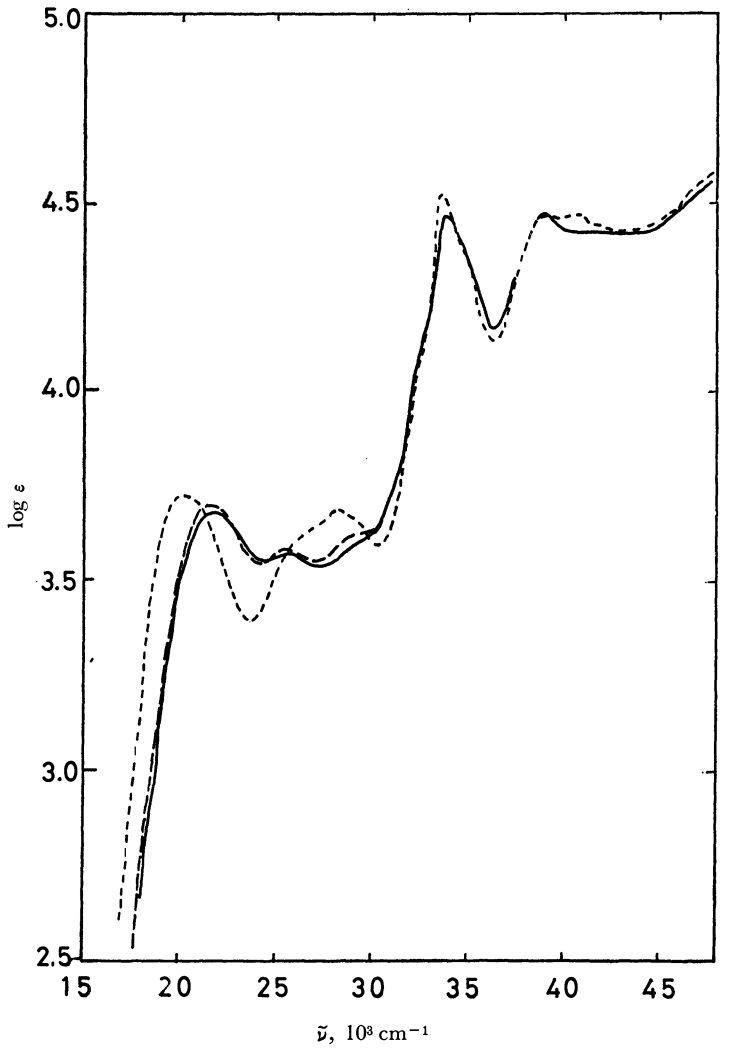

Fig 3. Absorption spectra of bipyridyl-tetracarbonyl molybdenum(0) in some solvents: —— in methanol, — — in methylacetate, - - - - in ethylether.

were accounted for by Eq. (1). The results are listed in Table 5 (analysis 1). The difference in wave number between the calculated and the observed, $\tilde{\nu}_{\text{calcd}}-\tilde{\nu}_{\text{obs}}$ amounts to 200 to 700 cm^{-1} (5 to 20 mμ), and it appears as if Eq. (1) cannot be applied to the present bands in its original form.

Application of McRae's Equation II. The difference $\tilde{\nu}_{\text{calcd}}-\tilde{\nu}_{\text{obs}}$ is, however, always positive for the alcohols, and always negative for the esters. Such a tendency suggests that different factors are operating in each solvent. The $\tilde{\nu}_{\text{gas}}$ of a given compound should be always the same, but A, B, and C can represent the terms operating differently according to the kind of solvent. These values are generally expressed as A', B' and C' henceforth and particular terms operating in the given solvent groups as A_a, B_a, C_a and A_e, B_e, and C_e, for the alcohol and the ester group, respectively. Thus Eq. (1) is modified as Eq. (2).

$$\tilde{\nu} = \tilde{\nu}_{\text{gas}} + (A' + B')\left(\frac{n^2-1}{2n^2+1}\right) + C'\left(\frac{D-1}{D+2} - \frac{n^2-1}{n^2+2}\right) \qquad (2)$$

The results for M$\rightarrow\pi^*_{\text{AA}}$(C. T. band of bipyridyl- and phenanthroline-tetracarbonyl chromium(0) are shown in Table 5 (analysis 2). The difference $|\tilde{\nu}_{\text{calcd}}-\tilde{\nu}_{\text{obs}}|$ in the alcohol and in the ester group are less than 60 and 100 cm^{-1}, respectively. All the $|\tilde{\nu}_{\text{calcd}}-\tilde{\nu}_{\text{obs}}|$ values obtained by this treatment for metal to amine charge transfer bands are less than 120 cm^{-1} (3 mμ) for molybdenum(0) complexes and less than 140 cm^{-1} (3.5 mμ) for tungsten(0) complexes. The reliability of the values $\tilde{\nu}_{\text{gas}}$ (A_a+B_a), (A_e+B_e), C_a and C_e is 80

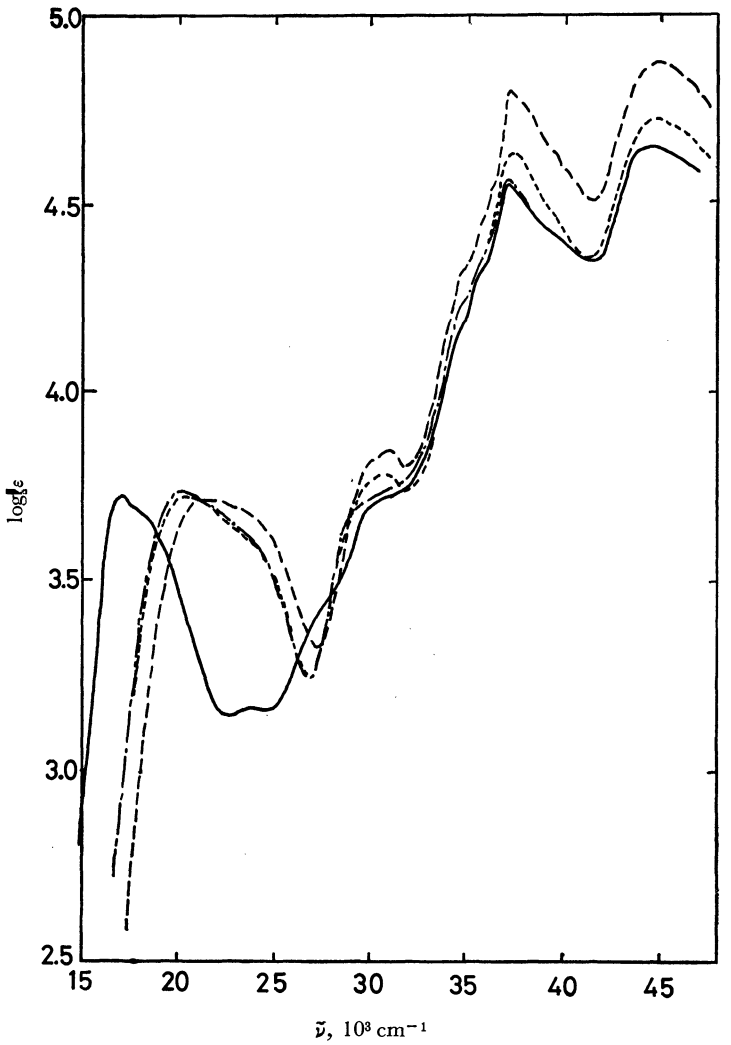

Fig. 4. Absorption spectra of phenanthroline-tetracarbonyl chromium(0) in some solvents: —— in cyclohexane, ---- in methanol, — - — in methylacetate, — — in acetonitrile (arbitrary scale intensity).

to 110 cm^{-1}. These constants are summarized in Table 7 and their meanings will be discussed in the following.

There would be no big difference among the physical properties of diamine-tetracarbonyl complexes with varying metals and amines except for the molecular radii, so that the interaction between a given solvent and a complex molecule would be very similar. Hence the difference in wave number of absorption maximum between any two complexes in a given solvent would be almost constant and equal to that in "vapor state." In Table 6 the mean differences in wave number among complexes in both groups of solvents and in "vapor state" are listed. They coincide well with one another.

The changes in values $A'+B'$, and C' in different solvent groups have similar trend for complexes with different central metals. The C_e value is always larger than the C_a but the difference is less than 30% relative corresponding to a shift less than 530 cm^{-1}. The absolute value for (A_a+B_a) is always larger than the (A_e+B_e), but the difference is even smaller (less than 15% relative).

Thus Eq. (2) seems to be applicable to the metal to amine charge transfer bands. The *d-d* transition, metal to carbonyl charge transfer ($M\rightarrow\pi^*_{CO}$[1] C. T.) and intraligand transition bands are shifted to a smaller extent in various solvents, but calculation has disclosed that Eq. (2) is more appropriately applied to all these bands than Eq. (1) is. The values $|\tilde{\nu}_{calcd}-\tilde{\nu}_{obs}|$ are less than 70, 100 and 50 cm^{-1}, for the *d-d* transition, the intra ligand transition and the metal to carbonyl charge transfer

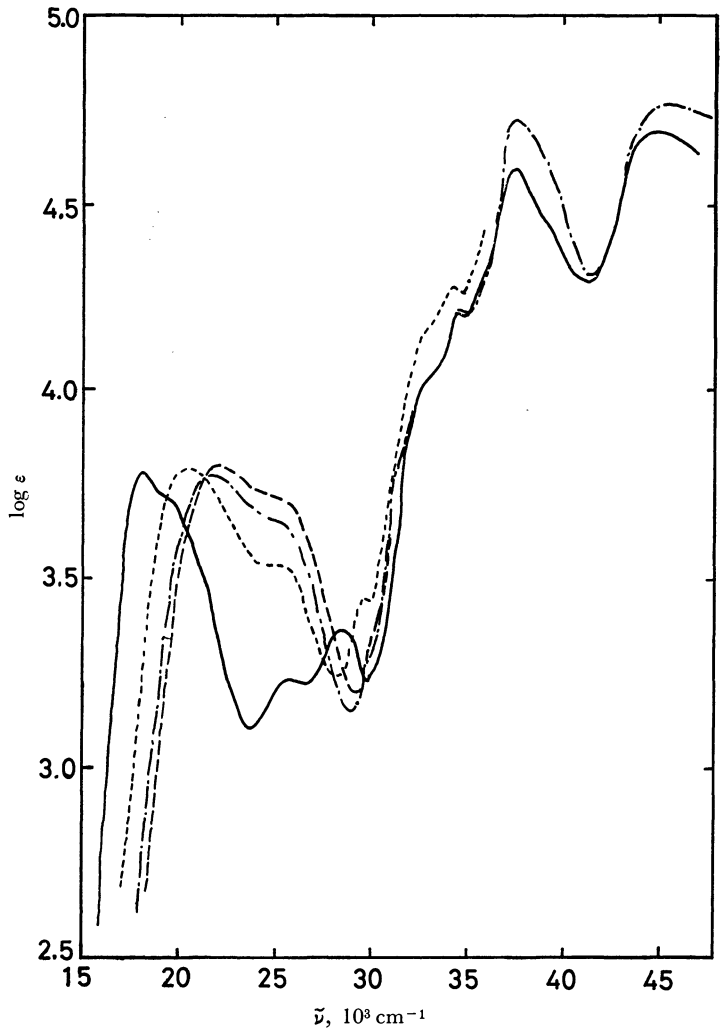

Fig. 5. Absorption spectra of phenanthroline-tetracarbonyl molybdenum(0) in some solvents: —— in cyclohexane (arbitrary scale intensity), - - - - in benzene, — - — in methanol, — — in acetone.

bands, respectively. The constants, $\tilde{\nu}_{gas}$ (A_a+B_a), C_a, (A_e+B_e), and C_e are listed in Table 7.

Discussion

It has been made clear that the shifts of the bands of these compounds are reasonably expressed by McRae's model of a simple electrostatic interaction in such solvents as alcohols, esters, ethers, acetonitrile and acetone. From the data in Tables obtained by Eq. (1) the solvents are arranged in the order of increasing $\tilde{\nu}_{calcd}-\tilde{\nu}_{obs}$ values as follows:

toluene $\simeq$ benzene $\simeq$ *p*-dioxane $<$ chloroform $\leq$ acetic acid $\simeq$ the "esters" $<$ carbon tetrachloride $\simeq$ the "alcohols" $<$ cyclohexane

In carbon tetrachloride and cyclohexane solution, split components are observed in the metal to amine charge transfer bands, but the mean absorption maximum of phenanthroline-tetracarbonyl chromium(0) in cyclohexane is estimated to be about 17400 cm^{-1}. This value is compared to 17530 and 18180 cm^{-1} expected from A_a+B_a and C_a and A_e+B_e and C_e, respectively. On the other hand, the split components in carbon tetrachloride are less obvious, so that the splitting can be neglected. A similar result is also seen for molybdenum(0) and tungsten(0) complexes. Hence these two solvents can be regarded as belonging to the alcohol group.

The anomaly given in benzene and toluene solution would be due to π interaction between the aromatic diamine in the ligand sphere and the solvent molecule. Such an interaction has been known in *e. g.* pyridine *N*-oxide solution.[4] *p*-Dioxane has strong local dipole moments which are compensated in the whole molecule and does not

fit the point-dipole approximation. Chloroform is said[10] to form π-hydrogen bonding with benzene from NMR studies and such an interaction might also occur with diamine-tetracarbonyl complexes to result in anomaly in band shift.

Short Range Dipole Interaction. Solvents of the alcohol and the ester group obey McRae's formula with differing constants. The difference does not seem to come from any special interaction other than electrostatic. One of such special interactions could be hydrogen bonding, but this force cannot play a role, because ethers, cyclohexane and carbon tetrachloride belong to the alcohol group, whereas acetic acid having a greater acidity than alcohols belong to the other ester group.

The nature of interaction represented by C' in Eq. (2) might involve a kind of short range dipole interaction, which has similar factors to those of long range dipole interaction, but is subject to significant steric influence. The dipole moments of solvent molecules belonging to the "ester" and the "alcohol" group are 1.8 to 4 and less than 1.8 debyes, respectively. In the former group, the dipole moment originates mainly from the functional group $>C{=}O$ or $-C{\equiv}N$. On the other hand, dipole distribution of diamine-tetracarbonyl complexes is considered as shown in Fig. 6.

Although the contribution of the metal amine bond is quite big, that of the metal carbonyl bond is also appreciable owing to the metal to carbonyl back donation.[11,12] The latter bonding is formally similar to the functional groups, $>C{=}O$, and $-C{\equiv}M$,

so that the symmetry of dipoles M–CO corresponds well to that of R_1R_2CO and R–CN. When such a part of the molecule (M–CO) interacts with the solvent molecule by a simple short range dipole-dipole interaction, anti-parallel orientation would be far preferable to parallel both energetically and

sterically. (Here the term "energetic" represents the contribution of such an interaction where no steric effect is taken into consideration.) Such short range interactions could be expressed by $(\alpha+\beta+\gamma)$ so that the last term of Eq. (2) is multipled by $(1+\alpha+\beta+\gamma)$ (Fig. 6). The first term, α represents the effect around the two metal-carbonyl bonds on M–NN plane, the second, β, that around the two metal-carbonyl bonds across M–NN plane and the last, γ, that around the metal-amine bonds. γ does not seem to involve big steric effect. From the values of dipole moments of the solvent, it could be estimated that $\gamma_e > \gamma_a > 0$, for phenanthroline- and bipyridyl-tetracarbonyl complexes and $\gamma_e \geq \gamma_a \geq 0$ for ethylenediamine-tetracarbonyl complexes. Suffixes e and a stand for values for the ester and the alcohol group, respectively.

For $\alpha+\beta$, the steric effect seems to be quite

important, but the energetic effect would be less so, because the absolute value of local dipole moment is rather small. Figure 7a illustrates the statistical dipole arrangement for the alcohol group solvent, where Onsager's approximation is applicable, *i. e.* $\alpha=\beta=0$. Figure 7b and 7c represent the cases where steric conditions are appreciable and short range interactions significant. A probable explanation is as follows.

The solvent molecules can orientate statistically as required by the overall dipole moment of the complex near the carbonyl ligands on the M–NN plane. On the other hand, such an orientation is hindered near those carbonyl groups in the plane across M–NN. Hence α is always positive, and β negative. The contribution of α would be slightly smaller in the case represented by Fig. 7b, than in the case represented by Fig. 7c, because the dipole moment of the whole complex is greater in the latter case, where the dipole of the amine ligand operates additive. By the same reason, the influence of β would be greater in the case Fig. 7b. Depending on whether the dipole moment of the whole complex molecule is greater or smaller than a certain value, $\alpha+\beta+\gamma$ has plus or minus sign. This value should be different for each central atom, because the cavity radius a and the dipole moment of M–CO are not expected to be equal in all the complexes. Ethylenediamine-, and bipyridyl- (or phenanthroline-) tetracarbonyl complex have dipole moments 8 to 10, and 9 to 11

(c) Large dipole of ligand diamine

Fig. 7. Schematic representation of the orientation of organic carbonyl radical around polar metal carbonyl (M-CO) bonds.

Debyes, respectively.[12] From the values of C_a and C_e in Table 5, it might be concluded that Fig. 7b and 7c represent the cases of the ethylenediamine and the bipyridyl (or phenanthroline) complex respectively. Regardless of the nature of absorption bands, C_e is always greater than C_a for phenanthroline- and bipyridyl-tetracarbonyl complexes, whereas the reverse is true for ethylenediamine complexes.

The short range dipole interaction can induce the change of $A'+B'$ values expected from Onsager's approximation. The $-(A_a+B_a)$ value for the alcohol group is larger than $-(A_e+B_e)$ values for the ester group in all the absorption bands. The maximum value of $-A_a$ and $-A_e$ can be estimated from (A_a+B_a) and (A_e+B_e), respectively, by use of the following relationship,

$$B' = \frac{1}{\boldsymbol{hc}a^3}(M_g^2 - M_e^2) \leqq \frac{2M_g}{\boldsymbol{hc}a^3}(M_g - M_e) = C', \quad (M_g,\ M_e > 0) \tag{3}$$

where $\boldsymbol{h}$ stands for Planck's constant, $\boldsymbol{c}$ the light velocity, a the cavity radius, M_g the dipole moment of the ground state and M_e that of the excited Franck-Condon state for the transition in question.

When $-A$ value is to be approximated by $2.14\times 10^{-14} fL_0/\tilde{\nu}a^3$, the ratio of the L_0 values for the alcohol and the ester group solvents could be calculated from the estimated A_a and A_e values, and measured $\tilde{\nu}$, on the assumption that f is equal for these two group solvents. The value L_0 (alcohol)/L_0 (ester) is 1.2. Generally L_0 is regarded to be independent of the solvent; McRae's consideration[2] suggests that ester group would have greater L_0, because esters themselves have strong absorption bands in low frequency region. Such discrepancies seem to suggest that the short range interaction is significant in the dispersion and the

induced force, too. Such an interaction might be a kind of π-π interaction, although not necessarily due to orientation. Bauer and Nicol[5] reported on the solvent effect for the ^1L_a transition of naphthacene, which is due to the dispersion force and the Stark effect of solvent. In this case varying solvents behave differently (difference, $\simeq 100\ cm^{-1}$). This fact also suggests that the dispersion effect can differ from one solvent group to another.

Consideration on Individual Bands. The metal to amine charge transfer bands show red shift by 2000 to 4000 cm^{-1} as compared with $\tilde{\nu}_{gas}$, owing to the big contribution of dispersion force. On the other hand, *d-d* transition bands of ethylenediamine-tetracarbonyl chromium(0) [$Cr(CO)_4en$] show a blue shift by 400 to 1000 cm^{-1}, owing to big contribution of orientation force. It appears as if the influence of dispersion force is quite significant for most organic compounds. It seems that the extinction coefficient is small for the *d-d* transition of [$Cr(CO)_4en$] and the electrons move in the interior molecule behind polarizable ligands to give only little influence upon the solvent molecule.

The large *C* values for the *d-d* band of [$Cr(CO)_4en$] could be attributed to the facts that the difference of permanent dipole moment between the ground and the excited Franck-Condon state is large and that the *a* values are rather small. The large difference in $M_g - M_e$ could be accounted for by considering that the d_π electron is polarized to the carbonyl ligand in the ground states, but the extent is decreased by transition to the d_σ* level. In this level the electrons would be localized appreciably on the central metal and the state of σ-bonding in CO ligand would remain unchanged. This view seems to be further supported by infrared and dipole moment studies.[12,13] The dipole moment of the excited Franck-Condon state is estimated from the *C* values as shown in Table 8. The M_g is indirectly estimated from Strohmeier's data[12] by simple addition of vectors. The cavity radii are estimated by adding 1 to 2 Å to the molecular radii calculated from the bond distance of diethylenetriaminetetracarbonyl chromium(0).[14] The values in Table 8 seem reasonable.

Table 8. Dipole moments in the excited Franck-condon state estimated from *C* values (in Debye units)

	Assumed cavity radius		
	M_g	a(Å)	M_e
[$Cr(CO)_4en$]			
$d \rightarrow d$	8.3	4	2.4—2.7
		5	3.0—3.7
[$Cr(CO)_4bq$]			
$Cr \rightarrow \pi^*_{bp}$C.T.	9.3	5	1.6—3.0
		6	4.9—5.7
$\pi_{bp} \rightarrow \pi^*_{bp}$	9.3	5	8.3
		6	7.6
[$Cr(CO)_4phen$]			
$Cr \rightarrow \pi^*_{phen}$C.T.	9.3	5	1.0—2.6
		6	4.4—5.4

The change of the electron distribution would occur in same directions but to different extents, for the metal to amine charge transfer and for the intra-ligand transition. Hence we can compare the values in Table 8 directly. The big change of dipole moments between the ground and the excited Franck-Condon state agrees with the assignment.[9]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 875—882 (1968)

The Reaction between Mercury(II) and Organic Compounds. IV.*[1] A Photometric Method for the Determination of Basic Amino Acids Precipitated with a Mercury(II) Perchlorate Precipitant and Some Properties of Their Products

Fumiaki KAI

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received October 2, 1967)

The particular reactivity of basic amino acids in presence of mercury(II) perchlorate gives white amorphous products (by X-ray powder diffraction). The structures of the products may be considered to be $[Arg\text{-}Hg]ClO_4 \cdot Hg(ClO_4)_2$, $[His\text{-}Hg]ClO_4 \cdot Hg(ClO_4)_2$ and $[Lys\text{-}Hg]ClO_4 \cdot Hg(ClO_4)_2$ on the bases of elemental analytical data and of infrared patterns showing the absorption bands of $\nu_{as}(Hg\text{-}O)$, $\nu(Hg\text{-}N)$ and perchlorate ions. The applicability of this peculiar reactivity to the separation and photometric determination of basic amino acids has been studied. The above mentioned products were obtained selectively as a mixture from a mixture of about twenty kinds of amino acids. The isolation of the mixture into each product could be performed satisfactorily by utilizing the different solubilities of the products in 10 N acetic acid containing sodium or potassium chloride (3.3 W/V %), and in an aqueous sodium hydroxide solution. Although the products showed characteristic ultraviolet absorption curves differing from those of the components, there were no absorption maxima in any case. The calibration curves, which followed Beer's law, could be obtained at any proposed wavelength. By using the calibration curves thus obtained, a very small amount of each basic amino acid could be determined spectrophotometrically in the 220—250 mμ region, within detection limits of about 10^{-5}—10^{-4} M. Constant absorbancies could be attained in the pH range of 1.5—10.7 of the sample solutions.

Numerous works of analyses of basic amino acids (Arg, His, and Lys) have hitherto been undertaken by many workers. The analyses, after the preparation of the derivatives of amino acids such as flavianate,[1] 3,4-dichlorobenzenesulfonate,[2] picrate,[3] and benzenesulfonate[4] are known as long-established techniques. Ion exchange resins,[5] electrophoresis,[6] various chromatographic techniques,[7] spectral reflectance,[8] and conductivity measurements[9] have also been used in recent years. Phosphotungstic acid[10] which is known specific for the simultaneous and preferential precipitant of basic amino acids, silver(I),[11] copper(II)[12] and mercury(II)[13] salts have been used as the coprecipitants of basic amino acids. Especially, mercury(II) chloride, acetate and sulfate had been used for the isolation of Asp, Glu, Cys, Met and Try besidese basic amino acids. However, in the separation of basic amino acids using mercury(II) salts by Warburg *et al.*,[13] His was almost exclusively obtained, while Arg and Lys were isolated by using silver salts.

In the previous paper[14] of this series,[14-16] the present author has shown that mercury(II) chloride as well as phosphotungstic acid reacted selectively and simultaneously with basic amino acids in various amino acids. He also suggested that instead of phosphotungstic acid, mercury(II) perchlorate, as well as chloride, could be utilized as selective precipitant.

The present investigation has been undertaken in order to establish the methods for the separation and determination of basic amino acids by mercury(II) perchlorate, and to discuss some properties of the resulting products.

The proposed methods are sufficiently rapid, precise, and accurate to be used for the selective and simultaneous separation and determination of a small amount of basic amino acids. Furthermore, there is no procedure, except that using phosphotungstic acid and that by mercury(II) chloride reported in the preceding paper,[14] for the selective and simultaneous separation of basic amino acids.

Experimental

Materials. All the amino acids were obtained from the Nippon Rikagaku Yakuhin Co., Ltd., while reagent-grade mercury(II) chloride was obtained commercially. Mercury(II) perchlorate was prepared from the chloride by a procedure similar to that reported previously.[15] All the other chemicals used were of an analytical or of a special grade; they were used without further purification. Solutions for the measurement of the absorption spectra were prepared using redistilled water.

Apparatus. The pH was measured with a glass electrode (Yokogawa type KPH-51A and Hitachi-Horiba type M-5). The ultraviolet absorption spectra and the absorbancies were recorded with a Hitachi recording spectrophotometer (EPS-2 type) and a Hitachi photoelectric spectrophotometer (EPU-2 type) with 10 mm cells respectively. The infrared spectra in the 4000—650 cm^{-1} and 700—200 cm^{-1} region were obtained using a Hitachi-Perkin Elmer (type 125) and a Hitachi EPI-L type spectrophotometer respectively. All the samples were examined as Nujol-mull.

The mercury contents in the products were determined by chelatometric titration or by colorimetric determination.[17] The pH was adjusted with dilute aqueous perchloric acid and sodium hydroxide solutions as occasion demands.

Procedure

The Selective Separation of Basic Amino Acids in a Mixture of Various Amino Acids. An aqueous solution of mercury(II) perchlorate below 10^{-2} M*2 was added to an acid sample solution (with $HClO_4$) composed of a mixture of about twenty kinds of amino acids. A dilute sodium hydroxide solution was then added, drop by drop, into the solution until the pH of the supernatant reached about 8.5. Thereby, the only basic amino acids were co-precipitated with mercury(II) perchlorate as [Arg-Hg]ClO_4·$Hg(ClO_4)_2$, [His-Hg]ClO_4·$Hg(ClO_4)_2$ and [Lys-Hg]ClO_4·$Hg(ClO_4)_2$. In order to certify the complete precipitation, a small aliquot of the supernatant was taken out and the same procedure was carried out again after the addition of a slight excess of mercury(II) perchlorate.

The Isolation of Each Basic Amino Acid from the Mixture. The isolation could be carried out by utilizing different solubilities of the precipitates under various experimental conditions.

His. Acetic acid (10 N) containing sodium chloride (3.3 W/V %) was added to a wet mixture of Arg, His and Lys as mercury salts. By shaking the mixture for a while at room temperature, only [His-Hg]ClO_4·$Hg(ClO_4)_2$ remained as it is, while [Arg-Hg]ClO_4·$Hg(ClO_4)_2$ and [Lys-Hg]-ClO_4·$Hg(ClO_4)_2$ were dissolved completely.

Arg and Lys. By adjusting the pH of the mother liquor separated from His to about 8, a mixture of [Arg-Hg]ClO_4·$Hg(ClO_4)_2$ and [Lys-Hg]ClO_4·$Hg(ClO_4)_2$ was reprecipitated. It was suspended in water, and then aqueous sodium hydroxide was added to the suspension until the pH reached to 12.1—12.3 at room temperature. When this suspension was heated to boil, only [Lys-Hg]ClO_4·$Hg(ClO_4)_2$ was dissolved, while [Arg-Hg]ClO_4·$Hg(ClO_4)_2$ remained at this pH; filtration was then carried out keeping the suspension hot, and the residue was washed with hot water at the pH 12.1. When the filtrate reached to room temperature, [Lys-Hg]ClO_4·$Hg(ClO_4)_2$ was reprecipitated.

Results and Discussion

The Structures and Some Properties of the Products. *Elemental Analysis.* The products were analyzed as follows:

Arg. Found: C, 8.01; H, 1.52; N, 6.99; Hg, 43.94; Cl, 13.51%. Calcd for $C_6H_{13}N_4O_{14}$·Hg_2Cl_3: C, 8.26; H, 1.49; N, 6.42; Hg, 45.98; Cl, 12.19%. Mp 206—208°C (decomp.).

His. Found: C, 9.06; H, 0.89; N, 4.56; Hg, 46.57; Cl, 13.45%. Calcd for $C_6H_8N_3O_{14}$·Hg_2Cl_3: C, 8.44; H, 0.94; N, 4.92; Hg, 47.0; Cl, 12.46%. Mp 215—218°C (decomp.).

Lys. Found: C, 6.10; H, 0.98; N, 3.20; Hg, 45.99; Cl, 14.78%. Calcd for $C_4H_9N_2O_{14}$·

Snell and C. T. Snell, "Colorimetric Method of Analysis," C. Van Nostrand Co., Philadelphia (1959), p. 63.

*2 At a higher concentration, the added mercury(II) perchlorate was apt to decompose to mercury oxide.

Hg_2Cl_3: C, 5.90; H, 1.11; N, 3.19; Hg, 49.24; Cl, 13.10%. Mp 188—190°C (decomp').

These analytical results indicate the ratio of 2 : 1 for mercury(II) perchlorate to basic amino acid in all the products. All of the products were amorphous (by X-ray powder diffraction).

Infrared Spectra of the Products and Relative Substances. Figures 1—3 give the infrared spectra of the precipitates (A—C) and related substances. In the spectra of the precipitates, the absorption bands

considered to be due to the ν_{as} (Hg–O)*3 shifted from the free carboxylic acid (A'—C') are shown in the 1565—1570 cm^{-1} region. The bands considered to be ν(Hg–N)[18] are seen at 624 cm^{-1} for A and B, and at 622 cm^{-1} for C. Strong absorptions due to the perchlorate ions[19] are seen at 1090 cm^{-1} for A, at 1100 cm^{-1} for B and at 1085 cm^{-1} for C. Although free amino acids (A'—C') as the components of the precipitates show many absorptions in the finger-print region, the precipitates give scarcely any absorptions in that region. Therefore, there is a possibility of the decomposition of the amino acids. However, since the stoichiometrical mixtures (A''—C'') of mercury(II) perchlorate and each basic amino acid (2 : 1) showed nearly the same absorption curves as those of A—C, the many absorptions in the finger-print region of A—C were considered to be hidden by the mercury(II) perchloarte which was predominant in quantity in the precipitates. As a result, the following structures of the precipitates are reasonable:

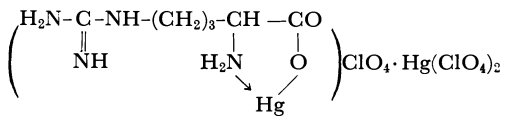

Abb. as $[Arg\text{-}Hg]ClO_4 \cdot Hg(ClO_4)_2$ (I)

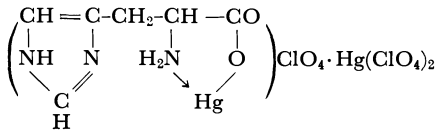
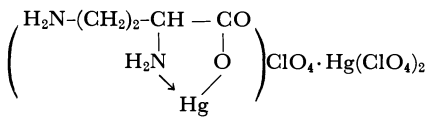
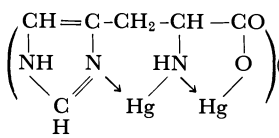


$[His\text{-}Hg]ClO_4 \cdot Hg(ClO_4)_2$ (II)

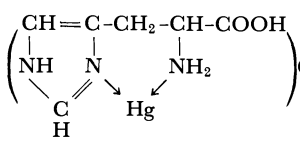


$[Lys\text{-}Hg]ClO_4 \cdot Hg(ClO_4)_2$ (III)

With respect to the II structure, the other structures shown below were considered possible:



(II')



(II'')

However, II' was considered to be unstable and II''*4 was unreasonable because the carboxylic group was expected to be fully utilized by the bonding with mercury(II).

The Solubilities of the Precipitates. The precipitates were insoluble in water and in organic solvents (even in DMF), but were soluble in aqueous mineral acid and alkaline solutions. Therefore, the amphoteric properties of amino acids remained. The I, II and III are soluble in hot alkaline solutions at the pH values of 12.8—13.0, 13< and 12.1—12.3 respectively. The II structure is, however, apt to decompose into mercury oxide under these conditions. Accordingly, isolation using different solubilities in alkali was not employed. In an acetic acid containing chloride ions (KCl, NaCl), it was found that I and III were dissolved completely, while II remained insoluble. Concentrations up to 10 N of acetic acid and up to 2% (W/V) of sodium or potassium chloride in acetic acid were required for a thorough dissolution.

When sodium or potassium acetate was used in place of chloride, I and III were insoluble. Accordingly, the presence of chloride ions seems to be indispensable for the dissolution of I and III. The isolation of I and III could be carried out by treating a mixture of them, obtained again in the way described hitherto, by utilizing their different solubilities in a sodium hydroxide solution.

Application to the Quantitative Determination of Basic Amino Acids. *The Stoichiometric Study of the Components.* The yields of the products varied with the ratios of the components. The results are illustrated in Fig. 4. The concentrations of both mercury(II) perchlorate and a basic amino acid in the original standard aqueous solutions were 5×10^{-3} M; the volume of each amino acid solution used was kept at 10 ml, corresponding to 5×10^{-5} mol. Into this solution of mixtures, dilute aqueous sodium hydroxide was added drop by drop while stirring. The yields of the products at a given ratio of two components were determined by the spectrophotometric method, by analyzing the nitrogen content, and by observing a ninhidryne reaction in a small aliquot of the supernatant. As can be seen in this figure, at the ratio of 1.0 the yields of Arg, His and Lys were 35, 42 and 45% respectively. Furthermore, at the ratio of 2.0, which was considered to be the theoretical value for a complete precipitate formation, the yields were no more than 65—77%. On increasing the ratio,

*3 In a homologous metal such as zinc, it is said that the band of ν(Zn–O) appears at 1656 cm^{-1}; Y. Sano and H. Tanabe, *J. Inorg. Nucl. Chem.*, **8**, 119 (1958).

sufficient yields were obtained at the ratios of 3.8, 4.5 and 4.8 for Lys, His and Arg respectively. Therefore, more than five times as much mercury(II) perchlorate as each basic amino acid was required at least. The influence of excess mercury(II) perchlorate (about ten times as much mercury as each basic amino acid) on the precipitate formation was also studied. The formation, however, was not affected by the addition of excess mercury(II) perchlorate, and nor was any production of mercury oxide observed under these experimental conditions.

The Effect of pH on the Precipitate Formation. The yields of the products were affected by the pH of the sample solution. A dilute aqueous sodium hydroxide solution was added, drop by drop, to mixtures consisting of 2×10^{-4} M of each amino acid and 1.4×10^{-3} M of mercury(II) perchlorate. The results, shown in Fig. 5, suggest that the pH values of the solutions of mixtures which gave substantial yields were 7.8—7.9, 6.2—6.3 and 7.2—7.3 for Arg, His and Lys respectively. Therefore, in order to obtain substantially a mixture of the three kinds of precipitates, the pH of the solution was required to be at least 8.0. In order to obtain precipitates from a solution of more dilute amino acids, the effect of several organic solvents (methanol, ethanol, *n*- and isopropanol, acetone, dioxane, *etc.*), which are soluble in water, on the

formation of precipitates was investigated. The results made it clear that the formation of precipitates was facilitated by ethanol (ethanol: sample solution=1 : 1); thereby a small amount of basic amino acids could be precipitated from about a 10^{-5} M solution. This effect may presumably be explained by a reduction in the polarity of an aqueous sample solution.

Spectrophotometric Analyses. The ultraviolet absorption curves for the products and for their components are illustrated in Fig. 6. The spectra of the acidic solutions of I (curve A), II (curve B) and III (curve C) showed characteristic curves differing from those of the components, Arg (curve A'), His (curve B'), Lys (curve C') and mercury(II) perchlorate (curve D). As can also be seen from this figure, since the corresponding free amino acid content in these samples was as small as 1.9×10^{-5} M, 9.0×10^{-6} M and 1.4×10^{-5} M for Arg, His and Lys respectively, the proposed quantitative determination by the spectrophotometric method can be employed for a micro amount of basic amino acids.

Calibration Curves. The optimum wavelength for the quantitative determination must be ascertained, because there is no maximum in any of the absorption curves of the products. After many trials, the calibration curves in a good linear relationship at the proposed wavelength were obtained, as is shown below. The concentrations scaled in Figs. 7—9 show the calculated amounts of free amino acids in the corresponding mercury salts of basic amino acids.

Arg. The calibration curves on Arg in an acidic aqueous solution ($HClO_4$, pH 2.5), shown in Fig. 7, were obtained at a wavelength fixed arbitrarily in

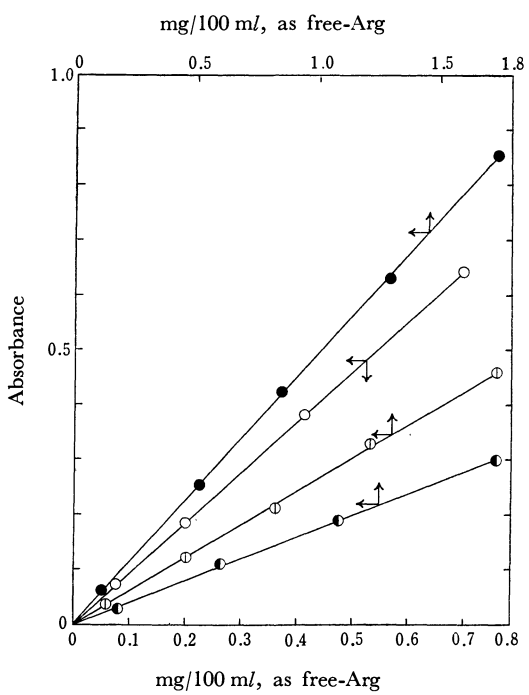

Fig. 7. Calibration curves on Arg, pH=2.5.
-○- 220 mμ -●- 230 mμ
-◑- 240 mμ -◐- 245 mμ

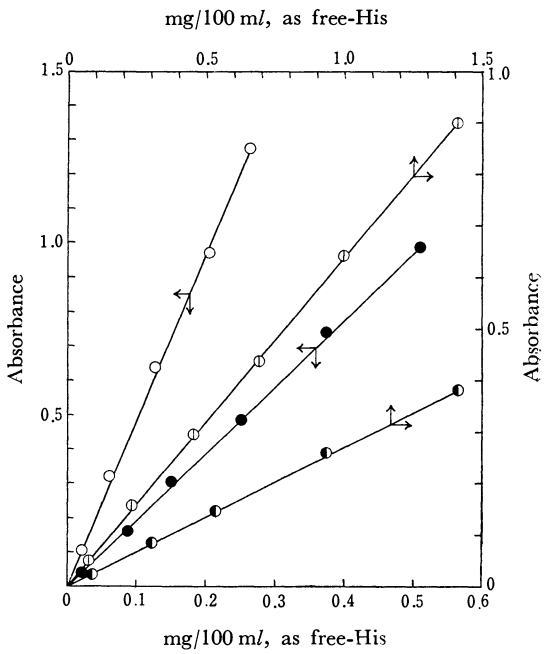

Fig. 8. Calibration curves on His, pH=2.0.
-○- 220 mμ -●- 230 mμ
-◑- 240 mμ -◐- 250 mμ

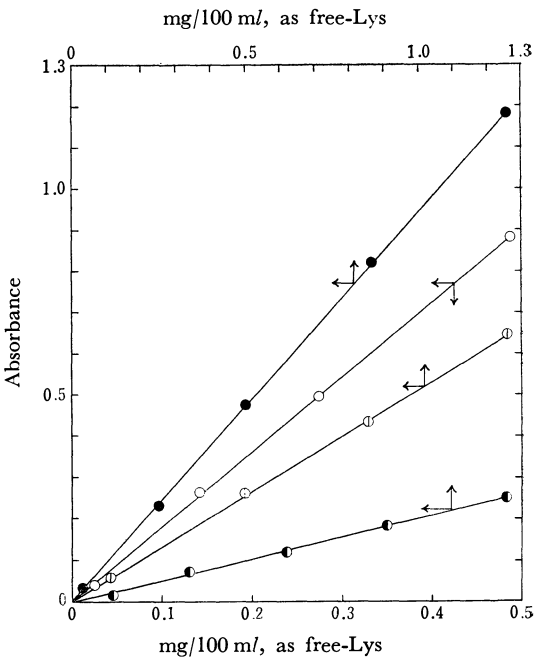

Fig. 9. Calibration curves on Lys, pH=2.3.
-○- 220 mμ -●- 230 mμ
-◑- 240 mμ -◐- 250 mμ

the region between 220—245 mμ. About 4×10^{-5} M of free Arg can be determined near 220 mμ, while about 1×10^{-4} M of free Arg can be determined in the 230—245 mμ region.

His. Figure 8 shows the curves of His (pH 2.0) in the range of 220—250 mμ. His up to 3.6×10^{-5} M in the 220—230 mμ and up to about 9.1×10^{-5} M in the 240—250 mμ region can be determined.

Lys. The curves for free Lys (pH 2.3) up to 3.5×10^{-5} M near 220 mμ and to 8.7×10^{-5} M in the 230—250 mμ region, shown in Fig. 9, have a fair linearity.

From these results, it was found that the quantitative determination of smaller amounts of basic amino acids may be carried out by the present calibration curves than those determined by using mercury(II) chloride[14] because the free basic amino acids contents in the products in this case of this perchlorate precipitant are lower than in those of chloride.

The Effect of the pH Value on the Absorbance of Sample Solutions. In order to study the effect of the pH on absorbancies, the pH of the sample solutions was adjusted to the required value with a dilute perchloric acid or a dilute sodium hydroxide solution.

Nevertheless these samples had been obtained at the pH values of 6—8 as described above (Fig. 5), at concentrations below 10^{-4} M of the sample solutions, there were, unexpectedly, neither any turbidity nor any conversion of the solution. The results are shown in Fig. 10. It was found that there are constant absorbancies extending over a wide range of pH values. His in the pH range of 1.5—8.5, Lys, in that of 2.5—10.7, and Arg, in that of 2.0—10.0 were determined at the respective constant absorbancies. Therefore, a precise set of pH values determined by a buffer solution was not necessary.

Recoveries by the Spectrophotometric Determination. The recoveries of basic amino acids by the present

method were examined; the data obtained are listed in Tables 1 and 2. Table 1 shows the results obtained when each aqueous testing solution was composed of a mixture of mercury(II) perchlorate and an individual basic amino acid, while Table 2 shows those obtained from an aqoeus solution of a mixture of mercury(II) perchlorate and all the basic amino acids. Sufficient recoveries were shown in all cases.

Further confirmation of the usefulness of the proposed method was obtained by measuring the

basic amino acids in an ovalbumin. By comparing the present results with the data reported by Folin *et al.*[20] and Wieland,[21] it was confirmed that the proposed method is sufficiently rapid, precise and accurate to be used for the preferential and simultaneous separation and determination of a small amount of basic amino acids.

The author wishes to express his deep gratitude to Professor Daisei Yamamoto of this University for his kind direction and encouragement throughout the course of this study. Thanks are also due to Dr. Minoru Nakamizo of the Goverment Industrial Research Institute, Kyushu, for his infrared spectral measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 882—888 (1968)

Spectrophotometric Determination of Formation Constants of Iron(III) Complexes with Chloride Ion in Dimethyl Sulfoxide*[1]

Goro WADA

Department of Chemistry, Nara Women's University, Nara

(Received October 4, 1967)

The formation constants of $FeCl^{2+}$ and $FeCl_2^+$ have been measured in dimethyl sulfoxide (DMSO) containing $Fe(ClO_4)_3$, NaCl, $HClO_4$ and $NaClO_4$. Some spectrophotometric methods giving the formation constants and molar extinction coefficients of the complexes were developed and gave, on the average, log $K_1=3.62$ and log $K_2=2.10$, at 0.02 M $HClO_4$ and an ionic strength of 0.10 M at 25°C. It is rather surprising that these values are only slightly larger than those in *N*-methylacetamide, which is expected, however, to give much smaller values than DMSO, due to its extraordinarily large dielectric constant. The species formed between Fe(III) and Cl^- ion is reasonably supposed to be a true complex bonded directly with each other and not an ion-pair association product. At higher concentrations of Fe(III), formation of polynuclear complexes can occur.

Dimethyl sulfoxide (DMSO) has recently come to be widely used as an advantageous medium for inorganic chemical reactions. Spectrophotometric and electron magnetic resonance studies showed that a small amount of tetrachloroferrate(III) ion was present in solution of iron(III) chloride in a number of organic solvents including DMSO, the formation being the smallest in the case of DMSO.[1] On the other hand, the predominant iron(III)

*1 Presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, No. 2B104, April, 1967.

1) T. B. Swanson and V. W. Laurie, *J. Phys. Chem.*, **69**, 244 (1965).

ion in DMSO was found to exist in the form of monochloroiron(III) complex ion in solutions of hexa-solvated iron(III) perchlorate and tetraethylammonium chloride at the concentration ratios of 1 and 2 between iron(III) and chloride ion when the concentration of iron(III) was 1.52×10^{-4} M.[2,3]

In an investigation of the electron transfer reaction between iron(III) and iron(II) in DMSO catalyzed by chloride ion, the formation constants for the chloride ion-containing complexes were required to be known in order to estimate the individual rate constants, which have been already reported.[4] Consequently, the present work was undertaken to obtain formation constants, and a couple of methods of calculation based on spectrophotometrically observed data were developed for the purpose.

Experimental

Materials. Commercial DMSO of analytical reagent grade was distilled under a reduced nitrogen atmosphere, shaken with activated alumina overnight, and redistilled under the same conditions. The purified DMSO contained water approximately at the concentration of 0.025 M at the highest, found using Karl Fischer reagent.

Crystals of $Fe(ClO_4)_3\cdot6DMSO$,[5] anhydrous sodium perchlorate and solutions of perchloric acid in DMSO were prepared by a procedure described previously.[6] Sodium chloride was twice recrystallized from water and dried.

Apparatus. A Beckman Model DU spectrophotometer with a thermostated cell compartment and quartz cells was used for the measurement of optical density.

Results and Calculations

Absorption Spectra. Figure 1 shows the absorption spectra of iron(III) species in the absence and the presence of chloride ion in DMSO. Curve A is the spectrum of $Fe(DMSO)_6^{3+}$ (written Fe^{3+} for simplicity), which agrees well with that of Drago and others.[3] Curve B represents the apparent spectrum of the mixture of Fe^{3+} and $Fe(DMSO)_5Cl^{2+}$ ($FeCl^{2+}$ for simplicity). By using the values of K_1 as will be obtained below, the true molar extinction coefficients of $FeCl^{2+}$ at various wavelengths were calculated from Curves A and B, and then Curve C was drawn as the true spectrum of $FeCl^{2+}$. There is an absorption peak at 340 mμ in the spectrum of $FeCl^{2+}$, whereas none

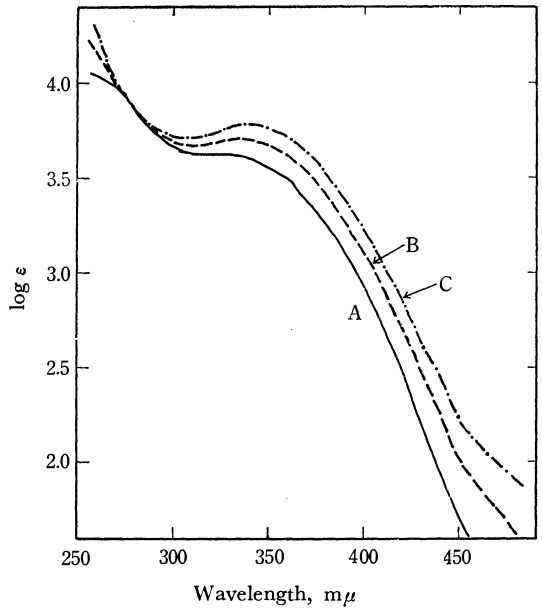

Fig. 1. Absorption spectra of Fe^{3+} and $FeCl^{2+}$ in DMSO, $[HClO_4]=0.02$ M, $\mu=0.10$, 25°C.
A: ——— Fe^{3+}
B: ——— $[Fe(III)]=7.0\times10^{-5}$ M, $[Cl]=6.3\times10^{-4}$ M
C: —·—· $FeCl^{2+}$

is observed in that of Fe^{3+}, and an isosbestic point at about 280 mμ is also recognized for the two spectra. The apparent spectra of iron(III) complexes in both solutions are not affected by acid concentration, indicating that the solvating DMSO molecule of iron(III) undergoes no appreciable solvolysis (proton donation), because DMSO is aprotic,[7] or rather slightly basic.[8]

Continuous Variation Method. Job's method of continuous variations[9] was used to indicate the formula of the prominent species, if any. Figure 2 shows the Job's curves at 450, 460 and 470 mμ with $C=[Fe(III)]+[Cl]=1.00\times10^{-2}$ M, $[HClO_4]=0.02$ M and $\mu=0.10$ M at 25°C, where [Fe(III)] and [Cl] stand for the total concentrations of iron(III) and chloride ion employed, respectively. The ordinate Y is defined as the difference between the observed optical density and the optical density which would have been obtained if no complex formation had occurred. At the wavelengths used here, absorption caused by the free ligand was negligible. The abscissa x is defined as $x=[Fe(III)]/C$.

Figure 3 shows the Job's curves at 400 mμ with $C_a=1.00\times10^{-3}$ M and $C_b=0.70\times10^{-3}$ M for

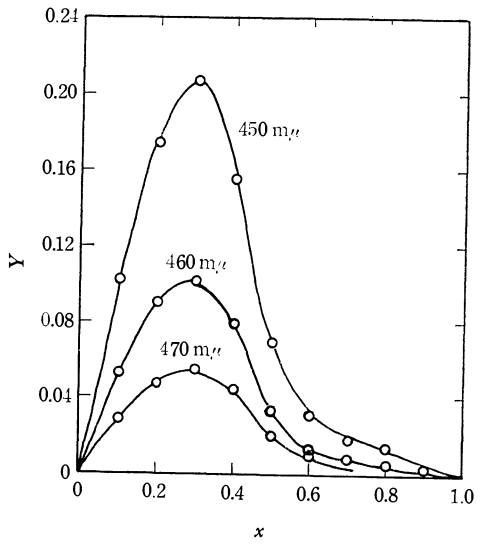

Fig. 2. Job's curves of Fe(III)+Cl⁻ system in DMSO. $C=1.00\times10^{-2}$ M, $[HClO_4]=0.02$ M, $\mu=0.10$, 25°C.

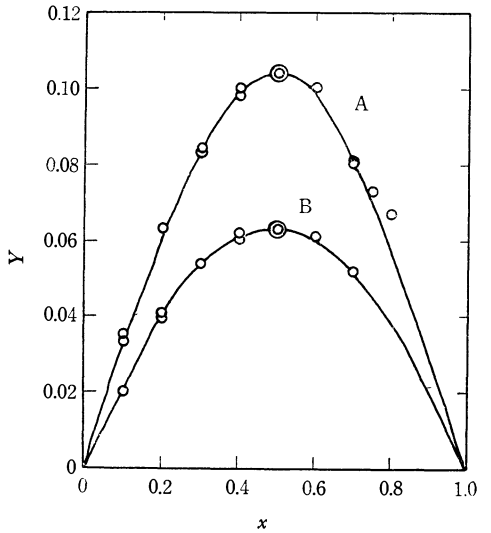

Fig. 3. Job's curves of Fe(III)+Cl⁻ systems in DMSO. $[HClO_4]=0.02$ M, $\mu=0.10$, 25°C, 400 mμ.
A: $C_a=1.00\times10^{-3}$ M B: $C_b=0.70\times10^{-3}$ M

Curves A and B, respectively, as well. Other conditions were the same as in Fig. 2. Quite similar plots to those in Fig. 3 but with smaller Y values, were obtained at 410 mμ, although they are omitted in the figure.

It would be reasonably concluded from Figs. 2 and 3 that, at a lower total concentration C, the 1 : 1 complex $FeCl^{2+}$ is predominantly formed, while, at a higher C, the system is more complicated, with the probable formation of polynuclear chloroiron(III) complexes, as well as polychloromononuclear iron(III) complexes. This is because the shift of the maximum point of Y from $x=0.5$ to approximately 0.3 as C is increased tenfold indicates the occurrence of polychloroiron(III) complexes, probably $FeCl_2^+$, and the sudden decrease in Y values at $x>0.4$ in Fig. 2 suggests the formation of polynuclear iron(III) complexes containing chloride ion, with smaller molar extinction coefficients than those of $FeCl^{2+}$ and $FeCl_2^+$, although their formulas are unknown.

In the following part of the text, simpler systems will be mainly taken into account, where $FeCl^{2+}$ plays the leading role, except as otherwise noted.

Calculation of K_1 from Job's Curves. In the system where simply $FeCl^{2+}$ complex is formed, Y and K_1 are expressed by the following relations, according to their definitions,

$$Y = \varepsilon_0[Fe^{3+}] + \varepsilon_1[FeCl^{2+}] - \varepsilon_0[Fe(III)] \quad (1)$$

$$K_1 = [FeCl^{2+}]/[Fe^{3+}][Cl^-] \quad (2)$$

in which ε_0 and ε_1 are the molar extinction coefficients of Fe^{3+} and $FeCl^{2+}$, respectively. By using the following relation

$$[Fe(III)] = [Fe^{3+}] + [FeCl^{2+}] \quad (3)$$

Eq. (1) is rewritten as

$$Y = (\varepsilon_1-\varepsilon_0)[FeCl^{2+}] \quad (4)$$

Method I of Common Y. In Fig. 3, consider a set of two points (x_a, Y) and (x_b, Y) on the Curves A and B, respectively, which have a common value of Y. Then, the following relation is established, where subscripts a and b correspond to the respective points on the Curves A and B,

$$K_1 = \frac{[FeCl^{2+}]_a}{[Fe^{3+}]_a[Cl^-]_a} = \frac{[FeCl^{2+}]_b}{[Fe^{3+}]_b[Cl^-]_b} \quad (5)$$

By solving Eq. (5),

$$[FeCl^{2+}]_a = [FeCl^{2+}]_b = \frac{x_a(1-x_a)C_a^2 - x_b(1-x_b)C_b^2}{C_a - C_b} \quad (6)$$

$$[Fe^{3+}]_a = x_aC_a - [FeCl^{2+}]_a \quad (7)$$

$$[Cl^-]_a = (1-x_a)C_a - [FeCl^{2+}]_a \quad (8)$$

and substituting for Eq. (5) the values from Eqs. (6), (7) and (8), the value of K_1 can be calculated. And ε_1 is also known from the following equation.

$$\varepsilon_1 = \frac{Y}{[FeCl^{2+}]_a} + \varepsilon_0 \quad (9)$$

Similar, but less complete methods have been reported by several researchers.[10] Table 1 shows an example of this method under the conditions $C_a=1.00\times10^{-3}$ M, $C_b=0.70\times10^{-3}$ M, $[HClO_4]=0.02$ M and $\mu=0.10$ M at 25°C and gives the

10) For instance, S. E. Turner and R. C. Anderson, *J. Am. Chem., Soc.*, **71**, 912 (1949); A. K. Mukerji and A. K. Dey, *J. Inorg. Nucl. Chem.*, **6**, 314 (1958); P. Sanyal, S. P. Sangal and S. P. Mushran, This Bulletin, **40**, 217 (1967).

Table 1. Derivation of K_1 and ε_1 by the method I of common Y

$C_a=1.00\times10^{-3}$ M, $C_b=0.70\times10^{-3}$ M, $[HClO_4]=0.02$ M, $\mu=0.10$ M at 25°C. $\varepsilon_0^{400}=845$, $\varepsilon_0^{410}=520$ $M^{-1}cm^{-1}$

λ mμ	Y	x_a	x_b	$K_1\times10^{-3}$ M^{-1}	$\varepsilon_1\times10^{-3}$ $M^{-1}cm^{-1}$
400	0.060	0.18	0.36	2.6	1.36
400	0.055	0.17	0.30	4.2	1.28
400	0.050	0.15	0.26	3.9	1.30
400	0.045	0.14	0.23	5.4	1.25
				Mean	1.30±0.05
410	0.035	0.16	0.31	2.2	0.88
410	0.030	0.14	0.24	3.7	0.81
				Mean 3.7±1.2	0.85±0.04

averaged values of $K_1=(3.7\pm1.2)\times10^3$ M^{-1} and $\varepsilon_1^{400}=(1.30\pm0.05)\times10^3$ $M^{-1}cm^{-1}$ and $\varepsilon_1^{410}=(0.85\pm0.04)\times10^3$ $M^{-1}cm^{-1}$.

In considering Y values for this method, such ranges of Y had better be avoided as where the differences between x_a and x_b are too small ($x_a<0.1$) or where the lower curve is too broad near its maximum point ($x_b>0.4$). In addition, only the left halves of the curves must be used, otherwise polynuclear iron(III) species might become effective.

Similarly, at the concentration of acid $[HClO_4]=0.07$ M, other conditions being the same, the method gave $K_1=(3.8\pm0.6)\times10^3$ M^{-1} and $\varepsilon_1^{400}=(1.24\pm0.02)\times10^3$ $M^{-1}cm^{-1}$. No dependence of K_1 upon acid concentration was recognized.

At 41.1°C and $[HClO_4]=0.02$ M, $K_1=(6.3\pm1.5)\times10^3$ M^{-1} and $\varepsilon_1^{400}=(1.29\pm0.02)\times10^3$ $M^{-1}cm^{-1}$ were obtained, which gave approximate values of $\Delta H_1=7$ kcal/mol and $\Delta S_1=40$ cal deg^{-1} mol^{-1}, in association with data at 25°C.

Other possible methods for obtaining K_1 from Job's curves will be described briefly in the following.

Method II Using Two Maxima. The Y values of the two maximum points on the two curves in Fig. 3 are denoted as Y_a^m and Y_b^m, respectively. At these points, as $[Fe^{3+}]=[Cl^-]$, the following relation holds.

$$K_1 = \frac{Y_a^m/(\varepsilon_1-\varepsilon_0)}{\{(C_a/2)-Y_a^m/(\varepsilon_1-\varepsilon_0)\}^2} = \frac{Y_b^m/(\varepsilon_1-\varepsilon_0)}{\{(C_b/2)-Y_b^m/(\varepsilon_1-\varepsilon_0)\}^2} \quad (10)$$

By solving this equation, the values of ε_1 and therefore K_1 will be obtained.

$$\varepsilon_1 = \frac{2(Y_a^m\sqrt{Y_b^m}-Y_b^m\sqrt{Y_a^m})}{C_a\sqrt{Y_b^m}-C_b\sqrt{Y_a^m}}+\varepsilon_0 \quad (11)$$

The results of the numerical calculation at $[HClO_4]=0.02$ M and $\mu=0.10$ M are that $K_1=3.1\times10^3$ M^{-1}, $\varepsilon_1^{400}=1.30\times10^3$ $M^{-1}cm^{-1}$ and $\varepsilon_1^{410}=0.81\times10^3$ $M^{-1}cm^{-1}$ at 25°C, and $K_1=6.7\times10^3$ M^{-1}, $\varepsilon_1^{400}=1.27\times10^3$ $M^{-1}cm^{-1}$ and $\varepsilon_1^{410}=0.79\times10^3$ $M^{-1}cm^{-1}$ at 41°C. This method is less accurate than the previous one.

Method III using a Single Curve. Taking a pair of points (x_1, Y_1) and (x_2, Y_2) on a single Job's curve, and defining the ratio $Y_1/Y_2=[FeCl^{2+}]_1/[FeCl^{2+}]_2$ as α, the following relation is established.

$$K_1 = \frac{\alpha[FeCl^{2+}]_2}{(x_1C-\alpha[FeCl^{2+}]_2)\{(1-x_1)C-\alpha[FeCl^{2+}]_2\}} = \frac{[FeCl^{2+}]_2}{(x_2C-[FeCl^{2+}]_2)\{(1-x_2)C-[FeCl^{2+}]_2\}} \quad (12)$$

Solving Eq. (12), a value for $[FeCl^{2+}]_2$ is obtained and therefore K_1.

$$[FeCl^{2+}]_2 = \left\{\frac{\alpha x_2(1-x_2)-x_1(1-x_1)}{\alpha(\alpha-1)}\right\}^{1/2}C \quad (13)$$

Then ε_1 is known from Eq. (9).

The results of the numerical calculation from 9 sets of data at $[HClO_4]=0.02$ M, $\mu=0.1$ M at 25°C when $C=1.00\times10^{-3}$ M are $K_1=(3.7\pm0.7)\times10^3$ M^{-1} and $\varepsilon_1^{400}=(1.28\pm0.03)\times10^3$ $M^{-1}cm^{-1}$.

Determination of K_1 and K_2 from Linear Relations of $\bar{\varepsilon}$. *Determination of* K_1. At concentrations of iron(III) and chloride ion low enough so that the amount of $FeCl_2^+$ formed is negligible, the apparent molar extinction coefficient of iron(III), $\bar{\varepsilon}$, is defined as

$$\bar{\varepsilon}[Fe(III)] = \varepsilon_0[Fe^{3+}] + \varepsilon_1[FeCl^{2+}] \quad (14)$$

By combining Eq. (14) with Eqs. (2) and (3), $\bar{\varepsilon}$ is expressed by a relationship linear with respect to $(\bar{\varepsilon}-\varepsilon_0)/[Cl^-]$.

$$\bar{\varepsilon} = \varepsilon_1 - \frac{1}{K_1}\frac{\bar{\varepsilon}-\varepsilon_0}{[Cl^-]} \quad (15)$$

Accordingly, plotting $\bar{\varepsilon}$ *vs.* $(\bar{\varepsilon}-\varepsilon_0)/[Cl^-]$ will give $-1/K_1$ as the slope and ε_1 as the intercept. Figure 4 shows this relation when $[Fe(III)]=3.00\times10^{-4}$ M and $[Cl]=8.0\times10^{-5}$—6.5×10^{-3} M were used at $[HClO_4]=0.02$ M and $\mu=0.10$ M at 25°C, observed at 400 mμ. As the concentration of chloride ion is raised, corresponding to a point moving from right to left on the abscissa, the observed $\bar{\varepsilon}$ goes off the straight line, indicating that the occurrence of $FeCl_2^+$ is no longer negligible. Only the linear part is to be taken account of so far as the calculation of K_1 is concerned. At first, [Cl] is used in place of $[Cl^-]$ and a rough value of K_1 is estimated from the slope. By using the first approximate K_1, a second approximate $[Cl^-]$ is calculated at the corresponding [Cl], and a more accurate straight line is drawn, followed by the recalculation of a more accurate K_1. On repeating the cycles until a self-consistent K_1 and $[Cl^-]$'s are obtained, the most reliable K_1 is finally decided. Actually, two cycles were enough for

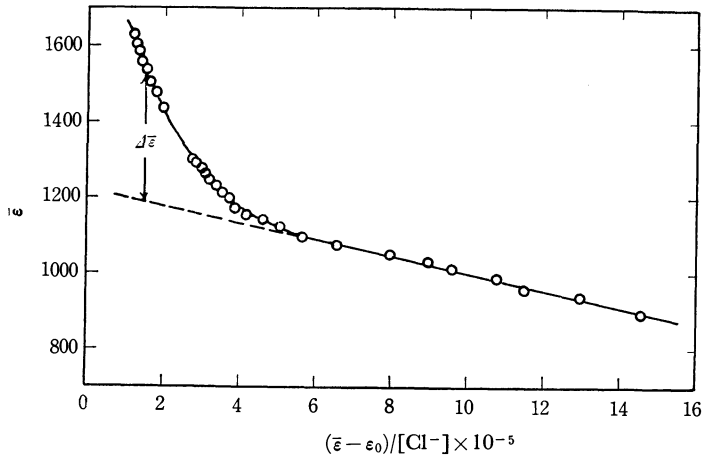

Fig. 4. The plot of $\bar{\varepsilon}$ *vs.* $(\bar{\varepsilon}-\varepsilon_0)/[Cl^-]$ at 400 mμ. $[HClO_4]=0.02$ M, $\mu=0.10$, 25°C.

the purpose. Computation for the slope and the intercept of a straight line was performed by the method of least squares.

As results, $K_1=(4.2\pm0.1)\times10^3$ M^{-1}, and $\varepsilon_1^{400}=(1.24\pm0.01)\times10^3$ M^{-1} cm^{-1}, both of which are in fairly good agreement with the values from Job's curves.

Determination of K_2. K_2 is defined as the stepwise formation constant of $FeCl_2^+$ in DMSO.

$$K_2 = [FeCl_2^+]/[FeCl^{2+}][Cl^-] \quad (16)$$

Equations (3) and (14) can be extended to the following, by taking the presence of $FeCl_2^+$ into account,

$$[Fe(III)] = [Fe^{3+}] + [FeCl^{2+}] + [FeCl_2^+] \quad (17)$$

$$\bar{\varepsilon}[Fe(III)] = \varepsilon_0[Fe^{3+}] + \varepsilon_1[FeCl^{2+}] + \varepsilon_2[FeCl_2^+] \quad (18)$$

in which ε_2 is the molar extinction coefficient of $FeCl_2^+$. Therefore, Eq. (15) is altered to

$$\varepsilon = \varepsilon_1 - \frac{1}{K_1}\frac{\bar{\varepsilon}-\varepsilon_0}{[Cl^-]} + (\varepsilon_2-\bar{\varepsilon})K_2[Cl^-] \quad (19)$$

with the third term on the right-hand side of Eq. (19), which causes the plot to deviate from a straight line at higher concentrations of chloride ion in Fig. 4, because ε_2 is larger than $\bar{\varepsilon}$. Consequently, the deviation $\Delta\bar{\varepsilon}$ is defined as the difference between the observed $\bar{\varepsilon}$ and hypothetical $\bar{\varepsilon}$ which would have been obtained if no $FeCl_2^+$ formation had occurred, and Eq. (19) can be rearranged into another form in terms of $\Delta\bar{\varepsilon}$.

$$\bar{\varepsilon} = \varepsilon_2 - \frac{1}{K_2}\frac{\Delta\bar{\varepsilon}(1+K_1[Cl^-])}{K_1[Cl^-]^2} \quad (20)$$

A plot of $\bar{\varepsilon}$ *vs.* $\Delta\bar{\varepsilon}(1+K_1[Cl^-])/K_1[Cl^-]^2$ will yield a straight line, whose slope and intercept indicate $-1/K_2$ and ε_2, respectively. In order to get the final correct values of K_2 and ε_2, a procedure similar to that in the case of K_1 has to be taken.

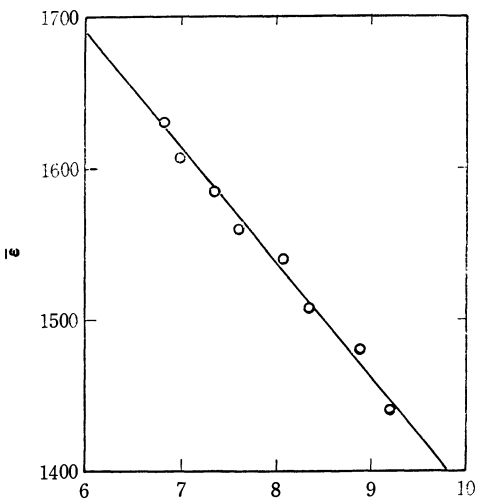

Fig. 5. The plot of $\bar{\varepsilon}$ *vs.* $\Delta\bar{\varepsilon}(1+K_1[Cl^-])/K_1[Cl^-]^2$ at 400 mμ.
$[HClO_4]=0.02$ M, $\mu=0.10$, 25°C

The linearity is obvious in Fig. 5 when $[Fe(III)]=1.50\times10^{-4}$ M and $[Cl]=(3.0\text{—}6.5)\times10^{-3}$ M were used at $[HClO_4]=0.02$ M and $\mu=0.10$ M at 25°C and 400 mμ. The results are $K_2=(1.33\pm0.05)\times10^2$ M^{-1} and $\varepsilon_2^{400}=(2.14\pm0.03)\times10^3$ M^{-1} cm^{-1}.

Other Complementary Methods. *Computer Method.* Collecting all the values of the optical density at many iron(III) and chloride ion concentrations as far as were measured, a high-speed digital computation yielded best fitted values of K_1 and K_2 along with the extinction coefficients as $K_1=(5.3\pm0.6)\times10^3$ M^{-1} and $K_2=(1.1\pm0.3)\times10^2$ M^{-1}, $\varepsilon_1^{400}=1180\pm16$ and $\varepsilon_2^{400}=2350\pm130$ M^{-1} cm^{-1}.[4,11]

TABLE 3. COMPARISON OF K_1, K_2, ΔH_1 AND ΔS_1 FOR THE FORMATION OF $FeCl^{2+}$ AND $FeCl_2^+$ IN WATER, NMA AND DMSO AT 25°C

Solvent	$\log K_1$	$\log K_2$	ΔH_1 kcal/mol	ΔS_1 cal/deg·mol	Dielectric constant
Water	1.48	0.65	8.5	35	80
NMA	2.88	1.11	—	—	178.9 (30°C)[15]
DMSO	3.62	2.10	7	40	46.7 (25°C)[7]

Kinetic Method. The electron transfer reaction between iron(II) and iron(III) in DMSO is accelerated by the presence of chloride ion. At very low concentrations of iron species, the apparent rate constant $\bar{k}$ is expressed by

$$\bar{k}[Fe(III)] = k_0[Fe^{3+}] + k_1[FeCl^{2+}] \qquad (21)$$

which is quite similar to Eq. (14) in appearance, except there are only k's instead of ε's. Accordingly a relationship corresponding to Eq. (15) is obtained as follows.[12]

$$\bar{k} = k_1 - \frac{1}{K_1}\frac{\bar{k}-k_0}{[Cl^-]} \qquad (22)$$

By applying 36 pieces of data measured by Wada and Reynolds,[4] K_1 and k_1 were found to be $K_1=(5.4\pm1.0)\times10^3$ M^{-1} and $k_1=176$ $M^{-1}sec^{-1}$ at $[HClO_4]=0.02$ M and $\mu=0.10$ M at 20°C. This is a convenient method to obtain k_1 without knowing K_1 separately measured in advance.

In Table 2, the values of K_1 and K_2 and ε_1 and ε_2 calculated by various methods are summarized together. In looking at the table, the agreement is good between the Job and the linearity methods with regard to K_1, although the computer and the kinetic methods give a little higher values. Besides this small discrepancy, K_2, ε_1^{400} and ε_2^{400} agree very well among their all measured values, respectively. Considering the accuracy and the reliability of the individual methods employed here, it seems safe to conclude that the most reasonable values are $\log K_1=3.62$ and $\log K_2=2.10$, and therefore $\log \beta_2=5.72$.

Discussion. The values of K_1, K_2, ΔH_1 and ΔS_1 in water[13] and in *N*-methylacetamide (NMA)[14] are listed in Table 3 together with those in DMSO. The decreasing dielectric constant of the solvent seems to favor increased formation of complex between iron(III) and chloride ion. This prevails in the cases of water and DMSO, where iron(III) ion is coordinated through oxygen atoms with the solvating molecules, as compared to nitrogen atoms in NMA. However, coordination through oxygen would favor increased dissociation of $FeCl^{2+}$ better than through nitrogen, considering the spectrochemical series of ligands. In fact, the larger values of K_1 and K_2 found in NMA than in water are really against expectation from the dielectric constant but due to the coordinating atom. The latter effect must be predominant over the former. The coincidence of ΔH_1 and ΔS_1 in water and DMSO seems to have come about rather by chance.

The electron transfer reaction between iron(II) and iron(III) in chloride ion-containing DMSO occurs through two paths.

$$Fe^{2+} + {}^*Fe^{3+} \rightarrow Fe^{3+} + {}^*Fe^{2+} \qquad (23)$$

$$Fe^{2+} + {}^*FeCl^{2+} \rightarrow FeCl^{2+} + {}^*Fe^{2+} \qquad (24)$$

The K_1 value obtained by the kinetic method means the formation constant of $FeCl^{2+}$ appearing in Reaction (24), which probably proceeds through the inner-sphere mechanism with an activated

complex bridged by a chloride ion.[4] Therefore, the approximate agreement between the K_1 values by the spectrophotometric and the kinetic methods, in other words, from independent sources of observation, will permit one to presume that the species of $FeCl^{2+}$ observed in the spectrophotometric method was the same as in the kinetic method, and accordingly, was not a mere association product between ions without liberating the solvating molecules to the ions, but a complex, in the true sense of the word, with a chloride ion, as a ligand, attached directly to the iron(III) ion.

The experimental part of the work was carried out at the Department of Chemistry, University of Minnesota, U. S. A. The author's sincere thanks are due to Professor Warren L. Reynolds for his helpful advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 888—892 (1968)

The Hydrogen Yields in the Radiolysis of Cysteine and Biscysteinatocobaltate(III) in 0.8 N Sulfuric Acid

Niro MATSUURA and Nobuyoshi SHINOHARA

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received October 13, 1967)

Radiation-induced oxidation of cysteine in an acid medium was studied by measuring the hydrogen yields at an initiation stage of radiolysis. In the deaerated system $G(H_2)=4.0$ along with the $G(-CySH)=7.1$ were observed and the results can be interpreted in terms of the yields of primary radicals from the radiolysis of water in 0.8 N sulfuric acid medium. From stoichiometric view point it is predicted that the radiolysis takes place through cysteine radical as intermediate to form cystine. In the aerated system on the other hand, the radiolysis of cysteine is much complicated. For a possible explanation satisfying all the G values obtained, 10.5 in the disappearance of cysteine, 4.0 in the formation of hydrogen peroxide and 0.4 in the hydrogen, the air oxidation of cysteine caused by the radicals, HO_2 and OH which produce H_2O_2 and O_2 by the radical recombination, is proposed as mechanism. The radiolysis of cysteine is greatly reduced by complexation with metallic ion as biscysteinatocobaltate(III) complex. The absence of hydrogen abstraction from cysteine by H atom, the isolation of cysteine from a ligand site and the extraordinary high G values in the disappearance of optical absorption of the complex can be cited as characteristics in the radiolysis of the biscysteinatocobaltate(III) complex. The intramolecular redox of the complex into Co(II) ion and cysteine is a best fit mechanism as over all reaction in the radiolysis of the biscysteinatocobaltate(III) complex.

In the literature so far appeared, the radiolysis of cysteine produces cystine along with some H_2S and alanine with G values around 3,[1-4] depending on the concentration of cysteine as solute. In the presence of dissolved oxygen from air the irradiated cysteine produces sulfate instead of H_2S.[1] A recent paper reported the formation of a lot of sulfur oxyacids and other several compounds as stable products from cystine in the radiolysis of its aerated solution.[5] The disagreement on the stoichiometric balance and therefore, on the resulted mechanism appears likely to be derived from the technique employed by different workers. In their studies secondary reaction intermediates are picked up to account for the radiolysis and make the interpretation rather complicated. One of our principal concerns is the establishment of stoichiometry with the primary reaction between the solute and the primary radicals from the radiolysis of solvent water. As an initiation of radiation-induced oxidation of cysteine an assumption was made of cysteine radicals CyS· as intermediate which was subsequently reformed to cystine as final stable product. In this investigation the cysteine oxidation to cystine at an earlier stage of radiolysis was confirmed by the hydrogen yields

from the cysteine in 0.8 N sulfuric acid under γ irradiation in the presence and absence of dissolved oxygen.

Experimental

Materials. Triply distilled water was used for preparing samples throughout the experiments. Cysteine solution was prepared by dissolving an appropriate quantity of reagent grade cysteine (Wako Pure Chem. Ind. Ltd.) in 0.8 N sulfuric acid for acid medium radiolysis. The complex salt was prepared from cobalt(II) chloride by the method in Schubert's paper.[6] The purification by recrystallization was repeated three times. The analysis provided the composition of the complex together with theoretical values in parentheses: Co, 16.5% (17.6%); H, 4.57% (3.0%); C, 20.98% (21.4%); N, 8.09% (8.35%) corresponding to the formula $CoH(CyS)_2 \cdot 2H_2O$[7] All other reagents used, acids and salts, are of reagent grade.

Irradiation. Sample solutions were saturated with air or flashed with nitrogen in telextube and were irradiated with γ-rays from 60-Co source of one kilo curie facilitated by the Institute of Physical and Chemical Research. Dose rates were measured by Fricke Dosimeter taking the $G_{Fe^{3+}}$ value equal to 15.6, and the molecular extinction coefficient for Fe^{3+} $\varepsilon=2150$ at 304 mμ and 20°C was employed.

Analysis. Decrease of cysteine and increase of cystine in a solution caused by irradiation was determined by the polarographic method described in the published work.[8]

Spectrophotometric and polarographic measurements of biscysteinatocobaltate(III) is effected by the procedure as follows. A solution of 1×10^{-4} M biscysteinatocobaltate(III) was taken as reference and irradiated sample solutions were diluted to a concentration nearly same as above. Photoabsorption maxima of biscysteinatocobaltate(III) lie at the wavelengths of 276, 345 and 430 mμ. By differential spectrum method the decrease of absorption was measured against gamma doses at 276 mμ.

Analysis of Hydrogen and Hydrogen Peroxide. The amount of hydrogen evolved from irradiated liquid sample was determined by gas chromatographic method using a GC-1B type Shimadzu Gas Chromatograph to which a liquid-separating line and a precolumn consisting of Molecular Sieve was attached. A similar method has been reported in detail by one of present authors as well as Swinnerton *et al.*[9,10]

Hydrogen peroxide in the irradiated solutions was colorimetrically determined by titan yellow method known as common usage.

Result

The Yields of Hydrogen from Cysteine. The radiolysis of cysteine proceeds in linear function of absorbed γ dose. The slope of the curve drawn by the plots of the amount of cysteine lost against the received γ dose provides a G value for a given cysteine concentration. The G values thus obtained are dependent on the cysteine concentration, hardly attainable to a maximum value independent of the cysteine concentration. Then, an inverse-plots method is required to find such a maximum G value which is independent of the cysteine concentration. The estimated G values are available for establishing stoichiometric balance relation. Concerning the disappearance yields of cysteine, the G values from our earlier data[7] are represented by the formula in Table 1 as a function of cysteine concentration.

Table 1. G values of cysteine lost
[CySH] designates the concentration of cysteine in M

$G(-\mathrm{CySH})$	O_2 present $\dfrac{10.5}{1+(1/6.2\times10^3[\mathrm{CySH}])}$
$G(-\mathrm{CySH})$	O_2 absent $\dfrac{7.5}{1+(1/2.5\times10^3[\mathrm{CySH}])}$

Figure 1 shows the amount of hydrogen determined by gas chromatographic analysis towards the received γ dose in the radiolysis in the deaerated system. In the deaerated system the maximum $G(H_2)$ was determined at a cysteine concentration higher than 2×10^{-3} M from the curve shown in Fig. 2. In the aerated system, on the other hand, the hydrogen yields were found to be no more than 0.4 over all the range of cysteine concentration.

This means that there is no hydrogen derived from the hydrogen abstraction from cysteine by

H atom and all of produced hydrogen is composed of unscavengeable H atom, whose yield is 0.4 in G value.

The Hydrogen Peroxide Yields in Aerated System. The determination of hydrogen peroxide yields is of much importance for the radiolysis of cysteine in the aerated system. The $G(H_2O_2)$ were 4.0 for the aerated system and 0.0 for the deaerated system. The dependency of the G values on cysteine concentration is illustrated in Fig. 3.

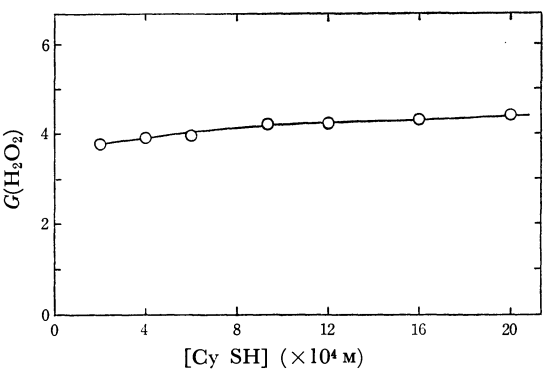

Fig. 3. $G(H_2O_2)$ as function of cysteine concentration (aerated system).
γ dose: 1.3×10^4 R/m*l*

The Hydrogen Yields from Biscysteinatocobaltate(III). The $G(H_2)$ are plotted in Fig. 4 against the concentration of the complex at a given γ dose of 2×10^4 R/m*l* or 1.2×10^{18} eV/m*l*. The observed G values did not exceed 0.4, corresponding to the primary molecular hydrogen yield. This fact suggests the chelated cysteine is no longer so sensitive to γ radiation as free cysteine is, even in deaerated system. In the radiolysis of this complex the G values with respect to the disappearance have been given by the formula in Table 2 established from our earlier data.[7]

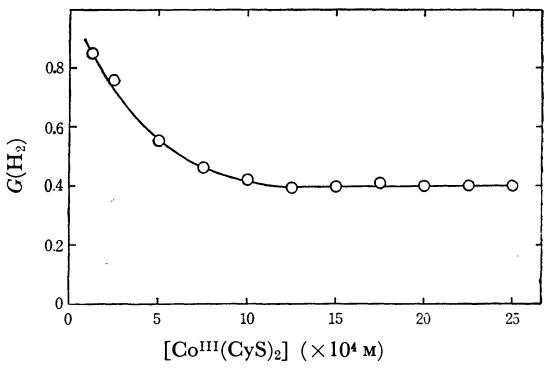

Fig. 4. Variation of $G(H_2)$ with the concentration of $Co^{III}(CyS)_2$ in deaerated system.

TABLE 2. G VALUES OF BISCYSTEINATOCOBALTATE(III) LOST
[$Co^{III}(CyS)_2$] designates the concentration of $Co^{III}(CyS)_2$ in M

$G(-Co^{III}(CyS)_2)$	O_2 present $\dfrac{12}{1+(1/5.5\times10^3[Co^{III}(CyS)_2])}$
$G(-Co^{III}(CyS)_2)$	O_2 absent $\dfrac{13}{1+(1/8.5\times10^3[Co^{III}(CyS)_2])}$

The Yields of Cysteine Liberation. In the radiolysis of biscysteinatocobaltate(III) a break point was observed as shown in Fig. 5A, indicating that there had been a secondary reaction accompanied by the retardation of radiolysis at a critical dose of 2×10^4 R/m*l*. The cause of secondary reaction, occuring in slower rate, could be ascribed to a primary radiolysis product as prohibitor toward the degradation of the complex. The presence of break point suggests that hydrogen abstraction from cysteine as ligand molecule was suppressed by the reduction of cobalt(III) complex to cobalt(II) which resulted in the liberation of

○ Aerated, ● Deaerated

cysteine from ligand position. The free cysteine thus liberated could be determined polarographically and by PCBM method[11] as function of received γ dose and a maximum yield was found at the corresponding critical dose cited above. The maximum yield of cysteine in the radiolysis of the complex, shown in Fig. 5B, can be accounted for by the loss of cysteine by oxidation after isolation from the complex in concurrence with the increase by isolation.

Discussion

Cysteine is regarded as one equivalent redox reagent when it is converted into cystine by the radiolysis in aqueous phase. If the final oxidation product of cysteine is assumed as cystine alone, so far as an earlier stage of radiolysis is concerned, the G values with regard to cysteine disappearance should be equal to the sum of primary radical yields, g_H+g_{OH}, attaining $3.6+2.9=6.5$ as a maximum G value in the deaerated system. The difference between the theoretical and experimental values, amounting to 1.0, is not small enough to be ignored as an experimental error. However, the observed $G(H_2)$ can account for the initiation of radiolysis by hydrogen abstraction to yield cysteine radical as intermediate product which forms stable cystine under our condition of the radiolysis at high scavenger concentration.

$$CySH + H(\text{or } OH) = CyS\cdot + H_2(\text{or } H_2O) \quad (1)$$

$$CyS\cdot + CyS\cdot = CyS : SCy \text{ (cystine)} \quad (2)$$

From Eqs. (1) and (2) the $G(H_2)$ is just equal to the sum $g_H+g_{H_2}=3.6+0.4=4.0$ in good agreement with the value experimentally found. The radiolysis in deaerated system gave no hydrogen peroxide which might be responsible to the shortage of the G value 1.0 as stated above. Since hydrogen peroxide is inert against cysteine because of its slow reaction rate, the oxidation of cysteine by hydrogen peroxide must be induced by the radiolysis through a certain reactive intermediate, like a cysteine radical. Nevertheless, a presumed value of $g_H+g_{OH}+2g_{H_2O_2}=3.6+2.9+1.6=8.4$ based on the two equivalent oxidation of H_2O_2 is too large to explain the experimental G value of 7.5.

As for the aerated system the stoichiometric relation is much more complicated, probably because of the dissolved oxygen taking part in the radiolysis of cysteine by the formation of some radical intermediate like a $CySO_2\cdot$ radical. In the aerated system the maximum G values were 10.5 with the $G(-CySH)$, 4.0 with the $G(H_2O_2)$ and 0.4 with $G(H_2)$. For possible explanation satisfying all these G values the schema (3) and (4), has to be introduced.

$$2CySH + HO_2(H+O_2) = CyS : SCy + \tfrac{1}{2}H_2O_2 + H_2O \quad (3)$$

$$2CySH + 2OH + \tfrac{1}{2}O_2 = CyS : SCy + H_2O_2 + H_2O \quad (4)$$

Under the assumption made for the schema (3) and (4) the stoichiometric balance between G values is quite self-consistent, because $G(-CySH)=2g_H+g_{OH}=2\times 3.6+2.9=10.1$, $G(H_2O_2)=(1/2)g_H+(1/2)\,g_{OH}+g_{H_2O_2}=4.1$ and $G(H_2)=g_{H_2}=0.4$. It is interesting to indicate that the reaction schema described in (3) and (4) are nothing but the recombination of radicals HO_2 and OH to H_2O_2 in the presence of cysteine as solute and the oxidation of cysteine by air oxygen induced by radiolysis.

The radiolysis of biscysteinatocobaltate(III) shows several characteristic features: the absence of hydrogen abstraction, the liberation of free cysteine from a ligand position and the high G value, 12—13, with regard to the disappearance of the complex. The latter yields are approximately twice as large as the sum of the primary radical yields $g_H+g_{OH}=6.5$. These facts could be interpreted in terms of the inner sphere reduction of the complex from Co(III) to Co(II) due to radicals H and OH.[13]

$$2Co^{III}(CyS)_2^- \xrightarrow{H,\ OH} 2Co^{2+} + 2CySH + CyS{:}SCy + H_2O \quad (5)$$

13) N. Matsuura, M. Muroshima and M. Takizawa, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **85**, 268 (1964).

The reaction (5) is based on the one molecule cysteine liberation per one molecule of the complex lost at an earlier stage of radiolysis with a dose below the critical value of 2×10^4 R/m*l*. It is indicated that the overall reaction (5) is nothing but an intramolecular redox of the complex caused by the radicals.

Generally speaking, so far as maximum G values are concerned or secondary reactions are excluded that might occur between free radicals and an intermediate product of radiolysis, a quantitative stoichiometric balance holds well. As initiation of radiolysis in the system of cysteine or metal-cysteine complex, the major product is likely the cystine produced by the recombination of cysteine radical CyS. Namiki *et al.*[14] have evidenced a stationary mixture of cysteine and cystine in equilibrium attained by the radiolysis of either cysteine or cystine used as starting solute. A number of products different from cystine reported by several workers could be ascribed to the results involving secondary reaction products in a large γ-dose region.

The authors extend their thanks for the financial aid from the Radiation Research Funds defrayed by the Ministry of Education, Japan.

Crystalline Complexes of Allylamine and Propylamine with Copper(I) Chloride and Bromide

Tetsuya OGURA, Takeshi HAMACHI and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshiku, Osaka

(Received November 21, 1967)

Crystalline 1 : 1 and 1 : 3 complexes of allylamine and propylamine with copper(I) chloride and bromide were synthesized *in vacuo*. Equilibrium vapor pressures of these complexes were measured at several temperatures and the enthalpy of ligation of each amine molecule was determined. Both the thermochemical and infrared absorption data indicate that in the 1 : 1 complexes of allylamine the ligand molecule serves as a bidentate, but in the 1 : 3 complexes the second and third ligand molecules link to the metal only through the amino nitrogen atom.

The ability of simple aliphatic amines to form metal coordination compounds have been examined and found to decrease in the series[1] $NH_3 > RNH_2 > R_2NH > R_3N$. Recently Yoke and his collaborators reported copper(I) chloride complexes of triethylamine,[2] diethylamine[3] and ethylamine.[4] However, the unsaturated amine such as allylamine has not yet been employed as the coordinating ligand. In this paper we report crystalline complexes of copper(I) chloride and bromide with allylamine and propylamine which were synthesized by the same method as that previously adopted in the syntheses of copper(I) chloride complexes of acrolein[5] and allyl alcohol.[6]

Experimental

Materials. Copper(I) chloride and bromide were prepared by the ordinary method[5] and purified by the distillation *in vacuo*. Allylamine (abbreviated as am in this paper), $CH_2=CHCH_2NH_2$, and propylamine (abbreviated as pm) were dried with Molecular Sieves Type 3A, Linde Co. and the freshly distilled sample was used in each experiment.

Syntheses of Copper(I) Halide - Amine Complexes with the Mole Ratio of One to Three. Allylamine or propylamine (10—15 g) was distilled into an ampoule containing pulverized copper(I) chloride or bromide (1g). In each case the exothermic reaction occurred and colorless, transparent and bulky crystals grew up on copper(I) halide powder. The reaction

mixture was kept standing overnight to complete the reaction, and the excess amine was then distilled back to the original ampoule. The copper(I) complex was dried completely without decomposition by keeping the two ampoules at 5 and 0°C respectively for 50 hr. The analytical data of four kinds of complexes thus prepared are as follows:

Found: Cu, 23.2; Cl, 13.1%. Calcd for $CuCl(C_3H_7N)_3$: Cu, 23.5; Cl, 13.1%.

Found: Cu, 20.1; Br, 25.2%. Calcd for $CuBr(C_3H_7N)_3$: Cu, 20.2; Br, 25.4%.

Found: Cu, 22.8; Cl, 13.0%. Calcd for $CuCl(C_3H_9N)_3$: Cu, 23.0; Cl, 12.8%.

Found: Cu, 19.3; Br, 24.5%. Calcd for $CuBr(C_3H_9N)_3$: Cu, 19.8; Br, 24.9%.

Syntheses of Copper(I) Halide-Amine Complexes with the Mole Ratio of One to One. The ampoule containing a copper(I) halide-amine complex with the mole ratio of one to three was kept at room temperature around 20°C and another empty one at 0°C which had been connected with each other and evacuated. The complex decomposed partially and expelled about two moles of amine per mole complex during standing overnight. The amine vessel was cooled with liquid nitrogen for further 24 hr and exactly two moles of amine was recovered. The copper(I) amine complexes prepared in this way showed the following analytical data.

Found: Cu, 40.1; Cl, 22.8% mp around 100°C. Calcd for $CuCl(C_3H_7N)$: Cu, 40.7; Cl, 22.7%.

Found: Cu, 31.8; Br, 39.8%; mp around 100°C. Calcd for $CuBr(C_3H_7N)$: Cu, 31.7; Br, 39.9%.

Found: Cu, 39.3; Cl, 22.6%; mp 22°C. Calcd for $CuCl(C_3H_9N)$: Cu, 40.1; Cl, 22.4%.

Found: Cu, 31.3; Br, 39.7%; mp 75°C. Calcd for $CuBr(C_3H_9N)$: Cu, 31.4; Br, 39.5%.

These copper(I) halide-amine complexes are all stable at room temperature. When they were heated to higher temperatures, 80—90% amine was recovered, but the quantitative dissociation could not be attained.

For comparison, copper(I) chloride complexes of deuterated amines, $CuCl(C_3H_5ND_2)$ and $CuCl(C_3H_7ND_2)$ were also prepared in the following way. Allylamine or propylamine (0.3 g) was distilled into heavy water (5 g) whose deuterium content was 99.8%. The solution was then distilled into an ampoule containing copper(I) chloride (0.2 g) and kept standing overnight. The complex was then dried at a temperature difference of room and dry ice temperatures as described above.

Vapor Pressure Measurement. The dried crystalline complex was prepared in an ampoule connected with a U-type mercury manometer. The equilibrium vapor pressure was measured at various temperatures by keeping the sample tube in appropriate thermostat baths.

Infrared Spectra. The infrared absorption spectra were measured with a Hitachi infrared spectrophotometer, EPI-2. The amine complex with the mole ratio of one to three is unstable and the crystalline specimen was mixed with Nujol and ground down quickly in a nitrogen atmosphere.

Results

Copper(I) halide complexes of allylamine and propylamine with the mole ratio of one to three are all colorless and transparent crystals, showing no difference in appearance. These compounds have appreciable vapor pressures and decompose spontaneously in an open atmosphere resulting in the complexes with the metal-ligand mole ratio of one to one. They are also very sensitive to air and change to deep blue color characteristic of the copper(II) amine complex.

On the other hand copper(I) halide complexes of these amines with the mole ratio of one to one are fairly stable against air or heat just as the monoammine adduct of copper(I) chloride is.

The Vapor Pressure Data. The equilibrium vapor pressure of the copper(I) halide-amine system was determined at various compositions and the following two equilibria were found to exist:

$$CuX + RNH_2 = CuX(RNH_2) \quad (1)$$

$$\tfrac{1}{2}CuX(RNH_2) + RNH_2 = \tfrac{1}{2}CuX(RNH_2)_3 \quad (2)$$

where X represents Cl or Br, and R stands for C_3H_5 or C_3H_7. However, the copper(I) complex of the composition, $CuX(RNH_2)_2$ or $CuX(RNH_2)_{1.5}$ was not identified.

The equilibrium dissociation pressure of the copper(I) halide complexes of allylamine and propylamine with the mole ratio of one to three was determined at various temperatures. The results obtained are shown in Table 1 and represented by Eqs. (3) through (6).

The vapor pressure of the copper(I) halide-amine complexes with the 1 : 1 composition was lower and determined at temperatures higher than 100°C. The results are listed in Table 2 and reproduced by Eqs. (8) through (11). However, data for allylamine complexes might be less reliable than those for the above 1 : 3 complexes, since some kind of chemical change of the ligated allylamine (possibly disproportionation to ammonia and diallylamine or triallylamine) was noticed to occur when the complex was maintained at temperatures higher than 130°C for several days.

From Eqs. (3) through (11) the heat of formation of each complex referring to Eqs. (1) and (2) was calculated and listed in Table 3. The vapor pressure data of allylamine were not available in literature and determined for the specimen which had been specially purified by formation and decomposition of copper(I) chloride complex with the mole ratio of one to three. The results obtained are represented by Eq. (7) in Table 2. The boiling point of allylamine calculated by means of Eq. (7) is 54.8°C which coincides fairly well with the literature value[7] of 55—58°C. As the heat of vaporization of propylamine the value of 7.3 kcal·mol^{-1} due to Stull[8] was used for calculation in Table 3.

TABLE 3. THE CONSECUTIVE ENTHALPY OF FORMATION OF COPPER(I) HALIDE COMPLEXES OF ALLYLAMINE AND PROPYLAMINE CALCULATED FOR ONE MOLE OF GASEOUS AMINE*

Compound	ΔH kcal·mol^{-1}	Compound	ΔH kcal·mol^{-1}
CuCl(am)	−25.2 (−17.3)	$CuCl(am)_3$	−13.9 (−6.0)
CuBr(am)	−25.7 (−17.8)	$CuBr(am)_3$	−14.3 (−6.4)
CuCl(pm)	−14.4 (−7.1)	$CuCl(pm)_3$	−12.5 (−5.2)
CuBr(pm)	−14.1 (−6.8)	$CuBr(pm)_3$	−10.4 (−3.1)

* The value in a bracket refers to the enthalpy of formation from the liquid amine.

Infrared Spectra. The infrared spectra of these complexes are very complicated in comparison with those of free amines. Several characteristic absorption bands due to NH_2 group were assigned on the observation of their shifts by the deuteration. They are listed in Table 4 together with the stretching frequency of the double bond of allylamine.

Propylamine has no way of coordination to the metal other than *via* nitrogen atom, and the remarkable shifts of the stretching and deformation frequencies of the NH_2 group by ligation indicate that this is the case. Allylamine, on the other hand, may be linked to copper(I) either by nitrogen atom or by the double bond. As shown in Table 4 coordinated allylamine shows similar shifts of $\nu(NH_2)$ and $\delta(NH_2)$ to the lower frequency side as propylamine does. This suggests that nitrogen atom of every allylamine molecule is used in bonding to copper(I). The stretching frequency of the double bond of allylamine in the 1 : 1 complex is lower by 110 cm^{-1} than that of the free amine. However, two peaks are observed at 1645 and 1535 cm^{-1} for the 1 : 3 complex, corresponding to the free and ligated double bond, respectively.

These results indicate that in the 1 : 1 complex every allylamine molecule is coordinated to copper(I) by both double bond and amine group, while in the 1 : 3 complex two kinds of allylamine molecules are contained, one acting as a bidentate and the other as a unidentate ligand which is linked solely by the amine group.

Discussion

Wilkins and Burkin[9] investigated the reactions of copper(I) halides with long-chain aliphatic amines such as *n*-octyl-, *n*-dodecyl- with *n*-octadecylamines, and identified $[CuBr(RNH_2)_2]_2$ and $[CuX(RNH_2)]_4$ where X is Cl, Br or I. Triethylamine was reported to form 1 : 1 complexes with copper(I) halides,[2] and diethylamine to form both 1 : 1 (tetrameric) and 1 : 2 (dimeric) complexes with copper(I) chloride. In the system of copper(I) chloride - ethylamine 1 : 1 and 1 : 2 complexes were isolated and 1 : 3 complex was noticed in the isothermal phase study at 0°C. In the present case 1 : 1 and 1 : 3 complexes were obtained for the copper(I) halides and allylamine or propylamine systems, but no indication of 1 : 2 complexes was observed.

As shown in Table 3 the enthalpy of formation of the 1 : 1 complex from solid copper(I) halide and liquid propylamine was determined as −7.1 kcal·mol^{-1} for the chloride complex and −6.8 kcal·mol^{-1} for the bromide complex, but the enthalpy of ligation of the second and third molecule of propylamine is −5.2 and −3.1 kcal·mol^{-1}, respectively. It is quite reasonable that the first ligand molecule coordinates to the metal atom more exothermically than the second or third one since more or less negative charge is brought in around the central metal by the ligand molecule. The fact is noticed that the heat evolved by ligation of propylamine to copper(I) bromide is a little less than that for copper(I) chloride. Bromine may make a more covalent bond and bring larger negative charge around the central metal than chlorine does, reducing the bond strength between copper(I) and the hard amine ligand.

The enthalpy of formation of $CuI(NEt_3)$ from CuI(s) and triethylamine(*l*) was reported[2] as −8.21 kcal·mol^{-1}, and ΔH for the second molecule of diethylamine(*l*)[3] and ethylamine(*l*)[4] ligating to each 1 : 1 copper(I) chloride complex was estimated as −7.8 and −6.65 kcal·mol^{-1}, respectively. These data together with our present ones indicate the possible region of values for the enthalpy of ligation of aliphatic amines to copper(I) halide. The observed values of ΔH for the second and third molecule of allylamine ligating to copper(I) chloride and bromide lie in this probable region suggesting that the ligand molecule in question coordinates to copper(I) through the amine group.

However, ΔH for the ligation of the first molecule of allylamine to copper(I) chloride or bromide is much more negative, and even more negative than those for other vinyl complexes as summarized in Table 5. This clearly indicates that the first

9) R. G. Wilkins and A. R. Burkin, *J. Chem. Soc.*, **1950**, 127.

molecule of allylamine coordinates to copper(I) atom with both the amino nitrogen atom and π-electrons of the double bond. In the case of allylamine ΔH's for copper(I) bromide are a little more negative than those for the chloride in contrast to the case of propylamine complexes. The softness of bromine in comparison with chlorine may enhance the bonding between copper(I) and the C=C double bond in which the contribution of back donation from metal to ligand is significant.

TABLE 5. THE ENTHALPY OF FORMATION OF 1:1 COPPER(I) CHLORIDE COMPLEX WITH SEVERAL VINYL COMPOUNDS AND THB SHIFT OF C=C STRETCHING FREQUENCY

Compound	$-\Delta H$ kcal·mol^{-1}	$\Delta\nu$(C=C) cm^{-1}	Ref.
CH_2=CH-CHO	11.8	90	5
CH_2=CH-CH_2OH	12.0	95	6
CH_2=CH-CN	14.9	100	10
CH_2=CH-CH_2NH_2	25.2	110	this study

The conclusion that in the tris(allylamine)-copper(I) complexes one ligand molecule coordinates to the metal with both nitrogen atom and the double bond but the second and third molecules only with nitrogen, is also supported by the infrared absorption data as mentioned already. Copper(I) usually prefers the coordination number four. If one of three molecules of allylamine is serving as a bidentate ligand, the 1 : 3 copper(I) halide complexes must be salts keeping the halide as outer-sphere anions. Some extensive studies such as the conductivity measurement of copper(I) halides in allylamine are desired but have not yet been performed.

There are summarized in Table 5 the enthalpy of formation of 1 : 1 copper(I) chloride complexes with several vinyl compounds together with the associated shift of C=C stretching frequency. A remarkable correspondence is noticed between these two properties. The X-ray analysis of the copper(I) chloride complex of acrolein revealed that each acrolein molecule is assuming the s-trans configuration and acting as a bridging ligand between two copper atoms.[11] On the other hand the allyl alcohol complex seems to exist as a dimer[12] with the chloride double bridge, the alcohol molecule acting as a chelating agent. In the present case the molecular weight of the 1 : 1 complex of copper halide with allylamine has not been determined owing to the lack of any suitable solvents, but it might be presumed by analogy with the allyl alcohol complex to exist as a dimer. Further information concerning the real structure must be offered by the X-ray analysis of this compound.

11) Y. Kushi, T. Ogura, S. Kawaguchi and H. Kuroya, Presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.
12) In a previous paper (Ref. 6) copper(I) chloride was reported to exist as a monomer in boiling allyl alcohol, but further detailed measurements revealed that this rather preliminary observation was wrong. Copper(I) chloride exists as a dimer in allyl alcohol even at the boiling point just as at lower temperature.

A Kinetic Study of the Free-Radical Bulk Polymerization of Ethylene

Sueo MACHI, Takashi SAKAI, Fujio SUGANUMA and Tsutomu KAGIYA

Japan Atomic Energy Research Institute, Takasaki Radiation Chemistry Research Establishment, Takasaki, Gunma

(Received January 16, 1967)

The bulk polymerization of ethylene was carried out under mild conditions, *i. e.*, pressures of from 183 to 400 kg/cm^2 and temperatures of from 30 to 140°C, using azobisisobutyronitrile as an initiator. In polymerization at the low temperature of 40°C, both the polymerization rate and the molecular weight of the polymer formed increased with the reaction time. At the above temperature, the polymerization rate was shown to be proportional to the amount of initiator, and the molecular weight was found to be independent of it. Furthermore, both the polymerization rate and molecular weight were found to be proportional to the 2.5th power of ethylene fugacity. The dependencies of the polymerization rate and the molecular weight on the reaction time decrease with the rise in reaction temperatures from 30 to 100°C. A kinetical discussion indicated that the rate of termination is almost zero at 30—40°C, but that it increases with the temperature. The polymerization rate and the molecular weight were shown to be proportional to the 0.8 and 0.2th powers of the amount of the initiator. The activation energy of the initiation reaction was evaluated to be *ca.* 27 kcal/mol.

The free-radical polymerization of ethylene has usually been investigated under severe reaction conditions, such as high pressures from 800 to 2000 kg/cm^2 and high temperatures from 130 to 250°C.[1-5] Such conditions are also used in the industrial process. Recently, however, a few studies have been conducted under milder conditions, namely, under lower pressures and at lower temperatures.[6,7] The possibility of the existence of a long-lived polymer radical was first pointed out briefly by Buchdahl[8] in his discussion of the paper by Laird *et al.*[2] Lyubetzky *et al.*[7] studied the polymerization of ethylene at 70°C with azobisisobutyronitrile (AIBN) in benzene, and pointed out that the propagation reaction occurs with the living polymer radical in the polymer crystalline phase.

We have reported several characteristics of the low temperature free-radical bulk polymerization of ethylene in a previous paper.[9] This paper, a continuation of that earlier paper, will be concerned with the kinetic study of ethylene polymerization in bulk with AIBN, at temperatures of from 30 to 140°C and at pressures of from 100 to 400 kg/cm^2.

Experimental

Polymerization was carried out in a static, unstirred, stainless-steel (SUS-27) high-pressure vessel with a capacity of 100 m*l*. After the desired amount of crystalline AIBN had been introduced, the vessel was flushed out six times with ethylene (10 kg/cm^2). The vessel was then cooled in a methanol-dry ice bath, ethylene being introduced from a reservoir. The vessel was warmed to the desired reaction temperature, and a very small amount of ethylene was released from the vessel to adjust the reaction pressure. Since the polymerization was carried out to a low conversion, the pressure, which was measured by a Bourdon tube gauge, was almost constant throughout the reaction. A temperature constant within ±1°C was also maintained by an automatic controller. At the end of the reaction, the unpolymerized ethylene was purged and the vessel was opened. After the unchanged initiator had been extracted by using boiling acetone, the polymer yield was determined.

The ethylene used had been commercially obtained and was 99.9% pure (free of CO and H_2S), containing 21 ppm acetylene and 0.3 ppm oxygen. The density and fugacity of ethylene at a given pressure and temperature were known from Benzler's pressure-enthalpy diagram.[10] AIBN was purified by recrystallization

from acetone. The molecular weight of the polymer was determined from its intrinsic viscosity in tetralin at 130°C. Tung's formula[11] was used in the calculation of the molecular weight, because the polymer has little branching, like a low-pressure polyethylene.[9]

Results and Discussion

Polymerization at a Low Temperature. The experimental results are summarized in Table 1.

Figure 1 shows the changes in the polymer yield (*i. e.*, the amount of polymerized monomer) and the molecular weight with the reaction time. The polymer yield is found to be proportional to the second power of the time, and the molecular weight, to the first power. The polymerization rate and molecular weight increase with the time. Similar features have been found as distinct characteristics in the low temperature bulk polymerization of ethylene induced by radiation.[12,13] These facts suggest that the rate of termination is very small. The polymer radical, therefore, accumulates as AIBN decomposes to radicals, and the rate of polymerization increases. The steady increase in the molecular weight suggests that the rates of both termination and transfer are very small.

TABLE 1. RESULTS OF THE POLYMERIZATION AT 40°C

Ethylene pressure kg/cm²	Amount of AIBN mmol	Reaction time hr	Polymer yield g	Molecular weight $\overline{M}_n \times 10^{-4}$
400	0.980	1.5	0.24	11.3

Figure 2 shows the effects of the ethylene pressure on the polymer yield and the molecular weight. Both the molecular weight and polymer yield increase rapidly with the ethylene pressure at a constant time. Their pressure exponents are found to be approximately two.

Figure 3 shows the influence of the amount of the initiator; the figure indicates that the polymer yield at a constant time is proportional to the number of moles of initiator added, and that the molecular weight of the polymer is independent of it. These facts are in contrast to the dependencies of the rate and molecular weight on the amount of the initiator in a polymerization where rapid bimolecular termination occurs.

The polymerization is considered to consist of the following steps:

Initiation

Decomposition of initiator $\quad I \xrightarrow{k_d} 2R\cdot \quad (1)$

Addition of a monomer $\quad R\cdot + M \xrightarrow{k_a} RM_1\cdot \quad (2)$

Propagation $\quad RM_1\cdot + M \xrightarrow{k_p} RM_2\cdot \quad (3)$

$\quad \vdots \quad \vdots \quad \vdots$

$\quad RM_{n-1}\cdot + M \xrightarrow{k_p} RM_n\cdot \quad (4)$

Transfer $\quad RM_n\cdot + Y \xrightarrow{k_{tr}} P_n + Y\cdot \quad (5)$

Termination $\quad RM_n\cdot + Z \xrightarrow{k_{t_1}} P_n \quad (6)$

$\quad RM_m\cdot + RM_n\cdot \xrightarrow{k_{t_2}} P_{m+n} \quad (7)$

The initiation step consists of two reactions, *i. e.*, the decomposition of the initiator, I, into free radicals, R·, and the addition of a monomer to form radicals, $RM_1\cdot$. Since the decomposition of AIBN has been shown to proceed *via* a first-order reaction independent of the reaction media, such as various organic solvents,[14,15] an aqueous solution of dioxane[16] and water[17] where AIBN is not soluble, a first-order decomposition is assumed in this system in the absence of a solvent. Thus, the rate of the primary radical formation at time t is:

$$d[R\cdot]/dt = 2k_dI_0 \exp(-k_dt) \quad (8)$$

where k_d represents the rate constant of the decomposition of the initiator, and where I_0 is the amount of the initiator at the initial stage. Some fraction of the primary radicals may initiate chains according to Eq. (2), and the other fraction tends to disappear through other reactions. The rate of the initiation of chain radicals is, therefore, given by:

$$R_i = d[RM_1\cdot]/dt = 2fk_dI_0\exp(-k_dt) \quad (9)$$

where f is the fraction of the radicals initiating polymerization chains, the so-called radical yield. Since the number of moles of polymer chains formed at a constant reaction time is independent of the ethylene pressure, as will be described below, the f fraction is not dependent on the monomer concentration.

At a low temperature of 40°C and at the initial stage, since the value of k_dt is much smaller than unity, R_i is approximately expressed as:

$$R_i = 2fk_dI_0 \quad (10)$$

Propagation proceeds by the addition of monomers to the chain radical to form the growing polymer radical, $RM_n\cdot$, which has n monomeric units. The rate of propagation, R_p, is:

$$R_p = k_p[RM\cdot]f_M \quad (11)$$

where [RM·] is the total concentration of radicals irrespective of size ($\sum_{n=1}^{\infty}[RM_n\cdot]$), and k_p, the rate constant of propagation. The ethylene fugacity, f_M, is used as a measured of ethylene activity under high pressure. The concentration of radicals at time t is given as the difference between initiation and termination:

$$[RM\cdot] = \int_0^t R_i dt - \int_0^t R_t dt \quad (12)$$

where R_t is the rate of termination. As has been mentioned above, the rate of termination is negligible. Thus:

$$[RM_n\cdot] \fallingdotseq \int_0^t R_i dt = 2fI_0\{1-\exp(-k_dt)\} \quad (13)$$

At low temperatures and at the initial stage of polymerization, Eq. (13) is approximately rewritten as:

$$[RM\cdot] \fallingdotseq 2fk_dI_0t \quad (14)$$

The rate of polymerization, which is essentially the same as the rate of propagation, is given by combining Eq. (11) and Eq. (14):

$$R \fallingdotseq R_p = R_p[RM\cdot]f_M = 2fk_dk_pI_0f_Mt \quad (15)$$

By integrating Eq. (15), the amount of the polymerized monomer, M_p, at time t is given:

$$M_p = fk_dk_pI_0f_Mt^2 \quad (16)$$

The experimental correlations described above between the amount of the polymerized monomer and the reaction time, as well as the amount of the initiator (that is, the amount of the polymerized monomer is proportional to the second power of the reaction time and to the first power of the amount of the initiator), have thus been shown to

coincide well with the theoretical equation (16) at the initial stage of polymerization.

The number of moles of polymer chains is calculated as the ratio of the moles of the polymerized monomer to the degree of polymerization of the polymer ($M_p/\overline{DP}_n$). Figure 4 indicates that the number of moles of polymer chains increase proportionally with the reaction time.

The relation between the amounts of the polymerized monomer and the molecular weights of the polymers formed at various ethylene fugacities

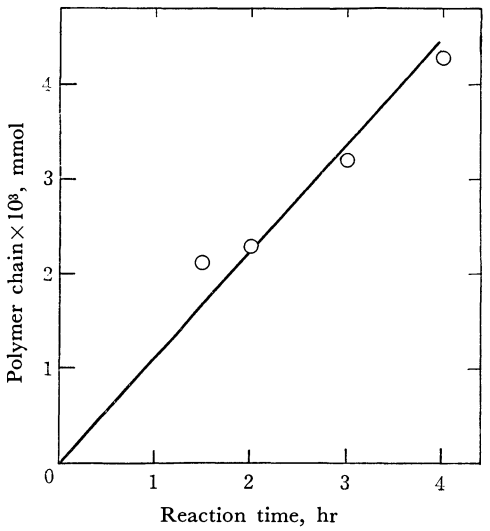

Fig. 4. Number of moles of polymer chains *vs.* reaction time.
(Reaction conditions : temperature, 40°C; AIBN, 0.98 mmol; pressure, 400 kg/cm²)

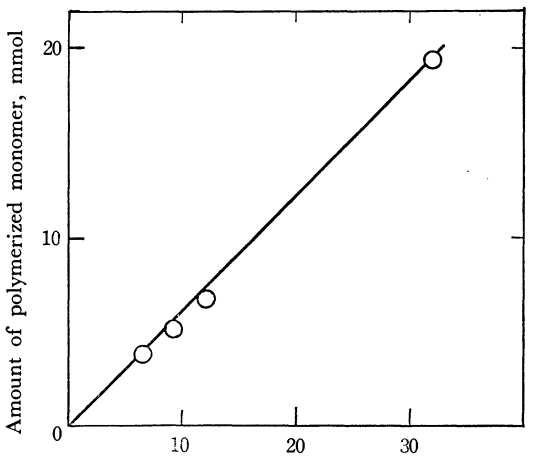

Fig. 5. Relation between amount of polymerized monomer and polymer molecular weight at various pressures.
(Reaction conditons: pressure, 138—400 kg/cm²; temperature 40°C; AIBN, 0.42 mmol)

is shown in Fig. 5. The fact that all the plots ride on the same straight line through the point of origin indicates that the number of moles of polymer chains formed at a constant time (*i. e.*, the initiation rate) is independent of the ethylene fugacity.

The effects of the ethylene fugacity on the polymer yield and the molecular weight are shown in Fig. 6, from which the fugacity exponents for them all are found to be the same, *i. e.*, 2.5. This demonstrates that the rate of propagation is linear to the 2.5 th power of the ethylene fugacity. The fugacity dependence of the propagation rate has also been determined to be *ca.* 2 by means of the two-stage polymerization method reported in other of our papers.[18,19] The reason for this high fugacity exponent of the propagation rate is not clear, but one possible reason is that the propagation is brought about by the addition of two or three associated monomer molecules, as will be described below.

The degree of the polymerization of the polymer ($\overline{DP}_n$) is given by the following equation when the termination and transfer are eliminated:

$$\overline{DP}_n = \int R_p dt \Big/ \int R_i dt = fk_dk_pI_0f_M t^2/2fk_dI_0t = 1/2 \cdot k_pf_M t \quad (17)$$

This equation means that the degree of polymerization is proportional to the reaction time and independent of the amount of initiator. The experimental facts, which are shown in Fig. 1 and Fig. 3, agree very well with Eq. (17). As for the dependence of the degree of polymerization on ethylene fugacity, however, the experimental results shown in Fig. 6 indicate that the exponent is *ca.* 2.5, which is higher than that expected from Eq. (17).

The empirical equations of the polymer yield and the degree of polymerization are thus obtained as follows:

$$M_p = k_1I_0f_M^{2.5}t^2 \quad (18)$$

$$\overline{DP}_n = k_2f_M^{2.5}t \quad (19)$$

The fact that the fugacity exponents of both the polymer yield and the degree of polymerization are higher than the theoretical values seems to be due to a higher-order dependence of the propagation rate on the monomer fugacity.

When ethylene reacts with a growing radical as associated form of n molecules, the rate of propagation is proportional to the fugacity of the associated

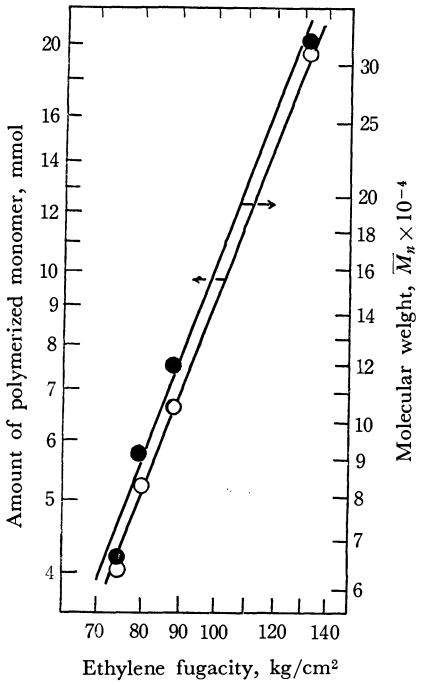

Fig. 6. Amount of polymerized monomer and polymer molecular weight *vs.* ethylene fugacity. (Reaction conditions are the same as for Fig. 2.)

monomers, which is proportional to the nth power of the monomer fugacity. The rate of propagation is thus given by Eq. (20) instead of Eq. (15):

$$R_p = k_p[\mathrm{RM}\cdot]f_M{}^n = 2fk_dk_pI_0f_M{}^nt \qquad (20)$$

By integrating (20) with t and by substituting Eq. (20) for R_p in Eq. (17), Eqs. (21) and (22) are obtained:

$$M_p = 2fk_dk_pI_0f_M{}^nt^2 \qquad (21)$$

$$\overline{DP}_n = 1/2\cdot k_pf_M{}^nt \qquad (22)$$

The fact that the observed exponent, n, is 2.5, as is shown in Eqs. (18) and (19), suggests that the propagation proceeds by the addition of associated monomers which consist of 2—3 units.

Effect of Reaction Temperature. The experimental results are listed in Table 2. The time-yield and time-molecular weight curves for the polymerizations at various reaction temperatures from 40 to 100°C are shown in Figs. 7 and 8 respectively. Figure 7 shows that the rate of polymerization is markedly accelerated with time at 30 and 40°C, but the acceleration becomes less remarkable with a rise in temperature. Figure 8 shows that the molecular weight of the polymer increases linearly with the time in the polymerization at 30—40°C, and when the temperature rises, the plots deviate from proportionality. These corresponding facts may indicate that the rate of chain termination increases with a rise in the temperature.

The dependence of the polymer yield and the molecular weight on the amount of the initiator in the polymerization at the higher temperatures of 100 and 140°C is shown in Fig. 9 and Table 3. It is well known that the exponents of the initiator of the polymerization rate and the molecular weight are 0.5 and −0.5 in polymerization with a rapid second-order termination, and 1.0 and 0 in polymerization with a rapid first-order termination with respect to the radicals.

From the slope of the lines in Fig. 9, the exponents of this polymerization are found to be 0.8

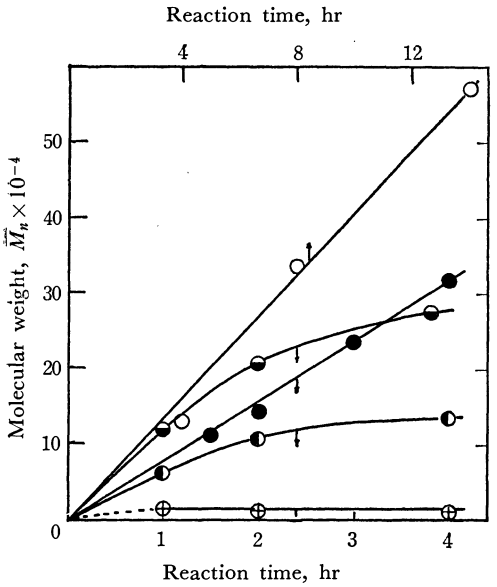

Fig. 8. Relation between polymer molecular weight and reaction time at various reaction temperatures.

(Reaction conditions: pressure, 400 kg/cm^2; time, 1.0 hr; temperatures, ○, ●: 100°C, ⊖, ◒: 140°C)

and −0.2, respectively, for the polymer yield and the molecular weight at a constant time. These high exponents indicate that the contribution of the first-order termination is larger than that of the second-order termination.

Considering the first-order termination and transfer reactions, and using the empirical rate equation of the propagation (Eq. (20)), Eqs.

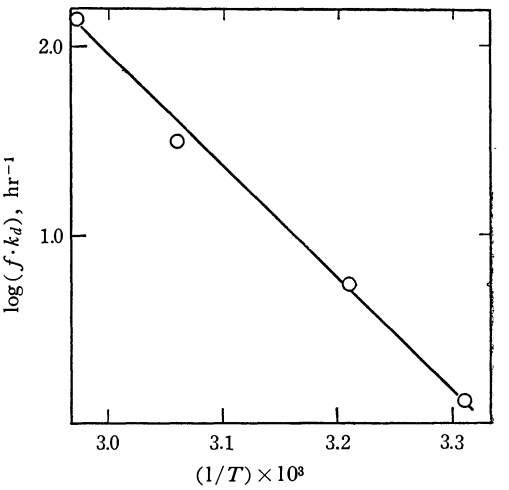

Fig. 12. Effect of temperature on the initiation rate constant, fk_d.

has been described above. The decomposition rate constant of AIBN, k_d, has been reported to be nearly constant, independent of the reaction media.[14-17] In the calculation of Eqs. (18) and (19), therefore, the value of k_d which was determined by Tobolsky[21] in benzene at various temperatures from 37 to 100°C was used. The plot of R_p/M_p against $(t-k_dt^2/2)/M_p$ according to Eq. (18) is shown in Fig. 10. The intercept on the axis of R_p/M_p gives the rate of termination $(k_t[Z])$. The rate of termination is thus shown to be approximately zero at 30 and 40°C and to increase with a rise in the temperature.

Figure 11 shows the plot of $1/\overline{M}_n$ against $(t-k_dt^2/2)M_p$ according to Eq. (19). Straight lines through the point of origin are obtained, their slopes corresponding to the rate of initiation. The correlation between the initiation rate and the temperature is shown in Fig. 12 as an Arrehenius plot. The activation energy of the initiation reaction is obtained as *ca.* 27 kcal/mol. The order of magnitude of the value is close to that of the decomposition of AIBN, *i. e.*, 30.8 kcal/mol.[14]

The fact that the lines in Fig. 11 pass through the point of origin indicates that the rate of the transfer reaction is approximately zero at temperatures from 30 to 65°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 904—909 (1968)

The Gas-phase Oxidation of Propylene in an Inert Fluidized Bed Reactor under Pressure. The Effects of the Reaction Conditions on the Formation of Oxidation Products*1

Etsuro ECHIGOYA,*2 Mitsuo MASAI and Kiyoshi MORIKAWA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 16, 1967)

The oxidation of propylene is studied in an excess-propylene atmosphere under pressure, using an inert fluidized bed reactor. The effects of the temperature, the pressure, and the concentration of oxygen on the reaction were examined. The so-called "negative temperature coefficient" is clearly observed with relation to the rate of the oxidation of propylene and the rates of the formation of acetaldehyde, propylene oxide, acrolein, carbon monoxide, methane, and ethylene. Therefore, the reaction courses involving these may be regarded as radical-chain reactions. Little effect of the pressure is observed. The molar fraction of oxygen exerts a profound effect on the yields of acetaldehyde, propylene oxide, and acrolein.

Many products such as aldehydes, epoxides, alcohols, and acids, are obtained in the course of the autoxidation of hydrocarbons in the gas phase.[1] In this paper, we will attempt to determine the reaction conditions which will give the optimum yields of acetaldehyde, propylene oxide, and acrolein.

Kamiya has reported that, in narrow tubular reactors, acetaldehyde, propylene oxide, acrolein, and allyl alcohol are produced in the oxidation of propylene under pressure with a small amount of oxygen.[2-4] On the other hand, propylene oxide has not been formed in the oxidation of propylene under reduced pressure.[1a]

A fluidized bed reactor has a large heat-transfer coefficient; therefore, the temperature gradient in the bed is almost negligible, except for the gas-inlet section, and the temperature in the reactor can be easily controlled and clearly defined. The fluidized bed reactor is therefore well-suited to the study of highly exothermic reactions, such as the autoxidation of propylene in a flow system.

In the present paper, the effects of the temperature, the pressure, and the molar fraction of oxygen on the reaction results are studied using a fluidized bed reactor with inert particles such as silicon carbide. In these experiments, the negative temperature coefficient is clearly observed, on the basis of this fact,[1b] a radical-chain mechanism is suggested for the formation of all the oxidation products except carbon dioxide. It is suggested that excess propylene is an important factor in producing good yields of acetaldehyde and propylene oxide, and also that acetaldehyde plays an important role in the formation reaction of propylene oxide.

Experimental

Materials. Propylene gas containing 5 mol% of propane, 1.3 mol% of ethane, and 0.2 mol% of C_4 hydrocarbons was supplied by the Nippon Petrochemicals Co., Ltd. The oxygen was obtained commercially. Fine particles of silicon carbide supplied by the Mitsui Mining and Smelting Co., Ltd., were washed by diluted nitric acid and water prior to the experiments.

Procedures. The flow sheet of the reaction apparatus is shown in Fig. 1. The propylene gas and oxygen were mixed after their flow rates had been measured and then introduced into the bottom of the reactor, R. The pressure of the product gas was reduced to a normal pressure by V, the reducing valve. The reduced gas was led to the cold traps, T_1 and T_2, and then to the wet gas meter. The linear velocity of the reactant gas was 1.5 cm/sec under the conditions of the oxidation experiments (on an empty-tube basis).

The reactor was made of stainless steel.*3 It was 56.3 mm i.d. and 700 mm long. The reactor contained 600 cc silicon carbide (greenish color) of 100—150 mesh (Tyler) as fluidizing particles, this is considered to be inert for this kind of reaction. The minimum fluidization velocity of the particle was measured as 1.13 cm/sec (on an empty tube basis), using nitrogen at a normal

temperature and pressure. The quiescent height of the fluidized bed was 320 mm. The reactor was heated electrically from outside, and controlled within ±5°C. No temperature gradient along the gas flow was observed except for the bottom gas-inlet section. The temperature was measured using chromel alumel thermocouples. The section from the outlet of the reactor to the sampling point, S_1, was kept at 100—120°C. The pressure of the reaction system was measured using a pressure gauge of the Bourdon type. The pressure was kept within ±0.1 kg/cm² by means of the pressure control valve, V.

Analysis. The product gas was analyzed in two gas chromatographs, using hydrogen as the carrier gas. Acetaldehyde, propylene oxide, and acrolein were analyzed using a 2.5 m dioctyl phthalate column (30 wt% on celite 545) at 80°C. The sample for this analysis was taken from S_1, using a glass syringe maintained at 40—50°C. The determinations of these three components were carried out precisely using absolute working curves calibrated every day. Oxygen, carbon monoxide, methane, and carbon dioxide were analyzed using a 2 m, activated charcoal column at 80°C. A fraction composed of oxygen plus carbon monoxide, and five fractions each composed of methane, ethane, ethylene, propane, and propylene respectively were separated using the 2.5 m column of activated alumina with 1.5 wt% squalane at 40°C. The samples for these two analysis were taken from S_2 by glass syringes.

Results and Discussion

The oxidation reaction was observed above 300°C. The temperature at the point 15 cm above the fluidizing surface was always kept under 240°C so as to minimize the oxidation reaction in the gas phase over the fluidizing surface; therefore, almost all the oxidation reaction is considered to proceed in the fluidizing bed.

Small amounts of polymerized substances were observed in every experiment, but they were not examined further, for the carbon balances of the oxidation experiments were almost entirely satisfactory, as Table 1 and Table 2 show. The acids were also not analyzed, because, Kamiya's results[3] indicate that acid formation is small.

Table 1. Carbon balances at 350°C

0.20	94
0.25	91
0.30	90

The effects of the surface of the fluidizing particles are considered to be small on the basis of other data, which will be discussed in a later paper.

The experimental results described below are represented using a *yield* (%) of a product determined as follows:

$$yield = \frac{\text{moles of a product}}{\text{moles of propylene in feed}} \times 100$$

The Effect of the Pressure. The reactant gas consisted of 15 vol% oxygen and 85 vol% propylene gas. The experiments were carried out at the reaction temperatures of 300, 350, and 400°C in the pressure range of 1.5—4.5 atm. Figures 2—4 show the effects of the pressure on the yields of

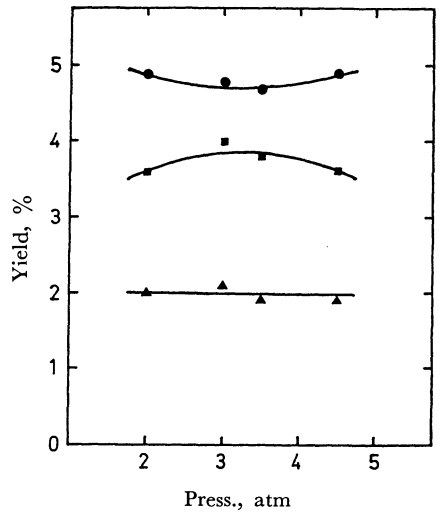

Fig. 2. Effect of press. on the yields of AA, PO and Acr at 300°C with mol fraction of O_2: 0.15.

● AA ■ PO ▲ Acr

acetaldehyde (AA), propylene oxide (PO), and acrolein (Acr).

At 300 and 350°C, little effect of the pressure is observed on the yields of AA, PO, and Acr, as Figs. 2 and 3 show. This observation differs markedly from that using narrow tubular reactors reported by Kamiya,[2-4] in his experiments the concentrations of AA and PO in the reacted gas showed steep maxima at 3—4 atm.*4 The yield of AA show a rapid decrease from 3 atm with the decrease in the pressure at 400°C, as is shown in Fig. 4. The yields of AA and PO decrease with a rise in the temperature, as may be seen by comparing Figs. 2—4.

A small effect of the pressure is observed on the conversion of propylene, as is shown in Fig. 5. The conversion of propylene at 400°C is lower than those at 300 and 350°C, as Fig. 5 shows. At 350°C the formation reactions of carbon monoxide, carbon dioxide, methane, and ethylene are also indifferent to the reaction pressure in the same pressure region. These results also differed markedly from those of Kamiya, his showed that the conversion of propylene and the concentrations of carbon monoxide, carbon dioxide, methane, and ethylene in reacted gas increased as the reaction pressure increased from 2 to 4 atm, reaching constant values beyond 4 to 6 atm at 315°C (1400

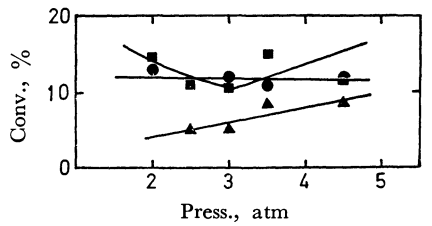

Fig. 5. Effect of press. on the conv. of C_3H_6 with mol fraction of O_2: 0.15.
● 300°C ■ 350°C ▲ 400°C

hr^{-1} of space velocity).[2] The rather slow rates of the oxidation reaction in the low-pressure region observed by Kamiya are very different from the present results, where the effect of reaction pressure is very small at 300 and 350°C. This difference is probably to be attributed to the effect of fluidizing particles, and/or to a difference in the surface area-to-volume ratio of the reactor, which is a measure of the wall effect of the reactor; this ratio differs by a factor of about seven. The reasons for considering the wall effect are as follows: the active species can easily reach the reactor wall rather than encounter propylene, *etc.* in Kamiya's narrow reactor (about 8 mm[2]) at a low pressure; when the pressure is sufficiently high, *i. e.*, above about 4 atm, the diffusion to the wall becomes minor.

*4 The yield and the concentration in the reacted gas show similar trends.

Therefore, result described above is observed. At present we have no clue by which to evaluate these two effects.

Table 1 shows good carbon balances of the oxidation experiments at 350°C.

The Effect of the Concentration of Oxygen. The experiments were carried out at 300, 350, and 400°C under 3 atm in the range of the molar fraction of oxygen from 0.1 to 0.35. The control of the reaction temperature and pressure became difficult with the increase in the molar fraction of oxygen in the reactant gas above 0.25 at 300 and 350°C. On the contrary, the reaction proceeded quietly at 400°C over the same range of concentration.

As Figs. 6—8 show, the yields of AA and PO increase at first, reach maxima and then decrease as the concentration of oxygen increases. A comparison of these figures indicates that the maximum yield of Acr probably shifts to the side of higher oxygen concentration. The yield of Acr decreases with a rise in the temperature (Figs. 6—8). The yields of AA and PO vary similarly with the change in the oxygen concentration (Figs. 6—8).

The yield of carbon monoxide increases as the concentration of oxygen increases and decreases as the temperature rises, as shown in Fig. 9. The

effect of the temperature on the yield of carbon dioxide is just the reverse, as shown in Fig. 10. The conversion of propylene increases as the concentration of oxygen increases and decreases with a rise in the temperature, as shown in Fig. 11. The formations of ethylene and methane decrease with a rise in the temperature, as Fig. 12 shows. At 350°C and 3 atm, the formations of methane and ethylene remain constant up to the molar fraction of oxygen of 0.2 and increase beyond this value. Propane retains its initial value (represented by an open circle in Fig. 12) within the limits of error. A comparison of the black square with the open square shows some formation of ethane, but it decreases as the reaction temperature rises, as shown in Fig. 12. It may be concluded, therefore, that propane and ethane, which are major impurities in propylene gas, do not play important roles in the oxidation reaction.

The trend of the effect of the oxygen concentration up to the molar fraction of oxygen, 0.2—0.25, at 300—350°C is nearly the same as that observed by Kamiya except for the yield of carbon dioxide.[3] His experiments were performed in the 7—24% range of oxygen content at 315°C between 3—6 atm, using a Pyrex reactor 12 mm in *i. d.* Kamiya's results show an increased formation of carbon dioxide with an increase in the oxygen concentration. In the present results, it is indifferent to the oxygen concentration up to a oxygen concentration of 0.25. This indicates that the existence of fluidizing particles (silicon carbide) prevents combustion reactions.

Table 2 shows the good carbon balances of the oxidation experiments at 350°C.

As has been described above, the yields of AA, PO, and Acr increase at first, reach maxima and then decrease with the oxygen concentration, as Figs. 6—8 show. In the increasing sector, the yields of AA and PO decrease as the temperature is raised. These yields *vs.* temperature relations are reversed in the decreasing sector of the said curves. The yields of carbon monoxide, methane, ethane, and ethylene decreased with a rise in the temperature (Figs. 9 and 12). It is known that propylene is a powerful inhibitor of the decomposition of a compound which contains the acetyl group,[5] and also that AA is easily decomposed by oxygen.[6] Therefore, AA is probably decomposed very easily in the range with high concentrations of oxygen. The combination of these two opposite effects may reasonably be expected to produce the maximum in the variation of the yield of AA against the concentration of oxygen. Therefore, up to an oxygen concentration which corresponds to the maximum yield of AA, species containing the acetyl group are decomposed to a lesser extent. It may be concluded from these results and discussion that the formation reaction of AA proceeds predominantly in the increasing sector of the curves, while the decomposition reaction of AA is enhanced in the decreasing sector of the curves (Figs. 6—8). In the decreasing sector of the curves for AA in Figs. 6—8, the temperature effect on the yield of AA is positive. In other words, there is a negative temperature coefficient of the decomposition of AA.

AA has been established to be a chain-branching agent in propylene oxidation at reduced pressures.[1] Imamura *et al.* obtained a relatively high selective production of PO by the direct addition of the oxidation products of AA to propylene;[7] they proposed that PO is formed by the addition of the

acetyl peroxy radical to the double bond of propylene and also by the reaction of peracetic acid with propylene.[7] Here, it can reasonably be estimated that the further predominant reaction of AA is the oxidation to the acetyl peroxy radical in the increasing sector and decomposition into the methyl radical and carbon monoxide in the decreasing sector. This assumption accords with the steep increase in the yield of carbon monoxide at a high oxygen concentration (Fig. 9). In the increasing sector, where AA is assumed to be converted into the acetyl peroxy radical, the formation reaction of PO may be the main course of the oxidation reaction. In the decreasing sector, where AA is estimated to decompose, the formation reaction of PO may become slight. Thus, the similar variation in the curves of AA and PO can be reasonably explained. Therefore, it may be suggested that AA plays an important role in the formation of PO.

Kamiya, Sekine and Yamakawa proposed that Acr is formed by the dehydration of allyl hydroperoxide in propylene oxidation.[8] It can be considered that the oxygen-catalyzed decomposition of AA efficiently increases the concentration of radicals (methyl and therefore, allyl) (*cf.* the discussion of Imamura *et al.*[7]). This increase in the said radicals will enhance the formation of the allyl peroxy radical by the reaction of the allyl radical and oxygen. Thus, the formation reaction of Acr will become the main course of the oxidation reaction as a result of the increased allyl peroxide which is formed by the reaction of the allyl peroxy radical and propylene. These considerations can explain the increasing yield of Acr in the decreasing sector. The decrease in the yield of Acr at higher oxygen concentrations may be ascribed to an increased combustion.

As has been discussed above, the variation in the curves for AA, PO, and Acr (Figs. 6—8) can thus be well explained. It may be concluded from the above discussion that a small amount of oxygen, in another words, a large excess of propylene, is an essential factor in producing high yields of AA and PO. This explains well why the formation of PO was not reported in past experiments,[1a] almost all of which were performed in an atmosphere with a relatively high partial pressure of oxygen and at a reduced reaction pressure. The reaction scheme mentioned to above will be discussed in detail in the next paper.

The so-called negative temperature coefficient is observed in the conversion of propylene and in the formations of AA, PO, Acr, carbon monoxide, methane, ethane, and ethylene. On the basis of the negative temperature coefficient,[1b] all the reactions of propylene oxidation may be considered to proceed through the radical-chain mechanism except for the formation reaction of carbon dioxide.

The authors wish to thank the Nippon Petrochemicals Co., Ltd., for supplying the propylene gas, and the Mitsui Mining and Smelting Co., Ltd., for supplying the silicon carbide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 910—919 (1968)

Mechanism of the Gas-phase Oxidation of Propylene in a Propylene-excess Atmosphere under Pressure*[1]

Mitsuo MASAI, Etsuro ECHIGOYA*[2] and Kiyoshi MORIKAWA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 16, 1967)

The mechanism of the oxidation of propylene is studied through the addition of *t*-butyl hydroperoxide, acetaldehyde, or propionaldehyde to the reactant (propylene and oxygen), and also through the direct addition of the products of the ($C_3H_5Br+O_2$ or CH_3CHO+O_2) reaction to propylene. The following conclusions are reached: acetaldehyde and not propionaldehyde is responsible for chain-branching, acetaldehyde is formed from the allyl peroxy radical alone, propylene oxide is formed mainly by the reaction of the acetyl peroxy radical with propylene, the allyl peroxy radical probably contributes to the formation of propylene oxide, propionaldehyde, and acrolein in an equal extent, and the recombination of radicals is highly retarded in this propylene-excess system. On the basis of the data obtained, a plausible reaction scheme is proposed.

The data presented in a previous paper[1] have demonstrated the negative temperature coefficient[2,3a] in the conversion of propylene and in the yields of all the products except carbon dioxide, and have also demonstrated that excess propylene is essential to obtaining the high yields of acetaldehyde and propylene oxide in the thermal oxidation of propylene with an inert fluidized bed reactor under pressure.

The mechanism of the oxidation of hydrocarbons is generally known to be a degenerate branching process accompanying the negative temperature coefficient.[2,3a] Concerning the branching agent in the low-temperature oxidation of propylene, higher aldehydes contribute to the degenerate branching process according to Mulcahy and Ridge[4] and also according to Batten and Ridge.[5] Among the higher aldehydes, acrolein is not a branching agent according to Mullen and Skirrow.[6] It has been concluded that only acetaldehyde is responsible for the branching process,[3b,4-6] however, the role of propionaldehyde has not yet been discussed. And the formation of acetaldehyde through the isomerization of the allyl peroxy radical was discussed by Shtern and Polyak.[3b]

The features of the oxidation of propylene can be explained by the proposed formation of the unreactive allyl radical according to Mullen and Skirrow.[6]

Contrary to the results presented above[3b,4-6] propylene oxide is one of the major products in the propylene oxidation in a propylene-excess atmosphere under pressure.[1,7] The scheme of the reaction was duscussed first by Kamiya *et al.*[8] Some parts of the reaction scheme were elucidated using carbon-14-labeled propylene by White, Davis, and Hammack.[9] Propylene oxide and propionaldehyde were considered by Cvetanović[10] to be formed through the addition of an oxygen atom to the double bond of propylene. Oba and Sakai recently demonstrated that the methyl group of propylene was retained in the resulting propylene oxide.[11]

The purpose of the present work is to obtain some experimentally probable views on the main routes of the reaction. Two kinds of experiments will be described. In the first (Exp. A), *t*-butyl hydroperoxide, acetaldehyde, or propionaldehyde

is added to the reactant gas (propylene gas and oxygen); in the second (Exp. B), the oxidation products of allyl bromide or acetaldehyde are added directly to the propylene gas. The following conclusions are obtained: acetaldehyde and not propionaldehyde is the branching agent in this reaction; acetaldehyde is formed from the allyl peroxy radical; propylene oxide is formed mainly through the addition of the acetyl peroxy radical to the double bond of propylene; the allyl peroxy radical contributes to the formation of propylene oxide, propionaldehyde, and acrolein to an equal extent, and the recombination of radicals is highly retarded by the excess propylene. A plausible reaction scheme is proposed on the basis of the data obtained here.

Experimental

Materials. The propylene gas and oxygen have been described before.[1] The acetaldehyde was prepared by the depolymerization of paraldehyde and distilled just before use. Allyl bromide of a G. R. quality was obtained from the Tokyo Kasei Kogyo Co., Ltd. (Tokyo). *t*-Butyl hydroperoxide of a 70% purity was obtained from the Lucidol-Yoshitomi Co., Ltd. (Osaka). Propionaldehyde of an E. P. quality was obtained from the Tokyo Kasei Kogyo Co., Ltd. The silicon carbide has been described before.[1]

Reactors. Two kinds of reaction experiments were carried out using two different reactors.

For Exp. A. The oxidation experiments featuring the addition of *t*-butyl hydroperoxide, acetaldehyde, or propionaldehyde to the reactant gas (propylene and oxygen) were carried out in a fluidized bed reactor, shown in Fig. 1. The reactor was made of stainless steel*3 and had the following dimensions; 24.5 mm i. d. × 460 mm length. It contained 70 cc of silicon carbide (150—250 Tyler mesh) as a fluidizing powder. The quiescent bed height was 200 mm. The mixer (evaporator), made of steel had the following dimensions; 20 mm i. d. × 150 mm length. It contained quartz chips washed with diluted nitric acid.

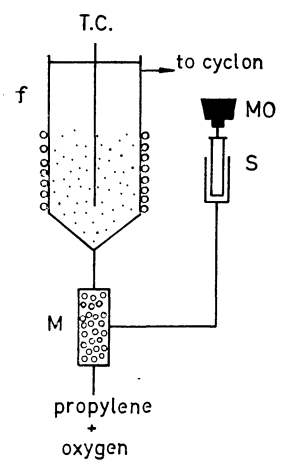

Fig. 1. Reactor for Exp. A.
f, fluidized bed reactor; M, mixer; MO, slow geared motor; S, syringe; T. C., thermocouple

*3 JIS SUS-27, AISI 304, Austenite.

For Exp. B. The reaction of propylene with the products of the $C_3H_5Br+O_2$ or CH_3CHO+O_2 reaction was carried out in the reaction apparatus shown in Fig. 2. The reactor, made of stainless steel,*3 consisted of two concentric tubes. The inner tubes, in which the oxidation of allyl bromide or acetaldehyde was carried out, had the following dimensions; 8 mm o. d. × 6 mm i. d. × 300 mm length. The outer tube, in which the reactions of propylene with the products from the inner tube were carried out, had the following dimensions; 24.5 mm i. d. × 360 mm length. The volume of the effective reaction zone in the inner tube was about 1.0 cc, while the volume of the effective reaction zone in the outer tube was about 46 cc. The reactor was heated from the outside; the temperature of the inner tube was higher than that of the outer tube by 5—10°C during the experiments.

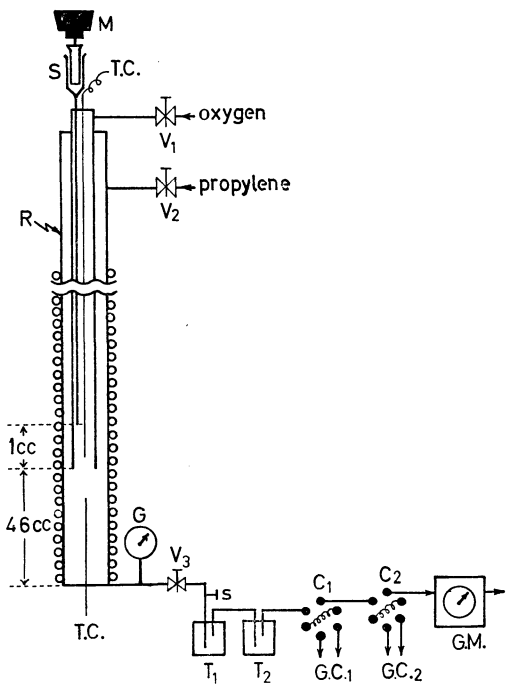

Fig. 2. Flow sheet of reaction apparatus for Exp. B.

Procedures. *Exp. A* was carried out under 3.5 atm, using a reactant gas consisting of 80 vol% of propylene gas and 20 vol% oxygen. The linear velocity of the reactant gas was kept constant at 2.5 cm/sec on the empty-tube basis under the reaction conditions. The additives were fed into the mixer (kept about 80°C) by means of a glass syringe whose plunger was pushed at a constant speed using a slow-geared motor; the

additives were then mixed with the reactant gas. The concentrations of the additives varied a little as the reaction temperature changed; they were 0.61—0.83 vol% for acetaldehyde, 0.14—0.20 vol% for *t*-butyl hydroperoxide, and 0.55—0.65 vol% for propionaldehyde.

Exp. B was carried out under 3.0 atm. Propylene gas was passed through the outer tube. Allyl bromide (in Exp. B_1) or acetaldehyde (in Exp. B_2), which had been fed through the syringe needle was reacted with oxygen in the space (1.0 cc) of the inner tube. The reaction products from this space immediately reacted with propylene in the space (46 cc) of the outer tube. The flow rates of the reactants (at a normal temperature and pressure in the vapor phase) were as follows; allyl bromide, 1.14 *l*/hr, oxygen, 1.05 *l*/hr, and propylene gas, 4.26 *l*/hr, for the experiments (Exp. B_1) at 340 and 280°C, acetaldehyde, 1.17 *l*/hr, oxygen, 0.9 *l*/hr and propylene gas, 5.6 *l*/hr, for the experiment (Exp. B_2) at 280°C, and acetaldehyde, 1.17 *l*/hr, oxygen, 1.1 *l*/hr, and propylene gas, 5.8 *l*/hr, for the experiment (Exp. B_2) at 255°C.

Analysis. The reaction gas was analyzed gas chromatographically. An activated charcoal column of one meter long was used for oxygen, carbon monoxide, and methane at 50°C. A two-meter column containing activated alumina with 2 wt% of squalane was used for ethane and ethylene at 70°C (Exp. A) or 50°C (Exp. B). An eight meter column containing 30 wt% of acetonylacetone S on Celite 545 was used for oxygen + carbon monoxide + methane, ethane + ethylene, carbon dioxide, propane, and propylene at about 10°C. A three-meter column containing 30 wt% of Reoplex 400 on Celite 545 was used for acetaldehyde, propylene oxide, propionaldehyde, and acrolein at 70°C for Exp. A. A six-meter column containing 10 wt% of Reoplex 400 on Diasolid M was used at 50°C for Exp. B. All the packing materials except the Diasolid M were obtained from the Nishio Kogyo Co., Ltd. (Tokyo). The Diasolid M was obtained from the Nippon Chromato Kogyo Co., Ltd. (Tokyo).

The analytical procedures were the same as have been described before,[1] except that two sampling cocks were used for the analysis of the non-condensed gas sample in Exp. B.

Results and Discussion

The reactions studied are tabulated in Table 1.

Experiment A (Effect of a small amount of additives). In the case of Exp. A_0 (the oxidation experiment without additives), the oxidation reaction took place above 360°C.

Addition of t-Butyl Hydroperoxide. As Fig. 3 shows, the oxidation reaction took place above 300°C. Methane is much increased by the addition of *t*-butyl hydroperoxide, while there is only a small increase in ethane, as shown in Fig. 3. The increased methane formation shows the increased formation of the methyl radical. However, these methyl radicals probably contribute only a little to the formation of ethane by the recombination reaction. These observations show that the recombination of the radicals can be neglected in this reaction system because of the inhibiting effect of excess propylene, as the discussion of Mullen and Skirrow[6] has established.

Addition of Acetaldehyde or Propionaldehyde. As Figs. 4 and 7, 5 and 8, and 6 and 9 show, the oxidation reaction took place above 300°C upon the addition of acetaldehyde (AA); a good agreement is observed between the results of Exp. A_0 and Exp. A_2 (AA-added experiments) above 360°C. The chain-initiating radicals are easily produced by the addition of AA; therefore, the oxidation reaction took place at 300°C in Exp. A_2, unlike Exp. A_0. On the other hand, the amount of AA added is so small that the concentrations of the radicals in this reaction are not changed from those of Exp. A_0; therefore, the reaction courses and the results vary little upon the addition of AA above 360°C. Thus, AA may be concluded to be the branching agent in the case of excess propylene under pressure, as in the case of reduced-pressure experiments with a relatively low partial pressure of propylene.[3b,4-6] The apparent reaction times were kept constant in the Exp. A series; the results

of Exp. A_2 indicate that the induction period of this oxidation reaction was shortened by the addition of a small amount of AA between 300—360°C as has already been found in static experiments.[5,6]

Imamura *et al.* studied the addition of a large amount of AA in nearly the same reaction system as in Exp. A_2 at normal pressure.[12] They showed that the selectivity of acetic acid was four times that of PO (propylene oxide),[12] and also that acetic acid decreased and PO increased with a decrease in the amount of added AA.[12] In our work, the amount of added AA is very small, as shown in Table 1, and the rates of the oxidation reaction are found to be increased only a little, as has already been found in static experiments.[5,6] The addition of AA probably enhances the rates of all the reaction paths. The branching reaction is as follows.[17a]

$$CH_3CHO + O_2 \rightarrow CH_3\dot{C}O + \dot{O}OH$$

Figures 4 and 10, 5 and 11, and 6 and 12 show that upon the addition of propionaldehyde (PA) the oxidation reaction still takes place at 360°C (Exp. A_3) as in Exp. A_0, and also that the results of the two experiments Exp. A_0 and Exp. A_3 disagree with each other not only in the trend of the curves

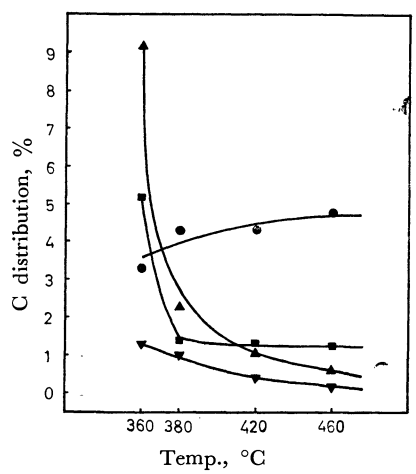

Fig. 12. Carbon distribution - temp. curves; with the addition of PA; under 3.5 atm with mol fraction of O_2, 0.2 (exp. A_3).

but also in the numerical values. Thus, PA is not the branching agent in this reaction.

Experiment B. Table 2 contains the results of Exp. B. Exp. B_0 did not take place at 255, 280, and 340°C. Therefore, the products shown in Table 2 must be formed by the reactions of the species produced in the inner tube.

Experiment B_1 $(C_3H_5Br+O_2)+C_3H_6$. At 280°C, the amount of AA formed is about ten times those of PO, PA, and acrolein (Acr) as Tables 2 and 3 show.

Table 3. Comparision of relative yield of AA, PO, PA and Acr in Exp. B with those in Exp. A_0 (The values of Acr in each experiment is taken as unity.)*

	Temp., °C	AA	PO	PA	Acr
Exp. A_0 (Fig. 4)	380	2.9	1.9	0.44	1
Exp. B_1**	340	8.7	2.0	1.2	1
Exp. B_1**	280	13	1.5	1.5	1
Exp. B_2**	280	—	5.0	1.2	1
Exp. B_2**	255	—	6.3	1.2	1

* Acr is observed to be relatively insensitive oxygenated product to the variations of experimental conditions in comparision with AA and PO as shown in the previous paper[1] and Figs. 4, 7 and 10 in this paper.

** Calculated from the data presented in Table 2.

In this case, allyl bromide is decomposed into the allyl radical and the bromine atom.[13] The allyl radical produced most likely reacts with oxygen to form the allyl peroxy radical in the inner tube of the reactor. The allyl peroxy radical has been considered to be the main active species in the homogeneous-gas-phase oxidation of propylene.[3b,6,8] The bromine atom which is converted into bromine or hydrogen bromide most likely affects the course of the reaction. Bromine is an especially active catalyst for the decomposition of AA, according to Fromherz.[14] Hurst, Skirrow and Tipper[15] discussed the result of the oxidation of butene containing hydrogen bromide, citing some Russian workers results reporting the decomposing action of hydrogen bromide on hydroperoxide. Thus, the decomposition of AA, allyl hydroperoxide, and perhaps the allyl peroxy radical should all be considered here. The products described in Table 2 are, then, formed by the succeeding reactions of the allyl peroxy radical and the allyloxy radical. The alkoxy radical produced from the decomposition of peroxide is considered to decompose according to the following reactions:[16]

$$CH_2{=}CHCH_2\dot{O} \rightarrow CH_2{=}\dot{C}H + CH_2O$$
$$\searrow\ CH_2{=}CHCHO + \dot{H}$$

The same kinds of products are obtained in Exp. B_1 and Exp. A_0, while the oxidation reaction did not take place in Exp. B_0. Therefore, the reaction paths in the oxidation of propylene are not extinguished in Exp. B_1 by the presence of bromine or hydrogen bromide; furthermore, these paths start from the same active species, which are present in Exp. B_1 and Exp. A_0. The active species must be the allyl peroxy radical, because this is produced almost only in the inner tube of the reactor (as Exp. B_0 shows, the oxidation reaction without an additive did not take place), and also because the presence of the allyl peroxy radical as an active species in the oxidation of propylene is generally accepted.[3b] The secondary reactions induced by the radicals from the inner tube can be neglected at 280°C, because only a low conversion of oxygen is observed, as shown in Table 2.

The yield of AA relative to PO, PA, and Acr in Exp. B_1 at 280°C is higher than that of Exp. A_0, as Table 3 shows.

The above discussion leads to the conclusion that only the allyl peroxy radical contributes to the formation of AA. Shtern and Polyak[3b] and Neiman *et al.*[3b] proposed, and demonstrated kinetically, the following scheme for the formation of AA:

$$CH_2{=}CHCH_2O\dot{O} \rightarrow \dot{C}H_2CH\text{-}CH_2$$
$$\qquad\qquad\qquad\qquad\qquad\quad |\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\quad O{-}O$$
$$\rightarrow \dot{C}H_2CHO + HCHO$$
$$\dot{C}H_2CHO + C_3H_6 \rightarrow CH_3CHO + \dot{C}_3H_5$$

This scheme does not contradict the results of Exp. B_1 at 280°C. Thus, it is reasonable to conclude that AA is formed by the isomerization of the allyl peroxy radical, as in Shtern and Polyak's scheme. The following modification may be suggested for this scheme, considering the propylene excess atmosphere:

$$\dot{C}H_2CH\text{-}CH_2 + C_3H_6 \rightarrow CH_3CH_2\text{-}CH_2 + \dot{C}_3H_5$$
$$\quad |\quad |\qquad\qquad\qquad\qquad\quad |\quad |$$
$$\quad O{-}O\qquad\qquad\qquad\qquad\quad O{-}O$$
$$CH_3CH\text{-}CH_2 \rightarrow CH_3CHO + HCHO$$
$$\quad |\quad |$$
$$\quad O{-}O$$

The allyl peroxy radical is most likely to be formed

according to the following scheme, as proposed by Shtern and Polyak[3b] for the oxidation of propylene;

$$CH_2{=}CHCH_3 + O_2 \rightarrow$$

$$CH_2{=}C\dot{H}CH_2 + \dot{O}OH$$

$$CH_2{=}C\dot{H}CH_2 + O_2 \rightarrow$$

$$CH_2{=}CHCH_2O\dot{O}$$

Contrary to the results of Exp. A_0, PO is formed in an amount comparable to PA and Acr at 280°C, as shown in Tables 2 and 3.*4 According to the above discussion concerning the formation of AA, allyl peroxy radical is the sole active oxygenated species formed in the inner tube, from which the oxygenated products are derived. The increased relative yield of PA in Exp. B_1 at 280°C may be compared with the small relative yield of PA in Exp. A_0 (Table 3). This fact strongly suggests that the reaction path to PA is emphasized by the presence of the allyl peroxy radical. The yield of PO is comparable to the yield of PA, as shown in Table 3. Cvetanović proposed the rearrangement of the oxygeneated biradical to PO and PA in the reaction of propylene and an oxgen atom as follows,[10] (he obtained almost equal amounts of PO and PA):

$$CH_2{=}CHCH_3 + O \rightarrow$$

$$CH_2\text{-}\dot{C}HCH_3 \rightarrow CH_2\text{-}CHCH_3$$

$$\dot{O}\cdot \qquad\qquad \diagdown\,O\,\diagup$$

$$\downarrow$$

$$CHCH_2CH_3$$

$$\|$$

$$O$$

Our results can also be explained well on the basis of Cvetanović's mechanism; *i. e.*, the allyl peroxy radical contributes to the formations of PO and PA to an equal extent. Since the allyl peroxy radical is the sole active species, as has been established above, the contribution of the allyl peroxy radical to the formation of Acr is considered to be feasible according to the discussion of Mullen and Skirrow.[6] The yield of Acr comparable to those of PO and PA (Table 3) suggests the same degree of contribution of the allyl peroxy radical to the reaction paths which produce the said three products. To summarize the above discussions, the allyl peroxy radical is the sole precursor of AA, and it also contributes to the formation of PO, PA, and probably Acr to almost equal extents. At a higher temperature (340°C), the amount of PO becomes greater than those of PA and Acr in Exp. B_1, as shown in Table 2. This result may be ascribed to the further reaction of AA, as will be discussed below.

Experiment B_2 $(CH_3CHO + O_2) + C_3H_6$. In the case of Exp. B_2, the amounts of PO produced are greater than those of PA and Acr at 225 and 280°C, as shown in Tables 2 and 3. As has already been described, at the same temperature of 280°C, the amount of PO produced is comparable to those of PA and Acr (Table 2) in Exp. B_1. In Exp. B_2, the relative amount of PO is greater than that in Exp. A_0 (Table 3). The concentration of AA in the inner tube in Exp. B_1 at 280°C should be much less than that of Exp. B_2. These facts show that the contribution of the oxidation product of AA to the formation of PO is superior to that of the allyl peroxy radical.

Here, AA is easily oxidized to the acetyl peroxy radical,[17a,18] its oxidation scheme is as follows;[17a,18]

$$CH_3CHO + O_2 \rightarrow CH_3\dot{C} + \dot{O}OH$$

$$\|$$

$$O$$

$$CH_3\dot{C} + O_2 \rightarrow CH_3CO\dot{O}$$

$$\|\qquad\qquad\|$$

$$O\qquad\qquad O$$

$$CH_3\dot{C} \rightarrow \dot{C}H_3 + CO$$

$$\|$$

$$O$$

In the propylene-excess atmosphere, the acetyl radical formed will react with propylene;

$$CH_3\dot{C} + C_3H_6 \rightarrow CH_3CHO + \dot{C}_3H_5$$

$$\|$$

$$O$$

Thus, it is reasonable to suggest that the most reactive radical in the above scheme—the acetyl peroxy radical—plays an important role in the main reactions in Exp. B_2.

Imamura *et al.* studied the same reaction system as in Exp. B_2 with lower oxygen under normal pressure at 180 and at 270°C.[12] Their reaction gas consisted of about 0.4 AA and about 0.2 air in the inner reactor and of about 0.4 propylene in the outer reactor.[12] They used a reactor, the reaction spaces of which were 135 m*l* for the inner reactor

*4 The data presented in Exp. B_1 of Table 2 show an increase in PO, PA and Acr with an increase in the temperature; this indicates a negligible interaction between these products and the allyl bromide or species derived from them. The known reactions of PO with allyl bromide, bromine and hydrogen bromide can be neglected under the conditions of Exp. B_1, such as the reaction time of 36—40 sec and the reaction tmeperature of 280—340°C [P. Bedos, *Compt. rend.*, **183**, 562 (1926); A. Rosowsky, "Heterocyclic Compounds with Three- or Four-membered Rings" (A. Weissberger, ed.), Part 1, Interscience Pub. New York (1964), pp. 436—455].

17) N. N. Semenov, "Some Problems in Chemical Kinetics and Reactivity," Japanese translation by T. Kwan and A. Matsuda, Vol. 1, 17a) p. 81, 17b) Chap. 7 § 2, 17c) Chap. 1 § 7, Iwanami Shoten, Tokyo (1963).

18) G. J. Minkoff and C. F. H. Tipper, "Chemistry of Combustion Reactions," Chap. 5, Butterworths Co., London (1962).

and 265 m*l* for the outer reactor; the outlet of the inner reactor had a narrow neck. They obtained considerable amounts of acetic acid, and peracetic acid and a small amount of PO. This supports the formation of the acetyl peroxy radical in Exp. B_2.

During the oxidation of propylene, PO retains the carbon skelton of propylene, according to the results of White, Davis and Hammack.[9] It has been proposed by Cvetanović[10] that PO is formed through the addition of an oxygen atom to the double bond of propylene. Oba and Sakai recently demonstrated that the methyl group of propylene is retained in PO in a homogeneous oxidation of propylene.[11] These results indicate that PO is formed by the addition of active species to the double bond of propylene. Concerning the active species which may introduce the oxygen atom to the double bond of propylene, there have been no definite discussions which have experimental support about gas-phase homogeneous reactions. Only the acetyl peroxy radical and acetyl hydroperoxide have been proposed by Imamura *et al.* on the basis of their experiments,[12] and they evaluated these reaction paths low because of the low selectivity of the PO formation. It is reasonable to assume that the molecular reaction of acetyl hydroperoxide with propylene is very much slower than the addition of the acetyl peroxy radical to the double bond of propylene in the gas-phase reaction,[17b] because the addition of a radical to the double bond generally always proceeds with a low activation energy.[17c]

Therefore, the following scheme may be concluded to hold for the route to PO in Exp. B_2; it is deduced from the results of Exp. B_2 already described and also from the discussions presented above:

$$CH_3\overset{\overset{\|}{O}}{C}O\dot{O} + CH_2{=}CHCH_3 \rightarrow$$

$$CH_3\overset{\overset{\|}{O}}{C}OOCH_2\dot{C}HCH_3$$

$$CH_3\overset{\overset{\|}{O}}{C}OOCH_2\dot{C}HCH_3 \rightarrow$$

$$CH_3\overset{\overset{\|}{O}}{C}O + CH_2\text{-}CHCH_3 \quad (\text{O bridging CH}_2\text{–CH})$$

PO is formed in Exp. B_1 in an amount comparable with those of PA and Acr, which are minor products in Exp. A_0 (Table 2, Fig. 4). Furthermore, the amount of PO formed in Exp. B_1 is distinctly small in comparision with that formed in Exp. B_2 (Table 2). These observations strongly indicate that the contribution of the allyl peroxy radical to the formation of PO is less than that of the acetyl peroxy radical. The route *via* the addition of the allyl peroxy radical is as follows:

$$CH_2{=}CHCH_2O\dot{O} + CH_2{=}CHCH_3 \rightarrow$$

$$CH_2{=}CHCH_2OOCH_2\dot{C}HCH_3$$

$$CH_2{=}CHCH_2OOCH_2\dot{C}HCH_3 \rightarrow$$

$$CH_2{=}CHCH_2\dot{O} + CH_2\text{–}CHCH_3 \quad (\text{O bridging CH}_2\text{–CH})$$

Thus, the route *via* the addition of the acetyl peroxy radical may be concluded to be the main route for the formation of PO in the gas-phase homogenous oxidation of propylene.*5 This conclusion accords with the discussion presented in the previous paper,[1] where the decomposition of the species containing an acetyl group was found to be retarded to some extent in an oxidation atmosphere with an excess of propylene.

The amount of PO increased at 340°C in comparison with the amount at 280°C in Exp. B_1 (Table 2); this fact indicates that the route *via* the acetyl peroxy radical becomes predominant as the amount of AA increases with a rise in the temperature. PO is regarded as a stable species under normal reaction conditions, according to the results of Kamiya.[19] The acetoxy radical produced will decompose as follows.[18] Here, Kamiya's results indicate the low formation of acetic acid in the same reaction system.[20]

$$CH_3\overset{\overset{\|}{O}}{C}O \rightarrow \dot{C}H_3 + CO_2$$

Two paths have been discussed for the formation of the methyl radical, *i. e.*, the decomposition of the acetyl radical and the decomposition of the acetyl oxy radical. On the basis of the low yield of methane, the methyl radical probably partly reacts with propylene to form methane and is partly burned to carbon dioxide. Therefore, it can not

*5 The activation energy of the $CH_3CHO+O_2\rightarrow CH_3\dot{C}O+\dot{O}OH$ reaction is 30 kcal/mol, and that of the $C_3H_6+O_2\rightarrow\dot{C}_3H_5+\dot{O}OH$ reaction is also about 30 kcal/mol or somewhat higher, according to the data tabulated in Semenov's book (N. N. Semenov, *loc. cit*, p. 268 and other parts). The reaction temperature is 360—460°C in Exp. A_0 and 255 or 280°C in Exp. B_2. These suggest that the concentration of the hydroperoxy radical in Exp. A_0 is not lower than that in Exp. B_2. A comparison of the yield of PO relative to those of PA and Acr in Exp. A_0 with that in Exp. B_2 reasonably suggest that the contribution of the hydroperoxy radical to the formation of PO is very small. On this point, Imamura *et al.* neglected the contribution of the hydroperoxy radical to the formation of PO, though they considered the formation of the hydroperoxy radical in their work.[12]

19) Y. Kamiya, *Sekiyu Gakkai Shi (J. Japan Petrol. Inst.)*, **5**, 573 (1962).

20) Y. Kamiya, *ibid.*, **5**, 398 (1962).

be decided which path is major. The allyloxy radical produced is considered to be energy-rich and to decompose as follows:[16]

$$CH_2=CHCH_2\dot{O} \rightarrow CH_2=\dot{C}H + HCHO$$

The formation of allyl alcohol is neglected, because it could not be detected in Exp. A_0.

Formation Reactions of PA and Acr. Comparable amounts of PO, PA and Acr were formed in Exp. B_1 at 280°C.

PA and Acr are also formed in Exp. B_2; this fact may be attributed to the secondary reaction by the allyl peroxy radical formed from radicals induced by the oxidation or decomposition of AA. This idea is supported by the higher conversion of oxygen (50%) in Exp. B_2 than that in Exp. B_1 (20%). According to the discussions presented in the preceding section (in Exp. B_1), the allyl peroxy radical is responsible for the formation of PA and probably of Acr also.

PA retains the carbon skelton of propylene during the reaction, according to the results of White, Davis and Hammack.[9] Cvetanović[10] has proposed that PA is formed through the isomerization of the oxygenated biradical which is formed by the addition of an oxygen atom to the double bond of propylene. Here, the following similar isomerization of the oxygenated radical may be suggested for the formation of PA:

$$CH_2=CHCH_2OOCH_2-\dot{C}HCH_3 \rightarrow$$

$$CH_2=CHCH_2OO\dot{C}H-CH_2CH_3$$

$$CH_2=CHCH_2OO\dot{C}H-CH_2CH_3 \rightarrow$$

$$CH_2=CHCH_2\dot{O} + HC\overset{\overset{\|}{O}}{C}H_2CH_3$$

It can be considered that an acetyl peroxy compound is more unstable than an alkyl peroxy compound. Therefore, this may be a reason for ruling out the route for the formation of PA*6 *via* the addition of an acetyl peroxy radical.

Acr may be formed by the following decomposition of the allyloxy radical,[16] as has been discussed above:

$$CH_2=CHCH_2\dot{O} \rightarrow CH_2=CHCHO + \dot{H}$$

The allyloxy radical is formed in line with the formation of part of PO (from allyl peroxy radical) and PA, as has been discussed above, so the yield of Acr should be less than twice the yield of PA. However, this is not satisfied in Exp. A_0 as shown in Fig. 4. This perhaps indicates that this reaction is minor. The yield of Acr in Exp. B_1 at 280°C is too low in view of the yields of PO and PA (Table 2). Therefore, this reaction is perhaps not feasible. The reaction *via* allyl hydroperoxide is considered to be feasible, however, the following reactions have been proposed by Mullen and Skirrow[6] and also by Kamiya, Sekine and Yamakawa[8] for the formation of Acr:

$$CH_2=CHCH_2O\dot{O} + C_3H_6 \rightarrow$$

$$CH_2=CHCH_2OOH + \dot{C}_3H_5$$

$$CH_2=CHCH_2OOH \rightarrow$$

$$CH_2=CHCHO + H_2O$$

The same scheme may be suggested for the formation of Acr.

Formation Reactions of Ethylene. White, Davis and Hammack[9] have proposed that ethylene is formed *via* the allyl radical. Ethylene is considered to be formed according to the following reactions, which are the competing reaction in the formation of AA by Shtern and Polyak:[3b]

$$CH_2=CHCH_2O\dot{O} \rightarrow CH_2=CH\dot{C}HOOH$$

$$CH_2=CH\dot{C}HOOH \rightarrow$$

$$CH_2=\dot{C}H + CO + H_2O$$

The same scheme may be suggested for the formation of ethylene.

Though $CH_2=\dot{C}H$ is also formed from the decomposition of the allyloxy radical, as has been described above, the reaction path through the isomerization of the allyl peroxy radical is considered to be predominant on the basis of the low contribution of the allyl peroxy radical to the formation of PO, and also on the basis of the low yield of PA in Exp. A_0. $CH_2=\dot{C}H$ most likely reacts with propylene to form ethylene.

Two paths have been discussed for the formation of carbon monoxide, *i.e.*, the decomposition of the acetyl radical and the decomposition of $CH_2=CH\dot{C}HOOH$. There is no experimental evidence, however, upon the basis of which to decide which path is major.

Formation Reaction of Water. It has been postulated that the hydroperoxy radical are formed in the course of the initiation reaction. The following reactions most likely proceed in the formation of water:

$$H\dot{O}O + C_3H_6 \rightarrow HOOH + \dot{C}_3H_5$$

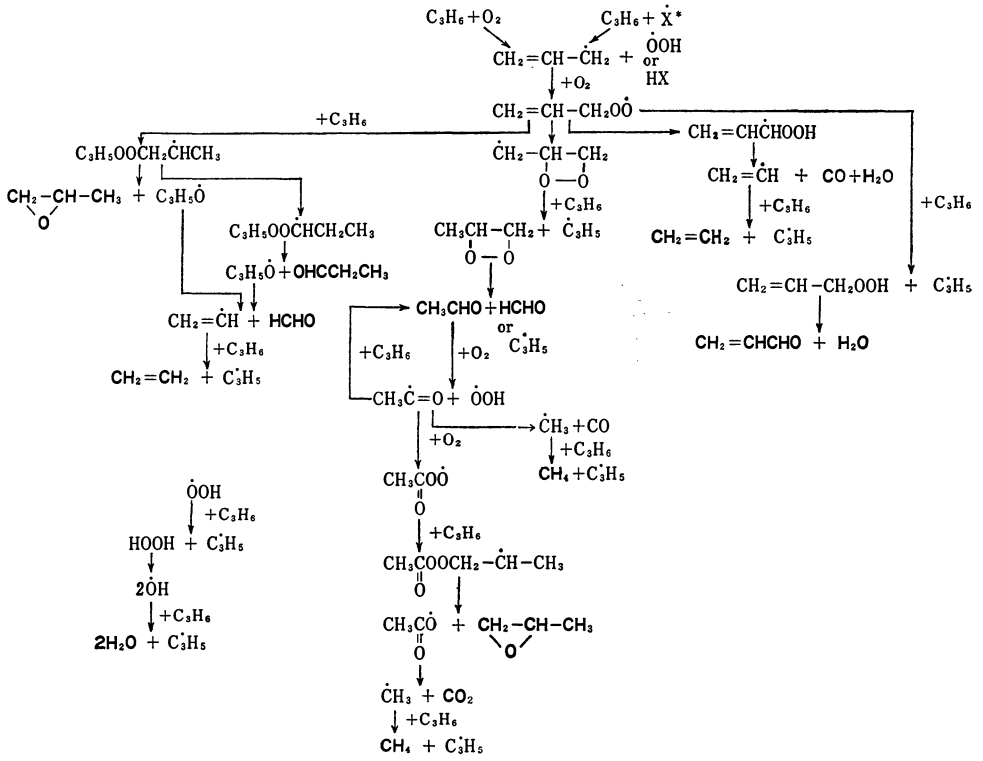
$$HOOH \rightarrow 2\dot{O}H$$

$$\dot{O}H + C_3H_6 \rightarrow H_2O + \dot{C}_3H_5$$

The Scheme of the Oxidation of Propylene in a Propylene-excess Atmosphere. To summarize the above discussions, a reaction scheme is

*6 The yield of PA relative to Acr is lower in Exp. A_0 than that in Exp. B_1, where the concentration of the hydroperoxy radical is very small. Therefore, the contribution of the hydroperoxy radical to the formation of PA is neglected.

TABLE 4. THE PROPOSED REACTION SCHEME (main courses)



* $\dot{X}$: $\dot{C}H_2CHCH_2$ (O–O), $\dot{C}H_3$, $CH_3\dot{C}$ (=O), $CH_2=\dot{C}H$, $C_3H_5O\dot{O}$, $HO\dot{O}$ and $H\dot{O}$

presented in Table 4. Because of the propylene-excess atmosphere, propylene behaves as the hydrogen donor for the radicals, which are $\dot{C}H_3$ and $CH_2=\dot{C}H$.

The scheme presented in Table 4 is proposed for the main route of the oxidation of propylene. Though this scheme is supported by reasonable evidence in the main, other evidence will be necessary before this scheme can be regarded as a "theory" which can explain the phenomena accompanying the oxidation of propylene.

The authors wish to thank the Nippon Petrochemicals Co., Ltd., for supplying the propylene gas, and the Mitsui Mining and Smelting Co., Ltd., for supplying the silicon carbide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 920—928 (1968)

Kinetic Study of the Gas-phase Oxidation of Propylene in a Propylene-excess Atmosphere under Pressure*1

Mitsuo MASAI, Etsuro ECHIGOYA*2 and Kiyoshi MORIKAWA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 16, 1967)

Reaction-rate equations are derived for oxygen, acetaldehyde, propylene oxide, carbon monoxide, and ethylene on the basis of a plausible reaction scheme. These rate equations are shown to fit the experimental results obtained using a flow-type reactor. It seems most reasonable to conclude that the above reaction mechanism is correct. The type of flow of the reactant gas through the reactor used in this work can be practically regarded as a plug flow from the measurements of the resisdence time distribution using the pulse-tracer method.

In our earlier papers dealing with the gas-phase oxidation of propylene in a propylene-excess atmosphere under pressure using an inert fluidized bed reactor, it was shown that the formations of oxygenated products, such as acetaldehyde and propylene oxide, were favored in a propylene-excess atmosphere,[1] and a plausible reaction scheme was presented which fit the experimental results obtained well.[2]

The purpose of the present paper is to discuss kinetically the reaction scheme reported earlier.[2] It is necessary to obtain a reaction scheme which can elucidate all the main phenomena accompanying this reaction. The reaction scheme proposed in the previous paper[2] fit well the experimental results obtained there. However, because of the complexity of the reaction system, and also because of the lack of other suitable analytical methods, the kinetic study is still a powerful method by which to ascertain what is proceeding in the reaction system predominantly. Among the several papers published concerning the kinetic study of the oxidation of propylene,[3] only Kamiya, Sekine and Yamakawa employed a flow method; they showed that the rate of oxygen consumption is first-order with relation to the concentration of oxygen at the total pressures of 4 and 6 atm, and also that the rate constant in this rate equation is proportional to the -0.75th power of the surface area of the reactor wall.[4]

The flow-type reactor is considered to be suitable for use in following a rapid reaction. The residence-time distribution in the reactor was measured by means of the pulse-tracer technique;[5] the residence time distribution in the reactor used here is practically neglected in the experimental region, so the correct reaction time in this flow reactor can be easily calculated.

On the basis of the reaction scheme reported earlier by the present authors,[2] the reaction-rate equations for the initial reaction step are derived for oxygen, acetaldehyde, propylene oxide, carbon monoxide, and ethylene, the major components in this reaction system. These equations demonstrably fit the experimental results obtained here well. Therefore, it seems most reasonable to conclude that the proposed mechanism of the reaction is correct.

Experimental

Materials. The propylene gas and oxygen have been described before.[1]

Apparatus. The kinetic experiments were carried out in a usual flow-type reactor, 14.8 mm i. d. $\times$ 803 mm length and made of stainless steel*3; the reactor was mounted vertically, as shown in Fig. 1. The pressure in the reactor was controlled by a needle valve of stainless steel*3 at the bottom of the reactor. The inner surface of the reactor was polished nearly to a mirror surface, and the reactor was heated from outside by a fused metal bath.

Procedures. The kinetic experiments were carried out in the region of the low conversion of oxygen;

i. e., the assumption of differential reactor nearly holds. The part of the reactor with temperatures higher than 360°C was regarded as a reaction space, on the basis of previously obtained results.[2] The volume change in the reaction was +3——4.9%, therefore, the volume change during the reaction was neglected. The temperature distributions through the reactor were similar for the same mean reaction temperatures. The mean reaction temperatures were evaluated by averaging the temperatures measured at 5—10 mm intervals along the gas flow with equation, $T_{aver}=(\sum T_i \times l_i)/(\sum l_i)$, where T_i is the measured temperature and l_i is the distance from the bottom of the reactor to the point where T_i was measured. The reaction rates were evaluated carefully from the gradient of the concentration *vs.* reaction time curves (Figs. 3—5, 7—12).

Analysis. The procedure was that described for Exp. B in an earlier paper.[2]

Rate Equations

The reaction scheme which was discussed in the earlier paper[2] was as follows:

0 $CH_2=CH-CH_3 + O_2 \rightarrow CH_2=CH-\dot{C}H_2 + H\dot{O}O$

1 $CH_2=CH-\dot{C}H_2 + O_2 \rightarrow CH_2=CH-CH_2O\dot{O}$

2a $CH_2=CH-CH_2O\dot{O} + C_3H_6 \rightarrow CH_2=CHCH_2OOCH_2\dot{C}HCH_3$

2b $CH_2=CHCH_2OOCH_2\dot{C}HCH_3 \rightarrow CH_2=CHCH_2OO\dot{C}HCH_2CH_3$

2c $CH_2=CHCH_2O\dot{O} + C_3H_6 \rightarrow CH_2=CHCH_2OOH + CH_2=CH\dot{C}H_2$

2d $CH_2=CHCH_2O\dot{O} \rightarrow \dot{C}H_2CHCH_2$ (O–O)

2e $\dot{C}H_2CHCH_2$ (O–O) $+ C_3H_6 \rightarrow CH_3CHCH_2$ (O–O) $+ CH_2=CH\dot{C}H_2$

2f $CH_2=CHCH_2O\dot{O} \rightarrow CH_2=CH\dot{C}HOOH$

3 CH_3CHCH_2 (O–O) $\rightarrow CH_3CHO + HCHO$

4a $CH_3CHO + O_2 \rightarrow CH_3\dot{C}O + H\dot{O}O$

4b $CH_3\dot{C}O + O_2 \rightarrow CH_3COO\dot{O}$ (O)

4c $CH_3COO\dot{O}$ (O) $+ C_3H_6 \rightarrow CH_3COOCH_2\dot{C}HCH_3$ (O)

5a $CH_3\dot{C}O \rightarrow \dot{C}H_3 + CO$

5b $CH_3\dot{C}O + C_3H_6 \rightarrow CH_3CHO + CH_2=CH\dot{C}H_2$

6a $CH_2=CHCH_2OOCH_2\dot{C}HCH_3 \rightarrow CH_2=CHCH_2O\dot{O} + CH_2CHCH_3$ (O)

6b $CH_3COOCH_2\dot{C}HCH_3$ (O) $\rightarrow CH_3CO\cdot$ (O) $+ CH_2CHCH_3$ (O)

7 $CH_2=CHCH_2OO\dot{C}HCH_2CH_3 \rightarrow CH_2=CHCH_2O\dot{O} + HCCH_2CH_3$ (O)

8 $CH_2=CHCH_2OOH \rightarrow CH_2=CHCHO + H_2O$

9 $CH_2=CH\dot{C}HOOH \rightarrow CH_2=\dot{C}H + CO + H_2O$

10 $CH_2=CHCH_2O\dot{O} \rightarrow CH_2=\dot{C}H + HCHO$

11 $CH_3C\dot{O}$ (O) $\rightarrow \dot{C}H_3 + CO_2$

12 $CH_2=\dot{C}H + C_3H_6 \rightarrow CH_2=CH_2 + CH_2=CH\dot{C}H_2$

13 $\dot{C}H_3 + C_3H_6 \rightarrow CH_4 + CH_2=CH\dot{C}H_2$

14 $H\dot{O}O + C_3H_6 \rightarrow HOOH + CH_2=CH\dot{C}H_2$

15 $HOOH \rightarrow 2\dot{O}H$

16 $\dot{O}H + C_3H_6 \rightarrow H_2O + CH_2=CH\dot{C}H_2$

17 $CH_2=CHCH_2O\dot{O} \rightarrow$ chain stop

Reaction (17) is postulated, because a wall effect was observed in our previous work; the oxidation reaction took place above 300°C with the reactor 56.3 mm in i. d.[1] and at 360°C with the reactor

24.5 mm in i. d.[2],*4 This strongly indicates the prolonged induction period for the 24.5 mm reactor discussed in Exp. A_0 of the previous paper.[2] The surface area-to-volume ratios of these reactors differ by a factor of about 2.3. Hence, the wall effect of these stainless steel reactors may be evaluated as stronger than that of the entire surface of the fluidizing particle (silicon carbide).*5 The induction period of a radical-chain reaction ends when a sufficient quantity of the branching agent is accumulated.[6] The branching agent of this reaction is acetaldehyde (AA), which, it has been proposed, is formed from the allyl peroxy radical.[2] Thus, the prolonged induction period can be attributed to the reduced rate of the accumulation of AA. The peroxy radical is considered to be decomposed rapidly on the metallic surface, according to the discussion of Walsh *et al.*[7] This must be the cause of the prolonged induction period with the reactor 24.5 mm in i. d. Therefore, reaction (17) is reasonable.

In the propylene-excess atmosphere under pressure, the probability of the encounter of radicals with propylene is very high, and propylene is assumed to react easily with radicals in the following two ways: the addition of radicals to the double bond, or the abstraction of hydrogen by radicals. Both these reactions produce other radicals. Therefore, the termination reactions in the gas phase is not considered here.

The following equations are obtained on the assumption of the stationary state of the concentrations of radicals. It is postulated that the stationary-state approximation can hold for the concentrations of peroxide molecules. In the initial step of the reaction, the concentrations of propylene and oxygen can be considered to be constant, the following kinetic equations are derived on this assumption.*6

In the following equations, the suffix of the rate constant k indicates a reaction described above, P, O, AA, PO, and C=C indicating propylene, oxygen, acetaldehyde, propylene oxide, and ethylene respectively.

The concentrations of main radicals are as follows:

$$[CH_2{=}CH{-}CH_2{-}O{-}\dot{O}] = 3[O](k_0[P] + k_{4a}[AA])/k_{17} \quad (1)$$

$$[CH_3{-}\dot{C}{=}O] = k_{4a}[AA][O]/G \quad (2)$$

$$[CH_2{=}CH{-}\dot{C}H_2] = 3F(k_0[P] + k_{4a}[AA])/k_1 \cdot k_{17} \quad (3)$$

where

$$G \equiv k_{4b}[O] + k_{5b}[P] + k_{5a}$$

$$F \equiv (k_{2a} + k_{2c})[P] + k_{2d} + k_{2f} + k_{17}$$

The concentrations of these radicals are positive functions of the concentration of AA, which was previously concluded to be the degenerate branching agent in this reaction.[2]

The rate of formation and the concentration of AA are as follows:

$$\frac{d}{dt}[AA] \equiv r_{AA} = \chi[P][O] + \varphi[AA] = \chi[P][O]\exp(\varphi t) \quad (4)$$

$$[AA] = \omega[\exp(\varphi t) - 1] \quad (5)$$

where

$$\varphi \equiv k_{4a}[O][(3k_{2d}/k_{17}) - (k_{4b}[O] + k_{5a})/G] \quad (6)$$

$$\chi \equiv 3k_0 \cdot k_{2d}/k_{17} \quad (7)$$

$$\omega \equiv \chi[P][O]/\varphi$$

Eqs. (4) and (5) show that the rate of the increase of AA is accelerated with the reaction time, and that the accumulations of the allyl, allyl peroxy and acetyl radicals are also accelerated with the reaction time, as may be seen from Eqs. (1)—(3).

Equations (8)—(11) are derived for O, PO, CO, and C=C respectively:

$$-\frac{d}{dt}[O] \equiv r_O = \alpha[O] + \gamma \cdot \omega(e^{\varphi t} - 1)[O] = \alpha[O] + \gamma[AA][O] \quad (8)$$

$$\frac{d}{dt}[PO] \equiv r_{PO} = \beta[P]^2[O] + \delta \cdot \omega(e^{\varphi t} - 1)[O] = \beta[P]^2[O] + \delta[AA][O] \quad (9)$$

$$\frac{d}{dt}[CO] \equiv r_{CO} = \theta[P][O] + \eta \cdot \omega(e^{\varphi t} - 1)[O] = \theta[P][O] + \eta[AA][O] \quad (10)$$

*4 The apparent reaction time is 21 sec for the experiment using the 56.3 mm reactor[1] and 8 sec for that with the 24.5 mm reactor.[2] It was confirmed further that the results of the reaction experiment with the 24.5 mm reactor varied only a little in the range of the apparent reaction time from 5 to 15 sec. This result indicates that the variation in the apparent reaction time in this order does not significantly affect the results of the reaction experiments using the fluidized bed reactor. Therefore, the above discussion about the length of the induction period is not disturbed by the variation in the apparent reaction time.

*5 A detailed discussion of the effect of several kinds of fluidizing particles will be published later.

*6 In the derivation of these rate equations, the rate of the formation of the hydroxy radical was regarded as being first-order with regard to the concentration of hydrogen peroxide, considering the initial step of the reaction.

$$\frac{d}{dt}[C{=}C] \equiv r_{C=C} = \varepsilon[P][O] + \zeta\cdot\omega(e^{\varphi t} - 1)[O]$$
$$= \varepsilon[P][O] + \zeta[AA][O] \quad (11)$$

where:

$\alpha \equiv k_0[P] + (3\,k_0\cdot F[P])/k_{17}$

$\beta \equiv 3k_0\cdot k_{2a}\cdot k_{6a}/k_{17}(k_{2b} + k_{6a})$

$\gamma \equiv k_{4a}(1 + k_{4b}[O]/G + 3F/k_{17})$

$\delta \equiv k_{4a}[3k_{2a}\cdot k_{6a}[P]/k_{17}(k_{2b} + k_{6a}) + k_{4b}[O]/G]$

$\varepsilon \equiv \frac{3k_0}{k_{17}}(k_{2f} + k_{2a}[P])$

$\zeta \equiv \frac{3k_{4a}}{k_{17}}(k_{2f} + k_{2a}[P])$

$\eta \equiv k_{4a}(3k_{2f}/k_{17} + k_{5a}/G)$

$\theta \equiv 3k_0\cdot k_{2f}/k_{17}$

As has been shown above, an exponential term or the concentration of AA is present in all kinetic equations. Therefore, these equations may be considered to accord well with the results of the previous work[2] in which AA was demonstrated to be the branching agent in this reaction; also, the relations between the concentration of AA and the reaction rates for O, PO, CO, and C=C can be obtained from the reaction scheme discussed in that earlier paper.[2] The values of α, β, γ, δ, ε, ζ, η, θ, and χ should be positive. As has been shown by Semenov,[6] the reaction rates described above are subject to the value of φ, which can be either positive or negative.

These rate equations represent the well-known "S-shaped rate-*vs.*-time curves" which are characteristic of a degenerate branching reaction, if the value of φ is positive and relatively small, as has been described by Semenov.[6]

The reaction scheme described above can not be a full and precise description of a "perfect reaction mechanism," however, a complete elucidation of such a mechanism is impossible at present. The scheme described above should thus be considered as a description of the predominant course of the homogeneous gas-phase oxidation of propylene in a propylene-excess atomsphere under pressure. Therefore, if the kinetic equations here derived fit the experimental results well, the reaction scheme presented certainly obtains experimental support.

Results

Residence-time Distributions. Figure 2 shows the standard curves of the residence-time distribution function for the Peclet-Bodenstein numbers of 50 and 100; in the figure these curves are compared with the experimental results at the reaction times of 1.1 and 0.3 sec. Their Peclet-Bodenstein numbers are evaluated from Fig. 2 as 70 and 90. On the basis of these values, the residence-time (reaction-time) distribution can be practically neglected under the conditions of the kinetic experiments described below. Thus, the reaction time in this reactor can be easily calculated on the basis of the plug flow.

The Effect of the Molar Ratio of Propylene to Oxygen. Experiments were carried out at 385°C, under 3 atm and with reaction times of 0.3—0.75 sec. The molar ratios of oxygen to propylene examined were 0.26/0.70, 0.22/0.74, 0.17/0.78, and 0.13/0.82; here, the molar fraction of propylene was regarded as roughly constant. The reaction rates were determined from the gradients of the straight lines shown in Figs. 3—5. The reaction order was determined from the gradients of plots, log (molar fraction of oxygen) *vs.* log (rate); Fig. 6 shows the plot of the rate of the comsumption of oxygen and the rates of the

formation of AA and PO. The rate equations and rate constants obtained are shown in Table 1.

Effects of Temperature. Experiments were carried out under the following conditions: 3 atm, molar ratio of 0.22/0.74 (oxygen/propylene), and temperatures of 374, 384, 399, and 421°C. The results for AA are shown in Figs. 7 and 8, and those for O, PO, CO and C=C, in Figs. 9, 10 11 and 12 respectively. Equations (4)—(5) and (8)—(11) were applied to these results; the constants in these equations were determined using the observed values of molar fractions or the rates at the short reaction times measured at the two points which have different gradients on each curve. The concentration-*vs.*-time curves for AA are shown in Figs. 7 and 8; here the black points represent observed values and the open points represent values calculated using Eq. (5). Table 2 contains the constants in Eqs. (4)—(5) and (8)—(11). The observed and calculated concentrations of AA and rates are compared with each other in Table 3.

Discussion

On the Reaction Scheme. As is shown in Figs. 7 and 8, excellent agreements are obtained between the observed and calculated values for the concentration of AA. The small deviations

which are observed in Fig. 8 at the longer reaction time can be ascribed to the failure of the postulation of the initial reaction step. Therefore, it may be concluded that Eq. (5) is suitable for describing the course of the change in the concentration of AA *vs.* the reaction time in the initial step of this reaction system.

As is shown in Table 3, the agreements between the observed and calculated values of r_O, r_{AA}, r_{PO}, r_{CO} and $r_{C=C}$ are satisfactory. It may be concluded, therefore, that Eqs. (4), (8), (9), (10) and (11) are quite satisfactory for describing the reaction rates in this reaction system for O, PO, AA, CO, and C=C. The first order rate equations obtained experimentally for O, AA and PO (Table 1) support this conclusion, because the exponential

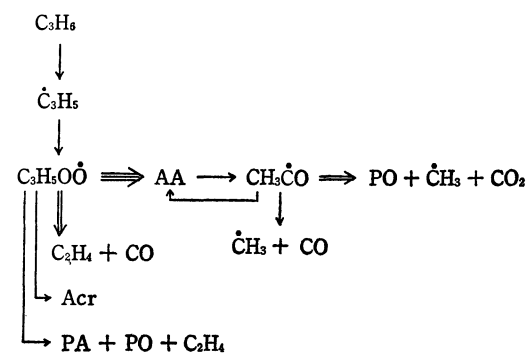
terms in Eqs. (4), (8) and (9) are not so large; when φt is small, as is shown in Table 2, these equations apparently become first-order rate equations. Thus all the kinetic equations derived have been proved to fit the experimental results.

Though many reaction schemes leading to the same rate equations are plausible, the authors' scheme has been supported by experiments and also by the results of many other authors' cited in the previous paper.[2] It seems, therefore, reasonable to conclude that the reaction scheme presented in this paper is a correct description of the main course of this reaction. In consideration of the values of the reaction rate constants (Tables 1 and 2) and the yields of the various oxidation products given in Figs. 4—6 of the previous paper,[2] the relative weight of the reaction paths may finally be considered to be as follows:



On the Slow Rate Period. From the above discussions, the characteristics of this reaction system can be represented in terms of the behavior of AA. In Fig. 8, for AA at 399 and 421°C a steep increase in AA formation is observed after a linear increase. This linear sector corresponds to the constant-reaction-rate region at the initial reaction time. As is shown in Fig. 7 for AA at 374 and 384°C, this linear sector continues to the end of the experiment; in this case, the values of φ are small, as shown in Table 2. The value of φ undergoes a sudden increase at some temperature between 384 and 399°C, as is also shown in Table 2.

In Eq. (4), the values of $\chi(\equiv 3k_0 \cdot k_{2d}/k_{17})$ decrease slowly with the rise of temperature, as shown in Table 2. Therefore, the $3k_{2d}/k_{17}$ term, in φ may also be considered to change slowly; moreover, it is reasonable to consider that $k_{4a}[O]$ the term in φ changes slowly. Thus, the sudden increase in φ may be attributed to the sudden decrease in the $(k_{4b}[O]+k_{5a})/(k_{4b}[O]+k_{5b}[P]+k_{5a})$ term in Eq. (6). Here, this term of φ may be written as $a/(a+k_{5b}[P])$. Therefore, the value of φ can increase rapidly upon the gradual increase in k_{5b} with the temperature. Thus, the difference between the kinetic curves of 374 and 384°C and those of 399 and 421°C can be reasonably explained.

The authors are indebted to Mr. Mitsuhiko Iwasaki for his advices on the pulse tracer technique and for his kind help for the digital computer calculation, also thank Nippon Petrochemicals Co., Ltd, for supplying the propylene gas.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 928—931 (1968)

Reactions of Triethylaluminum with α,β-Unsaturated Carbonyl Compounds

Yoshio BABA

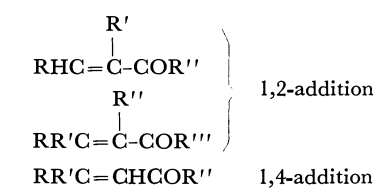
Resources Research Institute, Kawaguchi, Saitama

(Received April 17, 1967)

The reactions of triethylaluminum and its various ether adducts with α,β-unsaturated ketone, aldehyde, ester, and methyleneanthrone have shown that the addition occurs mainly at the 1,2-positions of the carbonyl function, and not at the 1,4-positions as has been observed in the Grignard reaction. The mode of addition was discussed in view of the reactivity of the organometallic compound and the steric factor of the unsaturated carbonyl compounds.

A possible mode of the addition of organometallic compounds to unsaturated carbonyl compounds has been studied by many investigators.

Cologe[1] has proposed correlations between the structure of α,β-unsaturated ketones and the mode of addition in the reaction of a simple Grignard reagent.



Gilman,[2] however, has reported that the reactivity of the organometallic compounds determines the direction of the addition. The relatively less reactive phenyl metallic compounds add to benzalacetophenone at the 1,4-positions, while the reactions with more reactive members afford 1,2-addition products.

Recently, Wittig[3-5] has proposed a mechanism of the addition reaction of organometallic compounds in which the mode of addition is effected by the ability of ate-complex formation. Thus, even though difficulty is encountered in the reaction of benzophenone with triphenylaluminum, the reaction of benzalacetophenone with triphenylaluminum proceeds readily to give the 1,4-addition product. The facile reaction of benzalacetophenone is interpreted as being due to the ability of ate-complex (I) formation, as is shown in Eq. (1):

1) J. Colonge, *Bull. Soc. Chim.*, (5), **2**, 754 (1935).
2) H. Gilman and R. H. Kirby, *J. Am. Chem. Soc.*, **63**, 2046 (1941).

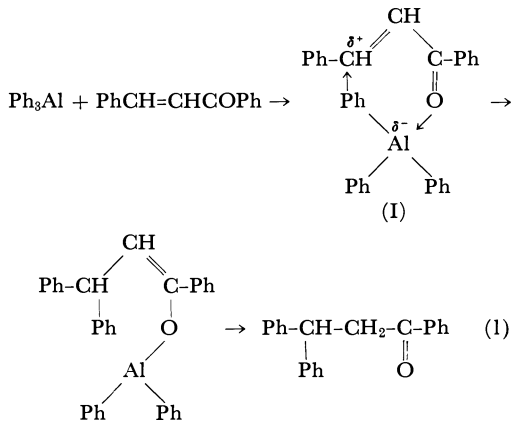
5) A. Luettringhaus and K. Scholtis, *ibid.*, **557**, 70 (1941).



Phenylsodium or phenyllithium, however, reacts with the same α,β-unsaturated ketone to give the 1,2-addition product because of its lack of the ability to make an ate-complex intermediate.

The present work was undertaken to study the possible modes of addition in the reaction of triethylaluminum with unsaturated carbonyl compounds.

Experimental

All the reactions were carried out in an atmosphere of dry nitrogen. The melting points were measured on a micro hot stage and were not corrected.

Materials. Triethylaluminum purchased from the Ethyl Corp. was used without further purification. Commercial di-*n*-propyl ether (bp 90°C), diisopropyl ether (bp 68°C), di-*n*-butyl ether (bp 142°C), di-*n*-amyl ether (bp 186°C), diisoamyl ether (bp 172°C), cinnamaldehyde (bp 93—94°C/5 mmHg), benzalacetone (bp 112—113°C/5 mmHg, mp 41—42°C), ethyl cinnamate (bp 127—128°C/7 mmHg), crotonaldehyde (bp 102°C), mesityl oxide (bp 129°C), methyl crotonate (bp 127°C), and benzophenone (bp 150—151°C/5 mmHg) were purified by distillation. Methyleneanthrone (mp 146—147°C) was prepared from anthraquinone *via* anthrone.[6] Ethyl ethylenetetracarboxylate (mp 52.0—52.5°C) was synthesized from diethyl malonate *via* diethyl bromomalonate.[7]

Analytical Procedure. The C=C double bond and carbonyl group were analyzed according to the Lucas[8] and Iddles[9] methods respectively.

Reactions of Benzalacetone with Triethylaluminum and Its Various Ether Adducts. A 30-weight-percent solution of an aluminum compound in dry benzene containing 0.1 mol of triethylaluminum or its ether adducts was added drop by drop, to an ice-cooled solution of benzalacetone (0.05 mol) in dry benzene. The reaction mixture was, after standing for 0.5 hr in an ice-bath, refluxed for 1 hr. The crude product obtained by the usual method was distilled under reduced pressure. The carbonyl component in the distillate was extracted with a Girard reagent ($(C_5H_5N-\overset{+}{C}H_2CONHNH_2)Cl^-$). The amounts of unchanged ketone and 1,4-addition product were then determined by C=C double bond and carbonyl group analysis in the carbonyl fraction by the methods described in the "analytical procedure" section, while the amounts of alcohol produced by the 1,2-addition reaction and its dehydrated product produced in the course of the distillation were determined by active-hydrogen and C=C double bond analysis of the non-carbonyl fraction.

Reaction of Benzophenone with Triethylaluminum. The reaction of benzophenone (9.1 g, 0.05 mol) with 0.075 mol of triethylaluminum in a benzene solution (refluxed for 1 hr) yielded 9.2 g of an oily product distilled at 143—150°C/5 mmHg. The above product was mixed with phthalic anhydride (6.0 g) and 24 g of dry pyridine. After a 3 hrs' refluxing of the reaction solution, the pyridine was removed by distillation and the residue was dissolved in 30 m*l* of benzene. From the benzene solution, the mono ester of the phthalic acid of secondary alcohol was extracted with a 10% potassium hydroxide solution, while the benzene solution, after drying over calcium chloride, was evaporated to give 4.3 g (42%) of crystals (mp 90—92°C). The recrystallization of the crude crystal from petroleum ether gave plates, mp 93—94°C, which showed no depression in melting point upon the admixture of diphenylethylcarbinol (mp 93—94°C), prepared from ethylmagnesium bromide and benzophenone. The alkaline solution containing the mono ester of phthalic acid of the secondary alcohol was boiled for 5—10 min, and then the separated oil was extracted with benzene. The benzene solution was dried over calcium chloride and the benzene was evaporated. The crude crystals (mp 65—66°C, 4.7 g, 51%) were recrystallized from ethanol, mp 66—67°C, needles, the melting point was undepressed by admixture with benzhydrol.

Reaction of Methyleneanthrone with Triethylaluminum. A powdered methyleneanthrone (5.2 g, 0.025 mol) was added to a strirred solution of triethylaluminum (0.076 mol) in dry petroleum ether. The solid methyleneanthrone dissolved readily, and a faint-yellow-colored solution resulted. The reaction solution was stirred for 4 hr at room temperature and then treated by the usual method. The faintly-yellow-colored oily product (7.0 g) was mixed with a small amount of ethanol and then allowed to stand for several days at room temperature. The crystals which separated were collected by filtration and washed with ethanol. The crude crystal (1.7 g, 33.0%) was recrystallized from ethanol; mp 283—284°C, undepressed by admixture with anthraquinone. The chromic acid oxidation of the oily product yielded 9-ethylanthrol (mp 106—107°C, from ethanol).

Found: C, 80.39; H, 6.35%. Calcd for $C_{16}H_{14}O_2$: C, 80.65; H, 5.92%.

Reaction of Ethyl Ethylenetetracarboxylate with Triethylaluminum. The reaction of ethyl ethylenetetracarboxylate (12.9 g, 0.041 mol) with 0.184 mol of triethylaluminum yielded 5.5 g (42.2%) of crystals, mp 75—76°C, from ethanol; the crystals were identified as ethyl ethanetetracarboxylate by a mixed melting point determination with a sample prepared from

ethylmagnesium bromide and ethyl ethylenetetracarboxylate according to the procedure reported by Hsing.[10]

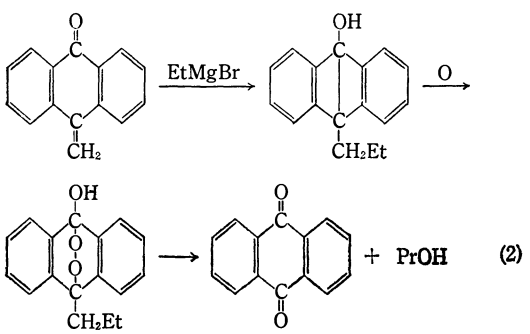
Results and Discussion

The results of the experiments of benzalacetone with triethylaluminum and its various ether adducts shows that, as Table 1 indicates, in every case the 1,2-addition reaction constituted the principal reaction, whether the free triethylaluminum or its ether adducts, which are considered to have some influence on the ate-complex formation, were employed. On the basis of these data, it seems reasonable to infer that the mode of addition in the reaction of triethylaluminum with α,β-unsaturated ketone is not influenced by the ability of ate-complex formation, but is rather defined by the reactivity of organometallic compounds.

Thus, even in the reaction of organometallic compounds with the same metal atom, such as triethylaluminum and triphenylaluminum, the highly reactive member permits the 1,2-addition, while the compound with a lower reactivity gives the 1,4-addition product.

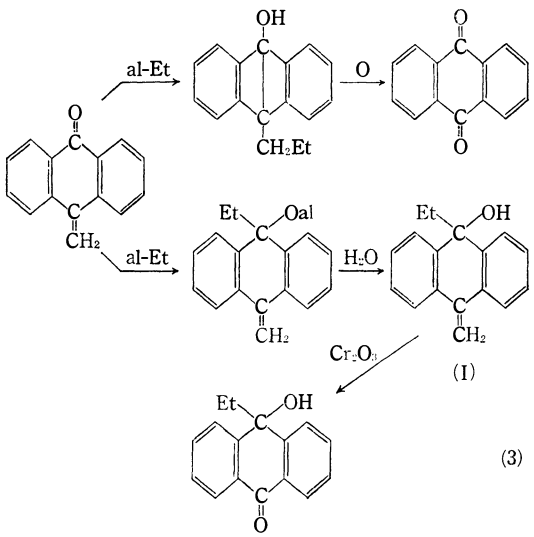
A higher reactivity of triethylaluminum as compared with triphenylaluminum was demonstrated by the reaction with benzophenone. Although benzophenone does not react with triphenylaluminum,[3] it reacts readily with triethylaluminum to give both the addition and reduction products, each in a 50% yield.

Bergman[11] has reported that the reaction of methyleneanthrone with ethylmagnesium bromide does not afford any of the alcohol expected from the normal Grignard reaction, but gives anthraquinone as the sole reaction product. Julian and Magnani[12] have studied this reaction and concluded that the reaction involves the 1,6-addition of ethylmagnesium bromide to the conjugated system in methyleneanthrone. They have verified the above mechanism by the isolation of the intermediate peroxide produced by the air oxidation of 1,6-addition product, and the formation of anthraquinone, by the decomposition of the peroxide, as shown in Eq. (2). They have also further disclosed that, in the case of a homolog of methyleneanthrone carrying a bulky group at the γ-position, benzalanthrone for example, the 1,6-addition is inhibited and the 1,2-addition is realized.



(2)

Methyleneanthrone reacted with triethylaluminum to give anthraquinone, an oxidative degradation product of the 1,6-addition product, in a 33% yield, but a substance carrying a hydroxyl group was obtained in a 32% yield as another product. A postulation that the alcohol (I) formation can be attributed to the 1,2-addition of al-Et to the conjugated system of methyleneanthrone was verified by the chromic acid oxidation of this alcohol to yield 9-ethylanthrol (II) (*cf.* Eq. (3)).



(3)

Thus it was found that triethylaluminum tends to add more readily to the carbonyl group of the conjugated system in methyleneanthrone than the corresponding magnesium compound, and that the mode of addition is defined both by the reactivity of the organometallic compound and by the steric factor of the unsaturated ketones.

The facile addition of trialkylaluminum to the carbonyl group in the unsaturated carbonyl compound could be verified from the reaction of triethylaluminum with the six α,β-unsaturated carbonyl compounds listed in Table 2; the 1,2-addition products were obtained as the major products.

A difficulty of the 1,2-addition of al-Et group to a carbonyl group in the unsaturated carbonyl compound was encountered in the reaction with ethyl ethylenetetracarboxylate. Hsing[10] has found that the reaction of ethyl ethylenetetracarboxylate with a large excess of ethylmagnesium bromide

does not cause the addition of metalalkyl linkage to the carbonyl group of the ester, but yields the reduction product of the C=C double bond and the product derived from the addition of the metal-ethyl linkage to the C=C double bond in yield of 43% and 56% respectively. The reaction of this unsaturated ester with eight moles of triethylaluminum was found to give the same product as expected from the analogy of the corresponding Grignard reaction.

The author wishes to thank Dr. J. Yoshimura, Professor of Tokyo Institute of Technology, for his many helpful discussions and suggestions during this work, and Y. Koenuma for his assistance in the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 932—936 (1968)

Catalytic Dehydrogenation of Secondary Alcohols with Reduced Copper. VI.[1] The Dehydrogenation of Isopropyl Alcohol (Part III)*[1]

Kazuaki KAWAMOTO, Yoshiharu NISHIMURA*[2] and Teruo HIRAKI

Institute of Commodities, Faculty of Economics, Kagawa University, Takamatsu

(Received May 12, 1967)

In order to determine whether the condensing activity of reduced copper is affected by the mode of preparation of the catalyst, the condensation of isopropyl alcohol to isobutyl methyl ketone, diisobutyl ketone, and isobutylmethylcarbinol was studied with catalysts prepared in different ways. It was found that the copper catalyst obtained by the hydrogen treatment of the oxide prepared from copper nitrate and an excess of sodium hydroxide was the most suitable catalyst for the condensation of isopropyl alcohol to isobutyl methyl ketone and diisobutyl ketone, and that the copper catalyst prepared with potassium carbonate was the most suitable catalyst for the dehydrogenation of isopropyl alcohol to acetone with no side reaction.

In a previous study,[2] it was found that isobutyl methyl ketone and diisobutyl ketone could be prepared in one step by passing isopropyl alcohol over various forms of copper catalysts heated at 220°C and 250°C, and that the relative amounts of the compounds in the reaction products depended not only upon the reaction temperature, but also upon the mode of preparation of the catalyst.

Adkins *et al.*[3] found that the nickel catalyst prepared by precipitation with ammonium carbonate was more active in the hydrogenation than those prepared with other precipitants (sodium hydroxide, sodium carbonate and sodium bicarbonate). Frolich *et al.*[4] reported that an active catalyst for the decomposition of methanol could be obtained by adding ammonia to a solution of copper nitrate.

Palmer[5] studied the influence of the reducing agents on the copper catalyst, which was used as the catalyst for the dehydrogenation of ethyl alcohol; he reported that the activity of the copper catalyst prepared with hydrogen was greater than those treated with methanol and with carbon monoxide.

No detailed study of the effect of solvents used in the preparation of copper catalysts on the dehydrogenation of a secondary alcohol have been reported.

The object of the present work is to discover how the precipitant, the solvent, and the reducing agent used in the preparation of a catalyst influence the activity and the selectivity of the catalyst, and to find the most suitable conditions and the best catalyst for the formation of isobutyl methyl ketone and diisobutyl ketone from isopropyl alcohol. Experiments were carried out at several temperatures between 185°C and 325°C; four different precipitants, six solvents, and three reducing agents were used.

Experimental

Preparation of Catalysts. The precipitates (Cu VII—Cu XXIV) were prepared as shown in Table 1. As a typical run, Cu XV was prepared as follows: A solution of 30 g of cupric nitrate hexahydrate in 900 m*l* of distilled water was kept at 22°C. An ammonia solution prepared from 12 g of ammonia (30%) and 300 m*l* of distilled water was brought to the same temperature and added rapidly to the stirred copper nitrate solution. After the mixture had been stirred at this temperature for 30 min, the precipitate was washed well with distilled water by decantation, collected on a glass filter, dried in an electric oven at 105°C for the time given in the table, powdered in an agate mortar, and finally stored in a stoppered bottle.

The precipitates were reduced in the following ways. When hydrogen was used as the reducing agent, the hydrogen was passed at the rate of 750—900 m*l* per hour over 10 g of the precipitate; the reduction temperature was always below 185°C. In the case of the reduction of the precipitate with isopropyl alcohol vapor, the isopropyl alcohol was charged at the rate of 10—11 g per hour, while the reduction temperatures were 185, 220, 250 and 325°C. In the case of the reduction of the precipitate with carbon monoxide, the flow rate of carbon monoxide was 800—900 m*l* per hour, and the reduction temperature was always below 140°C.

Apparatus and Procedure. The apparatus employed was similar to that used in the previous investigation, with the exception that an electrically heated furnace was used. A definite amount (10 g) of the precipitate was placed in the Pyrex reaction tube (18 mm in inside diameter and 1 m in length), which was set in an electrically heated furnace of the horizontal type. The furnace was heated to the reduction temperature and kept at this temperature for the period of reduction. The reducing agent was passed through the tube at a regular velocity; the resulting catalyst was then heated to the reaction temperature. Experiments were performed at 185, 220, 250, 300, and 325°C under ordinary pressure, and isopropyl alcohol was passed through the tube at a constant flow rate. The reaction products coming out of the reaction tube were removed by being passed through a condenser cooled with ice water, supplemented by two traps which were cooled with ice. The volume of gas evolved was determined by allowing it to displace the water from a 2 *l* graduated cylinder. All the values given in the present research are averages of two to three measurements under constant reaction conditions.

Analysis of the Products. The reaction products (acetone, isobutyl methyl ketone, diisobutyl ketone, and isobutylmethylcarbinol) were identified by comparing them with authentic samples obtained by gas chromatography. In addition, the reaction products were dried with anhydrous sodium sulfate and then fractionally distilled, and the constituents of the cut were identified by their boiling points, densities, refractive indices, and the formation of the corresponding derivatives. All derivatives for the identification of the reaction products were made by the Shriner, Fuson, and Curtin method.[6] Acetone was present in a fraction boiled at 56—56.5°C. From this fraction, the 2,4-dinitrophenylhydrazone, mp 128°C, and the semicarbazone, mp 187°C were obtained. The fraction of isobutyl methyl ketone gave the semicarbazone, mp 133—133.5°C, and the 2,4-dinitrophenylhydrazone, mp 93.5—94°C. The fraction of diisobutyl ketone gave the 2,4-dinitrophenylhydrazone, mp 92—92.5°C, and the semicarbazone, mp 122—122.5°C. The fraction of isobutylmethylcarbinol gave the phenylurethane, mp 142—143°C. No formation of unsaturated or hydroxy ketones, such as mesityl oxide, phorone or diacetone alcohol, were detected in the reaction products of any of the experiments. The gaseous product, when analyzed by gas chromatography, has found to be hydrogen. The reaction products were analyzed quantitatively by gas chromatography using a Shimadzu-Type GC-2B and a Shimadzu-Type CG-2C apparatus. A 5-m column of PEG-6000 was used at an operating temperature of 100°C and at a flow rate of 22.0 ml/min of helium. For the determination of water, a 3-m column packed with Shimalite F impregnated with PEG-1000 was used at 100°C with a hydrogen carrier at 11.5 ml/min. Further, the content of acetone was determined by the hydroxylamine method.[7]

Results and Discussion

The influence of the precipitant, the solvent, and the reducing agent used in the preparation of catalyst on the activity and the selectivity of the copper catalyst is summarized in Tables 2 and 3; the amounts of reaction products given in these tables are reproducible within 1 per cent. The evolution of gas measured at intervals of 15—20 min was found to be constant during the reaction time. Therefore, it was concluded that the sustained activity of the catalyst held over the period of the operation. Little dehydration of isopropyl alcohol to propylene seems to occur at temperatures below 325°C.

Influences of the Precipitants and the Solvents on the Dehydrogenating Activity and the Condensing Activity of Reduced Copper. As shown in Table 2, the dehydrogenating activity and the condensing activity of a copper catalyst vary considerably with the sort of precipitant and

* These columns show the products obtained when isopropyl alcohol was passed over the catalyst as the reducing agent at the temperatures described.

with the sort of solvent. Although the influence of the reaction temperature on the dehydrogenating activity of reduced copper is not listed in this table, at the highest reaction temperature (325°C) the catalyst prepared by the treatment with hydrogen of the precipitate (Cu IX) obtained by using potassium carbonate as a precipitant gave the highest yield of acetone (97.0%). The dehydrogenating activity of various copper catalysts is in the following order with respect to the precipitants: $K_2CO_3 > NaOH > (NH_4)_2CO_3 > NH_4OH$. Furthermore, it was found that the catalyst prepared by the treatment of Cu IX with hydrogen acted only to dehydrogenate isopropyl alcohol to acetone at all temperatures; the catalyst prepared by the treatment with hydrogen of the precipitates (Cu VII, Cu XV and Cu XVI) obtained by using sodium hydroxide, ammonia, and ammonium carbonate acted similarly at the highest temperature, but at lower temperatures (185—250°C) they gave not only acetone but also isobutyl methyl ketone, diisobutyl ketone, and isobutylmethylcarbinol. The copper catalyst prepared by precipitation with sodium hydroxide was more active in the condensation of isopropyl alcohol than those catalysts precipitated with ammonia and ammonium carbonate. The proportion of diisobutyl ketone in the condensation products increased with a rise in the reaction temperature.

From the fact that the copper catalyst obtained by using an excess of ammonium carbonate caused the condensation reaction, and that the copper catalyst prepared with an excess of potassium carbonate did not cause this reaction, it does not appear that this condensation was caused by traces of alkali contaminating the catalyst. Considering the information in the previous paper,[2] the formation of higher ketones in the present research seems to be attributable to the effect either of traces of water or of a lower oxide of copper in the catalysts.

When the precipitate prepared from ammonia water was used, the evolution of NO_2 gas in the course of reduction of the precipitate with hydrogen was noticed; this gas seems to be attributable to the nitrate ions remaining as an impurity in the precipitate. NO_2 gas tended to exert a strongly negative influence on the velocity of reduction, the reduction time being fifty hours. However, the gas had no appreciable change on the dehydrogenating activity.

Cu XVII and Cu XVIII, prepared in methyl alcohol and ethyl alcohol respectively as solvents, were nearly equal in their activity for the production of both the condensation product and acetone. When the reaction temperature was carried out at lower temperatures (220—250°C), Cu XX, prepared in butyl alcohol, had a relatively poor activity for the formation of the condensation product. However, at the reaction temperature of 220°C the copper catalysts obtained by the treatment with hydrogen of the precipitates (Cu XVII, Cu XVIII, Cu XIX, Cu XXI and Cu XXII) prepared in the other alcohols did give the condensation product. There was thus a marked difference in activity between the copper catalyst prepared in a higher alcohol and those prepared in lower alcohols with respect to the relative amount of condensation product formed. The maximum conversion to the higher ketones resulted when water was used as the solvent; the formation of the condensation product increased in the following order with respect to the solvent: water > methanol, ethanol > 2-propanol > 2-butanol > 1-propanol > 1-butanol. When the copper catalyst prepared in a higher alcohol was used at a low temperature, it gave a large quantity of unreacted alcohol. This seems to be caused by the adsorption of the higher alcohol on the catalyst. Because of the small extent of the condensation reaction, the degree of dehydrogenation was excellent over the catalyst prepared in the higher alcohol. When the copper catalysts obtained by the treatment with hydrogen of the precipitates (Cu XXIII and Cu XXIV) prepared with potassium carbonate in alcohols were used at 220—250°C, isopropyl alcohol yielded acetone and hydrogen, but not higher ketones. It has been found by Suito and Takiyama[8] that considerable differences in particle size occur with changes in the solvents used in preparing the precipitates. Accordingly, the dehydrogenating activity and the condensing activity of the copper catalyst is presumed also to depend on the particle size, which may vary with changes in the solvents.

Influence of Reducing Agents on the Dehydrogenating Activity and the Condensing Activity of Reduced Copper. The influence of the reducing agents and the reaction temperatures on the activity of the copper catalyst is shown in Table 3. The condensing activity of the copper catalyst varies considerably with the sort of reducing agent, the catalyst prepared by treatment with hydrogen showed the largest activity for condensation reaction. On the contrary, the reduction of the precipitate with isopropyl alcohol vapor, in place of hydrogen, prevented the formation of any condensation products. The fact that only a small amount of higher ketones was obtained when the catalyst reduced by isopropyl alcohol was used is interesting; probably, the most effective and simplest way to suppress the formation of condensation products is to use precipitates reduced with isopropyl alcohol. When the copper catalyst, prepared by treatment with sodium hydroxide followed by reduction with carbon monoxide, was used at 300°C, the condensation product was obtained, while the copper catalyst prepared with potassium

8) E. Suito and K. Takiyama, This Bulletin, **28**, 305 (1955).

carbonate acted only to dehydrogenate isopropyl alcohol to acetone at all temperatures.

The dehydrogenation activity of reduced copper catalysts depends also upon the temperature at which the oxide is reduced with the reducing agent and upon the velocity with which the reducing agent is passed over the oxide. The reduction of copper oxide with hydrogen is an exothermic reaction; the heat of reaction may accumulate on a part of the catalyst. Accordingly, this may cause sintering. On the other hand, when isopropyl alcohol was used as the reducing agent, the catalytic activity of dehydrogenation was not affected by the reducing temperature.

When isopropyl alcohol was passed over reduced copper, a small amount of isobutylmethylcarbinol was obtained. This compound is formed by the hydrogenation of isobutyl methyl ketone. Further, the present authors*[3] have found that the copper catalysts changed *l*-menthol to *l*-menthone, *d*-isomenthone, thymol, isomenthol and neomenthol, and allyl alcohol to acrolein, propargylaldehyde, propionaldehyde, and *n*-propyl alcohol, and the mixture of cyclohexene and hydrogen to cyclohexane. The reduced copper, therefore, is an effective catalyst for the hydrogenation.

Pease and Stewart[9] found that the addition of carbon monoxide to materials lowered the hydrogenation activity of a copper catalyst. When, however, the copper catalysts prepared by the reduction with carbon monoxide or hydrogen were used, isobutylmethylcarbinol was obtained. In this case, therefore, carbon monoxide seems to act somewhat as a poison with regard to the copper catalyst.

The Chemiluminescence of Indole Derivatives. III. On the Mechanism of the Chemiluminescence of 2,3-Dimethylindole and 5-Substituted-2,3-dimethylindoles in the Dimethyl Sulfoxide-Alkali System

Noboru SUGIYAMA, Masamoto AKUTAGAWA and Hiroshi YAMAMOTO

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received June 2, 1967)

A bright green light is observed on the treatment of a solution of 2,3-dimethylindole (I) and its hydroperoxide (II) in dimethyl sulfoxide (DMSO) with alkali (potassium *t*-butoxide or granular potassium hydroxide) under streams of oxygen and hydrogen respectively. The change in their ultraviolet and fluorescent spectra with the time and the chemiluminescent spectra is measured. The compound II is concluded to be the reaction intermediate of I; it decomposes to yield an excited singlet state of an *o*-acetamidoacetophenone anion (III*), a light emitting species in this reaction. The investigation, then extended to four 5-substituted-2,3-dimethylindoles, revealed that three of them displayed chemiluminescence through the same mechanism as in the case of I.

In relation to the luciferin of the bioluminescent marine organisms,[1-3] the chemiluminescence of indole derivatives is an especially interesting phenomenon; that of various simple indoles has recently been reported.[4-6]

We studied the relative light intensities of forty-one indole derivatives in the following two systems.[7]

(A) Sample-EtOH-KOH-H_2O_2-$K_3Fe(CN)_6$

(B) Sample-DMSO-KOH-AIR

We found that 2,3-dimethylindolenyl-3-hydroperoxide (II) emitted a bright flash of light in the B system. Although McCapra *et al.* suggested

the intermediacy of a indolyl-3-hydroperoxide and a hydroperoxide decomposition mechanism accompanying a light emission,[8,9] the mechanism of the chemiluminescence has remained obscure.

In a preceding paper, we proposed a mechanism of the chemiluminescence of the indole derivative involving the hydroperoxide as an intermediate.[10] In the present paper, the mechanisms of 2,3-dimethylindole and 5-substituted-2,3-dimethylindoles will be discussed in detail in the light of the spectral studies.

Experimental

2,3,5-Trimethylindolenyl-3-hydroperoxide (VIIa). VIIa was prepared as follows. 2,3,5-Trimethylindole (200 mg) was dissolved in warm light petroleum (bp 60—80°C, 20 ml), and then a trace of benzoyl peroxide was added to the solution in the presence of atmospheric oxygen. After an hour the solution became opaque and then began to deposit crystalline hydroperoxide (140 mg), which was collected and recrystallized from a mixture of ethyl acetate and light petroleum to produce almost colorless prisms.

Mp 111.5°C (decomp.) Found: C, 69.34; H, 7.09; N, 7.44%. Calcd for $C_{11}H_{13}O_2N$: C, 69.09; H, 6.85; N, 7.33%.

UV: λ_{max}^{EtOH} mμ (log ε) 223 (4.24) 267 (3.59).

IR: ν_{KBr} cm^{-1} 3440, 3070, 2750, 1595, 1470, 860, 830

Attempted Preparation of 5-Chloro-2,3-dimethylindolenyl-3-hydroperoxide (VIIc). An ether - light petroleum solution of 5-chloro-2,3-dimethylindole (VIc) was oxidized with atmospheric oxygen as has been described above. After 20 hr a brown amorphous solid deposited out. This solid could not be recrystallized from any solvent, but it showed the characteristics of indolenine (*e. g.*, λ_{max} at approx. 230 and 260 mμ in the UV spectrum, and a positive starch-iodide test.).

Materials. The following derivatives were synthesized in our laboratory by the methods described in the literature.[11-15]

2,3-Dimethylindole (I)[11]: Recrystallized from ligroin, colorless leaflets, mp 107—108°C (Found: C, 82.69; H, 7.70; N, 9.63%).

UV: λ_{max}^{EtOH} mμ (log ε) 283 (3.8) 290 (3.75).

IR: ν_{KBr} cm^{-1} 3380, 2900, 1590, 1460, 760.

2, 3, 5-Trimethylindole (VIa)[12]: Recrystallized from alcohol, colorless plates, mp 120°C (Found: C, 82.51; H, 8.30; N, 8.78%).

UV: λ_{max}^{EtOH} mμ (log ε) 231 (4.39) 288 (3.82).

IR: ν_{KBr} cm^{-1} 3380, 2900, 2840, 1590, 1475, 870, 790.

5-Methoxy-2,3-dimethylindole (VIb)[13]: Recrystallized from alcohol, mp 109°C (Found: C, 75.54; H, 7.51; N, 7.99%).

UV: λ_{max}^{EtOH} mμ (log ε) 230 (4.41) 278 (3.90).

IR: ν_{KBr} cm^{-1} 3390, 2920, 2850, 1590, 1475, 870, 790.

5-Chloro-2,3-dimethylindole (VIc)[13]: Recrystallized from benzene, glistening white plates, mp 140—141.5°C Found: C, 66.15; H, 5.64; N, 7.72%.

UV: λ_{max}^{EtOH} mμ (log ε) 235 (4.49) 293 (3.80) 301 (sh.) (3.74).

IR: ν_{KBr} cm^{-1} 3400, 2900, 1575, 1470, 860, 800, 750.

5-Nitro-2,3-dimethylindole (VId)[13]: Recrystallized from benzene, golden needles, mp 187°C (Found: C, 63.35; H, 5.55; N, 14.65%).

2,3-Dimethylindolenyl-3-hydroperoxide (II)[14]: Recrystallized from ethyl acetate-light petroleum, colorless prisms, mp 103°C (Found: C, 67.7; H, 6.3; N, 7.9%).

UV: λ_{max}^{EtOH} mμ (log ε) 225 (4.11) 260 (3.46).

IR: ν_{KBr} cm^{-1} 3400, 3060, 2800, 1600, 1455, 780.

5-Methoxy-2,3-dimethylindolenyl-3-hydroperoxide (VIIb)[14]: Recrystallized from ethyl acetate - light petroleum, colorless needles, mp 109°C (decomp.) (Found: C, 63.96; H, 6.59; N, 6.49%).

UV: λ_{max}^{EtOH} mμ (log ε) 223 (4.19) 281 (3.82).

IR: ν_{KBr} cm^{-1} 3450, 3050, 2800, 1595, 1470, 870, 810.

o-Acetamidoacetophenone (III)[15]: Recrystallized from ethanol-water, long colorless needles, mp 74—75°C.

2-Acetamido-5-methylacetophenone (VIIIa): VIIa was dissolved in boiling water and the solution was kept at room temperature; then VIIIa slowly separated. Recrystallized from methanol, slightly yellow leaflets, mp 123.5—124.5°C.

VIIIa was also prepared by treating the indole with ozonized oxygen.[12] Recrystallized from methanol, mp 123.5—124.5°C.

2-Acetamido-5-methoxyacetophenone (VIIb)[14]: Recrystallized from light petroleum, long yellow needles, mp 91—91.5°C.

2-Acetamido-5-chloroacetophenone (VIIIc): VIc (0.3 g in AcOH (27 ml) + H_2O (2 ml)) was treated with ozonized oxygen at room temperature until the indole spot disappeared on T. L. C. The product was isolated by basification and extracted with ether. Recrystallized from methanol, almost colorless silky needles, mp 134—134.5°C.

Measurement of the Total Amount of Chemiluminescence. The total amount of light which was emitted when a solution of the sample was mixed with a solution of the alkali in the presence of oxygen was measured by a modified Moldel 139 Hitachi Photometer.

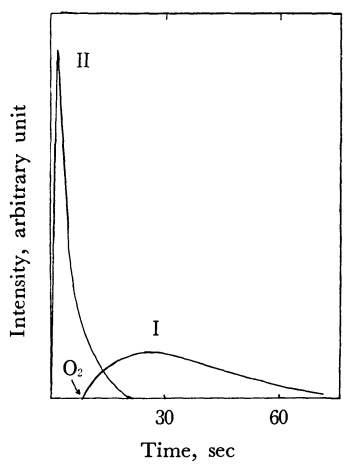

Fig. 2. Chemiluminescent curves of I and II.
10^{-4} mol/*l*, DMSO soln. 1 m*l* + 10^{-3} mol/*l*, BuOK DMSO soln. 1 m*l* + O_2(I) or Ar(II) stream

The change in the intensity of light with the time was recorded with a QPD 53 Hitachi Recorder, and the total emission was determined by the area of the emission curve. All measurements were carried out at 20°C.

One milliliter of a solution of a sample in DMSO (10^{-3} or 10^{-4} mol/*l*) was mixed with 1 m*l* of a potassium *t*-butoxide DMSO solution (10^{-2} or 10^{-3} mol/*l*) in an oxygen or argon stream, or 2 m*l* of a sample solution was added to 0.5 g of granular potassium hydroxide. The results are shown in Tables 1 and 3 and in Fig. 2.

Emission Spectra. In front of the slit of a spectrometer was set a test tube containing about 3 g of granular potassium hydroxide. Ten milliliters of the sample solution was at once added to this test tube. By means of a fine syringe needle, tiny bubbles of oxygen were continuously passed through this solution from the bottom of the test tube. Suddenly a brilliant emission of light was took place; it continued for a period of time. The emission spectrum of this light was measured.

Fluorescence Spectra. The fluorescence spectra were measured with a Hitachi Recording Spectrophotometer, Model EPS-2, equipped with an attachment for measuring the fluorescence spectrum. The 365 mμ line of a high-pressure mercury lamp was used for excitation. The chemiluminescent reaction was carried out by adding 10 m*l* of a solution of 2,3-dimethylindole (10^{-3} mol/*l*) in DMSO to an excess of granular potassium hydroxide in the oxygen stream. After periods of 1, 5, 10, and 30 min, 0.2 m*l* portions of this solution (solution A) were placed in a small Erlenmyer flask and diluted with 3.5 m*l* of the blank solution, which had been made by letting a quantity of DMSO stand with an excess of granular potassium hydroxide. These solutions were then used for the measurement of the fluorescence spectra.

In the case of 2,3-dimethylindolenyl-3-hydroperoxide (II), the chemiluminescent reaction was carried out in an argon stream and the fluorescence spectra was measured by the same procedure as above. The results are given in Fig. 4.

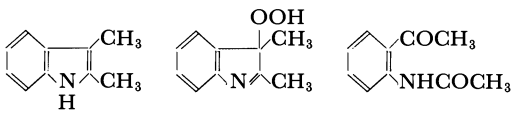
Ultraviolet Spectra. 0.2 m*l* of the solution A was diluted with 3 m*l* of ethanol after 0, 1/2, 5, and 30 min periods. These solutions were then used for the measurement of the ultraviolet spectra; the results are shown in Fig. 3.

Results and Discussion

Mechanism of the Chemiluminescence. In order to get accurate information about the chemiluminescence mechanism of indole derivatives, it is necessary to find a compound which posesses such desirable properties as being easily accesible in the pure state and showing a demonstrable intensity of light emission in a measureable period of time.

In addition, since the oxidation reaction is involved in the chemiluminescent reaction, it is even more important to be able to obtain an oxidation intermediate with the same properties.

It was found that 2,3-dimethylindole (I) and its hydroperoxide, 2,3-dimethylindolenyl-3-hydroperoxide (II), satisfy these requirements.



I II III

When **II** was dissolved in 0.1 N ethanolic potassium hydroxide, a weak light emission, detectable only by a photometer, continued for about six hours. However, when an oxidizing agent of the system A, a hydrogen peroxide-potassium ferricyanide solution, was added to the light-emitting ethanolic potassium hydroxide solution of II, the emission spontaneously disappeared, as shown in Fig. 1. Therefore, it is probable that, in the system A, II is not substantially connected with the light emission.

On the contrary, in the system B, II showed a bright flash of light, as has been previously reported.[7,10] Thus, it was assumed that **II** is an intermediate of the chemiluminescence of **I** in the system B.

This assumption was proved to be reasonable by the following results. When, under an oxygen atmosphere, 2-m*l* solutions of I and II in dimethylsulfoxide of a concentration of 10^{-4} mol/*l* were added to 0.5 g of granular potassium hydroxide, approximately equal amounts of light were emitted (Table 1). The emission period of I was longer than that of II, however, and the maximum intensity of I was lower than that of II (Fig. 2). Further, under a hydrogen atmosphere, the light emission was not observed in the case of I, although, in the case of **II**, a brilliant emission was observed. From these results, it seems probable that II is an intermediate and that the oxidation of I to II by oxygen is the rate-controlling step in the chemiluminescent reaction of I.

The emission spectra of both the solution of I (10^{-2} mol/*l*) and that of II (10^{-3} mol/*l*) appeared at 520 mμ, as shown in Table 2. This fact suggests that the same emitting species are concerned in the chemiluminescent reaction of I and II.

This was further supported by the following facts. After the light emission of the dimethylsulfoxide solution of I or II by potassium hydroxide was over, the ultraviolet absorption maxima of the

solution of I (284 and 292 mμ) and that of II (260 mμ) both shifted to 259, 267 and 325 mμ, values which are consistent with those of *o*-acetamidoacetophenone (III).

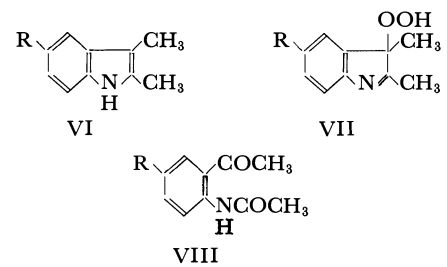
Furthermore, the fluorescence spectra of I and II varied similarly with the time and showed a maximum at 520 mμ, which completely coincided with that of III. The fluorescence spectra and ultraviolet spectra in the chemiluminescent condition are summarized in Figs. 3 and 4.

Now it can be concluded that II is the intermediate of the chemiluminescent reaction of I, that the product of this chemiluminescent reaction is III, and that the emitting species of the chemiluminescent reaction of I and II are the same. The emitting species may be the excited singlet state of the *o*-acetamidoacetophenone anion (III*), because the maximum of the fluorescence spectra of III in the same condition as chemiluminescence coincided completely with that of the emission spectra of I and II, and with their fluorescence spectra after the chemiluminescent reaction.

From these results the mechanism of the chemiluminescent reaction of 2,3-dimethylindole in the dimethylsulfoxide-potassium hydroxide oxygen system shown in Fig. 5 may reasonably be formulated.

Compound I is changed to the hydroperoxide anion, IV, by oxygen and a base, such as potassium *t*-butoxide or granular potassium hydroxide. On the other hand, Compound II requires only a base to change to IV. IV converts to the four-membered cyclic peroxide V, a short-lived intermediate, which then decomposes to an excited *o*-acetamidoacetophenone anion (III*). An excited state of III falls to the ground state with the emission of light.

Chemiluminescence of 5-Substituted-2,3-dimethylindoles. We prepared four 5-substituted-2,3-dimethylindoles and measured the total amount of light, they emitted by treating 10^{-3} mol/*l* solutions in DMSO with potassium *t*-butoxide and oxygen. The indoles were found to decrease in chemiluminescence efficiency in the order; VIa>I>VIb>VIc>VId (Table 3).



R=a: CH_3, b: CH_3O, c: Cl, d: NO_2

According to our experiment, 5-nitro-2,3-dimethylindole (VId) could not afford the hydroperoxide as II, and the chemiluminescence of VId was extremely weak.

The chemiluminescence maxima of indoles

* Under the same condition as chemiluminescent reaction.

(VIa, b, c) and the hydroperoxide (VIIa, b) are shown in Table 4. The hydroperoxide (VIIc) was too unstable to be obtained in the crystalline state. The fluorescence maxima of VI and VII after chemiluminescence and that of 5-substituted-2-acetamidoacetophenones (VIII) are shown in Table 5. After the chemiluminescent reaction of the solution of VI or VII, the solution was proved by T. L. C. to contain mainly VIII, which was also identified by a T. L. C. of the authentic samples. Thus VIII was the major product of the chemiluminescent reactions of both indoles (VI) and hydroperoxides (VII).

A good match was found between the chemiluminescence maxima of indoles (VI), those of the hydroperoxides (VII), and the fluorescence maxima of the major product (VIII). Therefore, it may be reasonably concluded that 5-substituted-2,3-dimethylindoles emitted light by the same mechanism as 2,3-dimethylindole.

Asymmetric Hydrogenation with Modified Raney Nickel.*1 IX

Yoshiharu IZUMI, Tadashi TANABE, Shinichi YAJIMA and Masami IMAIDA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received July 8, 1967)

The asymmetric hydrogenation catalysts were prepared from the Raney nickel catalyst by modifying it with L$_S$-3,3-dimethyl-2-hydroxybutyric acid and the corresponding amino acid, L-*t*-leucine, which have most methyl groups at the β-position. The asymmetric activities of the catalysts were measured by the hydrogenation of the methyl acetoacetate to methyl 3-hydroxybutyrate. The asymmetric activity of the catalyst modified with an aqueous solution of L$_S$-3,3-dimethyl-2-hydroxybutyric acid was very low, and the direction of asymmetric activity at pH 5.0 was inverted by the temperature of the modifying solution. However, there was a high asymmetric activity in the catalyst modified with L-*t*-leucine, and this activity was not so influenced by the temperature of the modifying solution. The aysmmetric activities of catalysts modified with α-hydroxy acids and the corresponding amino acids reported in this paper and the previous papers are compared, and the effect of the bulk of the α-alkyl substituent of the modifying reagent upon the asymmetric activity of the catalyst is discussed.

The asymmetric activities of Raney nickel catalysts, modified with various optically active amino acids or hydroxy acids, in the hydrogenation of methyl acetoacetate to methyl 3-hydroxy butyrate have previously been reported on by the present authors.[1-8]

The asymmetric activity of a modified Raney nickel catalyst was found to be influenced not only by the pH and temperature of the modifying solution,[1] but also by the structure of the modifying reagent. The "asymmetric activity" of a catalyst involves two factors. One is the direction of the asymmetric activity, which is expressed as the direction of the specific rotation, (+) or (−), of the hydrogenated product. The other is the degree of asymmetric activity, which is usually presented as the asymmetric yield. On modification at 0°C, the direction of the asymmetric activity of a catalyst is mainly controlled by the absolute configuration of the α-carbon of the modifying reagent. Catalysts modified with L-α-amino acids other than alanine, serine, proline, and cystine produce methyl D$_S$-3-hydroxybutyrate predominantly. However, on modification with L$_S$-2-hydroxy acids, methyl L$_S$-3-hydroxybutyrate is produced predominantly. However, the factor controlling the asymmetric yield has not been discussed. In the present work, *t*-leucine and 3,3-dimethyl-2-hydroxybutyric acid, which have a bulky *t*-butyl substituent on the α-carbon, were investigated as asymmetric modifying reagents, and the role of the alkyl group of the modifying reagent discussed in

Materials

Modifying Reagents.[*2] The optical rotations of the Ls(+)-3,3-dimethyl-2-hydroxybutyric acid and L-(−)-*t*-leucine used in this work are listed in Table 1.

Experimental

The preparation of the Raney nickel catalyst, the hydrogenation of methyl acetoacetate, and the measurement of the asymmetric activity of the catalyst were performed as has been described in a previous paper.[3]

Results and Discussion

Modification with Ls-3,3-Dimethyl-2-hydroxybutyric Acid (I). The Raney nickel catalyst was modified at 0°C or 100°C with an aqueous solution of Ls-3,3-dimethyl-2-hydroxybutyric acid (1) which had been adjusted to a specified pH with 1 N sodium hydroxide. The asymmetric activity of the catalyst modified at pH 3—12 and the neutralization curve of the 2% aqueous solution of 1 with 1 N sodium hydroxide (f=0.996) are shown in Fig. 1.

The optimum asymmetric activity of catalysts modified with 1 at 0°C was observed at pH 5.0. This pH value corresponds to the pH-jumping region of the neutralization curve of 1 observed with other hydroxy acids. The direction of asymmetric activity of the catalyst changed at the complete neutralization point.

On modification at 100°C, the catalyst showed its highest asymmetric activity at pH 3.2. The direction of the asymmetric activity of the catalyst modified at 100°C changed at a low pH value than in the case of modification at 0°C, this pH corresponded to the pH-jumping region in the titration curve. The values of the asymmetric activities of catalysts modified at 0°C and 100°C were both very low over the whole range of modifying pH values.

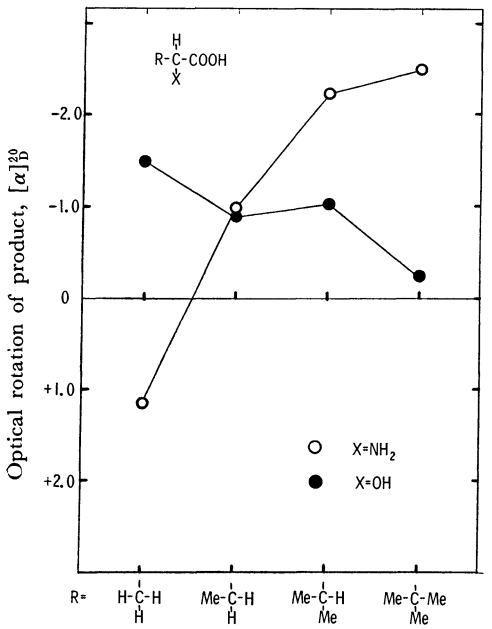

Fig. 3. Effect of substituent.

○ Modified at 0°C, isoelectric point
● Modified at 0°C, pH 5.0

The effect of the temperature of the modifying solution of 1 was studied at pH 5.0; the results are shown in Fig. 2. As is shown in Fig. 2, the asymmetric activity decreased with an increase in the modifying temperature, and the direction of asymmetric activity changed at about 50°C. Such an inversion of the direction of asymmetric activity by the modifying temperature has not been found in the modifications with β-substituted α-hydroxy acids reported in previous papers.[2]

Modification with L-*t*-Leucine (II). The asymmetric activity of the catalyst modified with an aqueous solution of L-*t*-leucine (2) at the isoelectric point (pH 6.2) was measured at various temperatures. The results are shown in Fig. 2. The asymmetric activity was fairly high, and the activity of the catalyst modified at 0°C was intermediate between the activities of the catalysts modified with L-valine and with L-alloisoleucine*3 at 0°C. The rough linear relation shown in Fig. 2 was also found between the asymmetric activity and the modifying temperature in catalysts modified with other α-amino acids, such as valine and isoleucine.

Effect of α-Alkyl Substituent on Asymmetric Activity of Catalyst. In order to make clear effect of the bulk of α-alkyl substituents in asymmetric modifying reagents on the asymmetric activities of catalysts, the asymmetric activities of the catalysts modified with α-hydroxy acids and the corresponding α-amino acids, reported in this paper and in previous papers,[2,3] are compared in Fig. 3. Figure 3 shows the asymmetric activities of the catalysts when the hydrogen atoms on the β-carbon of lactic acid or alanine are replaced with methyl groups, one by one. The catalysts were modified at 0°C, at the isoelectric point with amino acids, and at pH 5.0 with hydroxy acids. The asymmetric activity of the catalyst modified with amino acid increases with the increase in the bulk of the α-alkyl substituent, while, with hydroxy acids, the influence of the bulk of alkyl substituents is smaller than in the case in modifications with amino acids; asymmetric activity is the lowest with the acid having the most bulky alkyl substituent.

This research was supported by the Kawaken Fine Chemicals Co., Ltd., Tokyo.

*3 The asymmetric activity of this catalyst will be reported on later by the present authors.

Stereochemical Studies of Monoterpene Compounds. III.[1] Stereochemistry and Intramolecular Hydrogen Bonding of 1-Hydroxy-*p*-menth-3-en-2-one and Its Reduction Products[2]

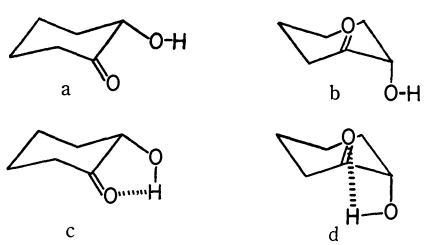
Takayuki SUGA, Tsuyoshi SHISHIBORI and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received July 20, 1967)

1-Hydroxy-*p*-menth-3-en-2-one (1) was prepared from α-terpinene by the *t*-butyl chromate oxidation. *trans*- and *cis*-*p*-Menth-3-ene-1,2-diols (4 and 5), 1-hydroxyisocarvomenthone (2), and 1-hydroxycarvomenthone (3) were also prepared from the compound 1 by lithium aluminum hydride reduction or by hydrogenation. The configurations of these compounds, 1—5, were identified on the basis of chemical evidence, and then the preferred conformation was determined by infrared spectroscopy on the basis of the conception of intramolecular hydrogen bonding. 1 and 2 were found to exist predominantly in the hydrogen-bonded conformations, 1a and 2a, respectively. With respect to 3, the existence of the conformational equilibrium, 3a⇌3b, was demonstrated by the presence of the free and bonded hydroxyl bands. Moreover, 4 and 5 were proved to take the preferred conformations of 4a and 5a respectively.

The conformational analysis of monoterpene cyclic diols[3] and monoterpene hydroxyketones[4] has been investigated in order to clarify the correlation between the formation of the intramolecular hydrogen bond and the conformation of the hydroxyl group in these compounds. α-Hydroxycyclohexanone derivatives can take the intramolecularly hydrogen-bonded forms, c and d, in addition to two interconvertible, unbonded chair-forms, a and b.



The conformer c contains intramolecular hydrogen bonding between the hydroxyl group and the lone-pair electrons on the carbonyl group (OH···O), whereas the hydroxyl group of the conformer d interacts with pi-electrons on the carbonyl group (OH···π). A characteristic hydroxyl-stretching absorption due to the OH···O-type hydrogen bond[4,5] gives a band at from 3480 to 3500 cm^{-1}. On the other hand, a band resulting from the OH···π interaction[5] appears at from 3600 to 3610 cm^{-1}. Hence, it is expected that the conformation of α-hydroxycyclohexanone derivatives may be determined on the basis of the conception of intramolecular hydrogen bonding. We wish to report here on the preparation of, and the correlation between the conformations and the intramolecular hydrogen bonding of, 1-hydroxy-*p*-menth-3-en-2-one (1), 1-hydroxyisocarvomenthone (2), 1-hydroxycarvomenthone (3), and *trans*- and *cis*-*p*-menth-3-ene-1, 2-diols (4 and 5).

Preparation and Configurations. 1-Hydroxy-*p*-menth-3-en-2-one (1) was prepared from α-terpinene by *t*-butyl chromate oxidation following a method previously reported.[6] The hydrogenation of 1 on palladium-charcoal gave a diastereoisomeric pair of ketols, 2 and 3, in the ratio of 2 to 1. In order to determine the configurations of 2 and 3, these ketols were further reduced with lithium aluminum hydride and then converted into *p*-menthane-1,2-diols, the configuration of which had already been established.[7] The ketol 2, was proved to be 1-hydroxyisocarvomenthone (2), since the reduction of 2 gave 1-hydroxyisocarvomenthol (6) and 1-hydroxyneoisocarvomenthol

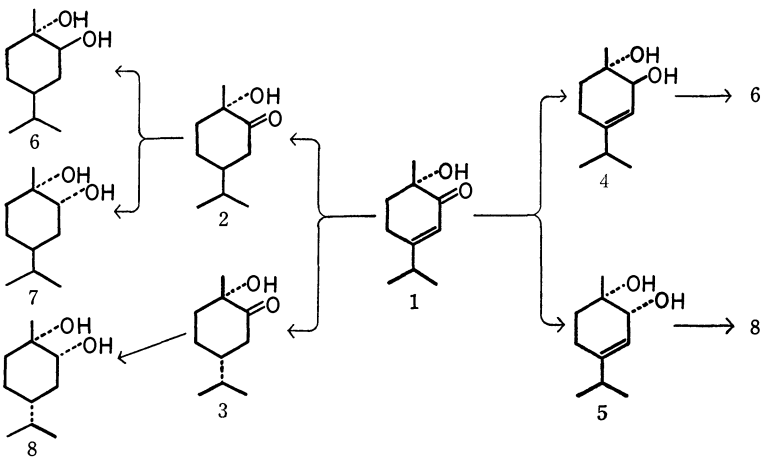
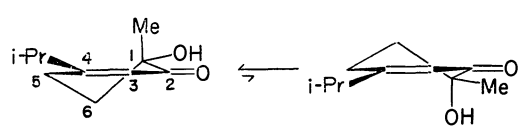


Scheme 1. The configurational assignment of 1-hydroxy-*p*-menth-3-en-2-one (1) and its reduction products.

(7). The reduction of 3 afforded 1-hydroxycarvomenthol (8), and so the ketol 3 must be 1-hydroxycarvomenthone (3).

The lithium aluminum hydride reduction of 1 gave the unsaturated diols 4, with a melting point of 57—58°C, and 5 with a melting point of 50—50.5°C, in the ratio of 3 to 1. The unsaturated diols, 4 and 5, were epimeric at the C-2 position, because both the diols were converted into the original ketone 1 on oxidation. The unsaturated diols 4 and 5 were further hydrogenated on palladium-charcoal in an attempt to assign the configuration of the hydroxyl groups; 4 gave a *trans*-diol, 1-hydroxyisocarvomenthol (6), and 5 yielded a *cis*-diol, 1-hydroxycarvomenthol (8). The unsaturated diols, 4 and 5, were thus proved to be *trans*- and *cis*-*p*-menth-3-ene-1,2-diols respectively.

Conformation and Intramolecular Hydrogen Bonding. As the configurations of the unsaturated hydroxyketone, 1, and its reduction products, 2, 3, 4 and 5, have been identified as above, the preferred conformation of these compounds was determined by considering a correlation between the hydroxyl-stretching absorption band and the distance of the intramolecular hydrogen bond.



1a 1b

1-Hydroxy-p-menth-3-en-2-one. 1-Hydroxy-*p*-menth-3-en-2-one (1) can exist in two interconvertible conformations 1a and 1b, in which the carbonyl group and the carbon atoms at C-1, C-3, C-4, and C-5 are co-planer, whereas only the carbon atom at C-6 is apart from the plane.

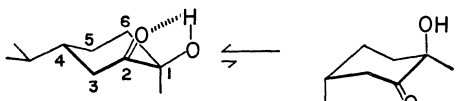
The hydroxyl group of 1 is pseudo-equatorial in the conformer 1a and pseudo-axial in the conformer 1b. An examination of a Dreiding model[8] showed that the distance between the hydroxyl and carbonyl groups (OH···O) is *ca.* 2.1 Å in the conformer 1a and *ca.* 2.9 Å in the conformer 1b. Hence, an OH···O-type intramolecular hydrogen bonding can be expected in 1a, while the OH···π interaction is preferable in 1b. The infrared spectrum of the hydroxyl-stretching region of 1 showed a concentration-independent band at 3517 cm^{-1} (ε 82), which can be attributed to the OH···O-type bonded hydroxyl group. In addition to this principal band, a weak hydroxyl band, probably due to the OH···π interaction, was observed at 3603 cm^{-1} (ε 12) in a dilute solution. This weak band disappeared in a concentrated solution, and a new broad band resulting from the intermolecular hydrogen bond appeared at *ca.* 3400 cm^{-1}. These facts imply that, in a dilute solution, the unsaturated hydroxyketone 1 exists in the conformational equilibrium mixture 1a$\rightleftarrows$1b, in which the conformer 1a is preferred, and that, in a concentrated solution, the hydroxyl and carbonyl groups of the conformer 1b interact intermolecularly with other molecules.

1-Hydroxyisocarvomenthone and 1-Hydroxycarvomenthone. 1-Hydroxyisocarvomenthone (2) and 1-hydroxycarvomenthone (3) may take two interconvertible chair-forms (2a and 2b, and 3a and 3b, respectively). In the conformers 2a and 3b, with an equatorial hydroxyl group, OH···O intramolecular hydrogen bonding between the hydroxyl and carbonyl groups is possible, since the OH···O distance is estimated by means of the Dreiding model[8] to be *ca.* 2.1 Å. On the other hand, such bonding is considered to be difficult in the conformers 2b and 3a, because of the longer OH···O

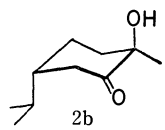
8) "Dreiding Stereomodels," W. Büchi Manufacture of Glass Apparatus Flawil, Switzerland. The OH···O distance was estimated by using this model.

distance of *ca.* 3.2 Å and the unfavorable direction of the orbital of the lone-pair electrons on the carbonyl oxygen atom, making it difficult to form a OH···O-type hydrogen bond.

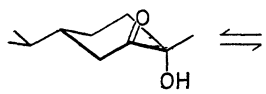
The infrared spectra of compound 2 revealed only a concentration-independent band at 3504 cm^{-1} (ε 100) due to the OH···O-type intramolecular hydrogen bond. This implies that the preferred conformation of 2 is the conformer 2a with an equatorial hydroxyl group, while that of the conformer 2b with a free axial hydroxyl group is not present or, if so, exists in a population so low as to make it impossible to observe its spectral band.



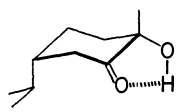
2a



2b



3a



3b

On the other hand, compound 3 showed two peaks, at 3610 (ε 53) and 3502 cm^{-1} (ε 74), in a 0.005 M carbon tetrachloride solution. The former is attributed to the free hydroxyl group, and the latter, to the OH···O-type hydrogen bond. Upon an increase in the concentration of the solution, the frequency of the band due to intramolecular hydrogen bonding did not show any shift, whereas the strength of a newly-appeared band at *ca.* 3450 cm^{-1} resulting from an intermolecularly-hydrogen-bonded hydroxyl group, increased, in contrast to the decrease in the free hydroxyl band, which finally disappeared in the neat sample. These facts indicate that the conformational equilibrium 3a⇄3b exists in a dilute solution, and also that the free hydroxyl groups of the conformer 3a interact with each other in a concentrated solution.

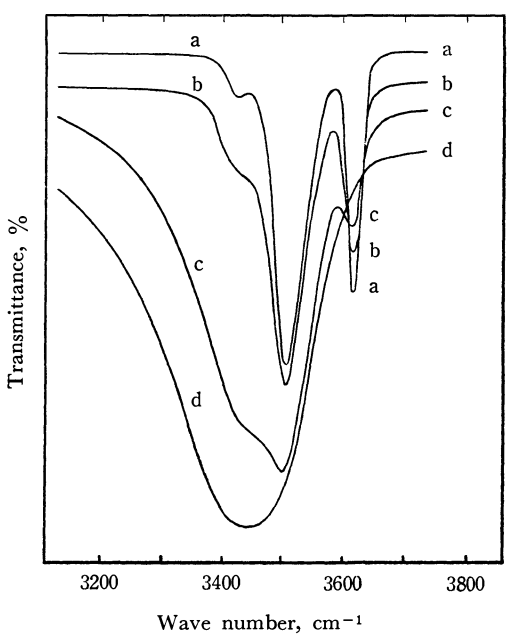


Fig. 1. Infrared spectra of 1-hydroxycarvomenthone (3) in a carbon tetrachloride solution of various concentration: a, 0.005 M; b, 0.05 M; c, 0.5 M; d, neat.

The difference in the conformational preference in the equilibrium mixture of the ketols 2 and 3 may be explained as follows. The difference in conformational free energy between the non-hydrogen-bonded form of the conformer 2a and the conformer 2b is expected to be of the value of *ca.* −1.1 kcal/mol.[9] In addition, the stabilization due to intramolecular hydrogen bonding between the hydroxyl and carbonyl groups in 2a can contribute to the conformational preference of the conformer 2a. Thus, the ketol 2 is thought to exist predominantly in the conformation 2a.

On the other hand, the difference in conformational free energy between the conformer 3a and the non-hydrogen-bonded form of the conformer 3b is expected to be of the value of *ca.* −3.1 kcal/mol.[9] If the stabilization due to intramolecular hydrogen bonding in 3b is sufficient to overcome the instabilization due to the steric repulsion among the 1,3-diaxial atoms and groups, the conformer 3b would be present. However, the stabilization due to intramolecular hydrogen bonding is expected to be of the value of $-\Delta G=1$ kcal/mol at room temperature, since the OH···O-type intramolecular hydrogen bond, forming a five-membered ring, results in a decrease in entropy ($-\Delta S=3.5$ e. u.), plus an enthalpy of the hydrogen bond ($-\Delta H=$ 2 kcal/mol).[12] Therefore, the 3a conformer with a free hydroxyl group, seems to exist preferentially in the conformational equilibrium 3a⇄3b.

trans- and cis-p-Menth-3-ene-1,2-diols. *trans-p*-Menth-3-ene-1,2-diol (4) may take three interconvertible half-chair forms, 4a—4c. Since the OH···O distances[8] are *ca.* 2.2 Å in 4b and 4c and *ca.* 4.0 Å in 4a, the intramolecular hydrogen bond is possible in 4b and 4c, which have equatorial

9) Estimated approximately by adding the corresponding values for a hydroxyl, a methyl, and an isopropyl groups, since such summation has been verified to be approximately correct in some cases.[10] The differences in free energy between the equatorial and axial forms of the hydroxyl, methyl and isopropyl groups are −0.7, −1.7 and −2.1 kcal/mol[11] respectively.

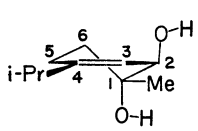
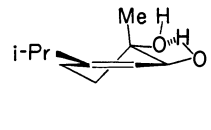
11) Ref. 10, p. 44.

12) L. P. Kuhn and R. A. Wires, *J. Am. Chem. Soc.*, **86**, 2161 (1964); C. Duculot, *Compt. rend.*, **241**, 1925 (1955).

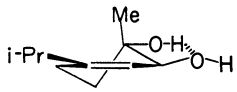
and quasi-equatorial hydroxyl groups, but such a bond is impossible in the conformer 4a, which has axial and quasi-axial hydroxyl groups. The infrared spectrum of 4 in a dilute carbon tetrachloride solution exhibited only a band at 3616 cm^{-1} due to the free hydroxyl group. *trans*-diol 4 was thus found to exist predominantly in the conformation 4a.



4a



4b



4c

cis-p-Menth-3-ene-1,2-diol (5) may take four interconvertible, internally-bonded half-chair forms, 5a—5d. Since each of the OH···O distances in 5a—5d is estimated to be 2.2 Å,[8] the intramolecular hydrogen bond is possible in all the conformers. The infrared spectrum of 5 showed two bands, at 3617 and 3578 cm^{-1}. The former was attributed to a free tertiary hydroxyl group, since the characteristic frequencies[13] for the unbonded tertiary hydroxyl group have been reported to be 3613—3619 cm^{-1}. The 3578-cm^{-1} band was assigned to an intramolecularly hydrogen-bonded hydroxyl group. Thus, *cis*-diol 5 would exist in the conformer 5a or 5b, in which the less basic secondary hydroxyl group is bonded to the oxygen atom of the more basic tertiary hydroxyl. However, the conformational preference in the equilibrium 5a$\rightleftarrows$5b can not be determined only on the basis of the $\Delta\nu$ in the infrared spectrum, because of the equality of the OH···O distances in 5a and 5b.

5d

The NMR spectra of the unsaturated diols 4 and 5 afforded further evidence for the conformational assignment described above. The carbinol proton on the C-2 position of the compounds 5 and 4 exhibited signals at δ 3.77 (doublet, J=3.4 cps, half-band width $W_{1/2}$=8 cps) and at δ 4.05 (broad singlet, $W_{1/2}$=6 cps) respectively, in a deuterochloroform solution. In general, the axial carbinol proton resonates at a higher magnetic field than does the equatorial carbinol proton, and the former has the wider half-band width than the latter.[14] According to this general rule, the carbinol proton on the C-2 position of the compound 4 is equatorial, and that of the compound 5 takes an axial conformation. Thus, it can be deduced that the unsaturated diol 4 exists predominantly in the conformation 4a. This result further supports the assignment resulting from the infrared spectrum measurement. Concerning the unsaturated diol 5, on the other hand, it was found that the conformation 5a seems to be preferential in such a conformational equilibrium, 5a$\rightleftarrows$5b, as is deduced from the infrared spectral data.

Experimental

1-Hydroxy-*p*-menth-3-en-2-one (1). The compound used in the present work was the same as that prepared from α-terpinene by *t*-butyl chromate oxidation in a previous paper[6]; it showed the follwoing properties: bp 99—100°C, n_D^{25} 1.4928, d_4^{25} 1.0074; ν_{max}^{neat} 3479, 1147 (OH), 3044, 1627, 878 (⟩C=CH–) 1430 (CH_2C=C); λ_{max}^{EtOH} 236 and 318 mμ (ε 13270 and 80); 2, 4-dinitrophenylhydrazone, mp 208—209°C, $\lambda_{max}^{CHCl_3}$ 392 mμ (ε 26000); phenylurethane, mp 132—132.5°C. The hydroxyl-stretching absorption frequencies in cm^{-1} (and the concentrationsin mol/*l*) were as follows: 3603, 3517 (0.005), 3603, 3517 (0.010), 3602, 3517, (0.05), 3602, 3515 (0.10), 3602, 3514 (0.25), 3601, 3510, (0.50), 3600, 3508 (1.0), 3480 (neat).

Catalytic Hydrogenation of 1. The unsaturated α-hydroxyketone 1 (2.84 g) in ethyl alcohol was hydrogenated in the presence of palladium-charcoal under an atmospheric pressure. The uptake of hydrogen amounted to 1.1 mol, and 1 was converted into a mixture of saturated hydroxyketones. The mixture was fractionated into two eluates by column chromatography on 200 g of silica gel with a mixture of *n*-hexane and ethyl acetate.

The first eluate (1.24 g) was 1-hydroxyisocarvomenthone (2): n_D^{25} 1.4627, d_4^{25} 0.9765; ν_{max}^{liq} 3494 (OH), 1712 (C=O), 1431 (CH_2CO), 1383, 1361 cm^{-1} (isopropyl). The hydroxyl-stretching absorption frequencies in cm^{-1} (and the molar concentration in a carbon tetrachloride solution) were as follows: 3504 (0.005), 3503 (0.050), 3502 (0.50), 3494 (neat).

The second eluate (0.92 g) was 1-hydroxycarvomenthone (3): n_D^{25} 1.4658, d_4^{25} 0.9852; ν_{max}^{liq} 3442 (OH), 1709 (C=O), 1425 (CH_2CO), 1384, 1360 (isopropyl). The IR spectra of 3 in the hydroxyl-stretching region

13) L. P. Kuhn, *J. Am. Chem. Soc.*, **74**, 2492 (1952); A. R. H. Cole, G. T. A. Müller, D. W. Thornton and R. L. S. Willix, *J. Chem. Soc.*, **1959**, 1218; A. R. H. Cole, P. R. Jefferies and G. T. A. Müller, *ibid.*, **1959**, 1222.

are shown in Fig. 1; the ν_{OH} values in cm^{-1} (and the concentrations in mol/l) were as follows: 3610, 3502 (0.005), 3610, 3502 (0.050), 3608, 3494 (0.50), 3441 (neat).

Reduction of 2 with Lithium Aluminum Hydride. To 0.14 g of lithium aluminum hydride in 10 ml of dry ether, there was added, drop by drop, over a 1 hr period, a solution of 0.81 g of 2 in 5 ml of dry ether; the mixture was refluxed for 5 hr and then allowed to stand overnight. The reaction mixture, after it had been treated as usual, afforded 0.80 g of a mixture of diols, which was fractionated into two eluates by column chromatography on silica gel with a mixture of *n*-hexane and ethyl acetate. The initial eluate (0.29 g) was 1-hydroxyneoisocarvomenthol (7): mp 72—72.5°C (lit.[7] 72.5°C); ν_{OH} in a 0.0035 M carbon tetrachloride solution, 3619, 3581 cm^{-1} (lit.[15] 3618, 3580 cm^{-1}). The second eluate (0.39 g) was 1-hydroxyisocarvomenthol (6): mp 51—52°C (lit.[7] 53°C); ν_{OH} in a 0.0032 M carbon tetrachloride solution, 3617, 3597 cm^{-1} (lit.[15] 3618, 3597 cm^{-1}).

Reduction of 3 with Lithium Aluminum Hydride. Hydroxyketone 3 (0.77 g) in 5 ml of dry ether was reduced with 0.14 g of lithium aluminum hydride suspended in 10 ml of dry ether in the same manner as was 2. The purification of the crude product by chromatography on a silica gel column gave 0.55 g of 1-hydroxycarvomenthol (8): mono-3,5-dinitrobenzoate, mp 116—117°C (lit.[7] 117°C); ν_{OH} in a 0.0032 M carbon tetrachloride solution, 3628, 3588 cm^{-1} (lit.[15] 3628, 3586 cm^{-1}).

Reduction of 1 with Lithium Aluminum Hydride. To 0.35 g of lithium aluminum hydride in 15 ml of dry ether, there was added, drop by drop, a solution of 2.00 g of 1 in 4 ml of dry ether; the mixture was stirred for 8 hr at room temperature, and then allowed to stand overnight. This treatment gave 2.00 g of a mixture of unsaturated diols. The mixture was fractionated into two eluates by column chromatography on 100 g of silica gel with a mixture of isopropyl ether and ethyl acetate. The initial eluate (0.38 g) was the unsaturated diol 5, and the final eluate (1.23 g) was the unsaturated diol 4.

The unsaturated diol 5 showed the following properties: mp 50—50.5°C; ν_{max}^{KBr} 3383, 1047, 1021 (OH), 3021 (>C=CH-), 1667 (C=C), 1383, 1368 (isopropyl), 1428 cm^{-1} (CH_2C=C). The hydroxy-stretching absorption maximum in a 0.0032 M carbon tetrachloride solution appeared at 3619 and 3578 cm^{-1}. The NMR spectrum showed signals at δ 1.03 (doublet, J=6 cps, 6H, 9, 10-Me), δ 1.20 (singlet, 3H, 7-Me), δ 3.77 (doublet, J=3.4 cps, $W_{1/2}$=8 cps, 1H, C-2 H), and δ 5.40 (doublet, J=3.4 cps, 1H, C-3 H).

Found: C, 70.69; H, 10.77%. Calcd for $C_{10}H_{18}O_2$: C, 70.55; H, 10.66%.

The unsaturated diol 4 showed the following properties: mp 57—58°C; ν_{max}^{KBr} 3351, 1130, 1110 (OH), 3097, 1161, 845 (>CH=CH-), 1379, 1362 (isopropyl), 1431 cm^{-1} (CH_2C=C). The hydroxyl-stretching absorption maximum in a 0.0032 M carbon tetrachloride solution appeared at 3616 cm^{-1}. The NMR spectrum showed the signals at δ 0.99 (doublet, J=6 cps, 6H, 9, 10-Me), δ 1.14 (singlet, 3H, 7-Me), δ 4.05 (broad singlet, $W_{1/2}$=6 cps, 1H, C-2 H), and δ 5.25 (broad singlet, 1H, C-3 H).

Found: C, 70.74; H, 10.92%. Calcd for $C_{10}H_{18}O_2$: C, 70.55; H, 10.66%.

On oxidation with *t*-butyl chromate for 2.5 days at room temperature, both 4 and 5 were converted into the original unsaturated ketol 1. This was confirmed by a comparison of the infrared spectra.

Catalytic Hydrogenation of the Unsaturated Diol 4. The unsaturated diol 4 in methyl alcohol was hydrogenated in the presence of prereduced palladium hydroxide on calcium carbonate under an atmospheric pressure. The uptake of hydrogen amounted to 0.97 mol, and 4 was converted into 1-hydroxyisocarvomenthol (6): mp 52—52.5°C (lit.[7] 53°C); ν_{max}^{Nujol} 3322, 1069 cm^{-1} (OH); ν_{OH} in a 0.0043 M carbon tetrachloride solution, 3620 and 3602 cm^{-1} (lit.[15] 3618, 3597 cm^{-1}); di-*p*-nitrobenzoate, mp 163—164°C (lit.[7] mp 164°C).

Catalytic Hydrogenation of the Unsaturated Diol 5. The same treatment of 5 as has been described above afforded 1-hydroxycarvomenthol (8): mp 40—42.5°C; ν_{max}^{liq} 3368, 1035, 995 (OH), 1386, 1368 cm^{-1} (isopropyl); ν_{OH} in a 0.0043 M carbon tetrachloride solution, 3627 and 3588 cm^{-1} (lit.[15] 3628, 3586 cm^{-1}); mono-3, 5-dinitrobenzoate, mp 116.5—117°C (lit.[7] mp 117°C).

Measurement of the Infrared Spectra in the Hydroxyl-stretching Region. The infrared spectra were measured by a Hilger H-800 double-beam spectrophotometer under the following conditions: calcium fluoride prism; wave number accuracy at 3500 cm^{-1}: ± 3 cm^{-1}; temperature, 25°C; solvent, spectro-grade carbon tetrachloride.

The authors wish to express their hearty thanks to Professor Shô Itô of Tohoku University for his NMR spectra measurements.

The Mechanism of the Alkaline Fusion of Halodiphenyl Sulfone and Halobenzenesulfinic Acids[1]

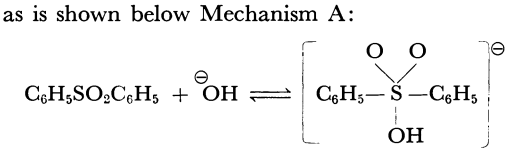
Naomichi FURUKAWA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received August 5, 1967)

The alkaline fusion of 2-chlorophenyl phenyl sulfone afforded phenol, benzene and chlorobenzene. The initial step of the reaction appears to be the aromatic S_N2-type replacement of chlorine to form 2-hydroxyphenyl phenyl sulfone upon which the hydroxide ion further attacks both phenyl carbon-1 and the sulfur atom of the sulfone group to form the final products. The ^{14}C tracer experiment indicates that the preference of the nucleophilic-attacking site of the hydroxide ion appears to vary with the reaction temperature. A similar alkaline fusion of 2-bromo-4-tolyl phenyl sulfone gave not only benzene, bromotoluene, and phenol, but also *o*- and *m*-cresol, indicating that the reaction proceeds through a somewhat different path. Meanwhile, the alkaline fusion of 2-chlorobenzenesulfinic acid appears to proceed through the *o*-sulfinic benzyne formation; thus 2-bromo-4-tolylsulfinic acid gave equal amounts of *o*- and *m*-cresols.

Previously we have shown, mainly through ^{14}C and ^{18}O tracer experiments, that the alkaline fusion of benzenesulfonic acid proceeded through an aromatic S_N2-type reaction at the ring-carbon-bearing sulfonic acid group.[2] The same conclusion has been reached through studies of the careful isolation of products from substituted aromatic sulfonic acids.[3,4] Subsequently, the mechanism of the alkaline fusion of diphenyl sulfone has been studied by means of the ^{14}C-tracer technique[5]; this study suggests that the reaction proceeds through a simple SN2-type path, and not one involving benzyne formation. However, an unanswered question has remained as to the site of the nucleophilic attack of the hydroxide ion. The successful isolation of benzenesulfonic acid during the reaction by Ingold and Jessop[6] and the strong affinity of the negative hydroxide ion toward the positively-charged sulfur atom of the sulfone group seem to favor the nucleophilic attack of the hydroxide ion on the sulfone group, as is shown below Mechanism A:



(Mechanism A)

Another mechanism, an aromatic S_N2 reaction on the carbon-atom-bearing sulfonyl group (Mechanism B), cannot be ruled out, however, since a similar alkaline fusion of benzenesulfonic acid is apparently a part of the aromatic S_N2 process, and benzenesulfinic acid has actually been isolated from the alkaline fusion of diphenyl sulfone.[7]

(Mechanism B)

Although there is no easy way to make a choice between the above two mechanisms, the alkaline fusion of *o*-halophenyl phenyl sulfone is an interesting problem in this connection, since the process involving the initial nucleophilic attack of the hydroxide ion on the sulfone group (Mechanism I) may lead to the formation of a benzyne intermediate, as in the reaction of *o*-chlorobenzophenone with potassium amide,[8] and the products formed will be somewhat different from those expected from the attack on the carbon atom. A more clear-cut difference in the distribution of products will be observed when 2-halo-4-tolylsulfone is used, as in the aminolysis of *o*-halobenzophenone. Another interesting problem is the behavior of *o*-halobenzenesulfinate ion in the alkaline fusion, since it will be one of the intermediate formed if the reaction follows the mechanism B.

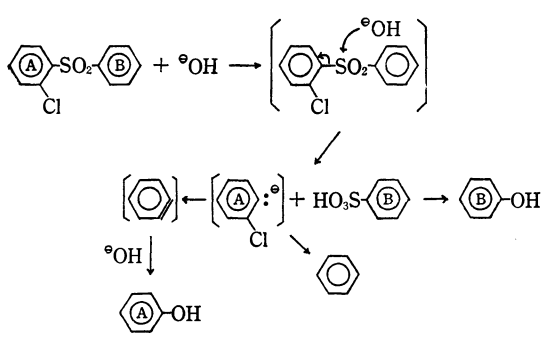
Thus, we have studied the alkaline fusion of 2-chlorophenyl phenyl sulfone, 2-bromo-4-tolyl phenyl sulfone, 2-chloro-benzenesulfinic acid, and 2-bromo-4-tolylsulfinic acid. The results we have obtained are somewhat different from what we anticipated, but they appear to suggest clearly that the nucleophilic attack of the hydroxide ion takes place at both the sulfone group and the aromatic ring carbon-1. By the use of 2-chlorophenyl phenyl-1'-^{14}C sulfone, the relative ratio of the nucleophilic attack of the hydroxide ion at the sulfone group and the aromatic ring carbon was estimated.

This paper will describe our experimental observations and discuss the mechanisms of these reactions.

Results and Discussion

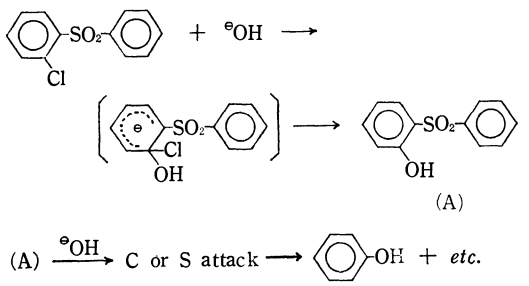
The reaction was generally carried out by heating a mixture of a starting compound with an excess of potassium hydroxide at around 300°C for several minutes in a nickel crucible under a slow stream of nitrogen gas; the products were analyzed by introducing them to their corresponding known derivatives or by a comparison of their gas chromatographic behavior and infrared spectra with those of the authentic samples.

***o*-Halophenyl Phenyl Sulfone.** While the alkaline fusion of diphenyl sulfone takes place slowly at below 300°C, that of the *o*-halo derivative is quite facile. A similar phenomenon was observed in the aminolyses of *o*-halobenzophenone and benzophenone, where the *o*-chloro compound undergoes a much facile cleavage, apparently forming a benzyne intermediate.[8] It appears that the substitution of the electron-withdrawing chloro group facilitates the nucleophilic attack of hydroxide on the molecule. When the alkaline fusion of *o*-chlorophenyl phenyl sulfone was carried out, the products identified were phenol, benzene, and chlorobenzene. This means that unlike the aminolysis of *o*-halobenzophenone the reaction does not seem to proceed only through the formation of benzyne (Mechanism I), since the mechanism involving the formation of benzyne would require phenol and chlorobenzene to be the only products of this reaction. Actually, the formation of a small amount of chlorobenzene suggests that at least a portion of the nucleophilic attack of the hydroxide ion takes place on the sulfone group (Mechanism I).



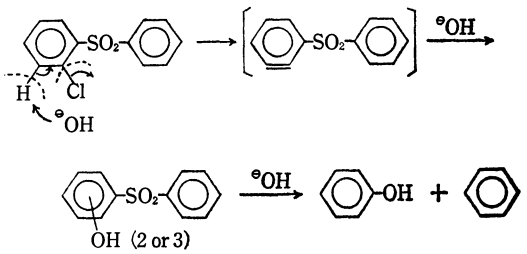
Mechanism I. Attack on the sulfone group.

The complete lack of catechol among the products suggests that the initial nucleophilic attack of hydroxide does not occur at the carbon-1 position of the A ring. This is rather strange, since the A ring would be more susceptible to nucleophilic attack because of its electron-withdrawing *o*-chloro group. However, since chloride is a better leaving group than the benzenesulfinate group, the initial nucleophilic attack on the A ring may take place at the 2-position, replacing chloride ion (Mechanism II).



Mechanism II. Initial chloride replacement subsequent nucleophilic cleavage.

In fact, the *o*-chloro group is highly activated by the phenylsulfonyl group and is susceptible to nucleophilic attack.[9] When *o*-chlorophenyl phenyl sulfone was treated with aqueous potassium hydroxide in dimethyl sulfoxide, *o*-hydroxyphenyl phenyl sulfone was isolated in a high yield. Thus, *o*-hydroxyphenyl phenyl sulfone is a very likely intermediate in this reaction, and the lack of catechol formation may be ascribed to the negative field effect of the hydroxyl group, which suppresses the nucleophilic attack at the A ring. Another possible mechanism is the one that involves the prior formation of *o*-sulfonyl benzyne (Mechanism III). Though the formation of a small



Mechanism III. Initial dehydrochlorination-addition subsequent nucleophilic cleavage.

** *o*-cresol : *m*-cresol : phenol = trace : 7 : 1

amount of chlorobenzene cannot be explained by this mechanism, it is possible that a portion of the reaction may proceed through this process.

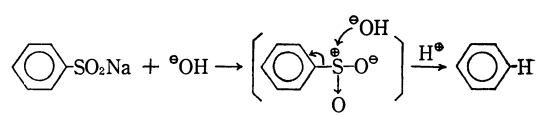
In order to test these possibilities, 2-bromo-4-tolyl phenyl sulfone was subjected to alkaline fusion. If the reaction follows the path of the III mechanism, one would expect to obtain nearly equal amounts of *o*- and *m*-cresols. As shown in Table 1, we did find *o*-cresol, but the amount was less than 1/20th that of *m*-cresol. The formation of such a small amount of *o*-cresol suggests that although a tiny fraction of the reaction actually goes through the III mechanism, it is by no means the major path of the reaction. The lack of *p*-cresol among the products is noteworthy, since it indicates that the initial benzyne formation through the nucleophilic attack of the hydroxide ion on the sulfone group does not occur in this reaction; however, the formation of a small amount of *m*-bromotoluene clearly suggests that the process involving the nucleophilic attack of the hydroxide ion on the sulfone group (Mechanism I) cannot be excluded. Moreover, the formation of 4-methylcatechol was not noticed in this reaction. Probably, here also, the major path of the reaction is the one involving the initial chloride replacement (Mechanism II).

Table 2. ^{14}C-tracer study

Compound	Reaction temp. °C	Activities cpm
	—	679
	270	812
	270—290	806
	300—330	681
(as tribromide)		

As has been shown above, phenol was the major product of the alkaline fusion of *o*-chlorophenyl phenyl sulfone. In order to shed further light on the reaction, 2′-chlorophenyl phenyl-1-^{14}C sulfone was subjected to the alkaline fusion. If the source of phenol is limited to either A or B ring, the specific activity of the resulted phenol is expected to be either nil or twice the ^{14}C activitiy of the original sulfone. Indeed, as shown in Table 2, the phenol obtained was found to have nearly the same specific activity as that of the starting sulfone, suggesting that the phenol comes from both A and B rings nearly in the same extent. However, when the alkaline fusion was carried out at somewhat lower temperatures, the specific activity of the phenol formed was found to show a somewhat higher value, suggesting that there is a preference in attacking site in the nucleophilic attack of the hydroxide ion. If the portion of the reaction that proceeds through the I mechanism increases at lower temperatures, it will increase the activity of the phenol formed. However, detailed analyses of the preference of the attacking site of the hydroxide ion will have to await further investigation.

o-Halobenzenesulfinic Acids. In the foregoing discussion, the alkaline fusion of benzenesulfinate was presumed to give only benzene, as was reported previously.[10] In fact, when this reaction was repeated, we found only the formation of benzene. Undoubtedly the nucleophilic attack of the hydroxide ion takes place only at the sulfonyl group, as is illustrated below:

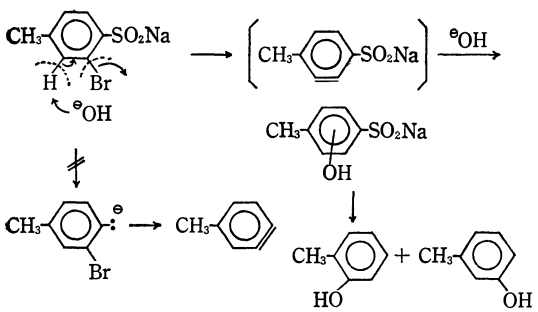


This desulfination is quite facile and is usually completed in a few minutes at around 300°C.

When *o*-chlorobenzenesulfinic acid was treated with an excess of potassium hydroxide, phenol was obtained, but the yield was not impressive; however, *p*-chlorobenzenesulfinic acid in the same reaction also afforded phenol in a much higher yield. In neither case chlorobenzene was isolated. The complete lack of chlorobenzene formation suggests that the nucleophilic attack in the sulfinate group to form chlorobenzene is not the initial process of this reaction; rather, the replacement of the chloro group by the hydroxide ion seems to follow the alkaline cleavage of the sulfinate group. This is clearly demonstrated in the alkaline fusion

10) R. Otto, *Ann*, **145**, 322 (1868).

of 2-bromo-4-toluenesulfinate, in which both *o*- and *m*-cresols were obtained as the main products; their yields were nearly equal. The results are shown in Table 1. The total absence of *p*-cresol suggests that the replacement reaction of bromine by hydroxyl takes place prior to the alkaline cleavage of the sulfinate group and that *m*-bromotoluene is not the intermediate, since the alkaline fusion of *m*-bromotoluene, presumably proceeding *via* the formation of benzyne,[11] would give not only *o*- and *m*-cresols, but also *p*-cresol. Thus, the equal distribution of *o*- and *m*-cresols suggests that the initial reaction is the dehydrobromination to form the benzyne intermediate, which upon the addition of hydroxide, forms both 2- and 3-hydroxytoluenesulfinates which in the succeeding step undergoes desulfination to afford *o*- and *m*-cresols, as is shown below:



The formation of a small amount of phenol appears to be due to the demethylation of cresols during the alkaline fusion, though its mechanism is not fully understood.

Experimental

The Preparation of *o*-Halosulfinic Acid and *o*-Halosulfone. *o*-Chlorobenzene Sulfinic Acid. *o*-Chloroaniline (12.8 g) was diazotized with 7.6 g of sodium nitrite in a mixture of 16 m*l* of concentrated sulfuric acid and 200 m*l* of water. Into the diazotized solution sulfur dioxide gas was bubbled until the weight of the mixture increased by 50 g. Then copper powder was then added into the solution to decompose the diazotized compound. The precipitate was washed with ether three times. The filtrate was extracted with ether, and the combined ether solution was extracted with a 5% sodium hydroxide solution. The alkaline extract was acidified with concentrated hydrochloric acid. Thus, the sulfinic acid (12.5 g) was obtained in a 90% yield; mp 108—110°C.

o-Bromotoluenesulfinic acid was prepared similarly from 9.5 g of 2-bromo-4-methylaniline in a 72% yield; mp 115—117°C.

o-Chlorophenyl Phenyl Sulfone. *o*-Chlorophenyl phenyl sulfide (33 g), prepared by the reaction of thiophenolate with *o*-chlorobenzene diazonium sulfate, was oxidized with 47.4 g of potassium permanganate in 200 m*l* of acetic acid at a temperature below 50°C. The sulfone thus obtained was recrystallized from benzene - *n*-hexane. The yield was 30 g (80%); mp 106-107°C.

2-Bromo-4-tolyl Phenyl Sulfone. 2-Bromo-4-tolyl phenyl sulfide (10.1 g), prepared by the reaction of a 2-bromo-4-tolyl diazonium solution with thiophenolate, was oxidized with 12.0 g of potassium permanganate in 75 m*l* of acetic acid. After the reaction, the mixture was quenched with a large amount of water; then SO_2 gas was introduced to decompose the excess potassium permanganate. The gummy solid cake was dried and recrystallized from 95% ethanol. The yield was 10.5 g (90%) mp 112—113°C, after repeated recrystallizations from 95% ethanol. The sulfone has characteristic IR absorption bands at 1150 and 1350 cm^{-1}.

The Alkaline Fusion of Sulfinic Acid and Sulfone. *A Typical Example of Alkaline Fusion.* The alkaline fusion of *o*-chlorosulfinic acid was carried out as follows. Sodium *o*-chlorobenzenesulfinate (5.5 g) was added to molten potassium hydroxide (15 g) placed in a nickel crucible, at a temperature kept between 260—300°C under nitrogen stream. Vigorous foaming occurred immediately. After the addition, temperature was kept at 300—330°C for 5 min, and then the vessel was cooled rapidly with running water. The solidified mixture was dissolved into water and acidified with concentrated hydrochloric acid, and the aqueous solution was distilled with steam. Into the distillate bromine water was added until the solution turned slight yellow. The tribromide thus obtained was filtered and washed with water. The yield of tribromophenol was 2.0 g; mp 94°C.

In some cases, the distillate was extracted with ether and directly gas chromatographed. The conditions of G. L. C. were as follows: Temp., 130°C; H_2 35 m*l*/min; column, silicone grease coated on Celite 545, 2 m long.

The results of the alkaline fusion of the other sulfinic acids are listed in Table 1; the conditions were nearly the same.

The Alkaline Fusion of o-Chlorophenyl Phenyl Sulfone. *o*-Chlorophenyl phenyl sulfone (3.0 g) was mixed with 15 g of potassium hydroxide and heated in a nickel crucible at a temperature between 300—350°C with a silicone oil bath. The liquid was trapped and then analyzed by G. L. C. After several minutes of heating, the vessel was cooled. The solidified product was dissolved into water and acidified with concentrated hydrochloric acid. The acidified solution was then distilled with steam. The distillate was extracted with ether, and the etheral solution was dried over magnesium sulfate. After ether was removed, the residue was distilled. The yield was 1.46 g (91%). The products were analyzed by G. L. C., the conditions of which were the same as in the case of the sulfinic acid. The compounds identified were benzene and phenol; catechol could not be detected by G. L. C.

The Alkaline Fusion of 2-Bromo-4-tolyl Phenyl Sulfone. This compound was treated similarly; from 3.0 g of the sulfone, 0.6 g of phenols and 1.0 g of an unidentified solid were obtained.

The liquid products were analyzed by G. L. C.; benzene, toluene, phenol, *m*-cresol, and a tiny peak of *o*-cresol were found. The ratio of the products is shown in Table 1.

o-Chlorophenyl Phenyl Sulfone with Potassium Hydroxide in DMSO. The sulfone (2.5 g) and 5.0 g of potassium hydroxide in 20 m*l* of DMSO containing 5 m*l* of water was refluxed over an oil bath for 24 hr. After cooling, the mixture was poured onto ice water. The aqueous solution was acidified with concentrated hydrochloric acid, and extracted with water. The ether extract was washed with water and dried over sodium sulfate. The ether was removed and the crystalline residue was recrystallized from benzene-*n*-hexane. The crystals were identified as *o*-hydroxyphenyl phenyl sulfone. The yield was 1.8 g (78.2%); mp 97—98°C.

2-Chlorophenyl Phenyl Sulfone-1-^{14}C. The synthesis of the sulfone was performed by the method described for unlabelled sulfone. From 2.0 g of aniline-1-^{14}C and *o*-chlorothiophenol prepared from *o*-chloroaniline and potassium xanthate, 2.5 g of 2'-chlorophenyl phenyl sulfide-1-^{14}C was obtained. The sulfide (2.5 g), when oxidized with potassium permanganate, gave 2.2 g of the titled sulfone. The alkaline fusion was performed as in the case of the unlabeled sulfone. The reaction conditions and products are listed in Table 1. The ^{14}C activity measurements were carried out by the Van Slyke wet combustion method by converting the samples as usual to barium carbonate pellets; the activities were recorded by a 2π gas-flow G. M. counter.

Polymerization and Isomerization of Allylbenzene and Propenylbenzene*1

Akihiko SHIMIZU,*2 Takayuki OTSU and Minoru IMOTO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received October 2, 1967)

In order to clarify the relationship between the isomerization and polymerization of α- and β-olefins by various types of catalysts, the isomerizations of allylbenzene and propenylbenzene during their polymerizations were studied. In the presence of cationic catalysts ($AlBr_3$, $BF_3O(C_2H_5)_2$, *etc*), neither the polymerization nor the isomerization of allylbenzene was observed, but propenylbenzene was found to be polymerized without the isomerization of the monomer to give a solid polymer which consisted substantially of a 1,2-structure, plus a minor unit of an isomerized structure. In the cases of the Natta catalysts [$TiCl_3$-$Al(C_2H_5)_3$, $Al/Ti \geq 2$], allylbenzene could easily be polymerized to a high-molecular-weight polymer with a 1,2-structure. During this polymerization, both positional and geometrical isomerizations of the unreacted monomer were observed, indicating that the propenylbenzene obtained from the isomerization did not participate in the polymerization of allylbenzene. It was also found that the polymerization and the positional isomerization of propenylbenzene by these catalysts did not occur.

In previous papers[1-3] it has been shown that some β-olefins, such as butene-2, pentene-2, and hexene-2, can be homopolymerized by the Natta catalyst to give high-molecular-weight polymers with a recurring unit of the corresponding α-olefins. As to the mechanism of the polymerization, it has been concluded that β-olefins were isomerized first to the corresponding α-olefins, which have less steric hindrance, and were then polymerized as α-olefins through a coordinated anionic mechanism. In such cases, it is characteristic that the isomerization of the unreacted monomer is observed, but that of a growing anion to give more stable anion species does not occur during the polymerization.

On the other hand, Kennedy and his co-workers[4] discovered and developed the isomerization polymerization of some branched α-olefins by cationic catalysts at lower temperatures. In this case, the isomerization of a growing cation, which is accompanied by a hydride shift to give a more stable carbonium ion, must occur during the polymerization, while no isomerization of the unreacted monomer is observed.

In order to clarify the relationship between the polymerization and isomerization of α-and β-olefins by various types of catalysts, we attempted to investigate the isomerizations of allylbenzene and propenylbenzene during their polymerizations in the present study. The polymerization of these

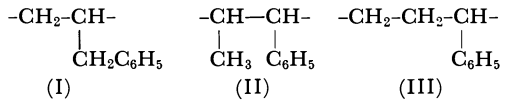
monomer is expected to give polymers with the following three types of recurring units:

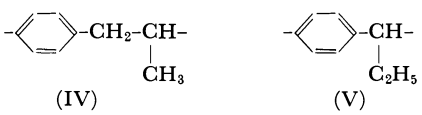


(I) (II) (III)

In 1935, Staudinger and Dreher[5] reported that, in the presence of boron trifluoride as a catalyst, propenylbenzene was polymerized to give a polymer with the structure III, but not the structure II. However, this experiment was reexamined in 1944 by Müller *et al.*[6] and the presence of a CH_3-C bond in the resulting polymer was established, negating Staudinger's findings.

Recently Murahashi, Nozakura, and their coworkers[7] found that propenylbenzene could be polymerized by a cationic mechanism to give the polymer with the structures II and III, and that the isomerization polymerization to the structure III was preferred by less acidic catalysts such as $BF_3O(C_2H_5)_2$, while the polymerization to the structure II was predominant with the BF_3 catalyst. They also reported that allylbenzene was polymerized by the BF_3 catalyst in methylene chloride at $-78°C$ to give a polymer which was somewhat different from the conventional polyallylbenzene I and polypropenylbenzene II. Similar results were independently reported by Kennedy.[8]

More recently, Murahashi, Nozakura, and their coworkers[9] pointed out that the polymer obtained by the cationic polymerization of allylbenzene contained the following two types of recurring units, IV and V:



(IV) (V)

Experimental

Materials. The allylbenzene was prepared according to the procedure of Hershberg[10] by the reaction of allyl bromide with phenylmagnesium bromide; bp 60—61°C/27 mmHg, n_D^{20} 1.5144 (lit.[11]; n_D^{20} 1.5135 for the cis-isomer). From the gas chromatographic analysis (4-m tricresyl phosphate column), it was found that this compound was 97.5% pure.

The propenylbenzene was prepared by the procedure described by Overberger and Saunder[12] through the thermal decomposition of ethylphenylcarbinol; bp 71—74°C/27 mmHg, n_D^{20} 1.5505 (lit.[13]): n_D^{25} 1.5480 for the trans-isomer). This propenylbenzene was 99.1% pure and was found by gas chromatography to consist of 86.9% trans-isomers and 13.1% cis-isomers.

The boron trifluoride - diethyl etherate used as a catalyst was distilled under reduced pressure; bp 126—127°C. The metal halides, titanium tetrabutoxide, and aluminum alkyls were commercially obtained, and were used without further purification.

The *n*-heptane was purified by washing it thoroughly with concentrated sulfuric acid, followed by washing with distilled water until it was neutral, whereupon it was distilled over metallic sodium.

Polymerization Procedure. Cationic polymerizations by the $AlBr_3$ or $BF_3O(C_2H_5)_2$ catalyst were carried out in a sealed glass tube in methylene chloride or in toluene. The charging of the required amounts of reagents into the tube was performed in a dry nitrogen atmosphere.

Coordinated anionic polymerizations were also carried out by charging as follows: to a hard glass tube containing a given amount of titanium trichloride or vanadium trichloride in *n*-heptane, there was added, through a rubber cap using a hypodermic syringe, the required amount of a *n*-heptane solution of aluminum alkyl in a dry nitrogen atmosphere. The catalyst mixture thus obtained was aged for an hour at room temperature, after which the monomer was charged into this tube and the tube was sealed off.

After polymerization in a thermostat for a given period, the tube was opened and the unreacted monomer was recovered and its isomer distribution determined by gas chromatography. The contents of the tube were then poured into a large amount of a hydrochloric acid - isopropyl alcohol mixed solution in order to precipitate the polymer formed. The conversion was calculated from the weight of the dry polymer obtained.

Characterization of the Polymer. The infrared spectra of the resulting polymers were obtained on KBr disks or in thin liquid films. The ratio in the optical density of the band at 2960 to that at 2925 cm^{-1}, $D(CH_3/CH_2)$, was used as a measure of the methyl-to-methylene ratio, *i. e.*, the ratio of the structural units of II to I, or of II to III, in the polymer.[7]

The obtaining solid polymer was extracted with hot toluene, and its crystallinity was expressed by the amount of the insoluble fraction in hot toluene.

Results

Cationic Polymerization with $AlBr_3$ or $BF_3O(C_2H_5)_2$ Catalyst. The results obtained in the polymerization of allylbenzene and propenylbenzene by the $AlBr_3$ or $BF_3O(C_2H_5)_2$ catalyst are shown in Table 1, in which the isomer distribution of the recovered monomer after polymerization and the ratio of the optical densities, $D(CH_3/CH_2)$, of the resulting polymers are also indicated.

e) [Monomer]=1.51 mol/*l* in toluene.
f) Colorless solid polymer.

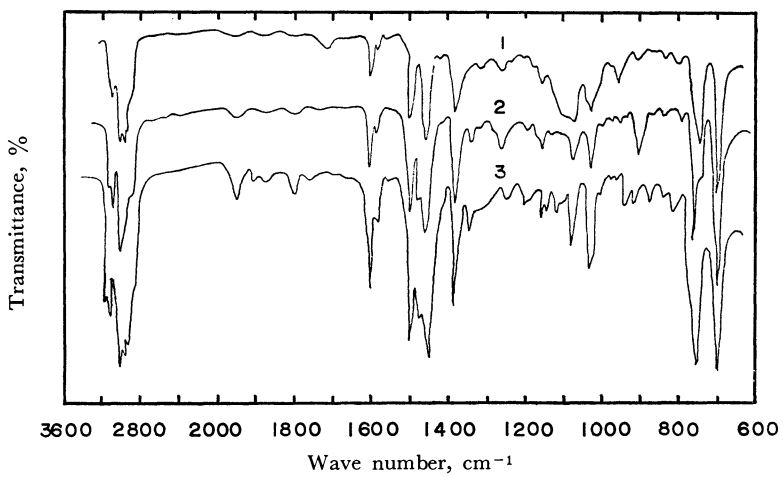

Fig. 1. Infrared spectra of polypropenylbenzene (film).
(1) Polymer obtained with $BF_3 \cdot O(C_2H_5)_2$ catalyst, (2) polymer obtained with $C_2H_5AlCl_2$-$TiCl_3$ catalyst, (3) polymer obtained with $TiCl_3$ catalyst.

As can be seen from this table, allylbenzene was neither polymerized nor isomerized by these catalysts during the reaction. However, propenylbenzene was polymerized by the $BF_3O(C_2H_5)_2$ catalyst, without the isomerization of the monomer, thus giving a colorless solid polymer which was soluble in benzene. The infrared spectrum of the obtaining polymer is shown in Fig. 1, where the $D(CH_3/CH_2)$ value was 1.00—1.21, indicating that the methylene group is present in the backbone of this polymer.

Polymerization with Catalyst Systems Containing $TiCl_3$. The results of the polymerization of allylbenzene by the catalyst systems of $TiCl_3$ alone and of $TiCl_3$-organoaluminum compounds are summarized in Table 2. By the addition of $TiCl_3$ alone, allylbenzene was found to be hardly polymerized at all and to be isomerized to propenylbenzene, giving a colorless viscous polymer. In its infrared spectrum, shown in Fig. 2, this polymer showed $D(CH_3/CH_2)$ values of 0.91—1.11, unmistakably confirming the presence of a methyl group attached to the backbone of this polymer.

In the presence of the binary systems of $TiCl_3$ and organoaluminum compounds, allylbenzene was readily polymerized to a solid polymer containing no methyl group ($D(CH_3/CH_2)=0$), as is indicated in Fig. 2. The polymer yields were found to depend upon the kind of organoaluminum compounds

and also on the Al/Ti molar ratios in the catalyst systems, indicating that the polymerization rate decreased with an increase in the cationic character of the catalyst systems (*i. e.*, from $Al(C_2H_5)_3$ to $Al(C_2H_5)Cl_2$ in the organoaluminum component, and from 2 to 0 in the Al/Ti molar ratio), while the $D(CH_3/CH_2)$ values in the resulting polymers increased from zero to 1.08 (see Fig. 2). In the case of the $TiCl_3$-$Al(C_2H_5)_3$ catalyst, it was also found that the positional isomerization of allylbenzene to propenylbenzene after the polymerization was accelerated upon an increase in the Al/Ti molar ratio.

Table 3 shows the results of the polymerization of propenylbenzene by these catalyst systems. It can be seen in this table that the polymerization of propenylbenzene by the $TiCl_3$ catalyst was observed, giving a yellowish oily product but without any positional isomerization to allylbenzene. This product was confirmed to be a dimer of propenylbenzene by a molecular-weight determination; it was showed an absorption band characteristic of the methylene group, *i. e.*, $D(CH_3/CH_2)=1.10$—1.33 (Fig. 1).

In these binary catalyst systems, the geometrical cis-trans isomerization of propenylbenzene was observed, accelerating with a nincrease in the Al/Ti molar ratio, but no positional isomerization occurred. A solid polymer which has no absorption band for the methylene group was obtained when only the $C_2H_5AlCl_2$-$TiCl_3$ catalyst was used. These isomerizations and polymerizations were dependent on the cationic character of the catalyst system, as are those of allylbenzene.

Polymerization with Catalyst Systems Containing VCl_3. Table 4 shows the results of the polymerization of allylbenzene and propenylbenzene by the binary catalyst systems of VCl_3. As can be seen from this table, no isomerization occurred in any case. Allylbenzene was polymerized by VCl_3-trialkylaluminum catalysts to give a solid polymer whose infrared spectrum indicated no absorption band for the methyl group in the polymer.

Polymerization with Catalyst Systems Containing $Ti(OC_4H_9)_4$. The results of the polymerization of allylbenzene and propenylbenzene by the binary catalyst systems of $Ti(OC_4H_9)_4$ are summarized in Table 5, in which the isomerization of the monomer during the reaction and the $D(CH_3/CH_2)$ values of the resulting polymers are also shown. In these cases, both the isomerization and the polymerization were observed to be dependent upon the cationic character of the catalyst systems used. A viscous polymer from allylbenzene and an oily product from propenylbenzene were obtained by the use of the $Ti(OC_4H_9)_4$-$Al(C_2H_5)_3$ catalyst.

Discussion

As can be seen from Table 1, neither the polymerization nor the isomerization of allylbenzene was observed in the presence of the $AlBr_3$ catalyst or the $BF_3O(C_2H_5)_2$ catalyst. However, propenylbenzene was found to be polymerized by the latter catalyst to give a solid polymer whose molecular weight was 720. Although the infrared spectrum of the produced polymers showed intense absorption bands due to the methyl group at 2960, 2878, and 1380 cm^{-1}, weak absorption bands due to the methylene group were also observed at 2925 and 755 cm^{-1}, indicating that this polymer consisted of the structure II, with a minor unit of the I or III structure. In view of the results shown in Table 1 (no isomerization of the monomer takes place during the reaction), the participation of the allylbenzene isomerized from propenylbenzene to give the structual unit I was not considered in this polymerization. Although the isomerization of a growing cation of propenylbenzene leading to the structual unit III was considered, it might be impossible to find a driving force to cause this type of isomerization to proceed, as has been pointed out by Kennedy[8] and Murahashi *et al.*[14] No other evidence for the presence of such isomerized structures was obtained, and the possible mechanism for its production is also uncertain at the present time. Figure 1 shows that the structural unit IV in this polymer was not present.

No isomerizations of the monomer were observed in the polymerizations of allylbenzene and propenylbenzene by catalyst systems containing VCl_3. On the other hand, both isomerizations from allylbenzene to propenylbenzene and from *cis*-propenylbenzene to *trans*-propenylbenzene occurred in the presence of the catalyst systems including $TiCl_3$; these isomerizations were found to be accelerated upon increase in the Al/Ti molar ratio (*i. e.*, an increase in the anionic nature of the catalyst system). These results were in agreement with those observed in the isomerization of butene-2 by the same catalyst systems.[3]

However, the positional isomerization from propenylbenzene to allylbenzene did not occur in the polymerization of propenylbenzene by any of the catalyst systems used. This fact leads to the conclusion that the high-molecular-weight polyallylbenzene (I) from propenylbenzene is not obtained in the presence of the Natta catalyst, just as in the polymerization of butene-2 with isomerization to butene-1.[3] The experimental results coincided with this conclusion.

From Tables 1—4, it is clear that the polymerization activities of allylbenzene toward the Natta catalysts decrease greatly with a decrease in the Al/Ti molar ratio and with an increase in the substitution of the chloride component in organoaluminum compounds of the catalyst systems (*i. e.* an increase in the cationic nature). On the other hand, the polymerization of propenylbenzene was observed when the cationic nature of the catalyst systems used increased, and the resulting polymers were low in molecular weight.

As is shown in Fig. 2, the infrared spectra of the polyallylbenzene obtained through a coordinated anionic mechanism by the Natta catalysts showed a strong absorption band for the methylene group at 2925 cm^{-1}, but none for the methyl group. This result indicates that allylbenzene is polymerized by an ordinary anionic 1,2-addition mechanism to give a high-molecular-weight polymer with the non-isomerized structure (I). In this case, it is clear that propenylbenzene does not participate in the polymerization of allylbenzene, just as in the production of polybutene-1 from butene-2.[3]

Figure 2 shows, however, that the infrared spectra of the polymers obtained from allylbenzene by the $TiCl_3$-$Al(C_2H_5)Cl_2$ or $TiCl_3$ catalyst, which might induce cationic polymerization, showed the absorption bands characteristic of the methyl group

14) S. Murahashi, S. Nozakura, K. Tsuboshima and Y. Kotake, This Bulletin, **38**, 157 (1965).

of 2960, 2878, and 1380 cm^{-1}, that of the methylene group at 2925 cm^{-1}, and those of substituted benzene at 1700—2000 and 830 cm^{-1}. Accordingly, it can be concluded that the polymer is obtained not only by an ordinary 1,2-addition mechanism of allylbenzene and of the propenylbenzene which is isomerized from it, but also by the Friedel-Crafts-type addition mechanism[9] of a growing cation to the benzene nuclei of the monomer or of the polymer, leading to the recurring units, IV and V.

In the presence of the $TiCl_3$-$Al(C_2H_5)Cl_2$ catalyst, it was found that propenylbenzene is readily polymerized, giving a heptamer whose infrared spectrum showed a absorption band for the methyl group, but none for the methylene group or for substituted benzene, suggesting that this catalyst induces the cationic polymerization by an ordinary 1,2-addition mechanism, thus giving a polymer with the structure II.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 959—964 (1968)

Studies on Isothiazoles. III.[1] A Novel Ring Closure to Isothiazoles by the Reaction of α-Amino Ketones with Thionyl Chloride or Sulfur Monochloride

Takayuki NAITO, Susumu NAKAGAWA, Jun OKUMURA, Kiyoshi TAKAHASHI and Ken-ichi KASAI

Bristol-Banyu Research Institute Ltd., Meguro-ku, Tokyo

(Received October 5, 1967)

New compounds, 4-hydroxyisothiazoles, have been prepared by the reaction of α-amino ketones with thionyl chloride or sulfur monochloride, which is a novel procedure for cyclization to an isothiazole ring. Polar solvents, especially dimethylformamide (DMF), were preferable for this cyclization. The reaction hardly proceeded in a nonpolar solvent such as benzene, but was accelerated by an addition of a small amount of DMF.

Mononuclear isothiazoles have been unknown until Adams and Slack[2] obtained in 1956 isothiazole-4,5-dicarboxylic acid by oxidation of 5-aminobenzisothiazole. Since then, many isothiazole derivatives have been prepared by several routes: oxidative ring closure of β-iminothioamides[3] or β-iminothioketones,[4] reaction of olefins with sulfur dioxide and ammonia in the presence of activated alumina,[5] cyclization with liquid ammonia of the addition product from acetylenic ketones and thiosulfate or thiocyanate,[6] cyclization of dicyanoethylene-thiolate with sulfur, chlorine or chloramide,[7] treatment of dithiolium salts with ammonia[8] and reaction of nitriles with sulfur and morpholine.[9] Now we wish to report a novel procedure for formation of the isothiazole ring from open-chain compounds and the resulting products, 4-hydroxyisothiazoles, which have been hitherto undescribed.

1-Amino-1-phenyl-2-butanone (I) readily reacted with thionyl chloride in dimethylformamide (DMF) to give an acidic product melting at 153—153.5°C, which showed the characteristics expected for those of 4-hydroxy-5-methyl-3-phenylisothizaole (II). The product is soluble in dilute sodium hydroxide, but insoluble in neutral or acid water. The IR spectrum shows a band at about 3200 cm^{-1}, but no band in the carbonyl region. Its NMR spectrum*1 in dimethylsulfoxide-d_6 has a singlet due to a phenolic hydroxyl proton at 9.62[10] together with a singlet of C_5-methyl protons at 2.46,[11] a multiplet due to meta- and para-protons of phenyl ring at 7.56—7.86 and a multiplet due to ortho-protons at 8.24—8.50. Acetylation of the product with acetic anhydride gave a neutral colorless oil, which showed a carbonyl band due to enol acetate at 1755 cm^{-1} in the IR spectrum. The NMR spectrum of the acetate in deuteriochloroform shows two methyl singlets at 2.24 and 2.34 and phenyl proton multiplets at 7.32—7.52 and 7.68—7.90. Methylation with diazomethane afforded a colorless oil which showed complete absence of hydroxy stretching band and appearance of new bands due to an aromatic ether at 1250 cm^{-1} and 1000 cm^{-1} in the IR spectrum. When I was allowed to react with sulfur monochloride in DMF under cooling, the same product (II) was obtained in 44% yield. However, the reaction under heating gave another acidic compound melting at 104—105°C, which was determined to be 5-formyl-4-hydroxy-3-phenylisothiazole (III). It shows a hydroxyl band at about 3400 cm^{-1} and a carbonyl band at 1655 cm^{-1}, and gives the corresponding 2,4-dinitrophenylhydrazone having an absorption maximum at 391 mμ. By acetylation the carbonyl band remains and the hydroxyl band disappears with an appearance of a new band due to enol acetate at 1770 cm^{-1}. The NMR spectrum of the acetate in carbon tetrachloride shows a methyl singlet at 2.46, multiplets of five phenyl protons at 7.54—7.82 and 7.94—8.18 and a singlet due to a formyl proton at 10.14.

* An oxazole derivative (V) was obtained (see, experimental section).

The reaction of I with thionyl chloride was investigated under various conditions. As shown in Table 1, the reaction under cooling (Method A) gave more than 70% yield of the product (II) with three equivalents or more of thionyl chloride. The reaction without thermal control (Method B) proceeded with nearly the same yield as Method A when two equivalents or more of thionyl chloride was used, while the yield decreased considerably with an equimolar of the reagent. As shown in Table 4, the solvent, DMF, can be substituted by other polar solvents, but with decrease of the yield. The reaction in dimethylsulfoxide gave only an unidentified tarry product with mercaptan-like odor. A nonpolar solvent such as benzene was not suitable for this reaction, but the addition of a small amount of DMF accelerated the reaction considerably.

*1 All NMR spectra in this paper were run with a Varian A-60 spectrometer, for which the authors are indebted to Assistant Professor M. Goto and Dr. Urushibara of Gakushuin University. Chemical shifts are represented in ppm from an internal reference, TMS.

Treibs and Suter[12] have reported that 3-acetamido-2-butanone was reacted with thionyl chloride to give 2,4,5-trimethyloxazole. Similarly 1-acetamido-1-phenyl-2-butanone (IV) was dehydrated by thionyl chloride to afford 5-ethyl-2-methyl-4-phenyloxazole (V). The reaction with sulfur monochloride did not give the oxazole derivative (V) but the above-mentioned isothiazole (II) in 17% yield by cyclization accompanied with *N*-deacetylation.

1-Amino-1-phenyl-2-propanone (VI) was subjected to a similar reaction with sulfur monochloride either under cooling or under heating. In both cases, the product was the same chlorine-containing acidic compound, 5-chloro-4-hydroxy-3-phenylisothiazole (VII). The mass spectrograph*2

* 6.3% of the starting amino ketone was recovered.
** 83% of the starting amino ketone was recovered.

*2 Mass spectra were run with a Hitachi RMU-6 spectrometer by a heating inlet system (Chember voltage, 80 V; reservoir temp., 120°C; electron multiplier voltage 2000 V), for which the authors are indebted to Professor S. Hishida of Nihon University.

12) A. Treibs and W. Suter, *Chem. Ber.*, **84**, 96 (1951).

of VII showed a molecular peak at *m/e* 211/213 with characteristic isotopic abundance and the NMR spectrum in dimethylsulfoxide-d_6 solution indicated signals of phenyl protons and a phenolic hydroxyl proton. 1-Acetamido-1-phenyl-2-propanone (X) was reacted similarly with sulfur monochloride to afford VII by cyclization accompanied with *N*-deacetylation and chlorination.

The reaction of VI with 2 equivalents of thionyl chloride in DMF gave the expected product, 4-hydroxy-3-phenylisothiazole (VIII), which showed a singlet of C-5 proton at 8.12[11] along with singnals of phenyl protons and a phenolic hydroxyl proton. On the other hand the reaction with 4 equivalents of thionyl chloride gave another acidic product which showed a molecular peak at *m/e* 384. The structure was established as bis-(4-hydroxy-3-phenyl-5-isothiazole) sulfide (IX) by lack of C-5 proton and elemental analysis. It was found that a minor amount of VIII was also present in a reaction mixture of VI with sulfur monochloride under mild condition. Moreover, VIII was converted into VII by sulfur monochloride, while treatment with thionyl chloride gave neither VII nor IX, but the starting material (VIII) was recovered.

1-Amino-1,3-diphenyl-2-propanone (IXa) was expected to give 4-hydroxy-3,5-diphenylisothiazole (XIIa) as a sole product, because substitution or oxidation would be blocked in the 5-position in XIIa. In fact, none of by-product was obtained when XIa was allowed to react with thionyl chloride or sulfur monochloride under the condition same as that yielding the abnormal products such as IX, III and VII. 2-Amino-3-pentanone (XIb) was reacted similarly with either one of the cyclization reagents to afford 3,5-dimethylisothiazole (XIIb), although the yield was poor. Also, 3-amino-1-phenyl-2-butanone (XId) was cyclized to 4-hydroxy-3-methyl-4-phenylisothiazole (XIId) by thionyl chloride. On the other hand, the reaction with 3-amino-2-butanone (XIc) gave only a chlorine-containing product (XIIc).

Experimental

α-Amino Ketones. According to the procedure of Dakin and West,[13-17] α-amino ketones were prepared by heating an α-amino acid or α-acetamido acid with an acid anhydride in the presence of pyridine followed by hydrolysis of the resulting α-acylamido ketone with 6 N hydrochloric acid. The results and properties are shown in Table 5.

4-Hydroxyisothiazoles. 4-Hydroxyisothiazoles were prepared by the following two methods and the results are shown in Table 1. The properties and analyses of the products are shown in Table 2.

Method A. There was added 0.1—0.2 mol of thionyl chloride or sulfur monochloride to 50 m*l* of DMF below 0°C with stirring. To the stirred solution was added 0.05 mol of an appropriate α-amino ketone hydrochloride with cooling in an ice-salt bath to maintain the temperature below 10°C. After an exothermic reaction had ceased, the bath was removed and the stirring continued for two hours. The reaction mixture was allowed to stand overnight at room temperature, then poured into 100 m*l* of ice water and extracted with three 50-m*l* portions of ether. The combined ethereal extracts were washed with two 50-m*l* portions of water and then back-extracted with two 50-m*l* portions of 5% aqueous sodium hydroxide solution. The combined alkaline extracts were evaporated under reduced pressure to remove low boiling materials and then acidified whit 20% hydrochloric acid with cooling to give the product which was collected by filtration and recrystallized from ligroin or benzene-ligroin.

Method B. There was added 0.05—0.2 mol of thionyl chloride or sulfur monochloride to 50 m*l* of DMF below 0°C and the solution was mixed with 0.05 mol of an appropriate α-amino ketone hydrochloride in one portion. An exothermic reaction began soon and the temperature of the mixture rose to 50—80°C. When the reaction had ceased, the reaction mixture was heated on a water bath at 60—90°C for 1.5—2 hr, then allowed to stand overnight at room temperature. The product was isolated by the procedure described in Method A.

4-Acetoxyisothiazoles. Acetylation of 4-hydroxyisothiazoles was carried out with acetic anhydride by a usual manner. The yields and properties of the resulting 4-acetoxyisothiazoles are shown in Table 3.

4-Methoxyisothiazoles. 4-Hydroxyisothiazoles were converted into the corresponding 4-methoxy derivatives with diazomethane in ether. The yields and properties are shown in Table 3.

Reaction of 1-Acetamido-1-phenyl-2-butanone (IV) and Thionyl Chloride. To a cold suspension of 5 g (0.025 mol) of IV in 25 m*l* of ligroin was added 12 g (0.1 mol) of thionyl chloride in one portion. The mixture was stirred overnight at room temperature and heated at 80—90°C for four hours. The reaction mixture was evaporated under reduced pressure, the residual oxazolium salt was washed with three 30-m*l* portions of ether and added to 30 m*l* of water to convert it to the oily free oxazole. The oil was extracted with two 30-m*l* portions of ether and the extracts were washed with 30-m*l* of water, two 30-m*l* portions of 2.5% sodium

**** Found: C, 68.55; H, 6.22; N, 5.68%. Calcd for $C_{15}H_{15}ON \cdot HCl$: C, 68.83; H, 6.16; N, 5.35%.

hydroxide solution and finally with two 30-m*l* portions of water and then treated by active carbon. The filtrate was evaporated and the residue distilled under reduced pressure to give 1.9 g (41%) of V as a pale yellow oil boiling at 150—152°C/13 mmHg (lit.,[20] bp 146—148°C/12 mmHg). NMR (ppm, in CCl_4): 1.30 (3H, triplet), 2.42 (3H, singlet), 2.87 (2H, quartet), 7.25—7.75 (5H, multiplet).

Reaction of 4-Hydroxy-3-phenylisothiazole (VIII) with Sulfur Monochloride. To a stirred solution of 1.24 g (0.007 mol) of VIII in 10 m*l* of DMF was added dropwise 2.84 g (0.021 mol) of sulfur monochloride with cooling. The mixture was stirred for four hours and allowed to stand overnight at room temperature. The reaction mixture was poured into 100 m*l* of ice water and extracted with three 30-m*l* portions of ether. The combined ethereal solution was extracted with 5% sodium hydroxide solution and the aqueous extracts were acidified with hydrochloric acid to afford 1.09 g (74%) of white precipitate, which was identical to an authentic sample of VII by IR spectrum and acetylation.

Reaction of 4-Hydroxy-3-phenylisothiazole (VIII) with Thionyl Chloride. A solution of 1.24 g (0.007 mol) of VIII in 10 m*l* of DMF was allowed to react with 2.5 g (0.021 mol) of thionyl chloride by the procedure described above. Acidification with hydrochloric acid gave 0.98 g (79%) of the starting material (VIII) which was confirmed by mixed melting point and IR spectrum.

Reaction of 1-Amino-1-phenyl-2-butanone (I) and Thionyl Chloride in Various Solvents (Table 4). To a mixture of 5.0 g (0.025 mol) of I in 15 m*l* of an appropriate solvent listed in Table 4 was added dropwise 6.0 g (0.05 mol) of thionyl chloride at room temperature with stirring. An exothermic reaction occurred and the temperature rose to 30—40°C. The mixture was allowed to react under the condition shown in Table 4. In Exp. Nos. (1) and (2), the reaction mixture was a homogeneous solution and the product was isolated by the same procedure as Method A described above. In. Exp Nos. (3) and (5), the reaction mixture contained insoluble precipitate which was the unreacted starting ketone (I). The ketone was removed by filtration and the filtrate was worked up by the same procedure as Method A to give the product (II). In Exp. Nos. (4), (6), (7) and (8), the reaction mixture contained insoluble precipitate or oil, which appeared to be the isothiazolium salt by IR spectrum. The salt was collected by filtration or decantation and converted into, the corresponding isothiazole (II) by treating with cold water. The filtrate or the supernatant was poured into ice water and extracted with ether. To the ethereal extracts was added the crude II which was obtained from the isothiazolium salt. The solution was treated by the same procedure as described in Method A.

The authors wish to express their thanks to Dr. Koichi Iwadare and Mr. Eiji Iwadare of Banyu Pharmaceutical Co., Dr. Joseph Lein of Bristol Laboratories and Dr. Hiroshi Kawaguchi of this Institute for their valuable suggestions and encouragement throughout the present work. They are also grateful to Mr. Fumihide Sakai, Mr. Kenji Masuko and Mr. Yukio Narita for their fine assistance.

Studies on Isothiazoles. IV.[1] A New Synthetic Route to 4-Cyanoisothiazoles

Takayuki NAITO, Susumu NAKAGAWA, Jun OKUMURA, Kiyoshi TAKAHASHI, Kenji MASUKO and Yukio NARITA

Bristol-Banyu Research Institute Ltd., Meguro-ku, Tokyo

(Received October 5, 1967)

4-Cyanoisothiazoles have been prepared by a novel procedure which comprises the reac-reaction of β-cyano enamines with thionyl chloride or sulfur monochloride. The reaction proceeds favorably in nonpolar solvents or in the absence of solvent. However, the cyclization did not occur in dimethylformamide and instead an amidine derivative was isolated. The preparations of the corresponding isothiazole-4-carboxylic acids are also described briefly.

Direct preparation of 4-cyanoisothiazoles from open-chain compounds has been carried out by reaction of methacrylonitrile with sulfur dioxide and ammonia in the presence of activated alumina,[2] by oxidative ring closure of α-cyano-β-iminothioamides[3,4] and by cyclization of dicyanoethylene thiolates with sulfur,[5,6] chlorine[7] or chloramide.[8] However, 4-cyanoisothiazoles having alkyl or aryl group(s) at position(s) 3 and/or 5 have not been prepared by any of the above procedures, but by the substitution reaction of 4-bromoisothiazoles with cuprous cyanide.[9-12] The present paper reports a direct formation of 3- and/or 5-alkyl- or aryl-substituted 4-cyanoisothiazoles by heating β-cyano enamines with thionyl chloride or sulfur monochloride.

The starting enamines were prepared by Thorpe condensation[13,14] of the corresponding nitriles in the presence of (a) metallic sodium, (b) sodium amide or (c) sodium hydride as shown in Table 1. The IR spectra of the enamines showed three bands in a range of 3100—3600 cm^{-1} due to N-H stretching vibrations. This suggests that these compounds are present as an equilibrium mixture of two tautomers, β-cyano enamine (A) and β-imino nitrile (B). In this paper the compounds of this family are represented and named by formula (A).

$$\mathrm{R\text{-}CN + R'\text{-}CH_2CH_2\text{-}CN} \rightarrow \begin{array}{l} \mathrm{R\text{-}C(NH_2)=C(CH_2\text{-}R')\text{-}CN} \quad \text{(A)} \\ \updownarrow \\ \mathrm{R\text{-}C(=NH)\text{-}CH(CH_2\text{-}R')\text{-}CN} \quad \text{(B)} \end{array}$$

The preliminary experiments were carried out in dimethylformamide (DMF) with thionyl chloride and 1-amino-2-cyano-1-phenyl-1-butene (Ia) under similar conditions to the preparation of 4-hydroxyisothiazoles.[1] An exothermic reaction occurred, but no desired product was afforded. The only product isolated was a compound **III**, which has cyano (ν 2230 cm^{-1}), -C=N- (ν 1635 cm^{-1}), dimethylamino (3H singlet at 2.84*1 and 3H singlet at 3.03), ethyl (3H triplet at 1.15 and 2H quartet at 2.54; J=7.7 cps), =C-H (1H singlet at 7.12) and phenyl groups (5H multiplet centered at 7.37).

The reaction proceeded in the desired direction to give 4-cyano-5-methyl-3-phenylisothiazole (IIa)[12] when Ia was treated with thionyl chloride or sulfur monochloride in benzene, toluene, tetrahydrofuran, ligroin or solvent naptha, or without any solvent as shown in Table 2. Similarly, 1-amino-2-cyano-1-(2,6-dichlorophenyl)-1-butene (Ib) and 4-amino-3-cyano-3-heptene (Ic) gave 4-

cyano-3-(2, 6-dichlorophenyl)-5-methylisothiazole (IIb) and 4-cyano-5-methyl-3-*n*-propylisothiazole (IIc), respectively.

The reaction of 1-amino-2-cyano-1-phenyl-1-propene (IVa) with thionyl chloride gave two kinds of cyanoisothiazoles, which were separated by an alumina column chromatography. The main product was the expected 4-cyano-3-phenylisothiazole (Va)[12] ($\nu_{C\equiv N}$ 2240 cm^{-1}; 5-H proton 9.30 ppm). The minor component was 5-chloro-4-cyano-3-phenylisothiazole (VIa) ($\nu_{C\equiv N}$ 2240 cm^{-1}; M^+ peak*2 at *m/e* 220 with the isotpe peak at *m/e* 222), which lacks the C-5 proton singlet in the NMR spectrum. Sulfur monochloride was allowed to react with IVa under similar conditions and Va was isolated, while VIa was detected by gas chromatography. In the reaction of 1-amino-2-cyano-1-(2,6-dichlorophenyl)-1-propene (IVb) with thionyl chloride or sulfur monochloride, 4-cyano-3-(2,6-dichlorophenyl)isothiazole (Vb) was isolated, but the 5-chloro derivative (VIb) was not detected.

*2 Mass spectrum was run with a Hitachi RMU-6 spectrometer by a heating inlet system (chamber voltage, 80 V; reservoir temp., 110°C; electron multiplier voltage, 2000 V), for which the authors are indebted to Professor S. Hishida of Nihon University.

4-Cyanoisothiazoles prepared in the present study were readily converted into the corresponding isothiazole-4-carboxylic acids either (a) by heating with sulfuric acid followed by treatment with aqueous sodium nitrite, or (b) by hydrolysis with potassium hydroxide in aqueous ethylene glycol (Table 4).

Experimental

β-Cyano Enamines (Table 1). Representative examples of the preparation of β-cyano enamines, Ia—c and IVa, b, are given below.

a) A mixture of 105 g (1.0 mol) of benzonitrile and 70 g (1.0 mol) of *n*-butyronitrile in 500 m*l* of ether was added slowly to a dispersion of 23 g (1.0 atom) of metallic sodium in toluene under stirring over a period of about 2.5 hr at 20—30°C. The color of the mixture gradually turned to red. The reaction mixture was stirred for 6 hr at room temperature and allowed to stand overnight. Excess sodium was decomposed by adding water slowly under stirring. The ether layer was separated, washed with three 200-m*l* portions of saturated aqueous solution of sodium chloride and dried with anhydrous sodium sulfate. The solvent was evaporated and the residue distilled under diminished pressure to give 79 g (46%) of Ia.

b) To 200 m*l* of liquid ammonia containing about 0.1 g of ferric nitrate was added portionwise 4.8 g (0.21 atom) of sodium at −40 to −50°C. To the blue solution of sodium amide was added dropwise a solution of 20.6 g (0.2 mol) of benzonitrile and 13.8 g (0.2 mol) of butyronitrile in 100 m*l* of ether. After the addition was completed, liquid ammonia was replaced with 200 m*l* of dry ether and the solution was refluxed for three hours. To the reaction mixture was cautiously added 200 m*l* of water and the ether layer which separated was washed with four 200-m*l* portions of water, dried over anhydrous sodium sulfate and the solvent evaporated. The residue was distilled to give 17.1 g (50%) of Ia.

c) A 50% dispersion of sodium hydride in mineral oil (4.8 g, 0.1 mol) was mixed with 100 m*l* of dry benzene and to the stirred mixture was added a solution of 10.3 g (0.1 mol) of benzonitrile and 6.9 g (0.1 mol) of butyronitrile in 100 m*l* of dry benzene at 40—50°C. After the addition was completed, the mixture was stirred for 4 hr at 70°C, then cooled to room temperature and 200 m*l* of water was cautiously added dropwise. The benzene layer was distilled under reduced pressure and a fraction boiling at 100—160°C/1.5 mmHg was collected and redistilled to give 1.8 g (11%) of Ia.

2-Cyano-1-(*N*,*N*-dimethylforamidino)-1-phenyl-1-butene (III). To a stirred solution of 1.7 g (0.01 mol) of Ia in 15 m*l* of DMF was added dropwise 3.6 g (0.03 mol) of thionyl chloride. An exothermic reaction occurred and the temperature of the solution rose to about 50°C. After the exothermic reaction had ceased, stirring was continued for 4 hr. The reaction mixture was poured into ice-water, made alkaline by dil. sodium hydroxide solution and extracted with ether. The extracts were washed with water and dried over anhydrous sodium sulfate. The solvent was evaporated and the residue distilled under reduced pressure to give 1.1 g (48%) of III boiling at 163°C/1.0 mmHg, which solidified at room temperature. Recrystallization from ligroin gave colorless prisms melting at 50—52°C. λ_{max}^{EtOH} 309 mμ (ε 28000).

Found: C, 74.20; H, 7.95; N, 18.25%. Calcd for $C_{14}H_{17}N_3$: C, 73.97; H, 7.54; N, 18.49%.

4-Cyanoisothiazoles (Tables 2 and 3). To a solution of β-cyano enamine in an appropriate solvent shown in Table 2 was added 3—5 mol of thionyl chloride or sulfur monochloride in one portion. The mixture was refluxed for a certain period of time as shown in Table 2, then allowed to stand overnight at room temperature, poured into crushed ice and extracted twice with 50 m*l* of ether. The combined ethereal extracts were washed with water and dried over anhydrous sodium sulfate. The solvent was evaporated and the residue crystallized from ligroin (IIb and Vb) or distilled under reduced pressure (IIc).

The residue obtained by the reaction with Ia dissolved in ligroin. The solution was subjected to an alumina column chromatography and developed with ligroin followed with ligroin-benzene (1 : 1), the eluate being divided into 100—200 m*l* portions. Each of the fractions was evaporated into dryness. The residues were subjected to gas chromatography and the fractions which appeared to be rich in IIa were combined and crystallized from ligroin to give a pure sample of IIa.

The residue obtained by the reaction with IVa was dissolved in ligroin, chromatographed on an alumina column and eluted with ligroin. The eluate was collected in 50-m*l* portions, each fraction being analyzed by gas chromatography. The second and third fractions of the eluate were combined and evaporated to dryness to give a crystalline residue. Recrystallization from petroleum ether gave colorless needles of 5-chloro-4-cyano-3-phenylisothiazole (VIa). Evaporation of fractions No. 4—No. 10 and subsequent recrystallization from ligroin gave 4-cyano-3-phenylisothiazole (Va).

The results are shown in Table 2 and the properties and analyses of the products in Table 3.

Isothiazole-4-carboxylic Acids (Table 4). Hydrolysis of 4-cyanoisothiazoles was carried out by either one of the procedures illustrated in representative examples given below.

a) 5-Methyl-3-n-propylisothiazole-4-carboxylic Acid. A mixture of 0.52 g (0.00314 mol) of IIc and 15 m*l* of concentrated sulfuric acid was heated at 70—75°C for 6 hr and allowed to stand overnight at room temperature. The reaction mixture was cooled below 10°C and a solution of 0.27 g of sodium nitrite in 1 m*l* of water was cautiously added dropwise. The mixture was stirred for 20 min at 5—9°C, for 30 min at room temperature and finally for 30 min at 40°C. The reaction mixture was poured onto 40 g of crushed ice, insoluble material removed and the filtrate extracted with ether. The ethereal extracts were dried with anhydrous sodium sulfate, the solvent being evaporated. The residue was dissolved in aqueous sodium bicarbonate, washed with ether, treated with a small amount of active carbon and acidified with dilute hydrochloric acid to give 5-methyl-3-*n*-propylisothiazole-4-carboxylic acid which was recrystallized from benzene-ligroin (1 : 2).

b) 3-(2,6-Dichlorophenyl)-5-methylisothiazole-4-carboxylic Acid. A mixture of 2.3 g (0.0085 mol) of II, 1 g (0.018 mol) of potassium hydroxide, 1.8 m*l* of water and 9 m*l* of ethylene glycol was refluxed for 48.5 hr

and the reaction mixture was poured into 50 m*l* of water. A small amount of insoluble material was filtered off and the filtrate was acidified with dilute hydrochloric acid to separate 2.15 g of the crude acid. Recrystallization from ligroin-ethyl acetate gave 3-(2,6-dichlorophenyl)-5-methylisothiazole-4-carboxylic acid.

The authors wish to express their thanks to Dr. Koichi Iwadare and Mr. Eiji Iwadare of Banyu Pharmaceutical Co., Dr. Joseph Lein of Bristol Laboratories and Dr. Hiroshi Kawaguchi of this Institute for their valuable suggestions and encouragement throughout the present work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 971—973 (1968)

The Structures and the Reactions of Acetyl- and Benzoylacrylic Acids and Their Esters

Noboru SUGIYAMA, Taketoshi GASHA, Hiroshi KATAOKA and Choji KASHIMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka Tokyo

(Received October 9, 1967)

The Structures and properties of α,β-unsaturated γ-oxo acid, acetyl- and benzoylacrylic acid, and their esters are studied.

It can be considered that the α,β-unsaturated γ-oxo acid exists in three isomeric forms, the *trans*-form (A), the *cis*-form (B), and the angelica lactone form (C). Scheffold has established[1] that acetylacrylic acid (I) has two forms, A and C, which convert to each other. However, according to Shaw, the compound (mp 59°C)[2] produced by the reaction of I with diazomethane was not a simple methyl ester of I, but 5-methyl-5-methoxy-2,5-dihydro-2-oxofuran (III-C). The compound (mp 60.5°C),[3] synthesized from bromoacetone and triphenylphosphine carbomethoxymethylene, was a simple methyl ester of I, methyl acetylacrylate (III-A).

2) E. Shaw, *J. Am. Chem. Soc.*, **68**, 2510 (1946).
3) H. J. Bestmann, F. Seng and H. Schulz, *Chem. Ber.*, **96**, 465 (1963).

On the other hand, it has been reported that the compound obtained by the Friedel-Crafts reaction of maleic anhydride with benzene was benzoylacrylic acid of the A form.[4] Furthermore, one of the simplest α,β-unsaturated γ-oxo acids, fumaraldehydic acid (V), is not present in the form of V-A, but in the form of V-C, 5-hydroxy-2,5-dihydro-2-oxofuran.[5]

Thus, there still remain some uncertainties about the structures and properties of α,β-unsaturated γ-oxo acid and their derivatives. In spite of this situation, recently, several natural products with a partial structure of the A, B, or C form have been reported, for example, Cytochalasine A,[6] Pyrenopholin,[7] and (±)-2-acetamido-2,5-dihydro-5-oxofuran.[8,9]

This paper will describe the structure of typical substances, acetylacrylic acid (I), benzoylacrylic acid (II), methyl acetylacrylate (III) and methyl benzoylacrylate (IV), on the basis of chemical and spectral studies.

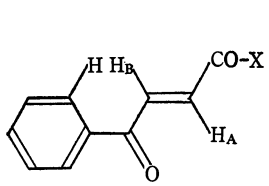
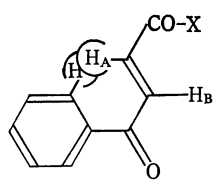
obtained from acetone and glyoxylic acid, and how the NMR spectrum of this acid showed the signal of olefinic protons at τ 3.20 (J=16.2 cps). The I compound, which we obtained by the elimination of hydrogen bromide from β-bromolevulinic acid,[10] showed the same NMR signal as I-A. The ultravioletspectrum showed λ_{max} 220 mμ.

Benzoylacrylic acid (II), which was obtained by the Friedel-Crafts reaction of maleic anhydride and benzene,[4] showed infrared absorption bands at 1700, 1670 and 1635 cm^{-1}, and no absorption between 1800 and 1750 cm^{-1}. In the ultraviolet absorption spectrum bands were observed at λ_{max} 238 mμ and λ_{max} 272 mμ. In the NMR spectrum, the signals of a pair of sharp doublets at τ 3.12 and 1.98 for the olefinic protons were observed. From the fact that the coupling constant, J=15.4 cps, of these olefinic proton signals is nearly equal to the J=16.2 cps of I-A, the structure of benzoylacrylic acid must be a II-A *trans* form.

Since the benzene ring and the remaining part of the molecule should be on the same plane as a result of the conjugation, two isomers, II-A′ and II-A″, are possible. However, inspection of the molecular model of II-A shows that II-A″ is not probable because of the steric hindrance between H_A and an ortho-H of the benzene ring. In II-A′, the deshielding effect of the benzene ring for H_B is expected to be present on account of its proximity to the benzene ring, but no such effect is expected for H_B in II-A″. From the NMR data for olefinic protons of methyl fumarate at τ 3.17,[11] the signal at τ 3.12 was assigned to H_A, and that at τ 1.98, to H_B. From the fact that H_B is more deshielded by the benzene ring, the II-A′ *trans* form is preferred as the structure of benzoylacrylic acid.



II-A′: X=OH
IV-A′: X=OMe



II-A″: X=OH
IV-A″: X=OMe

Methyl Acetylacrylate and Methyl Benzoylacrylate. *By the Elimination of Hydrogen Bromide.* Methyl acetylacrylate (III) was obtained by the elimination of hydrogen bromide from methyl β-bromolevulinate.[12] In the NMR spectrum of this product, an AB quartet signal for the olefinic protons, centered at τ 3.29 (J=15.4 cps), was observed. The infrared absorption spectrum showed carbonyl absorptions at 1725 and 1675 cm^{-1}, and no absorption in the region of the lactone carbonyl band. The ultraviolet absorption spectrum showed a λ_{max} of 220 mμ, similar to that of I-A. These data suggest that the structure of the product which we obtained by this method is in the III-A *trans* form.

By the elimination of hydrogen bromide from methyl β-bromo-β-benzoylpropionate, IV was prepared. In the NMR spectrum of IV we observed a pair of sharp doublets of the olefinic protons at τ 3.12 and 2.16 (J=15.4 cps). The infrared absorption spectrum of IV showed carbonyl absorption bands at 1725 and 1670 cm^{-1} and an olefinic double-bond absorption band at 1630 cm^{-1}, but no absorption band was observed in the lactone carbonyl region. Much as in II-A, the ultraviolet absorption spectrum of IV showed a λ_{max} value of 232 mμ and a λ_{max} value of 270 mμ. These results suggest that methyl benzoylacrylate was in the IV-A′ form.

By the Acid-Catalyzed Esterification. In the presence of sulfuric acid, II-A was esterified to IV.[13] The product was identified with IV-A′ on the basis of the spectral data and by thin-layer chromatography. In the case of the acid-catalyzed esterification of I-A, III-A was obtained in a 10% yield, and methyl α-methoxylevulinate,[14] in a 16% yield. These results suggest that the esterification of I-A and II-A by the acid catalyst occurs.

Isomerization. The treatment of III-A or IV-A with aqueous sodium hydroxide gave a hydrolyzed product, I-A or II-A. In the reaction mixture, the isomerized products were not detected. Thus, acetyl- and benzoylacrylic acids did not isomerize under the basic conditions.

It has been reported that I-A was isomerized by thionyl chloride to 5-methyl-5-chloro-2,5-dihydro-2-oxofuran (VI-C), which, in turn, was converted to I-C with an aqueous alkali.[1] Therefore, it is interesting to examine the reaction of II-A with thionyl chloride, followed by the reaction of methanol instead of an aqueous alkali.

In the NMR spectrum of the reaction mixture of II-A with thionyl chloride, followed by the reaction of methanol, we observed the signals corresponding to three substances, the normal esterified product, IV-A, and two anomalous products, 5-phenyl-5-methoxy-2,5-dihydro-2-oxofuran (IV-C) and methyl α-methoxy-β-benzoylpropionate. The molar ratio of these products was 49 : 21 : 30. The structure of IV-C was deduced from the spectral data. In the infrared absorption spectrum of IV-C absorption bands were observed at 1770 and 1630 cm^{-1}. The NMR spectrum showed olefinic proton signals at τ 3.98 and 2.82, J=5.5

Table 1. The NMR spectra

Comp.	R	X	τ_{Ph}	τ_{Me}	τ_{OMe}	τ_{OH}	τ_{HA}	τ_{HB}	J_{AB}
I-A	Me	OH		7.60		0.27	3.20		16.2
II-A	Ph	OH	1.8—2.8			−1.36	3.12	1.98	15.4
III-A	Me	OMe		7.67	6.22		3.29		15.4
IV-A	Ph	OMe	1.9—2.8		6.19		3.21	2.16	15.4
II-B	Ph	OH	1.9—2.8			−0.92	3.70	2.90	12.0
III-B	Me	OMe		7.73	6.28		3.84		12.5
IV-B	Ph	OMe	2.0—2.8		6.42		3.76	3.13	12.0
I-C	Me	OH		8.23		4.41	3.91	2.77	6.0
IV-C	Ph	OMe	2.0—2.8		6.73		3.98	2.82	5.5

cps. The corresponding J value of I-C was 6 cps. These results suggest that II-A is partly esterified, but also partly isomerized to lactone.

Reaction of II-A with Diazomethane. When II-A was treated with diazomethane, neither IV-A nor IV-C was detected by thin-layer chromatography in the reaction mixture. The reaction of of diazomethane with carboxylic acid frequently does not lead to the expected methyl ester. For example, the reaction of diazomethane with I-A gave the isomerized product III-C,[2] while that with *trans-p*-bromobenzoylacrylic acid gave 4-(*p*-bromobenzoyl)-3-carbomethoxypyrazoline.[13] Thus, α,β-unsaturated γ-oxo acids do not afford the simple methyl ester by reaction with diazomethane.

Photoisomerization. By the photoreaction, the *cis* isomer (B) was produced from the *trans* isomer (A). The details of the photoreactions of α,β-unsaturated γ-oxo acid and their derivatives will be reported in another paper.

Experimental

Acetylacrylic Acid. This acid was prepared by the mehtod of Wolff[10] and was recrystallized from benzene to give colorless crystals, mp 125—126°C.

IR (KBr): 1700, 1670, 1625 cm^{-1}.

UV (EtOH): 220 mμ (ε 13800), 340 mμ (ε 40).

Benzoylacrylic Acid. This acid was prepared by the method of Becker,[4] and was crystallized from benzene to give colorless crystals, mp 95.5—96°C.

IR (KBr): 1700, 1670, 1635 cm^{-1}.

UV (EtOH): 238 mμ (ε 11000), 272 mμ (ε 8900).

Methyl Acetylacrylate. This was prepared by the method of Pauly[12] and was recrystallized from an ether and hexane (1 : 1 v/v) mixture, mp 58.5—60°C.

IR (KBr): 1725, 1675, 1645 cm^{-1}.

UV (EtOH): 220 mμ (ε 14400), 338 mμ (ε 40).

In the presence of sulfuric acid, acetylacrylic acid was esterified, and the product was identified on silica-gel thin-layer chromatography (Wakogel B-5) with a benzene and ethyl acetate (9 : 1 v/v) mixture.

Methyl Benzoylacrylate. This ester was prepared by two methods, by the method of Kohler[15] and by the esterification of the corresponding free acid in the presence of sulfuric acid. In both cases, the crude product was purified by chromatography on silica-gel (Merk 7734) with a benzene and ethyl acetate (9 : 1 v/v) mixture; mp 34°C.

IR (liquid film): 1725, 1670, 1630 cm^{-1}.

UV (EtOH): 232 mμ (ε 15400), 270 mμ (ε 9800).

Base-catalyzed Hydrolysis of III-A and IV-A. To a solution of the III-A or IV-A ester (100 mg) in methanol (2 m*l*), potassium hydroxide (25 mg) in water (1 m*l*) was stirred over a 2-hr period at room temperature. The reaction mixture was then worked up by the usual method, and the product was identified by thin-layer chromatography and by a study of its absorption spectrum.

Isomerization of II-A by Thionyl Chloride. One gram of II-A was dissolved in 2 m*l* of thionyl chloride, after which the mixture was kept for 10 min at 50°C. The mixture was then poured into excess methanol at 0°C. The ratio of the products in the reaction mixture was measured by means of the NMR spectrum and was found to be 49 : 21 : 30.

NMR ($CDCl_3$): τ 6.20 (1.5 H) ester methyl of IV-A. 6.29 (0.9 H) ester methyl of methoxypropionate. 6.59 (0.9H) methoxy of methoxypropionate. 6.71 (0.6 H) methoxy of IV-C.

Reaction with Diazomethane. Benzoylacrylic acid was reacted with diazomethane in ether in the usual manner. The reaction product was chromatographed on a thin layer of silica gel (Wakogel B-5) with a benzene and ethyl acetate (9 : 1 v/v) mixture. No spot corresponding to IV-A or IV-C was observed.

NMR Spectra. The NMR spectra were measured on a Hitachi H-60 High-resolution Nuclear Magnetic Resonance Spectrometer. The solvent was deuterochloroform, and TMS was used as the internal standard. The spectral data are listed in Table 1.

The authors wish to express their thanks to Mr. Kyuzaburo Furuhashi of Department of Chemistry, Tokyo Kyoiku University, for his measurement of the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 974—979 (1968)

Selective Cleavage of Serine Peptides*1

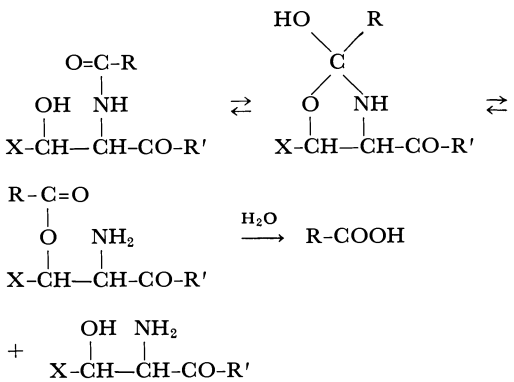
Takeo KANEKO, Ikuko TAKEUCHI*2 and Toshishige INUI*3

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received October 11, 1967)

The treatment of *N*-benzyloxycarbonyl-L-alanyl-L-serine methyl ester (I) with phosgene afforded the corresponding *O*-chlorocarbonyl derivative (II), which was then cyclized to methyl L-3-(*N*-benzyloxycarbonyl-L-alanyl)-2-oxo-oxazolidine-4-carboxylate (III) accompanied with *N*-benzyloxycarbonyl-L-alanyl-3-chloro-L-alanine methyl ester (IV) by refluxing in xylene. By the mild alkaline hydrolysis of III, *N*-benzyloxycarbonyl-L-alanine and L-2-oxo-oxazolidine-4-carboxylic acid (V) were isolated as a result of the selective cleavage of the peptide bond in which an amino group of the serine residue participated. This method was also applied to three other serine peptides; the same results were obtained.

The method of the selective cleavage of proteins by enzymes is very valuable in the elucidation of their structure.[1,2] On the other hand, the use of the selective cleavage of peptide bonds on the special amino acid residue in proteins by chemical reagents is also important in achieving fragments different from those obtained by enzymes and so in determining their sequences. Recently, the techniques for the selective chemical cleavage on tyrosyl, tryptophyl, histidyl and methionyl peptides have been developed by Witkop and others.[1,3-6] N→O Acyl group migration with acid and subsequent hydrolysis induced selective cleavage on the serine or threonine residue in proteins.[7] Threonine peptides were cyclized with phosgene to their oxazolidone derivatives, the hydrolysis of which with a dilute alkali also afforded selective cleavage at the peptide linkage involving the amino group of the threonine residue.[8]



X=H: Serine, X=CH_3: Threonine

Another hydroxy-amino acid, serine, was also cyclized with phosgene to an oxazolidone derivative.[9]

In a similar fashion, if serine peptides involving a peptide linkage between the amino group of the serine residue and the carboxyl group of another amino acid residue are cyclized with phosgene to the corresponding oxazolidone peptides at their serine residue, the peptides thus obtained will selectively be cleft in two parts at the amino group of the serine residue by alkaline hydrolysis. In order to investigate the selective cleavage of this type on serine peptides, *N*-benzyloxycarbonyl- L -alanyl- L -serine methyl ester (I), L-seryl-L-alanine (VI), *N*-benzyloxycarbonylglycyl-L-seryl-L-alanine methyl ester (VIII), and *N*-benzyloxycarbonyl- L -alanyl-L-alanyl-L-serine methyl ester (IX) were used as the model peptides in the present study.

I,[10] obtained from *N*-benzyloxycarbonyl-L-alanine and methyl L-serinate hydrochloride by using the *N*,*N'*-dicyclohexylcarbodiimide method, was converted with phosgene to the *O*-chlorocarbonyl derivative (II) by using the method of Bergel.[11] In threonine peptides, their *O*-chlorocarbonyl compounds were easily cyclized, under reflux in xylene, to the corresponding oxazolidone derivatives in good yields.[8] Under the same experimental conditions, II provided a crystal melting at 93—109°C; this was clarified as being a mixture of methyl L-3-(*N*-benzyloxycarbonyl-L-alanyl)-2-oxo-oxazolidine-4-carboxylate (II) and *N*-benzyloxycarbonyl-L- alanyl - 3 - chloro-L-alanine methyl ester (IV) by thin-layer chromatography with silica gel G (TLC) and by means of a study of the infrared spectra. The ratio of III to IV in the reaction mixture was established to be about two-to-one by an analysis of its infrared spectra. The separation of III from IV was achieved by using a column with silica gel and by eluting it with a mixture of benzene and methanol (19 : 1, v/v). The structure of III was confirmed by elemental analysis and by a study of its infrared spectra. On the other hand, the minor component, exhibiting a strongly positive Beilstein's test, was also confirmed to have IV by a study of its nuclear magnetic resonance spectra. Various conditions for cyclizing of II were then studied. The yield of the mixture which was obtained by the reflux of II in toluene was decreased to about two-thirds of that obtained under the above conditions, but the ratio of III to IV was increased to about eight-to-one. In another experiment, II was treated with an equivalent amount of pyridine in benzene; the product isolated was identified by TLC as IV, accompanied by a small amount of I.

The alkaline hydrolysis of III afforded *N*-benzyloxycarbonyl-L-alanine and L-2-oxo-oxazolidine-4-carboxylic acid (V) in yields of 89% and 68% respectively. The structures of the products isolated were confirmed by comparisons of their melting points, specific rotations, and infrared spectra with those of the corresponding authentic specimens. For comparison, the authentic V was prepared from L-serine by the method described for the cyclization of L-threonine.[12]

A peptide containing the serine residue as the amino terminal unit should be cyclized to an oxazolidone peptide without any change in the peptide bond. VI[13] was readily cyclized with phosgene to L-2-oxo-oxazolidine-4-carbonyl-L-alanine (VII) in an alkaline solution.

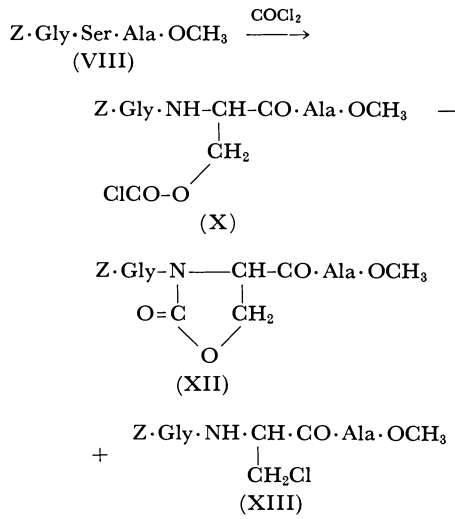
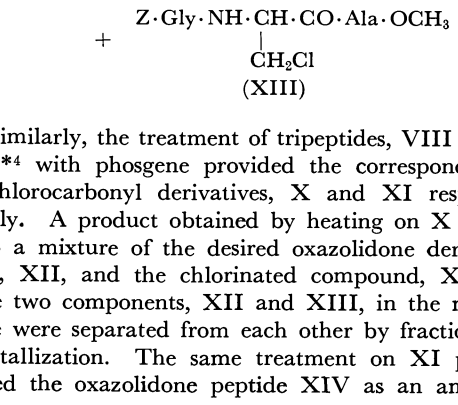
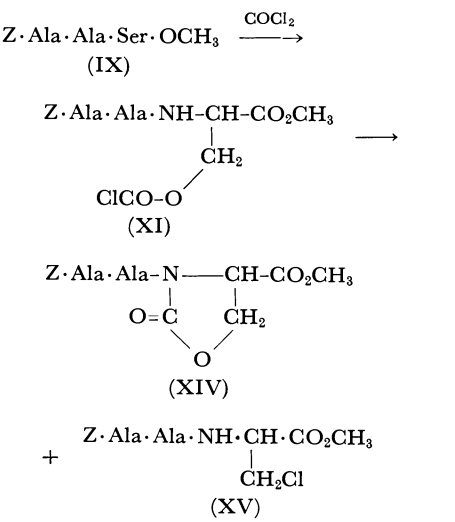
TABLE 1. RESULTS OF THE SELECTIVE CLEAVAGE OF SERINE PEPTIDES

Peptide	Oxazolidone derivative	Products isolated by alkaline hydrolysis (yields)	
I	III	Z·Ala·OH (89%)	V (68%)
VIII	XII	Z·Gly·OH (81%)	VII (40%)
IX	XIV	Z·Ala·Ala·OH (60%)	V (46%)







Similarly, the treatment of tripeptides, VIII and IX,*4 with phosgene provided the corresponding *O*-chlorocarbonyl derivatives, X and XI respectively. A product obtained by heating on X was also a mixture of the desired oxazolidone derivative, XII, and the chlorinated compound, XIII. The two components, XII and XIII, in the mixture were separated from each other by fractional crystallization. The same treatment on XI provided the oxazolidone peptide XIV as an amorphous solid (probably contaminated with a small amount of the chlorinated compound XV, for it gave a slightly positive Beilstein's test), which was used for the next step without further purification. The cleavage reactions of XII and XIV were also studied; the results were summarized in Table 1, plus those for III.

In conclusion, this selective cleavage of serine peptide occurs on the peptide linkage involving an amino group of the serine residue through its oxazolidone derivative without racemization.

Experimental*5

***N*-Benzyloxycarbonyl-L-alanyl-L-serine Methyl Ester (I).** A solution containing 22.3 g (0.10 mol) of *N*-benzyloxycarbonyl-L-alanine, 15.6 g (0.10 mol) of methyl L-serinate hydrochloride, and 14.0 m*l* (0.10 mol) of triethylamine in 225 m*l* of chloroform was treated with a solution of 20.6 g (0.10 mol) of *N,N'*-dicyclohexylcarbodiimide in 50 m*l* of chloroform. After the mixture had been stirred for 3 hr and then stood overnight at room temperature, the *N,N'*-dicyclohexylurea which precipitated was filtered off, and the filtrate was successively washed with water, dilute hydrochloric acid, and dilute aqueous sodium hydrogen carbonate solution. The dried solution was evaporated *in vacuo*, thus providing white crystals which were then recrystallized from ethyl acetate - petroleum ether. Yield, 22.5 g (70%), mp 134.5—135.5°C, $[\alpha]_D^{23.5}$ −17.7° (*c* 3.43, methanol), lit.,[10] mp 134—135°C.

Found: C, 55.80; H, 6.32; N, 8.64%. Calcd for $C_{15}H_{20}O_6N_2$: C, 55.55; H, 6.22; N, 8.64%.

***N*-Benzyloxycarbonyl-L-alanyl-*O*-chlorocarbonyl-L-serine Methyl Ester (II).** Phosgene was passed through a stirred suspension of 8.1 g (0.025 mol) of I and 3.0 g (0.025 mol) of *N,N*-dimethylaniline in 100 m*l* of benzene for 30 min at 5—10°C. After it had been stirred for 3 hr and then left to stand overnight below 20°C, the reaction mixture was bubbled with a stream of nitrogen (or carbon dioxide) until the excess phosgene had been removed, and then washed with dilute hydrochloric acid and water. The dried solution was evaporated *in vacuo*, thus providing white crystals which were then recrystallized by precipitation with the addition of petroleum ether to a solution of the product in a minimum amount of benzene. Yield, 7.6 g (79%), mp 93.5—94°C, $[\alpha]_D^{23}$ +20.1° (*c* 3.58, benzene).

Found: C, 49.76; H, 5.16; N, 7.63; Cl, 8.30%. Calcd for $C_{16}H_{19}O_7N_2Cl$: C, 49.68; H, 4.95; N, 7.24; Cl, 9.17%.

The treatment of a solution of II in benzene with an

*4 The preparations of these peptides, VIII and IX, will be described in Experimental section below.

*5 All melting points are uncorrected.

etheral solution of aniline gave the *N*-benzyloxycarbonyl-L-alanyl-*O*-(*N*-phenylcarbamoyl)-L-serine methyl ester; mp 146.3—146.8°C, $[\alpha]_D^{23.5}$ −7.8° (*c* 2.31, methanol).

Found: C, 60.02; H, 5.70; N, 9.40%. Calcd for $C_{22}H_{25}O_7N_3$: C, 59.58; H, 5.68; N, 9.48%.

Methyl L-3-(*N*-Benzyloxycarbonyl-L-alanyl)-2-oxo-oxazolidine-4-carboxylate (III) and *N*-Benzyloxycarbonyl-L-alanyl-3-chloro-L-alanine Methyl Ester (IV). A solution of 7.0 g (0.018 mol) of II in 70 m*l* of xylene was refluxed for 6 hr. The solution was then evaporated *in vacuo*, leaving an oil which was crystallized by seeding. Yield, 4.3—5.0 g, mp 93—109°C. It gave a positive Beilstein's test and exhibited two spots on TLC. The ratio of III to IV in the crystals was found to be 1.9—2.1 by an analysis of its infrared spectra.

A solution of 3.0 g of the crude product in 10 m*l* of hot benzene was adsorbed on a column (1.6×30 cm) with 30 g of silica gel, eluted with a mixture of benzene and methanol (19 : 1, v/v), and divided into four fractions by TLC.

The evaporation of the first fraction (170 m*l*) left no residue.

The second fraction (25 m*l*), exhibiting a single spot on TLC, was evaporated *in vacuo*, leaving III as white crystals. Yield, 1.1 g, mp 101.5—103°C. For analysis, it was also recrystallized from benzene - petroleum ether (3 : 1); mp 102.5—103.5°C, $[\alpha]_D^{23.5}$ −126.5° (*c* 3.09, methanol).

IR (Nujol mull): 1820, 1785 (C=O group in the oxazolidone ring); 1755 (C=O group in the ester); 1710 cm^{-1} (C=O group in the benzyloxycarbonyl group).

NMR (Chloroform solution): 1.46 (doublet, J=6.8 cps, CH_3 peak in the alanine residue); 3.82 ppm (singlet, CH_3 peak in the ester group).

Found: C, 54.99; H, 5.26; N, 8.02%. Calcd for $C_{16}H_{18}O_7N_2$: C, 54.85; H, 5.18; N, 8.00%.

The evaporation of the third fraction (20 m*l*) provided 0.8 g of a mixture of III and IV which melted at 95—108°C.

The evaporation of the fourth fraction (35 m*l*) provided 0.3 g of IV contaminated with a minor amount of III, as indicated by TLC. The recrystallization of the crude product, which melted at 120—134°C, from methanol and then from benzene raised the melting point to 150.5—151.3°C, $[\alpha]_D^{21.5}$ +14.1° (*c* 1.46, methanol).

IR (Nujol mull): 1655, 1530 (–CONH– group in the peptide bond); 1750 (C=O group in the ester); 1690 cm^{-1} (C=O group in the benzyloxycarbonyl group).

NMR (Chloroform solution): 1.26 (doublet, J= 7.2 cps, CH_3 peak in the alanine residue); 3.80 (singlet, CH_3 peak in the ester group); 3.91 ppm (doublet, J= 3.0 cps, $>CH_2$ peak in the $Cl{\cdot}CH_2{\cdot}CH<$ group).

Found: C, 52.73; H, 5.60; N, 8.31; Cl, 10.24%. Calcd for $C_{15}H_{19}O_5N_2Cl$: C, 52.56; H, 5.59; N, 8.17; Cl, 10.34%.

The refluxing of a solution of 3.7 g (0.0096 mol) of II in 40 m*l* of toluene for 6 hr provided another mixture of III and IV, in which the ratio of III to IV was 8.4. Yield, 1.7 g, mp 99—102°C.

L-2-Oxo-oxazolidine-4-carboxylic Acid (V). A solution of 4.2 g (0.04 mol) of L-serine in 80 m*l* (0.04 mol) of 0.5 N potassium hydroxide was treated with a solution of 4.8 g (0.048 mol) of phosgene in 20 m*l* of toluene in the presence of 8.3 g (0.06 mol) of anhydrous potassium carbonate for 3 hr at 0—5°C. The aqueous layer which separated from the toluene layer was acidified with 6 N hydrochloric acid to pH 1 and evaporated to dryness *in vacuo*. The residue was then extracted five times with hot ethyl acetate, and the dried extract was evaporated *in vacuo* to give crystals which melted at 116—117°C. Yield, 2.8 g (54%). Recrystallization from ethyl acetate - petroleum ether raised the melting point to 118.5—120°C, $[\alpha]_D^{22.5}$ −17.7° (*c* 3.44, water), lit.,[14] mp 118°C, $[\alpha]_D^{15}$ −10.95° (*c* 4.20, water).

Found: C, 36.80; H, 3.96; N, 11.03%. Calcd for $C_4H_5O_4N$: C, 36.65; H, 3.85; N, 10.69%.

Cyclohexylammonium salt; mp 155.0—155.8°C (decomp.), $[\alpha]_D^{19}$ −19.3° (*c* 3.11, water).

Found: C, 51.90; H, 8.12; N, 12.09%. Calcd for $C_{10}H_{18}O_4N_2$: C, 52.16; H, 7.88; N, 12.17%.

The hydrolysis of the sample of V with 6 N hydrochloric acid gave the L-serine; mp 214—215°C (decomp.), $[\alpha]_D^{21.5}$ +14.7° (*c* 2.91, 1 N hydrochloric acid).

Alkaline Hydrolysis of III. To a solution of 2.80 g (0.008 mol) of III in 40 m*l* of methanol 16.0 m*l* (0.016 mol) of 1 N potassium hydroxide were added, after which the reaction mixture was stirred for 1.5 hr at room temperature. After the evaporation of the methanol *in vacuo*, the residue was diluted with water and the aqueous solution was acidified with 8.5 m*l* of 1 N hydrochloric acid to pH 3.5. The separated oil was extracted with ethyl acetate. The dried extract was then evaporated to dryness *in vacuo*, leaving a crystalline *N*-benzyloxycarbonyl-L-alanine. Yield, 1.59 g (89%), mp 80—82.7°C and 86.0—87.3°C after recrystallization from chloroform - petroleum ether, $[\alpha]_D^{20.5}$ −13.0° (*c* 3.15, acetic acid); lit.,[15] mp 87°C, $[\alpha]_D^{27}$ −13.9° (*c* 2, acetic acid).

A mixed melting point with an authentic sample was not depressed.

An additional 8.5 m*l* of 1 N hydrochloric acid was added to the remaining aqueous solution. The residue, obtained by the evaporation of the acidic solution, was extracted three times with 20-m*l* portions of hot ethyl acetate; the evaporation of the combined extracts provided V as an oil which was crystallized by seeding. Yield, 0.71 g (68%), mp 95—103°C and 117—119°C after recrystallization from ethyl acetate - petroleum $[\alpha]_D^{20.5}$ −17.5° (*c* 3.43, water).

All the properties of the sample were identical with those of the cyclized product of L-serine.

L-Seryl-L-alanine (VI). This compound was prepared by the catalytic hydrogenation of 4.5 g (0.014 mol) of *N*-benzyloxycarbonyl-L-seryl-L-alanine [mp 157—158°C, $[\alpha]_D^{22.5}$ −12.5° (*c* 3, methanol)], which had been obtained from its methyl ester by hydrolysis with an equivalent amount of 1 N sodium hydroxide in methanol, with 0.5 g of 10% palladium on carbon in a mixture of 120 m*l* of methanol and 50 m*l* of water, according to the directions of Fruton.[13] Yield, 2.2 g (89%), mp 223—225°C (decomp.) after recrystallization from water-acetone, $[\alpha]_D^{24.5}$ −31.8° (*c* 6, 1 N hydrochloric acid), lit.,[13] $[\alpha]_D^{26}$ −30.4° (*c* 6, 1 N hydrochloric acid).

14) T. Saito, This Bulletin, **37**, 624 (1964).
15) M. Hunt and V. du Vigneaud, *J. Biol. Chem.*, **124**, 699 (1938).

Found: C, 40.99; H, 6.86; N, 15.85%. Calcd for $C_6H_{12}O_4N_2$: C, 40.90; H, 6.87; N, 15.90%.

L-2-Oxo-oxazolidine-4-carbonyl-L-alanine (VII). In the way similar to that described for the preparation of V, a solution of 3.7 g (0.021 mol) of VI in 44 m*l* (0.022 mol) of 0.5 N potassium hydroxide was treated with 25 g (0.025 mol) of a 10% solution of phosgene in toluene in the presence of 3.5 g (0.025 mol) of anhydrous potassium carbonate. The crude product which separated from the salt was dissolved in water, the aqueous solution was passed through a column of Dowex 50 (H^+ form), and the column was thoroughly washed with water. The combined aqueous solution was then evaporated to dryness *in vacuo* to give a syrup which was crystallized by the addition of petroleum ether to a methanol solution of the product. Yield, 2.5 g (60%), mp 178—181°C (decomp.). Recrystallization from ethanol - petroleum ether raised the melting point to 188—191°C (decomp.), $[\alpha]_D^{18}$ −28.3° (*c* 3, water).

Found: C, 41.43; H, 5.15; N, 13.96%. Calcd for $C_7H_{10}O_5N_2$: C, 41.58; H, 4.99; N, 13.86%.

Cyclohexylammonium salt; mp 196—197.5°C (decomp.) after recrystallization from methanol-ether.

Found: C, 51.83; H, 7.83; N, 14.12%. Calcd for $C_{13}H_{23}O_5N_3$: C, 51.81; H, 7.69; N, 13.95%.

***N*-Benzyloxycarbonylglycyl - L - seryl - L - alanine Methyl Ester (VIII).** A solution of 1.4 g (0.005 mol) of *N*-benzyloxycarbonylglycyl-L-serine methyl ester[10] [mp 96.5—98.5°C, $[\alpha]_D^{14.5}$ −4.0° (*c* 6, methanol)] and 0.5 m*l* of 85% hydrazine hydrate in 30 m*l* of ethanol was allowed to stand overnight at room temperature. The crystal, *N*-benzyloxycarbonylglycyl-L-serine hydrazide, which separated from the solution were collected by filtration. Yield, 1.3 g (93%), mp 220—221°C (decomp.) after recrystallization from ethanol-water, $[\alpha]_D^{13}$ −9° (*c* 1, acetic acid).

Found: C, 50.61; H, 5.97; N, 18.12%. Calcd for $C_{13}H_{18}O_5N_4$: C, 50.31; H, 5.85; N, 18.06%.

In a mixture of 50 m*l* of water, 5 m*l* of acetic acid, and 20 m*l* of 6 N hydrochloric acid, 3.1 g (0.010 mol) of the above hydrazide was dissolved and the resultant solution was cooled to −5°C. To the solution a cold 7-m*l* portion (0.010 mol) of a 10% aqueous sodium nitrite solution was added, and the mixture was stirred for 20 min at 0°C. The azide which separated from the reaction mixture was extracted with 250 m*l* of ethyl acetate, and the extract was washed with ice water, a 3% aqueous sodium hydrogen carbonate solution, and finally ice water below −5°C. To the cold, dried solution there was then added another cold, dried solution of methyl L-alaninate equivalent to 1.4 g (0.010 mol) of its hydrochloride in 20 m*l* of chloroform at 0°C. The reaction mixture was stirred for 2 hr below 5°C and allowed to stand overnight in a refrigerator. After washing with water, a 3% aqueous sodium hydrogen carbonate solution, 1 N hydrochloric acid, and water, the evaporation of the dried organic layer *in vacuo* provided 1.9 g (50%) of VIII. Mp 135.5—137°C after recrystallization from water, $[\alpha]_D^{11}$ −38.2° (*c* 3, methanol).

Found: C, 51.29; H, 6.33; N, 10.67%. Calcd for $C_{17}H_{23}O_7N_3 \cdot H_2O$: C, 51.12; H, 6.31; N, 10.52%.

***N*-Benzyloxycarbonylglycyl-*O*-chlorocarbonyl-L-seryl-L-alanine Methyl Ester (X).** In the same manner as has been described for the preparation of II, a solution of 3.9 g (0.01 mol) of VIII in 50 m*l* of anhydrous dioxane was treated with an excess of phosgene in the presence of 2.0 g (0.016 mol) of *N*,*N*-dimethylaniline below 10°C. After the excess phosgene had been removed, the reaction mixture was evaporated *in vacuo* and the residue was taken up with ethyl acetate. The ethyl acetate solution was washed with 0.1 N hydrochloric acid and water, and the dried solution was evaporated *in vacuo* to give an oil which was crystallized by adding petroleum ether. Yield, 3.2 g (73%), mp 126.5—127°C after recrystallization from acetone-petroleum ether, $[\alpha]_D^{18}$ −4.5° (*c* 0.7, dioxane).

Found: C, 49.39; H, 5.23; N, 8.93; Cl, 7.79%. Calcd for $C_{18}H_{22}O_8N_3Cl \cdot \frac{1}{2}C_3H_6O$: C, 49.25; H, 5.34; N, 8.89; Cl, 7.50%.

L-3-(*N*-Benzyloxycarbonylglycyl)-2-oxo-oxazolidine-4-carbonyl-L-alanine Methyl Ester (XII) and *N*-Benzyloxycarbonylglycyl-3-chloro-L-alanyl-L-alanine Methyl Ester (XIII). A solution of 4.8 g (0.010 mol) of X in 250 m*l* of toluene was refluxed for 4 hr under a stream of nitrogen and then evaporated to dryness *in vacuo*. The residue was extracted with chloroform, and the dried extract was again evaporated *in vacuo* to provide an oil which exhibited two spots upon TLC. From this oil, XII was separated as crystals by adding a small amount of petroleum ether and by scratching on the wall of the vessel. Yield, 1.2 g (27%), mp 155—160°C. Recrystallization from chloroform-petroleum ether and then from ethyl acetate - petroleum ether raised the melting point to 172.5—173°C, $[\alpha]_D^{14}$ −113.8° (*c* 0.9, methanol).

Found: C, 52.84; H, 5.17; N, 10.18%. Calcd for $C_{18}H_{21}O_8N_3$: C, 53.07; H, 5.20; N, 10.32%.

The mother liquor remaining after the filtration of XII was evaporated to dryness *in vacuo*, and to the residue there was added a large amount of petroleum ether in order to obtain XIII as another crystal, which was collected by filtration. Yield, 0.2 g, mp 137—139°C. Recrystallization from ethyl acetate - petroleum ether raised the melting point to 140.5—141°C. It gave a positive Beilstein's test.

Found: C, 51.19; H, 5.55%. Calcd for $C_{17}H_{22}O_6N_3Cl$: C, 51.06; H, 5.56%.

Alkaline Hydrolysis of XII. In a manner similar to that described for the hydrolysis of III, 1.0 g (0.0025 mol) of XII was hydrolyzed with a mixture of 5 m*l* (0.005 mol) of 1 N potassium hydroxide and 50 m*l* of methanol. After the evaporation of the solvent, the residue was diluted with water and acidified with 1 N hydrochloric acid to pH 3. From the ethyl acetate extract, 0.42 g (81%) of *N*-benzyloxycarbonylglycine was isolated, all the properties of which were identical with those of an authentic sample.

On the other hand, 0.2 g (40%) of VII was isolated from the aqueous solution as an oil which was purified as its cyclohexylammonium salt. No melting-point depression upon mixture with an authentic specimen obtained from the cyclized product of VI was observed.

***N*-Benzyloxycarbonyl-L-alanyl-L-alanyl-L-serine Methyl Ester (IX).** Seven and seven-tenths grams (0.025 mol) of *N*-benzyloxycarbonyl-L-alanyl-L-alanine hydrazide [mp 212—213°C, $[\alpha]_D^{18}$ −67.4° (*c* 1.84, 0.5 N hydrochloric acid)] were converted into its azide according to the directions of Erlanger.[16] To the cold,

16) B. F. Erlanger and E. Brand, *J. Am. Chem. Soc.*, **73**, 3508 (1951); E. Brand, B. F. Erlanger, H. Sachs and J. Polantnick, *ibid.*, **73**, 3510 (1951).

dried solution of the above azide in 200 ml of ethyl acetate-ether (1 : 1), there was added another cold, dried solution of methyl L-serinate equivalent to 6.1 g (0.039 mol) of its hydrochloride in a mixture of 45 ml of chloroform and 100 ml of ethyl acetate below 5°C. The reaction mixture was then stirred for 3 hr below 5°C and allowed to stand for 20 hr in a refrigerator. The crystals which separated were collected by filtration and washed with acetone, acetone-water (1 : 1), and finally acetone again. Yield, 6.4 g (65%), mp 197—198°C (sintered at 164°C). The melting point was unchanged after recrystallization from acetone. $[\alpha]_D^{16.5}$ −50.1° (*c* 3.53, methanol).

Found: C, 54.73; H, 6.54; N, 10.52%. Calcd for $C_{18}H_{25}O_7N_3$: C, 54.67; H, 6.37; N, 10.63%.

N-Benzyloxycarbonyl-L-alanyl-L-alanyl-O-chlorocarbonyl-L-serine Methyl Ester (XI). In a manner similar to that described for the preparation of II, 8.0 g (0.02 mol) of IX was converted to XI with phosgene in the presence of 2.4 g (0.02 mol) of *N,N*-dimethylaniline in 100 ml of anhydrous dioxane. Yield, 7.7 g (83%), mp 143.5—144.0°C (decomp.) after recrystallization from benzene, $[\alpha]_D^{12.5}$ −3.7° (*c* 2.72, dioxane).

Found: C, 50.34; H, 5.44; N, 9.24; Cl, 7.31%. Calcd for $C_{19}H_{24}O_8N_3Cl$: C, 49.84; H, 5.28; N, 9.18; Cl, 7.74%.

Methyl L-3-(N-Benzyloxycarbonyl-L-alanyl-L-alanyl)-2-oxo-oxazolidine-4-carboxylate (XIV). A solution of 10.0 g (0.022 mol) of XI in 130 ml of xylene was refluxed for 6 hr. The solvent was then evaporated *in vacuo*, leaving a syrup which was dissolved in 130 ml of ethyl acetate. The solution was treated with 3 ml of pyridine for 1.5 hr at room temperature under occasional shaking and then washed with dilute hydrochloric acid, a dilute aqueous sodium hydrogen carbonate solution, and water. The evaporation of the dried solution *in vacuo* provided a syrup, which was taken up with 50 ml of acetone. The decolorized solution was evaporated again to dryness *in vacuo* to give an amorphous solid. Yield, 6.2 g (67%). It gave a slightly positive Beilstein's test and exhibited a main spot, accompanied with two minor spots, upon TLC.

Alkaline Hydrolysis of XIV. In a way similar to that described for the hydrolysis of III, 4.67 g (0.011 mol) of the amorphous XIV was hydrolyzed with a mixture of 23.0 ml (0.023 mol) of 1 N potassium hydroxide and 75 ml of methanol. After the evaporation of the solvent, the residue was diluted with water and acidified with 1 N hydrochloric acid to pH 3. From the ethyl acetate extract, 1.96 g (60%) of crude *N*-benzyloxycarbonyl-L-alanyl-L-alanine were isolated, found to be contaminated with minor components upon TLC. It was purified and identified as its cyclohexylammonium salt*6 (0.73 g); mp 195—197°C (decomp.), $[\alpha]_D^{12}$ −34.7° (*c* 3.14, water).

V was isolated from the aqueous solution. Yield, 0.67 g (46%), mp 116—118°C after recrystallization from ethyl acetate-petroleum ether, $[\alpha]_D^{12}$ −17.8° (*c* 2.97, water). It was also identified as its cyclohexylammonium salt; mp 154—155°C (decomp.), $[\alpha]_D^{13.5}$ −19.8° (*c* 3.43, water).

The authors wish to express their thanks to the Ajinomoto Co., Inc., for supplying the amino acids.

*6 An authentic sample was prepared from *N*-benzyloxycarbonyl-L-alanyl-L-alanine[17] by the treatment of cyclohexylamine; mp 197—198°C (decomp.), $[\alpha]_D^{12}$ −35.0° (*c* 3.32, water). Found: C, 61.10; H, 8.00; N, 10.50%. Calcd for $C_{20}H_{31}O_5N_3$: C, 61.05; H, 7.94; N, 10.68%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 980—987 (1968)

Dihydroxyquinoxaline Studies. Solubility, Ionization Constant, and Chelating Behavior*[1]

Shoshichi OGUCHI

Department of Chemistry, Faculty of Education, The Tokyo Gakugei University, Koganei, Tokyo

(Received October 12, 1967)

The solubility, ionization constant, and chelating behavior of dihydroxyquinoxaline, mainly 5,8-dihydroxyquinoxaline (5,8-DHQ) derivatives, have been measured and will be discussed. The introduction of a hydroxyl group into quinoxaline greatly lowers the solubility. The order of the decreasing solubility of 2,3-disubstituted 5,8-DHQ in water (at 20°C) is: $O(CH_2)_2OC_2H_5 < H < OH < CH_3 < C_6H_5 < OC_2H_5 < Cl < SH < SC_2H_5$. For 5,8-DHQ the introduction of electron-repelling groups into 2,3-positions raises both the pK_{NH} and pK_{OH} values, while the introduction of electron-attracting groups into the same positions lowers both pK_{NH} and pK_{OH}. 5,8-DHQ and its derivatives form colored precipitates with metal ions, but some derivatives which have pK_{NH} values lower than zero fail to show any precipitation or coloration. 6,7-DHQ forms precipitate, and the precipitation colors distinctively with Cr(III) or Fe(II). The composition and stability constant (K) of copper(II) chelates of 5,8-DHQ and its derivatives in a dioxane-water (10 : 90 v/v) solution were studied spectrometrically. The copper chelate of 5,8-DHQ had a metal: ligand ratio of 1 : 1 and a log K value of 6.28 at pH 4.0. The structures of these copper chelates will be proposed.

It has been reported that 5,8-dihydroxyquinoxaline (5,8-DHQ) produces more deeply colored inner salts with many kinds of metallic ions[1] than 8-hydroxyquinoline, and that 5-hydroxyquinoxaline[2] and 5,8-DHQ[3] show a growth-inhibiting bacterial action. In this series of studies the author has attempted to find some useful knowledge about DHQ derivatives in the field of analytical chemistry and pharmaceutical science. Many derivatives of DHQ have been prepared,[4,5] and their solubility, ionization constants, and chelating behavior have been determined.

Experimental

Materials. All the reagents used in this work except 2,3,5,8-tetrahydroxyquinoxaline and 1,4-dimethyl-5,8-dimethoxy-2,3-dioxo-1,2,3,4-tetrahydroquinoxaline have been described previously[4,5] (see Table 1). Those two were prepared as follows.

2,3,5,8-Tetrahydroxyquinoxaline. A mixture of 2,3-dihydroxy-5,8-dimethoxyquinoxaline,[5] acetic acid, and hydrobromic acid (48%) was refluxed for 6 hr; then the mixture was poured into water and neutralized with aqueous ammonia. The precipitate thus formed was filtered and washed with water. The compound was hardly soluble in the organic solvents tested, even in pyridine or dimethylformamide. The compound was purified by repeated dissolutions in alkali and by reprecipitation by acetic acid. A colorless powder which does not melt below 360°C was produced. Yield, 75%.

Found: N, 14.37%. Calcd for $C_8H_6O_4N_2$: N, 14.43%.

1,4-Dimethyl-5,8-dimethoxy-2,3-dioxo-1,2,3,4-tetrahydroquinoxaline. 5,8-Dimethoxy-2,3-DHQ (1.5 g) was dissolved in a 2 N aqueous solution (60 m*l*) of sodium hydroxide and shaken with dimethyl sulfate (6 m*l*) for 2 hr. The reaction mixture was then cooled and extracted with chloroform. After the removal of the chloroform, the residue was repeatedly recrystallized from methanol. Yield, 1.1 g (65%). Colorless needles which melt at 180°C were produced. Found: C, 57.52; H, 5.38; N, 10.58%. Calcd for $C_{12}H_{14}O_4N_2$: C, 57.59; H, 5.64; N, 11.20%.

Apparatus and Procedure. Measurements of the absorbance in the visible and ultraviolet regions were made with a Hitachi EPU-2A spectrophotometer and an EPS-3T recording spectrophotometer, using quartz-stoppered cells with a light path of 10 mm.

pH Measurements were made with a Hitachi-Horiba Model P extension glass and calomel electrodes.

The first ionization constant of pK_{NH} quinoxaline derivatives, the so-called "*proton-gained* pK_a" value, was measured by the spectrometric method in a dioxane-water (10 : 90 v/v) solution in the usual manner.[6,7]

For the pH range from 1 to 9, a hydrochloric acid-formic acid buffer, acetate buffer, a phosphate buffer and a borax-potassium hydroxide buffer were used, in that order. For the compounds whose pK_a values lie below 1, hydrochloric acid or sulfuric acid was used and the pK_a values were calculated using the acidity function.[8,9] The first ionization constant of the pK_{OH} hydroxyl group, the so-called "*proton-lost* pK_a" value, was calculated from the data of the titration curve in a dioxane-water (50 : 50 v/v) mixture.[10,11] A mixed solvent was used because of the insolubility of DHQ in water.

The solubility in water was measured at 20±1°C spectroscopically and gravimetrically by the method Albert has reported.[12] A sample was dissolved in deoxidized water under a nitrogen stream at 100°C and left to stand at 20±1°C for one day under a nitrogen atmosphere before measurements.

Reactions with Metal Ions. The following metal ions were tested at pH 5.2 (A), 8.4 (B), and 12.4 (C) for precipitation and coloration: Mg(II), Ca(II), Cu(II), Cd(II), Hg(II), Al(III), Pb(II), Sn(II), Sn(IV), Th(IV), Zr(IV), Ce(IV), As(III), As(V), Cr(III), Mn(II), Fe(II), Fe(III), Co(II), Ni(II), Ag(I).

The degree of dissociation (α) and the stability constant (K) of chelate compounds were determined by the following formula, which was measured spectrophotometrically by the molar ratio method: $\alpha = (A_m - A_s)/A_m$, where A_m is the maximum extinction obtained from the horizontal portion of the curve and whose A_s is the extinction at the stoichiometric ratio. The stability constant, K, for a chelate compound, ML_n, was calculated by the following formula:[13,14] $K = (1-\alpha)/n^n C^n \alpha^{n+1}$, where C is the total concentration of the chelate in mol/*l*.

Results and Discussion

Solubility. The solubility of a number of quinoxaline derivatives has been determined; the results are shown in Table 1. The introduction of one hydroxyl group into quinoxaline lowers the solubility roughly 400 times. When two hydroxyl groups are introduced into quinoxaline, the solubility decreases from 1000 to 15000 times (Nos. 3—5). As Albert pointed in his study of pteridine[15] and purin series,[16,17] these decreases are probably to be attributed to unusually strong crystal lattice forces originating in the hydrogen bonding between the hydroxyl groups and the ring-nitrogen atoms of the neighbouring molecules of quinoxaline derivatives. These very hydrophilic groups in the organic molecules exert more attraction toward each other than toward water molecules. This is clearly demonstrated by the following facts. The alkoxyl derivatives or *N*-methyl derivatives of quinoxaline, which are not capable of forming hydrogen bonding, show a remarkable increase in solubility. 5-Methoxyquinoxaline is 22 times more soluble than 5-hydroxyquinoxaline (Nos. 1 and 2; see also Nos. 3 and 7, Nos. 4 and 8, and Nos. 10 and 19). *N,N'*-Dimethyl derivatives of 2,3-DHQ are 115 times more soluble than 2,3-DHQ (Nos. 5 and 31; see also Nos. 23 and 28), which exists predominantly in the diamide form in solution.[18] However, the *O*-methyl derivative (No. 9) of 2,3-DHQ (No. 5) shows an exceptionally smaller solubility than 2,3-DHQ.

Lipoid-solubilizing groups (*e.g.*, Me, Ph, Cl, OC_2H_5, and SC_2H_5) decreased the solubility of 5,8-dimethoxyquinoxaline (5,8-DMQ) and 5,8-DHQ. This phenomenon can be seen in the following compounds: Nos. 7 : 19, Nos. 3 : 10 (Me); Nos. 7 : 20, Nos. 3 : 11 (Ph); Nos. 7 : 26 Nos. 3 : 17 (Cl); Nos. 7 : 21, Nos. 3 : 12 (OC_2H_5), and Nos. 7 : 24 and Nos. 3 : 15 (SC_2H_5). The order of the decreasing solubility of 2,3-disubstituted 5,8-DHQ is: $O(CH_2)_2OC_2H_5 < H < OH < CH_3 < C_6H_5 < OC_2H_5 < Cl < SH < SC_2H_5$. Hydrophobic CH_3- and $(CH_3)_2N$- groups decrease the solubility of 5,8-DMQ, but the degree of decrease is small (Nos. 19 and 27). This phenomenon may be explained by the basicity increase of the ring nitrogen by electron-repelling groups, such as the CH_3 or $(CH_3)_2N$- group. The electron pair on the ring-nitrogen atom is able to form hydrogen bonds with water; this causes the 5, 8-DMQ to be more soluble in water than is expected from hydrophobic groups. The special insolubility of 6,7-DHQ and its derivatives may be attributed to a high crystal-lattice force between *o*-dihydroxyl groups and ring nitrogens. In harmony with this concept, 6,7-DHQ derivatives (Nos. 4, 32 and 33) do not melt below 360°C, but 6,7-DMQ and 2,3-dichloro-6, 7-DMQ (Nos. 8 and 35) melt at 151°C and 178°C respectively.

Ionization Constant. *a) pK_{NH} Value.* The results of the measurement of the pK_a values of quinoxaline and 8-hydroxyquinoline in aqueous dioxane are given in Tables 2 and 3. The pK_a values observed in a dioxane-water (10 : 90 v/v) solution are somewhat lower than those in water. This lowering effect is usually observed in mixed

* A, B and C indicate precipitaion under pH 5.2, 8.4, 12.4 buffer solution, respectively. Three drops of buffer solution, one drop of metal ion solution (1000γ/ml) and one drop of 0.025—0.005M of reagent solution in ethanol.

aqueous solution by Albert, show that the hydroxyl groups in the phenyl nucleus of quinoxaline has some electron-repelling effect; this effect also exists in 5,8-DHQ (0.61) and 6,7-DHQ (0.89) and their *O*-methyl derivatives (Table 3). From Table 3 it can also be seen that the base-strengthening effect of the methoxyl group is somewhat weaker than that of the hydroxyl group. It has been reported[18] that the pK_a values of 2-methoxyquinoxaline (0.28 in water) and 2,3- DMQ (−1.15 in water) are considerably smaller than that of quinoxaline (0.56 in water); this fact suggests that the inductive effect is more effective than the mesomeric effect at 2 and/or 3 positions of quinoxaline. Similar effects are observed in the following compounds: 2,3-diethoxy-, 2,3-bis(ethoxyethoxy)- and 2,3-bis(ethylthio)-substituents of 5,8-DHQ and 5,8-DMQ. The pK_a values of the 2, 3-DHQ derivatives can be expected to be the same as that of 2-hydroxyquinoxaline because of their same partial structures. However, their pK_a values could not be determined by the spectrometric method, because their spectra did not change with the pH of medium as in the case of 2,3-DHQ. Electron-repelling substituents, such as methyl and dimethylamino groups, in the 2,3-position raise the pK_a values of 5,8-DHQ and 5,8-DMQ. Phenyl groups in the same positions lower the pK_a value. In 2,3-dichloro-5,8-DHQ, chlorine atoms are expected to have a base-weakening effect. However, its pK_a value could not be determined by the spectrometric method. The introduction of the alkoxycarbonyl group into the 6,7-positions of 5,8-DHQ induces hardly any appreciable effect on the pK_{NH} value.

b) pK_{OH} Value. By comparing the pK_a value of the 8-hydroxyquinoline anion (in dioxane-water 50 : 50 v/v, 10.80) with 5-hydroxyquinoxaline (9.29 in dioxane-water 50 : 50 v/v,)[23] the lowering effect of the pK_a value upon the further introduction of ring nitrogen may be seen. On the contrary, the further introduction of the hydroxyl group into the 8-position of 5-hydroxyquinoxaline raises the pK_a value (by an acid-weakening effect) (Table 3). The introduction of electron repelling substituents such as the methyl group into the 2,3-positions of 5,8-DHQ raises the pK_{OH} value (11.36), while the introduction of electron-attracting substituents, such as ethoxy and chloro groups, into the same positions, or that of the ethoxycarbonyl group into the 6,7-positions, lowers the pK_{OH} value (10.04, 9.66, and 9.28 respectively).

Chelating Behavior with Metal Ions. Reactions with metal ions are shown in Table 4. 5,8-DHQ and its derivatives formed a colorful precipitate, but some 2,3-disubstituted 5,8-DHQ failed to show any precipitation or coloration with metal ions in the buffer solution tested. Table 4 also shows the metal chelates and pK_{NH} and pK_{OH} values of 5,8-DHQ and its derivatives. According to Irving,[16] a linear relationship between $\log\beta$ (β: stability constant of the metal chelate) and the pK_{OH} of ligand exists for the chelate formation of 8-hydroxyquinoline and related compounds. Form Table 4, it is found that a close relationship exists between the precipitation of the meatl chelate of 5,8-DHQ derivatives and the pK_{NH} value of the ligand, but the pK_{OH} value has not special relation with the precipitation of the chelate. The basicity of a precipitate-forming ligand is higher than that of a ligand which does not form any precipitate. The limit of the value of pK_{NH} for causing the precipitation and coloration of chelates of 5,8-DHQ derivatives seems to lie near 0 — −1 (obtained in dioxane-water, 50 : 50 v/v).

2,3-DHQ and its 5,8- or 6,7-dimethoxy-derivatives fail to show any precipitation or coloration with metal ions. 6,7-DHQ, however, gives a distinct coloration and precipitations with Fe(II) and Cr(III) like catechol.[25,26] It is interesting to note that 2,3,5,8-tetrahydroxyquinoxaline can form precipitates with a larger number of metals (Table 4).

Kawai *et al.*[27] reported that the composition of copper chelates of 5,8-DHQ was not in accord with the molar ratio of metal : ligand=1 : 1, whose ratio was based on the assumed structure of Fig. 1.

Though 5,8-DHQ and its derivatives give precipitates with copper salt in an aqueous solution, in aqueous dioxane the copper chelates were kept in a colloidal solution. The composition of the copper chelate of 5,8-DHQ in a dioxane-water (10 : 90 v/v) solution was measured by the following two methods:

(1) Job's Continuous Variation Method: Fig. 3. The composition of the chelate was determined to be 1 : 1 (reagent : copper) at pH 4; 400 mμ.

Ligand	Composition Cu : Ligand	α	log K	pH
5,8-DHQ	1 : 1	0.05	6.28	4.0
6,7-Bis(ethoxy-carbonyl)-5,8-DHQ	2 : 3	0.01	10.73	6.2
2,3-Dimethyl-5,8-DHQ	could not be obtained			

the copper chelates of 5,8-DHQ derivatives were measured (Figs. 5 and 6). The compositions, the degrees of dissociation (α), and the stability constants (K) of the copper chelates calculated are shown in Table 5. The composition of the copper chelate of 2,3-dimethyl-5,8-DHQ could not be obtained by these procedures, however, because the absorbance of the mixed solution of cupric ions and the ligand varied rapidly and the precipitates separated.

From these chelate compositions (Table 5), the structures of chelates may be represented as in Fig. 7.

The author wishes to express his deep thanks to Professor Sin'iti Kawai and Professor Noboru Sugiyama for their encouragement and support. Grateful acknowledgement is also made to Professor Jisuke Seki for his helpful advice.

Reaction Rates in Binary Mixed Solvents. IV[1)]

Yasuhiko KONDO, Yoshitoshi HONJO and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Higashinoda, Miyakojima-ku, Osaka

(Received October 18, 1967)

Three cases of combinations of the solvation free-energy differences in two solvents, with respect to a reactant and an activated complex, have been proposed. The theoretical expressions for the rate constant and for the activation energy in binary mixed solvents have been derived for each model. From the theoretical calculations based on these models, it has been demonstrated that the behavior of a system in which the reaction rates are mainly dependent on the difference in the solvation energies of an activated complex can be distinguished from behavior of a system where the reaction rates are controlled by the difference in the solvation energies of a reactant. The reaction rates of the Menschutkin reaction in binary mixed solvents containing liquid sulfur dioxide as one component of the mixed solvent have been analyzed on the basis of these models.

According to the theory of the absolute reaction rates,[2)] a rate constant is expressed as the difference in the free energies between reactants and activated complexes. Therefore, the rate constants in a solution would be affected not only by the individual solvation of the reactants or an activated complex, but also by the combinations of these factors in several ways. In the theoretical treatment of the effects of solvents on reaction rates, these facts should be taken into consideration.

Some of the factors which influence the rates of a reaction in solution might be made clear by an analysis of the rate constants measured in pure solvents, but the study of other factors might have to depend on investigations of the rate constants measured in mixed solvents.

In previous studies[1)] the present authors have reported the theoretical treatment of the reaction rates in binary mixed solvents.

In this paper we will discuss theoretically what information can be obtained on the solvation of a solute from an analysis of the reaction rates measured in binary mixed solvents.

Discussion

The Model of a Solvation and Reaction Rates in Solution. The effects of solvents on the rates of a reaction in solution can be replaced by the dependence of the activation free energies on the nature of a solvent. If the influence of a solvent on the reaction rates in solution is assumed to be caused by its influence on the solvation of reactants and an activated complex, then the following combinations of the solvation free-energy differences (Fig. 1) can be considered as factors which make the reaction rates different in two solvents; the solvent in which the reaction proceeds more rapidly is expressed by the subscript 1. $\Delta F_4^{\neq}$ and $\Delta F_1^{\neq}$ stand for the activation free energy in the solvents 4 and 1 respectively.

Model I represents a system in which both a reactant and an activated complex are more solvated in the solvent 1 than in the solvent 4.

Model II is a system where an activated complex is more solvated in the solvent 1, while a reactant is more solvated in the solvent 4.

Model III stands for a system where both a

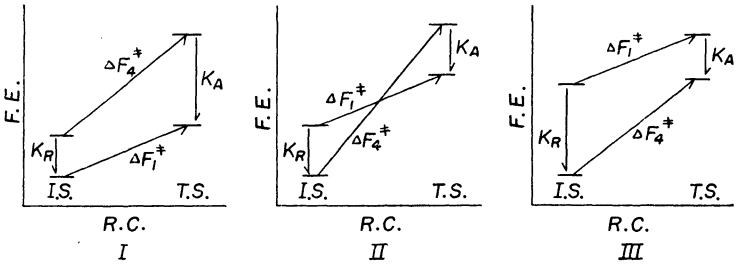

Fig. 1. The model of a solvation.

reactant and an activated complex are more solvated in the solvent 4 than in the solvent 1.

Any combination of the two solvents in which the rates of the same reaction are differentiated from each other should correspond to one of the three solvation models represented in Fig. 1.

Now, let us consider what variations should be introduced into the theoretical expressions for the rate constants and the activation energies in binary mixed solvents according to the solvation models presented above.

In previous papers[1] the authors have represented a system in which there are no specific interactions among the components by the construction of a regular solution, and have assumed the formation of an addition product as the model for a system in which attractive interactions are observed between the components. With the object of applying the above models to the three models mentioned previously, the following two assumptions will be made hereafter: 1) A system in which no specific interactions can be observed among the components constructs a regular solution, and 2) In the systems where a substantial difference in the solvation energies of a solute exists between the two solvents, we assume that the solute reacts to form an addition product with the solvent having the stronger solvating power, whereas the solute forms a regular solution with the other solvent, with the weaker solvating power.

Insofar as the above assumptions are adopted, the theoretical expressions for the rate constants and the activation energies in binary mixed solvents can be derived from suitable combinations of the expressions for Henry's constant in a regular solution and in an associated solution for all of the three models described previously.

The theoretical expressions for Henry's constant in binary mixed solvents and the relations between Henry's constants in pure solvents may be summarized as follows.

Shown below is a system in which the solute 2 constructs a regular solution with both of the two solvents, 1 and 4:[3]

$$\ln H_{2,\mathrm{mix}} = x_1 \ln H_{2,1} + x_4 \ln H_{2,4} - x_1 x_4 \alpha_{14} \quad (1)$$

$$(H_{2,1}/H_{2,4}) = \exp(\alpha_{21} - \alpha_{24}) \quad (2)$$

Shown below is a system in which the solute 2 reacts to form an addition product with the solvent 1, whereas it constructs a regular solution with the solvent 4:[1]

$$\ln H_{2,\mathrm{mix}} = x_1 \ln H_{2,1} + x_4 \ln H_{2,4} + x_1 \ln(K+1) - \ln(x_1 K + 1) - x_1 x_4 \alpha_{14} \quad (3)$$

$$(H_{2,1}/H_{2,4}) = \frac{1}{(K+1)} \exp(-\alpha_{24}) \quad (4)$$

Shown below is a system in which the solute 2 reacts to form an addition product with the solvent 4, whereas it constructs a regular solution with the solvent 1:

$$\ln H_{2,\mathrm{mix}} = x_1 \ln H_{2,1} + x_4 \ln H_{2,4} + x_4 \ln(K+1) - \ln(x_4 K + 1) - x_1 x_4 \alpha_{14} \quad (5)$$

$$(H_{2,4}/H_{2,1}) = \frac{1}{(K+1)} \exp(-\alpha_{21}) \quad (6)$$

The Theoretical Expressions for the Reaction Rate in Binary Mixed Solvents. In this paper the theoretical expressions will be derived for the general second-order reaction:

$$\mathrm{A} + \mathrm{B} \rightarrow \mathrm{M}^* \rightarrow \mathrm{Products}$$

For the sake of simplicity, the reactant A will be assumed to construct a regular solution with both of the two solvents, 1 and 4.

According to previous discussions,[1] the rate constant in a binary mixed solvent and the ratio of the rate constant in two sorts of pure solvents are expressed by Eqs. (7) and (8) respectively:

$$k_{\mathrm{mix}} = k_0 \left(\frac{H_{\mathrm{A,mix}} \times H_{\mathrm{B,mix}}}{H_{\mathrm{M}^*,\mathrm{mix}}}\right)\left(\frac{V_{\mathrm{mix}}}{RT}\right) \quad (7)$$

$$(k_1/k_4) = \left(\frac{H_{\mathrm{A},1}}{H_{\mathrm{A},4}}\right)\left(\frac{H_{\mathrm{B},1}}{H_{\mathrm{B},4}}\right)\left(\frac{H_{\mathrm{M}^*,4}}{H_{\mathrm{M}^*,1}}\right)\left(\frac{V_1}{V_4}\right) \quad (8)$$

Model I. Since, in this system, both a reactant and an activated complex are more solvated in the solvent 1, we assume that both the reactant B and an activated complex react to form addition products with the solvent 1.

The theoretical expression for the rate constant in a binary mixed solvent can then be derived by the substitution of Eq. (3) into Henry's constants of the solutes B and M* in Eq. (7).

3) J. P. O'Connell and J. M. Prausnitz, *Ind. & Eng. Chem. Fundamentals*, **3**, 347 (1964).

Accordingly, Eqs. (1) and (2) will be used for a solute, A, in all the equations.

$$\ln k_{mix} = x_1 \ln k_1 + x_4 \ln k_4 + \left\{x_1 \ln\left(\frac{K_R+1}{K_A+1}\right) - \ln\left(\frac{x_1K_R+1}{x_1K_A+1}\right) - x_1x_4\alpha_{14}\right\} + \ln V_{mix} - x_1 \ln V_1 - x_4 \ln V_4 \quad (9)$$

In Eq. (9), K_R and K_A stand for the equilibrium constants of a reactant and an activated complex respectively, when they form addition products with a particular solvent.

The ratio of the rate constant, (k_1/k_4), is given by the substitution of Eq. (4) into Henry's constants of solutes, B and M$^{\neq}$ in Eq. (8):

$$(k_1/k_4) = \exp(\alpha_{A1} - \alpha_{A4}) \times \exp(\alpha_{M^{\neq}4} - \alpha_{B4}) \times \left(\frac{K_A+1}{K_R+1}\right)\left(\frac{V_1}{V_4}\right) \quad (10)$$

The expressions for an activation energy are given by the differentiation of Eqs. (9) and (10) with respect to the temperature:

$$\Delta E^{\neq}_{mix} = x_1\Delta E_1^{\neq} + x_4\Delta E_4^{\neq} - x_1x_4\left\{\frac{\Delta H^\circ_R}{(1+1/K_R)(x_1+1/K_R)} - \frac{\Delta H^\circ_A}{(1+1/K_A)(x_1+1/K_A)}\right\} \quad (11)$$

$$(\Delta E_1^{\neq} - \Delta E_4^{\neq}) = \left\{\frac{\Delta H^\circ_A}{(1+1/K_A)} - \frac{\Delta H^\circ_R}{(1+1/K_R)}\right\} \quad (12)$$

where ΔH°_R and ΔH°_A stand for the enthalpy change of a reactant and an activated complex respectively, accompanied by the formation of addition products with a particular solvent.

Model II. Since an activated complex is more solvated in the solvent 1, while a reactant is more solvated in the solvent 4, we assume that an activated complex forms an addition product with the solvent 1 and that the reactant B forms an addition product with the solvent 4.

Thus, the theoretical expression for a rate constant is given by the substitution of Eqs. (3) and (5) for Henry's constants of an activated complex and the reactant B in Eq. (7):

$$\ln k_{mix} = x_1 \ln k_1 + x_4 \ln k_4 + \{x_4 \ln(K_R+1) - \ln(x_4K_R+1) - x_1 \ln(K_A+1) + \ln(x_1K_A+1) - x_1x_4\alpha_{14}\} + \ln V_{mix} - x_1 \ln V_1 - x_4 \ln V_4 \quad (13)$$

The ratio of the rate constant is given by the combination of Eqs. (2), (4), (6), and (8) as follows:

$$(k_1/k_4) = \exp(\alpha_{A1} - \alpha_{A4}) \times \exp(\alpha_{B1} + \alpha_{M^{\neq}4}) \times (K_A+1)(K_R+1)\left(\frac{V_1}{V_4}\right) \quad (14)$$

The expressions for an activation energy are given by the differentiation of Eqs. (13) and (14) with respect to the temperature:

$$\Delta E^{\neq}_{mix} = x_1\Delta E_1^{\neq} + x_4\Delta E_4^{\neq} + x_1x_4\left\{\frac{\Delta H^\circ_A}{(1+1/K_A)(x_1+1/K_A)} - \frac{\Delta H^\circ_R}{(1+1/K_R)(x_4+1/K_R)}\right\} \quad (15)$$

$$(\Delta E_1^{\neq} - \Delta E_4^{\neq}) = \left\{\frac{\Delta H^\circ_R}{(1+1/K_R)} + \frac{\Delta H_A^\circ}{(1+1/K_A)}\right\} \quad (16)$$

Model III. Since both a reactant and an activated complex are more solvated in the solvent 4, we assume that both the reactant B and an activated complex form addition products with the solvent 4.

The theoretical expressions for a rate constant and for the ratio of rate constants are given by combinations of Eqs. (1), (5), and (7) and of Eqs. (2), (6), and (8), respectively:

$$\ln k_{mix} = x_1 \ln k_1 + x_4 \ln k_4 + \left\{x_4 \ln\left(\frac{K_R+1}{K_A+1}\right) - \ln\left(\frac{x_4K_R+1}{x_4K_A+1}\right) - x_1x_4\alpha_{14}\right\} + \ln V_{mix} - x_1 \ln V_1 - x_4 \ln V_4 \quad (17)$$

$$(k_1/k_4) = \exp(\alpha_{A1} - \alpha_{A4}) \times \exp(\alpha_{B1} - \alpha_{M^{\neq}1}) \times \left(\frac{K_R+1}{K_A+1}\right)\left(\frac{V_1}{V_4}\right) \quad (18)$$

The expressions for an activation energy are given by the differentiation of Eqs. (17) and (18) with respect to the temperature:

$$\Delta E^{\neq}_{mix} = x_1\Delta E_1^{\neq} + x_4E_4^{\neq} + x_1x_4\left\{\frac{\Delta H^\circ_A}{(1+1/K_A)(x_4+1/K_A)} - \frac{\Delta H_R^\circ}{(1+1/K_R)(x_4+1/K_R)}\right\} \quad (19)$$

$$(\Delta E_1^{\neq} - \Delta E_4^{\neq}) = \left\{\frac{\Delta H^\circ_R}{(1+1/K_R)} - \frac{\Delta H^\circ_A}{(1+1/K_A)}\right\} \quad (20)$$

Since in the three sorts of combination the solvation of an activated complex and that of a reactant are taken into consideration at the same time, in the theoretical expressions for the rate constants, as well as those for the activation energies, there exist two sorts of parameters, which represent the solvations of a reactant and of an activated complex, *i. e.*, K_R and K_A for the rate constants, ΔH°_R and ΔH°_A, for the activation energies. However, these two parameters are related to one another by the theoretical expressions for the ratio of the rate constant, (k_1/k_4), or by those for the difference in the activation energies in pure solvents, $(\Delta E_1^{\neq} - \Delta E_4^{\neq})$.

Thus, there exists only one independent variable for the rate constant and for the activation energy

in binary mixed solvents. In order to compare the characteristics of these models, calculations have been made for the system where $(k_1/k_4)=100$, $(\Delta E_1^{\neq}-\Delta E_4^{\neq})=(-6.0)$ [kcal·mol^{-1}], $V_1=V_4=V_{mix}$, and all the interaction coefficients, α_{ij}, are zero. The results are shown in Figs. 2 and 3, while the parameters used in the calculations are summarized in Table 1.

In the limiting case of $K_R=0$, both the differences in the rate constants and in the activation energies in pure solvents should be dependent on the difference between the two solvents in the solvation of an activated complex.

Therefore, in this case the differences between the I and II models should vanish.

In the model I the curves approach Curve 3 in the order of 1→2→3, while in the model II they do so in the order of 5→4→3, as the values of K_R and $(-\Delta H_R^\circ)$ approach zero.

Similarly, in the limiting case of $K_A=0$, the influences of the solvents on the reaction rates in solution should be attributed to the differences between the two solvents in the solvation of a reactant.

Therefore, the differences between the models II and III should disappear. Then, in the model II the curves approach curve 9 in the order of 7→8→9, while in the model III they do so in the order of 11→10→9, as the values of K_A and $(-\Delta H^\circ_A)$ approach zero.

Curve 6 represents a system where $K_A=K_R$, and $\Delta H^\circ_A=\Delta H^\circ_R$. This is a system in which the solvation of an activated complex makes an contribution equivalent to that of a reactant to the

The dimensions, ΔH°_A and ΔH°_R: [kcal·mol]

differences in the rate constants and the activation energies between the two solvents.

As the solvation of an activated complex exceeds that of a reactant in the contribution to the reaction rate, the positive deviation from linearity increases in the rate constants, while the negative deviation from linearity increases in the activation energies *i. e.*, in the order of 6→5→4. In contrast, as the solvation of a reactant exceeds that of an activated complex, the negative deviation from linearity increases in the rate constant, while the positive deviation from linearity increases in the activation energies, *i. e.*, in the order of 6→7→8.

In principle, it should be possible to determine, from the analysis of the reaction rates in binary mixed solvents, whether the differences in the rate constants and in the activation energies are due to the differences in the solvation of an activated complex or in the solvation of a reactant.

Comparison of the Theory with the Experimental Results. In previous papers[1,4] the

present authors have reported that, in most cases, positive deviations from linearity have been observed in the plots of $\log k_{mix}$ *vs.* the composition of a solvent, and that these positive deviations from linearity should correspond to a significant specific solvation of an activated complex due to a more polar solvent.

According to the models proposed by the present authors, large negative deviations from linearity should be observed in systems where there exists a significant specific solvation of a reactant due to a less polar solvent.

The experimental results of the Menschutkin reaction in mixtures of liquid sulfur dioxide and aromatic solvents are shown in Figs. 4 and 5.

These results can be explained semiquantitatively by Model No. 9 in Table 1, as shown by the smooth curves of Figs. 4 and 5. Since, in that model, only the interaction between a reactant and liquid sulfur dioxide has been taken into consideration, only one parameter, that is, K_R, can be determined from the analysis of the experimental results.

It has been suggested by two of the present authors[6] that the rate of the Menschutkin reaction in liquid sulfur dioxide is mainly dependent on the specific solvation of amines by liquid sulfur dioxide. The semiquantitative agreement of the experimental results in binary mixed solvents with the calculated results based on Model No. 9 would then be reasonable, since in that model the specific interaction between a reactant and liquid sulfur dioxide is emphasized as the main source of the effects of the solvent on reaction rates.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 992—996 (1968)

Solvent Effect under High Pressure. II[1]

Yasuhiko KONDO, Miyoji UCHIDA and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Higashinoda, Miyakojima-ku, Osaka

(Received October 19, 1967)

The activation volume of the reaction of triethylamine with ethyl iodide has been measured in four solvents. A linear relationship has been observed between the values of $\Delta V_0^{\neq}$ for the Menschutkin reaction in various solvents and the products of the compressibility and the molar volume of the pure solvent, as has been suggested in a previous paper. From the slope of the plots of $(-\Delta V_0^{\neq})$ *vs.* KV°, the product of the solvation number and the average pressure within the solvation shell of an activated complex has been calculated to be 2.6×10^3 (kg·cm^{-2}) according to a model proposed by the authors. An abnormal acceleration due to pressure has been observed for the reaction of triethylamine with ethyl iodide in *p*-xylene and dioxane at 30°C. This acceleration effects has been attributed to the partial freezing of the solvent under high pressure.

A study of the effects of solvents on an activation volume would throw some light on the effects of solvents on reaction rates and mechanisms.

In a previous report[1] the present authors proposed a relation between the activation volumes in a variety of solvents and the compressibilities of the solvents on the basis of the electrostriction theory. In the present paper, it will be established that the expression then proposed by the authors is useful for the description of the variation in the activation volumes for the reaction of triethylamine with ethyl iodide and of pyridine with methyl iodide[2] upon a change of solvents.

An abnormal acceleration effect of the rates of the Menschutkin reaction due to pressure was reported by the present authors in the previous paper.[1] Compared with the results of the reaction rates in frozen solutions obtained by Pincock *et al.*,[3] this abnormal acceleration due to pressure has been attributed to the partial freezing of the solution resulting from the rize of the freezing point with an increase in the pressure. In order to establish this phenomenon further, the same reaction has been treated in dioxane and *p*-xylene solvents under high pressures.

Experimental

Materials. Triethylamine and ethyl iodide were purified by a method described earlier.[1] The solvents used were purified by known methods.[4]

Apparatus and Kinetic Procedure. The apparatus for kinetic runs under high pressure used in this experiment is that described in the previous paper.[1] As the reaction product, tetraethylammonium iodide, is insoluble in the solvents used in this experiment, the reaction rates were measured by batch processes with the use of polyethylene ampoules.

The activation volumes were evaluated by the graphical method developed by the authors, using Eqs. (1) and (2):

$$\log (k_p/k_1) = AP + BP^2 \quad (1)$$

$$\Delta V_0^{\neq} = -2.303\,ART \quad (2)$$

Typical runs under high pressures are represented in Table 1, while an example of the plot of $\log(k_p/k_1)/P$ *vs.* P is shown in Fig. 1.

The coefficients, A and B, of Eq. (1) for the reactions in various solvents are represented in Table 2.

Results and Discussion

A Solvent Effect on an Activation Volume. Recently, the relationship between the thermodynamic activation parameters and the dielectric properties of the medium, considered as a continuum, has been discussed by Hartmann and his collaborators.[2,5,6]

In the previous report[1] the following expression for the effects of solvents on the activation volumes of the Menschutkin reaction has been derived on the basis of the assumption that the partial molar volume of the activated complex is expressed as a function of the molar volume of a pure activated complex and the electrostriction of a solvent molecule surrounding an activated complex, while the partial molar volume of a reactant is independent of the nature of the solvent:

$$\Delta V_0^{\neq} = \{V_{\neq} - (\bar{V}_A^{\circ} + \bar{V}_B^{\circ})\} - ZKV^{\circ}\Delta P \quad (3)$$

In Eq. (3), $V_{\neq}$, $\bar{V}_A^{\circ}$, $\bar{V}_B^{\circ}$, Z, K, V°, and ΔP stand for the molar volume of an activated complex in its pure state; the partial molar volume of the reactants, A and B; the solvation number of an activated complex; the compressibility and the molar volume of a pure solvent, and the average pressure within the solvation shell of an activated complex respectively.

The activation volumes obtained by the authors are represented in Table 3.

In Fig. 2 the activation volumes for the reaction of triethylamine with ethyl iodide and those for the reaction of pyridine with methyl iodide[2] are plotted against the values for KV° at 25°C.

For these two reactions there exists a similar correlation between the values for $\Delta V_0^{\neq}$ and those for KV°; in addition, the slopes of the lines, *i. e.*, the values for $Z\cdot\Delta P$, are like one another.

Since the values for $Z\cdot\Delta P$ stand for the product of the solvation number and the average pressure within the solvation shell of an activated complex, these values will vary depending on the structure of the activated complex or on the degree of the development of ionic charges during the course of the reaction, *i. e.*, on whether the ionic charges developed or decrease as the reaction proceeds.

* The value for a compressibility, K, is that of *m*-xylene at 45°C.

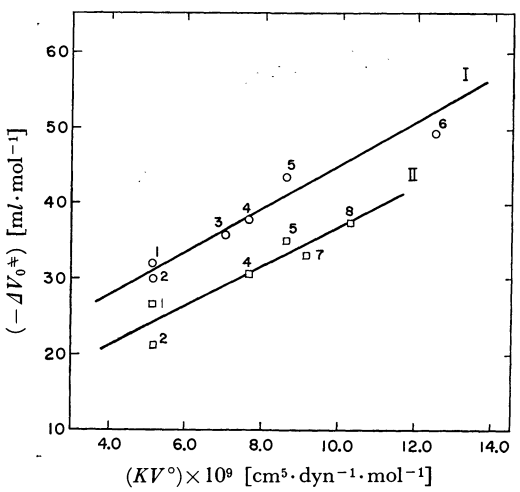

Fig. 2. Plot of $(-\Delta V_0^*)$ *vs.* $KV°$.
Curve I: $(C_2H_5)_3N + C_2H_5I$
Curve II: $C_5H_5N + CH_3I$
Solvent 1: MeOH, 2: $PhNO_2$, 3: PhBr, 4: PhCl, 5: Bz, 6: *p*-Xylene, 7: Acetone, 8: CCl_4

The values of $Z\cdot\Delta P$ for these two reactions, calculated from the slopes of Fig. 2, are about 2.6×10^3 (kg·cm^{-2}).

If we assume that the solvation number, Z, is equal to eight according to the theory of a non-electrolyte solution[8] or the solvation number of the quaternary ammonium salt in liquid sulfur dioxide measured earlier by the present authers,[9] a value of approximately 320 (kg·cm^{-2}) is obtained for the average pressure within the solvation shell of an activated complex.

In the estimation of the amount of the hydration of an electrolyte, the hydrated water within the hydration shell is assumed to be incompressible.[10]

The average pressure within the hydration shell of the alkali metal halides is calculated to be approximately 4300 (kg·cm^{-2}) from the measurement of the density and of the ultrasonic velocity in an electrolyte solution.[11]

The comparison of these results suggests that the activated complex is solvated to a lower extent than the ions of the reaction products.

Generally, ΔV_0^* has been treated as the sum of the two terms:[12]

$$\Delta V_0^* = \Delta V_1^* + \Delta V_2^* \qquad (4)$$

where ΔV_1^* is the change in the volume of the reacting particles during the formation of an activated complex and ΔV_2^* is the change in the volume of the solvent, resulting from the formation of the activated complex.

Since, in the model proposed by the authors, the first term on the right-hand side of Eq. (3) is independent of the nature of the solvent, whereas the second term is dependent, the former should correspond to the first term on the right-hand side of Eq. (4), whereas the latter should correspond to the second term.

Then, the value of ΔV_0^* obtained by extrapolating to zero the value of $KV°$ should represent ΔV_1^*, *i.e.*, the volume change of the reacting particles themselves.

Since the activation volume calculated on the basis of the Gonikberg model[13] should give the values of ΔV_1^* in Eq. (4), these values should correspond to the first term of Eq. (3), obtained by extrapolation.

* The value for the reaction of triethylamine with isopropyl iodide.

It has been established that, for the reaction of pyridine with methyl iodide, the activation volume obtained by extrapolation is nearly equal to the calculated value.

Therefore, the extrapolation method mentioned above will be useful in resolving the values of $\Delta V_0^{\neq}$ measured in various solvents into their components, *i. e.*, $\Delta V_1^{\neq}$ and $\Delta V_2^{\neq}$, definitely.

An Abnormal Acceleration under High Pressure. In their previous study[1] the authors observed a greater acceleration effect of pressure for the rates of the Menschutkin reaction in benzene and nitrobenzene than was expected from the power-series treatment.

After being compared with the results of the reaction rates in frozen solutions by Pincock *et al.*,[3] this acceleration effect has been attributed to the partial freezing of the solvent which results from the rise in the freezing point with an increase in an external pressure.[1]

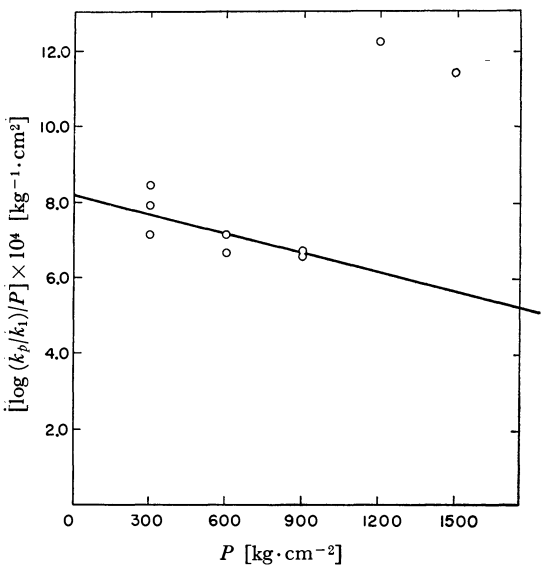

Fig. 3. Deviation from the linear relation between $\log (k_p/k_1)/P$ and P for the reaction of ethyl iodide with triethylamine in *p*-xylene at 30°C.

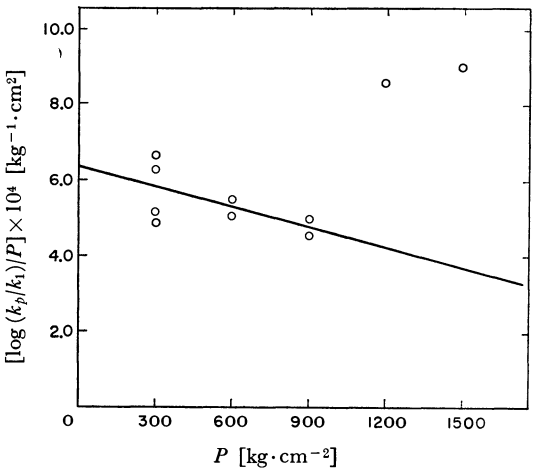

Fig. 4. Deviation from the linear relation between $\log (k_p/k_1)/P$ and P for the reaction of ethyl iodide with triethylamine in dioxane at 30°C.

In the previous study the experimental results in a high-temperature region were referred to the literature. With the object of obtaining the rate constants in both the low and high temperature regions; for the former the abnormal acceleration should be observed, but for the latter the plots of $\log (k_p/k_1)/P$ *vs.* P should be linear, the effects of the pressure on the rate constants of the Menschutkin reaction have been measured in two solvents, dioxane and *p*-xylene.

For the rate constants at 30°C large deviations from the linear relations of $\log (k_p/k_1)/P$ with the pressure have been found at the pressures of both 1200 and 1500 (kg·cm^{-2}) (see Figs. 3 and 4).

If this acceleration is caused by a freezing of the solvent similar to the phenomenon found by Pincock *et al.*,[3] the freezing points of these solvents at 1200 and 1500 (kg·cm^{-2}) should lie several degrees above the experimental temperature, *i. e.*, 30°C.

If we assume that the volume change on fusion per mole of a solvent, ΔV_f, is equal to ten percent of the molar volume of a pure solvent, on the basis of Eq.(5):

$$\left(\frac{dP}{dT}\right) = \left(\frac{\Delta H_f}{T\Delta V_f}\right) \tag{5}$$

the freezing points at 1000 (kg·cm^{-2}) are calculated to be 34°C and 30°C for *p*-xylene and dioxane respectively.

Therefore, in the region where the abnormal acceleration has been observed, *i. e.*, at 1200 and 1500 (kg·cm^{-2}), moderate portions of the solvent would be frozen.

Pincock *et al.*[3] examined the reaction of triethylamine with methyl iodide in frozen benzene solutions; they found that the reaction is accelerated

moderately and that the reaction in a frozen solution becomes a first-order reaction, in contrast to the second order in an unfrozen solution. They were able to explain their findings quantitatively by taking into account the fact that, if the reactants are soluble enough when the equilibrium is reached at a temperature above the eutectic temperature of the system, the reactants are rejected by the solid phase and become more concentrated in the unfrozen liquid region, and the fact that since, in this reaction, the reaction product, quaternary ammonium iodide, is insoluble in the solution, the walls of the reaction regions close in to hold the concentration of the remaining solute at a constant value.[3)]

As the reaction product of triethylamine with ethyl iodide, tetraethylammonium iodide, is almost insoluble in the solvents used in this experiment, the systems treated by the authors are similar to the system studied by Pincock *et al.*[3)]

The plots of log (concentration) against the time gave good straight lines for the reactions in the two solvents at the pressures of 1200 and 1500 (kg·cm^{-2}) (see Figs. 5 and 6).

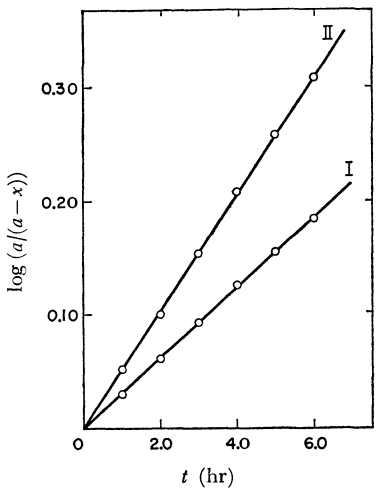

Fig. 5. First order plot for the reaction of ethyl iodide with triethylamine in *p*-xylene under high pressure at 30°C.
Curve I: at 1200 [kg·cm^{-2}]
II: at 1500 [kg·cm^{-2}]

However, at these pressures the plots of the reciprocal concentrations against the time were distinctly curved with equal concentrations of the reactants.

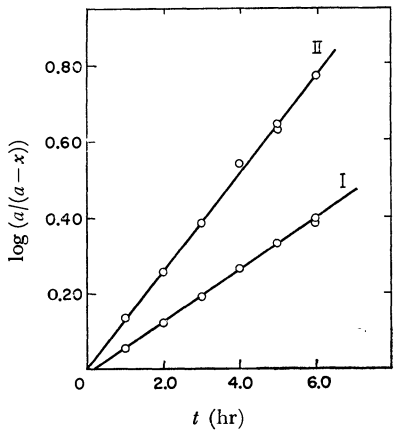

Fig. 6. First order plot for the reaction of ethyl iodide with triethylamine in dioxane under high pressure at 30°C.
Curve I: at 1200 [kg·cm^{-2}]
II: at 1500 [kg·cm^{-2}]

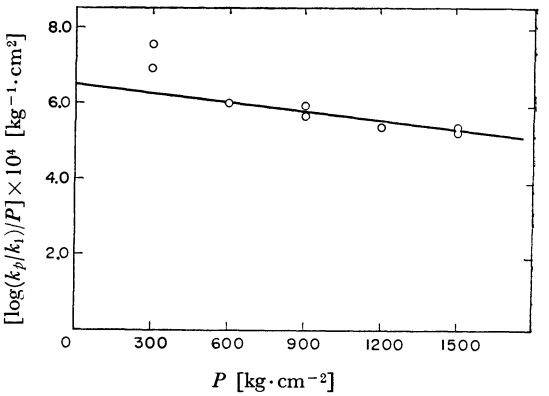

Fig. 7. Plot of log $(k_p/k_1)/P$ *vs.* P for the reaction of ethyl iodide with triethylamine in dioxane at 45°C.

The linear correlation can be expected to hold between $\log(k_p/k_1)/P$ and P over the region where no anomalous behavior such as the freezing of a solvent could be encountered at all.

The rate constants measured at a relatively high temperature, *i.e.*, 45°C, where the freezing of the solvent could not be expected even under the added pressures, show good correlations between log $(k_p/k_1)/P$ and pressure (see Figs. 7 and 1).

The facts mentioned above support the view that the abnormal acceleration observed in this experiment can be attributed to the freezing of the solvent under high pressures.

The Acid-catalyzed Bromination of Aromatic Compounds with Potassium Bromate in Aqueous Acetic Acid

Yoshiaki FURUYA, Atsushi MORITA and Iwao URASAKI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto

(Received October 24, 1967)

Bromobenzene is obtained in a 64% yield when an aqueous acetic acid solution containing a catalytic amount of sulfuric acid is slowly added to an aqueous acetic acid solution of benzene and potassium bromate at 60°C. It seems, according to the synthetic data, that the formation of bromobenzene is accelerated by an electron-releasing group. The rate of the consumption of active oxygen has been expressed as follows:

$$v = k_2[BrO_3^-][C_6H_6] + k_3[BrO_3^-][C_6H_6]^2$$

Here, both k_2 and k_3 gave a straight line against $-\log(C_{BH^+}/C_B)$, with a slope of *ca.* -2. The reaction is accelerated by sulfuric acid and does not occur at all in the absence of the acid. The evolution of oxygen gas was not observed during the reaction, but the presence of peroxyacetic acid and/or acetyl peroxide in the reaction mixture was indicated by paper chromatography. A mechanism which involves the rate-determining attack of protonated hypobromous acid and/or protonated acetyl hypobromite on benzene has been suggested.

The heterogeneous bromination of benzene with potassium bromate in the presence of sulfuric acid is well-known[1]; however, no kinetical study has yet been made. We now wish to describe some findings regarding the mechanism of this reaction in a homogeneous system, using 50 vol% aqueous acetic acid as the solvent.

It is well known that there are two theories[2,3] as to the bromination of aromatic ring with molecular bromine in the presence of an electrophilic reagent. In the present reaction, however, the attacking species is not the bromine cation but protonated hypobromous acid and/or acetylbromite.

Experimental

Materials. The Potassium bromate was recrystallized twice from hot water and dried at 120°C for 2 hr. The benzene[4] was treated with concentrated sulfuric acid and diluted aqueous sodium hydroxide, washed with water, and then rectified after drying on phosphorus pentoxide; bp 80.0°C. The acetic acid was rectified; bp 117—119°C. The sulfuric acid used was of a guaranteed grade. Peroxyacetic acid was prepared by the reaction of acetic anhydride with hydrogen peroxide.[5] Acetyl peroxide was prepared by dropping water into a suspension of sodium peroxide in an ethereal solution of acetic anhydride.[6] Aqueous hypobromous acid was prepared by the addition of an aqueous solution of bromine to an excess of mercuric oxide suspended in water.[7] Acetyl hypobromite was prepared by mixing an acetic acid solution of bromine and a suspension of silver acetate in acetic acid.[8]

Preparation of Bromobenzenes. An aqueous acetic acid solution containing a catalytic amount of sulfuric acid was added slowly to an aqueous acetic acid solution of benzene and potassium bromate kept below 60°C; the heating was continued at the same temperature until the total reaction time reached 3.5 hr. The organic layer separated was washed with diluted aqueous sodium hydroxide and water, dried on calcium chloride, and then distilled, yielding bromobenzene, bp 156—157°C. The results, including those of the other brominations, are shown in Table 1. The yields were calculated on the basis of the original potassium bromate.

Reaction Products Criterion. Bromobenzene was identified by gas chromatography in comparison with an authentic sample. *p*-Chlorobromo- and *p*-dibromobenzene were identified by mixed melting point determinations; mp and mmp, 67°C and 89°C respectively.

A Typical Procedure for the Rate Measurements. A 50% aqueous acetic acid solution containing known amounts of benzene and potassium bromate was brought to a temperature equilibrium at 50°C. A known amount of the same aqueous acetic acid solution of sulfuric acid was then poured into the solution in order to start the reaction. Aliquots (1 m*l* each) were pipetted out at

appropriate time intervals and poured into an ice-cooled aqueous solution of 50 ml of 0.02 N potassium iodide containing 1 N sulfuric acid. The iodine liberated by active oxygen was quickly titrated with a 0.01 N sodium thiosulfate solution.

Paper Chromatography of Reaction Mixture. A solution of the reaction products was developed with a mixture of diethyl ether and ethyl acetate (2 : 3 in vol) on acetylated Toyo Filter paper No. 54.[9] Two pink spots were observed upon spraying with a methanolic solution of 3% *p*-dimethylaminoaniline dihydrochloride. The values of R_f were found to be 0.64 and 0.83; these values agreed with those for authentic samples of peroxyacetic acid (0.66) and acetyl peroxide (0.82) respectively.

Measurement of the Isotope Effect. The rate constants, k_2 and k_3, were obtained from the plot of $k_{2\,obs}$ *vs.* the concentration of benzene on the reaction of various concentrations of benzene with 0.025 M potassium bromate in the presence of 3.0 N sulfuric acid in 50% acetic acid at 50°C. These constants, k_2 and k_3, were expressed as k_{2H} and k_{3H} for usual benzene, and as k_{2D} and k_{3D} for deuterobenzene, respectively.

Results and Discussion

Synthetic Results. The results of the bromination of benzene with potassium bromate in the presence of sulfuric acid are shown in Table 1. The substituent effect seems to suggest that the acid-catalyzed bromination involves an electrophilic attack on the benzene ring. The absence of sulfuric acid resulted in the complete recovery of benzene.

TABLE 1. BROMINATION OF SUBSTITUTED BENZENES IN AQUEOUS ACETIC ACID

$$v = k_{2\,obs}[C_6H_6][BrO_3^-] \quad (1)$$

The apparent activation energy and entropy for the reaction in 50% acetic acid were calculated to be 22.3 kcal/mol and −4.01 e.u. respectively from the following average values of $k_{2\,obs}\times10^3$ M^{-1}sec^{-1}: 40°C, 0.833; 50°C, 2.85; and 60°C, 7.11, where the initial concentrations of benzene and potassium bromate were both 2.5×10^{-2} M and that of sulfuric acid was 3.0 N.

Under a definite initial concentration of benzene, the apparent second-order rate constant, $k_{2\,obs}$, slightly decreased with an increase in the initial concentration of potassium bromate, as is indicated in Table 3. Such a decrease in the rate may result from a decrease in the effective acidity in the reaction medium[10] with an increase in the concentration of potassium bromate, as is indicated

5.02	2.68

9) J. Janoušek, *Faserforsch. u. Textiltech.*, **8**, 339 (1957).

10) To get experimental support for such an explanation, we tried to measure the acidity function (by the indicator method) for a given medium containing potassium bromate. However, this attempt was unsuccessful because of the fading of the indicator.

by the following equation:

$$\ln K_a = \ln K_c - 2A\mu^{1/2} + b\mu$$

Here, K_a and K_c are dissociation constants expressed by, respectively, activity and concentration in an equilibrium, $AH \rightleftarrows H^+ + A^-$; μ is the ionic strength of the medium, and A and b are constants. Hence, it is considered that the $k_{2\,obs}$ rate constant does not contain the concentration of potassium bromate.

On the other hand, the plot of $k_{2\,obs}$ against the initial concentration of benzene gave a straight line, with a definite slope which did not pass through the point of origin, as is shown in Fig. 1. Thus the rate equation would be given by:

$$v = \{k_2 + k_3[C_6H_6]\}[C_6H_6][BrO_3^-] \qquad (2)$$

The rate was also affected by the concentration of the acid catalyst. To obtain some information on the effective acidity, the indicator ratio (C_{BH^+}/C_B) at 415 mμ for each medium (without the bromate) were determined spectrophotometrically using *o*-nitroaniline. Since no accurate pK_a value

$$H_0 = pK_a - \log (C_{BH^+}/C_B) \qquad (3)$$

of *o*-nitroaniline in 50% acetic acid is available, we have plotted the values of $\log k_{2\,obs}$ against those of $-\log (C_{BH^+}/C_B)$ instead of H_0. As is illustrated in Fig. 2, a linear relationship with a slope of -1.81 was obtained. Therefore, both the k_2 and k_3 rate constants should involve the term of a square of proton activity. Thus, two corresponding paths yielding bromobenzene should involve protonation twice before each rate-determining step. On the other hand, the plots of $\log k_{2\,obs}$ *vs.* J_0[11] gave a straight line with a slope of -1.43. Thus, the attacking species are protonated hypobromous acid and protonated acetyl hypobromite, not the bromine cation.

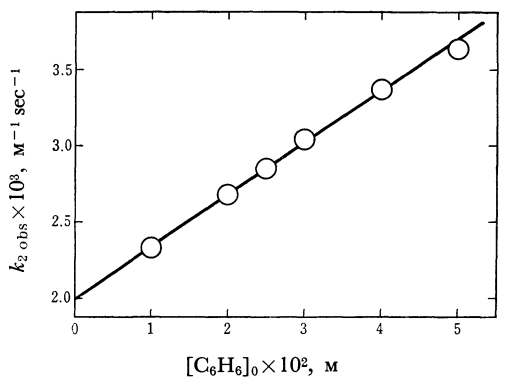

Fig. 1. The plots of $k_{2\,obs}$ *vs.* initial concentration of benzene in the bromination of benzene with 2.5×10^{-2} M potassium bromate in the presence of 3.0 N sulfuric acid at 50°C.

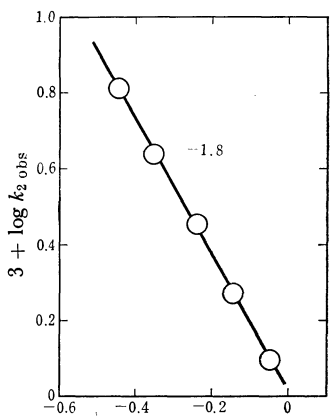

Fig. 2. The plots of $\log k_{2\,obs}$ *vs.* $-\log (C_{BH^+}/C_B)$ for the acid-catalyzed bromination of benzene with potassium bromate (both, 2.5×10^{-2} M) at 50°C.

The first participation of the proton would be the initial formation of bromic acid from the bromate anion:

$$KBrO_3 \overset{K_4}{\rightleftharpoons} K^+ + BrO_3^- \qquad (4)$$

$$H^+ + BrO_3^- \overset{K_5}{\rightleftharpoons} HBrO_3 \qquad (5)$$

The bromic acid thus formed may decompose to form hypobromous and perbromic acids, and the latter perhaps reacts with acetic acid to afford bromic acid and peroxyacetic acid:

$$3HBrO_3 \overset{K_6}{\rightleftharpoons} HOBr + 2HBrO_4 \qquad (6)$$

$$HBrO_4 + CH_3COOH \overset{K_7}{\rightleftharpoons} CH_3COOOH + HBrO_3 \qquad (7)$$

Acetyl peroxide will be formed by the reaction of peroxyacetic acid with acetic acid in the presence of sulfuric acid.[12] In fact, peroxyacetic acid and acetyl peroxide were detected by the paper chromatographic analysis of a reaction mixture. Unexpectedly, a mixture of the bromate and sulfuric acid in 50% acetic acid did not give any clear spots at the expected positions. This fact could be explained on the assumption that the equilibrium 6 lies too far to the left side. The addition of a substrate being brominated may cause the successive consumption of hypobromous acid, which is formed through Step 6, and the subsequent accumulation of peroxyacetic acid.

Previously, one of the present authors suggested the contribution of acetyl hypobromite as the active attacking species in the bromination of aromatic compounds with a mixture of peroxyacetic acid

11) These values were calculated from the results of N. C. Deno, J. J. Jaruzelski and A. Schriesheim, *J. Am. Chem. Soc.*, **77**, 3044 (1955).

12) Y. Ogata, Y. Furuya, J. Maekawa and K. Okano, *J. Am. Chem. Soc.*, **85**, 961 (1963).

and bromine in acetic acid.[13] A similar attack of acetyl hypobromite, which is thought to be formed from hypobromous and acetic acid, may also be expected in this bromination. Considering the effect of acidity on the rate, an activation of probable attacking species, such as hypobromous acid and acetyl hypobromite, by protonation would be necessary.

$$HOBr + H^+ \overset{K_8}{\rightleftharpoons} H_2\overset{\oplus}{O}Br \quad (8)$$

$$CH_3COOH + HOBr \overset{K_9}{\rightleftharpoons} CH_3COOBr + H_2O \quad (9)$$

$$CH_3COOBr + H^+ \overset{K_{10}}{\rightleftharpoons} CH_3\overset{\oplus}{C}(OBr)(OH) \quad (10)$$

$$C_6H_6 + H_2\overset{\oplus}{O}Br \overset{K_{11}}{\rightleftharpoons} \left[C_6H_5(H)(Br)\right]^{\oplus} + H_2O \quad (11)$$

(I)

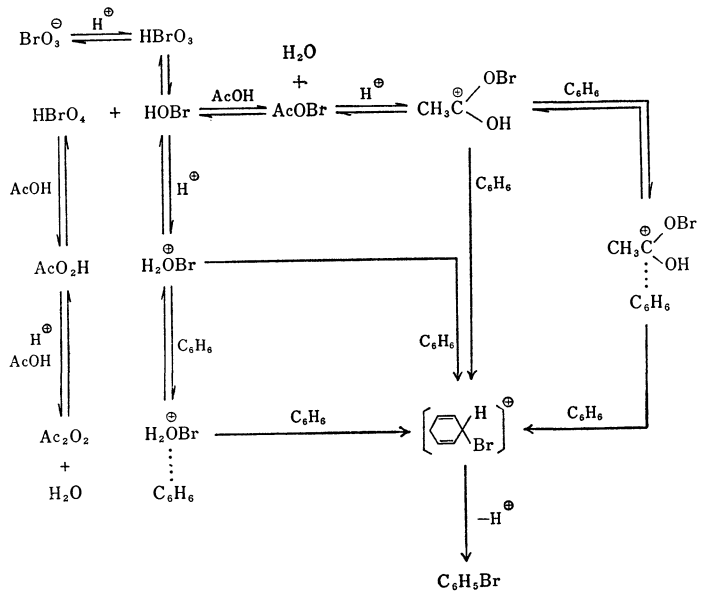
$$C_6H_6 + CH_3\overset{\oplus}{C}(OBr)(OH) \overset{K_{12}}{\rightleftharpoons} I + CH_3COOH \quad (12)$$

When deuterobenzene was used as the substrate, the isotope effect was not observed for the rate constants, k_2 and k_3. The ratios of k_{2H}/k_{2D} and k_{3H}/k_{3D} were 1.05 and 1.07 respectively. Hence, the rate-determining step on the reaction is not the step of deprotonation from the σ-complex I, but the forming step of the complex. The reaction expressed by the first term in Rate Equation (2) may consist of Steps 5—12, while the reaction of the second term may involve the rate-determining attacks on benzene by the π-complex of benzene with hypobromous acid and/or acetyl hypobromite, which were formed by the following equilibria:

$$H_2\overset{\oplus}{O}Br + C_6H_6 \rightleftharpoons H_2\overset{\oplus}{O}Br\cdots C_6H_6 \quad (13)$$

$$CH_3\overset{\oplus}{C}(OBr)(OH) + C_6H_6 \rightleftharpoons CH_3\overset{\oplus}{C}(OBr)(OH)\cdots C_6H_6 \quad (14)$$

The suggested over-all mechanism can be charted as below:



(Ac=CH_3CH)

The authors are indebted to Professor M. Okano for his helpful advice and Mr. M. Ishii and S. Miyazaki for their aids in performing these experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1001—1005 (1968)

Thermal Rearrangement of Mixed Dithiocarbamic-Imidic Anhydrides*[1]

Koshin MIYAZAKI

Research Department of Takaoka Plant, Nippon Soda Co., Ltd. Mukaino-hommachi, Takaoka-shi, Toyama

(Received November 9, 1967)

The various mixed dithiocarbamic-imidic anhydrides with the formula R_2N–C(=S)–S–C(=N–Ph)–Ph (I) rearranged to thiobenzoyl-thioureas with the formula R_2N–C(=S)–N(–Ph)–C(=S)–Ph (II) when kept at an elevated temperature in an inert solvent. This rearrangement was found to be reversible, and it followed first-order kinetics. The value of the forward rate constant (k_1) in *o*-dichlorobenzene at 100°C increased in the order: R = CH_3 > C_2H_5 > *n*-C_3H_7 > *n*-C_4H_9, and a good correlation between log k_1 and σ^* for R was obtained. The rearrangement following mixture of $(CH_3)_2N$–C(=S)–S–C(=N–Ph)–Ph and $(C_2H_5)_2N$–C(=S)–S–C(=N–C_6H_5Cl-*p*)–Ph gave no crossed products. A probable reaction mechanism was proposed.

In an earlier paper,[1] the thermal rearrangement of *O*-aryl - *S* - (*N*,*N* - dimethyl-thiocarbamoyl)-*N*-arylthiolimidocarbonates to 1,1-dimethyl-3-aryl-3-(aryloxy-thiocarbonyl)-2-thioureas was reported. Since it was of interest to investigate further the scope of this kind of rearrangement, the thermal rearrangement of *N*,*N*-dialkyldithiocarbamic-*N*-(phenyl)benzimidic anhydrides with the formula R_2N–C(=S)–S–C(=N–Ph)–Ph (I), which are similar to the thiolimidocarbonates mentioned above, was tested; moreover, the kinetics of the rearrangement for various compounds I (R = CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9) have been studied in order to establish a reaction mechanism.

Results and Discussion

Synthesis of Mixed Dithiocarbamic-Imidic Anhydrides (I). The various anhydrides were synthesized by the reaction of an appropriate sodium *N*,*N*-dialkyldithiocarbamate with a proper *N*-(aryl)benzimidoyl chloride (Eq. (1)):

$$R_2N\text{–}\underset{\underset{S}{\|}}{C}\text{–SNa} + Cl\text{–}\underset{\underset{Ph}{|}}{C}\text{=N–Ar} \rightarrow R_2N\text{–}\underset{\underset{S}{\|}}{C}\text{–S–}\underset{\underset{Ph}{|}}{C}\text{=N–Ar} \quad (1)$$

(I)

Data on their physical constants, *etc.*, are given in Table 1.

Thermal Rearrangement. In order to examine the possibility of the thermal rearrangement of I, a pale yellow solution of I in *o*-dichlorobenzene, containing 1 mg I/ml, was kept at 100°C. Upon being heated, the solution gradually turned deep yellow. In order to analyze the reaction products, the resulting solution was submitted to thin-layer chromatography on silica gel and separated into two kinds of compounds. One kinds of compounds were compounds I unchanged, while the others were newly-formed deep yellow substances (II). The results of elemental analysis showed that the composition of the compounds II was just the same as that of I. In the infrared spectrum of the compounds II, however, no $\nu_{C=N}$ at *ca.* 1620 cm^{-1} was observed, and a strong absorption band appeared at *ca.* 1510 cm^{-1}; this band may be assignable to the thioureido group.[2] On the basis of these data, it seems reasonable to assume that I gave rise to the same kind of rearrangement to thiol-imidocarbonates as has been reported previously,[1] involving the migration of the thiocarbamoyl group, thus producing 1,1-dialkyl-3-aryl-3-(phenyl-thiocarbonyl)-2-thioureas (II) with the following structure:

$$R_2N\text{–}\underset{\underset{S}{\|}}{C}\text{–}\underset{\underset{Ar}{|}}{N}\text{–}\underset{\underset{S}{\|}}{C}\text{–Ph}$$

(II)

The compounds II formed by the thermal rearrangement of I are listed in Table 2.

Kinetics of the Rearrangement. Studies of the kinetics on the rearrangement for all the compounds I were successfully carried out by observing the development of the above-mentioned yellow color using photoelectric techniques. As a result, it was found that an equilibrium existed in these systems. The values of the equilibrium constants (K), given by the equation of $K = C_{II}/C_I$, where C_{II} and C_I are the concentrations of II and I respectively at the equilibrium, in *o*-dichlorobenzene at 100°C were 2.33 for I-1, 1.08 for I-2, 0.89 for I-3, and 0.82 for I-4, and fairly good first-order forward rate constants (k_1) were derived from the

slopes of the straight lines obtained by plotting $x_e \cdot \ln(x_e/(x_e-x))$ against the time in min, where x and x_e are the concentrations of II at time t and at equilibrium respectively.

Figure 1 shows the slopes of the straight lines obtained by plotting $x_e \cdot \ln(x_e/(x_e-x))$ *vs.* the time: the results are summarized in Table 3.

From these data, it is observed that the change of the reaction rate closely parallels the structure of the alkyl group in compound I. Figure 2 shows the slope of the straight line obtained by plotting $3+\log k_1$ *vs.* σ^* for R.

It is now desirable to determine whether the reaction is intermolecular or intramolecular in order to ascertain the mechanism of the rearrangement of I to II. If the reaction is supposed to be an intermolecular mechanism such as Scheme 1, the order of k_1 should be contrary to the experimental results shown in Table 3, because the polar

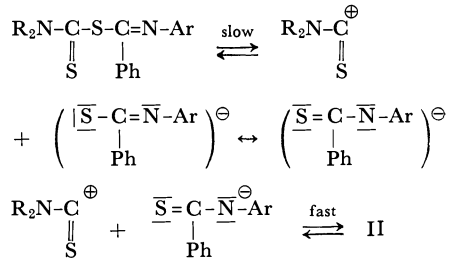
substituent constants (σ^*) of the alkyl group are 0.00 for CH_3, −0.10 for C_2H_5, −0.115 for *n*-C_3H_7, and −0.13 for *n*-C_4H_9[3]; thus, the stability of the *N,N*-dialkyl-thiocarbamoyl cation, which contributes to the reaction rate, should be increased in the order of R = *n*-C_4H_9 > *n*-C_3H_7 > C_2H_5 > CH_3.



Scheme 1

Furthermore, the crossed products, such as II-2 and/or II-5, should be detected from the crossed reaction mixture of I-1 and I-6 if the rearrangement follows the intermolecular mechanism mentioned above. In order to ascertain this fact, the crossed reaction mixture obtained was compared with the specimens of II-2 and II-5 by thin-layer chromatography. However, the chromatograms of that reaction mixture eliminated the possibility of the formation of crossed products (Fig. 3).

Taking these results into consideration, it seems plausible to conclude that the rearrangement is not intermolecular, such as Scheme 1, but intramolecular.

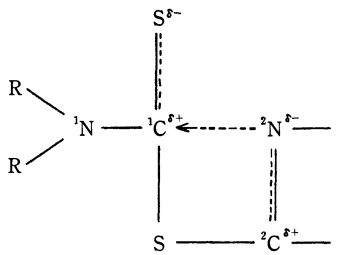
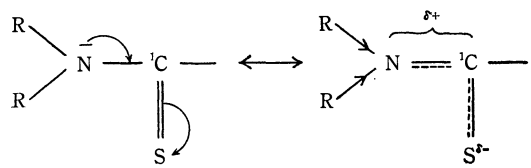
Consequently, the four-membered cyclic structure (Scheme 2) which may be formed by a nucleophilic attack of the ^2N atom of the imidocarbonyl group on the ^1C atom of the thiocarbonyl group can be considered as an intermediate in the rearrangement.



Scheme 2

The change in the rate of rearrangement with the nature of the alkyl groups can be explained by assuming as follows: The slope of the straight line in Fig. 2 shows that the rearrangement of I to II is a nucleophilic reaction ($\rho^* = 1.8$). Hence, it appears that the reaction rates depend on the reactivity of the electrophilic center on the ^1C atom. Accordingly, from a consideration of the mesomeric structure of the thiocarbamoyl group (Scheme 3), it can be supposed that a stronger electron-donating inductive effect of R, such as n-C_4H_9, can help to fill up the lack of electron density on the ^1C atom, thus resulting in a slower rate of the reaction. On the contrary, a weaker electron-donating effect of R, such as CH_3, results in a larger rate constant.



Scheme 3

Experimental

Materials. Sodium *N, N*-dialkyldithiocarbamates were prepared by the known method.[4] *N*-Phenyl- and *N*-(4-chlorophenyl)benzimidoyl chloride were prepared by the usual method.[5]

Mixed *N,N*-Dialkyldithiocarbamic-*N*-(phenyl)-benzimidic Anhydrides (I). The following general method was employed for the synthesis of the various compounds I.

A solution of sodium *N,N*-dialkyldithiocarbamate (0.05 mol) in 50 m*l* of acetone was cooled in an ice bath to a temperature of between 5 to 10°C, after which the proper *N*-(aryl)benzimidoyl chloride (0.05 mol) was gradually stirred in. After the addition had been completed, the mixture was warmed to 40°C for 5 min. It was then cooled to room temperature and poured into *ca.* 150 m*l* of cold water, by which the desired product was obtained as a pale yellow oil and crystallized spontaneously on standing. Recrystallization from a suitable solvent gave pale yellow crystals. The data are shown in Table 1.

1,1-Dialkyl-3-aryl-3-(phenyl-thiocarbonyl)-2-thioureas (II). A solution of I in an inert solvent (toluene, chlorobenzene, *o*-dichlorobenzene, *etc.* may be used) was heated on a boiling water bath for one to five hours,*2 after which the solvent was removed under reduced pressure. The crude product which remained was then purified by recrystallization or by chromatography on silica gel using as solvent benzene-*n*-hexane (2/1 v/v %).

Analytical Method. For the analysis of II in a mixture of I and II, it was advisable to use the absorbance at 452 mμ and to construct an absorbance-composition plot using a total concentration of the two components, I and II, of 100.0 mg/100.0 m*l* in *o*-dichlorobenzene. The calibration curves were obtained in this way. Since the rearrangement reactions were carried out at the same concentration, the composition of an unknown mixture could be determined by measuring the absorbance at 452 mμ and by reading the composition from the plot. The absorbance was determined with A. K. A. photo-electric-tube colorimeter (Kotaki-Seisakusho, Type No. 5-D).

Procedure for Kinetic Runs. To initiate a run, about 100 mg of I was weighed accurately. Next, in a 250 m*l* round-bottomed flask equipped with a sealed stirrer and a reflux condenser fitted with a calcium chloride drying tube, there was placed a suitable volume of *o*-dichlorobenzene (a G. R.-grade reagent was used after distillation) to make a solution of 100.0 mg I/100.0 m*l*; then the flask was immersed in a boiling water bath. When the inner temperature reached 100°C, the compound I already weighed was stirred into the flask. At appropriate intervals, a portion of the reaction mixture was taken out and cooled by immersion in cold water to room temperature. The absorbance was determined at 452 mμ, and the composition obtained from the plot. The data are shown in Fig. 1.

Equilibrium Constants (K). In the above run, the value of the equilibrium constant was derived from the analytical data of a reaction mixture heated until a constant absorbance was obtained. The values thus obtained were as follows:

$C_{II\text{-}1}/C_{I\text{-}1} = 70/30 = 2.33$, $C_{II\text{-}2}/C_{I\text{-}2} = 52/48 = 1.08$,

$C_{II\text{-}3}/C_{I\text{-}3} = 46.5/53.5 = 0.89$, $C_{II\text{-}4}/C_{I\text{-}4} = 45/55 = 0.82$

K Values Derived from Back Reactions. To confirm the K values obtained above, the following experiments were carried out: Pure accurately-weighed II (*ca.* 100 mg) was dissolved into *o*-dichlorobenzene to a concentration of 100.0 mg II/100.0 m*l*, after which the solution was heated on a boiling water bath. After 5 and/or 6 hr, a portion of the reaction mixture was

*2 1.5 hr for I-1, 2 hr for I-2, 3 hr for I-3, and 4 hr for I-4.

taken up and analyzed. The absorbances of the reaction mixture at the two intervals were equal, indicating the reaction to be equilibrium. The values of C_{II}/C_{I} measured by this method were 2.33 for II-1, 1.08 for II-2, 0.89 for II-3, and 0.82 for II-4; these values were equal to the K values derived from the corresponding forward reaction.

Reaction of Aluminum Haloalkoxide with Diazomethane

Takeo SAEGUSA, Shimpei TOMITA and Takashi UESHIMA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku Kyoto

(Received November 16, 1967)

In the reaction of diazomethane with four aluminum haloalkoxides, $Al(OCH_2CF_3)_3$ (I), $Al(OCH_2CCl_3)_3$ (II), $Al(OCH_2CBr_3)_3$ (III), and $Al[OCH(CH_2Cl)_2]_3$ (IV), a methylene insertion into the aluminum-alkoxyl linkage was observed along with the polymethylene formation. By the methylene insertion, an organoaluminum compound with a haloalkoxymethyl-aluminum linkage is formed. Among aluminum alkoxides, these four haloalkoxides are distinguished by this methylene insertion. The usual aluminum alkoxides of unsubstituted alcohols do not undergo a methylene insertion reaction, but only the polymethylene formation. The difference in the reactivity towards diazomethane between the four haloalkoxides and usual alkoxides has been explained by the difference in acid strength.

In the course of our studies of the catalytic behavior of aluminum alkoxide in the polymerization of cyclic ethers,[1,2] we prepared five aluminum haloalkoxides,[3] $Al(OCH_2CF_3)_3$ (I), $Al(OCH_2CCl_3)_3$[4] (II), $Al(OCH_2CBr_3)_3$ (III), $Al[OCH(CH_2Cl)_2]_3$ (IV) and $Al(OCH_2CHCl_2)_3$ (V). In comparison with usual aluminum alkoxides, four haloalkoxides (I to IV) are characterized by a strong electron-accepting power of aluminum (Lewis acid strength), and by a marked tendency to dissociate to solvated monomers in a donor solvent.[3,4]

In the present study, we have found that four aluminum haloalkoxides of I to IV react with diazomethane to produce the linkage of al-CH_2OR by the insertion of a methylene group into the al-OR bond:

$$\text{al-OR} + CH_2N_2 \xrightarrow{-N_2} \text{al-}CH_2OR \qquad (1)$$

(R = $-CH_2CF_3$, $-CH_2CCl_3$, $-CH_2CBr_3$, $-CH(CH_2Cl)_2$)

In the reaction of diazomethane with the usual aluminum alkoxides of unsubstituted alcohols, the above insertion reaction was not observed. The difference in reactivity between the haloalkoxides and usual alkoxides has been explained by the difference in acid strength.

The reactions of the methylene insertion into aluminum-alkyl, -halide and, -hydrogen bonds by diazomethane have been known.[5-7] The present paper will describe a finding of the methylene insertion into the aluminum-alkoxyl bond.

Experimental

Reagents. Five aluminum haloalkoxides, I to V, were prepared and purified by the procedures given in previous papers.[3,4] Aluminum isopropoxide was a commercial reagent which was purified by distillation. Aluminum *t*-butoxide was prepared by the reaction of aluminum turning and *t*-butanol, and was purified by recrystallization from diethyl ether.

A toluene solution of diazomethane was prepared by treating *N*-nitroso-*N*-methylurea with an aqueous solution of KOH in toluene.[8]

The Reaction of Aluminum Alkoxide with Diazomethane. A toluene solution of diazomethane was added, drop by drop, into a toluene suspension or solution of an equimolar amount of aluminum alkoxide

a) Based on diazomethane.
b) Diazomethane solution was added to the solid aluminum alkoxide.

under a nitrogen atmosphere at 0°C. The reaction system was kept at 0°C until the gas evolution ceased and the yellow color of diazomethane faded away. Then the reaction mixture was subjected to evaporation at 50—60°C under 0.1 mmHg for 7—10 hr. The residue of the vacuum evaporation was treated with a dilute aqueous solution of HCl. The acid hydrolysis mixture was then extracted with diethyl ether or with toluene, and the extract was examined by v.p.c. analysis for the haloalkyl methyl ether, which should have been formed by the acid hydrolysis of the product of the methylene insertion reaction if the insertion had occurred. Haloalkyl methyl ethers were identified by a comparison of the retention time of the v.p.c. with those of the corresponding authentic samples. Two columns, silicone DC 550 and PEG 20000, were employed in the v.p.c. analysis. The solid insoluble residue of acid hydrolysis was extracted with hot xylene to isolate polymethylene.

In the case of $Al(OCH_2CCl_3)_3$ (II), the reaction with diazomethane was carried out by the same procedure, and the residue of vacuum evaporation was hydrolyzed with heavy water. Deutrated methyl ether, $DCH_2OCH_2CCl_3$, was isolated by means of a preparative v.p.c. technique, and was identified by means of its NMR spectrum using Varian A-60 Spectrometer. In the NMR spectrum of a CCl_4 solution, a singlet at 3.97 ppm downfield from TMS ($CCl_3\underline{CH_2}$-, area 1.00) and a triplet with components of an equal intensity centered at 3.60 ppm ($DC\underline{H_2}$- area 1.06) were observed. The chemical shifts of these absorptions were almost the same as those of the nondeutrated methyl ether, $CH_3OCH_2CCl_3$.

Results and Discussion

The results are summarized in Table 1.

The methylene insertion reaction produces an aluminum-alkyl bond, which was examined by the formation of the corresponding methyl ether (VI) in the acid hydrolysis of the reaction mixture.

$$\text{al-OR} + CH_2N_2 \xrightarrow{-N_2} \text{al-}CH_2OR \xrightarrow{H^+} \underset{\text{(VI)}}{CH_3OR} \quad (2)$$

As to the methyl ether formation, it has been established[9] that alcohol reacts with diazomethane, in the presence of aluminum alkoxide as the catalyst, to produce alkyl methyl ether. Therefore, the formation of haloalkyl methyl ether in the present study might be ascribed to the reaction of alcohol, which was possibly produced by the partial hydrolysis of aluminum haloalkoxide with impure moisture. This reaction route does not lead to the formation of the aluminum-alkyl bond. This possibility, however, has been definitely eliminated by the following two observations:

a. The hydrolysis of the reaction mixture with heavy water produced the deutrated methyl ether (VII):

$$\text{al-}OCH_2CCl_3 + CH_2N_2 \xrightarrow{-N_2}$$

$$\text{al-}CH_2OCH_2CCl_3 \xrightarrow{D_2O} \underset{\text{(VII)}}{DCH_2OCH_2CCl_3}$$

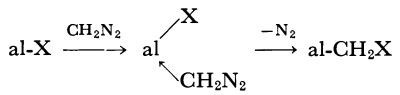
b. A reference experiment has shown that the vacuum evaporation of the reaction mixture before acid hydrolysis is quite effective in removing ether almost completely if it is present before the acid hydrolysis.

Thus, the production of haloalkyl methyl ethers in the acid hydrolysis of the reaction mixture is taken to indicate the occurrence of the methylene insertion.

Table 1 shows that the four aluminum haloalkoxides, I to IV, differ from others in their reactivity toward diazomethane. The former alkoxides react with diazomethane to form the linkages of alkoxymethylaluminum along with the formation of polymethylene. The alkoxide of V and the usual alkoxides of unsubstituted alcohols cause only the polymerization of methylene carbene from diazomethane.

Hoberg[5-7] has reported that, in the reactions of diazomethane with trialkylaluminums, alkylaluminum hydrides and alkylaluminum halides underwent the methylene insertion into aluminum-alkyl, -hydrogen, and -halogen bonds:

9) H. Meerwein and G. Hinz, *Ann.*, **484**, 1 (1930).



(X=alkyl, hydrogen, halogen)

It was also shown, however, that, in the reaction of alkylaluminum alkoxide with diazomethane, the methylene insertion into the aluminum-alkoxyl or the aluminum-alkyl bond did not take place. Only the formation of polymethylene occurred. The present study has indicated that $Al[OCH(CH_3)_2]_3$, $Al[OC(CH_3)_3]_3$, and V behave in almost the same manner as alkylaluminum alkoxide in their reaction with diazomethane, although $Al[OCH(CH_3)_2]_3$ and $Al[OC(CH_3)_3]_3$ have depressed catalytic activities for the polymethylene formation in comparison with Hoberg's alkylaluminum alkoxide and V. The present study is the first to observe the methylene insertion into the aluminum-alkoxyl bond, which is limited to haloalkoxides of aluminum.

The difference in the reactivity toward diazomethane between haloalkoxides and usual akloxides may reasonably be ascribed to the difference in acid strength. Hoberg[7] has suggested that the coordination of diazomethane onto aluminum was necessary prior to the methylene insertion. In this process, the aluminum compound acts as a Lewis acid.

By means of the Hammett indicator method as well as the extent of the shift of the infrared absorption of the xanthone carbonyl group, we have already shown that usual aluminum alkoxides and alkylaluminum alkoxides of unsubstituted alcohols are weaker acids than trialkylaluminums and alkylaluminum halides.[1] The four haloalkoxides, on the other hand, are shown to be stronger Lewis acids by the extent of the shift of the xanthone carbonyl band (Table 2). They are as strong as $AlEt_3$. Diazomethane coordinates onto haloalkoxides of strong acid, and hence the methylene insertion takes place. Unlike the four haloalkoxides, the haloalkoxide (V) does not undergo the methylene insertion reaction; this is explained by the finding that the alkoxide (V) is a much weaker acid than I—IV.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 40 1008—1013 (1967)

The Rotatory Dispersion and Stereochemistry of Organic Compounds. XIV.[1] Nitrobenzylidene Derivatives of Diethyl *d*-Tartrate

Yojiro Tsuzuki, Motoo Koyama and Koko Tanabe

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received November 21, 1967)

Anomalous optical rotation has been observed not only with the ortho-nitrobenzylidene derivative of diethyl *d*-tartrate (Tsuzuki, *Bull. Chem. Soc. Japan*, **14**, 35 (1939); *Sci. Pap. I. P. C. Res. (Tokyo)*, **35**, 425, 466 (1939)), but also with some acetylated ortho-nitrophenyl glycosides of the β-type (Capon *et al.*, *J. Chem. Soc.*, **1961**, 5172; Montgomery *et al.*, *J. Am. Chem. Soc.*, **64**, 690 (1942); Snyder *et al.*, *ibid.*, **75**, 1758 (1953); Tsuzuki *et al.*, *Bull. Chem. Soc. Japan*, **40**, 1208 (1967)). To investigate this anomalous effect of the ortho-nitro group the authors have made rotatory dispersion studies on several derivatives of diethyl *d*-tartrate as well as its alkylidene derivatives. Of these compounds examined, the compound (I) with a nitro group in the ortho-position of the phenyl group shows a positive Cotton effect at about 340 mμ, and it has been found that the nitrophenyl group is optically active. Furthermore, in order to inquire into this anomaly the authors have observed the CD, UV and NMR spectra of these compounds, from which it is concluded that the conformations of the acetal rings of all the compounds are nearly equal, and the anomalous dispersion of the compound I at about 340 mμ is assumed to be due to the n→π* transition of the nitro group with a slight shoulder appearing at 325 to 350 mμ. In view of these facts it is considered that the ortho-nitro group is twisted from the plane of the benzene ring caused by the steric hindrance of the bulky acetal ring.

Many years ago one of the authors found in the course of studies on the optical activity of some benzylidene derivatives of diethyl tartrate that the optical rotation was deeply influenced by the position of nitro group,[2,3] namely, the meta- and para-nitrobenzylidene derivatives are normally laevo-rotatory, whereas the corresponding ortho-compound shows a large positive rotation; however, such inversion of rotation can never be observed with the benzylidene derivatives that carry *o,p*-directing hydroxyl group as well as halogen atoms even in the ortho-position.

A similar anomalous ortho-nitro effect has also been noticed with other series of compounds. Of late years a number of related papers appeared on the rotation of acetylated nitrophenyl glycosides of the β-type.[4-7] Mislow *et al.*[8] found that 2,2'-dinitrobiphenyls exihibit Cotton effects at 330 mμ, the sign of which is related with the absolute configuration. Nevertheless, the cause of the anomaly has not been elucidated.

With a view to inquiring into this anomalous effect of the ortho-nitro group the authors have made rotatory dispersion studies on several derivatives of diethyl *d*-tartrate as well as its alkylidene derivatives. In order to obtain information on the conformations of these compounds the authors have furthermore observed the circular dichroism (CD), ultraviolet absorption (UV) and nuclear magnetic resonance spectra (NMR). The compounds examined were in total sixteen:

Diethyl *o*-nitrobenzylidene-*d*-tartrate (compound I),
Diethyl *m*-nitrobenzylidene-*d*-tartrate (compound II),
Diethyl *p*-nitrobenzylidene-*d*-tartrate (compound III),
Diethyl 2,5-dimethylbenzylidene-*d*-tartrate (compound IV),

1) Part XIII: Y. Tsuzuki, K. Tanabe, M. Akagi and S. Tejima, This Bulletin, **40**, 628 (1967).
2) Y. Tsuzuki *ibid.*, **14**, 35 (1939).
3) Y. Tsuzuki, *Sci. Pap, I. P. C. Res. (Tokyo)*, **35**, 425 (1939); *ibid.*, **35**, 466 (1939).
4) B. Capon, N. G. Overand and M. Sobell, *J. Chem. Soc.*, **1961**, 5172.
5) E. M. Montgomery, N. K. Richtmyer and C. S. Hudson, *J. Am. Chem. Soc.*, **64**, 690 (1942).
6) J. A. Snyder and K. P. Link, *ibid.*, **75**, 1758 (1953).
7) Y. Tsuzuki and K. Tanaka, This Bulletin, **40**, 1208 (1967). Here it was shown by studying the NMR spectra of some anomeric tetra-*O*-acetyl-D-glucopyranosides that the anomalous optical rotatory power should not be attributed to the particular conformation of the aryl group, and in particular the anomaly of *o*-nitrophenyl glucosides seems rather to be attributable to a certain property of the nitro group, such as the field effect of the group exerted upon the anomeric center through space.

Fig. 1. Structures of derivatives of diethyl tartrate examined.

Results and Discussion

In Fig. 2 are shown the RD curves of the compounds I, II, III and XIV together with the CD curve of the compound I. The compound I with a nitro group in the ortho position of the phenyl group shows a positive rotation in the region above 350 mμ and, moreover, exhibits a number of Cotton

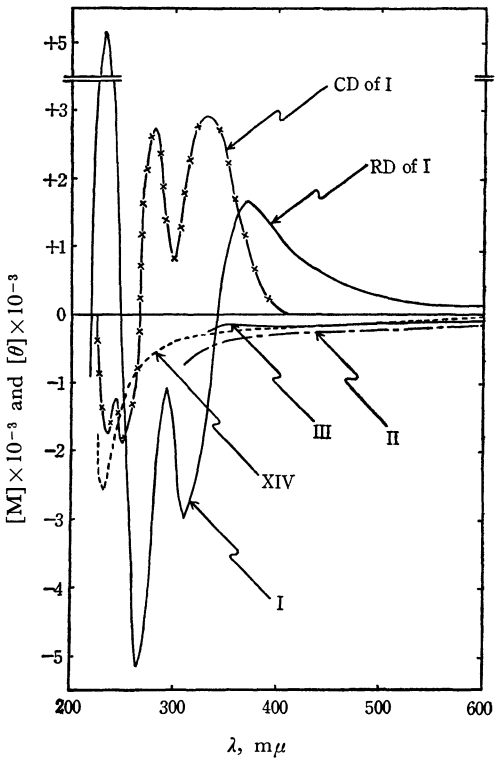

Fig. 2. RD of nitrobenzylidene derivatives and CD of I.

effects, namely two positive effects centered at 340 mμ and 280 mμ and a negative one near 248 mμ. The signs of these Cotton effects are supported by the CD curve I. On the other hand, the meta- and para-nitro derivatives (II and III) both exhibit negative plain RD curves with no anomaly near 340 mμ, which run just along their background curve XIV. The latter two compounds admitted of no RD measurement below 310 mμ due to the strong absorption.

In order to investigate whether the anomalous rotation of the compound I results from the distortion of the acetal ring effected by the steric hindrance due to the ortho-nitro group, the rotatory dispersions of the compounds IV—XVI were measured.

Figure 3 gives the RD curves of the compounds IV, V and VI, which carry a methyl group respectively on the ortho-, meta- and para-positions of the phenyl group. In Fig. 4 are shown the RD curves of the compounds VII, VIII, IX and X with a halogen atom occupying either the ortho- or para-position. Of these compounds no anomaly due to the ortho-substituent was observed. However, the *o*-iodo and *p*-chlorobenzylidene derivatives VII and X exhibit Cotton effects, though very weak, near 280 mμ. The other compounds, as are shown in Figs. 3 and 4, all exhibit negative plain curves in the region above 250 mμ, but the

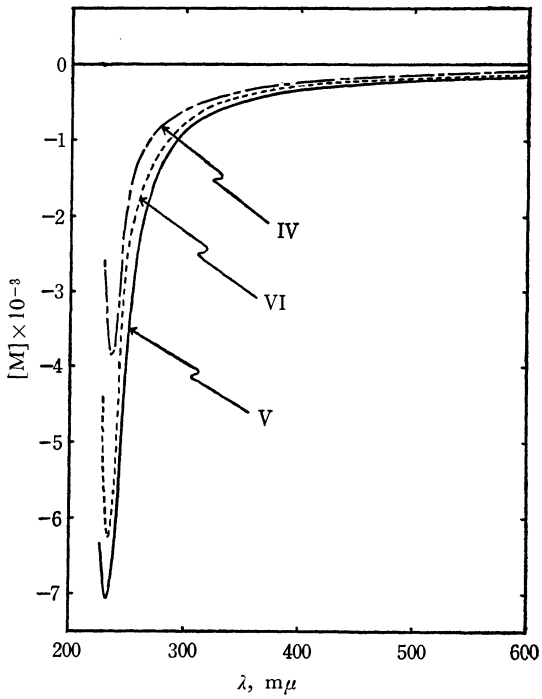

Fig. 3. RD of methylbenzylidene derivatives of diethyl tartrate.

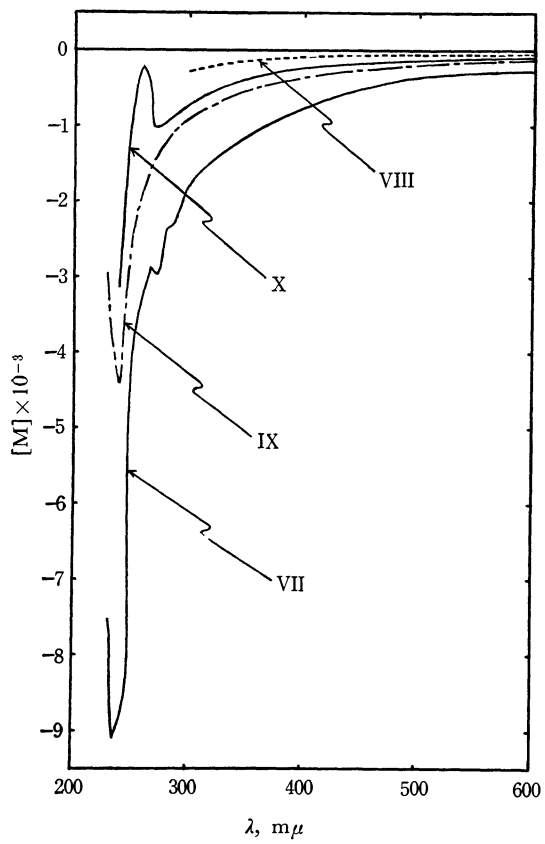

Fig. 4. RD of *o*- and *p*-halogenobenzylidene derivatives of diethyl tartrate.

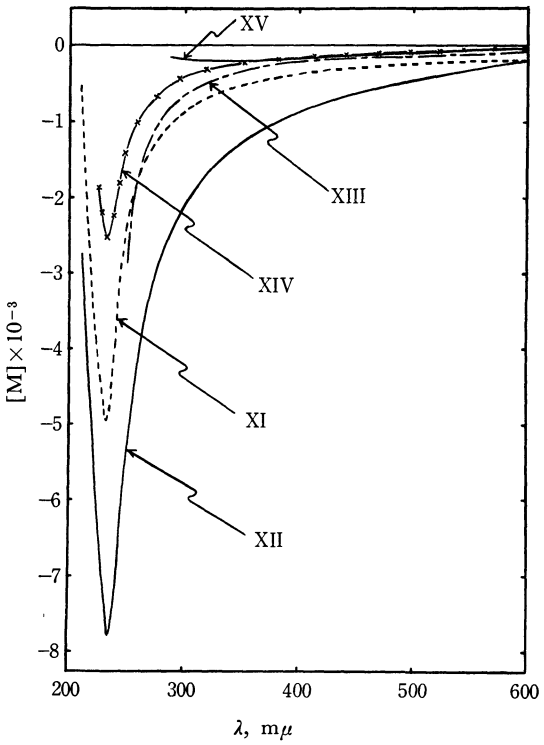

Fig. 5. RD of compounds XI—XV.

troughs appearing near 235 mμ are seen to show negative Cotton effects due to the carboxylate group.

In Fig. 5 are given the RD curves of the methylidene (XI), ethylidene (XII), vinylidene (XIII), benzylidene (XIV) and α-naphthylidene (XV) derivatives. These compounds exhibit negative plain curves in the region above 250 mμ and negative Cotton effects with troughs (near 235 mμ) similar in character to those shown in Figs. 3 and 4.

The RD curve of the compound XVI is illustrated in Fig. 6 together with the RD curves (I) and (IV) reproduced for comparison. In spite of the presence of ortho-nitro group, the compound XVI does not exhibit any Cotton effect near 340 mμ and the RD curve (XVI) runs closely along the background curve (IV) in the region above 340 mμ.

Furthermore, in view of the extraordinary optical rotation of *o*-nitrobenzylidene derivative (I), the conformation of the acetal ring was investigated by means of NMR spectrum. In the cases of R≠R', as may be seen in Fig. 7, the protons H_A and H_B are different in chemical environment, so that they interact to give a spin-spin coupling. From the coupling constant J_{AB}, as well as from Shimizu equation,[9]

$$J_{AB} = C + A|\cos\theta|,$$

9) H. Shimizu, "High Resolution Nuclear Magnetic Resonace," Maruzen, Tokyo (1962), p. 70.

where $C=0$ and $A=6.5+$ 1.5 cps in these cases, the angles, θ, of H_A–C–C–H_B can be calculated. The results are given in Table 1.

As may be seen in Table 1, the angles, θ, of the compounds are all in fairly good accordance with each other except for XVI. In other words, the stable conformations of the acetal rings of these compounds are nearly identical, where the two carboxylate groups of the tartrate are of the trans-form, and the acetal rings are, in all cases, of the half-chair form.

These compounds show in general negative rotations over all the wavelength range (Figs. 2, 3, 4, 5 and 6) but for the compound I. The fact that the angle, θ, of the compound XVI is considerably smaller than those of the others may be explained in terms of steric hindrance. It is thus concluded that the anomalous rotation of the *o*-nitrobenzylidene derivative (I) is not due to the distortion of the acetal ring that may be produced by the steric hindrance by the *o*-nitro group. It is, therefore, better to attribute this anomalous rotation to the property of the *o*-nitrophenyl group itself (Fig. 5).

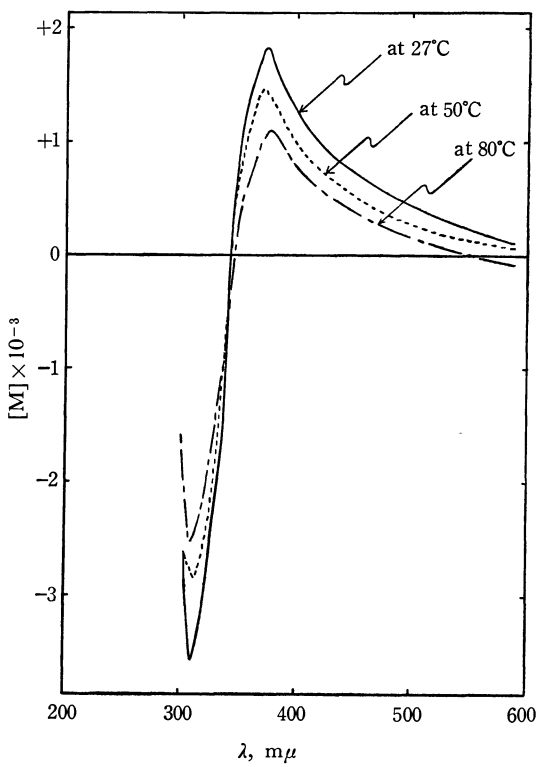

Fig. 8. Temperature variation of RD of I (in dimethyl formamide).

In addition, the authors have observed that the optical rotation of *o*-nitrobenzylidene derivative (I) varies with temperature: $[\alpha]_D^{27}$ +30.7°, $[\alpha]_D^{50}$ +20.9° and $[\alpha]_D^{80}$ −21.5° in dimethyl formamide, and with the increase of temperature the optical rotation tends to approach those of the *m*- or *p*-nitrobenzylidene derivatives, and have further noticed that the molecular amplitude of the Cotton effect near 340 mμ also diminishes with rise of temperature. The RD curves measured at 27, 50 and 80°C, of the compound I are shown in Fig. 8.

In view of these facts the ortho-nitro group must be twisted from the plane of the benzene ring by the steric hindrance of the bulky acetal ring, which may, on the other hand, be understood from the decrease of the strength of the UV absorption spectra. These can be regarded as charge transfer bands in view of Nagakura's report,[10] as is seen in Fig. 9; the compounds I and XVI each with a nitro group in the ortho-position of the phenyl group show $\varepsilon = 4.8 \times 10^3$ at 254 mμ and a shoulder at 243.6 mμ respectively, while the compounds II and III with a nitro group in the meta- and para-position show respectively $\varepsilon = 9.4 \times 10^3$ at 258.2 mμ and $\varepsilon = 10.2 \times 10^3$ at 260 mμ.

As may be seen in Fig. 6, the compound I could be measured down to 220 mμ, where the strong negative Cotton effect near 248 mμ appears to be due to the above-mentioned charge transfer band. In reality the UV spectra of the nitrobenzylidene derivatives have slight shoulders at 325—350 mμ due to the n–π^* transition that occurs possibly in the nitro group (Fig. 9). In the case of the compound I, this chromophore becomes optically active, but the compound XVI, in spite of its ortho-nitro group, does not exhibit any Cotton effect near 340 mμ. Furthermore, its UV absorption near 250 mμ is also very slight. However, the RD curve (XVI) also shows a Cotton effect near 290 mμ similar to the RD curve (I), although the former is very weak (see Fig. 6).

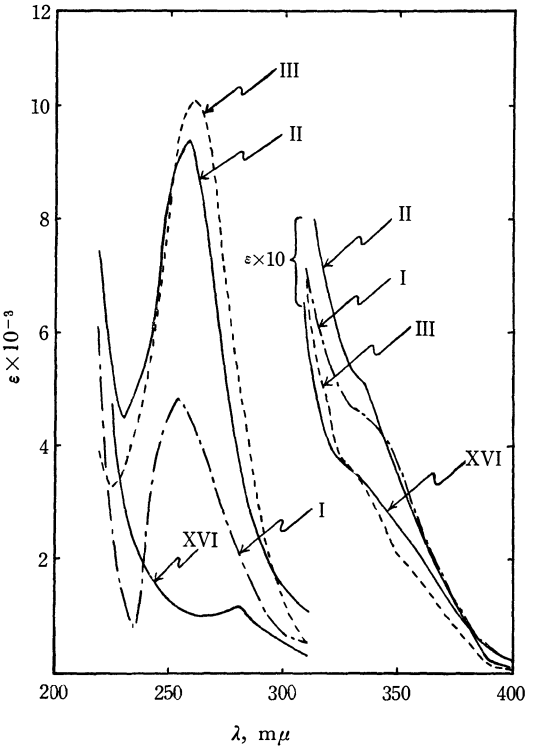

Fig. 9. UV spectra of nitrobenzylidene derivatives of diethyl tartrate.

According to the measurement and discussion by Nagakura *et al.*[10] of the absorption spectrum of nitromesitylene, the nitro group is twisted by 66.4° from the benzene ring plane and, accordingly, the conjugation between the mesityl and nitro groups must be prohibited to a great extent. Thus it is expected that the nitro group is in a similar manner twisted by about 30° in the *o*-nitrobenzylidene derivative (I) and by more than 66° in the 2-nitro-3,6-dimethylbenzylidene derivative (XVI).

These facts and considerations may lead to the conclusion that the anomalous positive rotation observed only in the *o*-nitrobenzylidene derivative is caused by its intense positive Cotton effect centered at 340 mμ, which dominates the positive sign of rotation further in the visible, and even if a nitro group is introduced in the ortho position, the nitro group cannot necessarily become optically active, as is seen in the compound XVI, which exhibit no anomalous rotation.

However, another important factor which induces the optical activity of the ortho-nitro group is to be sought for in the conjugation between the phenyl and nitro groups. The appearance of the Cotton effect at 260 mμ due to the charge transfer band shows that the *o*-nitro group is twisted unsymmetrically from the benzene ring plane under the influence of the unsymmetrical acetal ring, and the fact that molecular amplitude of the Cotton effect centered at 340 mμ distinctly decreases with rise of temperature may be interpreted in terms of the decrease of the unsymmetry of the twisted nitro group.

Anyhow, it must be admitted that further study will be needed to make clear the cause of the anomaly in rotation.

Experimental

The samples were all prepared according to the method described in the literature[11,12] at temperatures from 80 to 120°C. They were purified by recrystallization several times from ethyl alcohol or ethyl

alcohol-water, or by distillation in vacuum.

The rotatory dispersion was measured in ethyl alcohol at the temperatures 22 to 25°C in the wavelength region from 210 to 600 mμ with a Rudolph spectropolarimeter and JASCO optical rotatory dispersion recorder of the ORD/UV-5 type, and the circular dichroism was measured with the latter instrument. The NMR spectra were measured in carbon tetrachloride with tetramethylsilane as an internal reference with a Varian A-60 spectrometer. The ultraviolet absorption was measured in ethyl alcohol with a self-recording spectrophotometer of Hitachi EPU-II type.

Aminocyclitols. XVII. A Facile Synthesis of 2-Deoxystreptamine

Tetsuo SUAMI, Frieder W. LICHTENTHALER,* Seiichiro OGAWA, Yasuo NAKASHIMA and Hiroshi SANO

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo
**Institut für Organische Chemie, Technische Hochschule Darmstadt, 61 Darmstadt, Germany*

(Received November 21, 1967)

Bromination of *myo*-inosadiamine-1,3 dihydrochloride or its di-*N*-acetyl derivative with acetyl bromide and acetic anhydride yielded pentaacetyl-2-bromo-2-deoxy-*scyllo*-inosadiamine-1,3 (III), which upon reductive debromination afforded pentaacetyl-2-deoxystreptamine (IV). The configurations of the new compounds obtained were established by nuclear magnetic resonance and chemical evidences. A mechanism of the bromination reaction is presented, based on the configuration of the bromo-compound.

2-Deoxystreptamine has been found as a component of the antibiotics neomycin,[1] kanamycin,[2] paromomycin,[3,4] and gentamicin.[5]

The structure and configuration was established to be a 1,3-diamino-4,5,6-cyclohexanetriol with the all-trans configuration, by analogy of the stereochemistry of streptamine,[6] and this has been further confirmed by Lemieux by nuclear magnetic resonance (NMR) spectroscopy.[7]

In the present study we wish to report a two step synthesis of 2-deoxystreptamine from *myo*-inosadiamine-1,3.[8] When *myo*-inosadiamine-1,3 dihydrochloride (I)[9] or its di-*N*-acetyl derivative (II) are heated in a mixture of acetyl bromide and acetic anhydride in a sealed tube at 130—135°C for 6 hr, the identical products (mp 256.5—258°C dec.) are obtained in 48 and 16% yield. The structure and configuration of this product was established to be pentaacetyl-2-bromo-2-deoxy-*scyllo*-inosadiamine-1,3 (III) by elementary analysis, the NMR spectroscopic data and chemical evidence as described below.

The NMR spectrum of III in d_6-dimethylsulfoxide revealed two sharp signals at τ 8.04 (9H) and 8.23 (6H), which can be unequivocally assigned to three equatorial acetoxy groups and two equatorial acetamido groups on the basis of acetyl resonance ranges established for this solvent.[10] An axial acetoxy group, the resonance peak of which would be expected to appear between τ 7.80 and 7.86,[10] is not observed, thus establishing the preferential displacement of the axial hydroxyl group on C-2 by a bromide ion. The configuration of the bromo group, however, could not be deduced from the NMR spectrum, due to the rather complex multiplet patterns of the ring

protons.

Reductive debromination of III with Raney nickel under a hydrogen atmosphere (4 kg/cm²) in aqueous ethanol in the presence of Amberlite IR-4B afforded in 45% yield pentaacetyl-2-deoxystreptamine (IV), which was identified by comparison of mp, IR and NMR spectra with those of an authentic sample.[2]

On treatment of III with sodium acetate in aqueous 2-methoxyethanol followed by acetylation, hexaacetyl-*myo*-inosadiamine-1,3 (VII) is obtained in 62% yield. The stereoselectivity of this reaction can only be rationalized by proceeding *via* an oxazolinium intermediate[11,12] with subsequent cis-opening by water (V→VI). The formation of VI however requires an equatorial bromo group as in III, thus establishing its configuration. In the alternate configurational possibility with an axially oriented bromo group (VIII), an anchimeric assistance of the acetamido group is not possible and thus—under the same conditions—should give in a direct S_N2[13] displacement of the bromo group hexaacetyl-streptamine, contrary to the facts.

The mechanism of the bromination reaction is proposed as followings. The results found in the bromination of *myo*-inosadiamine-1,3 and *epi*-inosamine-2 (IX→X)[12] in a mixture of acetyl bromide and acetic anhydride give a strong evidence that the hydroxyl groups vicinal and in cis-position to an amino or acetamido group are preferentially displaced by bromine. Supporting this are the findings that streptamine dihydrochloride (XI) and di-*N*-acetyl-*myo*-inosadiamine-4,6 (XII), both having no *cis* amine-ol arrangement, fail to react with acetyl bromide in acetic anhydride, as evidenced by the isolation of the starting materials in the form of their hexaacetates. On the basis of these results, it seems obvious that any mechanism for the conversion of aminoinositols to bromo- or dibromo-derivatives with acetyl bromide and acetic anhydride must explain: (i) why the acetamido group is necessary for a facile bromination; (ii) why the *trans* amine-ol compounds fail to react and (iii) why an inversion of the configuration attends the replacement process. Of the many mechanisms considered, one involving what Boschan and Winstein[14] termed "front-side participation" seemingly meets the above described requirements.

As exemplified with *myo*-inosadiamine-1,3 or its di-*N*-acetyl derivative, the first step of the reaction is likely to be the formation of an intermediate XIII, generated by partial acetylation, since the axially oriented hydroxyl group on C-2 is less reactive towards acylation than the equatorial ones.[15,16] "Front-side participation" then yields an oxazolidine intermediate (XIV or XV) which is converted to an oxazolinium ion (XVI). Then XVI is opened by S_N2 attack of the bromide ion to give III.

This mechanistic course readily explains the facile formation of tetraacetyl-1,5-dibromo-1,5-dideoxy-*rac*-inosamine-6 (X) from *epi*-inosamine-2 as well as the inertness of *scyllo*-1,3- and *myo*-4,6-inosadiamines (XI and XII) towards this reaction.

A similar mechanistic course, with a participation of an acetoxy group, undoubtedly governs

the acetyl bromide-acetic anhydride bromination of *myo*- and *epi*-inositols, since it serves to explain the formation of 2-bromo-2-deoxy-*scyllo*-inositol and 1-bromo-1-deoxy-*rac*-inositol from the former[17] and of 5-bromo-5-deoxy-*allo*-inositol from the latter.[18]

Experimental

The melting points were determined in a liquid bath and are corrected. The infrared spectra were determined by pressed potassium bromide disks. The NMR spectra of the samples were determined at a frequency of 60 Mc with a Japan Electron Optics Laboratory JNM-C-60 spectrometer in deuteriochloroform or d_6-dimethylsulfoxide with tetramethylsilane as an internal standard. The peak positions are expressed by τ-values.

Pentaacetyl-2-bromo-2-deoxy-*scyllo*-inosadiamine-1,3 (III). a) A mixture of *myo*-inosadiamine-1,3 dihydrochloride (I) (882 mg),[9] acetyl bromide (1.2 m*l*) and acetic anhydride (2.6 m*l*) was heated in a sealed tube at 130—135°C for 6 hr. After cooling, 1.29 g of the crystalline precipitate was collected by filtration. The crude product was recrystallized from ethanol to give 586 mg of colorless needles melting at 256.5—258.5°C (dec.). The mother liquor was evaporated and the residue was acetylated with acetic anhydride (7.5 m*l*) and pyridine (7.5 m*l*) overnight at room temperature. After an excess amount of acetylating reagent had been removed, the residue was crystallized from ethanol giving 244 mg of colorless needles which was identical with the product in the first crop. The total yield was 48.3% (830 mg).

Found: C, 42.92; H, 5.06; N, 6.24; Br, 17.52%. Calcd for $C_{16}H_{23}N_2O_8Br$: C, 42.58; H, 5.14; N, 6.21; Br, 17.71%.

NMR: (d_6-DMSO) three equatorial acetoxy groups, τ 8.04(9H); two equatorial acetamido groups, τ 8.23 (6H).

b) Di-*N*-acetyl-*myo*-inosadiamine-1,3 (II, 644 mg)[19] was brominated in a mixture of acetyl bromide (0.8 m*l*) and acetic anhydride (1.7 m*l*) similarly as described above, giving 178 mg (16.1%) of III.

Hexaacetyl-*myo*-inosadiamine-1,3 (VII). A mixture of III (190 mg), sodium acetate (197 mg) and 90% aqueous 2-methoxyethanol (10 m*l*) was heated under reflux for 15 hr. Then the solution was evaporated under reduced pressure, and the residue was acetylated with acetic anhydride and pyridine. After an excess acetylating reagent was removed by evaporation, the residue was recrystallized from ethanol to yield 112 mg (61.6%) of colorless plates melting at 282—284°C. This product was identified with an authentic sample of hexaacetyl-*myo*-inosadiamine-1,3[19] by a mixed melting point determination and IR spectra.

Pentaacetyl-2-deoxystreptamine (IV). A 236 mg portion of III was hydrogenated in 50% aqueous ethanol (16 m*l*) with Raney nickel (1.5 spatulas) and Amberlite IR-4B (4 m*l*) under 4 kg/cm² of hydrogen pressure for 20 hr at 30°C. After the catalyst and the ion-exchange resin were removed by filtration, the filtrate was evaporated under reduced pressure. The residue was recrystallized from methanol, giving 87 mg (44.5%) of colorless prisms melting above 300°C. The product was identified with an authentic sample of pentaacetyl-2-deoxystreptamine which had been prepared from kanamycin[2] by IR and NMR spectra.

Bromination of Streptamine Dihydrochloride (XI). Streptamine dihydrochloride (1.00 g)[20] was heated in a mixture of acetyl bromide (1.5 m*l*) and acetic anhydride (2.5 m*l*) in a sealed tube as described above at 150—160°C. Hexaacetyl-streptamine (1.35 g) was recovered in 81.4% recovery, which was identified with an authentic sample[22] by IR spectra and its characteristic transition point at 248°C.

Bromination of Di-*N*-acetyl-*myo*-inosadiamine-4,6 (XII). Finely powdered di-*N*-acetyl-*myo*-inosadiamine-4,6 (1.00 g)[21,22] was heated in an acetyl bromide-acetic anhydride mixture as described above at 130—135°C. Then the reaction mixture was evaporated to dryness and the residue was recrystallized from ethanol

Reduction Product and Leuco-form of Flavanthrone*1

Junji AOKI

Department of Chemistry, Faculty of Science, Toho University, Okubo, Narashino, Chiba

(Received October 11, 1967)

By reducing flavanthrone (II), 8,16-diazapyranthrene (V) (denoted as flavanthrene) was obtained. On the other hand, leucoflavanthrone dibenzoate was also prepared. Since these two substanses give nearly identical absorption spectra, the leucobenzoate is considered to have the VI formula (5,13-dibenzoyloxy-8,16-diazapyranthrene) and to belong to the same conjugated system as flavanthrene. Consequently, it may be considered that the leuco-form of flavanthrone corresponds to the IV formula (5,13-dihydroxy-8,16-diazapyranthrene) in which two carbonyl groups are reduced, but not the **III** formula (8-hydro-13-hydroxy-5-oxo-8,16-diazapyranthrene) previously presented. In addition, the leucobenzoate can also be synthesized by boiling the quinone with zinc dust and benzoyl chloride in *o*-dichlorobenzene containing pyridine. This method, devised by the author, is easy to perform and gives a good yield.

Flavanthrone (II) is a yellow vat color and is also the diaza compound equivalent to pyranthrone (I) in the field of the polycyclic system. Studies of this substance and of related compounds have already been carried out by Scholl *et al.*[1] There are, however, some doubtful points in their results. For example, the leuco-form was assigned the III formula, in spite of the fact that the IV formula is more reasonable. Furthermore, diazapyranthrene (V) which corresponds to the skeleton of flavanthrone, has not yet been synthesized.

The present investigation was undertaken in order to prepare this reduction product and the related compounds; it has been found during this work that the leuco-form of flavanthrone corresponds to the IV formula.

As is well known, the leuco compound is very unstable in air. It is, therefore, very difficult to isolate it, but it is possible to prepare a kind of ester, "leuco-ester," by adding acid chloride to the vat. The leuco-ester (VIII) may be considered to be a derivative of the corresponding hydrocarbon, since it is not a compound of a quinonoid form (VII) but belongs to a conjugated system of the

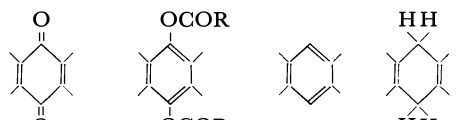
Leucoflavanthrone dibenzoate	348	367	395	416	442	475	508

hydrocarbon type (IX). In addition, it may be supposed that the ionization energy of the substituent ($-OCOC_6H_5$) is not small. It may, therefore, be considered that the absorption spectrum of the leuco-ester is about the same in appearance as that of the hydrocarbon and that the former appears in the region of somewhat longer wavelengths than the latter.



VII VIII IX X

The present author synthesized the lecuobenzoates of anthraquinone, pyranthrone, violanthrone, *etc.*,[2] examined their absorption spectra, and confirmed the suggestion mentioned above: these leucobenzoates gave absorption spectra nearly identical with those of the corresponding hydrocarbon, although they were somewhat red-shifted, as is shown in Table 1. These facts are not only useful for examining the structure of the leuco compound, but also give proof that the hydrocarbon*2 belongs to the aromatic hydrocarbon type (IX), but not its dihydro form (X).

Concerning flavanthrone (II), when the leucobenzoate was sysnthesized by the author's method, brown needles were obtained. On the other hand, when the zinc-dust fusion was applied to flavanthrone, a reduction product of the hydrocarbon type, a product which might be called "flavanthrene," was obtained as reddish brown needles which melted at 386—388°C. These two substances gave the absorption spectra shown in Fig. 1 and Table 1. By comparing these spectra, it may be found that the absorption spectrum of leucobenzoate is nearly identical with that of flavanthrene, although somewhat red-shifted.

As has been described above, this fact means that these two substanses belong to the same polycyclic conjugated system. The absorption band of flavanthrene is situated in a region of longer wavelengths than that of pyranthrene; the results of

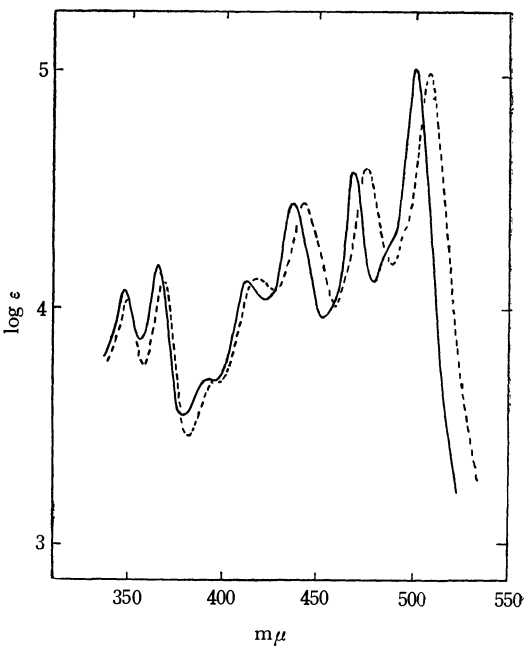


Fig. 1. Absorption spectra of flavanthrene and leucoflavanthrone dibenzoate (broken line) in 1,2,4-trichlorobenzene.

2) The synthesis of "leuco-ester" is generally carried out by adding acid chloride or acid anhydride to the vat, but a large excess of the reagent is necessary and still the yield is low. The following method, devised by the author, is easy to perform and gives a good yield.

A mixture of quinone (1 part), pyridine (1 part), and *o*-dichlorobenzene (30—50 parts) is refluxed, and then zinc dust (1 part) is added little by little. After several minutes, benzoyl chloride (1 part) is added, and the mixture is refluxed for 10—30 min; after cooling, the same volume of ethanol is added. After the mixture has stood overnight, the precipitate is collected and boiled with ethanol to remove the soluble impurities. Finally, it is recrystallized from a suitable solvent.

In addition, pyridine is indispensable for this reaction; indeed, more of it is necessary than the mole ratio of benzoyl chloride.

*2 Many kinds of condensed polycyclic hydrocarbons are prepared by the zinc-dust fusion of quinones. In this case, it is possible also to produce the dihydro compound.

the elementary analysis indicate that flavanthrene does not contain oxygen. From these facts, flavanthrene may be considered to be a compound with the V formula, 8,16-diazapyranthrene. Since the leucobenzoate corresponds to the derivative of flavanthrene and since the analysis indicates that it is dibenzoate, this ester may be considered to have the VI formula.

In addition, the author synthesized leucobenzoate by adding benzoyl chloride to the vat.*3 Since flavanthrone is readily vatted, the synthesis was carried out under six sets of conditions, from 20°C to 75°C; all the products gave absorption spectra identical with that of the ester described above.

These results mean that the author's method was useful in this case also and, further, confirm that the leuco-form of flavanthrone has the IV formula in which two carbonyl groups are reduced, not the III formula hitherto proposed.

Experimental

The melting points were measured in a liquid bath or in an air bath and are uncorrected.

Anthracene. The synthesis was carried out by the method described in Ref. 3. Colorless fine plates with a violet fluorescence were obtained by recrystallization from xylene. Mp 212.5°C (Ref. 3, 213°C).

Leucoanthraquinone Dibenzoate. A mixture of 5.0 g of anthraquinone, 5.0 g of zinc dust, 5.0 g of pyridine, and 200 m*l* of *o*-dichlorobenzene was refluxed for about 10 min. Then 5 g of benzoyl chloride was added, and boiling was continued for 30 min. After hot filtration, 200 m*l* of ethanol was added to the filtrate and the mixture was allowed to stand overnight. The crude product (5.2 g) was recrystallized from *o*-dichlorobenzene, giving pale yellow needles which melted at 292—293°C (Ref. 4, 293°C). This product is soluble in concentrated sulfuric acid with a yellow color.

Found: C, 80.62; H, 4.51%. Calcd for $C_{28}H_{18}O_4$: C, 80.37; H, 4.34%.

Pyranthrene. The synthesis was carried out by the method described in Ref. 5.

Leucopyranthrone Dibenzoate. Synthesis was carried out by the method described in Ref. 2 (pyranthrone: 2.0 g; *o*-dichlorobenzene: 80 m*l*). The crude product was recrystallized from trichlorobenzene, giving 1.4 g of fine, yellow-brown needles which colored at about 400°C but which did not melt below 450°C. This product is soluble in an organic solvent, giving a yellow color and a green fluorescence, while in a concentrated sulfuric acid solution it is blue.

Found: C, 85.86; H, 4.03%. Calcd for $C_{44}H_{24}O_4$: C, 85.70; H, 3.92%.

Violanthrene. The synthesis of the authentic sample has already been reported.[6]

Leucoviolanthrone Dibenzoate. The synthesis was carried out by a method similar to that used for pyranthrone. The crude product was recrystallized from *o*-dichlorobenzene, giving fine, red-brown needles which did not melt below 450°C, although they sintered at 358—364°C.*4 Although this product is hardly soluble in an organic solvent, its solution gives a yellow-green fluorescence, while a concentrated sulfuric acid solution shows a blue color.

Found: C, 86.71; H, 4.10%. Calcd for $C_{48}H_{26}O_4$: C, 86.47; H, 3.93%.

Leuco - 16, 17 - dihydroxyviolanthrone Tetrabenzoate. A mixture of 1.0 g of 16,17-dihydroxyviolanthrone dibenzoate,[6] 2 g of pyridine, 1.5 g of benzoyl chloride, and 200 g of *o*-dichlorobenzene was boiled, and then 1.0 g of zinc dust was added little by little. After the mixture had been refluxed for 10 min, the zinc dust was removed by hot filtration. The filtrate was concentrated and ethanol was added, whereupon 1.2 g of red crystals were obtained. They were recrystallized from chlorobenzene, giving fine, red leaflets which melted at 333°C (decomp.). This product is soluble in an organic solvent, giving a strong yellow fluorescence, while in a concentrated sulfuric acid solution it shows a violet-blue color.

Found: C, 82.02; H, 3.91%. Calcd for $C_{62}H_{34}O_8$: C, 82.11; H, 3.78%.

Flavanthrene (V). The synthesis was performed by the zinc-dust fusion of flavanthrone (II). A mixture of 1.0 g of flavanthrone, 1.0 g of zinc dust, 5 g of zinc chloride, and 1 g of sodium chloride was fused at 280—290°C for 10 min. After cooling, the reaction mixture was dissolved in water and the insoluble part was filtered off. Then, it was treated with an alkaline hydrosulfite solution and the unchanged material was removed as the soluble part. The excess of zinc dust was dissolved by treatment with a diluted hydrochloric acid solution. Yield, 0.90 g of a grey black powder. It was recrystallized from trichlorobenzene, giving 0.35 g of reddish-brown needles which melted at 386—388°C. This product is soluble in an organic solvent, giving a yellow color and a stronger and more yellowish-green fluorescence than pyranthrene, while in a concentrated sulfuric acid solution it is blue-green.

Found: C, 88.72; H, 3.82; N, 7.34%. Calcd for $C_{28}H_{14}N_2$ (V): C, 88.87; H, 3.73; N, 7.40%.

Leucoflavanthrone Dibenzoate (VI). *Method Performed in a Solvent.* A mixture of 0.5 g of flavanthrone, 0.6 g of zinc dust, 1 g of pyridine, and 50 m*l* of *o*-dichlorobenzene was refluxed for 10 min. Then, 0.6 g of benzoyl chloride was added, after which the reaction mixture was further refluxed for 30 min. After the mixture had then cooled, 50 m*l* of ethanol was added and the mixture was allowed to stand overnight. The precipitate was collected, and this crude product (1.05 g, containing zinc dust) was recrystallized from trichlorobenzene, giving 0.26 g of fine, brown needles which did not melt below 450°C, although they sintered at 358—362°C.*4 This product is soluble in an organic solvent with a strong yellowish-green fluorescence,

*3 The leucobenzoate prepared from a vat is an authentic sample equivalent to the actual leuco compound.

*4 It is considered that, during sintering, the original quinone with a high melting point is reproduced. Hence, the sintering may be regarded as a kind of decomposition.

while a concentrated sulfuric acid solution shows a green color.

Found: C, 80.93; H, 3.92; N, 4.41%. Calcd for $C_{42}H_{22}O_4N_2$ (VI): C, 81.54; H, 3.58; N, 4.53%. (Calcd for monobenzoate of III, $C_{35}H_{18}O_3N_2$: C, 81.70; H, 3.53; N, 5.44%)

Method Performed in a Vat. Flavanthrone (0.1 g) was vatted in 20 m*l* of an alkaline hydrosulfite solution (NaOH, 4%; $Na_2S_2O_4$, 2%). After the substance had then been kept at the reaction temperature (Table 2) for 20 min, 0.7 g of benzoyl chloride was added and the reaction mixture was further kept at the same temperature for 2 hr. Then, after cooling, the precipitate was filtered off and washed, successively, with an alkaline hydrosulfite solution and with water. Since it was inevitable that the crude product obtained by this method would contain considerable amounts of the unchanged material, further purification was carefully carried out by recrystallization from trichlorobenzene; the results shown in Table 2 were obtained.

Table 2. The results of vatting method

Reaction temp., °C	20	30	40	50	60	75
Yield, g	0.05	0.01	0.05	0.04	0.03	0.01

However, all of products gave absorption spectra identical with that of the sample prepared in a solvent.

The author wishes to express his thanks to Professor Saburo Nagakura, Professor Hiroo Inokuchi, and Dr. Yoshiya Harada of the Institute for Solid State Physics, The University of Tokyo, for their kind advice. He is also indebted to Mrs. Hisa Watanabe for her assistance.

NOTES

The Reaction of Triethylaluminum with Phthalic Anhydride

Yoshio BABA

Resources Research Institute, Kawaguchi, Saitama

(Received April 17, 1967)

In the Grignard reaction two different mechanisms have been proposed for the reaction with phthalic anhydride and for the reaction with ortho-disubstituted phthalic anhydride.

The present investigation of the reactions of triethylaluminum with phthalic anhydride, 4-methylphthalic anhydride, and 4,7-dimethylphthalic anhydride was undertaken in order to study the steric effect which has been observed in the case of Grignard reactions.

Experimental

All the reactions were carried out in an atmosphere of dry nitrogen. The melting points were measured on a micro hot stage and were not corrected.

Materials. Triethylaluminum purchased from the Ethyl Corp. was used without further purification. Commercial phthalic anhydride (mp 131—132°C) was purified by sublimation. 4-Methylphthalic anhydride (mp 115—116°C) was synthesized from piperylene-maleic anhydride adduct *via* 4-methyl-3,4,7,8-tetrahydrophthalic anhydride and the corresponding tetrabromide.[1] 4,7-Dimethylphthalic anhydride (mp 142—143°C) was prepared by the dehydration of the 3,5-dimethylfuran-maleic anhydride adduct.[1]

Reaction of Phthalic Anhydride with Triethylaluminum. A solution of triethylaluminum (11.1 g) in dry petroleum ether (bp 35—45°C) was added, drop by drop, at room temperature into a suspension of phthalic anhydride (14.8 g) in 100 m*l* of dry petroleum ether. The solid anhydride dissolved readily, resulting in a faintly brown-colored solution. After refluxing for 1.5 hr, the reaction mixture was cooled in an ice-bath, after which the aluminum compound was decomposed by adding 17.5 m*l* of ethanol. A solid precipitate, separated on the addition of 20 g of cracked ice, was collected by suction filtration. The filter cake was washed thoroughly with ether and poured into ice-cooled, diluted hydrochloric acid. The insoluble acid substance was extracted with ether. The unchanged phthalic acid which separated out when the crude oily product (13.4 g) was left standing, was collected by filtration; mp 189—191°C, 3.8 g (22.9%). The mother liquor was distilled under reduced pressure, and a fraction boiling at 150—160°C/5 mmHg (6.2 g) was collected; it solidified on standing, mp 72—73°C, from water; it showed no depression in melting point in a mixed melting point test with phthalide.

Reaction of 4,7-Dimethylphthalic Anhydride with Triethylaluminum. The reaction of 4,7-dimethylphthalic anhydride (6.2 g) with an equimolar amount of triethylaluminum under the conditions described above gave 5.4 g of a reaction product (mp

1) M. S. Newmann and C. D. McCleary, *J. Am. Chem. Soc.*, **63**, 1543 (1941).

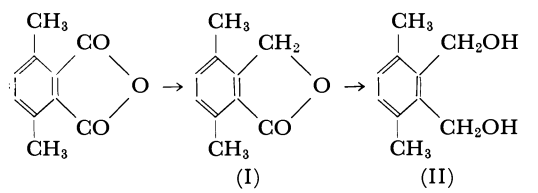
67—69°C); practically no unchanged anhydride was obtained. The recrystallization of the crude crystal from diethyl ether-petroleum ether afforded prisms, mp 72—73°C. 3,6-Dimethyl-2-α-hydroxypropylbenzoic acid.

Found: C, 69.48; H, 7.97%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.75%.

Results and Discussion

In their study of the reactions of Grignard reagents with substituted phthalic anhydride, Newman and Lord[2] have reported that, although the steric hindrance of the ortho-substituted methyl group of 4-methylphthalic anhydride was observed in the reaction with phenylmagnesium bromide, 4,7-dimethylphthalic anhydride reacted smoothly with phenylmagnesium bromide to give the expected keto carboxylic acid in a 81% yield. From the results of this experiment they concluded that, in the reaction of 4,7-dimethylphthalic anhydride, the initial addition of the Grignard reagent to the carbonyl group of the anhydride is not realized because of the steric hindrance of both methyl groups on the 4,7-positions; the reaction appears to be initiated by the cleavage of the anhydride ring.

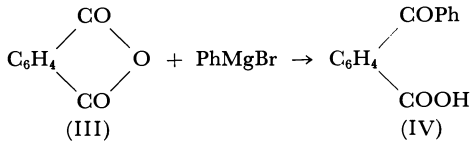
The reduction of 4,7-dimethylphthalic anhydride with lithium aluminum hydride, however, is reported to consist of the direct reduction of the carbonyl group of the anhydride, without the initial cleavage of the anhydride ring. Buchta and Loew[3] have reported that, because of the difficulty in addition of the hydrogen to carbonyl group caused by the steric hindrance of methyl groups on the 4,7-positions, the reduction of this anhydride with lithium aluminum hydride does not proceed to the formation of the corresponding diol (II) by one step and 4,7-dimethylphthalide (I) is produced in a 88% yield.



(I) (II)

(1)

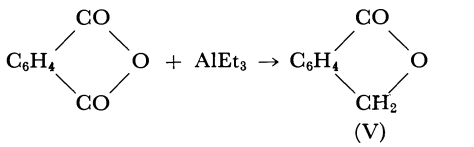
Phthalic anhydride (III) is known to react with one mole of phenylmagnesium bromide to give keto carboxylic acid (IV)[4]:



(III) (IV)

(2)

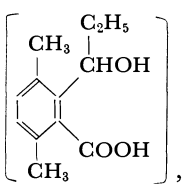
The reaction of III with an equimolar amount of triethylaluminum was found to give none of the keto acids expected from the analogy of the corresponding Grignard reaction, but afforded the reduction product or phthalide (V) in a 46.2% yield.



(V) (3)

4-Methylphthalic anhydride reacted with triethylaluminum under the same conditions as in the reaction with III to give unchanged anhydride in a 41% yield. From this apparent depression in the reactivity of 4-methyl homologue as compared with III, it might be concluded that the reaction of III and 4-methylphthalic anhydride proceeded through the direct addition of β-hydrogen of triethylaluminum to the carbonyl group.

The reaction of 4,7-dimethylphthalic anhydride with triethylaluminum found a parallel in the corresponding Grignard reaction rather than in the lithium aluminum hydride reduction. Unlike the reaction of III and 4-methyl homologue, 4,7-dimethylphthalic anhydride reacted readily with triethylaluminum under the same conditions as in the reactions with III and 4-methyl homologue, giving the product,



resulting from the addition of the ethyl group in a good yield; practically no unchanged anhydride was obtained.

The Reaction of Triethylaluminum with Esters

Yoshio BABA

Resources Research Institute, Kawaguchi, Saitama

(Received April 17, 1967)

It is the aim of the present paper to study the difference in the reactivity appearing to be present between triethylaluminum and the Grignard reagent, through experiments with esters known to have a carbonyl group of a lower reactivity than that of aldehyde or ketone, and to study if the steric effect which has been recognized in the cases of the Grignard reactions could be observed.

Experimental

All reactions were carried out in an atmosphere of dry nitrogen. The melting points were measured on a micro hot stage and were not corrected.

Materials. Commercial methyl benzoate (bp 198—199°C) and methyl phenylacetate (bp 84—85°C/6 mmHg) were purified by distillation. Ethyl 2,4,6-triethylbenzoate (bp 143—144°C/7 mmHg) was synthesized from 1,3,5-triethylbenzene *via* 2,4,6-triethylbromobenzene, 2,4,6-triethylbenzoic acid, and acid chloride.[1] *p*-Tolyl 2,4,6-triethylbenzoate (bp 205—207°C/5 mmHg) was prepared from the corresponding acid chloride and *p*-cresol. Triethylaluminum purchased from the Ethyl Corp. was used without further purification.

Reaction of Methyl Benzoate with Triethylaluminum. Methyl benzoate (0.18 mol) was added, drop by drop, to a gently refluxing 25.0 wt% solution of triethylaluminum in dry petroleum ether ($AlEt_3$ 0.37 mol). After 3 hrs' refluxing, the reaction mixture was cooled in an ice-bath, and the aluminum compound was decomposed with a theoretical amount of ethyl alcohol; then the reaction mixture was poured into an ice-cooled diluted sodium hydroxide solution. The distillation of the crude product gave 25.3 g of an oily product with a boiling point of 95—98°C/16 mmHg. The separation of alcohols in the above fraction by the method described in a previous paper[2] gave 8.1 g (33.3%) of phenylethyl carbinol and 2.2 g (12.5%) of phenyldiethylcarbinol. 3,5-Dinitrobenzoate of phenylethylcarbinol, mp 67—68°C, from ethanol, undepressed by admixture with an authentic sample. The tertiary alcohol fraction was distilled with anhydrous oxalic acid, and the dehydration product was then oxidized with an aqueous alkaline permanganate solution. 2,4-Dinitrophenylhydrazone of the oxidation product, mp 191—192°C, from diluted ethanol, was identified as that of propiophenone by a mixed melting point determination with an authentic sample.

Reaction of Methyl Phenylacetate with Triethylaluminum. The reaction of this ester with two moles of triethylaluminum yielded benzylcarbinol (phenylurethane, mp 79—80°C, from ethanol) and benzyldiethylcarbinol (phenylurethane, mp 99.5—100°C from ethanol).

Reaction of Ethyl and the *p*-Tolyl Ester of 2,4,6-Triethylbenzoic Acid with Triethylaluminum. Ethyl 2, 4, 6-triethylbenzoate (0.05 mol) was mixed with triethylaluminum (0.114 mol) benzene solution and then the reaction solution was refluxed for 6 hr. The crude product was distilled under reduced pressure, and a fraction boiling at 127—129°C/4 mmHg (10 g) was collected. A solution of the above fraction (4 g) in 20 m*l* of glacial acetic acid was mixed with 2 m*l* of 60% sulfuric acid and the mixture was refluxed for 2 hr with stirring. The alkaline permanganate oxidation of the dehydration product gave 3.2 g of an acid substance, mp 113—114°C, from diluted ethanol, which was identified as 2, 4, 6-triethylbenzoic acid by a mixed melting point determination with an authentic sample. A reaction with the *p*-tolyl ester afforded the same product as that obtained in the above reaction.

Results and Discussion

Like Grignard reagents, triethylaluminum reacted with simple esters to give a corresponding secondary alcohol as a principal product, accompanied by tertiary alcohol. Methyl benzoate and methyl phenylacetate, for example, reacted with triethylaluminum to yield the corresponding secondary alcohol as a major product by the normal addition, followed by reduction, and a small amount of tertiary alcohol as a normal addition product.

It has been reported that, in a reaction with an aromatic ester carrying alkyl groups at both the ortho positions of the ester group, such as the mesitoic acid ester, the normal addition of a Grignard reagent to the carbonyl group of the ester function is completely inhibited and carboxylic acid or ketone is obtained as a reaction product instead of the normal product, tertiary alcohol. Fuson[3] has reported that a mesitoic acid ester (I) carrying an alkyl group as the alcohol component of the ester, for example, ethyl mesitoate, does not cause the normal addition reaction with the Grignard reagent, and the corresponding carboxylic acid is obtained as the sole reaction product. On the other hand, in the case of a mesitoic acid ester having an aryl group as the group, R, indicated in Eq. (1), for example, *p*-tolyl mesitoate, the alkyl Grignard reagent can

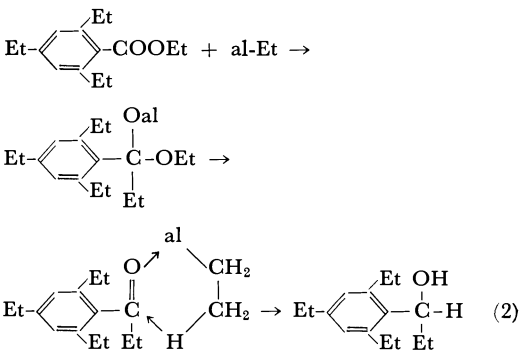
(1)

add to the carbonyl group of the ester, but the reaction product is a ketone consisting of the alkyl group of the Grignard reagent, instead of the corresponding tertiary alcohol expected from the normal addition reaction.

In the present study, it was found that ethyl 2,4,6-triethylbenzoate reacted with two molecular amounts of triethylaluminum to give neither carboxylic acid nor ketone, but a mixture of tertiary and secondary alcohols as the main reaction product. The analysis of the active hydrogen and secondary alcohol contents indicated that the secondary alcohol was the major product. That the reaction product mainly consisted of secondary alcohol was verified by the following facts. The oily product obtained from the reaction of ethyl 2,4,6-triethylbenzoate with triethylaluminum was subject to ready dehydration with 60% sulfuric acid, and the dehydration product gave the corresponding carboxylic acid, 2,4,6-triethylbenzoic acid, in a good yield by alkaline permanganate oxidation. This fact suggests that the reaction product might consist mainly of secondary alcohol or 2,4,6-triethylphenylethylcarbinol, as indicated in Eq. (2); thus, the reaction seems to proceed through the normal addition of one al-Et group to the carbonyl group of the ester followed by the reduction instead of the second normal addition of the second al-Et group.

The reaction of *p*-tolylester of 2,4,6-trisubstituted benzoic acid with triethylaluminum also differed from the corresponding Grignard reaction, the



(2)

former reaction found a parallel in the reaction with the ethyl ester of 2,4,6-triethylbenzoic acid.

It may be concluded from the results of these experiments that, in the case of a simple ester, there is practically no difference between the reaction with trialkylaluminum and that with the Grignard reagent. In the case of a sterically hindered ester, however, the reaction with triethylaluminum proceeds through the normal addition or reduction reaction as observed in the reaction of a simple ester; none of the abnormal reactions expected from the analogy of the Grignard reaction take place.

The author wishes to thank Dr. J. Yoshimura, Professor of Tokyo Institute of Technology, for his many helpful discussions and suggestions during this work.

Continuous and Simultaneous Removal of Anions and Dissolved Oxygen from Water by an Ion Exchange Membrane Cell

Zdeněk MATĚJKA

Research Institute for Industrial Water Treatment, Prague, Czechoslovakia

(Received May 20, 1967)

Dissolved oxygen can be removed from anion-free water by an ion-exchange process[1] based on the interaction of dissolved oxygen with a sulfite form of a strongly basic anion exchange resin, according to the equation

$$2R_2SO_3 + O_2 \rightarrow 2R_2SO_4 \qquad (1)$$

On passing the treated solution through the column of the anion exchanger in a sulfite form, the content of dissolved oxygen is reduced below 10 ppb. This process is discontinuous. After exhaustion it is necessary to convert the resin to a sulfite form with a sodium sulfite solution. This process has now been carried out continuously in an electrolytic membrane cell.

Apparatus. A 4-compartment membrane cell (Fig. 1) has been used for experiments. Electric conductivity has been measured with a conductometer Radelkis Budapest. Dissolved oxygen has been estimated by the Töller method,[2] with a sensitivity as low as 10 ppb.

Procedure. Sulfite ions are transported under the influence of an applied electric potential from compartment III across membrane AM_1 into packed compartment II, and thus particles of resin are continuously converted into the sulfite form. Sulfate ions, resulting from the reaction (1), are transported across membrane AM_2 into anode compartment I. Treated water passes through the packed compartment II, and a continuous uptake of dissolved oxygen takes place in this compartment. It has been found that only such an amount of sulfite ions should be transported across membrane AM_1 which can be immediately absorbed by the given amount of resin in compartment II. Under these conditions, sulfite and sulfate ions are transported across packed compartment II toward membrane AM_2 preferably within the resin particles and do not remain in the solution.

When a greater number of sulfite ions than can be absorbed by the anion exchanger in compartment II are transported across membrane AM_1, they remain in solution and contaminate the deoxygenated effluent, increasing the electric conductivity of the deoxygenated water (Table 1, Run 1).

TABLE 1. SIMULTANEOUS REMOVAL OF DISSOLVED OXYGEN AND ANIONS FROM WATER

Run No.	SO_3^{2-} inlet concn. (equiv·l^{-1})	SO_3^{2-} flow rate (l·h^{-1})	Current density (mA·cm^{-2})	Effluent electric conductivity (m℧·cm^{-1})
1	0.025	0.75	7.7	10.0
2	0.025	0.54	7.7	5.5
3	0.025	0.47	7.7	2.5
4	0.011	2.70	2.3	5.5
5	0.011	2.70	2.75	1.8
6	0.011	2.70	4.0	1.3

Dissolved oxygen content of the outlet in all runs below 10 ppb.
Treated solution:
in runs No. 1—5: distilled water (electric conductivity 5.5 m℧·cm^{-1}, flow rate 1.0 l·h^{-1});
in run No. 6: 0.002 N H_2SO_4 solution, flow rate 0.7 l·h^{-1}; SO_3^{2-} outlet concentration = 0.0092 equiv·l^{-1}

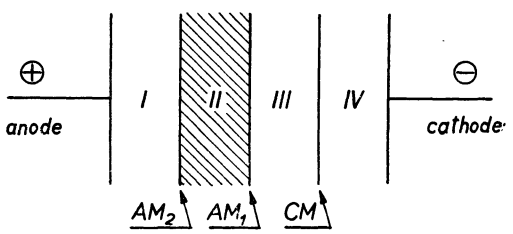


Fig. 1. 4-Compartment cell.

AM_1, AM_2: anion exchange membrane Permaplex A-20
CM: cation exchange membrane Permaplex C-20
Effective membrane area: 125 cm^2
Height of packed compartment: 25 cm
Width of packed compartment (distance of membranes): 0.3 cm
Material used: plexiglass
I: anode compartment
II: compartment packed with particles of the strongly basic anion exchange resin Zerolit FF (size 60—80 mesh)
III: SO_3^{2-} solution compartment
IV: cathode compartment

The number of sulfite ions transported across membrane AM_1 has been checked by evaluating the concentration polarisation, which causes a

2) K. Buriánek, *Energetika*, **7**, 21 (1957).

decrease in the transport numbers of the ions of the electrolyte.[3] A concentration polarisation arises under certain conditions (given by the concentration of the sulfite solution, flow rate and current density) on the surface of membranes AM_1 and CM in compartment III. The number of transported sulfite ions is, in this way, kept at the desired level. Contamination of effluent does not appear. Electric conductivity of deoxygenated water remains unchanged (Table 1, Run 2).

A strongly basic anion exchange resin in sulfite form in the column can be used for removing of dissolved oxygen from anion-free water only. Anions, present in the solution, displace, during the working period, sulfite ions into the effluent, causing both a capacity and efficiency decrease.

In the process of continuous removal of dissolved oxygen by the packed bed membrane cell, the presence of anions does not interfere. Resin in the packed membrane cell is continuously and simultaneously converted into sulfite and hydroxide forms and it is capable of the quantitative uptake of both dissolved oxygen and anions from water. By a variation in the conditions on which the concentration polarisation depends, one can vary the ratio of the functional groups converted into hydroxide and sulfite forms. It enables the treatment also of solutions which are rich in anions.
